For $z^+ > 1.0$, the results of the cross-correlation analyses show that the peak concentration occurs during the offshore wave stroke and furthermore that the cloud arrives slightly earlier at higher elevations. This result is consistent with the horizontal advection of the cloud from a distant source - if the clouds were propagating upwards from the bed directly underneath the sensor then they would arrive earlier at lower elevations (e.g., Hanes and Huntley, 1986). Thus, the clouds arriving on the offshore wave stroke above the ripple tops have been released from distant (shoreward) parts of the bed.

Figure 4. Cross-correlation function, ρ_w versus C at $z^+ = 0.7$. The peak concentration occurs at the same time as the peak onshore orbital velocity.

The field observations so far described are consistent with a vortex model of sediment entrainment in which sediment clouds are initiated at the bed and ejected into the flow on alternating wave strokes (e.g., Sleath, 1982). The roll-up of the cloud during the onshore wave stroke was restricted to $z < \eta$ (i.e. $z^+ < 1$): since flow visualization experiments have demonstrated that the vortex fills the ripple trough (e.g., Honji et al., 1980), it seems feasible that the ABS was looking down into a ripple trough.

Magnitude of Events

The fact that peak bed shear stress is synchronous with peak concentration in the vortex points the way to predicting the size of the sediment clouds that are ejected from the bed when the orbital velocity reverses. For this, we draw from well-known time-averaged theory in which the suspended-sediment reference concentration close to the bed is hypothesized to be a function of the skin friction that is in excess of critical stress:

$$C = \gamma_0 C_b S^n / X, \quad S = (|\tau'| - \tau_{cr}) / \tau_{cr} \quad (1)$$

(Smith, 1977). In equation (1), C is the time-averaged reference concentration which is specified at the top of the bedload layer; S is the time-averaged skin friction, τ' , in excess of the critical stress, τ_{cr} ; C_b is the bed sediment concentration; γ_0 is an empirical constant, $O(10^{-4})$. Smith and McLean (1977) used $X = (1 + \gamma_0 S)$ and proposed $n = 1$, although others have used different values for n (e.g., Shi et al., 1985). We hypothesize that, by analogy, the peak concentration in the vortex is related to the peak excess skin friction.

To evaluate the model, we replace C in equation (1) with \bar{C} the peak concentration in the vortex (i.e. from the region $z^+ < 1$), and S by $\bar{S} = (|\tau'_{cw}| - \tau_{cr}) / \tau_{cr}$, where τ'_{cw} is the total maximum skin friction, which is the sum of the maximum wave-induced and time-averaged components. τ'_{cw} was calculated by a combined-flow boundary layer model using the maximum observed half-cycle velocity and observed zero-downcrossing wave period. The roughness length was taken as proportional to the grain size of the bed sediment, thus these estimates are meant to represent the skin friction. The critical stress applicable to fully rough turbulent flow was found from a classical Shields curve, which has been shown to apply to rippled beds in combined wave and current flow provided the grain texture is used to scale the hydraulic roughness (Larsen et al., 1981). Finally, since the observed values for \bar{S} are $O(10^2)$ or less, X in equation (1) is set to 1.

Shown as the crosses in Figure 5 are the observed values of \bar{C} plotted against \bar{S} for the shoreward-directed cycle of 103 waves in which critical stress was exceeded. The line in the figure is the fit of the model to the data, which yielded an r^2 of 0.73, which is significant at the 95% level. The best-fit exponent, n , was 1.33 ± 0.23 at the 95% level, which is similar to Smith's proposed value of 1 for the time-averaged case. The corresponding value for γ_0 was 0.91×10^{-4} with a lower bound of 0.59×10^{-4} and an upper bound of 1.40×10^{-4} at the 95% confidence level.

Also shown in Figure 5 are 13 data points from offshore-directed wave strokes in which vortices were initiated at the bed. These points cluster around the model fit derived from the onshore data. This result is

Figure 5. Fit of equation (1) to data. The crosses represent peak concentration in the vortex generated on the onshore wave stroke and the filled circles represent peak concentration generated on the offshore wave stroke.

counter to Bijker et al.'s (1976) and Hanes and Huntley's (1986) suggestions that the local acceleration governs the size of the sediment cloud generated at the bed and ejected into the flow. If this were the case, the data from the two half-cycles, which exhibit markedly different accelerations on account of the wave skewness, would not cluster in this way.

Sleath (1982) suggested a mechanism that accounts for a link between bed shear stress and concentration in the vortex: he showed that the vortex is fed by a thin bedload layer that cascades over the ripple crest and into the developing vortex; equation (1) can be used to predict the size of the sediment cloud that is ejected into the flow when the orbital velocity reverses.

Discussion

Vincent and Green (1990) showed that the correlation flux for run 2046 contributed a significant fraction of the total flux, and was sufficient close to the bed to cause reversals in the direction of the total flux (Figure 6). The size of the correlation term is dependent on the phasing of the sediment cloud relative to the wave-orbital velocity: the magnitude of the correlation varies with elevation above the bed, becoming smaller at higher elevations as the sediment clouds disperse and lose their wave-scale structure. The sign of the correlation term also changes: below an elevation approximately equal to the ripple height, the peak suspension is in phase with the onshore motion in the potential-flow region of the wave, and above this elevation the onshore motion and suspension are $\sim 180^\circ$ out of phase.

Figure 6. Vertical profiles of cross-shore suspended-sediment flux, run 2046. \overline{UC} is the mean cross-shore flux, where \overline{U} is the mean velocity and \overline{C} is the mean concentration. $\overline{UC_w}$ is the correlation flux, where U_w and C_w are the wave (i.e. zero-mean) fluctuations in velocity and concentration respectively (see Vincent and Green, 1990, for details of how the flux profiles were estimated).

Since the bed shear stress controls the size of the sediment cloud ejected from the bed when the flow reverses, the vertically-integrated correlation flux above the level of the ripple crests will be opposed to the direction of wave skewness (assuming the mean current is negligible). Furthermore, since the vertically integrated flux below the ripple crest depends upon the characteristics of the vortices and the vortices are distributed periodically in space, then there exists the possibility of a periodic divergence in sediment flux close to the bed which could govern the bedform migration and modify the net flux close to the bed.

Conclusions

The periodic vortex entrainment and release of sand from a rippled bed causes a flux of sediment that may be comparable in magnitude and opposite in sign to the mean suspended-sediment flux. Transport predictions based on the time-averaged distributions of velocity and sediment concentration will neglect this component of the sediment flux and may therefore be in serious error.

MODELLING OF MULTICOMPONENT SANDY BEDS EVOLUTION
UNDER SHALLOW WATER WAVES

G. Chapalain¹ and B. Boczar-Karakiewicz²

ABSTRACT

A study of hydrodynamics and multicomponent sedimentary processes associated to unbroken water waves propagating in coastal areas is presented. For the specific case in which the waves are normally incident, weakly non-linear and dispersive, and the foreshore profile displayed a gentle slope, a model of wave-induced heterogeneous sand transport and resulting topographical and granulometric changes is developed. The general conclusion of this study is that the model presented describes some of the observed features of the sedimentology of longshore bars systems.

INTRODUCTION

Coexistence of several classes of sediments of varying sizes is a striking characteristic of coastal environments. This is due to the fact that the vectors for the sediment, i.e. rivers, transport granulates of various sizes. Coastal hydrodynamic forces subsequently redistribute the sediment within the medium. In the foreshore areas where sandbar systems develop, descriptive investigations (Sitarz, 1963; Davis and McGreary, 1965; Fox et al., 1966; Bajorunas and Duane, 1967; Mothersill, 1969; Saylor and Hands, 1970; Long et al., 1984; Forbes et al., 1986) have shown a high correlation between granulometry and bathymetry (Figures 1-2). The majority of observations reveals a localization of coarse fractions ($0 < \phi < 2$) in the troughs and fine grain fractions ($2 < \phi < 3$) at the crests. Moreover, the majority of observations shows that better sorted sediments are located at the crests and poorly sorted sediments are located in the troughs.

Various mechanisms have been invoked to account of the development of nearshore multiple longshore sand bars. These have included standing waves (Carter et al., 1973), edge-waves (Bowen and Inman, 1971), undertow and rip-cell circulation (Dyhr-Nielsen and Sorensen, 1970) and the non-linear interaction of higher harmonics in a regular incident wavetrain during shoaling (Boczar-Karakiewicz et al., 1981).

In the present paper, we focusse on the outer part of gently sloping profiles and therefore concentrate on the last mechanism which involves the non-linear evolution of progressive waves as they approach the shore. To proceed in an idealized way a two dimensional situation wherein a deepwater plane periodic wavetrain impinges on the shore is considered. It is assumed that the activity of edge-waves and breaking waves is reduced or confined close to the shore.

The model is composed of four constituents, describing processes involved in the mechanism of wave-bed interactions: (1) the surface hydrodynamics, (2) the near-bed boundary layer flow, (3) the sediment transport, and (4) the evolution of the bottom topography and composition. All four modules are linked together in a two-step morphological time-loop. In the first step, the fluid flow and the heterogeneous sediment flux are calculated over a bed configuration which is instantaneously fixed. In the second step, the temporal evolution of the seabed is calculated while keeping all variables describing the fluid and sediment flow constant. The two-step approximation is justified by observations in laboratory and in natural coastal environments (Boczar-Karakiewicz et al., 1987; Boczar-Karakiewicz and Davidson-Arnott, 1987)

WAVE FIELD DESCRIPTION

The incident regular two-dimensional wavetrain is characterized by an amplitude a and a wavelength L . It propagates in a domain described by a coordinate system (x, z) . The undisturbed water level is at $z = 0$ and $h(x)$ is the water depth at point x . The vertical deviation from equilibrium of the free surface at point x at time t is $\xi(x,t)$ and $q(x,t)$ is the depth-averaged horizontal velocity. All physical variables are non-dimensionalized and scaled:

$$h = \frac{\bar{h}}{H}, \quad x = \frac{\bar{x}}{H}, \quad t = \frac{\bar{t}}{\sqrt{H/g}}, \quad \xi = \frac{\bar{\xi}}{\alpha H}, \quad q = \frac{\bar{q}}{\alpha \sqrt{gH}} \tag{1}$$

where H represents a characteristic depth, g is the acceleration due to gravity, $\alpha = a/H$ is a relative wave amplitude parameter.

The Boussinesq set of equations describing the shallow water wave is modified by a dissipative term induced by the bottom shear stress of the underlying turbulent boundary layer:

$$q_t + \xi_x + \alpha q q_x = \frac{h^2}{3} q_{xx} + h h_x q_{xt} + \frac{1}{2} h h_{xx} q_t + \frac{R}{h} q \tag{2}$$

$$\xi_t + [(\alpha \xi + h) q]_x = 0 \tag{3}$$

In the derivation of the dissipative term $(R/h)q$ it has been assumed that friction is linear, where the constant $R = 3/4 \pi f_w \alpha q_{max}$ is expressed by constant flow and friction parameters: the depth-averaged maximum velocity q_{max} at $x = 0$, and Jonsson's (1978) friction coefficient f_w

$$\left\{ \begin{array}{ll} f_w = \frac{0.0605}{\text{Log}^2 \frac{27\delta_1}{k_b}} & k_b/a_b < 1 \\ f_w = 0.24 & k_b/a_b > 1 \end{array} \right. \tag{4}$$

where δ_1 , k_b and a_b are respectively the Jonsson's length, the roughness height and half of the near-bed orbital excursion (see Grant and Madsen, 1982).

Following Lau and Barcelona (1972) and Boczar-Karakiewicz et al (1987) we are seeking for a solution of (2) and (3) where the free surface elevation ξ is presented by a simple modal decomposition

$$\xi = \xi(x,X,t) = \sum_{j=1}^2 a_j(X) \exp [i (k'_j x - \omega_j t)] + c.c. \tag{5}$$

The first-order amplitudes a_j in (5) are taken to vary on the scale of wavelengths, and therefore depend on X which is a horizontal length-scale measured in wavelength L (i.e. $X = \bar{x}/L = \beta x$ where $\beta = H/L$ is the aspect ratio for the motion assumed to be of the order of α). In equation (5) c.c. stands for the complex conjugate of the quantity just preceding it. A similar representation is postulated for q .

In (5) ω_1 is the frequency of the postulated incoming wavetrain, and $\omega_2 = 2\omega_1$ is its second harmonic, k'_1 and k'_2 are wave numbers associated with ω_1 and ω_2 respectively.

It is further assumed that the principal features of the bottom variation are gradual, and therefore, it also may be taken that h is a function $h(X)$ (i.e. $h(X) = 1 + O(\alpha)f(X)$ where f is an $O(1)$ function) of the long variable, only.

The dispersion relation results from linear theory (first-order) and reads

$$k_j'^2 = k_j^2 + i \frac{R \omega_j}{1 - \frac{\omega_j^2}{3}} \quad (6)$$

where k_j denotes the first-order wave numbers obtained when friction is ignored.

The amplitudes ξ_j , and consequently of the depth-averaged velocities q result from solvability conditions for the second-order approximation (Lau and Barcilon, 1972)

$$\begin{cases} a_1 X + H_1(X) a_1 + S_1(X) \exp\left(\frac{\Delta k^I X}{\beta}\right) \exp\left(-i \frac{\Delta k^R X}{\beta}\right) a_1 a_2^* = 0 \\ a_2 X + H_2(X) a_2 + S_2(X) \exp\left(\frac{\Delta k^I X}{\beta}\right) \exp\left(i \frac{\Delta k^R X}{\beta}\right) a_2^* = 0 \end{cases} \quad (7)$$

where * denotes complex conjugation, $\Delta k' = \Delta k^I + i \Delta k^R = k_2' - 2k_1'$, H_1 , H_2 , S_1 and S_2 are known functions of X .

As shown in (6) and (7), the essential modifications induced by a linear friction term appear in the first-order dispersion relation (6). The non-linear equations (7) for the amplitudes a_j ($j = 1, 2$) remain identical when compared to the frictionless model (see Lau and Barcilon, 1972; Boczar-Karakiewicz et al., 1987), except that in all coefficients the frictionless wave-number k_j has to be replaced by k_j' .

For a chosen frequency ω_1 of the incident wave the set of equations (7) has to be completed by the initial values at $X = 0$:

$$a_1(0) = 1; \quad a_2(0) = 0 \quad (8)$$

reflecting the assumption that the incoming regime is composed of a single-frequency wavetrain.

The coupled system of non-linear evolution equations (7) supplemented by (8) are solved numerically using a stable and accurate fourth-order Runge-Kutta method.

WAVE-INDUCED NEAR-BED BOUNDARY LAYER PROCESSES

The governing equations for the near-bottom flow with suspended sediment are simplified by several assumptions. It is assumed that

- the suspended sediment concentration is sufficiently low to neglect particle interactions, but high enough to represent the mixture as a continuum,
- the fluid is newtonian,
- the inertia of the particles is assumed to be small and thus the sediment velocity is equal to the fluid velocity minus the particle fall velocity.

Completing the previous assumptions by Boussinesq's formulation of the Reynolds shear stress and the turbulent mass flux, the sediment-laden flow may be approximately described by the following system of equations

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho_f} \frac{\partial p}{\partial x} + \frac{\partial}{\partial z} \left(\nu_t \frac{\partial u}{\partial z} \right) \quad (9)$$

$$\frac{\partial c(K)}{\partial t} = w_f(K) \frac{\partial c(K)}{\partial z} + \frac{\partial}{\partial z} \left(\gamma_t(K) \frac{\partial c(K)}{\partial z} \right) \quad (10)$$

$$\rho = \rho_s C + (1-C) \rho_f, \quad C = \sum_{K=1}^{KM} c(K) \quad (11)$$

where u denotes the horizontal fluid velocity inside the boundary layer, p is the pressure, $c(K)$ is the volumetric concentration of suspended sediment of class K , KM is the number of classes, ρ is the density of the fluid-sediment mixture with ρ_f and $\rho_s (= 2.65)$ denoting respectively the fluid and sediment density, ν_t and $\gamma_t(K)$ are respectively the eddy viscosity and diffusivity of sediment of class K and $w_f(K)$ is the sediment fall velocity which can be determined as a function of the radius $r(K)$ of the sediment particles of class K by the Gibbs et al.'s (1971)

$$w_f(K) = \frac{-3\mu_f + \sqrt{9\mu_f^2 + g r(K)^2 \rho_f (\rho_s - \rho_f) (0.015476 + 0.19841 \cdot r(K))}}{\rho_f (0.011607 + 0.14881 r(K))} \quad (12)$$

(Notice that all the physical quantities are expressed in c.g.s. units and μ_f is the fluid dynamic viscosity).

The closure of the set of equations (9), (10), and (11) can be achieved at different levels of sophistication. For example a local "quasi-equilibrium" second-order closure is achieved by adding analytical expressions for the eddy viscosity ν_t and for the eddy diffusivity γ_t and two transport equations for the turbulent macroscale Λ and the turbulent kinetic energy q^2 (Sheng and Villaret, 1989).

Boundary conditions at the upper and lower limit of the boundary layer must be satisfied.

At the upper limit of the boundary layer it is required

(i) the mean horizontal velocities u to match the free stream velocity U_b (at $z = -h$) of the main water body,

$$u = U_b = \frac{\alpha}{2} \left\{ \sum_{j=1}^2 \left(1 - \frac{\beta^2 h^2 k_j^2}{6} \right) \left(-\frac{\omega_j}{k_j} \right) a_j(X) \exp \left[i(k_j x - \omega_j t) \right] + c.c. \right\} \quad (13)$$

(ii) the vanishing of all turbulence-related characteristics and suspended sediment concentration.

At the lower limit of the boundary layer it is required

(i) to provide a near-bed mean velocity condition,

(ii) to provide a turbulent macroscale length model,

(iii) the vanishing of the turbulent energy flux,

(iv) to estimate the near-bed flux of sediment particles into the suspension. Numerous fluorescent or radioactive tracer measurements have revealed the existence of mixture in the topmost sediments. Conceptually, this mixing layer lends support to the idea of modelling the bottom by a juxtaposition of elementary boxes, whose vertical dimension will henceforth be related to the depth of the shifted sand. This thickness is correlated with the local hydrodynamic conditions and therefore the characteristics of boxes should vary in space. Given the limitations of the global modelling procedure, however, it will be assumed that the number of particles contained in an elementary box remains constant. In an erosion zone the problem arises of replacing the sediment removed from the control volume. One possibility consists of refilling with underlying sediment of the initial composition. This procedure, however, tends to drive the granulometric distribution back to the initial distribution, which ought in principle to be "forgotten" as the calculation proceeds, i.e. with increasing time. There is another alternative for the approach of equilibrium. Replacement can be achieved with sediment whose characteristics are identical with those calculated at the current time step, i.e. with a number of particles slightly smaller to the INP (hereinafter referred to as INP) in each box. In the initial stage, i.e. on an undeformed bed, it is assumed that the spatial composition of the sediment substrate is uniform throughout. The population of each class present is taken to be represented by a normal distribution. It will be denoted $P^0(K)$, where K designates the class. This weight frequency distribution is characterized by its mean value ϕ^0 and its standard deviation σ^0 . The number of classes is fixed at nine with a ϕ -interval equal to $1/2$ (Figure 3). This distribution law was

selected because it represents the granulometric response to random hydrodynamic processes. The Initial Number of Particles in each class is then given by

$$N^0(K) = INP \cdot P^0(K) \quad (15)$$

The consequence of the superficial mixed layer concept on the near-bed flux of sediment particles into the suspension is an hypothesis of independence between the different fractions during the process of extraction and suspension of particles from the bed. Consequently, the near-bed sediment flux for each class K can be modelled by the Svendsen's (1977) pick-up function characterized by two peaks located at the free velocity reverses (i.e., phases when the vortices are released in the bottom boundary layer) and expressed as

$$p(K,t) = p_d(K) + \frac{p_d(K)}{1+\mu} \sum_{n=1}^m \frac{2(m!)^2}{(m+n)! (m-n)!} \left\{ \cos n(\omega t - \varphi^+) + \mu \cos n(\omega t - \varphi^-) \right\} \quad (14)$$

where the parameter $\mu = (U_b^-)^2 / [U_b^+]^2$ allows an account of non-linearities of the wave field. In (14) m is a parameter controlling the skewness of the peaks, superscripts $+$ and $-$ refer to the phases (φ^+ , φ^-) of the velocity reverse following respectively the maximum and the minimum outer flow velocity; the quantity denoted by $p_o(K)$ is equal to $\bar{C}_0(K) \cdot w_f(K)$ where $\bar{C}_0(K)$ is the mean bottom concentration is given by Nielsen (1979) as

$$\bar{C}_0(K) = 0.028 \left(\psi'(K) - \psi'_c(K) \right) \frac{2}{\pi} - \arccos \left(\frac{\psi'_c(K)}{\psi'(K)} \right)^{1/2} \quad (15)$$

with $\psi'(K)$ and $\psi'_c(K)$ are respectively Madsen and Grant's (1976) wave-extended Shields parameter and its critical value (Figure 4).

Conclusions resulting from numerical experiments using the coupled local "quasi-equilibrium" second-order turbulent closure model in single class version justify a simplification of the modelling procedure for a flow with a low sediment concentration (Chapalain, 1988; Boczar-Karakiewicz et al., 1988). In this procedure, the flow dynamics and the sediment concentrations are modelled separately. In pursuit of our goal consisting in studying heterogeneous sediment transport under wavetrains (i.e. in a two-dimensional configuration), a simple modelling which capture the main features of the flow is preferable to more complicated numerical solutions like this one mentioned above. To proceed in this way, we decide to test the capacity of a first-order decoupled model consisting in a constant (in time and space) effective eddy viscosity model.

The hydrodynamics of the wave-induced boundary layer flow is now described by an analytical approach using the following Reynolds averaged momentum equation

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} - \frac{\partial u}{\partial \eta} \int_0^\eta \frac{\partial u}{\partial x} d\eta = \frac{\partial U_b}{\partial t} + U_b \frac{\partial U_b}{\partial x} + \frac{1}{l^2} \left[v_t \frac{\partial u}{\partial \eta} \right] \quad (16)$$

where $\eta = z/l$ and l is a characteristic length scale of the boundary layer.

The required effective eddy-viscosity closure is obtained by applying following model

$$v_t = [U] \cdot [L] \quad (17)$$

where $[U]$ and $[L]$ are characteristic scales for the velocity and turbulent eddies respectively.

The velocity scale $[U]$ is estimated by the friction velocity

$$u^* = \sqrt{\frac{\tau_{bm}}{\rho}} \quad (18)$$

where τ_{bm} denotes the maximum bottom stress and the length scale $[L]$ in (17) is assumed to be the ripple height (Nielsen et al., 1982).

A classical perturbation analysis provides explicit expressions for the first- and second-order horizontal mean velocity. Both expressions are defined in Appendix.

Figure 4. Madsen and Grant's wave extended Shields (1976) diagram.

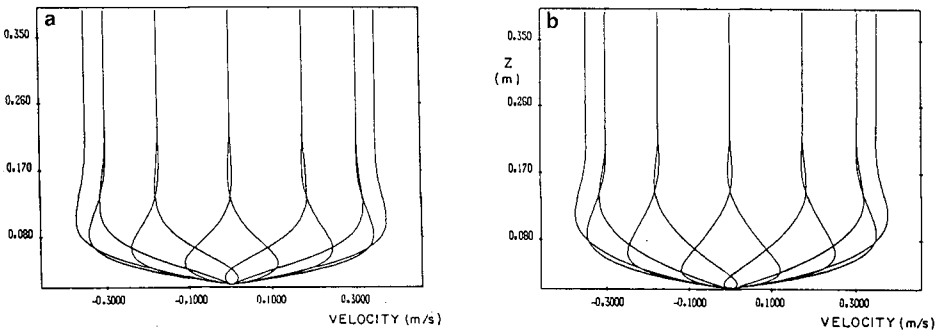

Figure 5. Mean velocity profiles calculated by the constant, time-independent eddy viscosity model [a], by the second-order turbulence closure model [b].

Figure 6. Observed bathymetric profile of Wasaga Beach.

The predicted velocity profiles for an oscillatory flow whose maximum velocity U_0 and period are 0.35m/s and 10s respectively are shown in Figure 5 for every 30° of the wave-cycle. Comparison with results of the second-order turbulent closure model shows a satisfactory agreement.

A simple analytical model can now be derived for prediction of sediment concentration for each independent class in the wave-induced near-bed boundary layer flow.

The time-periodic and modally decomposed (Nielsen, 1979) sediment concentration c ,

$$c(K) = \sum_n^n c_n(K) \exp(in\omega t) \quad (19)$$

is assumed to satisfy the advective-diffusive equation (10) and the above boundary conditions.

Following the original solution of Nielsen (1979) the spatial and temporal sediment concentration is described by an explicit analytical expression $c(K, X, z, t)$ (defined in the Appendix). In this expression the eddy diffusivity $\gamma_t(K)$ is assumed proportional to the eddy viscosity ν_t and dependent on the particle size according to Van de Graaff and Roelvink's (1984) relationship involving the fall velocity of the form

$$\gamma_t(K) = \frac{1}{1 + 23 \cdot w_f(K)} \quad (20)$$

SEDIMENT TRANSPORT RATE AND RELATED SEABED RESPONSE

The wave-induced, time-averaged flux of sediment of class K is estimated by the product of the instantaneous sediment concentration and the sediment velocity vector

$$Q_J(K) = \frac{1}{T} \int_0^T \int_0^\delta u(X, z, t) c(K, X, z, t) dz dt \quad (21)$$

where subscript J denotes the box index resulting from the spatial discretization (i.e. $X = J \Delta X$)

In order to analyse the quantitative contributions of time-independent and time-dependent flow velocities and concentrations to the sediment flux Q , the product u.c. in (21) will be formally decomposed

$$u(X, z, t) \cdot c(X, z, t) = \left\{ \alpha u^{(1)}(X, z, t) + \alpha^2 \beta [u_s(X, z) + u_p^{(2)}(X, z, t)] \right\} \cdot [\bar{C}(X, z) + c(X, z, t)] \quad (22)$$

where $u^{(1)}$ and $u_p^{(2)}$ denotes the first and second-order periodic velocity components, u_s is the time-averaged velocity, \bar{C} denotes the mean concentration and c is the instantaneous concentration.

In the following we are separating the local sediment flux into two components

$$Q_J(K) = Q_{m_J}(K) + Q_{n_J}(K) \quad (23)$$

where $Q_{m_J}(K)$ denotes the contribution of time-independent quantities and $Q_{n_J}(K)$ the contribution of time-dependent quantities.

The component $Q_{m_J}(K)$ is

$$Q_{m_J}(K) = \frac{S_J(K)}{T} \int_0^\delta \bar{C}(K, X, z) \cdot u_s(X, z) dz \quad (24)$$

where $S_J(K)$ controls the threshold of sediment movement and defined by

$$S_J(K) = \begin{cases} 0 & \text{if } \psi'(K) < \psi'_c(K) \\ 1 & \text{if } \psi'(K) > \psi'_c(K) \end{cases} \quad (25)$$

Choosing now for the mean sediment concentration in (24) the following expression (Rouse, 1937)

$$\bar{C}(K, X, z) = \bar{C}_0(K, X) \exp(-D(K) z) \quad (26)$$

with $D(K) = w_f(K) / \gamma_s(K)$

and substituting in (24) the mass transport velocity defined in Appendix, the component $Q_{mj}(K)$ may also be expressed by an explicit formula given in Appendix.

Proceeding now in a similar way with time-dependant quantities in (22) the component $Q_{nj}(K)$ may also be made explicit and the related expression is given in Appendix.

The "effective" sediment transport rate is obtained by weighting this latter quantity by the composition of the sediment substrate. Finally, the notion of "numerical" sediment rate is introduced for each class, such that

$$N_J^T(K) \simeq Q_J^T(K) \cdot P_J^T(K) / (4\pi r(K))^3 \quad (27)$$

The spatio-temporal evolution of the granulometric distributions is described by the continuity relation for each class of sediment. This procedure allows the calculation of the number of particles of each class present in the box J after exposure for a time ΔT to the ambient hydrodynamic conditions, i.e.

$$N_J^{T+\Delta T}(K) = N_J^T(K) + (N_{J,f}^T(K) - N_{J+1}^T(K)) \quad (28)$$

The new updated local distribution for the different sediment classes is determined by

$$P_J^{T+\Delta T}(K) = \frac{N_J^{T+\Delta T}(K)}{\sum_{K=1}^{KM} N_J^{T+\Delta T}(K)} \quad (29)$$

The total instantaneous sediment transport rate is the sum of the individual transport rates corresponding to each class:

$$Q_J^T = \sum_{K=1}^{KM} Q_J^T(K) \quad (30)$$

The overall variation in depth is calculated using an equation of conservation of matter expressed in the form

$$h_J^{T+\Delta T} \simeq h_J^T - \Delta T \cdot [Q_{J-1}^T - Q_{J+1}^T] / (\Delta X \cdot C_p) \quad (31)$$

where C_p is the concentration of the compact bed arbitrary taken equal to 0.74 like for the idealized rhomboedric arrangement.

APPLICATION

In order to contain the high costs of computation, the application of multicomponent modelling will be limited to the case of Wasage Beach located along the shore of Georgian Bay in Lake Huron. On account of its location in a narrow bay this area is hydrodynamically very well-controlled with waves whose period and height are respectively about 5s and 1m propagating exclusively from the north. The bathymetric profile illustrated in Figure 6 is characterized by a mean slope of 0.5% modulated by four bars. The granulometric analysis leads to consider a mean sediment grain diameter equal to 0.35mm. Even though local measurements of the granulometric distribution are not available on this profile, as an approximation one will apply here the synthetic results of Saylor and Hands (1970) pertaining to Great Lakes (Figure 1).

The initial granulometric curve has an average value of $\bar{\phi}^0 = 1.5$ (corresponding to a sediment of mean diameter equal to 0.35 mm) and a root mean square deviation $\sigma^0 = 0.5$. The main parameters associated to this initial distribution are listed in Table 1.

In order to facilitate the comparison with the single class modelling, the results from the single class version will be placed beside those of the multiclass model.

The sediment transport rate distribution across the foreshore zone is shown in Figure 7-I. It displays slightly lower transport rates magnitude than for the single class case (Figure 7-II). The horizontal gradients are very close in both cases. For this reason, a very similar bathymetric response is obtained, generated on a characteristic time scale of the deformation that closely resembles that obtained in the single case version.

Figure 8 illustrates the spatial structure of the mean value and the root mean square deviation of the granulometric curve. Comparison of these results with the associated topography reveals:

(i) a drift of the the granulometric curve towards fine sediments at the crest and towards coarse sediments in the troughs (Figure 8a). The simulation is in agreement with the observations described in the introduction (Figures 1-2). Characteristic granulometric curves for crests and troughs are shown in Figure 9 (curves B and C, respectively).

(ii) degradation of the sorting at the crests combined with an improvement in the troughs (Figure 8b). This specific result is contradiction with all the observations, apart from some (outer zone) of those of Long et al. (1984) (Figure 2)

CONCLUSION

Multicomponent simulation is an attempt to provide as realistic as possible a model for problems of sedimentation. From a quantitative point of view, this approach, although highly simplified, allows an appreciation of the impact of a fairly actual granulometric distribution on the transport of sediment across the foreshore profile. The global effect (i.e. on sediment transport rates and seabed response) proves insignificant on account of the crudeness of the modelling. The second, more novel, point which concerns the simulation of the spatial adjustment of the granulometric characteristics across the profile, shows that the model gives correct representation of what happens in nature as to the confinement of fine fractions at the crests of the bars and coarse fractions in the troughs between the bars. About the sorting of sediment classes, however, the model results are in contradiction with the main body of available in situ measurements. This discrepancy may suggest that there are many difficulties remaining and related to additional effects like for example wave breaking, reflected or trapped waves. Nevertheless, further effort to verify the basis of multiclass geomorphological modelling should be devoted to collect more data in laboratory and in the field in order to clarify the pattern of the sorting of sediment distributions across the bar systems.

APPENDIX: WAVE-INDUCED VELOCITIES, SEDIMENT CONCENTRATION AND RELATED SEDIMENT TRANSPORT RATES IN THE NEAR-BED BOUNDARY LAYER

Substituting a perturbation series for u

$$u = \alpha u^{(1)} + \alpha^2 u^{(2)} + \dots$$

into the Reynolds equation (16), the first-order oscillatory velocity component is

$$u = \alpha u^{(1)} = \alpha \operatorname{Re} \sum_{j=1}^2 U_j \exp [-(1+i) \eta_j] \quad (32)$$

$$\text{where } \eta_j = z / l_j = z / \sqrt{\frac{2\nu_t}{\omega_j}}$$

On account of the smallness of the imaginary part of the wave number k_j^I in geophysical conditions (Chapalain, 1988) the second-order steady velocity identified to the mass transport

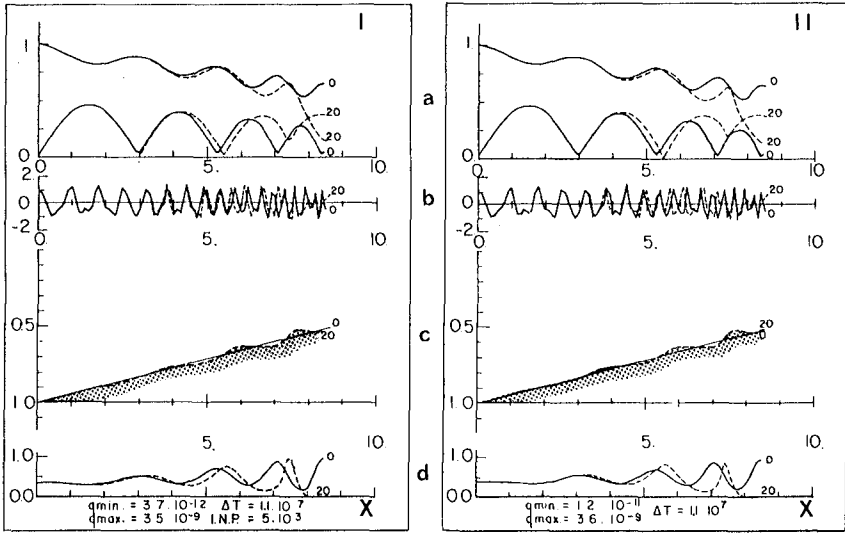

Figure 7. Multiclass model run (I) for Wasaga Beach, compared with single class model (II). (a) Two first harmonic component amplitudes non-dimensionalized by the wave amplitude. (b) Free surface elevation at a given time non-dimensionalized by the wave amplitude. (c) Near-shore topography non-dimensionalized by the incident water depth. (d) Total sediment transport rate Q . The horizontal distance X is measured in incident wavelengths.

Table 1. General Characteristics of sediment particles making up the multiclass substrate at Wasaga Beach in the numerical simulation.

velocity (Longuet-Higgins, 1953) may be approximated by

$$u_s = \frac{\alpha^2 \beta}{4} \sum_{j=1}^2 \left[1 - \frac{1}{6} \beta^2 k_j^R n^2 \right] \frac{\omega_j}{k_j^R} |a_j|^2 \exp\left(\frac{2k_j^I}{\beta}\right) H_j^I(\eta_j) \quad (33)$$

$$\text{where } H_j^I = -8 \exp(-\eta_j) \cos \eta_j + 3 \exp(-2\eta_j) + 5 \quad (34)$$

For convenience we omit to specify the sediment class index K in the following expressions. The expression for spatial and temporal evolution of the suspended sediment concentration is

$$c(X, z, t) = \sum_{n=0}^{\infty} \frac{\bar{C}_0}{1+\mu} \cdot \frac{a'_n}{\alpha_n} \left(\exp(-i n \Phi^+) + \mu \exp(-i n \Phi^-) \right) \exp\left(-\frac{w_f}{\gamma_t} \alpha_n z\right) \exp(in\omega_1 t) \quad (35)$$

$$\text{where } a'_n = \frac{2 (m!)^2}{(m+n)! (m-n)!}$$

$$\text{and } \alpha_n = \frac{1}{2} + \sqrt{\frac{1}{4} + i \frac{n\omega\gamma_t}{w_f}}$$

The time-independent sediment transport rate Q_m is

$$Q_m(X) = \frac{1}{4} \alpha^2 \beta \bar{C}_0(X) \sum_{j=1}^2 \frac{-8\delta_j}{(D\delta_j-1)^2 + 1} \left[\exp(D\delta_j-1)\eta_{sj} \left((D\delta_j-1) \cos \eta_{sj} + \sin \eta_{sj} \right) + 1 \right] \\ + \frac{3\delta_j}{D\delta_j-2} \exp[(D\delta_j-2)\eta_{sj}] + \frac{5}{D} \exp[-D\eta_{sj}] \quad (36)$$

The time-dependent sediment contribution Q_n in an integral form is

$$Q_n(X) = \frac{\delta}{2} \operatorname{Re} \left\{ \sum_{j=1}^2 \frac{\bar{C}_0}{(1+\mu)\alpha_j} U_j a'_j \left(\exp(-i j \Phi^+) + \mu \exp(-i j \Phi^-) \right) \int_0^{\delta} \exp\left(-\frac{w_f \alpha_j z}{\gamma_t}\right) (1 - \exp(-(1-i)\beta_j z)) dz \right\} \quad (37)$$

where $\eta_{sj} = \delta/\delta_j$

This expression can be made explicit after some tedious algebra (Chapalain, 1988).

CHAPTER 168

NEARSHORE SEDIMENT FLUX AND BOTTOM BOUNDARY DYNAMICS THE CANADIAN COASTAL SEDIMENT TRANSPORT PROGRAMME (C-COAST)

Brian Greenwood¹, Philip D. Osborne¹
Anthony J. Bowen², David G. Hazen²
Alex E. Hay³

ABSTRACT

The Canadian Coastal Sediment Transport Programme (C-COAST) is designed to increase our knowledge of the dynamics of non-cohesive shorefaces through field measurement of sediment transport and the response of the bottom boundary under combined waves and currents. Suspended sediment concentrations are measured using Optical Backscatterance Suspended Solids Sensors (OBS-1P - D & A Associates) and a new multi-frequency, Remote Acoustic Sediment Transport system (RASTRAN). Near-bed velocities are measured using electromagnetic and electroacoustic flowmeters; cross-products of velocity and concentration provide estimates of sediment flux. The bottom boundary response is determined at the roughness (bedform) scale using a High Resolution Remote Tracking Sonar (HRRTS II) and at the shoreface scale using Depth-of-Activity rods and standard survey. Suspended sediment flux is extremely episodic, responding to individual waves, wave groups and low frequency motions, including mean flows. A significant time-dependent transport is revealed in the vertical structure. Net transport includes contributions from wind waves, low frequency waves and mean flows. A sediment transport balance controlling local slopes can therefore be achieved by spatial and/or temporal divergence of these components. Reservations must exist with respect to transport models which use depth and/or time averaged terms and which fail to recognize the distinct components of fluid motion contributing to the total sediment transport.

INTRODUCTION

Perhaps the most intransigent problem restricting our understanding of coastal behaviour is the relationship between local sediment flux rates, sediment flux divergence and the response of the bottom boundary. Laboratory experimentation has been extensive and a number of parameterizations of the system have been proposed; however, they fail when applied to the prototype (see Seymour and Castel, 1989). Existing physically-based theory (e.g. Bowen, 1980a, Bailard, 1981) provide useful qualitative predictions, but include time and depth-averaged terms which remain questionable (Bowen, 1980b; Bailard, 1987). Few field data exist which have the necessary temporal and spatial resolution for evaluating either existing sediment transport theory or the underlying assumptions. A requirement in the testing of existing models and in the generation of new models is adequate field measurement of sediment transport and bottom boundary response. The Canadian Coastal Sediment Transport Programme (C-COAST) is a joint University venture, which has evolved from the Canadian Coastal Sediment Study (C²S² - Willis, 1987), and is designed specifically to measure sediment transport and the concurrent response of the bottom boundary under combined waves and currents on the shoreface. The overall objectives are to: (i) investigate the spatial and temporal behaviour of near-bed suspended sediment concentrations; (ii) compute suspended sediment fluxes and relate them to both the forcing agents and to the bottom boundary responses; (iii) investigate the mechanisms controlling the directions and rates of suspended sediment flux; (iv) understand the nature of cross-shore and alongshore sediment fluxes on barred and non-barred shorefaces. In this paper we summarize the methodologies adopted, focus on mechanisms for cross-shore suspended sediment flux and suggest implications for existing models of sediment transport and beach equilibrium.

EXPERIMENTAL DESIGN

In Phase I of the programme, four field experiments have been completed at: (i) Bluewater Beach, a single barred (1987) or double barred (1988) shoreface with a slope of 0.014 in medium-to-fine sands in Nottawasaga Bay, in the Canadian Great Lakes. (ii) Queensland Beach, Nova Scotia, a non-barred shoreface in medium sands, with a slope of 0.03-0.10 and a spring tide range of 2 m on the Eastern Seaboard of Canada. (iii) Stanhope Lane Beach, Prince Edward Island, a triple barred shoreface in medium-to-fine sands, with a micro-tidal regime in the Southern Gulf of St. Lawrence, Canada.

SEDIMENT FLUX DETERMINATION

Direct measurement of sediment flux in the field is still difficult and a wide range of techniques have been tried (for reviews of philosophy and methodology see Greenwood et al., 1979; Huntley, 1982; Horikawa, 1988; Basinski, 1989; Seymour, 1989). No reliable bedload sensor exists; however, development of reliable, high frequency response, optical and acoustic sediment concentration sensors provide, together with reliable velocity sensors, measurements of suspended sediment flux. The cross-product of velocity and sediment concentration vectors determined from "collocated" sensors is an approximation of the "instantaneous" sediment transport rate, assuming that the sediment moves at the same speed as the fluid. Time-averaging this product gives the "net" sediment transport rate. Assuming also that values of velocity and concentration are both composed of a steady (\bar{u}, \bar{c}) and an unsteady (u', c') part, then the "net" transport is:

$$\begin{aligned} \langle uc \rangle &= \langle (u + u')(c + c') \rangle \\ &= \bar{u}\bar{c} + \langle \bar{u}c' \rangle + \langle u'\bar{c} \rangle + \langle u'c' \rangle \end{aligned}$$

Since $\langle \bar{u}c' \rangle$ and $\langle u'\bar{c} \rangle$ must tend to zero then:

$$\langle uc \rangle = \bar{u}\bar{c} + \langle u'c' \rangle$$

where $\bar{u}\bar{c}$ is the "mean" transport and $\langle u'c' \rangle$ is the "flux coupling" induced by correlations between velocity and concentration (Jaffe et al., 1985). The latter can most conveniently be computed from the co-spectrum (Huntley and Hanes, 1987), which also reveals the relative importance of differing frequencies to the rate and direction of this "oscillatory" transport. Integration of the cospectrum (or part thereof) gives the "net oscillatory" (or part thereof) transport.

Such computations, however, depend upon accurate high resolution (temporal and spatial) measurements of the velocity and concentration vectors. Figure 1 illustrates a typical monitoring station used in the C-COAST programme. It consists of "collocated" vertical arrays of current and concentration sensors, together with a wave sensor, either a pressure sensor or a continuous resistance staff (see Greenwood et al., 1990 for details) and an underwater digitization and transmission system (UDATS; Hazen et al., 1988).

The structure of the local suspended sediment profile has been determined most usually from point measurements using Optical Backscatterance Suspended Solids Sensors (OBS-1P - see Downing et al., 1981; D & A, 1989). Quasi-

Figure 1. Typical sensor deployment configuration; note that neither RASTRAN nor HRRTS II are depicted.

continuous concentration profiles (2 cm resolution) is also possible using a new multifrequency (1, 2.5, 5 MHz) Remote Acoustic Sediment Transport system (RASTRAN, Hay et al., 1988). Direct multiple point measurements of sediment concentration are obtained using a modified Neilsen-type hydraulic sampler (Neilsen, 1984). Extensive calibrations of the optical and acoustic suspended sediment sensors have been undertaken and cross-calibrations between the two have been made in the laboratory and in the field (Figure 2 - see Greenwood et al., 1990 for details).

BOTTOM BOUNDARY DYNAMICS

The response of the bottom boundary to sediment transport has traditionally been determined at large scales using standard Survey Techniques and Depth-of-Activity Rods measured by SCUBA divers (Greenwood and Hale, 1980; Greenwood, 1987). Such techniques are restricted by environmental constraints to pre- and post-storm measurements; spatial and temporal resolution is, therefore, limited to time-averaged values and gross morphological shifts. In the C-COAST experiments, bed elevation changes have been monitored locally on a continuing basis using acoustic imaging. RASTRAN is capable of determining bottom elevations continuously to within a few centimeters, while a new High Resolution Remote Tracking Sonar (HRRTS II - see Greenwood et al.,

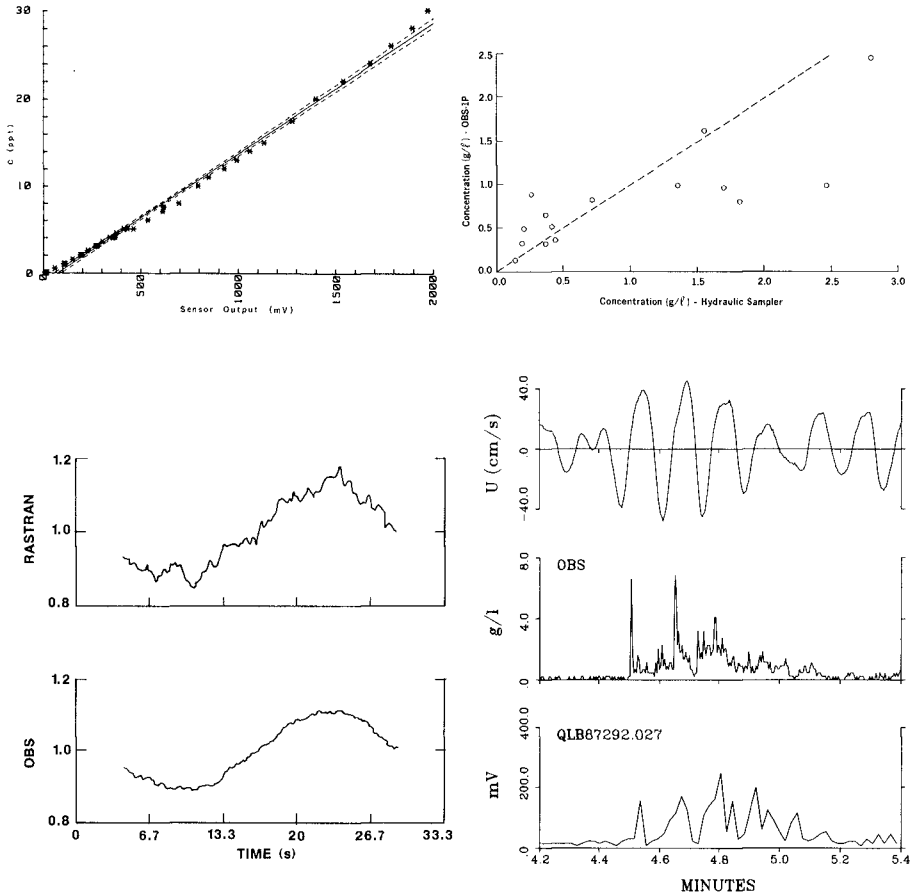

Figure 2 Optical and acoustic measurements of concentration: (a) calibration curve for the OBS-1P including the 95 % confidence band; (b) comparison between time-averaged concentrations using the OBS-1P and a Neilsen-type sampler; the 1:1 line is shown; (c) optical and acoustic signals from the same sediment concentrations generated in a suspended sediment jet - signals have been normalized with respect to the means; (d) field response of the OBS-1P (middle) and RASTRAN (bottom) to the same re-suspension event and the near-bed velocity field (top). Note: the uncalibrated RASTRAN signal was sampled at 0.8 Hz, whereas the OBS and velocity data were acquired at 4 Hz.

1985; Greenwood and Richards, 1991) can resolve bed elevations on a continuous basis to the order of less than one centimeter. Also the local bottom roughness (bedforms - Figure 3) can be measured over several meters with HRRTS II which uses a 5 MHz transducer, with a beam width of 0.72 degrees (nominal), a 30 s pulse length, a repetition rate of 20 Hz and , and which is driven mechanically along a track mounted on the bed.

FIGURE 3 Acoustic signature of the bottom boundary using HRRTS II: shown are an unfiltered signal sampled at 8 Hz and a filtered spatial series; note the phase shift associated with the six pole recursive digital filter. Asymmetric ripples with heights of 0.5-1.5 cm and spacings of 9-11 cm existed at this time; considerable sediment re-suspension creates much of the noise.

SEDIMENT RE-SUSPENSION

Sediment re-suspension is an extremely episodic process even under breaking waves; however, contrary to expectations, the suspended sediment concentrations do not exhibit strong spectral signatures typical of the major forcing function (near-bed velocity (stress) - Figure 4). Spectral peaks at the frequency of the primary wave and the first harmonic may be seen under shoaling waves and indicate a dependency upon stresses generated during both onshore and offshore half-wave cycles; this pattern disappears with increasing elevation. A large low frequency peak is present in this example. Under breaking waves, the high frequency peaks disappear and spectral density increases rapidly with decreasing frequency.

FIGURE 4 Spectra of cross-shore velocity (EM846X) and sediment concentration (OBS) at 4 and 10 cm elevation; the vertical bar indicates the 95% confidence limits, NP = sample size, DF = degrees of freedom BW = bandwidth.

A more appropriate expression of the dynamics of sediment suspension is achieved with time series (Figure 5):

(i) sediment concentrations respond to both individual wave cycles and, more importantly, to wave groups. As a group of large waves pass re-suspension occurs as a cumulative increase and then decrease in concentration lasting for several tens of seconds; fluctuations associated with individual wave cycles are superimposed. Spatially coherent re-suspension events can be identified as wave groups propagate across the nearshore, and even within surf zones dominated by spilling breakers. Since wave groupiness is ubiquitous in both wind forced wave fields (e.g. Great Lakes) and swell (e.g. East Coast) it plays an extremely important role in sediment transport.

(ii) small asymmetries in the near-bed velocity field associated with non-linear wind waves can induce significantly larger asymmetries in transport. Figure 5 illustrates the larger landward transports induced by wind waves shoaling over the lakeward slope of a bar.

(iii) concentrations decrease rapidly away from the bed in general (Figure 6), with maxima measured at 0.04 m elevation only rarely exceeding 10-15 g/l, even under spilling breakers. While time-averaged values decay exponentially with height (Osborne, 1990), this is not a good reflection of the transport process. Concentration gradients over the lowest 0.20 m vary within wave cycles

FIGURE 5 Time series of cross-shore velocity (u), sediment concentration (c) and sediment flux (uc) at one elevation, 85 m offshore in 1.8 m of water.

from large decay rates (6C), to near-uniformity (6N) and occasionally inversions with height (6F). This variation results from both the varying intensity of turbulence from one half wave cycle to the next as a wave group passes and the vertical propagation of separation vortices shed from rippled beds. The latter are common even in the surf zone, under flow conditions well above the threshold established by laboratory experiments for flat bed (Ollerhead and Greenwood, 1990).

(iv) phase lags between the near-bed maximum velocity and maximum sediment concentration are common and increase with increasing elevation above the bed. The lag does decrease with increasing velocity, as might be expected (Osborne, 1990).

(v) complex interactions involved in natural sediment re-suspension prevent identification of simple thresholds (velocity or acceleration) for the initiation of suspension. No simple functional relationships can be established between concentration increases and increases in the forcing function, even allowing for phase lags.

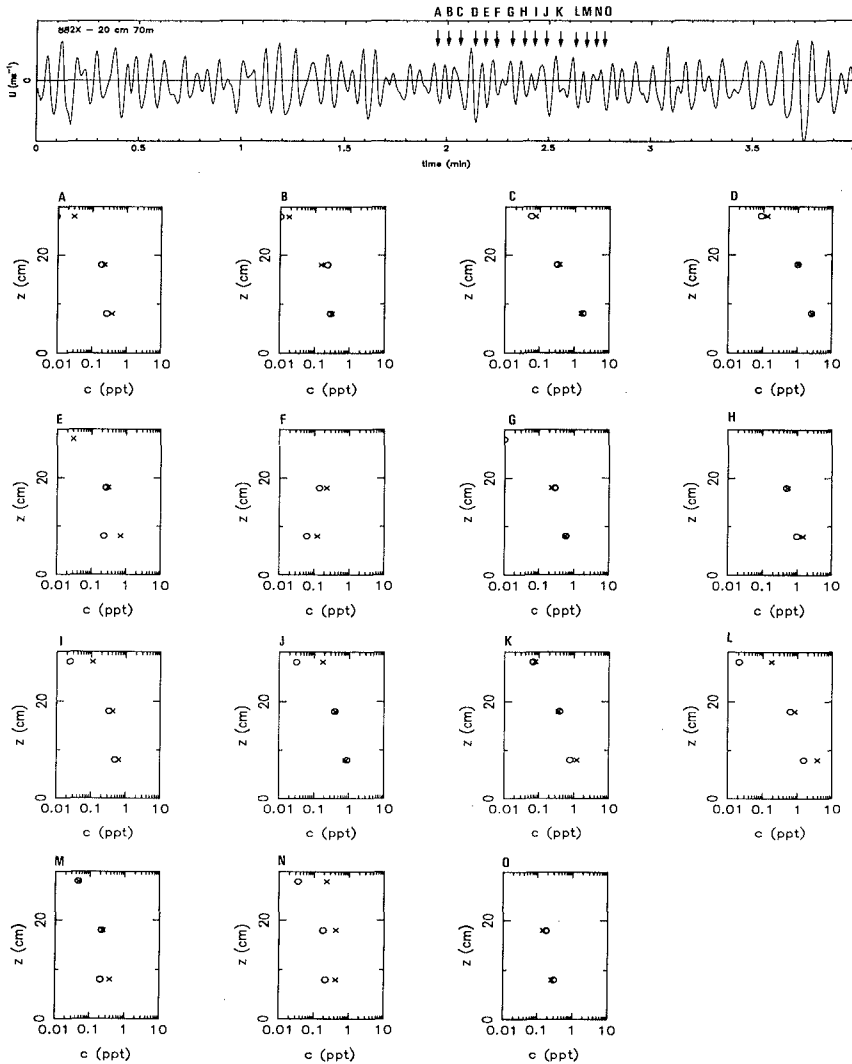

FIGURE 6 Time series of suspended sediment concentrations averaged over each half-wave cycle and at several elevations; crosses indicate the onshore phase of motion, the circles the offshore phase. The arrows indicate the fifteen wave cycles analysed.

The episodic, time-dependent nature of sediment re-suspension clearly influences both the directions and rates of transport at any particular elevation above the bed (Figure 5). Phase lags may cause actual reversals of

net transport within a short distance of the bed. Furthermore, the direction and rates of sediment transport reflect contributions from both oscillatory components of fluid motion and mean flows. Estimates of the oscillatory components can be determined from the co-spectrum (Figure 7). Note in this example: (a) large onshore transports at wind wave frequencies (all elevations); (b) at low frequencies transport is offshore near the bed and onshore higher in the water column. Contributions to the net transports from both "oscillatory" and "mean" components have been computed for a range of wave, current and bedform conditions (Osborne, 1990; Osborne et al., 1990) and it is clear that these contributions vary both with time and over space (with respect to distance above the bed and distance offshore). Figure 8 illustrates an example of the variations across shore in the transport contributions with respect to height above the bed for both non-breaking and occasionally spilling conditions on a non-barred marine beach. Under non-breaking waves, only a small amount of net transport was occurring; this was close to the bed and landward under wind wave asymmetries. Net oscillatory transport is generally landward under near-breaking waves while the mean transport is offshore at all levels. It is clear that the "oscillatory" and "mean" transport components can operate in different directions and at similar rates, such that large volumes of sediment may be transported but the net transport may be close to zero. This suggests the possibility of a locally balanced sediment transport system producing steady state slopes, even under high waves and large suspended loads.

DISCUSSION AND CONCLUSIONS

Both the OBS-1P and RASTRAN give coherent signals from sands suspended by waves and currents. Laboratory cross-calibrations and field comparisons of the time-averaged OBS-1P signals and hydraulic sampling of sediment concentrations supports the contention that both optical and acoustic sensors record sediment concentrations accurately. The acoustic system has the added capability of recording "continuous" vertical profiles and the advantage of being non-intrusive.

Suspended sediment transport is neither continuous nor a simple diffusive process under the combined flows (oscillatory and quasi-steady) of the shoreface. Rather it is extremely episodic and not always coherently related to single incident waves cycles, even under wave breaking. A strong association exists with the velocity structure (and stresses) induced by wave groups. The latter is true for environments with local wind-waves as

Figure 7 Velocity and concentration spectra (a) and associated cospectra (b) for transport 70 m offshore on a planar beach under near-breaking and spilling breakers. Note: the spectral estimates use 4096 values (17 minutes) with 70 degrees of freedom and a bandwidth of 0.03 Hz; the 95% confidence band for the spectral estimates is shown by the vertical bar.

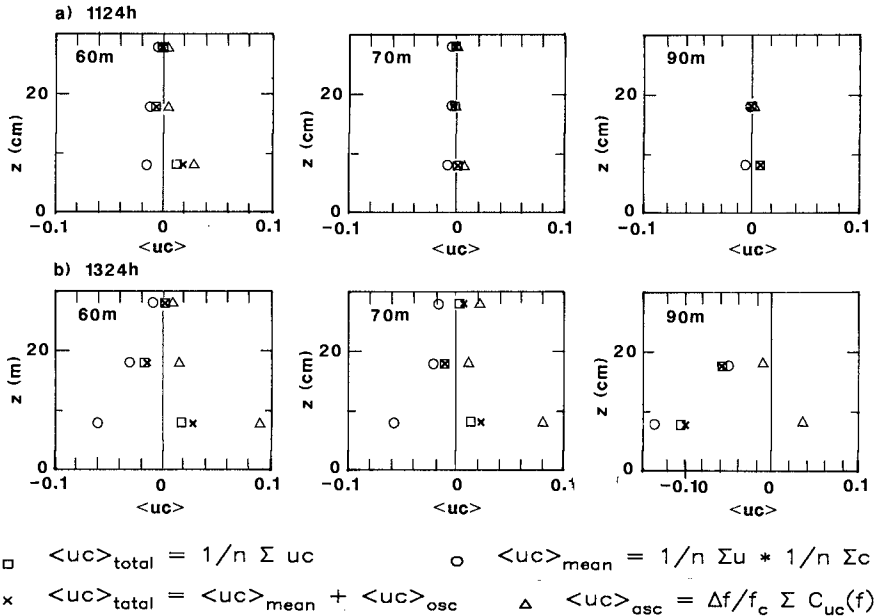

Figure 8 Vertical structure of net suspended sediment transport across shore on a non-barred shoreface, Queensland Beach: (a) shoaling waves; (b) near-breaking (90, 70 m) and occasionally spilling waves (60 m).

Sediment re-suspension also exhibits a strong time-dependency; significant phase lags exist between near-bed velocity (stress) and sediment concentration at any given elevation. Furthermore, vertical gradients in sediment concentration are variable at the wave cycle scale. Although time-averaged profiles of sediment concentration can be described by an exponential decay function, "instantaneous" profiles may show extremely large gradients or near uniformity in the near-bed water column during suspension events; "concentration inversions" are not uncommon. This temporal dependency with elevation clearly controls both sediment transport rates and directions at any specific elevation.

The bed geometry (bedforms) has a large influence on the vertical gradients in the sediment concentration. Sediment re-suspension is characterized by the vertical propagation of coherent turbulent vortices resulting from flow separation over rippled beds, which persist even under spilling breakers.

Present predictive models for cross-shore sediment transport fail to incorporate the effects of wave groupiness or the vortex-shedding effects of bed forms and inadequately model the depth and time dependant character of the system. Furthermore, the strong frequency dependence of suspension transport and the relative contributions to the total transport from wind waves, low frequency waves and mean flows have still to be effectively addressed.

CHAPTER 169

NEARSHORE NOURISHMENT IMPLEMENTATION, MONITORING & MODEL STUDIES OF 1.5M³ AT KIRRA BEACH

L.A. Jackson¹ & R.B. Tomlinson²

1.0 INTRODUCTION

Whilst the Gold Coast beaches are generally in long term equilibrium, the southern Gold Coast beaches have suffered serious erosion (approximately 7M m³) since construction in 1962-1964 of the Tweed River training walls, to the south (updrift) of the Gold Coast (Fig. 1).

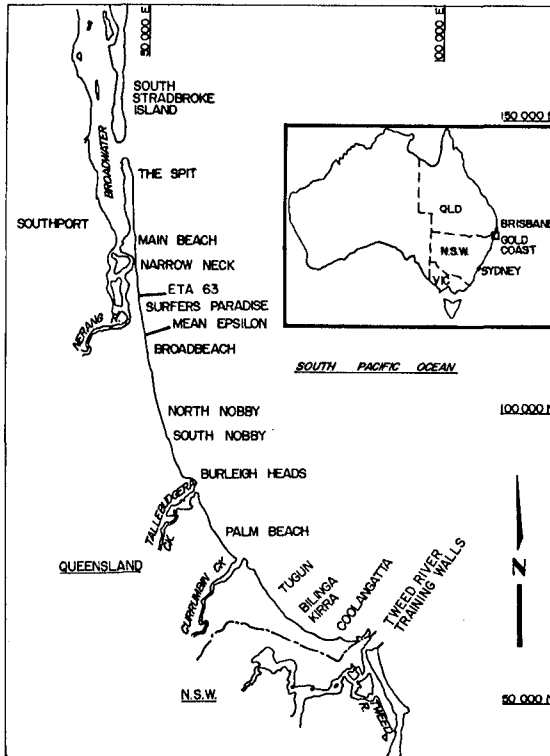

Figure 1.

1 Supervising Engineer, Special Projects, Gold Coast City Council, Qld, Australia.

2 Engineer, Water Research Laboratory, Univ. of New South Wales, Manly Vale, NSW, Australia.

Erosion first became evident in the late 1960's and since this time, various restoration works have been implemented:-

- 1972 Kirra Point groyne to stabilise Coolangatta beach.
- 1974 Kirra Beach nourished ($0.8M m^3$) and Miles Street groyne constructed to entrap a beach at South Kirra Surf Life Saving Club.
- 1983 Investigation into sand transport around Tweed River walls/delta commenced and various options considered due to further erosion as 1974 nourishment was inadequate to cope with ongoing erosion.
- 1985 A 300m section at North Kirra Surf Life Saving Club nourished ($0.315M m^3$) and stabilised by a sand-filled groyne.

The 1985 works (Ref. Jackson 1985) were implemented as an interim measure to restore the eroded public beach at the North Kirra Surf Life Saving Club whilst investigations into the sand transport and losses were continued. This nourishment utilised the offshore sand reserves and the work included nearshore and deposition at North Kirra as well as other Gold Coast beaches to evaluate the behaviour of nearshore nourishment (approximately 50% of the cost of pumping onshore). Observation of the natural storm bars which form approximately 500m offshore in 6-8m water depth showed that these natural bars dissipate the storm wave energy and in subsequent milder conditions move back onshore (Ref. Boczar-Karakiewicz & Jackson 1990). The nearshore nourishment trials, whilst limited, indicated that as expected, sand deposited shoreward of 9m water depth generally moved shoreward.

The erosion at the unnourished sections of Kirra continued and further works were planned for winter 1988, again using the offshore sand reserves. Further sand sampling showed adequate sand of suitable quality seaward of the 20m water depth.

As it was considered that nearshore nourishment would be the likely method chosen analytical studies were undertaken by the Water Research Laboratory for the Gold Coast City Council. This was to give a qualitative assessment of the impact on coastal processes of the dredging and nearshore nourishment at various depths and to examine the applicability of the modelling techniques for predicting future nearshore nourishment behaviour and options.

2.0 MODEL STUDIES

2.1 Wave Refraction Studies

Forward ray wave refraction computer modelling techniques were employed to examine the sensitivity of the shoreline wave climate to offshore dredging. The criterion for assessing the impact on the shoreline wave climate was the change in calculated refraction coefficients and wave angles from the initial bathymetric conditions to the post-nourishment condition.

In general, the study demonstrated that dredging in areas seaward of the 20m depth contour is not likely to have any significant effect on shoreline conditions. This was not a totally unexpected result as both the dredged area and the nourishment bar approximately follow the bottom contours.

Typical results for waves approaching from the dominant wave direction are shown in Figure 2.1. Three dredging and placement options were considered and the results expressed in terms of the average change in refraction coefficient K_R and the change in wave angle for sections of coast in the study area. The results showed changes in the wave climate, although these were generally within the order of accuracy of the technique. The study showed that dredging in depths greater than 20m would have negligible effect on the shoreline wave climate. This result was expected as the dredging operation was contour parallel. Placement of material on the nourishment bar resulted in some significant localised changes, but these were more a function of the irregularity in the schematised disposal pattern introduced by the model formulation.

2.2 Sediment Transport Predictions

The monitoring of a previous small scale nourishment at Kirra in 1985 indicated that although there was a rapid smoothing of the individual dump mounds, the deeper sections (to R.L. -10m) of the bar were slow to respond to gross sediment transport forces. The purpose of this study was to attempt to predict the rate of migration shoreward of a nourished bar as a whole in various conditions using a coastal sediment transport model.

The criteria for selection of a model was that it should be cost effective, user friendly and have been originally developed as an interpretive tool. The model chosen was that developed by Perlin and Dean (1983) and subsequently updated by Scheffner and Rosati (1987). This is a shoreline evolution model in which the beach profile is schematised into N contour levels. There are a number of severe limitations, but nevertheless it can assist in assessing sediment transport in some locations.

offshore bars to be modelled correctly. Furthermore, the profile must be schematised to a limited number of stepped changes, for computational reasons.

Profiles of a different shape can be modelled by inputting horizontal contour adjustment distances which represent the difference between the equilibrium profile and the actual profile. Dumped dredge material can only be modelled correctly if the seabed continues to slope down in the offshore direction. An additional limitation is that the model boundaries are fixed; that is, there can be no allowance for longshore transport into or out of the area modelled. The onshore-offshore transport rate is proportional to the bed steepness relative to the equilibrium profile steepness and hence is sensitive to the method of placement of the nourishment.

2.2.1 Schematic Models of Kirra

A preliminary assessment of whether this model could be used to predict the response of Kirra beach to dumping of dredged material offshore has been carried out. This was done using schematic beach profiles referred to an equilibrium profile chosen to represent the typical pre-nourished Kirra beach profile as shown in Figure 2.2. Three idealised cases have been examined in this preliminary assessment. They are:

- 1) Equilibrium beach profiles with dredge material dumped in a V-shaped mound, in 5 to 11m water depth.
- 2) Equilibrium beach profiles with material added uniformly along the shore to simulate as closely as possible an offshore bar in 3 to 7m water depth.
- 3) Equilibrium beach profiles with material added uniformly along the shore to simulate as closely as possible an offshore bar in 3 to 7m water depth and dredge dumped material in 6 to 10m water depth.

The equilibrium profile used a Dean coefficient, A , of 0.15 and a grain size of 0.2mm. The beach slope was set to 0.05 up to a berm level of 3m. The computational grid consisted of up to 39 alongshore grid cells at 50m spacing.

NOTE $\Delta K_R = (K_R(\text{initial}) - K_R(x))$ $\Delta \theta = (\theta_{\text{initial}} - \theta(x))$ (degrees)

OFFSHORE WAVE DIRECTION: S.E.
 OFFSHORE WAVE PERIOD: 14 secs.

Figure 2.1 Change in Shoreline Wave Climate

The Perlin and Dean model is based on the equilibrium beach profile concept. The seabed depth is assumed to increase monotonically in the offshore direction. The relationship used is the Dean equilibrium profile given by

$$h = Ay^{2/3}$$

where n is the water depth, y is the distance offshore and A is a coefficient. This profile does not allow

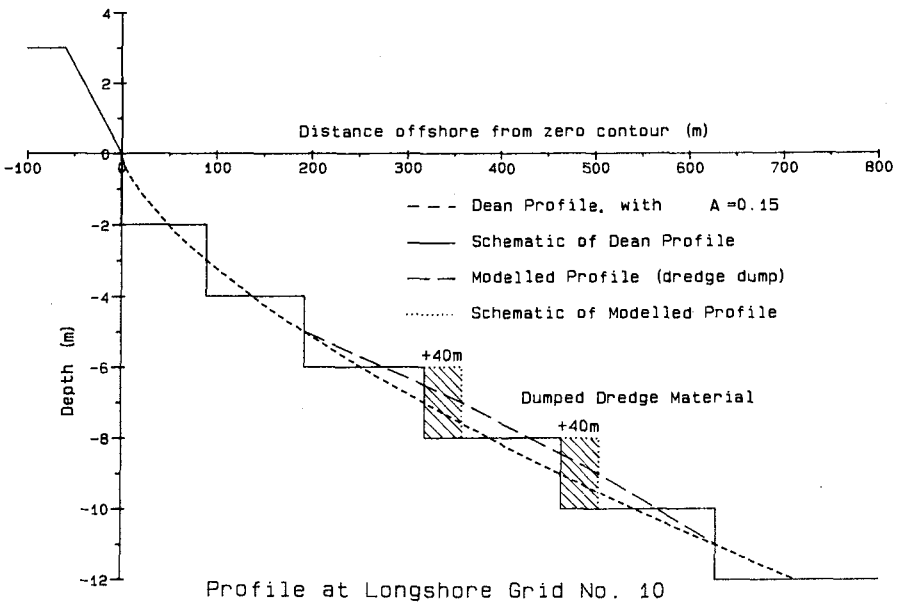

Figure 2.2 Equilibrium Profile Based on Typical Kirra Profiles

1. The rapid smoothing of the individual dredge dumps shown by the survey data was examined by simulating each dump as a V-shaped deposit. This was done by moving the R.L. -7 and R.L. -9m contours offshore as shown in Figure 2.3.

Profile at Longshore Grid No. 10
Figure 2.3 Schematic Profile of Individual Dredge Dumps

Running the model with an average annual wave climate caused the V-shaped contours to be smoothed out very rapidly even when the wave climate was mild. Figure 2.4 shows the initial and final contours for the case of a model run for one year using synthesised wave data.

Figure 2.4 Individual Dredge Pump Response

2. Material was then added to the model to simulate as closely as possible a real offshore storm bar. Surveyed beach profile data from Kirra was used for this purpose. Since the offshore depths must increase monotonically with offshore distance, a true bar could not be modelled. However the contours between R.L. 0 to R.L. -7m were adjusted either onshore or offshore by up to 65m to schematically represent the bar.

The model was run for a period of one year using the synthesised annual wave climate. This resulted in rapid changes to the nearshore areas, but no significant change to contours beyond R.L. -4m. There was no suggestion that with this wave climate the profile as a whole would move towards an equilibrium profile.

3. Having established that the response time was slow for this case, material was added to the storm bar profile to simulate the nourishment bar as shown in Figure 2.5. The equilibrium profile contours were adjusted onshore and offshore by up to 95m to schematise the nourished profile. The model was run using the synthesised wave data as well as specific storm data. The length of the idealised shoreline was varied to test the sensitivity of the model to the chosen grid spacing.

Figure 2.5 Schematic Profile of Nourished Profile

Figure 2.6 Idealised Nourished Bar Response

The results shown in Figure 2.6 were for a storm which occurred in April 1989 some five months after the nourishment. The significant wave height was 5 to 6m for

two to three days with wave periods of up to 12 seconds. A section of coastline was idealised as being a straight beach, and a uniformly placed nourishment was as shown by the initial conditions given in Figure 2.6.

The results of this run showed predominantly longshore transport to the north as was expected, given the SSE wave approach direction. It was found that of the material added to represent the nourishment, less than 10% was transported out of the control area. The survey results for the whole of the beach profile suggest that around 30% of the deposition was transported out of the region during the four months between surveys.

3.0 TENDER EVALUATION

Investigations had shown the whole active profile out to approximately R.L. -10m, to be depleted in the area to be nourished. The required quantity in this area was estimated to be approximately 1.5M m³. The tender documents specified nourishment of the whole profile from the beach to R.L. -10m as the preferred option. However, a range of options of nourishment locations was included. The tender prices were:

- a) Nearshore nourishment only: \$2.3M (WestHam Dredging)
R.L. -6 to -10m)
- b) Profile nourishment : \$6.8M
- c) Onshore nourishment only : \$8.3M

It was decided to accept the tender of WestHam Dredging Pty. Ltd. to carry out nearshore nourishment only (Fig. 3.1).

4.0 IMPLEMENTATION

The sand was dredged from seaward of R.L. -20 some 1,500m offshore and deposited between R.L. -6 to 10.5m using the trailing suction hopper dredge "W.H. Resolution" with bottom opening hopper gates to discharge the material. As stand-down conditions applied for H(sig) greater than 1.9m, and to evaluate the behaviour of the nourished bar, a wave rider buoy with a real time analysis system installed on both the dredge and in Council's offices.

The deposition operations involved grounding the bow of the dredge as far shoreward as possible in the deposition area (shoreward of the R.L. -10m contour) and moving shoreward as the load was dumped. This method resulted

in discrete mounds being left on the seabed with a crest level of approximately R.L. -6m. In order to verify quantities and the dredging/deposition location, two Council inspectors were stationed on board the dredge.

To optimise deposition placements, the contractor carried out daily surveys over the deposition area using a 43' survey vessel, which provided updated soundings daily to the dredge. The location of each load deposited was also plotted by the Council inspectors on board to verify acceptability of each load location and to provide details of areas filled to the dredge Captain.

Council also carried out regular surveys from the beach to R.L. -12m prior to and during the project. In order to be able to distinguish between individual mounds in the deposition area, these surveys were carried out approximately shore parallel at 10m max. spacing.

Unfortunately, the works were curtailed some 4,000m³ short of the 1.5M m³ due to heavy sea conditions and storm conditions were experienced repeatedly for over a year afterwards (Fig. 4.1). This severely restricted accurate surveys of the post-nourishment behaviour and data available for analysis. Despite the storm wave conditions which caused considerable erosion elsewhere and accelerated erosion of the depleted area to the north (downdrift) of the nourishment, significant onshore translation and accretion at the toe of the boulder wall has been measured as a result of the increased offshore wave breaking, decay and refraction over the artificial bar zone. Accretion to form a narrow beach in front of the boulder walls occurred between storms in most of the area nourished (Fig. 4.2).

As the erosion to the north threatened private foreshore properties (the nearshore nourishment was mainly seaward of foreshore fronted by public park), considerable public pressure from the affected residents resulted, and the Queensland Government implemented a scheme to fully restore the southern Gold Coast beaches.

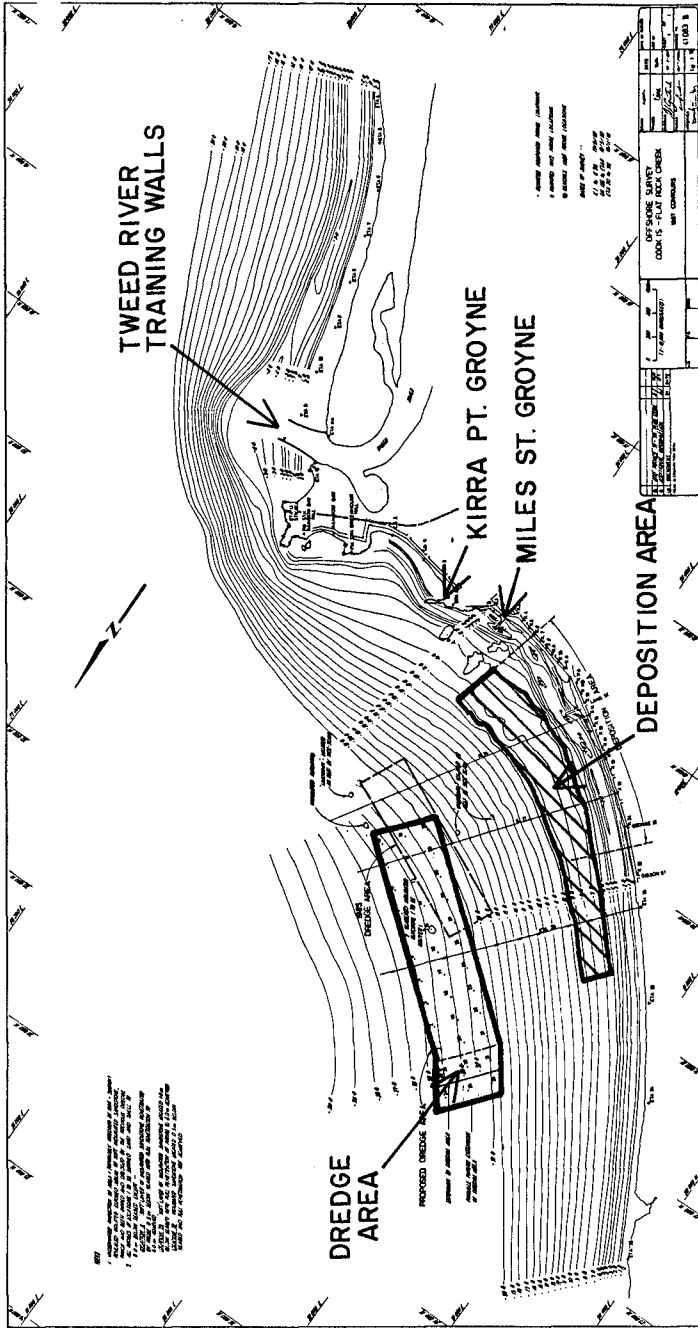

Figure 3.1 Plan of Kirra Nourishment Project (1988)

Figure 4.1 Kirra Waverider Buoy Records

Figure 4.2 Post Nourishment Profile (Typical)

5.0 CONCLUSION

Despite adverse conditions, the works carried out in 1988 appear, as predicted by the model investigations, to have been effective in protecting the foreshore and allowing accretion of a usable beach. The adverse weather conditions and the further works of $3.6M m^3$ implemented in November 1989 limited the survey data which could be collected and analysed. The results of the 1988 works are to be further analysed in conjunction with the 1989/90 works which included $400,000m^3$ nearshore nourishment.

CHAPTER 170

A New Approach to 3D Flow and Transport-Modeling

Johan C.M. Dijkzeul¹
Jan J. Leendertse²

Abstract

In recent years two-dimensional numerical models have been applied successfully not only to large scale tidal computations, but also to small scale detailed flow computations (Bosselaar et al., 1987, Leendertse et al., 1989). However the application of three-dimensional models for fine-grid computations is very limited due to the very high requirements for computer times, caused by the explicit numerical algorithms which are being used. This problem is now alleviated by use of an alternating direction implicit computation method for three-dimensional flow- and transport-modeling. With this method, presented in this paper, the effective computation time is about an order of magnitude smaller then with previous models with similar accuracy.

Introduction

Two- and three-dimensional numerical models are used more and more for fine grid computations. At the 20th I.C.C.E., Taiwan, 1986, small scale applications were presented of fine grid two-dimensional models for the Delta-project in the Dutch Eastern Scheldt estuary. In this case, flow patterns near the construction sites of the storm surge barrier and compartmentation dams at different stages have been computed (Bosselaar et al., 1986, Klatter et al., 1986).

The gridsizes in these models varied from 400 m. down to

¹Projectadvisor, Icim bv, P.O. Box 5809, 2280 HV Rijswijk, The Netherlands

²Manager, TRI-FLOW COMP Inc., 2672 Bayshore Av., Ventura, CA 93001, U.S.A.

10 m. In Figure 1 an example is given of a flow pattern in a two-dimensional model for the northern channel Hammen in the Eastern Scheldt estuary.

Figure 1.: Flow-pattern in the two-dimensional model of the Hammen

The results were used for example for stability-analysis of the bed protection by mattresses and the computation of sand losses. Therefore, velocities and shear stresses in the bottom layer were needed. The possibility of using three-dimensional models was investigated and 3D-computations were made with the available explicit 3D-code, developed by Leendertse and Liu (1973, 1987) (see Figure 2).

These 3D-computations appeared to be feasible but the computer-time needed was very large. This can be understood from table 1.

The gridsize in the 2D-model was 45 m., but for the comparison a gridsize of 90 m for the 2D- and 3D-models has been used. The 2D-modelling system WAQUA (Stelling, 1983) is using an implicit ADI-type of scheme, so a

Figure 2.: Flow-pattern in a cross-section of the three-dimensional model of the Hammen

model characteristics	2-dimensional model	3-dimensional model
gridsize (m)	90	90
timestep (s)	60	1.5
method	implicit ADI	explicit
number of layers	1	10

Table 1: characteristics of the 2D- and 3D-model Hammen

stability requirement is absent and timesteps of 0.5 to 1 minute are possible. The explicit 3D-scheme however, needs a timestep of 1.5 second for stability reasons. The 3D-model has 10 layers and a lot of CPU-time is needed for a computation.

It should be emphasized that for accurate flow-computations the approximation of the advection-terms in the momentum equations is very important. An inaccurate time- and space discretisation will introduce numerical (eddy-) viscosity or will make the scheme first order accurate (Stelling, 1983) and details in computed

velocity distributions will be lost. Only fourth order dissipation is introduced by the approximations in the schemes for the advection terms.

For successful investigations and detailed 3-dimensional flow-computations with numerical models an implicit 3D-scheme is required and the computation method used has to meet the following requirements:

- The computation method must be stable,
- The algorithm must have an accuracy of at least second order,
- Numerical (eddy-) viscosity must be absent,
- The computation method must allow for large timesteps and must be efficient.

Computation method

The requirements above are met by the two-dimensional system WAQUA and also by the extension in the 3D-algorithm, which will be explained briefly in the next sections. For more details about the equations, the finite difference approximations and the solution technique the reader is referred to (Leendertse, 1989).

In this three-dimensional system also an alternating direction implicit computation method is used. The variables in the three-dimensional field are solved by successive solution of sets of equations that are described in vertical planes. With the use of special advection term approximations, the three-dimensional problem is broken down in a sequence of two-dimensional problems, which in turn can be reduced to the solution of sets of one-dimensional problems.

The most important aspects of this three-dimensional solution technique are:

- The use of horizontal momentum and continuity equations for the different layers in the model,
- The use of an ADI-type of scheme on a horizontal and vertical staggered grid,
- The use of asymmetrical higher order advection term approximations developed for the cross-advection terms in a two-dimensional model by Stelling (1983),
- The hydrostatic pressure assumption,
- A second order accuracy of the solution method with fourth order dissipation,
- An unconditional stability of the computation,
- A limitation of the timestep by requirements for accuracy only.

For the one layer case, this 3D-method reduces to the original two-dimensional scheme, except for some minor details.

Flow-computation

The solution of the finite difference equations for each stage in the ADI-method are solved iteratively. In general, iterations are required only for the expressions for the advection term coefficients and for the upstream gradients in the advection terms in case the local flow direction is different from the dominant flow direction.

In the first half-time-step (stage 1) of the multistep operation, the horizontal V-velocities in the vertical planes in Y-direction are computed first. The coordinate system used is X and Y for the horizontal and Z for the vertical direction with velocities U, V and W respectively.

For each column the momentum equations for the V-velocities are implicitly coupled in the vertical by the approximation of WV_{zz} , resulting in a three-diagonal system of equations for V which can be solved very economic way.

In the vertical plane the implicit horizontal coupling in Y-direction, due to the upwind-differencing for the gradients V_y in the advection term VV_y , can be solved with 2 iterations in opposite Y-directions using just computed values of V during the ongoing iterations.

Also the implicit horizontal coupling in X-direction due to the upwind-differencing for the gradients V_x in the advection term UV_x can be solved with 2 iterations over the planes in opposite X-directions using just computed values of V in the planes during the ongoing iterations.

The solution of the horizontal velocities U, the vertical velocities W and the waterlevels in the other equations in stage 1 is more complicated. The velocities U are coupled in the vertical by the approximation of WU_{zz} in the U-momentum equations and in the horizontal by the approximation of the continuity equation. This coupling is solved as follows: substitution of the discretized U-momentum equations in the continuity equation and summation over the vertical results in a three-diagonal system of equations for the waterlevels to be solved. With the new waterlevels U and W can be solved respectively with the U-momentum and the continuity equations. Iterations are needed for the nonlinearities in the continuity equation.

The second half-time-step (stage 2) follows the same pattern described above for the first stage, but now first the U-velocities are computed implicitly with the U-momentum equations, followed by the implicit computation of V and the waterlevels with help of the V-

momentum and continuity equations.

The combination of both upwind- and central differencing alternatively in the 2-step scheme results in a second order accurate approximation in time and space of the horizontal advection terms with fourth order dissipation. If the advection is expressed upstream, and the coefficients of the nonlinear terms are constant during the timestep, the above presented computation method can be proven to be unconditionally stable.

Transport-computation

Not only the fluid flow is important in three-dimensional modeling. Dissolved substances, salinity distributions and sediment distributions need also to be computed simultaneously with the water motions. For accurate computations of transport and concentrations of dissolved matter in fine-grid models of for example estuaries, an accurate flow-computation is essential.

Experiments have shown (Ridderinkhof, 1990) that for small gridsizes advection is dominant for the dispersion of constituents. With an accurate transport-scheme also stratified flow or transport of sediments can be computed.

For this, a new numerical transport-scheme has been developed, is based on the principles explained above in the scheme for flow computation and is using the same asymmetrical approximations for the advection. The computation method is conservative, second order accurate and shows very limited spatial oscillations near steep fronts, due to the higher order of approximations.

Results

An example of both flow- and transport computation is the dispersion due to wind of a pollutant flowing into lake IJssel from the river IJssel in the Netherlands.

The different flow-directions in top- and bottom-layer caused by wind, results in quite different results in concentrations, compared to the results obtained with a two-dimensional model.

The first application of this new approach has been a management type of model of a closed-off estuary, lake IJssel. A wind driven circulation was generated by a south-easterly wind of about 11.3 m/s. An inflow into

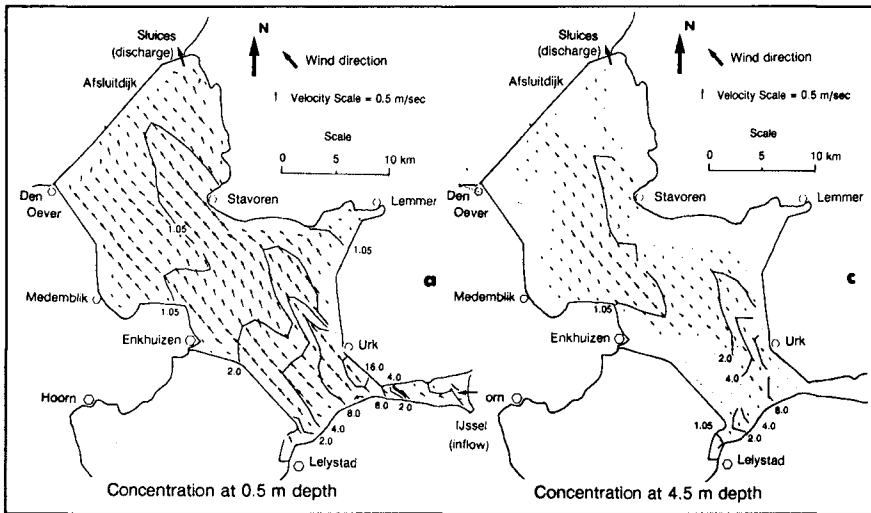

Figure 3.: Computed concentrations and velocities 72 hours after start of computation at 0.5 m depth (a) and 4.5 m depth (c)

the lake from the river IJssel of 500 m³/s was assumed with a concentration of 50 gr/m³ for a limited period to simulate a spill. The outflow at discharge sluices in the north was also set to 500 m³/s.

The lake was represented by a grid of 36 x 21 points in the horizontal plane. The gridsize was 1200 m, the vertical representation was made by five layers of 1 m, and the bottom layer was taken at 1.5 m. The timestep was 7.5 minutes.

Even with the limited depth the concentration distributions at the surface and near the bottom are quite different as is shown in Figure 3. Particularly during the first few days, considerable differences in concentrations over the vertical exist in the southern part of the lake as is shown in the timehistories of the concentrations in Figure 4.

Developments

The above presented computation method for flow- and transport computation is now being used by the Dutch Rijkswaterstaat and by Delft Hydraulics.

Further developments with this scheme are:

- The incorporation of (curvilinear-) transformations

Figure 4.: Computed time-series of the concentration at station A at 0.5 m depth (a), 1.5 m depth (b), 2.5 m depth (c), 3.5 m depth (d), and 4.5 m depth (e) (timestep=7.5 min.)

in the horizontal direction and (σ -) transformations in the vertical direction (de Vriend, 1990),

- The use of a higher order approximation for the advection in the vertical with a different computation method,
- The incorporation of a turbulent energy (K-epsilon) model for vertical diffusion,
- The incorporation of vertical field accelerations for near field computations.

Conclusions

With the presented (ADI) computation method, implicit three-dimensional flow- and transport-computations can be made which are stable and second order accurate.

Large timesteps can be used, compared to explicit codes for small-scale and fine-grid applications, therefor the algorithm is effective in CPU-demand.

CHAPTER 171

The Analysis and Role of Bars on the Protection of a Beach System Gold Coast, Queensland, Australia

B. Boczar-Karakiewicz¹ and L.A. Jackson²

Abstract

Gold Coast beach profile changes have been analysed using a dynamical model describing wave-bed interactions. The model explains the formation and dynamics of prominent longshore bars which are characteristic features of the studied nearshore. Model predictions are compared with field observations and measurements in several locations. Obtained results justify protection measures (eg. nourishment of offshore bars) applied in the study area by the Gold Coast City Council.

1. Introduction

According to observations over a period of the last 100 years, the beach system in the Gold Coast (Fig.1) area is extremely dynamic. At times of severe storm and cyclones events, the beaches are exposed to

high energy waves up to 8.5 m with corresponding wave periods of 14.0 secs. The amplitudes of highest waves observed in this region over to 12.0 m and the largest wave periods are of 17-18 secs (McGrath and Robinson 1973, Gold Coast City Council 1990).

In those conditions, the beaches are eroded but subsequently restored under mild weather conditions and swell waves. After the worst recorded erosion in 1967, the recovery of the

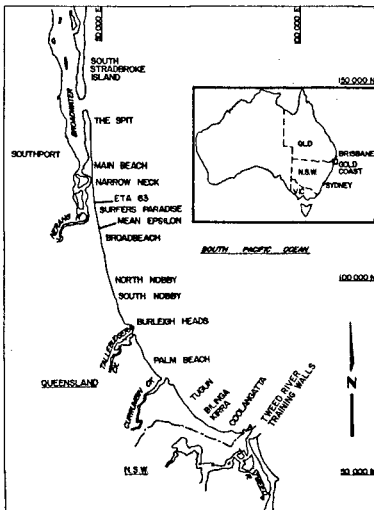

Figure 1. Location map

¹Professor, INRS-Océanologie, Rimouski (Québec) Canada, G5L 3A1

²Engineer, Gold Coast City Council, QLD 4217, Australia

upper beach took a period of some 18 months. With a frequency of major storm and cyclone events lower than 1/18 month, the beach system may recover under conditions that a natural buffer zone comprising the dunes is conserved, and that the sediment supply from the local Tweed River compensates losses of sediment due to the wave-induced longshore transport (Jackson, Smith and Piggot 1988). However, the conservation of a sufficiently large natural dune system has been difficult given the rapid expansion of the recreational usage of the Gold Coast area (Smith and Jackson 1990). Additionally, the construction and subsequent extension of the training walls of the Tweed River (1910 and 1964, respectively) have significantly modified the local sediment supply. The extension of the walls caused an approximated deficit of sediment of some 250,000 m³/yr. Therefore, in recent years quite severe effects of erosion were observed mainly in the southern part of the Gold Coast propelling gradually downdrift to central beaches.

To date some 9 M m³ of beach nourishment has been carried out but protection of the beach and foreshore development requires more beach nourishment to compensate intrusion into the active beach zone by past developments (Chapman 1980, Smith and Jackson 1990). Nourishment has been placed onshore, nearshore and a combination of both. The cost and efficiency of nourishment varies considerably with the location of placement. As nearshore nourishment is generally considerably less expensive in the Gold Coast case, research has been carried out on the behaviour of natural and artificial (nourished) nearshore bars.

To better understand the natural beach system and the effect of natural and artificial bars on the protection of the upper beach, a model has been developed. An analysis of beach equilibrium is presented and based on observations and mathematical modelling of large scale sand bars which are prominent features of the Gold Coast nearshore. Aerial photography shows evidence of offshore sand bars in the entire nearshore of the Gold Coast area. The geometry of bars, their appearance and stability varies in different parts of the coast. Generally they are strongly related to the incidence of predominant storm waves and swell. Typically, the outer shore-parallel bar lies in a water depth of 6-10 m and at distances of 400-500 m from the mean position of the shoreline.

The Gold Coast beach system is extremely mobile with changes occurring in several very different time scales: incident wave trains are changing during normal weather conditions in several tens of hours, the weather over a few days, the climate over years, sediment supply over decades and the shape of the seabed in days to several months.

Observations and measurements show, however, that the complex beach system periodically reaches some kind of dynamical equilibrium which in turn is controlled only by two main factors. These factors are the incident waves and the shape of the underlying seabed from its deepwater end (extending to some 20-25 m of water depth) up to the visible beach (Smith and Jackson 1990).

The incident wave and seabed parameters are the only free parameters in the dynamical model applied in the presented analysis. Model predictions have been compared with observations and resulting conclusions justify the use of nearshore nourishment as a protection measure applied in the study area by the Gold Coast City Council.

2. The model

The model has four constituent processes describing wave-bed interactions, namely (1) the hydrodynamics of the main water body, (2) the near-bed boundary-layer flow, (3) the sediment transport, and (4) the evolution of the bed topography. These four modules are linked together and the resulting model is discretized for numerical integration. The integration procedure consists of a two-step time loop. In the first step, the fluid flow and the sediment flux are calculated over a bed configuration which is instantaneously fixed. In the second step, the temporal evolution of the seabed is calculated while keeping all variables describing the fluid and sediment flow constant. This two-step approximation is justified both on mathematical grounds, and by observations in the laboratory and natural coastal environments which indicates significant changes in bed topography are only observed over a period of many thousands of wave periods. A time-scale is quite long when compared to rapid changes in the fluid flow that can occur during one wave period (Boczar-Karakiewicz *et al.* 1987, Boczar-Karakiewicz and Davidson-Arnott 1987).

The first model constituent describes surface-wave motion in a typical nearshore setting in which the wavelength λ of a peak-period storm wave is large, compared with local water depth h . Following Keller (1988), the recent surface wave description has been derived directly from Euler equations and continuity for a fluid flow bounded by a free surface at $\bar{z} = \zeta(\bar{x}, \bar{t})$, and by a fixed bed at $\bar{z} = -\bar{h}(\bar{x})$. Application of Keller's approach allows us to solve the earlier defined problem of wave propagation in three spatial dimensions in a curvilinear coordinate system (x, z) , where x , is the path of the wave ray (Boczar-Karakiewicz *et al.* 1990).

At the present stage of modelling, it is assumed that the incident waves and the nearshore bathymetry do not vary appreciably in the longshore direction so that both the wave and bed motion are two-dimensional as indicated in Figure 2.

Figure 2. Notation scheme

In this idealized version of the bed-fluid system, it is assumed that the incident wave propagates shoreward from the deep water end of the nearshore and that the incoming wave train is of constant amplitude and frequency. The horizontal coordinate, in Figure 2, is $\bar{x} = 0$ at the deep end of the nearshore where $\bar{z} = -H$, \bar{z} is the vertical coordinate with $\bar{z} = 0$ at the undisturbed, free water surface. The surface wave is assumed to be progressive in the whole spatial domain and the free surface elevation ζ is expanded into a power series and modally decomposed,

$$\zeta = \zeta(x, X, t) = \sum_{j=1}^2 a_j(X) \exp(ik_j x - i\omega_j t) + c.c., \quad (1)$$

In equation (1), X is an independent, horizontal variable defined by $X = B \cdot x$. The small parameter β ($\beta \leq 0.1$) is evaluated from incident water depth H , and wave length λ , thus $\beta = H/\lambda$. The notation c.c. stands for the complex conjugate of the quantity just preceding it, so in this case,

$$c.c. = \sum_{j=1}^2 a_j^*(X) \exp(i\omega_j t - ik_j x).$$

In equation (1), ω_1 is the frequency of the postulated incoming wave train and $\omega_2 = 2\omega_1$ is its second harmonic, k_1 and k_2 are wave numbers associated with ω_1 and ω_2 , respectively. The complex, first order amplitudes a_1 and a_2 are taken to vary on the scale of wave lengths, and therefore, are dependent only on the variable X . The symbol a_j^* denotes the complex conjugate of a_j . In equation (1), dimensional variables have been nondimensionalized and scaled according to the scheme,

$$(h, x, z) = \frac{1}{H} \bar{h}, \bar{x}, \bar{z}, t = (g/H)^{1/2} \bar{t}, \zeta = \frac{1}{\alpha H} \bar{\zeta}, \quad (2)$$

where H denotes a characteristic water depth (e.g. depth at the deep water end), g is the magnitude of acceleration due to gravity, and $\alpha = a/H$, where a denotes the wave amplitude. A similar representation to equation (1) is postulated for the velocity potential ϕ . Assuming the principal features of the bottom variation to be gradual, it may also be taken that h is a function $h(X)$ of the variable X , only.

Requirements that ζ and ϕ are to satisfy Euler equations and continuity, in conjunction with the above hypotheses yield the linear dispersion relation from which k_1 and k_2 are determined,

$$k_j \tanh k_j h = \omega_j^2, \quad j = 1, 2. \quad (3)$$

Solvability conditions for the second order solutions provide a coupled pair of nonlinear ordinary differential equations for the complex amplitudes a_1 and a_1^* ,

$$\frac{da_1}{dx} = -\frac{1}{2C_1} \frac{dC_1}{dx} a_1 - \frac{1}{2} i \frac{\alpha}{\beta} a_1^* a_2 \exp(-i \frac{\Delta k}{\beta} x) \frac{B_1}{C_1} \tag{4}$$

$$\frac{da_2}{dx} = -\frac{1}{2C_2} \frac{dC_2}{dx} a_2 - \frac{1}{2} i \frac{\alpha}{\beta} a_2^2 \exp(i \frac{\Delta k}{\beta} x) \frac{B_2}{C_2}$$

where functional coefficients B_j ($j = 1,2$) depend on ω_j , k_j and X . The symbols C_j and dC_j/dX in (4) denote the group velocity and its spatial derivative given in the present approximation by following expressions,

$$C_j = \frac{1}{2} \frac{1}{\omega_j k_j} [\omega_j^2 - h(\omega_j^4 - k_j^2)]; \quad j = 1, 2, \tag{5}$$

$$\frac{dC_j}{dx} = \frac{k_j^2 - \omega_j^2}{k_j} \frac{\omega_j (h\omega_j^2 - 1)}{\omega_j^2 (h\omega_j^2 - 1) - hk_j^2} \cdot \frac{dh}{dx}, \quad j = 1, 2,$$

and $\Delta k = 2k_1 - k_2$ denotes the difference of wave numbers of the two modal wave components in equation (1).

As shown by Keller (1988), equations (4) are coupled transport equations. The linear dispersion relation, equation (3) and the transport equations (4) constitute the first component of the model. These equations, when supplemented with boundary conditions for α , ω_1 , a_1 and a_1^* at $X = 0$, provide an approximate description of the evolution of the waveform ζ and associated velocity field over a given bed configuration h .

The derivation of the second and third model constituents in which the boundary layer flow and resulting sediment flux are evaluated have been presented in earlier work (Boczar-Karakiewicz and Bona 1986, Chapalain and Boczar-Karakiewicz 1989, Boczar-Karakiewicz *et al.* 1987).

The fourth model constituent relates through continuity the differential of the sediment flux $\partial Q/\partial X$ to the desired temporal evolution of the seabed topography h , thus,

$$\frac{\partial h}{\partial \tau} = \chi \frac{\partial Q}{\partial X} \tag{6}$$

where τ is the time scale of bed deformation and χ denotes the threshold constant. Equation (6) has to be supplemented by sediment parameters (grain diameter, fall velocity, etc.) required in the second, third and fourth model constituents.

Eventually, the coupled system of equations (4),(5) and (6) supplemented by boundary conditions specifying the incident wave parameters (α , ω_1 , a_1 , a_1^*), the initial bed topography h' at $\tau = 0$, and

sediment characteristics, constitutes the dynamic description for wave-bottom interactions.

Results of a typical numerical experiment with a set of incident and initial data for waves of $T = 17$ s and a uniform sloping bed ($\tan \phi = 0.0125$) are presented in Figures 4a-d. At the chosen incident water depth $H = 18$ m the incident wave is assumed to "feel" the presence of a shallow seabed ($\beta = H/\lambda = 0.1$). The incident wave parameter $\alpha = a/H = 0.1$. Selected wave and bed data characterize an extreme cyclonic event in the central region of the Gold Coast area (Broadbeach, see Figure 1 for location).

The instantaneous wave profile ζ over the final bed profile (at $t = 6 \Delta\tau$) is shown in Figure 3a. The harmonic amplitudes $|a_1|$ and $|a_2|$ of the two modal components of the interface ζ are presented in Figure 3b and the relative phases between a_1 and a_2 , $\psi = k_1 - 2k_2 + \arg a_2 - 2 \arg a_1$, are shown in Figure 3c. The initial and final state of the bed topography is shown in Figure 3d (at $t = 0$ and $t = 6 \Delta\tau$, respectively) and $\Delta\tau$ denotes the time step in this experiment.

Figure 3. Model predictions of bar formation by cyclonic waves ($T = 17$ s): a) the surface wave profile ζ° , (over h°) and $\zeta(\tau)$ (over $h(\tau)$); b) the Fourier decomposition of ζ into two modal components; c) the initial state h° , and final state $h(\tau)$ of the seabed. The symbol L denotes the repetition length.

The most important aspect of the evolution of the surface wave, which is seen transparently in the evolution of the free surface ζ , is the slow oscillation of the first and second harmonics that is superimposed upon the mean increase in the energy of the second harmonic due to shoaling.

According to the model, energy is exchanged between the modal wave components in a nearly periodic fashion. The horizontal distance between two successive minima of the second harmonic amplitude $|a_2|$ is referred to as the local repetition length L . Such an energy transfer towards higher harmonics has been observed in both laboratory experiments with regular waves (Boczar-Karakiewicz *et al.* 1987) and in spectra of wind waves propagating in a nearshore (Boczar-Karakiewicz and Davidson-Arnott 1987). The repetition length L , which is typically several times the length associated to the surface wave, is also a characteristic length scale in the pattern of the associated velocity field and, consequently, the same scale is induced in the sediment flux pattern Q . The continuity described by equation (6) relates the divergence of the spatially oscillating sediment flux Q , with instantaneous, temporal changes in the bed configuration $h(X)$. Thus, the repetition length L determines the spacing of the sand bars that evolve from the initially featureless bed topography as shown in Figure 3d, (erosion occurs, forming the troughs of the sand bars where $\delta Q/\delta X$ is negative, while sand bar crests are formed where $\delta Q/\delta X$ is positive).

Dynamic equilibrium in a beach system : predictions and comparisons

Formation of sand bars by cyclonic waves simulated on the model and presented in Figure 3 indicate that pronounced changes in the bathymetry may be considered in a zone confined between the isobath of -10 m up to the shoreline. The following experiments are restricted to this narrower part of the nearshore and attention will be focused on time scales of the wave-bed interaction process. Results presented in Figure 3 show two very different time scales considered in the model : the time scale of the surface wave parametrized by its wave period T , and the time scale of bed evolution τ introduced in equation (6). The later can be made explicit by using the parameters of incident waves,

$$\tau = \alpha^5 \beta^{-2} \frac{\bar{f}}{T} \quad (7)$$

and by assuming that sediment concentration and the boundary layer thickness both depend upon the wave amplitude (Boczar-Karakiewicz and Bona 1986). In the following we will investigate the time scale τ carrying out a series of numerical experiments simulating a sequence of wave-bed interaction events typical for the Gold Coast beach system.

The first experiment (Figure 4a) reproduces the event of extreme cyclonic waves ($T = 17$ s, $\alpha = 0.2$; $\beta = 0.5$) resulting in the formation of a two-bar system h . The experiment is initialized now at the water depth of $H = 10$ m from an initial state $h' = X \tan \phi$. The final state h is established after a time $t = 6 \Delta\tau$ (where $\Delta\tau$ denotes the time step

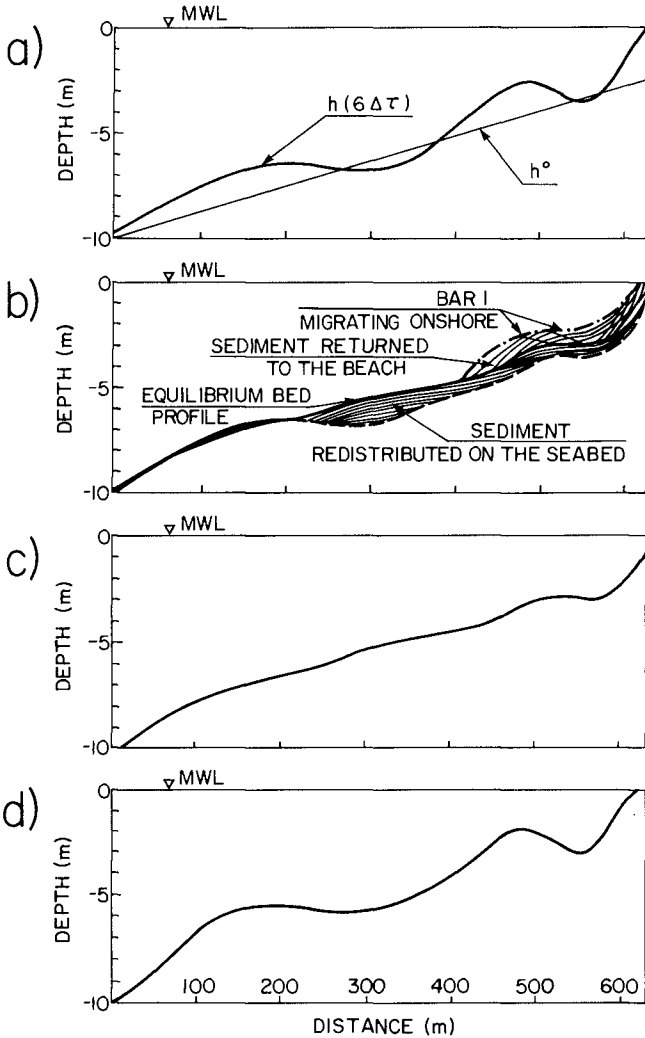

Figure 4. Model predictions of a full cycle of beach transformation: a) formation of a two-bar profile by cyclonic waves ($T = 17$ s) from an initial uniform slope h° ; b) stages of formation of the equilibrium profile by moderate storm waves ($T = 10$ s); c) final equilibrium state; d) reformation of bars by cyclonic waves ($T = 17$ s) from equilibrium state shown in c.

in the present experiment). The second numerical experiment (Figure 4b) simulates moderate storm wave activity ($T = 10$ s, $\alpha = 0.1$, $\beta = 0.1$) which interacts with the seabed which initial state h' that has been formed by cyclonic waves in the previous experiment. Broken lines in Figure 4b represent consecutive stages of the seabed evolution into its final state h of dynamical equilibrium which has been reached after a time $t = 12 \Delta\tau$, (where $\Delta\tau$, denotes the time step in experiment 4b). In the equilibrium state, the seabed remains constant under the action of a wave train of constant parameters. In this state, the offshore bar (bar 1 in Figure 4) is flattened; the trough between bar 1 and bar 2 is filled up with sediment and bar 2 is shifted shorewards. The area between the initial post-cyclonic bed profile and the final equilibrium profile in Figure 4b provides an estimate of sediment volume redistributed on the seabed and of the volume moved onshore, toward the beach. Figure 4c shows again the state of beach equilibrium which constitutes the initial state h' for a following simulation of a cyclonic event under extreme waves ($T = 17$ s, $\alpha = 0.2$, $\beta = 0.05$) presented in Figure 4c. After a time $t = 6 \Delta\tau$, a final state of two bars, denoted by h , is reestablished. Comparisons of h in Figure 4d and 5a shows a close similarity. The final state in Figure 4d terminates a full cycle of nearshore transformation simulated by the sequence of experiments shown in Figure 4b-4d.

The cycle of beach transformation is shown in a three-dimensional version in Figure 5. The initial bar formation (Figure 5a) is followed by two successive stages of profile recovery (Figure 5b) which are terminated by the equilibrium stage (Figure 5c). The stability of the equilibrium state is shown in Figure 5d under moderate storm waves ($T = \text{const}$, $a = \text{const}$). Eventually the reformation of the two-bar post-cyclonic bed profile is shown in Figure 5e.

Time scales in Figures 4 and 5 will now be calibrated using equation (7) and observations from the Gold Coast nearshore. Observations report a typical period of beach recovery under moderate storm conditions in a period of 18 months (Jackson, Smith and Piggot 1988) that provides an estimate of the time step $\Delta\tau$, in the corresponding numerical experiment (Figure 4b), $\Delta\tau = 45$ days. Given the ratio of α and β^{-1} for cyclonic and moderate waves being of the order of 2, the estimate for the time step $\Delta\tau$ in experiment 4a and 4b equals $\Delta\tau = 0.35$ day. Consequently, the period of cyclonic activity forming the two-bar system (Figure 4a and 4d) is approximately equal to two days. Comparisons of model predictions in which the earlier calibrated time scales were used are presented for two sites in the Gold Coast area in Figures 6 and 7. The location of bar crests, their number and dynamics under both extreme and moderate waves is in a quite satisfactory agreement with observations. However, the amplitude of the predicted offshore bar (bar 1) is generally lower than indicated by observations. The latter is maybe not surprising given the extreme simplicity of the model and the extreme complexity of the prototype nearshore.

The post-cyclone seabed profile for the southern part of the Gold Coast area (Kirra, see Figure 1 for location) is presented in Figure 8b. Predictions show that in case of a gradually decreasing mean slope gradient given by observations (Figure 8a) the mean position of the shoreline shifts into the shoreward direction. It may be inferred that

Figure 5. A three-dimensional presentation of model predictions of the cycle of beach transformation : a) formation of post-storm bathymetry by cyclonic waves ($T = 17$ s); b) beach recovery by moderate waves ($T = 10$ s); c) formation of equilibrium by moderate waves ($T = 10$ s); d) equilibrium state under moderate waves ($T = 10$ s); e) bar reformation by cyclonic waves ($t = 17$ s).

observed changes in the nearshore topography are at least partially caused by the deficit of sediment supply in this location, subsequent of the extension of the Tweed River training walls.

3. Conclusions and protection measures for the Gold Coast beach system

The wave-bed interaction model applied in the present paper simulates correctly a typical observed cycle of beach erosion and recovery in the Gold Coast nearshore caused by extreme cyclonic events and followed by periods of moderate storm activity (Figures 4 and 5). Predictions and observations show that beach erosion occurs during a couple of days of an extreme cyclonic event (see Figures 4a and 4d, Figures 5a and 5e) in association with a formation of a prominent two-bar system in the area of the nearshore, limited approximately by a water depth of 10 m. Beach recovery and formation of a nearly uniform featureless equilibrium bed profile has been shown to result from moderate storm wave activity (see Figures 4b-c, Figures 5b-d) during a period of several months.

The simulation of a transformation cycle from post-cyclonic bars into an equilibrium bed profile provides an estimate of sediment volume redistributed over the nearshore and returned to the beach (Figure 4b).

The transformation of the post-cyclonic barred nearshore into recovered equilibrium is shown to be reached when assuming a non-deficit sediment supply and a fully dissipative beach system. The latter requires a conservation of a buffer zone which temporary allows erosion during extreme weather events. The presented beach transformation cycle requires a sufficiently long period of moderate storm-wave activity between two successive extreme storm events (of the order of 18 months, see Figure 5b-c).

In presented calculations, extreme cyclonic waves (characterized by peak periods of 17 secs) were simulated by a regular wave train with a period $t = 17$ s, and a wave amplitude of $a = 2$ m at the incident water depth $H = 19$ m. Moderate wave activity was simulated with an incident wave train of a wave period $T = 10$ s and an amplitude $a = 1.0$ m at the incident water depth $H = 10$ m. Model predictions compared with observations in two chosen locations of the central Gold Coast area have shown a satisfactory agreement for both the pre- and post-cyclonic bars (see Figures 6 and 7).

Presented results compared with available observations suggest beach protection measures in the Gold Coast area, which would compensate progressing erosion resulting from a deficit in sediment supply and from development pressures.

Suggested method of beach nourishment consists of the formation of a post-cyclonic profile, i.e. in placing sediment pumped from offshore in the location of the two offshore bars. The volume of the placed sediment will compensate the local deficit in the sediment supply, will be partially redistributed over the active nearshore and be partially returned to the beach after several months of moderate wave activity. The reconstruction of bars by beach nourishment will additionally provide protection to the beach due to energy dissipation caused by a multiple offshore breaking of the incident wave. However, according to presented results, sediment for nourishing the nearshore

should be removed from areas lying deeper than the isobath -20 m which constitutes the outer limit of the active nearshore for extreme cyclonic waves.

Results of model simulation in the area of Kirra (Figure 8) indicate that construction of seawalls is only a temporary measure of protection. The constantly decreasing mean nearshore slope of the seabed in this region due to acute sediment deficit results in a constant shoreward shift of the mean shoreline position. The latter causes slumping of seawalls which themselves have a negative effect on nearshore stability associated with strong wave reflection.

Acknowledgements

Support for this project was provided by the Ministry of Fisheries and Oceans (Government of Canada) and by the Natural Sciences and Engineering Research Council of Canada (Grant no A2621). Both authors also acknowledge the Gold Coast City Council, QLD, Australia, for releasing survey data for this publication.

CHAPTER 172

SEA BOTTOM TOPOGRAPHY WITH IMAGING RADAR

J. Vogelzang¹, G.J. Wensink², D. van Halsema³
and G. van der Burg⁴

ABSTRACT

Mapping sea bottom topography with imaging radars or optical sensors can add valuable information to traditional bathymetric surveys. This paper describes a series of (already performed or planned) experiments in which the Dutch Bottom Topography Group is involved. It is shown how radar and optical imagery can be used to map the sea floor.

1. INTRODUCTION

The first observation of sea bottom topography with imaging radar (Side Looking Airborne Radar, SLAR or Synthetic Aperture Radar, SAR) was made in 1969 by de Loor and his co-workers (de Loor and Brunsveld van Hulten, 1978 ; de Loor, 1981). At that time it was not understood why sea bottom topography could be visible on radar images: since sea water is almost a perfect conductor at radar frequencies, the penetration length is a fraction of the radar wave length (which was about 1 cm in these observations). Therefore the radar beam never penetrates to the bottom.

The phenomenon received little attention until SEASAT was launched in 1978. This satellite carried among other sensors a L-band SAR. With this instrument dramatic images of sea bottom topography in the Southern Bight of the North Sea and the English Channel (Alpers and Hennings, 1984), and the Nantucket Shoals (Shuchman, Lyzenga and Meadows, 1985) were obtained. All SEASAT images revealing bottom related structures are reviewed by Kasischke et al. (1983). Also internal waves (Rufenach and Smith, 1985) and ship wakes (Vesecky and Stewart, 1982) were clearly visible on SEASAT images.

The SEASAT mission has provoked much interest, both from the experimental and the theoretical side. It has stimulated further experimental research (McLeish et al., 1981; Valenzuela et al., 1985, Apel et al., 1985, Chubb et al., 1989). It was also found that bottom topography is visible in the optical range (Kasischke and Tanis, 1986; Hennings, Doerffer and Alpers, 1988).

From these studies it appeared that sea bottom topography can be visible with imaging radar in shallow seas (maximum depth about 50 m) with (tidal) currents of 0.5 m/s or more at a wind speed between 2 and 10 m/s.

In this paper the research activities in the Netherlands are described. In section 2 the imaging mechanism is described. Section 3 is devoted to past and future experimental campaigns. In section 4 the conclusions are stated.

2. IMAGING MECHANISM

Several theories have been proposed to describe the imaging mechanism. It is now generally accepted that the mechanism consists of three steps:

- (1) Interaction between (tidal) flow and bottom topography produces modulations in the surface current velocity.
- (2) Modulations in the surface current cause spatial variations in the wind generated spectrum of water waves.
- (3) Variations in the wave spectrum are visible as modulations in the radar backscatter.

Models of this kind have been proposed by Alpers and Hennings (1984), Shuchman, Lyzenga and Meadows (1985), Holliday, St-Cyr and Woods (1986) and by van Gastel (1987). Internal waves also cause variations in the surface current, so the second and third step of this mechanism can be used to describe their signature on radar images. The mechanism also applies to other regions than the microwave part of the electromagnetic spectrum.

The first step is usually described using the continuity equations (mass conservation)

$$U_{per} = C_{per}/h \quad , \quad (1a)$$

$$U_{par} = C_{par} \quad , \quad (1b)$$

where U_{per} stand for the component of the surface current perpendicular to the (elongated) sand bank or sand wave, U_{par} for the parallel component and h for the depth, C_{per} and C_{par} being constants. Equations (1a) and (1b) are in general valid for the depth averaged current velocity, but not for the surface current velocity which also is influenced by the wind. A better description of the surface current field can be obtained from a (quasi) three-dimensional flow model.

The second step, the wave current interaction or hydrodynamic modulation, is described by the Action Balance Equation. This is a transport equation with a source term describing the combined effect of wind input, dissipation and non-linear wave-wave interactions. The precise form of this term is not well known. Therefore most authors use simple relaxation forms for the source term, which is either linear (Alpers and Hennings, 1984 ; Holliday, St-Cyr and Woods, 1986 ; Hennings, 1990) or quadratic (Shuchman, Lyzenga and Meadows, 1985) in the action spectrum. Van Gastel (1987) includes the effects of wind input, dissipation and non-linear interactions in a rigorous way.

The scattering of radar from the ocean surface is usually described with first-order Bragg scattering. In this approach, the radar cross section of the sea is proportional to the spectral density at the so called Bragg wave number k_B , given by

$$k_B = 2k \sin(\theta) \quad , \quad (2)$$

where k is the wave number of the incident radiation and θ the angle of incidence.

Vogelzang (1989) has compared these models by solving the action balance equation numerically, showing that these models give almost the same results. At high radar frequencies (X-band) and at wind speeds exceeding 5 m/s or more, the effect of advection can be neglected as in the original model of Alpers and Hennings (1984). In this case, the radar cross section is proportional to the gradient of the surface current, or, using the continuity equations (1a) and (1b), to the bottom slope.

At L-band, the simple relaxation models predict modulations of the order of 10 per cent, in agreement with the experimental data. At X-band, however, these models underestimate the modulation by an order of magnitude. By including non-linear interactions (van Gastel, 1987) or other scattering mechanisms than first-order Bragg (Holliday, St-Cyr and Woods, 1986) the modulation is increased to its correct value.

3. EXPERIMENTS

In this section the research activities of the Dutch Bottom Topography Group will be described. The group is formed by representatives from Rijkswaterstaat, Delft Hydraulics, Physics and Electronics Laboratory TNO and National Aerospace Laboratory NLR. International cooperation has been established with institutes from Germany, the United Kingdom and the United States of America.

3.1 DDSLAR

A first experiment was performed on January 19, 1988 using the Dutch Digital SLAR (DDSLAR) to investigate the possibilities and limitations of mapping sea bottom topography with imaging radar for cartographic purposes. The experiment was performed in a test area 30 km off the Dutch coast (see figure 1). The bottom topography in this area is dominated by sand waves with a height between 2 and 6 m and a crest-to-crest distance of typically 500 m at a mean depth of about 22 m.

This area was chosen for the following reasons :

- (1) the bottom topography is simple and quasi one-dimensional.
- (2) the access time to the test area is short.
- (3) it is close to the Measuring Platform Noordwijk (MPN), an oceanic research platform that is part of the North Sea Monitoring Network.
- (4) the area has been studied in earlier experiments.

The test area has been recorded with the Dutch Digital SLAR, an airborne X-band HH polarized SLAR system operated by the National Aerospace Laboratory NLR. With this system and the processing facilities available at NLR it is possible to obtain both geometrically and radiometrically correct images. During the experiment the current velocity profile was measured from two ships near the centre of the test area. The position of one of these ships was recorded using HYPERFIX with a precision of 1.5 m. Therefore the image of this ship could be used as a position fix, and the position in the radar image could be determined with an

error of two pixel sizes (30 m) at most. An ordinary bathymetric map of the test area has been digitized.

Figure 1. The test area off the Dutch coast.

During the experiment, the wind speed varied between 7 and 8 m/s, while the surface current during the radar overflights was between 0.6 and 0.8 m/s. Under these circumstances one expects that the bottom slope is visible on the radar images. Figure 2 shows a radar image, a simulated radar image using the model of Alpers and Hennings (1984) and the bathymetry of the test area. The radar image is rather noisy due to the low sensitivity of the DDSLAR.

Figure 3 shows the correlation between the intensity and the bottom slope, which should have a minimum at $j = 0$ if the radar cross section is proportional to the bottom slope (note that the constant of proportionality is negative).

Figure 2. Radar image (upper left), simulated image (upper right) and bathymetry (lower).

Figure 3. Correlation between intensity and bottom slope for two of the radar images recorded during the experiment

From this experiment the following conclusions were drawn :

- (1) At wind speeds of 5 m/s or more, X-band radar imagery shows the bottom slope, as predicted by simple relaxation models. The sand waves in the test area have an asymmetric profile, with the steeper slopes directed to the NorthEast. Therefore the steeper slopes are visible as a pattern of bright or dark lines, depending on the direction of the tidal current, while the gentle slopes act as a background.
 - (2) The positional accuracy in radar images can be about two pixel sizes. For most radar systems this is of the order of 20 m.
 - (3) The sensitivity of the radar system is a crucial parameter for mapping bottom topography.
- More information can be found in the final report of this project (Vogelzang et al., 1989).

3.2 JPL-SAR

On August 16, 1989, the test area was recorded with the airborne P-, L- and C-band polarimetric SAR of NASA/JPL, to study the effect of radar wave length and polarization. The sand waves are clearly visible on the P- and L-band images, but not on the C-band image. This is due to the low sensitivity of the C-band SAR. These images are now under study. They will be compared with predictions of a one-dimensional model for the imaging mechanism. The surface current field in this model is generated by a detailed quasi three-dimensional flow model of the test area. The flow model includes the effect of the wind on the surface current. The action balance equation will be solved in one dimension using existing simple expressions for the source term. The radar cross section will be evaluated using a two-scale scattering model. Such a scattering model includes the effect of longer waves by integrating the first-order Bragg scattering over the tilt caused by longer waves.

3.3 Future research

The test area will be studied with the C-band SAR carried by the first European Remote Sensing satellite (ERS-1). Wind and wave data will be collected at MPN, while the surface current will be hindcasted using the quasi three-dimensional flow model. Since the ERS-1 will make images of the test area at different points in the tidal cycle and under different wind conditions, these images can be used to fix the optimum hydro-meteorological conditions for mapping sea bottom topography with imaging radar. Also the dynamical behavior of the bottom topography can be studied, since the ERS-1 mission extends over a longer period.

In collaboration with the Universities of Hamburg and Kiel (Germany) and the University of North Wales (UK) the bottom topography in the same test area will be studied using both microwave and optical sensors. The goal of this research, sponsored by the Commission of European Communities (CEC) in the framework of the Marine Science and Technology (MAST) program, is to establish how remote sensing methods can be used as input in morphodynamic models which are currently being developed. To achieve this goal, a large experiment is planned for April 1991. The model for the imaging mechanism will be extended to two dimensions. To compare the experimental results with the bathymetry, a precise bathymetric survey with a multi-beam echo sounder will be held in the test area after the experiment.

The models developed during these experiments can be tested in a region with a more complicated bottom topography during the SIR-C/X-SAR mission with multi-polarization L-, C- and X-band SAR. A preparatory flight with the airborne P-, L- and C-band SAR of NASA/JPL is planned for 1991.

The final goal of this research is to obtain information about the bathymetry from microwave (and optical) imagery, using data-assimilation techniques as indicated in figure 4. Starting with an initial guess or an old bathymetric map, the radar image can be calculated. The simulated image is compared with the observed image. By changing the input-bathymetry, the simulated image is matched to the observed image. When both images match, the input-bathymetry equals the actual bathymetry. The next MAST program would be suited for investigating this possibility.

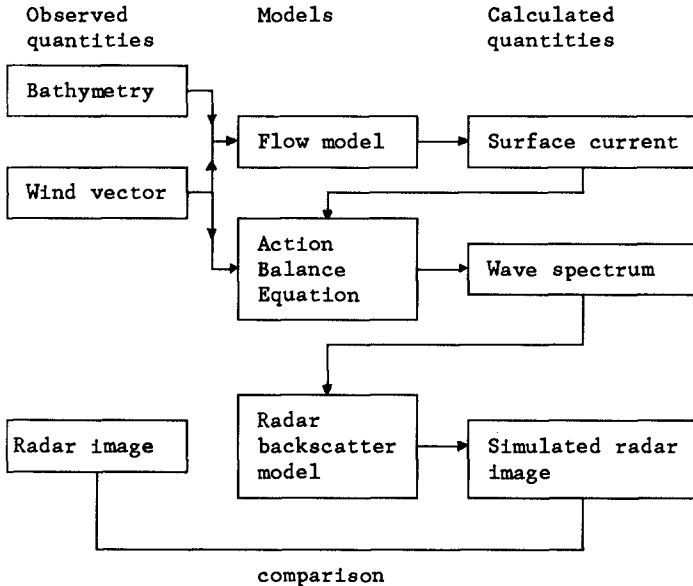

Figure 4. Modelling.

4. CONCLUSIONS

Under favorable conditions (low wind speed and strong tidal current) sea bottom topography in shallow seas can be mapped with imaging radar. At wind speeds of 5 m/s or more, X-band radar imagery reveals the region with large bottom slopes. The horizontal accuracy can be of the order of two pixel sizes, which corresponds to about 20 m for existing systems.

If the processes involved in the imaging mechanism are well modelled, data-assimilation techniques can be applied to obtain bathymetric information from radar images.

It is not expected that remote sensing methods will replace traditional bathymetric surveys. However, remote sensing methods give an overview over large areas at low costs. This information can be used for validating and steering morphodynamic models and optimizing bathymetric surveys.

ACKNOWLEDGEMENTS

Part of this work has been financially supported by the Netherlands Remote Sensing Board (BCRS) as a part of the National Remote Sensing Program (NRSP).

The project in the framework of the Marine Science and Technology Program (MAST) is supported by the Commission of European Communities, Directorate General XII (Science, Research and Development).

The authors wish to thank W. Alpers (University of Hamburg), I. Hennings (University of Kiel), J. Matthews (University of North Wales) J. Klein (Jet Propulsion Laboratory) and G.P. de Loor for their fruitful collaboration.

CHAPTER 173

APPLICATION OF EQUILIBRIUM BEACH CONCEPTS TO SANDY GREAT LAKES PROFILES

M. Todd Stockberger*
(Associate Member ASCE)
William L. Wood**
(Member ASCE)

ABSTRACT

This study was designed to evaluate the equilibrium beach concept for conditions of "rapidly" varying water level, experienced on the North American Great Lakes. It was determined that the mathematical expression $h(x) = Ax^{2/3}$ is appropriate for describing sandy beach and nearshore profiles of the Great Lakes. In addition, a correlation was found between lake-level change and the shape factor A, that indicates a phase lag in beach and nearshore response to "rapidly" changing water level. Results from this study also raise some questions about the reliability of determining the shape factor A directly from sediment size. Reliability in the determination of A may be related to the stability shape of the profile relative to its equilibrium shape.

INTRODUCTION

During the past two and one half decades many researchers (Bruun, 1962; Edelman, 1968, 1972; Swart, 1974, 1976; Le Mehaute and Soldate, 1980; Kriebel and Dean, 1985; Hands, 1979, 1980, 1984; Weishar and Wood, 1983; Wood and Weishar, 1984) have investigated the response of the beach and nearshore to changes in water level. Concern has

* Research Engineer, Black & Veatch, P.O. Box 8405, Kansas City, MO 64114

** Associate Professor of Ocean Engineering and Director, Great Lakes Coastal Research Laboratory, School of Civil Engineering, Purdue University, West Lafayette, IN 47907

primarily been with rising water level since it is recognized as being a major contributor to the cause of increased shore erosion. While the focus of research has been on increases in water level and the corresponding shore response, there has been little similar research concerning rapidly changing or decreasing water level and the resulting effects on the beach and nearshore.

Recently, efforts have been made to apply the equilibrium beach concept to a variety of coasts, including the Great Lakes (Hands, 1979, 1980, 1984; Dean, 1977; Hughes, 1978). Dean (1977) proposed that nearshore profiles assumed a form consistent with $h(x) = Ax^{2/3}$, where h is the depth, x is the distance offshore, and A is a parameter dependent upon sediment characteristics of the profile being examined. Hands (1984) extended this formulation to the Great Lakes and hypothesized that the effects caused by rising lake level would simply be reversed by falling levels.

It appears reasonable to base a predictive model for Great Lakes beach profile response on the equilibrium beach concept. However, it must be shown that the nearshore profiles of the Great Lakes respond on a time scale similar to that of lake-level change. If the nearshore does not respond on a time scale similar to that of lake-level, serious limitations would be imposed on the ability of the equilibrium beach concept to predict nearshore response.

DATA COLLECTION AND ANALYSIS

The data used for this research consists of two series of nearshore profiles collected along the southeastern shore of Lake Michigan (see inset Figure 1). The first series consists of beach and nearshore profiles taken at 6 locations downdrift of the Michigan City, Indiana Harbor ("MTB" series, Figure 1). A total of 42 profiles were collected during the years 1975 through 1978, 1981, 1983, and 1985. Sediment samples were taken at the time of profiling for each line at water's edge and at the 1, 2, 3, 4, 5, 6, and 7 meter isobaths. The second series consists of beach and nearshore profiles taken at 6 locations updrift of the Michigan City Harbor ("SR" series, Figure 1). A total of 57 profiles were collected during the years 1966 through 1973, 1980, and 1988. Sediment data was also collected for this series for the years 1966 through 1973 (Hawley and Judge, 1969); however, these data were not available for analysis.

Figure 1 Study Area

Analysis of the Profile Form: $h(x) = Ax^m$

In order to determine whether the equilibrium profile form $h(x) = Ax^m$ is appropriate in describing Lake Michigan profiles, each profile was fit (using the method of least squares) from water's edge to closure depth. This analysis was used to obtain the distribution of the values of the exponent m and coefficient A . If the distributions of both m and A are found to be similar to those found by Dean (1977) and Hughes (1978), it can be concluded that an equation of the form $h(x) = Ax^{2/3}$ is valid for describing the profiles examined. If dissimilar distributions are found, then either a different exponent or a new equation describing the profile form can be established.

Analysis of Coefficient A and Mean Sediment Size

Dean (1977), Hughes (1978), and Moore (1982) showed that a relationship seems to exist between mean sediment size and the shape factor A . Therefore, it is reasonable to analyze the data in such a manner as to determine if this relationship holds true for Lake Michigan profiles. The measured profiles are separated into three sections (Figure 2). The first section consists of that part of the

profile extending from water's edge to the point of inflection within the trough of the inner bar. The second section consists of that part of the profile lakeward of the inner bar trough and extending to the point of inflection within the trough of the outer bar. The third section consists of that part of the profile lakeward of the outer bar trough and extends beyond the depth of closure. Although the second slope break occurs at a point coincident with the trough of the outer bar, the outer section of the profile is actually initiated just lakeward of the outer bar. By using the section of the profile which is initiated just past the outer bar, any numerical ambiguity associated with the trough is avoided. The difference in the value of A was calculated for the outer section using both locations for section initiation and the error was found to be on the order of a few tenths of a percent.

Figure 2 Nearshore Profile Sections

The first, or inner, section of the profile ranges in depth from water's edge to approximately the 1 to 1.5 meter isobath; therefore, the mean grain size at the 1 meter isobath and at water's edge were averaged to characterize the mean grain size of the inner section. The second, or middle, section of the profile ranges from approximately the 1 to 1.5 meter isobath to approximately the 2.5 to 3

meter isobath; therefore, the mean grain size at the 2 and 3 meter isobaths were averaged to characterize the middle section. The third, or outer, section of the profile ranges from approximately the 2.5 to 3 meter isobath to approximately the 7.5 meter isobath. The mean grain size of the 3, 4, 5, 6, and 7 meter isobaths were averaged to characterize the mean grain size of this section. The A value of each section of each profile is plotted against its characteristic mean sediment size. A comparison is then made with the findings of Moore (1982) to determine if his empirically determined curve is valid for the Great Lakes.

The Effect of Water Level Change on Shape Factor A

On the Great Lakes water level changes on a much shorter time scale and a much larger vertical scale than on ocean coasts. The rate of mean still water level change on the Great Lakes is of the order of 10's of centimeters per year. In order to determine whether Great Lakes profiles respond on a time scale similar to that of water level change, the average value of A for all profiles, for each survey period and with each of the two series considered separately, are plotted against time. If the profiles respond on a time scale slower than that of water level, the mean A values will be seen to vary in correspondence with the water level. If the profiles respond on a similar time scale, the mean A values will remain relatively constant.

RESULTS

Nearshore Profile Form

The values of the exponent m and coefficient A were determined for all 99 profiles used in the study. Figure 3(a) shows the distribution of exponent m for all profiles. This distribution compares favorably to the distribution of m values found by combining the results of Dean (1977) and Hughes (1978). The mean m value for Lake Michigan profiles is 0.632 which is in agreement with the values found by Dean, 0.66, and by Hughes, 0.671.

The results of this analysis support Dean's finding that a value of m equal to $2/3$ is appropriate in describing nearshore profiles. Figure 3(b) shows the distribution of the coefficient A for all profiles. This distribution also compares well to the distribution found by combining the results of Dean (1977) and Hughes (1978). Owing to the

Figure 3. Frequency Distributions of: a) exponent m, and b) coefficient A

Figure 3. continued

similarity between the distributions of m and A for Lake Michigan profiles and the distributions found by Dean and Hughes, it appears that the nearshore profiles of Lake Michigan can, in general, be described by the equation $h(x) = Ax^{2/3}$.

Variation of Shape Factor A with Mean Grain Size

Figure 4 shows the joint distribution of coefficient A and grain size for the Lake Michigan profiles plotted with a set of curves developed by Moore (1982). Each of the three sections of the nearshore profiles were examined individually to evaluate any relationships that may exist between A and grain size. In general, the majority of data points lie within the range of expected values. The data for the inner sections of the profiles show the most variability in mean sediment size and the best correlation with Moore's curves. Both the middle and outer sections exhibit very little variation in mean grain size, thus, the data points for these sections result in nearly vertical distributions in A (Figure 4).

Figure 4. Distribution of A versus Grain Size for the Inner, Middle, Outer Sections of the Profiles.

The data for the inner sections of the nearshore profiles have been plotted separately on the set of curves

developed by Moore (Figure 5). The data for the inner section lie primarily between the curve representing Moore's averaged data and the "smooth curve" developed by Moore. In order to better evaluate the relationship between the calculated values of A and the curves developed by Moore (1982), a statistical analysis was performed (Table 1). The results of this analysis show that a correlation between the A data of this study and the curves developed by Moore does not exist. This result raises questions concerning the relationship between sediment size and the shape factor A.

The Effect of Water Level Change on Shape Factor A

In order to evaluate whether the nearshore profiles of the Great Lakes respond on a time scale similar to that of water level change, the average values of A for each year were plotted against time. Figure 6 shows the mean value of A for the inner sections of the SR series plotted against time, with changes in water level superimposed.

Figure 5. Distribution of A versus Grain Size for the Inner Sections Only

The horizontal hash marks show the respective limits of the coefficient A for plus and minus one standard deviation. The coefficient of determination, r^2 , (where r is the correlation coefficient) was calculated for all lines and all sections except for the outer section of the SR lines.

It could be seen from graphical analysis of this outer section that the plot of mean A values with time was essentially a horizontal line, thus showing no correlation with water level change. The coefficient of determination, r^2 , represents the amount of variation in the mean values of A that can be predicted or accounted for by water level change. Table 2 shows the values of the correlation coefficient and the coefficient of determination for the analyzed sections.

For Comparison to Moore's Data Curve				
Section	error	rms error	r	r^2
Inner	-0.000 9	0.023	0.32	0.1
Middle	-0.061	0.076	---	---
Outer	0.003	0.050	---	---
For Comparison to the Smooth Curve				
Section	error	rms error	r	r^2
Inner	0.0185	0.030	0.36	0.13
Middle	-0.011	0.050	---	---
Outer	0.0023	0.034	---	---

Table 1. Statistical Results for Sediment Size versus Coefficient A Data Comparison to Moore's Curves

Examination of Table 2 indicates that A value variations within the inner section of the profile correlate well with water level change. However, A value variation within the middle and outer sections of the profiles show no correlation with water level. To better illustrate the correlation between water level change and shape factor A for the inner section, demeaned values of A and demeaned values of the water level elevation are plotted against each other (Figure 7). The parallel trend illustrated in Figure 7 supports the argument that profile change is lagging water level change. The estimated lag time is not easily discernible from the data, but is of the order of years.

DISCUSSION AND CONCLUSIONS

Discussion

The equilibrium beach concept is based essentially on two premises. The first is that the form or shape of the nearshore profile is known, the second is that the nearshore profile responds on a time scale similar to that of water level change. The results of this study have shown that the nearshore profile form found by Dean (1977), $h(x) = Ax^{2/3}$, is appropriate for use in describing the "average" or characteristic nearshore profile found on the Great Lakes. However, the results have also shown that nearshore profiles respond on a much longer time scale than that of mean annual water level change. These results indicate that the equilibrium beach concept should not be used to predict nearshore response to short term water level changes on the Great Lakes. However, use of this concept may be appropriate for prediction of changes in the nearshore due to changes in water level which occur over a relatively long period of time (order of years). These results are similar to those found by Hands (1980). Hands concluded that response of nearshore profiles on the Great Lakes appeared to be "out-of-phase" or lagging behind that of water level change. In addition, Hands concluded that the lag between profile response and water level change was on the order of a few years.

The effect of falling water level on the nearshore profiles could not be determined due to the slower than

expected response of the profiles to water level change. Since questions still exist as to the applicability of the equilibrium beach concept to falling water level, it is strongly suggested that this concept not be applied under conditions of falling water level.

Results of this investigation fail to support the argument that the shape factor A is dependent on mean sediment size. Although some paired data grouped around the curves developed by Moore (1982), there were not significant relationships supported by statistical analysis. This result is contrary to the findings of Dean (1977), Hughes (1978), and Moore (1982).

It is important to note that the parameters m and A are interdependent and that the effect of setting m to a constant is to force the values of A into a much tighter distribution about the mean, thus reducing the amount of information that can be gained by examining the joint distribution. Perhaps the restricted application of the equilibrium profile equation $h(x) = Ax^{2/3}$ is not appropriate. It is recommended that determination of both variables should be carried out in a statistical context.

Conclusions

The following conclusions were reached as a result of this study.

1. The equilibrium profile form determined by Dean (1977), $h(x) = Ax^{2/3}$, is adequate for use in describing the "characteristic" nearshore profiles found on the Great Lakes.
2. The equilibrium beach concept should not be used to predict nearshore profile changes for short periods of time. However, the equilibrium beach concept may be adequate for use in predicting changes to the nearshore due to water level changes which occur over a long period of time.
3. The shape factor A does not appear to be well correlated with mean sediment size.

CHAPTER 174

ADVANCES IN NUMERICAL MODELING OF DUNE EROSION

David L. Kriebel¹

INTRODUCTION

Estimating dune erosion during severe storm events continues to be a major coastal engineering problem. In the United States, for example, numerous state and federal regulatory programs now require an estimate of the erosion caused by the 100-year hurricane or extratropical storm. In addition, most beach replenishment projects include storm protection berm and dune systems that must be sized to survive some design storm event.

Given these requirements, methods of predicting dune erosion must continue to evolve and improve. Before the early 1980's, most dune erosion methods were based on geometrical arguments. Since then, however, the two most widely-used methods for predicting dune erosion in the United States have been the empirical model of Vellinga (1983, 1986), based on extensive large wave tank tests, and the numerical model of Kriebel and Dean (1985), based on a finite-difference solution of simplified governing equations. A recent model by Larson and Kraus (1989) is also being used by the Corps of Engineers and is based on governing equations similar to those used in the Kriebel and Dean model. These models have been successful largely because of their simplicity in describing the macroscopic cross-shore profile changes without considering details of surf zone hydrodynamics or sediment transport.

For widespread application in the U.S., however, it is generally recognized that neither the Vellinga model nor the Kriebel and Dean model are sufficiently general to accommodate all beach profile, storm surge, and wave conditions of interest. The most critical limitation on both models is that they have been developed for the case of high dunes that extend infinitely landward and which

¹Assistant Professor, Ocean Engineering Program
U.S. Naval Academy, Annapolis, Maryland 21402 U.S.A.

are not overtopped by storm surge or wave uprush. In the U.S., however, most coastal locations do not have such massive frontal dunes. Dune erosion models must, instead, be capable of simulating profiles with low dunes that may be overtopped, narrow dunes that may be eroded completely, multiple dune ridges that may erode sequentially, or dunes that are backed by shore protection structures.

In this paper, revisions to the Kriebel and Dean model are reviewed that remove some of the previous limitations. These modifications, primarily in the onshore boundary region, enable more realistic simulation of a variety of beach and storm conditions while retaining the general simplicity of the original model.

BACKGROUND

The original Kriebel and Dean erosion model predicts the time-dependent evolution of beach and dune profiles based on time-histories of storm surge and wave height, as described by Kriebel and Dean (1984, 1985). This model is based on Dean's (1977) equilibrium profile theory, in which the profile form that will ultimately be attained if water level and wave conditions are held constant indefinitely is of the form

$$h = A x^{2/3} \quad (1)$$

where h is the water depth at a distance x from the shoreline. This form is consistent with the uniform dissipation of wave energy per unit volume in the surf zone based on shallow water spilling breaker assumptions. The parameter, A , is related theoretically to a value of the energy dissipation per unit volume, D_E , which must occur everywhere across the profile when the system is in equilibrium. Dean (1977, 1987), Moore (1982) and others have then related A empirically to the median sand grain size.

The time-dependent profile response is then simulated by solving two simplified governing equations in finite-difference form. These are the continuity equation

$$\frac{dx}{dt} = - \frac{dQ}{dh} \quad (2)$$

and a simplified expression for the net sediment transport rate at any location in the surf zone

$$Q = K (D - D_E) \quad (3)$$

based on the difference between the energy dissipation at any location, D , and the equilibrium value, D_E .

Based on shallow water spilling breaker assumptions, the energy dissipation per unit volume is given by

$$D = \frac{1}{h} \frac{dF}{dx} = \frac{5}{16} \rho g^{3/2} k^2 h^{1/2} \frac{dh}{dx} \quad (4)$$

where k is the ratio of the breaking wave height to the water depth, assumed to be 0.78. Based on equation (4), energy dissipation is a function only of the local water depth in the surf zone such that the sediment transport rate across the surf zone is dictated only by the shape of the profile relative to its equilibrium shape for a given water level.

The rate parameter, K , in equation (3) is the only free parameter in the governing equations and is used to calibrate the model. In the recent model by Larson and Kraus, equations (1) and (3) are modified to also include a gravity driven slope-dependent term, at the expense of introducing an additional parameter which then must be empirically determined. In the original model by Kriebel and Dean (1984, 1985), the value of K was adopted from a previous study by Moore (1982). An initial verification was then carried out in a simulation of erosion during Hurricane Eloise. In this case, one representative or average profile was used for the initial condition and computed erosion volumes were found to agree reasonably well with county-wide average erosion values. Steepening of the dune during erosion was not simulated, however, so that predicted recession of specific dune elevation contours did not agree closely with observed values.

In a subsequent study, Kriebel (1986) performed a more detailed calibration and verification of the model using several measured profiles from the Hurricane Eloise data set. In that study, one profile was selected and used to calibrate the numerical model. This profile, denoted R-41, was previously used by Hughes and Chiu (1981) to verify a small-scale physical model for dune erosion. This profile was also used by Vellinga (1986) to verify the Dutch dune erosion model for hurricane conditions. As a result, this profile has become a sort of calibration standard. From this, a value of the transport parameter, K , was found to be about $0.0045 \text{ ft}^4/\text{lb}$ ($8.75 \times 10^{-6} \text{ m}^4/\text{N}$). This is larger than the value originally adopted from Moore (1982) but it provided results that were accurate to within about 25% when 20 other Hurricane Eloise profiles were simulated in detail. A comparison of the calibrated numerical model and the measured post-storm profile is shown in Figure 1.

Figure 1. Example of predicted profile response for calibration profile R-41 from Hurricane Eloise data set.

MODEL REVISIONS

The revised numerical model uses the same governing equations to describe onshore-offshore transport and to solve for profile changes. The major revisions are in the initial profile description and in the onshore boundary conditions. In the original model, wave runup was not simulated and the entire dune face was required to erode while maintaining its initial slope. In the revised model, provisions for realistic wave runup limit are included along with a new method for estimating sediment transport rates on the beach face. This allows formation of a dune scarp along with flattened post-storm beach face slope.

Initial Profile Form

As shown in Figure 1, the initial profile is no longer limited to the two idealized forms used in the original model. Previously, the profile was defined only by the position of the dune crest, the slope of the dune face, the position of the berm, and the slope of the beach face. Dunes were assumed to be of infinite width which extended landward indefinitely at the elevation of the dune crest. In the revised model, the initial profile closely simulates a measured profile. Dunes of finite width may be simulated by specifying both a landward and a seaward position of each elevation contour to define the dune width at each elevation.

For narrow dunes, each elevation contour can then erode only until it reaches the landward contour location. Once erosion reaches this position at each elevation, no sand remains at or above that contour and the upper limit of the active profile is then taken at the next lower elevation contour. This routine also enables simulation of vertical and sloping seawalls when the wall location is used as the landward limit of each elevation contour. In these cases, once the eroding contour reaches the wall location, the upper limit of the active profile is again transferred to the next lower contour.

Runup Limit

Provisions are then made for input of a realistic runup limit to describe the upper limit of the active swash zone and to fix the transition from a flattened post-storm beach face to a near-vertical erosion scarp. This does not represent the true wave runup limit since runup for some waves in a random sea may reach above this elevation on the dune scarp. In some erosion models, such as the Dutch method of Vellinga (1983), the dune scarp is fixed at the peak storm surge level. This may be a good approximation in areas of high dunes where large amounts of sand are fed to the beach face by dune undermining and slumping. Most post-storm conditions in the U.S., however, show a distinct erosion scarp at an elevation above the peak surge level.

A more realistic upper limit on the eroded profile may be established from local field observations of previous storm events. For example, in the Hurricane Eloise data, the elevation of the dune scarp is about 2 feet (0.6 m) above the estimated peak still water level. This is below the elevation of debris lines surveyed after the storm and illustrates that the dune scarp usually forms below the maximum wave runup elevation.

For more general application, the elevation of the erosion scarp may be estimated by any of the available methods of predicting wave runup. One effective method is to estimate this elevation according to the Hunt formula

$$R = m_* (H_{rms} L_o)^{1/2} \quad (5)$$

where the deep water rms wave height is used along with an estimate of the equilibrium post-storm beach slope, m_* , to be discussed. Since the swash is saturated during severe storms, use of higher wave height descriptions, such as the significant wave height, seem to overestimate the dune scarp elevation. The above method seems to predict runup elevations that correspond closely with observed dune scarp locations and is of a comparable level of simplicity as the rest of the numerical model.

Post-Storm Beach and Dune Slopes

Methods are also required to describe the post-storm slopes of the beach face and dune face. The Vellinga model fixes the dune scarp at the peak surge level and assumes a 1:1 slope for the eroding dune face. This has recently been adopted in a similar erosion model for the National Flood Insurance Program described by Hallermeier and Rhodes (1988). This method works well for dune erosion in large wave tank tests but does not work as well for field conditions where a flattened post-storm beach face is usually evident below the dune scarp at an elevation above the peak surge level. In addition, most natural dunes are vegetated and display near-vertical post-storm slopes.

In the present model, any realistic post-storm dune scarp slope may be specified. For simulation of large wave tank tests, a slope of 1:1 is appropriate; however, for field conditions, slopes of 5 vertical to 1 horizontal are more reasonable. For the beach face slope, observations in the area of interest are usually the best guide when available. Lacking these, predictions can be made based on the observations of Sunamura (1984) where the beach slope was found to vary with sediment and wave conditions as

$$m_* = 0.12((gd_{50})^{1/2}T/H_{rms})^{1/2} \quad (6)$$

It is found that offshore rms wave height works well in equation (6). However, Sunamura does not specify which wave height should be used in random waves and equation (6) was developed using observed breaker heights.

Sediment Transport on Beach Face

A major problem encountered in all numerical models of cross-shore beach response is that no simple descriptions are available of sediment transport rates in the swash region. This problem is symptomatic of a more fundamental problem: the lack of valid wave transformation models that describe wave conditions in the swash zone. As a result, existing numerical models for cross-shore transport must include ad hoc treatments of the sediment transport rate on the active beach face.

In the original model, sediment transport rates were calculated only in regions of finite water depth. The energy dissipation and the sediment transport rates were calculated by equations (3) and (4) for all points in the surf zone up to the last submerged depth. At this point, the transport value was determined and the transport distribution was then assumed to decrease linearly to zero at the runup limit. This leads, however, to uniform retreat of the beach face from equation (2) since the gradient in transport is the same at all elevations.

In the revised model, a simple algorithm is used to provide an estimate of sediment transport rates on the beach face based on geometrical arguments. Water level and wave conditions are established at each time step and two reference elevations are located. The depth h_* is first established at the transition depth where the equilibrium profile, with an $Ax^{2/3}$ form, is tangent to the equilibrium beach slope, m_* . The elevation h_u is then defined at the upper limit of the active profile, either at the runup limit or at the crest of the remnant dune if the dune is overtopped. Based on equation (3), the transport rate Q_* is then determined at the transition depth h_* . The volume of sand that must be eroded from the beach face between the elevation contours h_* and h_u over one time step is then $V_* = Q_* \Delta t$.

An estimate is then made of the potential eroded volume, V_p , between h_* and h_u . This so-called potential erosion prism is depicted in Figure 2 for three basic cases: two for beach face rotation and one for beach face translation. In Case I, the equilibrium slope is steeper than the existing slope. The erosion prism is then defined by passing the equilibrium slope through the runup limit, h_u , so that contours near h_* have the greatest erosion potential. In Case II, the equilibrium slope is milder than the existing slope. The erosion prism is defined by passing the slope m_* through the transition depth h_* so that contours near h_u have the greatest erosion potential. In Case III, the existing slope is in equilibrium. All elevation contours have the same erosion potential and the erosion prism is then defined by translating the beach slope landward until V_p equals V_* .

In general, the potential volume V_p defined in Cases I and II does not equal the demand volume V_* . When the potential volume is too large, only the fraction V_*/V_p is actually eroded over the time step. When the potential volume is too small, the additional volume must then be supplied by translating the equilibrium slope m_* landward. In this way combinations of Cases I and III and Cases II and III are used to obtain the final potential volume V_p .

The estimated distribution of sediment transport on the beach face is finally established according to the fraction of the potential volume that may be eroded from above each elevation contour. Denoting the potential volume above contour n as V_n , the transport rate at elevation contour n is estimated as

$$Q_n = Q_* (V_n/V_p) \quad (7)$$

For the cases depicted in Figure 2, this gives the transport distributions depicted in Figure 3.

Figure 2. Illustration of potential erosion prism for fundamental cases of beach face rotation and translation.

Figure 3. Illustration of sediment transport distributions for example cases shown in Figure 2.

For Case I, the beach slope steepens since the transport distribution is concave with the largest gradients near h_* . For Case II, the beach face must flatten since the transport distribution is convex with the largest gradients near the runup limit h_u . For Case III, the beach face maintains its initial slope as it erodes since the transport distribution is linear with uniform gradients at all elevations. With this method, the beach face evolves toward the specified equilibrium slope while the submerged profile evolves toward the $Ax^{2/3}$ form. An example of the computed slope evolution is shown in Figure 4 for one of Saville's (1957) large wave tank tests. In this case, the equilibrium slope is steeper than the original 1:15 slope and slope steepening is simulated by the above method.

Figure 4. Example of slope steepening introduced by the potential erosion prism method.

Examples of Model Application

In order to validate the revised model, several large wave tank results of dune erosion using random waves were simulated. These included tests described by Vellinga (1986) as well as tests described by Dette and Uliczka (1987). In each case, the initial profile form, water level, wave conditions, and sand grain size were obtained from the references cited. The A parameter for the equilibrium profile form was obtained from Dean (1987) based on the median grain size. The equilibrium beach slope, m_* , was estimated using equation (6). A post-storm dune slope of 1:1 was assumed and the elevation of the

dune scarp was estimated from equation (5). The offshore breaking depth, forming the offshore limit to sediment deposition, was adopted as 1.06 times the rms wave height, in accordance with observations by Vellinga (1983).

One example of these simulations is shown in Figure 5. Numerical results are shown for simulation times of 0.1, 0.3, 1, 3, 6, and 10 hours while the measured profile obtained after 10 hours in the Delta Flume is also shown. For this case, the dune scarp elevation and horizontal location are slightly underpredicted but, in general, the scarp formation and the eroded volume are predicted to within about 10% from their measured values. Similar results were then obtained from the other tests with numerical results generally being within about 10 to 20 percent of the measured values.

Figure 5. Comparison of erosion simulation to measured profile response for test #2 of Vellinga (1986).

A similar comparison is shown in Figure 6 for the case of a sand beach backed by a sloping dike tested by Dette (personal communication). The predicted profiles are shown at times of 0.25, 0.5, 1.25, 2.75, and 4.0 hours and are compared to the measured profile after about 3 hours. In this case, the final profile form at the base of the dike is predicted reasonably well. Once the upper contours eroded back to the wall location, the upper limit of the active profile is transferred to the next lower contours and it is found that these erode faster for a time until they approach equilibrium.

Figure 6. Example of profile backed by seawall tested by Dette (personal communication).

In Figure 7, field conditions documenting the complete erosion of a narrow dune are simulated, based on data presented by Chiu and Dean (1986) for Hurricane Frederic on the Alabama coast. This storm was similar to Hurricane Eloise in that the storm duration was very short. However, Hurricane Frederic was more severe in that the peak surge elevation was higher and since the storm struck an area with relatively low dunes that were overtopped. As shown in Figure 7, the numerical model predicts the formation of a dune scarp for the first profile, 3.2 hours before the peak surge. On the next profile, 1.6 hours before the peak surge, wave runup overtopped the remnant dune. On the third profile, at the time of the peak surge, the dune was submerged and was then quickly flattened afterward.

At present, the numerical model simulates only off-shore transport at the crest of the remnant dune and does not simulate landward transport of sand due to overwash. Trial calculations with an upper boundary condition that includes overwash transport gave a faster planing of the remnant dune crest and results that agree more closely with the measured profile. However, more accurate data is needed to verify this algorithm. With the present approximation, reasonably realistic estimates of the time at which the dune is breached can be obtained.

Figure 7. Example of erosion of narrow dune during Hurricane Frederic as reported by Chiu and Dean (1986).

As a final example, Figure 9 shows results from the simulation of a long-duration winter storm from the coast of New Jersey. In this case, data were provided to the author by Jeff Gebert of the Philadelphia District of the Corps of Engineers. A total of 17 profiles were measured out to a depth of about 10 meters 1 to 2 days before the storm and were then remeasured just 3 to 4 days after the storm. Wave and water level conditions were both measured during the duration of the storm. This data set probably constitutes the most well documented storm erosion case on the U.S. East coast.

This condition is also interesting since: (1) the median grain size (from the beach face) is much larger than any other condition previously simulated, (2) the storm lasted for more than 2 days but included a peak surge elevation of only 6.1 feet (1.86 meters), and (3) the eroded volumes are very large, on the order of 1100 ft³/ft (100 m³/m). Results in Figure 9 are shown since they represent examples of model under and overprediction, in this case occurring on adjacent profiles located just 175 meters apart. Some post-storm recovery had occurred by the time of the post-storm survey and the presence of beach cusps may explain some of the differences observed on the beach face in the two profiles. These cases demonstrate, however, that the numerical model gives reasonable results for long-duration storm events.

Figure 9. Examples of storm simulation for March 1984 storm at Pt. Pleasant, New Jersey.

CONCLUSIONS

Numerical algorithms may be readily developed to handle most dune erosion conditions to a first level of approximation which retains an overall level of simplicity in terms of required parameters and numerical code. For example, a simple method has been presented for estimating sediment transport rates on the beach face. Such numerical algorithms may then be incorporated into other macroscopic profile response models to enhance their applicability to a broad range of dune geometries. However, other more physically-based methods of predicting wave transformation and sediment transport on the beach face are needed, along with new lab and field data for model verification.

CHAPTER 175

BEDFORMS, SEDIMENT CONCENTRATIONS AND SEDIMENT TRANSPORT IN SIMULATED WAVE CONDITIONS

Jan S. Ribberink¹⁾ and Abdullah Al-Salem²⁾

Abstract

Two series of experiments were conducted in a new Large Oscillating Water Tunnel of Delft Hydraulics with the main objectives to study the behaviour of bedforms and the transport of sand in controlled wave conditions simulated at full scale (1:1). The main results are:

- i) Bedform dimensions are strongly influenced by the type of oscillatory flow. The transition from rippled bed to plane bed conditions - as predicted by Nielsen's (1979) empirical relations - was not observed for sinusoidal waves but did occur for (ir)regular asymmetric waves.
- ii) The net sediment transports as measured during (ir)regular asymmetric wave experiments in plane or almost plane bed (sheet flow) conditions show a consistent linear relation with the third-order moment of the velocity $\langle U^3 \rangle$ and show a good agreement (within a factor 2) with the energetics total load sediment transport model of Bailard (1981). A calibrated formula of the form $q_s = A \cdot \langle U^3 \rangle$ shows a reasonable agreement (within a factor 1.5-3) with available existing datasets over a wide range of measured values (factor 1000).

Introduction

For the transport of sediment in the marine coastal environment the complex interactions between the wave and sea bed itself (bedforms, sediment stirring) play a key role. After several years of experimental research in a small oscillating water tunnel, recently a new large oscillating water tunnel was constructed at DELFT HYDRAULICS with the aim to extend the research to full scale (1:1) conditions.

Sediment transport under the influence of waves and current is generally divided into transport as carried by the current and transport as carried by waves. By splitting up of the horizontal velocity U

-

 - 2) Kuwait Institute for Scientific Research, presently: Guest Researcher, DELFT HYDRAULICS, PO Box 152, 8300 AD, Emmeloord, The Netherlands

and the sediment concentration C at a certain level in a time-averaged component and a fluctuating component due to the waves, the horizontal sediment flux at that level ϕ_{cw} can be split up in a current-related part ϕ_c and a wave-related part ϕ_w , as follows. For a colinear situation (i.e. current and wave propagation have the same or opposite direction):

$$U = U_0 + \tilde{U}$$

$$C = C_0 + \tilde{C}$$

$$\begin{aligned} \phi_{cw} = \langle UC \rangle &= \phi_c + \phi_w \\ &= \langle U_0 C_0 \rangle + \langle \tilde{U} \tilde{C} \rangle \end{aligned}$$

Much of the research on sediment transport in the past has been concentrated on the transport component as carried by the current (often dominant in longshore direction). The waves are treated as an additional stirring mechanism for the sand. The sediment transport component as carried by the waves (e.g. due to wave asymmetry outside the surfzone) is much less understood, which is probably caused by the complex character of this type of sediment transport which is governed by the intra-wave processes taking place in a relatively thin layer (millimeters to centimeters) near the sea bed. Nevertheless, the wave-carried transport is of great importance for especially the transport in cross-shore direction. For example, wave asymmetry (leading to relatively high orbital velocities in the direction of the wave propagation and relatively low orbital velocities in the opposite direction) is generally held responsible for the onshore motion of sand on the upper shoreface and for example for the onshore motion of offshore bars.

The experimental research programme around the new tunnel was therefore started with the objectives: i) to obtain a better understanding of the wave-carried sediment transport and ii) to verify and improve existing concepts for the description of this type of sediment transport.

Large Oscillating Water Tunnel

A general outline of the new tunnel is given in Figure 1. The horizontal test section has an approximate length of 15 m, an inner width of 0.3 m and an inner height of 1.1 meter. The complete test section can be provided with a sand bed with a layer thickness of 0.3 meter, leaving 0.8 m height for the oscillatory flow above the bed. A desired oscillatory water motion (regular or irregular) can be imposed by a computer controlled hard driving system, which consists of a hydraulic servo-cylinder moving a steel piston in one of the cylindrical risers. The other cylindrical riser is open to the atmosphere. The maximum amplitude of the piston is 0.75 m which coincides with a maximum semi-exursion length of water particles in the test section of app. 1.75 meter.

Figure 2 shows the working regime of the new tunnel in terms of period and maximum velocity amplitude of the oscillatory flow, in comparison with the small tunnel of DELFT HYDRAULICS and the existing large tunnels at SCRIPPS (USA) and ISVA (TU Copenhagen). The main feature of the new tunnel is that it has the possibility of

controlled simulation in the relevant velocity/period regime (scale 1:1). A desired regular and irregular oscillatory flow can be produced in the test section with a limited deformation. Figure 2 shows that the tunnel covers the bedform regimes from initiation of motion to sheet flow ($D_{50} = 0.2 \text{ mm}$).

Figure 1 Large Oscillating Water Tunnel

Figure 2 Velocity-amplitude and period regime

Set-up of experiments

Because bedforms are essential features for the sediment transport process, a first set (series A) of experiments was focussed on

bedform behaviour under the influence of regular sinusoidal oscillations, covering the major part of the tunnel's working regime. Twenty-nine tests were conducted with periods 4-10 s and velocity amplitudes 0.3-1.5 m/s using quartz sand with $D_{50} = 0.21$ mm. The main objectives of this first series were: i) to compare the observed bedforms (dimensions, transition to sheet flow) with existing datasets and empirical formulations (tunnel validation) and, ii) to study the bedform behaviour in the still very unknown high velocity ($U > 1$ m/s) and large period ($T > 5$ s) regimes.

A second set of experiments (series B) was focussed on the net sediment transport as induced by wave asymmetry. Only a limited set of data is available on this type of transport especially in the high velocity regime (Horikawa et al, 1982 and Sawamoto & Yamashita, 1986). A series of 12 experiments were carried out in the large tunnel with irregular (exps. 1-6) and regular (exps. 7-12) asymmetric oscillatory flow in which the net sediment transport, bed form dimensions and time-averaged suspended concentration profiles were measured. The experimental conditions are summarized in Table 1 (U_{rms} = root mean square value of the measured velocity in the tunnel, $T_{(peak)}$ = (peak) period of the oscillatory flow).

12	0.97		

Table 1 Experimental conditions series B (wave-asymmetry)

The irregular wave experiments are based on a JONSWAP spectrum for the water surface elevation in combination with a second-order Stokes wave theory (Liu and Dingemans, 1989). The 2nd-order theory is also applied for the regular wave experiments. Figure 3 shows an example of a time series of the applied non-linear (asymmetric) velocity signal in comparison with the linear (symmetric) signal. The degree of asymmetry, expressed in (significant) crest velocity U divided by the sum of (significant) crest and trough velocity ($U_c + U_t$), was kept constant (0.62-0.65).

Two different oscillation (spectral peak) periods were used (6.5 and 9.1 s) for similar velocity time series in order to study the validity of a quasi-steady approach for the description of the sediment transport.

A laser-doppler system is used for the measurement of the horizontal velocity variation outside the boundary layer (20 cm above the sand bed). The net sediment transport rate in the middle of the test section (not disturbed by boundary effects at the two ends of the test section) is determined with a mass-conservation technique. The measured bed-level change along the test section and the collected sand volume in two sand traps at both ends of the test section during a certain time interval (5 - 50 min) are used for the integration of the sediment continuity equation, yielding the distribution of the net transport rate along the test section. By repeating each experiment 5-8 times the net transport rate could be determined with an error of approximately 10-15%. Totally 93 tests were carried out in the above mentioned 12 different conditions.

Figure 3 Irregular asymmetric velocity signal

The data analysis was concentrated on the bedform behaviour and the sediment transport rate. For information about the measured suspended concentration profiles (time-averaged), reference is made to Ribberink and Al-Salem (1989, 1990).

Bedforms

Figure 4 gives an impression of the bedform behaviour in the test section (central 8 m) for different velocity amplitudes and periods (series A: regular sinusoidal oscillations). The bedform length and height increase for increasing velocity amplitude and period. Very large bedforms developed in the high velocity/period regime ($U > 0.9 \text{ m/s}$) which, although considerably larger than generally observed in small wave flumes, show a clear consistency with results from other wave tunnels and flumes in the world (see Fig. 5, $X_2 = D_{50}/\Delta g T^2$).

Figure 4 Bed geometry, regular sinusoidal flow (series A)

Figure 5 Ripple length as a function of orbital excursion length

It is shown that the measured dimensionless bedform length λ is roughly a linear function of the dimensionless total orbital excursion length d_o of water particles near the bed ($\lambda \approx 0.5 \cdot d_o$).

The new tunnel observations (DH, 1989) show a good agreement with the measurements conducted by Sakakiyama et al (1986) in the large Japanese CRIEPI wave flume (field scale).

The transition to sheet flow conditions in the high-velocity regime did not coincide with the transition to plane bed conditions. For example, for $\hat{U} = 1.5$ m/s large bedforms could be observed with a length $\lambda \approx 0.5 \cdot d_o$, with sheet flow taking place in a thin layer (appr. 0.5 cm) along the bedforms and without vortex generation in the bedform troughs (no flow separation on the bedform crests).

This behaviour is also shown in Figure 6A in which the measured bedform lengths are compared with Nielsen's (1979) empirical formulations (laboratory and field conditions).

In Figure 6: $\hat{x} = 0.5 \cdot d_o$ and $\hat{U}^2/\Delta g D_{50}$ is the mobility number with $\Delta = (\rho_s - \rho)/\rho$, ρ_s = density of sediment, ρ = density of water and g = gravity acceleration.

Although the transition to sheet flow indeed took place for mobility numbers $> 100-200$, the (dimensionless) bedform length measured in the tunnel but also in the CRIEPI flume did not show the expected decrease.

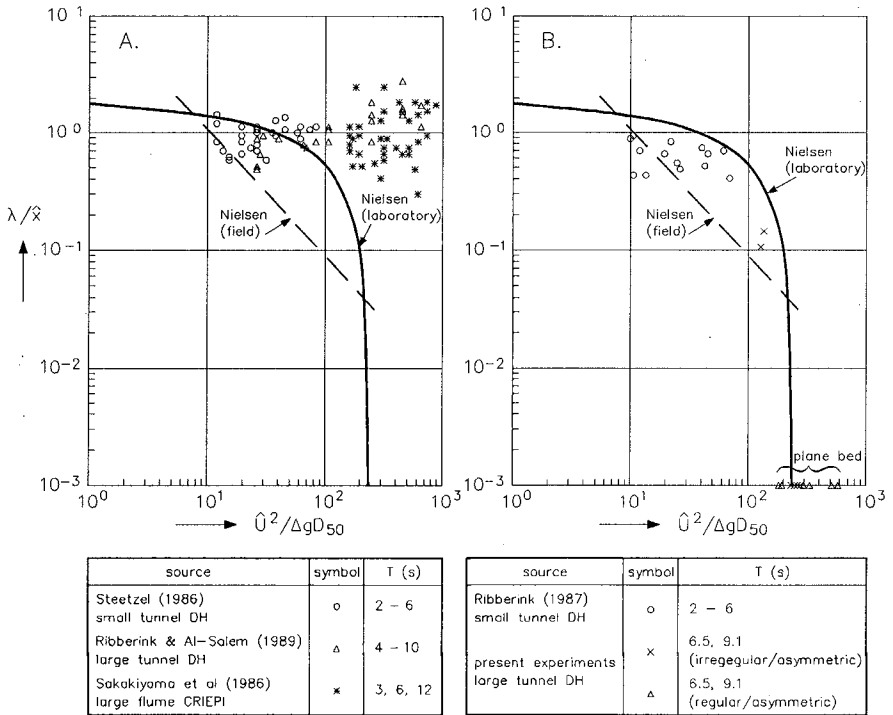

Fig. 6 Dimensionless ripple length as a function of mobility number

However, the situation changed in case the oscillatory flow becomes asymmetric (experimental series B) as shown in Figure 6B. Only the experiments 2 and 5 showed the presence of small two-dimensional rolling grain ripples, during the other 10 experiments the bed was plane and sheet flow was present. Now the reduction in ripple length roughly coincides with Nielsen's relations.

Similar results were obtained for the measured ripple height. For more details, see Ribberink and Al-Salem (1990).

Sediment transport induced by wave asymmetry

For the modelling of sediment transport as carried by waves several approaches exist varying from relatively simple to very sophisticated (research) formulations. In the most simple approach the instantaneous transport during the wave cycle is directly related to the instantaneous horizontal velocity above the wave boundary layer near the sea bed. It is assumed that (time) phase lags between transport rate, sediment concentration and bed-shear stress and between bed-shear stress and velocity above the boundary layer can be neglected (quasi-steadiness). A general notation for this kind of transport concept is:

$$q_s(t) = A|U(t)^{(n-1)}|U(t) \quad (1)$$

in which $q_s(t)$ = transport rate during the wave cycle expressed in volume per unit width and time, $U(t)$ = horizontal velocity during the wave-cycle above the wave boundary layer, n = power and A = factor depending on several parameters such as grain size and friction factor.

Madsen & Grant (1976) base their transport description on the transport formula for uni-directional steady flow of Einstein-Brown, yielding $n = 6$.

Bailard (1981) proposes formulations for bed-load and suspended transport based on energy considerations of Bagnold, yielding $n = 3$ for bed-load transport and $n = 4$ for suspended transport.

For plane bed conditions also more sophisticated model concepts exist in which the detailed behaviour of sediment concentration and water/grain velocities during the wave cycle (also vertical structure) is described. For example, a wave-boundary layer flow model is used in combination with a convection-diffusion model (see Fredsøe et al, 1985). The above-mentioned phase lag effects are taken into account and for example, the delayed response of suspended particles to the varying (unsteady) flow conditions is modelled. Although even more extensive modelling efforts are carried out (see e.g. Bakker and van Kesteren, 1987), a general problem is the lack of detailed measurements for the verification of the various concepts. Observations and measurements are often done in small laboratory flumes and tunnels in which the orbital velocities and wave periods are generally far below their natural values.

During all tunnel experiments in series B: i) the bed was plane or almost plane (rolling grain ripples in expts. 2 and 5), ii) a uniform (net) transport distribution could be realized in the central 8 meters of the test section, and iii) a net 'onshore' transport was measured. The latter agrees qualitatively with the power-law formulation eq. (1) (power $n > 1$) in combination with a velocity signal $U(t)$ based on 2nd-order Stokes wave theory.

The validity of the power law approach was verified by testing the relation between the measured net transport rates $\langle q_s \rangle$ and the velocity moments $\langle |U^{n-1}|U \rangle$ with $n = 3, 4$ and 6 (see Fig. 7). Hereto, the horizontal velocity signal, as measured (lda) during the complete experimental duration, was substituted into the power-law formulation and averaged over this duration. It is shown in Figure 7 that a clear correlation exists between the velocity moments and the net transport rate and that the power $n = 3$ yields the best results (i.e. dashed and solid line almost coincide).

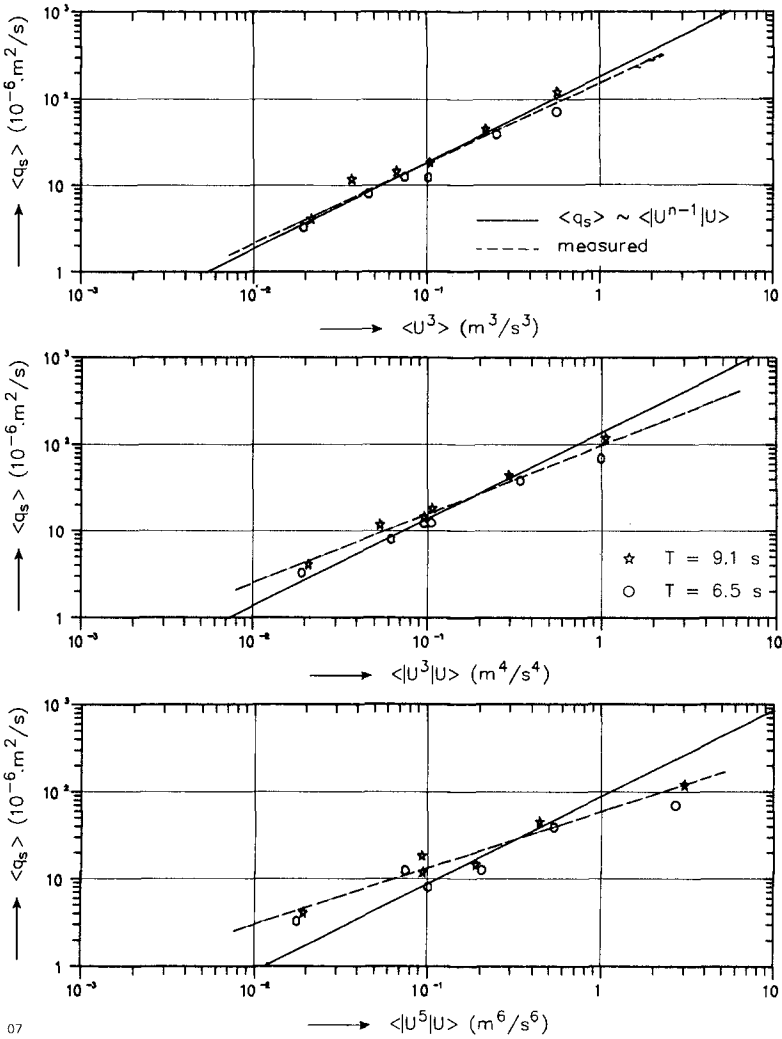

Figure 7 Net transport rate as a function of velocity moments

The experiments with regular and irregular oscillatory flow seem to follow the same line, which confirms the quasi-steady approach of the power-law description. Nevertheless, a wave period influence is present (see Fig. 8) as for the experiments with $T = 9.1$ s the measured net transport rates are systematically higher (20-60%) than for the experiments with $T = 6.5$ s. This indicates that phase-lag effects (or acceleration/inertia effects) are present and should be taken into account for more accurate transport modelling.

Figure 8 Period influence

In Figure 9 the formulas of Bailard (1981) and Madsen & Grant (1976) are verified in an absolute way by comparing computed net transport rates with the measurements. It is shown that the formula of Bailard (1981) can produce the measured transport rates within inaccuracy limits of a factor 2. The Madsen & Grant formula not only has the wrong power $n (= 6)$ but also clearly overpredicts the transport rate in the high-velocity regime.

Remark: In both formulae the friction factor formulation of Jonsson (1980) was used with roughness height $k_s = D_{50}$ and the significant water particle semi-excursion length (x_s^{sig} for the tests with irregular waves). The Bailard formula was applied with bed-load efficiency factor $\epsilon_b = 0.1$ and suspended-load efficiency factor $\epsilon_s = 0.02$ as suggested by Bailard.

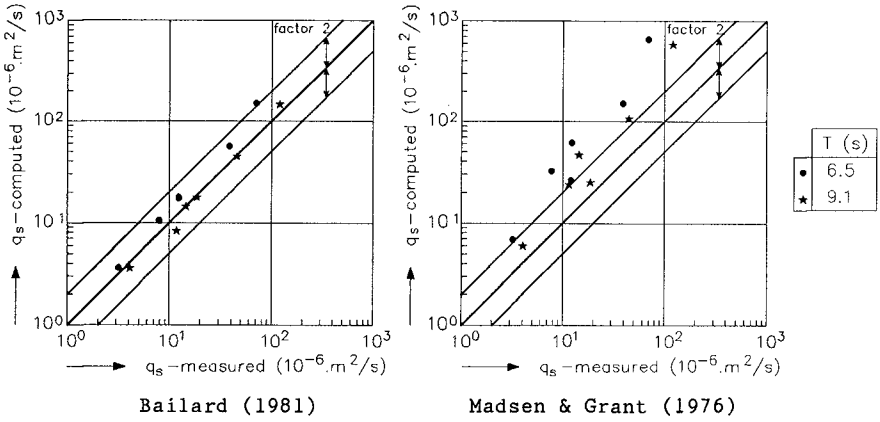

Figure 9 Verification of transport formulae of Bailard (1981) and Madsen & Grant (1976)

Figure 10 Comparison with other measurements ($D_{50} \approx 0.2 \text{ mm}$)

In Fig. 10 a comparison is made between the present measurements and other available datasets. The measurements of Horikawa et al (1982) and Sawamoto & Yamashita (1986) were carried out in tunnels in the sheet flow regime using almost the same sand as during the present experiments ($D_{50} = 0.2 \text{ mm}$). However, sinusoidal oscillations

were applied (Horikawa: $T = 2-6$ s and Sawamoto: 3.1 s) and the transport per half wave cycle ($\langle q_s \rangle_{1/2}$) was measured. The measurements of Roelvink and Stive (1988) were carried out in the large wave flume of DELFT HYDRAULICS (DELTA flume) using the same sand as used for the present tests. A net (onshore directed) transport $\langle q_s \rangle$ (due to wave asymmetry) was measured in case of irregular waves ($T_{\text{peak}} = 5.1, 6.1$ s, $U_{\text{rms}} \approx 0.3$ m/s). The inter-comparison of the different data sets is made through the power-law formulation₃(1), as calibrated with the new tunnel data (factor $A = 0.18 \cdot 10^{-3}$ s²/m and $n = 3$) and applied to the other datasets. A reasonable agreement is obtained (within a factor 1.5-3) over a wide range (factor 1000) of measured values. Although the data of Horikawa and Sawamoto are systematically underpredicted by the calibrated formula (effect of wave period, 1/2 cycle transport?), the validity of the power $n = 3$ is clearly confirmed (see slope of the data points in Fig. 10).

Conclusions

Two series of experiments were conducted in a new Large Oscillating Water Tunnel of Delft Hydraulics with the objectives to verify and develop (existing) relationships for sediment transport carried by waves, for suspended sediment concentrations and for bedform dimensions in controlled full-scale (1:1) conditions. Series A was conducted with regular sinusoidal waves, series B with regular and irregular asymmetric waves.

Bedforms

For regular sinusoidal waves the observed ripples:

- i) were considerably larger in the high velocity regime (sheet flow) than as predicted by the empirical relations of Nielsen (1979) and did not show the expected transition to plane bed,
- ii) had dimensions (height/length) which were linearly correlated with the orbital excursion length and showed a clear consistency and agreement with existing datasets including the large wave flume measurements of Sakakiyama et al (1986).

For (ir)regular/asymmetric waves the expected transition to plane bed conditions (sheet flow) did occur and agreed well with the relations of Nielsen (1979).

Sediment transport

The net sediment transports as measured during the regular and irregular asymmetric wave experiments in plane or almost plane bed (sheet flow) conditions showed:

- i) a consistent linear relation with the third-order moment of the velocity $\langle U^3 \rangle$,
- ii) a systematic (20-60%) wave-period influence (phase-lag effects),
- iii) a much better agreement with the energetics total load sediment transport formula of Bailard (1981) (within a factor 2) than with the bed-load formula of Madsen & Grant (1976).

A formula of the form $q_s = A \cdot \langle U^3 \rangle$, calibrated with the new experimental data ($A = 0.18 \cdot 10^{-3}$ s²/m), showed a reasonable agreement (within a factor 1.5-3) with the small number of existing datasets (Horikawa et al, 1982, Sawamoto & Yamashita, 1986 and Roelvink,

1988, all: $D_{50} \approx 0.2$ mm) over a wide range of measured values (factor 1000).

Acknowledgements

The measurements were carried out by Mr. T. van Maar of DELFT HYDRAULICS. The necessary software for the generation of the desired oscillatory flow in the water tunnel was developed by Mr. G. Klopman and Mr. L. Verhage. The authors appreciate the comments of Prof. E.W. Bijker as given during the research work. The work was funded in the framework of the 'Coastal Genesis' Research Programme of the Ministry of Transport and Public Works (Rijkswaterstaat).

CHAPTER 176

THE IN SITU MEASUREMENTS OF SEDIMENT TRANSPORT AND BOTTOM TOPOGRAPHY CHANGES

by

Yoshiaki KAWATA¹ M.ASCE, Hiroshi YOSHIOKA²
and Yoshito TSUCHIYA³ M.ASCE

Abstract

In order to get the data about bed-load transport rate and bottom topography changes under storm wave conditions, field equipments were newly developed and tested at the T-shaped Observation Pier(TOP) on the Ogata coast facing the Japan Sea. The surf sled with a pressure sensor can precisely detect the spatial water depth changes along the survey lines. Based on the compiled data, the 3D bottom topography changes for a winter season connect with the appearance of a dip and shoal system on the Ogata coast. The bed-load sampler has also developed to operate in rough sea state in a plane bed conditions. The data were well fitted with the law of cross-shore bed-load transport proposed by Kawata(1989a).

1. INTRODUCTION

A meaningful field study of nearshore sediment dynamics requires the in situ measurement of sediment transport and bottom topography changes. The validity of various proposed sediment transport relationships by waves has not been evaluated in the field. For lack of extensive 3D bottom topography data under severe wave conditions, the reliability of any analytical and numerical prediction methods of beach processes is still ambiguous. Recent field observations such as NSTS program(Seymour, 1987), C²S²(Willis,1987) and Duck85(Mason et al.

¹Associate Professor, Disaster Prevention Research Institute,
Kyoto University, Goka-sho, Uji, Kyoto, 611 Japan

²Instructor

³Professor

1987) had been carried out but no one did not directly measure these variables. In our field study, simultaneous measurements were also made of waves, water particle motion and nearshore currents at various locations along the T-shaped Observation Pier(TOP) in the surf zone.

In the field, the rate of sediment transport normal to the beach has been measured with a newly developed bed-load trap in a series of field experiments conducted at the TOP. The law of sediment transport formulated by Kawata(1989a) can be verified with the field and experimental data. At the same time, a sounding method in rough sea state around the TOP has been also developed to discuss the beach processes on the Ogata coast.

2. PROCEDURE

The field experiments were conducted in the three winter seasons in 1988,1989 and 1990, the periods that encompass the more intense wave activity on the Ogata coast which is a straight sandy beach of 20km long facing the Japan Sea as shown in Fig.1. The TOP extends 250m offshore and parallels the shore for 100m at the offshore end. Usually, seven ultrasonic type wave gauges (aerial emission type) and one 2D and two 3D ultrasonic type current meters are installed for routine observation. In addition, intensive observation uses extra two 3D ultrasonic type current meters whose spacing is 1m in the vertical direction and ten capacitance

Fig.1 Locations of the Ogata coasts and T-shaped Observation Pier(TOP)

type wave gauges as shown in Fig.2. A wave-rider buoy is anchored at the 3km offshore. The buoy is on a production of the pier axis(almost NW direction) so that in the case of normal incident waves, wave transformation can be analyzed accurately. The nearshore zone in which the water depth is more than about 4m has a very mild slope of around 1/120. At the offshore end of the pier, the water depth is about 6m. All data are gathered and compiled at Ogata Wave Observatory.

2.1 Bed-load trap

The unique design of a bed-load trap has been evolved over several years. Some operation and setting problems had been solved one by one with some ideas. The trap can operate under moderate to severe wave conditions because it is installed by using the local scour around the trap itself. Photo 1 shows the shape, attached equipments and size. Before the setting of the trap on the sea bottom, the sand bed condition is confirmed to be the plane bed with a measuring comb of 1.8m long with 61 stings which are coated with the grease as shown in Photo 2. The small scale bottom undulations in the cross-shore direction can be measured.

Fig.2 TOP and setting of surf sled, wave gauges, current meters and other equipments

Fig.3 Procedure of setting of bed-load trap using local scouring

(a) Plane view

(b) Side view

Photo 1 Bed-load trap

Photo 2 Measuring apparatus of small scale bottom undulations

Usually, at the breaker zone the plane bed condition is observed.

Fig.3 shows the setting process of the trap. Firstly, the opening(10cmx5cm) on the top steel plate of the trap is capped with a small cover which is fixed on the trap with an adhesive tape. This cover can be easily removed from the deck of the pier by pulling a fine string. Secondly, the trap is taken down into the sea by a crane and the air inside the trap is released through the intake pipe. Thirdly, the trap is touched on the bottom. The next moment local scouring around the trap advances. At the stage 3 in Fig.3, the trap is gradually stabilized in accordance with the development of the local scouring. The measurement of the bed-load transport starts in a moment when the string removes the cover from the opening of the trap. A compact videocassette recorder and two components electromagnetic current meter (the probe is set at the height of 17.3cm from the top plate of the trap) were equipped on the trap.

The net onshore (or offshore)bed-load transport rate can be just trapped through the opening on the plate. The inflow and outflow of sea water through the opening connected with a pipe as shown in Photo 1 keeps the one-way bed-load measurement. This system surely corresponds to the periodic changes of flow direction of water particle motion.

2.2 Surf sled

A surf sled (1.5m long, 0.7m wide, 40kg in weight) with a semiconductor pressure transducer has been also developed as shown in Photo 3. The sled can be operated in the cross-shore direction by two winches and roop rope system. The A-D converted data are compiled in the datalogger in a watertight stainless housing. With the sled the beach profiles were measured at longshore intervals of 5m. The sampling interval is 2.5s and average moving speed of the sled is 19.4cm/s. The overall error of the sounding keeps less than 5cm in any sea state. Preliminary tests show that low pass filter of 0.03Hz is adequate to eliminate the effect of incoming waves.

Photo 3 Surf sled

3. FIELD MEASUREMENTS

3.1 Bed-load transport

Fig.4 shows the sea bottom conditions at some measuring sites. In the surf zone on the Ogata coast, the rippled bed is usually observed and at the breaker zone, a plane bed condition is formed.

Fig.5 shows the cumulative curves of sediment on the bed and in the trap at site B. The mean diameters of the bed and of trapped sediment are 0.25mm and 0.3mm respectively. It was found that the relatively coarse part of the bed sediment moves as bed-load and therefore the standard deviation of the trapped sediment is smaller than that of the bed one.

(a) Measuring site around the pier

(b) Bottom conditions

Fig.4 Small scale bottom topography

Table 1 lists the results of observations on onshore sediment transport rate. These data are plotted in Fig.6 in which q_* ($=q/u_*d$) is dimensionless sediment transport rate and τ_* is dimensionless tractive force (the Shields number). In the arrangement, some unknown variables were estimated with the small amplitude wave theory and the friction factors introduced by Jonsson (1966). The visual observation with a VTR shows that bed-load movement on the plate of the trap was very smooth and made a parallel stripe pattern of accumulated sediment on the plate of the trap in the cross-shore direction. When the direction of water particle motion changes to offshore, the discharge from the opening through the pipe can blow off sediment which usually falls into the trap as offshore sediment transport rate. Therefore, it was confirmed that the trap efficiency of onshore sand transport is very high. The solid line in the figure shows the theoretical relationship of cross-shore sediment transport rate given by Kawata (1989a) as follows:

The theoretical reduction for cross-shore sediment transport is based on the momentum conservation of a cloud of saltating sand particles on a sloping beach.

(a) In the case of onshore sediment transport

$$\begin{aligned}
 q_{*u} = & a_1 [1 + e + (1 - e) \sqrt{\sin \theta} / (\sqrt{3}/2 A_r \sqrt{C_D \tau_*}) \\
 & - \{1 - e + (1 + e) \sqrt{\sin \theta} / (\sqrt{3}/2 A_r \sqrt{C_D \tau_*})\}^2 \\
 & + 8(1 - e) \cos^2 \theta / (3 \lambda C_D A_r^2 \tau_*^2)^{1/2}] (\tau_* - \tau_{*c}) \quad \text{--- (1)}
 \end{aligned}$$

(b) In the case of offshore sediment transport

$$\begin{aligned}
 q_{*d} = & a_1 [1 + e - ((1 - e)^2 + 8 \cos^2 (1 - e - 2e \lambda \tan \theta) \\
 & / (3 \lambda C_D A_r^2 \tau_*^2)^{1/2}] (\tau_* - \tau_{*c}) \quad \text{--- (2)}
 \end{aligned}$$

$$a_1 = (e/1 - 1) \tan \beta_m (1 + \rho/\sigma) A_r / \sqrt{\cos \theta}$$

$$\tau_{*c} = \tau_{*o} \{ \cos \theta \pm (\sigma/\rho) / (\sigma/\rho - 1) (\sin \theta / \tan \varphi) \}$$

* Parenthesis means offshore direction.

** Substance volume (porosity is assumed to be 0.4)

in which θ :beach slope, e :rebound coefficient of sand particle , C_D :drag coefficient, $A_r=8.5$, $\lambda/4$:ratio of height to length of a saltating sand particle, σ and ρ :densities of sand and fluid respectively, φ :angle of repose, τ_* :the Shields number and suffix u , d and c :upward slope, downward slope and critical condition respectively.

Typical variables are shown in Fig.6, in which the experiments of saltation of a sand particle were done in a water stream. In the horizontal bed, Eqs.(1) and (2) completely coincide. It should be noted that the trend of the field data calculated with mean wave height and period as well as experimental data in a plane bed condition is in reasonable agreement with the theory. However, arrangement with characteristics of significant waves is not adequate.

Fig.5 Sieve analysis of sediment

3.2 Bottom topography changes

(1) Wave characteristics

The intensive observation was conducted from November 28 to December 7, 1987. In this period, some storms came on the Ogata coast. Fig.7 shows the time series of wave climate recorded by a wave-rider buoy, a capacitance type wave gauge at the east end of the pier. The wave directions were analyzed with the linear array of four capacitance type wave gauges at the offshore end. The water depth of about 6m at the offshore end of the pier controls the maximum wave height. The tidal range is less 40cm. Usually, low pressures move eastwards in the midst of the Japan Sea in winter season, so that wave directions change from west to east at the offshore. However, in the records of the wave directions at the pier, they are not widely distributed but have a sharp peak around 90° (This means that wave angles at the pier are perpendicular to the beach) as shown in Fig.8. In the peak, wind waves from WNW to NW and swell waves from NW to NNW are included. This results reveals that the longshore sediment transport in the coast is small in spite of a straight sandy beach.

(2) Erosion and deposition area

Fig.9 shows the bottom topography on December 9 and 10, 1987 and March 13, 1988 in which D and S depict dip and shoal respectively. Over this period, waves are usually very small, so that it is assumed that the bottom topography is not remarkably changed in other seasons except by typhoon. Firstly, it was pointed out from Fig.9(a) that the contour lines in the shallow area which is less than 4m are parallel each other, two shoals are appeared at the both offshore ends of the pier and a dip with the maximum water depth of 5.2m expands to the central zone of the pier. In Fig.9(b), it was found that the distance of two shoals becomes short and the dip further extends to west direction(upper side of the figure). In general, water depth around the pier increased after winter season. This is partly due to forced offshore sediment transport. The armour unit mounted in the foreshore reflects the incoming waves and makes this coast an wave energy reflected beach defined by Short(1979).

The erosion and deposition diagram as shown in Fig.10 was made from the bottom topography changes between two observation date. In the figure, a hatched line is a boundary between erosion and deposition areas. As the characteristics of bottom topography change, the areas of erosion and deposition are not uniformly distributed in the cross-shore direction. Moreover, the positions of dips and shoals are almost fixed around the pier. Fig.11 shows the depth sounding chart in July 1986 and 1987 around the pier and Fig.12 reveals the pattern of dip and shoal in another place on the Ogata coast(kawata, 1989b). The distribution

pattern of dip and shoal was not changed annually, so that this system is stable and crescentic bars are formed on the Ogata coast. As before mentioned, there are two dominant wave directions on the Ogata coast. Their breaking points are usually a little different in the offshore direction, i.e., the fully-developed wind waves break relatively offshore in comparison with the breaking of the swell waves. Moreover, their incoming angles are slightly different. This characteristics may introduce the typical crescentic bar systems.

(b) 13 March 1988

Fig.9 bottom topography around the TOP

Fig.10 Deposition and erosion diagram

Fig.11 Depth sounding charts in Summer

(3) Beach profile changes

Along the pier the depth sounding with a lead has been conducted every week. The sounding interval in the cross-shore and longshore directions is 1.25m. The width of the pier is 4m so that we have two set of data along the pier in the cross-shore direction. The discrepancy of the mean beach profiles is very small so that the west side data were used in the analysis. The temporal difference from the mean beach profile are shown in Fig.13 in which black and grey areas show erosion and accretion from the mean beach profile respectively. In early winter, the offshore area beyond $x=70\text{m}$ was eroded, but this tendency was gradually eliminated and finally the deposition area was appeared. As shown in Fig.9,

Fig.12 Typical bottom topography changes on the Ogata coast

Fig.13 Beach profile changes in winter

this area is a "battle" zone of accretion and deposition areas. It is explained that westward longshore sediment transport may contribute the deposition in this area in winter season. From the data of the ultrasonic type current meter, strong undertow was observed around this place so that local changes of bottom topography may largely depend on the 3D nearshore current system.

4. CONCLUSIONS

A new type bed-load trap has been developed with two ideas. The principles are as follows: local scouring around the trap stabilizes the trap itself and an intake pipe keeps the onshore or offshore sediment transport rate in the trap. The effectiveness of the trap was certified with VTR analysis under sheet flow conditions. The field data as well as experimental one on a plane bed confirmed the validity of the law of cross-shore sediment transport proposed by Kawata(1989).

A surf sled is also applicable to the measurement of bottom topography changes under rough sea state. The accurate sounding data can reveal the beach processes on the Ogata coast. This sandy straight beach has a series of crescentic bars which correspond to the dip and shoal system in the longshore direction. Under small longshore transport rate due to almost normal incoming waves, their positions are annually stable. The slight discrepancy of incoming wave angles between fully- developed wind waves and swell ones makes the direction of sediment transport complex and may lead to formation of the crescentic bar systems.

CHAPTER 177

Single-phase fluid modelling of sheet-flow toward the development of "numerical mobile bed"

by

Kazuo NADAOKA ¹⁾ and Hiroshi YAGI ²⁾

ABSTRACT

As a first step to develop "numerical mobile bed" as a promising tool for the study of sheet-flow problem, a computational scheme based on a single-phase fluid model has been constructed by formulating the vertical transport of mass and momentum within the sheet-flow layer. The numerical results have shown the satisfactory agreements with the experimental results in velocity profile, sediment transport rate, and others. Further the difference in the period of oscillation was found to have appreciable influence on the temporal evolution of the sheet-flow thickness, indicating the importance of unsteadiness in the sheet-flow dynamics.

1. Introduction

The sheet-flow is a mode of sediment transport in the condition of large bottom shear stress and has quite important role in nearshore sedimentary process because of its large transport rate. For the sheet-flow study, however, the efficiency of conventional approaches for sediment transport study, i.e., laboratory experiments and field measurements are limited because of the similitude problem for laboratory wave-flume experiments and the lack of measuring devices in field measurements. The use of U-shaped tank to generate oscillatory flow with large velocity amplitude is one of possible ways to avoid

1) Associate Professor, Department of Civil Engineering, Tokyo Institute of Technology, Tokyo 152, Japan.

2) Research Associate, Department of Civil Engineering, Tokyo Institute of Technology, Tokyo 152, Japan.

the similitude problem in the wave tank experiments (Horikawa et al. 1982, Sawamoto & Yamashita 1987). However, such simplification of the flow field from the original wave field into a pure sinusoidal oscillatory flow field may yield significant difference in the dynamics of the sediment movements in the sheet-flow layer, as demonstrated theoretically by Nadaoka et al. (1988, 1990).

As a promising tool to overcome these difficulties, the authors emphasize the need to develop the "numerical mobile bed (NMB)", corresponding to the recent idea of the "numerical wave tank" or "numerical wind tunnel". The benefits of NMB are quite obvious; i.e., it makes possible to simulate the sheet-flow under arbitrary wave conditions, and in the NMB we can easily see its internal structure.

Although two-phase fluid modelling is most desirable for the development of NMB, there exist no reliable constitutive equations to express the momentum transport through the sediment collision process, which is one of most essential processes in the sheet-flow dynamics. Hence in the present study, as a first step toward the development of NMB, a computational scheme based on a single-phase fluid concept has been constructed by modelling the vertical transport of mass and momentum within the sheet-flow layer.

2. Formulation and modelling of sheet-flow phenomenon

(1) Basic equations

For the "numerical wave tank" and "numerical wind tunnel", there exist definite basic equations, i.e., Laplace's equation and the Navier-Stokes equation, respectively. For the "numerical mobile bed (NMB)", however, the basic equation to describe the dynamical process of sediment-fluid mixture has not yet been well established in the form having universal applicability. This is mainly attributable to the fact that there exist no reliable ways to formulate the vertical transport of mass and momentum in the sheet-flow layer. Especially for the modelling of sheet-flow as two-phase fluid we have no constitutive equation to evaluate the momentum exchange through sediment collision described as follows, although the basic equations can be easily expressed in the two-phase forms as shown by, e.g., Kobayashi and Seo(1985).

Since the pioneering work by Bagnold(1954), many studies have been made for the additional shear stress attributable to the presence of solid particles, which is so-called "grain stress". According to Bagnold(1954), the flow regime of particle-laden two-phase flow can be divided into "grain-inertia region", "macro-viscous region", and "intermediate region" between them.

Estimates of order of magnitude can show that the sheet-flow in usual condition falls into the viscous or intermediate regions (e.g., Bakker and Kesteren, 1986). As the experimental formula of the grain stress, τ_g , for these regions, Bagnold(1954) suggested the following expression.

$$\tau_g = 2.25\lambda^{1.5}\mu_0 \frac{\partial u}{\partial z} , \quad (1)$$

where λ is the linear concentration, μ_0 is the viscosity of intergranular fluid and $\partial u/\partial z$ is the rate of shearing. More recently Ahilan & Sleath (1987) arranged the experimental data by Savage and McKoewn (1983) and obtained the following formula of τ_g for the use in their numerical computation of oscillatory sheet-flow.

$$\tau_g = 1.2\lambda^2\mu_0 \frac{\partial u}{\partial z} . \quad (2)$$

However, for the viscous region, the actual mixed shear stress cannot legitimately be split into grain and fluid elements as described by Bagnold(1954). This is reflected in the fact that these experimental formulae have the forms with linear dependence on the fluid viscosity μ_0 ; hence τ_g becomes zero as $\mu_0 \rightarrow 0$. Therefore these experimental formulae cannot be used for the expression of the shear stress due to the grain-grain interaction in the two-phase formulation.

Considering such state of the limited knowledge on the constitutive equations at present, we have adopted a single-phase fluid formulation as one of realistic approaches. In this formulation, the equations of motion can be express as

$$\frac{Du}{Dt} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{1}{\rho} \left[\frac{\partial}{\partial x} \left(\mu_e \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial z} \left(\mu_e \frac{\partial u}{\partial z} \right) \right] + \frac{\partial}{\partial x} \left(\Omega_x \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial z} \left(\Omega_z \frac{\partial u}{\partial z} \right), \quad (3)$$

$$\frac{Dw}{Dt} = -\frac{1}{\rho} \frac{\partial p}{\partial z} + \frac{1}{\rho} \left[\frac{\partial}{\partial x} \left(\mu_e \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial z} \left(\mu_e \frac{\partial w}{\partial z} \right) \right] + \frac{\partial}{\partial x} \left(\Omega_x \frac{\partial w}{\partial x} \right) + \frac{\partial}{\partial z} \left(\Omega_z \frac{\partial w}{\partial z} \right), \quad (4)$$

where u and w are horizontal and vertical components of composite velocity of the sediment-fluid mixture, p is the pressure, ρ is the density of the mixture, Ω_x and Ω_z are x and z components of eddy viscosity, and μ_e is an equivalent viscosity to represent sediment collision effect. In order to obtain a closed system of the basic equations, we need further the continuity equation(5) and mass conservation equation(6) for the sediments.

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0, \quad (5)$$

$$\frac{\partial c}{\partial t} + \frac{\partial}{\partial x}(cu) + \frac{\partial}{\partial z}\{c(w-w_f)\} = \frac{\partial}{\partial x}\left[K_x \frac{\partial c}{\partial x}\right] + \frac{\partial}{\partial z}\left[K_z \frac{\partial c}{\partial z}\right], \quad (6)$$

in which c is the volumetric concentration of sediments, K_x and K_z are their horizontal and vertical diffusion coefficients, and w_f is the settling velocity of the sediment particles.

(2) Modelling of mass and momentum diffusivities and fall velocity of sediments

The accuracy of the present numerical model entirely depends on the way to specify the diffusion coefficients, μ_e , Ω_x , Ω_y , K_x , K_z and the settling velocity w_f . Unfortunately, however, there exist no established methods for the modelling of these quantities. Hence, in the present study, we have introduced tentative modellings of these factors as described in what follows.

a) Vertical diffusion coefficients of momentum

The factors governing the physical process of momentum exchange within the sheet-flow layer are

- 1) Momentum exchange through the sediment collision,
- 2) Viscous stress within the intergranular fluid,
- 3) Reynolds stress in the intergranular fluid.

Among these, in the present model, 1) and 2) are incorporated by an effective viscosity μ_e varying with sediment concentration c . The functional dependence of μ_e on c is assumed to be formulated as eq.(7) after Eilers (1941).

$$\frac{\mu_e}{\mu_0} = \left[1 + \frac{1.25c}{1-c/c_{\max}}\right]^2. \quad (7)$$

In this formula, as c becomes the maximum possible concentration c_{\max} , μ_e attains infinitely large value. This behavior of $\mu_e(c)$ near c_{\max} is consistent with the fact that the particles with the concentration of c_{\max} remain at rest. Although Eilers specified c_{\max} to be 0.74, the concentration c for the real sand particles in the sheet-flow layer can attain 0.65 at most. Hence, in the present model, c_{\max} is assumed to be 0.65. Furthermore, in order to avoid the infinitely large number to appear in the numerical calculation when c becomes c_{\max} , eq.(7) has been slightly modified as eq.(8) for the use in the present numerical simulation.

$$\frac{\mu_e}{\mu_0} = \left[1 + \frac{1.25c}{1-0.95(c/c_{\max})} \right]^2 \quad (8)$$

Reynolds stress within the intergranular fluid is another important factor for momentum transfer in the sheet-flow layer and it may be formulated most simply through a mixing length theory such as

$$\Omega_z = l^2 \left| \frac{\partial u}{\partial z} \right| \quad (9)$$

However, there arises a difficulty in the way to define the mixing length for the fluid domain with "fuzzy" boundary such as sheet-flow layer. Namely, for the sheet-flow with a typical vertical profile of the sediment concentration c as shown in Fig.1, the vertical location of the boundary can not be prescribed definitely. Hence, in the present study, a tentative new model of the mixing length has been introduced by considering a physical aspect of the eddy structure in the sheet-flow layer. Namely, within the sheet-flow layer, the eddy scale is not prescribed with the local concentration $c(z)$, but is considered to be governed by the overall feature of $c(z)$ profile. On the other hand, far above the sheet-flow layer, the layer acts as if it is a fixed boundary for the eddy structure. Hence at the far field above the sheet-flow layer, the mixing length should be almost coincide with that for the rigid boundary.

As one of possible models being consistent with these consideration, a new mixing model defined by equation (10) have been introduced, which is shown schematically by the solid curve for the mixing length $l(z)$ in Fig.1.

$$l(z) = \kappa \int_{-\infty}^z \frac{c_{\max} - c(\zeta)}{c_{\max}} d\zeta, \quad (10)$$

where κ is the Karman constant (=0.4).

b) Vertical diffusion coefficients and fall velocity of sediments

Another important factor to be modeled is the vertical mass transport of the sediments in the sheet-flow layer. This is considered to be governed by the following three factors.

- 1) Particle collisions,
- 2) Turbulence of interstitial fluid,
- 3) Particle settling.

Among these, the former two factors have been estimated by a similar diffusion model with a mixing length.

$$K_z = (\beta d + \alpha l)^2 \left| \frac{\partial u}{\partial z} \right| + K_0, \quad (11)$$

in which the scale of mixing is assumed to be the sum of those proportional to the particle diameter, d , and to the turbulent mixing length, l . The former scale is introduced by considering that the minimum mixing scale should be governed by the sediment diameter. The values of α and β were determined as 0.35 and 1.7 respectively so that the calculated c-profiles fit the experimental results by Horikawa et al. (1982) as well as possible. K_0 is a coefficient introduced to stabilize the numerical calculation, and was set to be $5\nu_0$ by trial and error, where ν_0 is the kinematic viscosity of the intergranular fluid. The particle settling velocity, w_f , varies with the sediment concentration, c , because of the hindered effect by particle collision. This dependence of w_f on c has been proposed by several researchers to be expressed as

$$\frac{w_f}{w_{f0}} = \left(1 - \frac{c}{c_{\max}} \right)^n, \quad (12)$$

where w_{f0} is the settling velocity in the still water. Although the exponent n in this equation has been reported to have several values by the experiments, the optimal value of n for complex unsteady flow conditions such as sheet-flow can not be specified. Hence, in the present study, the value of n was set simply to be one.

(4) Boundary conditions

At the left and right boundaries of the computational domain, the periodic conditions are used for u and c . At the upper boundary, on the other hand, the conditions

$$u=U_0, \quad cw_f + K_z \frac{\partial c}{\partial z} = 0, \quad (13)$$

are imposed, where U_0 is the sinusoidally oscillating velocity at the outer edge of the sheet-flow layer. Hence the horizontal pressure gradient can be given by U_0 as

$$\frac{\partial p}{\partial x} = -\rho_0 \frac{\partial U_0}{\partial t}. \quad (14)$$

where ρ_0 is the density of the pure fluid.

At the lower edge of the sheet-flow layer, the following simple rest condition is imposed, because for

unsteady two-phase flows there exist no reasonable condition such as the yielding stress for static problems.

$$u=0 \quad \text{for } c > 0.999c_{\max}, \quad (15)$$

where the coefficient of 0.999 is a factor to allow the computational error in c so that it does not yield any unrealistic influence on the rest condition.

3. Computational results and discussion

(1) Comparison of calculated values with experimental data

To confirm the validity of the present model, it has been applied to an oscillating sheet-flow problem, for which several experimental results are available for the comparison. Figure 2 is an example showing the vertical profiles of the sediment concentration c , horizontal velocity u and sediment flux q with the experimental data by Horikawa et al.(1982), and demonstrates that the present model can simulate the overall feature of these profiles and their time evolution.

Figure 3(a) shows the phase-variation of the sheet-flow depth h , representing that the present numerical model can give almost the same magnitude of variation of h within a half-cycle, as compared with the experimental results. However, the large difference in h between the acceleration and deceleration phases as seen in the experimental result cannot be reproduced by the present model. This is due to the fact that the characteristic difference of turbulent flow structure between at acceleration and deceleration phases cannot be represented by the zero-equation turbulence closure such as the mixing length model, which we have adopted for the present formulation

Figure 3(b) shows the phase-variation within a half cycle of the instantaneous sediment transport rate Φ defined as eq.(16).

$$\Phi(t) = \frac{1}{w_{F0}d} \int_{-\infty}^{\infty} q(z, t) dz. \quad (16)$$

There arises appreciable discrepancy between the calculated and measured values around the peak and decelerating phases. This is mainly attributable to the fact that the magnitude of the experimental velocity exhibits smaller values at the deceleration phases as shown in Fig.2.

(2) Dependence on Shields parameter

Figures 4(a) and (b) represent the dependence of the phase-variation of h and the nondimensional sand transport rate averaged over a half cycle, Φ , on the Shields parameter, ψ_m defined as eq.(17). The figures indicate that as the Shields parameter increases, the phase-variation patterns of h and Φ become skewed shapes having their peak behind the phase of $\pi/2$.

$$\psi_m = \frac{1}{2} \frac{u_{*m}^2}{sgd}, \quad (17)$$

where u_{*m} is the maximum friction velocity, s is the specific gravity of sediments in fluid and g is the gravitational acceleration.

Figure 5 shows the relation between $\bar{\Phi}$ and u_{*m}/w_f . The full line in the figure represents the experimental formula by Sawamoto & Yamashita(1987) obtained by reexamining the formula by Madsen & Grant(1976) with their own experimental data. Comparison with this experimental line indicates that the present model can estimate the mean transport rate with acceptable magnitude, though its dependence on u_{*m}/w_f is slightly weaker than that of the experimental formula.

(3) Effect of unsteadiness

The conventional ways to estimate the sediment transport rate is based on the assumption of quasisteadiness of the sediment transport process. For example, Madsen & Grant (1976) derived a formula to estimate $\bar{\Phi}$ by assuming that the instantaneous transport rate $\Phi(t)$ can be evaluated by Brown's formula(1950) for the unidirectional steady flow. In order to investigate the validity of this assumption, the effect of the unsteadiness of the sheet-flow phenomenon has been examined.

The dashed-line in Fig.3(b) indicates the instantaneous sand transport rate calculated by the Brown's formula under the assumption of such quasisteadiness. The quasisteady value of Φ is found to exhibit rapid increase and decrease pattern around its peak phase as compared with the experimental and present computational results. This fact strongly suggests that the unsteadiness has quite important role in the sheet-flow dynamics, hence it is indispensable factor for the sheet-flow modelling.

In order to investigate this point more clearly, the calculations have been executed for various values of the oscillating period T with the same Shields parameter ψ_m . Figure 6 shows the phase-variation of the sheet-flow depth h for the three periods indicated. It is found that as the period decreases the relative magnitude of h -

variation within the a half cycle also decreases, and the depth value attains its peak at more later phase. This is closely correlated with the fact that as the oscillating period becomes shorter, the sediment pick-up and successive settling process cannot catch up with the phase-variation of the flow field without any phase lag. Existence of such strong dependence of the sheet-flow evolution on the oscillating period T indicates that we should treat the sheet-flow phenomena as a nonstationary process for its modelling.

4. Conclusions

Although the present model is still rather simple and primitive in contrast with our final goal to develop the "numerical mobile bed", the present model can estimate the essential feature of sheet-flow dynamics, such as temporal evolution of sheet-flow profiles and their overall dependence on the Shields parameter. Further the difference in the period of oscillation was found to have appreciable influence on the temporal evolution of the sheet-flow thickness, indicating the importance of unsteadiness in the sheet-flow dynamics.

CHAPTER 178

SITE INVESTIGATION ON SAND CONCENTRATION IN THE SHEET- FLOW LAYER

Z. YU¹, H.D. NIEMEYER² and W.T. BAKKER³

ABSTRACT

Field measurements of sand concentration in the sheetflow layer have been carried out in the swash zone on a beach on the island of Norderney. Simultaneous registration of both sediment concentration at three levels and the velocity of wave induced water movement in the boundary layer gives an impression of the phenomenon sheetflow for prototype conditions.

1 INTRODUCTION

The development of sheetflow due to oscillating water movement for laboratory conditions was already reported 35 years ago by MANOHAR (1955). HORIKAWA et al. (1982) measured the vertical distribution of sand concentration and orbital velocities in the sheetflow layer in a wave tunnel. Meanwhile the observation of sheetflow in the

prototype has also been mentioned and recently numerous theoretical studies and laboratory experiments have paid attention to the subject of sheetflow (BAKKER et. al 1989).

Under the umbrella of a Dutch-German cooperation site investigations on sheetflow has been started on the East Frisian island of Norderney, East Frisia, F.R. of Germany. Purposes of this study have been:

- a. to obtain measured prototype data of sheetflow, which can provide some pictures of the reality of sheetflow,
- b. to gain experience for future large scale field measurements.

2 MEASURING SITE AND INSTRUMENTATION

The measurements have been carried out in the measuring array (Fig. 1) of the Coastal Research Station Norderney (CRS), where a matrix of wave and current meters is installed on the beach (NIEMEYER 1991). Additionally electrical resistance probes for measurements of sand concentration are used during the experiments, which have originally been developed and manufactured by DELFT HYDRAULICS for laboratory investigations. Due to limited financial resources only three probes have been available for this pilot study.

Fig. 2: Measuring set-up, right: front- and top-view of the set-up, left: detail position of probes on the lower bar of the frame

In the first stage of the study trials have been carried out to get a suitable frame construction (Fig. 2). The basic conception, which had been developed at Delft University of Technology had to be improved step by step due to prototype experience. Design and manufacturing was carried out at the Coastal Research Station. This construction meets the following requirements:

- a: limited disturbance of water and sediment movements which should be unaffected in the area around the probes,

b: flexible, exact adjustable vertical level for each probe.

This instrumentation was already described by BAKKER et al. (1989).

3 CALIBRATION

The probes had only been used at DELFT HYDRAULICS for freshwater. For prototype measurements in salt water it was therefore necessary to adapt their measuring range and to carry out a corresponding calibration. Its final goal is to get a general function

$$U = f(\text{field parameters}) \quad (1)$$

where U is the output of the probe [V].

The calibration procedure was carried out in consideration of the following four parameters with respect to the output signal of the probes:

1. characteristics of sediment particles
2. sand concentration
3. temperature
4. salinity

The first parameter was taken into account by using sand from the measuring site. This allows the simplification of formula (1) to

$$U = f(c, S, T) \quad (2)$$

with c: volumic sand concentration [%]
 S: salinity [ppt]
 T: temperature [°C].

A suitable experiment set-up was installed in the soil mechanics laboratory of the CRS. Sand-water mixtures with variable 'composition' (c, S, T,) were created by use of a mixer to simulate conditions according to prototype boundary conditions:

- uniform suspension in the entire water column for sand concentrations from 0 to 45 %
- variation of salinity between 20 and 35 ppt
- controlled water temperature for a range of 2 - 20 °C

The treatment of calibration data was done by multiple regression analysis. As a result the following calibration function was established:

$$U = \sum_{j=1}^3 \sum_{i=1}^3 a_{ij} x_i^{b_{ij}} x_j^{b_{ji}} \quad (3)$$

where: a_{ij} , b_{ij} , b_{ji} are constants derived from the regression-analysis and

$$x_1 = 1 - c$$

$$x_2 = S$$

$$x_3 = T$$

Fig. 3: left: Fitting of calibration function to data for variations of temperature and salinity, right: Fitting of calibration function for variations in sand concentration

Scatter diagrams for calibration data in comparison to the calibration function for variations of sand concentration, salinity and temperature demonstrate its applicability and soundness (Fig. 3).

4 EXECUTION OF FIELD MEASUREMENTS AND DATA ANALYSIS

The installation of the probes with the frame (Fig. 1 and 2) took always place at low tide close to one current meter of the existing measuring array (NIEMEYER 1991). The probes had a cable connection to a data acquisition system which was established in a container close to the beach (Fig. 1). For the performance of the system two cooperating crews are acting: one at the measuring site and the other one in the container.

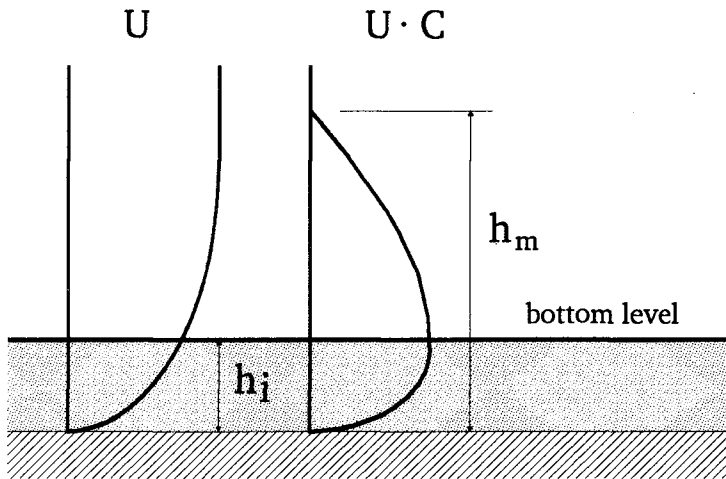

Fig. 4: Definition of intrusion depth and thickness of moving layer

The measuring procedure was started, when the sea bed near the probes was covered by water of the rising tide. It is very important to ensure that the probes 'stay' in the moving layer (definition: Fig. 4). The crew in the container acts therefore as steering group. By observation of the measuring signals on a strip chart recorder the current position of the probes and necessary readjustments could be evaluated:

- the probe is in water ($c = 0$)
- the probe is in sand ($c = c_0$, c_0 : maximum concentration)
- in the moving layer ($0 < c < c_0$, variable in time)

The measuring strategy is to keep the lowest probe at the level where sand particles will just move or not. This is necessary for the estimation of the intrusion depth h_i and guarantees that the two higher placed probes will catch the moving layer. If a readjustment of the probes is required due to erosion or sedimentation, orders will be given from the container crew by radio to the beach crew in order to follow the moving layer by heightening or lowering the frame. The measurements could be continued in this manner until rising water level and increasing wave heights force the crew to leave the beach.

Additionally temperature T and salinity S are measured in order to establish proper data sets. For this case function (3) may be reduced to

$$g(c) = 0 \quad (4)$$

which allows the derivation of c by iteration.

5 RESULTS OF THE MEASUREMENTS

Several measurements have been performed in the swash zone on the beach of Norderney. As the electromagnetic current meters must keep within a certain distance from the sea bed, velocity registrations show many disturbances at begin of each time series, because the sensor head is not continuously covered by water. If the sensor head falls dry, it measures wind speed. Data of one time series will be discussed here concerning the following aspects:

- concentration in the moving layer h_m ,
- intrusion depth of the sheetflow h_i ,
- local morphological change during the measurement.

Additional boundary conditions of the measuring set-up and initial beach geometry are:

- height of current meter sensor head above sea bed:
70 mm
- beach slope: $\sim 1 / 60$
- vertical difference between probe levels:
3 mm between 1 (highest) and 2 (center);
2 mm between 2 and 3 (lowest)

Measured concentrations at three levels and the cross- and longshore components of wave induced currents are plotted in Fig. 5. At the beginning (mark A) probe 3 is just at the lower boundary of the moving layer (level of the intrusion depth) and probe 1 is above the sea bed. It only measures sand concentrations, if high velocities occur. The intrusion depth h_i of the sheetflow should be about 2 mm and the total moving layer h_m might have a thickness of nearly 7 mm at mark A and B. The current meter is from time to time exposed to air, especially in the final stage of backwashes. Between the marks C and D a layer with a thickness of 2 mm or more is eroded, but is afterwards again restored by sedimentation.

The continuation of this registration is shown in Fig. 6: At mark E there is an intrusion depth of less than 2 mm and a moving layer of about 4 mm. Responding to large velocities as well higher concentrations occur as the layer thickness increases (mark F: $h_i \sim 3$ mm, $h_m \sim 8$ mm). Noteworthy is also the rapid change of onshore-offshore current directions. This specific feature of wave induced currents in the swash zone is totally different from the orbital motions which are reproduced in wave tunnels in order to generate sheetflow conditions there, as e. g. done by HORIKAWA et al. (1982) or BAKKER et al. (1988).

The maximum intrusion depth occurs often in coincidence with flow direction changes (long backwash followed by large uprush) which is obviously the case at mark F and again at mark G. At mark F both probe 2 and 3 are still covered with sand ($c=c_0$). But then both are subsequently eroded and the resedimentation is only sufficient to recover probe 3 which is finally eroded at mark G. This resulting step by step erosion does occur in the final stage of long backwash movements with increasing offshore directed velocities. Even the comparable high onshore directed velocities of the uprush do not have the same effectiveness with respect to resedimentation, as the uprush duration is remarkably lesser than that of the backwash.

This causes a continuous erosion during the first stage of the rising tide. At the measuring point an erosion of about 5 mm has taken place some 30 minutes after the start of the registration. During the following 10 minutes a layer of another 4 mm sand has additionally been washed away. As documented in Fig. 7 the erosion process could even accelerate: the frame is lowered at mark H to a level which is 4 mm lower than before. But within less than three minutes this layer is again eroded (mark I).

Another 10 minutes later the probes are already 24 mm lower than at the beginning (Fig. 8). This tendency remains stable for the whole measuring period: After an hour plus a few minutes a total erosion of about 55 mm has taken place.

With respect to the development of sheetflow conditions it seems noteworthy that a thickness of 2 mm does often occur and in some cases (e. g. mark F; Fig. 6) a thickness of 5 mm with concentrations of more than 5 mm. This is about twenty times of mean local sediment diameter.

6 CONCLUSIONS

6.1 INSTRUMENTATION

1. The measuring set-up is suitable (up to a water depth of about 1 m) for sheetflow measurements in the swash zone. However for measurements in the surf zone the system must be remote controlled in order to adjust the position of the probes with respect to bottom level fluctuations.
2. Measurements with three probes provide a quite good impression of the reality of sheetflow in field. Detailed studies will require more probes, because the large vertical gradients in sheetflow demand for distances of not more than 1 mm. In order to overcover the moving layer h_m with an expected maximum thickness of about 8 mm a measuring height of 10 mm is recommended.
3. The distance of the current meter of 70 to 100 mm to the sea bed causes disturbances due to measurements of wind speed when it falls dry. A lower position might effect scouring, especially for the occurrence of high velocities and intensive sediment transport. The use of a finer shaped current meter might reduce this handicap.

6.2 Sheetflow and Beach Erosion

1. The measured maximal intusion depth h_i of sheetflow is about 2 to 5 mm and the maximal moving layer h_m is about 8 mm.
2. A moving layer can be observed if the near bottom velocity in the boundary layer exceeds a value of about 1.3 m/s. This takes mostly place in the final stage of the backwash.
3. At the measuring point a 55 mm thick sand layer was eroded within an hour and an average erosion rate of 1.5 mm/min does occur during the last 30 minutes of the measurement.
4. There is a certain correlation between erosion and backwash with long periods.

ACKNOWLEDGEMENTS

The authors wishes to thank their colleagues of the Coastal Research Station for the support they got, especially Messrs. Brandt, Gerrelts, Glaser and Meemken. Mr. Groeneveld (Delft University of Technology) had constructed the initial version of the frame.

CHAPTER 179

Two-Phase Flow Model on Oscillatory Sheet-Flow

Toshiyuki Asano

1. INTRODUCTION

Under stormy waves on a sandy beach, a flat movable bed may appear when ripples have been washed out. Studies of the sheet flow have recently received much attention because a large amount of sand is transported under such conditions. However, most of the existing studies on the sediment transport are dealing with the phenomena under small tractive forces because this is easily reproduced in a small wave tank. Until now, very little understanding has been obtained on the sheet flow phenomena.

The first systematic study on the sheet flow is likely the work of Horikawa et al.(1982). They measured the sediment transport velocity and sediment concentration in an oscillatory flume. The reported velocity and concentration profiles were different from existing results obtained under the condition of small amount of sediment movement. Yamashita et al.(1985) and Ahilan-Sleath(1987) performed similar experiments with light artificial particles as the sediment. These experiments have increased the understanding of sheet flows. However, difficulties in the measuring densely mixed sediment-fluid flow prevent investigating the detailed structures of the flow. In addition, the limited size of the experimental flume may cause several problems in generating idealistic conditions.

Since a numerical model has an advantage of being free from the restrictions imposed on the experiment, several models on the sheet flow have recently been proposed. Ahilan-Sleath modelled sediment-fluid mixture flow as a mono-phase flow with varying density in time and depth. Since this model ignores the sediment-fluid interaction, the accuracy is likely to decrease as the sediment concentration becomes higher.

Associate Professor, Department of Ocean Civil Engineering, Kagoshima University, 1-21-40, Kourimoto, Kagoshima, 890, JAPAN

The present paper develops a numerical model to analyze the oscillatory sheet flow. The mathematical formulation based on fluid-sediment two phase flow is performed by expanding models from a unidirectional flow (Bogardi(1974), Kobayashi-Seo(1985)) into an oscillatory flow. The developed model predicts the velocity field, properties of friction and sediment transport rate. The model is shown to describe existing experimental data for oscillatory sheet flow.

2. SOLID - FLUID MIXTURE MODEL FOR OSCILLATORY SHEET FLOW

(1) Basic assumptions and mathematical formulation

The mathematical model derived herein is based on a continuum assumption for fluid and a uniform cohesionless sediment mixture. The analysis is performed for the case of two dimensional oscillatory flow over a plane bed. Molecular diffusion and viscous stresses are assumed to be negligible compared with those due to turbulence.

The continuity equation for the fluid phase is

$$\frac{\partial}{\partial t}\rho(1 - c) + \frac{\partial}{\partial x_j}\rho(1 - c)u_j = 0 \tag{1}$$

in which ρ : fluid density, c : volumetric concentration of sediment, and u_j : fluid velocity in the x_j direction. The continuity equation for the sediment phase is

$$\frac{\partial}{\partial t}\rho_s c + \frac{\partial}{\partial x_j}\rho_s c u_{s,j} = 0 \tag{2}$$

in which ρ_s : density of sediment, and $u_{s,j}$: sediment particle velocity in the x_j direction.

The momentum equation for the fluid phase is described by

$$\frac{\partial}{\partial t}\rho(1 - c)u_i + \frac{\partial}{\partial x_j}\rho(1 - c)u_i u_j = -(1 - c)\frac{\partial p}{\partial x_i} - \rho(1 - c)g\delta_{i2} - f_i \tag{3}$$

in which p : pressure, g : gravitational acceleration, δ_{ij} : Kronecker delta, and f_i : x_i component of interaction force per unit volume between the sediment and fluid.

The momentum equation for the sediment phase is expressed by

$$\frac{\partial}{\partial t}\rho_s c u_{s,i} + \frac{\partial}{\partial x_j}\rho_s c u_{s,i} u_{s,j} = -c\frac{\partial p}{\partial x_i} + \frac{\partial \gamma_{ij}}{\partial x_j} - \rho_s c g \delta_{i2} + f_i \tag{4}$$

in which γ_{ij} : intergranular stress tensor.

(2) Simplification of the equations

In the following analysis, the x-axis is taken in the horizontal direction, and the z-axis is taken upward from the origin placed at the top of the immovable

layer where the sediment transport velocity is always zero. The velocity component in the x and z directions is given by u and w , respectively. The equation for the mean quantities can be derived by first decomposing the instantaneous quantities in Eqs.(1) ~ (4) into the steady, oscillatory and turbulent components, and then averaging the resultant equations with respect to time. Some simplifications are made by assuming $u \gg w$, $u_s \gg w_s$, and $uc'w' \gg c'u'w'$. For example, a fluid shear stress term which arises in the x -momentum equation is given by

$$\tau/\rho = -\{(1-c)\overline{u'w'} - c\overline{u'w'}\} \quad (5)$$

The turbulent eddy viscosity K_v and the turbulent diffusion coefficient K_c are introduced to represent the turbulent correlation terms by the mean quantities as shown by

$$\overline{c'w'} \simeq \overline{c'w'_s} = -K_c \frac{\partial c}{\partial z} \quad (6)$$

$$\overline{u'_s w'_s} \simeq \overline{u'w'} = -K_v \frac{\partial u}{\partial z} \quad (7)$$

Assuming that proximity effects among the sediment particles may be ignored and that the added mass force acting on a sediment particle is negligible as compared with the drag force, the interaction force between the sediment and fluid may be expressed as the sum of the buoyancy and drag force.

$$f_i = \rho c g \delta_{i2} + \frac{\rho}{2} C_D \left(\frac{\pi d^2}{4} \right) \frac{c}{\pi d^3 / 6} u_{i,r} \sqrt{u_r^2 + w_r^2} \quad (8)$$

in which $u_r = u - u_s$ and $w_r = w - w_s$ denote the relative velocities between the fluid and sediment and C_D is the drag coefficient. The interaction force in the x -direction is approximated by

$$f_x = \frac{\rho}{2} C_D \left(\frac{\pi d^2}{4} \right) \frac{c}{\pi d^3 / 6} |u_r| u_r \quad (9)$$

Rubey's formula is used to estimate the drag coefficient.

$$C_D = 24/Re + 2 \quad (10)$$

in which the Reynolds number is defined as $Re = u_r d / \nu$.

Although the intergranular stress resulted from the momentum transfer from solid to solid is not well understood yet even for steady flows, the constitutive equation of Savage-McKeown(1983) is adopted here as

$$\gamma_{xz}/\rho = 1.2\lambda^2 \nu \partial u_s / \partial z \quad (11)$$

in which λ : the linear concentration related to c and to the maximum possible static concentration of uniform spheres c_{max} .

$$\lambda = 1/[c_{max}/c]^{1/3} - 1] \quad (12)$$

The following dimensionless variables are introduced,

$$\begin{aligned}
 u &= \bar{u}u_0, \quad u_s = \bar{u}_s u_0, \quad u_r = \bar{u}_r u_0, \quad w = w_{f_0} \bar{w} / \sqrt{R}, \\
 w_s &= w_{f_0} \bar{w}_s / \sqrt{R}, \quad x = \frac{g\xi}{\omega^2}, \quad z = \sqrt{\nu/\omega} \zeta, \\
 t &= \tau/\omega, \quad p = \rho \left(\frac{g}{\omega}\right) u_0 \bar{p}, \quad K_c = \sqrt{\nu/\omega} u_0 \bar{K}_c, \\
 K_v &= \sqrt{\nu/\omega} u_0 \bar{K}_v, \quad \sqrt{R} = u_0 / \sqrt{\nu\omega}
 \end{aligned}
 \tag{13}$$

in which u_0 : free stream velocity amplitude, w_{f_0} : settling velocity of a single sediment particle in pure water, ν : kinematic viscosity of the fluid, and ω : angular frequency of the oscillatory flow. The dimensionless form of the continuity equation for the sediment phase is obtained from Eq.(2) as follows

$$\frac{\partial c}{\partial \tau} = -\frac{w_{f_0}}{u_0} \frac{\partial}{\partial \zeta} (c\bar{w}_s) + \sqrt{R} \frac{\partial}{\partial \zeta} \left\{ \bar{K}_c \frac{\partial c}{\partial \zeta} \right\}
 \tag{14}$$

The dimensionless equation for the fluid phase momentum in the x-direction is given by

$$\begin{aligned}
 &\frac{\partial}{\partial \tau} \{c^* \bar{u}\} + \frac{w_{f_0}}{u_0} \frac{\partial}{\partial \zeta} \{c^* \bar{u} \bar{w}\} = \\
 &\sqrt{R} \frac{\partial}{\partial \zeta} \left\{ \bar{K}_v c^* \frac{\partial \bar{u}}{\partial \zeta} - \bar{K}_c \bar{u} \frac{\partial c}{\partial \zeta} \right\} - c^* \frac{\partial \bar{p}}{\partial \xi} - \frac{3}{4} R \left(\frac{u_0 d}{\nu}\right)^{-1} C_{Dc} \left| \bar{u}_r \right| \bar{u}_r
 \end{aligned}
 \tag{15}$$

in which $c_* = 1 - c$.

The dimensionless equation for the sediment phase momentum in the x-direction is

$$\begin{aligned}
 &\frac{\partial}{\partial \tau} \{c \bar{u}_s\} + \frac{w_{f_0}}{u_0} \frac{\partial}{\partial \zeta} \{c \bar{u}_s \bar{w}_s\} = \\
 &\sqrt{R} \frac{\partial}{\partial \zeta} \left\{ \bar{K}_v c \frac{\partial \bar{u}_s}{\partial \zeta} + \bar{K}_c \bar{u}_s \frac{\partial c}{\partial \zeta} \right\} - \frac{1}{s} c \frac{\partial \bar{p}}{\partial \xi} + \frac{1.2}{s} \frac{\partial}{\partial \zeta} \left(\lambda^2 \frac{\partial \bar{u}_s}{\partial \zeta} \right) \\
 &\quad + \frac{1}{s} \frac{3}{4} R \left(\frac{u_0 d}{\nu}\right)^{-1} C_{Ds} c \left| \bar{u}_r \right| \bar{u}_r
 \end{aligned}
 \tag{16}$$

in which $s = \rho_s/\rho$ denotes the specific density of the sediment. Adding Eq.(1) to Eq.(2) yields the following relation

$$(1 - c) \bar{w} + c \bar{w}_s = 0
 \tag{17}$$

From the vertical momentum equation for the fluid phase given by Eq.(4), an equation for the pressure would be derived. From the corresponding equation for the sediment phase given by Eq.(5), an equation describing the relationship between the intergranular stress term $\partial \gamma_{zz} / \partial z$ and the fluid-sediment interaction term f_z would be derived. Since these equations are related to u, u_s, w, w_s, p and c in a highly non-linear fashion, the simultaneous differential equations

are difficult to solve even numerically. Therefore, according to experimental results on the settling velocity in dense fluid-sediment mixture by Richardson et al.(1979), the vertical sediment velocity is assumed to be given by

$$w_s = w_{f_0}[1 - (c/c_{max})]^n \quad (18)$$

in which n is an experimental variable, which is taken to be 2.3 in this study. The velocity for the fluid phase w can be calculated from Eq.(17) with estimated w_s . The pressure is assumed constant throughout the boundary layer.

The parameters involved in Eqs.(14), (15) and (16) are as follows:

$$s = \frac{\rho_s}{\rho}, \quad R = \frac{u_0^2}{\omega\nu}, \quad \frac{u_0^2}{gd}, \quad \frac{u_0 d}{\nu} \quad (19)$$

The variable of w_{f_0}/u_0 in Eqs.(14), (15) and (16) is also expressed by the above parameters if w_{f_0} is given by Rubey's formula.

The sediment transport field is conventionally divided into the following two regions: the bed load region where the sediment concentration is high and the particles are mainly supported by the intergranular stress, and the suspended load region where the sediment concentration is small and the particles are mainly supported by the fluid turbulent stress. According to the experiment of Wilson(1984), the thickness of bed load region, z_G , is given by

$$z_G = 10(\theta - \theta_{cr})d \quad (20)$$

in which θ is the Shields number and θ_{cr} is the critical Shields number. The thickness of the suspended load region, z_s , is assumed to be equal to the turbulent oscillatory boundary layer for fixed beds. That is,

$$z_s = \kappa u_* / \omega \quad (21)$$

in which κ : Karman constant, and u_* : friction velocity.

In the bed load region, the mixing length may be governed by the distance among the sediment particles d/λ ; whereas, in the suspended load region, the mixing length may be assumed to be the mixing length for the pure fluid flow with modifications of flow stratification. The turbulent eddy viscosity K_v may be expressed as follows

$$K_v = \kappa u_*(t)\beta(d/\lambda) : z < z_G/2$$

$$K_v = \frac{\kappa u_*(t)(z - z_G/2)}{1 + 4.7(z/L)} + \kappa u_*(t)\beta(d/\lambda) \Big|_{z=z_G/2} : z \geq z_G/2 \quad (22)$$

in which \hat{u}_* : amplitude of the friction velocity, β : constant (here assumed to be 10), and L : Monin-Obukhov length written by

$$L = \hat{u}_*^3 / (\kappa g(s-1)w_{f_0}c) \quad (23)$$

According to the model of Brevik(1981), K_v is assumed to be constant for $z \geq z_G + \Delta$, in which Δ is given by

$$\Delta = 0.036\{2d(u_0/\omega)^3\}^{1/4} \tag{24}$$

Fig. 1 shows an example of the profile of the turbulent eddy viscosity.

The friction velocity amplitude \hat{u}_* is estimated using the roughness height k_b based on the formula of Grant-Madsen(1982). Since the efficiency of the turbulent transfer for mass is generally different from that for momentum, K_c is not really the same as K_v . However, for lack of reliable data for oscillatory flow, K_c is assumed herein to be the same as K_v .

The boundary conditions for \bar{u} and \bar{u}_s are given as follows

$$\bar{u} = \bar{u}_s = 0, \quad \partial\bar{u}_s/\partial\zeta = 0 \quad : \zeta = 0$$

$$\partial\bar{u}/\partial\zeta = 0 \quad : \zeta = \bar{\delta} \tag{25}$$

Near the immovable layer where c is nearly equal to c_{max} , the intergranular stress in the vertical direction is assumed to equal the submerged weight of the sediment above it as hypothesised by Bagnold to avoid divergence of the calculated results.

$$|\partial\bar{u}_s/\partial z| \leq (s-1)g \tan \phi \int_z^\infty c dz / (1.2\lambda^2\nu) \tag{26}$$

The boundary conditions for the sediment concentration are given by

$$c = c_{max} \quad : \zeta = 0$$

$$-(w_{f_0}/u_0) \frac{1}{\sqrt{R}} c \bar{w}_s + \bar{K}_c \frac{\partial c}{\partial \zeta} = 0 \quad : \zeta = \bar{\delta} \tag{27}$$

Fig. 1
Profile of turbulent eddy
viscosity K_v

Fig. 2
Profiles of sediment con-
centration c

The basic equations for the numerical calculation have been obtained as Eqs.(14),(15),(16). These equations were discretized by a Crank-Nicolson implicit scheme. The number of the vertical grids was 140, and the time increment was $1/5000$ of an oscillatory period. The calculation was continued until the calculated results in successive cycles converged. It was found that most of the deviation from the converged solution disappeared typically after half a period.

3. CALCULATED RESULTS

The profiles of the sediment concentration c shown in Fig.2 indicate that the concentration decreases gradually from c_{max} in the region $z/\delta \leq 0.2$, exponentially for $z/\delta \geq 0.2$.

Fig.3 shows the profiles of the fluid velocity u and the sediment transport velocity u_s . The sediment transport velocity u_s is found to be nearly zero close to the immovable layer around $z/\delta \leq 1/6$ because the intergranular stress term becomes very large in this region. The fluid motion is also suppressed due to the drag resistance between the fluid and sediment. In the region $1/6 \leq z/\delta \leq 1/3$, a phase precedence over the free stream velocity is observed. In the region $z/\delta \geq 1/3$, $|u|$ is always larger than $|u_s|$ in the accelerating phase, and smaller in the decelerating phase. This property is caused by the difference of the inertia between the sediment and fluid particles.

Fig. 3 Profiles of horizontal fluid velocity u (solid line) and sediment transport velocity u_s (dotted line)

The phase variation of the concentration is depicted in Fig. 4. The phase variations of the fluid velocity are given in Fig. 5. The results at $z/\delta = 0.1$ and 0.15 near the immovable layer show peculiar variations which are similar to the variations of the pressure gradient $-\partial p/\partial x$. The fluid flow around this level resembles a seepage flow because the concentration there is close to the maximum packing concentration. At $z/\delta = 0.2$, u and u_s increase gradually up to the maximum, then decrease suddenly. This result can be related to the temporal variation of the concentration.

Fig.6 is a semi-log plot of the horizontal fluid velocities at the phase = 0π for various values of the specific density s . The velocity profiles can be approximated by log-linear lines over a wide range. The intersection, z_0 , of the z -axis with the extended log-linear line, which corresponds to the roughness

Fig. 4 Phase variation of sediment concentration

Fig. 5 Phase variation of horizontal fluid velocity

height, decreases with the increase of s . The gradient, α , of the log-linear line decreases slightly with the increase of s . The log-linear part of the velocity distribution is described by

$$u/u_0 = \alpha \ln(z/z_0) \tag{28}$$

Fig.7 (a) and (b) show the variations of z_0/d and α with the specific gravity s , respectively. The figures show that both z_0 and α increase with a decrease of s . These result seems to be reasonable because the decrease of s results in more intensive movement of the sediment. However, it is noted that the results do not approach the values for fixed beds, $z_0/d = 1/15$ and $\alpha = \sqrt{f/2}/\kappa$, even when s becomes large. That is because the present model assumes the fluid-sediment mixture flow as a continuum, consequently it is not applicable to flow conditions when only a few layers of sediment particles move.

Variation of z_0/d and α with specific gravity s

4. COMPARISON WITH EXISTING EXPERIMENTAL DATA

Three sets of data of Ahilan-Sleath(1987), Horikawa et al.(1982) and Yamashita et al.(1985) are used to examine the validity of the present model. All three experiments were carried out in oscillatory tunnels. Horikawa et al. used fine sand, whereas the others used light plastic particles. The experimental conditions are summarized in Tabel-1.

First, comparisons on the sediment transport velocity at phase = 0π between the measurements of Ahilan-Sleath and the predicted results are made as shown in Fig.8. The results of cases (a) and (b) were obtained using nylon particles with a small specific density ($s=1.137$), while case(c) uses particles of slightly higher density($s = 1.44$). The calculated velocity for case (c) becomes very small in the region $z \leq 3$ cm. Considering that the location of the immovable layer may not be easily determined in the experiment, the plotted data points are shifted upward by 3cm for this case.

Table 1 Test condition of existing data

		s	T (sec)	u_0 (cm/sec)	d (cm)	R (*10 ⁵)	$\frac{u_0^2}{gd}$	$\frac{u_0 d}{\nu}$	$\frac{u_0^2}{(s-1)gd}$
Ahilan-Sleath (1987)	Test-2	1.137	3.67	45.0	0.40	1.18	5.17	1800	37.7
	Test-5	1.137	3.59	31.5	0.40	0.57	2.53	1260	18.5
	Test-9	1.44	4.86	122.0	0.43	11.5	38.0	5246	86.3
Horikawa et al. (1982)	Case 1-1	2.66	3.60	127.0	0.02	9.24	823	254	496.0
Yamashita et al. (1985)	Case-2	1.58	3.10	80.6	0.50	3.21	13.3	4030	22.9

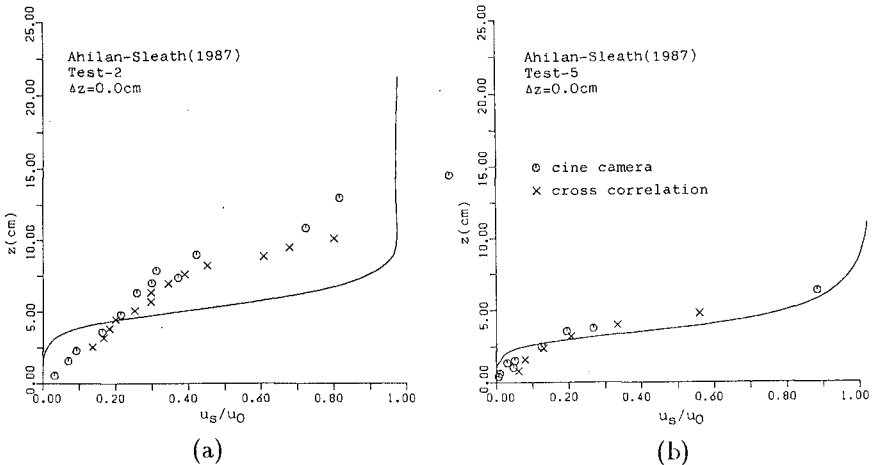

Fig. 8 Comparison between Ahilan-Sleath(1987)'s data and predicted results on sediment transport velocity

Fig. 8 (c) (conti.)

Finally, the data of Horikawa et al are examined. The predicted results do not agree well with this data set, because the measured values of u_s and c vary only in a thin region close to the immovable layer. The cause of the discrepancy, which is not obvious however, might be due to the very fine sand particles they used as the sediment.

5. CONCLUSIONS

A mathematical model is developed to describe the flow field under oscillatory sheet flow. The model is based on the conservation of mass and momentum for the fluid and sediment. In order to simplify the model, certain assumptions on the settling velocity, turbulent stress and intergranular stress are introduced. The trend of the calculated results on the concentration, the fluid velocity and the sediment transport velocity are examined. Finally, comparisons with available data are made. The conclusions obtained herein are as follows:

- (1) In the high concentration region close to the immovable layer, the sediment transport velocity approaches zero due to the intergranular stress, and consequently the fluid velocity becomes small in this region due to the fluid-sediment drag resistance. The phase variation of the velocity in this region is similar to that of a seepage flow. In the low concentration region, the sediment transport velocity becomes smaller than the fluid velocity during the accelerating phase and larger during the decelerating phase.
- (2) The changes of the fluid velocity profiles can be described by the gradient and z -intersection of the logarithmic distribution. These two parameters can be described by the four dimensionless parameters involved in the present model.
- (3) The present model is capable of predicting most of the experimental data considered here.

Second, the data of Yamashita et al. on the fluid velocity and sediment transport velocity are compared. The compared results are shown in Fig.9 for different phases. Although small discrepancies are found, the predicted results are consistent with the following experimental properties: the heights where the velocity starts to increase from 0, the phase precedence of the velocity variation from the free stream velocity, and the decrease of the sediment transport velocity relative to the fluid velocity during the accelerating phase.

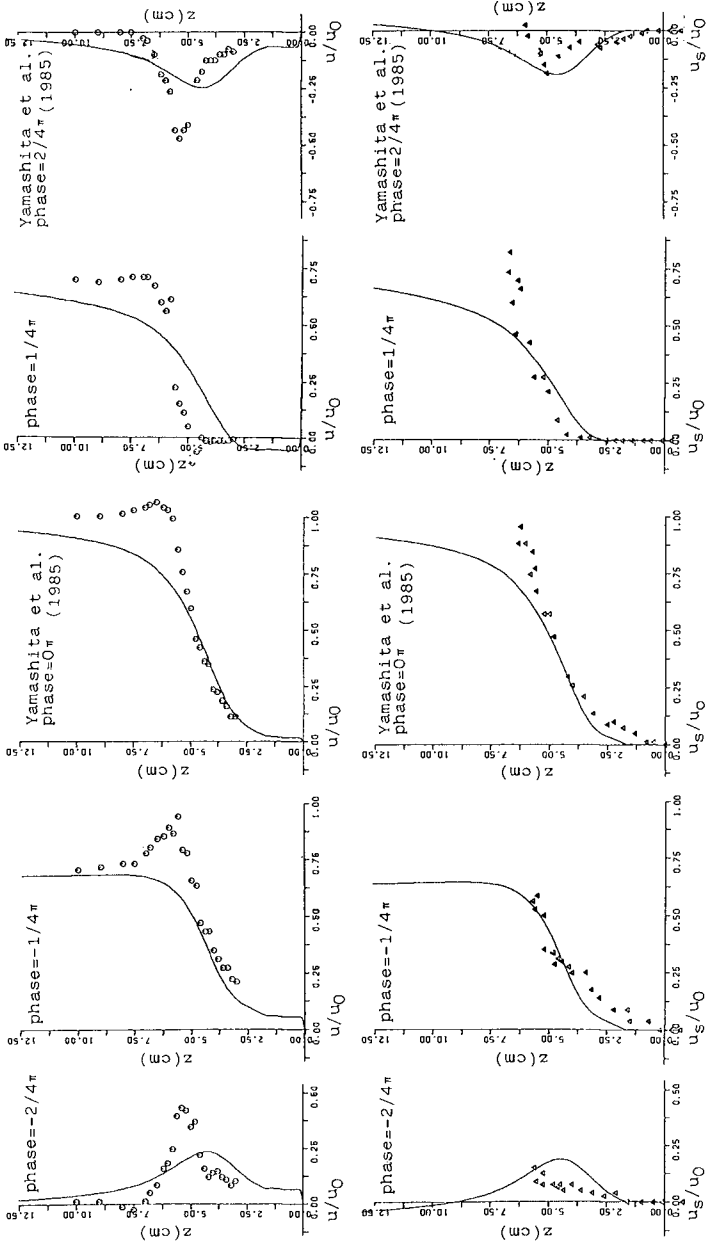

Fig. 9 Comparison between Yamashita et al. (1985)'s data and predicted results on fluid velocity (the upper row) and sediment transport velocity (the lower row).

The present model has tentatively adopted the empirical relationship for the intergranular stress which was originally obtained for a unidirectional flow. There remains the future work of re-examining the assumed distributions for the turbulent eddy viscosity and turbulent diffusion coefficient. Studies on the basic mechanisms involved in a sediment laden oscillatory flow is essential to improve the model accuracy, and accumulation of reliable experimental data is also needed.

ACKNOWLEDGMENTS

Part of this study was carried out at the Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Technical University of Denmark. The staff at ISVA are appreciated for their useful comments and their helpfulness. The author would also like to thank Prof. N. Kobayashi, Delaware University, for constructive comments, and Prof. J. F. A. Sleath, Cambridge University, for sending his useful data.

CHAPTER 180

Abrasion at the Tanah Lot Temple - Bali - Indonesia, and Its Counter Measures

Syamsudin and Kardana *)

1. INTRODUCTION

Tanah Lot Temple is situated in Tabanan Regency - Bali, on the coast of the Indonesian Ocean. Due to continuous wave attack, wind force, and weathering of the rock bank where the Temple stands, abrasion has occurred which is more and more threatening the existence of the Temple. Considering that Tanah Lot Temple is a sacred place for the Hindu Balinese people and a place of high cultural value, and also an important tourism, steps to save the Temple are imperative. The Central as well as the Regional Authorities, and also the Balinese community are very much interested in the effort to keep the Temple intact.

Measures have been undertaken to protect both the sea-side and land-side banks of the Temple rock bank. This paper only discusses counter measures of the sea-side bank of the Temple.

2. SITUATION AND CONDITION

Tanah Lot Temple is located on a small island with an area of about 1000 m². The Temple was established in the 16th century. Because of lack of information, we don't know precisely whether the temple was built on the island separated from or connected with the land. If the temple was built unseparable with the land and the separation with the land such a present condition is resulted from abrasion processes, it was truly remarkable work. Eventhough man at that time did not recognize sophisticated technology, they were able to locate the temple on the more stable area than of already eroded by wave and weather. Therefore, they are forced to wait for the tide to flow out, which lasts for a relatively short time only, to make their offerings. If there is a great number of templegoers, making the offering meets with difficulties. Not only because

*) Institute of Hydraulic Engineering, Ir. H. Juanda 193, Bandung, Indonesia.

of the tide, but also of the relatively small area of the Temple, and the narrow access path which is used by the people both coming to and leaving the temple. Figure 1.a shows the situation of Tanah Lot Temple and figure 1.b shows coastal cross-section at the location of the temple. It can be shown from the figure the island where the temple is located rest on a reef flat that relatively solid. The temple is located around 30 m from the reef and 100 m from the land. At low tide the reef flat appears above low water level (LWL), while at high-tide the depth is about 2 m. Therefore, visitors are only able to reach the temple at low-tide. The outer reef is an area where its depth is relatively hard to be measured since the area is the location of breaker-zone. Water depth in front of reef-edge that can be sounded is about 150 m from reef-edge with depth of about 30 m. The depth at outer reef as read in the figure is based on linear approximation, with zero references = LWL. The condition of the Temple is critical, particularly at the southern corner where there is a hollow as shown on figure 1.c which might cause the Temple to collapse.

The process of abrasion of Tanah Lot can be explained as follows :

- a. The sea-waves break on the rock bank at the front part of the Temple. The wave energy erodes the bank and the bottom of the coast. Measurements reveal that the waves reach a height (H) of 2 to 3 M, with a wave period (T) ranging from 5 to 10 seconds.
- b. The mass of water flowing landward through the right and left banks of the Temple at high speed in conjunction with the incoming waves have created cracks/hollows in the bottom will take the bank stability at the upper part.
- c. The cracks resulting from geologic process and cavities made by sea-animals have agravated the abrasion process.

3. PLAN OF COUNTER MEASURES

Protection of Tanah Lot Temple to be carried out using landward revetment that indirectly attacked by waves. Landward revetment consists of pillars and concrete flat as a buffer of sectors that possibly broken. The buffer pillar and concrete flat are modified in such a way so that look natural according to original temple bank condition. As stated in the introduction, the protection of the temple in the land direction could not be explained in detail since this protection is ba-

sically structural engineering and arsitecture not aspects of coastal engineering protection.

Protection of Tanah Lot Temple on the sea-side covers:

- Constructing a structures to protect the sea-side bank,
- Installing wave breaker in front of the sea-side of the island,
- Placing of stones and concrete blocks between the wave breaker and Temple bank.

Fig. 1.a. Situation of Tanah Lot Temple

Fig. 1.b. Cross section of the beach (A - A)

Fig. 1.c. Longitudinal section of the beach (B - B)

3.1. Information from the Public

From discussions, interviews and exchanges of ideas with the community the following were obtained :

- 1) The space both on the land-side and sea-side is not permitted to be closed.
- 2) To facilitate the offerings especially at times when there is a great number of temple-goers, the community propose :
 - to extend the area of the Temple grounds
 - to make different paths for going to and from the Temple.
- 3) For aesthetic, it is proposed to execute the coping of the problem with the assistance of an art so that the result could be natural and harmonious in line with the environmental condition.

3.2. Protection of the Sea Side Bank

Seaward revetment consists of lean concrete casted and joined with original temple bank, the thickness of lean concrete is 1.50 m. The use of lean concrete not only to strengthen but also to enlarge the area of temple and to construct road for outway from the temple. Originally the entrance and outway of the temple are in one channel and narrow make the visitors and pilgrimage have dif-

difficulty doing praying. However, after two-way road already constructed, the difficulty can be overcome. Like landward revetment, lean concrete also has been modified so that look natural.

3.3. Wave Breaker

Many alternatives in planning for wave breaker has been made such as by constructing seawall and concrete wall. However, because of difficulty in the implementation, the choice is by using wave breaker type rubble structure from tetrapod, and the weight of each unit of tetrapod is calculated on the basis of the design wave height $H = 3.0$ m. To place the tetrapods, heavy equipment is needed or a helicopter.

By the Hudson 1) formula,

$$W = \frac{W_r \cdot H^3}{K_d (S_r - 1)^3 \cotg \phi}$$

the weight of each tetrapod for various slopes ($\cotg \phi$) is :

$\cotg \phi$	Body (kg)	Head (kg)
1,5	2,490	3,950
2,0	1,900	2,450
3,0	1,250	2,250

3.4. Filled Material

Filled material is placed behind wave breaker, casted after wave breaker has been carried out. On the lower layer, it consists of graded stones with diameter between 0,1 and 0,4 m filled with concrete block and the thickness of the blocks are 0,50 m. By using layer cap made from concrete blocks, the area of the temple seaward become larger. It can be used at low-tide while at high-tide overtopping as a result of wave breaking continually occurs. In addition to enlarge the area, the main purpose of filled material is to stabilize wave breaker and to support wave attenuation. From field inspection, it is obvious that after setting filled material waves that attack the wall is relatively high. It results from watermass entering tetrapod arrangement. After casting of

filled material wave attenuation works well.

4. TECHNICAL EXECUTION

Since field situations are hard and narrow while local road is impossible to be passed by heavy vehicles the tetrapods are transported by helicopter, which has a maximum capacity of 2.0 tons. For this reason, it has been decided to use tetrapods with a maximum weight of 1.9 tons. In the execution, the helicopter will be able to place the tetrapods only 20 m at the nearest from the temple bank. The crest of the breakwater will be as high as the highest water level (HWL). The wave breaker will be ± 125 m in length, and the number of tetrapods to be placed 2,800. It has been explained in Chapter 3.1 that there will be an opening in the middle of the breakwater. Filled material will be placed behind the breakwater. The bottom part consists of an arrangement of stones and the surface of a concrete plate 0.5 m in thickness. Overlaying the concrete plate will be modified concrete blocks to produce a natural view. In the first stage of implementation, ten tetrapods which are placed separately move toward the temple bank because the bottom of beach is relatively slippery. However, after it was constructed in one unit type, the tetrapod arrangements are able to stand against waves. Until now part of body is relatively stable while in head sectors are estimated to transform to get its stability.

5. MONITORING RESULT

5.1. Change in Wave Characteristics

After the tetrapods have been placed, the waves will not directly hit the temple bank but break on the tetrapod arrangement. As the tetrapod arrangement has holes in it, breaking of the waves will be different from that on a massive surface. Fig. 2a shows the condition of the waves before construction of wave breaker. Waves break directly on the bank of the temple.

Fig. 2b shows the wave condition after construction of wave breaker. From Fig. 2b it is obvious that the tetrapod arrangement dampens the waves well. From point of view of protection, wave breaker already worked well while from the type of wave breaking, wave breaker have changed the original form.

Considering that one of the attractive features of Tanah Lot Temple is the beautiful wave - breaking against the rock, dampening of the waves might

reduce the attraction of the Temple. In order to produce a wave condition similar to the original one it seems that the tetrapod arrangement has to be cast to become a massive unit. Fig. 2c, shows the estimated wave condition after the tetrapods are casted. Casting can be done after the tetrapod arrangement has become stable.

5.2. Condition of tetrapod arrangement

The monitoring result reveals that the body part of the tetrapod arrangement, which currently has side slopes of 1 : 1.5, is relatively stable. The head part (ends of the tetrapod arrangement) with side slopes of 1 : 2, however, is not yet stable. Calculation in Chapter 3.1 turns out that for a tetrapod weighing 2,244kg and a wave height of 3 m, the side slopes are 1 : 3. A tetrapod arrangement with a weight of ± 1.9 tons is estimated to still undergo changes in its stabilization process.

6. CONCLUSIONS AND RECOMMENDATION

1. The tetrapod arrangement serving as a wave breaker is functioning well. However, if one desires a protective structure with a natural look, this break water should be modified.
2. It is estimated that the tetrapod arrangement will still be modified, especially the head parts, in view of the stability process.
3. Damping of the waves is successful, but it probably reduces the attraction of Tanah Lot Temple in terms of breaking of the waves. It is suggested to create a massive tetrapod arrangement in order that the breakers will be as beautiful as before.

CHAPTER 181

MAN-MADE BEACHES MORE THAN 20 YEARS ON

FRANCK ROUCH¹
BERNARD BELLESSORT²

Abstract

This article is an overview of the behaviour of artificial beaches based more particularly on three important examples designed by SOGREAH: La Croisette (Cannes), Larvotto (Monaco), Prado (Marseille).

The main conclusions are:

- . a man-made beach in an urban area is generally very well received by the general public,
- . the general behaviour of beaches has proved to be satisfactory and as forecast on the basis of sedimentological scale model studies from the following points of view: stability, water quality, safety, maintenance.

1. Introduction

When SOGREAH was called upon in 1960 to study the possibilities of widening the Croisette beaches in Cannes, this proved to be the first man-made beach ever built. With the rapid growth of tourism since that time, SOGREAH has designed throughout the world more than 60 beaches out of which about a half have actually been built. It is interesting to make a hindsight assessment of the various man-made beaches.

With focusing on three important examples designed by SOGREAH: la Croisette (Cannes), Larvotto (Monaco), Prado (Marseille).

¹ PROJECT ENGINEER SOGREAH, 6 rue de Lorraine,
38130 Echirolles, France
² Ph. D. Oceanology. Senior Engineer SOGREAH

2. Characteristics of artificial beaches

a) La Croisette (Cannes)

As a matter of fact, the idea of developing a new beach in front of the shoreline of La Croisette Promenade originated in the need for the town of Cannes to widen the Promenade in order to extend the vehicle traffic and to improve the area reserved for the pedestrians along the shoreline.

Widening directly the Promenade in accordance with the needs would have involved of setting the small beach that existed partially along the Promenade at the time. So, SOGREAH proposed to build a new beach before widening the Promenade. The new shoreline was not parallel to the natural shoreline. It is the reason with the new beach is divided in three parts by groins. The main characteristics of the beach are:

- . widening of the natural beach by 20 m over a distance of 1040 m,
- . deposition of 125.000 m³ of sand with a mean diameter of 0.8 mm,
- . three 60 m stabilisation groynes,
- . expected equilibrium slope: 6.5%,
- . construction over a period of 2 years (1962-1964).

b) Larvotto (Monaco)

Larvotto is doubly an artificial beach:

- . first, this beach was built on a quite rocky coast,
- . secondly, the material used to built the beach was fully artificial: crashed dolomite limestone.

This project presented three difficulties:

- . coastline quite rocky and bottoms slope very steep,
- . wave climate very high ($H_{1:10}$: 8 m),
- . any natural sand available.

Main characteristics of the new beach are:

- . length: 400 m,
- . construction of an underwater platform levelled at -2.5 m,
- . deposition of 80,000 m³ of 3-8 mm gravel on the platform,
- . protection with three 80-100 m long breakwaters spaced 80 m apart in water 6-10 m deep and connected to the shore by groynes,
- . construction took place from 1965 to 1967.

c) ___ Prado (Marseille)

The scheme involved the development of 33 hectares of reclaimed area in the sea and the building of new beaches totalising an area of 9 hectares with a total length of 2800 m and an average width about 50 m.

The renourishment material used was 3-8 mm diameter gravel (150,000 m³).

Protection is provided by three breakwaters, 150-220 m long and in water 4 m deep, connected to the shore.

3. Changes in beaches since their constructiona) ___ Renourishment material. Prado beach:

Precise monitoring was carried out at the Prado beach and after 15 years, the following conclusions could be reached:

- the gravel (hard limestone) is worn and rounded only in an area of the beach that is subject to wave action,
- the average diameters have decreased from 5.5 mm to 3.2 mm (in the area subject to wave action), but wear has stabilised with time. There is no noticeable difference between samples taken between 12 and 15 years after completion,

- the larger the particles, the greater the wear,
- from the methodological point of view, the Los Angeles test appears to provide significant results concerning particle wear. The experimental conditions were:
 - . Los Angeles machine,
 - . 20 kg of gravel + 40 l of sea water,
 - . rotation speed: 30 rpm,
 - . number of rotations: 30 000.
- . La Croisette beach:

No change at all in grain size for the sand.
- . Larvotto beach:

No measurement data are available but visual observations lead to similar conclusions from the qualitative point of view.

b) Behaviour of beaches

In the three cases, and as confirmed by the slight amount of consolidation carried out (see 3.3), the artificial beaches have behaved in a highly satisfactory manner and, generally, speaking, as forecast, particularly with regard to:

- . slopes: of the order of 10% with gravels (Larvotto and Prado, protected by breakwaters) and coarse sand (Croisette, with no protection),
- . no major loss offshore,
- . shoreline: as forecast and stable (within the usual known limits of change).

However, the following points must be underlined:

- . At Cannes, there is a discrepancy between plan view of the promenade and that of the beach because the groynes are not long or high enough (for environmental needs). So, it must be accepted some littoral drift from East to West. Every year before the summer season, some sand (about 2 000 m³) has to be redistributed from the western part of the beach to the eastern part in order to balance its width.
- . In the three cases, a ridge is formed on the upper part of the beach, mainly in winter, accompanied by a steeper beach profile. This makes it necessary to rework the profile at the start of the summer period.
- . At Larvotto, during severe storms, beach material is thrown together with sea water to the back of the beach where shops and costly equipments are located. Protective boarding is needed in winter. This is removed during the summer.
- . The beach slopes of the order of 10% appear to be steep for bathers and, in particular, for children.

In the three cases, the renourishment required for correct beach maintenance has been limited and has been quite acceptable from both the technical and financial viewpoints:

- . Cannes:
 - Initial renourishment: 125 000 m³
 - Maintenance (over 20 years): 5 000 m³

- . Larvotto:
 - Initial renourishment: 80 000 m³
 - Maintenance (over 23 years): 5 000 m³

- . Prado:
 - Initial renourishment: 150 000 m³
 - Maintenance: none to date

To interpret these satisfactory results, the following points need to be taken into account:

- . the absence of any tide,
- . the large particle size of the material, which favours stability,
- . the protective and stabilisation structures (groynes, brakwaters) built near the beaches.

This being so, these are highly instructive examples of how artificial beach projects should be designed to ensure reliable use.

4. Water quality

In the three cases, treatment work was carried out in parallel with the construction of the beaches. Water quality monitoring shows that, in general, the water is of class A (good quality) or B (moderate quality), and thus poses no problems for bathers.

For example at Cannes, the water is 70% class A and 26% class B. Exceptionally, polluted water has occurred, but this was the result of very heavy rains. In one case, the pollution was due to a burst pipe.

The water at Larvotto is of good quality, but there are temporary problems of pollution in certain places around the central landfill platform. As at Cannes, there is a correlation between pollution and rainfall.

Measurements taken at Prado beach (1988) show that the water is of good quality. Measurements at different times of the day show that use of the beach by bathers does not notably affect the water quality.

5. Operating problems

Problems of beach operation are not connected with the fact that they are artificial but with their used and more particularly with access and parking facilities.

Maintenance of gravel beaches has proved to be easy with screening machines.

At 8-10%, the beach slopes, which are connected with the particle size of the material used, have appeared to be just acceptable for bathers and particularly for children.

The use of consolidation material with the same particle size as the gravel (3-8 mm) does not appear to be an inconvenience for bathers (the limit of discomfort appears to begin around 5 mm).

6. Conclusions

In conclusion, as these three exemples of most important artificial beaches along the French Mediterranean coast show, it is of a great importance to carry out proper design studies before construction of artificial beaches. In this way, the beach is assured of a long lasting stability of the beach with minimal maintenance at litte or no cost.

CHAPTER 182

Littoral Transport Rate

J. William Kamphuis¹ M. ASCE

Abstract

This paper describes a study of littoral sediment transport rate based on three-dimensional hydraulic model experiments performed with regular and irregular waves. Deep water wave conditions, wave heights through the surf zone, wave breaking angles, longshore current velocity distribution and the bed load and suspended load sediment transport distributions were measured simultaneously to form a coherent data set. An expression is developed linking sediment transport rate to wave steepness, beach slope, relative grain size and breaking angle. The expression compares well with published field data.

1. Introduction

This paper describes the continuation of research on alongshore sediment transport described in Kamphuis and Readshaw (1978), Kamphuis and Sayao (1980) and Kamphuis et al. (1986). A new set of three dimensional mobile bed hydraulic beach model results is used; a summary of the tests is shown in Table 1; the experimental layout is shown in Figure 1 and more detail about the tests may be found in Kamphuis and Kooistra (1990).

2. General Description of the Tests

The section of the wave basin used was 23.4 m long by 10.0 m wide. An initial plane sand beach slope of 1:10 was prepared for each test. The depth of water in Table 1 was measured at the toe of the sloping beach.

Constant regular and irregular wave climates were generated for approximately 7 hours; the irregular waves consisted of a Jonswap spectrum with $\gamma = 2.3$ and the random wave signal typically repeated itself after 200

¹Professor, Queen's University, Department of Civil Engineering, Kingston, Ontario K7L 3N6 CANADA

waves. Each test was divided into one hour segments. Wave heights, wave angles, longshore current velocity distributions, sediment transport rates and distributions, and beach profiles were measured in an hourly cycle.

Waves were measured at a sampling rate of 10 HZ, offshore and at 15 locations, 0.2 m apart from offshore of the breaker, through the surf zone, into the swash zone. Breaking wave angles were measured for eight of the tests using an overhead video camera (Table 1).

Alongshore current velocities were measured at 0.1 metre intervals across the surf zone using a ducted mini-impeller flow meter.

A sediment trap was located at the downdrift end of the beach but within the lines of the wave guides. It was designed to separate bedload from suspended load and to measure their distributions across the swash and surf zone (Figures 2 and 3). Each trap box extended from above the swash zone to well offshore of the breakpoint and was sub-divided into a number of compartments permit measurement of the distribution of sediment transport across the surf zone.

Templates supporting the trap covers were vertically adjustable to ensure the top of the trap matched the beach profile near the trap. The covers contained slots which extended the full length of the boxes from above the swash zone to offshore of the breakpoint. The slot width (in the sediment transport direction) over the updrift box was adjustable so only bedload was trapped. Any sediment transported past this slot was considered to be suspended load and was trapped through much wider slots over the downdrift boxes.

Sediment was supplied at the updrift end of the beach by a feeder at a rate comparable to the sediment transport rate along the beach. Beach profile measurements and observations of the waves breaking along the beach verified that the beach contours were maintained reasonably parallel by this procedure.

Beach profiles were recorded at the beginning of each test and at the end of each one hour segment using an automatic bed profiler. Profiles were measured at one metre intervals alongshore; depths were recorded at .01 metre intervals offshore. Only the centre 5 m section of the model beach was profiled, resulting in 6 profiles for each one hour segment.

More detail about the experimental procedure may be found in the Kamphuis and Kooistra (1990) and Kamphuis (1991).

FIGURE 3 SEDIMENT TRAP COVERS AND DETAILS

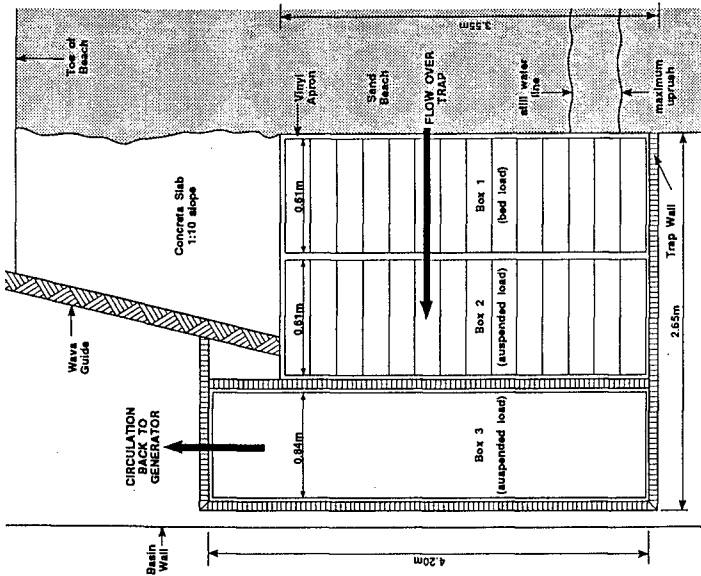

FIGURE 2 SEDIMENT TRAP LAYOUT

3. The Data Analysis

3.1 WAVES

For the irregular waves, the wave period was determined from the peak of the offshore wave spectrum. Significant and rms wave heights were determined at each probe position using a zero crossing analysis. For every hour of the test, wave heights were plotted against probe position as shown in Figure 4. The magnitude and location of the breaking wave height, H_b and X_b respectively, were thus defined and the corresponding values of breaking depth (δ_b) and the distance from the still water line to the breakpoint (λ_b) were determined from the measured beach profiles. The wave transformation for these tests is discussed in Kamphuis (1990); the wave breaking in Kamphuis (1990a).

3.2 SEDIMENT TRANSPORT

The immersed mass of sediment trapped as bedload, suspended load and total load was measured every 15 minutes and plotted as a function of time as shown in Figure 5. For each one hour segment of the test, the slope of the curve was calculated to determine the sediment transport rate, Q , in kg/s. After approximately three hours of testing, the sediment transport rate approached a steady-state as the beach profile approached equilibrium. At this stage in the test, the trap boxes were pumped completely empty of all sediment and the distribution of sediment transport was measured over the next 3 or 4 hours under equilibrium conditions. A typical plot of the sediment transport distribution is shown in Figure 6.

4. Results

4.1 DIMENSIONAL ANALYSIS

Dimensional analysis for bulk sediment transport rate in the turbulent breaking zone leads to:

$$\frac{Q}{\rho H^3/T} = K \left(\frac{H}{L_0}\right)^a m_b^b \left(\frac{H}{D_{50}}\right)^c \sin^d 2\alpha_b \quad (1)$$

as demonstrated in Kamphuis (1991). Here a, b, c and d are exponents. Sediment transport is thus a function of wave steepness, beach slope, relative grain size and wave angle and since bulk sediment transport rate is normally assumed to be closely related to alongshore wave thrust, the wave angle term used was $(\sin 2\alpha_b)$.

FIGURE 4 BREAKER HEIGHT AND LOCATION

FIGURE 5 MEASURED SEDIMENT TRANSPORT

FIGURE 6 SEDIMENT TRANSPORT DISTRIBUTION

FIGURE 7 IRREGULAR WAVE TESTS

4.2 IRREGULAR WAVE TESTS

Figure 7 shows how:

$$\frac{Q}{\rho H_{sb}^3 / T_p} = 1.3 \times 10^{-3} \left(\frac{H_{sb}}{L_{op}} \right)^{-1.25} m_b^{0.75} \left(\frac{H_{sb}}{D_{50}} \right)^{0.25} \sin^{0.6}(2\alpha_b) \quad (2)$$

fits the experimental data for the irregular waves well. Here H_{sb} is the breaking significant wave height, T_p is the peak period of the offshore wave spectrum and L_{op} is the deepwater wave length corresponding to the peak wave period. It is seen that there is no systematic difference between the tests with the two different grain sizes. The standard error of estimate, $s(y/x)$, is 0.10 log cycles, i.e. 95% of the points lie within a factor of ± 1.6 times Equation 2.

Sensitivity analysis on the exponents of Equation 2 shows that the actual exponents could vary over the following ranges without materially affecting the result:

$$\begin{aligned} -1.15 < a < -1.30 & ; 0.6 < b < 0.85 \\ 0.15 < c < 0.30 & ; 0.55 < d < 0.6 \end{aligned}$$

A similar analysis using H_{rms} resulted in:

$$\frac{Q}{\rho H_{rms}^3 / T_p} = 2.6 \times 10^{-3} \left(\frac{H_{rms}}{L_{op}} \right)^{-1.25} m_b^{0.75} \left(\frac{H_{rms}}{D_{50}} \right)^{0.25} \sin^{0.6}(2\alpha_b) \quad (3)$$

with $s(y/x)$ the same as for Equation 2.

Inspection of Equations 2 and 3 shows that Q varies with H^2 . If the wave height distribution at breaking approximates a Rayleigh distribution, one would expect the constant in Equation 6 to be twice that in Equation 2. Since this is indeed the case, it would indicate that for bulk sediment transport calculations, a Rayleigh distribution may be assumed for breaking wave heights.

4.3 REGULAR WAVES

Figure 8 shows that if H and T are substituted for H_{rms} and T_p in Equation 6, the regular waves line up exactly with the irregular wave results. Earlier regular wave results obtained by Readshaw (1978) for much larger grain size ($D_{50} = 0.56$ mm) also fit the relationship well. This would indicate that the sediment transport process is indeed closely related to wave energy and that the diameter effect is well simulated by Equation 1.

FIGURE 9 FIELD DATA USED

FIGURE 10 MODEL AND FIELD DATA WITH EQUATION 2

FIGURE 11 FIELD DATA ONLY WITH EQUATION 2

FIGURE 12 CERC EXPRESSION

FIGURE 13 MODEL AND FIELD DATA WITH EQUATION 4

4.4 FIELD DATA

The extensive field data set described by Kamphuis et al (1986) is used in the present study. Kamphuis et al (1986) derived a sediment transport expression, based on these field data:

$$\frac{Q}{\rho H_{sb}^3 T_p} = 0.6 \times 10^{-3} \left(\frac{H_{sb}}{L_{op}} \right)^{0.5} m_b^{1.0} \left(\frac{H_{sb}}{D_{50}} \right)^{1.0} \sin(2\alpha_b) \quad (4)$$

The field data and their fit to Equation 4 are shown in Figure 9.

Figure 10 shows how Equation 2 fits the irregular wave data and the field data. For the complete data set in Figure 10, $s(y/x)$ is 0.18 log cycles. Figure 11 shows how Equation 2 fits through the field data alone; $s(y/x) = 0.33$. Clearly Equation 2 represents field conditions as well as model conditions.

To fill the gap between the model and field data, the gravel beach tests of Van Hijum and Pilarczyk (1982) were investigated and Equation 2 appears to be completely robust covering model and field beaches of sand and gravel.

4.5 EARLIER EXPRESSIONS

Figure 12 demonstrates how the well-known CERC expression (Shore Protection Manual - 1984) fits the irregular waves and field data set. It is clear that the CERC expression over-estimates sediment transport for the model tests, particularly for the larger incident wave angles. $s(y/x)$ is 0.60 log cycles for the complete data set and 0.35 for the field data only. If the constant in the CERC expression is changed from 0.39 to 0.12 (the line of best fit), $s(y/x)$ is 0.30 for the complete set and 0.49 for the field data alone.

The same data set is plotted with Equation 4 in Figure 13. It is seen that this expression fits the data better than the CERC expression; $s(y/x) = 0.27$ for the complete data set and 0.29 for the field data alone.

5. Discussion of Results

Equations 2 and 3 may be reduced to the form:

$$Q = K \rho (g/2\pi)^{1.25} H^2 T^{1.5} m^{0.75} D^{-.25} \sin^{0.6}(2\alpha_b) \quad (5)$$

It is seen that the sediment transport rate is proportional to H^2 . This exponent of H is smaller than for Equation 4 and the CERC expression. This smaller sensitivity to wave height, corrects a criticism often levelled at the earlier expressions, i.e. that they overpredict sediment transport at high wave heights.

The present expressions are more sensitive to wave period than the earlier expressions.

Sediment transport rate increases with beach slope, a phenomenon noted during the Pointe Sapin field study (Kamphuis et al - 1986). It also shows some inverse variation with grain size. This is as might be expected intuitively, but the small exponent explains the fact that for many years, sediment transport rate expressions have ignored grain size at no great peril.

Sediment transport rate varies with $\sin 2\alpha b$ to a power smaller than 1. It is clear that $\sin 2\alpha b$ overestimates the sediment transport at higher incident angles (Figures 12 and 13). Part of the reason is wave-current interaction as discussed by Kraus and Sasaki (1979) and Liu and Dalrymple (1978). But this does not account for all of the observed decrease in sediment transport with wave angle, relative to an expression with $\sin 2\alpha b$. The present $\sin^{0.6}(2\alpha b)$ is a much more severe wave angle effect than the results given for mean values of longshore currents by Kraus and Sasaki.

8. Conclusions

A bulk sediment transport expression has been presented, based on an extensive, coherent set of laboratory experimental data. The expression correctly predicts sediment transport over a wide range of grain sizes and for field data presented in the literature.

Sediment transport rate is found to be proportional to wave energy since regular wave data and irregular wave data using Hrms form one population.

Sediment transport rate is proportional to H^2 , which results in a smaller transport during major storms, as compared to earlier expressions.

Sediment transport rate is a function of beach slope and depends only slightly on grain size. The commonly used wave angle term $\sin 2\alpha b$ over-predicts sediment transport rate.

CHAPTER 183

Causes of Damage to Saldanha Sand Breakwater

J S Schoonees*, J W J Kluger*** and J A Zwamborn*

1. Abstract

The Port of Saldanha, situated 120 km north-west of Cape Town, South Africa, is protected from the dominant south-south-westerly swell conditions by a sand breakwater which is presently eroding. This paper summarises the results of the monitoring of the breakwater, which consisted of aerial and beach photographs as well as hydrographic surveys. Another part of the investigation was to examine the reasons for the erosion (found by the monitoring to be increasing) on the basis of the prevailing environmental conditions such as wind, waves and currents. To do this the wind and nearshore wave climates were determined. Subsequently, the optimum alignment of the sand breakwater was calculated by three different methods. The equilibrium slope of the breakwater, which was also determined, indicated that the design slope was too steep. Of the remedial measures considered, namely, the use of sand or rock, the latter was chosen.

2. Introduction

The Port of Saldanha, situated some 120 km north-west of Cape Town on the South African west coast was constructed mainly for the export of iron ore. Shelter from the swell conditions that occur there was obtained by building a sand (or spending beach) breakwater between Hoedjiespunt on the mainland and Marcus Island (Figure 1). Zwemmer and Van't Hoff (1982) describe the design and construction of the breakwater in detail.

About 20 million m³ of sand was used for the construction of the 1,9 km long breakwater. Some difficulty was encountered in obtaining this quantity. It was also found that rock protection (as a spur before placing sand) was necessary in order to build the breakwater. This resulted in a sand breakwater with some rock protection, mainly above the low-water mark. See Zwemmer and Van't Hoff (1982) for details.

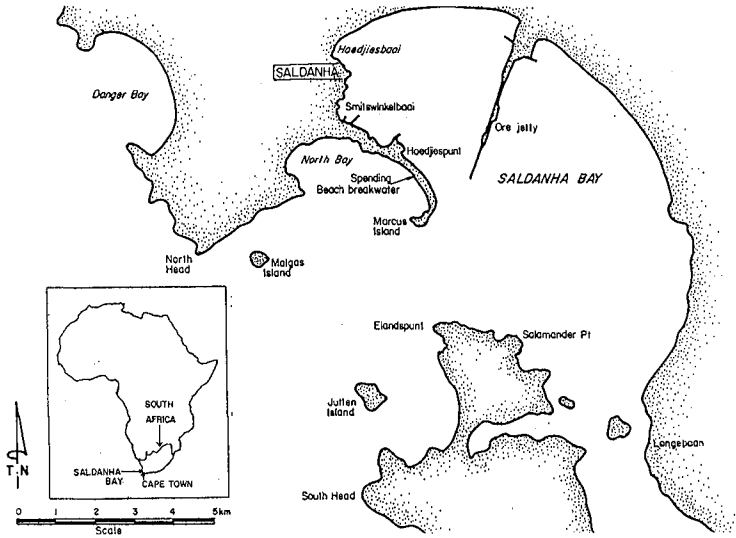

FIGURE 1 : LOCALITY MAP

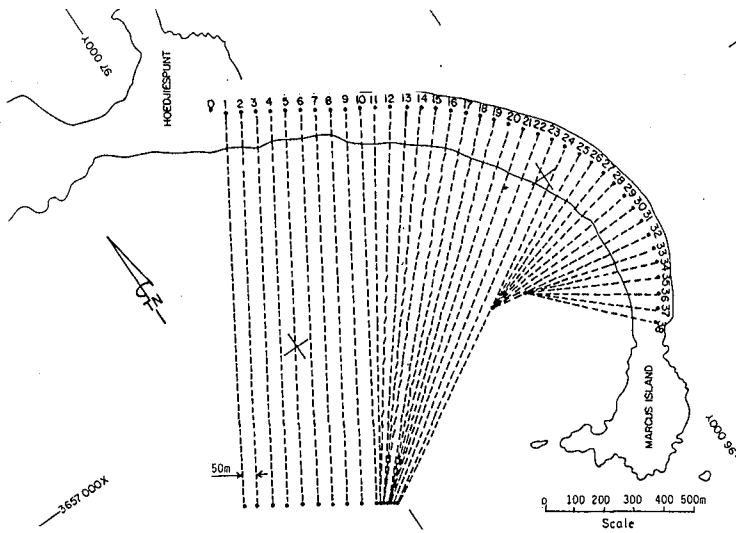

FIGURE 4 : POSITION OF THE SURVEY LINES

A preliminary study of the stability of the sand breakwater (CSIR, 1985) was commissioned by the then South African Transport Services (now Portnet). This study, by using the then available hydrographic and beach survey data, concluded that sand is eroded steadily from the breakwater at a rate of approximately 50 000 m³/year. Based on a recommendation of this study, a detailed investigation (CSIR, 1988) was undertaken to establish the reason(s) for this erosion on the basis of the prevailing environmental conditions such as wind, waves and currents. It was further recommended that the breakwater be monitored on a regular basis.

CSIR (1988), of which this paper is basically a summary, deals with the photographic and hydrographic monitoring of the breakwater, the effect of wind, the wave climate, the optimum alignment of the breakwater and the equilibrium slope of the breakwater as well as possible remedial measures.

3. Monitoring of the Breakwater

3.1 General

The monitoring consisted of low-altitude aerial photography, beach photography and beach and hydrographic surveys.

3.2 Aerial Photography

The aim of the aerial photography, conducted at roughly three-monthly intervals and taken at low water, was to establish whether overall changes of the breakwater, and especially the erosion areas detected previously in the rock protection placed during construction, had taken place.

Figure 2 is an example of a photomosaic compiled from such photographs.

The aerial photography showed that no drastic change of the erosion areas occurred and that the overall appearance of the breakwater has virtually stayed the same during the period August 1985 to November 1986.

3.3 Beach Photography

The main purpose of the close-up beach photographs was to provide an indication of the movement of stone and of possible degradation of the stone of the rock protection itself.

An aluminium tripod, giving a camera elevation of 3 m above ground level, was used to photograph the beach. One leg of the tripod consisted of a ladder which provided access for the photographer to the top of the tripod (Figure 3). At each position of the tripod, a horizontal area of 4,2 m × 4,2 m was photographed. Thus, by moving the tripod 4 m along a selected line after taking each photograph, a continuous strip of the beach 4,2 m wide and as long as required, could be photographed.

Seven beach photography areas were chosen, namely, survey lines 2, 4, 9, 15, 21, 27 and 37. See Figure 4 for the positions of these survey lines and Figure 5 for an example of such photographs.

FIGURE 2 : AERIAL PHOTOMOZAIC TAKEN ON 26 JUNE 1986

FIGURE 3 : TRIPOD USED FOR THE BEACH PHOTOGRAPHY

FIGURE 5 : AN EXAMPLE OF THE BEACH PHOTOGRAPHY ON SURVEY LINE 15

No measurable stone degradation could be detected on the beach photographs taken during the 11-month recording period. These photographs, however, indicated that stones up to 1,5 m in size (approximately 3 t) moved on the beach slope below +4 m CD (CD = chart datum which is 0,90 m below mean sea level (MSL)). The most severe movement took place between survey stations 3 and 9 and stations 27 to 37.

3.4 Beach and Hydrographic Surveys

Hydrographic surveys were done by measuring nearshore profiles along survey lines (Figure 4) with an echosounder mounted on a boat. Depths up to about -20 m CD were recorded. The beach profiles were surveyed on the beach along the same survey lines by using a theodolite and a staff.

Figure 6 shows a fair chart of one of the surveys. Note that there is a gap between the beach and hydrographic surveys. This, is unfortunately, in the area where most of the seabed changes occur. This is due to the restriction imposed by the draught of the available survey vessel as well as by the rough wave conditions normally encountered at the breakwater.

Volume differences between surveys were calculated (in the gap between beach and hydrographic surveys, linear interpolation was used). The following table summarises these volume changes:

Date	Volume difference ¹ (m ³)	Period (months)	Calculated rate (m ³ /year)
27-06-78			
	-43 500	3,75	-139 300
20-10-78			
	-93 400	6,25	-179 400
26-04-79			
	+168 800	7,00	+289 400
28-11-79			
	-271 700	35,00	-93 200
29-10-82			
14-11-84			
	-362 600	17,75	-245 100
07-05-86			

¹ + means accretion

- means erosion

FIGURE 6 : HYDROGRAPHIC SURVEY OF 86-05-07

From this table it is clear that considerable volume changes (erosion and accretion) occurred. Statistical comparison of the last erosion rate, of -245 100 m³/year, with the previous rates indicates (at a 90 % confidence level) that the erosion rate increased significantly during the period November 1984 to May 1986. Although this rate is small in comparison with the total volume of sand placed to form the breakwater, this loss of sand may endanger the breakwater. It is, therefore, important to monitor the breakwater in future to establish whether this tendency continues. If so, it is important that remedial measures be undertaken.

Every effort should be made to minimise the gap between the future hydrographic and beach surveys because some of the large variation in the volume differences between surveys and possibly the accretion, can be attributed to this.

The beach profiles showed either erosion or remained basically stable. The most severe beach erosion occurred at profiles 2 and 36.

4. Wind

Based on hourly wind recordings over a 3-year period at nearby Elandspunt (see Figure 1 for the position of Elandspunt), the dominant wind directions were found to be SSW, SW, S and NNE. Calms occur on average 6,9 % of the time.

It was found that, because of the very limited availability of sand on the breakwater owing to stone and vegetation cover and because of short wind fetch lengths for the major wind directions, the effect of wind on the breakwater is negligible.

5. Wave Climate

For sediment transport computations, simultaneous recordings of wave height, wave period and wave direction are necessary. The only wave data sources that met this requirement, namely, clinometer (graded telescope) and VOS data (estimates from voluntary observing ships), were compared with other available measurements of wave characteristics (Waverider records). The clinometer data were found to be the better data source. Deep-sea clinometer wave directions were accepted unaltered while clinometer wave period and deep-sea wave heights were adjusted by means of exceedance curves to give 'equivalent' Waverider periods and deep-sea wave heights.

Figure 7 gives the details of the deep-sea wave climate. Combinations of deep-sea wave directions from SSE, S, SSW...NW and peak wave periods between 6,2 s and 23,8 s were compiled to serve as input for a wave refraction study.

This study was to transfer the deep-sea wave climate to shallow water at the spending beach breakwater. For this purpose extensive coverage of the irregular bathymetry of the area at and surrounding the spending beach breakwater was obtained from hydrographic maps. The bathymetry was then

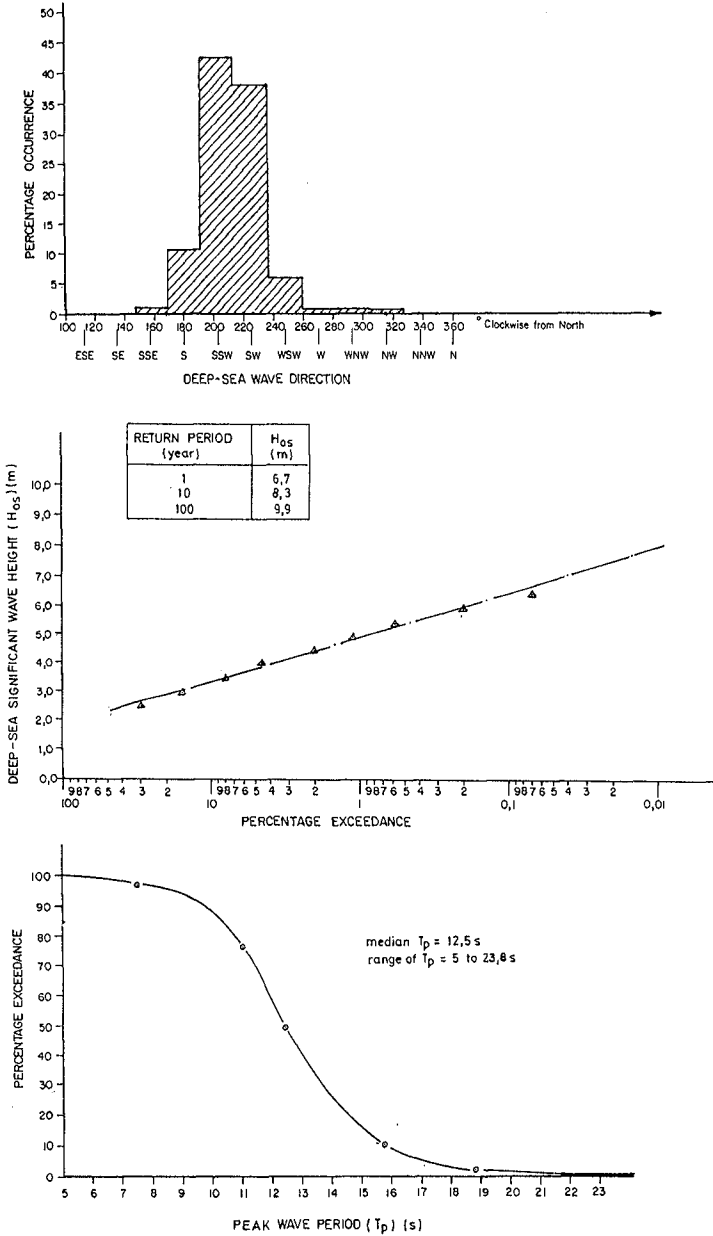

FIGURE 7 : DEEP-SEA WAVE CHARACTERISTICS

represented in eighteen model grids in which the grid squares became progressively smaller from deep to shallow water.

Refraction and shoaling of each of 37 recorded deep-sea wave conditions were done. Figure 8 shows a refraction diagram. For each deep-sea wave direction/wave period combination, the nearshore wave characteristics at the 3 m (to MSL) contour were compiled every 200 m along the breakwater.

6. Optimum Alignment of the Breakwater

6.1 General

The optimum alignment of the breakwater was calculated in two ways (Methods 1 and 2). A third and empirical method (Method 3) was used to check the results of Methods 1 and 2.

6.2 Method 1

The optimum alignment of the breakwater was calculated by determining at different points along the breakwater, what the alignment of the breakwater should be for each wave condition in order to make the longshore sediment transport potential due to obliquely incident waves zero. A weighted mean alignment of the breakwater at the different points was then computed. This is similar to the way in which the alignment of the breakwater was initially determined (Zwemmer and Van't Hoff, 1982).

The approach of Shore Protection Manual formula for longshore sediment transport given in US Army Corps of Engineers (1984) was applied. This formula is valid for non-cohesive sediment of grain sizes between 160 μm and 1 mm. Although it does not contain sediment grain size, it has been shown by Swart (1976) and Bruno *et al.* (1981) that the 'constant' in the formula is actually a function of the grain size. Therefore, although the breakwater consists predominantly of sand (but covered by a stone capping at and above the water line), the form of the formula can be regarded as being the same for coarser material even though the 'constant' will change. Therefore, if the wave incidence angle is zero, no longshore transport will occur, irrespective of the grain size.

The weighted mean values were used to plot, in Figure 9, the general alignment of the breakwater if it is to be left alone as well as the realignment needed for reconstruction.

The alignment calculated by Method 1 neglects the effects of secondary flows due to diffraction-type currents. This shortcoming is eliminated in Method 2.

6.3 Method 2

The basic procedure followed was the same as in the first method, except that the longshore current velocity in the middle of the surf zone, due to obliquely incident waves and a longshore variation in breaker wave height was set to zero and the corresponding orientation of the breakwater calculated. Because the longshore sediment transport is a function of the longshore current

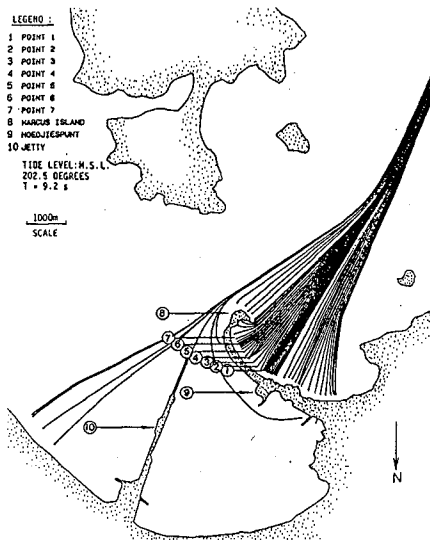

FIGURE 8 : WAVE REFRACTION DIAGRAM

FIGURE 10 : EQUILIBRIUM TREND IN THE MOVEMENT OF THE -14m CD CONTOUR

FIGURE 9 : OPTIMUM ALIGNMENT OF THE BREAKWATER

velocity, this means that the longshore transport will be zero if no longshore current is generated. Again, a weighted mean alignment was computed along the breakwater (at 21 points, 100 m apart).

A formula by Komar (1975) for the determination of the longshore current velocity (v) distribution across the surf zone due to obliquely incident waves and a longshore variation in breaker heights, was applied in the same way as in Schoonees (1986) to calculate the wave incidence angle at which $v = 0$ in the middle of the surf zone.

The results of this method are also illustrated in Figure 9.

6.4 Method 3

Building on the earlier work of amongst others, Yasso (1965), Silvester (1970) and Silvester and Ho (1972), Hsu *et al.* (1989) proposed new relationships to determine the equilibrium planform of bays.

The weighted mean wave approach angle at Marcus Island was calculated in order to apply the method. Figure 9 shows the predicted planform of the breakwater according to Method 3.

6.5 Discussion

Although the results of the first two methods differ somewhat, as can be expected, the same conclusions can be drawn from them. These are:

- (i) It is not feasible to realign the breakwater considering the volume of material (approximately 500 000 m³) that will be required. Furthermore, no suitable (medium to coarse) sand is available.
- (ii) If the breakwater is left indefinitely to realign itself, it may be in danger of eventually being breached.

The equilibrium planform of the breakwater according to Method 3 agrees reasonably well with the planform of the breakwater needed for reconstruction obtained from the other two methods.

7. Equilibrium Slope of the Breakwater

7.1 Method

The equilibrium beach and nearshore profile at a specific position along the breakwater was determined in the following way from the surveys available at the time of the analysis:

A series of plots of distance of the contour from the survey station versus time for different depths (+4 m, +2 m, 0 m,... -20 m CD) were drawn. An example of such a plot is included as Figure 10.

These plots were used to deduce the long-term (equilibrium) trend in the movement of the specific contour (Figure 10). In other words, the equilibrium distance of the specific contour from the station was obtained. By

plotting the depths of the contours versus these equilibrium distances, an equilibrium beach and nearshore profile was acquired.

Equilibrium profiles were determined opposite survey stations 2, 12 and 24 (see Figure 4 for the positions of these stations). These positions were chosen to be representative of the breakwater. The profiles are plotted in Figure 11.

7.2 Results

The predicted equilibrium slope at the three stations is virtually identical ($1/45$) and considerably flatter than the design slope of $1/35$. This explains why erosion occurs above approximately -4 m CD and accretion below this level.

Therefore, while the breakwater is realigning itself alongshore, sediment is being steadily moved in an offshore direction from the breakwater. Thus when the breakwater has reached its optimum alignment, it will recede slowly as a whole and may in time be in danger of being breached.

8. Remedial Measures

Using sand as a solution was not considered feasible for the following reasons:

- (i) A large volume (approximately $500\,000\text{ m}^3$) of sand would be needed for realignment. In addition, regular maintenance of the breakwater requiring about $50\,000\text{ m}^3/\text{year}$ of suitable sand (medium to coarse) would be needed.
- (ii) Suitable sand is not readily available. All available sources were utilised during the construction of the breakwater.
- (iii) Some sort of expensive toe protection at about -14 m CD is most probably necessary to prevent excessive sand losses to deep water.

It was therefore recommended that a suitable rock protection be provided along the spending beach breakwater.

Before rock can be placed as protection, the erosion areas (Figure 2) should be filled up with sand. This should be followed by a geo-textile on the sandy areas and a layer of 0.5 m of well-graded filter stone (2 kg to 5 kg) over the whole area to be treated. Rock protection using stone between 1 t and 6 t should be placed as conceptually shown in Figure 12. The foundation of geo-textile and filter stone should extend beyond the toe of the rock armouring to provide scour protection. About $50\,000\text{ m}^3$ of rock will be needed for the erosion areas and approximately $150\,000\text{ m}^3$ for the entire sand breakwater.

It was recommended to check and optimise the design of the rock armouring in a model study using random waves. Flume tests to this effect were subsequently carried out (CSIR, 1989). The results of this investigation, however, fall outside the scope of this paper.

FIGURE 11 : EQUILIBRIUM PROFILES

FIGURE 12 : CONCEPTUAL LAYOUT OF ROCK PROTECTION

It was also recommended that a hydrographic survey together with aerial photography be conducted annually and that beach profiles and beach photography be done more often to monitor the breakwater and the erosion areas. Particular attention should be given to obtain nearshore profile data in the surf zone.

CHAPTER 184

Numerical Modeling of the Dredged Spoil Disposal

Cao Zude¹ Wang Guifen²

Abstract

To calculate the sediment movement under waves and currents, a simulating system called CW system has been developed by the authors. It can determine the effect of the dredged spoil disposal.

1 Introduction

Under the interaction of the wind wave and the tidal current some fluid mud and sediment suspension caused by dredged spoil disposal transport and flow complicatedly. Its propotion varies with the hydragraphic conditions.

We have measured the movement of the fluid mud by using "Neutron activation" and have developed a series of 2-dimensional and 3-dimensional numerical models to simulate the movement of suspended load, the fluid mud and their transformation by using the moving ADI method (Chen and Cao, 1990)

By field data, spoil materials were casted into the sea area, 70~90% of which were fluid mud on the bottom and 10~30% suspended load.

The fluid mud flows along the bottom by gravity, wave and current. The suspended load moves with water. Both fluid mud and suspension deposit by and by. Some times in case of strong

2. Engineer of coastal and Estuary Engineering. Tianjin Research Institute of Water Transport Engineering, Xingang, Tanggu, Tianjin, P.O.300456, China

wind-wave the fluid mud becomes suspended. When the sea is calm the suspended load turns into the fluid mud.

The process is shown in Fig.1 as follows.

Fig. 1 Movement of dredged materials

Numerical modelling of the processes are shown in the Fig.1 of appendices.

2 Basic differential equations

2-1 Tidal current

2-1-1 Two dimensional equations (Cao et al.,1989)

In case of no wind

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} (uh) + \frac{\partial}{\partial y} (vh) = 0$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + g \frac{\partial \zeta}{\partial x} + \frac{g u \sqrt{u^2 + v^2}}{c^2 h} - fv = A \Delta u$$

$$\frac{\partial v}{\partial t} + v \frac{\partial v}{\partial y} + u \frac{\partial v}{\partial x} + g \frac{\partial \zeta}{\partial y} + \frac{g v \sqrt{u^2 + v^2}}{c^2 h} + fu = A \Delta v$$

In case of wind-wave

$$\frac{\partial \zeta}{\partial t} + \frac{\partial}{\partial x} (uh) + \frac{\partial}{\partial y} (vh) = 0$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + g \frac{\partial \zeta}{\partial x} - fv - \frac{c_s \rho_a}{h \rho} |W - U| (\omega_x - u)$$

$$+ \frac{1}{h} \frac{\tau_x}{\rho} + \frac{1}{\rho h} \left(\frac{\partial s_{xx}}{\partial x} + \frac{\partial s_{xy}}{\partial y} \right) = A \Delta u$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + g \frac{\partial \zeta}{\partial x} + f u - \frac{c_s \rho_a}{\rho h} |W - U| (\omega_y - v) \\ + \frac{\tau_y}{\rho h} + \frac{1}{\rho h} \left(\frac{\partial s_{yx}}{\partial x} + \frac{\partial s_{yy}}{\partial y} \right) = A \Delta v$$

2-1-2 Three dimensional equations (Cao et al., 1988)

$$\frac{\partial \zeta_k}{\partial t} - \frac{\partial \zeta_{k-1}}{\partial t} + \frac{\partial (u_k h_k)}{\partial x} + \frac{\partial (v_k h_k)}{\partial y} = 0$$

$$\frac{\partial h_k}{\partial t} = - \frac{\partial u_k h_k}{\partial x} - \frac{\partial v_k h_k}{\partial y}$$

$$\frac{\partial u_k}{\partial t} + u_k \frac{\partial u_k}{\partial x} + v_k \frac{\partial u_k}{\partial y} + \omega_k \frac{\partial u_k}{\partial z} + g \frac{\partial (\zeta_k - \zeta_{k-1})}{\partial x} - f v_k + \frac{1}{\rho h_k}$$

$$\times (\tau_{xk-1} - \tau_{xk}) = A_x \Delta u_k$$

$$\frac{\partial v_k}{\partial t} + u_k \frac{\partial v_k}{\partial x} + v_k \frac{\partial v_k}{\partial y} + \omega_k \frac{\partial v_k}{\partial z} + g \frac{\partial (\zeta_k - \zeta_{k-1})}{\partial y} + f u_k$$

$$+ \frac{1}{\rho h_k} (\tau_{yk-1} - \tau_{yk}) = A_y \Delta v_k$$

2-2 Wave

The wave forecast and refraction are used in the CW system

2-3 The dispersion equations of suspended load

In case of 2-D (Cao et al., 1989)

$$\frac{\partial}{\partial t} (sh) + \frac{\partial}{\partial x} (suh) + \frac{\partial}{\partial y} (svh) + F_s = \frac{\partial}{\partial x} \left(D_x h \frac{\partial s}{\partial y} \right)$$

$$+ \frac{\partial}{\partial y} \left(D_y h \frac{\partial s}{\partial x} \right)$$

In case of 3-D (Cao et al., 1988)

$$\frac{\partial}{\partial t} (S_k h_k) + \frac{\partial}{\partial x} (u_k S_k h_k) + \frac{\partial}{\partial y} (v_k S_k h_k) + (\omega - \omega_s) \times$$

$$s \left| \frac{z_k}{z_{k-1}} - \varepsilon_z \frac{\partial s}{\partial z} \right| \frac{z_k}{z_{k-1}} = \frac{\partial}{\partial x} (k_x h_k \frac{\partial S_k}{\partial x}) + \frac{\partial}{\partial y} (k_y h_k \frac{\partial S_k}{\partial y})$$

2-4 The fluid mud movement equations. (Cao et al., 1988, 1989).

$$\frac{\partial h_m}{\partial t} + \frac{\partial}{\partial x} (u_m h_m) + \frac{\partial}{\partial y} (v_m h_m) + F_s + F_b + F_c = 0$$

$$\frac{\partial u_m}{\partial t} + u_m \frac{\partial u_m}{\partial x} + v_m \frac{\partial u_m}{\partial y} + g \frac{\rho}{\rho_m} \frac{\partial \zeta}{\partial x} + g \frac{\Delta \rho}{\rho_m} \frac{\partial \zeta_m}{\partial x} +$$

$$\frac{1}{\rho_m h_m} (\tau_{bx} + \tau_{Bx} - \tau_x) = D_m \Delta u_m$$

$$\frac{\partial v_m}{\partial t} + u_m \frac{\partial v_m}{\partial x} + v_m \frac{\partial v_m}{\partial y} + g \frac{\rho}{\rho_m} \frac{\partial \zeta}{\partial y} + g \frac{\Delta \rho}{\rho_m} \frac{\partial \zeta_m}{\partial y} +$$

$$\frac{1}{\rho_m h_m} (\tau_{by} + \tau_{By} - \tau_y) = D_m \Delta v_m$$

2-5 Morphology

$$\frac{\partial \zeta_b}{\partial t} = F_s / \gamma_c$$

where ζ is the vertical displacement between the water level and the still water level; u, v, w are respectively component velocities in x, y and z directions; h —the water depth; f —Coriolis acceleration; H —the wave height; L —the wave length; C —the wave velocity; S —the concentration of suspended load; F_s —the Function of siltation and deposition; S_{xx}, S_{xy}, S_{yx} and S_{yy} —the radiational stress; τ_b —the shear stress on bottom; τ_ω —the shear stress on surface by wind; τ_B —Bingham stress; and footnote "K"—the K-layer on 3-D; footnote "m"—fluid mud; footnote "b"—sea bottom.

These differential equations mentioned above can be solved by the determined boundary conditions and initial conditions.

3 Applications (for example)

3-1 Computational regions

Based on these differential equations mentioned above the simulating system called CW system has been developed by the writers in Tianjin Research Institute of Water Transport Engineering, China.

The CW System has been used to study the effects of the dredged spoil disposal on the environment and siltation in Tianjin Port.

As there is lack of boundary condition required in numerical simulations in Tianjin Port Area, 4 calculational regions with different ranges are set up by using the method of nesting small model in a large one. Bohai Sea is the first calculational region; Bohaiwan Bay—the second; The Tianjin Harbour Area—the third and the spoil ground—the fourth. These four regions are nested with each other.

The calculated results of the former regions provide the boundary conditions for the latter. The open boundary conditions of the first region are controlled by M_2 , S_2 , K_1 , O_1 component tides.

Table 1 characteristics of calculation regions

no.	1	2	3	4
name	Bohai Sea	Bohai Bay	north part of Bohai Bay	dredged spoil ground
area(km ²)	168,000	10,800	5,400	25
simulation method	moving ADI method	moving ADI method	moving ADI method	explicit method
dimension	2	2	2	3
space step				
Δx (m)	10,000	5,000	500	500
Δy (m)	10,000	5,000	500	500
Δz (m)				2
time step (s)	1,800	900	90	90

As contracted by the storage capacity, two dimensional modellings are used for the former three regions by means of "moving ADI method". and three dimensional modelling is used for the fourth region with explicit method. The "moving ADI method"

not only remains ADI method's characteristics but also has following advantages—fast in convergence; high in stability; simple in calculation and convenient in programming (Wang, 1989).

The pictures of four calculational regions mentioned above are shown in Fig.2 and the technical functions of these regions are listed in table 1.

Fig. 2 Diagram of each calculation network

3-2 Verification

Five aspects are verified for these numerical modelling. The computational results agree well with the field data as follows.

3-2-1 Water level

The water level process at the center of spoil ground in spring tide on Aug. 1st 1988 is shown in Fig 3.

Fig. 3 Verification of water level process of spoil ground

3-2-2 Velocity

The velocity processes of five stations on the spoil ground during spring tide on Aug. 1st of 1988 are shown in Fig.4.

The velocity processes of the four stations in both side of the channel during spring tide on Aug.1st , 1988 are shown in Fig. 5

Fig. 4 Verification of current velocity process of spoil ground

Fig. 5 Verification of current velocity of measuring stations to the south and north of the channel

The velocity distributions of velocity on the Aug. 1st 1988 in the center of the spoil ground at different time are shown in Fig. 6.

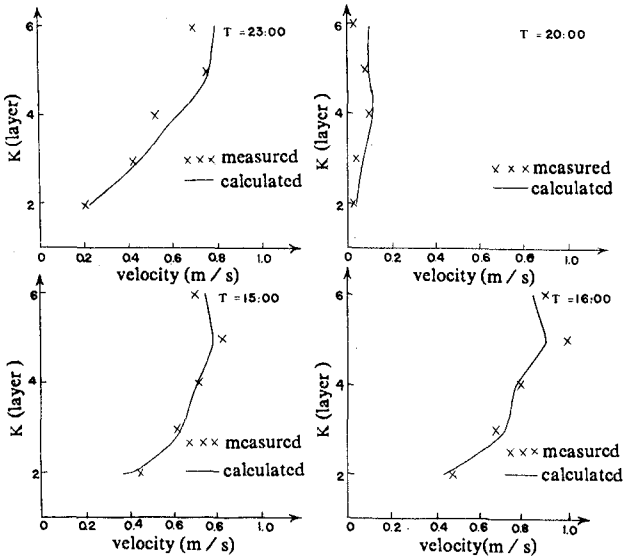

Fig. 6 Vertical distribution of current velocity of spoil ground

3-2-3 Tracing floats

Tracing floats from the center of the spoil ground at the flood tide and ebb tide are shown in Fig.7.

Fig. 7 Diagram of flow tracks of flood tide and ebb tide

3-2-4 Concentration of suspended load

The vertical distributions of concentration of suspended load in the center of the spoil ground at different time are shown in Fig. 8.

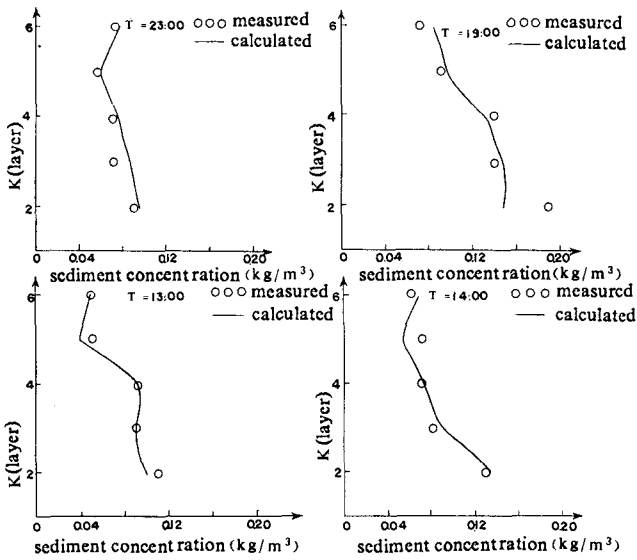

Fig. 8 Verification of vertical distribution of suspended sediment concentration at different times

Fig. 9 Process curves of sediment concentration and morphologic erosion

3-2-5 Morphologic processes.

Sediment concentration and morphologic variation of 3 locations (the entrance of Tianjin port, near the lighthouse and the center of spoil ground) under the action of the northeast gale are shown in Fig 9.

The simulated results are in good agreement with the measured in field.

3-3 Simulation of dredged materials

The dredged materials are disposed to the spoil ground with the self-propelled trailing suction hopper dredger as follows:

1. Disposing one boat of spoil materials;
2. Disposing a boat of spoil materials continuously at the interval of every two hours a week.
3. Simulating the effects of wind-wave process on the movement of spoil materials. The following simulated results are obtained:

The variation suspension and fluid mud under the effect of the northeast gale are shown in Fig 2 and 3 of appendices.

It is inticated from Fig 2~3 of appendices that the dredged materials on the existed spoil ground have no direct effect on the siltation of Tianjin Port.

4 Conclutions

By comparing the simulated value and the field data we believe the CW system is an effective tool to study the movement of the spoil disposal

CHAPTER 185

MODELING OF WAVE-CURRENT INTERACTION AND BEACH CHANGE

Susumu OHNAKA* and Akira WATANABE**

ABSTRACT

This paper presents a mathematical model of waves, currents and beach change with wave-current interaction. The wave model is based on the time-dependent mild-slope equations extended to a wave-current coexisting field, and is applicable to the computation of wave deformation due to combined effects of shoaling, refraction, diffraction, reflection, breaking and currents. Some examples of numerical computation are shown, and effects of the wave-current interaction on the nearshore waves, currents and beach evolution is discussed. In addition, a simple treatment of obliquely incident wave condition as well as improvement of sediment transport rate formulas are presented.

1. INTRODUCTION

Not a few mathematical models of nearshore processes have recently been developed and applied to the prediction of nearshore waves, currents and beach evolution. In most models, however, effects of the interaction between waves and currents are neglected. In actuality nearshore waves induce currents through radiation stresses, and resultant currents conversely affect the wave field; namely, the wave-current interaction always takes place to a greater or less extent. Under certain conditions, it will become very important to take the interaction effects into consideration for an accurate prediction of nearshore waves and currents as well as resultant sediment

* Research Engineer, Technical Research Institute, Toa Corporation, 1-3, Anzencho, Tsurumi-ku, Yokohama, 230 Japan

** Professor, Department of Civil Engineering, Univ. of Tokyo, Hongo-7, Bunkyo-ku, Tokyo, 113 Japan

transport and beach change.

In order to incorporate the wave-current interaction into nearshore process models, the wave deformation due to currents should be included in the computation of waves. For a wave field coexisting with a varying current in the water of non-uniform depth, a few kinds of wave models have been proposed (Booij, 1981; Liu, 1983; Kirby, 1984). These models are based on elliptic-type partial differential equations, which are in general rather difficult to solve numerically. Hence these equations are sometimes approximated by parabolic equations, but then they become inapplicable to a wave field including significant reflection from structures. On the other hand, Ohnaka et al. (1988) have proposed another kind of numerical computation model for a nearshore wave field with a varying current and depth. Their model employs time-dependent mild-slope equations, and is applicable to the computation of wave deformation due to combined effects of shoaling, refraction, diffraction, reflection and breaking as well as wave-current interaction.

In the present study, this wave model is utilized as a part of a mathematical model of nearshore processes, and the effects of the wave-current interaction on the nearshore waves, currents and beach change are discussed on the basis of the results of numerical computation for two typical cases. Treatment of obliquely incident waves and improvement of sediment transport formulas are also presented.

2. BASIC EQUATIONS AND METHODS IN THE MODEL

2.1 Wave Computation

Ohnaka et al. (1988) have proposed time-dependent mild-slope equations for a wave-current coexisting field, which are applicable to the computation of wave deformation due to combined effects of the shoaling, refraction, diffraction, reflection and breaking as well as the wave-current interaction. The equations have been derived by separating the mild-slope equation for waves coexisting with a current proposed by Kirby (1984) into the following two equations expresses in terms of the water surface elevation ζ and the depth-integrated flow rate vector Q :

$$m \cdot (\partial \zeta / \partial t) + \nabla \cdot (U \zeta) + \nabla \cdot (n Q) = 0 \quad (1)$$

$$\partial Q / \partial t + \omega C^2 \nabla (\zeta / \sigma) + f_b Q = 0 \quad (2)$$

$$m = 1 + (\sigma / \omega)(n - 1), \quad n = C_s / C \quad (3)$$

where t is the time, ∇ is the horizontal gradient operator, C and C_g are the phase and group velocity vectors and U is the ambient current velocity vector. The last term in Eq. (2) is the energy dissipation term, where f_D is the energy dissipation coefficient to be defined later; this term has been added in order to deal with the wave decay and recovery after breaking. The apparent angular frequency ω is defined by the following dispersion relation for a wave-current coexisting field:

$$\omega = \sigma + k \cdot U, \quad \sigma = g k \tanh k h \quad (4)$$

where σ is the intrinsic angular frequency, k is the wave number vector, h is the water depth, and g is the acceleration due to gravity. If the ambient current velocity vector U is set to be zero, Eqs. (1) and (2) reduce to the original time-dependent mild-slope equations proposed by Watanabe and Maruyama (1986).

We need a value of the wave angle at every point to solve the above dispersion relation, Eq. (4). Since this wave model is based on the time-dependent equations, we can calculate the wave angle from values of ζ and Q which have already been computed in the previous cycle over one wave period.

To determine the location of wave breaking, we adopted the breaker index for compound waves proposed by Watanabe et al. (1984), which is given by the ratio of the orbital velocity at the wave crest to the phase velocity as a function of the deepwater wave steepness and the local bottom slope. This breaker index will be applicable to the wave-current coexisting field by using values relative to the current for both the orbital velocity and the phase velocity.

As for the energy dissipation coefficient f_D , Eq. (5) proposed by Watanabe and Dibajnia (1988), which can express not only the wave decay but also the wave recovery in the surf zone.

$$f_D = \alpha_D \tan \beta \sqrt{\frac{g}{h}} \sqrt{\frac{Q_m - Q_r}{Q_r - Q_s}} \quad (5)$$

where $\tan \beta$ is a representative bottom slope around a breaking point, α_D is a nondimensional coefficient whose value is 2.5, Q_m is the amplitude of Q , Q_s is the flow rate amplitude of breaking waves on a uniform slope, and Q_r is that of recovering waves in a constant depth region. The quantities Q_s and Q_r are expressed as

$$Q_s = \gamma_s c n, \quad Q_r = \gamma_r c h \quad (6)$$

According to experimental data, the coefficients γ_s and γ_r are given by

$$\gamma_s = 0.4(0.57 + 5.3 \tan \beta), \quad \gamma_r = 0.4(a/h)_b \quad (7)$$

where $(a/h)_b$ is the ratio of the wave amplitude to the water depth at a breaking point.

It has been demonstrated by Ohnaka et al. (1988) that the above breaker index and the energy dissipation factor are applicable to the computation of cross-shore distribution of wave height in a wave-current coexisting field with sufficient accuracy.

2.2 Current Computation

The current field is calculated by commonly used depth-average equations of the mean flow as follows:

$$\frac{\partial \bar{\zeta}}{\partial t} + \frac{\partial U(h + \bar{\zeta})}{\partial x} + \frac{\partial V(h + \bar{\zeta})}{\partial y} = 0 \quad (8)$$

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} + g \frac{\partial \bar{\zeta}}{\partial x} + R_x + F_x - M_x = 0 \quad (9)$$

$$\frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + g \frac{\partial \bar{\zeta}}{\partial y} + R_y + F_y - M_y = 0 \quad (10)$$

where (x, y) are Cartesian coordinates in a horizontal plane, (U, V) are the corresponding velocity components of the mean flow, $\bar{\zeta}$ is the elevation of the mean water surface measured from the still water level, (R_x, R_y) are the radiation stress terms, (F_x, F_y) are the bottom friction terms, and (M_x, M_y) are the lateral mixing terms.

In order to treat the wave-current interaction, alternate computations of waves and of currents are necessary. An efficient iteration scheme is required so as to obtain the convergence of solutions in a computation time as short as possible. For this, no-current condition is assumed in the first step of wave computation as shown in Fig. 1. Then reduced values of radiation stresses R_1' are used in the first cycle of current computation, because if the actual values of radiation stresses R_1 calculated from the wave solutions are adopted, a large number of iterations are required to attain the convergence. Waves in the next step are calculated using the resultant reduced current velocity U_1 . The reduction rate of radiation stresses is

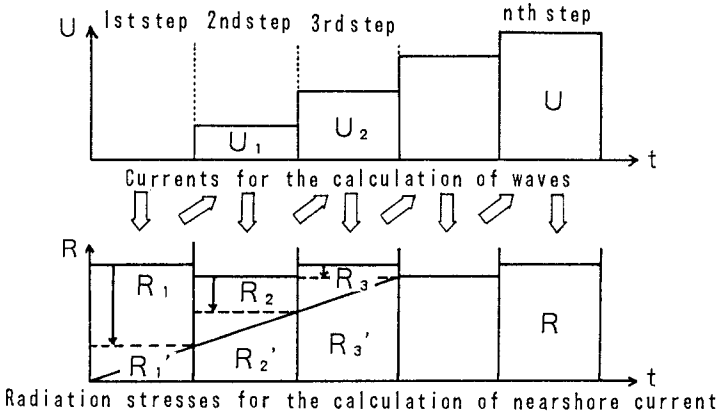

Fig. 1 Iteration of computations for waves and currents.

gradually decreased for every step, and finally full values of the radiation stresses and resultant currents are adopted for the calculation of currents and of waves, respectively.

2.3 IMPROVEMENT OF FORMULAS FOR SEDIMENT TRANSPORT RATES

Watanabe et al. (1986) proposed formulas for sediment transport rates under combined action of waves and currents on the basis of the power model concept. In their formulas the sediment transport rates are treated as summation of those due to waves q_w and due to currents q_c , which are expressed, respectively, by

$$q_w = A_w (\tau_b - \tau_{cr}) F \hat{u}_b / (\rho g) \tag{11}$$

$$q_c = A_c (\tau_b - \tau_{cr}) U / (\rho g) \tag{12}$$

where A_w and A_c are nondimensional coefficients, values of which should be empirically determined, τ_b is the maximum value of the bottom shear stress in a wave-current coexisting system, τ_{cr} is the critical shear stress for the onset of general movement of sediment grains, \hat{u}_b is the amplitude of the near-bottom wave orbital velocity vector, ρ is the density of water, and F_D is the net transport direction function. The bottom shear stress τ_b for a wave-current coexisting system is evaluated by the friction law proposed by Tanaka and Shuto (1981). Since this friction law is based on the bottom boundary layer theory, its applicability to the surf zone, where turbulence due to wave breaking is

predominant, is questionable. In the present model, therefore, the effects of the breaker-induced turbulence are incorporated in addition to the bottom shear stress as sediment-entraining forces in the surf zone. Namely the improved formulas for sediment transport rates are expressed as follows:

$$q_w = \{A_w(\tau_b - \tau_{cr}) + A_{wb}\tau_t\} F_D \hat{u}_b / (\rho g) \quad (13)$$

$$q_c = \{A_c(\tau_b - \tau_{cr}) + A_{cb}\tau_t\} U / (\rho g) \quad (14)$$

where τ_t is the breaker-induced turbulent stress, and A_{wb} and A_{cb} are nondimensional coefficients. The magnitude of τ_t is evaluated from the rate of energy dissipation by the following formula based on a dimensional analysis and experimental data:

$$\tau_t = \rho^{1/3} (n f_D E)^{2/3} \quad (15)$$

where $n f_D E$ is the breaker-induced energy dissipation rate per unit area and time.

To examine the applicability of these formulas, numerical computation has been conducted for the cross-shore sediment transport rates on a beach with initially uniform slope of 1/20. Figure 2 shows the comparisons between the computation and measurements of cross-shore distributions of the transport rates. The upper figure is for the case of offshore transport, while the lower is for that of onshore transport. The dash-dot lines

Fig. 2 Cross-shore distributions of transport rates.

show the measured transport rates and solid lines indicate the calculated ones. The component due to the bottom shear stress q_{wt} and that due to the breaker-induced stress q_{wb} are shown by the dash and the dot lines, respectively. Computed transport rates agree fairly well with the measured ones.

The change in local bottom elevation, z_b is calculated from the spatial distribution of the sediment transport rates by solving the following equation for the conservation of sediment volume:

$$\frac{\partial z_b}{\partial t} = - \frac{\partial q_x'}{\partial x} - \frac{\partial q_y'}{\partial y} \quad (16)$$

$$q = q_w + q_c = (q_x, q_y)$$

where (q_x', q_y') are the components of the transport rates in the x- and y-directions corrected in order to include the bottom slope effect, and are given by

$$q_x' = q_x - \varepsilon_s |q_x| \frac{\partial z_b}{\partial t}, \quad q_y' = q_y - \varepsilon_s |q_y| \frac{\partial z_b}{\partial t} \quad (17)$$

where ε_s is the dimensionless coefficient of the order of unity.

3. NUMERICAL COMPUTATION METHOD FOR WAVES

Equations (1) and (2) are solved by using a finite difference method. For the discretization of the convection term due to mean flow in Eq. (1), the Alternating Direction Explicit (A. D. E.) scheme is adopted in order to solve explicitly without numerical diffusion as follows:

$$\left(\frac{\partial (U \zeta)}{\partial x} \right)_{\text{point}=i} = \frac{U_{i+1/2} \zeta_{i+1/2}^{j+1/2} - U_{i-1/2} \zeta_{i-1/2}^{j+1/2}}{\Delta x} \quad (18)$$

$$\zeta_{i+1/2}^{j+1/2} = 0.5(\zeta_i^j + \zeta_{i+1}^j), \quad \zeta_{i-1/2}^{j+1/2} = 0.5(\zeta_i^j + \zeta_{i-1}^j)$$

Namely, as for ζ at a point (i-1) which is needed for the discretization of the convection term at a point (i), its values at a time-step (j) are successively replaced with values at a time-step (j+1) calculated just before.

Now let us consider boundary conditions in the wave computation. The boundary conditions must be imposed on all the boundaries surrounding the computation region: namely, the offshore open boundary, shoreline boundary,

and two side boundaries.

Waves on the offshore open boundary are expressed as the superposition of the incident waves ζ_I and the outgoing waves ζ_R as shown in Eq. (19).

$$\begin{aligned}\zeta'(x_0, y_0) &= \zeta_I'(x_0, y_0) + \zeta_R'(x_0, y_0) \\ \zeta_I'(x_0, y_0) &= a_I \sin(k x_0 \cos \theta_I + k y_0 \sin \theta_I - \sigma t) \\ \zeta_R'(x_0, y_0) &= \zeta'^{-\tau}(x_0, y_0) \\ &\quad - a_I \sin \{ (k(x_0 + \Delta x) \cos \theta_I + k y_0 \sin \theta_I - \sigma(t - \tau))\}\end{aligned}\tag{19}$$

where a_I is the incident wave amplitude, Δx is the grid length normal to the boundary, and the subscript 0 denotes quantities at the boundary. The time shift τ is defined by

$$\tau = \Delta x \cos \theta_n / C\tag{20}$$

where θ_n is the direction angle of the outgoing wave component measured from the normal line to the boundary.

The shoreline is treated as a moving boundary to include the change in its location caused by the change in the mean water elevation due to wave setup, and ζ is kept equal to 0 on this moving shoreline boundary.

In case of obliquely incident waves, one of the side boundaries becomes an incident boundary, while the other becomes an open boundary. For the open side boundary, the value of ζ at a point (x_0, y_0) on the boundary at time t is set equal to the one at an adjacent inner point $(x_0, y_0 - \Delta y)$ at time $t - \tau$ as follows:

$$\zeta'(x_0, y_0) = \zeta'^{-\tau}(x_0, y_0 - \Delta y)\tag{21}$$

The time shift τ is defined by

$$\tau = \Delta y \sin \theta / (C + U \cos \theta + V \sin \theta)\tag{22}$$

where θ is the wave direction angle measured from the x -axis.

On the other hand, ζ on the incident side boundary is expressed as follows:

$$\zeta'(x_0, y_0) = a(x_0) \sin \left(\int_0^{x_0} k \cos \theta dx + k \sin \theta y_0 - \sigma t \right)\tag{23}$$

In this equation, however, the wave amplitude $a(x_0)$ is unknown because it changes towards the onshore direction owing to the shoaling, refraction, breaking, etc. The problem is how to determine $a(x_0)$ along the boundary.

In the present study we propose a simple and practical computation method, in which the wave amplitude $a(x_0)$ on the boundary is calculated from the quantities in the inner region by assuming the local wave periodicity in the alongshore direction. For this, an imaginary computation region is attached to the incident side boundary of the actual computation region as shown in Fig. 3. Assuming shore-parallel straight bottom contours in this region, we obtain Eq. (24).

$$L_y = L/\sin\theta = \text{const.} \tag{24}$$

where L_y is the wavelength in the alongshore direction. If the width of the imaginary region is set equal to L_y , waves change periodically in the alongshore direction, and consequently the following relation holds:

$$\zeta_{1,j} = \zeta_{N_y,j} \tag{25}$$

where $\zeta_{1,j}$ is the water surface elevation on the lower boundary, and $\zeta_{N_y,j}$ on the upper boundary of this imaginary region. Using this condition, we can calculate ζ and Q in the imaginary region without specifying any values on the side boundaries.

Figures 4 and 5 are the results of numerical computation in imaginary regions for cases of constant depth and of uniform slope, respectively. Waves come into the region with an incident angle of 60 degrees. The width equal to L_y has been divided into 15 grids. The left and the right figures respectively show the distributions of the normalized wave height and of the phase. These results are quite satisfactory and indicate the validity of this treatment.

The values of $\zeta_{N_y,j}$ thus obtained are given along the incident side boundaries in the computation for the actual region. Figure 6 is an example of the wave field computed for the case of obliquely incident waves. The

left and the right figures show the distributions of the wave height and the wave angle, respectively. As indicated in these results, incident waves come into theregion across not only the offshore boundary but also the lower side boundary.

4. EXAMPLES OF APPLICATION OF THE MODEL

The present numerical model has been applied to the computations of waves, currents and beach change for two typical cases involving the wave-current interaction.

The first case is for a region around detached breakwaters on a beach with initially uniform slope of $1/25$. The incident wave height is 2.5 m, the period is 8 s and the incident direction is normal to the shoreline. It is difficult at the present stage to evaluate proper values of the coefficients in the sediment transport rate formulas because of insufficient experimental and field data. Values of $A_w=0.15$, $A_c=0.50$, $A_{wb}=0.03$, and $A_{cb}=0.10$ has been adopted in this computation according to some experimental results. The grid size is $\Delta x=\Delta y=2.5$ m for the calculation of wave field and $\Delta x=\Delta y=5.0$ m for the calculation of nearshore current and beach change. Iteration in the calculation of waves and currents to include the wave-current interaction has been conducted nine times, and in the first four iteration steps values of the radiation stresses has been increased gradually by 25% for each step.

Figure 7 shows the wave height distribution, where the upper half gives the result computed with the wave-current interaction, and the lower half without the interaction. The differences of the wave height in the surf zone and of the breaker line are clearly observed. The distribution of the wave direction is shown in Fig. 8. Refraction due to nearshore current is observed when the wave-current interaction is considered. The distribution of nearshore currents is presented in Fig. 9, where reduction of the current intensity due to interaction and the shoreline change induced by the wave setup are well recognized. The distribution of the mean water elevation is presented in Fig. 10. Significant wave setup variation near the shoreline without the wave-current iteration is smoothed out when the interaction is considered. Figure 11 is the resultant beach topography, in which significant effects of the wave-current interaction appear near the shoreline.

The second case is for a region around a rip channel as shown in Fig. 12. Figure 13 shows the normalized wave height distribution. The difference of the

Fig. 7 Distribution of normalized wave height.

Fig. 9 Distribution of nearshore current.

Fig. 10 Distribution of mean water elevation.

Fig. 11 Distribution of bottom topography.

Fig. 12 Initial bottom topography around a rip channel.

Fig. 13 Distribution of normalized wave height.

Fig. 14 Distribution of nearshore current.

Fig. 15 Distribution of Bottom topography.

breaker lines is clearly seen. The distribution of nearshore currents is presented in Fig. 14. The computation region is extended along the shoreline by the wave setup and in this expanded region a strong longshore current is observed. Rip current velocity is considerably reduced when the wave-current interaction is included. Figure 15 shows the resultant beach topography. In this case the sand transport due to waves has been ignored in order to emphasize the difference induced by the currents with and without the wave-current interaction. It is seen that the beach topography change is reduced when the wave-current interaction is considered.

5. CONCLUSIONS

A numerical computation model for nearshore waves, currents and beach change with wave-current interaction was presented, and the influences of the wave-current interaction were examined. It was shown that the wave-current interaction affected the wave field, current field and beach change in the nearshore zone. A treatment of the side boundary condition for the case of obliquely incident waves and improvement of sediment transport rate formulas were also presented, and their validity was demonstrated.

CHAPTER 186

VALIDATION OF MOVABLE-BED MODELING GUIDANCE

Steven A. Hughes¹ and Jimmy E. Fowler¹

Abstract

A 1-to-7.5 scale (midscale) movable-bed physical model was used to validate model scaling criteria selected as most appropriate for turbulence-dominated, erosion of sediment by waves. Two-dimensional flume tests successfully reproduced profile evolution observed in prototype-scale wave flume tests conducted in Germany under both regular and irregular wave conditions. For the case of regular waves, a sloping concrete revetment was exposed, thus validating the scaling guidance for use in studying scour at coastal structures. Comparisons between regular wave and irregular wave profile evolution indicated that best correspondence is achieved when the significant wave height equals the monochromatic wave height, although irregular wave profile evolution takes about twice as long.

Introduction

Physical models at reduced scale offer an alternative for examining coastal phenomena that are beyond analytical approaches. However, engineers must temper their enthusiasm for physical models by remembering the model's usefulness is directly related to the ability to understand the inherent lab and scale effects; and, when possible, to correct for these effects in the design and conduct of experiments.

Similitude relationships for modeling hydrodynamic phenomena are well established and thoroughly tested against prototype-scale data. Scaling effects in movable-bed models are not as well understood and are difficult to quantify.

A multitude of scaling relationships for modeling coastal sedimentary processes has been proposed over the years (see Hudson et al. 1979, and Kamphuis 1982 for overviews and lists of references). Hudson et al. (1979) give the basic philosophy for movable-bed scale modeling as fully understanding the physical processes involved and ensuring that the relative magnitudes of all dominant processes are the same in model and prototype. They also state, "This is an impossible task for movable-bed models . . ." because of the complications of the fluid-sediment interactions, and thus it is necessary to attempt to reproduce the dominant process "... with the anticipation that other forces are small."

¹Research Hydraulic Engineers, US Army Engineer Waterways Experiment Station, Coastal Engineering Research Center, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199

Similar views are held by Dean (1985), who lists two major requirements in proper physical modeling of sand transport processes: (a) knowledge of the character of the dominant forces and (b) an understanding of the dominant response mechanisms of the sediment.

In the absence of fundamental knowledge of the dominant processes and associated sediment response necessary to develop scale relationships, movable-bed scale models can be used to investigate the effects of certain parameters in systematic ways to establish general behavior patterns (Gourlay 1980). Alternately, the researcher can abandon the idea of reproducing the dominant physical processes and instead attempt to maintain similitude of important observed engineering characteristics such as beach profile shape or longshore transport rates (Hudson et al. 1979).

Regardless of the approach taken to develop scaling relationships for movable-bed models, the nearly unanimous opinion among researchers is that it is important to verify the scaling laws by reproducing prototype-scale events. Preferably, the scale model should be validated using field data, but often this is not practical, and large-scale laboratory results must suffice. Only after validation can credence be given to the model results, and then only for situations which seem to be governed by the same processes that were assumed dominant in the validation.

The purpose of the research described herein was to verify previously suggested movable-bed scaling criteria for modeling turbulent wave-induced scour phenomena in small-scale movable-bed physical models. This verification involved model replication of the spatial and temporal evolution of a beach fronting a sloping revetment as observed in a prototype-scale flume experiment conducted using monochromatic waves. Because the sloping concrete revetment became exposed during the course of the experiment, the structural influence on the profile evolution made this case particularly germane to the study of scour at structures.

Further validation of the movable-bed scaling criteria was achieved by midscale model reproduction of profile evolution caused by irregular waves in the prototype-scale flume. In this case, no structure was exposed to complicate the profile evolution.

Selected Scaling Guidance

Generally, movable-bed modeling criteria can be divided into two broad categories based on the transport mechanism: bed shear-stress-dominated transport, and turbulence-dominated transport. The present research focussed on the latter case.

Historical Perspective

Many investigators have expressed opinions regarding the important physical parameters and scaling requirements to be considered in formulating guidance for movable-bed models of coastal sedimentary processes. Perhaps the most relevant requirement for modeling coastal scour, as well as nearshore beach dynamics, is to attain similarity of the equilibrium beach profile between prototype and model, particularly in the surf zone. Parameters that appear to correspond to features of the equilibrium profile are similarity candidates for developing scaling criteria.

In the nearshore region, turbulent water motions play a greater role in mobilizing and transporting sediment; and in this region there is increasing evidence that the

dimensionless fall speed parameter, given as:

$$\frac{H}{wT} \quad (1)$$

where H = wave height, T = wave period, and w = vertical fall speed of the sediment, should be similar in both prototype and model.

The use of the fall speed parameter to characterize nearshore processes began in the late 1960's, and it was popularized by Dean (1973) when he incorporated it into an expression for distinguishing between swell and storm profiles. One physical interpretation of the parameter was given by Gourlay (1968) who pointed out that H/w represented "... the time taken for a sand particle to fall a distance equal to the wave height." If this time is large compared with the wave period, he reasoned the particle would remain in suspension and move as suspended load. Conversely, if the time is equal to or less than the wave period, then the sediment will move primarily as bed load. Hughes and Fowler (1990) summarize several of the research efforts that have led to acceptance of the fall speed parameter for describing certain aspects of nearshore sediment processes.

Dalrymple and Thompson (1976) were among the first to propose movable-bed modeling criteria that maintained similarity between prototype and model values of the fall speed parameter. Kamphuis (1982) concluded that preservation of the fall speed parameter eliminates most of the scale effects associated with attempting to geometrically scale the grain size diameter of quartz sand. Vellinga (1982) and Hughes (1983) proposed different distorted model relationships; however, the undistorted versions were identical and conformed to that recommended by Dalrymple and Thompson (1976).

Dean (1985) reviewed previous movable-bed modeling criteria and considered the dominant physical mechanisms involved in surf zone sediment transport. He argued that the Shield's criterion need not be met in the surf zone because turbulence, not bed shear, is the dominant cause of sediment mobilization; and therefore, bed shear is not an important consideration above Reynold's numbers constituting the fully rough range. Dean made specific recommendations for successful modeling of surf zone processes:

- a. Undistorted model (equal horizontal and vertical length scales).
- b. Hydrodynamics scaled according to Froude similarity.
- c. Similarity of the fall speed parameter between prototype and model.
- d. Model is large enough to preclude significant viscous, surface tension, and cohesive sediment effects so that the character of the wave breaking is properly simulated.

Dean (1985) argued that, in an undistorted model, the fall trajectory of a suspended particle must be geometrically similar to the equivalent prototype trajectory and fall with a time proportional to the prototype fall time. This is accomplished by ensuring similarity of the fall speed parameter between the prototype and the undistorted model.

The scaling recommendations of Dean (1985) were specifically tested in undistorted, erosive movable-bed models by Kriebel, Dally, and Dean (1986) and by Vellinga (1986). Both studies documented success in reproducing prototype-scale profile development. Other acceptance of the scaling criteria is discussed in Hughes and Fowler (1990).

In conclusion, efforts aimed at reproducing surf zone profile response in small-scale movable-bed models during erosive conditions have converged on scaling criteria that preserves the parameter H/wT between prototype and geometrically undistorted model, with the hydrodynamics (waves primarily) being scaled by the Froude criterion. As Dean (1985) discussed, the model law preserves similarity in wave form, sediment fall path, wave-induced velocities, break point, breaker type, and wave decay (provided the model is large enough to preclude viscous and surface tension effects.) The bottom shear stress will not be correctly scaled using the fall speed parameter criteria because the bottom boundary layer and ripple formations are not reproduced. This will result in noticeable scale effects when wave breaking turbulence is **not** dominant in the domain being modeled.

Scale Relationships

The selected scaling guidance consists of simultaneously satisfying two scaling criteria in an undistorted movable-bed model. The first is the well-known Froude criterion for the hydrodynamics that results in the relationship

$$N_t = \sqrt{N_\ell} \quad (2)$$

where N represents the prototype-to-model ratio of the subscribed parameter, t is time, and ℓ is length. In deriving Equation 2, the gravity scale, N_g , was set equal to unity.

The second criterion requires maintaining similarity of the fall speed parameter between prototype and model, i.e.,

$$\frac{H_p}{w_p T_p} = \frac{H_m}{w_m T_m} \quad (3)$$

where the subscripts p and m represent prototype and model, respectively. Rearranging Equation 3 and expressing it in terms of scale ratios yields

$$N_H = N_w N_T \quad (4)$$

Recognizing in an undistorted model that $N_H = N_\ell$ and that the wave period will scale the same as the hydrodynamic time scale, the combination of Equations 2 and 4 results in the unique scaling relationships satisfying both criteria:

$$N_t = N_w = \sqrt{N_\ell} \quad (5)$$

Xie's Scaling Guidance

As mentioned, various parameters other than the fall speed parameter have been suggested for use in characterizing sediment transport processes. Xie (1981) conducted numerous small-scale movable-bed model tests to examine the scouring of bed material adjacent to a vertical seawall subjected to nonbreaking waves. After testing several parameters, including the fall speed parameter, Xie presented a criterion for distinguishing between the two scour patterns that depends on the grain size of the bed material and on the wave conditions. The criterion is based on the parameter

$$\frac{U_{max} - U_*}{w} \quad (6)$$

where U_{max} = horizontal component of the maximum orbital water particle velocity near the bed, U_* = critical velocity for incipient motion of the sediment, and w = sediment fall speed. High values of the parameter imply movement by suspension (turbulence-dominated), and low values correspond to bed-load-dominant conditions.

Xie (1981) suggested that similarity of the parameter given by Equation 6 should be maintained between prototype and model, but noted that this would be difficult at times because of the dependence of both U_* and w on grain size.

The scaling criterion derived from maintaining similarity of Xie's parameter in an undistorted Froude model requires that:

$$\left(\frac{U_{max} - U_*}{w}\right)_p = \left(\frac{U_{max} - U_*}{w}\right)_m \quad (7)$$

Rearranging Equation 7, using the notation for scale ratios, and noting that, in an undistorted Froude model, the scale for the water velocity will be the same as the time scale, Equation 7 becomes

$$N_* N_t = N_w = \sqrt{N_t} \quad (8)$$

where

$$N_* = \frac{\left(1 - \frac{U_*}{U_{max}}\right)_p}{\left(1 - \frac{U_*}{U_{max}}\right)_m} \quad (9)$$

In essence, the scaling guidance given by Equation 8 is a more generalized version of the guidance determined with the fall speed parameter (Equation 5). Equation 8 agrees with that given by Equation 5 if the scale ratio N_* is equal to unity.

Examining Equation 9, there are two conditions by which N_* could approach unity. The first is if $U_{max} \gg U_*$ in both the prototype and model. This would be representative of highly turbulent conditions, such as exist in the surf zone during energetic wave conditions; and in the limit it corresponds somewhat to the physical description given by Gourlay (1968) and Dean (1973) for a suspended grain falling through the water column under the influence of horizontal currents.

The other conditions leading to unit value for N_* is if the ratio U_*/U_{max} is kept similar between prototype and model. In general the investigator will be unable to satisfy both the fall speed scale and the grain size scale necessary to meet this condition. Even if possible, the scaling would be valid for only one specific hydrodynamic condition because U_{max} depends on wave period and wave height, whereas U_* is independent of wave height. This would hamper investigations using irregular waves, as well as studies in which numerous regular wave periods were of interest.

Applicability of Selected Scaling Criteria

The selected movable-bed scaling criteria given by Equation 5 are for undistorted Froude models where the sediment size is selected so that the fall speed parameter is held constant between prototype and model. Past experience with these and similar scaling criteria, coupled with the assumptions used in formulating the guidance, restricts application of this type of physical modeling to coastal sediment problems and processes that are chiefly erosional in nature, with the erosion occurring in an energetic, turbulence-dominated region such as the surf zone. Typically, the scaling is intended

to replicate the short-term response of the sea bed to storm-induced waves. Examples of situations that may be candidates for modeling with the selected criteria include: beach and dune profile response to storm events, initial beach-fill adjustment to larger waves, beach-fill response to storm events, and storm-related short-term scour at the toes of structures.

Validation

All tests described in this paper were conducted in a 1.8-m-wide wave tank at the Coastal Engineering Research Center (CERC) during 1988–1989. Hughes and Fowler (1990) provide details on laboratory setup, experimental procedures, and detailed results.

Regular Wave Validation With Revetment

Movable-bed physical model tests conducted by H. Dette and K. Uliczka at the Großer Wellenkanal (GWK) facility in Hannover, Federal Republic of Germany (Dette and Uliczka 1987; Uliczka and Dette 1987; Uliczka and Dette 1988) served as the prototype-scale target conditions for reproduction at midscale. In the prototype experiments, sand with a median diameter of 0.33 mm was placed in front of a concrete structure with a slope of 1 on 4. The sand was molded to the same initial slope as the concrete structure shown by the long-dash line in Figure 1. Subsequent exposure of the solid revetment during testing makes this regular-wave case particularly useful for validation of movable-bed scaling guidance intended for modeling of scour processes.

The fall speed scaling relations of Equation 5 were used to determine the movable-bed model parameters. Fine quartz sand having a median diameter of 0.13 mm and specific gravity of 2.65 was used to simulate the 0.33-mm median-diameter prototype sand. The Froude scaling criterion was used to determine model wave period and the time scale for morphological development. Table 1 gives prototype and model experimental values and sediment fall speeds used to calculate the undistorted length scale ratio of 7.5 (prototype) to 1 (model).

Table 1: Prototype and Model Experiment Parameters

Parameter	Prototype	Model
Sediment Median Diameter	0.33 mm	0.13 mm
Mean Sediment Fall Speed	4.47 cm/s	1.64 cm/s
Wave Period	6.0 s	2.2 s
Wave Height	1.5 m	0.20 m
Water Depth	5.0 m	0.67 m
Horizontal Berm Width	11.0 m	1.47 m
Berm Thickness	2.67 m	0.36 m

The validation testing consisted of reproducing the experiment procedure used in the GWK during the prototype tests. Representative profile comparisons between

prototype and model after equal numbers of waves (Froude scale for morphological development) are given in Figure 1. In these plots the model results have been scaled up to prototype dimensions using the length scale ratio of 7.5.

Figure 1: Prototype-Model Comparison, Regular Waves (RMS = root-mean-squared)

The profile comparison after 370 waves is relatively good, particularly in the surf zone and in the vicinity of the bar. The berm in the model was not eroded as much as in the prototype, and not as much sediment was moved to the region seaward of the breakpoint bar. An RMS (root-mean-squared) variation between profiles was calculated to be 0.49 m.

The center-line profile after 1,650 waves (Figure 1) represents the equilibrium condition for this test, and the comparison produced an RMS variation of 0.44 m. The model did not succeed in eroding the final portion of the berm on the upper portion of the revetment, and the model did not succeed in moving enough sediment to seaward of the breakpoint bar. Consequently, the scouring in the surf zone was not as severe as evidenced in the prototype.

The observed difference between prototype and model in the region offshore of the bar is most likely a result of the scaling relationship selected. This scaling relationship works best for regions dominated by turbulence-induced sediment transport. Because the model sand grains are not scaled according to the geometric length scale, they undergo a transition from suspended mode to bed-load mode of transport before this transition occurs in the equivalent prototype flow regime. With the selected scaling criteria, the bed-load mode of transport is not properly scaled in the model; consequently the model sand grains are at rest under scaled conditions that still result in offshore sediment transport in the prototype.

Figure 2: Prototype-Model Comparison, Waves Increased 10%

Figure 2 compares the prototype results to profiles obtained at midscale with the wave heights increased by 10% over the properly scaled value. As seen in Figure 2, better correspondence between prototype and model profiles resulted. The increased wave-induced water velocities in the offshore region appear to have transported sediment in the model to a greater offshore depth that more closely corresponds to the prototype. This increased *sediment demand* was met by the removal of more sand in the nearshore region; consequently, better profile reproduction, both in the final equilibrium and in the developmental stages, was achieved.

Table 2 gives values of Xie's parameter calculated at different water depths in the offshore region for the prototype (*Proto*), the basic validation model test (*Base*), and the model test with wave height increased by ten percent (*+10%*). Model values were calculated using the model depth equivalent to the prototype depth listed in the table. Columns 5 and 6 in Table 2 present the ratio of Xie's parameter in the prototype to that of the model. For the *Base* test, this ratio was always greater than one, approaching unity as the depth decreases. However, the ratio for the *+10%* test was nearer to unity over the range of offshore depths, and appears to be a reasonable compromise over the extent of the offshore portion of the profile.

The better comparison to prototype shown by the *+10%* test suggests a modification to the selected modeling criteria that includes a procedure for adjusting the scaled model wave height in such a manner as to achieve better similarity of Xie's parameter in the offshore regions of the modeled regime. This adjustment is dependent upon the wave period and should probably be limited to the more dynamically active portion of the offshore profile rather than being extended to full depth of closure.

Table 2: Prototype and Model Values of Xie's Parameter

Prototype Depth (m)	$(U_{max} - U_*)/w$			Ratio of Xie's Parameter	
	Proto.	Base	+10%	Proto/Base	Proto/+10%
5.0	20.86	18.15	20.42	1.15	1.02
4.5	23.57	20.84	23.33	1.13	1.01
4.0	26.83	24.09	26.83	1.11	1.00
3.5	30.89	28.09	31.19	1.10	0.99
3.0	36.12	33.33	36.80	1.08	0.98
2.5	42.23	39.42	43.36	1.07	0.97
2.0	51.83	48.97	53.67	1.06	0.97

Irregular Wave Validation Without Revetment

Prototype tests were also conducted in the Großer Wellenkanal using irregular waves that conformed to a JONSWAP spectrum. In these tests additional sand was added in front of the revetment so that the structure would not be exposed during profile development. The significant wave height and peak spectral period had the same prototype values as given in Table 1 for the regular wave tests. This prototype condition was reproduced as an additional midscale validation test. Every attempt was made to recreate the experiment in the same manner as it was conducted in the GWK. Representative profile comparisons between prototype and model after equal numbers of waves (Froude scale for morphological development) are given in Figure 3.

Reproduction of the irregular-wave prototype-scale flume experiment was considered to be very successful as indicated by the RMS differences shown in Figure 3. This further validates the selected movable-bed modeling guidance as being appropriate for energetic regimes of sediment transport. It is significant that close reproduction was obtained over the entire extent of the profile using properly scaled irregular waves. Recall from previously presented results that the regular wave tests suggested augmentation of the model wave height to provide a better correspondence of the Xie parameter between model and prototype. Because this was not required for the case of irregular waves, it is tentatively concluded that the natural variations within the irregular wave field were sufficient to assure correct redistribution of sediment over the entire extent of the modeled profile.

Irregular Wave Equivalence

Much of the established design guidance for sediment transport has been derived in part from laboratory tests conducted with movable-bed models using uniform, regular wave trains. For engineering design based on this guidance, the irregular wave condition which exists in nature is commonly represented by a single statistical wave height parameter that is taken as being equivalent to the regular wave height in the design formulae. Therefore, it is important to determine which irregular parameter best matches the regular wave parameter used to establish the design guidance.

Figure 3: Prototype-Model Comparison, Irregular Waves

Midscale tests employing irregular waves were conducted using the initial revetment configuration shown in Figure 1. In one test the significant wave height was chosen so that the energy present in the irregular wave train was equivalent to the energy of the regular waves used in the validation test. This resulted in a value of $H_{1/3}$ about 41% greater than the regular wave height (H_{mono}). In the other test, $H_{1/3}$ was set equal to H_{mono} .

Irregular Wave Energy Equal to Monochromatic Wave Energy

The purpose of this test was to examine whether equivalent energy levels are necessary to obtain similar profile development between model regular and irregular wave physical model tests. Figure 4 compares the irregular wave case (solid line) with the regular wave test (dashed line). The irregular waves resulted in greater erosion of the berm area and also resulted in movement of the sediment farther offshore than in the regular wave case. The comparison after 1,650 waves also reveals a significantly different profile in the region of wave breaking and seaward of breaking.

Irregular $H_{1/3}$ Equal to Monochromatic Wave Height

Figure 5 compares regular-wave profiles with corresponding profiles from the irregular test with $H_{1/3} = H_{mono}$ after approximately the same number of waves (equal elapsed time of wave action).

Figure 4: Irregular Wave Comparison, $H_{1/3}$ Equals 141% H_{mono}

Figure 5: Irregular Wave Comparison, $H_{1/3}$ Equals H_{mono}

Generally, the irregular wave condition (solid line) produced similar erosional history as the regular wave case (dashed line), but at a slower rate. After the initial adjustment, evolution of the profile under irregular wave action was less than in the regular wave case, with the most noticeable region of difference being the berm recession. This observation follows the same trend as reported by Mimura, Otsuka, and Watanabe (1986) and Uliczka and Dette (1987). The irregular wave-induced profile reached a near-equilibrium state after 1,650 waves, which corresponds to the same response of the profile under regular wave action. The good comparison shown in Figure 5 indicates that best equivalence between regular and irregular waves is found when $H_{1/3} = H_{mono}$.

The time lag in profile development under irregular waves was estimated by comparing irregular and regular wave profile that had been shifted in time. Figure 6 shows irregular wave profiles (solid) compared to regular wave profiles (dashed) that developed in about half the time. The good comparison qualitatively supports morphological development taking approximately twice as long if equivalent irregular waves are used instead of regular waves.

Figure 6: Time-Shifted Irregular Wave Comparison, $H_{1/3}$ Equals H_{mono}

Conclusions

Prototype-scale experiments conducted in the Großer Wellenkanal were reproduced at a prototype-to-model scale of $7\frac{1}{2} : 1$ using both regular and irregular wave trains. The testing procedures were designed to duplicate those used in the GWK tests. Conclusions resulting from the midscale tests are listed below:

- a. Mid-scale test results support preservation of the dimensionless fall speed parameter in an undistorted Froude model as a viable method of scaling models intended to replicate wave erosion under turbulence-dominated situations.
- b. For tests involving regular waves, model designers should consider augmenting the Froude-scaled experimental wave height to provide better prototype-to-model correspondence of the Xie parameter in the offshore region. This correspondence should be limited to the more active portions of the offshore and need not extend out to closure depth.
- c. Tests conducted using irregular waves do not require the augmentation described in (b) above.
- d. Comparable profile development can be achieved between regular and irregular wave models when the irregular significant wave height, $H_{1/3}$, is equal to the regular wave height. Profile development will take approximately twice as long in the irregular wave model.

CHAPTER 187

Large Scale Laboratory Tests of Dune Erosion

M. F. Overton, Associate Member ASCE¹

A. L. Stone, Associate Member ASCE³

Introduction

An ongoing research program at North Carolina State University (NCSU) has investigated the viability of a mechanics based swash induced dune erosion model. Early work includes both small scale laboratory and field experiments. The overall objective of the experiments was to determine the relationship between the swash characteristics and dune erosion under a variety of conditions. A linear relationship between the specific swash force (per unit width of the dune) as defined by the bore depth and velocity, and the specific volume eroded has been documented for an individual swash (in the lab), Overton et al. (1988) and for a series of swash events (in the field) Fisher et al. (1987). Problems of scale, dune material and manner of construction in the field led to a series of experiments in the large wave tank at Oregon State University (OSU). The objective of the OSU tests was to investigate the relationship between the swash force and the volume eroded for two prototype scale dunes of different sand grain size.

Experimental Design and Setup

The experiments were designed to simulate dune erosion under storm conditions at prototype scale. The experimental design and procedure summarized in the following are described in detail in Stone (1989). The OSU wave tank has a length of 104 m, a width of 3.7 m and a height of 4.6 m and is equipped with a programmable wave generator. The permanent bottom of the flume is flat with a 3.6 m step at one end. In order to accommodate the beach and dune requirements, the tank was modified in two ways. One, a beach with a 1:10 slope was installed. Two, side walls were constructed at the location of the dune to increase the height of the tank to 2.5 m. This would allow for the dune to be built with a height of approximately 2 meters.

Two dunes were constructed on the step portion of the tank as shown schematically in Figure 1. The economics of testing dictated that the dunes were built during the initial tank modification and setup phase of the experiments. Therefore, two dunes were built with a depth along the length of the tank of approximately 4 m with a plywood barrier placed at point B to separate the two. Similar material, fine sands, with median sand grain sizes, d_{50} , of 0.32 mm and 0.23 mm were used for construction. This material was locally available river sand. Dunes were constructed by placing sand in the

Figure 1. Schematic of the experimental setup.

flume with the aid of a Bobcat front-end loader. Sand was added to the flume in 30 cm layers. A vibrating compactor was then used to consolidate the material. The compactor was run across the top of the dune at least twice for each layer. This procedure was repeated until the dunes were approximately 1.5 m high.

Swash data was collected by three capacitance type wave gages placed on the beach in front of the dune. The probe closest to the dune was set 2.5 m away so that as the dune began to erode and collapse the dune material would not bury the probe. Bore depth was determined from the record at this probe. The subsequent probes, intended for use in determining the velocity of the leading edge of the bore, were placed 1 m apart, Figure 1.

Dune position was documented by a 35 mm camera before, during and after each experiment. Each photograph of the dune included the profile of the dune face and a 60 cm by 60 cm standard grid to determine scale. Specific volume eroded for a given event is defined as the difference in area between the original dune position and subsequent position at the defined interval of time.

Each experiment proceeded as follows. The pre-test beach and dune profile was surveyed. Instrumentation was calibrated and synchronized. Pre-test dune position was documented on film. Waves were generated which eroded the dune face. The experiment continued until sufficient erosion was recorded, at which time the wave generator was shut down. Post-test profiles and position of the dune were then determined.

Eleven experiments were successfully conducted. The conditions of each test are given in Table 1. Five of the tests were on dune one ($d_{50} = 0.32$) and six on dune two ($d_{50} = 0.23$). The wave height and the wave period were held constant for the duration of an individual test, however, the beach slope and distance from the dune altered with the subsequent erosion and adjustment of the beach. The test wave heights ranged from 0.46 m to 1.02 m while the wave period ranged from 5 secs to 10 secs. Four tests, numbers 6, 8, 7 and 9, conducted on dune two, had the same wave conditions in order to look at the repeatability of results. With each test, the horizontal distance from the mean water level and the dune changed as the dune eroded, however the tank was filled several times to bring the water level back within range. This distance varied between approximately 0.9 m and 3.0 m.

Test #	Wave Period (secs)	Wave Height (m)	Beach Slope	Distance from Dune (m)	Grain Size (mm)
1	7.0	0.86	0.18	2.18	0.32
2	7.0	0.61	0.10	0.92	0.32
3	10.0	0.46	0.12	1.92	0.32

Data Reduction

The experimental data were analyzed for two parameters, specific swash force and specific volume of dune eroded. Earlier work, both small scale laboratory and field work, indicates that a linear relationship exists between these two factors, (Fisher, 1987 and Overton, 1988). Specific swash force is quantified as

$$SF = \rho v^2 d \quad (1)$$

where ρ is the density of the water, v is the leading edge velocity of the swash and d is the depth of swash immediately after impact with the dune. These data were determined from the records of the three capacitance swash gages placed on the beach in front of the dune. A sample of this data is shown in Figure 2. For each time history for an individual swash the following characteristics are observed. One, a dramatic increase in the water depth marks the time that the swash hits the probe. The rule of thumb used was if the depth increased 3 cm in 0.1 seconds it was assumed that a swash was on the beach. Because the probes were buried in the beach approximately 30 cm, the background reading in the absence of a swash indicates the moisture in the sand. Two, the depth of the swash increases and then levels off. This plateau is taken to be the maximum depth of the swash before the backwash moves down the beach and interferes with the signal. Three, there is a subsequent rapid increase and decay in the depth which signifies the

Figure 2. Swash depth versus time at the dune.

passing of the backwash. The depth of swash required in computing the specific force is the difference between the background depth and the depth of the plateau before backwash, Figure 2.

The velocity of the leading edge of the swash is determined by identifying the time at which the bore hits the first and last probes on the beach. An example of this data is given in Figure 3. The characteristic shape of each depth time history is above. The feature required for the determination of velocity is the time the bore hits the probe. From this, the velocity is calculated based on the distance traveled between two swash probes (2 m) and the time of travel, dt .

The force for each bore was calculated using Equation 1. While quantifying the force for an individual bore is possible, it was not always possible to measure the amount eroded due to that loading. Therefore, the summation of the force in a given interval of time versus the volume of dune eroded in the same time

Figure 3. Depth versus time at two probes placed 1 m apart.

interval becomes the quantity evaluated. The duration of an experiment is the time between the first swash that hit the dune and the last slide taken to document the position of the dune.

Specific volume eroded was determined from the before and after profiles of the dune face as recorded on 35 mm film. Pre-test profiles were shot to record the initial dune face position. Then, during the test, photos were shot at a minimum of three minute intervals for the duration of the test. The time of the shot was recorded either in the field book or on the photo by the data back on the camera. This enabled not only before and after quantification of the dune position but the progressive erosion as well. In order to differentiate between beach erosion and dune erosion, the initial face of the dune was used to define the seaward extent of the dune. Regardless of the orientation of the material as the dune failed and the beach readjusted, the volume lost from the dune was determined as material lost landward of the original dune face. Obviously, the numerical value

of the volume eroded could vary with the interpretation of the differentiation of dune and beach material.

In order to quantify the data, the black and white 35 mm film was developed and mounted as slides. These slides were projected and the dune image traced in order to digitize volumes. The reference grid included in each frame was used to determine the scale. The original plan was to record the erosion by photography on both sides of the flume; however, due to equipment malfunction a complete set of data on one side of the flume only was available. Therefore, the numbers used in the analysis represent one side of the dune and the assumption is that the erosion was uniform across the dune face.

Results

The results of the experiments, as quantified by specific force and erosion, are given in Table 2.

TEST NUMBER	SWASH FORCE (kN/m)	VOLUME ERODED (m ³ /m)
1	90.6	0.20
2	195.5	0.39
3	101.3	0.05
4	133.0	0.16
5	233.6	0.54
6	158.4	0.25
7	50.0	0.10
8	187.8	0.29
9	54.0	0.08
10	258.0	0.37
11	93.0	0.23

Table 2. Specific swash force and volume eroded.

The data were analyzed with three objectives in mind. One, were the experiments valid with respect to reproducibility? Two, would the linear relationship established in the earlier work hold up for prototype wave and dune conditions? Three, would grain size effect this relationship?

In order to examine the first question, two experiments were conducted with identical offshore wave conditions. Experiments 6 and 8 were conducted with a 7 second period and a wave height of 0.61 meters. Results from these tests presented in Table 2 indicate that conditions in experiment 8 netted a higher force and a correspondingly higher volume eroded than in experiment 6. This can be accounted for by the duration of the experiment. Experiment 8 was approximately 200 seconds longer than experiment 6. Given the wave period, this represents approximately 28 additional swashes that attacked the dune. Using intermediate photography, it was possible to analyze experiments 6 and 8 at durations of 499 and 509 seconds, respectively. Therefore, the specific force and the specific volume eroded for these intervals were 126.4 kN/m and 123.5 kN/m and 0.190 m³/m and 0.184 m³/m, respectively, representing a 4% difference in results. Likewise for experiments 7 and 9, in which in which the measurable difference between experimental results is a specific force of 4 kN/m and a specific volume eroded of 0.02 m³/m. It is felt that these measures indicate the reproducibility of the experimental conditions and results.

The linearity of the relationship is examined by plotting and analyzing the data. The data were first analyzed as two distinct sets, characterized by sand grain size. Separately, the hypothesis of a linear relationship holds as these data fit with r squared values of 0.74 and 0.86 for sand grain size 0.32 and 0.23 respectively. Given this, the question was asked if the data could support the conclusion that these two lines (relationships) were unique, i.e., that based on these tests that sand grain size had a significant impact on the results. In order to answer this question a test for parallelism was performed. It was hypothesized that the relationships were parallel (and thus the same). Statistically, this hypothesis could not be rejected. This indicated that the data did not support the hypothesis that the force erosion relationship could be distinguished by sand grain size. Thus, Figure 4 presents the data and the line which best fits the data presented as a single dataset. Forcing the line through the origin (no force, no erosion), the slope of the best fit line is 0.00174. This correlates with an r squared value of 0.78.

Conclusions

The results from the large scale laboratory experiments at OSU support the hypothesis that the volume

Figure 4. Specific force versus specific volume eroded.

of dune eroded during swash attack is linearly related to the summation of the swash force during that event.

However, the investigation into the effect of sand grain size is incomplete based on these experiments. While the data do not show that sand grain size is important, several aspects of the experiments which could influence this should be kept in mind. One, this conclusion is based on a limited number of experiments: a dataset of five for dune one and a dataset of six for dune two. Perhaps a more significant factor is that while the sands were distinguished by different d_{50} 's, they both could be classified as fine sands. Thus, the effect of sand grain size on the force erosion relationship cannot be determined at this level.

CHAPTER 188

PRACTICAL APPLICATION OF THE THREE-DIMENSIONAL BEACH EVOLUTION MODEL

Takuzo Shimizu¹, Hitoshi Nodani² and Kosuke Kondo³

ABSTRACT

The long-term bottom topography changes around the entrance of a fishery harbour were simulated by using the three-dimensional beach evolution model. The practical applicability of the model was demonstrated through comparisons with the actual topographical changes. And the equilibrium state of beach evolution due to construction of a coastal structure could be also predicted by repeating the calculation of the wave and current field and that of the bottom topography change.

1. INTRODUCTION

In constructing a harbour on a sandy coast, it is necessary to give careful consideration not only to countermeasures against sand deposition at the entrance of or inside the harbour, but also to the effects on the neighbouring beaches. So, the beach evolution due to construction of a coastal structure must be predicted in order to design a suitable layout plan of breakwaters.

In recent years, a numerical simulation model of beach evolution, so-called a three-dimensional beach evolution model, has been rapidly developed and applied to many practical problems in Japan, since Watanabe et al.(1986) proposed a model and confirmed its validity on the basis of laboratory experimental data. However, quantitative verification of its applicability to the actual field has not been thoroughly discussed.

In this study, we aimed to discuss quantitatively, through comparisons with field data, the applicability of the model to the long-term topographical changes around Iioika Fishery Harbour, Chiba, Japan.

2. OUTLINE OF THE MODEL

The numerical simulation model used in this study is fundamentally similar to the model proposed by Watanabe et al. (1986). Figure 1 shows the calculation flow of the model. The total model consists of three submodels for calculation of waves, nearshore currents and beach changes. At the first step, the wave field is computed under a certain incident wave condition and the initial bottom topography in the study area. Next, the nearshore current field is computed from the spatial distribution of radiation stresses which is estimated by using the results of the wave field computation. Finally, the sediment transport rates are computed at the local points from the wave-current conditions calculated in advance, and then the three-dimensional bottom topography change is computed by solving the equation of sediment mass conservation.

The incident wave conditions change daily and the change in bottom topography produce changes in the nearshore waves and currents. So, the short time-interval iterations are needed in the computations of waves, currents and topography changes. In practice, the iterations using daily wave conditions are not possible, because the computation time of each model is not sufficiently short. But only one step of the iteration is useful to predict the tendency of the spatial distribution of bottom topography change under a representative wave condition. This way of application of the model is effective to discuss relatively the merits or demerits of layout of breakwaters.

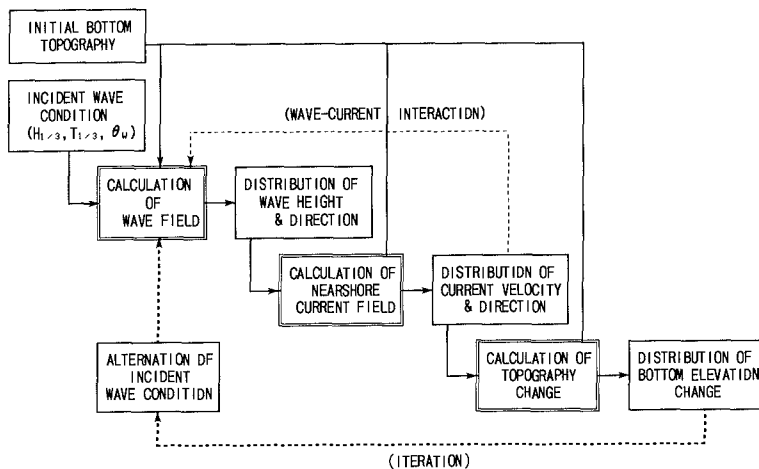

Fig.1 Flow chart of computation

On the other hand, in order to quantitatively predict the long-term beach evolution due to construction of the coastal structures, the interaction between the wave and current field and the bottom topography change cannot be ignored and several iterations are needed. So, we attempted to reduce the number of iterations by using a simply modelled series of wave conditions.

Table 1 shows the calculation methods of waves, currents and beach changes. The wave field is computed using the energy flux equation as described with the directional wave spectrum presented by Karlsson(1969). The wave heights in the surf zone are estimated by the model of random wave breaking proposed by Goda(1975). This equation is applicable only for wave shoaling and refraction, and is not for wave diffraction in a strict sense. Recently, more accurate equations for combined refraction and diffraction such as the mild-slope equation and its approximate parabolic-type equations are often adopted. Watanabe and Maruyama(1986) also presented the time-dependent mild-slope equations. These are applicable to calculate all kinds of wave transformation including wave breaking as well as shoaling, refraction and diffraction. But the applicability of the computation models based on these equations are generally restricted to the linear regular wave. The reason for using the method based on the energy flux equation is because treatment of random waves is important for practical applications and because the computing time of the actual random wave field in a wide region is relatively short.

In computing the nearshore current field, the spatial distributions of radiation stresses were estimated as regular waves; the wave energy and the principal direction at the local point were estimated from the directional wave spectrum calculated in the wave field computation, and the group velocity and the wave celerity were estimated by using the significant wave period.

As the momentum exchange coefficient, the expression proposed by Longuet-Higgins(1970) was adopted. The mixing length is generally set to be the distance from the shoreline, but in this study, it was set to be the shortest length either from the breakwater or from the shoreline. Then, the nearshore current field including circulation near the breakwater could be reproduced better.

In calculating bottom elevation change, we employed the formula of local sediment transport rate in a wave-current coexistent field proposed by Watanabe et al.(1986). This model is simple and practical. The sediment transport rate is divided into the transport due

to mean currents and that due to waves. The cross-shore sediment transport rate due to waves is assumed to be important to the short-term beach deformation, and not so important to the long-term change. In many cases, sediment transport due to nearshore currents is the dominant feature of long-term change caused by construction of a coastal structure. So, in this study, only the sediment transport due to nearshore currents were taken into account. The local sediment transport rates were evaluated using the quantities corresponding to the significant wave and the principal direction.

Table 1 Calculation methods of three submodels

CALCULATION OF WAVE FIELD
(REFRACTION) Wave energy flux equation (Karlsson, 1969) (BREAKING) Goda's model (1975) (DIFFRACTION) Energy flux transmitted from the breakwater is zero
CALCULATION OF NEARSHORE CURRENT FIELD
Vertically integrated equations of mean momentum and of continuity
CALCULATION OF BOTTOM ELEVATION CHANGE
Equation of sediment mass conservation [Local sediment transport rate formula proposed by Watanabe et al. (1986)] Sediment transport due to mean currents q_c : $q_c = A_c (\tau - \tau_c) u_c / \rho g$ where A_c : a non-dimensional coefficient, τ : the maximum value of the bottom shear stress in a wave and current coexistent field, τ_c : the critical shear stress for the onset of sediment movement, u_c : the mean current velocity.

3. PRACTICAL APPLICATION OF THE MODEL

3.1 TOPOGRAPHY CHANGES AROUND IIOKA FISHERY HARBOUR

Figure 2 shows the location map of Iioka Fishery Harbour. Iioka Fishery Harbour faces directly to the Pacific Ocean and is located at the northeastern end of the Kujyukuri Coast. This coast is one of the most famous sandy beaches with the continuous coastline of 55km and bounded at both ends by eroding sea cliffs. The northern sea cliff, Byobugaura, stretches northeastward 10km long and is bordered immediately on the north by Iioka Fishery Harbour. And the Byobugaura Cliff has supplied considerable amounts of sediment to the Kujyukuri Coast.

Judging from an aerial photograph taken in February of 1986 shown in Photo 1, it was a little stormy day with the significant wave height of about 2m. Looking at the crestlines of waves, we will find that the incident wave attacks the harbour much obliquely and then the longshore drift to the southwest is predominant.

As Iioka Fishery Harbour is located at the passing point of longshore drift from the Byobugaura Cliff to the Kujyukuri Coast, a large portion of longshore sand drift has been obstructed by the harbour. Consequently, not only harbour shoaling but also beach erosion of the neighbouring beaches have occurred.

Figure 3 shows the bottom topography change around the harbour during approximately one and half years from June of 1986 to November of 1987. The upper figure shows the comparison of bottom contours and the lower shows the distribution of depth changes. Considerable accretion took place along the breakwater on the updrift side of the harbour, especially around the entrance. On the other hand, erosion took place on the downdrift side. The mechanism of these beach deformations can be explained by the following two kinds of nearshore currents. One is the longshore current developing westward on the eastern side of the harbour, and another is the clock-wise nearshore circulation in the sheltered area of the breakwater on the western side. This is a typical case of beach deformation in constructing a structure on a sandy coast with considerable amounts of longshore drift.

3.2 VERIFICATION OF THE WAVE AND CURRENT COMPUTATIONS

In order to verify the wave and current field computations, the field observation was carried out around Iioka Fishery Harbour over a period of approximately one month from September to November in

Fig.2 Location map of investigation site

Photo 1 Aerial photograph (February, 1986)

Fig.3 Bottom topography change around lioka Fishery Harbour(1986.6-1987.10)

1987. Figure 4 shows the measuring points around the harbour where wave directions and nearshore currents were observed using electro-magnetic current meters. Incident wave conditions such as wave heights, periods and directions were also measured using a combination of an ultra-sonic wave gauge and an electro-magnetic current meter at a water depth of 15m offshore in front of the harbour. During the observation, storm waves greater than 2m in significant wave height were frequently encountered. Therefore, we could collect much data on the large waves caused by typhoons.

Figure 4 also shows the computation area which is about 4km long in the alongshore direction and about 6km long in cross-shore direction. Three cases of wave height conditions were treated, that is, the significant wave height of 2m with its period of 8s, 3m with 10s and 4m with 12s. With respect to these three cases of wave height conditions, three wave directions of ESE, SE and SSE were considered. And totally nine cases of computations were performed. According to these nine cases of calculations, measured data of wave directions and mean currents were divided into nine classes in total. And the mean values of wave directions and mean currents at each point in every class were regarded as the measured values and compared with the results of the computations.

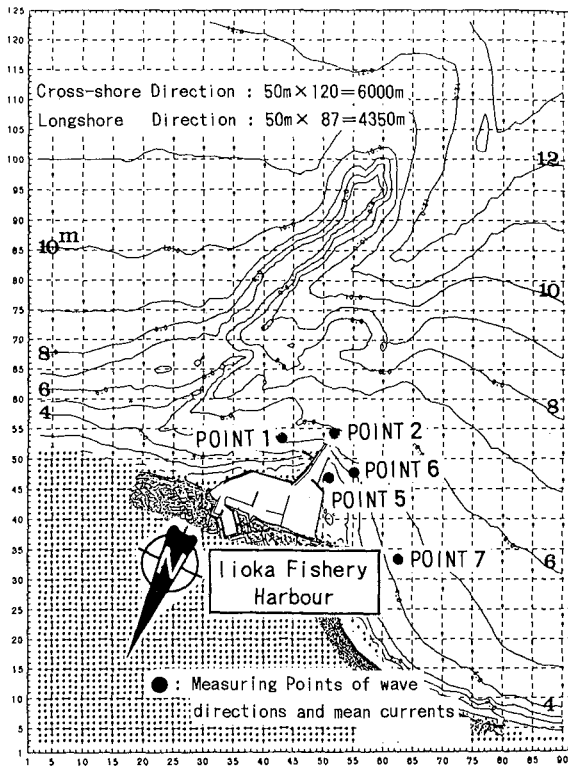

Fig.4 Location of the current meters and the area of numerical simulation

Figure 5 shows comparisons between the measured and the computed principal wave directions. As the wave propagating directions are scarcely affected by the incident wave periods in the range of 8 to 12 seconds, the results of computations of 3m in wave height with 10 seconds in wave period were used. The computed results show fairly good agreement with the observed.

Figure 6 shows the examples of the nearshore current computations under the wave direction of ESE. The measured vectors are also shown in this figure and expressed by bold arrows in the different scale from the calculated vectors. The longshore current develops westward along the eastern breakwater and passes the entrance of the harbour quickly. And the clock-wise circulation occurs remarkably around the western side of the harbour entrance. The observed dominant current pattern is reproduced satisfactorily by the numerical simulation.

Figure 7 shows comparisons between measured and computed absolute values and directions of mean current vectors. The computed results are compared with only reliable data which satisfy such conditions that the current velocity is beyond 5 cm/s and the current direction is stable. There exists a little disagreement between the measured and the calculated. However, in spite of assuming the quasi-stationary wave and current field and neglecting the wave-current interaction, the computed results agree well with the measurements, especially at the POINT 2 in front of the harbour entrance.

Fig.5 Comparison between the measured and the calculated principal wave direction

Fig. 7 Comparison between the measured and the calculated velocities and directions of the nearshore current

3.3 REPRODUCTION OF THE LONG-TERM BEACH EVOLUTION

We tried to reproduce quantitatively the long-term topography changes around Ilioka Fishery Harbour during approximately one and half years shown in Figure 3. The numerical simulation was performed by repeating the calculation of the wave-current field and that of the beach changes alternatively. In order to shorten the computation time, we attempted to use the three modelled wave conditions. These have one, two, or four series of severe waves for the investigation period of one and half years (peak significant wave height is 4m). The occurrence frequency of severe waves was determined on the basis of the observed wave climate data, and each modelled wave condition has the same occurrence frequency in total. The wave conditions with the significant wave height below 2m were not taken into account, because the longshore current could not reach the entrance of the harbour and little accretion took place under such a calm wave condition.

Figure 8 shows the calculated time series of mean depth variations in the four areas around the harbour entrance. In every case, the calculated depth variations after one and half years (130 days of severe waves) show accretion of about 1.0m in Area 1 and 2, and erosion of about 0.5m in Area 3 and 4. These results agreed quantitatively with the actual topographical changes.

Investigating more precisely the results of case 2, in Area 1 along the breakwater on the updrift side, rapid accretion takes place during the first severe wave series. And the depth change reaches an equilibrium state after the first severe wave series. In Area 2 at the harbour entrance, rapid accretion takes place after accretion advanced in Area 1, and the depth change then reaches an equilibrium after the second severe wave series. On the other hand, in case 1, an equilibrium state is not reached in Area 2 after only one series of severe waves.

Figure 9 shows comparisons between the measured and the computed bottom elevation changes. Big symbols indicate the average in each area and small symbols indicate the values at each calculation grid. Although there exist a little disagreement at the local points, the averaged value of calculation in each area shows good agreement with that of observation. In spite of greatly simplifying the wave conditions, it is found that the long-term beach evolution around the harbour entrance and its consequent bottom topography change can be reasonably simulated by using a model with two or more series of severe waves.

4. CONCLUSIONS

The bottom topography change around a fishery harbour during one and half years were simulated by using the three-dimensional beach evolution model under the simplified wave condition. It is concluded that the model has the required accuracy for practical use and that the equilibrium state of topography change can be also predicted.

ACKNOWLEDGMENTS

We would like to express our thanks to Dr. Yamamoto of National Research Institute of Fisheries Engineering and Mr. Nishi of the Japanese Institute of Technology on Fishing Ports and Communities (now, Fisheries Agency) for their advice and useful discussion.

CHAPTER 189

SAND TRANSPORT RATE UNDER WAVE-CURRENT ACTION

Akira Watanabe¹ and Masahiko Isobe²

Abstract

Laboratory experiments were conducted to obtain data on sand transport processes and transport rates under combined action of waves and currents using an oscillatory-steady flow tank. The sand transport processes were classified into seven types. Four kinds of non-dimensional flow power parameters were defined, and their linear relations with the non-dimensional net transport rates were found for all the transport types.

1. Introduction

Considerable efforts have been devoted in recent years to developing mathematical models of beach evolution, which will be generally classified into three groups: "shoreline change models (e.g. Hanson et al., 1989)", "beach profile change models (e.g. Larson et al., 1989; Watanabe & Dibajnia, 1989), and "beach topography change models (e.g. Watanabe et al., 1986; Vriend & Ribberink, 1989)". Topography change models generally require formulas for estimating local sediment transport rates under combined action of waves and currents. The model developed by Watanabe et al. (1986) employs simple but useful sediment transport formulas based on the power (or energetics) model concept, and has been applied to various engineering practice in Japan (e.g. Shimizu et al., 1990). However we have not yet established highly-reliable formulas to be built in topography change models for accurately evaluating net rates of sediment transport under general conditions of waves and currents.

Purposes of the present study are to obtain fundamental experimental data on net rates of sand transport due to combined action of waves (oscillatory flow) and currents (steady flow) under a simplified condition where the directions of oscillatory and steady flows are parallel, and to investigate relations between the

¹ Professor, Dept. of Civil Eng., Univ. of Tokyo, Bunkyo-ku, Tokyo, 113 Japan.

² Associate Professor, ditto.

net transport rates and relevant hydraulic parameters on the basis of the power model concept.

2. Experimental Procedure and Results

2.1 Experimental procedure

The experiments were conducted using an oscillatory-steady flow tank, in which a steady flow was superimposed in parallel on an oscillatory flow with an arbitrary time variation of velocity as shown in Fig. 1. The time histories of the oscillatory flow velocity were sinusoidal in some cases, but in most case they were non-sinusoidal and asymmetric between positive and negative velocities as illustrated in the figure. The test section was 2 m in length, 24 cm in width and 31 cm in height.

Fig. 1 Definition sketch for combined-oscillatory-steady flow.

The oscillatory flow conditions were changed for the period, $T = 3$ and 6 s, the total amplitude of velocity u_T from 54 to 86 cm/s, and the velocity asymmetry defined by the ratio of the positive (or onshore) velocity amplitude u_C to the total amplitude u_T , for $u_C/u_T = 0.5$ (sinusoidal oscillation), and for 0.6 and 0.7 . The steady flow velocity U was also changed between -30 cm/s and $+25$ cm/s.

Two kinds of sand with the median diameter $D = 0.18$ and 0.87 mm were used. For each condition, 1) first the sand bed was made even, 2) next oscillatory-steady flow was generated for a time duration of $600T$, 3) then bottom profiles in dynamical equilibrium were measured, 4) again the same flow was generated for a period of 10 to 60 s, and 5) lastly final bed profiles and volumes of the sand trapped at both ends of the test section were measured. Bed profiles were measured along ten cross-shore lines with electric resistance-type bed profilers. Net rate of sand transport was evaluated at the mid-cross-section of the test section from the bed profile changes and trapped sand volumes.

Sand ripples were formed in all the cases; two-dimensional ripples with long parallel crests in relatively weak flows and three-dimensional ripples with ladder-shaped short crests in intensive flows. The sand movement was recorded on a VTR. For all the flow conditions, the velocity was measured with an LDV above a fixed flat bed. The velocities measured at an elevation 10 cm above the bed will be used in the following data analysis.

2.2 Net transport rate and sand movement types

Let us define a non-dimensional net sand transport rate Φ by

$$\Phi = \frac{(1 - \epsilon_v) q_{net}}{w_0 D} \tag{1}$$

where q_{net} is the volumetric net transport rate per unit width per unit time, and ϵ_v , w_0 and D are the porosity, fall velocity and median diameter of the sand, respectively. For the fine sand ($D = 0.18$ mm), $\epsilon_v = 0.44$ and $w_0 = 2.1$ cm/s, whereas for the coarse sand ($D = 0.87$ mm), $\epsilon_v = 0.47$ and $w_0 = 8.2$ cm/s. The direction of the net transport is taken positively into that of the positive (onshore) velocity.

Figure 2 shows the relations between the non-dimensional transport rate Φ and the steady flow velocity U for each oscillatory flow condition for the fine sand. It is seen that the net transport rates are mostly negative, which corresponds to the offshore transport. For example, for the oscillatory flow condition indicated by the inverted triangle symbols, the net transport rates took the largest negative magnitude when there was no steady flow, decreasing in magnitude with the increase in the steady flow velocity U , either positive or negative, and it became positive only for the large positive U .

Fig. 2 Non-dimensional net transport rate Φ vs. steady flow velocity U for fine sand.

The relations between Φ and U for the coarse sand are shown in Figure 3. For the coarse sand, the net transport rates Φ are mostly positive, namely the onshore transport was predominant even for the negative steady flow velocity U with moderate magnitude.

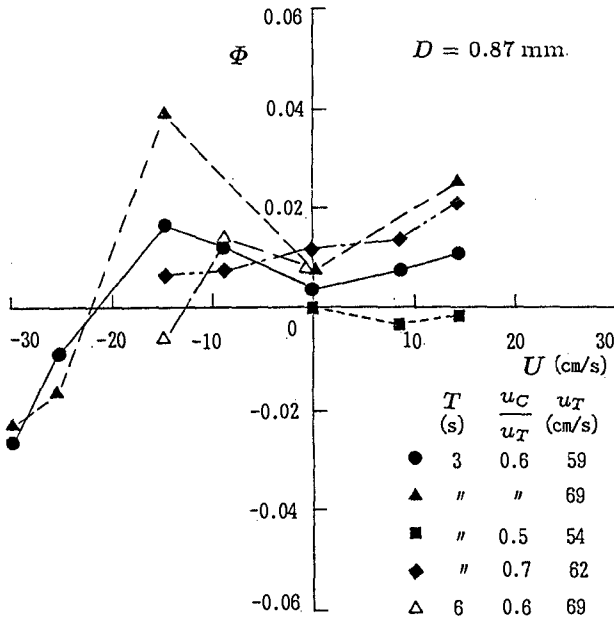

Fig. 3 Non-dimensional net transport rate Φ vs. steady flow velocity U for coarse sand.

These figures indicate that the dependency of the net transport rate on the steady flow velocity and on the oscillatory flow conditions is not simple or monotonic at all. Their interrelations appear too complicated to express by a single general formula.

Now, according to the observation of sand movement in the experiments, it has been concluded that the sand transport processes in the present experiments will be classified into the following seven types.

The first four types are for the fine sand. The sand transport process of **Type I** was observed when $T = 3$ s and $|U| < 20$ cm/s. For this type, the sand was set in suspension by lee-vortices formed during positive velocity, and was transported into the offshore direction during negative velocity, whereas the sand suspended during negative velocity was transported shoreward during positive velocity. Because of the asymmetric velocity change, the net transport was into the offshore (negative) direction (see Fig. 4). **Type II** appeared for the cases of

strong onshore steady flow ($T = 3\text{ s}$, $U > 20\text{ cm/s}$), and **Type III** took place for those of strong offshore flow ($T = 3\text{ s}$, $U < 20\text{ cm/s}$). For **Type II**, the sand suspended during the large onshore flow velocity was transported into the shoreward direction (Fig. 5), whereas for **Type III**, the suspended sand was transported into the offshore direction (Fig. 6). **Type IV** was observed when $T = 6\text{ s}$, namely, the oscillatory flow was of relatively long period. For this type, the sand was suspended up to an elevation higher than in the previous types, and was transported mainly by the steady flow. Hence the direction of the net transport agreed with that of the steady flow (Fig. 7).

Fig. 4 Transport process of Type I.

Fig. 5 Transport process of Type II.

Fig. 6 Transport process of Type III.

Fig. 7 Sand transport process of Type IV.

The remaining three types are for the coarse sand. **Type V** occurred when $U \geq 0$. For this type, bedload transport was predominant, and the sand was transported into the onshore direction by both the oscillatory flow and the steady flow (Fig. 8). **Type VI** took place when the steady flow was strong and in the offshore direction ($U < -20$ cm/s). Again bedload transport was predominant, and the sand was transported into the offshore direction by the very strong offshore flow (Fig. 9). The last type, **Type VII**, appeared when -20 cm/s $< U < 0$. For this type, the sand suspended during negative velocity as well as bedload during positive velocity contributed to the onshore net transport (Fig. 10).

Fig. 8 Sand transport process of Type V.

Fig. 9 Sand transport process of Type VI.

Fig. 10 Sand transport process of Type VII.

3. Net Transport Rate and Flow Power

We will now attempt to relate the net transport rate with the flow condition for each type applying the power model concept. For this let us first define the excursion lengths d_{0+} and d_{0-} and the Shields numbers Ψ_+ and Ψ_- for the positive velocity period T_+ and the negative velocity period T_- , respectively, (see Fig. 11) by

$$d_{0+} = \int_{T_+} u dt, \quad d_{0-} = - \int_{T_-} u dt \tag{2}$$

$$\Psi_+ = \frac{f_{cw+} u_C^2}{2sgD}, \quad \Psi_- = \frac{f_{cw-} (u_T - u_C)^2}{2sgD} \tag{3}$$

where s ($= \rho_s/\rho - 1$) is the immersed specific gravity of the sand, and f_{cw+} and f_{cw-} are the friction factors in a coexistent wave-current field and are determined from the hypothetical sinusoidal oscillation velocities and the steady flow velocity (Fig. 11) with the frictional law proposed by Tanaka and Shuto (1981). The median diameter D of the sand grains was used as the equivalent roughness k_s ($= 30z_0$) in spite of the presence of sand ripples.

Fig. 11 Definition sketch for computing excursion lengths and Shields numbers.

With the consideration of the transport processes for the above seven types, let us further define four kinds of non-dimensional flow powers, P_I , P_{II} , P_{III} and P_{IV} , and examine their correlations with the non-dimensional transport rate Φ .

a) Type I

On the basis of the power model concept, we assume that the immersed-weight of the sand set in suspension per unit horizontal area during the positive velocity period T_+ is proportional to the excess shear stress $(\tau_+ - \tau_c)$ times (T_+/T) , where $\tau_+ = \rho s g D \Psi_+$ is the amplitude of the bed shear stress during T_+ , and τ_c the critical shear stress for the onset of the general movement. We further assume that the offshore displacement of this suspended sand during T_- is proportional to the excursion length d_{0-} . Then the resultant offshore transport rate q_- averaged over the period T is to be proportional to a kind of flow power $(\tau_+ - \tau_c) (T_+/T) (d_{0-}/T)$. In a similar way, the onshore transport rate q_+ will be in proportion to $(\tau_- - \tau_c) (T_-/T) (d_{0+}/T)$, and then the net transport rate q_{net} will be given by the difference between q_+ and q_- .

Hence if we define a non-dimensional flow power P_I by

$$P_I = (\Psi_- - \Psi_C) \frac{T_-}{T} \frac{d_{0+}}{w_0 T} - (\Psi_+ - \Psi_C) \frac{T_+}{T} \frac{d_{0-}}{w_0 T} \tag{4}$$

where Ψ_C is the critical Shields number, then we can expect the non-dimensional net transport rate Φ to be proportional to P_I .

Figure 12 shows the relation between Φ and P_I for Type I. Since this type includes the transport of the fine sand only, the critical Shields number Ψ_C was set as equal to 0.11 (see Watanabe et al., 1981). Although the scatter of the plotted data is not small, it is clear that Φ and P_I have a positive correlation, which is expressed approximately by the following linear relation:

$$\Phi = 1.5 P_I \tag{5}$$

Fig. 12 Net transport rate Φ vs. flow power P_I (Type I).

b) Types II, III, V and VI

In the transport processes of these four types, just contrary to Type I, the sand set in motion by the onshore flow was transported into the onshore direction, and the one agitated by the offshore flow was carried toward the offshore. Hence we define a non-dimensional flow power P_{II} by

$$P_{II} = (\Psi_+ - \Psi_C) \frac{T_+}{T} \frac{d_{0+}}{w_0 T} - (\Psi_- - \Psi_C) \frac{T_-}{T} \frac{d_{0-}}{w_0 T} \tag{6}$$

According to Watanabe et al. (1981), a value of Ψ_C for the coarse sand (Types V and VI) should be about 0.06, but it was changed to 0.04, because noticeable sand movement was observed even when $\Psi_C < 0.06$ in the experiments.

The results shown in Fig. 13 indicate that, although the data for Type II show much scatter and are deviated from those for the other types, an overall relation is expressed fairly well by

$$\Phi = 0.15 P_{II} \tag{7}$$

Fig. 13 Net transport rate Φ vs. flow power P_{II} (Types II, III, IV & V).

c) Type VII

For this type, both the bedload during the positive velocity period and the sand suspended during the negative velocity period contributed to the onshore net transport. Therefore the combination of the onshore components of P_I and P_{II} will be appropriate as an effective flow power P_{III} for Type VII, which is defined by

$$P_{III} = (\Psi_- - \Psi_C) \frac{T_-}{T} \frac{d_{0+}}{w_0 T} + 0.1 (\Psi_+ - \Psi_C) \frac{T_+}{T} \frac{d_{0+}}{w_0 T} \quad (8)$$

where the factor of 0.1 in the second term was determined by considering the proportionality coefficients in Eqs. 5 and 7.

Figure 14 shows the relation of Φ with P_{III} , which is well approximated by

$$\Phi = 2.7 P_{III} \quad (9)$$

It should be noted that the sand ripples were two-dimensional in all the cases of this type.

Fig. 14 Net transport rate Φ vs. flow power P_{III} (Type VII).

d) Type IV

For this type, the suspended sand was transported mainly by the steady flow, and the direction of the net transport changed with that of the steady flow. (The sand ripples were three-dimensional.) Hence the net transport rate will be given by the summation of the component due to the steady flow and that due to the oscillatory flow as in the transport rate formula proposed by Watanabe et al. (1986). Let us therefore define a non-dimensional flow power P_{IV} for this type by

$$P_{IV} = (\bar{\Psi}_C - \Psi_C) \frac{6U - u_T/2}{w_0} \quad (10)$$

where $\bar{\Psi}_C$ is the representative time-mean Shields number defined by

$$\bar{\Psi}_C = \frac{\Psi_+ T_+ + \Psi_- T_-}{T} \quad (11)$$

The relation between Φ and P_{IV} for this type is shown in Fig. 15, and is approximately expressed by

$$\Phi = 0.08 P_{IV} \quad (12)$$

Fig. 15 Net transport rate Φ vs. flow power P_{IV} (Type IV).

4. Concluding Remarks

Experimental data were obtained on the net sand transport rate in combined-parallel-oscillatory-steady flows. The sand transport processes in the experiments were classified into seven types. Considering typical features of the transport process of each type, we defined four kinds of non-dimensional flow power, and found that the net transport rates under combined action of waves (oscillatory flow) and currents (steady flow) were well correlated to the relevant flow powers. It should be mentioned that the relations between the non-dimensional net transport rates and flow powers obtained in this study don't involve explicitly the size and shape of sand ripples in spite of their presence.

The formulas presented in this paper cannot be directly built in mathematical models; we need to accumulate more experimental data and to study more detailed sand transport processes. However these results would provide us yet with very useful information such as for the establishment of generalized sediment transport rate formulas, and for the development of numerical simulation models of sand grain motion over a rippled bed under waves and currents, on which our group is now working.

This paper is a part of the outcomes of our study supported by National Science Foundation of the Ministry of Education, Science and Culture, to which we would like to express our thanks. We also appreciate the efforts of Mr. M. Sakinada in conducting the experiments.

CHAPTER 190
DYNAMIC NUMERICAL MODELS FOR SAND WAVES
AND PIPELINE SELF-BURIAL

by

Carsten Staub ¹⁾ and Romke Bijker ²⁾

ABSTRACT

Two independent numerical models for prediction of sand wave heights and migration rates and for calculation of pipeline/cable seabed interaction have been developed. Both models are fully dynamic and respond to detailed and comprehensive input describing environmental conditions, seabed and soil characteristics and pipe/cable data. The models are based on state-of-the-art knowledge and include theoretical developments, model tests, field data and advanced sediment transport formulations. The models have been validated and calibrated against field data of sand waves and buried pipelines.

1. SAND WAVE MODEL

1.1 Introduction

Erodible sea beds will not usually remain plane when exposed to changing environmental conditions. A variety of different bed forms may emerge and continuously modify and adjust in response to varying wave/current conditions. The bed forms and their response to environmental conditions are also highly dependent on the bed material. Dimensions of wave/current generated bed forms observed in the offshore environment vary considerably from small ripples of a few centimetres height to the large tidal banks of heights up to 50 metres and many kilometres long.

1) Carsten Staub, M.Sc., Chief Engineer, Subsea Technology Division, Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark.

2) Romke Bijker, M.Sc., Manager, Offshore Section, Delft Hydraulics, Voorsterweg 28, P.O. Box 152, NL-8300 AD Emmeloord, The Netherlands.

The most important bed form in relation to marine pipelines is the offshore sand wave. Sand waves can at the same time be large enough and migrate fast enough to cause bed level changes, which are significant compared with the diameter of the pipeline. Furthermore, the sand wave is a widespread form which is observed in a large number of tidal areas but may also occur in deep water where density differences are responsible for relatively high current velocities near the bed.

1.2 Description of the model

The numerical model for sand waves is based on state-of-the-art theories for sand waves and for sediment transport in combinations of current and waves.

Basic theory

Deigaard and Fredsøe (1986) combined a theory for fully developed sand dunes in rivers by Fredsøe (1982) with a detailed model for sediment transport in current and waves developed by Fredsøe et al. (1985). The result was a calculation model for equilibrium sand waves in an offshore environment with waves and a unidirectional current perpendicular to the sand wave front.

This model was taken as a basis in the development of the present sand wave model.

The basic elements of the theory are:

- continuity equation for sediment
- constant form sand waves assumed
- sediment transport model
- description of deposition "downstream" of sand wave crest.

The equations to determine migration rate and height of equilibrium sand waves thus become (see e.g. Deigaard and Fredsøe, 1986)

$$a = - \frac{1}{1-n} \frac{dq}{dD} \quad (1)$$

$$A = \frac{q_D}{(1-n)a} \quad (2)$$

$$q_D = q_B + q_S (1 - \exp(-6A/L_S)) \quad (3)$$

The following notation is used:

- a : Sand wave migration rate
- A : Sand wave height
- q_D : The part of the sediment transport which is deposited downstream of the sand wave crest
- n : Porosity of the sea bed
- D : Water depth at sand wave crest
- q : Total sediment transport rate at sand wave crest
- q_B : Bed transport rate at sand wave crest
- q_S : Suspended transport rate at sand wave crest
- L_S : Length scale for the lag of the suspended sediment

The length scale of the lag of the suspended sediment, L_S , can be estimated from the concentration profile as:

$$L_S = \frac{U_C \cdot y_C}{w_s} \quad (4)$$

where y_C is the height of the centroid of the concentration profile above sand wave crest level, U_C is the flow velocity at the height, y_C , and w_s is the settling velocity of the suspended sediment.

A key assumption for the prediction of sand wave height is that the deposition of sediment at the front, and thus the migration rate of the sand wave, can be calculated directly on the basis of the sediment transport at the crest of the sand wave. The basis for this assumption is that flow separation occurs at the (instantaneous) sand wave front, leading to a vanishing sediment transport capacity in the separation zone. Thereby all the bed load and some of the suspended load which passes the sand wave crest will be deposited downstream of the crest. The deposition rate described by (3) assumes that the separation zone has a length of 6 times the sand wave height. Note that (3) has been slightly modified compared with the corresponding expression by Deigaard and Fredsøe (1986).

The model of Deigaard and Fredsøe (1986) has been extended to include:

- non-equilibrium sand waves
- arbitrary angles between waves and currents and sand waves (including reversing tidal currents)

- effects of short-crested sand waves
- effects of high water waves
- effects of wave generated ripples

The extensions are further described below.

Sand_wave_length

The sand wave length, λ , is in the model determined by a purely empirical relation

$$\lambda = 64A \quad (5)$$

The factor 64 was determined from field observations with significant variation in length/height ratio.

In pure steady current experiments show that the bed shear stress after a step attains a local maximum 16 times the step height downstream of the step indicating that for situations with dominant bed load transport the dune length would be 16 times the dune height. Presence of suspended load would cause the dunes to become longer but for the current and depth conditions prevailing in offshore areas this effect would be very limited.

There is presently no satisfactory explanation of why offshore sand waves are approx. 4 times longer than dunes of the same height in rivers.

Effect_of_high_waves

Flow separation downstream of the sand wave crest is essential for the formation of sand waves. Deigaard and Fredsøe (1986) described briefly the separation suppression effect of relatively high water waves. When waves are present together with a current, the tendency towards separation of the mean current is reduced. A crude criterion for suppression of flow separation was taken to be that the oscillating part of the shear velocity, U_{fw} , associated with the wave motion is larger than 7 times the shear velocity, U_{fo} , characterizing the mean current in the wave boundary layer.

In the present model the above criterion has been applied to form a correction factor by which the equilibrium sand wave height is reduced to zero (smoothly) when U_{fw} exceeds 7 times U_{fo} . The effect of waves on flow separation has been described in more details recently by Deigaard (1990).

Non-equilibrium sand waves

The wave and current conditions are normally highly variable, and it is therefore of interest to predict the behaviour of sand waves that are not in equilibrium under the actual hydraulic conditions. The adaptation time of a sand wave will depend on the sediment transport rate and on the volumes of the equilibrium versus the actual sand waves, i.e. the amount of sediment that has to be shifted in order to form the equilibrium sand wave.

Fredsøe (1979) and (1981) presented a model for the change of dune dimensions subject to a change in hydraulic conditions. The rate of change in dune height is found assuming a given shear stress distribution evaluated on the basis of an idealized triangular dune shape. A simple expression for the rate of change of dune height is readily derived from Fredsøe's formulas

$$\frac{dA}{dt} = \frac{a}{\lambda} (A_{eq} - A) \quad (6)$$

where

- A : Actual sand wave height
- A_{eq} : Instantaneous equilibrium sand wave height
- a_{eq} : Actual sand wave migration rate
- λ : Actual sand wave length
- t : Time

The above equation (6) has been applied in the present model to calculate the transient behaviour of the sand waves.

Directions of waves and current

The Sand Wave Model has been developed to deal with arbitrary directions of both waves and currents relative to the direction of the sand wave crest. The migration rate of a sand wave is calculated in a direction perpendicular to the sand wave crest. When the direction of the total sediment transport forms an oblique angle with the sand wave crest, only the sediment transport component perpendicular to the crest is taken into account in the calculation of sand wave migration and development.

It is assumed that long-crested sand waves will not affect the direction of a current approaching at an oblique angle i.e. streamline refraction has not been taken into account in the model.

Tidal flow conditions with reversing flow direction characterize many sand wave areas. A reversing tidal current may significantly change the shape of the sand wave crest region during a tidal cycle and thereby affect the migration and development of the sand wave. No effects of the sand wave profile shape have, however, been included in the model.

Effect of short-crested sand waves

Field data show some systematic differences in sand wave morphology from one area to another. One of the most pronounced is the difference in relative crest length. The present model is not able to explain this difference, but the effect of short-crestedness on sand wave development has been included in the model in a simplified way as described in the following:

If the sand wave crest lengths are not large compared to the sand wave length then the three-dimensional structure of the bed will result in a three-dimensional flow pattern. There will be a decrease in the water discharge over the crest peaks. The decrease is partly due to the energy loss in the separated flow downstream of the crest and partly due to the decreased water depth at the crest of the sand wave.

Fredsøe (1989) calculated analytically the equilibrium height of sand waves as a function of their length/width ratio, λ/w . He assumed a double periodic bed topography, did not include wave effects and found that a short crested sand wave will have a larger equilibrium height, A_{3D} , than the height, A_{2D} , of a sand wave with infinitely long crest.

$$A_{3D} = A_{2D} (1 + (\lambda/w)^2) \quad (7)$$

Eq. (7) has been included in the present sand wave model as a correction applied to the equilibrium sand wave height.

Effect of wave generated ripples

The detailed sediment transport model originally developed by Fredsøe et al. (1985) is applied as an important submodule for the Sand Wave Model. This transport model was developed for plane sea bed conditions i.e. without wave generated ripples. This situation will occur during storm conditions which are very important in relation to

sand wave development and migration. More calm wave conditions where ripples are present are, however, also important. The sediment transport module has therefore been further developed to handle both situations without and with wave generated ripples. The modifications to the sediment transport model include descriptions of the processes involved as and are briefly outlined as follows:

- estimates of ripple dimensions as function of wave-current conditions.
- estimates of contribution to eddy viscosity due to ripples.
- estimate of mean concentration at the level of the ripple crests.
- estimate of the roughness due to the influence of ripples on the current.

The ripple dimensions, the eddy viscosity and the mean concentration are calculated from empirical formulas presented by Nielsen (1979). The ripple roughness is calculated by a formula of Raudkivi (1988).

1.3 Example of calculation

In a simulation of sand wave development the equilibrium sand wave height is first calculated i.e. the height that would exist after a long time with the same wave/current conditions. Sand waves will form for a certain range of current velocities and the height may theoretically be up to about 30 percent of the mean water depth. Wave action generally tend to increase the sand wave height (except when they totally dominate the current) and particularly when the waves travel perpendicular to the sand wave crests.

Fig. 1 shows part of the input and the output time series for a 10 days Sand Wave Model simulation. The example which is taken from a location in the Southern North Sea illustrates the effect a stormy period has on sand wave development and migration in an area dominated by tidal currents. Directions of waves and currents which are also part of the input are not shown in this figure.

Fig. 1 Sand wave development and migration during a 10 days period with a storm. Example from Southern North Sea. Water depth: 35 m, Sediment: $d_{50}=0.35$ mm.

2. SELF-BURIAL MODEL

2.1 Introduction

Self-burial of submarine pipelines has been subject to study since 1978. At that time, a sudden, and unexpected, self-burial of a just-laid pipeline triggered extensive research programs.

The Dutch authorities almost immediately recognized the potential of self-burial as a cost-effective burial method and approved a large number of pipelines to become self-buried. As result of this attitude, significant experience with self-burial of submarine pipelines has been gained. Fig. 2 shows the self-buried pipelines in the Dutch sector. However, a reliable method to predict the self-burial of submarine pipelines did not yet exist.

The aim of the present development has been to achieve a model which is able to predict the self-burial behaviour of submarine pipelines as a function of environmental conditions (waves and currents), seabed and sediment characteristics and pipeline dimensions.

2.2 Description of the model

The concept of the Self-Burial Model is based on the observation of two dominant erosion processes under and around the pipeline: tunnel erosion and leeside erosion.

Tunnel erosion is a short term process with a time scale of the order of hours or days. After initiation of scour through seabed irregularities or vigorous water movements, a tunnel will be eroded under the pipeline.

Leeside erosion is an erosion process with a time scale of the order of weeks or months. It affects a much larger area of the seabed than tunnel erosion. A pipe protruding from the seabed disturbs the flow causing turbulence on the leeside of the pipe and thus increases the capacity for sediment transport. When the flow reverses, the leeside erosion now takes place at the other side of the pipe and some backfilling occurs at the upstream side. During a tidal cycle, however, the leeside erosion generally dominates over this backfilling effect. As a consequence the leeside erosion lowers the seabed near the pipe and at a certain moment the pipe will again be exposed to tunnel erosion.

Both tunnel and leeside erosion have been clearly observed in large scale two dimensional flume tests (scale 1:1 to 1:2).

Small scale flume tests and field data confirmed the existence of the third process which determines the actual burial of the pipeline: the natural backfilling.

As the local seabed around the pipe and the pipe itself sink relative to the original seabed, the capacity of the upstream eroded hole to capture sediment increases, so that backfilling becomes more and more dominating over leeside erosion.

The environmental conditions (waves and currents) determine to a large extent the equilibrium position of the pipe. In fact, each set of environmental conditions result in a different equilibrium position. It means that for instance a storm may trigger further lowering of the pipe after a period of stable pipeline position.

2.3 Calibration of the model

The model is primarily based on flume tests and numerical models of the two-dimensional situation of the behaviour of a cross-section of the pipeline. As a consequence, the pipeline diameter and the pipeline configuration (plain or fitted with piggy-back or spoiler) are in fact the only pipe related parameters taken into consideration in the formulations. Pipeline stiffness and weight are not (yet) explicit input parameters.

The calibration of the model has therefore been very important. Fortunately a relatively large number of pipelines in the Dutch sector of the continental shelf have self-buried and regular surveys showing the lowering process were available.

The shortcomings of a 2D model concept has been compensated by extensive calibration of the model against actual field (3D) survey data.

Actual waverider buoy measurements covering the survey periods of the calibration pipelines have been used to ensure correct representation of the wave conditions. The importance of this is clearly demonstrated in Figure 3. It shows the measured and the computed position of pipe and seabed of the Mobil P6AB pipeline. The effect of storms is evident after approximately 90 and 160 days.

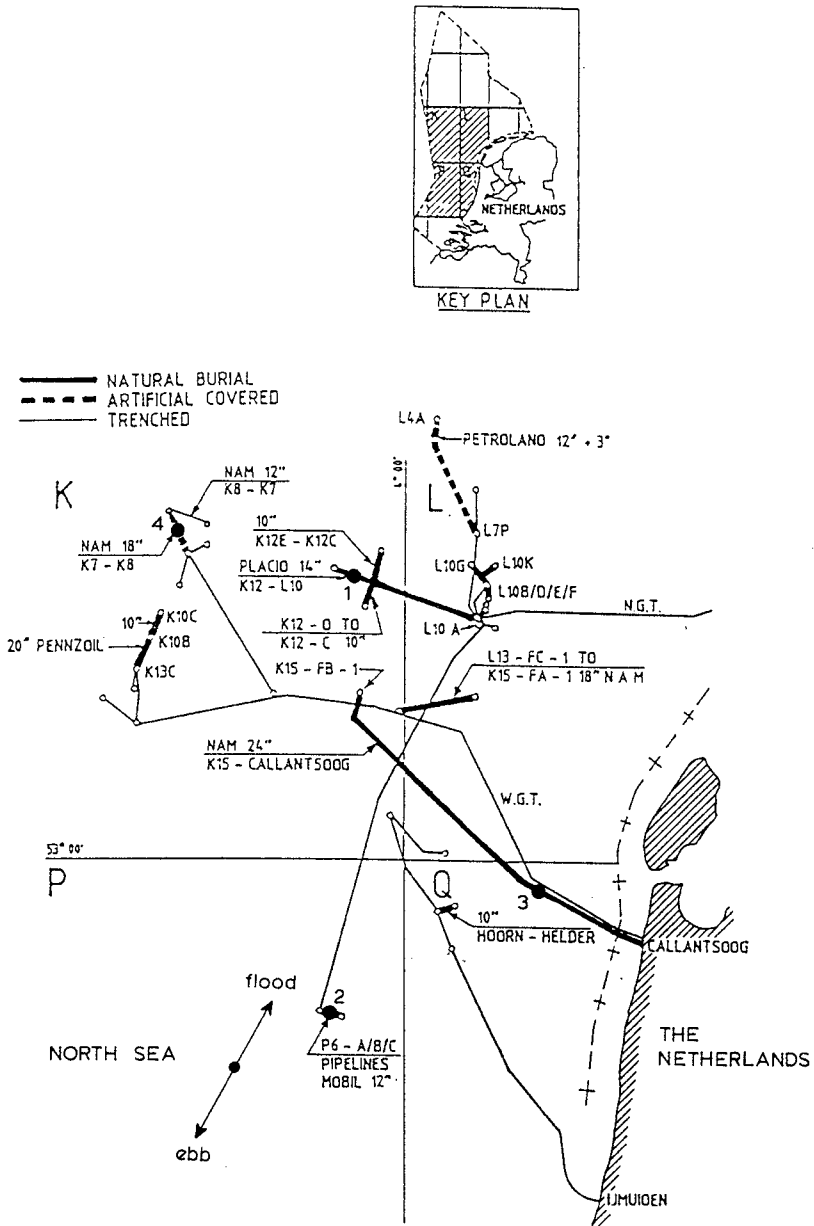

Fig. 2 Pipeline locations in North Sea.

Fig. 3 Computed and measured pipe position of CASE 2: MOBIL P6AB

3. CONCLUSIONS

Two independent PC based computer models have been developed. Both models require comprehensive environmental input data in the form of time series of wave/current data. By the new developments existing theoretical models have been integrated to useful tools that are operational in engineering practice.

The Sand Wave Model:

- the model has been developed from existing theoretical models.
- modifications and extensions of the existing theory has been made with respect to:
 - . non-equilibrium sand waves
 - . varying directions of waves and currents
 - . effects of short-crested sand waves
 - . effects of high water waves
 - . effects of wave generated ripples.
- the model does not include the presence of any structure.
- future extensions of the existing model should focus on including the observed natural variability of sand waves.

The Self-Burial Model:

- the Self-Burial Model integrates the effects of the physical processes of tunnel erosion, leeside erosion, pipe lowering and backfilling.
- the model has been based on flume tests and numerical models.
- effects of pipeline stiffness is not included directly in the (2D) model but enters through extensive calibration against actual (3D) pipelines.
- future extensions of the existing model should focus on modelling of the development of free spans and pipe lowering in the scour holes.

4. ACKNOWLEDGEMENTS

The authors wish to thank Professor E.W. Bijker and Professor J. Fredsøe who both acted as scientific specialist consultants for the project team.

CHAPTER 191

Even/Odd Analysis of Shoreline Changes Adjacent to Florida's Tidal Inlets

Paul A. Work¹ and Robert G. Dean²

Abstract

Measured shoreline changes up- and downdrift of several tidal inlets on the eastern coast of Florida are decomposed into even and odd components. The odd component of shoreline change is compared to both analytical and numerical predictions of shoreline response to a shore-normal littoral barrier. A best-fit iterative scheme is used for application of the analytical solution. The numerical solution improves upon the analytical approach by accounting for refraction, diffraction, and wave energy dissipation on the ebb tidal shoal. Predicted and measured changes agree reasonably well for several cases, and future refinements and improved long-term wave data are expected to allow more accurate prediction of smaller-scale features.

Introduction

Formation of a tidal inlet, whether resulting from natural events or human activity, often leads to large-scale, long-term shoreline changes, as the inlet represents an interruption of longshore sediment transport. This is particularly true where the inlet is stabilized by training structures, as is common along the eastern coast of Florida. The wave climate that provides the energy to mobilize the sediment is in turn altered by the evolving beach-inlet system. The resulting situation is often a complex wave field where wave breaking, diffraction, and refraction due to both tidal currents and time-varying bathymetry are all important.

A shore-normal littoral barrier placed along a coast having a strongly dominant direction associated with its longshore sediment transport will typically lead to the familiar result of accretion updrift and erosion downdrift of the barrier. In the field, other processes often complicate the picture. For this reason, a method is presented by which the "shoreline signature" of an inlet may be decomposed for study. The method has been applied to a number of tidal inlets along Florida's eastern coast, and analytical and numerical simulations of shoreline change have been generated for comparison. Figure 1 shows the locations of the tidal inlets addressed in this paper.

²Graduate Research Professor, Coastal and Oceanographic Engineering, University of Florida, Gainesville, Florida 32611 USA

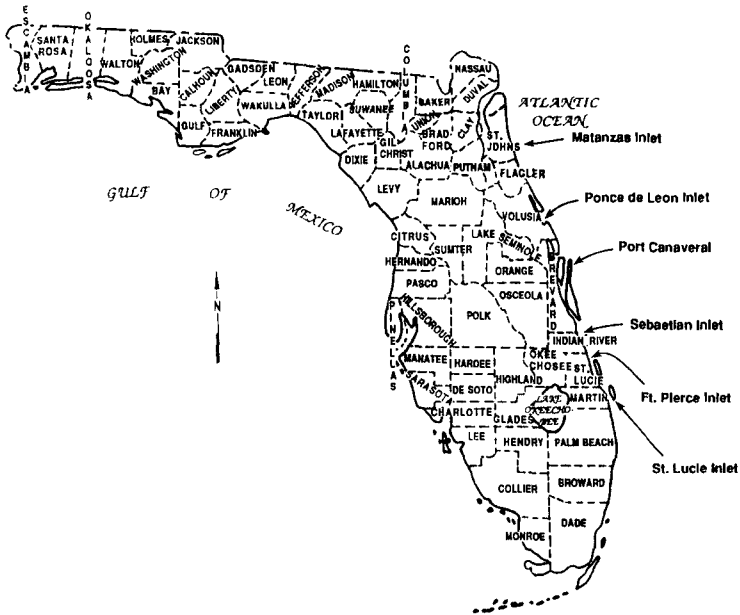

Figure 1: Locations of tidal inlets studied.

Several goals of the study were defined: to investigate and interpret shoreline changes at tidal inlets, examine the effectiveness of methods for prediction of these changes, and suggest improvements to these methods. The focus throughout the study was on changes directly attributable to the presence of the inlet.

Analytical Solution

A method by which shoreline response to a shore-normal littoral barrier may be predicted was proposed by Pelnard-Considère (1956). It is assumed that all offshore contours behave similarly, reducing the problem to the description of the position of one contour, typically the shoreline (hence the term “one-line model”). The x -axis is placed along the shoreline and the y -axis directed offshore. The coordinate system origin is at the point where the initial shoreline and the littoral barrier intersect.

Assuming that the wave crests are nearly shore-parallel, a sediment continuity equation may be combined with a dynamic sediment transport equation and linearized to show that the problem is governed by the heat, or diffusion equation (Pelnard-Considère, 1956):

$$\frac{\partial y}{\partial t} = G \frac{\partial^2 y}{\partial x^2} \quad (1)$$

where G is a diffusivity parameter containing, most importantly, the breaking wave height:

$$G = \frac{KH_b^{5/2}\sqrt{g/\kappa}}{8(s-1)(1-p)(h_*+B)} \quad (2)$$

where

- K = Dimensionless transport coefficient of order 1
- H_b = Wave height at breaking
- g = Acceleration of gravity
- $\kappa = H_b/h_b$ (Spilling breaker assumption)
- h_b = Water depth at breaking
- s = Sediment specific gravity
- p = Sediment porosity
- h_* = Maximum depth of sediment motion, or depth of closure
- B = Berm height

Note that G has units of length squared per unit time.

A solution to Equation 1 requires application of appropriate boundary conditions, and an initial condition:

$$y(\pm\infty, t) = 0, \quad \text{for all } t \quad (3)$$

$$y(x, 0) = 0, \quad |x| < \infty \quad (4)$$

specifying no change in the far-field and a shoreline that is initially straight. The boundary condition at the barrier consists of two parts, the second part being invoked subsequent to the initiation of sediment bypassing around the tip of the littoral barrier:

$$\left. \frac{\partial y}{\partial x} \right|_{x=0} = \tan \theta_b \quad 0 < t < t_{bp} \quad (5)$$

$$y(0, t) = \pm l \quad t \geq t_{bp} \quad (6)$$

where θ_b is the angle (measured counter-clockwise) between the shore-normal and the wave ray at breaking, and l denotes the length of the littoral barrier. The positive sign in Equation 6 corresponds to the updrift side of the barrier. The first part of this boundary condition forces the shoreline at the structure to parallel the wave crests, resulting in zero longshore transport past the structure. The second part (which is approximate) fixes the shoreline to the end of the barrier.

The time of bypassing, t_{bp} , may be expressed in terms of known quantities:

$$t_{bp} = \frac{\pi}{G} \frac{l^2}{4 \tan^2 \theta_b} \quad (7)$$

The solution to this problem is given by Equations 8 and 9. The solution is presented here only for $x > 0$, but it is noted that the solution is anti-symmetric about the y -axis, i.e. $y(-x, t) = -y(x, t)$.

$$y(x, t) = \frac{-\tan \theta_b}{\sqrt{\pi}} \left[\sqrt{4Gt} \exp\left(-\frac{x^2}{4Gt}\right) - x\sqrt{\pi} \operatorname{erfc}\left(\frac{x}{\sqrt{4Gt}}\right) \right] \quad \text{for } t < t_{bp} \quad (8)$$

and

$$y(x, t) = -\frac{\tan \theta_b}{|\tan \theta_b|} \operatorname{erfc} \left(\frac{x}{\sqrt{4Gt}} \right) \quad \text{for } t \geq t_{bp} \quad (9)$$

where erfc denotes the complimentary error function. The solution given by Equations 8 and 9 will be applied for the prediction of shoreline changes at a tidal inlet by assuming that the inlet itself has negligible width. Several additional assumptions have been invoked to achieve this result: the littoral barrier is assumed impermeable, the shoreline is homogeneous, and the wave climate does not vary in the x -direction or in time. Also note that sediment is conserved; all sediment bypassing the structure reaches the downdrift shore. These assumptions are not well-suited to all field sites, suggesting that attempts be made to relax some of them. One approach is described below.

Even/Odd Decomposition of Measured Shoreline Changes

At this point it is appropriate to consider the measured shoreline changes to which predictions will be compared. Digitized historical charts and surveys were obtained from the Department of Natural Resources, State of Florida (Foster and Savage, 1989; Savage and Foster, 1989). Using the coordinate system of the previous section, surveys from different dates were compared to determine a net shoreline change "function", $y_N(x)$. An attempt was made to select a first survey corresponding to the time at which the inlet was constructed or stabilized. The second (later) survey was chosen to place it before any beach nourishment or sand bypassing projects, but long enough after inlet construction that long-term shoreline changes dominated over seasonal changes.

It was decided to divide the shoreline change function, $y_N(x)$, into even (symmetric about the y -axis) and odd (anti-symmetric) components. This can be done easily for any function, with the two components given as follows (Berek and Dean, 1982; Dean and Pope, 1987):

$$y_E(x) = \frac{y_N(x) + y_N(-x)}{2} \quad (10)$$

$$y_O(x) = \frac{y_N(x) - y_N(-x)}{2} \quad (11)$$

The justification for this approach becomes evident when one considers the contributions to shoreline change at a tidal inlet. The interruption of longshore sediment transport should, according to the analytical solution of the previous section, contribute only an odd component. Storms and sea level rise will tend to exert similar influences on both sides of the domain, leading to an even component. Refraction and diffraction effects will vary, possibly contributing to both even and odd components.

It can easily be demonstrated that sand bypassing will add a "negative" odd component; i.e. an odd component that reduces the offset created by the presence of a littoral barrier, and that beach nourishment will tend to contribute to both even and odd components. The effects of factors leading to the presence of an even component are often difficult to predict, and most would exist even without the presence of the inlet. The primary influence of the inlet is a blockage of longshore sediment transport, so it was decided to compare predicted shoreline

Figure 2: Analytical solution with superimposed uniform background erosion of 25 m in 75 years. $l=75$ m, $H_b=0.5$ m, and $\theta_b=1^\circ$. All shoreline change plots are oriented to place the ocean at top.

changes to the odd component of measured shoreline changes.

A simple, illustrative example is helpful. If a uniform background erosion is superimposed upon the analytical solution of the previous section, the result shown in Figure 2 is obtained. Note that for this case, decomposition into even and odd components simply returns the initial constituents, since the analytical solution is odd and the background erosion even. Also note that any loss or gain of sediment within the domain is revealed by the integral of the even component, as the integral of the odd component is zero.

Best-Fit Analytical Solution

Application of the analytical solution requires confident estimates of several parameters, including wave height and direction at breaking, and the length of the jetty. The jetty length may seem to be well known, but three factors complicate selection of a value for this parameter: structure permeability, physical modifications which take place during the time period of interest, and the fact that portions of the active, updrift profile extend beyond the jetty tip well before the shoreline reaches the jetty tip. These factors suggest the use of an "effective" jetty length. Lacking long-term values for the parameters, a best-fit technique was developed to compare the analytical solution to the odd component of measured shoreline change.

An iterative scheme was developed to find parameters that minimized the mean square difference, or error, between the analytical solution and the odd component of measured shoreline change. This error is defined as follows:

$$\epsilon^2 = \frac{1}{N} \sum_{i=1}^N [y_A(x_i, t) - y_O(x_i)]^2 \quad (12)$$

where x_i denotes the longshore coordinate of the i th point, $y_O(x_i)$ the value of the odd component at that point, $y_A(x_i, t)$ the analytical solution, and N the number of data points available.

The best fit will exist when the derivative of ϵ^2 with respect to each parameter is zero. Initially, only the pre-bypassing portion of the analytical solution, which has no dependence on jetty length, was used. The two parameters allowed to vary were the diffusivity, G (containing the wave height at breaking), and the tangent of the wave angle at breaking, $\tan \theta_b$. Figure 3 gives contours of equal values of ϵ , plotted against G and $\tan \theta_b$, for Ft. Pierce Inlet. This inlet was constructed in 1921, but the first of the two surveys used to determine the odd component of shoreline change is from 1928. For cases such as this, the analytical solution used in the best-fit procedure is defined as the difference between the solution at the time of the second survey (t_{end} , 46 years for this case) and the solution at the time of the first survey (t_{start} , 7 years here). All times are thus referenced to the construction of the inlet.

The best-fit methodology was then extended to include both parts of the analytical solution (pre- and post-bypassing) and thus allow for the variation of jetty length, l . This then accommodates three scenarios, depending on whether the surveys are dated before or after initiation of bypassing. Note that if both surveys are pre-bypassing, jetty length cannot be inferred, since the pre-bypassing solution has no dependence on jetty length. Similarly, if both surveys are post-bypassing, wave direction is indeterminable. Only if the first survey is pre-bypassing and the ending survey post-bypassing can wave height, direction, and jetty length all be determined. This last scenario occurred for only one case, that of Ft. Pierce Inlet. For each of the other cases, the pre-bypassing solution provided the best fit. Figure 4 compares the measured odd component for Ft. Pierce Inlet to the two best-fit solutions; Figure 5 illustrates the error surface when the full analytical solution is allowed. This error surface depends on three variables, and is therefore four-dimensional. The jetty length has been "frozen" at its best-fit value for illustration. Note that the full solution for this case provides a very good fit, but the associated wave angle (8.4 degrees) appears unreasonably large for a long-term average.

The error surface that results when the full analytical solution is used (Figure 5) should have at least three relative minima: one corresponding to the case where both surveys predate bypassing; one where the surveys lie to either side of the time of bypassing; and one where both surveys post-date initiation of bypassing. Recall that the time of bypassing depends on G , $\tan \theta_b$, and l , so varying any of these parameters changes the time of bypassing. One could allow any number of the available parameters to vary, but it was felt that the three chosen contained the most uncertainty.

Numerical Model

A numerical model was developed to investigate the effects of wave refraction due to both bathymetry and tidal currents, diffraction of energy into the "shadow zone" in the lee of the downdrift jetty, and the sheltering effect of an ebb tidal

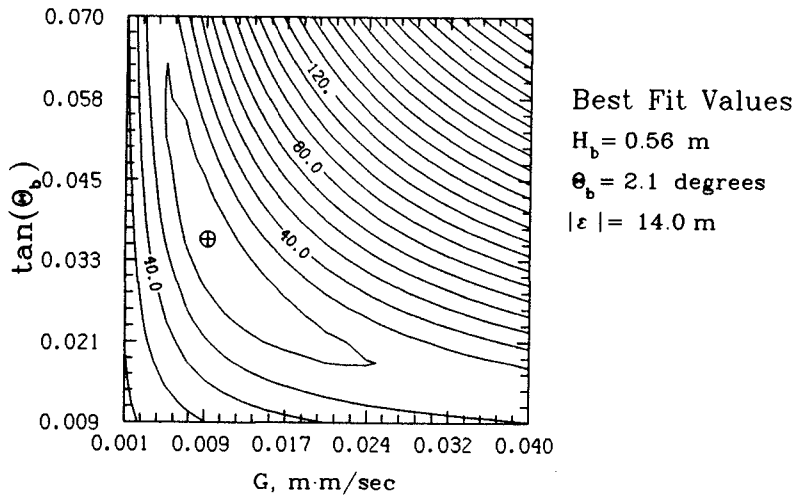

Figure 3: Contours of equal error, $|\varepsilon|$, for Ft. Pierce Inlet, 1928-1967. Pre-bypassing solution only.

Figure 4: Measured odd component and the two best-fit solutions for Ft. Pierce Inlet, 1928-1967.

Figure 5: Error surface for Ft. Pierce Inlet, 1928-1967. Full analytical solution.

shoal.

The model includes a two-dimensional finite-difference wave propagation routine, providing the nearshore wave climate for computation of shoreline change by a one-line finite-difference model. The primary advantage of this method over the analytical solution is that spatial and temporal variability in the nearshore wave climate can be accommodated. The governing equation and boundary conditions for the sediment model remain unchanged.

Wave conditions at the offshore boundary are specified and the bathymetry and tidal currents approximated analytically. The dispersion relationship including the effects of currents is given in terms of an intrinsic wave frequency, σ :

$$\sigma^2 = gk \tanh kh \quad (13)$$

where

$$\begin{aligned} \sigma &= \omega - \vec{k} \cdot \vec{u} \\ \omega &= \text{absolute frequency} = 2\pi/T \\ T &= \text{wave period} \\ \vec{u} &= \text{mean current vector} \\ \vec{k} &= \text{wavenumber vector} \\ h &= \text{water depth} \end{aligned}$$

Irrotationality of the wavenumber vector specifies wave direction:

$$\nabla \times \vec{k} = 0 \quad (14)$$

and conservation of wave action is applied to solve for wave height:

$$\nabla \cdot \left[\frac{E}{\sigma} (\vec{u} + \vec{C}_g) \right] = 0 \quad (15)$$

where

$$E = \text{Wave energy density} = \rho g H^2 / 8$$

$$\vec{C}_g = \text{wave group velocity vector}$$

Starting at the offshore boundary, Equations 13, 14, and 15 were applied iteratively at each grid point to solve for wavenumber vector, \vec{k} , and wave height, H . To account for wave energy dissipation across a shoal or other bathymetric feature, the wave height was checked at each point and truncated to 78% of the water depth if it exceeded this height. Diffraction of wave energy into the sheltered area behind the jetty was included through application of the method of Perlin and Dean (1985).

The best-fit analytical solution was used to determine the offshore wave climate for the numerical model. The best-fit wave direction and height were transformed offshore using Snell's Law and conservation of wave energy flux. For each inlet studied, the analytical and numerical predictions of shoreline change differ little. The primary factor accounting for this is that the wave climate used as input to the numerical model represents a long-term average, with a relatively small wave height, and the direction deviates little from shore-normal. Thus wave energy dissipation on the shoal (where one is present) and wave diffraction are thought to be under-predicted in the numerical model.

Sensitivity tests indicate that moderate tidal currents have little effect on the results. This appears reasonable, since the modelled domain typically extends up to 10 km to either side of the inlet, well outside the zone of strong tidal influence.

Results

Shoreline changes at each of the tidal inlets along the eastern coast of Florida for which data were available were studied by the techniques described above. As might be expected, the analytical and numerical predictive methods appear to be best suited to inlets that are stabilized at the time of construction by relatively impermeable jetty structures.

Figure 6 shows the odd component of measured shoreline change, the best-fit analytical solution, and the numerical simulation for Ft. Pierce Inlet. The pre-bypassing best-fit solution is used here, as the full solution yielded unreasonable wave parameters. Agreement is fairly good except near the inlet, suggesting for this case that the initial accretion/erosion immediately adjacent to the inlet is underestimated. Reversals in the direction of longshore sediment transport could also contribute to this feature. Note that the predictions do not include any of the small-scale deviations seen in the measured odd component. The models tend to smooth out any irregularities in the shoreline, given sufficient time.

Results for St. Lucie Inlet, which was constructed in 1892, are presented in Figure 7. The inlet was initially stabilized only on its north side, the south jetty being added in 1982. The shape of the solutions match the measured odd component well, despite the fact that several of the assumptions implicit in the solutions (impermeable structures on both sides of the inlet, homogeneous shoreline, no temporal variation in wave climate) are not well-satisfied at this inlet. As with each of the inlets discussed here, the net longshore transport of sediment is directed to the south, but reversals are common in the summer season.

Figure 6: Measured odd component and predictions of shoreline change for Ft. Pierce Inlet, 1928–1967 (inlet constructed 1921). $H_b = 0.56$ m, $\theta_b = 2.1$ degrees.

Figure 8 presents results for Sebastian Inlet. This inlet was constructed in 1924, but closed naturally in 1941–42. It was then re-opened in 1948 and has remained open to date. The results shown in Figure 8 neglect the closure of the inlet from 1942–1948. The magnitude of the shoreline change for this case is smaller, so small-scale deviations from the predicted changes are more evident.

Figure 9 provides results for Port Canaveral, constructed in 1951. Agreement between the measured and predicted changes is not as good here, and it is seen that there is a spike in the measured odd component for $x = \pm 4000$ m. Inspection of only the odd component of measured change does not allow determination of whether this feature is accretional or erosional. Inspection of the net shoreline change for this case reveals that this is an accretional feature on the updrift side of the inlet. Natural or man-made shoreline features can often introduce shoreline inhomogeneities that do not satisfy the assumptions of the methods used here. One possible future improvement to the numerical shoreline change model would be to account for inhomogeneities by allowing the diffusivity parameter, G , to vary along the domain.

Shoreline changes at inlets not well-suited to the assumptions implicit in the predictive methods presented here must often receive careful consideration for thorough understanding. Figure 10 shows the net shoreline change, and its even and odd components for Ponce de Leon Inlet, 1952–1973. This is a natural inlet that was stabilized by jetties in 1971, the northern jetty incorporating a weir in order to facilitate sand bypassing to the southern shore. The weir was closed in 1984 to reduce erosion on the northern side. The erosion on the updrift side (north; left in Figure 10) is evident in the figure, as is a very large accretional zone immediately downdrift of the inlet. This accretion is due primarily to the configuration of the downdrift jetty; as built, it formed a “pocket” that tended to trap material.

Figure 7: Measured odd component and predictions of shoreline change for St. Lucie Inlet, 1883-1967 (inlet constructed 1892). $H_b = 0.62$ m, $\theta_b = 4.4$ degrees.

Figure 8: Measured odd component and predictions of shoreline change for Sebastian Inlet, 1946-1970 (inlet constructed 1924). $H_b = 0.75$ m, $\theta_b = 0.8$ degrees.

Figure 9: Measured odd component and predictions of shoreline change for Port Canaveral, 1951-1970 (inlet constructed 1951). $H_b = 1.07$ m, $\theta_b = 1.4$ degrees.

Another case of interest is that of a natural, unstabilized tidal inlet. Figure 11 provides the shoreline change components for Matanzas Inlet, 1923-1986. The position of the downdrift boundary of this inlet is partially restrained by a bridge abutment, and the downdrift shore is now heavily armored, but there are no jetty structures. Note that the even component of shoreline change indicates a slight gain of sediment within the domain, and the expected pattern of accretion updrift and erosion downdrift is present. Another future goal is to be able to accurately predict both bypassing rates and shoreline changes at an unstabilized tidal inlet.

Conclusions

Computation of shoreline changes at many of Florida's tidal inlets and decomposition of these signals into even and odd components reveals a fairly consistent updrift offset pattern, particularly at entrances that have been stabilized on both updrift and downdrift sides. Several inlets deviate from this trend, but the reasons are usually evident upon consideration of the history of the area.

The best-fit analytical solution developed matches the odd function well at several inlets showing a significant updrift offset, although it is not capable of predicting the small-scale features seen in the field. Reasonable values for the long-term wave climate are generated using the pre-bypassing analytical solution. Lack of reliable, long-term, directional wave data hinders complete assessment of results and remains a limitation to improved modelling efforts.

Refinement of the numerical model will be necessary to predict the small-scale features seen in the field. The wave transformation model could be improved by using higher-order wave theory, including wave-current interaction, providing a more sophisticated method for computation of tidal currents, and improving the wave breaking computations. Directional wave data would allow simulation of

Figure 10: Net, even, and odd components of measured shoreline change for Ponce de Leon Inlet, 1952-1973.

Figure 11: Net, even, and odd components of measured shoreline change for Matanzas Inlet, 1923-1986.

the longshore sediment transport reversals known to occur at many of Florida's inlets. The sediment transport model could be refined to account for the inhomogeneous nature of the shoreline in both the longshore and cross-shore directions.

The problems of interpretation and prediction of shoreline evolution adjacent to tidal inlets remains of both considerable interest and difficulty. Further refinement of the methods applied to date should lead to improved predictive ability.

CHAPTER 192

Behaviour Of Mobile Beds At High Shear Stress

Kenneth C. Wilson¹ and Fidelia N. Nnadi²

Introduction

Beds of granular material show various types of behaviour as the dimensionless shear stress or Shields ordinate, Y , is increased. This quantity is defined as $\tau/\rho g(S-1)d$, where τ is boundary shear stress, ρ is fluid density, g is gravitational acceleration, S is the ratio of solids density to fluid density and d is particle diameter. No movement occurs until Y exceeds a critical value. As Y is increased beyond the critical sand waves form, first increasing and then decreasing in steepness with successive increases in Y . Finally, in the high-shear-stress region, say $Y \geq 0.8$, the bed becomes plane (or exhibits antidunes in cases of critical or supercritical free-surface flow). This high-stress condition, sometimes called the upper plane-bed region, may be encountered for rivers in flood, large flows in estuaries, and closures or breaches of cofferdams or dykes. Because of the very high rates of sediment transport this type of flow has a disproportionate effect on both natural topographic features and engineering works. It is not easy to investigate this behaviour by traditional flume experiments, but the use of enclosed pressurised conducts can eliminate many of the experimental difficulties (Wilson, 1966).

Analysis

At high shear stress the bed load moves in a near-bed zone (the shear layer or sheet-flow layer), with thickness δ_s . Within this layer, the grains comprising the bed load (also called the contact load) are supported by intergranular contacts, which may be either continuous or sporadic. For this type of motion Bagnold (1956)

¹ Professor, Department of Civil Engineering, Queen's University, Kingston, Ontario, Canada K7L 3N6

² Grad. Student, Department of Civil Engineering, Queen's Univ., Kingston, Ontario, Canada K7L 3N6

demonstrated the existence of both an intergranular normal stress, σ_s , and an intergranular component of shear stress, τ_s . The latter is equal to $\sigma_s \tan \phi'$, where ϕ' is the dynamic equivalent of the friction angle used in soil mechanics. At the bottom of the shear layer all of the applied shear stress τ is resisted by the intergranular shear stress, which must equal $\tan \phi'$ times the normal intergranular stress at that location. This normal stress equals the submerged weight of the contact-load solids in the shear layer, which can be written $\rho g(S-1)\bar{C} \delta_s$ where \bar{C} is the average volumetric concentration of bed-load solids within this layer. Rearrangement gives

$$\delta_s = \tau / [\rho g(S-1)\bar{C} \tan \phi'] \quad (1)$$

showing that δ_s/d equals $Y/(\bar{C} \tan \phi')$. It was suggested earlier (Wilson, 1989) that for typical values of \bar{C} and $\tan \phi'$ this relation gives δ_s/d as roughly $10Y$. More recent analysis of concentration-profile data obtained in Saskatchewan (Daniel, 1965; Shook and Daniel, 1965) indicates that a value of $7.5 Y$ is better, i.e.

$$\delta_s/d \approx 7.5 Y \quad (2)$$

Previous analysis of the velocity distribution within the shear layer (Wilson, 1984, 1989) had demonstrated that the ratio of local velocity to shear velocity (U/U_*) can be expressed in terms of the relative height within the shear layer, y/δ_s . Thus at the top of the shear layer, where $y/\delta_s = 1.0$, the ratio U/U_* has a specific value which can be used as a match point for the logarithmic profile of the velocity in the main flow above the shear layer. On this basis the ratio of mean velocity to shear velocity can be calculated, leading to the overall friction relation. This analysis indicated that mobile beds at high shear stress are neither smooth boundaries nor rough ones, but obey their own frictional law analogous to the other cases but with characteristic length proportional to δ_s .

When this law is compared with the rough-boundary equation it is found that the roughness k equivalent to the mobile-bed friction law is about $0.5 \delta_s$, i.e. the value of k/d is not constant (as for the rough boundary law) but increases approximately linearly with Y . This conclusion was verified (Wilson, 1989) using the results of closed-conduct experiments carried out with sand (relative density $S = 2.67$) and nylon ($S = 1.14$). These are shown on Fig. 1, together with results of a more recent research program using particles of Bakelite ($S = 1.56$). The plot covers a considerable range of both variables, and although some scatter is present, the general increase of k/d with Y is very clear.

Up to this point it had been assumed in the analysis that the boundary shear stress τ was applied to all levels of the shear layer, i.e. the variation of total shear stress with height was ignored. However, for some of the experiments δ_s occupies a sizable fraction of the waterway height, implying a significant variation of τ within the shear layer. This variation depends directly on the ratio δ_s/R , (R is hydraulic radius). As the friction factor itself depends on R/k , and k is proportional to δ_s , no additional parameters were required for the analysis with variable τ , and the algorithm was re-written to incorporate this case.

Fig. 1 Plot of Effective Roughness Ratio

By use of Eq. 1 it is readily seen that the ratio R/δ_s depends only on $(S-1)/i$, i.e.

$$\frac{R}{\delta_s} = \frac{(S-1)}{i} (\bar{c} \tan \phi') \approx 0.13 \frac{(S-1)}{i} \tag{3}$$

For constant τ , it was predicted that a plot of the velocity ratio \bar{U}/U_* versus the logarithm of $(S-1)/i$ should form a straight line. These axes can also be used to show the new calculations for variable τ . The resulting curve is plotted on Fig. 2, together with points for the data sets mentioned above.

Fig. 2 Velocity-Ratio Plot

It is most encouraging to see the agreement between theory and experiment which is displayed on Fig. 2. From a practical point of view, however, the curve shown on this figure is not convenient to use, and it is preferable to approximate it by a simpler function such as a power law. If necessary, the curve can be divided into several regions, and a separate approximating power law found for each region.

In applying this approximating technique, it was found that a single power law was adequate to cover a broad range of conditions of practical interest i.e. subcritical flow with particles having S of 2.6 or more. For these conditions the approximating function was found to be

$$\frac{\bar{U}}{U_*} = 9.55 \left[\frac{(S-1)}{i} \right]^{0.11} \quad (4)$$

or

$$\bar{U} = 9.55 (S-1)^{0.11} i^{0.39} \sqrt{(gR)} \quad (5)$$

This equation can also be re-written to give the Darcy-Weisbach friction factor, i.e.

$$f = 0.088 \left[\frac{i}{(S-1)} \right]^{0.22} \quad (6)$$

The form of the approximating function given by Eq. 5 may be considered as a replacement for the Manning formula, for use with mobile beds at high shear stress ($Y \geq 0.8$). As friction does not depend on particle diameter for this type of behaviour, this equation involves no roughness coefficient (such as n in the Manning formula) and thus is exceptionally simple to apply. This point can best be illustrated by an example. Consider the flow over a mobile bed in an estuary, with R of 6 m, and mean velocity of 4 m/s. With $(S-1)$ taken as 1.65, Eq. 5 is readily solved for i , which is found to be approximately 5×10^{-4} . The shear stress τ , i.e. $\rho g R i$, is about 30 Pa, and Y is 1.8, verifying that the flow is in the appropriate range. The thickness of the shear layer δ_s will be about 14mm and U_* about 0.17 m/s.

The values of τ (and U_*) found above can themselves be used to estimate the transport rates of bed-load and suspended load. This matter has been analysed by Wilson and Pugh (1988), who noted that the suspended load occurs as an addition to the bed-load particles considered previously. This addition can have only a secondary effect on the thickness of the sheet-flow layer that

contains the bed load, and the same applies to the velocity at the top of this layer. Hence it is expected that suspended load will have, at most, a minor influence on the numerical coefficients of Eqs. 4 to 6.

Conclusion

Experimental evidence from flows in pressurised conduits has provided striking verification of the predictions from the analysis. Both analysis and experiment show that mobile-boundary flows at high shear stress do not obey the rough-wall friction law, (as had been imagined for many years). Instead, they follow their own law, with frictional length scale proportional to the shear stress itself. In this case equations based on rough-wall friction, such as the Manning formula, do not apply and the friction factor depends on the ratio $i/(S-1)$. A power-law approximation to this function gives a simple friction equation which can replace the Manning formula for high-shear-stress mobile-boundary flow.

CHAPTER 193

TO RETREAT IN ORDER TO BETTER FIGHT : LITTORAL PROTECTION OF SHINGLE BEACHES IN THE NORTH OF FRANCE

Bruno Manoha¹ and Charles Teisson²

Abstract

Rather than endeavouring to protect a shoreline under severe waves attack, on the northern coast of FRANCE, a new solution a retreat landwards up to 800 m. With a slight retreat (180m), the orientation of the new shoreline is drawn according to the dominating wave climate and enables the stabilization of the beach. A larger retreat (800 m) could allow the re-estuarisation of a valley. These solutions are tested on a physical movable bed model.

1. INTRODUCTION

Several parts of littoral in the North of France, constituted of chalky cliffs and shingle beaches are suffering today severe erosion, due to past human action : extraction of shingle for industrial purpose, construction of seawards harbour breakwaters interrupting littoral transport.

Previous responses of coastal engineers to this problem have been to construct classical seawalls or groynes, with unequal issue, problems usually shifting downcoast. Today, on the most critical site, annual shingle renourishment is employed : this is a soft, but onerous method, with bleak outlook, as the renourishment disappears downcoast in winter, during storms.

This most exposed site lies at the outlet of a valley, a 1 km indentation between the cliffs, with the beach lined landwards by a sea front road (fig. 1). Rather than protecting at any cost the present shore, with ineffective long term perspective, a new solution considers a retreat of the shore line in the valley. This draw back could be realized in two ways :

- either a slight retreat at the entrance of the valley,
- or even a re-estuarisation of the valley, with the sea entering landwards up to 800 meters.

¹ Head of Maritime Group

² Research Engineer,

EDF - Laboratoire National d'Hydraulique, 6, quai Watier 78400 Chatou FRANCE.

Fig 1 : Map of the site

Beyond the response to present problem, this approach integrates long term tendencies, as the annual recession of 0.20 m of surrounding cliffs exposing seawards the present sea front road, and possible sea level surelevation due to greenhouse effects.

This innovative solution, with strong local impact - destruction of the sea front road, partial intrusion of the sea in the valley - is tested and optimized on a physical movable bed model.

2. SEDIMENTOLOGICAL BACKGROUND

As a general manner, shingle beaches differ from sandy beaches by a steeper equilibrium slope and their mode of transport restricted to the swash zone, landward of the breaker line (MUIR WOOD, 1970).

In the North of France, likewise, shingles created from the cliff erosion lay down at the foot of the cliffs along the 140 km of the littoral and build up as a beach 20 to 30 meters wide, with an equilibrium slope of 10 %. Due to the westerly dominating wave climate, it exists an easterly littoral transport of 20 000 m³ per year. As the annual production of shingle from cliff erosion is also 20 000 m³, the sedimentary budget was well balanced in the past.

But, since the beginning of this century, various coastal developments as harbours breakwaters have deeply disturbed this natural transit, causing the breaking up of the shingle line into accumulation of dead stocks to the west of the breakwaters and its disappearance on the eastern parts. Quarrying of shingle for industrial purpose has also contributed to weaken the shingle line : half of the 5 millions m³ of the stock existing at the beginning of the century has disappeared in that manner.

In some areas, as Criel sur Mer, one of the most critical site, the annual easterly departure of shingle reaches, in spite of existing groynes, is 15 000 m³ per year, while the natural transit, cut down to 1000 m³ per year, can not feed the beach in a satisfactory way.

Therefore, since the last ten years, artificial shingle renourishment has relieved the nature, supplying the beach by lorries on an amount of 10 to 15 000 m³ per year in an attempt to fill up the deficit. This is a soft but onerous method, with ineffective long term perspective, as the renourishment disappears downcoast in winter, during storms.

Innovative planning policies, to save the beach while reducing drastically renourishment budget required to be tested on a physical movable bed model (TEISSON and al, 1989).

3. THE PHYSICAL MODEL

Bathymetry and shoreline have been represented in a 28 x 33 m tank, at an undistorted scale of 1/150.

Shingle of 30 mm mean diameter (D_{50}) is satisfactorily represented by bakelite of 1.5 mm, a lightened artificial material. After preliminary test with uniform granulometry, extended granulometry measured in the prototype (5-50 mm) has been set up in the model in order to reproduce the effects of sorting.

Sand is also simulated by another artificial material ; at the present time this sand is passing in front of the site ; it is expected to deposit in the future in the new sheltered area. The tank is fitted out with a mobile random wave generator, and tide generator. Measurements are carried out by digital waves gauges and limnimeters and by an automatic bottom probe sensor for bottom evolution.

Calibration of the model has been performed in two steps :

- to seek for the sedimentological time scale from the situation in the past, i.e. a stable beach with a littoral transport of 20 000 m³/year,
- to verify and reproduce present erosion problems.

For that purpose, random waves from various directions respecting wave climate, tide level with associated storm surges, are reproduced in the tank, in order to simulate evolutions up to 15 years in the future with the new lay out.

4. TESTS AND RESULTS OF PLANNING POLICIES

4.1. Bounded shore line retreat

The purpose of the planning policies is to adapt the beach line with the present situation, characterized by a very weak natural sediment supply. The idea is therefore to destroy the sea front road, badly orientated and to draw a new shore line well adapted to the westerly dominating wave climate.

We extended for shingle beaches the concept of static equilibrium bay, developed by SILVESTER in the 70's for sandy beaches, using the latest results of HSU et al. (1989). In stable condition, the tangential section downcoast is parallel to waves crests approaching the coast from offshore ; the incoming waves will refract and diffract into the bay and break simultaneously, arriving more normal to the coast along the whole peripheries (fig. 2).

These results have been used to define theoretically a so called logarithmic spiral beach shape in the valley (fig. 3). Tests on the physical movable bed model have enabled to optimize the maximum indentation in the valley to 180 m, bounded by a sea wall. The part of the beach sheltered in the valley, with an initial replenishment of 40 000 m³ of shingle is fully stable (fig. 4) : vertical cross sections of the beach after 6 and 12 years (fig. 5) show very little evolution. Sand, presently passing in front of the site, tends to deposit at the toe of the shingle beach. Annual renourishment could be carried back to 2500 m³, six times less than now, devoted to the eastern part of the beach below the cliffs, protected by a lengthened easterly groyne.

4.2. Estuarization of the valley

This most ambitious project (fig. 6), after destruction of the sea front road leaves the sea to intrude the valley ; topography of this flat valley lies 1 meter below the highest tide level. At the beginning of the century, during a major storm, the sea invaded the valley 2 km landwards. Nowadays, estuarization would be limited to 800 m by a sea wall, to protect the city.

One of the main point of interrogation is the behavior of the soft, water saturated meadows under the waves attacks : new equilibrium slope, transition time. This aspect cannot be reproduced on the physical model, in the absence of similitude laws. An expertise has therefore been conducted from geological surveys (fig. 7), to deliver a first shape of this estuary (LAFOND, 1990). This high perched estuary, with a small tidal prism, has been set up on the physical model. Waves will diffract and vanish behind the western chalky cliff (fig. 8) : erosion of the meadows by waves would be limited to the first 300 meters. Upstream, topography of the valley would remain unchanged, forming a high marsh, irregularly flooded, only for the 10 % highest tides. Downstream, consolidated soil below the present road and shingle beach would act as a barrier and limit the thickness of the eroded layer to 4 or 5 meters. Behaviour of shingle and sand has been surveyed over 15 years : littoral transport appears too weak to form a westerly spit. Superficial deposits of sand are noticeable at the mouth of the estuary.

5. CONCLUSIONS

Thus, littoral protection of this site reflects the evolution in coastal engineering state of mind : from hard solutions as groynes, then soft approach as beach nourishment, and finally a retreat to build up a new equilibrium shore line.

This new shore line, rather than fighting endless against the sea, is well adapted to the depletion of littoral transport and waves attack.

This approach as a retreat appears valuable when no worthwhile patrimony has to be safeguarded landwards.

6. ACKNOWLEDGEMENTS

This study has been granted by the Conseil Général de Seine-Maritime under the control of Direction Départementale de l'Équipement de Seine-Maritime.

CHAPTER 194

Experimental Results on the Sediment Grain Threshold under Short-Wave Action

C.I.Moutzouris¹

Abstract

Results on the conditions of initiation of first sediment movement on a flat bed under the action of monochromatic short waves are presented in this paper from a laboratory study. The results indicate the existence of a correlation between the Ursell number and the parameter a . The correlation is of the $a = \lambda U^n$ type. The values of n and λ , as defined from the experiments, were not unique and were different from the values found in an earlier study by Sunamura. Therefore it was considered necessary to cross-check the values of n using data from real-world beaches.

Introduction

The Laboratory of Harbour Works, National Technical University of Athens, is conducting a research programme on the sediment distribution on the bed of real-world beaches under the action of waves. The beaches from which field data are collected are located along the coastline of Greece, which is an almost tideless environment. This means that the collected data are free of tidal effects, which may influence the results considerably. Other specific features of the beaches are as follows: slopes are, generally speaking, steeper than in many other parts of the world, and sedimentary environments are of the mixed type as far as grain size is concerned.

A rather important conclusion derived from the programme is that grain size changes considerably in the cross-shore direction of beaches. Grain size distribution is found to be related to the wave energy level. Consequently, grain size-related parameters, which are known to influence nearshore processes significantly, are found to change in the cross-shore direction. Results from the

¹ Director, Laboratory of Harbour Works, National Technical University of Athens, Patission 42, 10682 Athens, Greece

programme have been reported in a series of past papers (Moutzouris,1989,Moutzouris and Kypraios 1987,etc.).

In almost all cases, it was found that cross-shore changes mainly occur in a zone extending from the line of maximum wave run-up to a critical depth d_c . In the zone seawards of d_c , changes become almost insignificant (see Fig.1). d_c is believed to depend upon the previous sea state, the prevailing sediment size and the bed topography. From one point of view, d_c could be equivalent to the "closure depth" of van de Graaff, in which the profile of a beach becomes insensitive to changes. From another point of view, d_c could be related to the critical depth of initiation of grain movement under wave action.

In the present paper, an attempt is made to investigate whether a correlation exists between d_c and the critical depth of initiation of grain movement. Results from the laboratory are presented on the sediment grain threshold and field data are also used.

Fig.1.-Cross-shore distribution of sediment grain size (D_{50} is the median grain diameter)

Methodology and Experimental Apparatus

A number of beaches were selected along the coastline of eastern Attica, Greece. The beaches were surveyed four times a year, namely in spring, summer, autumn and winter. Sediment samples from the sea bed were collected along transect lines on each beach. The cross-shore distributions of grain size on these beaches were computed. The critical depth d_c in each case and the corresponding median diameter D_{50c} of grains were then evaluated. d_c and D_{50c} are defined in Fig.1.

A first attempt to compare the above values of d_c found on the beaches to the depth of initiation of sediment movements d_s , as computed from various existing empirical formulae, did not lead to any decisive conclusion. One major reason for this is believed to be the lack of adequate knowledge of the wave disturbance, which had caused the sediment distributions found on the beaches.

It was thus considered necessary to define precisely the critical values of wave height, wave period and the water depth at which initiation of the first movement of grains of diameter D_{50c} occurs on the sea bed. For this purpose, experiments were conducted in a concrete wave flume with a glass sidewall, 27m long, 1.50m deep, and 60cm wide. At one end of the flume, a piston wave-maker created monochromatic waves and at the other end, an absorbing mildly sloping beach was installed. An aluminium tray 1.00m long and 60cm wide was placed on the bottom of the flume. The bed material used consisted of natural sediment grains obtained from a single sieve fraction, in order to obtain the same diameter as the median diameter D_{50c} in nature. A sediment layer consisting of beach material several millimeters thick was placed on the tray. The surface of the sediment was smoothed and waves were then allowed to act on the sediment grains. In each experiment, the grain diameter was kept constant and the wave-induced bed shear stress τ was progressively increased. Starting at a value of $\tau=0$ and increasing τ , the layer initially stayed at rest. After τ reached a critical value τ_c , the first grain movement was observed and then bed load transport started occurring. Five kinds of well-sorted sediment of a constant density (2.6) but different diameter were used in the experiments. All diameters tested had been found in nature to be D_{50c} and are presented in Fig.2. Numerous water depths were tested. The experiments are described by Loisidou (1989).

Experimental results

Various dimensionless parameters were computed using the data obtained from the experiments. Among others, the Hallermeier parameter F , which indicates the intensity

Fig.2.- Sediment grains used in the experiments (w_s is the settling velocity)

of sediment movement, the Shields parameter Ψ , the Ursell number U , which represents the skewness of the water particle velocity profile, the Reynolds number R , the Dean number and finally the parameter a , which is defined by equation(2). It was found that the best correlation existed between the Ursell number and the parameter a , defined as follows:

$$(1) \quad U = \frac{HL^2}{d^3}$$

$$(2) \quad a = \frac{u_m^2}{\gamma'_s g (D_{50} A_0)^{1/2}}$$

$$\gamma'_s = \frac{\rho_s - \rho_w}{\rho_w}$$

where H and L the wave height and length, respectively, d is the corresponding water depth, g is the gravitational acceleration, D_{50} is the diameter of the grains tested, γ'_s is the specific gravity of immersed sediment, and ρ_s and ρ_w are the densities of sediment and water, respectively. A_0 and u_m are respectively the near-bottom orbital diameter and velocity of water particles, as computed using the Airy theory. All wave-related parameters in equations (1) and (2), namely H, L, u_m and A_0 , represent values at the moment of occurrence of initiation of first grain movement.

Fig.3.-Dimensionless parameter a versus U
(from laboratory measurements)

A plot of the correlation obtained is shown in Fig.3. The correlation is of the following type:

$$(3) \quad a = \lambda U^n$$

where λ and n are constant. The lefthand of equation (3) is similar to Shield's relative stress. The correlation obtained shows a scatter, which does not allow a unique set of (λ, n) values to be defined from the experiments. The following ranges of values emerge instead, as is also shown in Fig.4:

$$(4') \quad \begin{array}{lll} \lambda = 0.04 & \text{to} & 0.075 \\ n = 0.6 & \text{to} & 1 \end{array}$$

The best fitting curve is the one with:

$$(4) \quad \lambda = 0.05 \quad \text{and} \quad n = 1$$

The above correlation between a and U is not surprising. In a previous similar experimental study by Sunamura (1980), a qualitatively similar relationship was derived for a flat bed with:

$$(5) \quad \lambda = 0.1 \quad \text{to} \quad 0.2 \quad \text{and} \quad n = 0.25$$

The considerable quantitative differences between equations (4') and (5) may partly be attributed to the different initial conditions in the two studies. The conditions examined by Sunamura were as follows

$$2 < U < 300$$

which were different to the ones in the present study, namely:

$$0.5 < U < 8$$

The ranges of values tested in the two studies are shown in Fig.5. The relationship derived by Sunamura is compared to the present one in Fig.4.

According to the Komar and Miller (1975) laboratory results for sediment threshold on a flat bed with monochromatic waves:

$$\lambda = 0.21 \quad \text{and} \quad n = 0 \quad (D < 0.5\text{mm})$$

which means that initial sediment movement is independent of the skewness of the water particle velocity profile. These values were derived from the best fit to their data. It is believed (Drake et al., 1985) that lower values of λ should be expected, when the characteristics of the largest waves in a spectrum are used.

Fig.4.-Equation (4') compared to experimental results

Fig.5.-Range of conditions tested in the present study and in the study of Sunamura

As a result of the above uncertainties and contradicting values of λ and n , it appeared useful to verify the values of λ and n using data from field measurements.

Field Results

Combining equations (1),(2) and (3) and rearranging leads to the following equation:

$$(6) \quad F_w = \frac{1}{\lambda} F_b$$

with

$$(7) \quad F_b = \frac{\pi}{2} \frac{\rho_w}{\rho_s - \rho_w} \left(\frac{d}{D_{50}} \right)^{0.5}$$

$$(8) \quad F_w = \left(\frac{H}{L} \right)^{n-1.5} \left(\frac{d}{L} \right)^{0.5-3n} f$$

with

$$f = \cosh kd (\sinh kd)^{0.5}$$

where k is the wave number. F_b is a function of the sediment parameters and the bed morphology whereas F_w is function of the local wave parameters only. Both F_b and F_w change in the cross-shore direction of a beach. Equation (6) indicates that grain movement occurs when a certain number of wave, bed and sediment-related parameters combine in a way to satisfy the criterion indicated by this equation. Initiation of grain movement occurs when F_b/λ becomes larger than F_w .

It now seems appropriate to look closer at both functions F_b and F_w and how they change in the cross-shore direction. Equation (7) may be written as:

$$(9) \quad F_b = C \left(\frac{d}{D_{50}} \right)^{0.5}$$

with

$$C = \frac{\pi}{2} \frac{\rho_w}{\rho_s - \rho_w}$$

Sediments usually found on beaches have a value of $\rho_s=2.4$ to 2.6. In a previous paper (Moutzouris,1988), it was reported that ρ_s does not seem to change considerably across-shore (see Fig.6).

It therefore seems reasonable to assume that for the beaches examined, C is almost constant in the cross-shore direction with values in the following range:

$$(10) \quad C = 1.02 \text{ to } 1.15$$

The cross-shore distribution of $(d/D_{50})^{0.5}$ is now examined using field data. Typical cross-shore profiles of d and D_{50} are shown in Fig.7. The local depth normalized by the corresponding median diameter for a number of cases is shown in Fig.8.

Fig.6.-Cross-shore distribution of ρ_s

The envelope of all cross-shore distributions found on the beaches studied is shown in Fig.9, which is also the envelope of F_b if a multiplication factor of 1.02 to 1.05 is applied. It is seen that F_b was never found to be larger than, say, 110 (see equations 9 and 10). In most cases F_b was smaller than, say, 80. A rather important conclusion is that F_b is very much dependent on the cross-shore distribution of D_{50} .

The cross-shore change of F_w is now computed using the Airy theory. Values of n introduced in equation (8) range from 0.25 to 1. F_w is computed for wave steepnesses $\gamma_0 (=H_0/L_0)$ in deep water ranging from 1 to 4%. The energy flux conservation principle is applied. The results are shown in Fig.10.

From the analysis it was found that F_b and F_w change in the cross-shore direction of a beach. In deeper water F_w is always larger than F_b/λ , which means that no sediment movement occurs. The criterion of sediment movement is satisfied in the zone of shallow water. The depth of first grain movement depends upon the bed form, the cross-shore distribution of sediment grain sizes and the wave characteristics. The data from the beaches did not lead to any clear conclusion concerning the values of n . It seems that n depends upon the conditions prevailing on each beach.

It was then decided to adopt the values of n and λ from the best fitting curve to the laboratory results. Equations(3) and (4) were used to compute the depths of initiation of sediment movement d_s for the beaches where depths d_s had been defined, as mentioned earlier. Depths d_s were then compared to d_s . This second attempt again did not lead to any conclusion, which means that d_c was not found related to d_s .

(continued)

Fig.8.-Typical cross-shore distributions of the parameter $(d/D_{50})^{0.5}$

Fig.9.-Envelope of cross-shore distributions of $(d/D_{50})^{0.5}$

Discussion

The results from laboratory measurements on the conditions of initiation of sediment movement under the action of monochromatic short waves confirm the existence of a correlation between the Ursell number U and the parameter a , as defined by equation (2). The coefficients of the correlation n and λ were not found to be unique and are different from the values found in an earlier study. A first explanation could be that the values of U tested in the two studies were different. The use of data from various beaches did not help to a better definition of the correlation coefficients.

The depth of initiation of sediment movement was not found to be correlated to the depth of stabilisation of grain size on a beach.

CHAPTER 195

Movable Bed Modeling Criteria For Beach Profile Response

Hsiang Wang,¹ Takao Toue,² and Hans H. Dette³

Introduction

Modeling coastal phenomena using movable bed means is a complicated problem with no general solution at present. Most modeling laws that are realizable in the laboratory usually only apply to certain restricted conditions. This paper, like many others, elects to deal with a restricted case, here, the two dimensional beach profile changes under the influence of wave action.

Numerous papers have been written on this subject. A general review can be found in Hudson et.al. (1979), LeMenhaute (1990) and Wang (1985). Those of particular relevance to the present study are briefly reviewed here. Noda (1978) examined several theoretical scaling laws but recommended a completely empirical model Law based on similarity of equilibrium profiles in the breaker zone. His model involves three scaling parameters, the sediment diameter ratio, the vertical and horizontal length scales. Vellinga (1982) and Graaff (1977) conducted a comprehensive laboratory study by using different scales in attempting to duplicate the beach and dune erosion of the Dutch's coast. Vellinga also settled on a pair of empirical relationships. The geometrical scale relationship bears certain resemblance to the Noda's with an additional fall velocity scale incorporated into it. A morphological time scale is also added. Both Noda's and Vellinga's laws require that the wave steepness and the Froude number be preserved. Hughes (1983) presented a model based upon preserving the Froude number and a non-dimensional fall velocity parameter. Hughes' model allows for wave distortion. There are similarities as well as very settled differences among the three modeling laws. All these modeling laws compared well with its own data set. Inter comparisons in most cases were not successful.

Kamphis (1974) using an entirely different approach listed four different non-dimensional parameters as requirement for complete similarity. Realizing that preserving all of them in the model is impractical, he proposed a set of four different modeling laws requiring preservation one or more non-dimensional parameters but not all of them. Each modeling law is suitable for a specific range of environmental conditions. There was no comparison with Laboratory data reported. Table 1 summarized the modeling laws by these authors.

Table 1 Existing Beach Profile Modeling Laws

<u>Author</u>	<u>Requirement</u>	<u>Modeling Law</u>
Noda (1978)	$(\frac{H_a}{L_o})_p = (\frac{H_a}{L_o})_m$	$N_D = (N_\delta)^{0.55}$
	$F_p = F_m$	$N_\delta = (N_\lambda)^{0.76}$
Vellinga (1982)	$(\frac{H_a}{L_o})_p = (\frac{H_a}{L_o})_m$	$N_T = N_t = (N_\delta)^{\frac{1}{2}}$
	$F_p = F_m$	$N_\delta = (N_W)^{0.44} (N_\lambda)^{0.78}$
Hughes (1983)	$F_p = F_m$	$N_T = N_t = N_\lambda / (N_\delta)^{\frac{1}{2}}$
	$(\frac{H}{TW})_p = (\frac{H}{TW})_m$	$N_\delta = (N_W N_\lambda)^{\frac{2}{3}}$
Kamphis (1974)	$(N_{R*}) = 1$	
	$(N_{F*})_p = 1$	
	$\frac{(N_{\rho*})}{N_\rho} = 1$	
	$\frac{N_a}{N_D} = 1$	

δ : Vertical Scale; λ : Horizontal Scale; D : Sand Size;
 T : Fluid Motion Time Scale; t : Morphological Time Scale;
 W : Fall Velocity.

Judging from the argument used by the authors and the evidence provided by them, the modeling laws by the first three authors are clearly based on suspended-load dominated case. Kamphis' model did not specify the mode of transport. From the selection of the parameters, it appeared that the resulting modeling laws should be more pertinent to bed-load dominated cases.

In the first three modeling laws, Noda's and Vellinga's are undistorted but Hughes' is distorted. This needs some clarification. In the modeling law itself, the vertical and horizontal scales are all distorted as can be seen from Table 1. The distortion or non-distortion originates from the requirement. Noda and Vellinga both require the wave steepness to be preserved, thus, the wave form should be undistorted. Hughes' model, on the other hand, preserves non-dimensional fall velocity, thus, permits wave form distortion. If one insists upon a consistent undistorted model (wave form treated as a geometrical scale) by letting $N_\delta = N_\lambda = 1$, then Noda's model reduces to $N_D = N_\delta^{0.55}$ and Vellinga's and Hughes' models yield identical results in both morphological scale and fall velocity scale:

$$N_T = N_t = N_\delta^{\frac{1}{2}}$$

$$N_W = N_\delta^{\frac{1}{2}}$$

This is of great comfort that all the model laws are somewhat consistent at undistorted scale except none of the authors actually intended to propose $N_\delta = N_\lambda = 1$ as quite evident from the formulas they presented.

Modeling Law By Inspectional Method

So far all the above modeling laws were derived from dimensional analysis of physical quantities. A slightly different approach is taken here by the inspection of the basic governing equation. The two-dimensional sediment conservation equation states that

$$\frac{\partial h}{\partial t} = \frac{\partial q}{\partial x} \quad (1)$$

where h is the bottom elevation, q is the volumetric sediment transport rate in the x direction; t is time and x is on-off shore direction. This equation can be non-dimensionalized as follows:

$$\frac{\partial \bar{h}}{\partial \bar{t}} = \frac{q_n t_n}{\delta \lambda} \frac{\partial \bar{q}}{\partial \bar{x}} \quad (2)$$

where the overbar refers to non-dimensional quantities and q_n , t_n , δ and λ represent, respectively, the reference values of sediment transport rate, the morphological time scale, vertical geometrical scale and horizontal geometrical scale. To maintain similitude between the model and prototypes requires

$$\frac{N_q N_t}{N_\delta N_\lambda} = 1 \quad (3)$$

where N refers to the ratio of prototype to model.

Suspended Load Transport

The suspended load transport rate can be expressed by depth averaged properties:

$$q_s = hVc \quad (4)$$

where h is equal to depth; V is equal to mean transport velocity and c is equal to depth-averaged mean sediment concentration. The suspended sediment concentration is directly proportional to the ratio of stirring power due to turbulence and the settling power due to gravity and can be expressed as (Hattori and Karvamata, 1980):

$$c \propto \frac{\rho u'}{(\rho_s - \rho)W} \propto \frac{u'}{SW} \quad (5)$$

where u' is the turbulent intensity, W is the particle settling velocity and S is the submerged specific weight. Thorton (1978) suggested that the ratio of turbulent velocity and wave induced velocity is a function of surf zone parameter, ξ , i.e.,

$$\frac{u'}{u} = f(\xi) \quad (6)$$

The surf zone parameter is defined as $Tan \beta / \sqrt{H_o/L_o}$ with $Tan \beta$ the beach slope, H_o and L_o , the deepwater wave height and length, respectively. Physically, this equation states that if the surf zone property is similar, the turbulence intensity should be proportional to the mean velocity scale, a plausible assumption. Since in a wave field u is proportional to H/T , substituting Eqs. (5) and (6) into Eq. (4) and then combining it with Eq. (3) leads to

$$\frac{N_o N_{f(\xi)} N_t N_H}{N_\lambda N_W N_T N_S} = 1 \quad (7)$$

If we let $N_{f(\xi)} = 1$, or $\xi_p = \xi_m$, we require

$$[g^{1/2} T \cdot Tan \beta / H_\delta^{1/2}]_p = [g^{1/2} T \cdot Tan \beta / H_\delta^{1/2}]_m \quad (8)$$

which when expressed in basic scaling quantities becomes:

$$N_T = N_\lambda / N_\delta^{1/2} \quad (9)$$

Here the wave height is treated as a vertical scale parameter. In Froude-number similitude, the horizontal velocity is scaled in accordance with $N_\delta^{1/2}$, i.e.,

$$N_F = \frac{N_V(\text{horizontal})}{(N_g N_\delta)^{1/2}} = 1 \quad (10)$$

or

$$N_V(\text{horizontal}) = N_\delta^{1/2} \quad (11)$$

Thus, Eq. (9), in essence, is the scale ratio of horizontal distance to horizontal velocity in a distorted model. Now, substituting Eq. (9) into Eqs. (7) and (4) and letting $N_{f(\xi)} = 1$, we obtain a pair of model laws as follows:

$$N_q = \frac{(N_\delta)^3}{N_s N_W N_\lambda} \quad (12)$$

$$N_t = \frac{N_s N_W N_\lambda^2}{(N_\delta)^2} \quad (13)$$

Morphological Time Scale and Field Evidence

Equations (12) and (13) essentially form the proposed modeling laws with the basic modeling requirement that the surf zone parameter be matched. One of the important but also more difficult aspects of beach profile modeling law is the determination of morphological time scale. Two different hypotheses are tested here. First, if we assume that the number of incoming waves per unit time is preserved for the similitude of erosion rate, then,

$$N_t = N_T = \frac{N_\lambda}{N_\delta^{1/2}} \quad (14)$$

Substituting the above equation into (13), one obtains

$$N_\delta = (N_s N_W)^{2/3} N_\lambda^{2/3} \quad (15)$$

This equation when expressed in dimensional form becomes:

$$h = \alpha_1 \left(\frac{SW}{g^{1/2}} \right)^{2/3} x^{2/3} \quad (16)$$

with α_1 , a constant of proportionality. This equation is similar to Dean's empirical equilibrium profile which was deduced from field data provided the scale parameter "A" in Dean's equation equals to $\alpha_1 \left(\frac{SW}{g^{1/2}} \right)^{2/3}$.

Second, if we assume that instead of preserving the number of waves, the trajectory of a fallen particle be preserved in the erosion rate, then the morphological time scale becomes

$$N_t = \frac{N_\delta}{N_{v(\text{horizontal})}} = N_\delta^{1/2} \quad (17)$$

Again substituting the above equation into Eq. (13) results in

$$N_\delta = (N_s N_w)^{2/5} (N_\lambda)^{4/5} \quad (18)$$

The dimensional counter part is:

$$h = \alpha_2 \left(\frac{SW}{g^{1/2}} \right)^{0.4} X^{0.8} \quad (19)$$

This is very close to the empirical equilibrium profile form proposed by Vellinga (1982) which was derived from field data along the Dutch coast.

Laboratory Data

As was shown, the proposed modeling laws are consistent with field data even though the morphological time scale remains somewhat unclear. In this section, laboratory experiments were compared. We put our emphases on inter comparisons among data sets from different laboratories and on the morphological time scale. We shall refer to Eqs. (14) and (15) as model "A" and Eqs. (17) and (18) as model "B".

The selected data sets used in the inter-comparisons are listed in Table 2, with the key parameters associated with each experiment. Here, Saville's experiment is treated as the reference and the vertical scales of the other tests are all referred to it. Figure 1 shows the comparison between Saville and Kriebel. According to the proposed modeling law, the model has no geometrical distortion by either Law "A" or Law "B", i.e., $N_\delta = N_\lambda = 9.6$ from both "A" and "B". The comparison is good except in the foreshore where the mode of transport in the small scale (may be even in the large scale) can no longer be considered as suspended-load dominated. Since there is no geometrical distortion, Law "A" and Law "B" yield the same morphological time scale as they should. Hughes and Fowler (1990) recently presented the results of a mid-scale experiment intended to duplicate the large scale experiment of Dette and Uliczka (1986). The model was also geometrically undistorted and the comparisons were judged to be excellent. Both sets of data support the modeling law but are not able to differentiate Law "A" from Law "B".

Figure 1: Comparison between Saville and Kriebel (from Kriebel, et.al. 1986).

¹ 3D test

² estimate base on average slope between shoreline and breaker bar

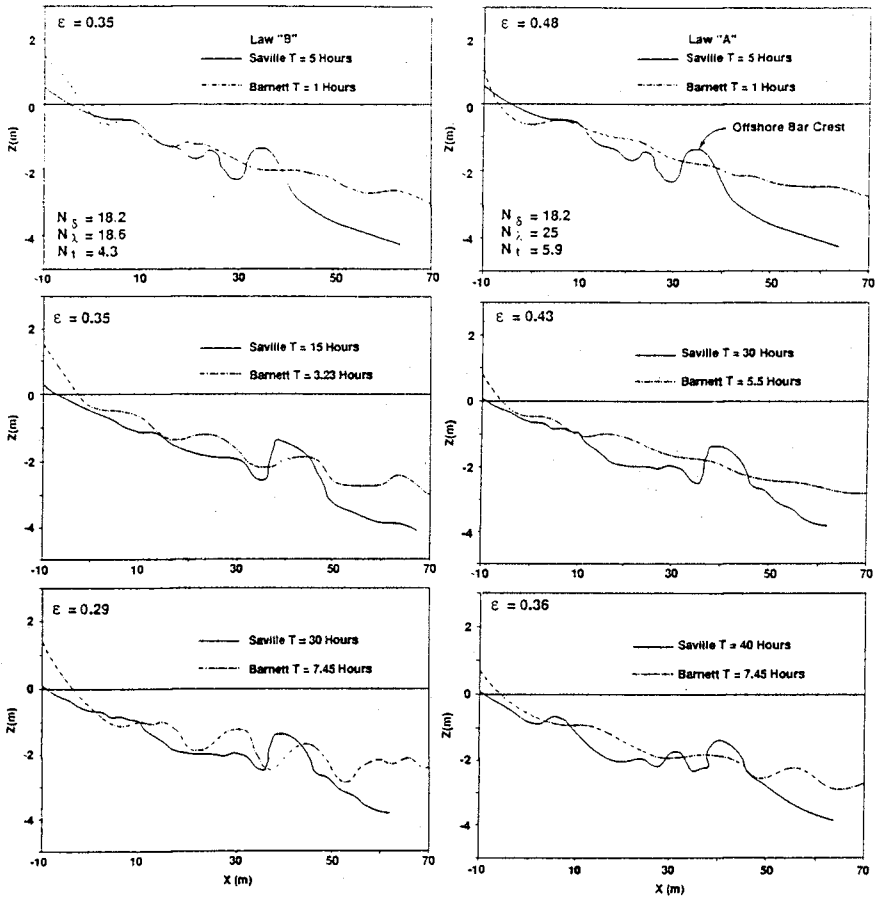

Figure 2: Comparisons between Saville's and Barnett's results.

The second comparison is between Saville's and Barnett's experimental results. Barnett's experiments were not intended for verification of modeling laws; rather were designed for testing the effects of seawalls on the fronting beaches. However, his bench mark cases of beaches without seawalls could be used for the present purpose. As stated earlier, the initial condition in Saville's tests was a beach of uniform slope of 1 to 15. The initial condition in Barnett's tests, on the other hand, was a beach of equilibrium shape in accordance with $h = AX^{\frac{2}{3}}$, with $A = 0.075m^{\frac{1}{3}}$. Since the surf zone parameter is defined with single beach slope value, we define here an equivalent slope as the mean slope value within the surf zone:

$$\bar{m} = \frac{\int_0^{X_b} m dx}{X_b} \tag{20}$$

where m is local slope and X_b is the surf zone width. Assuming $H_b = 0.8h_b$

Figure 3: Comparisons between GWK and $\frac{1}{10}$ Scale Model with $N_f = N_\lambda = 10$ and $N_t = 1$ (from Dette and Uliczka, 1986).

and $h_b = 0.075x_b^{\frac{2}{3}}$, the \bar{m} value is found to be equal to 0.06 or 1 to 16.7, which is very close to 1 to 15 used in Saville's tests. Barnett tested three wave conditions; the one suitable for comparison was with $H_o = 8.8\text{cm}$ and $T = 1.3\text{ sec}$. For this case, the corresponding ξ is 0.33, very close to Saville's value of 0.37. The comparisons are shown in Figure 2. It should be noted here that the morphological time scale could only be preserved approximately as profiles were measured at discrete time intervals selected at the convenience of the investigators in the respective experiments. This is also the case for other comparisons reported here after. To evaluate the goodness of the comparison, the RMS values of the profile elevation differences were computed from the shoreline to the crest of offshore bar (see Figure 2), by the following equation

$$\epsilon = \left[\frac{1}{n} \sum_{i=1}^n (h_i^S - h_i^B)^2 \right]^{\frac{1}{2}} \quad (21)$$

where h^S and h^B are profile elevations of Saville and Barnett, respectively. These values are also given in Figure 2. From these values, it can be seen that Law "B" performs better than Law "A". Also, as time progresses, the modeling law becomes better as the influence of initial condition becomes less.

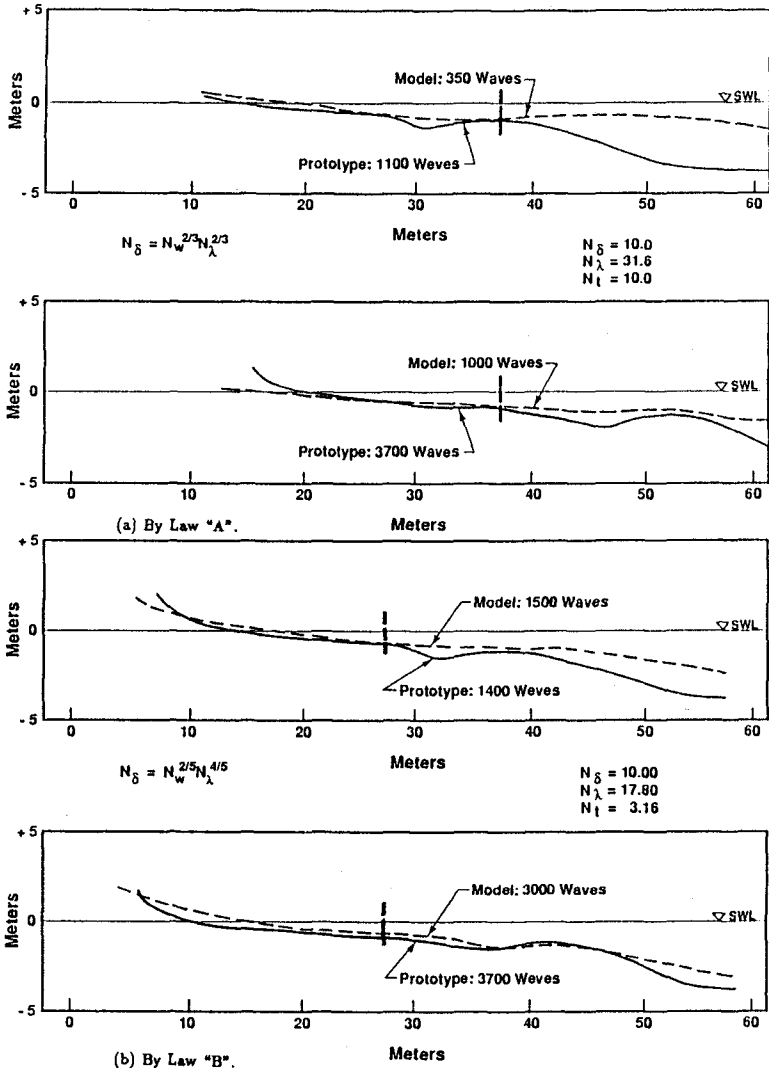

Figure 4: Comparisons Between GWK and $\frac{1}{10}$ Model Using Proposed Modeling Law.

Detle and Uliczka (1986) performed small scale tests treating results from large wave channel (GWK) as prototype. The small scale tests were conducted using same size sand as the prototype at an undistorted geometrical scale of 1:10. Straight comparisons with $N_\delta = N_\lambda = 10$ and $N_t = N_T$ or $N_t = 1$ were unsuccessful. Figure 3, for instance, shows their comparisons with $N_t = 1$ (which is the better of the two time scales according to the authors). The data are replotted in Figure 4 according to the proposed modeling laws. The comparisons are much more favorable, particularly with Law "B". Therefore, the experiment although has the appearance of an undistorted model is actu-

ally highly distorted according to the proposed modeling laws (a horizontal to vertical distortion of 3.2 or 1.8 depending on whether Law "A" or Law "B" is adopted). The reason for this high distortion is because the size of sand is the same in the model and prototype. Since the fall velocity ratio is now unity, the geometrical scale has to be highly distorted to compensate for the fall velocity effect.

The results of the last two cases seemed to suggest that preservation of wave form and/or initial beach geometry are not essential, though might be desirable. The following case further reinforces this observation.

The GWK test and Kriebel's test have very different initial geometry and different H_o/L_o values. However, the ξ value of GWK's composite slope test matches well with the Kriebel's and the fall velocity ratio of the two tests lead to small geometrical scaling distortion according to the proposed laws. All these are favorable conditions to test the proposed modeling laws. The various scale ratio between these two experiments are summarized as follows:

$N_{(H_o/L_o)}$	N_ξ	N_δ	N_W	$N_\lambda(Law A)$	$N_\lambda(Law B)$
0.81	0.86	9	2.22	12	10.5

The ratio is defined as GWK/Kriebel; the initial geometry of GWK is $\frac{1}{4}$ followed by $\frac{1}{20}$ slopes whereas the initial geometry of Kriebel is $\frac{1}{15}$ uniform slope. The comparisons are given in Figure 5. Again like the previous cases Law "B" performs better than Law "A". When time progresses, the effects of the initial condition gradually disappear and the agreement becomes better.

Figure 5: Comparisons of GWK and Kriebel.

Graaff (1977) and Vellinga (1982) used different vertical scales and sediment sizes in their experiments. Realizing that the surf zone in the model will be compressed, they purposely distorted their initial beach profiles in the model in accordance with a hypothetical profile representing the prototype Dutch coast condition. This, however, makes it difficult to compare their results with others and even among themselves. Table 3 summarizes their test conditions and scaling requirement according to Law "A" and Law "B". The N_H values in the first column are in reference to prototype scale. For the convenience of inter-comparisons we designate the case $N_H = 26$, $D_{50} = 225$ as the reference, thus, all the corresponding scale values are unity for this case. Two major difficulties arose; the surf zone parameters are difficult to determine because of the distortion and the composite nature of the profiles; secondly, the N_T values used in the tests do not match those required by the current modeling laws. Here, we simply selected cases (indicated by underline in Table 3) that the actual N_T values approximately meet the requirement and ignored the surf zone parameter criterion completely. Thus, the comparisons could only be viewed as qualitative. Figure 6 shows the results. Law "B" seemed to yield acceptable results considering the crude nature of the comparisons.

Toue's (1989) experiment is the only 3-dimensional laboratory test available. His results revealed a number of points worth mentioning. 1). He separated the suspended-load and bed-load dominated cases. 2). For suspended-load dominated cases, his results compared well with the 2-dimensional counterpart carried out by Barnett for natural beaches but less desirable for beaches with seawall backings. 3). For bed-load dominated cases, the modeling law given above failed to produce reasonable results.

About the Scale Parameter in Equilibrium Profile

The concept of Equilibrium profile has gained wide acceptance. The correct functional form of the scale parameter "A" remains unsettled. Moore (1982) first proposed "A" to be a function of particle size "D" with a dimension of $M^{\frac{1}{2}}$.

Figure 6: Comparisons of Graaff Results at Different Model Scales.

Figure 7: Profile Scale Parameter vs Sediment Fall Velocity Parameter.

Vellinga (1982), through empirical data fitting, proposed a dimensional coefficient $A = 0.39 W^{0.44}$. Based upon the analysis presented in the paper, the correct form of A should be $\alpha \left(\frac{SW}{g^{\frac{1}{2}}} \right)^n$ where α is now a non-dimensional coefficient. The value of n should be either equal to 0.67 or 0.4 depending upon which law is adopted. Dean (1990) re-plotted the A values as a function of W as shown in Figure 7. The results of GWK tests and all the Delft data are also added to the figure. The best fit is found to be $A = 0.51 W^{0.44}$. This relationship is very close to Vellinga's empirical formula as well as to the analytical form of law "B". This presents another favorable evidence that law "B" might be a better choice.

Bed Load Transport

Various formulas have been proposed for bed load transport; practically all of them relate bed load transport to the Shields parameter. Therefore, they will lead to the same modeling requirement by matching model Shields parameter to that of the prototype. The scaling of the transport rate and the relationship of morphological time are different for different transport equations. Table 4 summarizes the results based on different transport equations. We note here that the third row in Table 4 is consistent with the "best model" referred by Kamphuis (1974). By leaving f as an independent parameter allows greater flexibility in selecting scales and material.

Table 4 Bed Load Transport Scaling Law

Transport Equation	Modeling Requirement*	N_q	N_t
$q_b = w D^2 (\varphi - \varphi_c)^n$	$N_D = N_s N_f N_\delta$	$\frac{(N_\delta)^{\frac{3}{2}}}{N_\lambda} N_s N_f$	$\frac{(N_\lambda)^2}{N_s N_f (N_\delta)^{\frac{3}{2}}}$
$q_b = W D \varphi^3$	$N_D = N_s N_f N_\delta$	$N_w N_s N_f N_\delta$	$\frac{N_\lambda}{N_s N_f N_w}$
$q_b = (sg D^3)^{\frac{1}{2}} (\varphi - \varphi_c)^n$	$N_D = N_s N_f N_\delta$	$N_s (N_f)^{\frac{3}{2}} (N_\delta)^{\frac{3}{2}}$	$\frac{N_\lambda}{N_s (N_f)^{\frac{3}{2}} N_\delta^{\frac{3}{2}}}$

Symbols

w : Wave Frequency	s : Specific Weight of Submerged Sand
φ : Shields Parameter	φ_c : Critical Shields Parameter
f : Friction Factor	*Assuming $\varphi \gg \varphi_c$.

Conclusions

The advantage of the proposed modeling criteria over those presented by previous investigators is its ease to implement in ordinary laboratory facilities. It is restricted to cases that either bed load or suspended load dominates. Also, only the gross effect of transport and profile changes are modeled without concern whether the detailed flow pattern or the sediment motion is accurately portrayed.

For suspended load dominated case, the proposed modeling law is in consonance with the equilibrium beach profile concept. The surf zone parameter appears to be the most important similarity criterion that should be matched between the prototype and the model. In general, the modeling law leads to geometrical distortion. The degree of distortion is affected mainly by the sediment fall velocity ratio. Two different hypothesis of morphological time scale are tested. It appears that the preservation of particle trajectory lead to the correct morphological time scale. Laboratory results from various sources seem to support the proposed modeling law. For bed load dominated case, laboratory information is not available. Further investigation is suggested.

Finally, the scale limitations are such that the laboratory flow field should

maintain turbulent boundary layer (Jonsson's flow regime criteria, for instance, 1966) and the mode of sediment should be correct (Shibayama and Horikawa's sediment transport classification, for instance, 1980). It is always prudent to verify the flow and the mode of transport prior to data collection.

CHAPTER 196

STORM EROSION ON A SANDY BEACH

Jesús Martínez *
Ricardo Alvarez *
Ignacio Alonso *

Abstract

Present paper describes the different behaviour of the foreshore of a sandy beach faced with stormy events. Two storms have been selected, since they present a fairly distinct wave approaching direction between them, according with wave forecast maps.

For the first stormy situation waves came for west, and the effect was an accretion on the north end of the beach while an important erosion happened on the south side. With regard to the second storm in which waves came from northwest, an erosive trend was observed all along the beach.

Sandy movements are quantified as net volume changes as well as by means of the erosion and accretion percentages, defined from the sedimentary variability indice.

Description of the beach under study

The beach under study has a total length of 3000 m., is located in the north coast of the Island of Gran Canaria (Spain), and is sheltered from the prevailing northeastern wind and swell. (Fig. 1)

According with Larson's (1988) definition of the backshore and the foreshore, in certain areas the width of the foreshore can reach 100 m. and that of the backshore 50 m. The submerged beach is partially broken up by a fragmented rocky bar that emerges at low tide and affects the larger part of the beach.

* Department of Física, University of Las Palmas de G. C. Apartado 550, Las Palmas, Spain.

This beach is divided into two principal sub-environments, according with the beach stages proposed by Short (1978): Las Canteras North between ranges 10 to 16, and Las Canteras South between ranges 1 to 8. The former behaves as a reflective beach while the latter one as a dissipative beach. There is an small central sector called "Short Beach" between ranges 8 to 10 which is studied separately due to its peculiarity, since it is considered an small pocket beach 90 metres long that is in the middle of a much larger pocket beach. (Fig. 2).

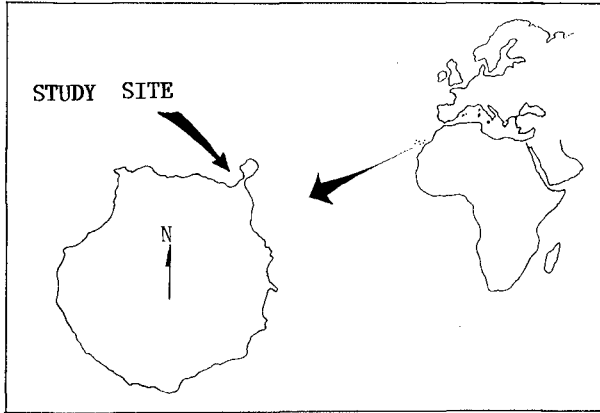

Figure 1. Location map of the beach under study.

Figure 2. Sketch of Las Canteras beach showing position of the different rangelines and the rocky bar.

If the whole beach is considered, the major accretions take place during the summer period, when the prevailing swell is coming from northeast. The major erosions show up during the fall-winter period, coinciding with the seasonal northwestern storms.

Methodology

Profile data

Sixteen rangelines across the beach have been surveyed between June 26, 1987 and July 24, 1990, approximately at monthly intervals. Surveys were always carried out at low tide using a leveling method, down to about 1 to 1.5 metres below MSL (Martínez et al, 1990).

With regard to the first stormy event, the survey of December 7, 1987 was carried out almost at the end of the storm, but the previous survey was carried out just a month before. In the second situation, an extra survey was carried out just at the end of the storm, only four days after the previous survey which was almost at the beginning of the higher waves.

Sedimentary accretions and erosions on the foreshore were calculated according with Kriebel et al (1986).

Storm characteristics

Two stormy situations have been selected:

- First one between December 2 and 9, 1987.
- Second one between December 26, 1989, and January the second, 1990, although the strongest point took place on December 29 and 30.

First stormy situation corresponded to an strong Atlantic squall centered westward Portugal, that produced barometric lows of 1006 mb. over the Canary Islands, and winds up to 75 km/h where registered. To estimate the approaching wave direction, wave forecast maps were employed. It can be seen the sea coming from west. (Fig. 3).

Significant wave heights higher than 4 metres, and maximum heights around 7.5 metres were recorded by means of a wave gauge placed 1800 metres offshore the beach. (Fig. 4).

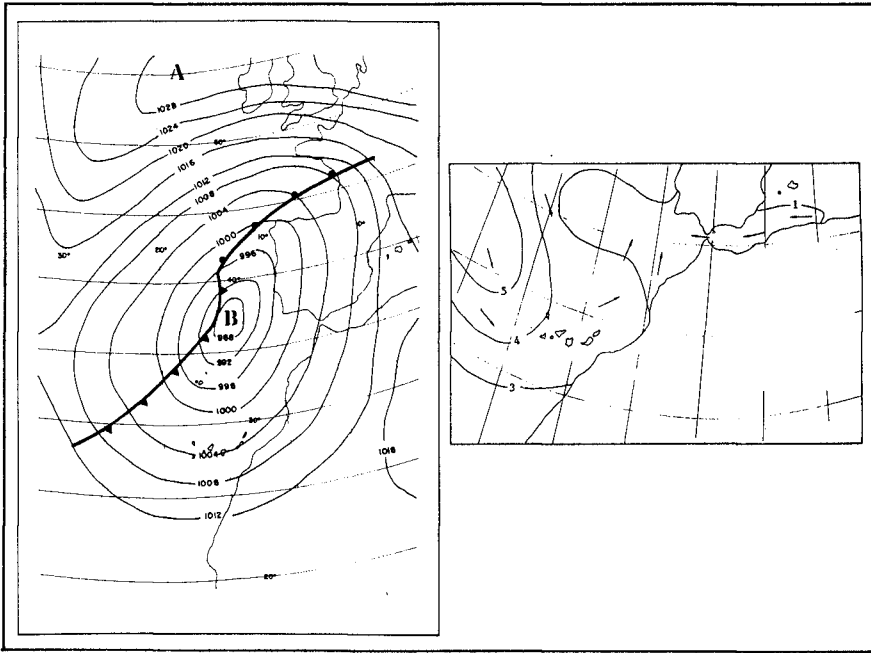

Figure 3. Weather chart and wave forecast map corresponding to December 3, 1987.

Figure 4. Evolution of significant wave height (H_s) and period (T) during the first storm.

The second storm was due to another squall centered northeast Canary Islands, that produced barometric pressures of 1000 mb and winds up to 100 km/h in the Canary Islands area.

Unfortunately, the wave gauge was out of service, so wave characteristics were estimated from the wave forecast maps provided by the National Meteorological Service. As a result, mean wave heights up to 4 to 5 metres coming from northwest were predicted. (Figure 5).

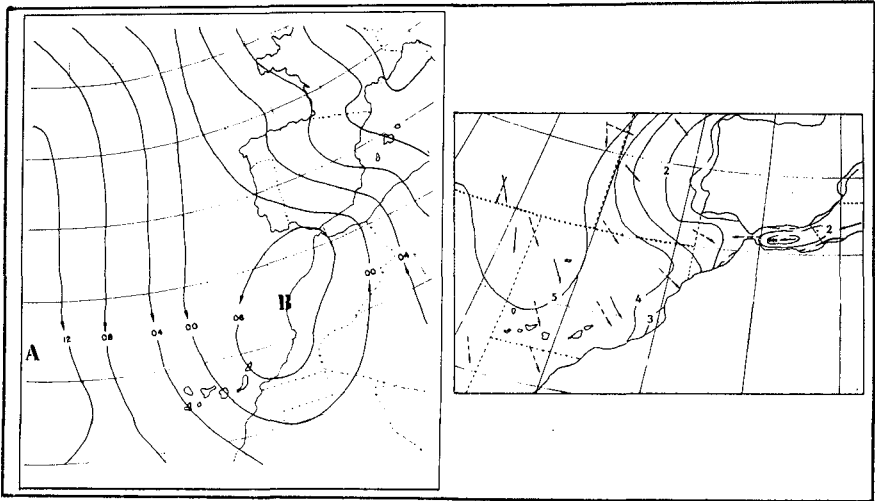

Figure 5. Weather chart and wave forecast map corresponding to December 30, 1989.

New parameters

To analyze the morphological evolution of the beach with regard to these situations, the sedimentary variability indice was employed, defined as the change of mean height between highest accretion to lowest erosion and vice versa, which happen on the beach surface within a sedimentary cycle.

This indice is obtained dividing the net losses or accumulations of sand, in cubic metres, by the delimited surface. Starting from this indice, the erosion and accretion percentages are obtained.

The erosion percentage is defined as the percentage of decrease of the sedimentary variability indice between two surveys, within an erosive period.

On the other hand, the accretion percentage is the percentage of increase of the indice between two surveys, but in this case, within an accretionary subcycle.

Both percentages are good to evaluate the relative magnitude of the erosive / accumulative processes in a given period, within the relative erosive / accretive subcycles. It is necessary to take into account that an accumulative process may happen within a general erosive trend, and vice versa.

Discussion and Conclusions

In relation to the first stormy situation, we estimate sedimentary losses of about 2000 cubic metres on a 21 metre wide foreshore strip, all along the beach. (Table 1).

Date	Whole Beach	Las Canteras North (Profs.10-16)	Short Beach (Profs.8-10)	Las Canteras South (Profs. 1-8)
Nov.7-Dec.7 1987	-1944 (-4.2)	2088 (10.5)	-406 (-21.1)	-3677 (-14.4)
Dec.29,1989 -Jan.2,1990	-5988 (-12.6)	-3806 (-19.1)	-96 (-5)	-2077 (-8.1)

Table 1. Sedimentary losses and accumulations in m³ for both storms, only in a 21 metres wide foreshore strip. Data in brackets are the average heigth changes in cm. on the same area.

These losses assume an erosion percentage of 15.5 % of a sedimentary variability indice of 0.27 m., corresponding to the erosive subcycle.

The above-mentioned erosion percentage has a low value in relation to the others of the same sub-cycle. These others reach up to 41.4 % at monthly intervals, out of significant stormy situations. (Table 2).

Table 2. Values of erosion percentages (E.P.) and accretion percentages (A.P.) on Las Canteras Beach. Column 1 is the whole beach and columns 2, 3 and 4 are the different sectors (Las Canteras North, Short Beach and Las Canteras South respectively). Dates of studied storms are highlighted with *. Erosive and accretive subcycles are separated with horizontal lines.

There was a distinctly different behaviour in the two main sectors of the beach: while a significant erosion took place in Las Canteras South, an important accretion happened in Las Canteras North.

In Las Canteras South, the storm caused an erosion percentage of 35.1 %, of a sedimentary variability indice of 0.41 m. corresponding to the erosive subcycle. That is to say, the foreshore had a mean drop of 0.14 m.

On the other hand, las Canteras North had an accretion percentage of 61.8 % of a sedimentary variability indice of 0.17 metres calculated for the accretionary subcycle. This represents a mean accumulation of 10 cm. for the foreshore along this sector.

This tilt was due to the strong westerly waves, and explains the low erosion percentage for the whole beach, since sedimentary losses and accumulations become balanced between the two main sectors of the beach.

However, it is necessary to take into account that the above-mentioned sandy movements, might be not only due to the storm, but also to other less important sedimentary processes that happened during the 25 previous days to the storm, and that could be responsible for the softening of the final erosion.

If the whole sedimentary cycle is considered, the most important erosion percentages are not precisely related to this significant storm, which was the most energetic one. In the specific case of Las Canteras South, mean sedimentary losses larger than those measured during the storm, were calculated for the pre-stormy period.

An explanation for this fact can be based on by considering that a beach, immediately after having reached its maximum accretion, is very susceptible to suffer great sand losses due to slight increases in waves energy. In this case, these situations happen with the first sporadic manifestations of northwestern swell and with the fall of the dominant northeastern winds.

In relation with the second stormy situation, we estimate sedimentary losses of nearly 6000 cubic meters in only 4 days for the same foreshore strip defined for the previous case, all along the beach. This amount of eroded sediments involves a decrease of 12.6 cm. all along the beach (see Table 1). The calculated sedimentary variability indice was 0.52 m., and the relative erosion percentage was 24.1 % within an accumulative subcycle (see Table 2).

Although the whole beach was eroded, the average decrease was around 8.1 cm. in Las Canteras South and 19.1 cm. in Las Canteras North. The respective erosion percentages were 22 % and 25 %, and the sedimentary variability indice was 0.37 m. for the northern sector and 0.76 m. for the southern sector, but in both cases within accumulative subcycles.

In this case there were no tilt, but the greatest erosion took place where the accumulation was previously produced.

The difference in the behaviour of the beach, in view of the two stormy situations analyzed, can be explained due to the different characteristics of the storms, specially as for the waves approaching direction. In the first situation waves were coming from west while in the second one were approaching from northwest.

CHAPTER 197

A REGIONAL STUDY OF COASTAL MORPHOLOGY

I H Townend¹, C A Fleming¹, P McLaren² and A Hunter-Blair³

ABSTRACT

In 1987 Anglian Water (now the National Rivers Authority, Anglian Region) initiated a coastal management study covering 750 km of coastline, the largest and most comprehensive study of its kind in the UK. Stage I involved the selection of the best technical approach to the problem. In Stage II the successful consultants adopted a philosophy of maximising the use of existing data sources through a geographic information system (GIS) incorporating a database and powerful enquiry facilities. In all 19 main variables were included in the GIS database, each with complex data structures in order to provide a comprehensive description of any particular variable. The main variables were selected on the basis that they either provided information on the direct influences or responses of the coast or on their implications with respect to any protection strategy that may be implemented.

Analysis of the data through the GIS led to a number of significant findings with respect to dominant processes on the coast. This work also highlighted the areas in which further data collection and study would be beneficial to formulating the most appropriate long term management strategy. As a result Stage III of the study has been initiated in order to develop a better understanding of the physical processes responsible for the mechanisms identified.

INTRODUCTION

In 1953 a major storm surge in the southern part of the North Sea caused severe flooding in south east England, leading to the loss of some 200 lives, as well as domestic livestock, wildlife and devastating damage to property and agricultural land. As a result there was a major reconstruction of the sea defences along the east coast of England. These defences have been maintained, extended and rebuilt during the ensuing years, but the time has now come to

¹Sir William Halcrow & Partners Ltd, Swindon, UK; ²GeoSea Consulting Ltd, Cambridge, UK; ³National Rivers Authority (Anglian Region), Peterborough, UK.

re-think the sea defence system as a whole and make some major reinvestments. Overall there are some 300 km of first line sea defences and it has been estimated that it will cost £130 m over the next 10 years to bring these defences up to standard.

Anglian Water, realising the problems that must be faced in the future, and being responsible for one the longest and most vulnerable coastlines in Britain stretching from the estuaries of the Humber to the Thames, commissioned a study of the foreshore, which would help them to establish a coastal management strategy based on sound scientific principles. Thus the Anglian Sea Defence Management Study emerged and is one of the most extensive studies of coastline properties and processes to have been carried out in the UK.

The general terms of reference for the investigations were to provide an understanding of the mechanisms causing changes in foreshore levels along the Anglian Coast and this is the focus of this paper. For completeness a brief outline is given of the study as a whole, together with some indication of the form of the management strategy.

THE STUDY

Study Area

Anglian Water's sea defences run from Canvey Island on the Thames to Trent Falls on the Humber Estuary. Given that the objective of the study was to establish management procedures based on a sound regional understanding, it was felt necessary to extend the northern boundary of the study area to incorporate the Holderness coast. This thereby includes an important sediment source for the East coast. In contrast the Kent coast, on the south side of the Thames Estuary, was not considered to interact significantly with the regime along the Essex coast and was not therefore included. The extent of the study area is shown in Figure 1.

Stage I

The first stage was a form of competition, where three consultants were invited by the Authority to present their approach to the problem. In effect they were asked the question "If this was your problem, what would you do about it?" The winning proposal focused on making maximum use of existing data sources to develop an integrated management strategy for the whole coastline.

Stage II

The rationale of the approach adopted was to extract a coherent picture from the wide range of information that was already available. This philosophy was adopted because it was felt that over such a large and diverse area, any attempt to apply numerical models to examine processes and coastal genesis would inevitably be constrained by limited knowledge of the governing mechanisms. The

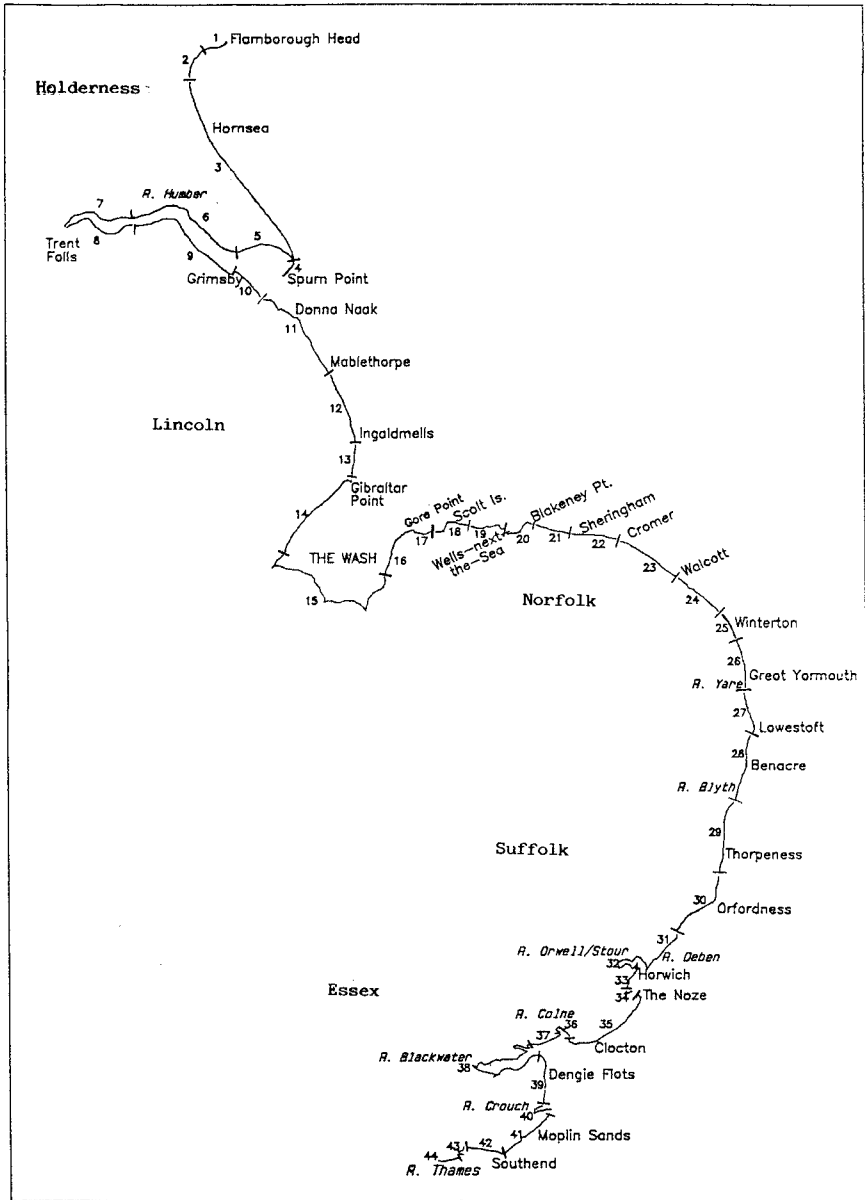

Figure 1: Study Area with Coastal Units

prime objective was therefore to structure the data in such a way that it could be rapidly manipulated. A thorough analysis of existing sources of information could then be made, to both gain insights and focus the objectives of future field work and numerical model studies.

As the first stage a referral database was established. This database essentially provides a listing of relevant references and data sources. It includes entries for reports, papers and relevant literature, as well as details of the type, extent and holder for the various sources of measured data that were identified. The database was set up using Ashton Tate's 'dBASE III' software using two separate record structures; one for references and the other for environmental data. Searches can be constructed in several ways, to give either comprehensive listings (eg all references for the Lincoln region), or much more specific responses (eg the data on waves collected during 1982 in the Norfolk region).

It was recognised from the outset that a number of important variables could not be adequately defined by simply using existing sources. As a consequence six supplementary studies were undertaken, with the objective of providing additional data and/or some further understanding. These studies provided:

- a definition of the wave climate offshore and at approximately 10 km intervals along the coast;
- an understanding of the coupling between the residual flow regime in the southern North Sea and local wind effects, in determining nearshore current residuals;
- detailed analysis results of beach profiles taken over the last 10 to 25 years;
- a description of extreme sea levels around the coast;
- a quantification of sea level rise, tectonic movement and subsidence in a geological setting;
- a summary of recent literature on the subject of coastal processes relevant to the Anglian coast.

After being screened and compiled into the desired format, all the various data were entered into a database capable of storing the geographical location of the data. The system is based on a geographical information system (GIS) and has a database which is able to handle not only single attributes but also attributes which themselves have complex data structures. Configured for this particular application the system is referred to as the 'Coastal Management Database' (CMD) and was used to meet the following objectives:

- to map relevant variables for the entire coastal region;
- to use the graphical output of the system to present each variable or combination of variables on a series of maps;
- to assess the inter-relationships among variables and their contribution to coastal erosion;

- to produce interpretive maps which form the basis of a coastal management policy.

The variables included in the database, were selected on the basis that they either provide information on the direct influences and responses of the coast (eg waves, coastal morphology, rate of retreat, etc) or on their implications with respect to the impact of the erosion and any defence strategy that may be implemented (eg present coastal works, SSSIs, land use, etc).

The development and application of the GIS is described more fully by Fleming and Townend (1989) and Townend (1990).

DISCUSSION OF RESULTS

A detailed examination and intercomparison of data sets has led to a number of general conclusions with respect to governing processes. These were used with more localised interpretations to assess coastal regimes and to establish a series of coastal units (Townend and McLaren, 1989).

For the purposes of this study the coastal zone is defined as made up of five parts; hinterland, backshore, foreshore, nearshore and offshore (Figure 3). The hinterland is landward and includes any cliff or dune system, the backshore (if it is present) extends to high water, between high and low water is classed as the foreshore, from low water out to an approximate limit of storm erosion (d_L) is taken as the nearshore, and from there on out is the offshore.

Governing Processes

The data interpretation is wide ranging and a number of key insights have been found. In many cases these were established as a result of the contrasts existing along the coast. A necessary qualification is therefore that if there is no contrast in a particular variable on the coastline, then the associated understanding may not have been picked up. Sea level rise is one such possibility, where an appreciation was derived by testing the data against an accepted "rule", rather than a direct correlation of cause and effect. Furthermore associations were only sought as a first step in seeking to develop a better understanding of the underlying physical processes.

i) Coastal Retreat/Advance Classification

An examination of long term estimates of coastal retreat and advance (established using historic Ordnance Survey maps) reveals that a very large proportion of the Anglian coast is retreating. Recent beach profile data, although more variable, reveal consistent trends.

The long term retreat data were used to develop a retreat/advance classification system which characterises the different types of

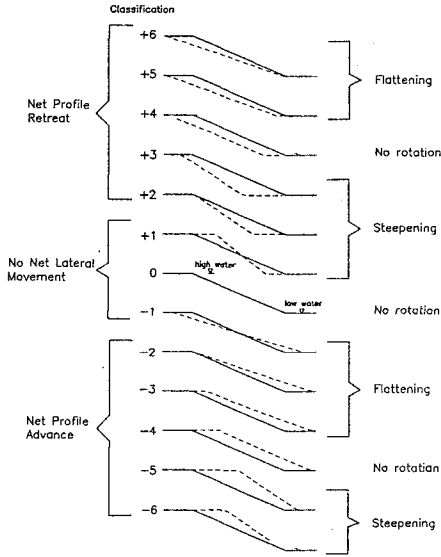

Figure 2: Retreat/Advance Classification

Figure 3: Coastal Zone Definition

Figure 4: Differential Beach Retreat

beach movement. Rates of retreat at high and low water are combined to define horizontal and rotational movements of the foreshore. In all 13 combinations have been defined and these are illustrated in Figure 2. The results for the Anglian coast, excluding the Humber, the Wash and the Essex rivers, reveal that some 70% of the coast has been subject to retreat, with 15% advancing and 15% showing no horizontal movement (Table 1). The problem of erosion on the Anglian coast is therefore clearly a substantial one.

The coastal retreat/advance classification also highlights one other characteristic that has been found to be particularly significant on the Anglian coast. Classification types +1, +2 and +3, totalling 67%, represent types of retreat in which the beach is steepening and types -5 and -6, totalling 11%, describe types of advance, again where the beach is steepening. Thus beaches appear to be steepening (to a varying extent) for 78% of the total shoreline. This is therefore an ongoing mechanism, which is of prime importance where coastal works are sited at the top of the beach.

Table 1 : Summary of Retreat/Advance Classification Data

	Net Profile Retreat		No Net Movement		Net Profile Advance	
	Type	%	Type	%	Type	%
Steepening	+2	15.1			-6	1.9
	+3	41.4	+1	10.8	-5	9.1
No Rotation	+4	10.2	0	3.2	-4	2.4
Flattening	+5	3.8	-1	0.3	-3	1.3
	+6	0.0			-2	0.5

Note: results exclude the Humber, the Wash and the Essex Rivers

In addition to providing a broad overall summary of the retreat data, the retreat/advance classification also provided extremely useful information for the interpretation task. There is considerable variation of classification type along the coast and this variation is often quite rapid. In some cases the fact that the mode of retreat did not change helped to define the limits of a coastal unit. Elsewhere it was the consistent way in which classification type changed along the shore which helped to identify particular features.

ii) Geological Setting

The retreat/advance classification provides a clear indication of the extent of the beach steepening phenomenon. Beach steepening is not however, happening uniformly along the coast (Figure 4). Indeed on

the coast between Great Yarmouth and Harwich it is hardly happening at all, despite the fact that the rate of retreat is comparable with other areas. What is striking is the marked change at either end of this particular length, which appears to correlate with the change in geology. To the north and south the coast comprises tills, alluvium and clays and is therefore essentially cohesive. In contrast the intermediate length is composed of Pleistocene Crags which makes it a predominantly non-cohesive shore.

Examining the geology set against the retreat rate, reveals that beach steepening is remarkably consistent along the till cliff frontages of Holderness, whereas the more complex stratigraphy of the North Norfolk cliffs results in more variable rates. This variability increases substantially in low-lying areas such as the barrier beach system from Weybourne to the Wash, where there are marked changes in the sediments which provide the geological setting. Interestingly, the Lincoln and Clacton coasts have very similar retreat characteristics and both comprise sand veneer beaches overlaying a clay bed, suggesting that there is much in common in the way these two areas behave. This all emphasises the importance of the nearshore geology.

One further association that has been noted is the increase in nearshore width in areas with the highest rate of beach steepening. Figure 5 shows the two data sets at approximately a 10 km resolution, and the correlation is clear. Examining the data at a finer resolution (eg 1 km) the correlation is less obvious because the beach steepening in areas with high nearshore widths is very erratic. Thus high values of beach steepening occur when the nearshore width is high, but the converse does not necessarily hold.

This is fortuitous because it provides a setting in which steepening can take place. The corollary must be that there is a threshold at which steepening no longer takes place (possibly because retreat increases to a point where the additional sediment supply becomes sufficient to protect the resultant, much narrower beach).

The geological setting has been found to induce beach steepening. The physical explanation is less clear. It has been postulated that this is a consequence of increased downcutting towards low water on cohesive shores, where the erosion process is irreversible (once a clay surface is eroded the fines are rapidly washed away). It may also reflect a changing tidal regime as a consequence of sea level rise.

iii) Coastal Orientation

A surprising feature of the coastal retreat data is an apparent rhythmic variation along the shore. Further analysis revealed that there is indeed a cyclic variation along the entire coast with a periodicity of between 3 and 6 kilometres.

Figure 5: Comparison of Nearshore Width with Beach Steepening

Figure 6: Influence of Coastal Structures on Mode of Retreat

In the search for an association with this rhythmic variation, coastal orientation was examined. The data was prepared by taking off the bearing of the normal to the coast at one kilometre intervals, using the latest edition of the 1:50,000 OS retreat revealed no obvious association. However by deriving the rate of change of orientation along the coast a good match was found. Maximum retreat occurs within embayments and minimum retreat or accretion takes place on bulging shores. This is indicative of a natural instability where erosion at one point produces an exaggerated response which is then countered by an under-response on the adjacent shoreline.

There are two types of feature which can cause a reversal of this relationship. The first is the presence of structures which can force a localised reversal on the natural perturbation (eg the accretion updrift and erosion downdrift of an outfall), or exaggerate the perturbation (eg where a coastline is over-constrained by a seawall). The second variation occurs at natural features such as nesses, spits and points which involve major changes in coastal orientation. Again these can be explained in terms of the interaction of cyclic perturbations on a line which changes direction.

The exciting mechanism for the perturbations is unclear, as is the reason for the variation in the periodicity on different lengths of coast. The understanding of this phenomenon is at a very preliminary stage. Its presence on the whole of the Anglian coast is seen as particularly significant and may well be of major importance for a proper understanding of the morphological genesis of the coast. Given the interaction with structures that has been noted, such an understanding will also aid the proper planning of coastal works.

iv) Tides and Waves

No correlation could be established between the wave energy incident on the shore and the long term retreat. Furthermore only on the Lincoln coast and from Blakeney Point to Gore Point is the potential of alongshore littoral drift clearly uni-directional. Elsewhere the variations are such that the direction of net drift can reverse from year to year.

The presence of beach steepening on both accreting and retreating features, together with the fact that rates vary significantly with the presence of channels in the nearshore seabed, suggests tidal currents (and most likely tidal residuals) play a dominant role over much of the coast from Flamborough to the Thames. Much local evidence and data for individual lengths of coast supports this finding.

A study of beach volume changes around the coast indicated that growth and depletion of the beach on a given stretch of coast shows more coherence in time than it does alongshore. This therefore suggests that major beach volume changes are due to onshore/offshore movement.

These various findings lead to the conclusion that waves are significant for moving material locally and over short time-scales. However, the major movement of material and consequently the long term geomorphological development for the majority of the coast is tidally dominated. This movement is back and forth in the nearshore, interacting with the foreshore by onshore/offshore movement. The material supplied to the beach is then moved by alongshore wave activity, the significance of which will vary according to the amount of material available for movement on the beach and the consistency of the drift direction. For example when beach levels are low on the Lincoln coast (such that the clay layer is exposed) there is little drift despite the high drift potential. In contrast when beaches are full, the groynes play an important role in reducing alongshore movement. Alternatively on the beach between Great Yarmouth and Lowestoft, the drift direction is highly variable such that the movement on the beach due to alongshore wave energy is back and forth. (Note: the strong interaction with the nearshore on this frontage results in a net southerly drift for the system as a whole).

v) Sea Level Rise

It might be argued that rises in mean sea level, and hence the levels on the beach swept by the tide, has induced the observed coastal retreat. However, an examination of potential retreat due to sea level rise based on the "Bruun rule" (Bruun,1962), shows that generally this is less than the rate actually experienced. This suggests that the retreat is not due to sea level rise alone. Indeed, work on the Dengie Flats has shown that although the margins are eroding, the main body of the marsh is accreting at a rate in excess of the rise in sea level (Reed 1988).

vi) Coastal Structures

The retreat/advance classification data was used to evaluate the influence of coastal structures on the extent and type of movement which is occurring. The deductions that have been made took advantage of the similarities between the Lincoln and Clacton coasts and the Holderness and North Norfolk cliffs. Certain other data sets, such as the actual rates of retreat and the description of backshore widths led to further amplification of the conclusions.

- a) Where there are no structures on an open cliff coast, then the cohesive shoreline is retreating and steepening, whereas the non-cohesive shore is retreating uniformly (no steepening).
- b) On cohesive shores which supply material to the coastal system (Holderness, North Norfolk), the type of structure has no discernible effect on the type of erosion taking place, but does locally slow the rate of retreat.

- c) On cohesive shores which receive sediment from other sources (Lincoln, Clacton) then the type of erosion is dependent on both the type of structure and the presence or absence of a backshore. Where there is no backshore then all structures result in beach steepening. In contrast where there is a backshore, then walls were found to induce retreat and steepening (similar to cliff coastlines) whereas lengths with revetments or embankments exhibit only steepening (no significant movement of the high water mark); the latter not necessarily being a consequence of the structures presence. This correlation is illustrated for the Lincoln and Clacton coastlines in Figure 6.

vii) Offshore Banks

A study of the offshore zone has suggested that the region can be divided up into a number of areas based on the different type of bank systems which are present. The most significant areas with respect to the Anglian coast are the Great Yarmouth banks and the series of linear banks further to the north-east.

The linear bank system may well derive from the Anglian coast via the nearshore banks at Great Yarmouth (Townend and McLaren, 1990). It is postulated that material is in circulation off Great Yarmouth, where the amount of sediment being moved is substantially greater than the present supply from the north at Winterton and south at Benacre. This circulation cell initiates new banks in the vicinity of North Cross Sands and Winterton Overfalls (to the northeast of Great Yarmouth), which evolve as linear banks moving offshore in a north-easterly direction. By examining sea level rise and historic shoreline positions it has been estimated that the supply from the coast would have been sufficient to progressively develop the bank system over the last 7-8,000 years.

Changes in Time

Not only the coast itself, but the processes which influence the coast are changing with time. Indeed the conclusions with respect to a number of the governing mechanisms described above suggest that the coast is not in dynamic equilibrium with the environment. Rather the changes taking place are altering the shore from flat and low-lying, characteristic of a low energy dissipative shore, towards a much steeper, high energy reflective shore. This change is on a geological timescale and seems to be a consequence of the initial setting of the coast, prior to, and during the Flandrian transgression.

The Anglian coast is all to the south of what was once the main sea basin which now forms the northern North Sea. It sits alongside the ridge which divides the northern and southern basins of the North Sea, and the southern basin itself. The latter developed as a tidal river estuary and only following the rise in sea level and coalition

with the northern basin could it be considered as a sea basin. Thus the coastal setting is one of a shoreline on the edge of a newly formed sea basin and still adjusting to this much more dynamic environment.

CONCLUSION

There have been a number of aspects to the Stage II studies which have each seen significant advances. The first is the development of a methodology which allows the data (either raw or in some summary format) to be freely explored. This has involved the use of a sophisticated database and much has been learned about both the limitations and potential of mapping analysis. The application of this approach has led to an extensive interpretation of the coast both on a regional and a local scale. With the understanding that this has provided, there are a number of implications for the efficient and cost-effective management of the coast. These include:

- Beaches on cohesive shores are generally steepening, although this may also be a consequence of the geological setting.
- The rate of retreat exhibits a cyclic variation along the coast and this is related to the rate at which the coast changes its orientation.
- Tidal influence has been found to play a major role in the long term development of the coast.
- Retreat rates were found to be in excess of that which could be attributed to sea level rise.
- The type of structures found on the shoreline influence both the rate and type of erosion which takes place.
- The bank system off the North Norfolk coast has an important interaction with the coast.

These findings are all important for the proper management and, where appropriate, design of works, in the coastal zone. A more localised interpretation was developed in order to divide the coast up into a series of coastal units. These are not necessarily independent units but are based on the presence of coherent characteristics within the unit (Figure 1).

The basis of the short term management strategy, developed following the Stage II studies, has been described by Fleming and Townend (1989). The context of this development in terms of the overall formulation of a management framework is considered by Townend (1989, 1990).

In view of the substantial nature of some of the insights derived, a number of further investigations have been initiated as Stage III of the study. This comprises a wide range of tasks aimed at filling in data gaps, developing a better understanding of the coastal mechanisms identified, and refining the "management system" as a fully operational tool for coastal managers. There are essentially four aspects to the work; field measurements, detailed studies, preparation of monitoring guidelines and further development of the GIS based management system (Townend and Fleming, 1990). It is anticipated that these studies will lead to specific recommendations for future sea defence works, and provide a coherent framework for the long term management of this coast.

CHAPTER 198

FUNCTION OF DETACHED BREAKWATER TO CONTROL LONGSHORE SEDIMENT TRANSPORT

Toru Sawaragi¹, Iehiro Deguchi² and Ga-Ya Kim³

ABSTRACT

The function of offshore detached breakwater of controlling longshore current and resulting sediment transport under oblique wave incidence is examined mainly through experiments. Although the offshore detached breakwater can effectively reduce incident wave energy, it has little influence on longshore current. More than 50% of the volume of sediment transported in the longshore direction on the natural beach is trapped behind the breakwater. The total longshore sediment transport rate around the breakwater can be predicted more precisely by integrating the local longshore sediment transport rate estimated from the flux model than by the empirical formula of Savage type.

INTRODUCTION

Various coastal structures have been used to construct protective works against beach erosion. Among them, offshore detached breakwaters are the most popular structures in Japan. This is because they can effectively reduce and absorb incident wave energy. A crown height of the offshore detached breakwater in Japan is usually determined to be one half of the design wave height higher than the high water level. So, the offshore detached breakwater often detracts from natural coastal views and prevents effective utilization of coastal regions. Strongly diffracted waves by the offshore detached breakwater also creates concavoconvex shoreline.

¹ Professor and ² Associate Professor, Dept. of Civil Engineering, Osaka University, Yamada-oka 2-1, Suita-city, Osaka 565, Japan

³ Head Researcher, Municipal Administration Research Inst., Pusan city, Korea

Recently, there is increased concern with preservation of coastal environments and easy access to the shoreline. To cope with these requirements, another coastal protection works such as sea dikes of gentle slope, artificial reef with a submerged breakwater, head-land defence works and so on have been newly planned and constructed in Japan. However, all offshore detached breakwaters cannot be replaced by these new structures. The applicability of these engineering works depends on the causes and local situations of potential disasters together with the ability of these structures to control sediment movement.

As regards the offshore detached breakwater, it became possible to predict wave deformation behind it by some numerical procedures (for examples, Ohnaka, et al., 1988) and the authors have already developed numerical model for predicting wave-induced current behind it (Sawaragi et al., 1981). Formations of salient or tombolo behind the offshore detached breakwater have also been investigated by many researchers. However, until now, only a few studies have been carried out about the wave-induced current and sediment movement around the offshore detached breakwater under the condition of oblique wave incidence.

On the other hand, a suitable plane-arrangement of coastal protective works against beach erosion caused by longshore sediment transport can be effectively determined by predicting the shoreline deformation based on the so-called one-line theory. In such cases, it is very important to know how the offshore detached breakwater affects the longshore sediment movement on a natural beach.

The aim of this study is to investigate the function of the offshore detached breakwater of controlling obliquely incident waves, longshore current and resulting longshore sediment transport by conducting 3-D experiments.

EXPERIMENT

Method of experiment:

Experiments were carried out in a wave basin of 20m long, 10m wide and 0.6m deep. A model beach of the slope of 1/10 whose contour lines made an angle of 30° to the wave generator was constructed in the basin as shown in Fig.1. The experimental wave height and period were 6.5cm and 1sec. In this study, effects of the offshore detached breakwaters on waves, wave-induced current and longshore sediment transport caused by this

wave arc investigated. The dimensions of the model offshore detached breakwater are summarized in Table 1. The wave height, water depth and direction at the breaking point on the natural beach were 7.7cm, 7.5cm and 18°.

In this paper, the following notations and coordinate system are used: x axis is taken offshore from the initial shoreline and y axis is in the direction of longshore. X_b is the width of the breaker zone and X_{off} is the distance between the initial shoreline and the breakwater, l is the length of the breakwater, B is the opening between breakwaters when they are constructed as a pair, and L_0 is the wave length in deep water.

Fig.1 Wave basin and coordinate system

Table 1 Experimental conditions

[Fixed bed experiment]		[Movable bed experiment]		
X_{off}/X_b		X_{off}/X_b	l/L_0	B/l
l/L_0	0.57, 0.86, 1.7	0.86	0.5	---
B/l	0.25, 0.5, 1.0	0.86	1.0	---
		1.70	0.5	---
		1.70	1.0	---
		0.86	1.0	1.0
		0.86	1.0	0.5
		1.70	1.0	1.0
		1.70	1.0	0.5

Through the whole movable bed experiments, sand of median grain size of 0.05cm was used to make a movable bottom. Distributions of wave heights and directions, velocity of wave-induced current and topographic change around the breakwater were measured at time intervals determined in advance.

Data analysis:

Based on the measured change in the water depth, $\Delta h(x,y,t_k)$, longshore distributions of total longshore sediment transport rate, $Q_{ye}(y)$, was evaluated to investigate the effect of offshore detached breakwater on the longshore sediment transport. The water depth was measured at grid points set at the distance $\Delta x=12.5\text{cm}$ and $\Delta y=25\text{cm}$ in the wave basin. The change in the water depth, $\Delta h(x,y,t_k)$, is defined as a difference of water depths measured at time $t=t_{k+1}$ and $t=t_k$

$$\Delta h(x,y,t_{k+1})=h(x,y,t_{k+1})-h(x,y,t_k). \quad (1)$$

A continuity equation of the total longshore sediment transport, $Q_y(y,t)$, is expressed as follows:

$$\frac{\partial A(y,t)}{\partial t} = \frac{1}{(1-\lambda)} \frac{\partial Q_y(y,t)}{\partial y} \quad (2)$$

where $A(y,t)$ is the sectional area shown in Fig.2 and is defined as

$$A(y,t) = \int h(x,y,t) dx \quad (3)$$

The total longshore sediment transport rate in the experiment is calculated by transforming Eq.(2) into the following difference form and is represented by $Q_{ye}(y,t)$.

$$Q_{ye}(j,t_{k+1}) = \frac{\Delta y}{\Delta t} (1-\lambda) \sum [A(j,t_k) - A(j,t_{k+1})] + Q_{ye}(j-1,t_{k+1}) \quad (4)$$

where j indicates the j -th grid point along the shoreline and $y=j*\Delta y$.

Fig.2 Definition sketch of Δh , ΔA and Δl

An eigenfunction analysis becomes a great help to understand the mode and characteristics of sediment movement around the breakwater (for example, Deguehi et al., 1986). In this study, measured changes in water depth $\Delta h(x, y, t_k)$ are expanded into the products of longshore and cross-shore eigenfunctions $C_i(y) \cdot E_i(x)$.

$$\Delta h(x, y, t_k) = \sum_{i=1}^{\infty} C_i(y) \cdot E_i(x) \quad (5)$$

WAVE HEIGHT AROUND BREAKWATER

Figure 3 illustrates comparisons of measured wave heights along the line of $x/X_b=0.28$, i.e., near the shoreline behind the offshore detached breakwaters of different lengths ($X_{off}/X_b=0.57, 0.86$ and 1.7). A vertical axis is the ratio of measured wave height, H , around the breakwater and that measured on the natural beach, H_n , at the same point.

Fig.3 Wave height distribution behind breakwater ((a): $X_{off}/X_b=0.57$, (b): $X_{off}/X_b=0.86$, (e): $X_{off}/x_b=1.7$)

Solid, dotted, broken and chainlines in these figures are the wave height around the breakwaters whose lengths l correspond to $l/L_0=0.5, 0.75, 1.0$ and 1.5 , respectively.

As the distance between the line of $x/X_b=0.28$ and the breakwater increased, that is in the case where the breakwater was constructed outside the breaker zone, the longshore distribution of wave height approaches uniform due to the interaction of two diffracted waves from both sides of the breakwater.

An attenuation of wave height behind the breakwater also becomes less significant because the wave height at the depth along $x/X_b=0.28$ is depth-limited. Naturally, the longer the breakwater, the larger attenuation of wave height took place. However, when the length of the breakwater is larger than the incident wave length, the maximum attenuation behind the breakwater is almost the same.

WAVE-INDUCED CURRENT AROUND BREAKWATER

It is well known that wave-induced current behind the breakwater caused by the normally incident waves is featured by the formation of a pair of circulation cells. However, under conditions of oblique wave incidence, as were the cases of our experiments, longshore current flowed behind the breakwater smoothly as can be seen from Fig.4.

Fig.4 Flow pattern of wave-induced current ($X_{off}/X_b=0.86$)
 ((a): $l/L_0=0.5$, (b): $l/L_0=1.0$, (c): $l/L_0=1.5$)

Figure 4 is the flow patterns of wave-induced current around the breakwater of various length. Arrows in the figures are the velocity vectors obtained by tracing floats in the experiments.

Although wave heights decrease to a great extent behind the breakwater, these wave field have little influence on the longshore current behind the breakwater.

TOPOGRAPHIC CHANGE AROUND BREAKWATER

Figure 5 shows three examples of the topographic changes took place around the breakwaters during 1hr after wave generation. Figures (a) and (b) are the cases of the single breakwater constructed within and outside of the breaker zone. Figure (c) is the case of a pair of breakwaters constructed outside the breaker zone.

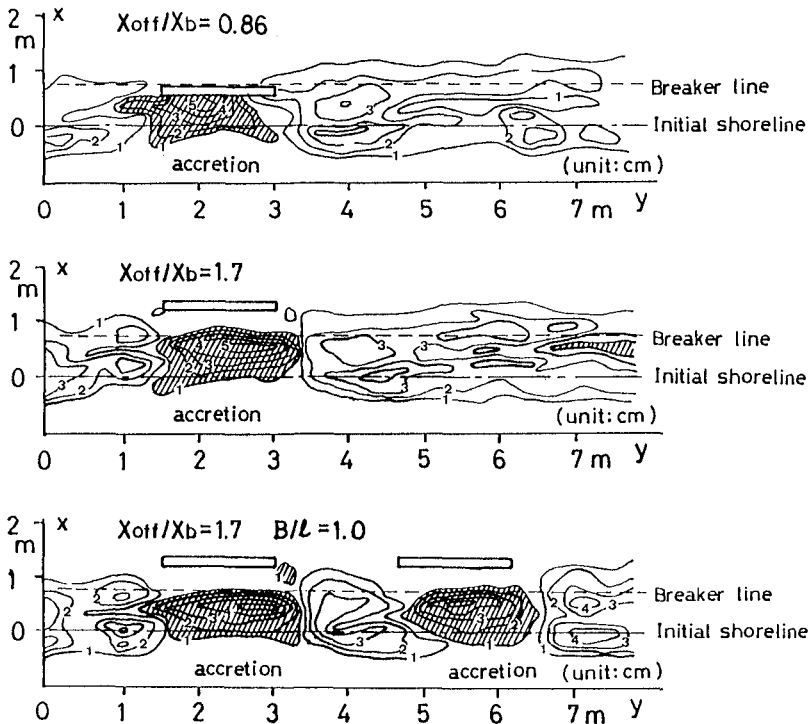

Fig.5 Topographic change around breakwater ($l/L_o = 1.0$)
 ((a): $X_{off}/X_b = 0.86$, (b): $X_{off}/X_b = 1.7$ and
 (c): $X_{off}/X_b = 1.7$, $B/l = 1.0$)

In the figure accreted regions are shown by the hatched area. A significant deposition took place behind the breakwater in every cases.

To discuss the function of the offshore detached breakwater of controlling sediment transport, it is necessary to examine where did these deposited sand come from, ie, from the upstream side, downstream side or from the offshore. The authors investigated this point by analyzing the topographic change, $\Delta h(x,y)$, at a measuring grid point (x,y) in two different ways. One is to examine the distribution of the total longshore sediment transport rate, $Q_{ye}(y)$, and the other is the empirical eigenfunction analysis.

EFFECT OF BREAKWATER ON CONTROLLING LONGSHORE SEDIMENT TRANSPORT

Total longshore sediment transport rate:

Solid line in Fig.6 shows some examples of estimated longshore distribution of the total longshore sediment transport rate, $Q_{ye}(y)$, calculated from Eq.(4).

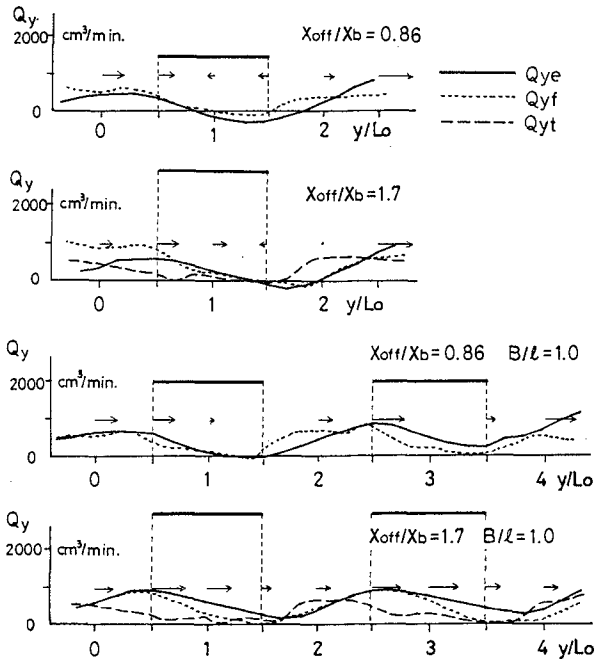

Fig.6 Total longshore sediment transport rate around breakwater ((a): $X_{\text{off}}/X_b = 0.86$, (b): $X_{\text{off}}/X_b = 1.7$, (c): $X_{\text{off}}/X_b = 0.86$, $B/l = 1.0$, $X_{\text{off}}/X_b = 1.7$, $B/l = 1.0$)

When the single breakwater was constructed within the breaker zone, the value of Q_{ye} becomes negative in the lee-side of the breakwater which means that sediment was transported in the opposite direction of the longshore current in this region. On the other hand, when a pair of breakwaters was constructed, no significant negative value of Q_{ye} appears regardless of its position.

Cross-shore and longshore eigenfunction:

Figures 7 illustrates examples of the longshore and cross-shore eigenfunctions with the maximum eigenvalue. The ratio of these maximum eigenvalues to the traces are more than 60%.

Fig.7 Cross-shore and long-shore eigenfunctions correspond to the largest eigenvalue($X_{off}/X_b=1.0$)
 ((a): $l/L_o=1.0$, (b): $l/L_o=1.0, B/l=1.0$)

Figure(a) is the case where the single breakwater was set at $x/X_b=1.7$. Figure(b) is the result of the case where a pair of breakwaters was constructed at the same location. As can be seen from these figures, $E1(i)$ is positive throughout the whole region and $C1(y)$ indicates both positive and negative values along the longshore direction. Especially, behind the breakwater, the value of $C1(y)$ is negative. Therefore, it can be judged that the pattern of the topographic change represented by the product $C1(y)*E1(x)$ was caused by the longshore sediment transport.

Ability of breakwater to trap sediment:

The ratio of the volume of deposited sediment behind the breakwater and the volume of eroded sediment in the upstream side of the breakwater is also estimated by the ratio of the area of hatched region A_e and the area of dotted region A_a . If A_a is greater than A_e , more sediment transported from the upstream side of the breakwater was deposited behind the breakwater. This means that the sediment in the downstream side of the breakwater was transported in the opposite direction of longshore current by the diffracted waves. If A_a is smaller than A_e , a part of sediment transported from the upstream side of the breakwater in the longshore direction was transported to the lee-side through behind the breakwater.

Figure 8 shows the ratio of A_a/A_e of the whole cases carried out in the experiments. Open circles are the cases of single breakwater and the breakwater of upstream side. Closed circles are the results of the lee-ward breakwater.

Fig.8 Ratio of A_a/A_e

In the case of $X_{off}/X_b=0.86$ and $l/L_o=1.0$, the ratio of A_a/A_c becomes almost 1.5. In this case, the sediment in both upstream-side and lee-side of the breakwater was transported behind the breakwater and settled down there. The same conclusion has already been derived from the analysis of the distribution of Q_{ye} .

When the length of the breakwater is 1/2 of the incident wave length, 60 to 70% of the amount of the sediment transported in the longshore direction is trapped behind the breakwater and the rest is flow through behind the breakwater to the leeward. Furthermore, the each breakwater constructed as a pair has a high efficiency to trap sediment behind them when compared to the single breakwater of the same dimension.

Relation between ΔA and Δl :

Figure 9 shows the relation between the change in sectional area ΔA and the shoreline displacements Δl . It is found that relatively high correlation exists between ΔA and Δl regardless of the location and dimension of the breakwater.

Fig.9 Relation between ΔA and Δl around breakwater

From these results, a so-called one-line theory can be applied for the prediction of shoreline change which

will take place around the offshore detached breakwaters provided that the longshore distribution of total longshore sediment transport rate can be given.

ESTIMATION OF TOTAL LONGSHORE SEDIMENT TRANSPORT RATE AROUND THE BREAKWATER

The total longshore sediment transport rate is generally estimated by the following empirical formula of Savage type.

$$Q_y = \alpha (ECg)_b \sin(2\theta_b) \quad (5)$$

where $(ECg)_b = (\rho g H^2 C_g)_b / 8$ is the incident energy flux at wave breaking point, θ_b is the wave breaking angle and α is the empirical coefficient. According to Eq.(5), Q_y is directly related to the wave conditions at breaking point. Therefore, the total longshore sediment transport rate around the structures constructed in the breaker zone can not be predicted by this kind of formula.

There also remains another problems in the expression of Q_y because the direction of the longshore sediment transport is uniquely determined by the wave breaking angle. It seems reasonable to assume that the longshore current play a more important role in the longshore sediment transport than the wave breaking angle does.

We can also estimate the total longshore sediment transport rate by integrating local longshore sediment transport rate, q_y . Some formulas for predicting the local longshore sediment transport rate have already been proposed. In this study, the value of q_y is estimated from the flux model (Sawaragi et al., 1985). The wave field and the velocity of wave-induced current were obtained by the numerical simulation based on the unsteady linear mild slope equations (Ohnaka et al., 1988) and depth and time averaged basic equations of wave-induced current (Sawaragi et al., 1981).

In Fig.6, the total longshore sediment transport rate, Q_{yf} , calculated by integrating the local longshore sediment transport rate are shown by the dotted line. Broken lines in the figure are the total longshore sediment transport rate, Q_{yt} , calculated from the empirical formula of the form of Eq.(5). The value of Q_{yt} can be estimated only in the cases where the breakwater were constructed outside the breaker zone. In the calculation of Q_{yt} , simulated results of wave height, water depth and direction at the wave breaking point were used and the value of α was tentatively determined to be 1.

As can be seen from Fig.6, there is a large discrepancy between Q_{ye} and Q_{yt} . On the other hand, Q_{yf} calculated by integrating local longshore sediment transport rate gives more accurate estimation of the total longshore sediment transport rate, Q_{ye} , estimated from the topographic change.

CONCLUSIONS

1. Waves behind the offshore detached breakwater under the obliquely incident waves attenuate significantly as is the case of normal wave incidence. However, these wave fields have little influence on the longshore current behind the breakwater. Longshore current flowed smoothly behind the breakwater. No circulation cell of wave-induced current appeared.

2. In spite of the flow pattern of longshore current, a large amount of sediment transported in the longshore direction is trapped behind the offshore detached breakwater. The pair of offshore detached breakwaters has higher efficiency to trap sediment transported in the longshore direction than the single breakwater does.

3. The total longshore sediment transport rate behind the offshore detached breakwater can be predicted more precisely by integrating the local longshore sediment transport rate estimated from the flux model than by the so called Savage type formula.

CHAPTER 199

OSCILLATORY FLOW INVESTIGATIONS IN POROUS MEDIA

Gregory M. Smith¹ and Kevin R. Hall²

INTRODUCTION

A series of experiments has been conducted at the Coastal Engineering Laboratory of Queen's University in order to investigate the characteristics of accelerating flow through porous media. The nature of the steady flow law in coarse granular material has been reasonably well defined from a large number of previous studies. Variations on this steady flow law have been applied to the case of oscillatory flow, in numerical models of forces in breakwaters for example, with the explicit assumption that the steady law is applicable to the unsteady case. Few experimental investigations have been conducted to verify this assumption. Hence the present study was designed specifically to test the applicability of the steady flow law (Forchheimer's equation) to oscillatory flow.

EXPERIMENTAL PROCEDURE

Parameters relevant to this study include the grain size and porosity of the test sample (and shape), bulk or macroscopic velocity of flow through the sample and the pressure loss associated with the flow. A test programme was established to measure these quantities for both steady unidirectional and oscillatory flows.

Tests were conducted in an oscillating water tunnel (Figs 1,2). A test section of porous material was installed in the centre of the measuring section. Both unidirectional and oscillatory flows could be generated within the tunnel. The

² Assist. Prof. of Civil Engineering, Queen's University, Kingston, Ont. Canada K7L 3N6.

test section had a height of 85cm, width of 45cm and the length varied according to the test material.

Tests were made on three different types of materials: 75 mm diameter plastic spheres, 42 mm spheres (golf balls) and one sample of rock ($M_{50}=1.43$ kg; $D_{50}=100$ mm). Each type of sphere was tested at high and low porosities (cubic and rhombohedral packings, respectively). The effect of the dimples on the golf balls was not considered in the analysis. The use of these different sizes of spheres allowed an illustration of the wall effect of the tunnel on the measurements. In situ porosity measurements were made on all samples.

Head losses across the test section were measured with four pressure transducers (Data Instruments AB/99; 0 to 6 psi), installed in the centre of the sample; two near the upstream end and two near the downstream end. Samples were measured at 10 Hz for all tests; this provided adequate resolution of the pressure traces while minimizing the storage space required. Sampling was controlled by a Zenith 386 microcomputer.

The transducers were calibrated over their full range in a 4.5 metre high water column periodically during the test programme but it was found that no significant changes occurred to their calibration curves. For tests on the spheres, the transducers were mounted inside of the spheres for placement in the test section (Figure 3). This allowed for measurement without interference with the flow. For the test on the rock sample the transducers were set in the voids and rocks were placed around them so as to hold them securely and prevent movement. During the first test series, the 75mm spheres in rhombohedral packing, two transducers were installed side by side, but facing opposite directions at both the upstream and downstream ends of the section. This was to compare measurements of the transducers themselves and to test if orientation altered the readings. Orientation made no difference and both sets of transducers provided identical readings. Subsequent tests were made with two sets of transducers located at two elevations within the section to investigate any differences due to possible flow variations. The majority of tests showed no difference in these readings. Where differences did occur, the readings were averaged; no attempt was made to include effects of non-uniformities in flow or pressure readings.

Velocity measurements were made using a laser doppler anemometer (LDA). This consisted of a DISA 15 mW helium-neon laser, photomultiplier and a frequency tracker. Only the amplifier component of the tracker was used; since no frequency shifting was employed the tracker was not adequate to measure small and reversing flows generated for the experiments. Instead, the photomultiplier signal was sampled directly by a VAXstation 3200 mini computer, via an analogue to digital converter. The photomultiplier outputs

a voltage signal, the frequency of which is directly proportional to the velocity of flow. After this signal was acquired (and time stamped), its peak (Doppler) frequency was determined by power spectrum analysis software. Velocities were computed by the relation

$$V = \frac{\lambda}{2 \sin \frac{\theta}{2}} \times f_D$$

where V = velocity of flow
 λ = wavelength of laser light = 632.8 nm
 θ = beam intersection angle
 f_D = Doppler (signal) frequency.

For each flow condition tested, velocities were measured at several locations across the tunnel section in order to determine the average velocity. The velocity distribution was not uniform, varying typically +/- 10% from the mean from top to bottom and inside to outside walls of the tunnel. Measurements were taken at only one position along the length of the tunnel, that being approximately 2.1 metres upstream of the upstream end of the test section. This was due to space restrictions for location of the laser equipment. As it was only the "bulk" or average velocity that was required, this was considered adequate since the flow rate at any given instant in time must be constant along the length of the tunnel. No effects of the non-uniformity of the velocity profile were considered and only (spatial) average velocities and hydraulic gradients were compared.

A concern of velocity values derived from bulk discharge measurements is that higher discharge rates occur near the walls of the permeameter. This causes the "bulk" velocity value to be higher than that actually flowing through the centre of the section. Direct measurement of velocities near the centre of the tunnel should minimize this error. Ideally the velocity measurements should be made adjacent to the test section but it was found that large fluctuations occur in that area due to rapid expansions and contractions from the pore exits and entrances. Without the use of a frequency shifter and a two component LDA it was not possible to obtain reasonable measurements in that location.

Steady flows in the tunnel were generated with a constant speed pump. The flow rate was varied by means of two valves which controlled the amount of water directed into the measuring portion of the tunnel. Water prevented from entering the test section was recirculated into a stilling basin behind the tunnel. Flow rates tested in these experiments ranged from approximately 1.5 cm/sec to 30 cm/sec.

Oscillatory flows were generated by means of a piston driven by a variable speed motor. The stroke length of the piston was also variable. Tests were conducted with stroke lengths of 2.5 cm, 5.0 cm and 10.0 cm for each sample, and periods ranging from 3 seconds to 12 seconds. These values represented the widest ranges that could be tested without damaging the test sections, although the piston is capable of operating over greater ranges.

The porosity of each sample tested was measured by sealing off the test section from the rest of the tunnel and adding measured amounts of water. The volume of water added indicated the volume of voids in the section. The section was sealed using metal plates fitted with a rubber gasket around the edges, which could then be expanded outward by tightening a series of screws, thereby providing a tight seal around the edges of the tunnel. However, initial measurements revealed significant leakage from the lower corners of the plates as well as through the false floor inside the tunnel (although no water leaked out of the tunnel itself). Further attempts to seal these areas were only partially successful at preventing leakage as the head of water in the section increased. To further reduce leakage secondary partial barriers were installed in the tunnel, adjacent to the metal plates and the space between was filled with water to the same elevation as that within the section. This was found to adequately minimize any leakage.

Water was added to the section by buckets, each bucket containing a known volume, and the water level in the section was measured after each bucket was added. This provided a means to determine if any leakage had occurred (fig 4). For the sections with spheres in rhombohedral packing, no half spheres were used around the edges so the porosity was much higher in that region. In order to calculate the porosity of the section proper, the volume of these extra voids was calculated and subtracted from the volume of water added. Porosity values for the five test sections are listed in the table below.

The values for the spheres differ slightly from the theoretical values which can be calculated precisely. These differences arise from the fact that the packing arrangements were not perfect, since the spheres did not fit exactly into the tunnel section; there were always some small gaps here and there that caused the porosity to be somewhat higher than that for perfect packing.

No attempt was made to make highly accurate measurement of the porosity in this study. Previous work has shown that permeability is highly sensitive to porosity while accurate measurements of porosity are very difficult to make owing to factors such as surface adsorption and air entrapment in the voids. This has been discussed by Dudgeon (1968). On the other hand, the goal of such research is to provide a method of predicting the hydraulic performance of coarse granular structures where porosities can not be accurately estimated. Porosities were measured in this study only to provide some comparison to other work, rather than to define the exact form of their relationship to the

hydraulic conductivity of the sample.

RESULTS

The Forchheimer equation can be linearized if written as

$$\frac{S}{V} = a + bV$$

where S = hydraulic gradient
 V = macro. velocity
 a,b = coefficients

The coefficients a and b can be found by regression analysis. Steady flow data for each test is plotted on figure 5 and the associated a and b values are:

	a (sec/m)	b (sec/m) ²	porosity
75mm spheres			
Rhombohedral:	0.32	12.0	0.32
Cubic:	0.06	2.60	0.52
44mm spheres			
Rhombohedral:	0.38	26.1	0.30
Cubic:	0.06	5.92	0.52
Rock:	0.06	3.25	0.49

It is evident that geometrically similar packing arrangements display similar values of the intercept a, indicating similar permeability coefficients as defined by Ward (1964) but the slope b is steeper by a factor of two for the smaller 42mm spheres. The length of the test section was 15 diameters for both the large and small spheres, hence the amount of surface area of each sample was of similar magnitude (within 10%). Evidently, using material that is large compared to the tunnel dimension will lead to underestimation of the energy losses. The 42mm spheres correspond to the general rule of maximum grain size to container dimension of 1/10 as proposed by Rose and Rizk (1949). The data for the rock sample falls close to the cubic arrangement of the 75mm spheres, ie. offering the least resistance.

Results from the oscillatory tests are presented in phase averaged form. Typical phase averaged curves for velocity and hydraulic gradient are shown in figure 6. When this data is plotted in the form of figure 5 above, it becomes apparent that the points do not all follow the steady flow curves

(figure 7). Also, the traces for increasing velocity are slightly different than those for decreasing velocity and the differences increase as acceleration increases. There also seems to be a general trend that the magnitude of these differences increases as the period decreases, which supports the findings of den Adel (1987), who concluded that inertial effects are most dominant at smaller periods, especially at periods less than 1 second.

Figure 8 shows values of S/V vs. V for two periods (5 and 10 seconds) for the 42mm spheres in cubic packing, along with the steady flow regression line. The steady flow line passes through the lower curve for both data sets. As is the trend with all results, the upper ends of the oscillatory curves follow the steady flow regression lines. At smaller velocities, however, significant deviations occur as the accelerations increase. These deviations are larger for smaller periods with the associated higher mean velocities, ie. with higher magnitudes of acceleration. Den Adel (1987, 1990 pers. comm.) has shown that such deviations can arise from a phase shift between the velocity and hydraulic gradient. The occurrence of an added mass effect may also cause part of this deviation, as proposed by Hannoura and McCorquodale (1978) and Abdel-Gawad and McCorquodale (1985).

Similar effects are evident in figure 9, which shows data for various piston stroke lengths. The period of oscillation was constant at 8 seconds and stroke lengths of 25, 50 and 100mm were tested. Shorter stroke lengths produce smaller flow velocities and therefore smaller accelerations.

Results presented herein are preliminary in nature and more detailed data analysis is in progress. Specifically, the effect of phase shifts between velocity and hydraulic gradient and the presence of added mass effects will be given further consideration. At the present time, the data suggests that the steady coefficients in the Forchheimer equation describe oscillatory conditions reasonably well where the velocities are maximum and accelerations minimum. At higher accelerations, differences between steady and oscillatory curves can be significant.

CHAPTER 200

INSTANTANEOUS SEDIMENT CONCENTRATION DUE TO WAVE ACTION AT PROTOTYPE SCALE

Klemens Uliczka*

1. INTRODUCTION

At sandy coasts the sediment transport due to wave action can cause beach erosion and loss of protecting dunes. In order to calculate the wave-induced sediment transport the physical parameter of wave height, wave-induced current, instantaneous sediment concentration and bottom elevation have to be known or measured. The following study was concerned with field measurements and extreme conditions (wave-induced sheet-flow transport), which were simulated at prototype scale in the Large Wave Flume (GWK) in Hannover.

2. MEASURING EQUIPMENT

From first investigations in the year 1987 with respect on wave-induced sediment concentration at velocities in the range up to 1.2 m/s followed the development of an electro-resistance- type-sediment-concentration-probe (ERSC) for prototype conditions. The idea arose from the small scale probe ERSC, used at wave tunnel experiments by HORIKAWA et al. (1982). The electric system enables the measurement of the bottom ($c/c' = 1.0$) and nearbottom concentrations at ripple as well as sheet-flow conditions.

The aim of the test series was, to get experience with the system. The probe ist still in development at the Leichtweiss-Institute in Braunschweig, and it has to be

*Research Engineer, Dr.-Ing., Bundesanstalt für Wasserbau
-Aussenstelle Küste-, Wedeler Landstrasse 157,
D-2000 Hamburg 56, Fed. Rep. of Germany

solved some structural problems. It will be presented, that the ERSC-probe is in principle prepared for measurements and that the results warranted the continuing development of the probe.

2.1 ERSC-PROBE IN FIELD TESTS

Since the GWK could be used only for a limited time for experiments with sand bottom, a prototype of the ERSC-probe, developed at the Leichtweiss-Institute of the Technical University of Braunschweig, was tested under field conditions at the island Norderney in the German Bight. The ERSC-probe had 6 electrodes in steps of 1 cm, connected to WHEATSTONE-half-bridges.

The ERSC-probe was positioned in the middle of an groyne field in the north-west part of the island. The water depth during the measurements was about 1.0 m, and the wave height about 0.5 m. The water temperature was $T_w = 9^\circ\text{C}$. The sand near the test section had the mean diameter D_{50} of 220 μm and the geometric standard deviation was $\sigma_g = 1.43$.

The probe was installed after calibration under field conditions in the breaker zone during ebb tide, so that all electrodes were covered by sand. The assumption, that due to wave action the electrodes will be exposed, was verified by the electric signals. The reflection of waves from the groynes strongly influenced the measurements as seen from the current-vector during 40 s in Fig. 1. The wave-induced orbital velocity in on- and offshore direction could not be defined.

The time sequence of a measurement over 40 s is shown in Fig. 2. The upper part of Fig. 2 shows the measured wave induced velocity with a maximum of 1.38 m/s, registered about 0.1 m above the bottom. Below are plotted the signals of 4 ERSC-electrodes, calculated from the extreme values of clear water and packed sand.

The correlation of the sediment concentration with the wave induced velocity is very difficult and the result cannot be used for basic research because of the current vector (see Fig. 1).

Figure 1. Current vector during 40 s of the measurement at the island Norderney

Figure 2. Time sequence during 40 s of the measurement at the island Norderney

Fig. 3 illustrates the variety of the vertical sediment concentration distribution during 40 s. The distance between the electrodes was 1 cm. The distribution between the measured values was plotted linear.

At the beginning of the measurement all wires were covered by sand and at the end the probe registered clear water, so that for the analysis the calibration values could be taken directly from the measurement. But, changing water temperature and conductivity has to be compensated in further developments. Scours due to vertical supports were assumed, but could not be observed visually.

Figure 3. Sediment concentration distribution during 40 s of the measurement at the island Norderney

The results presented demonstrate the problems with information gathering particularly on sediment concentration in the surf zone which can be used for basic research. The necessity of instantaneous data on wave induced sediment concentration and the possibility to simulate high orbital velocities in the GWK in Hannover led to further investigations on the development of the ERSC-Probe.

2.2 THE ERSC-GWK-PROBE

The ERSC-GWK-probe (GWK: Large Wave Flume in Hannover) was developed at the Leichtweiss-Institute for large scale conditions. It recorded the instantaneous sediment concentration in the range of 7 cm (in steps of 1 cm) over the bed, and was steered by optical sensors, so that it should follow the bottom elevation as it changed due to hydraulic conditions.

The change of water temperature and conductivity was compensated with electrodes about 0.5 m above the bottom shielded against suspended material. These wires were connected parallel to the measuring electrodes within the WHEATSTONE-half-bridges. Consequently, only the sediment concentration was registered inside the electric field, of which 90 % were measured with a radius of 2.2 mm around each electrode. Starting from the principle, that an electric resistance has to be linear, the probe was calibrated for both extreme boundary conditions: clear water ($c/c'=0$) and wave-induced packed sand ($c/c'=1$). The scattering of both of these values yielded a measure of the accuracy.

The diameter of the wires was reduced from 1 mm (Norderney-probe) to 0.8 mm and the horizontal distance of the lateral supports was 8 cm. The measuring section of 1 cm length on each wire was placed in the middle between the vertical supports. Fig. 4 shows a sketch of the ERSC-GWK-probe.

Two optical sensors, one in vertical, the other in horizontal direction at the tip of one support recorded the distance of the lowest ERSC-wire to the sand bed. The sensitivity of the optical sensors was tuned in the laboratory in such a way, that the vertical sensor had all the time to register sediment concentration greater than about 1,000 g/l. The horizontal sensor had to measure clear water. The distance between both sensors was 1 cm. The hydraulic power steering, by means of on/off connections, should keep the probe near the bottom, so that the lowest wire, ERSC I, should register the near bottom concentration.

Under prototype conditions in the GWK the sensitivity of the optical sensors had to be tuned new before each test series. Therefore a constant distance was not kept for all test series. As the sensitivity was to less,

the lowest wires were covered by sand.
 The time-analysis of the vertical movements yielded the order of magnitude of the bottom elevation changes even during a single wave.

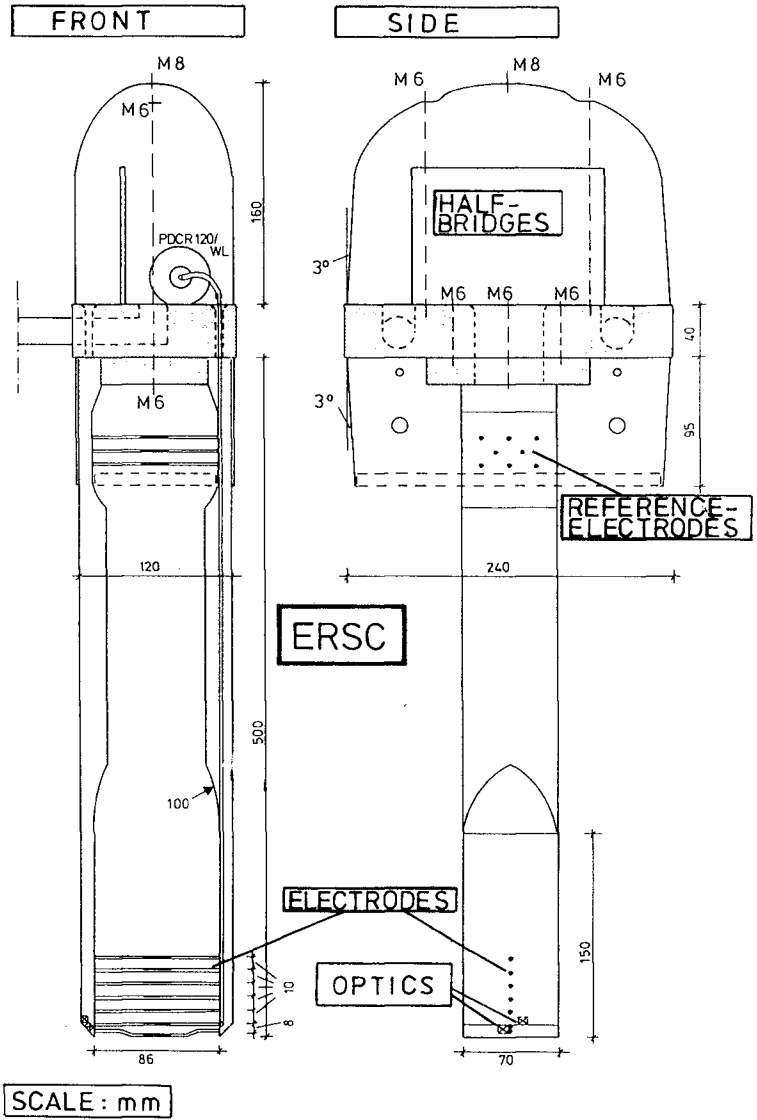

Figure 4. Sketch of the ERSC-GWK-probe

3. INVESTIGATION IN PROTOTYPE SCALE

3.1 TEST SECTION IN THE GWK

The investigations in August and September 1989 were carried out in the GWK in Hannover, in which waves of the size up to 1.8 m were generated.

A sand bed of 0.5 m thickness was installed in the flume extending 40 m in both directions of the test section (110 m from the wave generator). The transition to the concrete of the wave flume floor was at an initial slope of 1 to 40 (Fig. 5).

Figure 5. Test section in the GWK (not scaled)

3.2 USED SAND

About 250 m³ of sand was used, originating from the west coast of the island Norderney. It had the following parameters:

$$D_{50} = 220 \mu\text{m}, \sigma_g = 1.48, w = 0.0284 \text{ m/s}$$

where σ_g is the geometric standard deviation and w the mean fall velocity of sand at 18 °C.

The wave-induced packed sand below water had the mean dry density of 1708 g/l. With this value the relative concentration was calculated in g/l. The band width of error from five density samples was about ± 1 %.

3.3 CALIBRATION

The ERSC-Probe was calibrated for the limiting conditions: clear water and wave-induced packed sand. The signals from the ERSC-Probe were registered before each test series first in clear water. Then the probe was covered with sand and consolidated by 100 monochromatic waves of 0.3 m wave height. This procedure was repeated three times and results were compared.

The mean scatter from one calibration of ERSC II, III and IV yielded 0.5 % for the water and 2.6 % for the sand in terms of the full measuring-range of each electrode.

The mean standard deviation of the water values yielded 21 mV (mean value: 171 mV; deviation: 12 %), the standard deviation of the sand values yielded 97 mV (mean value: 6111 mV; deviation: 2 %).

Since at times at control after an experiment the water value changed from test to test, the assumption was made, that the thin wires were deformed by larger shells or stones, enclosed in the natural sand. Therefore only a limited number of tests could be analysed for sediment concentration, those for which also the limiting conditions were registered and the band width of error could be decreased.

3.4 ANALYSIS OF TIME SEQUENCES

The analysis of orbital velocity, near-bottom sediment concentration and bottom elevation was aimed at the interaction during single waves as well as a sequence of waves.

The experiments were run with monochromatic waves as well as wave-spectra. The water depth was varied from $d = 4.5$ m to $d = 3.5$ m above the horizontal sand bottom. The oscillating velocity 0.1 m above the initial sand bed was measured up to $u_{max} = 1.3$ m/s. In the following some selected results are presented.

Fig. 6 illustrates a 20 s sequence of waves showing instantaneous wave height, orbital velocity and sediment concentration from the test at the GWK.

Figure 6. Wave sequence of the ERSC-GWK-probe at large scale conditions (21.09.89/01, 495 s to 515 s)

The ERSC-GWK-probe shows concentration signals from 4 electrodes ranging from high concentration near the bottom electrode and clear water ($c/c'=0$) at the electrode 4 cm above. The wave conditions were:

Monochromatic waves, $H = 1.8$ m, $T = 6$ s, $d = 4.5$ m

at water temperature $T_w = 19.1$ °C.

The results illustrate the highly time-dependent sediment concentration about 1 cm above the sand bed (from $c/c'=0.05$ to 0.95) and the phase-shift between the concentration maxima at different levels (about 2.5 s) as well as orbital velocity 10 cm above the bed

($u_{max} = 1.25$ m/s at wave trough).

The orbital velocities measured were in the range of sheet-flow-conditions indicated for the sand used and an horizontal bed. The actual bed showed formations with mean λ / d -values of about 0.05 ($\lambda = 0.1$ m, $d = 1.9$ m). This could be the reason why the sediment concentration has not the same phase as the oscillating velocity.

The wave conditions for the measurement, shown in Fig. 7, were:

Monochromatic waves, $H = 1.15$ m, $T = 6$ s, $d = 4.0$ m

The maximum orbital velocity was recorded at $u_{max} = 1.0$ m/s and $T_w = 19.2$ °C.

Noticeable during this sequence was the stepwise up and down movement of the probe. From observations at the window of the flume the position of the probe before test run was on the face (Luff) of a flat dune ($\lambda = 0.14$ m, $d = 1.1$ m); additionally sheet-flow conditions were possible (ALLEN, 1984). The upwards movement of about 1 mm was recorded 0.7 s after the start of the return current at $u_{mean} = 0.5$ m/s. The downwards movements were in the range of 1 to 4 mm, mean value 2.4 mm, at return current of $u_{mean} = 0.9$ m/s, at $t_{mean} = 1.7$ s after the maximum velocity below the wave trough.

The maximum of the sediment concentration was measured about 0.5 s after the wave crest, about 0.4 s after the maximum of orbital velocity. A phase shift between the recorded signals of the three wires is not indicated at every wave.

Figure 7. Wave sequence of the ERSC-GWK-probe at large scale conditions (25.09.89/01, 422 s to 442 s)

3.5 SINGLE WAVE ANALYSIS

One single wave will be presented from the monochromatic wave series. The wave was divided in 9 steps, corresponded with $\pi/4$.

Fig. 8 shows the phase dependent sediment transport after about 0.8 s due to:

Monochromatic waves, $H = 1.8 \text{ m}$, $T = 6 \text{ s}$, $d = 4.5 \text{ m}$.

At the right top corner the instantaneous phase - here phase 1 - was plotted. Below from left the measured orbital velocity, the sediment concentration and the calculated sediment transport is shown. The minus values of the orbital velocity stand for return current below the wave trough.

The near bottom orbital velocity was calculated from a simple parabolic distribution from the lowest current meter down to the instantaneous bed. The instantaneous sediment transport was calculated from the time dependent orbital velocity times the instantaneous sediment concentration.

Fig. 9 demonstrates the phase dependent sediment transport during this single wave.

Figure 8. Example of phase dependent sediment transport after about 0.8 s ($H = 1.8 \text{ m}$, $T = 6 \text{ s}$, $d = 4.5 \text{ m}$)

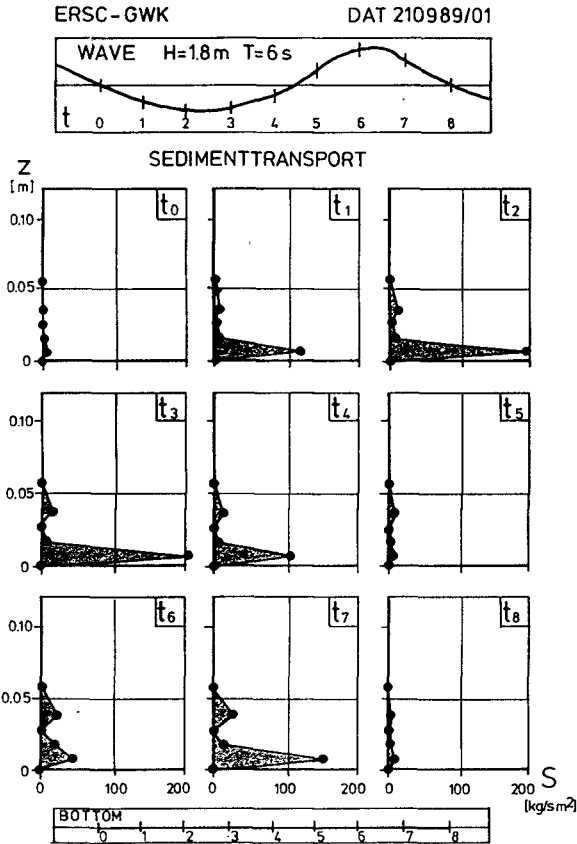

Figure 9. Phase dependent sediment transport due to wave action (Monochromatic waves, $H=1.8\text{ m}$, $T=6\text{ s}$, $d=4.5\text{ m}$)

During this wave no vertical movement of the ERSC-probe was recorded. The maximum sediment transport rate was calculated to about $200\text{ kg/s}\cdot\text{m}^2$ at phase no.3, 2.2 s after wave start. About 10 cm above the bed the orbital velocity was 1 m/s . These should be sheet-flow-conditions.

It is open to discussion, whether the very high sediment transport was affected by sheet-flow or resulted from the multiplication of the sediment concentration with the assumed parabolic distribution of the velocity. After 0.8 s , phase no.4, the velocity as well as the sediment transport was reduced to half.

The zigzag distribution above ERSC III points to sediment transport in clouds and whirls.

4. CONCLUSIONS

Experiments were run in the Large Wave Flume (GWK) in Hannover with the aim of obtaining data on wave-induced instantaneous sediment concentrations. The measurements were made with an electro-resistance-type-sediment-concentration-probe (ERSC-GWK-probe). The data presented illustrate features of time dependent sediment concentrations under waves, particularly the instantaneous values and their phase dependency. Likewise problems which arose during the calibration, the measurement as well as the analysis have been indicated. The results were sufficiently encouraging and warranted the continuing development of the ERSC-probe as a means of measurement of instantaneous sediment concentrations under wave actions. The probe is still under development at the Leichtweiss-Institute in Braunschweig.

5. ACKNOWLEDGEMENTS

The investigations were carried out as part of basic research in connection with prototype experiments on dune and beach erosion at the GWK within the research project "A6" of the "Sonderforschungsbereich 205" : "Interaction between foreshore and coastal structures". The funding by the German Research Foundation ("Deutsche Forschungsgemeinschaft") is gratefully acknowledged. The ERSC-probes were developed at the Leichtweiss-Institute of the Technical University of Braunschweig. The author like to express his sincere thanks also to Professor Dr.-Ing. E.h. A.J. RAUDKIVI, University of Auckland, and Dr.-Ing. H.-H. DETTE, Leichtweiss-Institute for their generous support and their stimulating remarks during the preparations of the investigations.

CHAPTER 201

UNDERGROUND WATER TABLE AND BEACH FACE EROSION

MICHIO SATO¹

Abstract

Numerical results show that the beach face of a tidal beach could be considered erosive due to the action of the surface flow formed by the escape of groundwater unless the action of moderate accretive waves, and that the effect will be intensified when the mean level of water table is higher than the mean sea level. Experimental results show that waves act to conceal the effect on the whole. These results suggest that the action of accretive waves are indispensable to maintain a tidal beach in an equilibrium condition. They also suggest that the cause of erosions of Surigahama beach and Iso beach was accumulative workings of the surface flow and insufficient wave action for the restoration during high tides.

Introduction

Field measurements of underground water table at Surigahama beach and Iso beach of Japan showed that the mean level of the watertable was higher than the mean sea level, and suggested that beach face erosion of the beaches was caused by the surface flow on the beach formed by the efflux of underground water. Another feature common to the beaches was that waves acting on these beaches are small all year around.

Previous researchers have considered about the effects of watertable and tidal cycle on changes in equilibrium beaches. Emery and Foster (1948), and

¹Professor, Department of Ocean Civil Engineering, Kagoshima University, 1-21-40 Korimoto, Kagoshimashi, 890 JAPAN

Grant (1948) found that groundwater escaping to the surface of the foreshore during a low tide contribute to the sorting through elutriating silt from the beach, and the running water cut small streams known as rill marks. They also noted that the water enhances erosion of beach face through not only increasing velocity and depth of backwash flow by adding to the backwash but dilating the sand. And conversely, during a high tide, a low water table may result in pronounced aggradation of the foreshore (Grant,1948). Therefore, we may expect that eroded beach face during a low tide will restore during a high tide in usual states unless erosive storm waves act.

Minute changes in foreshore during tidal cycles were discussed by Duncan (1964), Otvos (1965), Strahler (1966), Schwartz (1969) and Hurrison (1969) based on their own field observation.

In this study, a little different situation in that mean level of water table is higher than mean sea level is considered in association with erosions of beach face at Surigahama beach and Iso beach. Firstly, the erosions of foreshore at Surigahama and Iso beach are outlined. Then, thin flow on a beach face, formed by the efflux of underground water from the beach face, and beach materials which were washed away are discussed based on a numerical model. Lastly, the role of waves in the profile change of a beach where there is an inclined water table is considered based on some experimental results.

Field Measurements

Surigahama beach is famous for natural sandsteam baths and is one of the main features of a well-known hot spring town, Ibusuki. The beach is a small part of the Ibusuki coast, and is located on Kagoshima bay, Kagoshima Prefecture, Japan (Figure 1).

In 1951, a big typhoon struck the coast and caused heavy erosion. The shoreline is said to have retreated up to one hundred meters. Although most parts of the coast gradually recovered beaches from the erosion, the Surigahama beach did not restore at all.

As the beach is one of the important tourist attractions, many different measures, such as seawalls, jetties, detached breakwater and the like, have been tried to preserve the small beach area since 1950's (Figure 2). The beach is now surrounded by concrete structures.

According to Sunamura (1980), $C=18$ defined by the following relationship demarcates erosion and accretion of natural beaches.

$$\frac{H_0}{L_0} = C(\tan\beta)^{-0.27} \left(\frac{D}{L_0}\right)^{0.67} \quad (1)$$

where H_0 is deep water wave height, L_0 is deep water wave length, $\tan\beta$ is average nearshore bottom slope to a depth of 20m.

Long term measured wave data was not available. But, waves had been hindcasted for the period from 1971 to 1975. And we conducted wave measurement for 16 days using three capacitance type wave gauges in 1978 (Figure 3). These results showed that 80 percents of the significant wave heights were smaller than 0.2m and 80 percent of the wave periods were between 2 and 4 seconds. They also showed that the probability of wave heights exceeding 1m is one percent. On the otherhand, the erosive wave height is estimated to be over 1.2m from the above relationship. Therefore, this beach may be taken to

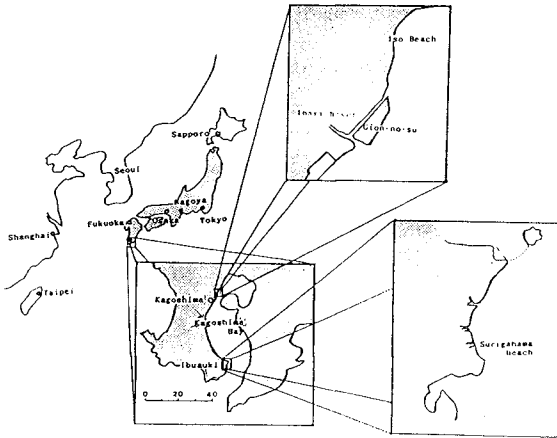

Figure 1. Location Map

Figure 2. Measures taken since Ruth typhoon

Figure 3. Results of wave measurements

be accretive. However, in spite of the great effort for many years to preserve the beach, it still needs artificial nourishment work.

A condition unique to the beach is the existence of hot springs underneath it. Besides, the range of spring tide is about 2.8m. Paying attention to these facts, we conducted a field measurement of the watertable under the beach.

In order to measure the level of water table, 18 pipes 3m long were driven into the sand. The inside diameter of each pipe was 40 mm. All of the measurements were repeated at half-hour intervals during the period between 9 and 13 of December, 1981.

Figure 4 is the contours of mean level of the water table and shows that the mean level of the water table is higher than the mean sea level. Figure 5 shows the water table at low tide. As the tide falls, underground water began to seep to the foreshore surface and cut meandering channels as shown in Figure 6. The temperature of underground water measured at the same time varied from 40 degree C to 80 degree C according to the tide. The high temperature reduces viscosity of the water and increases the permeability up to the double of the value under normal condition.

Iso beach is a similar example in that the mean water table is higher than the mean sea level. This is due to the topographical reason that there is a hilly area close to the beach (Figure 7). The beach is located about forty kilometers north from Surigahama beach and also on Kagoshima bay.

It had been nourished with the sediments supplied from the Inari river several kilometers south of the beach until the land between the river and the beach was reclaimed. The reclaimed land began to block the longshore sediment transport from the river to the beach, as did the highly developed waves from the south. Since the reclamation, Iso beach has been nourished artificially by supplying sand. Waves acting on this beach are smaller than the ones acting on Surigahama beach on the average throughout the year.

Measurements of the profile changes of the water table transverse to the shore line in respond to the changing tide level were made at one hour interval in September, 1982. We can see that the mean level of the water table is higher than the mean sea level from the results shown in Figure 8.

From the above mentioned observations, it is necessary for us to take the effects of difference between mean water table and mean sea level on beach face erosion into account so that we could plan more effective measures for the situation under consideration.

Numerical model

Though coastal aquifers often contain two fluids, freshwater and saltwater, for simplicity we consider only single fluid. Assuming two dimensional motion of underground water, the following equations were used for the analysis of the water table.

$$k \left(\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} \right) = S_s \frac{\partial h}{\partial t} \quad (2)$$

$$h = y + \frac{p}{\rho g} \quad (3)$$

Figure 7. Changes of the area around Iso beach

Figure 8. Measurements of water table at Iso beach
H = 13.5 m

Figure 9. Definition sketch

Figure 10. Numerical results of water table
H = 16.5 m

Figure 11. Tide cycle change of effluent zone

$$u = -\frac{\partial h}{\partial x}, \quad v = -\frac{\partial h}{\partial y} \quad (4)$$

where S_s is specific storage, h is the elevation of water table from the sea level, and k is the coefficient of permeability. The positive x-axis and y-axis point seaward and upward respectively.

Initial conditions are specified by prescribed functions for water table and head as

$$h(x, y, 0) = h_0(x, y) \quad (5)$$

$$\eta(x, t) = \eta_0(x) \quad (6)$$

The boundary condition on the left boundary A1 is

$$h(x, y, t) = H = \text{constant} \quad (7)$$

and on the boundary A1'

$$h(x, y, t) = H(t) \quad (8)$$

where $H(t)$ is the sea water level and assumed to vary sinusodally with the period of 12.5 hours and the amplitude of 1 meter.

On the bottom of the aquifer, the boundary condition for a prescribed flux is given by

$$k \left(\frac{\partial h}{\partial x} l_x + \frac{\partial h}{\partial y} l_y \right) = -V \quad (9)$$

where V is the velocity of drain from the bottom and taken positive downward, (l_x, l_y) is a unit vector normal to the boundary. In the following model, we put V equal to zero. On the free surface, two conditions must be satisfied

$$\eta(x, t) = h(x, y, t) \quad (10)$$

$$k \left(\frac{\partial h}{\partial x} l_x + \frac{\partial h}{\partial y} l_y \right) = S_y \frac{\partial h}{\partial t} \quad (11)$$

where S_y is the storage coefficient. The boundary condition for the seepage surface, along S , is

$$h = y \quad (12)$$

Introducing the variational principles, the functional χ of a minimizing function h is

$$\chi(h) = \int_R \left[\frac{k}{2} \left\{ \left(\frac{\partial h}{\partial x} \right)^2 + \left(\frac{\partial h}{\partial y} \right)^2 \right\} + S_s \frac{\partial h}{\partial t} \right] dR + \int_{A_2} V h dA_2 + \int_{F_s} S_y \frac{\partial h}{\partial t} l_y h dF_s \quad (13)$$

The finite element method based on the Rayleigh-Ritz method was used to obtain the head h from equation (13). The temporal change of the watertable h was obtained by using finite difference method.

The computation program was checked by comparing with an existing theoretical result and an experimental result obtained by the equipment described later.

As any detailed data on the aquifer were not available, we adjusted parameters so that the computation results satisfied the data of the elevation of ground water obtained from two wells, an old well about 140m from the beach and an observational well on the beach.

The results of the profile of the water table are shown in Figure 10. From this result we can see the temporal variation of the effluent zone as shown in Figure 11. The efflux from the beach face forms a thin surface flow. We attempted to investigate the natures of the flow two dimensionally neglecting the three dimensional characters for simplicity. The surface flow was analysed based on equation(14), and the depth averaged mean velocity was obtained. The derivation of the equation is given in Appendix.

$$\frac{dd}{dx} = \frac{i - \frac{q^2}{c^2 d^3} + \frac{H w_b}{q} - \frac{q w_b}{g d^2}}{1 - \frac{q^2}{g d^3}} \quad (14)$$

where i is the slope of the beach, d is the depth of the surface flow, w_b is the velocity of the efflux at the beach face, H is the elevation of the free surface of the flow measured from a datum, c is Chezy constant, g is the acceleration of gravity, and $q = \int_0^x w_b dx$. In this equation, the positive x-axis points downstream along the beach surface.

The results are shown in Figure 13. The calculated depth increases approximately linearly to the downstream of the flow and the maximum depth at the downstream end is small and less than 1cm. The calculated velocity of the flow is shown in Figure 14. The result shows that the velocity is about 14cm/sec and almost constant from the upper end to the downstream end except the flow after 150 minutes from the highest tide. The efflux from the beach face increases the depth. However, it does not accelerate the flow in this case.

When the velocity exceeds a threshold of sediment movement, the beach materials are washed away by the flow from the beach face. And this threshold was estimated to be 1.74cm/sec. Therefore, the whole flow has enough intensity to erode the beach face.

In order to contrast these results with the case in which there is no difference between the mean level of water table and mean sea level, similar computations were made. The results are shown in Figures 15, 16 and 17. In this case, the area of the effluent zone becomes a little smaller. However, these results show that the beach face will be eroded by the flow formed on it even if mean level of water is equal to mean sea level. And, in order for a tidal beach to be maintained in a equilibrium condition, the action of the changing tide must be canceled, or the beach must be restored during high tide, by the action of waves.

Figure 18 is the measured results of the effluent zone. This shows that the upper limit of the effluent zone does not become lower in comparison with the numerical result. And the length becomes double of the calculated value. We are not certain about the reason of this discrepancy. In any case, this result

Figure 12. Definition sketch of surface flow

Figure 13. Change of thickness of surface flow

Figure 14. Change of velocity

Figure 15. Numerical Result of water table

Figure 17. Change of thickness of surface flow and the velocity

Figure 15. Numerical result of water table

shows that the erosion due to the surface flow will be enhanced as the mean level of landward water table becomes higher than sea level.

Experiments

In order to investigate two dimensional beach profile change due to waves under the situation where there is an inclined water table, some experimental studies were carried out. The main purpose of these experiments was to know the roles of waves acting on a tidal beach rather than to do model experiments of a special beach.

A wave channel of 13 m long, 0.4m wide and 0.4m deep was used (Figure 19). Three types of model beach with 1/10 slope were installed at the end of the channel. The grain sizes of the beaches were 0.2mm, 0.7mm and 0.7mm+0.2mm (2cm thick) respectively. The water level behind the beach model was adjusted to be +20cm, 10cm, 0cm, -10cm, -20cm higher than the sea level. Water levels were measured by using 10 manometers which were connected with the bottom of the model beach through porous stones. Beach profiles were measured at 0.5, 1, 2, 4 and 8 hours after waves began to act. Final beach profiles for all runs are shown in Figure 20. Solid line and dashed line inside the beach denote water tables under the action of waves and without it respectively. We expected a little different beach profile changes for a different condition of water table even if the wave conditions were the same, considering the importance of the water table characteristics pointed out by Harrison (1969) as that no laboratory experiment on beach formation would adequately model a natural beach unless provisions for simulation of them were included. Results did not show a remarkable difference of beach profile change due to the existence of the gradient of the watertable. Waves have a tendency to reduce the gradient of water table when the water level behind the beach is higher than the sea level, and this will weaken the efflux of the groundwater from the beach face. This is due to the effect of wave setup and infiltration of swash. When the water level behind the beach is lower than the sea level, the gradient becomes steeper and this will increase the subtraction of water from the backwash. However, these effects were too small to result in a remarkable difference of the beach profile change and waves acting on the beach concealed the effects as far as our experimental results were concerned.

Conclusion

Numerical model showed that tidal beaches could be considered to be erosive due to the flow formed on the beach surface whether or not the mean level of water table was higher than mean sea level without waves. When the mean level of water table is high, the effect will be intensified. However, when waves act on a beach, it is deduced from the experiments that waves act to conceal the effect on the whole. Therefore, moderate accretive waves are indispensable to preserve a beach in an equilibrium condition.

Judging from these results, the erosion of Surigahama and Iso beaches may be concluded to be caused by accumulative workings of surface flow. The surface flow is formed on the beach face by the efflux of underground water which washes the beach materials away, and small waves are insufficient for the recovery. Therefore, measures for beach erosion due to heavy wave attacks, some of which

Figure 18. Measured tide cycle change of effluent zone

Figure 19. Experimental equipment

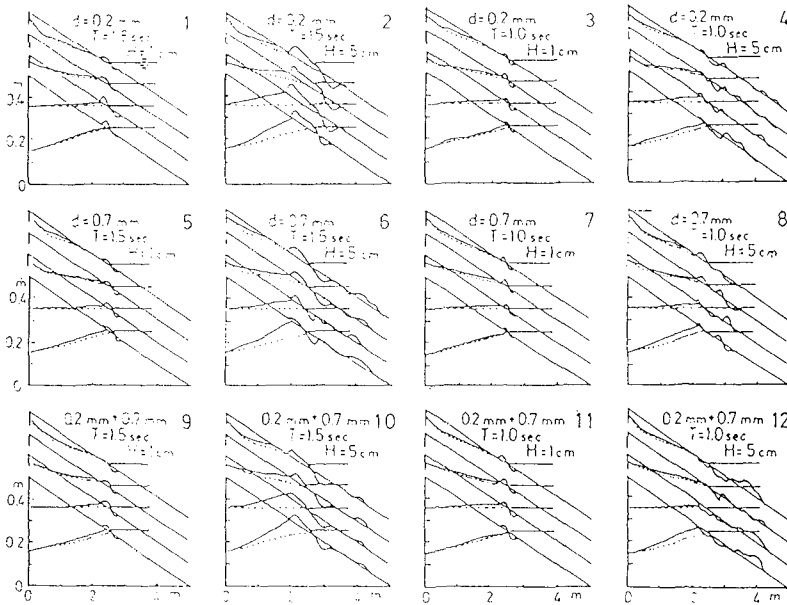

Figure 20. Experimental results of beach profile change

have been adopted at Surigahama beach, will not be effective for the cases considered.

Appendix

Multiplying velocity component v_i ($i = 1, 2, 3$) and Reynolds equation for each component for incompressive steady flow and adding them, following expression is obtained.

$$v_i \frac{\partial E}{\partial x_j} = v_i \frac{\partial \tau_{ij}}{\partial x_j} \quad (A1)$$

$$E = \frac{\rho}{2} \overline{q^2} + \rho \Omega + p, \quad \overline{q^2} = \sum_{i=1}^3 v_i^2 \quad (A2)$$

where τ_{ij} is Reynolds stress tensor, p is pressure and Ω is given by (see Figure 12)

$$\Omega = g(Z_0 + Z \cos \theta), \quad Z_0 = (x_0 - x) \sin \theta \quad (A3)$$

Integrating equation (A1) from section I to section II, using Divergence Theorem and adopting conventional assumptions for slowly varied one dimensional flow, we obtain the following equation.

$$\int \int_S E v_n dS = - \int \int \int_V (-\rho \overline{u'v'}) \frac{\partial u}{\partial z} dV \quad (A4)$$

where S and V denote the surface area and the volume of the domain of the integration, respectively. Using w_b , left-hand side of this equation becomes

$$\int_0^{d_1} Eudz - \int_0^{d_1} Eudz - E_b w_b dx$$

On the other hand, using mean-value theorem for integral, right-hand side becomes

$$\left\{ \int \int_A (-\rho \overline{u'v'}) \frac{\partial u}{\partial z} dA \right\}_{x+\theta dx} dx, \quad (0 < \theta < 1)$$

where A denotes the area of the cross-section of the flow. Assuming that the depth is small compared with the width, we consider unit width of the flow. Substituting above expressions into equation (A4) and dividing it by dx , the following equation is obtained in the limit of $dx \rightarrow 0$.

$$\frac{d}{dx} \int_0^d Eudz = E_b w_b - \int_0^d (-\rho \overline{u'v'}) \frac{\partial u}{\partial z} dz \tag{A5}$$

As $p = \rho g(d - z) \cos \theta$, $E_b w_b$ in the right-hand side becomes as follows

$$E_b w_b = \rho g(d \cos \theta + z_0) w_b$$

And left-hand side may be written as follows

$$\frac{d}{dx} \left\{ \alpha \frac{\rho}{2} q v^2 + \rho g(d \cos \theta + z_0) \right\}$$

where

$$q = \int_0^d u dz = vd, \quad \alpha = \frac{1}{qv^2} \int_0^d u^3 dz$$

Putting the head loss of the flow H_l as

$$\frac{dH_l}{dx} = \frac{1}{\rho g q} \int_0^d (-\rho \overline{u'v'}) \frac{\partial u}{\partial z} dz = f' \frac{1}{d} \frac{v^2}{2g}$$

We obtain the following expression for equation (A5).

$$\frac{d}{dx} \left(\frac{\alpha v^2}{2g} \right) = \frac{H w_b}{q} - f' \frac{1}{d} \frac{v^2}{2g} \tag{A6}$$

where $H = d \cos \theta + z_0$. From this equation, the following flow equation is obtained

$$\frac{dd}{dx} = \frac{\sin \theta - \frac{f' q^2}{2g d^3} + \frac{H w_b}{q} - \frac{q w_b}{g d^2}}{\cos \theta - \frac{q^2}{g d^3}} \tag{A7}$$

When we put $\cos \theta \approx 1$ and $\sin \theta \approx \tan \theta \approx i$ and use $\frac{2g}{f'}$ for friction factor f' , we obtain equation (14).

CHAPTER 202

A NUMERICAL MODEL FOR SAND TRANSPORT UNDER COMPOUND WAVES

Shinji Sato

Norihiko Mitsunobu

Shizuoka Prefectural Government

1. INTRODUCTION

In order to understand sediment transport around various maritime structures, it is essential to elucidate the mechanism of sand transport under compound waves. Although numerous studies have been carried out on sand transport, most of them have been concentrated to the sand movement mechanism under one-component wave. Laboratory experiments and numerical modeling of sand movement under compound waves are required for better understanding sand transport due to three-dimensional waves.

The objectives of the present study are to describe sand transport mechanism under three-dimensional compound waves through laboratory experiments and to develop a numerical model to estimate the net sand transport rate under compound waves. As a simple example of compound wave field, we selected the wave field in front of a breakwater with obliquely incident waves. This is because under such conditions the water particle near the bottom moves in various orbits, from linear to elliptic or circular orbit, so that they cover a wide range of conditions encountered in general compound wave conditions.

2. EXPERIMENTS

Experiments were performed in a 9m by 9m wave basin. A breakwater model was installed in the wave basin obliquely to the direction of wave incidence as shown in Fig. 1. The angle α between the breakwater and the incident wave was varied to 30, 45 and 60 degrees. All the bed in the wave basin was fixed except in a tray

Fig. 1 Experimental setup.

installed in front of the breakwater. The tray was 120cm long, 40cm wide and 2cm deep. Well-sorted sand of median diameter $D = 0.16\text{mm}$ was filled in the tray to make an initially flat test bed. The depth in the wave basin was changed from 12 to 16cm. The period of incident waves was varied in a range from 0.65 to 1.41s. Thirty three runs of experiments were carried out for the condition of perfect reflection by changing the incident wave height so that experiments covered a wide range of conditions from weak sand movement to vigorous sand movement.

The reflection coefficient r of the breakwater was adjusted by changing the height of the top of the breakwater. Seventeen runs of experiments were performed for the condition of partial reflection by using a submerged breakwater model. The total number of experimental runs was 50.

The distribution of wave height was measured by capacitance-type wave gages. The variation of near-bottom velocities was measured by using a two-component electro-magnetic current meter. The sensor of the current meter shaped a cylinder of 1cm in diameter. The data were recorded on a magnetic tape through a personal computer system.

The development of sand ripples and the change of bottom profile in the test bed was measured in detail by vertically inserting a transparent film coated with grease oil. The sand surface level as well as the sand ripple geometry were evaluated from the trace of sand particles attached to the transparent film.

The test bed was divided into twelve parts and the sand in each part was collected separately after each run of experiments. The volume of sand was measured by using a mess-cylinder. The sand was repeatedly thrusted by a stick until it reached densely packed condition. The distribution of net sand transport rates in x (parallel to the breakwater) and y (perpendicular to the breakwater) directions were evaluated from the amount of the collected sand.

3. RESULTS OF EXPERIMENTS

3.1 Wave field and near-bottom velocities in front of a breakwater

Figure 2 shows an example of wave height distribution, bottom profile and net sand transport rates measured in front of a breakwater. The wave field was found to be calculated in a good accuracy by a third-order nonlinear wave theory (solid line) derived by Hsu *et al.* (1978). The net sand transport rate q_x parallel to the breakwater was found to be positive at nodes and negative at loops, which was also the case in most of the experimental runs.

Fig. 2 Distributions of wave height, bottom profiles and net sand transport rates.

Fig. 3 Near-bottom velocity field in front of a breakwater.

Figure 3 shows the orbital motion due to waves as well as mass transport velocity in front of the breakwater with perfect reflection. The water particle near the bottom moves in circular, elliptic and linear orbit dependent on the distance from the breakwater. The nonlinear theory predicts that the wave orbital velocity becomes asymmetric in such a way that the velocity under wave crest is larger than that under wave trough. Measurements with an electro-magnetic current meter and dye injection supported the validity of the third-order wave theory in the estimation of the wave induced orbital velocity and the mass transport velocity.

3.2 Sand ripple geometry

Figure 4 shows sand ripple pattern observed in front of a breakwater. Three types of sand ripples were observed, that is, two-dimensional (2-D) ripples parallel to the breakwater, brick pattern ripples and 2-D ripples perpendicular to the breakwater.

Fig. 4 Sand ripple pattern observed in front of a breakwater.

Figure 5 shows the classification of ripple patterns in terms of the Shields parameter Ψ and d_{oy}/d_{ox} , where d_{ox} and d_{oy} are diameters of water particle displacement in x and y directions. The Shields parameter was expressed by

$$\Psi = \frac{f_w u_m^2}{2sgD} \quad (1)$$

where $s(=1.65)$ was the specific gravity of sand particle in water, g the gravity acceleration, f_w the friction factor and u_m the maximum velocity near the bottom. The friction factor was estimated by using Jonsson's formula in terms of the maximum velocity and the diameter of near-bottom water particle displacement. The roughness element was assumed to be the diameter of the sand particle.

It was found that brick pattern ripples developed in the range

$$0.5 < d_{oy}/d_{ox} < 2 \quad (2)$$

Fig. 5 Classification of sand ripples under compound waves.

and two-dimensional ripples developed for

$$d_{oy} / d_{ox} < 0.5 \text{ and } d_{oy} / d_{ox} > 2 \quad (3)$$

It was also found that the wavelength and wave height of sand ripples were able to be evaluated in terms of d_{ox} , d_{oy} and Ψ . The wavelengths λ_x and λ_y of sand ripples were found to be estimated by

$$\begin{aligned} \lambda_x &= 0.6 d_{ox} \\ \lambda_y &= 0.6 d_{oy} \end{aligned} \quad (4)$$

for both 2-D and brick pattern ripples. The ripple wave steepness was predicted by

$$\eta / \lambda = 0.15 \quad (5)$$

for 2-D ripples and

$$\eta / \lambda = 0.11 \quad (6)$$

for brick pattern ripples. These equations will be used in the numerical model to estimate sand ripple geometry.

3.3 Sand movement mechanism

Significant sand suspension was observed in most of experimental runs. The suspended sand concentration was observed to be determined by the asymmetry in the near-bottom velocity variation. The concentration was high under wave crests and low under wave trough since the velocity magnitude under wave crests was larger than that under wave trough in nonlinear wave field. The net direction of sand transport was determined by the balance between the transport due to the asymmetry in velocity variation and that due to the mass transport velocity.

Sand suspension was not significant in the area where brick pattern ripples were developed. The reason for this was considered that the maximum velocity was in general small over brick pattern ripples and that a strong vortex which contains a large amount of sand was not developed efficiently on the lee side of brick pattern ripples.

4. NUMERICAL MODEL

4.1 Sand entrainment at the ripple crest

In order to estimate the sand transport rate under compound waves, a numerical model was developed which evaluated the net sand transport rate above rippled bed by using near-bottom velocities calculated by the nonlinear wave theory. The outline of the model is schematically shown in Fig. 6.

Nielsen (1986) proposed on the basis of laboratory experiments a relation between the temporally-averaged sand concentration C_o at the bottom and the Shields parameter by

$$C_o = 0.005 \Psi_r^3 \tag{7}$$

where Ψ_r was the Shields parameter corrected by the flow acceleration at the ripple crest defined by

$$\Psi_r = \Psi / (1 - \pi \eta / \lambda)^2 \tag{8}$$

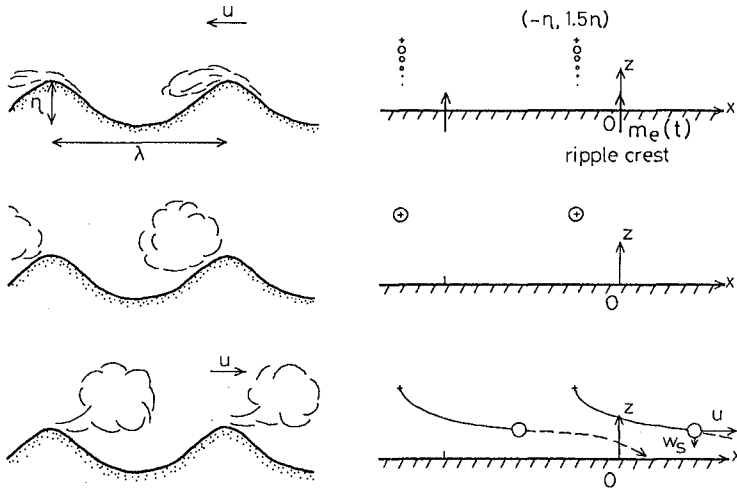

Fig. 6 Schematic diagram of the numerical model.

The rate $m_e(t)$ of the sand entrainment at ripple crests was assumed to be proportional to the third power of the instantaneous Shields parameter $\Psi_r(t)$ as,

$$m_e(t) = \alpha_c \Psi_r(t)^3 w_s \lambda \quad (9)$$

where w_s denotes the settling velocity of sand particles, λ the wavelength of ripples, α_c a nondimensional constant and $\Psi_r(t)$ was instantaneous Shields parameter at ripple crest defined by

$$\Psi_r(t) = \frac{f_w u(t)^2}{2sgD(1-\pi\eta/\lambda)^2} \quad (10)$$

The value of α_c was determined so that the entrainment during a period be the same as that estimated from the suspended sand concentration above rippled beds. According to Eq.(7) the amount M_s of sand entrained during one wave period over one wavelength of ripples was estimated by

$$M_s = 0.005 \Psi_r^3 w_s T \lambda \quad (11)$$

By assuming that the velocity variation is sinusoidal as a first approximation and that the total amount of entrainment was prescribed by Eq.(11), we can evaluate α_c in Eq.(9) as 0.016.

The numerical calculation was proceeded with a time step of $\Delta t = T/40$. On the rippled bed, sand was carried on the upstream slope of ripple crest and was thrown at the ripple crest into suspension. In order to simplify the complicated mechanics of sand movement on the ripple slope, an assumption was made in the present model that all the sand was entrained at the ripple crest. The amount m_s of sand entrained during each time step was given by

$$m_s = m_e(t) \Delta t \quad (12)$$

4.2 Transport of suspended sand particles

The entrained sand was assumed to be trapped in the vortex on the lee side of ripple crest and be transported after the flow direction changed. The movement of suspended sand cloud was numerically traced on the assumption that each sand cloud was transported with the same speed as the near-bottom water particle velocity due to wave orbital motion plus the Eulerian mass transport velocity. Net sand transport rates were evaluated from the settling position of the each sand cloud.

4.3 Application to the compound wave field

When we apply the model to compound wave fields, an assumption is needed on the position of suspended sand cloud formation. Figure 7 shows an example of water particle displacement at a node of obliquely incident standing waves. The water particle displacement

Fig. 7 Example of water particle displacement near the bottom.

was calculated by using the third order nonlinear theory. The figure illustrates that water particles near the bottom move in an 8-shaped orbit so that the velocity component v in the y direction is positive when the velocity is maximum. As sand moved most vigorously when the velocity was maximum, the most appropriate position would be the position on the lee side of ripple crest in the direction of the maximum velocity. The transport of sand cloud was calculated in the same manner as in the one-dimensional case.

4.4 Comparison with experiments

The applicability of the numerical model was examined by calculating the net sand transport rate under the following three-conditions; a finite-amplitude progressive wave, a standing wave and the compound wave field in front of a breakwater with oblique incidence.

Sato and Horikawa (1986) carried out movable bed experiments in an oscillatory flow tunnel and measured net sand transport rates over sand ripples for the condition of asymmetric oscillatory flows. Velocity histories of the oscillatory flows were simulated by using the fifth-order Stokes and the third-order cnoidal wave theory. Figure 8 shows a comparison between net sand transport rates $|\Phi_c|$ calculated by the numerical model and those $|\Phi_m|$ measured by Sato and Horikawa (1986) for the condition of asymmetric oscillatory flows. It was confirmed that the present model was able to estimate the net sand transport rate for asymmetric oscillatory flows observed in shallow water progressive waves.

Fig. 8 Comparison of net sand transport rate for asymmetric oscillatory flows.

Irie and Nadaoka (1984) classified the seabed scour pattern under standing waves into two types. They defined L-type movement in which bed materials move from nodes to loops and N-type movement in which bed materials move from loops to nodes. Based on laboratory experiments, they concluded that the occurrence of the two types depended on the Ursell number of the incident wave and the ratio of near-bottom velocity amplitude to the settling velocity of sand particles.

The present model was applied to the condition of standing wave with normal incidence. The condition of calculation was varied systematically in a range with the water depth 8-30cm, the incident wave height 2-10cm, the wave period 0.8-2s and the sediment

Fig. 9 Classification of sea bed scour under standing wave.

diameter 0.1-0.5mm. Figure 9 shows the occurrence of N- and L-type movement in the numerical calculation. The symbol \circ indicates the L-type movement and \blacksquare indicates the N-type movement. The solid line indicates the criterion empirically proposed by Irie and Nadaoka (1984) on the basis of laboratory movable bed condition and the broken line indicates that judged from the movement of sand particles distributed on a fixed bed. Although the model tends to produce L-type movement even for smaller values of u_b/w_s , the numerical model reproduces the tendency that the bed type changes from N-type to L-type with the increase of u_b/w_s .

Figure 10 shows a comparison of net sand transport rates under compound waves. The agreement between the experimental data and the calculation supports the applicability of the present model to the sand transport under compound waves.

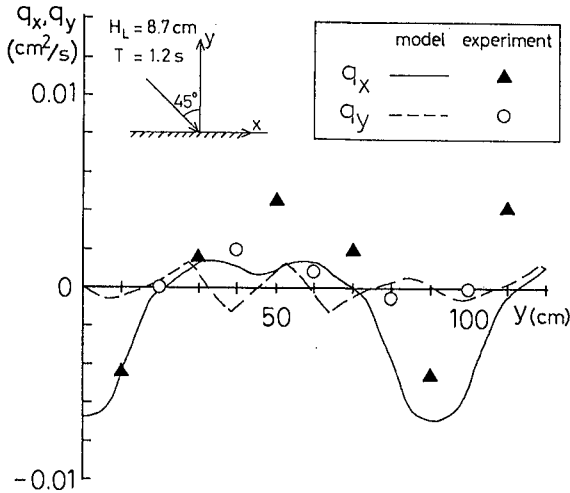

Fig. 10 Comparison of net sand transport rate for obliquely incident waves.

5. CONCLUSIONS

Characteristics of sand movement under compound waves were described through laboratory experiments. A numerical model of sand transport due to compound waves was presented which involved the process of sand suspension above rippled beds. The applicability of the model to a variety of conditions was confirmed with experimental data. As the model requires only the velocity variation near the bottom, it will be easy to apply the model to three-dimensional directional waves.

CHAPTER 203

Dike Failure Calculation Model Based on In Situ Tests.

Chr. Laustrup M.Sc.¹
H. Toxvig Madsen M.Sc.²
John Jensen M.Sc.²
L. Poulsen M.Sc.³

Abstract

A method has been developed to determine the strength of a dike expressed as the mean return period for the critical load.

The method is based on tests carried out on prototype dikes.

1. Introduction.

As severe storms in 1981, 1984 and 1985 caused a number of dike failures, the Danish Government decided to lay down guidelines for future economic compensation in the event of major flooding.

These guidelines were based on a study dealing primarily with the following subjects:

- a) Mathematical simulation of historic storms to generate statistics of extreme water levels at any point along the 7,000 km Danish coastline, see figure 1.
- b) Establishing a data bank with information about buildings in low-lying areas and the construction details of the 350 km dikes of varying quality.
- c) Developing a method for the evaluation of dike strength in terms of return period of failure.

This paper summarizes the work of item c.

1) Chief engineer 2) Senior engineer 3) Project engineer

Denmark.

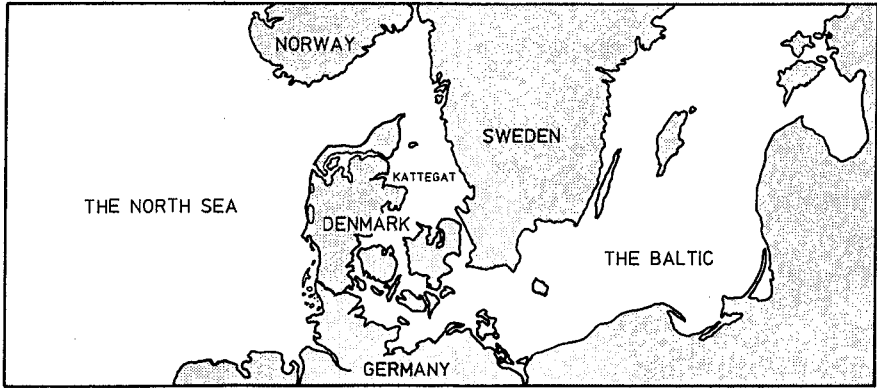

Figure 1. Waters Around Denmark.

2. Basic Description of the Method.

A diagram illustrating the dike strength calculation method is shown in figure 2. As can be seen, the calculation starts with a certain water level in deep water outside the specific dike. Using this water level and corresponding waves we then calculate whether this situation causes front or back slope failure of the dike.

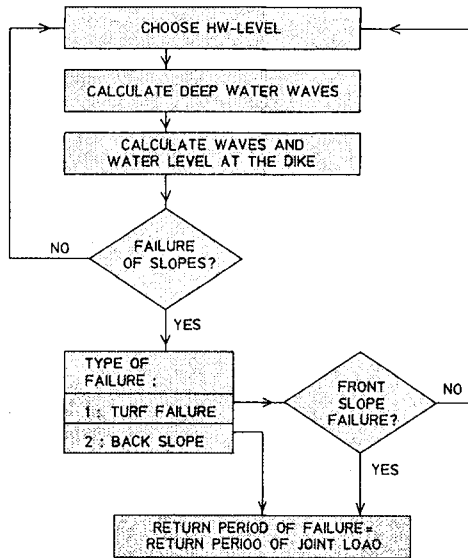

Figure 2. Calculation Diagram.

If the dike does not fail the calculation is repeated using a higher water level. This process continues until we find the lowest water level at which the dike fails.

The mean return period for this combination of water level and waves is determined and used as an expression of the dike strength.

The different steps in the calculation diagram are treated below.

3. Local Extreme Water Level Statistics.

Extreme water level statistics were calculated using a truncated Weibull-distribution to describe the size-distribution, and the Poisson-distribution to describe the arrival-process.

The statistics were prepared using partial series of either recorded or calculated extreme water levels. Reliable recorded water levels are always preferable to calculated water levels. Unfortunately, reliable recorded water levels are relatively scarce in Denmark.

Therefore all major storms in the Kattegat and in the Baltic Sea from 1965 to 1984 were simulated mathematically by The Danish Hydraulic Institute.

The recorded and calculated water levels during these storms were stored in a data base. This makes it possible to calculate extreme water level statistics for any location on the Danish coastline.

4. Duration of High Water Level.

The typical duration of the water level above a certain value was determined in order to be able to determine the number of waves causing erosion of the dike core, see section 9.

Naturally there are large variations in the water level curves around the maximum value. Therefore a number of water level curves for different storms and localities were incorporated by plotting the maximum water levels at the same point.

On the basis of these curves a connection was established between the difference in water level between a given level and the maximum value, and the duration of this water level interval.

5. Estimation of Storm Waves.

The waves were generally estimated by using the procedure described in The Shore Protection Manual (1984). The fetch used was calculated as the average value of the fetches in the 90° angle evenly distributed around the direction perpendicular to the coastline.

In cases where there are large shallow sea areas in front of the dike the storm waves were estimated according to the procedures outlined by Siefert (1974).

6. Simultaneous Onshore Waves and High Water Level.

On many Danish coasts high water level situations can arise without simultaneous onshore waves.

However, clearly the most dangerous situation is a combination of high water level and onshore waves.

The conditional probability $P(\text{onshore waves} \mid \text{water level} > \eta)$ was estimated by considering the storms used in the mathematical simulation mentioned in section 3.

The number of storms where the wind direction at the time of maximum water level was within the 90° sector around the perpendicular to the coast was enumerated. This figure, divided by the total number of storms, is used for the conditional probability $P(\text{onshore waves} \mid \text{water level} > \eta)$.

7. Waves and Water Level at the Dike.

The water level and waves at the dike can be calculated on the basis of the water level and waves in deep water.

The calculation is based on successive breaking and shoaling of the waves, with specific criteria for the transition between these phases.

The breaking criterion is defined according to Goda (1985) as

$$\frac{H_B}{L_0} = 0.17 \left\{ 1 - \exp \left[- \frac{1.5 \pi h}{L_0} (1 + 15 \tan^{4/3}(\varphi)) \right] \right\} \quad (1)$$

where H_B is the wave height at breaking, L_0 is the wave length in deep water, h is the water depth and $\tan(\varphi)$ is the bottom slope.

Using small amplitude wave theory the governing equations are

$$\frac{db}{dx} = -\frac{3}{16} \cdot \frac{1}{h} \cdot \frac{d(H^2)}{dx} \quad (2)$$

$$\frac{dE_f}{dx} = \begin{cases} 0 & \text{no breaking} \\ -E_{f,B}/l_{DISS} & \text{breaking} \end{cases} \quad (3)$$

where b is the wave setup, x is a horizontal distance increasing onshore, h is the local water depth, H is the local wave height, E_f is the energy flux, $E_{f,B}$ is the energy flux at the point of breaking, and l_{DISS} is the dissipation distance.

l_{DISS} is a fixed value at a given point of breaking. l_{DISS} is chosen so the local ratio of wave height to depth, H/h , decreases monotonically. The following expression is used for l_{DISS}

$$l_{DISS} = \frac{2}{5} \cdot h_B \left(1 + \frac{3}{8} \left(\frac{H_B}{h_B}\right)^2\right) \cdot \tan^{-1}(\psi) \quad (4)$$

where B denotes the point of breaking.

The transition from wave breaking to shoaling is governed by the criterion given by Deigaard et al. (1986).

$$\frac{H}{h} = 0.5 \quad (5)$$

The surf zone calculations are carried out using a PC-programme.

8. Strength of a Turf Revetment.

For dikes covered with turf, a front slope failure starts with failure of the turf and continues with erosion of the dike core, see section 9.

Methods to predict failure of the turf slope and erosion of the dike core are not known to the authors. Therefore such methods had to be developed.

A series of tests were carried out to find the resistance of turf as a function of the dry weight of grass roots per m^2 and the particle velocity in the breaking wave. The tests were carried out on prototype dikes.

Wave breaking was simulated with a water jet from a 4" pipe. A total of 16 tests were carried out on turf of 4 different qualities. These tests indicate that there is a certain critical particle velocity of the breaking

wave which initiates damage to the turf. Figure 3 shows the test results from one site. Each test with a certain water velocity was repeated four times.

Figure 3. Example of Test Results.

In figure 4 the critical velocities found are plotted as a function of the dry weight of the grass roots in the turf.

Figure 4. Critical Velocity as a Function of Dry Weight of Grass Roots in the Turf.

For dike slopes covered with turf and steeper than 1:6 it is assumed that the slope fails when the velocity in the plunging breaker exceeds the critical velocity for the turf.

The impact velocity V_A is calculated assuming that the plunging breaker falls from a height of $0.78 \cdot H_B$ above the mean water level. H_B is the wave height at breaking.

$$V_A = \sqrt{g(h_B + 1.56 H_B)} \quad (6)$$

where g is the acceleration of gravity and h_b is water depth at breaking.

The wave is assumed to hit the slope at the intersection between the slope and the mean water level.

9. Erosion of the Core Material.

In this study, front slope failure is defined as the situation where the front slope turf has failed and the erosion of the dike fill has reached the back slope, see figure 5.

Figure 5. Model of Front Slope Failure.

The horizontal erosion l is described by the following expression

$$l(t) = k_c \cdot k_e \cdot V_A \cdot \frac{t}{T} \quad (7)$$

where t is time, k_c is a calibration constant, k_e is a core material constant, V_A is the impact velocity and T is the wave period.

The core material constant was determined for different core materials. The method used was repeated flushing with a well-defined velocity.

Figure 6 shows a typical set of test results. As can be seen, the erosion depth is roughly proportional to the number of jets.

The following material constants k_e have been determined from the tests

Sand, small amount of silt (10%)	$1.35 \cdot 10^{-3}$ sec/jet
Sand, large amount of silt (17%)	$0.89 \cdot 10^{-3}$ sec/jet
Clay with sand (60%)	$0.059 \cdot 10^{-3}$ sec/jet

The equation for horizontal erosion was calibrated on real front slope failures recorded at the Rejsby dike after a severe storm in 1976. In figure 7 the horizontal erosion for each failure is plotted as a function of the time the water level remained above the bottom of the indentation.

Figure 6. Results from Simulation Tests with Core Erosion.

Figure 7. Horizontal Erosion and Duration of High Water Level for Real Dike Failures.

The calibration factor k_c in equation (7) was determined from figure 7.

10. Wave Overtopping.

The run-up level Z_{PCT} exceeded by a certain percentage of the waves can be determined by using the formula

$$Z_{PCT} = 0.77 \sqrt{2 - \log(PCT)} \cdot 0.7 \cdot T \sqrt{gH_0'} \tan(\varphi) \quad (8)$$

given in Technical Advisory Committee (1974). PCT is the percentage of the waves, T is the average wave period, H_0' is the equivalent wave height in deep water and φ is the bottom slope angle.

In dimensioning the Danish Wadden Sea dikes 2% was used in the formula as the critical overtopping percentage for back slope failure.

This percentage was considered too conservative for this study. Records show that overtopping in excess of 50% can occur without dike failure.

Therefore the critical overtopping percentages shown in table 1 have been used in this study.

Overtopping percentages	Dike surface		
	Unprotected	Turf, sandy	Turf, clayey
Slope:			
1:1.5	2%	10%	10%
1:2	2%	20%	50%
1:3	2%	30%	90%

Table 1. Critical Overtopping Percentages.

11. Geotechnical Failure of the Back Slope.

The risk of back slope failure has also been examined using geotechnical calculations.

Figure 8. Geotechnical Description of Back Slope Failure.

Assuming stability in the box indicated in figure 8, and assuming completely cohesive soil, the critical cohesion C_{crit} along the failure line can be described by the following equation

$$C_{crit} = [b (\gamma_w + \gamma_m) + \frac{A_{o1}}{l} \cdot \gamma_w] \cos^2 \beta \quad (9)$$

where b , l and β are defined in figure 8, γ_w is the specific gravity of water, γ_m is the specific gravity of saturated fill and A_{o1} is the cross section area of the overtopping water.

This critical cohesion is compared to the shear strength in the back slope determined by vane tests. The vane test results are reduced to between $1/3$ and $1/4$ due to fractures in the soil.

Equation (9) has been confirmed by full-scale tests on two dikes. One test resulted in back slope failure and one test gave no failure. Both results were in accordance with the formula. The tests showed that relatively low levels of overtopping result in complete saturation of the soil.

The main drawback of this geotechnical method in evaluating the stability of the back slope is the large number of vane tests required.

12. Calculation of Dike Strength.

A dike fails either when the water level reaches the top of the dike or when a combination of high water level and onshore waves causes front or back slope failure.

The shorter of the mean return periods for these two events is used as an expression of the dike strength.

The mean return period for the situation where the water level reaches the top of the dike is calculated using the water level statistics for the particular location.

The situation with onshore waves has a mean return period which can be calculated using the value for the conditional probability $P(\text{onshore waves} | \text{water level} > \eta)$ determined in section 6.

13. Conclusions.

A usable method has been developed to calculate the strength of dikes of varying quality. The method is based on results from rather simple tests on prototype dikes. The test results have been calibrated using re-

sults from real failures recorded at a Danish dike following a severe storm.

The model has been used to calculate the strength of about 30 Danish dikes. The results are consistent with the known lifetime of the dikes and the storms they have withstood without damage.

CHAPTER 204

HOW TO ANALYSE BEACH PROFILE MEASUREMENTS ?

Jan van de Graaff ^{*})

1 INTRODUCTION

A manager of a sandy coastal area is by virtue of his or her profession interested in the behaviour of that coastal area. Is the coast eroding, accreting or, by chance, stable? And, if the coast is not stable: what are the erosion or accreting rates?

It is almost trivial to mention that the basic information can be acquired with a measuring program.

In collecting data almost always a more or less 'natural' evolution can be noticed. One starts often collecting data which can be simply acquired. E.g. aerial photographs or surveys of the position of the waterline only.

A next step in a 'natural' evolution consists often of more extended measurements. E.g. entire cross-sections are measured on a regular basis. These extended measurements are often necessary to really understand what happens with the coast. That doesn't mean, however, that the former, simple, measurements become useless. A special treatment is necessary to 'couple' the results of the simple measurements to the results of the extended measurements. If that is possible indeed, mostly a data set holding over a longer period can be acquired.

If, after a couple of years, a series of measurements is available, the question arises: how to analyse the data in order to get a clear insight in the behaviour of the coast?

In this contribution mainly two topics are discussed:

- analysis of entire beach profiles
- coupling procedures of 'simple' measurements to 'extended' measurements.

^{*}) Senior scientific officer
Delft University of Technology
the Netherlands

2 BEHAVIOUR OF A STRETCH OF COAST

Fig. 1 shows in plan view a piece of a sandy coast. The coastal zone manager likes to know 'the' behaviour of stretch AB of the coast. Many coastal zone managers pay their attention often mainly to the behaviour as a function of time of the position of the waterline or line DD'. Line DD' is the so-called dune foot line; generally the transition between the beach and the mainland. Fig. 2 shows schematically what can occur as a function of time with the position of point P (see Fig. 1) with respect to an arbitrary reference line. The three possibilities, accreting, stable and eroding can simply be discerned. We will confine ourselves further (mainly) to the eroding case.

To quantify reliably the rate of the average yearly retreat (that is in the simplified case of Fig. 2 the slope of the fitted line through the measuring points), is just a very important topic. These erosion-numbers are important, for instance, to predict the position of the coastline in near future.

Often a coastal zone manager is almost forced (e.g. by 'society') to combat the erosion. Counter-measures have to be taken to stop the erosion or to overcome the detrimental effects of the erosion. Planning and designing the appropriate counter-measures is only possible if one 'understands' what the real reasons are of the underlying erosion problem. It is self-evident that sediment transports are the basic reason of any coastal erosion problem.

Fig. 1 Coastal processes in stretch of coast

Fig. 2 Behaviour of coast as a function of time

In Fig. 1 some sediment transport vectors have been indicated; the magnitude of these vectors 'steer' the sand volume in the area AA' B' BA. A decrease of the volume of sand in that area is in principle the real reason of the erosion problem. So generally (gradients in) longshore transports and/or cross-shore sediment transports are the reason of the erosion problem.

In Fig. 1 the longshore transports have been split up in two components (LA_1 and LA_2 through section AA'; through section BB' similar). If desired, a further splitting up of the longshore transport in more vectors can be considered. (Or only one vector can be taken into account.)

Let us consider a time period of one year. In order to quantify the variation of the volume of sand in that year in the area AA' B' BA one has to calculate the yearly net transport of the contributions LA_1 , LA_2 , C_3 , LB_2 , LB_1 and C_1 . However, due to very inaccurate sediment transport formulae and due to the often highly varying boundary conditions (like wave height, wave direction and tidal current velocities), it is in fact almost impossible to quantify the several yearly contributions properly.

In some classes of coastal erosion problems this calculation-first-method is in fact the only possibility to tackle the problem. In many other classes of problems, however, the 'field' shows already clearly the coastal behaviour (often an unacceptable erosion). A proper analysis of that behaviour may yield 'true' volume variation figures. Sediment transport calculations can be carried out next. If these calculations yield eventually similar results as the 'true' volume variations, the

sediment transport calculation method can be used to predict (or better: to estimate) the behaviour of the coast in (near) future. E.g. changes in the coastline position due to expected changing boundary conditions can be estimated in this manner. Or, in cases without changing boundary conditions, the results of sediment transport calculations can be used as a more or less sophisticated extrapolation method. Most likely the calculated sediment transport rates depend for example on the actual position of the coastline; changing positions yield so different transports.

Artificial beach nourishments are nowadays increasingly considered and increasingly used as a fair method to solve erosion problems. [See e.g. Manual on Artificial Beach Nourishment (1987).] Also for the design of an artificial beach nourishment scheme a proper insight in the actual loss of sand out of the problem area is desired.

In conclusion it can be stated that it is essential to quantify the sediment volume (and its variation with time) in areas like area AA' B' BA in Fig. 1. In the next Section it will turn out that the selection of the proper boundaries of area AA' B' BA is in fact a difficult and also tricky task.

3 QUANTIFICATION OF VOLUME VARIATIONS

Whether a certain stretch of coast is considered or only a single cross-section, is not principally different. In the latter case the stretch of coast has (accidentally) a length of 1 m only!

Let us next consider a set of yearly measured cross-shore beach profiles. Let us assume that a set of 20 yearly measurements is available. Fig. 3 shows, as an example, the shape of the cross-sections for three distinct profiles from the series; the 17 other profiles have been left out to avoid confusion.

The aim of the analysis is to quantify (the trends in) the variations in the volume of sand in the cross-section. Cross-shore profiles can, however, be extended indefinitely. As well from a practical point of view as from a coastal morphological point of view, the length of cross-shore profile measurements must, however, be limited. A requirement for the length, covered by measurements, is that the so-called closure-points (depths) are included by the measurements.

In a beach profile in fact two closure-points can be discerned; a landward- and a seaward closure-point. The landward (seaward) closure-point in the profile is the

position in the beach profile where landward (seaward) of that position apparently no systematic profile variations do occur. All systematic profile variations (losses and gains) take place consequently between the landward- and seaward closure-points (the so-called control area).

Fig. 3 Beach profile measurements in several years

Although this definition seems sound, in practice the relevant time- and length scales of the problem have also to be taken into consideration.

The loss of sand out of the control area through a chosen landward closure-position of say $1 \text{ m}^3/(\text{m year})$ due to landward directed winds, might be very important if the formation of dunes on a geological time-scale is considered. If, in contrast, the erosion problem in the lee-area of a newly built harbour is considered, the same loss of $1 \text{ m}^3/(\text{m year})$ plays most likely a minor role only.

In the present paper only classes of problems are considered where losses or gains (if any) out of the control area of orders of magnitude of $1 \text{ m}^3/(\text{m year})$ are negligible small.

If the series of profiles (represented by Fig. 3) are analysed, the choice of the landward closure-position is next relatively simple to make. By visual inspection the selection of line E'E seems to be a good choice. All profile fluctuations take apparently place seaward from line E'E.

The choice of the seaward closure-position (F'F) is far more difficult. In the example case of Fig. 3 the measurements have been extended over a distance of almost 1000 m. That seems rather long. However, even a visual inspection yet of the measured profiles, points already to noticeable fluctuations at the very seaward end of the profiles. That complicates much the selection of a

reliable (so covering all relevant volume fluctuations) seaward closure-position.

Requirements for the selection of a single standard point as the seaward closure-position cannot be given. A procedure is, however, proposed which meets the proper selection problem to some extent. The analysis of the results of the proposed procedure will furthermore enlarge the insight in the morphological processes which apparently take place.

In the procedure as proposed the position of the seaward closure-position (in Fig. 3 the line F'F) is systematically varied. With the selected (fixed) landward- and (varied) seaward closure-position, the 'volume' of sand in the profile as has been indicated in Fig. 3, is calculated for each profile of the long-continued series of yearly measurements. In Fig. 3 the 'datum' level (e.g. mean sea level; MSL) is selected as reference level. The volume per running m of 'sand' above datum is considered as positive; the volume of 'water' below datum as negative.

In Fig. 4 the thus calculated volumes per running m have been plotted as a function of time. (Fig. 4 holds for the case that the position of F'F is selected at 510 m from the reference line; see Fig. 3.)

Although some scatter does occur, a distinct trend can be noticed in Fig. 4. If a linear trend line is fitted through the calculated volumes from the profile measurements (e.g. with a least square method), apparently an average yearly loss of sand occurs between the limits E'E and F'F of approximately $25 \text{ m}^3/\text{m}$. [According to Fig. 4 the resulting 'wet' volume (so negative values) of the profiles increases, so a loss of sand is found indeed; on an average of $25 \text{ m}^3/(\text{m year})$.]

Fig. 4 Volume as a function of time

The standard deviation of the differences of the individual points of Fig. 4 with the fitted line is about $100 \text{ m}^3/\text{m}$. Real fluctuations in the volume of sand in the profile, but also measuring errors, contribute to that seemingly rather high value. A standard deviation in the volume of $100 \text{ m}^3/\text{m}$ over 650 m of the profile (distance between E'E and F'F) yields a standard deviation per measuring point of about 0.15 m . That value is, however, a quite usual figure for the standard deviation of even the measuring errors only of this type of profile measurements. So $100 \text{ m}^3/\text{m}$ is not unacceptable large.

Whether it is allowed to represent the results like in Fig. 4 by a simple straight line, has to be investigated from case to case. In some cases for example also periodic fluctuations with a period of several years can be discerned.

The result of Fig. 4 [loss of $25 \text{ m}^3/(\text{m year})$] holds for the selected position of F'F. By varying the position of F'F different yearly losses (or gains) are found. Next a plot of the average yearly variation as a function of the position of F'F can be made. Fig. 5 shows four typical results of real Dutch cases. Fig. 6 shows the locations along the Dutch coast. All results are based on at least 20 yearly profile measurements (period: 1964 - present).

Fig. 5a Case 5a

Fig. 5b Case 5b

Fig. 5c Case 5c

Fig. 5d Case 5d

Fig. 5a (an accreting case) is the easiest one to handle. It is apparently possible to select a proper (according to the definition) seaward closure-point. The horizontal course of the line seaward of say 500 m from the reference line means that from that position no additional losses or gains do occur. A slightly wrong selected seaward closure-position will not yield fundamentally different results. From Fig. 5a an indeed total gain of about $15 \text{ m}^3/(\text{m year})$ can be determined.

Fig. 5b (also an accreting case) is more difficult to handle. Apparently seaward from say 500 m from the reference line, still relatively large profile fluctuations do occur; resulting in an ever increasing yearly accreting volume for the profile the farther the seaward 'closure-position' is selected. In fact a real closure-position is not yet reached with the present length of the profile measurements. Consequently the total (in this case) gain of sand in the profile cannot be determined. The description of 'the' behaviour of the beach profile as a function of time remains still open.

Fig. 6 Location of profiles along coast

Fig. 5c (an overall eroding case) shows a remarkable pattern. Starting from the landward closure-position (-400 m) and looking in seaward direction, first a small gain is noticed. (Apparently some sand is accumulated in the dunes seaward of the landward closure-position.) Further seaward an ever increasing erosion appears. Between -150 m and 300 m from the reference line the yearly rate of erosion does not change very much; however, seaward of 300 m the total

average yearly erosion is ever increasing. Apparently due to additional losses in that area. Also in this case a description of 'the' behaviour of the beach profile is in fact impossible.

In Fig. 5d an ever increasing yearly erosion takes place up to 450 m from the reference line (average yearly erosion $40 \text{ m}^3/\text{m}$). Seaward of 450 m accumulation of sand does occur, resulting in an ever decreasing erosion figure. At the end of the measurements (approximately at 700 m from the reference line) the total erosion yields still yet approximately $23 \text{ m}^3/(\text{m year})$.

Also in the case of Fig. 5d 'the' behaviour of the profile depends largely on the distance over which the profile fluctuations are considered.

4 DISCUSSION QUANTIFICATION OF VOLUME VARIATIONS

About 2000 cross-shore profiles are measured along the Dutch coast yearly. In most of these cases it is rather easy to find a reliable seaward closure-position; in many cases directly; in some other cases by some acceptable slight extrapolation. The cases of Fig. 5a up to 5d are in this respect by no means fully representative to the total Dutch situation. There remain, however, many cases where it is, notwithstanding the distance of often 800 m from the waterline over which profile measurements have been carried out, very difficult to determine the behaviour of the profile properly.

The question arises whether that is a real problem or in fact some kind of an artificial problem. If for instance in all cases a distance of up to say 600 m seaward of the reference line is considered, the gains or losses in just that zone can be calculated and can be taken as a basis for further considerations. It is of course next possible to calculate transport vectors holding especially for that part of the profile. In that case, however, an essential contribution to the sand-volume balance is then due to cross-shore transports through the vertical at 600 m from the reference line. (Cf. vector C_3 in Fig. 1.) Since the reliable computation of cross-shore sediment transports is often considered as far more difficult than the computation of longshore transports [see Van de Graaff (1988)], extra complicating elements are introduced in the entire analysis of the coastal behaviour. To analyse cases where real seaward closure-points are found, is far easier. Also in these cases cross-shore transports play their role in the behaviour of the coast, but they can, at least in first instance, be considered as a redistribution factor only. By cross-shore sediment transport processes, volumes of sand are redistributed over the active part of

the profile; the real gains or losses are then mainly due to (gradients) in longshore sediment transport rates.

In conclusion it can be stated that seaward closure-points are extremely important in coastal morphology studies. Along the Dutch coast these seaward closure-points are sometimes apparently situated beyond the limits of the standard yearly measurements. (Sometimes beyond approximately 800 m from the position of the waterline.) If 'new' standard measuring programmes are planned, it is recommended to extend the measurements beyond the seaward closure-point.

5 MEASUREMENTS OF CHARACTERISTIC DEPTH CONTOURS

Often series of measurements of only some characteristic depth contours are longer lasting than series of regularly measured entire beach profiles.

In the Netherlands, for instance, over approximately 140 years results are available of yearly measurements of the position of the MLW -, the MHW - and the Dune Foot line for each kilometer of the Dutch coastline. (Systematic entire profile measurements for each 200 - 250 m along the coast are available in the Netherlands over 'only' 25 years; for some portions of the coast longer lasting series.)

This long lasting series can in principle serve as a very valuable data base.

A plot of e.g. the MHW -line in a cross-section as a function of time, shows often a lot of scatter (in the Netherlands these plots are therefore often indicated with 'lightening-plots'). With filter-techniques often clear trends can be derived of such long series of measurements; sometimes even clear long-periodic fluctuations can be noticed in the plots.

For many phenomenological studies these measurements are very valuable. The coastline behaviour from the past to present can be described with the help of these measurements. The measurements can also be fruitfully used to predict the position of the coastline in (near) future. (Some extrapolation is probably allowed.) From the results even time-average yearly erosion - or accreting rates can be derived. However, these rates are expressed in m/year.

As has been discussed in Section 2 the real reason of coastline development with time is due to variations of sediment transports along the coast and sediment transports in the cross-shore direction. And to understand what really happens, insight in these actual sediment

transports is necessary. A time-average coastline recession rate of say x m/year is in reality associated with a loss of sand out of the beach profile of y $\text{m}^3/(\text{m year})$. The latter value is next directly associated with (gradients in) sediment transport rates. [Also eventually expressed in $\text{m}^3/(\text{m year})$.]

Consequently the use of long lasting series of measurements of the position of a few depth contours only in sediment transport studies, calls for conversion factors. (E.g. what is the relationship between x and y as mentioned in the preceding paragraph?)

Fig. 7 Eroding beach profile behaviour

Fig. 7 shows a rather simple model to derive a conversion factor. In the sketch of Fig. 7 it is assumed that the shape of the active profile remains constant. A yearly retreat of the 'coastline' with x m means that all depth contours in the active part of the profile will retreat with the same x m. If this model is true y and x are related as follows:

$$y = x (d + h) \quad (1)$$

where: y : average yearly loss/gain of volume of sand in the beach profile [$\text{m}^3/(\text{m year})$]
 x : average yearly erosion/accretion of the 'coastline' (e.g. average position of MLW- and MHW line) [m/year]
 d : height of dunes/mainland above MSL [m]
 h : depth of seaward closure-point below MSL [m]

An arbitrary selection of 23 cases has been made, more or less regularly divided along the Dutch coast. Only 14 cases have been ultimately used in the further analysis. In these 14 cases the time-averaged yearly losses or gains exceed $10 \text{ m}^3/(\text{m year})$. (If the yearly losses or gains are too small the accuracy of the conversion factors to be derived, becomes too low.)

The series of measurements of entire beach profiles have been used (more than 20 yearly measurements). Of these profiles also the average position of the MLW- and MHW line (so say the coastline) has been determined.

Two methods to check Eq. (1) have been used.

In Method I plots have been made of the average position of the MLW- and MHW line in every year versus the volume of sand in every year. (To determine the volume of sand in the beach profiles the entire measured profiles have been used. According to Fig. 5 it is not quite sure that the relevant volume is covered entirely in all cases.) The trend line through the more than 20 yearly measurements has next been calculated. The slope of that trend line yields an estimate of the ratio y/x , so an estimate of a proper conversion factor. In Fig. 8a that conversion factor is compared with the height $(d + h)$. [The magnitude $(d + h)$ has been measured from profile measurements.] It is remarkable that the conversion factor as calculated with Method I is in all cases smaller than $(d + h)$. The 4 cases with time-average yearly losses/gains which are larger than $30 \text{ m}^3/(\text{m year})$ score relatively better than the other cases.

In 4 cases it was clear (from figures like Fig. 5) that the real control area is not covered by the measurements and that y is consequently underestimated. That could be a reason of the low conversion factors as derived in comparison with the height $(d + h)$ in these cases. (In 8 cases of Fig. 8a the proper control area was covered by the measurements.)

Fig. 8a

Conversion factor versus $(d + h)$

Fig. 8b

In Method II first linear trend lines have been determined in plots showing the volume as a function of time as well as in plots showing the average position of the MLW- and MHW lines. Next the two resulting trends have been divided, yielding an other estimate for a conversion factor. Fig. 8b shows the comparison between this conversion factor and the height ($d + h$). A great deal of scatter can be noticed. Under-estimations as well as over-predictions can be observed in this comparison.

6 DISCUSSION MEASUREMENTS CHARACTERISTIC DEPTH CONTOURS

The Method I and Method II to calculate a conversion factor, yield different results. (Method I is felt to be slightly 'better' than Method II.) In both cases, however, large differences do exist from the simple model according to Fig. 7. That means in fact that, based on the results of this research, a single simple conversion factor does not exist. So it is still difficult to couple series of measurements of a few characteristic depth contours to series of measurements of entire profiles. It is not excluded, however, that with longer joint series (longer than say 20 - 25 years) a more conclusive result will be obtained.

If the results of Fig. 8a are considered as 'true', the basic idea of Fig. 7 (a constant shape of the profile) does apparently not hold. Due to the general under-estimation two hypotheses can be considered to 'explain' the behaviour, viz.:

- a) systematic flattening of the entire profile
- b) (temporarily) steepening of the profile

Re a)

If the beach profile flattens systematically the (e.g.) regression of the MLW- and MHW lines is faster than the deeper depth contours. The associated volume loss out of the profile is consequently less than expected from Fig. 7.

Re b)

In a structural eroding beach profile the erosion of the dunes or mainland occurs mostly more or less shock-wise. Under usual conditions the erosion of the beach and foreshore takes already gradually place, but the dunes or mainland are not reached by the water and waves. The erosion of the dunes 'waits' for rather rare more severe conditions. The profile adjustments in the dunes 'necessary' according to the model of Fig. 7, can only occur during a storm (surge). Especially if rather short series are considered (however, is 20 - 25 years short?), it is not excluded that the necessary adaptations in the dunes or mainland have not yet been finished due to lack

of stormy weather. Due to the storm (surge) the volume of sand in the profile will not change in principle, but the position of the MLW- and MHW lines will do.

7 CONCLUSIONS

- Systematic measurements of entire beach profiles are indispensable in analysing the behaviour of coasts (coastlines).
- Insight in systematic volume changes in profiles (losses/gains) is an important analysing goal of profile measurements.
- Even very good (rather long lasting) series of entire profile measurements (like in the Netherlands) cannot always be analysed straightforwardly.
- The length over which the measurements extend in seaward direction calls for special attention (often too short).
- 'New' series of systematic measurements should be analysed as soon as possible in order to check whether the measurements fulfil the requirements. (The set-up of the measurements have to be adapted possibly.)
- With a restricted number of arbitrarily selected beach profiles along the Dutch coast as basis, it turned out to be very difficult to determine a simple conversion factor to couple series of measurements of a few characteristic depth contours and series of measurements of entire beach profiles.

ACKNOWLEDGEMENTS

The data of entire beach profile measurements as used in the present study, have been provided by the Tidal Waters Division of Rijkswaterstaat.

Results of the MSc.-thesis of Mr. B. P. van den Bunt have been used to prepare the present paper.

CHAPTER 205

GRAIN-FLUID INTERACTION IN COUETTE FLOW

by

Willem T. Bakker ¹, Walther G.M. van Kesteren ² and Wim H.G. Klomp ²

1. ABSTRACT.

This paper is a continuation of the papers of Bakker & Van Kesteren (1986) and Bakker et al. (1988). In this paper the results are presented of ring shear tests on mixture of oil and spheres with the same density (880 kg/m³). In order to study in detail the behaviour of a sand water mixture at high concentrations in a Couette like shearflow in the viscous regime the grain diameter and viscosity are enlarged by a factor 100: respectively 15 mm and 10⁻⁴ m²/s. The test are executed in the so called grain carousel with shear rates up to 75 s⁻¹ (Bagnoldnumber N=240). The experimental set up is such that only constant volume test could be performed.

The test results indicate that at concentration below 30% (vol.) no dispersive stresses are generated. At higher concentrations the generated dispersive stresses increases with concentration and shearrate. From videofilms it was observed that the grains are moving in layers with only small mutual exchange (grainswop).

2. SCOPE OF PAPER.

This paper reports on a continuation of a study on the bottom-boundary layer in oscillatory flow. This series started with a paper of Bakker (1974) on suspended sediment in a horizontally uniform oscillating flow. After considering the near bottom velocity field more into detail (Bakker and Van Doorn, 1978; Bakker and Van Kesteren, 1984) the study proceeded with a closer investigation of the sand transport mechanism at the bottom under sheetflow conditions (Bakker and Van Kesteren, 1986, 1987; Bakker, Van Kesteren and Yu, 1988).

²) Delft Hydraulics, P.O. box 177, 2600 MH Delft, The Netherlands.

In the last-mentioned paper experiments in a grain Carrousel and measurements in nature were mentioned. The present paper gives more data and some analysis concerning the Carrousel measurements. New prototype data, measured with the Harp during the Lohengrin project are reported on in the subsequent paper (Yu, Niemeyer and Bakker).

In a reliable mathematical model on sheetflow as well the shear stresses between shearing layers of grains as well as the normal stresses should be well reproduced.

With the theory of Bagnold (1954,1956) and a simple analytical model it is possible to reproduce concentration profiles and intrusion depth in sheetflow reasonable well, however, velocity profiles and shear stress distribution found in this way are based upon too primitive assumptions and thus do not match nature very well (Bakker and Van Kesteren, 1986, fig.6 and 7).

Furthermore, Bagnold's theory is designed for stationary flow.

In a numerical model (Bakker and Van Kesteren (1986)), in which layers of grains (with a rigid rectangular structure) are sliding over each other, it was not possible to reproduce Bagnold's dispersive stress in the case of a Couette shearflow at constant volume. Because the model is based on viscous motion, squeezing pressures found when the grains move to each other are cancelled by equal tensile forces when the grains move from each other.

Thus the questions arise:

- a. if rigid layers are shearing over each other, will there be dispersive stress?
- b. which are the stresses, when two grains from different layers nearly touch each other?
- c. is it reasonable to schematize a Couette flow of grains with a layer model?
- d. under which circumstances will dispersive stress be created?

This leads to the following aims of the experiments planned:

- insight in the physical background of the Bagnold stresses;
- visualisation of the grain motion during grain-grain interaction.

3. EXPERIMENTAL SET-UP.

A ring shear apparatus ("Carrousel") has been developed (fig.1, Bakker and Van Kesteren, 1986). Detailed description of experiments accuracy and calibration has been given by Klomp (1990).

Between two plan-parallel rings placed in a circular flume (diameter in the center 1.13 m; internal width 0.07 m) a Couette like shear flow of a mixture of polypropene spheres (diameter $D=14$ mm; Young's modulus 1300 N/mm²), immersed in oil (medical oil Shell code M.W.O.95 or V7047) with the same density (oil: 889 kg/m³; spheres: 860 ± 30 kg/m³) is generated by rotating the upper ring, where the lower ring is fixed. The level of the upper ring is adjustable. Both rings have a spacing in the circular flume of 1 mm on both sides.

Fig.1 Carousel.

The viscosity of the oil is 10^{-4} m²/s at a temperature of 20° Celsius. It has been chosen in this way, that the shear Reynold's number (see ch.7 eq.2) in the tests was of the same order of magnitude as occurs in oscillating sheetflow in the prototype. The bottom ring rests on three supports (under a mutual angle of 120° with respect to the center of the flume), provided with strain gauges, which all measure normal force, where one of those measures the tangential force. The other

two supports are provided with a skirt-like construction to prevent transducing of any shear stress. After mounting a static and dynamic calibration with and without oil was performed. Elaborate accuracy analysis with respect to the gap width between the rings is given in Klomp (1990) and Bakker et al.(1990).

On upper- and lower ring each 4 rows of 199 hemi-spheres are glued in a regular pattern. For visual observation, three glass windows with a length of 29 cm each were made in the carousel. Sampling occurs with a frequency between 60 and 540 per second, depending on the experiment.

4. EXPERIMENTS.

Five series of experiments have been carried out:

- NO: no interjacent spheres;
- SOME: half a row of interjacent spheres (100 spheres)
- 1LR: (about) one layer of interjacent spheres (510 spheres)
- 3LR: three to five layers of interjacent spheres (3641 spheres).
- VIS: Visual observations, using ca. 3600 grains

Going from series NO to series 3LR the probability of dispersive stress increases, which forms the motivation of these succession of series of tests.

The experiments are determined by the distance between the rings and the turning period of the upper ring. The following table 1 gives the schedule. The table consists of combinations of 2 columns indicating resp. the variables "height between rings" (h) and "revolution period" (T). The mean velocity gradient or shearrate S is given by:

$$S = 2 \frac{\pi R}{T h} ; R = (\text{central}) \text{ radius ring} = 565 \text{ mm} \quad (1)$$

Table 1. Experiments carried out.

Series:	height between rings [mm]	revolution period [sec]
NO	14.9	20 ?
	16 17 18 20 25 50	3 4 5 7 10 20
SOME	25 35 50	3 5 10 20
1LR	35 50 65	3 5 10 20
3LR	51	20
	53	7 10 20
	55	4 5 7 10 20
	60 65 75	3 4 5 7 10 20
VIS	48	5 10.3
	60	4 7.8
	78	2.7 9.5

For each of the indicated heights of the rings tests have been carried out for all of the revolution periods, mentioned on the same line.

Other combinations, which could be imagined have not been carried out because of practical disadvantages: too large forces on the gauges or the destruction (loosening) of the hemispheres on upper and lower ring. The blanks in table 1 show the limits of the possibilities because of blocking.

For instance: during the firstmentioned experiment (of series NO) the distance between upper and lower ring has been reduced as much as possible, up to 14.9 mm. Although according to the schedule still a gap width of 0.9 mm should exist, accuracy analysis made clear, that the utmost extruberance of the upper ring could easily "hit" the utmost extruberance of the lower ring. The experiment had to be stopped soon, in order to avoid destruction, and therefore the revolution period has not been measured accurately.

Mind, that it was possible to carry out experiments with $h=25$ mm (less than $2D$, where D is the grain diameter) in the series SOME; however, this was not the case in the series 1LR, although technically all spheres used in series 1LR could find a place in one layer.

Using a distance between the rings of $3.6 D$ (51 mm) during the series 3LR, it was only possible to measure with a slow revolution period of 20 sec. Here the allowable forces on the measuring system were used as criterion.

During the visual tests the force measuring device was blocked and the allowable torque on the Carrousel (with respect to the motor) could be used as criterion, which gives the opportunity to reduce the distance to $3.44 D$ (48 mm).

With respect to the series VIS (table 1), as well as in series 3LR the grains have been dumped randomly in the Carrousel. Paradoxally, this gave less blocking than an initially arranged order of the grains in a similar way as the one of the hemispheres on both rings. In the arranged order the initial spacing was rather large, which gave freedom for disorder.

Apart from the measurements, photographs in a succession of 0.04 seconds were made from series SOME, and video-films from series VIS. These photographs were analyzed by Bakker, Van Kesteren and Yu (1988; ch.3). The analysis of the video's will be treated in ch.6.

5. GEOMETRIC CONSIDERATIONS.

If it is assumed that in 3 adjacent grainlayers resp. 5, 4 and 5 rows of loose spheres are stacked (in closest packing) in the Carrousel. and the layers would be perfectly flat, only 3548 grains could be stacked. However, when the layers show a certain "waviness" (wave length 2 grain diameters; amplitude 1.5 mm), all 3641 grains can be stored. This waviness occurs anyway, as the lowest loose grains will partly be situated in the hole between 4 hemi-spheres, partly will have their center point in the cross-section perpendicular to the flume through the center of the hemispheres. This gives a variation in height of the center points of those loose spheres (with respect to the lower ring) between 7.83 and 12.12 mm. Thus $4 \times 10 = 40$ mm is considered the minimum distance for storing the grains in the Carrousel (conc.=62.7%).

When the distance between 2 layers of grains becomes more than 12 mm, theoretically those layers should have the probability to slide with respect to each other. Thus a slide plane can occur when the distance between the rings exceeds 42 mm (conc.59.7%).

The effect of the waviness of the layers on the shearing resistance is not quite clear. As the undulating layers can reshape each other during the shearing process, the effect will be less than the one of a fixed roughness. Still, the extra 2 mm allowing for shearing anyway will be a minimum. The minimal distance between the rings when 3 layers of 5 rows in simple cubic piling turn around in the Carrousel becomes 48 mm (conc.=52.2%). This asks for a distance of $2(D+10)$ mm (the center of the grains of the lowest layer are 10 mm above the lower ring, as in the former case). If all layers are fully occupied, 3801 grains are needed, i.e. more than available. Mind, that 48 mm was the minimum distance for which the uperring of the Carrousel was able to rotate in test VIS.

6. VISUAL OBSERVATIONS; GRAIN SWOPS.

From Bakker, Van Kesteren and Yu (1988), ch.3, especially the theoretical and phenomenological aspects of the "centering effect", mentioned in that paper should be remembered (photo 4 a,b,c of that paper).

When there is enough space between the various loose spheres in the same row (in series SOME somewhat more than a grain diameter) the grains move to a central position between the rings and turn around in a stable position, having half the velocity of the upper ring. Furthermore these rotate around their axis.

When the distance between the rings increases or the velocity decreases the effect becomes less distinct (photo 4a of Bakker, Van Kesteren and Yu (1988)); then doublets of spheres can be formed, which can tumble around as a unit (Vand, 1948; Batchelor and Green, (1972)).

During the series LLR (about one layer loose grains) the centering effect turned out to be not large enough to enable a small distance between the rings. A single grain blocking between the hemi-spheres of upper or lower ring could disturb already the order, after which total blocking was just a matter of time.

During experiments in the series VIS carried out with a height between the rings of 60 mm or less, 3 layers were to be distinguished; in the other 2 experiments ($h=78$ mm) 5 layers were observed. In fig.2 the horizontal and vertical velocities of the centers of the visible spheres are shown for the test with a height of 48 mm and a revolution time of 5 s ($S=14.8$ s⁻¹). The vertical coordinate is the position of the spheres with respect to the fixed bottom ring. The velocities are obtained from the digitized videofilm.

The figure shows clearly that the grains move in layers: the vertical position of the centers of the grains is concentrated at three different (grainlayer) levels. Also it must be concluded that the

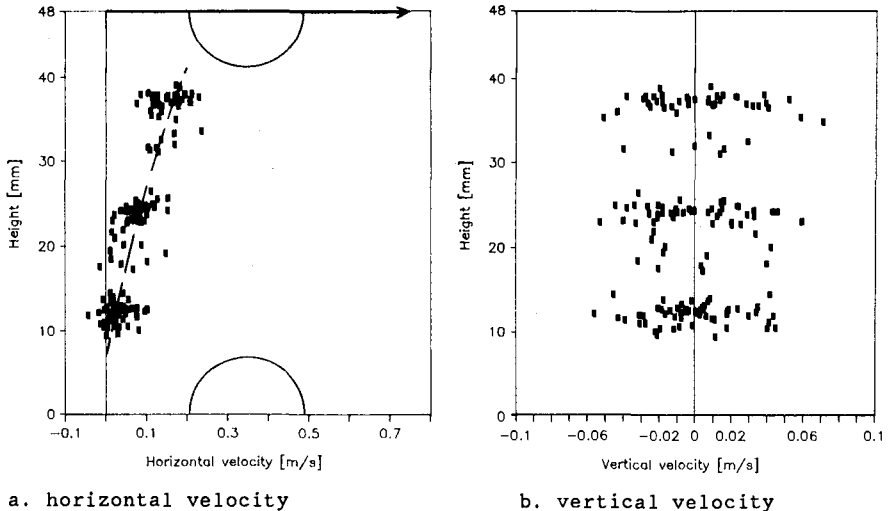

Fig.2 Grain velocities testserie VIS (height $h=48$ mm, period 5 s)

velocity gradient is not constant over the height: in the lower half the velocity gradient is about half the installed velocity gradient. In the upper half of the Carrousel concentration is less than in the lower half, notwithstanding the fact, that the grains are as an average very slightly buoyant and concentrate on the upper part in the starting position. Apparently, the same shear stress can be transmitted with high velocity gradient and low concentration as well as with low velocity gradient and high concentration. Although only some tests have yet have been elaborated in the present way, it is the impression that relative low concentrations occurred on the topside of the Carrousel in all tests. Reason for deviation from symmetry can be: the walls, remaining at rest or relatively large shear stresses near the top ring during the initiation of motion.

A certain grain, emerging in a certain layer on the lefthand side of one of the windows, was followed with the eye until it disappeared on the right hand side. It was registered, whether this grain was at that moment in the original layer, or one or two layers higher/lower. Fig. 3 shows the probability of grain swop in various tests; on the first line for the tests where the grains divided themselves in 3 layers, on the second one for the tests, where 5 layers could be observed. Vertically the various layers are indicated; horizontally the percentage of observed grains, found in this layer at the end of the observation time. With an arrow the layer is indicated, in which the grains emerged on the lefthand side of the window. These observations have been elaborated in the following way. Call a "grain encounter" the event, that two grains of adjacent layers "meet" each other, i.e. (nearly) come into contact with each other.

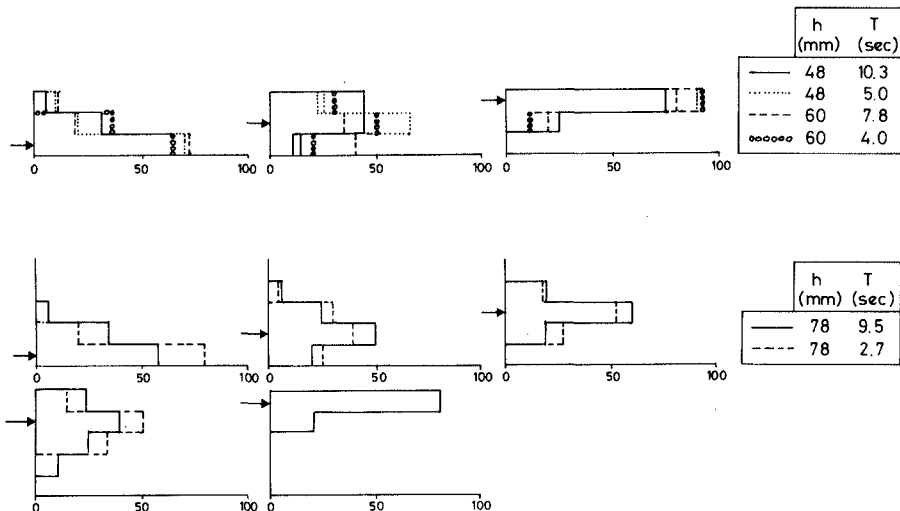

Fig.3 Probability of grain swop in various tests

The number of grain encounters during the observation time (the time during which the grain is visible in the window) can be calculated from the (expectation of the) increment in velocity of a higher layer compared to the one of the adjacent lower layer. It also depends on the distance between the grains in one layer, which can be approximated as $(1 + 1/\lambda)D$ (λ =linear concentration according to Bagnold (1954)) and of the length of the observation time, which is smaller for the higher layers than for the lower layers. Thus is found (Bakker,1989) that the number of grain encounters during the observation period equals $\lambda L/\{(\lambda+1)kD\}$, where L is the length of the window (29 cm) and k the number of the layer (counting from downwards to upwards).

During each encounter the two grains involved can either remain in the layer in which they are, either exchange position. This last event will be called a "grain swop". Let p be the probability of a grain swop per encounter. For the upper or lowest layer thus the probability Pr that a grain still is in the same layer in which it started equals:

$$Pr = (1 - p) \lambda L/\{(\lambda+1)kD\} \tag{2}$$

This under the assumption, that the probability can be neglected, that a grain returns to its former layer after swopping to another layer.

If a layer is enclosed by two adjacent moving layers grain swop can occur to two sides and "1-p" in (2) should be replaced by "1-2p".

From the results, depicted in fig. 3, with the aid of (2) the probability p of a grain swop per encounter has been calculated as function of the linear concentration λ and the shear Reynolds number Re_s , where Re_s is defined as:

$$Re_s = r^2 S/\nu \tag{3}$$

Here S is the velocity gradient, ν the kinematic viscosity and r the radius of the grain (i.e.D/2).

Fig. 4 shows the result with its confidence limits. The probability of grain swops tends to decrease with increasing velocity gradient and increasing concentration.

Fig.4 Probability of grain swop as function of λ and Re_s

Bakker (1989) calculated the increase in shear stress caused by momentum transfer from one layer to another. Only the direct transfer - a grain with its momentum comes suddenly in the next layer - has been calculated (the effect of the whole process of blocking and collision, during which a grain could transfer as well the momentum of other grains in its layer to the adjacent layer has not been taken into account). It was found, that the increase of viscosity, caused by this process is proportional to Re_s and p ; for the present tests this increase only amounts to 10 % of the viscosity of the oil.

7. PREVIEW OF THE RESULTS OF THE MEASUREMENTS.

The measured normal forces on the bottom ring in the tests NO showed the occurrence of a propagating pressure wave in phase with the revolution of the upper ring. In the shear force data these fluctuations were absent. Putting separating screens in the space of the carousel below the lower ring, in order to attenuate these waves, gave some improvement, but not enough.

Using Fourier analysis, the signal with the revolution period has been filtered away and a mean normal pressure time series during a period of encounter between two hemispheres of resp. upper and lower ring could be determined. The result, a nearly symmetrical curve with its confidence limits, is shown in fig.5.

Fig 6 shows the tension/pressure in one pressure gauge as function of time in the case of nearly-touching (the first-mentioned experiment of series NO; see table 1 and text ch.6). A very large pressure peak is followed by a small peak of tension. Cavitation could be the cause.

Fig.5 Course of pressure during encounter of hemi-spheres (height=16 mm)

Fig.6 Tensile force in test NO (nearly touching hemi-spheres).

8. ELABORATION OF THE MEASUREMENTS.

By averaging over an integer number of revolutions, summation over the number of supports (i.e. 3) and by division over the area of the lower ring (0.23 m²) the normal forces are converted into pressures (or tractions). The shear stress can be found by direct division by the area of the lower ring.

Data will be presented as function of the shear Reynolds number (eq.(3)) and in the dimensionless Bagnold parameters N and G^2 , defined by:

$$N = 4 \sqrt{\lambda} \cdot Re_s \quad (4)$$

$$G^2 = \tau/\tau_0 \quad \text{or } p/p_0 \quad \text{with } \tau_0 = p_0 = \rho \cdot v^2 \cdot \lambda/D^2 \quad (5)$$

Here S is the velocity gradient, ν the kinematic viscosity, ρ the common specific density of grains and fluid, r the radius of the grain and τ_0 (p_0) is a reference shear stress (pressure). Mind that G^2 according to Bagnold entails one of two variables; it is rather a dimensionless way of presenting τ and p than a variable. Furthermore λ is the linear concentration ϵ/r , where ϵ is half the smallest distance between two adjacent grains.

It thus may be found from:

$$\lambda = \{(c_{\max}/c)^{1/3} - 1\}^{-1} \quad (6)$$

where c_{\max} is the maximum concentration.

Presenting the data on the way of Bagnold thus has no other meaning than presenting the shear stress (c.q. normal stress) versus the velocity gradient at a certain, by Bagnold described dimensionless way. If one wants to compare with Bagnold's results, it should be kept in mind, that Bagnold starts from the conception, that shear stress can be divided into shear stress, acting on the fluid and shear stress acting on the grains, where the present idea is: an integral shear stress, acting on the fluid only and transmitted via the fluid on the grains. It must be kept in mind, that the "correction" of the shear stress for fluid shear stress is not applied in this paper.

9. PRESENTATION OF RESULTS.

Shear stress:

A plot of the shear stress according to Bagnold (G^2 versus N) of the NO-series (fig 7) shows, that the slope of the line follows Bagnold's theory; however, the shear stress is an order 2 lower than Bagnold predicts. Similar results were found in the series SOME (shown in Klomp, 1990 and Bakker et al., 1990) and 1LR (fig.8) apart from one

Fig.7 Shear stress as function of velocity gradient; series NO

Fig.8 Shear stress as function of velocity gradient; 1LR

Fig.9 Shear stress as function of velocity gradient; 3LR.

Fig.10 Relative apparent viscosity vs. concentration.

test with smallest distance between the rings in series SOME and two tests with the same conditions in series 1LR, giving a shear stress being orders higher, which can be attributed to blocking.

In series 3LR (fig 9) each concentration gives a different line in the Bagnold graph, being especially for higher concentrations somewhat flatter than the Bagnold line. For high concentration the shear stress is orders of magnitude larger than Bagnold predicts, probably due to the boundary condition of no dilatation and the rigid boundary of hemispheres at the rings in the present tests. Mind (fig.8) that given a relatively high concentration (17.4% in series SOME, 19.1 % in series 1LR) no blocking occurred at relatively high velocity gradient.

In fig.10 the relative apparent viscosity (determined from the experiments) as function of concentration is compared with the theory of Bagnold, Einstein and the numerical theory (Bakker and Van Kesteren 1986). For high concentrations the numerical theory predicts quite well the increase of the apparent viscosity with increasing concentration. The blocking during the series SOME and 1LR appear clearly in this figure.

Normal stress:

In the series NO,SOME and 1LR under some circumstances traction forces on the lower ring are registered instead of pressure, as Bagnold predicts. This makes a presentation impossible according to the Bagnold way, implying a logarithmic plot of the pressure. For

series 3LR, always pressure forces are found; the Bagnold plot of this series is given in fig. 11. Linear plots of fig.11 (Klomp, 1990; Bakker et al.1990) show dispersive pressure and shear stress build up, approximately linear with the velocity gradient. However, the linear relation has a zero-shift: one gets the impression that in the "soil mechanics region" (neglegible motion, non-neglegible strains and stress field) shear stresses and pressures build up, which are enhanced during the motion in the viscous region. The relation between shearstress and normal stress is depicted in fig.12 including the stress points, determined by extrapolation, corresponding to a zero velocity gradient. It appears that the results for different concentrations together form a single unique relation similar to failure envelopes in soil-

Fig.11 Normal stress as function of velocity gradient; 3LR.

Fig.12 Shear stress vs. normal stress

mechanics. From this relation it can be concluded that the same stress point (shear stress - normal stress) can occur at a high velocity gradient and low concentration or at a low velocity gradient and high concentration.

10. CONCLUSIONS.

- a. Dispersive stresses are found in the grain carousel, when the concentrations exceed 30%.
- b. Probably because of the rigid boundaries (fixed hemispheres, no dilatancy allowed) the dispersive stresses in these cases are (especially at high concentrations) much higher than those found by Bagnold.

A much stronger relation between dispersive stress and concentration was found than according to Bagnold's theory.

- c. Most probable reason of this dispersive stress is blocking (although no straight-forward theory can yet be given concerning the mechanism).

In the case that no blocking occurs (series NO and the most experiments of series SOME and 1LR) only for small shear Reynolds number a minimal dispersive pressure is found; for larger shear Reynolds number even traction forces between the layers are measured.

If no blocking occurs, the shear stress found is about 2/3 of the value predicted by Bagnold.

- d. The grains in a high-concentrated mixture move generally in layers. Only a small percentage of grain swops occur.
- e. When the grain motion is not blocked (exp. series NO, SOME and 1LR) the spheres tend to move in a central position between the rings. This can be explained by the centering force acting on grains, moving between two plates (Bakker et al., 1988).

CHAPTER 206

EVALUATION OF RADIOACTIVE SAND TRACERS TO MEASURE LONGSHORE SEDIMENT TRANSPORT RATES

G. Drapeau¹, B. Long¹ and J.W. Kamphuis²

ABSTRACT

This paper analyzes and compares radioactive sand tracer experiments with beach profile measurements and calculations of littoral sand transport rates performed at Pointe Sapin, N.B. in the Gulf of St. Lawrence, Canada. The three methods give comparable results. In theory, all sediment tracers should be dealt with the same way, but in practice the nature of the tracers has to be taken into account. Tracers do fulfill the purpose for which they are used and they can solve sediment transport problems when used with knowledge and care. The wide variation among littoral sediment transport formulas should not be attributed to the lack of accuracy of tracer experiments but rather to the fact that expressions are over-simplistic and important factors such as the influence of beach slope and grain size are not taken into account.

1. INTRODUCTION

The determination of alongshore sediment transport rate remains one of the fundamental problems of coastal engineering. The Canadian Coastal Sediment Study (C²S²) brought together oceanographic, geological, and engineering researchers in Canada to study coastal processes and improve the knowledge of sand transport on beaches (Willis, 1987). One of the main achievements of (C²S²) has been to coordinate different experiments at two sites in the Gulf of St. Lawrence: Pointe Sapin, N.B. and Stanhope Lane, P.E.I. The purpose of this paper is on the one hand to analyze and compare radioactive sand tracer experiments with beach profile measurements and calculations of littoral sand transport rates performed at Pointe Sapin and on the

other hand to compare these results with sand tracer experiments carried out elsewhere.

As the sediment tracer measurements are compared with other measurements and calculations of sediment transport carried out simultaneously at the same site, it permits verification of the capabilities as well as the limitations of the sediment tracer technology. Sediment tracer results have been one of the main sources of information to develop littoral transport formulas. The behavior of tracer particles in the longshore sediment transport system has been examined by Madsen (1987) who points out that sediment tracer experiments must meet many assumptions to sustain the theory on which the sediment tracer technology is based and he concludes that in his opinion whether or not the longshore sediment transport system invalidates the assumptions behind the use of tracer methodologies is not yet resolved.

In this study the spatial integration of radioactive tracers is used to determine sediment transport rates. The basic assumption behind the use of tracers is that advection, the downstream transport of sediments associated with the flow in the transport system, dominates diffusion and dispersion. The use of tracers to measure longshore transport of sand in the surf zone is based on the principle of continuity described by a continuity equation such as:

$$Q = V_a b \quad (1)$$

where V_a is the mass velocity of the tracer and b is the thickness of the mobile sediment layer.

Inherent to the use of tracers is the problem of defining to what extent the observed movement of tracer grains is representative of the movement of sediment within which the tracer grains have been injected. There are two premises: one is that the trajectory of tracer grains is the same as that of the sediment in which they are injected, and the other is that the depth of mixing of the tracer is representative of the thickness of the mobile sediment layer.

The centroid of all tracer grains detected during a given survey is used to determine the mass velocity (V_a) of the tracer which is obtained by dividing the distance the centroid of the tracer cloud has moved between two surveys by the time elapsed between these two surveys. Tracers with the same grain size and density as the parent sediment are assumed to follow similar paths. The depth of mixing of tracer grains is more difficult to assess because sediment tracers are usually deposited at the water-sediment interface and their mixing within

the sediment mobile layer is not instantaneous. The thickness of the moving sediment layer was estimated using an analytical solution developed by Sauzay (1967). Cores of the beach were also taken during the tracer experiment. The distribution of tracer within the cores shows different patterns depending on location and time, but a parabolic distribution is found in many cases that confirms Alquier's experimental verification (Alquier et al. 1970) of Sauzay's model as well as the theoretical tracer distribution, based on "waiting time considerations", developed by Galvin (1987).

In theory, all sediment tracers should be dealt with the same way, but in practice the nature of the tracers has to be taken into account. The time scale and the space scale of luminescent tracers and radioactive tracers differ by one order of magnitude. Luminescent tracer experiments are measured in terms of hours and tens of meters, while radioactive tracer experiments last many days and cover hundred of meters. These large differences imply that the results are interpreted differently.

2. EXPERIMENTAL SETTING

2.1 Location of study area

Two sites were selected in the Gulf of St. Lawrence for the Canadian Coastal Sediment Study; one was located at Pointe Sapin, N.B. and was occupied during the fall of 1983 and the other was located at Stanhope, P.E.I. and occupied during the fall of 1984. The present paper is dealing with the Pointe Sapin experiment (Fig. 1).

Figure 1. Location of study area.

Pointe Sapin is a small fishing harbor on the coast of New Brunswick in the Gulf of St. Lawrence. The location of this site is such that it is exposed to long fetches exclusively from the north-east. The Pointe Sapin site is then subjected to an almost unidirectional alongshore sediment transport, which is an advantage for studying the transport of sediments. Furthermore, the littoral sediment drift is terminating in a sand trap, a detached breakwater designed to keep Pointe Sapin Harbor entrance open (Fig. 2-A).

Figure 2. A) General setting. B) Measured (Dobrocky) and calculated (Queen's) transport rates. C) Sediment tracer distribution before and after Nov 4 storm.

2.2 Field measurement program

The Canadian Coastal Sediment Study measured: 1) directional waves at 4 km and 750 m. offshore 2) cur-

rents at 1100 m. and 700 m. offshore and in the surf zone, 3) beach profiles, 4) volumetric sand transport at the trap, 5) suspended sediment concentration, and 6) dispersion of radioactive tagged sand.

2.3 Sand trap at Pointe Sapin

The study site at Pointe-Sapin benefits from a detached breakwater that serves as a sediment trap filling up on a yearly basis. Figure 2-A shows the evolution of the sand trap that had been dredged in September 1983, prior to the field operations, and then partially filled during the field study, mostly during the passage of two north-easterly storms over the area (October 25th and November 4th, 1983).

2.4 November 4th storm

Two north-easterly storms developed during the field experiment; one on October 25th and the other on November 4th. The results from the present study are centered on November 4th storm. Periods of dominant waves varied from about 3 seconds during calmer conditions, up to nearly 10 seconds for the two storm events. Immediately prior to the Nov. 4th storm, the wave period gradually increased, as typical of a developing local storm system. Because of the geometry of the coastline and the adjacent islands, the wave field did not shift in direction significantly as the storm front passed. This is largely due to the narrow window through which waves may pass to impinge onto Pointe Sapin. During the November 4th storm, significant wave height exceeded 1.25 m, propagating towards 272-273 degrees TN with periods of 8.5 seconds, growing to 9.8 seconds near the end of the storm (Aubrey and Spencer, 1984).

3. RESULTS

3.1 Volume measurements of erosion and sedimentation

Beach and bathymetric profiles of the sand trap and the adjacent beach and nearshore zone were measured regularly and also after each storm by the Dobrocky-Seatech group (Gillie, 1984). Consecutive sets of profiles were compared to determine the volumes of erosion and sedimentation. A complete survey was carried out before (Oct. 30th) and after (Nov. 7th) the November 4th storm. The erosion and sedimentation of the beach and sand trap resulting from that storm are shown in Fig. 2-B.

3.2 Tracer measurements

The radioactive element used for the sediment tracer study was gold¹⁹⁸ (2.7-day half-life) incorporated in glass grounded to the size of the beach sediment. One kilogram of sediment tracer was injected on November 1st at the location of marker #6 as shown in Fig. 2-C (Long, 1984). Twelve surveys of the radioactive tracer were carried out during the nine following days (Table 1). The distribution of tracers before (03 Nov. 15:00 hrs) and at the end of the storm (04 Nov. 15:00 hrs) is shown in Fig. 2-C.

Y = crossshore coordinate of tracer cloud centroid

3.3 Calculations of erosion and sedimentation

Kamphuis *et al.* (1986) developed a model based on the wave energy flux to calculate littoral sand transport rates. This model was used at Pointe Sapin to calculate sand transport rates as well as erosion and sedimentation in the study area for the November 4th storm (Kooistra and Kamphuis, 1984). The results are shown in Fig. 2-B and in Fig. 3.

Figure 3. Time series starting at 00:00 hrs Nov. 1st 1983.

 Breaking wave height (Hb [cm]).
 B) sediment transport rates.

4. DISCUSSION AND CONCLUSIONS

4.1 Coherence of Pointe Sapin results

Estimates of total volume of sediments transported during the November 4th storm are shown in Tab. 2.

Table 2

Transport using volume method	5200 m ³
Transport using tracer method	
30 m. wide beach	5300 m ³
40 m. wide beach	7100 m ³
Calculated transport:	6070 m ³

These results outline the good agreement between the three methods used at Pointe Sapin. As explained above,

the Pointe Sapin site is particularly appropriate to perform comparative studies because uniform conditions are maintained during storm events. Time series of littoral drift estimates based on: a) 12-hourly tracer surveys, b) 6-hourly calculations based on Queen's model (Kooistra and Kamphuis, 1984), c) 12-hourly calculations based on CERC formula are compared in Fig. 3-B, using wave height, tide and beach slope of Fig. 3-A. These time series show that the tracer method estimates concur with the littoral drift calculations. It is worth noticing that although the tracer method calculations for littoral drift are based on a spatial integration, they are nonetheless sensitive to short-time variations of the wave climate. Fig. 3-B also shows that the CERC formula is directly linked to the wave climate exclusively, while the Queen's formula also incorporates the beach slope. This is the reason why at hour 120 in Fig. 3-B the CERC formula shows a peak which is reflected neither by the Queen's estimate nor by the tracer measurements.

4.2 Comparison with other studies

Extensive field experiments on longshore sand transport in the surf zone have been carried out in Japan. The results of these experiments were synthesized by Kraus *et al.* (1982). Eight sand tracer experiments were performed in energetic surf zones on natural beaches and on beaches near structures to measure short-term longshore sand transport rates. Tracers of up to four distinct colors were used to better outline the distributions of the longshore sand advection velocity and transport rate.

The transport rate of sediments is related to the fluid energy dissipation on the shore. Kraus *et al.* (1982) obtain the relationship:

$$Q = 0.024H_b^2V \quad (2)$$

where Q is the volumetric transport rate, H_b the wave height at breaking and V the average longshore current, assuming a beach slope of 1/50 and a breaking index of 0.8. This equation is plotted in Fig. 4 as well as the results from the Japanese tracer program. It can be seen that the equation is a good descriptor of the Japanese tracer data from which it is derived. Tracer results from Pointe Sapin are shown on the same figure. The energy dissipation levels are comparable for the two sets of data but the corresponding transport rates are one order of magnitude larger in the case of Pointe Sapin.

Figure 4. Volumetric transport rate.
 O = Kraus et al. 1982 data.
 * = This study.

Kraus et al. (1982) arrive at that definition of equation 2 using two other equations derived empirically from their field measurements:

$$V_a = 0.014V \quad (3)$$

$$b = 0.027H_b \quad (4)$$

where V_a is the tracer cloud centroid advection velocity, b the depth of tracer mixing and the other parameters are the same as Eq. 2.

Figure 5. Sand advection velocity.

O = Kraus et al. 1982 data.

* = This study.

Equation 3 establishes a relationship between the mean longshore current (\bar{V}) and the sand advection velocity (V_a). The results from the Japanese program and those from Pointe Sapin are plotted on the same diagram in Fig. 5. In this case the results from Pointe Sapin and those from Kraus *et al.* (1982) concur, which implies that for comparable conditions the advection of sand in the longshore transport process is essentially the same be it on Japan beaches or in the Gulf of St. Lawrence.

Equation 4 which correlates the depth of tracer mixing to the wave height is plotted in Fig. 6. Here again the results from Pointe Sapin are one order of magnitude larger than those from Japan beaches. It indicates that transport rates obtained for the present study are different from those obtained by Kraus *et al.* (1982) for comparable energy conditions because esti-

mates of thicknesses of the mobile sediment traction layer are different.

Figure 6. Depth of mixing.
 O = Kraus et al. 1982 data.
 * = This study.

The thickness of the mobile layer is determined indirectly when radioactive tracers are used. It is based on the evaluation of the diminution of tracer signal as a function of depth of burial into the sediment (Sauzay, 1967). With luminescent tracers the thickness of the mobile layer is determined by coring the sediment and sampling at different intervals. Kraus (1985) has examined the vertical mixing of luminescent tracer within the sand of the surf zone for the eight

Japanese experiments referred above. He takes the thickness of the mobile layer to be the depth where 80 percent of the total tracer included in the core is reached. The results of Kraus *et al.* (1982) plotted in Fig. 4, 5 and 6 are based on that premise.

Galvin (1987) has reviewed the problem of vertical distribution of sand tracers in the littoral zone. He approached the problem using a stratigraphic as well as a hydraulic analogy and developed the concept of waiting time. This concept explains, from theoretical considerations, how a given quantity of tracer grains evolves as a function of time as well as a function of distance from the tracer source. These results show that the depth of mixing and also the distribution of tracer change as time passes after the initial tracer release. This is particularly relevant when radioactive tracer experiments are compared with luminescent tracer experiments. Luminescent tracer experiments last less than a day and cover a few tens of meters. By contrast radioactive tracer experiments last for many days and cover hundred of square meters.

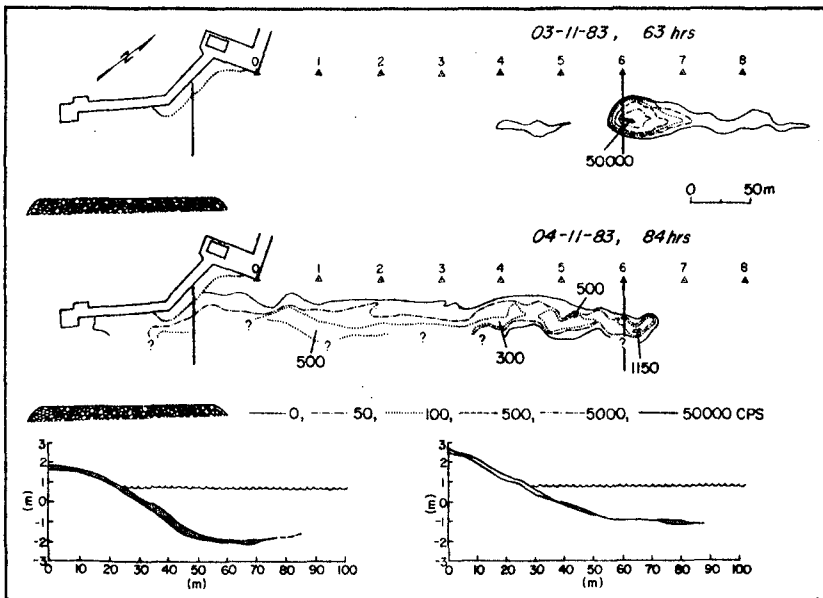

Figure 7. Distribution of tracer cloud before the November 4th storm (03/11/83 63 hrs) and after the storm (04/11/83 84 hrs) Beach profiles surveyed on Oct. 30 and Nov. 7, at station #6 and at the wharf, are shown on the lower portion of the figure. Sedimentation is identified by gray tone.

It is not surprising then that the estimates for the depths of mixing are not the same. If one refers to Galvin's (1987) Fig. 5, it can be seen that if radioactive and luminescent tracer experiments were performed at the same site they would produce different results, the radioactive tracer experiment yielding deeper mixing depths because it lasts longer and covers a larger area.

Data from Tab. 1 show that the depth of mixing during the first 40 hours of the Pointe Sapin experiment is comparable with what was measured on Japanese beaches. The values obtained for the depth of tracer mixing at Pointe Sapin are verified by comparing depth estimates of tracer mixing with beach profile measurements. Beach profiles across the tracer clouds are shown in Fig. 7. Profiles surveyed before and after the Nov. 4th storm are drawn on that figure. Erosion is dominant along profile #6 while sedimentation is prevails along the beach profile extending between the wharf and the detached breakwater. The thicknesses of erosion and sedimentation obtained by comparing beach profiles are in agreement with the depths of mixing estimates shown in Tab. 1.

Conclusions that can be drawn from this study are: 1) tracers do fulfill the purpose for which they are used and they can solve sediment transport problems when used with knowledge and care; 2) the wide variation among littoral sediment transport formulas should not be attributed to the lack of accuracy of tracer experiments but rather to the fact that expressions are oversimplistic and important factors such as the influence of beach slope and grain size are not taken into account.

Coastal Estuarine and Environmental Problems

CHAPTER 207

Beach Erosion Due to Large Coastal Structure and Its Control

Yoshito Tsuchiya¹, Member ASCE, Takao Yamashita² and Richard Silvester³,
Member ASCE

1. Introduction

Beach erosion has recently been recongnized as accelerating due to the influence of coastal structures. This tendency is especially severe in Japan where coastal structures are over abundant. Blockage of the longshore sediment transport and changes in the wave field are the most common causes of structure induced beach erosion. In this paper, these are indentified as the first and second causes of erosion. Examples of such beach erosion in Japan are provided.

In order to explain the two common erosion causes and beach erosion control, results of numerical simulations of shoreline change by a coastal structure and nearshore currents due to wave fields changed are also shown. In the numerical simulation, a countermeasure for beach erosion which is caused by changing of nearshore currents by the coastal sturcture is proposed.

The scenario for the beach erosion can be easily described by Figure 1. In this figure beach erosion due to the first erosion cause, the blockage of longshore sediment transport, is shown in (a) which explains the continuous erosion extending downstream in longshore sediment transport. Beach erosion due to the second erosion cause, the change of nearshore currents by the coastal structure, is shown in (b) which describes ersoion taking place within a limited area. Due to both the first and second erosion causes, beach erosion generally takes place. Beach erosion control should be considered by taking into account these erosion processes, and more strictly speaking for the beach erosion the sandy beach being eroded must be stabilized. For this purpose a dynamical background for the formation of stable

Figure 1 Shoreline changes by two common beach erosion causes.

sandy beaches has to be established. Applying our recent theory of nonuniform longshore sediment transport along the sandy beach, a theory of the formation of stable sandy beaches was recently established by Tsuchiya and Refaat(1990). The theoretical result is very briefly introduced, and then a methodology for the structure induced beach erosion is proposed with a special reference to the Ogata coast facing the Japan Sea.

2. Beach Change by Large Coastal Structure

In order to describe beach changes such as changes in shoreline and bottom topography, an example of the Ogata coast beach erosion is shown in Figure 2. The Naoetsu Harbour shown in this figure has recently been enlarged. NW or WNW and N or NNE waves are predominant to the coast, the former waves are 8 to 10 sec in wave period with a very high wave height, and the later ones are 12 to 14 sec with a small wave height. The predominant direction of longshore sediment is therefore mostly easterly and sometimes changed. In the area just upstream the Naoetsu Harbour, the Seki river is flowing into the area to supply sediment which is the main sediment sources for the coast. The harbour breakwaters were constructed on the right side of the river mouth. Since no longshore sediment can be transported downstream, severe beach erosion has then taken place, and it has recently been accelerated by extending the breakwaters.

Changes in shoreline due to the construction of the breakwaters are shown in Figure 3 where the origin of the distance is taken at Gotsu and the harbour is located

Figure 2 Locations of Ogata coast and Naoetsu Harbour, and refraction diagram of WNW waves with a period of 10sec.

around 4 to 7km. In reference to the shoreline positions in 1911 and 1947 the shoreline changes are shown in (a) and (b) of the figure, respectively. It should be understood that the beach erosion has advanced greatly and the erosion waves have been propagated in the easterly direction, showing some undulations in the waves. To the contrary on the west side, sediment deposition has recently taken place due to the effect of waves reflected by the breakwaters.

To prevent beach erosion, sea dikes were first constructed, but beach erosion had advanced and sandy beaches no longer existed. Secondly, offshore breakwaters were constructed and a great number of concrete units were used. However, the beach erosion have been still in progress and accelerated by structure reflected waves. The water depths have deepened in front of sea dikes and offshore breakwaters. As seen in Figure 4, concrete unit weight to be used increased with an increase in water depth in front of the structures. In advance of beach change beach profiles become generally steep. An example of beach profile change is shown in Figure 5 where the beach profiles measured in 1968, 1972 and 1976 are compared. At that time in 1968 the coast was so-called wave energy dissipative beach, but gradually changing beach profiles more steep they have already become so-called wave energy reflective beach. Catastrophic beach change has therefore sometimes taken place in the coast. This may mean that nature intends to recover the beach profiles to her native ones. It can therefore be concluded from these cases that more natural sandy beaches must be

(a) Shoreline change from 1911 to 1974

(b) Shoreline change from 1947 to 1980

Figure 3 Changes in shoreline due to construction of breakwaters of Naoetsu Harbour.

Figure 4 Changes in concrete unit weight used and contour-line of water depth of 5m.

recovered for erosion control (Tsuchiya, 1987).

3. Numerical Simulations of Changes in Shoreline and Nearshore Currents and Their Control

By use of one line models for shoreline change, calculation was made to predict changes in shoreline in a model condition. One of the numerical results of shoreline change by the breakwaters is shown in Figure 6 where the incident wave conditions being 4 m in wave height, 7 sec in wave period and 10 degrees in wave direction from the north are given. It can be easily understood by the time sequence in shoreline change that the shoreline change occurs continuously to extend in the downstream direction, and that as shown in Figure 2 beach change severely takes place in the area where the two common causes for beach erosion exist.

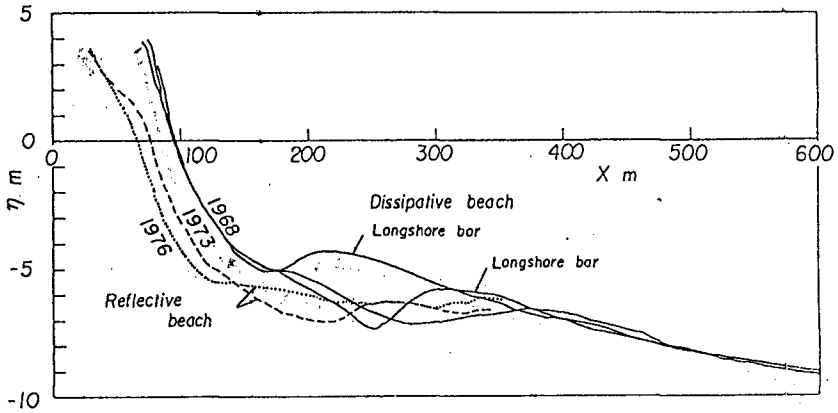

Figure 5 Changes in beach profiles at Ogata coast.

As discussed in Figure 2, the breakwaters generally induce change in the nearshore currents. By use of a nearshore current model numerical calculations were made to find changes in wave field in the area where breakwaters exist and in the

Figure 6 Numerical result of shoreline change due to blockage of longshore sediment transport.

structure induced nearshore currents. Figure 7 shows an example of the numerical calculations where the incident wave conditions being 4 m in wave height, 7 sec in wave period and normal wave incidence were given. In the numerical simulations the

Figure 7 Numerical result of wave field in the area where a breakwater exists.

so-called sponge layer was employed both in the offshore and shoreline areas. The upper figure shows the wave height distribution and the lower figure does the equi-phase lines. Using this wave field nearshore currents were calculated as shown in Figure 8. It is clearly shown that there clearly exist a couple of nearshore

Figure 8 Numerical result of nearshore currents in the area where a breakwater exists.

circulations, which are shown by A and B exist in the area behind the breakwaters. In order to control beach erosion caused by the changing wave field, these circulation must be reduced. Numerical consideration was made of changing nearshore currents by a small groin. Figure 9 shows the wave field in the case where a small groin is constructed in the nearshore circulation A. Using this wave field nearshore circulation was calculated as shown in Figure 10. It is concluded that the groin is

Figure 9 Numerical result of wave field in the area where a breakwater and groin exist.

Figure 10 Numerical result of nearshore currents in the area where a breakwater and groin exist.

very effective to reduce the nearshore circulations. In the construction of offshore structures such as breakwaters, the beach erosion due to the change in wave field may be controlled by constructing a small groin in the area behind the breakwater.

4. The Formation of Stable Sandy Beaches

The authors have demonstrated that, as schematically shown in Figure 11 there exist static and dynamic equilibrium sandy beaches which are sometimes identified as static and dynamic stable ones (Tsuchiya, Silvester and Shibano, 1979 and Silvester, Tsuchiya and Shibano, 1982). The static stable beach and its application to beach erosion control was first proposed by Silvester(1956). He proposed the geometry of stable beaches as shown in Figure 12 where the solid curve

Figure 11 Schematic diagram of static and dynamic stable beaches.

indicates his empirical formula for static sandy beach and the values shown are field data of stable sandy beaches such as those in the Amanohashidate beach and others (Tsuchiya, Silvester and Shibano, 1979). Recently a theory of the formation of stable sandy beaches was proposed by Tsuchiya and Refaat (1990) by applying the non-equilibrium longshore sediment transport and equation of continuity of beach change. It was concluded by the theory that the stable sandy beaches can be formed by the upstream and downstream boundary conditions in the formation of sandy beaches. The existence of the stable sandy beaches was qualified and theoretical configuration of the stable sandy beaches were also obtained. Figure 12 shows an example of the theoretical configurations of dynamic stable beach which are compared with those of sandy beaches formed between two groins at the Amanohashidate Beach where a sediment amount of about 4,000 m³ is bypassed annually. It is therefore noted that, based on this theoretical background stable sandy beaches can be formed by two headlands for beach erosion control.

5. Application of the Headland Control Methodology to Ogata Coast

As already described in Section 2, the Ogata coast has being eroded severely

Figure 12 Comparison between theoretical and measured configurations of dynamic stable beaches.

following the construction of the breakwaters of Naoetsu Harbour. Numerous methods of beach erosion control by coastal structures have been implemented including sea dikes and offshore breakwaters. The reflection of incident waves due to such structures, as already shown in Figure 5, can transform a dissipative sandy beach with a longshore bar, into a reflective beach without a longshore bar, thus accelerating the erosion process (Tsuchiya, 1987). This particular situation may be labeled as a third main cause of structure induced shoreline erosion.

Sandy beaches are thought to possess a stable configuration based on the properties of the predominant waves and beach sediments. This stable configuration is frequently altered by man's interaction, from its normal dissipative beach state to a reflective one, and erosion will proceed only until its normal dissipative state recovers. The three previously described main beach erosion causes are harnessed by the previously mentioned headland control, thus providing the necessary influence to restore and retain the dissipative beach form. Based on the theoretical background of the formation and existence of static and dynamic stable sandy beaches, the headland control methodology can be applied for beach erosion control at the Ogata coast. In order to examine the principal methodology of erosion control mentioned above, numerical and physical simulations of the beach change were carried out. By use of

the results of these investigations, the proposed erosion control method is shown in Figure 13 as a series of dissipative sandy beaches to be formed by man-made

Figure 13 The proposed beach erosion control for Ogata coast by headland control methodology.

headlands. In this proposal, due to the economical sense in the construction, the man-made headlands are constructed slightly offshore the breaker depth and the water depth at which the headlands are constructed decreases in the downstream direction. The dimensions of the headlands and their spacings, as shown in the figure, are decided according to the first and second beach erosion causes. At the downstream end their dimensions become small, as shown in Figure 14, their influence must be vanished to reach the natural situation. Additionally a sediment amount of about $5,000 \text{ m}^3$ per year may be bypassed. The headlands are of T-shaped groin type with a mild offshore face. A couple of these are now under construction.

6. Conclusion

In this paper, structure induced beach erosion causes were classified into the first and second, and their erosion processes were examined with a special reference to the Ogata coast facing the Japan Sea and by numerical simulations of shoreline and nearshore currents. In the headland control methodology, the theoretical background of the formation and existence of stable sandy beaches was very briefly described based on our current investigation.

Based on the theoretical background of the existence of stable sandy beaches, a series of stable, dissipative sandy beaches were proposed and they are to be formed by the headland control methodology.

CHAPTER 208

BEACH EROSION CONTROL BY SUBMERGED FLOATING STRUCTURE

Naokatsu SHIMODA¹
Noritaka MURAKAMI²
and
Koichiro IWATA³

ABSTRACT

This paper is to investigate experimentally the beach erosion control function of a submerged tension-moored breakwater. Two- and three-dimensional laboratory experiments are performed.

The single-peaked, double-peaked and triple-peaked cusped spits are formed by placing the submerged tension-moored breakwater on an accreted-type or intermediate-type beach. When the submerged tension-moored breakwater is placed on an eroded-type beach, the shoreline denudation is stopped and the shoreline is restored to the original location.

The submerged tension-moored breakwater is concluded to be possibly one of effective measure works against beach erosion in an inner gulf area in which huge waves do not attack.

1. INTRODUCTION

So far, a semi-submerged bottom-seated offshore breakwater made with natural stones and concrete armour units

- 1 B.Eng., Vice-Head, General Technical Research Lab., Gikenkogyo Co.Ltd., Hachioji, Tokyo, Japan
- 2 B.Eng., Graduate student, Dept.of Geotechnical Eng., Nagoya Univ., Nagoya, Aichi 464, Japan
- 3 M.ASCE, D.Eng., Professor, Dept.of Civil Eng., Nagoya Univ., Nagoya, Aichi 464, Japan

have been constructed to protect beaches from severe erosion as well as to prevent the coastal zone from wave-caused disasters. The offshore breakwater has been verified to be an effective measure against beach erosion as well as an useful disaster prevention work, and Japanese coasts have been protected by many numbers of this kind of offshore breakwater.

Very recently, however, the bottom-seated offshore breakwater made with concrete armour units is pointed out to have some demerits such as (1) poor sea water exchange between the onshore and offshore side of the breakwater, (2) destruction of beautiful scenery and (3) bad barrier for marine sports. Therefore, research and development of new type of beach erosion control works is strongly requested in relation to re-development of urban water front in the bay area in which huge waves do not attack.

The artificial reef work utilizing a submerged sea-dike made with natural rocks are under construction, in some Japanese coasts, as a new measure work against beach erosion. All the measure works against beach erosion which have been put into practical use utilize bottom-seated structures. Another possible choice instead of the bottom-seated structure will be a moored-type structure. However, very few researches regarding the measure work using moored structures have been conducted.

With this background in mind, this paper deals with a submerged tension-moored breakwater from the view point of (1) good sea water exchange between onshore and offshore side of breakwater, (2) no destruction beautiful scenery and (3) no bad barrier for marine sports and discusses the beach erosion control function by means of two- and three-dimensional laboratory experiments.

2. TWO-DIMENSIONAL LABORATORY EXPERIMENT

1) Equipment and procedure

A wave tank in 1m width, 1.5m height and 50m length at Gikenkogyo Co.Ltd. was used to discuss 2-dimensional beach deformation. Experimental waves were all regular ones and their wave steepness (H_o/L_o : H_o ; deep water wave height, L_o ; deep water wavelength) were 0.01, 0.03 and 0.06, which were selected so as to produce the accreted-type, intermediate-type and eroded-type beaches without structures (Horikawa and Sunamura (1974)). Bed material was fine sand of 0.38mm medium diameter (d_{50}) and the initial bottom slope ($\tan\theta$) was 1/10. The floating breakwater was fixed to the bottom with tension using 4 stainless wires of 3mm diameter. The initial mooring force (F_o) of one wire was about 7.2kg. The dimension of model breakwater was 10cm in height (D), 30cm in width (B) and 99cm in length (A). The schematic illustration of experimental set-up is given in Fig.1.

Fig.1 Schematic illustration of experimental set-up

The waves were generated for about 4 hours until the beach approached to an equilibrium state. The beach profiles at 0.5, 1, 2,3 and 4 hours from the initiation of wave generation were measured carefully with point gauges. The incident and partial standing wave in front of the breakwater were measured with capacitance-type wave gauges. Experiments were carried out, changing the location and submerged depth of the breakwater. Table-1 shows experimental conditions and total experimental runs were 32.

Table-1 Experimental condition

T(s)	Ho/Lo	d/h	lx/L	D/h	d50/Ho
1.0	0.007	0	0.63	0.286	0.0039
1.8	0.019	0.288	}	}	0.0040
		0.330			0.0081
		0.358			0.0111

2) Dimensional analysis

The equilibrium beach profile is mainly dominated by the following dimensionless 6 parameters, due to a dimensional analysis;

$$\left(\frac{H_o}{L_o}, \frac{D}{h}, \frac{d}{h}, \frac{l_x}{L}, \frac{d_{50}}{H_o}, \frac{F_o}{\rho g d^2} \right) \text{ ----- (1)}$$

where, h is the stillwater depth at breakwater, d the submerged water depth, l_x the offshore distance of breakwater from shoreline, g the gravitational acceleration and ρ the fluid density.

There are so many leading factors, but the laboratory experiments are limited. Therefore, the effect of l_x/L and d/h to beach deformation are mainly discussed here.

3) Result and discussion

Experiments showed, as a general feature, that the change of bottom configuration mainly takes place in shallower water depth than the setting location of the breakwater and the magnitude of bottom configuration change becomes smaller with increasing l_x/L and with decreasing D/h .

Figures 2 and 3 show some examples of bottom configuration change taken place by placing the breakwater. The bottom configuration shown in Figs.2 and 3 correspond to the equilibrium state beach. Figure 2(a) shows that the beach without the breakwater is eroded by the wave whoes

steepness is 0.06 ($H_o/L_o=0.06$). However, by placing the submerged tension-moored breakwater, the eroded beach was changed to the uneroded-type or a little accreted-type beach, as shown in Fig.2(b) and (c). The reason of this is that the steep incident wave is broken by the breakwater and the attenuated wave encouraged onshore sediment transport. On the other hand, in case of the accreted-type or intermediate-type beach, the bottom configuration change by the breakwater is not drastical. The intermediate-type and accreted-type beaches were never changed to the eroded-type beach by the breakwater. As shown in Fig.3, the intermediate-type beach was still intermediate-type ones even by placing the breakwater.

The bottom configuration is closely correlated with six dimensionless parameters as shown by Eq.(1). Among them, D/h , d/h and l_x/L were found to be significantly important parameters. With increasing of D/h and decreasing of d/h , the wave breaking-caused vortex and incident wave attenuation become larger, which bring larger change of bottom configuration. In the experiments, large change of bottom configuration was observed to take place under the conditions of $0.33 \leq D/h \leq 0.83$ and,

$$d/h=0 \text{ and } 0.63 \leq l_x/L \leq 2.5 ; \quad 0 \leq d/h \leq 0.33 \text{ and } 0.63 \leq l_x/L \leq 2.2$$

(for eroded-type beach)

$$d/h=0 \text{ and } 0.63 \leq l_x/L \leq 2.5 ; \quad 0 \leq d/h \leq 0.33 \text{ and } 0.63 \leq l_x/L \leq 0.9$$

(for intermediate-type beach)

The bottom around the submerged tension-moored breakwater was scoured in case that the clearance between the breakwater's bottom and beach was less than the breaker height. Material on onshore-bed of the breakwater is

Fig.2 Bottom configuration change (eroded-type beach)

Fig.3 Bottom configuration change (intermediate-type beach)

suspended by wave breaking-caused vortex and is washed away mainly toward offshore ward by the return flow. This scouring was clearly observed in case of the eroded-type and intermediate-type beaches. The maximum scoured depth Δh is closely related to l_x and d , and the dimensionless maximum scoured depth $\Delta h/H_0$ is less than 0.65, as shown in Fig.4.

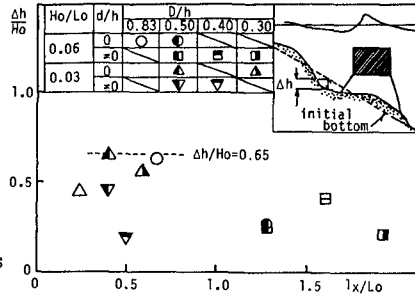

Fig.4 Nondimensional maximum scouring depth $\Delta h/H_0$

3. THREE-DIMENSIONAL LABORATORY EXPERIMENT

1) Equipment and procedure

A wave basin in 10m width, 0.65m height and 30m length at Nagoya University was used to investigate the combined effect of the transmitted and diffracted waves to beach profile. Three plywood breakwaters whose dimensions are $D=10\text{cm}$, $B=30\text{cm}$ and $A=130\text{cm}$, $D=10\text{cm}$, $B=30\text{cm}$ and $A=65\text{cm}$, and $D=5\text{cm}$, $B=30\text{cm}$ and $A=130\text{cm}$ were employed, and they were fixed to the beach with tension by stainless wires of 0.3cm diameter. The bed material and initial bottom slope were quite the same as those of two-dimensional experiments. The stillwater depth at wave paddle was 40cm. Experimental waves were all regular ones and they were generated for about 6 - 12 hours until the beach approached to an equilibrium state. The incident wave was measured with capacitance-type wave gauges. Water particle velocities at bottom around the breakwater were measured with electro-magnetic velocimeters to study the wave-induced current. Particle velocities at 20 different locations were collected. Figure 5 illustrates an outline of experimental set-up. Experimental condition is given in Table-2. The total experimental run was 48.

Fig.5 Sketch of experimental set-up

2) Dimensional analysis

The equilibrium beach profile is largely dominated by the following 8 parameters, due to a dimensional

analysis,

Table-2 Experimental condition

$$\left(\frac{H_o}{L_o}, \frac{D}{h}, \frac{d}{h}, \frac{l_x}{L}, \frac{d_{50}}{H_o}, \frac{A}{l_x}, \frac{F_o}{\rho g d^2}, \frac{K}{A} \right)$$

Ho/Lo	d/h	lx/L	0/h	d50/Ho	A/L	K/A
0.007	0	0.63	0.415	0.0040	0.22	0.25
0.030	0.10	}	0.500	0.0081	}	0.50
0.060	0.25		0.588	0.0111		1.00
		0.33	1.65	0.833	1.09	

--- (2)

where, K is the gap between two breakwaters as shown in Fig.5. When one breakwater is placed, the term K/A is neglected. The initial mooring force (Fo) was about 10kg for all experimental runs, although Fo differed a little from 10kg depending on experimental conditions. There are many leading factors which dominate the bottom configuration change. However, since the laboratory experiment runs are limited like two-dimensional ones, the effect of D/h, d/h, lx/L A/lx and K/A to beach deformation are mainly discussed hereafter.

3) Result and discussion

3-1) Case of one submerged tension-moored breakwater

A) Intermediate-type and accreted-type beaches

Beach morphology was found, as a general feature, to be largely changed by nondimensional quantities relating to a setting location and dimension of the breakwater such as D/h, d/h, lx/L and A/lx.

The cusped spit is generally formed by placing the breakwater on the intermediate-type and accreted-type beaches. Laboratory experiments revealed that the cusped spit is classified into three types such as the single-peaked, double-peaked and triple-peaked cusped spits, as shown in Fig.6. In Fig.6, Lc is the wavelength at the depth of h=40cm in front of the 1/10 bottom slope(tanθ), and the bottom contour is depicted with lcm depth interval. The beach morphology is an equilibrium state one.

The tombolo is well known to be formed by the bottom-seated structure. However, tombolo was not formed in our experiments. This is due to the reason that the incident wave breaks at the breakwater and the overtopped breaking wave suspends onshore-side sediment and stops the growth of the cusped spit. This is a remarkable feature of the submerged tension-moored breakwater, which quite differs from the bottom-seated offshore breakwater made with concrete armour units whose crown height is higher than the water level.

Fig.6(a) is one example of the single-peaked cusped spit in case of d/h=0. The shoreline behind the breakwater is seen to advance offshore-ward. The diffracted wave dominates over the transmitted wave in this case, and then

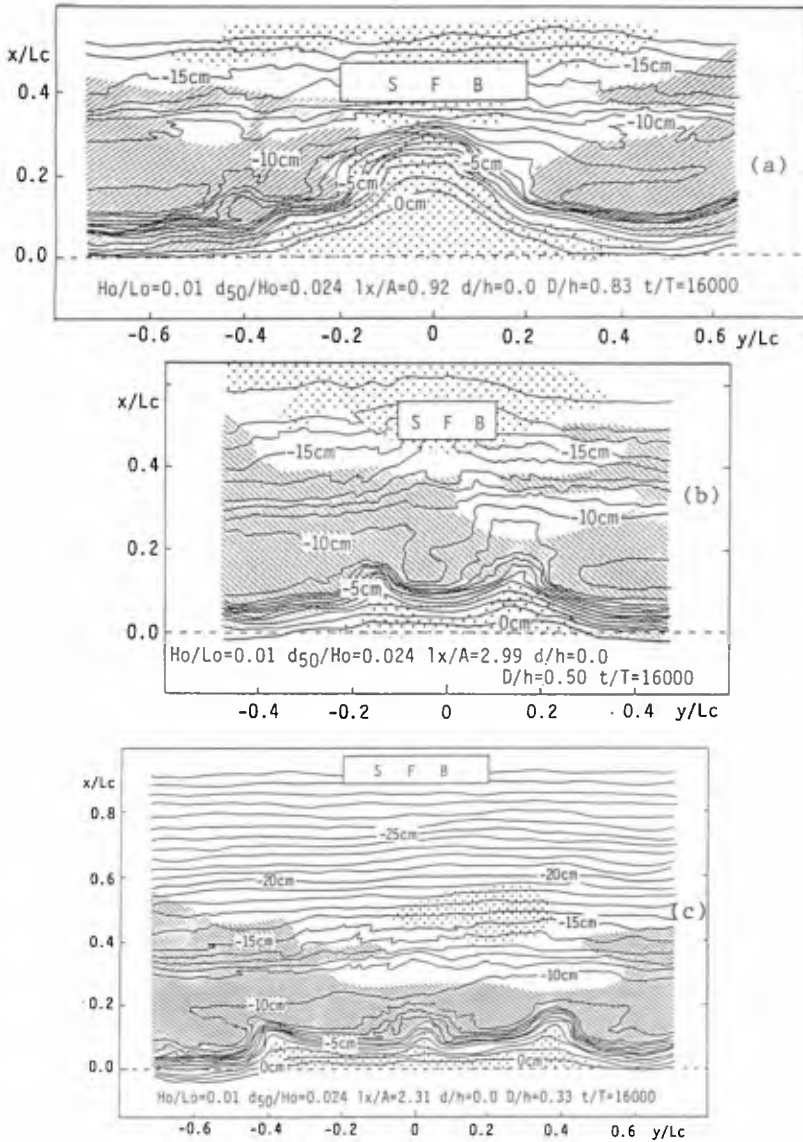

Fig.6 Examples of single-peaked, double-peaked and triple-peaked cusped spits formed by the submerged tension-moored breakwater placed on accreted-type beach (▨; erosion, ▤; accretion)

Fig.7 Schematic illustration of relationships among cusped spits, transmitted wave, diffracted wave and run-up/run-down wave

the bed material in the near-shore regions of both sides of the breakwater is transported toward shadow area of the breakwater, resulting in the formation of single-peaked cusped spit, as shown in Fig.6 (a) and Fig.7(a).

Fig.6(b) is one example of the double-peaked cusped spit. Two peaks are formed behind the breakwater due to the combined effect of the transmitted and diffracted waves. With decreasing of D/h and A/lx , the triple-peaked cusped spit is apt to be formed behind the breakwater. The amount of sediment accumulation around the shoreline is much less than that of the single-peaked and double-peaked cusped spits. The mechanism of forming the triple-peaked cusped spit is different from those of the other cusped spits. As shown schematically in Fig.7(c), the run-up waves obliquely climbed on dry bed run down concentratedly to the same region corresponding to the trough area of double-peaked cusped spit. The frequency of occurrence of the triple-peaked cusped spit was very low in the experiments.

The cusped spit shapes formed by the submerged tension-moored breakwater are very close to those formed by bottom-seated breakwaters made with concrete armour units and natural stones. However, the leading physical parameter which dominates the shapes is different between the two types of structures. lx/A (offshore distance/breakwater width) is the leading parameter in case of the bottom-seated breakwater, and the shoreline shape is classified by lx/A (Shinoda and Ikeda (1972)). However, in case the submerged tension-moored breakwater, D/h and d/h as well as lx/A change largely the morphology of the beach.

Figs.8(a),(b) and (c) show examples of change of equilibrium bottom configuration due to change of D/d and d/h .

Figure 8(a) shows the single-peaked cusped spit in case of $d/h=0$. Only by increasing d/h from 0 to 0.17 with the other quantities fixed, the double-cusped spit is formed as shown in Fig.8(b). This is due to the reason that the transmitted wave becomes larger with increasing d/h and then the transmitted and diffracted waves contribute a lot to beach deformation. d/h is an important parameter relating to the magnitude of wave breaking, as the magnitude of breaking wave-caused vortex tends to be smaller with increasing of d/h . Therefore, the local scouring around the

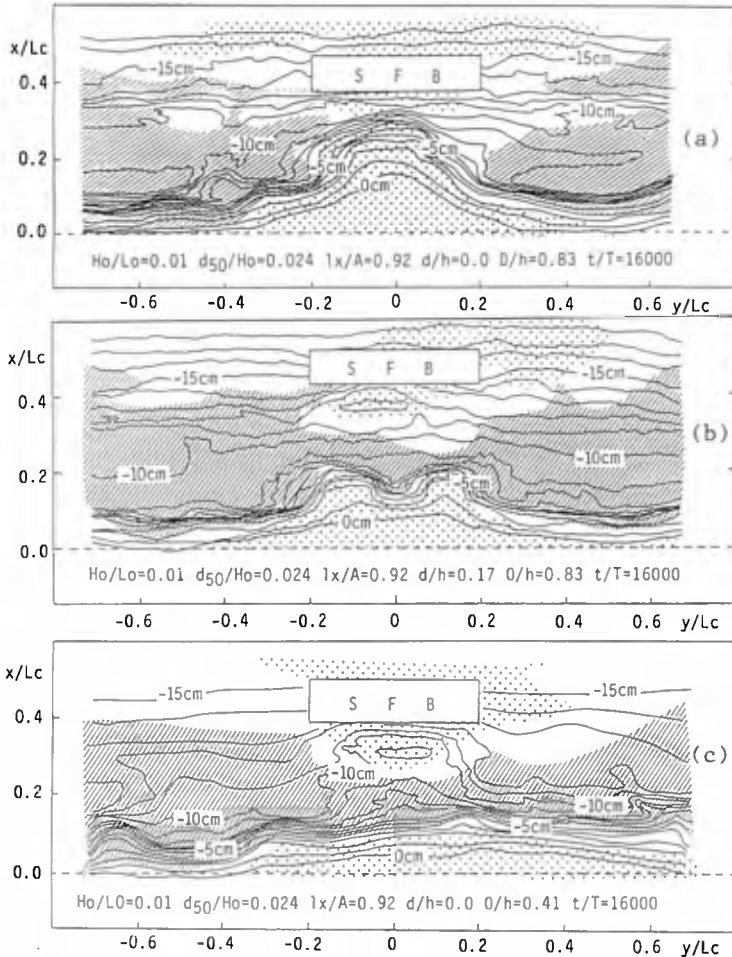

Fig.8 Effects of D/h and d/h to beach deformation (//////; erosion,; accretion)

diminishes generally with increasing of d/h , especially on eroded-type beach.

The dimensionless parameter D/h is more important than d/h , since D/h controls largely the diffracted and transmitted wave height. That is, increasing of D/h enlarges the diffracted wave height and diminishes the transmitted wave height. As shown in Figs.8(a) and (c), decreasing of D/h from 0.83 to 0.41 clearly diminishes the amount of sediment accumulation around the shoreline. This reason is that the diffracted wave in case of $D/h=0.41$ becomes smaller than the case of $D/h=0.83$ and becomes less effective to accumulate the sediment around the shoreline.

The other dimensionless quantities such as $d50/H_0$ and lx/L are also important parameters which deform the beach. However, their effects to beach deformation cannot be discussed here in details due to the limited laboratory experiments.

B) Eroded-type beach

In case of the eroded-type beach, the cusped spit was not formed in the experiments. In the experiments, it was observed that the shoreline erosion (shoreline denudation) is stopped in the shadow area behind the breakwater, by placing the submerged tension-moored breakwater.

Fig.9 shows one example of change of beach configuration by placing the breakwater on eroded-type beach. The cross-sectional change at the section B located at x/Lc at $y/Lc=-0.9$ is very little, as in Fig.9(c). However, beach profile at section A located at $y/Lc=0$ (centerline) shows clearly that the shoreline denudation is stopped and the shoreline advances to the initial position.

Thus, it is clear that the submerged tension-moored breakwater has high function of protection of beaches from erosion in the shadow area of the breakwater. However, it should be noted that onshore-side bottom in front of the

Fig.9 One example of placing breakwater on eroded-type beach (//; erosion, . . . ; accretion)

breakwater is eroded by breaking wave-caused vortex, as shown in Figs.9 (a) and (b).

(C) Local scouring around the breakwater

The onshore-side bottom beneath the breakwater is always scoured on the eroded-type beach and sometimes scoured on the accreted-type and intermediate-type beaches. The maximum dimensionless scouring depth $\Delta h/H_0$ obtained in the experiments is shown in Fig.10. $\Delta h/H_0$ is seen to vary with d/h , D/h and lx/L_0 . The maximum value of $\Delta h/H_0$ is 1.1, which is larger than that of two-dimensional experiments. This may be caused by following reason. The moored structure in three-dimensional experiments has six-degree-freedom motions, different from three-degree-freedom motions in two-dimensional experiments, and a lot of desiment are suspended and transported to both on-offshore and alongshore directions.

Fig.10 Dimensionless maximum scouring depth $\Delta h/H_0$

(D) Range forming cusped spits

Drift and transportation of bed materials is largely controlled by the wave-induced current. In case of bottom-seated breakwater made with concrete armour units, a pair of current cells is known to be formed behind the breakwater.

On the other hand, the current cell was not formed clearly in case of the submerged tension-moored breakwater. The gap between breakwater's bottom and seabed weakens forming the wave-induced current cells and encourage the return flow toward offshore, although the diffracted wave dominates over the transmitted wave with increasing of D/h and decreasing of lx/A and d/h . Figure 11 shows one example of velocity vectors of the wave-induced current, in which left-half of the breakwater is shown because velocity vectors in right-half is almost equal to the left-half. Figure 11 shows no clear current cell, although the return flow is observed.

Fig.11 One example of velocity vectors of wave induced current

As already mentioned, three types of cusped spits are

formed on the accreted-type and intermediate-type beaches. The outline of range in which three kinds of cusped spits take place in case of $d/h=0$ is shown in Fig.12, in which experimental results for bottom-seated breakwater made with concrete armour units are shown simultaneously (● and ■).

From Fig.12, it is seen that double- and triple-peaked cusped spits are formed in the limited ranges of $D/A=0.3 - 0.7$ and $(lx/A)(h/L) \leq 0.27$. On the other hand, the single-peaked cusped spit is shaped under wider range of D/h and $(lx/A)(h/L)$ than those of the double-peaked and triple-peaked cusped spits.

Fig.12 Range which cusped spits are formed. ($\tan\theta=1/10$, $d/h=0$, $0.64 \leq lx/L \leq 2.2$ and $0.004 \leq d50/Ho \leq 0.0081$)

3-2) Case of two submerged tension-moored breakwaters

When the natural beach is an accreted-type and intermediate-type beach, cusped spits are formed by two submerged tension-moored breakwaters. The magnitude of the cusped spits depends on K/A as well as D/h , lx/A and lx/L . Figures 13(a), (b) and (c) show examples of cusped spits. It was found that the magnitude of the cusped spit decreased with decreasing of relative gap between two breakwaters (K/A), as shown in Fig.13. Each shape of two cusped spits formed behind the breakwater in case of $K/A=1.0$ is very similar to that formed in the case of one breakwater. This would imply that when K/A is larger than 1, the coupling effect of two breakwaters to beach deformation is vanished and each breakwater deforms independently the beach.

When two breakwaters were placed on the eroded-type beach, the shoreline denudation behind the breakwaters was stopped, as shown in Fig.14. Therefore, summarizing the above-mentioned, the submerged tension-moored breakwater is concluded to have a function of protecting beaches from erosion.

4. CONCLUDING REMARKS

In this paper, beach deformation by the submerged tension-moored breakwater is discussed experimentally.

The experiments have revealed that the single-peaked,

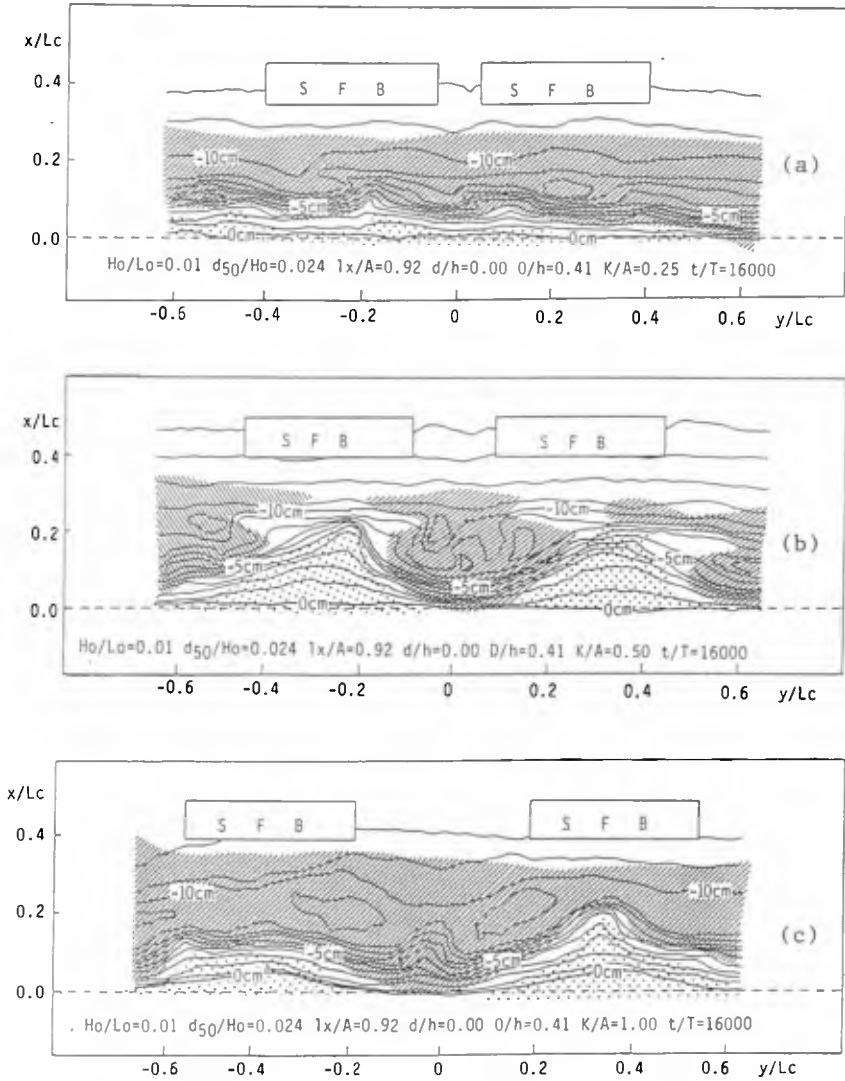

Fig.13 Some examples of beach deformation by two breakwaters placed on the accreted-type beach

Fig. 13 One example of beach deformation by two submerged tension-moored breakwaters on eroded-type beach

double-peaked and triple-peaked cusped spits are formed behind the submerged tension-moored breakwater on the accreted-type and intermediate-type beaches. The magnitude of these kinds of cusped spits are largely controlled by the location and dimension of breakwater.

In the case that the submerged tension-moored breakwater is placed on the eroded-type beach, the shoreline denudation behind the breakwater is stopped.

Therefore, it is said that the submerged tension-moored breakwater has a high function of beach erosion control and is possibly one of the useful measures against beach erosion in an inner gulf area in which huge waves do not hit.

In this paper, the relationship between beach deformation and motions of breakwater is not discussed. The present authors are going to investigate this problem.

CHAPTER 209

FUNCTION OF SAND FENCE PLACED IN FRONT OF EMBANKMENT

Shintaro Hotta¹ and Kiyoshi Horikawa²

ABSTRACT

In order to find the optimum sand fence porosity and the best position for placing a sand fence in front of an embankment, a series of experiments were conducted in a large wind tunnel. The results obtained were that a fence with 40 % or 50 % porosity should be placed at a distance between 15 H and 20 H in front of the embankment, where H is the fence height.

I INTRODUCTION

Sand fence are often employed to control wind-blown sand. However, the characteristics of sand fences are not well understood. The reasons why the characteristics of sand fences have not yet been entirely clarified are that (1) the air flow around the fences is governed by the Navier-Stokes equations and the equations are difficult to solve in practical problems, and (2) the mechanisms that govern the air flow near the sand surface and the interaction with the surface itself, which is constantly changing due to accumulation or erosion, are not clear. Therefore, the function of sand fences has mainly been studied through experiments performed in the field or the wind tunnels. Recently Hotta et al. (1987) made a comprehensive literature survey on the function of sand fences. The review summarized the operational characteristics of sand fences and provided specific guidelines for their use.

Recently in Japan, expressways have been constructed along the coastline. Also, to protect conservation

forests or residential and cultivated land from coastal disasters such as tsunami, storm surge or contamination by wind blown sand, embankments are often constructed along sandy beaches. Wind-blown sand often intrudes beyond these embankments and contaminates conservation forests and residential and cultivated land. Sometimes wind-blown sand accumulating on the expressways will prevent vehicles from passing. Sand fences are often placed in front of the embankments to interrupt the wind-blown sand. In order to find the optimum fence porosity and the best position for the fence in front of the embankment, a series of experiments were conducted in a large wind tunnel. The purpose of this paper is to describe the results of the experiments. Because of the space limitation, results obtained from a mobile sand bed experiment will be described. A description of results concerned the wind flow field will defer to a future paper.

11 EXPERIMENTAL FACILITY AND PROCEDURES

2.1 Experimental Facility

Experiments were carried out using a blow-off type wind tunnel with a cross-section that was 1.1 m high and 1.0 m wide, and with a length of 20 m belonging to the Central Research Institute of Electric Power Industry. The experimental section was located at a segment of the tunnel from 14 m to 18 m from the upstream end. On the top of the tunnel in the segment, a 4-cm wide groove wide was cut along the center line in the direction of the wind. Small rails were laid along to the groove with a spacing of 20 cm for carrying an anemometer array and a profile indicator for measuring changes in the sand surface elevation.

Wind speed was measured with an array of hot-film anemometers consisting of fifteen anemometers. An amplifier unit of anemometer equips A-D converter itself and changes data into RS232C signal. Data were transferred to a personal computer and recorded on a floppy disk. The sampling frequency was 10 Hz.

For visualizing flow patterns around the fence, a smoke tube with a 5-mm diameter having a funnelled-shaped mouth with 1-mm diameter was employed.

In order to measure changes in the sand surface elevation, a profile indicator developed especially for this study and modified from the indicator commonly employed in sounding the sea bottom topography in wave tank experiments was used. The output from the indicator was recorded with an open-reel type digital data recorder, simultaneously monitoring the signal with a chart recorder.

The sand used in the mobile-bed experiment was taken from a natural beach having a median diameter of 0.3 mm and a uniformity coefficient of approximately 1.7. The uniformity coefficient is defined as d_{60}/d_{10} where d is the grain size and the subscript denotes the cumulative percentage. More information on the sand characteristics are given in Horikawa et al. (1983).

2.2 Model Fences

The model fences employed in the experiments were slat-type fences made of small pieces of wood. Each slat had a thickness of 2 mm. The porosity of the fence, which is defined as the ratio of space area to total projected area, was changing by varying the width of the slats while keeping a constant gap of 2 mm between the slats, i.e., widths of 2 mm, 3 mm, 5 mm, 8 mm and 18 mm gave 50 %, 40 %, 28.5 % (hereafter this porosity is referred to as 30 % for convenience), 20 %, and 10 % fence porosity. The slats were glued to horizontal slide bars that were 5 mm in width. Therefore, porosity of 10, 20, 30, 40 and 50 % correspond to 9, 18, 25, 36 and 44 %, respectively if definition is strictly followed. The height of the fence was 9 cm on the fixed-bed experiments for measuring the wind speed field. The height of the fence on the mobile sand experiments was 12 cm, but the

Fig. 1 Dimensions of the model fence.

lower 3-cm part of the fence was buried in sand implying a 9-cm effective height as in the fixed-bed experiments. Figure 1 shows the dimensions of the model fence.

2.3 Experimental Procedures

At first, the flow patterns were observed by using smoke tubes and the wind speed field was measured by an anemometer array on the fixed surface glued sand grains, which were used in a mobile bed experiment. After completing the experiments with the fixed sand surface, the bed was replaced by a mobile bed. Then, experiments on a mobile sand bed were carried out in the order as follows:

- (1) Experiments for fences with 0, 10, 20, 30, 40 and 50 % porosity on a flat bed without an embankment.
- (2) Experiment for an embankment without fences.
- (3) Experiment for fences with 20, 30, 40 and 50 % porosity with an embankment, varying a fence position at 5 H, 10 H, 15 H and 20 H in front of embankment.

The sand surface change was measured by the profile indicator. The measurements of sand surface elevation were made a time interval of 10 min and the experiment duration was 60 to 90 min, depending on the specific run.

In the mobile bed experiments, the vertical distribution of the wind speed was measured at the elevation 10, 20, 35 and 50 cm at a location of 14 m from the upstream end on the tunnel.

Figure 2 shows the model beach and locations of fence placed.

Fig. 2 Model beach and employed location of the fence.

III RESULTS AND DISCUSSION

3.1 Vertical Distribution of Wind Speed on the Fixed Sand Surface

Figure 3 shows an example of the vertical distribution of the wind speed on the fixed sand surface measured without a fence and an embankment. A logarithmic velocity distribution provided a satisfactory description. Attempts were made to keep a constant wind speed of 9.8 m/sec at the reference point throughout the experiments. However, some experimental errors occurred. The shear velocities calculated from the measured vertical distri-

bution in the runs ranged from 41 to 45 cm/sec with an average value of 43 cm/sec, which gave a wind speed of 9.8 m/sec at the reference point.

Fig. 3 Vertical distribution of wind speed on a fixed bed.

3.2 Sand Trapping Efficiency of Porous Fences

Figure 4 shows the time evolution of the sand accumulation around porous fence. For the 60 % fence, no experiment was conducted because it was inferred from the wind reduction conditions around the fence that the sand trapping ability would be low. In Fig. 4, the undulation of initial sand surface is vertically exaggerated since the horizontal distance is reduced by 1/14.5 compared to the vertical distance (figures are drawn at a scale of 1/1.1 in the vertical direction and 1/16 in the horizontal direction).

The time evolution of the sand accumulation is quite different depending on the fence porosity. Sand is mainly accumulated in front of the fence for the 0, 10, 20 and 30 % porosity fence. In contrast, sand is accumulating at a high rate behind the 40 and 50 % porosity fence. Sand was rapidly accumulating during the early stage of the experiments but with time elapsed the rate

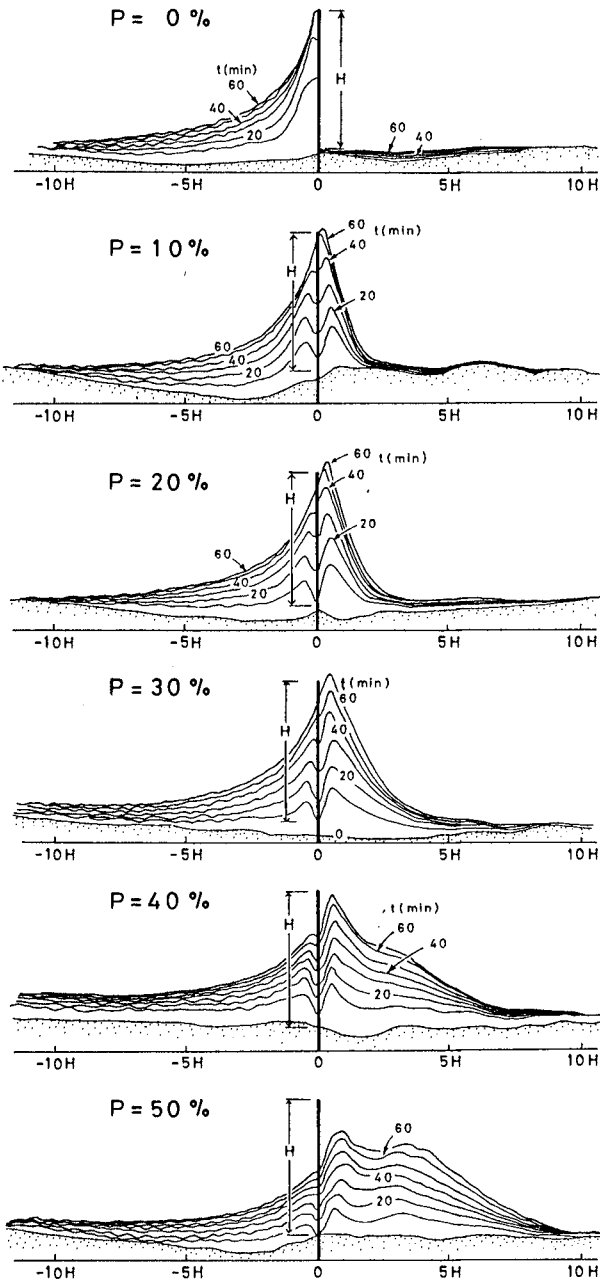

Fig. 4 Time evolution of the sand accumulation.

of accumulation was reduced. The small depression in the sand surface at the fence position caused by local scour due to the accelerating wind passing through the fence gaps, and the scour disappeared when the fence was buried to about 80 % of its height as seen for the 10, 20 and 30 % porosity fences. Also, the rate of sand accumulation rate became considerably smaller when a fence was buried at this stage of the experiment. That is, the sand fence practically loses its sand trapping function when the fence is buried to about 80 % of its height.

A lowering of the sand surface was observed at the downwind area from a distance around 15 H behind fence, although no figure are shown here. This is probably due to the fact that sand is not conserved for this region. The fence trapped sand coming from the updrift side and the amount of sand flowing into the area was smaller than the amount flowing out from the area. As a result, the sand surface in the area was lowered.

A dune was formed immediately behind the fence and Figure 5 shows the growth of the dune crest taking the initial sand surface as the zero elevation. Figure 5 shows that among the five porous fences tested the fence porosity for which the dune crest grew most rapidly was 20 %.

As seen from Fig. 4, almost all of the sand accumulated in a region defined by a distance of 10 H in front and behind the fence. Figure 6 shows the accumulated sand volume with elapsed time. The sand volume was determined as the cross-sectional area measured on the

Fig. 5 Dune crest growth rate with elapsed time for different fence porosity

distorted figures as described before. The ordinate gives the distorted area. Figure 6 shows that for a fence porosity of 40 % a large amount of sand accumulates rapidly. Thus, with respect to the fence porosity. The porosity of 40 % may be considered to be the optimum fence porosity. Fences with 20 % and 30 % porosity trapped nearly equivalent volumes of sand, although the shape of the sand accumulation was different.

Fig. 6 The time evolution of the sand accumulation for different fence porosity.

3.3 Sand Accumulation in front of an Embankment

Figure 7 shows the time evolution of the sand accumulation in front of the embankment. Sand is mainly accumulated in a region extending from the foot of the embankment to a location 10 H in front of the embankment.

Fig. 7 Sand accumulation in front of an embankment.

The sand accumulation in this region is almost equivalent to the 10 % porosity fence (see Fig. 6). From the experimental results it may be concluded that a 40 % or 50 % porosity fence should be placed at locations ranging from 15 H to 20 H in front of the embankment if rapid sand accumulation is expected in front of the embankment. Otherwise, for low rate of sand accumulation a low porosity fence (10 % or 20 %) should be placed in front of the embankment.

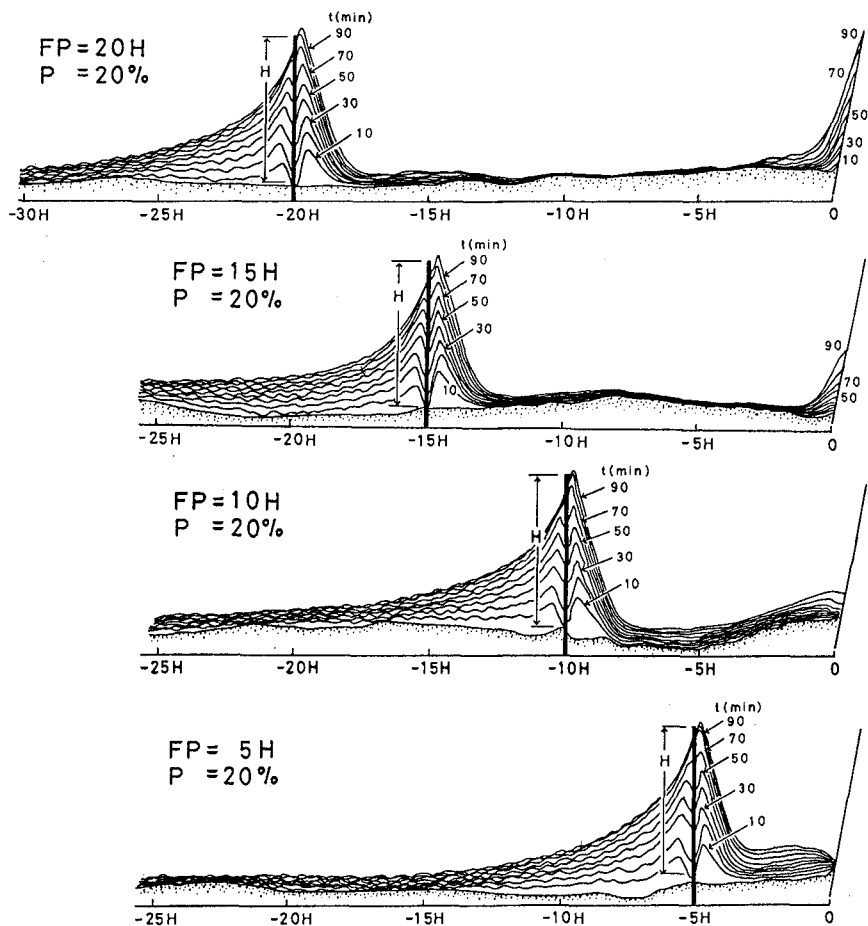

Fig. 8(a) The time evolution of the sand accumulation around fence placed in front of an embankment ($P=20\%$).

3.4 Sand Accumulation in front of an Embankment with a Fence

Figure 8 shows the time evolution of the sand accumulation for the 20, 30, 40 and 50 % porosity fences placed at the locations 5 H, 10 H, 15 H and 20 H in front of the embankment. It is difficult to determine the optimum location from these figures. Figure 9 displays a comparison of the cross-sectional area of accumulated sand in the region extending from 10 H in front of the fence to the foot of the embankment. The cross-sectional area was measured with a planimeter on the distorted figures (the ordinate is given as the distorted

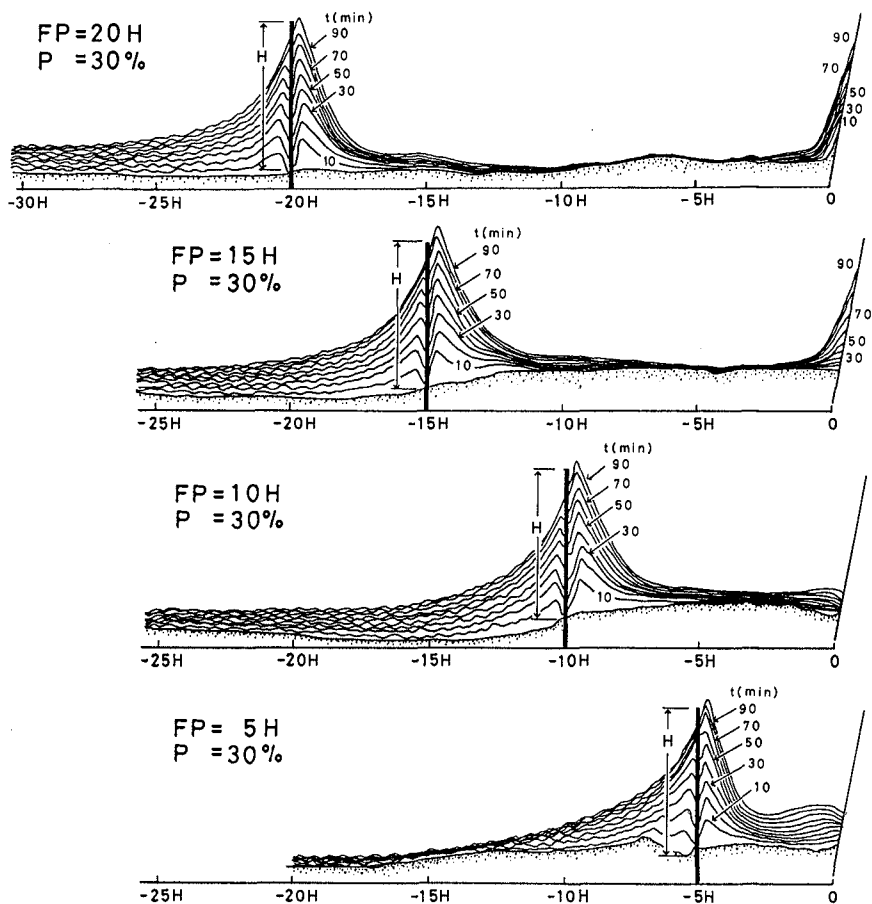

Fig. 8(b) The time evolution of the sand accumulation around fence placed in front of an embankment ($P=30\%$).

area). In Fig. 9, there is a tendency that the sand accumulation was the largest when the fence was placed at a location of $15H$, although a fair amount of scatter in the data is seen.

3.5 Sand Weight Transported beyond the Embankment

Figure 10 shows a comparison among different porosity of the sand weight transported beyond the embankment for the 90-min experiment duration. The amount of sand transported beyond the embankment was different during each stage of the experiment depending on the conditions in front of embankment. However, the fences with 20 %

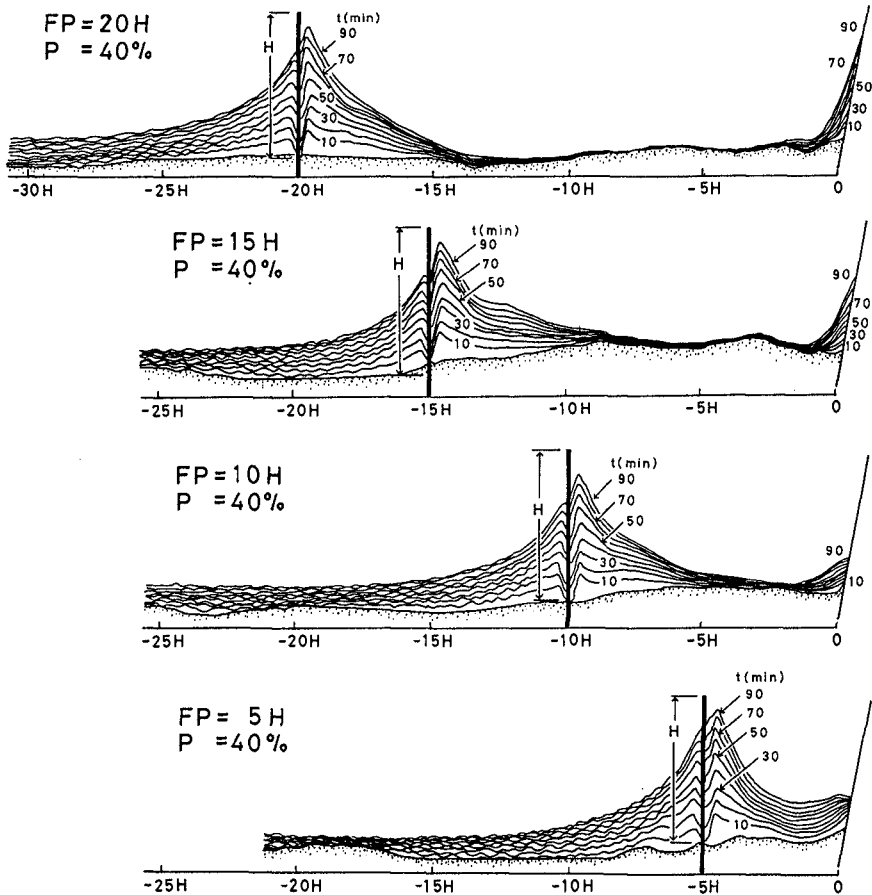

Fig. 8(c) The time evolution of the sand accumulation around fence placed in front of an embankment ($P=40\%$).

and 30 % porosity were completely buried at every location during the entire experiment and the fence with 40 % and 50 % porosity were buried to more than 60 % of its height. If it is assumed that the fences have lost their sand trapping function at this stage, the transported sand weight shown in Fig. 10 may be used as an index to determine a suitable location for the fence. The amount of sand transported was small when fences with 40 % and 50 % porosity were placed at locations of 15 H or 20 H in front of the embankment. This is an important conclusion for the present research work.

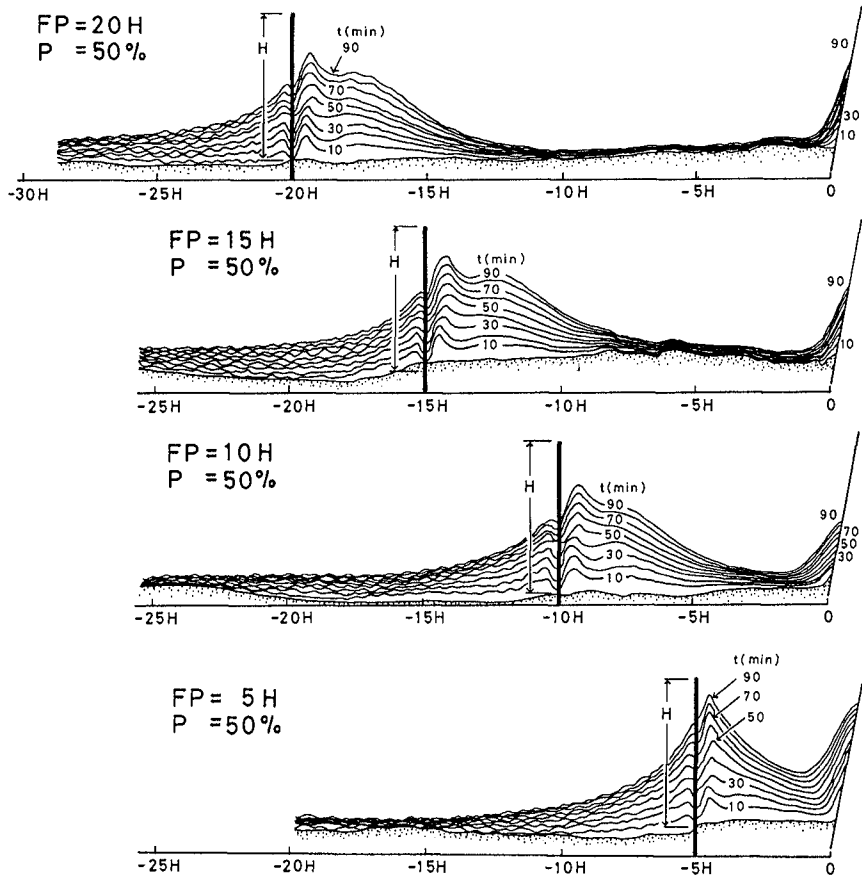

Fig. 8(d) The time evolution of the sand accumulation around fence placed in front of an embankment ($P=50\%$).

Fig. 9 Cross-sectional area of accumulated sand as a function of fence porosity and position.

Fig. 10 Sand weight transported beyond embankment as a function of fence porosity and position.

IV CONCLUSIONS

The results obtained in this study may be summarized as follows:

1. The fence porosity for which sand accumulated most rapidly in large quantities was 40 %.
2. The fence porosity which produced the most rapid dune

crest growth was 20 %.

3. The fences lost their sand trapping function if they were buried to 80 % of their height.
4. Sand accumulated in a region extending from 10 H in front of the fence to the foot of the embankment, and the maximum accumulation occurred when the fence was placed 15 H in front of the embankment.
5. The amount of sand transported beyond the embankment was small when the 40 % and 50 % porosity fences were placed at a distance of 15 H or 20 H in front of the embankment.

Based on the above observations, the overall conclusion of this study is that, for controlling wind-blown sand in front of the embankment, a fence with 40 % or 50% porosity should be placed at a distance between 15 H to 20 H in front of the embankment.

Finally, some comments regarding the experiments should be given. This experiment was a distorted model experiment where the wind speed and sand employed were prototype-scale. The fence height was about 1/10 of a prototype-size fence which commonly has a height of 1 m (about 3 ft). Scale effects are anticipated during the experiments, although it is not possible to evaluate how the scale effects influenced the results. The wind speed employed in this experiment was of moderate strength commonly encountered on natural beaches. Sand accumulations characteristics around fences are different depending on the wind speed, especially for wind speed over 15 m/sec, requiring further studies in future. The wind blowing in the field is irregular in time and space. These facts must be kept in mind when the results obtained in this study are applied to field condition.

ACKNOWLEDGEMENTS

The authors would like to thank the Central Research Institute of Electric Power Industry, for permission to use the wind tunnel. A portion of this study was supported by the General Individual Research Grant, Nihon University Research Grants for 1989, and the Grant-in-Aid for Scientific Research (No. 63550381) from the Ministry of Education, Science and Culture of Japanese Government.

CHAPTER 210

RECENT PERFORMANCE OF LINKED CONCRETE MAT ARMOR UNDER WAVE AND ICE IMPACT

P.E. Gadd, M. ASCE and C.B. Leidersdorf, M. ASCE¹

INTRODUCTION

Concrete mat slope armor has been used for many years to provide slope protection in mild inland and coastal wave environments. Presently, flexible block revetments are gaining popularity for application in moderate wave climates where more conventional types of slope protection are uneconomical or unavailable. European investigators have undertaken design and model testing of placed (non-linked) concrete block revetment systems (Burger, et al., 1990, for example). Systems requiring physical linkage of adjacent blocks have been designed and deployed as well (Hayley, et al., 1987; Leidersdorf, et al., 1988; Munday and Bricker, 1987).

Previous authors have described linked concrete mat systems in detail and suggest its promise for both Arctic and non-Arctic applications (Hayley, et al., 1987; Leidersdorf, et al., 1988; Munday and Bricker, 1987). The objective of this paper is to describe the results of on-going performance monitoring of linked concrete mat systems deployed upon a man-made island in the rigorous Arctic offshore environment. We wish to place particular emphasis upon recent observations that indicate performance limitations of existing concrete mat technology when subjected to the combined effects of severe Arctic wave and ice impacts at offshore deepwater sites.

LINKED CONCRETE MAT ARMOR

Concrete mat slope protection has been advanced by numerous investigators as an alternative to more conventional discrete-unit slope armor. Principal advantages to the concrete mat alternative are related to enhanced stability of light-weight armor units (by

(1) Principals, Coastal Frontiers Corporation, P.O. Box 515,
Altadena, California 91003, USA

virtue of physical linkage), ability to accommodate changes in subgrade without loss of underlying gravel fill, and suitability for quick and economical modular placement. In addition, Arctic applications require ease of removal (for short-lived oil exploration structures) and resistance to ice abrasion and impact.

As indicated above, several large oil industry projects in Arctic Alaska that utilized the linked concrete mat concept have been described previously. The mat system under study is composed of individual blocks having plan dimensions of 1.2 m square. Block thickness can vary with application but has typically measured 0.23 m. Block linkage is provided by galvanized shackles and chain segments.

PERFORMANCE MONITORING OBSERVATIONS AT NORTHSTAR ISLAND

Northstar Island was constructed at an unprotected offshore location having a water depth of 13.7 m located approximately 25 km northwest of Prudhoe Bay, Alaska. This island has provided a unique setting in which environmental influences on the slope protection system have been carefully monitored annually since the completion of construction in 1985. The design of Northstar Island has been described previously (Hayley, *et al.*, 1987; Leidersdorf, *et al.*, 1988), and is summarized in Figure 1.

FIGURE 1: NORTHSTAR ISLAND DESIGN

The slope armor system is composed of linked concrete mat in the zone of primary wave and ice impact (El. +1.5 m to -6.1 m, MLLW)

placed upon a slope of 1 (vertical) on 3 (horizontal). On the slopes up-slope and down-slope from the concrete mat, large (1.5 to 3.0 m³ capacity) gravel-filled fabric bags are placed. The overlapped placement configuration of the gravel bags on the upper slope of the island reduces wave run-up elevation.

Northstar Island is an oil exploration island having an intended design life of three years. The design storm event was expected to be accompanied by storm surge of 1.0 m and to exhibit a significant wave height of 3.7 m, and a significant wave period of 9.6 sec.

Prior to the construction of Northstar Island, shallow water installations of linked concrete mat slope armor in the Arctic in water depths of 2-4 m met with success. Owing to the mild wave and ice conditions at these locations, significant damage has not been noted to date. At Northstar Island, however, degradation of the mat revetment has been noteworthy, related to the alternating impacts of large storm waves and massive ice features.

In the 1987-1988 period, the performance of the mat system degraded following significant damage imposed by multiple episodes of large wave and ice impact. The discussions in this paper seek to describe the damage that has occurred on Northstar Island since its construction in 1985 and to offer insights that will improve the existing state of engineering knowledge concerning deployment of linked concrete mat slope protection in the Arctic offshore.

WAVE-INDUCED CONCRETE MAT DAMAGE

Effects of Angle of Wave Incidence

During a strong northwest storm accompanied by wave heights in the three to four meter range that occurred in late September 1986, significant uplift and undulation of the concrete mat at Northstar Island first occurred. It was clearly noted, however, that the extent of mat uplift was not uniform around the island circumference. Photo 1 is presented to show the condition of the island sector that received the incoming wave impact at a normal (i.e. wave ray approach = 90° from waterline) angle of incidence. The undeformed nature of this slope suggests that mat uplift did not occur along this island sector.

Conversely, along the sides of the island which experienced wave passage at highly oblique angles of incidence, mat uplift and the resulting mat undulation was severe, as shown in Photo 2. Wave-induced mat instability was noted along the island slopes on the lee side of the island as well, where wave crests did not detach from the island slopes, but proceeded along the slopes at angles of incidence greater than 45°.

PHOTO 1: POST-STORM CONDITION, NORMAL ANGLE OF WAVE INCIDENCE

PHOTO 2: POST-STORM CONDITION, OBLIQUE ANGLE OF WAVE INCIDENCE

We believe that the reasons for the destabilizing effect of oblique wave passage over the concrete mat at Northstar Island is based both on hydrodynamic effects that impose negative wave pressures on the mat, and as a consequence of asymmetrical mat linkage tension imposed during the construction process. The

hydrodynamic effects that produce greater wave uplift for oblique angles of wave attack (relative to normal incidence) have been noted by researchers utilizing three-dimensional physical model studies at Delft Hydraulics, The Netherlands (Bezuijen, A., and A.M. Burger, personal communication).

Asymmetric block linkage tension within the mat was caused as a result of the construction process, undertaken during August-September, 1985. In placing the mat upon the island slopes, narrow mat segments were used incorporating 22 blocks in the upslope-downslope direction by two blocks across. As the placement crane lowered the mat to its above-water anchorage position and boomed the mat offshore, high tension was achieved in the upslope-downslope mat direction. Successive mat sections were placed closely side-to-side to allow divers to easily connect the mat beneath the water. Consequently, substantial slack resulted in the side-to-side block linkage. The resulting lack of side-to-side restraint in the mats surrounding the island promotes mat instability in response to oblique wave attack. Conversely, the lack of alongslope linkage tension would seem not to affect mat stability given a normal angle of wave incidence where side-to-side restraint would be less important. This indeed appears to be the case, given the visual observations of the effects of wave-induced uplift at Northstar Island.

Effects of Island Subsidence

Northstar Island is composed of approximately 800,000 m³ of terrestrial gravel that was trucked to the offshore island site in winter over a floating ice road. Such an Arctic gravel placement project undertaken in winter typically results in the dumping of gravel having a temperature of -20° to -40° C. into ocean water exhibiting a temperature of -2° C. As a result, ice forms in the interstitial spaces within the gravel fill. With time, summer thawing and long-term creep of the ice within the fill can result in island subsidence. Such subsidence has been noted continuously at Northstar Island within the 1985-1989 inspection period. Figure 2 shows the nature of the subsidence as evidenced at several benchmarks located on the island. The rate of subsidence is generally noted to be 10 cm annually, yielding a total subsidence of about 40-50 cm since the conclusion of construction in 1985.

The effect of island fill consolidation results in the inward relative motion of the individual concrete blocks within the mat surrounding the island. This subtle effect leads to a gradual decrease in the space that exists between adjacent blocks. As the block spacing decreases, relief of hydraulic pressures that build within the fill during the alternating action of wave run-up and wave run-down becomes increasingly more difficult to accomplish.

Originally, the design of Northstar Island specified a block spacing of 5.0 to 6.4 cm, yielding a "percent open area" (the area of open space within the mat relative to the total area) of 19%.

FIGURE 2: NORTHSTAR ISLAND SUBSIDENCE, 1985 - 1989

As a result of island subsidence/fill consolidation and a block fabrication process that yielded slightly oversized blocks, the existing "percent open area" is now estimated to be 11%, based on recent measurements of block spacing. This reduction in block open area will yield a propensity for mat uplift at lower wave height thresholds and also for greater vertical block uplift when wave-induced uplift does occur.

Effect of Mat Underlayer

A durable and permeable mat underlayer is important for the successful deployment of concrete mat armor over the granular fill material commonly used in the Alaskan Arctic offshore. At Northstar Island, a highly permeable non-woven polyester filter fabric was used for this three year design life application. The characteristics of the fabric are summarized as follows:

Fabric Weight = 510 gm/m^3
 Tensile Strength = 525 N/cm
 Permeability = 0.65 cm/sec .

In addition, the fabric readily sinks in seawater--an important detail that greatly aids the construction effort.

Successive mat uplift events can cause abrasion and parting of the underlying fabric, allowing the loss of gravel fill beneath the mat. Given the abrasive nature of concrete block slope armor relative to the underlying filter fabric, it is apparent that mat

uplift must be eliminated if long-term survival of the fabric is to occur.

Inspection of the concrete armor at Northstar Island following large storm events indicates that uplift pressures beneath the filter fabric have been excessive. This has become evident at areas where gravel fill, completely encased in filter fabric, has been forced through block spaces to form outward pockets of gravel on the upper surface of the mat. An instance of this occurrence is shown in Photo 3.

PHOTO 3: FILTER FABRIC AND GRAVEL PROTRUSION BETWEEN BLOCK SPACES

Once these gravel bulges formed, ice or wave motion causes failure of the fabric pocket leading to filter fabric voids. Initially, the localized and infrequent nature of this occurrence did not render it of serious concern to the integrity of the slope protection system. However, the filter fabric shortcomings related to permeability were clearly indicated.

Repeated instances of wave-induced mat uplift at Northstar Island resulted in filter fabric abrasion and parting that caused loss of gravel fill beneath the mat. Major damage to the filter fabric in this regard occurred during the November 1987 storm event, when large waves and multi-year ice impacts heavily damaged the eastern side of Northstar Island. Repeated profiling of the island slope (as shown in Figure 3) shows the effect of the 1987 storm, and indicates the large volume of gravel lost from beneath the concrete mat due to filter fabric voids.

The damage sustained by the filter fabric at Northstar Island indicates that a more durable and permeable filter medium is vital

in promoting improved performance of concrete block slope armor. Stronger, more permeable filter fabrics do exist in the geotextile industry and should be carefully considered for Arctic offshore applications.

FIGURE 3: TYPICAL PROFILE CHANGES, EAST SIDE, 1985 -1989

For long-lived offshore production facilities, consideration has been given to the use of small quarrystone or concrete rubble as underlayer for concrete mat armor. The concrete alternative can be unreinforced and cast in shapes of the required size in a conventional concrete stamping procedure. These durable underlayers would benefit from their high permeability and abrasion resistance relative to fabric alternatives. Important issues related to construction placement and the effect on concrete block support must be resolved to render these materials viable for use as an underlayer/filtration medium.

ICE-INDUCED CONCRETE MAT DAMAGE

The concrete blocks used at Northstar Island were constructed at Prudhoe Bay, Alaska, using a highly mechanized "dry cast" block fabrication technique. The concrete mix exhibited low water:cement ratio ($w/c = 0.32$), high cement content (392 kg/m^3), air entrainment (5-7%), and use of fly ash pozzalon (10% by weight). The resulting concrete product exhibited an average compressive strength of 55 MPa (8,000 psi). By contrast, the expected compressive strength of ice impacting this site is 2.8 MPa.

Despite the high strength characteristics indicated, isolated instances of concrete block breakage were noted during the summer

of 1986, the year following island construction. Samples of broken concrete blocks were tested at that time to determine the characteristics of the failed blocks. Test results indicated that the broken blocks were not atypically weak blocks, but exhibited the same high compressive strength characteristics that were noted during the block fabrication period.

In November 1987, a high-energy easterly storm occurred along the northern coast of Alaska for a period of 14 days. The storm was accompanied by alternating periods of ice-free water (leading to large wave generation) and the incursion of large ice floes (leading to damaging ice impacts). Erosion of nearby islands protected solely by gravel bags was excessive during this storm period.

Damage to the slope protection at Northstar Island during this storm included major displacement of the concrete mat in response to wave-induced uplift and ice impact, breakage of concrete blocks due to direct ice impact and/or inter-block collision induced by ice impact, loss of underlying gravel fill material through filter fabric tears and voids induced by storm-related processes, and failure of steel chain/shackle linkages caused by ice impact forces.

During July of the following summer, large-scale damage to the concrete blocks occurred on the east and north sides of Northstar

PHOTO 4: BLOCK BREAKAGE CAUSED BY ICE IMPACT

Island as a result of the collision of massive ice features with the island during the open-water season. The nature of the damage included block breakage (as had been noted in rare instances in 1986), mat displacement caused by impacts of large ice features, and surface abrasion of the mat armor by ice impact.

Concrete mat breakage has proven to be impressive at Northstar Island, primarily affecting blocks located above an elevation of -3.7 m (MLLW). Block breakage has occurred, in which cracks propagate through the block without substantial loss of concrete volume. In addition, blocks have been stripped of concrete cover, leaving only the steel reinforcement where the concrete mass had once been. Photo 4 is presented to show an example of excessive block damage of this type.

When the slopes of Northstar Island were pristine and free from irregularities and undulations, the early winter ice would collide with the concrete and form ice piles that would build seaward from the waterline. These ice piles would form a barrier providing protection from the larger ice features that might impact the island later in the freeze-up period. Later, following the storm damage of September 1986, undulations in the concrete mat slope caused by wave-induced mat uplift, generated irregularities within the mat surface upon which incoming ice forces could act. As a result, deformation and displacement of the concrete mat armor occurred as large ice features collided with the irregular island slopes. With time, therefore, the ability of the island slopes to safely withstand large ice impacts degraded. Damaging mat displacements during both winter and summer were noted. Photo 5 shows the results to a particularly forceful ice collision with the north slope of Northstar Island during late July 1988. The nature of the concrete mat damage that occurred as a result of this incident is shown in Photo 6, following the natural ablation of the ice that caused the damage.

Figure 4 is presented to illustrate the sequence of the damage experienced as a joint result of both wave and ice processes at Northstar Island. Initially, wave-induced mat uplift occurred that led to deformation and undulation of the pristine "as-built" island slope. Subsequent to this event, incoming ice features, which had previously been ineffective in displacing the uniformly smooth mat, were capable of imparting force to the various mat irregularities, thereby inducing significant mat displacements. Such displacements further permitted filter fabric degradation and loss of underlying fill material. Therefore, elimination of concrete block uplift is of ultimate importance--to prevent abrasion of the underlying filter medium and subsequent loss of gravel fill, and to prevent the development of slope irregularities and deformations that allow large ice features to impart significant damage and displacement to the slope armor.

PHOTO 5: BLOCK DISPLACEMENT BY LARGE ICE IMPACT, AUGUST 1988

CONCLUSIONS AND RECOMMENDATIONS

Recent experience at Northstar Island has allowed an evaluation of linked concrete mat performance when subjected to the harsh wave and ice environment of the Alaskan Arctic offshore. Observations

have been made that could not be observed accurately in any other method of investigation. While performing as an oil exploration island, Northstar Island has also performed as a prototype laboratory in which the interaction of Arctic ice forces, three-dimensional wave impact, and the linked concrete slope

FIGURE 4: NORTHSTAR ISLAND MAT DAMAGE SEQUENCE, 1985 - 1989

protection system could be observed. The valuable lessons learned from this experience are ongoing. To date the following conclusions are worthy of note:

- o Oblique Wave Impact: Wave impact arriving at high angles of wave incidence to the slope effectively induce mat uplift more readily than the same wave conditions arriving at a normal incident angle. This is due both to hydrodynamic effects yielding higher negative wave pressures from oblique wave attack, and also to the lack of side-to-side tension in the linkages of the Northstar Island mat system.
- o Reduction of Mat "Open Area": The void space within the mat system ("open area") allows relief of hydraulic pressures that are created within the island fill during periods of wave run-up. This "open area" must be sufficient to allow adequate hydraulic relief initially, and must be maintained with time if mat performance is to continually achieve the design intent. One factor that has caused a reduction in the "open area" at Northstar Island is island subsidence. Due principally to

thermal effects within the gravel fill, the elevation of the island has decreased approximately 40-50 cm since 1985. This subtle effect has contributed to a decrease in the "percent open area" of the mat from the designed value of 19% to the present (summer 1990) measured value of 11%.

- o Underlayer Characteristics: Important factors related to the proper performance of an underlayer for the concrete mat are high permeability and durability. While the filter fabric selected for use at Northstar Island exhibited excellent performance in both of these areas relative to other fabrics, it is clear that improvement of underlayer performance is vital to future concrete mat installations in this environment. Should fabric permeability be lacking leading to creation of excessive uplift pressures beneath the fabric, mat uplift may occur. Once the concrete blocks uplift periodically in response to wave passage, failure of the fabric through block abrasion will follow. Fabric voids caused by mat abrasion will lead to loss of gravel fill from beneath the fabric and subsequent slope deformations. For long-lived offshore structures, concrete or quarystone rubble may provide more suitable underlayer characteristics for concrete block revetments. An expensive alternative to a highly permeable underlayer is the utilization of heavier concrete blocks that can adequately withstand the wave-induced uplift pressures.
- o Side Slope Configuration: Improvements in linked concrete mat performance will result from consideration of slope alterations that include the incorporation of milder slopes and/or horizontal benches having a width of perhaps 10-20 meters in the zone of wave impact. Previous physical modelling efforts (Potter, et al., 1983) have noted that such slopes reduce block uplift, lower wave run-up, reduce ice impact forces, and improve overall block stability against wave impact relative to the straight smooth 1 (vertical) on 3 (horizontal) slopes utilized on Northstar Island. In addition, the inclusion of a flat bench of significant width near the waterline will provide a safety buffer to restrict any damage that may occur to areas of the slope that are distant from the island work surface.

CHAPTER 211

THREE DIMENSIONAL EFFECTS OF SEAWALL ON THE ADJACENT BEACH

Takao Toue¹
Hsiang Wang²

ABSTRACT

The effects of seawall on the adjacent beach is examined by the three dimensional physical model test. The experiment results are analyzed by means of the volumetric change analysis and the shoreline change analysis. The results show that the groin effects are dominant but they are localized within a region spanning three or four times of seawall length for the cases tested

1. Introduction

Beach erosion is found along many portion of the coast of the world. The cause of the erosion could be sea level rise, reduction in sediment supply, interruption of the littoral drift by structures. There are several conventional engineering solutions to combat such erosion. Those are (1) coastal structure such as groins, seawalls, breakwater and coastal dike, and (2) non structural solutions, such as beach nourishments. Among them, seawalls might be the most efficient and direct method to protect the up-land property provided that they are designed adequately.

Recently, the adverse effects of seawalls on their fronting and adjacent beaches have great attention and raised criticism about the use of seawalls in the coastal area. The most often alleged effects are (1) offshore profile slope steepening, (2) intensified local

scour, (3) transport of sand to a substantial distance offshore, (4) adverse down drift erosion and (5) delay post-storm recovery (Dean, 1986). Although numerous examples can be found from articles in newspaper or popular magazine reporting the adverse effects of seawall, reliable and scientific based document is actually scarce. Moreover, the conclusion derived from the few technical reports on the adverse effects of seawalls remains controversial. Considering the merits of seawall altogether as means of coastal protection without firmly establishing their effects might be irrational. Therefore, there is a need to examine the effects of seawall carefully and to quantify them if possible. Also, by examining the cause and effects of seawall might lead more rational design in the future. The main objectives of the present study is to attempt to quantify the three dimensional effects on beach changes. In order to gain a fundamental understanding it was decided to conduct three dimensional model tests in the laboratory environment.

2. Possible Mechanisms of Seawall Effects

The effects of seawall are not well understood, but several possible mechanisms can be deduced from our general knowledge in coastal engineering. These are illustrated in Fig. 1 and also described below.

(1) flanking effects; Flanking due to wave refraction and diffraction is expected to occur on the corners of the seawall to cause local erosion.

(2) cross wave effects; During storm surge period, the water depth in front of seawall is likely to be larger than that along beach and wave reflection will occur as shown in Fig. 1(b). Consequently, the longshore current together with more reflected wave energy trapped in the trough will remove sand in front of seawall and transport them to down drift location.

(3) groin effects; If the shoreline retreat due to littoral drift, the seawall will eventually protrude seaward and act like a groin. Although this groin effect does not remove sand from the system it inverse downdrift erosion pressure.

(4) sand supply cut off; Seawall prevents sand from being added to the littoral system, which again adds erosional stress downdrift and could result in lower bar profile in front of seawall during the storm surge period.

3. Model Test Apparatus and Test Condition

The model test is carried out in the wave basin of the Coastal and Oceanographic Engineering Department, University of Florida. The dimension of the basin is

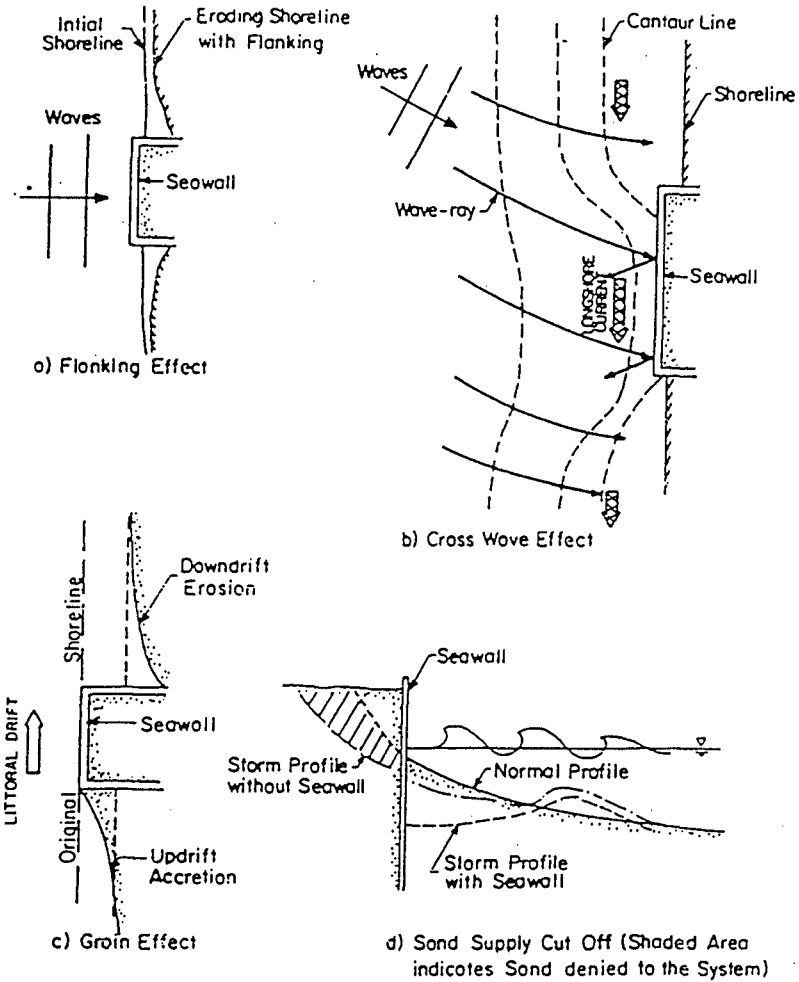

Fig. 1 Possible Mechanisms of Effects of Seawall

approximately 28m x 28 m and 1m deep. The beach and seawall system used in the experiments is shown in Fig. 2. The beach is composed of 125 tons of well sorted

Fig. 2 Model Test Apparatus

quarts sand. Both side of the beach are constrained by wooden template cut into a design beach profile shape. This design allows wave induced long-shore current to circulate unimpeded through the backside of beach. The beach profile is shaped in accordance with the concept of equilibrium beach profile (Dean 1977). The length of seawall is 3.0m and with 1.0m return walls on each side to prevent flanking. The height of seawall is 45 cm which is sufficient to prevent wave over topping. The toe of the seawall is located at 45 cm above the basin bottom which corresponds to the mean water level in the present test configurations.

The beach was subjected to the test wave condition for a designated duration. During test period, profile measurements were carried out at regular intervals. A total of 21 profiles were surveyed at equal spacing of 75 cm. Surveys were conducted at 0, 1, 2, and 4 hrs. Wave height was 11 cm and wave period was 1.74 s. The test conditions are summarized in Table 1.

Table 1 Test Condition

Case	wave height (cm)	wave period (sec)	water depth (cm)	wave angle (°)	seawall	elapsed time (hour)
Case1	11.0	1.74	45.0	0	no	4.0
Case2	11.0	1.74	45.0	0	yes	4.0
Case3	11.0	1.74	45.0	5	no	4.0
Case4	11.0	1.74	45.0	5	yes	4.0
Case5	11.0	1.74	45.0	10	no	12.0
Case6	11.0	1.74	45.0	10	yes	5.0

4. Volume Change Analysis

The coordinate system in this study is shown in Fig. 3.

Fig. 3 Coordinate System

Based on the coordinate system, the rate of volumetric change in a local control area centered around the seawall, $v_1(t)$ is defined as

$$v_1(t) = \int_{x_c - W/2}^{x_c + W/2} \int_0^{y_0} \frac{\partial z}{\partial t} dy dx, \tag{1}$$

where z =profile elevation, x =shore-parallel axis, y =shore-perpendicular axis, x_c is the location of the center of seawall, y_0 = measurement length, W is the width of control area and t is time. .

The ratio of the volumetric change, with(v_s) and without(v_n) is plotted against the non - dimensional control width(W/L_s) where L_s is the length of seawall in Fig. 4. If the ratio is larger than 1.0, the rate of erosion is larger with seawall than without seawall and vice versa.

In Fig.4(a), the ratio of v_s and v_n is plotted for the updrift and down drift region separately. In the updrift region, v_s/v_n is always less than 1 irrespective the width of the control region and the wave angles. Thus, in the case of normal incident wave, this value less than one because more sand is retained by the seawall in the backshore than the additional material being eroded in front of seawall, when compared with the natural beach case. For cases with oblique waves on the other hands, sand is retained in the updrift due to groin effect. They also make this ratio less than unity. On the down drift side, the situation is different, As expected, under normal incident waves v_s/v_n is less than 1.0 much the same as the updrift side. Under oblique waves, v_s/v_n is less than 1 when $W/L_s = 0.5$, or when the control region coincides with seawall length much the same as the two dimensional model test case by Barnett (1988). Apparently, even under oblique wave, the material retained from the scouring trough in front of seawall. However, when W/L_s become larger than 0.5, v_s/v_n also become larger than 1.0. The presence of seawall now interrupt the normal longshore transport and cause down drift erosion to be greater than the natural beach condition.

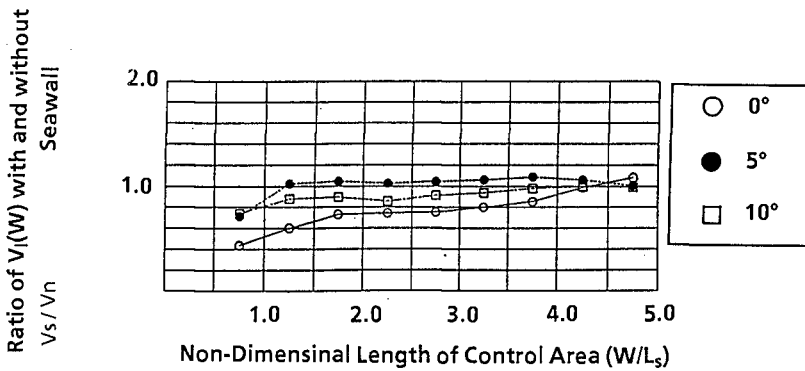

Finally, in Fig. 4(b) the ratio of total volumetric change including both updrift and down drift region are given. It can be seen that when $W/L_s < 1.25$, $v_s/v_n < 1.0$. When $W/L_s > 1.25$, the ratio of v_s/v_n become constant and approaches 1 as it should do when W/L_s becomes large. Therefore, the effects of seawall appears to be quite localized, certainly within 3 to 4 times of seawall length for the cases tested.

5. SHORELINE CHANGES

Fig. 5 shows general view of bathymetric change of four hours elapsed time for all cases tested. It can be seen that for the natural beach under normal incident waves the shoreline almost uniformly recessed. As wave angle is larger, the recession of the shoreline becomes

a) Ratio of Volumetric Change with and without Seawall Up-Drift ,Down Drift Separately

b) Ratio of Volumetric Change with and without Seawall

Fig. 4 Volumetric Change in Local Control Area

larger. For the seawall backed beach under normal incident waves, the shoreline also uniformly recessed, but under oblique waves, the recession of the shorelines of down-drift side is larger than that of natural beach, and that of up-drift side are smaller. The scour hole can be seen in front of seawall and the contour lines in front of seawall protrude shore ward there.

Shoreline changes are examined by means of Empirical Eigenfunction (EEF) analysis. For a multi variate function such as the three dimensional contour line represented by $h(x,y,t)$ there are several possible combinations of eigenfunction representation such as

$$h(x,y,t) = \sum_m w_m c_m(t) e_m(x) f_m(y), \quad (2)$$

$$h(x,y,t) = \sum_m w_m c_m(t) e_m(x,y), \quad (3)$$

$$h(x,y,t) = \sum_m w_m c_m(x,t_0) e_m(y,t_0), \quad (4)$$

where w_m is the weighting function, c_m, e_m, f_m are eigen vectors and m is the mode. These combination are, however, not independent of each other. The hope is to have the right choice such that most of the variance in the data set will be accounted for in fewest terms. Unfortunately, at present, there is no criterion for making such a choice and one has to rely on intuition and trial and error. After a number of preliminary tests, it is decided to use the distance from a baseline to shoreline, $d(x,t)$, as the dependent variable. Thus, we assume that this distance can be represented by the linear sum of spatial eigenfunction, $S_m(x)$, and temporal eigenfunction $T_m(t)$, of the following form:

$$\begin{aligned} D(x,t) &= d(x,t) - d(x,t_0) \\ &= \sum_{m=1}^{\infty} w_m S_m(x,t_0) T_m(t), \end{aligned} \quad (5)$$

where $D(x,t)$ is the difference between the distance of the shoreline at time t and that of the initial shoreline, and t_0 is the initial time.

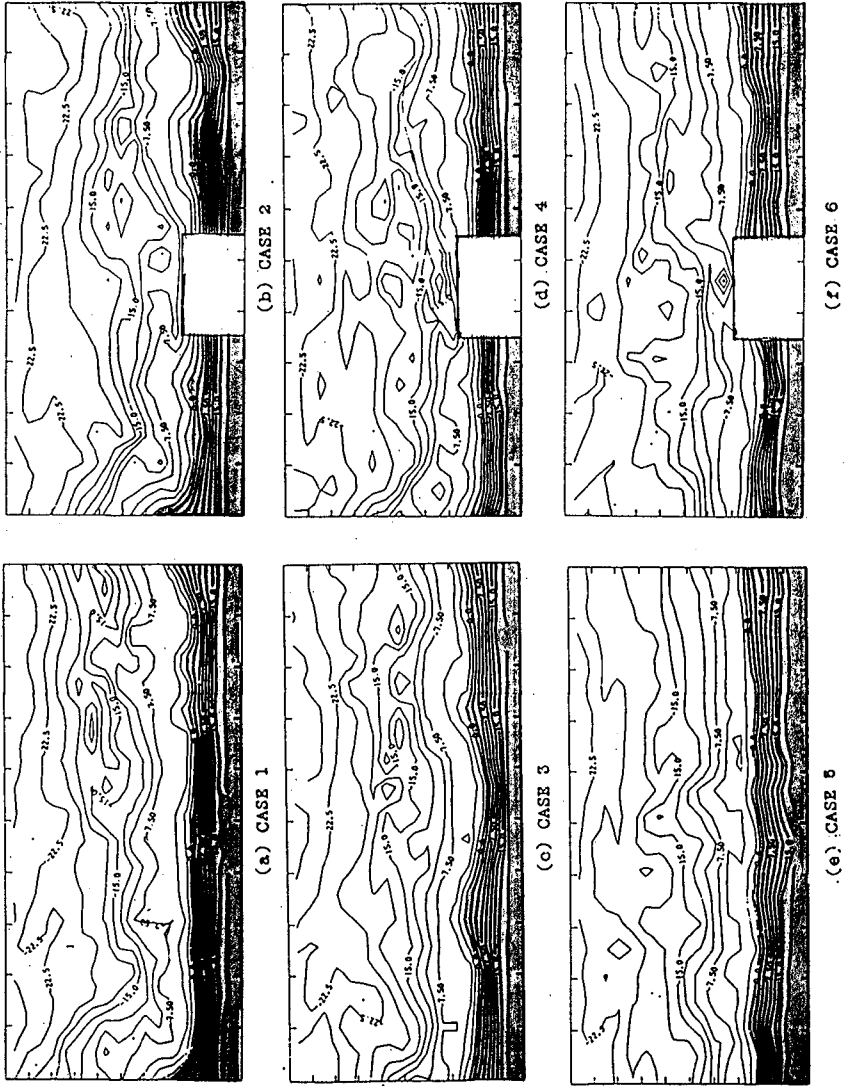

Fig. 5 Contour Maps for Four Hours Elapsed Time

In applying the procedure outlined here to the present experiment data set, a number of problems are identified that require special attention:

(1) Owing to the existence of offshore shoals and bars, $d(x,t)$ has, at times, multi-values. Care must be exercised to select the depth contour that is physically meaningful. (2) In EEF analysis, the contour lines near it are clearly not continuous. In such case, the contour lines are divided into segmented continuous lines and EEF analysis is performed to each line individually.

Fig. 6 shows the results of EEF analysis for all cases. In all the cases tested, the first eigen vector appears to account for more than 90% of the variance. Therefore, there is no surprising that the real shoreline changes is similar to the first spatial eigen vector. For cases of erosional waves with normal incident angle, ideally the shoreline would recede uniformly as there should be no longshore component of sediment transport. By examining Fig. 6 for the case of no seawall, the first spatial eigen vector is almost a parallel line with the exception near the edge where the three dimensional effects come into play. For the case with seawall, the first spatial eigen vector is almost a parallel line. The flanking effects, if any, is not visible. The temporal vectors are almost identical for both cases.

Under oblique waves, for the case of no seawall, the first spatial eigen vector exhibits a rhythmic features in addition to a uniform recession. The first temporal vectors appear to be similar to the case of normal incident waves. With presence of seawall, the rhythmic features on the updrift sides becomes more pronounced. Again, the temporal vectors possess similar characteristics as the previous cases. Now, as the wave angle increases (to 10 degree), this rhythmic features diminishes in amplitude. The groin effects becomes more evident that results in severe down-drift erosion immediately in the shadow of the seawall.

6 Correlation between Shoreline Changes and Volumetric Change

The correlation between shoreline changes and volumetric changes are examined here. The one-line theory for shoreline change is based on the following continuity equation of sediment flux:

$$\frac{1}{h} \frac{\partial S}{\partial x} + \frac{\partial d_s}{\partial t} + p = 0, \quad (6)$$

where d_s denotes shoreline change, S is the longshore sediment transport, h is the water depth at a closure point, p is the sink/source of sediment. Eq.(8) can be written in this finite difference form neglecting the term, p ,

$$\Delta d_s = -\frac{1}{h} \frac{\Delta t}{\Delta x} \Delta S = -\frac{1}{h} \Delta V, \quad (7)$$

where ΔV is the volumetric change per unit length along shore.

The value of h is usually treated as a constant. Therefore, according to one-line model the shoreline changes, Δd , has a linear relation to the cross-sectional volumetric changes. Fig. 7 shows the comparison of the calculated shoreline changes based on Eq (7) to the measured shoreline changes. As can be seen, agreement are good for beach with no seawall. The agreement actually becomes better as the test duration increases. This is because the profile gradually reaches the new equilibrium configurations. For beaches with seawall the agreement is poor at the initial stage but improved progressively as the duration of test becomes longer. Obviously, during the early stage of profile adjustment, the main mode of sediment transport is in the cross-shore direction. The one-line model which assumes no profile adjustment between time steps cannot be applied. As time elapses the profile becomes stabilized and longshore transport takes over as the main mode of sediment transport. The presence of seawall will create profile disturbance in both up-wave and down wave directions away from the seawall as can be seen in Fig 7. However, as time progress, the disturbance, instead of spreading further, actually, tends to diminish and the beach will revert back to the natural state of no seawall with the exception of the very localized effects just adjacent to the seawall.

7. Concluding remarks

To examine the effects of seawall, volumetric change analysis and shoreline changes analysis were employed. In volumetric change analysis, it was found that under normal incident wave, the rate of volumetric erosion as well as the total eroded volume in front of seawall was smaller than that of natural beach. For oblique waves, due to groin effects the erosion of down drift side is severe, but the effects were found to be localized within a region spanning 3 to 4 times of seawall length of fronting beach centered around seawall.

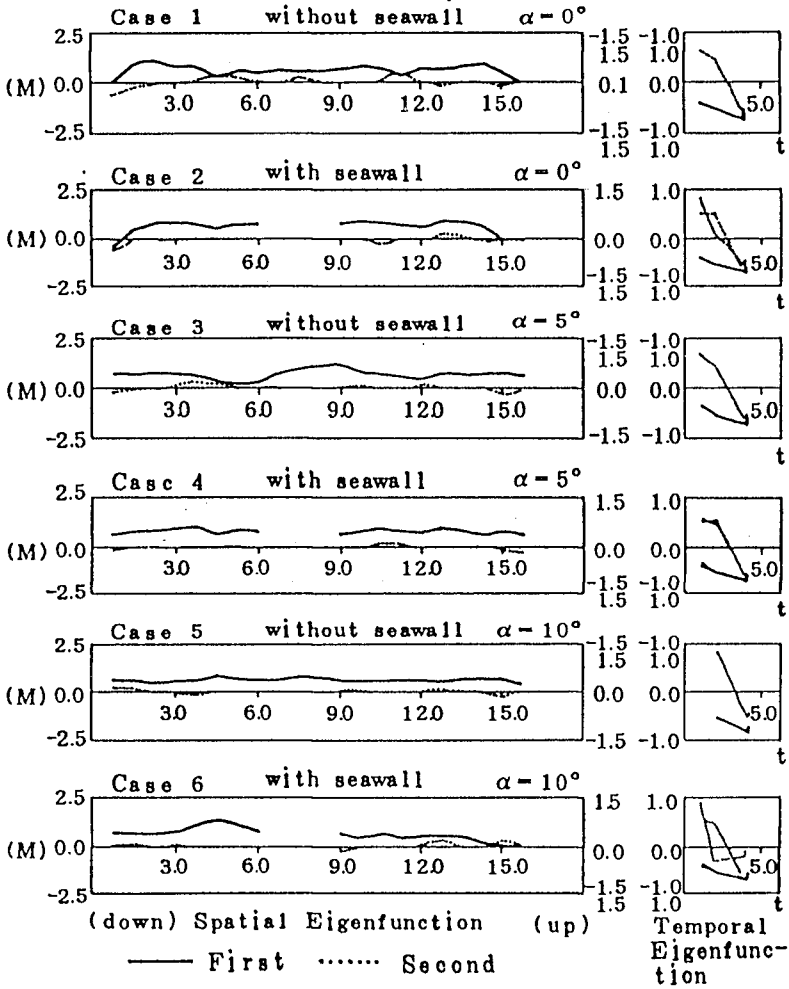

Fig. 6 Spatial and Temporal Eigenfunction

Fig. 7 Comparison of Shoreline Changes Calculated and Measured

In shoreline change analysis, empirical eigen function were utilized. EEF was applied to the shoreline changes. The first spatial eigen function accounted for 90 % of the variance of shoreline data. Under normal incident wave, the spatial eigenfunction manifested a uniform recession and was very similar for a natural beach and seawall backed beach. Under oblique wave, the local effects of increased down drift erosion and decreased updrift erosion were evident.

The validity of one-line model for seawall backed beach was examined. Comparison between the measured shoreline and calculated shoreline supported the validity of one-line model for natural beach , but for seawalled beach especially at the initial stage of profile evolution while shoreline changes were dominated by on/off shore transport, one-line model was not valid well.

CHAPTER 212

PREDICTING DAMAGE BENEFITS OF SHORE PROTECTION PROJECTS

Kevin R. Bodge, Ph.D.¹

ABSTRACT

A numerical simulation method is described to estimate damage and associated benefits to oceanfront (and "backrow") properties without-, with- and adjacent to shore protection project areas. Damage to structures, land, and structure contents is described -- as is the effect of shoreline armoring. Input data include property attributes and estimates of beach recession for various intensity storms. Projects are described by their geometry, life expectancy, construction intervals, and effect upon the chronic and storm-induced recession. Projects can include nourishment, armoring, or other types which have a quantifiable effect upon chronic and storm-induced recession. Damage is computed based upon (1) the encroachment of the eroded bluffline to the property by chronic (historical) erosion stress and by storms, and (2) functions which depend upon structure type or land use. Spatial and temporal resolution is adaptable to the user's needs.

1. INTRODUCTION

Shore protection projects such as beach nourishment, dune enhancement, and shoreline armoring decrease the potential damage to upland properties associated with chronic annual erosion and episodic storm events. These effects are central to the benefit/cost and cost-sharing analyses necessary for most shore protection projects. While a basic approach to predicting shorefront damage generally exists, actual methodologies are not standardized and vary greatly in their level of sophistication.

¹Senior Engineer, Olsen Associates, Inc., 4438 Hershel St., Jacksonville, Florida 32210 U.S.A.

This paper presents a rational, automated technique to predict shorefront damage due to combined chronic and episodic storm-related beach erosion. Damage due to flooding and wind are excluded. The technique utilizes input data which are fairly readily obtainable. Damage to any particular property is predicted as a function of the property's structural, siting, and beach-profile characteristics. Individual rows of property (shorefront, second row, third row, etc.) can be separately evaluated. Both existing and simulated post-project conditions can be evaluated in a year-by-year, property-by-property approach with various levels of temporal and spatial resolution, as desired. The effects of a project both inside and outside the project area can be investigated. The results can be used directly in a benefit/ cost analysis or can be used to develop a project's cost-sharing formulae. Additionally, the technique complies with current U.S. Federal guidelines regarding prediction of storm damage benefits of coastal works (U.S. Army, 1989).

2.0 OVERVIEW OF METHOD

The technique requires that shorefront properties be grouped into contiguous, self-similar parcels. Data which describe physical and economic attributes of the property within each parcel are tabulated (Section 3.2). The recession due to various return-level storm events is then predicted for each property parcel through a dune-erosion (or similar) model (Section 3.3).

Damages to property are calculated by "tracking" changes of a reference location on the beach. This, in turn, allows one to track changes in the setback distance between the property and the reference location. This reference location is typically the vegetation line, dune crest or bluff escarpment -- and is hereafter referred to as the "bluffline". Changes in the bluffline location may be the result of (i) chronic (historical) erosion stress, (ii) storm induced erosion, and/or (iii) a shore protection project.

The method by which property damage is computed is identical for with- and without-project conditions. The effect of a shore protection project is accounted for by changes in bluffline location and storm recession estimates. Damage benefits of a shore protection project are simply the difference between the damages computed for with- and without-project conditions.

The actual damage prediction algorithm is in the form of a numerical simulation. Input to the simulation includes two data files: The "property" data base in-

cludes economic values and various physical characteristics of each of the property parcels along the study area. The "erosion" data base includes estimates of dune recession expected for various-intensity storm events for each of the property parcels. Output from the simulation includes, for each time step, the cumulative damage to structures and the loss in land value at each of the property parcels.

3.0 PREPARING INPUT DATA

3.1 Parcel Division

The shorefront properties are first grouped into contiguous parcels self-similar in (1) beach profile characteristics, (2) property depth, (3) structural set-back, (4) structure size and construction-type, and (5) historical shoreline erosion rate. If cost-sharing estimates are of interest, then the use or function of the properties within each parcel should also be similar. That is, publicly-owned properties should be isolated from privately-owned properties; commercial properties should be isolated from residential properties, etc.

The shore-parallel length of each parcel is not particularly important. It is only important that the properties within each parcel are self-similar, and that the parcels are not so long that they obscure potential project boundaries.

It is convenient to establish an artificial baseline along the shorefront's bluffline by which the endpoints of each parcel can be referenced. A baseline with 1000-ft or 200-m station intervals drawn upon aerial photographs or plat maps is usually appropriate.

3.2 Property Data Base (Input)

For each property parcel, the following items are identified (see Figure 1):

- (1) location along a shore-parallel baseline, Y_1 & Y_2 ;
- (2) structure value, V_S ;
- (3) land value, V_L ;
- (4) average set-back distance of the structures from the initial (year-zero) bluffline, S ;
- (5) average footprint (depth) of the structures, F ;
- (6) lot depth, L ;
- (7) structure type (piles, slab-on-grade, etc), S_t
- (8) historical bluff or dune erosion rate, dx/dt ; and
- (9) an index number identifying the appropriate storm recession data which apply to the parcel (see Section 3.3).

These data (for each parcel) are entered to a data file. Items 1 through 7 are developed through aerial photography, ground truthing, and appraisal or tax records. Item 8 is developed through historical shoreline analysis. Item 9 is described below.

Figure 1: Attributes of an oceanfront property parcel.

3.3 Storm Recession Data Base (Input)

For several representative beach profiles along the study area, the recession of the existing (year-zero) bluffline is predicted for K storms of various return-period intensity using a dune erosion model. This is done for both existing (no-project) conditions and simulated post-project conditions. In this way, a pair of storm recession estimates is computed for each representative beach profile which includes

- * without-project conditions, R_{0k} , and
- * with-project conditions, R_{pk} .

(See Figure 2). The subscript k refers to various return period storm intensities; e.g., $k=1$ is a 5-yr event, $k=2$ is a 10-yr event, etc. Generally, $K=5$ to 10.

An identifying index number is assigned to each pair of storm recession estimates. One of these index numbers is then assigned to each property parcel (item 9, above) to describe the storm recession for that parcel. For quasi-uniform alongshore conditions, a single profile (or single pair of storm recession estimates) will usually characterize several adjacent parcels.

COMPOSITE PROFILE 51-90 : WITHOUT PROJECT

COMPOSITE PROFILE 51-90 : 75 FOOT PROJECT

Figure 2: Storm recession for (a) without- and (b) with-project conditions. The recession R for storm k=5 is indicated for both.

4.0 COMPUTING EROSION DAMAGE AND BENEFITS

4.1 Tracking Non-Armored Bluffline Location

Chronic (Historical) Erosion Stress - For each time step Δt (usually one year), the present position of the bluffline $x(t)$ for each parcel is updated based upon historical trends or current project conditions. In the absence of an active beach nourishment project (or shoreline armor), the bluffline position x at time t is

$$x(t) = x(t_r) + (t-t_r-z) \frac{dx}{dt} \quad \text{for } (t-t_r) > z \quad (1)$$

where $x(t_r)$ is the bluffline location at the time of the most recent nourishment t_r , z is the project life, and $(t-t_r) > z$. If there have been no nourishments, then $t_r=t_0$ (where t_0 is the initial time $t=0$), and $z=0$.

In the presence of an active beach nourishment project, the bluffline position is computed as a function of the project's life z and initial equilibrium berm width W :

$$x(t) = x(t_r) + (1 - (t-t_r)/z) W \quad \text{for } (t-t_r) \leq z \quad (2)$$

where t_r is the time of the last nourishment, and where $(t-t_r) \leq z$. If $(t-t_r) > z$, then the project is not "active" and Equation 1 applies. (If the beach is historically accretive such that $dx/dt > 0$, then the value $(dx/dt)\Delta t$ can be added to the right hand side of Eq. 2. However, it is unusual that a shore protection project would be built upon an historically accretive beach.)

For parcels downdrift or adjacent to an active nourishment project, historically erosive shoreline change rates (dx/dt) are set to zero to conservatively simulate the effects of beach fill "feeding". Alternately, an alongshore diffusion model could be used to modify the dx/dt values adjacent to a project (Dean, 1988; Phlegar and Dean, 1989).

Storm Erosion - In the absence of an active beach nourishment project (or shoreline armor), the bluffline location resulting from a given storm is the superposition of the current [no-storm] bluffline location, $x(t)$, and the storm's recession estimate R_{Ok} :

$$x_k(t) = x(t) + R_{Ok} \quad \text{for } (t-t_r) > z \quad (3)$$

where R_{Ok} is the computed "no-project" recession for storm k . If $(t-t_r) \leq z$, then a project is "active" and Equation 3 is replaced by Equation 4, below.

In the presence of an "active" beach nourishment project, the bluffline location resulting from a given storm is the superposition of the [no-storm] bluffline location prior to the nourishment, $x(t_r)$, and the storm recession R -- where R is the given storm's recession estimate tempered by the project's status. During the first year of an "active" project, R is simply the storm recession computed for full-project conditions; $R=R_{pk}$. As the project approaches the end of its life, R approaches the storm recession computed for no-project conditions; $R=R_{ok}$. Between these limits, the storm recession is computed linearly. That is,

$$x_k(t) = x(t_r) + (1-(t-t_r))R_{pk} + (t-t_r)R_{ok} \quad (4)$$

for $(t-t_r) \leq z$

Note that Eqs. 3 and 4 implicitly assume that the recession for various storm events is independent of the current bluffline location. For real beaches, this is not true unless the beach and dune profile remains geometrically similar as the shoreline chronically retreats or advances each year. However, this assumption eliminates the time-consuming task of re-computing the storm erosion for each chronic change of the bluffline location.

4.2 Tracking Armored Bluffline Location

Chronic Erosion Stress - For parcels which are predominantly armored, the chronic erosion rate of the bluffline, dx/dt , is equal to zero in Eq. 1 -- until the armor is estimated to fail due to chronic erosion stress.

The year at which existing armor might fail can be estimated in several ways; e.g.,

1.) The chronic erosion rate can be transformed to a volumetric rate -- and the impact of this cumulative volumetric loss to the armor's toe stability can be projected to a year of catastrophic failure.

2.) The return-period of the storm surge which will result in a wave height significantly exceeding the armor's design condition can be computed. This return-period can then be conservatively assigned as the armor's ultimate life. (This simplistically assumes that the catastrophic storm which will destroy the armor is certain to occur at least within the storm's return period interval.)

The results of both techniques should be computed and compared in order to guide selection of a reasonable life-span of the armor.

Subsequent to armor failure, the bluffline location is assumed to rapidly retreat to the location of the bluffline at the adjacent parcels. A simple geometric simulation of this is to set the armored parcel's post-failure erosion rate to:

$$dx/dt = \frac{1}{2} (x(t-\Delta t) - x(t)) \quad (5)$$

where $x(t-\Delta t)$ is the bluffline location at the armored parcel's previous time step, and $x(t)$ is the average current location of the bluffline at the immediately adjacent parcels. This implies that the "bulge" in the shoreline left by the failed armor will only be $1/2^n$ of its initial size at n -years after the failure. That is, the shoreline at the previously armored parcel will be within 12.5% of the neighboring shorelines after 3 years, and within 3% after 5 years, etc.

Storm Erosion - At armored properties, storm recession is generally zero for storms less severe than that storm which is estimated to cause armor failure. The severity of this catastrophic storm can be estimated by: (1) examining the extent of toe scour predicted at the armor's toe for various storms, or (2) back-calculating the storm surge (and its frequency) which would produce waves significantly beyond the armor's design condition. Both techniques require one to consider both no-project and with-project conditions. For storms more severe than that which is estimated to cause armor failure, the recession can be computed by simply ignoring the armor - or preferably, by failing the armor during the storm event.

4.3 Damage Computation for Structures

The damage to shorefront structures due to both chronic (historical) erosion stress and storm-induced erosion is a function of the bluffline's location relative to the structures' set-back S and the structures' footprint F . That is,

$$\begin{aligned} d_s(t) &= f\{ -(S+x(t))/F \} \cdot V_s \\ &= f\{u\} \cdot V_s \end{aligned} \quad (6)$$

where $d_s(t)$ is the dollar damage to structures at year t due to chronic erosion stress, and where $x(t)$ is given by Eq. 1 or 2.

Likewise,

$$\begin{aligned} \hat{d}_{sk}(t) &= f\{ -(S+x_k(t))/F \} \cdot V_s \\ &= f\{\hat{u}\} \cdot V_s \end{aligned} \quad (7)$$

where $\hat{d}_{sk}(t)$ is the the dollar damage to structures in year t due to storm k , and where $x_k(t)$ is given by Eq. 3 or 4.

The nature of the function $f(u)$ or $f(\hat{u})$ in Eqs. 6 and 7 is determined by the structure type. The following are suggested examples. In each, u and \hat{u} are interchangeable.

For slab-on-grade foundations:

$$f(u) = \begin{cases} 0 & \text{for } u < 0 \\ 2u + 0.1 & \text{for } 0.45 \geq u \geq 0 \\ 1.0 & \text{for } u > 0.6 \end{cases} \quad (8)$$

such that the structure is 100% damaged if the bluffline or storm recession extends through 45% of the structure's footprint. Some damage (10%) occurs when the bluffline or storm recession reaches the seaward face of the structure.

For some spread-footer or non-engineered pile foundations:

$$f(u) = \begin{cases} 0 & \text{for } u < 0 \\ u & \text{for } 1.0 \geq u \geq 0 \\ 1.0 & \text{for } u > 1.0 \end{cases} \quad (9)$$

in which case the structure is 100% damage when the bluffline or storm recession extends to the landward edge of the footprint.

For engineered structures on piles or substantial spread-footers:

$$f(u) = \begin{cases} 0 & \text{for } u < 0 \\ 2/3 u & \text{for } 1.5 \geq u \geq 0 \\ 1.0 & \text{for } u > 1.0 \end{cases} \quad (10)$$

such that 100% damage occurs only when the bluffline or storm recession extends 50% of the structure's footprint beyond its landward edge.

While the damage caused by chronic erosion in a single year is simply that of Eq. 6, the damage expected in a single year due to storms is determined by the storms' probabilities of occurrence. That is, the probabilistic -- or expected -- storm damage in each year is the weighted sum of the damage estimated for each of the K storm events considered. This is estimated by:

$$E[\hat{d}_s] = \hat{d}_s = p_1 \frac{\hat{d}_{s1}}{2} + \sum_{k=2}^K (p_{k-1} - p_k) \frac{\hat{d}_{sk-1} + \hat{d}_{sk}}{2} \quad (11)$$

Maximum Damage Limit - Maximum limits should be placed on structure damage. For example, it is convenient to assume that a structure will be demolished or relocated (and removed from analysis) if its cumulative damage exceeds some multiplier of its original value (say, 1.5) -- or if the probabilistic damage in a single year exceeds, say, 50%.

Additionally, structures can be demolished or relocated when the bluffline location $x(t)$ reaches a critical distance from the structure's seaward edge. Criteria vary locally. For example, in North Carolina (USA), the rule is 10 ft (3 m) plus 5.0 times the average annual erosion rate. The cost of relocation or demolition can be included in the analysis at the appropriate year.

4.3 Computing Damage to Structure Contents (Furnishings)

If damages to contents are to be considered, it is imperative to identify only those damages associated with erosion or with the flooding which may be prevented by the project under consideration (if any). Contents damage due to chronic (historical) erosion is assumed to be zero (because it is assumed that the owner will have plenty of time to remove the contents before chronic erosion causes damage). However, storm erosion may cause damage to contents due to its unexpected nature.

For storms which are not anticipated to cause flooding beyond that prevented by the shore protection project (if any), contents damage is conservatively assumed to occur at half the magnitude of the structure's damage function. (For example, if 40% of the structure value is lost, 20% of the contents value is lost. The other 80% is assumed to be salvageable.) For storms which cause flooding beyond that prevented by the project, no contents damage is calculated. This conservatively assumes that all contents damage is due to flooding and none is due to erosion.

The value of a structure's contents is assumed to be a fraction, c , of the structure's value, V_s . The fraction c depends upon the structure's use. From insurance underwriters,

Single- & Multi-Family Residences:	$c = 0.55$
Restaurants:	$c = 0.35$
Hotels & Motels:	$c = 0.25$

Concisely, the damage to contents for storm k in year t is:

$$d_{ck}(t) = \begin{cases} f\{\hat{u}\} \cdot c \cdot V_s & \text{for storms w/o flooding} \\ 0 & \text{for storms w/ flooding} \end{cases} \quad (12)$$

where $f\{ \}$ is from Eq. (7), or as from Eqs. (8), (9), or (10). The probabilistic contents damage in each year is found as through Eq. 11, above.

4.4 Computing Damage to Land

Loss of coastal land value may be due to (1) chronic erosion and/or (2) acute storm impacts. To ensure conservative valuation (and to avoid potential "double-counting") the author accounts only for the former. This implicitly assumes that land lost to a storm recovers 100% (minus any chronic year-to-year losses).

Generally, loss of land value at time t is expressed as:

$$d_L(t) = g\{ -x(t)/L \} \cdot V_L \quad (13)$$

where g is a function of the eroded bluffline location $x(t)$ relative to the lot depth L , and V_L is the original (non-eroded) land value. The function $g\{ \}$ can vary; i.e.,

1.) Land value is lost linearly with erosion:

$$g\{ -x(t)/L \} = \begin{matrix} -x(t)/L & \text{for } -x(t)/L \leq 1 \\ 1.0 & \text{for } -x(t)/L > 1 \end{matrix} \quad (14)$$

This is identical to assuming that land is valued uniformly.

2.) Land value is lost in proportion to erosion, but the lot is completely de-valued when the erosion reaches a certain fraction, a , of the total lot depth L :

$$g\{ -x(t)/L \} = \begin{matrix} -1/a x(t)/L & \text{for } -x(t)/L \leq a \\ 1.0 & \text{for } -x(t)/L > a \end{matrix} \quad (15)$$

where, for example, $a = 2/3$.

3.) Land value is lost in proportion to erosion, but the lot is completely de-valued when some "minimum" lot depth L_{\min} is left:

$$g\{ -x(t)/L \} = \begin{matrix} x(t)/(L_{\min} - L) & \text{for } -x(t) \leq L - L_{\min} \\ 1.0 & \text{for } -x(t) > L - L_{\min} \end{matrix} \quad (16)$$

4.5 Cumulative and Present-Worth Damage & Benefits

The predicted damage which occurs over the time step t at time t is the sum of (1) the probabilistic storm damage d at time t (Eq. 11), and (2) the increase in damage due to chronic erosion between time t and the previous time step, i.e., from $d(t-\Delta t)$ to $d(t)$.

For example, structure damage over the time step Δt at time t is

$$D_S(t) = \hat{d}_S + [d_S(t) - d_S(t-\Delta t)] \quad (17)$$

The present worth (P.W.) of this damage is

$$DPW_S(t) = D_S(t) * (1+i)^{-t} \quad (18)$$

The cumulative structure damage at year t is simply

$$\int_0^t D_S(t) dt$$

and the P.W. equivalent is simply $\int_0^t DPW_S(t) dt$.

Project benefits are simply the difference in damage computed for without- and with-project conditions. This can be calculated on, for example, a year-by-year basis (Eqns. 17 & 18), or on a cumulative basis.

4.0 DISCUSSION

The simulation technique and algorithms described above feature useful flexibility, some features of which are highlighted below.

Sensitivity of Damage Functions - The damage functions for structures, $f\{\}$, and land, $g\{\}$, are defined functions -- and can be easily modified for sensitivity tests without altering the rest of the simulation code. While damage functions are suggested herein for various structures and land conditions, others can be easily created and tested as appropriate to the study area.

Project Simulation - Virtually any traditional shore protection project can be analyzed by the technique. The parameters which describe the project's effects appear in three controlled groups: (1) project characteristics (i.e., boundaries, life, width (if applicable), construction interval/timing, and storm intensity up to which flooding is prevented (if any); (2) chronic erosion rates (dx/dt), and (3) storm recession data.

"Backrow" Properties - Properties two, three, or more "rows" from the oceanfront can be explored by creating additional property data bases. For these, the structural set-back distance is the total distance from the structure's seaward face to the bluffline, as usual. Land loss is computed by accounting for the "margin" of land, M , between the subject property and the bluffline. Equation 13 then becomes:

$$d_L(t) = g\{ -(M + x(t)) / L \} \cdot V_L \quad (19)$$

Figure 3: Average expected storm damage to structures (normalized by structure value).

such that loss of land value does not occur until the recession extends through the margin and into the "backrow" lot.

Simplification of Damage Functions - Damage to a property is a function of many parameters: e.g., set-back, width, storm frequencies, beach profile, storms, chronic erosion rates, structure type, local armoring, etc. Because each is of similar importance, attempts to express an average damage multiplier as a function of only one or two of these parameters is not advised. As an example, Figure 3 depicts the annual probabilistic (expected) storm damage vs. the local set-back distance for (i) 179 property parcels along a 40-mile segment of Brevard County, Florida, (ii) 21 parcels along a 3-mile segment of Bonita Beach, Florida, and (iii) seven parcels along a 2-mile segment of St. Simons Island, Georgia. While a general envelope is suggested, a simple relationship is not discernable. Inclusion of one or two additional parameters does not significantly improve the correlation (Bodge, in review).

CHAPTER 213

THE IMPACTS OF SHORELINE PROTECTION STRUCTURES ON BEACHES ALONG MONTEREY BAY, CALIFORNIA

Gary B. Griggs*
James F. Tait*
Katherine Scott*

Abstract

As a result of severe coastal storm damage in recent years along the California coast and the continuation of development and redevelopment in hazard prone oceanfront areas, large numbers of coastal protection structures have been built. This same trend has been observed on the Atlantic and Gulf coasts as well. At present, fully 12%, or 130 miles of California's 1100 miles of shoreline have been armored. As the number of structures and their coastal frontage has increased, concern along the California coast and elsewhere has arisen in regard to the impacts of these protective structures on the adjacent beaches. Three Atlantic coast states (Maine, New Jersey, and North Carolina) have responded to this concern by establishing state-level policy which prohibits construction of any new "hard" protective structures.

Although considerable laboratory scale research has been carried out on this problem, field work has been extremely limited. A study along the central California coast was initiated in order to resolve some of the most critical questions regarding the impacts of protection structures on beaches. Based on 4 years of precise, biweekly, shore-based surveys in the vicinity of different types of seawalls along the shoreline of northern Monterey Bay along the central California coast, some consistent beach changes have been documented. All of the changes observed to date have been seasonal and are best developed in the fall and winter months during the transition from summer swell to winter storm conditions. The effects or changes documented include:

(1) Loss of summer berm sooner in front of seawalls and revetments

* Earth Sciences Board, University of California, Santa Cruz, Ca. 95064

relative to adjacent unprotected beaches with the onset of winter storm waves.

(2) No significant or consistent differences in the beach profiles at the contact between a vertical impermeable seawall and a permeable revetment despite the apparent differences in permeability and reflectivity.

(3) A lack of significant difference in matured winter profiles seaward of seawalls or revetments relative to adjacent unprotected beaches.

(4) Accelerated berm retreat and beach scour up to 150 m downcoast from seawalls due to a combination of end reflection and upcoast sand impoundment.

(5) Late spring/summer berm rebuilding independent of any protective structure, resulting in a continuous, uniform alongshore berm crest well seaward of the seawall.

Introduction

Much attention of coastal planners is focussed on the impacts of seawalls and revetments on beaches. A body of opinion exists that such impacts are adverse and promote erosion. Pilkey (1981) has asserted that building a seawall dooms the beach in front of it. Other researchers deny this, asserting that such claims are not based on an understanding of coastal processes (Dean, 1988). One reason for recent focus on seawalls is the increased development along our coastlines with a simultaneous increase in demand for coastal protection. Unfortunately, our knowledge of the long- and short-term effects of seawalls on beaches is limited. Planners and decision-makers are becoming more hesitant about granting permits or authorizing funding for such structures while the issue of impacts remains unresolved. One of the principal complaints of the decision-making community is that not only are they being told one thing by some scientists and something else by others, but they are frequently being told different things at different times by the same scientists.

Central to this dilemma is the lack of sufficient field data with which to resolve the claims. Most of our ideas are based on theoretical or laboratory models which have their own limitations. The coastal environment is extremely complex and does not readily lend itself to reductionism. In order to be manageable, mathematical models rely on a number of simplifying assumptions. In the study of seawalls and revetments, such assumptions as infinite length and perfect wave reflection have been used (e.g., Jones, 1975). Similarly, hydraulic models used by engineers (e.g., movable bed experiments conducted in wave tanks or basins) have serious problems with sediment and wave

scale. Even when near-prototype scale wave basins are employed, the waves used are usually monochromatic, or at best unidirectional spectra and three-dimensional processes are not accounted for; in general, reality is oversimplified. Furthermore, the results of such modeling are frequently not checked in the field.

For the most part, the lack of field results is a direct outcome of the large expense in both time and money that such studies require. A number of very good reviews of the seawall problem are now available. Dean (1986) and Everts (1985) have authored speculative synopses which are both comprehensive and well reasoned. Kraus (1988) has reviewed the literature concerning laboratory, field, and theoretical studies and provides an excellent critique. In October, 1986, Griggs and Tait (1988) began a study of beach response to four seawalls along northern Monterey Bay, California (Figure 1). Objectives included:

- (1) How do beaches backed by seawalls change seasonally in response to changing wave climate compared to adjacent beaches without seawalls?
- (2) What bearing does seawall design have on beach response?
- (3) Does the position of the seawall on the beach profile (i.e. farther seaward relative to another structure) exert any effect on seasonal beach changes?
- (4) Do seawalls exert alongshore control on beach development, cross-shore control, or both?

Four monitoring sites were initially selected with the objectives of observing different types of protective structures at different locations on the beach profile. Both vertical impermeable seawalls and sloping permeable revetments were monitored. These structures varied in their location from being placed at the base of the seacliff to as far as 75 m seaward on the beach profile. Precise biweekly shore normal surveys were carried out between October 1986 and May 1989. In addition, more frequent winter surveys were carried out at one site during the winter of 1989-1990. Profiles extended either from the seawall or back of the berm offshore as far as feasible using a field assistant in a wet suit (typically to 100 to 150 m offshore to depths of -1 or -2 m MSL).

The profile lines were spaced at 30 m intervals alongshore at locations where seawalls abutted unprotected beaches. A Leitz EDM and pole mounted prism reflector were used for surveys. Approximately 2000 individual profile lines have been surveyed.

The coast of California forms a marked contrast to the Atlantic and Gulf coasts of the United States where other researchers have

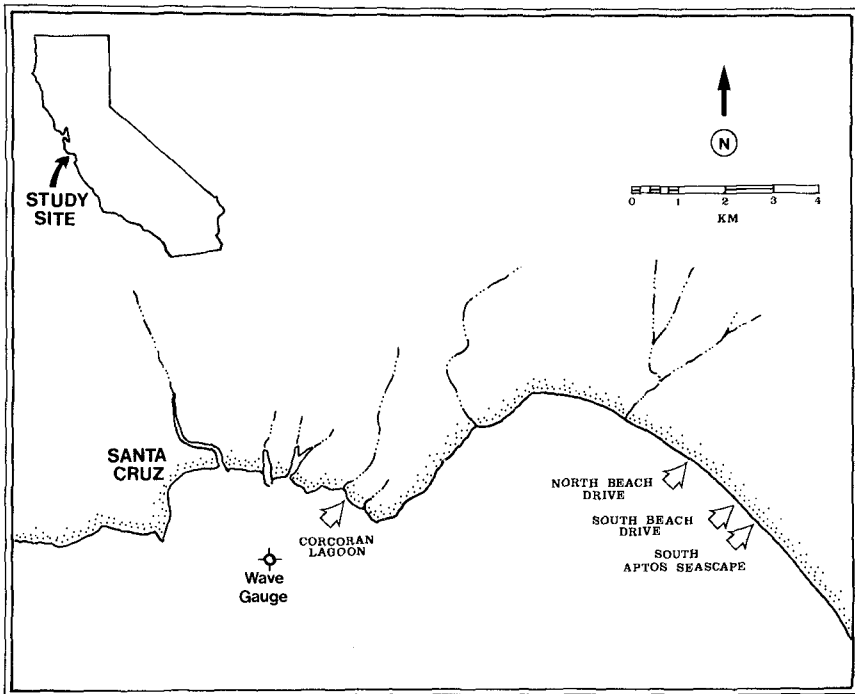

Figure 1. Location map of study area in Monterey Bay, California

carried out some post-hurricane seawall monitoring. The study area in Monterey Bay is fronted by a broad equilibrium beach (Figure 2) which, while undergoing seasonal variations in width, is not undergoing net erosion. The Atlantic and Gulf coasts are typically fronted by barrier islands which are migrating landward in response to sea level rise, and are also subject to hurricane overwash and breaching. Seawalls along these coasts attempt to fix the position of the shoreline on a coast which is otherwise retreating. The long term effects thus appear to be quite different due to basic difference in geomorphic and tectonic setting than the coastline of California.

Beach Response

Beach response is the morphological transformation of a beach due to gradients in sediment transport. Field studies show the response of a beach in front of a seawall to storm waves to be quite variable. The following beach responses have been observed at seawalls (Figures 3 and 4):

Figure 2. South Aptos Seascape site where beach in front of and up and downcoast from concrete seawall were monitored.

Figure 3. Types of beach response observed by Griggs and Tait (1988) before berm retreats past seawall.

Figure 4. Types of beach response observed by Griggs and Tait (1988) after berm retreats past seawall.

- Scour Trough- a linear trough or depression fronting a seawall
- Deflated Profile- the lowering or erosion of the beach face
- Beach Cusps- crescentic or semi-circular embayments on the beach face
- Rip Current Trough- a trough or embayment crossing through the surf zone
- End Scour- erosion of the unprotected beach adjacent to the end of a seawall
- Upcoast Sand Accretion- the impoundment of sand on the upcoast or updrift end of a structure

Many of the types of beach response can be divided into two broad categories: "frontal effects" and "end effects". Scour trough, deflated profile, and cusping are all examples of "frontal effects". End scour, sometimes referred to as "flanking", and upcoast sand accretion are examples of "end effects". Rip current embayments appear to be a more complicated case, affecting both the profile in front of the wall and the profile alongside the wall. Any of the above may occur as a response to wave-seawall interaction. Or, beach response at a seawall may be indistinguishable from that on neighboring beaches which have not been modified by structures.

Results

A number of consistent beach changes related to the presence of seawalls and revetments have been recognized during the

course of four years of surveying. These are discussed below in a chronological fashion.

(1) **SUMMER BEACH CONDITIONS:** At the start of each new season of monitoring (early fall) the beach at each of the monitoring sites had accreted to the point where the berm was well seaward of the seawall and there was no wave-seawall interaction. The summer berm was continuous alongshore with no deflection or difference in the vicinity of the seawall. Thus, although the summer berm varied somewhat each year in both its seaward extent and height, the beach/seawall system retained no memory of the previous winter conditions.

(2) **EROSION OR RETREAT OF SUMMER BERM:** During the transition from summer to winter (dissipative to reflective) beach state, the berm is usually cut back sooner in front of the seawalls monitored relative to the adjacent unprotected control beaches. Thus a flatter winter profile is attained sooner in front of the seawalls in contrast to the adjacent beach which will still have a relict summer berm. The difference in elevation between the beach in front of the seawall and the adjacent berm may vary from a few tens of centimeters to over a meter and the berm offset may be up to 12 m (Figure 5). The timing and extent of this premature berm erosion is controlled by the width of the initial summer berm fronting the seawall and the winter wave climate. The berm is typically lost first from those walls which are farthest seaward on the beach profile.

Figure 5. Example of winter berm erosion in front of rip-rap prior to berm removal on adjacent unprotected beach.

It is believed that this premature berm removal is due to wave reflection from the seawalls and revetments at high tide. Waves which overtop a berm of an unmodified beach will expend their energy over the width of the berm, depositing whatever sediment they carry. Waves colliding with a seawall before their energy is spent will be partially reflected and are still capable of scour. An issue of some controversy along the California coast is whether permeable revetments produce less reflection and beach scour and are, therefore, preferable to impermeable seawalls. Although several sites were studied where vertical impermeable concrete seawalls abut sloping permeable revetments, there was no consistent difference in the beach profiles at these sites over three years of monitoring (Figure 6) indicating that under the wave conditions experienced, that the difference in apparent permeability was not a significant factor affecting berm erosion.

(3) WINTER OR STORM PROFILE: As winter waves continued to erode both the seawall backed beach and the unprotected beach, the berm on the unprotected beach retreated until it was landward of the seawall (Figure 7). Once this winter state had been reached there was no significant difference in the profiles between the protected and the unprotected beaches (Figure 8).

Figure 6. Uniform winter beach conditions at contact between permeable revetment and impermeable seawall.

Figure 7. Early winter conditions. Berm has retreated behind revetment leaving uniform planar beach in front of revetment and control beach.

There has been considerable controversy in recent years regarding whether or not seawalls are responsible for beach scour. In 4 years of surveying (3 years of biweekly surveying and a year of storm surveying) we have never observed a scour trough directly fronting any of the seawalls studied. Relative to some of the more severe coastal storms of the past decade, however, the winter wave conditions during the four years of monitoring have been only of moderate height (maximum significant wave heights in the range of about 1.5 to 2 m).

(4) END EFFECTS OF SEAWALLS: Direct wave reflection from the end sections of seawalls was commonly observed. As a result of this increased wave energy at the downcoast or downdrift ends of seawalls, an arcuate zone of localized scour typically developed in the winter months which extended downcoast from 50 to 150 m (Figure 9). The downcoast extent of this impact depended upon wave height and wave period or the arrival of the next wave uprush which tended to override and dissipate the reflected wave. Additional factors which appeared to influence this end effect were the end geometry and permeability of the structure, the angle of wave approach, and tidal stage. The extent of end scour was consistently greater at a structure which offered the greatest angle to the incoming wave and which had the most reflective surface.

Figure 8. Winter profiles at Aptos Seascape site showing similarity in beach fronting seawall (profiles 11-15) and control beach (profiles 18-21).

Upcoast sand accretion counteracted the modest increased scour at the downcoast end of the structures. The significance of this groin effect or upcoast accretion is dependent upon the location of the seawall on the beach profile and the winter position of the berm crest relative to the seawall.

(5) RECONSTRUCTION OF SUMMER BERM: With the change from winter to spring and summer wave conditions, the berms in the study area began to rebuild during May and June, a process which continued into July and August. Sequential biweekly surveys of this accretionary phase indicate that the berm on the unprotected beach advances seaward until it reaches the seawall, and then the berm in front of both seawall and adjacent beach advance together (Figure 10). Thus, while the winter erosional phase of the seasonal beach cycle was influenced to some degree by the presence of the seawall, this was not the case for the summer accretionary or rebuilding phase. At the end of this reconstruction phase a uniform alongshore berm crest exists well seaward of the seawalls.

Figure 9. Localized scour adjacent to downcoast end of seawall.

Discussion

Overall, relatively little field research has been conducted on the problem of beach-seawall interactions. The few studies to date indicate that beach response can be variable with a number of processes at work and with the factors controlling the type and magnitude of beach response interdependent (Tait and Griggs, 1990). Kriebel et al (1986), for example, noted the presence of a scour trough in front of a vertical impermeable seawall during hurricane conditions. In this study, on the other hand, we never encountered a trough in front of any of the seawalls or revetments monitored, but instead observed a more rapid retreat of the summer berm. We have observed downdrift scour, yet Kriebel et al (1986) observed no flanking in a downdrift area where it was expected. Both of these studies, however, found that beach recovery was approximately as rapid in front of seawalls as it was on adjacent natural beaches.

Beach response to seawalls appears to be variable because of the number of factors involved; furthermore, these factors are interrelated, and each factor influences other controlling factors. Attempts to assess the potential impacts of a seawall on a beach should be site specific. The following basic controls appear to be important in governing seawall-beach interactions (Tait and Griggs, 1990):

South Beach Drive - 04-26-88

06-09-88

08-18-88

Figure 10. Spring/summer berm reconstruction with no seawall effect.

- (1) Longterm shoreline trends
- (2) Position of seawall on the beach profile
- (3) Coastal Geomorphology
- (4) Sediment supply/beach width
- (5) Offshore gradient/width of surf zone
- (6) Wave energy and exposure
- (7) Seawall design (height, permeability, slope)
- (8) Length of seawall

More studies are needed, particularly on the Atlantic and Gulf coasts where the beach/seawall controversy has reached a peak. Most of the processes and controls involved in beach/seawall interaction have not been measured in the field. Measurements of parameters such as suspended sediment concentration, sediment transport, nearshore current fields, and beach water table levels in the vicinity of seawalls are necessary before beach/seawall interactions can be predicted with any confidence. Kraus (1988) makes some excellent suggestions for future seawall studies and monitoring programs. To underscore the speculative nature of the processes currently being associated with beach/seawall interactions, Dean (1986) points out that a rational argument, based on momentum flux considerations, can be advanced to show that increased wave reflection at a seawall actually reduces sediment transport.

CHAPTER 214

Fate of dredged material dumped off the Dutch shore

R. Spanhoff, Tj. van Heuvel, and J.M. de Kok ¹

Abstract

In the North Sea off the Dutch shore annually tens of millions cubic meters dredged material are dumped. Recent progress in assessing and predicting the fate thereof is described. Field studies and modelling activities are both required in the considered relatively complex situations.

Introduction

At several places along the Dutch shore harbours and their entrance channels have to be regularly dredged. Tens of millions cubic meters of dredged material are involved per annum. Notably the silt fraction therein attracts more and more attention in recent years because of its potential to transport and accumulate adsorbed contaminants. Therefore, the fate in the marine environment of dumped cohesive sediments is studied. Two locations are considered here, namely the dump site for the Scheveningen harbour near The Hague, respectively the site for the Rotterdam harbour region.

The latter dump site, called Loswal Noord, is of special interest because of the relatively large quantities of material dumped there, at present circa 15 million m³ per annum. In the last ten years or so this site has been the subject of field studies, on the one hand to monitor the impact of the dumping on the development of the region, and on the other hand since the dumped amount should provide a noticeable signal in the sediment transport along the Dutch shore. In studying this signal tools can be developed to predict the transport and fate of fine sediments entering the marine environment at specific places. The strongest tool would be a sediment-transport model with a prognostic capacity. We are working towards

¹Project engineers, Tidal Waters Division, Rijkswaterstaat
P.O. Box 20907, 2500 EX The Hague, The Netherlands

such a model for the considered region. A proper dumping management would greatly benefit from such a tool which helps in deciding where to dump how much of a specific material.

History

The western part of Holland, which lies below sea level in the Rhine-Meuse-Scheldt delta, has been created over centuries in a continuous struggle of man with water. One has not only changed the shore line, but also the outflow routes of the mentioned rivers. For instance, the Nieuwe Waterweg, the canal to the original Rotterdam harbours, was constructed in the previous century in traversing the dunes, a natural protection against the sea. With the more recent completion of the so-called Delta Works, in which among others several river arms in this delta were closed in order to prevent a repetition of the 1953 inundation of the area, the Nieuwe Waterweg became the most important outlet of the river Rhine. The run-off through the Waterweg is regulated to a large extent, with a (tidally averaged) value in the order of $1500 \text{ m}^3/\text{s}$ during most of the year.

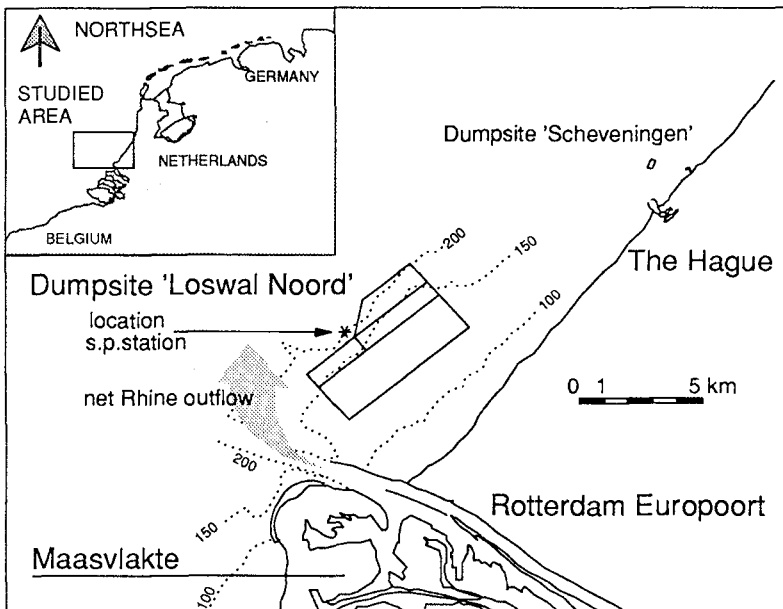

Figure 1. Studied area off the Dutch shore with two dump sites. The man-made Maasvlakte, the residual Rhine outflow and some depth contours (cm) are indicated

Another major man-made change in the present study area depicted in figure 1 was the construction in the beginning of the sixties of the extensive Europoort Harbour region and of the land acclimation Maasvlakte. Since then the need for dredging has increased significantly. The initial capital dredging concerned mainly sand. The later maintenance dredging, that turned out to be required permanently, involves mostly mud and fine sand (ratio circa 1:2 by weight). These materials are dumped on the Loswal Noord (see fig. 1) since 1961, annually on the average circa 20 million m^3 . Polluted muds from the Rotterdam harbours are stored on land since 1982 (order 1 million m^3 per year).

The actual spots of the Loswal Noord to be used have gradually shifted towards its more northern sections, because of the induced rise of the sea bottom and of the larger draughts of more modern hopper dredgers. The area was selected according to the best available knowledge of that time, among others balancing the extra costs of a larger distance from the harbour with the possible risk of a return of the dumped material to the sites to be dredged. For instance, the long-term residual currents are known to be directed to the North along the Dutch shore, so it is likely that sediments are transported in the same direction.

Area description

The sea bottom in the present study area is relatively flat outside the dump site, as can be seen in figure 2, with typical values in the range 10 - 20 m below mean sea level. A circa 25 m deep gully into Europoort harbour leads far to the open sea. Horizontal maximum tidal velocities are of the order of 1 m/s, and the tidal range is circa 1.8 m. Prevailing winds come from the Southwest thus lining up with the local shore line.

The fresh-water discharge of the Rhine through the Nieuwe Waterweg (the northern branch of the canal shown in fig. 1) is relatively large with a typical value of 1500 m^3/s . Fourfold values may occur during large river run-offs. Mixing of fresh and salt water in the tidally influenced region of the Waterweg is limited leading to stratified water masses entering the North Sea. Within a radius of 10 km around the mouth of the Nieuwe Waterweg mostly a strong and stable density stratification exists, leading to totally different residual current patterns in upper and lower layers.

The outflowing river water in the upper layer, influenced by Coriolis forces takes its way to the Northeast (fig. 1) together with the fluvial sediments suspended in it. The sediments originating from the dump site Loswal Noord are confined to the lower layers, where residual currents are determined by the large density gradients of

the outflow plume, ranging until 30 km off coast. Up to ten km around the entrance of the Nieuwe Waterweg residual bottom currents are directed towards the outflow point and have magnitudes of 10-20 cm/s or more. More to the North, where the influence of the upper layer is larger, there is a tendency to follow the large-scale residual current pattern, that is directed to the North-east but cross-shore, southeastward components still amount 2-3 cm/s.

The resulting horizontal and vertical density gradients strongly influence the water and sediment transports along the Dutch shore, up to the Wadden Sea (Van Alphen et al. 1988). For instance, relatively high suspended-sediment concentrations result (see fig. 4) because of the rather permanent landward residual current near the bottom, where the sediments prefer to reside.

Investigations

Several activities have accompanied the use of the dump site Loswal Noord. They ranged from routine measurements with an operational purpose, such as echo soundings to check navigational depths, till scientific attempts to give a firmer basis for the chosen dump location. Emphasis was on field studies with an occasional laboratory experiment. Since a few years we have incorporated numerical modelling in our program as well, since we think that an integration of experimental and theoretical approaches is required to make progress. In the following some of the activities and their results are discussed.

Mass balance

The changes in the bottom topography at the Loswal Noord as a consequence of the dumpings there, were regularly monitored.

Every two years a finely-spaced depth sounding program was performed, with cross-shore sections 250 m apart. An example of the results is shown in fig. 2 in a three-dimensional presentation.

In addition, every two or three years bottom-sampling campaigns were held, often with a relatively narrow grid size of 1x1 km². Thus, the mud content in the upper bottom layer could be determined.

From an analysis of the various depth-sounding charts of the region the amounts of material stored there can be determined. They were compared with the amounts dumped, for which a book keeping is available (see figure 3). For instance, for the period 1968-1986 in total 119 million m³ was stored, from the 291 million m³ dumped. Accounting for the estimated fractions of mud, sand and water in the hopper and at the site, respectively, a net loss of mud from the site is calculated. We have calculated the values

Figure 2. Three-dimensional presentation of the sea bottom echosounded in 1979, seen from the West

for the various considered time frames assuming constant loss rates therein. These are plotted in fig. 3 as well; the average value amounts circa 80 kg/s. Some 80 per cent of the dumped mud leaves the site. Since the beginning of the eighties this value tends to decrease to about 50 per cent; by dumping into deeper waters the mud probably has a better chance to settle permanently there. The sand fraction of the dumped material turns out to be stored rather permanently at the site, albeit that some 30 per cent migrates to its surroundings.

Hydrodynamics and sediment transport

Salinity and current profiles were regularly measured during 13 hours (covering a full tidal cycle) with ships at specific positions. Various stations in the area have been visited over the years. Clear vertical and horizontal gradients were observed, see e.g. figure 4. The relatively small survey vessels could operate at moderate wind conditions only. In a few cases moored self-recording current meters have been deployed that could measure during storm periods as well.

From these survey vessels in many cases sediment-concentration profiles were measured also, with in-situ optical turbidity sensors as well as by water sampling and subsequent filtering and determining the sediment's weight.

Figure 3. Top : Amounts of material dumped annually at the Loswal Noord
 Bottom: Cumulative amounts dumped and stored materials and the calculated loss per second

Combining the current and concentration profiles as measured over a tidal cycle provides indications of the rates of suspended-sediment transport in the area. These rates were much lower than expected when assuming a constant emission from the dump site, suggesting that special conditions such as storms or phenomena that escape detection play a dominant role. Current data under storm conditions were scarce while sediment-concentration information was lacking completely. Therefore, instruments were developed under contract for Rijkswaterstaat to fill these gaps, the so-called semi-permanent stations.

The chosen set-up consists of a complete package of sensors, batteries and electronics to be installed at the sea bottom in up to 25-m deep water that can measure and register the data autonomously for one or two months, thus also under storms, according to a preset program. The measuring intervals are chosen in a compromise between total operation time (data-storage capacity, power) and the frequencies of the phenomena of interest. At present, recordings are made every one to five minutes.

The sensors are mounted on one or two poles and are situated between 15 and 100 cm above the sea bottom, in

Figure 4. Current, sediment-concentration and conductivity profiles measured from ships (top)
Near-bottom sediment concentrations measured at the semi-permanent station (bottom)

practice. In general two optical (infrared) concentration probes are combined with one electromagnetic current sensor, but other configurations including more types of probes are possible. The equipment is brought into position by a diver at relatively calm weather conditions at the turn of the tide. The electronics and batteries are placed in a hole in a concrete foundation stone in the sea bottom to protect them against possible damage from the rather intense fishery in the area. Sometimes a sensor pole is overturned or even lost.

The equipment now has reached an operational stage, and it will be used almost continuously. Several weeks of data have been obtained in 1988 and 1989 with prototype versions. A result of a measured (time-filtered) sediment-concentration recording is presented in figure 4.

Description of the paths and fate of dumped materials

As a prerequisite for the best judgement of the costs and possible effects on the coastal-water system of the dumping of dredged materials, a description of the paths and fate of the latter is needed. A general insight in the existing situation has been required with the above field investigations, but predictions of the consequences of changes in the dumping scenario's, such as the use of alternative dump sites, have a qualitative nature only. For more stringent predictions more powerful tools such as models with some prognostic capability are required. The degree of sophistication of the tools to be used, and thus in practice among others the amount of physics incorporated in the model, depends on the acceptable uncertainty margins in the required predictions.

Important processes with respect to cohesive-sediment transport take place near the bottom. This follows not only from the increased values there of the measured concentration profiles but also from the observation of (temporary) sedimentation areas. Thus processes as settling, sedimentation and erosion may be important. Furthermore, the salinity and current profiles in the study area of fig. 1 display strong vertical gradients, with different residual currents for the top and bottom layers of the water, respectively. Therefore a full 3D description of water and sediment transport is appropriate in this case, including some of the mentioned processes of the latter.

As an example figure 5 is discussed. It was prepared as a 'first-order (3D) sediment transport model' at a time (1986) we did not have a hydrodynamic 3D model of the region. In this approach emphasis on the near-bottom suspended-sediment transports was put by considering current measurements made at circa 1 m above the bottom: a large collection of ships measurements in the area was normalized to mean-tide conditions and arranged according

to a standard time (high tide in Hook of Holland) with respect to the tidal phase. Thus it was possible to calculate at every time step for every place in the field the current vector by linearly interpolating between values observed at neighbouring stations. The sediment transport at 1 m above the bottom was simulated by considering the net displacements (in a large number of time steps) over a full tidal cycle of a large number of particles in the varying current field. The particles were moving with the water when the local current exceeded some critical value, and they returned (instantaneously) to the bottom as soon as the current was less than another fixed value, thus accounting for sedimentation and erosion.

A fair picture emerged of the transport directions from the Loswal Noord and Schevevingen dump sites. It should

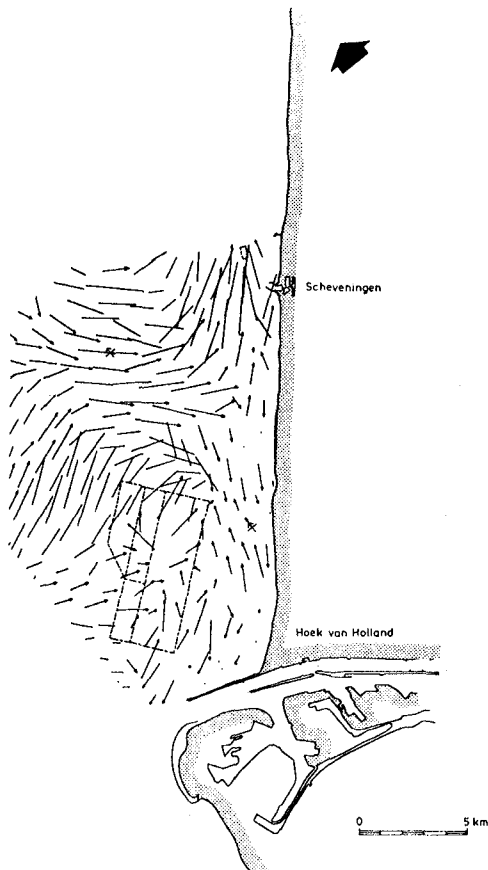

Figure 5. Residual near-bottom displacements of sediment particles calculated with measured current data

be noted that this picture applies to fair-weather conditions only because of the used current data (see above). Still, the picture is probably valid more generally, since it agrees quite well with the mud-content pattern in the bottom as deduced from the bottom samplings, see figure 6. The latter for instance also suggests a return flow along the shore to the South of mud dumped at the Loswal Noord.

3D sediment-transport model

As a further step towards a prognostic capacity a numerical 3D sediment-transport model was developed. It combines a hydrodynamic model with a sediment-transport part. The hydrodynamic-model equations are the momentum and mass balance equations, with hydrostatic and Boussinesq

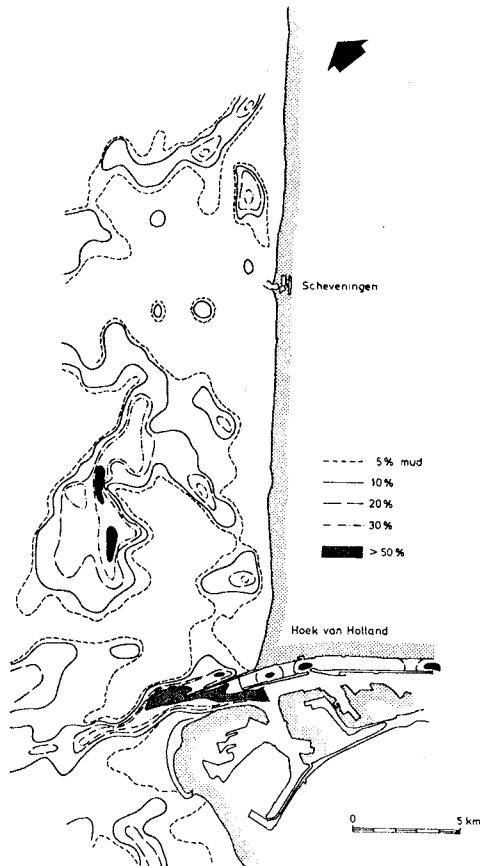

Figure 6. Mud contents (5%,10%,20%,30%,>50% contours) in samples of the upper bottom layer

assumptions, integrated over the layer depth in order to assure mass conservation. An explicit leapfrog difference scheme is used on a space staggered grid (Leendertse 1973).

The lower layers have a uniform, small depth for good near bottom resolution of the model with a horizontally uniform numerical error. Since layers are not horizontal anymore, both vertical and horizontal density gradients are represented in the momentum equations.

For salinity a separate advection-diffusion equation is solved and coupled to the momentum equations via the density gradients. Also the vertical turbulent exchange of momentum and mass is influenced by the vertical density gradients via the turbulent diffusion coefficients.

Sediment concentrations are computed with an advection-diffusion equation, with a fall velocity superimposed on the vertical velocity field, and an extra bottom layer for sedimentation and resuspension, depending on bottom shear stresses. No consolidation is taken into account yet.

In order to obtain a good reproduction of point releases a highly accurate finite difference method has been developed, with the possibility of representation of subgrid-scale details like first and second mass moments and cross moments. In de Kok (1989,1991) more details are given.

The modelled area was a coastal strip of 15 x 56 km, on a grid with a horizontal mesh width of 1 km, and a vertical mesh width of 1 m at the bottom until 10 m for the surface layer, depending on the depth. There were everywhere 5 layers. Time step size was 60 s for the hydrodynamic part and 500 s for the sediment transport part.

Boundary conditions were obtained via a series of coarser nested 2-DH models, beginning with a Continental Shelf model, then a North Sea model, then a Southern Bight model and finally a two layer coastal model.

Values for bottom roughness, eddy viscosity and eddy diffusivity were calibrated with observational data of velocity and salinity. Special attention had the maximum flood velocities, and the annual means of salinity and velocity in certain cross sections.

Computations were done for several wind and salinity conditions, and for several sediment grain sizes.

The transport of fine sediments from various sources, such as an individual dump release at a specific place, can be calculated for chosen environmental conditions. Various scenario's including the present situation can thus be simulated.

In the calculated (Lagrangian) velocity field for particles near the bottom an anticyclonic gyre in the residual currents around the present dumping site is emanant (see figure 7). It corresponds nicely with the transport

directions suggested independently by the mud contents in the bottom (see above), thus an appreciable return flow to the harbour mouth is likely. Furthermore a direct residual current to the mouth from the western part of the dump site is predicted, also in accordance with the mud chart. The latter current is induced by density differences. The former gyre is located in the lee of the relatively strong flood current of the land acclamation Maasvlakte extending into sea, and it is probably largely caused by it, as well as by the bottom topography around the dump site. Sediment concentrations calculated near the bottom with the 3D model confirm the above trends of a return flow (see figure 8).

Discussion

A large number of variables determines the hydrodynamics in the area of fig. 1, such as the tide, the wind which induces among others strong circulation currents and waves, swell, the only partially mixed variable Rhine outflow with its strong density gradients and induced residual currents, etcetera. Thus the hydrodynamics are hard to measure and to model. This holds even stronger for the sediment transport, being not only determined to a large extent by the hydrodynamics but also being subject to often poorly understood processes in flocculation, settling, sedimentation, consolidation and erosion. Thus at present, and in the near future, any sediment-transport model in the considered region has to be a mix of deterministic physics, parameterized formulations and empirical phenomenology.

Figure 7. Near-bottom Lagrangian residual currents calculated with the 3D model

This is reflected in our program in which we combine field studies and numerical modelling. Proces-related field studies give clues of what proces should be included in the model and how. In turn, various processes, e.g. taken from the literature, can relatively easily be incorporated in the model that can predict in a kind of sensitivity analysis what the consequences in the field would be and where they should be clearly detectable. Thus the (expensive) field program can be directed. For instance, at present we assume that the dumped material is spreading below the hopper dredger over the bottom and that the transport of the major part of the finer fractions is governed quickly by the water movement there. This hypothesis is hard to verify directly in the field but it can be tested indirectly with the registrations of our sediment platforms at the bottom when combined with model calculations. Other points thus to be addressed are the hypotheses that spring tides have a dominant effect because the stronger currents only then exceed the critical erosion velocities at many places, respectively that storms influence the sediment transports not only by induced currents but also by their waves that help in faster eroding the bottom. If so, the present relatively simple parametric formulation of the latter effect in our model then will be verified. With the approach sketched we anticipate a constant improvement of the quality of our model predictions. In the mean time the model is used as a tool to analyse the present situation, with respect to return flow etcetera,

Figure 8. Calculated near-bottom sediment concentrations (arb. units) five days after a release at the indicated dump site. Note the high near-shore concentrations extending southwards

and to develop alternatives in terms of dump sites, for instance.

One of the questions to be addressed is how much the sediment concentrations in the Dutch coastal zone, and thus e.g. in the Wadden Sea, are affected by the dumping. This problem is relevant, since the amounts of mud disposed of are comparable with those transported in a 20-km wide zone along the Dutch shore (Van Alphen 1990). To answer this question, the present detailed analysis of the area of fig. 1 is required. Namely, the amounts of fine sediment returning to the harbour region that are dredged several times do not contribute to those concentrations. Furthermore, the presently dumped sediments originate from the sea and thus are artificially trapped by the man-made constructions in the area. Viewed on a large scale the dumping in first order simply compensates for this effect, but by injecting the material at one specific site local changes in the coastal zone may be induced, with some bearing on the large-scale sediment distributions. The problem can be tackled by nesting the present model, once validated, in a larger model for the whole of the Dutch coastal zone.

Conclusion

Field studies and model results suggest a relatively strong return flow of mud dumped at the present dump site Loswal Noord, largely due to an observed gyre in the residual currents and to density differences. In combining field studies, with innovative equipment, and modelling activities a promising program towards a more quantitative assessment is performed.

CHAPTER 215

DEVELOPMENT OF WATER LEVEL CHANGES IN THE GERMAN BIGHT, AN ANALYSIS BASED ON SINGLE VALUE TIME SERIES

Jürgen Jensen*, Hans-Eckart Mügge**
and Wolfgang Schönfeld***

Abstract

Time series of semidiurnal single values of Tidal High Water and Tidal Low Water and their occurrence times from certain tide gauges in the German Bight were evaluated. Detailed analyses were performed to detect distinct periodicities and changes in the trends not only of water levels but also of the occurrence times by means of mathematical-statistical methods.

Introduction

The eustatic variations of the global sea level are strongly influenced by worldwide changes in climate. There is no longer any doubt that the "greenhouse effect" and other human activities have a definite impact on our climate. In many parts of the world changes and accelerations in sea level rise have been detected, such as the east coast of the USA, the Gulf of Mexico, and the Bay of Bengal. In the North Sea, and even in the German Bight, an enhanced rise of the sea level will also lead to far-reaching alterations. In this context not only changes in mean sea level are important, especially alterations in Tidal High Water (THW), Tidal Low Water (TLW) and Tidal Range (TR) will play a decisive role. Changes in tidal dynamics of the flat coastal regions affect erosion, endangering of storm surges, changes in ground water level, and shipping.

In the project "Water Level Changes in the German Bight", the evaluation of time series of semidiurnal THW and TLW shows rises of THW up to 6 mm/year for cer-

*Senior Research Engineer, Dr.-Ing.,

Research Engineer, Dipl.-Ing., *Dipl.-Oceanogr.

BUNDESANSTALT FÜR WASSERBAU - AUSSENSTELLE KÜSTE; F.R.G.

tain sites on the German coastline, whereas the TLW decreases (Jensen et.al.,1988). This leads to the assumption, that during the last three decades a change in the tidal dynamics of the German North Sea coast may have taken place (Führböter, 1986, Siefert, 1984).

The Data

In order to achieve satisfactory results in determination of long term (secular) changes in water level and tidal dynamics, the analysis must be based not only on comparatively prolonged series of observations or records, but also on data which are highly accurate.

The database of the present examination consists of more than 500000 single values of semidiurnal THW and TLW. The data were recorded at 12 sites in the German Bight (Fig.1).

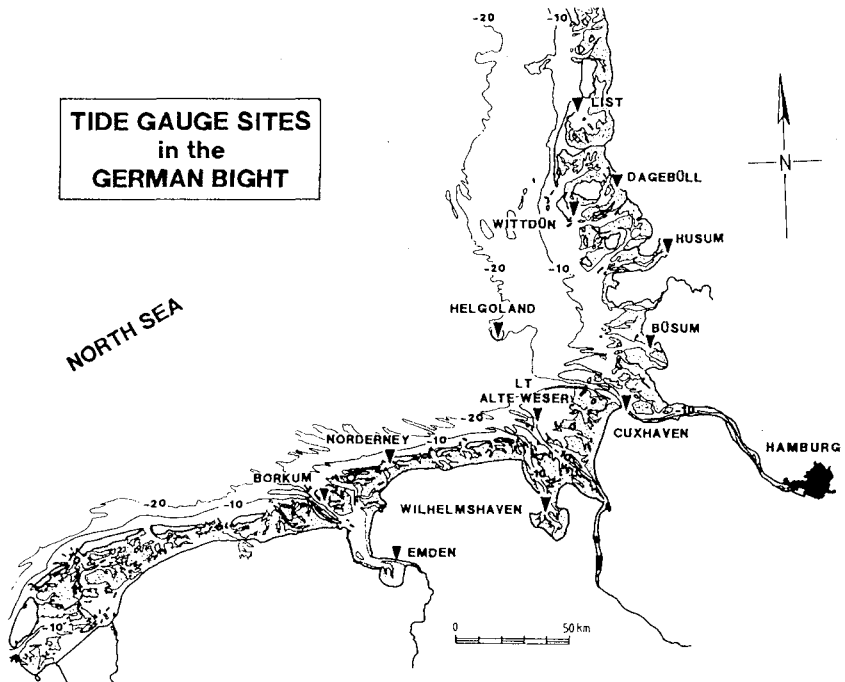

Fig. 1: Tide gauge sites in the German Bight.

The tide gauges are located in the south eastern part of the North Sea. The sites are on islands (Borkum, Norderney, LT Alte Weser, Helgoland, Wittdün/Amrum, and List/Sylt), in tidal estuaries (Emden, Wilhelmshaven, and Cuxhaven), and in small harbours (Büsum, Husum, and Dagebüll). The area includes most of the wadden sea. Big parts of the coastal region are below the sea level. The whole coastline is protected with dykes. The oldest continuous tide gauge recordings considered here had been performed in 1843 at Cuxhaven.

The time series of the tide gauges had to be as long as possible and should not much be influenced by antropogenic or morphologic factors. The data had been carefully checked and adjusted to a unique reference level. Changes in the location and vertical alterations of the tide gauges also had been taken into account. Gaps in the older parts of the time series had to be closed with the aid of linear regression and double-sum-analysis.

Linear Trends

The linear trends are determined with the aid of least square methods, as $H(t) = H_0 + S_T * t$. S_T denotes the average rise or fall of THW, TLW, TR, or Mean Sea Level (MSL) within the time period examined. The trends can be expressed either in mm/year or, as some authors do, formally extrapolated to a century and expressed in cm/100 years as secular trends (Führböter and Jensen, 1985).

In the German Bight a rise of the THW of 20 - 30 cm per century, i.e. 2-3 mm/year, has been observed since the beginning of regular water level observations in the middle of the last century (Rhode, 1977). Pirazzoli (1989) anticipated a rise of MSL in the North Sea of 1 - 1.5 mm/year. Woodworth (1987) estimated a global eustatic rise of 1 - 2 mm/year based on U.K. tide gauge data. In the current project, linear regressions show an increase of THW up to 6 mm/year at some tide gauges on the German North Sea coast. The TLW remains constant or decreases with maximum rates of 4 mm/year at certain tide gauges.

Table 1 shows spatial averaged trends of THW, TLW, TR, and MSL and their standard deviations over different time periods of the last 100, 50, 25, and 19 years (\approx period of the nodal tide). The mean trends are obtained by computing linear trends for each tide gauge separately and then taking spatial mean values.

TIME SERIES	LINEAR TRENDS $S_T \pm \sigma$ [mm/YEAR] MEAN VALUES GERMAN BIGHT			
	Tidal Low Water	Tidal High Water	Tidal Range	Mean Sea Level
1890-1989 (100 Years)	0.0 \pm 0.7	2.5 \pm 1.0	2.6 \pm 1.0	1.2 \pm 0.6
1940-1989 (50 Years)	-0.7 \pm 0.6	3.3 \pm 0.8	3.9 \pm 0.8	1.2 \pm 0.6
1965-1989 (25 Years)	-0.2 \pm 0.6	4.0 \pm 0.6	4.2 \pm 0.5	2.1 \pm 0.6
1971-1989 (19 Years \approx nodal tide)	4.0 \pm 0.6	6.7 \pm 0.7	2.6 \pm 0.5	5.3 \pm 0.6

Table 1: Mean trends over different time periods
(S_T : regression coefficient,
 σ : standard deviation)

The increase of the trends in THW can clearly be seen, the trends of TLW are much smaller, at some tide gauges TLW even is decreasing. Due to this development the trends of TR increase faster and those of MSL rise much slower than the trends of THW. Conspicuous alterations have taken place in the last decades. Compared with the longer trends, the trends from 1971 to 1989 reveal the first time an increase of TLW. So the rise of TR becomes smaller and therefore the MSL increases much faster during this period of time.

The alterations of the trends of THW and TLW at the tide gauge Cuxhaven from 1890 to 1987 are shown in Fig.2. The trends are computed within 25-year time-windows and the value is expressed in cm/100 years. The

trend is plotted at the end of the 25-year period. Negative values indicate decreasing water levels within the 25-year period. The differences to the 25-year trends in table 1 arise from the different time periods. In table 1 only data until 1987 are considered.

Fig. 2: Alterations of the trends of THW and TLW at the tide gauge Cuxhaven from 1890 to 1987, computed with 25-year time-windows.

The trends reveal strong temporal variations. In the middle of this century (the trend within the time period from 1941 to 1965 is plotted in 1965) the trend of THW clearly is rising and the trend of TLW is decreasing (negative values since 1965). Hence an increased rise of TR took place. The rise of the TR is of great importance for the tidal dynamics. Enhancement of tidal energy will lead to increased current velocities and sediment transports. This has great impact on the morphological structure of the coastal regions.

Frequency Analysis - Fast Fourier Transform

The corrected time series of tide gauge observations were transformed from periodic functions of time into the frequency domain using the Fast Fourier Transform.

Fig. 3 shows as a result of the FFT the frequency distribution of THW at the tide gauge Cuxhaven. The amplitudes of the frequencies for 1, 14, and 28 days as well as for 1 year are clearly seen. Furthermore some longperiodic oscillations of 4.2, 6.2, 7.8, 13.3, and 18.6 years can be recognized.

Fig. 3: Frequency distribution of THW at tide gauge Cuxhaven for the years 1894 to 1986.

The periods up to 1 year and the 18.6 year period obviously are of astronomical origin. The origin of higher amplitudes in periods between 3 and 13.3 years are at present not clear. Meteorological or hydrological cycles may play a role (eg. a supposed 6 to 7 year meteorological cycle).

Fig. 4 shows the frequency distribution of the TR at the same tide gauge. Here the 18.6 year period (nodal tide) with an amplitude of 4 cm, this is a range of 8

cm, can clearly be seen. At other gauge sites the range of this partial tide amounts up to 12 cm.

Fig. 4: Frequency distribution of the TR at tide gauge Cuxhaven.

Filtering

With the "Inverse Fast Fourier Transform", a retransformation of the frequency spectrum can be performed. By omitting distinct frequencies one gets digitally filtered time series.

A retransformation of THW and TLW at tide gauge Cuxhaven was performed with a low-pass-filter, all periods shorter than 2.7 years have been omitted. So long periodic oscillations can be recognized and analyzed. Fig. 5 shows an increase of the amplitudes of long periodic oscillations in the last decades.

Fig. 5: Retransformation of THW and TLW at tide gauge Cuxhaven (from 1843 to 1986).

In another application of the inverse FFT, first distinct periods of TR time series have been filtered out and then the other components were superposed.

Fig. 6 shows the oscillations of the TR with periods of 13.3, 18.6, and greater 23.3 years. The upper curve is the sum of these oscillations with periods greater than 13.3 years. The curves for 13.3, 18.6, and greater 23 years all have a maximum approximately at the same time, so the curve of the sum of these components has an extraordinarily maximum at the beginning of the eighties. The 13.3 year cycle cannot yet be explained.

Fig. 6: Superposition of periods > 13.3 years

Nodal Tide

The nodal tide arises from the relative movement of moon and earth to each other. The lunar and the earth's orbit are inclined with an angle of $5^{\circ}9'$. The point of intersection of the lunar orbit and the ecliptic changes its position within a period of 18.6 years. Due to this, the declination of the moon varies between 18.5° and 28.5° around the equator.

From a viewpoint on the earth this effect is depicted in Fig. 7. At the minimum declination, the tide generating force of the nodal tide has a maximum. The last minimum declination was in 1979.

Fig. 7: Declination of the moon

The nodal tide effect is mainly detectable in the TR. In the time series of THW and TLW this signal is considerably weaker. At the tide gauges in the German Bight the contribution of the nodal tide on the TR is about 7 cm. Other investigations reveal the TR at the dutch tide gauge at Vlissingen a portion of ≈ 12 cm and at certain english tide gauges more then 16 cm (Woodworth et al., 1990).

Occurrence times of THW and TLW

The previous investigations considered only the variations of water levels and TR. Water level changes, however, also cause temporal changes in the tidal dynamics. The investigations of tidal dynamics include the time series of the occurrence times of semidiurnal THW and TLW.

The tidal regime of the North Sea is dominated by the semidiurnal M₂-tide. The tidal wave from the Atlantic Ocean enters the North Sea through the entrance to the north and through the English Channel. First the tide

propagates counterclockwise along the english coastline southward and turns east near the dutch coast. In the German Bight the tide turns northward and leaves the North Sea along the norwegian coastline. Therefore the time of occurrence of THW and TLW at the North Sea coastline takes place in a definite sequence. Temporal alterations of the tidal regime will change the time when THW or TLW occur at certain tide gauge sites.

The tide in the North Sea is not directly determined by the astronomical potential, it depends on the tidal wave of the Atlantic Ocean. Nevertheless there is a relation of the position of the moon and the occurrence time of semidiurnal THW and TLW in the North Sea. Therefore the time of transition of the moon through the Greenwich meridian is chosen as a reference time. This reference time only depends on astronomical factors. The investigations of temporal variations are based on the time difference between occurrence of THW and TLW at several tide gauges in the German Bight and the transition of the moon through the Greenwich meridian. The data are not affected by vertical movements, eustatic effects or changes in reference levels.

Table 2 shows the averaged time differences between the occurrence of THW and TLW and the transition of the moon through the Greenwich meridian for selected tide gauges in the German Bight. The differences are averaged over a period of 34 years from 1954 to 1987. At tide gauge Norderney eg. the THW occurs in 1987 approximately 17 min earlier than in 1954 with respect to the transition of the moon through the Greenwich meridian.

GAUGE SITE	MEAN TIME DIFFERENCE		ALTERATION WITHIN 34 YEARS	
	$\Delta t(\text{THW})$ [min]	$\Delta t(\text{TLW})$ [min]	$T_T \pm \sigma$ $T_T(\text{THW})$ [min/34a]	$T_T \pm \sigma$ $T_T(\text{TLW})$ [min/34a]
NORDERNEY	613	253	-17±1.2	-21±0.7
HELGOLAND	637	297	- 7±1.2	- 3±0.7
WILHELMSHAVEN	711	334	-25±1.2	-26±0.7
CUXHAVEN	716	378	- 9±1.2	-12±0.7
HUSUM	764	406	-15±1.3	- 8±0.8
LIST	802	425	- 6±1.4	- 8±0.6

Table 2: Mean time difference between the occurrence of THW and TLW and reference time

The development of the time difference at tide gauge Wilhelmshaven from 1936 to 1987 is depicted in Fig. 8 . Generally the time differences reveal a negative trend. Since the beginning of the sixties an enhanced reduction of the time differences can be detected. Presumable this is due to construction works in the Jade Waterway.

Fig. 8: Development of mean time difference between the occurrence of THW at tide gauge Wilhelmshaven and reference time.

At all tide gauges considered here, the time differences of occurrence of THW and TLW and reference time has been reduced in the last decades. So it can be resumed, that also changes in tidal dynamics have taken place in the German Bight.

Conclusions

These evaluations reveal, that there is no uniform trend in the tidal regime of the German Bight. The secular rise strongly depends on the location of the tidal gauge and on the period of time considered. One obtains different results depending upon whether the MSL (predominantly used parameter) or THW and TLW are computed. Based on the historical development of MSL in the German Bight, no extraordinary rise can be detected when taking time periods of more than 25 years into account. Only computations of trends over shorter periods reveal an enhanced increase of the MSL in the German Bight. As mentioned above, more interesting developments have occurred with respect to the extreme values of the tidal regime. The rise of THW compared with constant or decreasing TLW leads to an enhanced increase of the TR. The rise of the TR is of great importance for the tidal dynamics. Enhancement of tidal energy will lead to increased current velocities and sediment transports. This has great impact on the morphological structure of the coastal regions and is of high importance for coastal engineering purposes.

The evaluations of occurrence times lead to the assumption, that the propagation velocity of the tidal wave has increased in the last decades.

More insight into the development of tidal phenomena in the German Bight may also be gained when taking meteorological time series into account.

CHAPTER 216

DAY VISITOR PONTOON GREAT BARRIER REEF, AUSTRALIA

ALAN ALBERT CAMPBELL GRUMMITT
B.E., M.I.E.(Aust.), MICE., M.ASCE.

1.0 ABSTRACT

This paper describes the structural and environmental aspects considered in the installation of a 45 metre x 16 metre steel pontoon equipped as a day visitor centre and installed at Wistari Reef, a southern section of the Great Barrier Reef, Australia.

In order to achieve environmental acceptability, any floating facility has to be structurally adequate and moored in such a way to withstand the most serious cyclonic weather without breaking free and damaging the reef.

The paper details the process of studying the reef environment, analyzing the structure, and obtaining the prerequisite approvals. It then discusses the actual installation of the pontoon and details ongoing monitoring requirements imposed by the Great Barrier Reef Marine Park Authority.

Managing Director, Cullen Grummitt & Roe Pty Ltd,
Consulting Engineers, 126 Wickham Street, Fortitude
Valley, Qld, 4006, Australia

2.0 INTRODUCTION

The Great Barrier Reef is a natural Coral Reef formation stretching from the northern tip of Eastern Australia parallel to the eastern coastline to its southern extremity near Bundaberg in Queensland, covering a distance of some 1850 km.

The reef is recognised as one of the wonders of the world, and is of major significance in both World Heritage terms and for its commercial value as a tourist destination.

It is protected by Federal and State Government legislation to ensure that any activity within its boundaries is environmentally acceptable.

Our client, P & O Resorts Pty Ltd, leases and operates a world famous Barrier Reef tourist resort at Heron Island on the Great Barrier Reef located some 88 km off the Queensland coast and almost on the Tropic of Capricorn.

The island is a renowned dive site to natural corals, has prolific bird life and is a major turtle nesting area.

P & O Resorts Pty Ltd purchased the nearly completed pontoon and thus commenced the task of modifying the pontoon for the exposed location proposed on the southern end of the Great Barrier Reef and obtaining the necessary statutory approvals for its installation.

As part of the statutory requirements a public environmental report was prepared and subjected to public scrutiny. The proposal was then modified to accommodate the requirements of the public and of the authorities and the pontoon was finally installed at the reef. The company agreed that it would obtain a Lloyd's classification on the reef pontoon and mooring system to satisfy the Marine Park Authorities requirements. In order to achieve this a full structural analysis of the pontoon, its mooring system and anchor components had to be completed and full detailed calculations submitted to Lloyd's register of shipping to obtain the necessary approvals. In addition many of the major components of the structure and in particular the mooring system including anchor chains, shackles and fasteners all had to be load tested and certified.

The Great Barrier Reef, and the pontoon installation, came ultimately under the control and standards of five bureaucracies and two permanent tenants on Heron Island. Finally the Lloyd's Register of Shipping certification had to be obtained for both the pontoon and its anchoring system.

It is fair to state that the frustrations, difficulties and, at times sheer pettiness and pedantic approach of some of these groups was certainly well beyond any expectations. By contrast some of the parties and bureaucrats were extremely helpful in the process.

3.0 ENVIRONMENTAL CONSIDERATIONS

Included in the environmental consideration of the site were:-

- (a) Existing Environment
 - . Physical
 - . Biological
 - . Socio Economic
- (b) Environmental Impacts
 - . During installation
 - . During operation
- (c) Control of Impacts
- (d) Monitoring of Impacts
- (e) Existing Environment

3.1 Existing Environment

The site initially chosen for the pontoon installation was on a reef shelf on the North Western end of Masthead Island and the Public Environment Report concentrated its attention to this preferred site. Seven alternatives were also considered in the P.E.R. and in the final result, it was not Masthead Island, but Wistari Reef, one of the seven alternatives for which approval was received.

Masthead Island is a typical tropical coral cay.

One of the major attractions of the Masthead site was the proximity of the island itself, affording visitors the opportunity to spend part of their day excursion on a typical tropical island paradise.

Regrettably, the approved site at Wistari reef does not have any island and guests are able to be taken ashore to reef walk only during low tides.

In the study of the existing environment, each of:

- . physical
 - . biological
 - . socio economics
- was addressed

Physical:-

The P.E.R. contained a complete description of the physical environment of Masthead.

The pontoon was to be moored in approximately 8 - 9m of water, with the underwater observatory looking onto a large (c. 4m diameter) living Porites coral bommie. This bommie, composed of two main colonies, rises to about 5m below the surface. Beyond this bommie the staghorn corals thin and the relatively flat substrate is covered by numerous small coral colonies dispersed in an otherwise sandy area.

In the original proposal, the human waste generated on the pontoon by 100 day visitors was to be treated in a twin three stage Microphor MC300 treatment system.

The effluent from the system is guaranteed within the following limits:-

- 100 guests per day maximum
- 4200 litres/day of diluted effluent
- 26 dumps each of 1.1 minutes each day
- 145 litres/minute dump
- less than 15mg/litre suspended solids
- better than 10mg/litre B.O.D
- Nitrate-Nitrogen 0.13mg/litre
- Soluble phosphates: Phosphate-phosphorus
2.14mg/litre
- Particulate phosphates: Phosphate-phosphorus
1.42mg/litre

The effluent standards were generally accepted as high, and quite suitable for the operation. The one reservation was that the treatment process did not remove nitrates and phosphates.

The presence of nitrates and phosphates in reef waters is undesirable as they can accumulate and act as nutrients for the growth of algae which in turn kills live coral. An extensive study was therefore undertaken to investigate the risk of such a nutrient build up.

Numerical simulations of hydrodynamic and advection/dispersion were completed to assess the potential contamination of reefs by sewerage effluent proposed to be discharged from the pontoon.

The models indicated that in one particular combination of spring tides and light onshore winds, retention of material around the reef chain was significant for several days.

In view of this perceived risk of nutrient accumulation during the combination of spring tides and light onshore winds, the decision was taken not to discharge the effluent into the sea but to take the treated effluent ashore for alternative disposal.

Other aspects of the physical environment impacts addressed included:-

- . Solid Waste Management
- . Disposal of shower water
- . Disposal of dish washing water
- . Disposal of deck washing
- . Fuel spill prevention
- . Disposal of food scraps
- . Effect of antifouling paint

Biological:-

The biological environment identified:-

- . terrestrial insects, birds and plants;
- . turtles;
- . sessile benthic (corals, algae and other);
- . fish.

Plants:

Plant species were predominantly *Pisonia* forest, fringed with *Casuarina* and *Pandanus* trees and grasses. A total of 41 plant species was identified.

Birds:

Masthead Island is a principal rookery for White-capped Noddies, a major rookery for the Wedge-tailed Shearwater, Silver Gulls, Crested Terns and Bridled Terns, and additionally supports colonies of Reef Heron, Roseate Tern, Black-naped Tern, Lesser-crested Tern, Sooty Oyster-catchers and Ospreys (Environment Science and Services, 1984).

Turtles:

The World Conference on Sea Turtle Conservation, held in Washington D.C., U.S.A. in November 1979 identified the Capricorn-Bunker Group as being of world significance for sea turtle conservation, being one of the eleven most important green turtle breeding areas and one of the worlds three major loggerhead turtle breeding areas. Masthead Reef, like other reefs in the region, supports resident populations of immature and adult green, loggerhead and hawksbill turtles throughout the year.

Coral:

A coral comparison for some of the alternate sites investigated shows the following results:-

Reef	Algae	Diversity	Size	Aesthetics
Erskine	1.38	1.88	1.38	2.13
Heron	0.63	2.17	1.80	2.74
Masthead	1.17	2.46	2.00	3.00
Polmaise	3.25	1.88	1.38	2.75
Wilson Is.	0.70	2.50	2.10	3.70
Wistari	0.59	2.55	1.90	2.79

Values given are means for the cover of each category where cover is marked on a scale 0 (0%) to 6 (76%-100%).

It can be seen from the table that the site finally chosen - Wistari Reef - was inferior in coral in all categories except diversity to the preferred site at Masthead.

This aspect was regarded as unfortunate, given that the prime attraction for visitors to a coral reef is the coral itself.

The figures, however do refer to average coral over the reef area, and the local site finally selected at Wistari Reef contains very attractive and impressive coral colonies and is not regarded as locally inferior to the local coral at the preferred Masthead site.

In order to minimize impact of the pontoon and its anchorage system on the coral, yet place the pontoon as close as possible to attractive coral colonies for viewing both by snorkeling and from the underwater observatory, a detailed site search was carried out in company with a marine biologist. The search was done from helicopter boats and finally in the water using scuba and snorkeling equipment. Once the actual site was selected, the pontoon shadow was pegged on the sea bed, as was the actual position of each anchor and anchor chain.

A detailed coral and fish survey of the site was completed.

General Comments on Fishes

Fish communities observed over the duration of the survey (12 - 14 December 1988), appeared typical of similar reefs in terms of species, composition, and numbers of individuals, with respect to the two principle habitat types encountered. Associated with the major inshore bommies, staghorn thickets and to a lesser extent the scattered hard coral patches, there was a much more diverse assemblage of fishes. Families Apogonidae, Chaetodontidae (eg. Cheetodon spp.), Haemulidae (Plectorinchus sp.), Labridae (eg. Thalassoma spp.) Pomacentridae and, Serranidae (eg. Epinephelus spp., Plectropomus maculatus) were visually dominant.

Dolphins, green turtles and game fish (probably long-tail tuna, Thunnus tongol) were seen from the dive boat when on station over the survey site.

Socio Economic

The examination of socio economic effects considered:-

- . existing private use of the area;
- . existing commercial tourist oriented use;
- . tourist impact on the local community in Gladstone, the adjacent mainland city;
- . impact on the central Queensland tourist trade.

The studies concluded that the facility would provide a positive socio economic effect on the area; that it would not intrude unduly on the existing private use and that the extensive international advertising, conducted by a major tour operator (P&O) would bring more positive impact to the only existing operator that the negative effect resulting from increased competition.

3.2 Environmental Impacts

Environmental impacts were divided into two categories:-

- . impacts during installation; and
- . impacts during operation.

Impacts during installation included:-

- . Towing to site and associated risks;
- . Accidental grounding of pontoon or tug;
- . Disturbance of Benthos and Substratum;
- . Disturbance to Marine Life.

To minimize accidents in the towing and installation phase, the operation was planned to occur, and did in fact occur, during very calm clear weather. Visibility both above and below water was excellent.

Some coral transplanting occurred before the anchors were laid to ensure minimum disturbance to coral by either physical damage or as a result of shading from the pontoon. All coral transplanting was done by qualified marine biologists under the direct supervision of an officer of the National Parks and Wildlife Service.

Impacts during operation included:-

- . Shading of coral;
- . Damage from mooring chain movement;
- . Damage from snorkeling, coral viewing, reef walking;
- . Collecting;
- . Disposal of wash water;
- . Effects of fish feeding.

Impacts during operation have been minimized by a number of operational procedures, limitations imposed both by the operator and the authorities and general care and attention to detail.

For example:-

- . sewerage effluent and all solid waste is taken ashore for disposal;
- . all coral in shade footprint has been transplanted;
- . coral in the anchor and anchor chain corridors have been transplanted;
- . an extensive educational program, and trained guides and observers ensure snorkeling, coral viewing and reef walking are confined to specific areas and paths, collecting is prohibited etc;
- . environmentally unacceptable antifouling paint is not used;
- . fish feeding occurs by releasing the food well below surface level to prevent the attraction of seagulls.
- . the pontoon is moved to a cyclone mooring whenever a cyclone alert reaches predetermined levels;
- . procedures and precautions are in hand for accidents such as fuel spills, equipment failure, fire, collision, explosion, weather, etc.

4.0 STRUCTURE

As previously mentioned, the pontoon structure and its anchoring system had to be checked for acceptability at the exposed location and in order to gain Lloyds Classification.

The pontoon itself consists basically of a rectangle fabricated from 1.5m diameter x 8mm wall thickness steel tube, strengthened by 8mm plate stiffener frames at 1.2m centres throughout. One end transverse compartment consists of a steel underwater observation chamber for viewing of the adjacent coral and fish.

Two basic design weather conditions were considered:-

- (a) Cyclonic winds combined with current and impulsive wave forces; and
- (b) Breaking - wave forces.

To establish significant wave heights, two techniques were used.

Firstly, use was made of cyclonic wave hindcasts for the Masthead Reef vicinity carried out by Dr Mike Gourlay of the University of Queensland and Mr Charles McMonagle.

Cyclone	Date	Time	H_s	Tav.	T_p	Dir.
Dinah	27/1/67	02.15	4.32	7.46	7.17	339
Fiona	21/2/71	23.30	2.52	5.46	5.96	314
Daisy	9/2/72	15.00	5.07	7.96	8.46	355
Emily	1/4/72	03.00	3.51	6.53	7.14	329
Zoe	9/3/74	13.00	2.41	5.25	5.56	327
David	19/1/76	14.00	2.84	5.58	5.61	294
David	19/1/76	21.00	2.86	6.05	7.11	287
Beth	21/2/76	13.30	2.36	5.13	5.54	314
Simon	25/2/80	07.30	3.72	6.33	7.05	185??

Where: H_s = significant wave height (metres).
 Tav = Average wave period (seconds).
 T_p = Peak energy wave period (seconds).

In addition, the design storm surge at the site was calculated as 3.3m.

Secondly, the traditional methods of wave forecasting, based on:-

- . wind velocity,
- . wind duration, and
- . fetch distance

were used.

For non cyclonic waves, the US Army Coastal Engineering Research Centre "Shore Protection Manual" was used.

For cyclonic waves, Design Wave Characteristics for Tropical Cyclones in the Australian Region by R L Nelson was the text. Analysis based on these texts, and cross checked against hindcasting by Gourlay/McMonagle led to design criteria of:-

	<u>Non Cyclonic</u>	<u>Cyclonic</u>
Wind Speed	75 knots	110 knots
Wave Height	7.3 metres	9.0 metres
Wave Period	11.1 seconds	12.5 seconds

All forces have been applied in three directions viz:-

- (a) Abeam;
- (b) Fore and Aft; and
- (c) Shoulders/Quarters.

The hull structure has been analyzed in two wave support conditions viz:-

- (a) spanning between wave crests at extreme ends; and
- (b) straddling a single central wave crest and unsupported each end.

Early analysis of the pontoon and mooring system showed that the hull and mooring system were competent to withstand all applied force combinations except that of a wave breaking on the beam. The forces from a breaking wave or cyclonic winds on parts of the superstructure elements would certainly be destructive. The mooring system is such as to restrain the pontoon on all four corners.

To take best advantage of the coral and local currents for boat activities, the pontoon is moored with its long axis NE - SW and its short axis SE - NW. This places the major beam directly into the NW, the direction from which maximum waves are generated. In all other directions, the site is protected by reefs and islands.

On the Wistari Reef site, it therefore became necessary to install a cyclone mooring in adjacent deep water outside the breaking wave zone in the wave climate profile anticipated, and to plan to move the weather conditions in the region are predicted to exceed preset values. These predictions are provided by the Australian Bureau of Meteorology Cyclone Strike Probability Service, in the form of a percentage probability that wind speeds will exceed preset values within the coming 36 hours.

This service commences at a time when the probability of winds in excess of a predetermined velocity at the site within 36 hours is 1%. The three hourly updates then continue until the probability no longer exists.

If...

- . the probability of winds exceeding 50 knots exceeds 70%,
 - . the cyclone path is adverse, and
 - . the maximum wind speed in the cyclone exceeds 70 knots,
- the TOW decision is taken.

5.0 INSTALLATION

In preparation for the installation of the pontoon the immediate footprint of the pontoon together with a strip 4 metres wide around each side of the pontoon, the position of the anchors, the alignment of the anchor chains together with a strip 2 metres each side of the anchor chains, were all cleared of live coral by transplantation. Much of the coral transplanted was able to be moved by hand by the marine biologists working with scuba gear. For the larger pieces, airbags were used as lifting devices and large coral sections were gently prized away from the surrounding sand bed, lifted by airbag and shifted from the anchoring position to a temporary site some distance away. After the installation these large coral pieces were returned to the south east corner of the pontoon where they added to the existing coral to form an enhanced coral garden immediately visible to the underwater observatory.

The need for careful planning, attention to the detail of how the pontoon was to be received, taken over from the tug, attached to the anchors and finally secured in position, and the need for skilled seamanship to prevent grounding of the tug and/or the pontoon were all prerequisites.

By the afternoon of Easter Saturday 1989 the pontoon was secured in its final operation position and preparation began to make it ready to receive its first visitors. Some time later the cyclone anchorage was installed using similar techniques so as to avoid damage to any of the adjacent coral.

After all systems had been checked the first paying guests arrived at the pontoon on the high speed passenger catamaran Reef Adventure II on the 30th of April 1989. Since then the pontoon has been operating successfully as a commercial venture and a large number of day visitors has had the opportunity to enjoy the beauty of Australia's Great Barrier Reef.

6.0 INSERVICE MONITORING

As part of the approval process a condition imposed on the installation of the pontoon by the Great Barrier Reef Marine Park Authority following the completion of the preliminary site selection and site environmental study, was that a baseline study be established at the site and that an ongoing environmental monitoring programme be introduced in order to assess, over time, the effect which the pontoon had on the environment. The baseline study conducted by approved marine biologists was such as to produce a complete coral map of the area and a complete fish survey of the area.

In addition two remote sites were selected as control sites to monitor variations which were independent of the pontoon itself. These two sites were located, permanently marked, and were also accurately mapped for both coral and fish populations.

As part of the baseline study each outcrop of coral was tagged and catalogued. Additionally each outcrop was photographed to show its position relative to the pontoon and anchor lines and as a series of closeups using a one metre square grid to provide a scale. The grid was fitted with a photographic standard colour spectrum enabling accurate colour correction.

A balanced three factor analysis of variance performed on the resulting data for total percentage cover indicated that:-

1. there was no significant difference between the pontoon and control sites;
2. there was a significant difference between zones (footprint, north anchor line, east anchor line, etc.);
3. there was a significant difference between strata; and
4. samples within strata were not significantly different.

An Anova table was generated. Cochran's homogeneity of variance test was applied prior to analysis of variance: data was analysed untransformed.

Data pertaining to percent cover by species was collated in readiness for similar analyses based on sampling over time. This will provide an indicator of change-over-time in community structure.

At the time of preparation of this paper one subsequent site study has been completed and the data obtained from this study has been compared against the baseline data. To date no significant variation from the baseline state has been determined and no remedial works or procedures have been found to be necessary. Already some of the acropora which had suffered minor damage is showing remarkably good recovery and regrowth.

So the final word is the area is alive and well, and the facility and Heron Island well worth a visit.

APPENDIX - BIBLIOGRAPHY

Some 31 references were used in the environmental studies alone. Many of these were papers reporting specific environmental studies of particular elements of the ecosystem. Additional references for the mooring and structural analyses were:-

SALT INTRUSION IN TIDELESS ESTUARIES

Ewa JASIŃSKA¹

ABSTRACT

The data of several field measurements performed in different types of estuaries along the Polish Baltic Coast are presented here. The results of measurement showed how unsteady and changeable the flow conditions and the motion of salt water in tideless estuaries are. The salinity and velocity distributions in the tested estuaries demonstrate that the change of current direction occurs at different depth and different times. It has been stated that the dynamics of the flow in tideless estuaries is similar to that of the tidal estuaries. A method of determination of longitudinal dispersion coefficient for tideless estuary is presented. The results from calculations for tidless estuary using a threedimensional estuary model previously developed for tidal estuaries are presented.

1 INTRODUCTION

Most rivers enter the sea at the place where there is enough tidal rise and fall to modify flow near their mouths. The area where there is an interaction between river and sea waters is called an estuary. This paper deals with a penetration of salt waters into tideless estuaries which are typical of the Southern Baltic Coast.

Distributions of salinity and velocity in tideless estuaries are primary determined by variation of water level at both extremes of the estuary, flow rate, density of fresh and salt water and the geometry and bathymetry of water bodies. They are also affected by wind and wave and sometimes by the Coriolis force. The interaction of fresh and salt water in estuaries provides a circulation of water and transport typical of each estuary. The circulation and transport in estuarine waters are generally turbulent and time-dependent and often have threedimensional character. The relation between magnitudes of barotropic and baroclinic horizontal pressure gradients has a vital importance to the flow characteristic. The prediction of changes in salinity distribution in each estuary, caused by changes of some above mentioned parameters is a problem that often arises. The forecast requires the recognition of the physical processes and forces taking place in the estuary.

Some results of testing relevant physical processes by field measurements and numerical simulations in estuaries along the Polish Baltic Coast are presented in

¹ Ph.D., Institute of Hydroengineering Polish Academy of Sciences, Kościarska 7, 80-953 Gdańsk, Poland

this paper. To describe the above mentioned processes field measurements were conducted in the following estuaries: Odra, Łeba, Łupawa, Piaśnica and Wisła (Fig. 1).

Fig. 1 Estuaries along the Polish Baltic Coast

It is proved that a profound knowledge of the hydrodynamic conditions and the character of motion of salt water in the estuaries are very important to water quality observation in these areas. A method of determination of the longitudinal dispersion coefficient for a tideless estuary and some results of calculations using a three-dimensional baroclinic model adapted for the Odra estuary are also presented in the following sections.

2 CHARACTER OF FLOW AND SALT INTRUSION

The problem of intrusion of salt waters and character of flow was tested by the Institute of Hydroengineering in Gdańsk. It was done for several different types of estuaries along the Polish Baltic Coast. In this paper as the example is presented the data for two estuaries: Odra and Łupawa, whose size and topography are quite different. The Odra estuary (Fig. 1) is a very complex system in the western part of the Polish Baltic Coast. The river Odra flows into the sea through Szczecin Bay and three straits: Piana, Świna and Dziwna. The straits connecting the Szczecin Bay with Pomeranian Gulf, part of the Baltic Sea. The total area of Szczecin Bay together with the straits is 910 km². The area of the bay is 686.9 km² and the length of its coast line is about 243 km. The greatest extension of the bay along the east-west axis is around 50 km, the smallest width 7.8 km. Depths are small, except in the central part, where the depth reaches 6 m. Through the bay runs the navigational channel from Szczecin to the Baltic Sea which has a mean depth of 10 m and is 250 m wide (Jasińska et al. 1988).

The water exchange between the bay and the sea through the straits varies from one to another and depends on the water level differences on the ends of straits and meteorological conditions. The water levels in Pomeranian Gulf are mainly caused

by storm surge and in extreme situations they changed in range + 1.96 m and - 1.34 m. The tide range in the Baltic Sea in this region is around 0.04 m and is negligible. The velocities of the water rise may reach 0.20 m/h and about 1 m within 10 – 12 hours. Water levels in the Szczecin Bay oscillated from + 1.29 m to - 0.72 m. Average water level in the Szczecin Bay is a little bigger than in the Pomeranian Gulf.

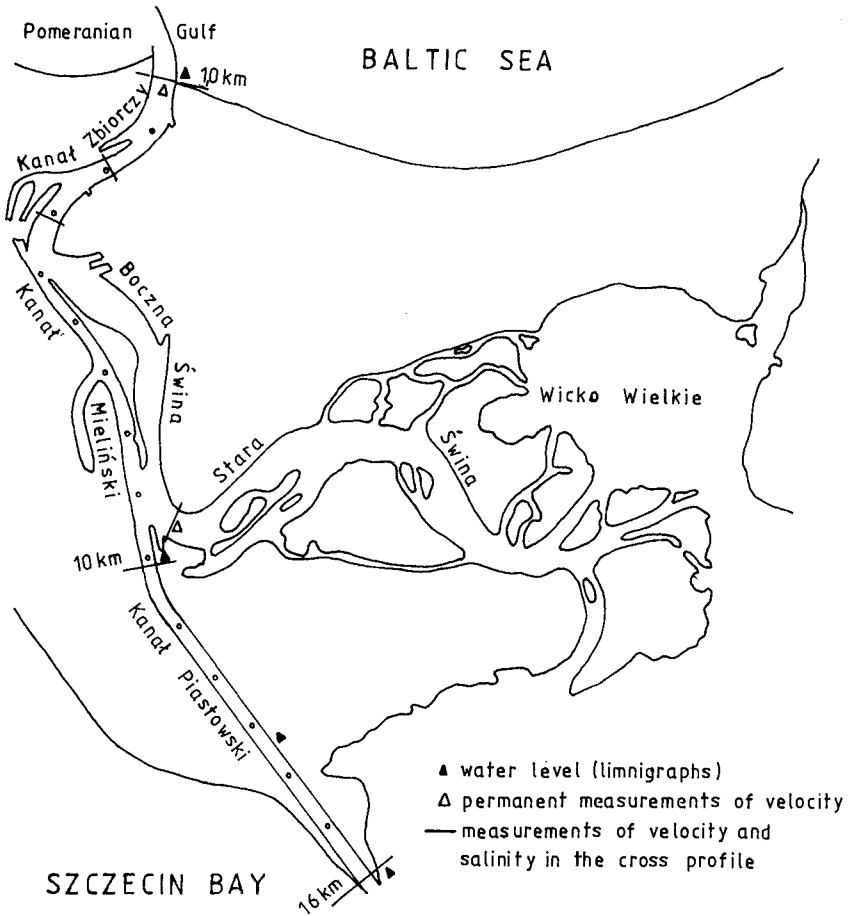

Fig. 2 The Świna Strait

The Świna Strait (Fig. 2), the main connection of the Szczecin Bay with the sea, consists of natural canals and man-made canals. Its length is 16.3 km and water areas are 13.2 km². Particular part of Świna Strait are of the following depths: Kanal

Zbiorczy (KZ) 15 – 17 m (at some places up to 21 m), Kanał Mieliński (KM) 10 – 12 m, Kanał Piastowski (KP) 10 m and Boczna Świna and Stara Świna 5 – 6 m.

The field measurements mainly concerned the water level and the distributions of velocity and salinity in so many points as possible. Very interesting results were obtained from continuous registration of velocity and water level during a longer period of time. In the analysis of the measurement data (Jasińska 1987) cyclic changes of the directions and values of currents and the distributions of salinity were noticed. Small changes of the water level and of its slope (Δh) caused a considerable oscillation of the value and direction of the velocity and in the distribution of salinity (Fig. 3).

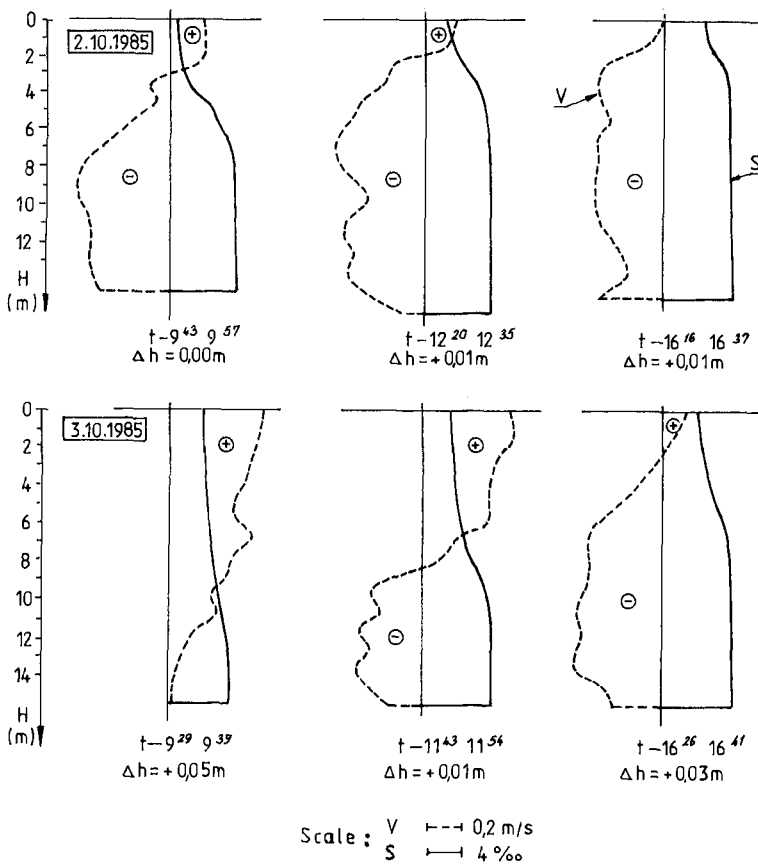

Fig. 3 Distributions of salinity and velocity at the small Δh in the Świna Strait

The strong inflow changed the conditions of flow and salt water filled the whole Świna Strait (Fig. 4) and also the part of Szczecin Bay within a short time.

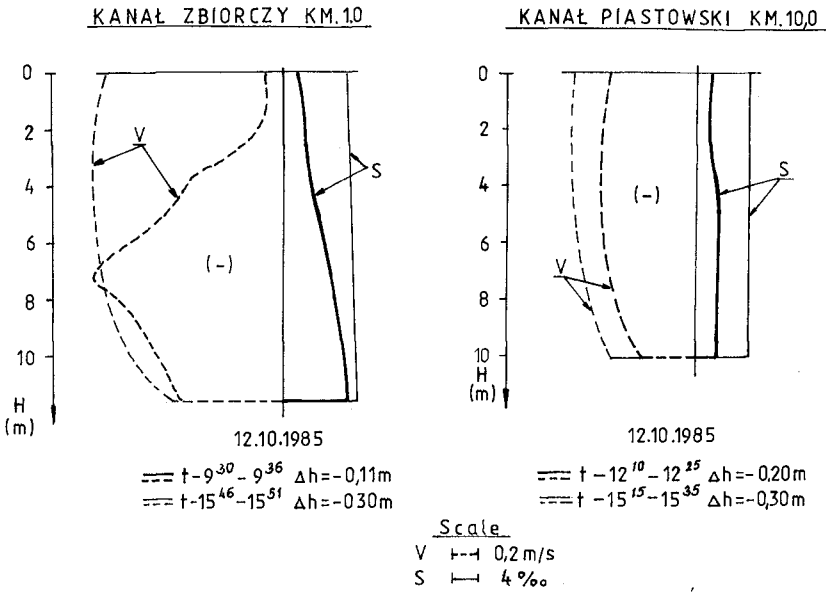

Fig. 4 Distributions of salinity and velocity at strong inflow in the Świna Strait

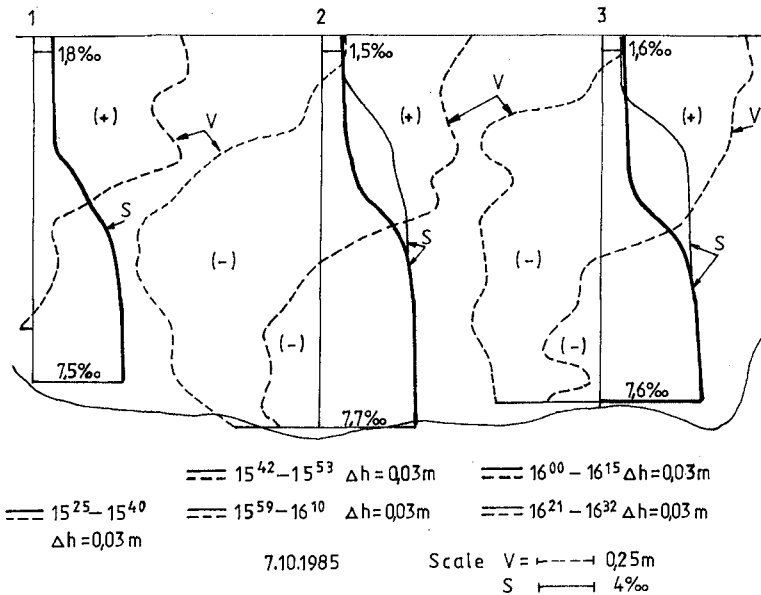

Fig. 5 Example of dynamic changes of flows and water salinity in cross-section, KZ - 1.00 km

Dynamic changes of flows are reflected in changes of water salinity (Fig. 5). As a result of a systematic increase of slope the salt water was gradually displaced out of the surface layers. Between 16.00 and 16.30 a sudden change in water salinity as well as in velocity was recorded within a few minutes. Measurements were taken directly succeeding one another and in vertical 3 an increase in the thickness of the salty layer from 5 m to 10 m (from the bottom) was recorded. The difference of water level between the two end of estuary changed from 0.0 m to 0.05 m and it was a typical example of salinity and velocity distributions under conditions of twodirectional flow of unsteady character.

When the water level difference between the sea and the bay under calm weather conditions is smaller than about 0.05 m the baroclinic pressure gradient has the main effect on the current causing two layer stratified flow. When the differences (Δh) are bigger than ± 0.05 m there is an outflow or inflow, when the differences are between $+ 0.05$ m and -0.05 m may take place outflow, inflow or twodirectional flow.

Sometimes fronts between the salt Baltic and the brackish bay water in horizontal and vertical plane appear. As a result of the intensive turbulence after inflow the salinity gradients in the vertical plane quickly disappear.

The Lupawa estuary is located in the middle part of the Polish Baltic Coast. In the lower part of the Lupawa river (Fig. 6) there is a shallow lake Gardno. The two km long section of the river joins the lake with the sea. Between the bridge (500 m from the mouth) and the sea there is a fish harbour Rowy. The river in this part is a harbour chanel with concrete walls on both sides. There is continuous dredging work in this region because of the strong sedimentation in the river mouth. The depths are 1.5 m to 2.0 m and the average width is 20 m.

Fig. 6 The Lupawa estuary

The measurements were carried out in May 1989 in the area between the lake and the sea. In Fig. 6 there are shown profiles and verticals where the measurements

were performed. The water levels in the lower part of the Łupawa during the measurements and in the period before were slightly changeable but had an oscillating character. The periods of oscillation were from a few minutes to several hours. The water level difference between the bridge and the sea were very small from + 0.12 m to - 0.03 m but most of them were close to zero. In May and particularly at the time of expedition winds were weak but changeable in their directions.

In spite of such small variations of water level and weak winds very substantial changes of flow conditions with strong inflows of salt waters into Łupawa estuary were noticeable. The flows were noticed in the whole profile towards the sea or towards the Gardno lake. The two-direction flows with a wedge of salt water were observed too. The existence of homogenous fresh or salt water in the whole profile was noticed. There were also completely or partially mixed waters with stratification. The salinity of the water in the Łupawa estuary changed from 0.8‰ to 9.2‰ (Jasińska 1990).

As an example of the penetration of salt water into the Łupawa estuary the situation observed on May, 15th is presented (Fig. 7 and Fig. 8). At the almost zero gradient of the barotropic pressure there was a typical baroclinic inflow. At 8 o'clock in the morning there was a beginning of a set of measurements in the profiles and verticals. The measurements were started in profile 400 m towards the bridge, the velocities were small up to + 0.10 m/s, the salinity of water was about 1.2‰ in the whole area (Fig. 7). The wind was from NE with the velocity from zero to 2 m/s. Because of the observed change of flow conditions at 9.40 a set of continuous measurements was begun. It was made in profile 230 m in the vertical near the west pier.

During the first period only the salinity and water temperature were measured because the velocities were close to zero. The time of measurements in the whole vertical ($H = 1.90$ m) every 0.20 m was about three minutes. The inflow with the salinity changing at the bottom from 1.2‰ to 9‰ (Fig. 8) was registered. The conditions were changing very quickly and the whole process lasted to 11 o'clock. The velocities increased up to - 0.15 m/s at the bottom, but at the surface they were still close to zero. The water slope was almost constant close to zero and all the time was towards the sea. It appears from the continuous registration at profile 310 m that the direction of the flow was changed and it took place at 9.40 and again at 12.40 and the velocities were about - 0.10 m/s.

After 11 o'clock there was a gradual decrease in salinity in profile 230 m. The velocities there were close to zero. At 11.10 a new set of measurements was begun in the longitudinal profile in the Łupawa in order to define the range of inflow. The salt water filled the whole cross section of the Łupawa up to the profile 310 m (Fig. 7), further the salinity gradually decreased in the surface layer but at the bottom it was still about 9‰ in the distance - 100 m (above the bridge). The velocities changed from - 0.20 m/s near the sea to zero in the region of the profile 60 m. They were two-directional above the bridge. The water slopes were still very small.

The similar situations repeated a few times during the measurements. These results confirmed the intrusion of salt water into the tideless estuaries in spite of small variations of water level in the sea.

On basis of the results of field measurements the classification of the tested estuaries was performed. The estuaries are classified according to two basic quantities:

Fig. 7 The change of conditions of flow and salinity in the Lupawa - 15.05.1989

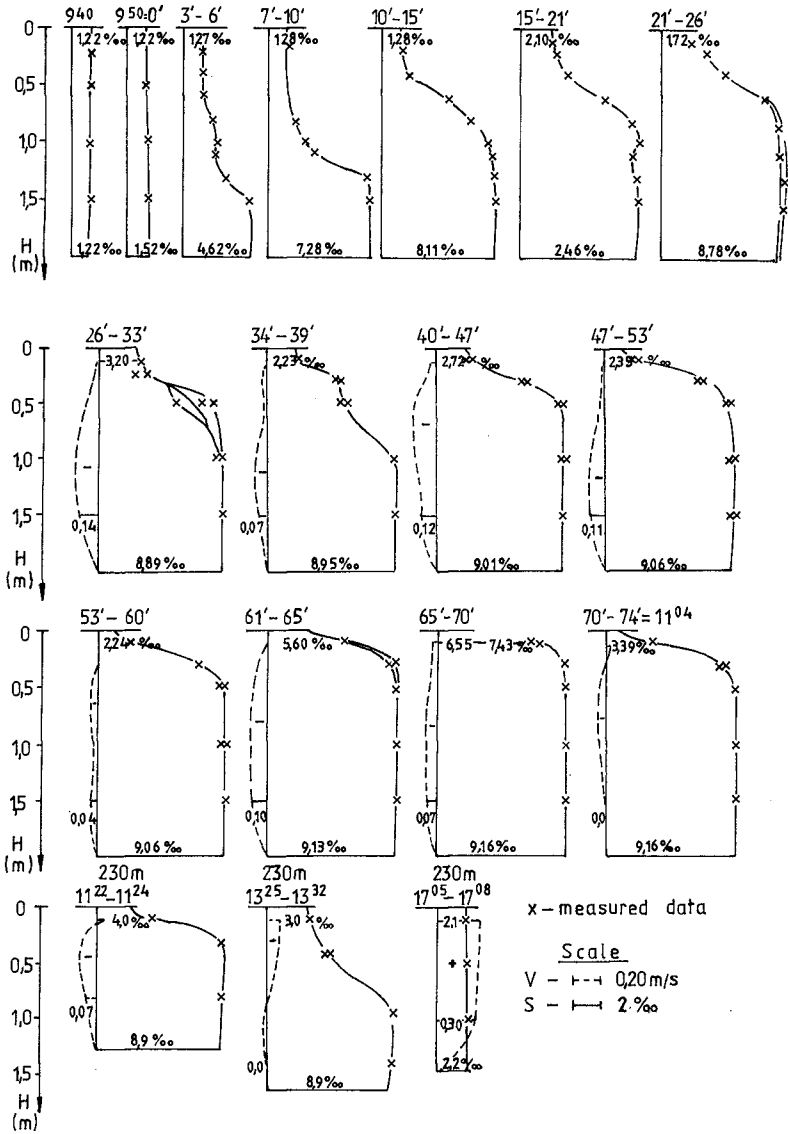

Fig. 8 The baroclinic inflow of salt water into the Lupawa - 15.05.1989

topography and structure of salinity. The estuaries along the Polish Baltic Coast are well or partially mixed and also temporary highly stratified with a salt wedge. The type of an estuary may change when there are changes in the river flow or in the dynamics of the inflow of the salt water.

3 RESULTS OF NUMERICAL SIMULATION

Parallely to the field measurements theoretical analysis and calculation based on one- two- and three- dimensional numerical models were carried out. First results were obtained from the onedimensional model. For this calculation it was necessary to determine the longitudinal dispersion coefficient. A method of determination of the longitudinal dispersion coefficient for a tideless estuary (Jasińska 1983) has been based on the Ippen and Harleman's (1961) approach made for a tidal estuary. The analysis of the field data has exposed a new dimensionless parameter L_u

$$L_u = \frac{D_o}{v_f Z}$$

where: L_u - the Estuary Number, D_o - the dispersion coefficient at $x = 0$, v_f - the fresh water velocity, Z - the distance in the seaward direction, where the salinity is equal S_o - sea water salinity. During an analysis of the field data it was found that the Estuary Number maybe correlated with the dimensionless values \bar{S}/S_o , v_f/v_s and Z/D charakterizing the estuary and its processes, where \bar{S} - instantaneous salinity averaged over the cross-section, v_s - the salt water velocity, D - the depth in $x = 0$. The correlations (Fig. 9 and Fig. 10) were established for the conditions of tideless estuaries along the South Baltic basing on the results from the field measurements of Leba and Dziwna. The effect of estuary depths, fresh water flow rate and changes in salt water in the flow into the estuary on the dispersion coefficient may be described from these correlations.

The complexity of the hydrodynamic regime and their threedimensional characteristics require the use of a threedimensional model in order to get better results. For the Odra estuary a threedimensional baroclinic model of high resolution in the vertical and horizontal plane (Duwe et al 1983, Pfeiffer and Duwe 1987) has been used for the simulation of hydrodynamic conditions and the movement of salt water. The adaptation and verification of this model were done for the Odra estuary (Jasińska and Nöhren 1988) using the data of the above mentioned measurement. The calculations were done in cooperation with the Institute of Oceanography Hamburg University. This model takes into account the horizontal momentum equations, the continuity equation, the transport of salinity and an equation of state. Hydrostatic equilibrium, kinematic boundary conditions at the free surface and Newton-Taylor bulk - formulas for wind stress and bottom friction are applied additionally. Detailed description of the model and its numerical scheme were done by Duwe et al. (1983).

The area of the model extends over the straits of Piana, Świna and Dziwna, the Szczecin Bay and the Odra to Gozdowice. The horizontal grid size of the rectangular net is 250 m as the main waterway through Szczecin Bay is 200 m to 300 m wide. In the vertical there are eight layers with a thickness of 2 m each. The time step is chosen to be 600 s, which is sufficient to resolve the dominant oscillations.

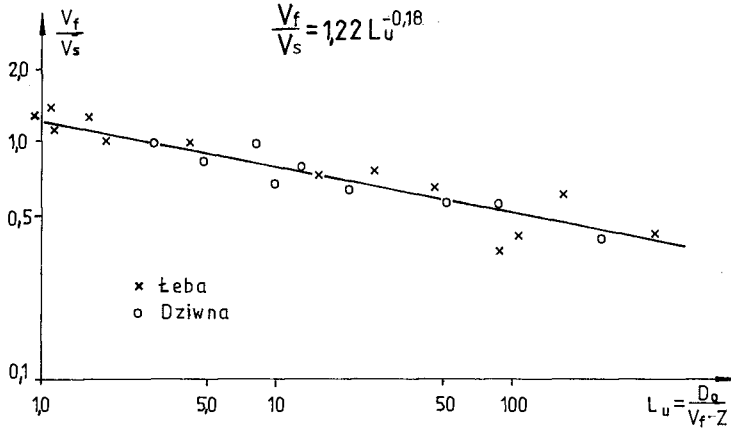

Fig. 9 Velocity distribution vs L_u

Fig. 10 Concentration vs L_u

Fig. 11 Changes of salinity and velocity at points KZ - 1 km and KP - 10 km

As a boundary conditions water level elevations and time dependent vertical salinity distributions were given at the boundary to the Baltic Sea (the mouth of Piana, Świna and Dziwna). At the landward open boundary the Odra discharge in Gozdowice was given. For the wind field, the data set was taken from the measurements in Świnoujście and was assumed to be uniform in space.

The comparison of the computation with the measurement data showed a good accordance, some results are present in Fig. 11. In the figure time series of velocity and salinity in the surface and bottom layers for the points Kanal Zbiorczy - 1.0 km and Karsibór 1 - 10 km are shown. The difference between measured and computed results is small. The measured velocities, their values and directions, are correctly reproduced by the computation. The agreement between measured and computed values for the salinity is also very good. There is a very well reproduced change of salinity in the vertical as well as in longitudinal direction.

Summarizing the results of calibration and verification it can be concluded that generally the flow phenomena and the motion of salt water in the Odra estuary are well reproduced by this model. The results will be applied to determination of boundary conditions for more detailed model of the subarea of the Odra estuary which is now being made in the Institute of Hydroengineering in Gdańsk. In future the model will be improved by additional data from field measurement and numerical studies in order to get a better insight into the dynamics of estuaries along the Polish Baltic Coast and possibility of forecast.

4 CONCLUSIONS

The above described study increased considerably the knowledge of the circulation and the transport processes in the tideless estuaries along the Polish Baltic Coast. It has been stated that the dynamics of the flow in tideless estuaries is similar to that of the tidal estuaries. In spite of very small changes in the gradients of barotropic pressure and of weak wind there are significant changes in the flow conditions. The intrusion of marine waters appeared not only at a storm surge but also during calm weather conditions. During calm weather a weak balance of the barotropic and baroclinic pressure gradients is present which yields changeable inflow and outflow conditions. Under these conditions the intrusion of salt water in the tested estuaries is probably caused by the change of pressure conditions above the Baltic Sea. It is very difficult to define and predict the flow conditions when the water slope is small what happens very often. Under such conditions there may be an outflow, inflow or two-directional flow.

The continuous measurement showed how unsteady the flow conditions are. The velocity and salinity distributions in the tested estuaries demonstrate that the change of current direction occurs at different depth and different times, thus there is a need of threedimensional numerical modelling. The applied threedimensional numerical model reproduces the flow phenomena and the motion of salt water in the Odra estuary very well.

The model can be advised for design and exploitational purposes as well as for the analysis of transport problems. It is planned to develop a separate section model for the Świna Strait with the boundary conditions obtained from the whole Odra estuary model which has been already verified.

CHAPTER 218

COASTAL LAGOON ENTRANCE DYNAMICS

A D GORDON¹

1. INTRODUCTION

The coastline of New South Wales (NSW), Australia features numerous lakes and lagoons. The ocean entrances of the lakes tend to be continuously open to the sea. The lagoons, however, experience only intermittent periods of ocean influence following breakouts across the beach. Although the lagoons and their catchments vary markedly in size and overall geometry their hydraulic behaviour is remarkably similar. This is particularly true of their entrance dynamics.

The lagoons, which are the subject of this paper, were formed during the Holocene sea level rise in embayments where the onshore movement of sand impounded small estuaries behind the coastal sand barriers (Roy 1984). They are generally 1 to 2m deep, have a water surface area of between 3 and 300 ha and are located in catchments ranging in size from 5 to 40 km².

The main lagoon water body is generally located immediately landward of the ocean beach and foredune system. It can become connected to the sea if the sand barrier is breached by natural or mechanical means. Following barrier breaching the lagoon becomes tidal

¹Manager, Manly Hydraulics Laboratory, Public Works Department, NSW, Sydney, Australia.

until, after a time, the entrance is resealed with a sand plug transported into the mouth by the interaction of ocean tide and wave processes.

Because there has been a history of building waterfront housing on the shorelines of these lagoons, social pressures have developed for the control of both lagoon water quality and of the low lying land around the lagoon.

These issues can be related to the lagoon water balance and entrance behaviour. The more frequently the entrance is open to the sea, the better the water quality and the lower the frequency of high flood levels. The desire for lagoon management has in turn generated a need to develop a better understanding of the processes governing entrance dynamics and lagoon water level behaviour.

2. FIELD STUDIES

Studies of both the lagoon water balance and the entrance behaviour were commenced in the mid 1970's on a small lagoon at Dee Why, a northern beach suburb of Sydney (Gordon 1981). This lagoon has a water surface area of 25 ha and a catchment area of 5 sq km. The catchment is undulating sandstone country, much of which has been developed for residential and commercial purposes. During the studies twenty-five lagoon breakouts and closures were observed, of which five were studied in detail. Information on the lagoon water balance was based on water level data obtained from an automatic water level recorder, a network of rainfall gauges in the catchment and a study of the phreatic line through the dune barrier and beach.

In the mid to late 1980's these studies were extended to a lagoon at Narrabeen, 3km north of Dee Why (Kulmar et al, 1989). Narrabeen Lagoon has a surface area of 250 ha and a catchment of 55 sq km. The catchment is principally sandstone country however only some 30 per cent of the catchment has been developed, the remainder is natural bushland. Between 1984 and 1988 twenty-one breakouts and closures were observed at Narrabeen. Nine of these events were studies of which three of the

breakouts and four of the closures were examined in detail. Lagoon water levels were continuously recorded through the study period by an automatic water level gauge. Rainfall records were available for the catchment from a network of gauges. In addition, weekly photographs of the entrance configuration were taken from a nearby headland which overlooks the entrance.

More recently, information has become available for a larger lagoon (Aber and Downey, 1989). This lagoon is Lake Wollumboola, on the South Coast of New South Wales some 130 km south of Sydney. It has a surface area of 650 ha and its catchment consists of sandy barrier deposits backed by clay slopes. The catchment is mainly natural bushland.

3. MODEL STUDIES

During the late 1970's a three dimensional moving bed model of a lagoon entrance was constructed at Manly Hydraulics Laboratory using fine beach sand ($D_{50} = 0.16\text{mm}$) placed in a 3m x 4m x 0.3m model basin. An entrance sand plug was established and then the water level raised on the lagoon side until overtopping occurred. The "breakout" channel development observed in the model displayed similar characteristics to that observed at the prototype lagoon entrances, however, difficulty was experienced in appropriate selection of model scales to achieve simultude throughout the entire breakout sequence.

4. LAGOON WATER BALANCE

There are two distinct water balance regimes for the coastal lagoons. The first is the tidally dominated condition; entrance open (Figure 1(a)). The second regime is governed by the balance of inflows and outflows which occurs when the entrance is closed (Figure 1(b)).

4.1 Entrance Open

With the the entrance open the lagoon water level behaviour is determined by the tidal forcing at the

ocean entrance and by the occasional flood (fresh water) event. The tidal phase lag and head loss through the entrance channel combine to superelevate the mean daily water surface of the lagoon (see Figure 2).

Figure 1 Lagoon Water Balance

The superelevation varies over 28 days from a high during the spring to a low during the neap tide cycles; this spring tide pump-up effect is a subtle but important factor in the ecology and sediment process of the lagoon. During the spring tide period the superelevation typically is of the order of 0.4m while during the neaps it is 0.2m.

Figure 2 Lagoon Tidal Superelevation

Other factors such as ocean storm events producing storm surge at the entrance and wave setup in the surf zone adjacent to the entrance, can also superelevate the mean water level for a period of days. For the NSW lagoons this can produce an increase of some 0.3m in excess of the tidally induced superelevation.

In addition, there appears to be evidence of a weak seasonal periodicity in superelevation. This is thought to be caused by seasonal variations in mean air pressure due to the northward shift of the low pressure belt during winter and to seasonal changes in the ratio of onshore/offshore winds.

4.2 Entrance Closed

With the entrance closed the mean lagoon water level is dictated by the inflows - stream, groundwater and direct rainfall on the lagoon's water surface; and the outflows - evaporation and percolation through the sand barrier to the ocean (Figure 1(b)). During the period immediately following closure wave overtopping of the entrance sand bar can also provide a short term inflow mechanism. These factors generally produce lagoon water level between 0.8m and 1.4m above mean sea level, with the entrance closed.

Percolation losses through the barrier sand deposit, including the entrance bar is a function of the lagoon water level and the tailwater conditions on the ocean side of the sand barrier. This latter factor is determined by the ocean tide, wave run up and wave set up on the beach. The combined effect of these factors produces an effective tailwater level which is generally elevated between 0.5 and 1.6m above MSL (Figure 3).

Figure 3 Phreatic Surface

5. ENTRANCE BREAKOUT

Two types of breakout have been observed: mechanical opening using earth moving equipment; and natural breakout. This paper concentrates on the latter mechanism.

Natural breakout is associated with lagoon overtopping of the entrance barrier as a result of rainfall runoff from the catchment. Ocean wave action tends to close rather than open an entrance (Gordon 1981).

For the natural breakout case, three distinct stages have been identified (Figure 4):

- * the initiation channel stage (IC), Froude No. <1
- * the weir/hydraulic jump stage (WHJ), Froude No. >1
- * the river flow stage (RF), Froude No. <1

Figure 4 Three Staged Behaviour of Breakout

5.1 The Initiation Channel

At first bar overtopping occurs as a thin sheet. This flow only extends a short distance downslope on the ocean side of the barrier before it is absorbed into the beach. Gradually as overtopping increases a preferred scour channel develops from the crest, down the slope towards the ocean. Once the channel becomes

established bed slope adjustment takes place from the downstream end (Gordon 1981).

In the early part of this first stage the scour rate is low because threshold conditions are only marginally exceeded. As the stage develops however bed ripples, and then small dunes, develop and the Froude No. of the flow approaches unity. The formation of a sand delta at the channel discharge point in the swash zone of the beach, and bank collapses, can result in local slope flattening which produces choking of the channel. At this stage of the breakout flood tide and/or wave conditions may seal the initiation channel causing the breakout to fail, particularly if the runoff from the catchment reduces. If, on the other hand, runoff continues, the scour channel will develop.

For the two lagoons where this process has been repeatedly observed, Dee Why and Narrabeen, the initiation stage generally takes between 80 and 100 minutes. The factors which control time for this stage include: rate of rise of lagoon water level, the differential head between the lagoon and the ocean water level, porosity of beach, width and cross-sectional shape of the barrier at the entrance and the wave conditions. Towards the end of the IC stage the channel width is generally 1 to 2m, the flow depth is 0.2 to 0.25m and the velocity 1.4 to 1.5m/sec.

5.2 The Weir/Hydraulic Jump

Stage two develops quite rapidly. A semi circular weir forms in the sand at the upstream end of the channel, the flow becomes supercritical on the crest and a plunge pool and a series of undulating hydraulic jumps develops downstream. The unsteady downstream flow conditions caused by the undulating jumps initiates a series of bedforms which progressively become steps in the channel (Figure 5). The flow accelerates on the downstream face of these steps and a standing roll wave develops at their base. Bed scour is most pronounced on the downstream face of the steps and hence they are translated up the channel towards the plunge pool. As each step arrives at the plunge pool there is a sudden increase in weir face erosion and hence the weir is

Figure 5 Breakout Channel Geometry

translated further inland. The channel then re-adjusts and a new step forms at the downstream end. Hence channel bed slope adjustment translates upstream from the downstream end.

An interesting feature of the weir geometry is that it is determined by the minimum specific energy condition, that is it forms an efficient dam spillway crest shape (Gordon, 1981). Discharge can be approximated using the weir formula:

$$Q = 3.97LH^{3/2}$$

Where H is the lagoon water level height above the crest and L is the length of the crest.

The principal factors which determine the duration of the WJH stage include: lagoon water level; ocean water level; and the width and cross-sectional geometry of the barrier. Wave action has little impact during the WHJ stage. The outflow is sufficiently energetic that it dominates the normal nearshore surf zone processes.

Velocities in the channel are in the range 3 to 4 m/s with peak short term velocities of 6 m/s. The Froude

No. is generally between 1.2 and 1.8; hence the undulating jump formation. The stage usually lasts between 100 and 140 minutes. Figure 6(a) which is based on data gathered for the WHJ stage of the three lagoons studied, summarises the development in mean channel width downstream of the plunge pool while Figure 6(b) presents the cumulative volume of sand removed over time.

Figure 6 Channel Characteristics, WHJ Stage

5.3 River Flow Stage

The final stage is reached approximately 180 to 240 minutes after overtopping first commences. The weir feature completes its upstream translation through the barrier and disappears. The Froude No. reduces to below unity and a steadier flow regime is established. However, scour of the channel continues for as long as threshold conditions are exceeded. The larger the lagoon and/or the runoff event the greater the final channel width. Of the three stages, this is the only one whose duration is in part dependent on the lagoon and catchment size. As the head level difference between the lagoon and the ocean decreases, the discharge reduces. Within a matter of hours the lagoon becomes tidally dominated and the entrance starts to infill.

5.4 Breakout Sediment Transport

Different approaches are required for the three stages. The IC stage is mainly bedload dominated, transport capacity is rapidly achieved, however, percolation losses into the adjacent beach berm and intermittent bank slumping are important considerations.

Stream flow during the WHJ stage is highly energetic with Froude Nos. from 1.5 up to 2 and is therefore outside the domain of most existing theories. Visser (1988) has developed an interesting approach for dike-burst. Based on a modified Bagnold (1966) formulation, the Visser approach includes an expression for calculation of the progressive sediment load uptake in a channel. The approach can be summarised as:

$$S(x) = \frac{x}{l_a} S_s \quad \text{where } S(x) \text{ is the sediment load transport and } x \text{ is the distance down the slope}$$

$$l_a = \frac{q}{w \cos \beta} \quad \begin{array}{l} \text{where } q \text{ is the discharge per unit width} \\ w \text{ is the fall velocity} \\ \beta \text{ is the slope angle} \end{array}$$

$$S_s = \frac{e C_f u^4}{(1-p)\Delta g w \cos^2 \beta}$$

where e is the efficiency factor

C_f is the bedform drag

u is the depth averaged velocity

p is the porosity

Δ is $(\rho_s - \rho) / \rho$

g is gravity

While the Visser formulation is conceptually attractive, it is highly sensitive to the value of stream velocity. Unfortunately, this variable is the most difficult to measure during the energetic WHJ stage. Coupled with the need to determine relevant values for C_f and e , the velocity sensitivity has to date hampered evaluation of the Visser approach. Further, it is felt that the differences in channel slope (Visser case $\beta = 14^\circ$, Lagoon case $\beta = 1.5^\circ$) and

hence velocities (Visser case $u = 20$ m/s, Lagoon case $u = 4$ m/s) and bedform size (Lagoon channel bedform height ≈ 0.5 depth) requires some modifications of Visser's assumptions to adapt the approach to the WHJ stage.

Sediment transport during the RF stage can be satisfactorily assessed using a traditional approach such as that of Ackers and White (1973).

6. ENTRANCE CLOSURE

Infilling of the entrance channel commences on the first flood tide following breakout. Initially infilling is rapid (Figure 7). During flood tides the wave stirring in the surf zone adjacent to the entrance entrains sediment which is then available to be transported into the entrance by the tide and deposited in the entrance channel. In addition, wave obliquity on the beach face at the entrance combined with wave overwash into the channel across the beach, erodes material from the beach berm and deposits it along the channel edge.

On the ebb tide, however, as the impact of wave stirring on re-entrainment of the sediment in the entrance is limited to the downstream region of the mouth, the outflowing water is unable to achieve a

Figure 7 Entrance Plug Re-establishment

matching removal of sand. Thus, there is a net imbalance favouring flood tide transport of sediment into the lagoon. Progressively an hydraulic choke which limits the tidal prism, develops in the entrance.

The flood tide imbalance is exacerbated by the asymmetry of the flood and ebb tidal flows. Flood tides produce relatively high velocities near the peak flow of the tide as compared with the ebb tide which generates longer lasting but lower flow conditions (Kulmar et al, 1989). The relationship between flow velocity and sediment transport being highly non-linear, the flood tide produces a greater transport of sediment than the ebb. Hence the channel trends towards closure under normal oceanographic and meteorological conditions.

As the entrance choke develops, the channel starts to meander across the beach berm. The wave obliquity prevailing at the time causes the channel to be deflected in a down drift direction. The slope of the channel reduces as the meander length increases. This in turn reduces tidal velocities hence entrance shoaling is accelerated.

Because of the relative sensitivity of the entrance behaviour to the prevailing wave and tidal conditions, daily changes in entrance geometry are often significant. These changes are so rapid that to date, numerical simulation of entrance behaviour has not proved a practical proposition for anything other than a short period of time. Winton and Mehta (1981) have developed a numerical model, based on the Bruun approach (1978), which can however be usefully applied to predict the rapid lagoon closure situation associated with storm wave events.

Modelling of entrance behaviour for those lagoons which experience extended periods of opening is further complicated by freshwater flood events; storm surge events; and by the spring/neap pump-up effect. Intermittent freshwater floods produce entrance scour which reverses the normal closure trend. A storm surge and/or wave setup event initially produces a net inflow of water and sediment into the lagoon. However, on the

falling stage it can also result in entrance scour as the lagoon level returns to normal. The spring tide pump-up phenomenon produces a similar effect.

The time a lagoon is open is dependent on the the tidal prism of the lagoon and the gross sediment transport environment of the adjacent beach. At Dee Why the average time the lagoon was open was found to be 17.5 days (Gordon, 1981). While at the larger Narrabeen lagoon the average time was 89.2 days (Kulmar et al, 1989). The sensitivity of entrances to the variable oceanographic and meteorological conditions can be illustrated by examining the standard deviations and range of the times for which the entrances are open. For Dee Why the standard deviation was found to be 13 days and the range was 2 to 44 days. At Narrabeen the standard deviation was 122 days and the range was 5 to 365+ days.

With the channel in a choked condition, closure can occur quite suddenly; commonly over one tidal cycle. Closure is normally associated with any one, or any combination of the following: a flood tide, a storm surge event, elevated wave energy conditions, the spring tidal cycle and low rainfall in the catchment. Once the entrance is closed, the plug rapidly develops over a period of 10 days after which the crest height is at an elevation of 1.4 to 1.6m above sea level; the normal elevation of wave uprush (see Figure 7). After this initial rapid build up the rate of plug development substantially reduces. Aeolian processes take over as the dominant formation mechanism, assisted at times by wave uprush during spring tides and/or storm waves. The plug gradually assumes the geometry of the surrounding beach berm with its crest level at an elevation of between 2 and 3m above mean sea level.

7. DISCUSSION

Investigations to date have concentrated on developing an overall conceptual understanding of lagoon water level behaviour and entrance dynamics. Further studies are planned to examine breakout sediment transport in more detail.

CHAPTER 219

Extent of Contaminated Marine Sediments and Cleanup Methodology

John B. Herbich, Ph.D., P.E.¹

Abstract

The problem of contaminated marine sediments has emerged as an environmental issue of national importance. Harbor areas in particular have been found to contain high levels of contaminants in bottom sediments due to wastes from municipal, industrial and riverine sources. The paper examines the extent and significance of marine sediment contamination in the United States; reviews the state-of-the-art of contaminated sediment cleanup and identifies research and development needs.

Introduction

Contamination of marine sediment in all areas of the world, particularly in the shallow water areas, poses a potential threat to marine resources and human health. Improving the capability to assess, manage and remediate these contaminated sediments is critical not only to the well-being of the marine environment but as well as to its use for navigation, commerce, fishing, and recreation.

This paper concentrates on the problem of contaminated marine sediments in U.S. waters which has emerged as an environmental issue of national importance. The summary is based on the results of the study conducted by a Committee on Contaminated Marine Sediments of the Marine Board, Commission on Engineering and Technical Systems, National Research Council. Members of the Committee were: Kenneth S. Kamlet (Chairman), A.T. Kearney, Inc., Williams J.

¹Director, Center for Dredging Studies, Holder of W. H. Bauer Professorship, Civil Engineering Department, Texas A&M University, College Station, TX 77843-3136, USA.

Adams, Monsanto Company, A. Karim Ahmed, Environ Corporation, Henry J. Bokuniewicz, State University of New York, Thomas A. Grigalunas, University of Rhode Island, John B. Herbich, Texas A&M University, Robert J. Huggett, College of William and Mary, Howard L. Sanders, Woods Hole Oceanographic Institution, and James M. Thornton, Department of Ecology, State of Washington. Charles A. Bookman is the Director of the Marine Board.

The expertise of the members of the Committee spanned the fields of aquatic toxicology, dredging technology, resource economics, sediment dynamics and transport, benthic ecology, environmental law and public policy.

The nature of the problem has resulted from using coastal waters, intentionally or unintentionally, for waste disposal for many decades. Confined or partly confined areas where low wave and current energies are present (such as harbors) contain high levels of contaminants in bottom sediments due to wastes from urban, industrial and riverine sources. Such areas where flushing action is unlikely (except during hurricanes) have accumulated contaminants which may now be buried by fine sediment deposits of recent years that contain no, or low levels of contaminants.

Legislative authority for the management of contaminated marine sediments falls largely under three statutes: the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA), the Marine Protection, Research, and Sanctuaries Act (MPRSA), and the Clean Water Act (CWA). The Comprehensive Environmental Response Compensation and Liability Act of 1980, as amended by the Superfund Amendments and Reauthorization Act (SARA) of 1986, is aimed at the cleanup and remediation of inactive or abandoned hazardous waste sites, regardless of location. Superfund sites are currently ranked by the Environmental Protection Agency (EPA) based on the hazard they may pose to human health and the environment via releases to groundwater, surface water, and air. Underwater accumulations of hazardous wastes in marine environments are unlikely to threaten human health except by way of food chain exposure, which is not currently addressed in EPA's hazard-ranking process. Under the 1986 Superfund amendments, however, EPA was required to modify its Hazard Ranking System to address "the damage to natural resources which may affect the human food chain and which is associated with any release (or a hazardous substance)" S(Section 105(a)(2)).

Meanwhile, the Clean Water Act of 1970, as amended by the Water Quality Act of 1987, gives EPA lead responsibility for safeguarding the quality of U.S. coastal and inland waters. This includes regulating the disposal of dredged and fill materials (shared with the U.S. Army Corps of Engineers, under Section 404), and removing in-place toxic pollutants in harbors and navigable waterways (under Section 115). The 1987 amendments added new authorities requiring EPA to study and conduct projects relating to the removal of toxic pollutants from Great Lakes Bottom sediments (Section 118(c)(3)); and to identify and implement individual control strategies to reduce toxic pollutant inputs into contaminated waterway segments (Section 304(1)).

In response to Title II of the Marine Protection, Research, and Sanctuaries Act of 1972 (PL 92-532) and the National Ocean Pollution Planning Act, the National Oceanic and Atmospheric Administration (NOAA) Office of Marine Pollution Assessment conducts comprehensive interdisciplinary assessments of the effects of human activities on estuarine and coastal environments. Among these assessment activities is the National Status and Trends Program (NST), which attempts to create, maintain, and assess a long-term record of contaminant concentrations and biological responses to contamination in the coastal and estuarine waters of the United States. This assessment provides some insight into the extent of contamination nationally.

As a result of legislative responsibility and programmatic interests, a wide variety of federal agencies have shown active interest in this subject. EPA's responsibilities under Superfund and the CWA are the source of its interests in water quality concerns and remediation of uncontrolled hazardous waste sites. The U.S. Army Corps of Engineers (COE) is involved because of its responsibility to dredge and maintain navigable rivers and harbors. The COE also assists in the design and implementation of remedial cleanup actions under Superfund. NOAA has responsibility for assessing the potential threat of Superfund sites to coastal marine resources as a natural resource trustee as well as under its NS&T program. The U.S. Fish and Wildlife Service has legal authority for various endangered coastal species, food chain relationships, and habitat considerations, all of which are potentially impacted by contaminated sediments. The Navy has had experience in assessing contaminated sediments and now must grapple with such problems in locating and maintaining homeports for Navy vessels.

Procedure

There are many definitions of contamination of sediments. The Committee defined the contaminated sediments for the purpose of the study as follows:

"Contaminated sediments are those that contain chemical substances at concentrations which pose a known or suspected environmental or human health threat."

A symposium and a workshop was organized to examine the extent of contamination nationwide, the methods for classification of sediment contamination, risks to human health and the ecosystem, sediment re-suspension and contaminant mobilization, remedial strategies and technologies for handling contaminated sediments. In addition, five case studies were examined of the different ways in which a variety of sediment contamination problems are being handled. They include the PCB problem in New Bedford Harbor, Massachusetts; PCBs in the upper Hudson River, New York; kepone contamination of the James River, Virginia; the variety of chemicals contaminating Commencement Bay, Washington; and the Navy Homeport Project in Everett Bay, Washington.

The main purposes of the study included a) examination of the extent and significance of marine sediment contamination, b) a review of the state-of-the-art of contaminated sediment removal and remediation technology, c) identification and appraisal of alternative sediment management strategies, and d) identification of research and development needs and issues for future technical assessments (Marine Board, 1989).

Extent of Contamination

Many contaminated marine sediments are found along all coasts of the contiguous U.S., both in local "hot spots" and distributed over large areas. There is a wide variety of contaminants including: heavy metals, polychlorinated biphenols (PCBs), DDT, and polynuclear aromatic hydrocarbons (PAHs). At present, there are no generally accepted sampling techniques or testing protocols.

Classification Methodologies for Determining Sediment Contamination

There have been some research efforts in classifying the extent of contamination and some States have collected data for special purposes. No uniform

methods have been adopted by various State of Federal agencies.

A variety of classification methods are available:

- a) Sediment bioassays - sediment toxicity on a crustacean, infaunal bivalve and infaunal polychaetes. Essentially marine life is subjected to various levels of toxicity and their survival noted.
- b) Sediment quality triad:
 - 1) contamination quantified by chemical analysis,
 - 2) toxicity determined by laboratory bioassays, and
 - 3) benthos community structure determined by taxonomic analysis of biofauna.
- c) Apparent effects threshold technique equilibrium partitioning (AET) - A tool for deriving sediment quality values for a range of biological indicators to assess contaminated sediments. The AET is the contaminant concentration in sediment above which adverse effects are always expected for a particular biological indicator.

Recommendations

To ensure that decision making is informed and scientifically based, continued research and use of assessment methodologies should provide information to determine:

- a range of concentrations of chemicals in sediments that will result in biological effects, and
- whether in-place sediments are causing biological impacts.

A tiered approach to the assessment of contaminated sediments should be used. The approach would progress from relatively easy and less expensive (but perhaps less definitive) tests to more sensitive methods as needed.

Contaminated Sediment Management Strategies

Although the dredged material management strategy developed by the Corps of Engineers may be relevant to severely contaminated sediments, it is important from a management standpoint to differentiate them from less contaminated sediments. In particular, most

highly sophisticated remedial technologies (i.e, those involving treatment or destruction of associated contaminants) are likely to be cost-effective only in small areas and for sediments with relatively high contamination levels. Sediment contamination problems often involve large volumes of sediment with relatively low contamination levels. As a result, some highly sophisticated technologies may be inapplicable or inefficient for remediating contaminated sediments.

"No action" may be the preferred alternative in cases in which the remedy may be worse than the disease - e.g., where dredging or stabilizing contaminated sediments results in more biological damage than leaving the material in place. Contaminants generally accumulate in depositional zones, and, if the source is controlled, new clean sediments will deposit and cap the contaminated material over time. In effect, no action alternatives in such cases may result in natural capping.

1. No action may be an acceptable option if the contamination degrades or is buried by natural deposition of clean sediment in a short period of time.

2. In-place capping may be a useful option if the sediments are not in a navigation channel or if groundwater is not flowing through the site.

3. Removal and subaqueous burial off-site may be a viable option, although the experience with this technique is limited to relatively shallow water (less than 100 ft).

4. Incineration seems to be viable only for sites with relatively small amounts of sediments containing high concentrations of combustible contaminants.

5. Other techniques to assist in remediation of contaminated sediment may be appropriate in special cases. Examples include a variety of sediment stabilization or solidification techniques, and biological and/or chemical treatment.

Recommendations

- Additional evaluation should be conducted to determine the applicability of the Corps of Engineers' dredged material management strategy to more severely contaminated sediments.

- No action should always be considered as an alternative strategy for minimizing biological damage. In using the no-action strategy as a form of natural capping of contaminated material, consideration should be given to the length of time it takes for contaminants to be isolated from the food chain.

Remedial Technologies

From a remediation standpoint, the most important factors are likely to be a definition of the clean-up target, technical and cost feasibility, natural recovery estimates, and ability to distinguish and/or control continuing sources of contaminants.

Dredging technology exists that is capable of greatly reducing turbidity and resuspension in connection with dredging of bottom sediments in most applications (Herbich and Brahme, 1990).

The selection of proper dredging equipment is important to achieve an efficient removal of contaminated sediments, and to prevent additional contamination generated during dredging. The selection depends on a number of factors:

- 1) characteristics of sediments,
- 2) quantity of sediments to be removed,
- 3) degree of contamination,
- 4) toxicity of contaminants,
- 5) location,
- 6) environmental conditions at the site (waves, currents, tides, etc.),
- 7) distance to the disposal site,
- 8) type of disposal, and
- 9) availability of particular equipment.

Since conventional type of dredges designed for removal of large volumes of sediment are generally not suitable for small operations to remove pockets of contaminated sediments, special purpose dredges have been developed to dredge contaminated sediments while minimizing sediment resuspension and contaminant release. The specialty dredges may be placed in three categories:

1. mechanical - watertight clamshell,
2. mechanical-hydraulic - Mud Cat, remotely controlled Mud Cat, and clean-up system,
3. hydraulic - Refresher, waterless, matchbox, and wide sweeper, cutterless dredge, and
4. pneumatic - Pneuma and Oozer.

Watertight clamshell. A watertight clamshell was developed in Japan (Figure 1) and evaluated by the U.S. Army Engineer Waterways Experiment Station (Hayes et al., 1988). Experiments indicated that the watertight bucket significantly reduced water column turbidity.

Figure 1. Open and closed positions of the watertight clamshell bucket

Mud Cat. The Mud Cat has a horizontal cutter-head equipped with knives and spiral augers that cut the material and move it laterally toward the center of the augers where it is picked up by the suction. The dredge can remove sediments in a 2.6-m width and in water depths up to 4.9 m. The dredge operates on anchor cables, and the manufacturer claims that it leaves the bottom of the dredged area flat. By covering the cutter-auger combination with a retractable mud shield the amount of turbidity generated by Mud Cat's operation can be minimized.

Remotely-controlled Mud Cat. A remotely-controlled unit has been developed in which the control cab is located on land and is remotely connected to the Mud Cat by an umbilical cord. This allows safe dredging of hazardous or toxic materials. The remote control provides the shore-based dredge master with a variable traversing winch control, a variable auger control, a variable dredge pump speed control, and a manually-controlled emergency shut down.

The "Clean-up" System. The clean-up head consists of a shielded auger that collects sediment as the dredge swings back and forth and guides it toward the suction of a centrifugal pump. The auger is shielded and a moveable wing covers the sediment as it is being collected by the auger. An underwater TV camera and sonar devices indicate the topography of the bottom (Figure 2). Fairly large volumes have been excavated by "Clean-up" dredges in soft muds and sand containing various contaminants such as mercury, cadmium, PCBs, oily and organic substances (Sato, 1984).

Figure 2. The "Clean-up" system (Sato, 1984)

Refresher. The material being dredged is confined by a specially-designed flexible enclosure that completely covers the cutter, preventing escape of sediments to the outside of the immediate dredging area (Figure 3). The working open section is always on the swing side of the cutterhead. A gas removal system is also installed and can be activated as needed to prevent gas moving up the suction pipe. The flexible enclosure of the cutterhead is automatically adjusted to bottom contours (Figure 4) (Shinsha, 1988).

Figure 3. "Refresher" dredge (Shinsha, 1988)

Figure 4. Description of a "Refresher" dredge (Shinsha, 1988)

Matchbox dredge. A special suction head was developed by a dredging contractor in the Netherlands to replace the traditional cutterhead (d'Angremond et al., 1984). The main design points are as follows:

1. A large plate covers the top of the dredge head to avoid inflow of water and escape of gas bubbles.
2. Adjustable angle between the drag head and the ladder to create an optimum position of the drag head independent of the dredging depth.
3. There are openings on both sides of the drag head to improve dredging efficiency. During swinging action the leeward side is closed to prevent water inflow.
4. Dimensions of the head must be carefully designed for the average flow rate and swing rate.

A direct comparison between a Matchbox suction head, a conventional cutterhead and a clamshell was made by the Waterways Experiment Station in Calumet Harbor (Hayes et al., 1988). The Calumet Harbor demonstration indicated that the clamshell dredge generated the largest suspended sediment plume affecting the entire water column. The cutterhead slightly outperformed the Matchbox dredge in this field experiment.

Pneuma pump. The Pneuma pump is a compressed-air-driven, displacement-type pump with several major components (Herbich, 1975). The pump body, the largest of these components in dimensions and weight, incorporates three large cylindrical pressure vessels, each having a material intake on the bottom and an air port and discharge outlet on top. Each intake and discharge outlet is fitted with a check valve, allowing flow in one direction only. Pipes leading from the three discharge outlets join in a single discharge directly above the pressure vessels. Different types of attachments may be fitted on the intakes for removal of varying types of bottom material. Pneuma pump was evaluated by the U.S. Army Engineer Waterways Experiment Station (Richardson et al., 1982).

Oozer dredge. The Oozer pump was developed by Toyo Construction, Japan. The pump operates in a manner similar to that of the Pneuma pump system; however, there are two cylinders (instead of three) and a vacuum is applied during the cylinder-filling stage when the hydrostatic pressure is not sufficient to rapidly fill the cylinders. The pump is usually mounted at the end of a ladder and equipped with special suction heads and cutter units depending on the type of material being dredged. The conditions around the dredging system, such as thickness, bottom elevation after dredging, and amount of resuspension, are monitored by high-frequency acoustic sensors and an underwater television camera. A large Oozer pump has a dredging capacity ranging from 300 to 500 m³/hr. During one dredging operation, suspended solids levels within 3 m of the dredging head were all within background concentrations of less than 6 mg/liter.

Recommendations

• Source control measures must be considered in all cases, including no action. Federal and state regulatory agencies requiring remedial action should implement source control measures as a component of remedial action when applicable and appropriate. Use of financial incentives through strict liability for assessment cost, remedial actions, and damages also may

play an important role in source control, provided that trustees make aggressive efforts to hold responsible parties liable for releases into the environment.

- Aggressive technology and information transfer mechanisms are needed to ensure that knowledge gained and lessons learned from all remedial actions are available and accessible to managers confronting new remediation problems at federal, regional and local levels. Knowledge gained should be systematically compiled in guidance documents. Lessons learned regarding the feasibility of sophisticated remedial technologies under varying conditions of contamination severity and extent should be documented and made widely available to facilitate future decision making. Lastly, experience gained through the use of screening procedures at large sites should be distilled and generalized into routine methodologies for economically assessing smaller sites.

- When possible, remediation projects should be designed to take advantage of existing navigational dredging activities that may already be authorized in conjunction with the Clean Water Act, Section 115 or Section 10/404.

- Research and development should be encouraged by the federal government to develop technology and equipment for efficiently removing contaminated sediments and to make it available in the United States. Foreign technologies should continue to be examined relative to their appropriateness in this country. Efforts to conduct and fund research and development as a partnership between government and industry should be encouraged.

- Although capping might not, in the strictest terms, be considered a remedial technology, it should not be ignored because it can play a valuable role in remediating contaminated sites.

- Monitoring programs should be well-focused on testing forecasts made during design of the remediation plan. To the extent possible, monitoring should be extended to remove uncertainties in the basic understanding of contaminated sediment behavior. For example, monitoring of capped areas might focus on changes of cap thickness, erosion around boundaries, and leakage of contaminant through the cap.

Remediation and Source Control: Economic Considerations

Remedial actions are costly and become more expensive as additional levels of clean-up or treatment are pursued. The role of tradeoffs between possible technologies at and among sites must be considered, given the scarcity of funds to clean up contaminated sites and the potentially great number of sites.

The use of the benefit-cost analysis as part of the remedial action decision process would provide perspective on the issues involved. It would place investments in this area on the same footing as other public investments. However, difficulty in quantifying benefits from remedial actions in monetary terms makes reliance on benefit-cost analysis infeasible in a number of cases. Nonetheless, in light of the high cost of remedial actions, it is important that implicit (if not explicit) consideration be given to potential benefits before remedial actions are undertaken.

Removal of contaminated sediments can be very expensive, varying widely from several hundred thousand dollars to tens of millions of dollars. Data on 15 clean-up sites indicate that total clean-up costs can reach \$500,000 to \$1,000,000 per acre* (U.S. Congress Office of Technology Assessment, 1988). This compares with an average unit cost of navigation dredging of \$1 to \$2 per cubic yard of sediment dredged. The average unit cost of all dredging, both government and private, is estimated in 1988 at \$1.67 per cubic yard of material dredged. On site incineration, one of the remedial measures proposed at various sites, is also very expensive. The estimates quoted are from \$186 to \$750 per cubic yard.

Recommendations

- In view of the high cost of remedial actions in most cases, greater use should be made of benefit-cost comparisons over ecologically relevant time periods in order to place investments in this area on the same economic footing as investments in other public projects.

- Cost-effectiveness analysis of alternative remedial actions should consider both short- and long-term costs. Comparisons at and among sites should be based on costs estimated using a consistent approach.

- In evaluating the degree of remediation to be conducted at a site, it should be recognized that incremental costs typically will increase rapidly as additional levels of clean-up are sought.

- The decision as to whether or not remedial actions are undertaken should be based on a balanced

*For purposes of comparison, assume that a one-acre clean-up involved removing overburden to a depth of one yard, or a total of 43,560 yds³ of contaminated material. In that event, total clean-up costs would range from \$11.50 to \$23.00 per yd³.

comparison of the anticipated environmental and public health benefits of actions with their costs, including possible environmental and health risks.

Clearly infeasible options should be eliminated at the outset, before alternative remedial actions are considered in depth.

CHAPTER 220

DESIGNING FOR STORM AND WAVE DAMAGE IN COASTAL BUILDINGS

Spencer M. Rogers, Jr.*

1. INTRODUCTION

Gulf Shores is a small town on the Gulf of Mexico near Mobile, Alabama (Figure 1). The area is geologically part of a wide peninsula extending from the eastern side of Mobile Bay. Several brackish water lakes along the peninsula create barrier island-like features along the Gulf shoreline. Gulf Shores, like many other beach communities, gradually evolved from fishing shacks and modest beach cottages into a resort community of primarily single-family residences and second homes. By 1979, the national boom in beach resort development was beginning and several motels and condominiums had been completed, others planned.

2. NATIONAL FLOOD INSURANCE PROGRAM

The NFIP evolved from the National Insurance Act of 1968. The act was intended to reduce public disaster relief expenditures in river basins and to limit private flood losses, particularly in areas where such losses were severe or reoccurring. With the incentive of making federally subsidized flood insurance available to anyone in the community, local governments were encouraged to adopt and enforce certain floodplain management regulations in identified flood prone areas. The program

* Coastal Engineer, Dept. of Civil Engineering, N. C. State University and Sea Grant Marine Advisory Service, P.O. Box 130, Kure Beach, NC 28449.

received minimal interest until legislative changes in 1973 required flood insurance for any loan that is supervised, regulated or insured by a federal agency. For identified flood-prone areas, it was a simple amendment: no insurance, no bank loan. Interest in the program skyrocketed. Owners and lenders have grown to appreciate the financial protection provided by the insurance.

Floodplain management regulations evolved from the most common Riverine protection scheme: Elevate the building higher than the water so it does not get wet. The NFIP modeling and mapping of the predicted 100-year flood level, having a 1 percent chance of occurrence in any given year, has been completed in most flood prone areas. In exchange for flood insurance availability, most local governments have willingly established local ordinances requiring lowest floor elevations to be above predicted levels. Similar methods have been adopted in coastal areas even though the cause of the 100-year flood is usually a hurricane, another severe coastal storm, or in some Pacific areas, a tsunami.

Coastal flood maps denote ground elevations below the 100-year flood elevation as A-zones and prone to flooding (NFIP, 1988). Higher elevations are mapped as B-and C-zones. B-zones are flooded on an average of once in 100 to 500 years. C-zones are above the predicted 500-year flood area. Within the A-zone, the minimum floor elevation may be reached by any normal construction method, including the placement of fill.

The most significant accommodation for coastal flooding is the additional identification of "coastal high hazard" or "velocity" zones, which are denoted on the maps as V-zones. The V-zone designation attempts to define an area subject to waves 3 feet or higher during the 100-year storm. A wave threshold of 3 feet was adopted after a Corps of Engineers study estimated that it was a reasonable design limit for typical wood frame construction (Corps of Engineers, 1975). Initially, the same still water elevations were applied in the V-zone as in the adjacent A-zone. But in the V-zone, a piling foundation was required and building on fill was not allowed. The floor elevation in the V-zone was redefined as the bottom of the floor joists, in effect raising the finished floor elevation about 1 foot higher than in the A-zone. Insurance rates were higher in the V-zone.

3. CONSTRUCTION REGULATIONS

Like many resort communities, Gulf Shores developed with little or no regulation of building construction standards, even after its incorporation in 1956. Adoption of the NFIP standards was one of the first

significant regulatory changes. The first flood hazard boundary maps were published by NFIP in 1971 (NFIP). Based on those maps, minimum floor elevation standards were adopted throughout the town as part of an updated zoning ordinance in April 1972 (Alabama Development Office). The adjacent unincorporated areas of Baldwin County adopted similar elevation and construction requirements that were effective May 1973 (Baldwin County Commission). In both areas, the minimum floor elevation requirement was set at +11.5 feet NGVD (3.5 M) based on the predicted 100-year storm surge elevation. Piling foundations were required in the V-zone. In the A-zone owners of most new buildings voluntarily chose to elevate on piling foundations. This was probably to gain underhouse parking and to lower the cost over bringing in large amounts of fill.

4. HURRICANE FREDRIC

In September of 1979, Hurricane Fredric made landfall across Dauphin Island on the west side of Mobile Bay, approximately 30 miles west of the center of Gulf Shores (COE, 1981). On the Saffir/Simpson hurricane scale of 1 to 5, Hurricane Fredric was ranked as a high category 3, a major hurricane. Damage to Alabama, Mississippi and Florida was severe and widespread. The worst damage was within Gulf Shores and along Dauphin Island. The Corps of Engineers and the U.S. Geological Survey have estimated still-water elevation rose to +11.4 feet NGVD (3.5M) within the town limits. The storm surge was essentially identical to the predicted elevation on which the original construction standards were based.

One of the previously identified weaknesses of NFIP coastal flood regulations was the use of a still-water elevation to set minimum floor elevations. The minimum levels are appropriate for riverine floods, but in coastal flooding, wave damage at elevations above the recorded still-water elevation was being substantially underestimated. Even small breaking waves can generate extremely high forces on a building. Waves are often the worst cause of major structural damage in coastal floods. Before the storm, a National Academy of Science committee recommended a methodology to add wave heights to the NFIP storm surge model (National Academy of Science, 1977). After Fredric, Gulf Shores became the first community in the nation to have its flood maps revised to include wave height elevations.

Using the same storm surge elevation and applying linear wave theory, the minimum floor elevations were raised to include depth limited waves over the existing ground elevations. The lower the ground elevation, the deeper the water and the bigger the wave. Unfortunately,

the model can be substantially distorted by small sand dunes and other erodible topographic features which may be altered during a severe storm. Since the topography of Gulf Shores had already been flattened by waves during Fredric, it offered the ideal site to use the new wave model. The original still-water elevations were increased to include wave heights based on the post-Fredric ground elevations. The first flood maps to include wave heights were released April 1980 (NFIP). Significant revisions were published again in April 1981 (NFIP).

About the same time, NFIP developed a different storm surge model to predict still-water elevations specifically for flood insurance mapping purposes (Tetra Tech, 1981). The new model replaced previous models that were developed and prepared by the National Weather Service and the Corps of Engineers for other purposes, primarily life safety and evacuation. In January 1985 new flood maps were released based on the revised storm surge model and incorporating the same wave height methods applied previously. The elevation standards were reset significantly lower than any of the previous elevation requirements.

A variety of factors make Gulf Shores an ideal site for a case study of the flood regulations. Most importantly, Fredric's peak still-water elevations appear to have been extremely close to the previously predicted 100-year flood elevation. A wealth of post-storm damage data was accumulated by the Corps of Engineers and others. The topographic features that can distort the wave height predictions in most other areas were all flattened by Fredric's waves, making the post-storm wave predictions more accurate than is normally possible. The pre-storm construction was not designed for wave heights since those maps were released after the storm. However, since the predicted still-water elevation equaled the recorded elevation, the later maps should closely estimate the actual elevation of peak wave damage during Fredric. Therefore, the more recent maps should reflect relatively higher damage levels where higher waves are predicted.

If elevation requirements are an effective method of reducing damage to buildings, then there should be a difference between the damage to buildings pre-dating the 1971 flood map and the newer elevated buildings built before Fredric. The benefits of the construction standards should be most apparent in areas where the predicted still-water elevation reasonably reflected the actual conditions during Fredric.

5. METHODS

A study area was selected that was entirely within the 1985

corporate limits of Gulf Shores extending inland 1000 to 2500 feet (300 to 800 M) landward from the Gulf. After the low sand dune was flattened during Fredric, the ground elevations rose gradually inland from the Gulf. Post-storm surveys indicate that the entire study area was flooded during Fredric (U.S.G.S., 1980). The Disaster Report was the primary source of building damage data (COE, 1981). The Corps compared post-storm aerial photographs taken one day after Fredric by the Florida Department of Transportation and with aerial photos taken in March 1979 six months before the storm. The destroyed buildings were marked with a symbol on the post-storm photos. The Corps data was augmented when necessary by careful inspection of the original post-storm aerial photos or with ground inspections and ground photography made 10 days after the storm by the author.

The age of each building in the study area was determined by overlaying the Corps damage photos with transparencies of U.S.G.S. aerial photos taken in May 1972. The photos were taken around the time of the adoption of the minimum elevation requirements in Gulf Shores and Baldwin County. Buildings in existence in 1972 were coded as "old," pre-dating the elevation requirements. Buildings only appearing in the more recent photos were coded as "new", constructed after the minimum elevation requirements were implemented.

A scale-corrected, transparency of each flood map was produced, delineating the elevation zones within the study area. The transparencies were overlaid on the damage sheets previously coded by age. The buildings in each zone were tabulated. It was noted whether the building survived or was destroyed, and whether it was old or new. Any building located in more than one zone was considered to be in the higher of the two risk zones. Also, the distance between the seaward end of each building and the waterline position mapped by the Corps was measured.

To assess the effects of the elevation requirements, it is desirable to remove as much of the wind damage as possible. Wind damage can be extensive in areas with weak construction standards and sustained winds over 100 mph. Damage patterns are usually distinct. Partial damage to a roof, wall or foundation may leave the building beyond salvage, but large, visible remnants usually remain. Even small waves can create forces several orders of magnitude higher than design wind forces. Wave damage often leaves little debris nearby. It is not uncommon to find only a few leaning pilings. Most destroyed buildings in Gulf Shores appeared to be caused by water damage. Where the photography indicated extreme wind damage, buildings were considered to have "survived" for the purposes of this study even though it may have been a total insurance loss.

The majority of buildings in the study area were single-family residences. Piling-supported houses frequently had underhouse enclosures for parking, storage and finished living areas. The lower enclosures usually had "breakaway" walls. In principle, little or no damage should occur to the rest of the building when the lower walls fail. In such cases, destruction of the underhouse improvements did not affect the classification of "survived" for the rest of the piling-supported building. Buildings that floated away from their foundations were considered destroyed even though the buildings were intact and potentially salvageable. Roughly 5 percent of the buildings in the study area were larger, commercial motel and condominium buildings. Most were constructed on much heavier and deeper piling foundations. When these larger buildings lacked adequate floor elevation, the first floor rooms were frequently gutted by waves but remained structurally sound with the upper floors intact. Since the lower non-bearing walls were never intended to be breakaway, the buildings were considered destroyed even if the upper floors remained.

6. RESULTS

A typical shoreline cross section showing the required elevations of the various flood maps is shown in figure 2. Minimum elevations in the V-zones have been labeled 1 foot higher than mapped to account for the different definition of lowest floor elevation (bottom of the joists). In 1971 there were only two zones both very close to Fredric's surge elevation. In 1980 six different elevation zones were identified. In 1981 many buildings in the middle zones were reclassified into less restrictive elevations. No reason for the rapid restudy was provided. The 1985 maps, implementing the newer storm surge model, significantly lowered the predicted surge elevation therefore dropping the wave height elevation compared to all

Figure 2.

Distance from Gulf

previous maps. The most seaward zone in the 1980, 1981 and 1985 maps was located seaward of the mean high water line and contained no buildings. Only one new building was located in the next most seaward zone and its results cannot be considered statistically significant.

Of the 1056 buildings in the study area 377 (36 percent) were destroyed. Of the total, 777 were old, 279 new. New buildings constructed on pilings and meeting the minimum elevation standards performed slightly better than earlier designs: 32 percent of the new buildings destroyed vs. 37 percent of the old. Clearly the loss of 32 percent of the buildings in a design storm indicates significant problems with the standards. Figure 3a displays the damage distribution based on the 1971 maps. In the A-zone there was a 10 percentage point reduction of damage in new buildings over old, but 13 percent of the new buildings were still destroyed in the area where the original standards should have performed best. New buildings in the V-zone were more frequently damaged than the old. Although a modest improvement can be seen in the A-zone, the standards resulted in no improvement in the original V-zone.

Damage Distribution by Flood Map

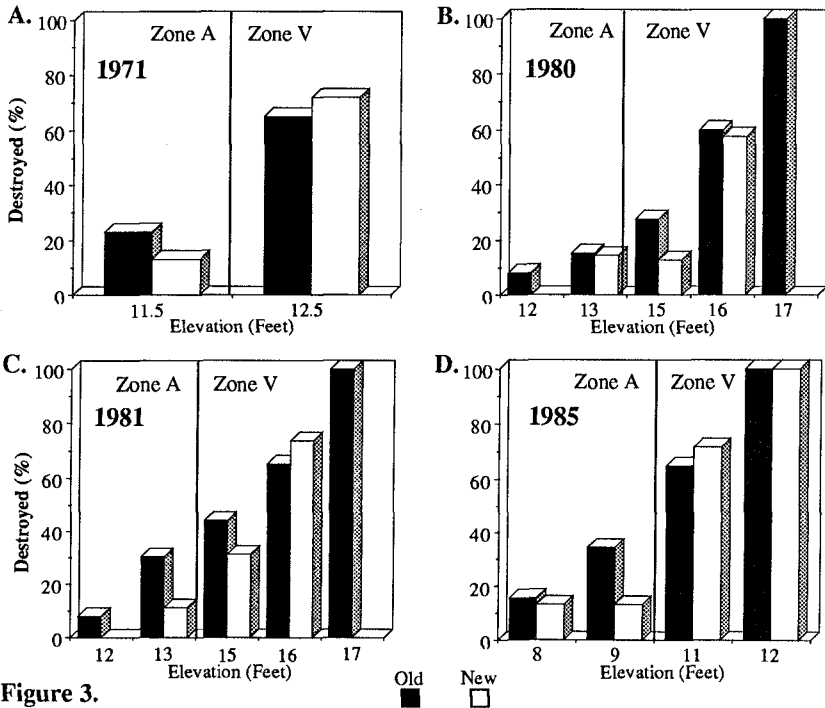

Figure 3.

The wave height predictions included in the 1980 and 1981 maps (figures 3b & 3c) were used as a hindcast of actual wave heights in the hurricane. Increasing levels of damage to both old and new buildings occurred as the predicted elevations increasingly exceeded the original standard. Improved survival of new buildings can be observed in the three most landward zones (elevation 12, 13 & 15), but no improvement in the most seaward zone with a significant sample size (el. 16). No new buildings were destroyed in the most landward zone compared with losses of 8 percent of the old buildings in the same areas. Damage to new buildings rose to unacceptable levels in all zones farther seaward (14 and 11 percent at el. 13). Every old building in the most seaward, developed zone (el. 17) was destroyed.

The 1985 maps show similar damage trends but cannot be considered a wave hindcast since the revised storm surge prediction is 3.5 feet (0.9 M) lower than the predicted still water elevation used in all earlier maps and measured after Fredric (figure 3d). After the addition of wave heights, the minimum elevation standards in 1985 were lowered 4 to 7 feet (1.2 to 2.1 M) below the 1980-81 maps and 0.5 to 4 feet (0.2 to 1.2 M) below the standards adopted with the 1971 maps.

One week before Fredric, the Alabama Coastal Area Board voted to establish a statewide, gulf-front construction setback line (Hegenbarth, 1985). The Town of Gulf Shores eventually adopted a setback ordinance requiring all new construction to be located more than 40 feet landward of the pre-Fredric dune crest, except in the central, commercial district where the setback for larger buildings was reduced to five feet landward of the crest. The regulation took effect in March 1981.

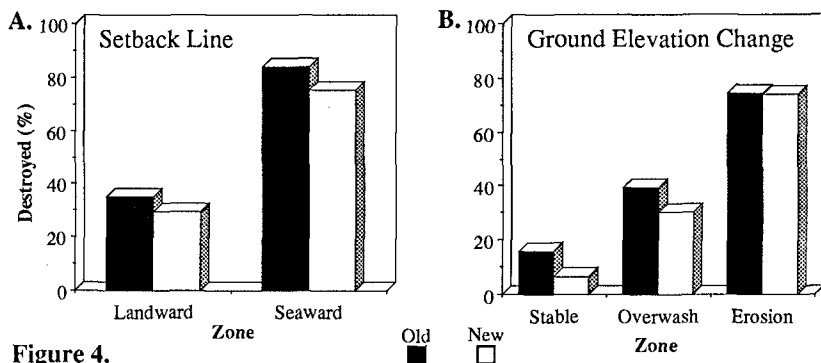

Figure 4.

The study analyzed what the effect of the setback would have been if it had been enforced for all earlier construction. A pre-development setback would have relocated or reduced in size less than 5 percent of

the buildings in the study area. But it would have included many of the largest motels and condominiums. Eleven percent of the damaged buildings were seaward of the setback. Eighty-four percent of those old buildings and 75 percent of the new buildings were destroyed (Figure 4a). Although an earlier implementation of the setback would appear to have reduced damage levels, the setback without other construction regulations farther landward would not have reduced damage to acceptably low levels in the community. Even if the most seaward buildings had been constructed a few feet farther inland, most would still have been damaged. Eighty-nine percent of the damaged buildings were landward of the setback. If an even more restrictive setback had been established along to the north side of the Gulf-front road, prohibiting up to three rows of single-family houses, 39 percent of the destroyed buildings would have been even farther inland.

The influence of ground elevation changes was also measured. The Corps of Engineers (1981) reported erosion occurred 300 feet landward of the post-storm waterline. Overwash deposition was mapped from post-storm photography and appeared to correlate with wave damage to low elevation buildings. On average the overwash penetrated 700 feet (210 M) inland of the waterline. In figure 4b there are similar percentage point improvements in stable ground and overwash but much higher overall levels in overwash. In the erosion area approximately 75 percent of both the old and new buildings were destroyed.

Buildings in the study area were sorted by distance from the waterline and grouped in increments of 100 feet (30 M). The results are displayed in Figure 5. The most dependable points are more than 100 feet and less than 900 feet. Outside that range there were too few buildings for reliable results.

Figure 5.

When the average hazard zone distances are added to the graph, the benefits and limitations of the NFIP construction regulations become more apparent. The effect of the regulations is revealed as the shaded difference between the two lines. The reliable points in the stable but flooded zone show significantly lower damage levels for new NFIP standard buildings than for pre-NFIP buildings. Throughout most of the overwash zone, the damage rates of new buildings show a similar relative improvement as in the stable zone, averaging 13 percentage points better than the older ones. However, the overall likelihood of damage in both

groups increases moving seaward, from an overall average of 22 percent to 37 percent. The steep trend of higher losses closer to the ocean is continued through the erosion zone. All groups closer than 400 feet to the waterline showed remarkably consistent damage levels in old and new buildings.

7. DISCUSSION

The construction standards based on the 1971 maps reduced losses during Hurricane Fredric. The shaded area in figure 5 represents the benefits of the NFIP standards. The survival of 19 buildings out of the 279 constructed between 1972 and 1979 appears to be attributed to the regulations, preventing damage in 7 percent of new construction (Photo 1). If equally effective regulations had been implemented for the 777 older buildings in the study area, about 72 buildings could have been saved by the construction standards as adopted from the 1971 maps.

Photo 1. Typical buildings elevated to meet construction standards. Note foundation of demolished building in foreground.

For design storm conditions, unacceptable levels of damage were allowed by the regulations. Eighty-nine new buildings (32 percent) were destroyed during Fredric. The initial maps show the improvement occurred only in the original A-zone (Figure 3a). The V-zone revealed higher damages in new buildings than in old, the opposite of the desired effect. The addition of wave heights in the 1980 and 1981 maps was an obvious and necessary improvement. The V-zone construction standards specify minimum floor elevations for piling construction but do not address piling embedment. Field inspections indicated that local practice prior to the storm provided 3 to 10 feet (1-3 M) of embedment below existing grade, consistently too little to survive in the erosion zone (photo 2). At its best the A/V zone designations still used by NFIP can address wave height

Photo 2. Undermined foundation of "new" building in erosion zone.

variations and floor elevations but are not suited to address erosion or foundation embedment requirements. The most likely benefit of the wave height additions will be improved survival in the overwash (wave) area in figure 4b and 5 as well as photo 3.

Photo 3. Wave damage to "old" building in the overwash zone. Originally and presently an A-zone, but a V-zone in 1980-1.

Construction setback lines could have reduced the number of damaged buildings but not enough to be the sole method of damage prevention in extreme, but relatively rare storms such as Fredric. Adequate construction standards are necessary to adequately control

building damage on low elevation shorelines that are expected to be overtopped by waves like Gulf Shores. Setbacks appear more likely to be successful if properly applied along high elevation shorelines or if used to control damage caused by long-term erosion.

More realistic coastal hazard zones have been previously suggested in the literature. The Model Minimum Hurricane Resistant Standards for the Texas Gulf Coast (Texas Coastal and Marine Council, 1978) proposed the use of hazard zones for scour, battering by debris, flooding, and wind. The results of this study suggest slightly different designations. On low elevation shorelines where inland flooding is likely, the threats to buildings can be separated into four zones: I) erosion, II) waves (overwash), III) flooded (without waves) and IV) wind (without flooding) as in figure 6a.

High velocity winds can be expected in the entire coastal area, all four zones. Flooding takes place in the three most seaward zones, comparable to the present NFIP flood maps. In the two most seaward zones wave heights must be addressed as well as some foundation considerations for overwash deposition, similar to present V-zones standards. The most seaward zone by definition receives all of the erosion as well as the worst of the previous hazards. Foundation embedment is a critical design consideration that is not adequately addressed in NFIP standards.

On high elevation shorelines the hazard zones can be further simplified. The eroded dune or bluff defines both the limit of erosion and all flooded areas. Zone II and III cannot occur. The erosion of zone I is bounded by the high winds without flooding of zone IV (figure 6b).

It should be noted that this study only addressed the effect of a single, but very severe, short-duration storm. The construction standards

in this study have been in place for only seven years, too short a period to be significantly affected by the long-term erosion in Gulf Shores. In areas of significant long-term erosion it seems prudent to expect the zones to move landward with the erosion rate over the lifetime of any new building constructed. Additional approaches like setbacks or erosion control projects may be required to adequately protect buildings.

5. CONCLUSIONS

The NFIP building construction standards in Gulf Shores significantly reduced damage in buildings constructed between 1972 and 1979. However damage levels were far too high to be considered successful in meeting the reasonable damage-reduction goals in design storm conditions. Damage patterns indicate that wave height considerations in 1980 and 1981 were an appropriate improvement that should reduce damage to buildings constructed after the storm but prior to the 1985. Due to the large drop in the predicted storm surge, buildings constructed to the minimum standards after 1985 can expect higher levels of damage than 1971-1985 buildings if a storm of equal severity occurs. In such a storm, post-1985 buildings are likely to receive damage at levels similar to the unregulated, (old) buildings.

The original construction standards proved to be totally ineffective in areas that experienced erosion. Appropriate foundation penetration standards must be established if damage to small buildings is to be reduced to acceptable levels in 100-year design conditions along the coast.

The identification of more realistic hazard zones is already technically feasible. A variety of existing two-dimensional, dune erosion models can be used to define the erosion zone when the dune is not overtopped (figure 6b). The models are less precise in predicting overtopping and overwash but are still useful when applied with sufficient engineering judgment. Additional considerations for long-term erosion are necessary for buildings to avoid storm damage over a normal useful life.

CHAPTER 221

CROSS-SECTIONAL STABILITY OF ESTUARY CHANNELS IN THE NETHERLANDS

BY

F. Gerritsen¹, H. de Jong², A. Langerak³

ABSTRACT

In this paper, stability characteristics of tidal channels of the Western Scheldt and of the Wadden Sea are compared.

The Western Scheldt is a major estuary in the southern part of the country and is the only remaining open sea-arm in that area after construction of the Delta Project. The Wadden Sea is situated in the northern part of the country and the inlets form the connection between the North Sea and the Wadden Sea.

Stability parameters used for the comparison are the maximum discharge, Q_{max} , the Flood Volume FV (of Tidal Prism) and the mean tidal velocity.

It appears that linear trends can be established between the cross-section and the various stability parameters, for each of the two systems, but that the regression relationship is not the same.

Attempts have been made to develop a universal relationship by introducing a dimensionless stability parameter, in which the dominating hydraulic characteristics are combined. The results are interesting but further research is required to refine this method. The established morphological relationships can be used to predict the changes in channel equilibrium when external changes in the estuary system are introduced. For the Western Scheldt the one-dimensional numerical tidal model IMPLIC will be combined with distinct morphological relationships for the estuary to be used as a predictive tool for the new equilibrium situation created by dredging works.

1. Introduction

During recent years the interest in morphological behavior of estuarine channels has significantly increased. There is a distinct need to predict the morphological changes in a system after man-made works have been carried out. Among the latter are the dredging of navigation channels and the construction of guide dams to maintain channel depth. Another important reason for the rising interest is the prediction of the effect of sea level rise on the estuarine system on a longer time scale.

Examples of man-made interventions in The Netherlands are the development of the New Waterway leading to the Port of Rotterdam, the dredging operations in the Western Scheldt and the construction of coastal protection works in and near the Texel Inlet (see Figure 1).

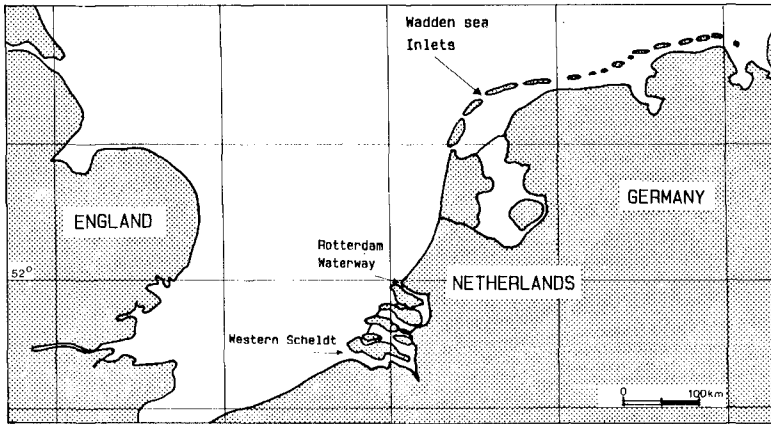

Figure 1. Inlets on the Dutch coast.

The study of morphological behaviour of hydraulic systems such as estuary channels and tidal inlets can follow two different lines of approach. In the first the governing hydraulic equations are combined with equations for the movement of sediment and for the conservation of the mass of sediment. Up to present this avenue has not led to satisfactory results mainly because of uncertainties in the transport equation for the sediments. The second approach is to combine hydraulic calculations with appropriate morphological relationships between channel dimensions and tidal flow.

Detailed studies of the Western Scheldt as a whole and of the Wadden inlet systems (including the channels in the flood tidal delta) have shown that a number of morphological relationships are well defined and consistent so that they can be used as predictive tools to predict future equilibrium. A combination of these relationship (one of them) with a tidal numerical model is seen to be of great significance for future morphological studies.

The objective of this study is to compare cross-sectional stability criteria for the Western Scheldt Estuary and the Wadden Inlets. As stability parameters we will use the

maximum discharge (Q_{max}), the flood volume (FV), the stability shearstress s and the mean tidal velocity, v . In addition a dimensionless stability parameter will be introduced to account for the influence of different hydraulic characteristics on the stability relationship. Finally the one-dimensional numerical model IMPLIC will be used in combination with distinct stability relationship as a predictive tool for morphological development.

2. Regression Analysis

In this section regression relationships for the selected parameters will be discussed for both the Western Scheldt and the Wadden Inlets and conclusions will be drawn regarding the usefulness of these parameters as stability indicators.

Western Scheldt

In previous studies (Gerritsen and De Jong, 1984,1985) it has been suggested that the maximum discharge Q_{max} may well be related to the cross-sectional profile A_c^1 , which is the cross-section of the channel below the tide level, at which the maximum discharge occurs.

In this paper characteristic tidal parameters are related to the mean tide. Although in some cases the mean springtide condition may be a better criterion for stability analysis (because bedforming conditions are likely to be associated with springtide) for our study area this difference appears not to be significant. The relevant stability relationships for the Western Scheldt are shown in Figures 2 to 5 (incl.).

The Western Scheldt is a well mixed estuary; the contributing river Scheldt originates in the southern part of Belgium with a mean discharge of $105 \text{ m}^3/\text{s}$, which is small compared to the maximum tidal discharges in various locations along the estuary itself. Although the river discharge is small, it creates a density gradient along the estuary and has a minor effect on the vertical velocity distribution. However, in the stability analysis no significant influence has been detected from the river discharge or density gradient.

Figures 2 to 4 show the various transects across the Western Scheldt, numbered 1 through 13 (location 13 at the mouth). The dots in the graphs numbered 1-13, correspond with the transects shown in the Figures.

Figure 2 shows the regression between Q_{max} and A_c^1 for flood flow. The dotted line represents the computed regression relationship. For the calculation of this line the cross-sections 12 and 13, which show a somewhat deviating behaviour, have been excluded. This deviating behaviour is also visible in other graphs (see Figures 3 and 4) and can be explained by the effect of wave action on the stability relationships. The presence of waves affects the shearstress near the bottom and thereby affects the stability relationship.

The remaining cross-sections 1 through 11 are grouped around the mean regression line, but some distinct deviations are also noticeable, such as for cross-sections 7 and 11. In these locations the estuary is narrower than would be expected from the overall trend due to bank stabilization works and the profiles are consequently somewhat deeper and

Figure 2. Regression between Q_{max} and A_c^1 for cross-sections in the Western Scheldt (flood conditions, mean tide).

Figure 3. Regression between Ω and A_c for cross-sections in the Western Scheldt (flood conditions, mean tide).

Figure 4. Regression between $\frac{Q_{max}}{C \sqrt{\tau_s / \rho g}}$ and A_c^1 for cross-sections in the Western Scheldt and constant value of τ_s related to mean tide (flood conditions).

Figure 5. Regression between Q_{max} and A_c for flood channels in the Western Scheldt (mean tide).

the velocities somewhat higher than in the other profiles, for which the width is not controlled.

The relationship between Flood Volume FV (Tidel Prisma) and cross-sectional area A_c (taken below M.S.L.) is shown in Figure 3.

Cross-sections 12 and 13 again deviate from the regression curve (because of wave action), but the profiles 7 and 11 now fall into place. The correlation coefficient is slightly higher than for the relationship between Q_{max} and A_c^1 .

The third regression relationship of interest is that between $\frac{Q_{max}}{C \sqrt{\tau_s / \rho g}}$ and A_c^1 , in which τ_s represents the stability shear converted to mean tide conditions) and C is Chézy coefficient. The mean fluid density is ρ and the acceleration of gravity is denoted by g .

In this analysis the stability shear stress τ_s selected in such way that the regression line makes an angle of 45 with both axis. The two transects 12 and 13 again show a deviating behaviour.

Corrections for the influence of waves can be made by considering the effect of waves on the sediment transport by currents. For this correction use is made of the Bijker

formulation (Bijker, 1967) and the method for this is discussed in Gerritsen and De Jong, 1984. This correction changes the points 12 and 13 to 12a and 13a, which is a significant improvement in the overall relationship.

An estuary like the Western Scheldt is characterized by the existence of flood and ebb channels, in which the flood respectively the ebb dominates.

Figure 5 shows the relationship between Q_{\max} and A_c for the typical flood channels. It appears that a high correlation occurs, but it is also evident that the slope of the line is somewhat steeper than in the similar relationship of Figure 2.

A steeper line indicates that maximum velocities (average over profile) are higher for the channels than for the entire cross-section between banks, which is to be expected.

Wadden Inlets

The Wadden Inlets connect the North Sea with a shallow inland sea, called the Wadden Sea (fig. 6). In the early part of this century the Wadden Sea was in open connection with a large but shallow sea, the Zuiderzee, between Noord-Holland and Friesland and the other eastern provinces. The construction of the Zuiderzee enclosing dam, which was accomplished between 1928 and 1932, affected a significant change in the tidal characteristics and flow conditions of the remaining Wadden Sea. The body of water south of the dam is now called IJssel Lake. A small amount of fresh water is discharged from the lake into the Wadden Sea through sluices in the dam. The effect of this freshwater flow on the larger discharge rates in the Wadden Inlets is considered negligible.

Figure 6. Dutch Wadden Sea (Western part) and Tidal Inlets.

One of the consequences of the closing has been a significant increase in Q_{\max} in the Texel Inlet (cross-sections 1 and 5, Figure 6), which resulted in a strong morphological adjustment (first a reduction followed by an enlargement) of the channel cross-section. Although some parts of the Wadden Sea itself may not have reached a new equilibrium it is found that the Wadden Inlets have reached a condition with a new equilibrium.

In the following some of the prevalent stability relationships will be discussed.

Figure 7 shows the relationship (regression) for all the inlet cross-sections shown in Figure 6. Again we will notice that cross-sections 5 and 6, which are exposed to the open North Sea and are affected by wave action, show a deviating behaviour. The regression line for sections 1-4 shows a high correlation

($r = 0.960$). It is to be noted that the cross-sections 1 through 4 have widely different cross-sections and depths. The Q_{\max}/A_c^1 value (which represents

Figure 7. Regression between Q_{\max} and A_c^1 for Wadden Inlets (flood conditions, mean tide).

the average maximum velocity) is not the same for all profiles but increases with the size of cross-section. The regression line consequently does not pass through zero, which is an important characteristic of this relationship.

Figure 8 shows the regression between the flood volume (FV) and the area A_c . The solid line represents the calculated regression line for all sections, exclusive 5 and 6 (which are affected by wave action), whereas the dashed line represents the corresponding line for the Western Scheldt cross-sections (excluding profiles 12 and 13). It appears that the values for the Eyerlandse Gat, E, (section 2) somewhat deviate from the line, but that the other inlets fit the general relationship well.

It is to be noted that the Eyerlandse Gat is a relatively shallow part of the Wadden Sea

in which the depth of the major channels is much less than that of the other parts. The above suggests that a smaller depth corresponds to a lower maximum velocity, which would plot the points for cross-section E (or 2) below the average regression line.

A comparison between the solid and the dotted line shows that the trends for the two systems, the Western Scheldt and the Wadden Inlets, are somewhat different. The suspected effect of velocity on the plottings in Figure 8 is proven by plotting the value of the tide average velocity against the hydraulic radius R (Figure 9). In the data points information for the Wadden Inlets as well as for the Western Scheldt is included. The trend is clear and convincing: the hydraulic radius (or depth) plays a significant role on the velocity, which translates into effects on Q_{max} and FV as well. The data points of the Eyerlandse Gat (E) now fit well in the overall relationship of Figure 9, as do the values for the Western Scheldt (W).

Figure 8. Regression between FV (Ω) and A_c for Wadden Inlets and compared with relationship for Western Scheldt.

It may be concluded that the difference in hydraulic radius (or depth) is one of the principal reasons why regression relationships show deviating trends.

Figure 9 presents important information to calculate and predict the expected behaviour. The relationship between A and Ω (FV) may be adjusted by the dependency on R

(or h). Using the data of Figure 8 we may express that relationship between \bar{v} and R by:

$$\bar{v} = \alpha R^\beta \tag{4}$$

Figure 9. Relationship between v and R for Dutch inlets.

Figure 9 provides the data to calculate the values of α and β : $\alpha = 0.353$ and $\beta = 0.25$
 From the relationship between v and Ω or (FV)

$$v = \frac{2 \Omega}{A_c T} = \alpha R^\beta \tag{2}$$

$$A_c = \frac{2 \Omega}{T \alpha R^\beta}$$

Substituting the experimental values of α and β , and taking a semi-diurnal tide, we have:

$$A_c = 1.269 \times 10^{-4} \frac{\Omega}{R^{0.25}} \tag{3}$$

This relation shows an influence of R on the dependency between A_c and Ω
 In a relatively wide and shallow estuary the hydraulic radius R is almost equal to the mean depth h; equation (3) then develops into:

$$A_c = 1.269 \times 10^{-4} \frac{\Omega}{h^{0.25}} \tag{4a}$$

For relatively deep channels R is retained. Writing $R = \frac{A}{P}$ where p is the wetted perimeter, equation (3) develops into

$$A_c = (7.64 \times 10^{-4}) p^{0.2} \Omega^{0.8} \quad (4b)$$

In shallow channels $p \approx b$, so that

$$A_c = (7.64 \times 10^{-4}) b^{0.2} \Omega^{0.8} \quad (4c)$$

which equation reminds us of the early O'Brien equation with power 0.85.

The equations 4a through 4c express the influence of the form of the cross-section (wide and shallow versus deep and narrow) on the relationship between A_c and Ω .

In the Western Scheldt overall depths in the various channels vary between 9 and 11 m, thus the effect of depth on the relationship between A_c and Ω will be small.

Exceptions are Transects 7 and 11, where the mean depth is over 15 m and for which a small deviation from the overall trend can be expected.

3. Dimensionless stability parameter

A philosophical discussion on stability problems in tidal inlets and estuaries reveals that hydraulic and sedimentological characteristics play a role in the total stability equation (see Bruun and Gerritsen, 1959, Bruun, 1978).

The following parameters may be considered:

Hydraulic Characteristics

Mean tidal velocity, \bar{v}

Hydraulic radius, (or average depth) R

Bottom roughness, k

Chezy coefficient, C

Wave action, H_s

Density of water (sea and estuary), ρ

Sedimentological characteristics

Diameter bottom material, D_{50} and D_{90} .

Density of sediment, ρ_s

Concentration of sediment, \bar{c}

Littoral drift, M

Unfortunately field data do usually not contain a significant range of the various parameters which allow the determination of the influence of these various parameters on the stability problem.

The inlets and estuary under consideration all have for instance a large $\frac{Q_{max}}{M}$ ratio, meaning that tidal flow by passing, if it occurs, is prevalent. The one exception may be the Eyerlandse Gat which has a smaller tidal prism.

With these large tidal flows it is thus expected that the rate of littoral drift does not significantly affect the stability relationships. If water density differences are neglected and the effect of wave action is eliminated (by excluding the profiles exposed to strong wave action) the following parameters remain as essential to the problem:

Relationship between Q_{max} and gross rate littoral drift, M

Diameters of bottom material D_{50} , D_{90}

Chezy coefficient C

Relative density of sediment $\Delta = \frac{\rho_s - \rho}{\rho}$

Ripple effect on sediment (μ)

Depth of channel (h)

It is of interest to formulate a dimensionless parameter, in which the above characteristics are grouped together, either directly or indirectly.

One approach is to consider the similarity between the natural conditions and those in a hydraulic model with movable bed. The design of a movable bed model is based on the condition that the transport scale (the ratio in which sediments in the field and in the model are transported) must be invariant. Only then will a movable bed model give a correct representation of the field conditions to be simulated. In a tidal inlet or estuary channel stability is associated with the condition that

$$\frac{\partial q_s}{\partial s} = 0 \quad (5)$$

Only then a stable cross-section can be expected. This condition represents a self similarity condition comparable to the one for a moveable bed model.

In order to determine what type of relationship provides such (self) similarity a distinction is made between two conditions: one in which the bedload transport dominates and another one, in which the sediment transport in suspension provides the larger portion of the sediment transport. We will consider bed load predominance here. If bedload may be obtained from Bijker (1967) he finds that for the invariance of the transport scale the following condition must be met:

$$n_v = \left(\frac{n_D n_A}{n_\mu} \right)^{1/2} n_c \quad (6)$$

in which scale relationships are identified by n and

$$\frac{V}{\left(\frac{\Delta D}{\mu} \right)^{1/2} C} = \text{const.} \quad (7)$$

The velocity V in the above expression refers to the time averaged velocity v , as well as to the maximum velocity V_{\max} . The value of the constant will consequently differ for these two characteristic velocities.

In the present analysis we will use the value and the corresponding constant we identify with A_1 :

$$\frac{\bar{v}}{\left(\frac{\Delta D}{\mu} \right)^{1/2} C} = A_1 \quad (8)$$

In the above expressions 6 - 8, C represents the Chezy coefficient and μ the ripple coefficient, which expresses the ratio between the bottom shear stress acting on the grain and the total bottom shear stress in the channel where is calculated from

$$\mu = \left(\frac{C_{D90}}{C} \right)^{3/2} \quad (9)$$

in which C_{D90} represents the Chezy coefficient corresponding to the grain size D_{90} .

Using data from the Western Scheldt the values of A_1 have been calculated and are plotted against A_c in Figure 10. The average value of the calculated data points is $A_1 = 0.37$.

Figure 10. Dimensionless parameter A_1 versus cross-section A_c for Western Scheldt.

In a similar way values of A_1 are calculated for the Wadden Inlets and for the channel system inside the Vlie Inlet. Values of A_1 for the Wadden Inlets were respectively:

- All inlets (incl. 5, 6) $A_1 = 0.43$
- Channels $A_1 = 0.40$

It is concluded that with the present formulation the objective of finding a universal constant that fits all data is not met.

However, a certain amount of precaution is warranted. The determination of the values of A_1 includes the use of hydraulic parameters (μ and C) which have values, that may deviate from the calculated ones, because of lack of precise formulation for the values of these parameters.

It may also be true that the conditions that underlie the basis for A_1 (predominant bedload transport) are not as they were assumed and that suspended transport plays a more dominant role in the process than assumed.

Further analysis will be required to clarify this uncertainty.

It is of interest to confront the condition expressed in equation (7) with the validity of the assumption that the stability shear stress may constitute a stability parameter.

Equation 7 may be converted to:

$$\frac{\mu \tau_s}{(\rho_s - \rho) g D_{50}} = \text{const.} = A_2 \tag{10}$$

It is concluded that a constant value of s is not in agreement with a constant value of $A2$, but that the stability condition requires

$$\frac{\tau_s}{(\rho_s - \rho)g D_{50}/\mu} = \text{const.} \quad (11)$$

4. Computer Simulation

The use of morphological stability relationships in computer simulation of these processes is based on the use of an appropriate numerical model (for hydraulic calculations) and an additional morphological submodel to be incorporated in the numerical scheme.

In the Western Scheldt the numerical hydraulic model IMPLIC, which is a one-dimensional tidal model, provides an efficient basis for the calculations.

In order to find out whether or not the present schematization for the IMPLIC model is accurate enough to allow formulation of stability relationships, model data have been used to verify the possible use of stability relationships in the model. Figure 11 shows the present channel system of the Western Scheldt and Figure 12 the corresponding set of interconnected channels that form the IMPLIC model.

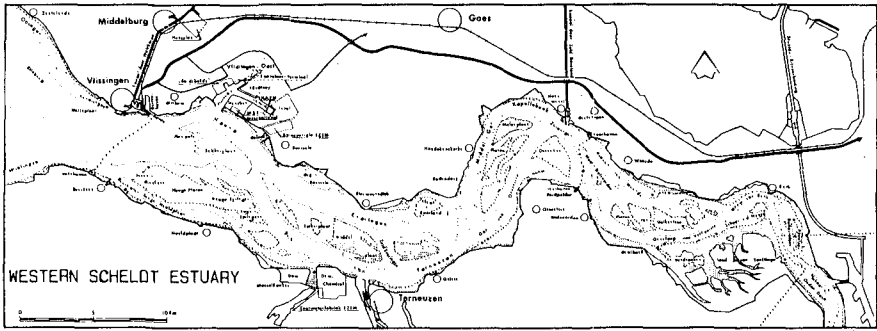

Figure 11. Western Scheldt Estuary.

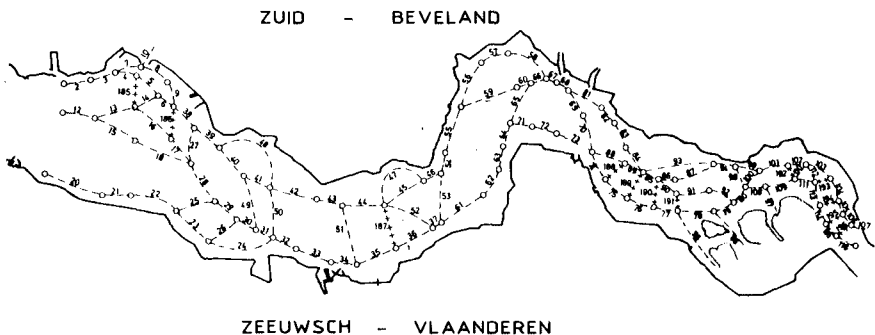

Figure 12. Schematization of Western Scheldt for IMPLIC model.

It appears that the schematization of the model is accurate enough to allow the establishment of morphological relationships from the model data.

That the present model has the capabilities to be used in conjunction with predescribed stability relationship to calculate stability conditions after technical changes have been made in the system.

The procedures of computation are in an iterative mode. After a change has been made in the system, (which is in equilibrium) tidal calculations are made with IMPLICIT to determine the changes in discharge. In general the system will be out of equilibrium after the change is made and will turn back to a new equilibrium. An example is the deepening of a navigational channel by dredging, which has been the case in the Western Scheldt.

Suppose the increase in cross-section from a dredging operation equals ΔA . Depending on the extent of the dredging operation tidal velocities in the system will change (usually decrease) after the dredging and the system will develop into a new equilibrium. In the computations cross-sections are adjusted gradually until a new equilibrium stage is obtained, in which the morphological parameter which is selected for the computations, corresponds with the adjusted cross-section.

Morphological adjustment usually develops in an exponential way as a function of time. This corresponds with the assumption

$$\frac{\partial A}{\partial t} = -\lambda \Delta A = -\lambda (A - A_0) \quad (12)$$

in which A_0 represents the equilibrium cross-section and λ a time scale factor. If A_i is the initial cross-section immediately after dredging integration gives

$$\frac{A - A_0}{A_i - A_0} = e^{-\lambda t} \quad (13)$$

The coefficient determines the time scale of the process. An estimate for the value of λ can be obtained from the gradient of sediment transport that has been induced into the system.

The continuity equation for sediment transport can be written in the form

$$\frac{\partial A}{\partial t} + \frac{\partial \bar{Q}_s}{\partial s} = 0 \quad (14)$$

In which \bar{Q}_s is the mean rate of sediment transport through the cross-section over a tidal cycle.

Using equation 12 thus leads to:

$$\frac{\partial A}{\partial t} = -\frac{\partial \bar{Q}_s}{\partial s} = -\lambda (A - A_0) \quad (15)$$

$$\lambda = \frac{\partial \bar{Q}_s}{\partial s} / A - A_0 \quad (16)$$

$$\lambda_i = \left(\frac{\partial \bar{Q}_s}{\partial s} \right)_i / A_i - A_0 \quad (17)$$

Where the index i denotes the initial condition after dredging.

The value $\partial \bar{Q}_s / \partial s$ can be calculated using an appropriate formulation for sediment transport from which λ can be calculated.

5. Conclusions and recommendations

1. Both for the Western Scheldt Estuary and for the Wadden Inlets morphological relationships have been established that provide a valuable tool for morphodynamic analysis.
2. Morphological relationships can be established for entire cross-sections, but also for separate flood or ebb channels, if the corresponding flood flow or ebb flow is taken as the relevant parameter.
3. The hydraulic radius or mean depth appears to be a significant scaling parameter in comparing large and small tidal inlets. The established relationship between v and R can be used to modify the relationship between A_c and v , taking the effect of depth into account.
4. The introduction of a dimensionless parameter is intended to make morphological relationships independent of grain size, material density mean depth and channel roughness.
A first approach is promising but needs further work.
5. Morphological relationships can be used in combination of a numerical tidal model. The model IMPLIC has been selected to be used for the Western Scheldt.

CHAPTER 222

Variations in rheological properties of muds in the Gironde estuary

Pascal Galichon*, Alain Feral**,
Jérôme Granboulan**, Jacques Viguier*

ABSTRACT

In numerous navigation channels, the bed consists of muds. The navigability threshold adopted by many ports is currently that which corresponds to a specific gravity of 1.2. This virtual standard does not fully take into account the rheological characteristics of the muds, which may differ from one site to another.

Investigations were carried out to determine the rheological properties of the Gironde estuary muds. Analyses were carried out in the laboratory on samples taken from different sites and on different dates and in situ, using the SR 10 probe developed by SOGREAH and ultrasonic sedimentometric probe developed by the Bordeaux Port Authority. The results demonstrated the occurrence of major spatial and temporal variations.

The two principal phenomena revealed by the research were that with the same dry sediment content:

- . muds were less rigid at the front of the maximum turbidity zone than at the back, by a factor of about 1.6 to 2.5,
- . the greater the annual flood, the lower the rigidity.

A proper understanding of the spatial and temporal variations of rigidity is therefore essential to determine and adjust the navigability threshold.

INTRODUCTION

The beds of navigation channels consist of muds. Today, the nautical depth is considered to be the depth of water between the unconfined surface and a given level of density (or specific gravity) referred to as the nautical bottom.

A specific gravity value of 1.2, which corresponds to a dry sediment density of around 300 g/l, is currently adopted as navigability threshold by ports such as Rotterdam, Zeebrugge, Nantes-Saint-Nazaire and Bordeaux. However, the establishment of this virtual standard does not fully take into account the rheological behaviour of the muds. With the same concentration levels, muds at different sites may have widely varying rigidity values. Thus, defining the notion of navigability threshold on the basis of a rigidity criterion rather than specific gravity could in some cases result in an increase in the nautical depth.

In order to examine whether this type of procedure would be possible, the Bordeaux Port Authority commissioned SOGREAH to compare the rheological characteristics of muds from the Gironde with those from other ports where the navigability threshold is based on a specific gravity value of 1.2 and where rheological measurements were available. The study consisted of three parts: preliminary investigations, in situ measurements and additional rheological analyses.

1. PRELIMINARY INVESTIGATIONS

Preliminary investigations involved comparing the rheological curves for Gironde mud obtained in the laboratory and dating from before March 1987 with similar curves for muds from the Loire and Mahury.

The same rheological analysis methodology has been used at the Laboratoire Central d'Hydraulique de France and at SOGREAH for nearly 30 years. It enables a comparison to be made between different investigations. Here, the initial rigidity is defined as the torque required to set in motion a rotor immersed in the mud.

This rigidity varies with the dry sediment concentration, following a relation of the type: $\tau_y = aT_z^b$, in which τ_y is the initial rigidity and T_z is the concentration. Two different domains - liquid and plastic - may be defined, where a and b are different (fig. 1). These are separated by what is referred to as critical values, namely critical initial rigidity and critical dry

sediment concentration. Determination of these values enables a comparison to be made between muds from different sites.

Figure 2 shows the critical dry sedimentation concentration for different sites. It appears that mud from the Gironde passes from a liquid to a plastic state at higher concentrations (340-620 g/l) than muds from the other sites considered (250-350 g/l).

Figure 3 shows that the initial rigidity for a dry sediment concentration of 300 g/l is less in the Gironde estuary than at the other sites. Seen from another point of view, the initial rigidity of muds from the Gironde at 350 g/l corresponds to that found for concentrations of 300 g/l (i.e. a specific gravity of the order of 1.2) from the other sites.

However, there was a certain spread of the results (figure 4) showing that the trend observed would have to be confirmed by other investigations, namely in situ measurements and additional rheological analyses.

2. IN SITU MEASUREMENTS

The aim of the in situ measurements was:

- . to establish an approach for in situ rheological characteristics variations in relation to density,
- . to make comparisons with the measurements carried out in other ports.

2.1. CONDITIONS AND MEANS EMPLOYED

The SD 105 ultrasonic densitometric probe, belonging to the Bordeaux Port Authority and the SR 10 probe were mounted on the same structure (fig. 5). This was done in such a way as to ensure that the two probes, separated horizontally by about 20 cm, should remain at the same level as they descended vertically. In this way it was possible to measure, in situ and applied to the same mud, the pair of values for the density (ultrasonic probe) and a rheological characteristic of the mud (SR 10 probe).

2.1.1 PRINCIPLE OF THE SR 10 RHEOLOGICAL PROBE

The probe comprises a cylindrical body, at the end of which a cone rotates at a constant speed (240 rpm). The electrical intensity required to maintain a constant rotating speed is measured. It is then correlated, after laboratory calibration, in relation to the initial rigidity.

2.1.2 SR 10 PROBE LABORATORY CALIBRATION

Two measurements are made for single mud sample:

- . on the one hand the initial rigidity using a Brookfield viscometer,
- . on the other hand measurement of the electrical intensity using the SR 10 probe.

In this way an initial rigidity-intensity pair is obtained for each sample.

The probe calibration curve is established on the basis of all the pairs (initial rigidity, intensity) obtained using samples of varying concentration.

Figure 6 illustrates the various values obtained on different sites. The low dispersion of values should be noted, and a standard calibration curve may be used for an initial approach, regardless of the site.

Due to the lack of a specific calibration curve, the standard calibration curve was adopted for this investigation.

In this way, it is possible to establish a correspondence between an intensity obtained by the SR 10 probe and a single initial rigidity, which we shall refer to as the "associated initial rigidity".

2.1.3 SD 105 PROBE PRINCIPLE

The SD 105 probe measures attenuation of ultrasonic sound attributable to the mud passing between the transmitter and the receiver. This is proportional to the concentration. Laboratory calibration using Gironde mud made it possible to establish the mud concentration. It should be noted that the probe was used here for vertical measurements, but a version does exist which may be pulled behind a ship. This latter makes it possible to make horizontal density measurements in navigation channels.

2.2 MEASUREMENTS CARRIED OUT

2.2.1 METHODOLOGY

Three vertical investigations were carried out on three different sites, with the probes mounted on the same structure. Subsequently a single vertical investigation was carried out on one site, with the probes separated.

During each of the vertical investigations, pauses in the descent were made. At each pause, a pair of SD 105 attenuation (concentration) and SR 10 intensity (associated initial density) values was noted. Fig. 7 shows an example of a recording.

2.2.2 MEASUREMENT RESULTS

Sites 1, 2 and 3

Figure 8 shows the concentration and associated initial rigidity variations in the axis of the channel, on the basis of the measurements made for the first three sites.

It would appear that in the area of site 3, the furthest downstream, one pass was filled by density currents coming from upstream. In the light of measurements made elsewhere, the slope of approximately 0.4% between sites 1 and 2 appears to be sufficient to produce a flow of this type carrying with it a higher proportion of sandy matter. In addition the vertical rigidity and density gradients show that, in all probability, the uppermost layer on site 3, over approximately 30 cm, is a recent arrival which has not yet had the time to solidify.

Site 4

On this site the two probes were separated.

As is shown in figure 7, the two probes detected a superficial layer, about 20 cm thick, with a higher density and rigidity than the layer immediately below. The measurements, carried out at the end of the ebb-tide, indicate a contribution from upstream, which supports the previous hypothesis concerning flow from upstream to downstream and in addition the possible existence of a negative density and rigidity gradient (but certainly only temporarily).

2.3 COMPARISON WITH MEASUREMENTS MADE ON THE GIRONDE IN OCTOBER 1984

The circumstances of the two missions, both in terms of space and time, are very different; the two sites are situated about 30 kilometres apart and the first investigations were carried out in the autumn, the second in the spring. However it should be noted, as G. Allen showed (1972), that sites may correspond to the respective positions of the maximum turbidity zone, which is located further downstream in March than in October.

Figure 9 makes it possible to compare the results of the two investigations: it appears that the majority of the points correspond to the range of values noted during the last mission. (The 1984 values nevertheless appear slightly lower, as a whole, than in 1987).

2.4 COMPARISON WITH MEASUREMENTS CARRIED OUT ON OTHER SITES

Comparison with measurements carried out on the Seine and the Loire (cf figure 10) show that in two cases Gironde mud appears in situ to be less rigid than that from other estuaries. For example a concentration of 300 g/l in the Loire corresponds to an associated initial rigidity of 15 N/m², which would correspond to a 350 g/l concentration in the Gironde.

Consequently, after taking account of the in situ measurements, it appears that in comparison with the other ports and taking account of the hydro-sedimentary conditions encountered during the different investigations, the Gironde muds are less rigid in situ. Consequently this result would justify admitting a navigability threshold situated at a higher density than 1.2. However, to be sure that such steps may be taken, it seems appropriate to acquire increased knowledge on spatio-temporal variability of rigidity levels in situ, for the comparison of different analyses of mud samples collected at different places and times show that significant variations may occur. During this assignment, samples were taken for analysis. The mud proved to be more rigid than that studied previously. It was then decided to carry out rheological analyses on samples in order to show up any spatio-temporal variations in rigidity.

3. SPATIO-TEMPORAL RIGIDITY VARIATION

These analyses were carried out on 10 samples taken between March 1987 and April 1988. They concluded that in general, mud from 1987 was more rigid than that from 1984. In an attempt to explain the cause of initial

rigidity value dispersion, the 300 g/l rigidities were entered in a graph. This was done for all the samples collected in the Gironde, whose date and place of collection was known. The position of the maximum turbidity zone, as observed by G. Allen in 1970-71 (figure 11) was also entered on the same graph.

It should be noted that movement of the mud zone may vary in time. It depends on variations in river flow.

It has been established that in general mud collected to the rear of the mud zone, in relation to the direction in which it is moving, appears more rigid than mud collected to the front of the zone. The ratio varies between 1.6 and 2.5. It seems probable that the age of the mud partly explains the phenomenon, but there may exist other factors such as grain sizes or changes in the mineral composition.

3.1 VARIATION IN RIGIDITY WITH RIVER FLOW

In addition, taking the samples collected between March and April and tracing the 300 g/l initial rigidity variations in relation to river flow in February (the month in 1984, '87 and 88 when flow was highest - cf. figure 12), it is clear that at PK 72 (the only PK for which measurements are available for three different years) the 300 g/l initial rigidity drops at the same time as the flow.

A relation of this sort deserves confirmation on the basis of other measurements.

The high rigidity values observed in 1987 seem to be accounted for by the absence of significant flood flow that year, and inversely, the low values obtained in 1984, in particular in May, seem to be attributable to the heavy flooding in February 1984.

4. CONCLUSIONS

The results of the 1987 measurements did not confirm that Gironde mud is systematically less rigid than that from the other sites. Because of this, in the present state of information, no decision can be reached with respect to the systematic adoption of a navigability threshold corresponding to a specific gravity of more than 1.2. However, it is likely that this would be possible in certain cases.

Indeed, the study showed that at a given spot, the rheological properties of the Gironde muds appear to be in relation to the hydrosedimentary conditions (and more particularly the river discharge).

In particular, it would appear that the rigidity of a mud is lower when the deposit is the result of suspended sediment introduced recently into the estuary. In the lower reaches of the river, fluid mud generally forms after the initial floods. Consequently, under these circumstances, the rigidity of the mud in the downstream reaches of the estuary is lower than that at other sites. Hence, a navigability threshold corresponding to a specific gravity higher than 1.2 could be considered.

Far more data is available for the Gironde than for the other sites. More information, obtained under varying hydrosedimentary conditions, will be needed for these sites before statistically valid comparisons can be made.

CHAPTER 223

Hydraulic Aspects of the construction of the Eastern Scheldt Storm Surge Barrier

Jan Konter¹ and Leo Klatter²

1. Abstract

The paper gives an overview of the results of the evaluation studies of the hydraulic aspects of the construction of the Eastern Scheldt Storm Surge Barrier. Subjects discussed are: methods used, design philosophy, results of flow modelling, stability of rubble stone structures, local scour and morphology.

2. Introduction

The Eastern Scheldt Storm-Surge-Barrier has been built across the three main tidal channels in the mouth of the Eastern Scheldt, from North to South respectively Hammen, Schaar and Roompot (see figure 1).

Figure 1: Location of the Storm-Surge-Barrier in the mouth of the Eastern Scheldt

^{1,2} Rijkswaterstaat, Construction Division, Hydraulic Branch, P.O. Box 20.000, 3502 LA Utrecht

The three barrier sections are interconnected by dams, that have been constructed upon the shallow tidal flats between the main channels. The construction of the barrier took place in the original channels, without a building pit. This construction method was chosen to minimize the effect of the construction activities on the tidal movements. To enable such a construction method, prefabricated elements were used when and where possible. The original seabed served as a foundation. After soil improvement and compaction the sand-bed was covered with large prefabricated mattresses 41 m wide and 200 m long. Upon the filter mattresses the piers were placed (see figure 2).

Figure 2: Elements of the Eastern Scheldt Barrier

The piers were packed by a rubble sill, that was built up in layers. A concrete sill beam and upper beam frame the actual flow opening, which can be closed by a gate. This gate is operated by hydraulic cylinders which were placed on top of the piers. The entire structure was assembled under open sea conditions. The construction activities took place simultaneously in the three channels.

The type of the structure, as well as the construction method inflicted a number of hydraulic problems that had to be solved:

- flow problems
- stability of rubble stone and bottom protection
- local scour at the borders of the bottom protection
- morphology of the mouth of the Eastern Scheldt
- environmental aspects.

3. Set up of the Investigation

The construction of the Barrier often resulted in conflicting interests, e.g.

- the time schedule of the work favoured finishing one channel after another, but this was unacceptable for morphological reasons.
- Closing already installed gates, created favourable working conditions in the vicinity of the Barrier, but closing of some gates may create problems at locations where the gates were not closed, with the stability of stones and bottom protection. The complete closure of one channel was also not allowed for morphological and environmental reasons.

This indicates that numerous possible geometries of the Barrier under construction were possible, each with its own complex flow pattern. Therefore a flexible prediction system for the flow conditions was necessary. This could be accomplished by choosing a selected number of hydraulic parameters as "load" parameters and to relate the "strength" of the item considered (e.g. stability of stones) to the selected "load" parameter. The selected hydraulic parameters fulfill two important criteria:

1. It can be predicted with reasonable accuracy
2. It governs the process to the hydraulic problem.
In other words there must be an unique relation between this hydraulic parameter and the strength.

In table 1 some examples are given of the flow parameters that were used as "governing hydraulic parameters" for the hydraulic problems encountered.

aspect	hydraulic parameter
environmental aspects	tidal difference γ
morphology at the mouth of the Eastern Scheldt	Δh_s
stability of rubble sill: - during construction - at final situation	q/A Δh
hydrodynamic loads on the large structural elements (piers, sill beams, upper beams, gates) during positioning	q/A
stability of bed protection	Δh
scour	Q

Table 1

To represent the flow conditions in the vicinity of the Barrier the following basic hydraulic parameters were selected

- Q = discharge through a main channel (m^3/s)
 Δh = head difference over the Barrier (m)

- Δh_s = difference in water level between two main channels (m)
- q/A = average velocity at the axis of the Barrier, defined as discharge per barrier section divided by the wet cross section (m^3/s)
- Y = tidal difference in Yerseke (selected harbour in the Eastern Scheldt).

With this approach the flow parameters that had to be predicted (Q , Δh , Δh_s , q/A and Y), depended only on the global geometry of the Barrier under construction (expressed as μA).

Details of the flow pattern are not important for the behaviour of these parameters. In general these parameters can be predicted by a one dimensional flow model, eventually combined with a resistance model to get q/A (See figure 3).

The prediction of the wave characteristics can be done in the same way with a wave model. Basic flow parameters and wave characteristics are the boundary conditions for the structure and the input for eventually necessary three-dimensional scale models.

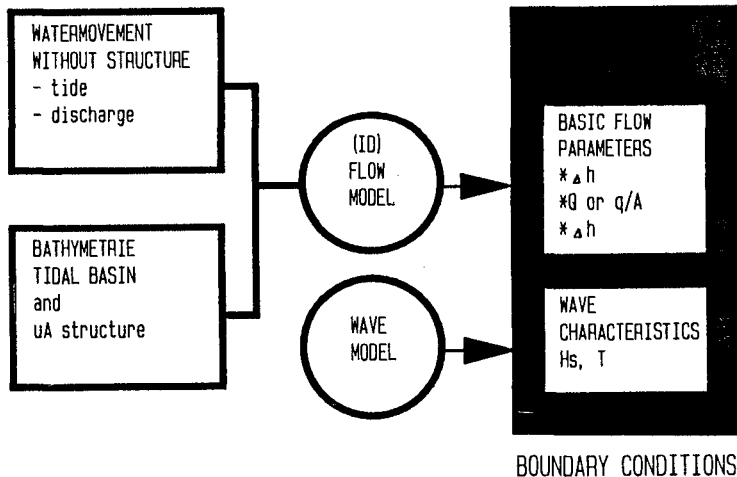

Figure 3: determination of boundary conditions

The next step is to find the "load-strength" relations, or the relation between the basic flow parameters and the design problems. It is strongly recommended to select a model that can express the strength in the same way as the loads (See figure 4) for example:

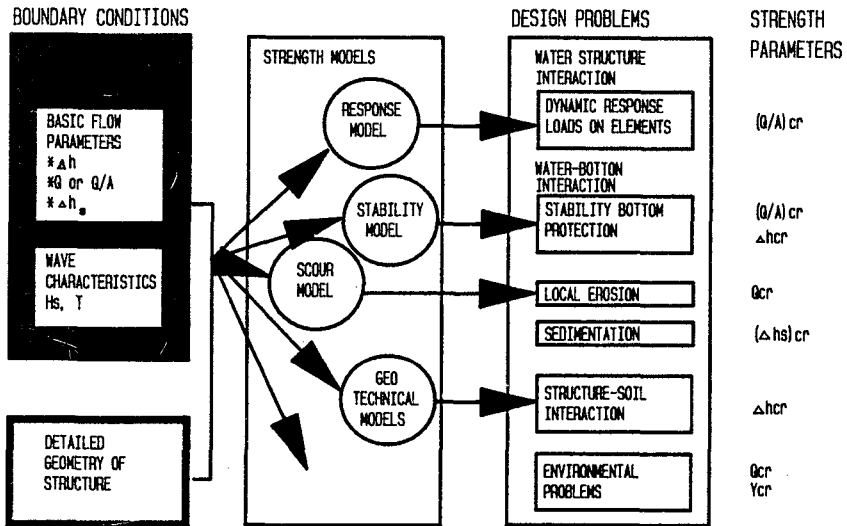

Figure 4: "load-strength" relations

Δh_{cr} and $(q/A)_{cr}$ are for example the critical values of Δh and Q/A at which the strength is not enough anymore (movement of stones, or to much erosion, etc.). In this way insight can be obtained in the interaction between the different hydraulic aspects, and with this insight the optimal solution for the conflicting hydraulic problems can be found. Beside this, expressing the loads and strength in the same parameter is necessary for probabilistic calculations.

It is noticed that as input for the strength models the detailed geometry of the structure is necessary. Therefore a three-dimensional model is necessary, in which the geometry of the structure can be reproduced correctly. The most reliable way to study the "load-strength" relation is the use of physical scale models. Also for the Eastern-Scheldt Barrier studies, a lot of attempts were made to find the "load-strength" relation by mathematical models. A reliable mathematical model for the complex three-dimensional interaction between structure-structure element bottom and water movement needs still a lot of effort and time before the same accuracy can be reached as a physical (scale) model. The mathematical model, gave more insight in the "black-box" of the physical scale model, but for most of the design purposes of the Barrier the results of the scale models were used.

A combination of relatively simple 1D or 2D-mathematical

models (finding the boundary conditions or "loads") and 3D scale models (finding the "load-strength" relations) proved to be the optimum tool.

4. Results

The approach described in section 2 proved to be very successful. The selected governing parameters made an integration of all items possible, and in most cases an optimal solution could be found between the conflicting interests.

A continuous evaluation of field experience during the construction period served as a check on the relations that were used. By means of the experience gained, the reliability of the predictions could be improved significantly.

After completion on the Barrier, it was decided to perform evaluation studies on the main hydraulic aspects of the construction (flow modelling, stability of rubble stone and bottom protection, local scour and morphology). In this evaluation study was looked at the accuracy of the used models, not from a scientific point of view, but as a design tool.

4.1 flow modelling (Klatter et al, 1986, 1989)

A comparison between (tidal) scale models and numerical models showed that overall tidal models can be safely substituted by numerical models, either one - or two dimensional (vertically averaged). The choice between one dimensional and two dimensional depends on the geometry of the estuary and type and extend of the results that are needed, e.g.

- a one dimensional model can predict Q , Δh , Δh_s and Y
- a two dimensional model can also predict the horizontal velocity distribution.

A detailed scale model is strictly needed if three-dimensional phenomena play a significant role. For large structures, such as the Eastern-Scheldt Barrier, the combination of a numerical model and detailed scale models will provide an optimal design tool.

The correct reproduction of the hydraulic characteristics of the Barrier was vitally important for the application of all models, both numerical and scale models. The hydraulic characteristics of the Barrier could be simulated correctly in a two-dimensional (depth-average) numerical model by using the discharge coefficients, determined from flume tests on representative sections of the structure.

For use in a one-dimensional numerical model, an overall

discharge coefficient had to be used. This discharge coefficient must be determined from either a scale model of the entire structure or through a two-dimensional numerical model combined with flume tests.

Verification of the models was of major importance, since the basic design parameters (Q , Δh) were determined with these models. The verification procedure was set up in such a way that each step in the forecast procedure was checked systematically. In this way not only the final results of the forecast system (predicted design parameters) were evaluated, but also the models as individual elements in the forecast system.

In this paper only a summary of the results of the verifications is presented for the following items:

- discharge in the main channel Q
- head difference over the Barrier Δh .

Discharge in the main channel Q

The measured discharges were compared with hindcast of the tidal motion during the respective day of measurements. The results of this comparison were used to determine the need of a re-calibration of the 1D-model, especially for the discharge coefficients of the barrier.

The experience gained by the verification was that, as the construction of the Barrier progressed, the discharge characteristics of the Barrier more and more dominated the tidal flow in the estuary. The influence of the overall discharge coefficient became more important than the schematization of the Eastern Scheldt itself. Additionally a verification was performed of the predicted design values of the discharge at maximum (ebb/flood) flow Q_{max} . This was done by transforming the measured Q_{max} to the corresponding value at average tidal conditions. The results of the verifications, both for design values and hindcast of the discharge at maximum flow are summarized in table 2.

Table 2 gives the average and standard deviation of the difference between measurement and forecast (in %)

relative deviation	design values Q_{max}				hindcast Q_{max}			
	max. ebb		max. flood		max. ebb		max. flood	
	mean	σ	mean	σ	mean	σ	mean	σ
[%]								
Roompot	-1.5	6.2	4.1	4.8	1.5	5.4	3.1	4.7
Schaar	-5.3	10.2	2.5	11.3	-2.7	3.9	4.4	5.0
Hammen	2.6	9.6	3.8	5.6	-2.4	6.4	-2.4	3.3
Total	-1.6	8.9	3.5	7.5	-2.1	5.1	1.7	5.2
Overall	mean=0.9% σ = 8.5%				mean=-0.2% σ = 5.4%			

Table 2: Results of verification Q_{max} 1D-model IMPLIC

The conclusions from the results presented in Table 2 are:

- The model errors mostly had a random character.
- The errors in the hindcasts were less than in the design values.
- The accuracy of the initial calibration of 10% (maximum error) had also been achieved with the hindcast ($2 \sigma \approx 10\%$).

In figure 5 the predicted design values of the mean velocity between two piers Q/A have been plotted against the measured values. In this figure low velocities corresponded to early construction stages and high velocities to later stages. The overall error in the Q/A forecast proved to be 12.4% (σ/μ), against 15% that was assessed before hand.

Figure 5: Results of the verification of the velocity forecasts at the location of the barrier.

Head difference across the Barrier Δh

The use of the parameter Δh depended strongly on the narrowing of the channel, and thus of the construction stage of the Barrier. Δh increased from less than 0.2 m in early construction stages to over 1.0 m in the later stages (overage tide conditions).

The accuracy, in which this parameter could be predicted turned out to be 10% to 20% (narrowing of the channel with more than 75%). Once experience was gained with a specific geometry of the barrier re-calibration diminished the errors in Δh computation with 5% to 10%.

4.2 Stability of rubble sill and bottom protection

Prediction of the stability of the rubble sill and several types of bottom protections at structures like the Storm-Surge-Barrier is only possible in a scale model based on Froudes law of similarity (see De Groot et al, 1984 and Konter et al, 1988).

The scale rules for a stability model are rather simple. The geometry of the structure and the dimensions of the bottom protection must be reproduced on the same linear length scale. Beside this the density and shape of the stones or blocks in the model must be the same as in nature. It can be shown that also stiffness and water-permeability can be reproduced correctly.

In general, it proved to be possible to build in all the relevant strength properties of stones and other types of bottom protections in a Froude model. With such a model the "load-strength" relation can be determined very well. However, a close interaction between modeler, designer and contractor during the whole test-program proved to be important.

The influences of changes in geometry, changes in the stone-size during construction, inaccuracies in the layer thickness due to the construction method must be investigated. Also the bed-roughness of the subsoil may have a great influence on the stability, especially in case of a filter layer directly laying on a (smooth) geotextile. All these aspects have to be incorporated in the test-program.

A result of a test series is given in figure 6.

Figure 6a: Test result

Figure 6b: Design graphs

Figure 6a gives the relation between basic flow parameter and the number of displaced stones, for three different stone sizes. It is recommended to test the whole range of the flow parameter because in some cases, unexpected changes occurred in the vertical flow pattern and therefore also in the relation between flow parameter and damage. The damage is also a function of the exposure time. A representative exposure time for extreme conditions has to be defined. With this exposure time figure 6a gives for each tested stone-size the critical value of the flow parameter for initial movement and failure, which can be plotted in figure 6b. The require stone size can be found, comparing figure 6b with the boundary conditions.

For the Eastern-Scheldt Barrier tests had been done in scale models with length scales varying between $N_L=80$ and $N_L=13$. Also a test in nature with coloured stones placed on the bottom protection has been carried out. The results of these tests, were in agreement with each other, if taken into account all the aspects (different exposure time, stone size diameter, geometry).

4.3. Local scour (Konter et al, 1986)

A method has been developed to predict the scour development in time, during the several construction stages of the Barrier. This method is based on a systematic investigation, which has resulted in the following empirical relations (see figure 7).

$$t_1 = \frac{330 \cdot \Delta^{1.7} \cdot h_0^2}{(\alpha U - U_{cr})^{4.3}} \quad (1) \quad \text{and} \quad \frac{h_{max}}{h_0} = \frac{t}{t_1}^p \quad (2)$$

Figure 7: Empirical relations for local scour

in which:

- Δ = relative density of the bed material under water (-)
- t = time (hours)
- t_1 = time in which $h_{\max} = h_0$ (hours)
- U = current velocity (= Q/A_{total} or q/A) m/s
- U_{cr} = critical velocity for initiation of bottom material m/s
- α = geometry parameter, depending on the geometry of the structure (construction stage)
- p = coefficient (in two dimensional flow conditions $p=0.4$) in three dimensional flow conditions p = varying between 0.2 and 0.6 depending on the water-depth.

The time scale of the scouring phenomenon can be deduced from relation (2).

$$n_t = n_1^2 \cdot n_{\Delta}^{1.7} \cdot n_{(\alpha U - U_{\text{cr}})}^{-4.3}$$

The values of α and p are the same in model and nature. For a particular construction stage $h_{\max}(t)$ can be measured in a scale model, in which the geometry is represented on length scale. The values of α and p can be determined with this model tests and the relations mentioned above.

In nature the values of α , U , U_{cr} and Δ are known, so the time scale is known, and the development in time can be determined. The influence of unsteady flow and upstream sand transport can be introduced (see Konter et al, 1986).

Relation (2) indicates that the erosion capacity depends mainly on the scour rate parameter αU . It proved to be important to investigate the value of αU for each specific construction stage

Figure 8 gives a direct insight in the construction stages with maximum erosion. The maximum scour rate occurs downstream the part of the Barrier at which the sill beams have not yet been placed. Downstream the already placed sill beams αU has a lower value, which can be seen in figure 8, when placing the sill beams in one channel is completed. The translation of αU to $h_{\max}(t)$ can be made using the relations mentioned above.

It has been proved by the scour development in nature (see Konter et al, 1986) that there is a reasonable similarity between model and nature for construction stages with αU values greater than 3.0. For situations with αU -values lower than 3.0 the scour development is

strongly depending on the (often) uncertain amounts of cohesive parts in the bottom material and the upstream sand transport. In such situations the prediction method can only give an upper limit of the scour development in time 0.3 m in a month).

The model tests can also give insight in the steepness of the upstream slopes for a specific geometry (construction stage).

Figure 8: The values of αU (flood) during placing of the the sill beams

It showed that vortices with vertical axes cause very steep slopes (in model) and therefore relatively dangerous for the geo-technical stability of the bottom protection. These dangerous geometries configuration with (partly closed gates in a channel) were avoided and therefore no evaluation in nature was possible.

The method mentioned can also be applied for situations without a bottom protection, and gives a very accurate prediction of the time development of local scour (high values of αU).

4.4 Morphology (Bliek et al, 1986)

During the construction of the Barrier, the three main channels were unequally constricted. This might cause water-level differences between the main channels, with increasing flow velocities and therefore unacceptable developments in the morphology. Even short cut channels could be initiated or deepened. One of the dangers of short cut channels is the progressive erosion that might occur.

- the initial increase of flow velocities could result in erosion on the shoal
- the deepening of the shoal due to erosion could reduce its flow resistance and cause an extra increase in velocities, with an increase erosion rate and so on

- finally, there may be a significant change in the main channel system in the mouth of the estuary, with its influence on the design parameters (Q and Δh) of the channels
- change in the design parameters have its influence on the other hydraulic aspects (stability bottom protection, scour).

Short cut channels cannot be compared with main tidal channels where, in general, an increase in flow velocities, will cause a widening of the profile and a reduction of the flow until a new equilibrium is reached. The approach to study the effects of short cut channels is presented in fig. 9.

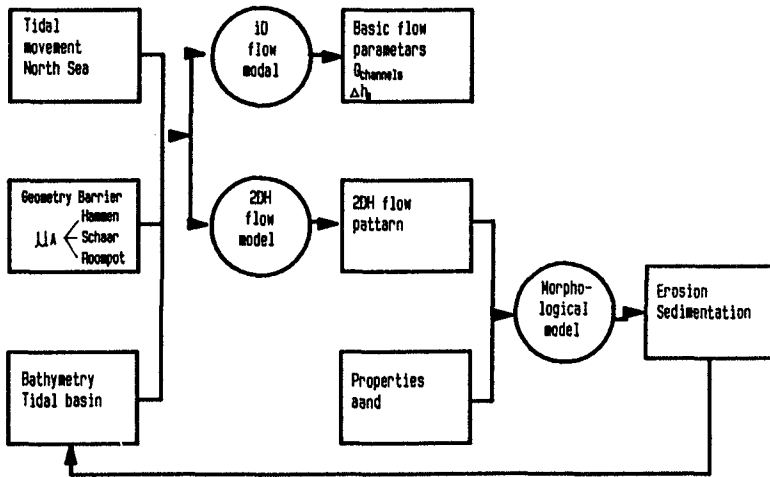

Figure 9: Set up morphological investigation

- investigation of the change of the governing load parameters Δh_s for the different geometries of the Barrier by means of a 1D-model, from which the critical construction stages can be derived
- calculation of the flow pattern for a selected number of critical construction stages by a 2DH-model
- quantifying the erosion under extreme conditions and what's most important the consequences of an extreme erosion on the basic flow parameters (that means other hydraulic aspects).

This approach proved to be very successful, also because the used mathematical models appeared to be applicable and reliable.

5. Conclusions

- * For large hydraulic structures a combination of scale models and numerical models will provide optimal results, in general:
 - 1D or 2DH numerical models to predict the boundary conditions
 - 3D scale models to find the "load-strength" relations.
- * To ensure optimal use of hydraulic research results, a careful selection of "governing" hydraulic parameters is very important. Both the "loads" and the "strength" have to be expressed in these parameters.
- * A scale model based on Froudes law on similarity can solve almost all hydraulic problems at hydraulic structures. In general a correct reproduction of the flow pattern is more important than a correct reproduction of all the stability parameters.

CHAPTER 224

INVESTIGATION ON IMPROVEMENT OF YANGTZE ESTUARY

Yen Kai & Yan Yixin

Abstract

The improvement of the Yangtze Estuary has attracted much attention in China. The fluvial processes of the estuary are rather complicated. The frequent move of sandbanks in the estuarine channels and the bar forming at the mouth give much trouble to navigation.

Investigation on the guiding principles and schemes for the improvement of the Estuary has been carried out since 1958. Comprehensive field survey, laboratory experiments and numerical modeling as well as planning work have been done in the past 30 years with some preliminary achievement. A scale model study with horizontal scale 1:1600 and vertical scale 1:120 was conducted by the Nanjing Hydraulic Research Institute.

Introduction

The Yangtze River is the largest river in China, with a total length of 6300 km and a catchment basin of 1,800,000 km². The 145 km stretch from Xuliujing to the sea forms the estuary. As a result of interaction of river flow and tidal current, the estuary is splitted into several channels. It is bifurcated by the Chongming Island into North and South Branches. The former undergoes serious accretion and the latter is now the main passage for runoff and navigation. The South Branch is further divided into North and South Waterways by Changxing and Hengsha Islands. Finally the South Waterway is again bifurcated into the North and South Channels(Fig.1).

Yen Kai, Professor and Honorary President, Hohai University, Nanjing 210024, China
Yan Yixin, Associate Professor of the same university

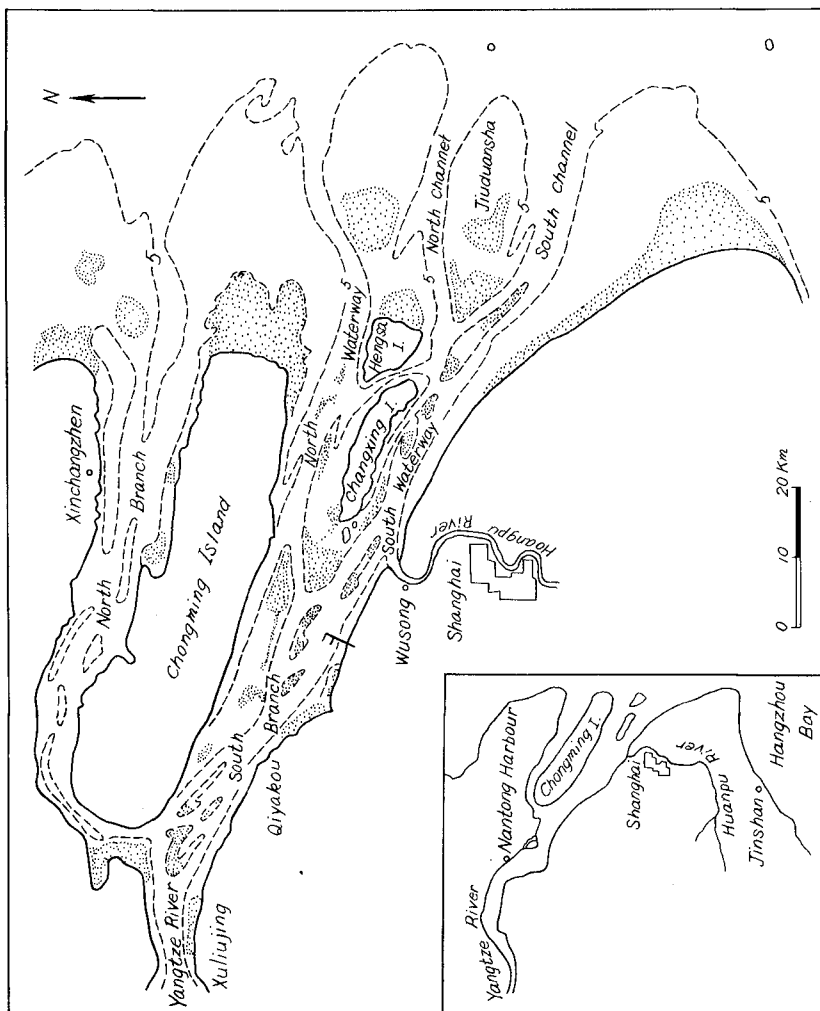

Fig.1 The Yangtze River Estuary

As the Yangtze Estuary, serving as a vital passage for foreign trade and the gateway of the largest port of China, Shanghai, has a great value in the development of China's national economy, its comprehensive improvement has attracted much attention in China.

Hydrological Features of the Estuary

Both the river runoff and the tidal flow play important role in moulding the estuary. The yearly mean total runoff amounts to $925 \times 10^9 \text{ m}^3$ with an average discharge of $29,300 \text{ m}^3/\text{s}$. The max. discharge is $92,600 \text{ m}^3/\text{s}$ and the min. is $4620 \text{ m}^3/\text{s}$. The tide in the estuary is semidiurnal tide, with a mean tidal range at the mouth of 2.66 m, a max. of 4.62 m and a min. of 0.17 m. The intensity of tidal current varies with seasons, generally it is high in the flood season. For example, in the flood season, at the mouth of South Channel the average current velocities during flood and ebb tide are respectively 0.91 m/s and 1.13 m/s, the respective max. values are 1.64 m/s and 1.88 m/s. The tidal current could reach as far as 300 km from the mouth and the effect of tidal action could be felt at the Datung Station, some 640 km from the mouth in the low water season with strong tide.

The total silt load is on the average $486 \times 10^6 \text{ t}$ per year, with a mean silt concentration of 0.54 kg/m^3 , being high in the flood season, attaining 1.00 kg/m^3 , and low in dry season, amounting to 0.10 kg/m^3 .

The salinity at the mouth of the estuary is on the average 16%. It varies with seasons, reaching 20% in dry season and 10% in flood season. The estuary belongs to the partly mixing type, but during the flood season with high river runoff it may be changed into a weak mixing type and in dry season into well mixed type.

Morphological Characteristics of the Estuary

The mouth of the Yangtze Estuary was located about 200 km inland of its present position some 3000 years ago and the land of Shanghai and Chongming Island were formed by the alluvial deposition during the last thousand years. Under the action of Coriolis force the ebb current is deflected to the right bank of the channel and the flood current to left. This gives rise to a divergence of ebb and flood currents in the channel, causing deposition of sediment in the slack water zone between the two currents paths. As the process of deposition goes on shoals are formed which in the course of time may be developed into islands, such as the Chongming Island and the Hengsha Island. Take the Chongming Island for example, it divides the estuary into two branches.

More or less influenced by the Coriolis force the main ebb current enters the South Branch and in the North Branch the flood current predominates. The flood current in the North Branch, being close to the north bank, causes bank erosion with consequent accretion at the south bank, i.e. the north waterfront of the Chongming Island. As to the South Branch, the erosion of the south bank has been long since checked by the construction of bank protection works, thus aggravated the erosion of the north bank, i.e. the south waterfront of the Chongming Island. There is, therefore, a tendency of gradual shifting of islands or sandbanks to the north in the Yangtze Estuary, which may eventually result in their attachment to the north bank.

As the South Branch is now the main passage for runoff and navigation, it has called much of our attention. One important feature of the South Branch is the periodic shifting of the bifurcation point of the North and South Waterways, the range of shifting may attain 20 km or more. Such shifting has in turn influence on the fluvial processes of the two Waterways, causing frequent move of sandbanks in the channels. The cause of shifting is rather complicated. One important point is that, when the main current takes one of the Waterways, say the North Waterway, then more sediment, particularly the bed load, is also carried into this Waterway, causing accretion, reduction of channel capacity and increase in flow resistance. The main current is thereby obstructed and gradually turned into the South Waterway. In the meantime, due to the encroachment of the bifurcation point, it shifts gradually downstream, twisting the channel leading to the North Waterway, thus further increases its flow resistance and reduces its discharge capacity. When the flow in the South Waterway is increased to such an extent that its channel capacity is not sufficient to take over the increased ebb flow, a new channel leading to the North Waterway will eventually be cut through the sandbanks upstream of the bifurcation point, and a new bifurcation point is thus formed. The old bifurcation point is then gradually abandoned. A similar cycle of such change will occur when the main ebb flow turns from the South Waterway to the North Waterway. Nevertheless, a relative stable condition could occur when the ebb flow is approximately equally divided into the two Waterways.

As a partly mixing type, the Yangtze Estuary shows its typical salinity distribution as shown in Fig.2. It can be seen that there is a longitudinal salinity gradient which affects the ebb and flood currents and sediment movement. In the course of a tidal period

Fig. 2 Salinity Distribution in South Channel
Dec. 23-24, 1963 Tidal Range 2.77 m
Discharge 15000 m³/s Salinity in %.

when the ebb flow turns into the flood flow, we can find a stagnation point somewhere near the river bottom where the net velocity is zero. Around stagnation point there is a stagnation zone where deposition of sediment most likely to take place. The settling of suspended sediment here is further facilitated by the flocculation process caused by the mixing of river runoff with sea water. As a result bars are formed at the mouths of the North Waterway, the North Channel and the South Channel, which extend for a distance of 10 to 20 km or more.

As a rule, deposition on the bars takes place during the flood season and in the dry season the bars are subjected to erosion.

Guiding Principles and Schemes for the Improvement of the Estuary

The improvement of the Yangtze Estuary is chiefly aimed at navigation, with due consideration of the benefits of land reclamation, irrigation and drainage of the adjacent land, water supply, flood protection, tourism industry and environment protection. The South Branch, being the main waterway connecting the inland and ocean navigation, in its natural state is insufficient to answer the growing demand of water transportation. The length of the stretch of the South Branch from Xuliujing to Wusongkou, the confluence of Huangpu River to the Yangtze Estuary, is 69 km. As we know, most of the quays of the port of Shanghai are situated along the banks of the Huangpu River. The upper reach of this 69 km river stretch, from Xuliujing to Qiyakou, for a distance of 35 km is called Baimousa stretch, and lies between the two "nodal points". We take Xuliujing and Qiyakou as "nodal point" or sub-nodal point", because the channel here is relatively stable and is contracted to only about 5 km

and 9 km in width respectively. The Baimousa stretch is splitted by the Baimou Sandbank into a north channel and a south channel, the latter is now the main navigation waterway having a water depth of 10 m except at the upper end, where auxiliary dredging is needed to increase the depth required for navigation.

The lower reach of the 69 km river stretch from Qiyakou to Wusongkou is 34 km long and is called Three-Bank stretch, because there are three sandbanks, viz. the Central Sandbank, the Biandan Sandbank and the Liuhe Sandbank in the estuary, which are very unstable. The width of Three-Bank stretch increases from 9 km at Qiyakou to 17 km at Wusongkou, which leads to the formation of shoals here and there in the estuary, among which the three sandbanks are the most prominent ones. The bifurcation point of North and South Waterway lies in this stretch, shifting up and downstream for a distance of ca. 20 km in a period of some 30 years, as mentioned before. The unstable channel condition and the shoals in the channel give much trouble to navigation, although a water depth of 10 m can be maintained for the most part of this river stretch.

Based on the results of investigation, the guiding principles and schemes for the improvement of the Yangtze Estuary may be summarized as follows:

1. Regulation of Upper Reach of South Branch

For the regulation of the upper reach of the South Branch, i.e. the Baimousa river stretch, it is important to protect the two "nodal points" at Xuliujing and Qiyakou. The Xuliujing "nodal point" has the function of stabilizing the direction of main current and refraining shoals upstream from moving downstream into this river stretch. The Qiyakou "sub-nodal point" exercises similar function to the lower reach of the South Branch, which is important for the creation of stable channels.

The existing north and south channels of the Baimousa river stretch will be maintained, but the direction of flow and the river discharges into these two channels have to be readjusted by the construction of regulation work in combination with land reclamation as shown in Fig.3.

2. Regulation of Lower Reach of South Branch

In order to maintain a stable deep channel in this river stretch it is necessary to contract the channel, stabilize the bifurcation point of the North and

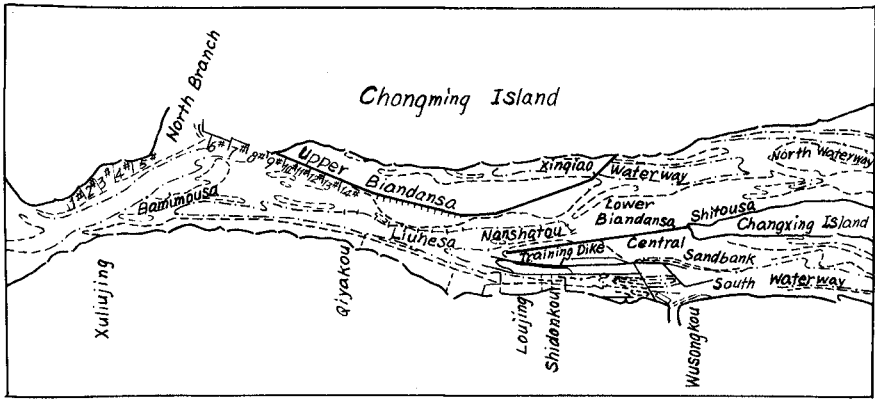

Fig.3 The South Branch of Yangtze Estuary

South Waterways and adjust the discharges into the two Waterways. After analysing the morphological changes in the past it is found that in 1971 when the bifurcation point was situated at a location about 10 km upstream of the Shitousa on the Central Sandbank the channel was relatively stable as shown in Fig.4. So this point may be taken as the project bifurcation point. At present the bifurcation point is several km upstream of the project point and is shifting downstream at a rate of 1 km per year. It is therefore advisable to stabilize the bifurcation point in time to avoid the difficulties incurred when it moves too far downstream.

Fig.4 South Branch in 1971

Once the bifurcation point is stabilized, it is still necessary to take measure to control the flow condition so as to approximately equally divide the ebb discharge into the North and South Waterways. Such a discharge distribution is favorable to the maintenance of stable channel condition for both Waterways, each of which is important to navigation. Because the South Waterway is at present the main waterway for seagoing vessels and quite a few important enterprises are situated on its south bank, while the North Waterway is indispensable for the navigation of the Chongming Island and is also a prospective deep outlet channel to the sea.

The waterway channels should be contracted. Studies have been made for the layout and orientation of the channel regulation lines, beyond these lines land reclamation and construction works are prohibited. Some of the branch channel cutting through the sandbanks should be dammed up to reduce the random flow over them.

The stabilization of the Biandan Sandbank is of particular importance to the regulation of the lower reach. The regulation of the upper reach and the stabilization of the bifurcation point of the North and South Waterways are favourable to the stabilization of this sandbank. But due to the existence of the Xinqiao Waterway on the north side of the sandbank there is still random discharge over the latter, affecting its stability. Therefore training work has to be constructed on the south side of the sandbank to cut off the random discharge and to stabilize its south boundary.

The regulation work will be carried out in stages. As the first stage, the work for the stabilization of the bifurcation point should be built in the coming few years. Several schemes have been investigated, and the one comprising a training dike connecting Nanshatou to the Shitousa on the Central Sandbank has been selected (Fig.3). Besides stabilizing the bifurcation point at the project location, it has also the function of refraining the shoals upstream from moving into the river stretch Luoqing-Shidankou and confining the ebb flow into this river stretch, both are favorable to the maintenance of a stable and deep water channel. This is important because the Baoshan Iron and Steel Work, a key enterprise, as well as the prospective deep water berths of the Port of Shanghai are located on south bank of this river stretch. Moreover, the dike will check the flow over the sandbank and prevent the formation of new cut off channel, which would endanger the stabilization of the bifurcation point.

For preliminary study a scale model has been constructed in the Nanjing Hydraulic Research Institute.

Owing to the immense extent of the estuary, a highly distorted model was built with a horizontal scale 1:1600 and a vertical scale 1:120. The model has an overall length of 120 m and a maximum width of 32.6 m. The upper end of the model was connected to an arbitrary meandering channel stretch, 200 m long, representing the waterway upstream of the estuary. Two different tide generating devices, consisting of a tidal chamber and a tail water gate, are installed at the lower end (Fig.5). From the test results it can be seen that, with the construction

Fig.5 Model Layout of Yangtze Estuary

of the training dike, the ebb velocity flanking the south bank of the south channel is increased, which is favorable to the maintenance of deep water in front of the Baoshan Iron and Steel Work and the project new berths of Shanghai Port, while the current velocities at Qiyakou, Wusongkou and other places in the North and South Waterway are practically unchanged, showing the regulation work will not exercise notable influence on the flow regime upstream and downstream. This means that the training dike as the first stage of the work of regulation can well coordinate with the successive stages of regulation to be followed. The model was essentially a fixed bed model, but some tests were conducted with partly movable bed to observe the fluvial processes of the lower reach of the South Branch. Only fresh water tests were performed, the facilities and techniques for conducting experiments with salt water are now in preparation.

3. Improvement of Outlet Channels to the Sea

As mentioned before, bars are formed at the mouth of the North Waterway, the North Channel and the South Channel, the water depth over the bars is generally 6.0 - 6.5 m. After dredging a water depth of 7 m is now maintained over the bar of the North Channel. Vessels with draft of 9.5 m could enter the estuary by saving the tide.

In the near future it has been proposed to increase the depth to 7.5 m. In prospect, a deep outlet channel of 9.5 m is considered appropriate. Of the three possible outlets, the bar of the North Waterway is shortest and that of the South Channel is longest. To acquire a deep outlet channel dredging alone is impracticable. At present, the yearly maintenance dredging for a 7 m outlet channel is as high as $14 \times 10^6 \text{ m}^3$, that of a 9.5 m channel would evidently many-fold of this. Training work has to be carried out, supplemented by dredging and land reclamation. Other possible solutions have been proposed, such as the creation of a by-pass outlet channel beyond the influence of bar-forming.

4. Improvement of the North Branch

The North Branch is now under the process of gradual accretion. The sea water intrusion caused by flood tide carries part of the sediment and salt water upstream along the channel and turns them into the South Branch, which is unfavourable to the improvement of the latter as well as to the North Branch itself. In order to reduce the sea water intrusion and to maintain a relatively stable channel in the North Branch, regulation work is also necessary. One way is to confine the North Branch by contraction work or in combination with land reclamation. An alternative is to dam up or partly enclose the North Branch. Feasibility study has to be made to make the final decision.

Conclusions

The improvement of the Yangtze Estuary is a rather complicated problem. Although comprehensive field investigation, laboratory experiment and numerical modeling, as well as planning work have been carried out in the past 30 years, yet still much remains to be done. The compilation of basic data, particularly at the mouth, should attract much of our attention. The study of fluvial processes should be continued with the aim to find out the optimal scheme and layout of the works of regulation. For this, movable bed model tests with salt water installation should be conducted.

CHAPTER 225

CONSOLIDATION AND RHEOLOGICAL PROPERTIES OF MUD DEPOSITS

Claude MIGNIOT and Luc HAMM (1)

Abstract

The temporal evolution of consolidation and associated rheological properties of mud deposits has been studied by means of laboratory experiments for more than 40 sites throughout the world.

Standard procedures have been used for all these experiments.

The present paper describes the experimental procedures and gives a summary of the results obtained.

1. Introduction

Typical engineering studies involving mud carried out for 30 years by SOGREAH(Grenoble) and Laboratoire Central d'Hydraulique de France (Maisons-Alfort) have covered the main fields of port and coastal engineering, namely:

- Maintenance of depths in harbour basins, navigation channels and water intakes,
- Navigation in muddy waters(Brossard et al.,1990),
- Evolution of waste disposal sites.

In order to adequately describe the mechanical properties of mud deposits, standard laboratory experiment procedures have been developed and applied.

Two basic parameters are measured to characterize these properties:

- The dry sediment density $T_s(z,t)$ in kg/m^3 or g/l
- The yield value $\tau_y(T_s)$ in N/m^2

with z : depth in the deposit and t :time

6 rue de Lorraine 38130 Echirolles France -

2. Consolidation experiments

2.1 Description of the procedure

These experiments are carried out in settling tubes 0.10m in diameter. Mud samples are diluted in pure or salt water to obtain an homogeneous fluid mud with an initial dry sediment density (Tsi) varying between 5 and 300 g/l and an initial height (Hi) varying between 0.25 and 3m. The temperature is kept around 20°C. The evolution of the mean dry sediment density is monitored by measuring the position of the water-mud interface.

The density profile over the depth is measured at different time intervals with a gamma-ray source and a detector(non-destructive measurement).The duration of the test is usually 100 days.

2.2 Evolution of the mean dry sediment density

The mean dry sediment density is deduced from the position of the water-mud interface by the relationship:

$$Tsm(t) = Tsi * [H(t) / Hi] \quad (1)$$

Results are plotted on a semi-log diagram. Typical results are presented hereafter(fig 1).

Figure 1. Consolidation tests - typical results

Figure 2. Consolidation tests:Wouri estuary
Influence of the initial dry sediment density

Figure 3. Consolidation tests:Dunkirk harbour
Influence of the initial dry sediment density

After 100 days the consolidation process has reached its final state in a few cases. Equatorial muds (Mahury, Douala, Owendo) with high kaolinite contents and a very fine particle size have a very low rate of consolidation and have not reached their final state. European estuarine muds (Loire, Escaut, Gironde, Orne, Dives) are made of a mixture of several clay minerals (illite, smectite, kaolinite, chlorite) and include quartz, feldspar and a variable proportion of silt. In these cases, the consolidation is a function of composition.

The comparison of results with the same initial height but different initial dry sediment densities shows the greater the initial density, the greater the final density. A typical result is shown on fig 2 (Wouri estuary, Cameroon). In a few cases, when a small proportion of sand is included in the mud, the opposite trend is observed as shown on fig 3 (Dunkirk harbour, France, 5% of sand). This is due to the segregation of sand particles, which form thin drained beds increasing the final density.

The comparison of results with the same initial dry density but different initial deposit heights shows that the final density is not too influenced by this parameter when it varies between 0.25 and 3 m. Typical results are shown on fig 4.

Figure 4. Consolidation tests: influence of the initial height of deposit

2.3 Evolution of the vertical profile

During the consolidation test, a vertical gradient appears and increases with time. Figure 5 shows a typical result in the Gironde estuary. Study of the influence of the initial deposit height shows that the gradient increases when the height decreases (fig 6). These results can be applied to increase the stability of waste disposal sites by depositing thin layers and letting them consolidate a few days in between.

($T_{si} = 200 \text{ g/l}$; $H_i = 0.75 \text{ m}$)

Figure 6. Consolidation tests: Loire estuary
Vertical profiles after 6 days ($T_{si} = 100 \text{ g/l}$)
Influence of the initial deposit height

3. Rheological measurements

3.1 Purpose of the measurements

Knowledge of the dry sediment density of a mud deposit is not enough to characterize its mechanical properties in the presence of hydrodynamic forces. Flume tests have given evidence that the erodability of cohesive sediments is primarily a function of their rheological properties, which are not simply related to the dry density.

The complexity of natural sediments precludes a fundamental interpretation of their rheology. That is why a simple and standard procedure has been used in order to obtain good comparative results and be able to develop empirical relationships to be applied in engineering projects.

3.2 Description of the procedure

The measurements are made with a BROOKFIELD LVT viscometer using 4 rotating cylinders with the following dimensions:

	1	2	3	4
diameter(mm)	18.84	10.25	5.88	3.20
length (mm)	65.10	53.95	42.86	31.01
range of use (N/m ²)	< 1.	1.to 4.	4.to 10.	>10.

The speed range varies between 0.3 and 60 rpm and the temperature is usually kept at 20°C.

The yield value is determined with the following procedure:

- Strong homogenization of the mud,
- Introduction of the rotating cylinder,
- Keeping at rest during 2 to 5 min in order to avoid thixotropy on one side and consolidation on the other.
- Starting with the lowest speed of 0.3 rpm.

The yield value (τ_y) is defined as the peak value of the recorded shear stress as illustrated by figure 7. In some cases, rheograms are determined by increasing the speed.

3.3 Typical results

Measurements are carried out with the same mud and different dry sediment densities. Results are plotted on a log-log diagram as illustrated by figure 8. These results show that in many cases, two domains can be observed. At low concentrations the mud sample looks fluid. When the concentration increases, the mud becomes plastic and the yield value increases dramatically.

For such a fluid mud, the relationship between the yield value and the dry density is usually of the form:

$$\tau_y = C_1 \quad Ts^3 \quad (2)$$

For a plastic mud, this relationship becomes:

$$\tau_y = C_2 \quad Ts^6 \quad (3)$$

C_1 and C_2 are parameters depending on the site studied. The limit between the two domains usually lies within 1 to 3 N/m².

4. Applications

The above measurement data are usually used for particular engineering projects including desk studies, mathematical simulation of mud transport or physical scale models. Two more general applications can be noted: The first deals with navigation in muddy waters where it is necessary to define the nautical depth in the turbidity maximum of many estuaries. Galichon et al (1990) describe in detail the use of the yield value to define the nautical depth in the Gironde estuary.

A second application is the investigation of relationship between the critical shear stress for erosion (τ_{ce}) under a steady current and the yield value. First results from small-scale flume tests have shown that such a relationship can be written as:

$$\tau_{ce} = 0.17 \sqrt{\tau_y} \quad \text{for fluid mud}$$

$$\tau_{ce} = 0.10 \tau_y \quad \text{for plastic mud}$$

CHAPTER 226

INTEGRATED COASTAL RESEARCH IN THE SW NETHERLANDS

Jan P.M. Mulder¹, Teunis Louters², Frank P. Hallie², Renske Postma³,
Johan A.Craeymeersch⁴ and Olivier Hamerlynck⁵

ABSTRACT

The geomorphological and ecological response of the ebb tidal deltas of the SW Netherlands to implementation of the Delta Project during the last decades, has been the subject of an integrated research project. General observed geomorphological trends are: erosion of the delta fronts and of the relic tidal bars in the landward parts of the deltas, and sedimentation in the tidal channels and in longshore bars at the edges of the deltas. Ecologically, a general trend towards richer benthic fauna communities is observable. The integrated approach in coastal research combining geomorphological analysis of field data with numerical modelling, and integrating hydraulic, geomorphological, sedimentological and biological data, has appeared very promising. Progress in this field would be stimulated by further research of the driving processes in the interaction of hydrodynamics - sediment - biota. The level of detail (spatial and temporal) in geomorphological contributions to such research will have to be much higher than usual in current coastal morphological studies.

1. IMPACT OF DELTA PROJECT ON EBB TIDAL DELTAS OF THE SW NETHERLANDS

Implementation of the Delta Project in the SW Netherlands has induced major changes. The closure of the Haringvliet and Grevelingen estuaries in 1970 and 1971 respectively, and the completion of the Oosterschelde storm surge barrier in 1986, have initiated a dramatic change in hydraulic conditions and the geomorphology of the former ebb tidal deltas. The changes in physical boundary conditions affect the total ecosystem of the coastal area and entail consequences for various human activities. This environmental impact creates a challenge to integrated water- and coastal management (Hallie et al., 1990).

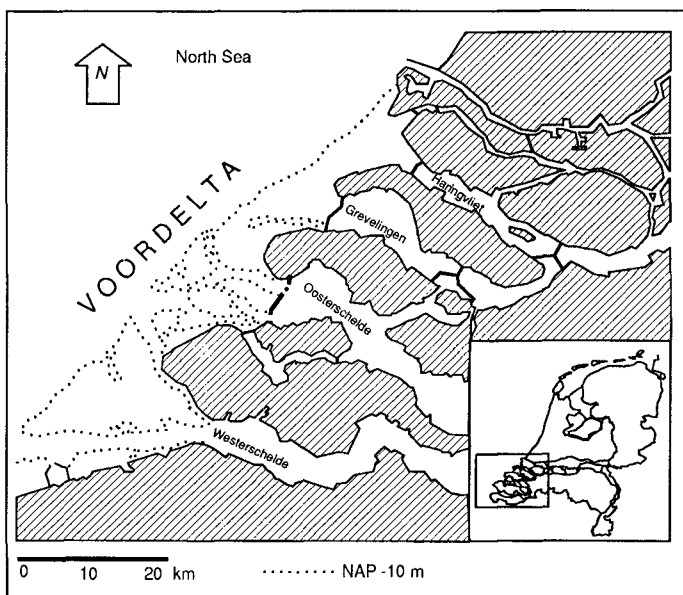

Fig. 1 Study area: the Voordelta

2. INTEGRATED RESEARCH PROJECT

The developments of the former ebb tidal deltas of the Grevelingen, Haringvliet and Oosterschelde - area known as the Voordelta (Fig. 1) have been the subject of an integrated research project, aimed at

- describing the recent developments and present situation of both geomorphology and ecology; and
- predicting on an intermediate time scale (1990 - 2010), the change in geomorphology and possible shift in ecological functioning of this area.

The results are being used as basic information to develop an integrated policy plan during 1990.

This paper summarizes the general results of the research project.

Specific results have been described in more detail by Kohsiek (1988), Steijn et al. (1989), Mulder (1989), Hallie et al. (1990), Louters et al. (1990), Postma et al. (1990), Craeymeersch et al. (1990) and Hamerlynck et al. (1990).

3. PHYSICAL CHARACTERISTICS OF THE STUDY AREA VOORDELTA

The actual geomorphology of the Voordelta is characterised by interlinked (former) ebb tidal deltas extending 10 - 15 km seaward from the coastline. The delta fronts are marked approximately by the depth contour of -10 mNAP [NAP= mean sea level as defined for Amsterdam]. Maximum depths of tidal channels range from -23 mNAP at the Oosterschelde -, through -14 mNAP at the Grevelingen -, to -10 mNAP at the Haringvliet ebb tidal delta. Maximum heights of longshore - and tidal bars range between -1 and +1mNAP. The mean grain size in the area varies from 150 - 350 micron.

The dominant tidal currents run parallel to the coast: northward during flood, southward during ebb. The semi-diurnal vertical tide has a mean range of ca. 2.6 m and can be classified as mesotidal. Maximum current velocities at the Oosterschelde ebb tidal delta, still with a substantial east - west component to and fro the basin, presently amount 1 - 1.2 m/s; at the Grevelingen - and Haringvliet ebb tidal deltas maximum velocities range from .40 - .60 m/s. These values imply the significant velocity reductions that have occurred due to the construction of dams: the Oosterschelde storm surge barrier (1986) induced a reduction of ca. 30%, closure of Haringvliet and Grevelingen (1970/71) reductions of 45 - 80% (Kohsiek,1988).

For the prevailing winds (southwest to northwest), the wave climate is characterised by a significant wave height (H_s) of 1.2 m (Louters et al., 1990).

4. INTEGRATED APPROACH

The Voordelta research project has been characterised by an integrated approach at two levels (Fig. 2).

At the level of geomorphological research an integration took place of results from field data analyses and from numerical modelling. Ecological research was based on an integrated analysis of hydraulic, geomorphological, sedimentological and biological data.

4.1 Geomorphological research

Echo sounding maps of the study area have been recorded almost yearly since the early 60's. These soundings have provided the basic data for geomorphological research.

First a qualitative analysis has been performed comparing different sounding maps. Then, after preparing 200*200 m and 100*100 m grid squares with interpolated depth values, changes in sediment volume

Fig. 2 Schematic representation of the integrated approach both in geomorphological and in ecological research

of the ebb tidal deltas and specific sub units have been quantified. Trends in these changes have been analysed statistically. Parallel to the analysis of bathymetric data, numerical modelling has been applied to study the dominant processes: a 1D model of CROSS-shore TRANSPORT (CROSTRAN) to investigate the adaptation of the cross shore profile (Stive, 1986) and a 2DH model of COastal MORphology (COMOR) to study the spatial interaction between tide- and wave induced currents and sediment transports (de Vriend and Ribberink, 1988; Steijn et al., 1989). Integrating results from bathymetric analyses and numerical modelling a conceptual model of the dominant processes and actual sediment transport patterns has been defined (Louters et al., 1990).

A prognosis of geomorphological developments on an intermediate timescale has been based on a procedure during which the following activities have been executed in an iterative way (Postma et al., 1990):

After defining a conceptual model of dominant processes, specific geomorphological units have been defined (e.g. the delta front and individual shoals and channels, or parts of these). Each unit definition, preferably was based on explicit geomorphological and process characteristics. Successively, each unit has been described by certain geomorphological parameters and the trend of each parameter since 1970, has been extrapolated towards the year 2010. Extrapolation mostly occurred according to an exponential function, fitted for the observed trends over the period 1970 - 1987. In each case the prognosis has been tested to be consistent with predicted developments of other units and with the earlier defined conceptual model. Finally, a check has been performed on the total sediment balances of the areas.

4.2 Ecological research

The ecological impact of the change in physical boundary conditions has been studied mainly on developments in benthic fauna.

The study has concentrated on macrozoobenthos, representing a vital link at the base level of the food chain in the marine ecosystem. Macrozoobenthos are animals of sizes over 1 mm, living in the toplayer (ca. 10-20 cm) of the sediment. Main representatives are worms (Polychaeta), small shrimps (Crustacea), shellfish (Bivalva) and echinoderms (Echinodermata).

Beside macrozoobenthos, attention has been paid to epibenthos (animals living on top of the sediment surface or in permanent contact with it: demersal fishes like flat-fish, cod and gobies, and adult shrimps, crabs and starfish) and on hyperbenthos (animals living in the lower parts of the water column, dependent on the vicinity of the sediment surface: macrozoobenthos larvae, mysids, eggs and larval stages of fish).

Basic data for the macrozoobenthos research were provided by an inventory sampling campaign during 1984, 1985 and 1986 covering a total of 457 locations scattered randomly over the Voordelta, including the ebb tidal delta of the Westerschelde (Fig. 1). During 1987 and 1988 monthly sampling was performed at a total of 150 sites in two key areas on the Grevelingen - and Oosterschelde ebb tidal delta respectively.

At each location have been determined from direct sampling: macrozoobenthos biomass and species composition, soil parameters (silt content, median grainsize, sorting) and water depth. Other hydraulic parameters (maximum current velocity, wave heights, near bottom orbital velocity) have been derived indirectly from numerical modelling. Water quality parameters (salinity, chlorophyll-a and suspended matter) were determined from data supplied by a campaign of water quality sampling at 60 locations, executed with monthly intervals during 1986.

All macrobenthos samples taken in autumn were classified according to macrobenthic species composition by a statistical classification program. Then, canonical correspondence analysis and multiple discriminant analysis were applied to correlate the animal assemblages to abiotic environmental variables (Craeymeersch et al., 1990; van der Meer, 1988).

Epibenthos and hyperbenthos data were sampled in the Grevelingen and Oosterschelde key areas during campaigns of 1987 and 1988. Sampling was performed with a specially constructed 'hyperbenthos sledge' (Hamerlynck and Mees, 1990). Statistical analysis has been applied to investigate correlations with abiotic variables.

An indicative prognosis of a future shift in ecological functioning of the Voordelta has been based on the statistical relations derived for the study area.

5. GENERAL RESULTS

5.1 Geomorphological development

Sediment balances of the Haringvliet and Grevelingen ebb tidal deltas indicate a mean yearly sedimentation surplus of respectively circa 3 and 2 million cubic meters since 1972. Between 10 and 30 percent of this surplus has been estimated to be marine mud, deposited mainly in former ebb tidal channels. A major part of the sedimentation surplus most probably is due to a net northward longshore sediment transport from the south (Louters et al., 1990). A continuing sedimentation in the relic tidal channels (Fig. 3) is a typical phenomenon of the geomorphological changes in the study area.

Fig. 3 Sedimentation in the the former main tidal channel of the Grevelingen ebb tidal delta since 1970

Typical erosive areas are the delta front, indicated by a continuing landward shift of the -5 mNAP depth contour, and the relic tidal bars in the landward parts of the deltas (Fig. 4).

Fig. 4 Erosion of the main relic tidal bar in the landward part of the Grevelingen ebb tidal delta since 1970

The most striking phenomenon however is the development of large long shore bars at the edges of the Haringvliet and Grevelingen ebb tidal deltas (Fig. 5). The sedimentation trend at these bars is continuing but the growth rate is stagnating at a height around mean sea level. This stage had been reached circa 1980. From then on the

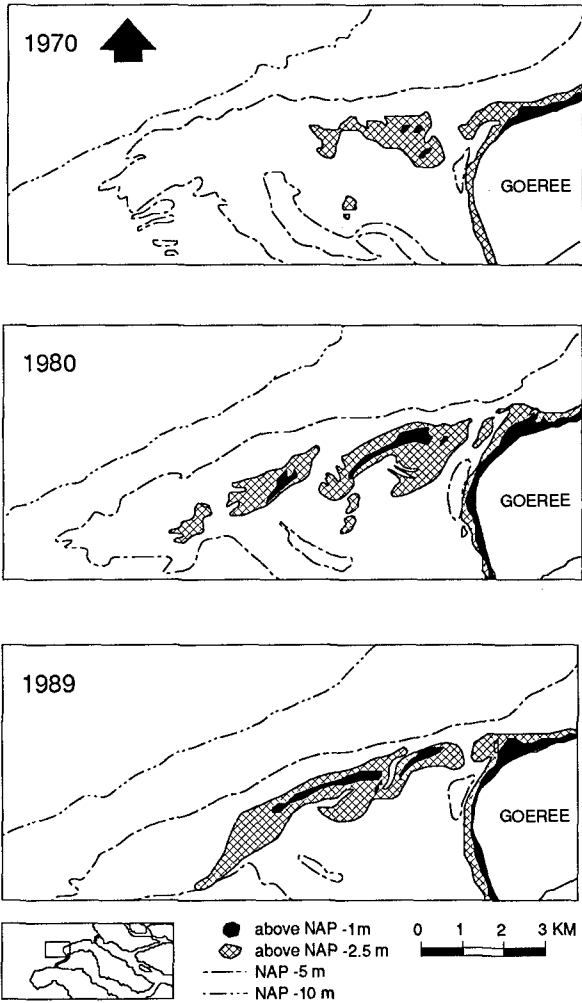

Fig. 5 Development of longshore bars at the edge of the Grevelingen ebb tidal delta since 1970

longshore bars are only showing a tendency towards a continuing shift in landward direction (Kohsiek, 1988; Louters et al., 1990). The total geomorphological change apparently is to a large extent due to a local redistribution of sediments.

The first observations of the Oosterschelde ebb tidal delta after completion of the storm surge barrier in 1986, indicate a tendency of changes similar to the changes of the Haringvliet and Grevelingen deltas: erosion of the delta front and tidal bars in the landward

parts of the ebb tidal delta, and sedimentation of the channels. However, until now no indication has been derived of developing long shore bars.

Among the driving forces of the geomorphological changes observed at the Haringvliet and Grevelingen ebb tidal deltas, a prominent one is represented by the asymmetrical wave orbital motion, inducing upslope sediment transport responsible for the initial development of long shore bars (Stive, 1986; Kohsiek, 1988). At later stages this bar development is depending on the equilibrium of four different mechanisms (Kohsiek, 1988): (-) a decrease in upslope sediment transport by the mentioned force due to an increase of the time mean of seaward flow under breaking waves; (-) a wave driven landward sediment transport over the crest of the longshore bars during storms, especially from the northwest; (-) a residual tide induced seaward sediment transport over the crest of the longshore bars; and (-) a wave induced longshore sediment transport during low water on the seaward side of the longshore bars. Since the prevailing winds are from westerly directions the residual longshore sediment transport is to the northeast.

Analyses of COMOR model results largely have confirmed this picture (Steijn et al., 1989). The mentioned mechanisms represent the main components of the conceptual model of dominant processes, as defined for the area (Louters et al., 1991).

The prognosis of future geomorphological changes (see e.g. Fig. 6) indicates that on an intermediate timescale (1990 - 2010), the generally observed trends will continue. The rate of change however, will reduce due to the assumption of exponentially decreasing process velocities. It then appears that, on an intermediate timescale, nor the available space between neighbouring geomorphological units, nor the spatial interaction between driving processes does impose definite limits to the development of any defined unit or to the activity of any presently acting process.

On longer time scales the geomorphological developments are less certain, as these are influenced by uncertainties in e.g. the effects of an increased sea level rise or a change in the net northward longshore sediment transport to the study area (Louters et al., 1991).

5.2 Ecological development

The intermediate position of the Voordelta on the ecological gradient estuary - open sea, becomes apparent from its macrozoobenthos characteristics; both its diversity and its total biomass. In the Voordelta a total of 150 different species of macrozoobenthos have been observed, with a mean total biomass of ca. 20 gADW/m² (ADW= Ash free Dry Weight i.e. the weight of biologically active parts). A total number of species which is significantly lower than generally observed in the North Sea, but higher than in the estuaries of the SW Netherlands. On the other hand the mean total biomass observed in the Voordelta appears approximately twice as high as in the open North Sea, but twice as

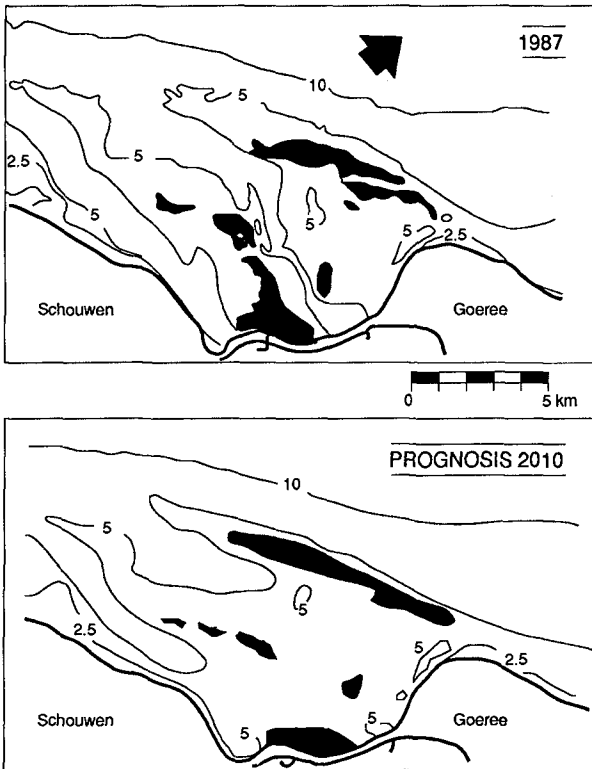

Fig. 6 Actual (1987) and predicted (2010) geomorphology of the Grevelingen ebb tidal delta. Indicated in black are the sandy shoals (above -2.5 mNAP).

low as in e.g. the Oosterschelde estuary.

Epibenthos observations showed a total of 48 different species, of which 40 species of fish.

Statistical analysis has demonstrated that the total Voordelta (including the Westerschelde ebb tidal delta) may be characterised by 6 different communities of macrozoobenthos, of which 4 communities occur in the key areas at the Grevelingen and Oosterschelde ebb tidal deltas. Each macrozoobenthos community has its own typical species composition, density (individuals/m²) and total biomass (Fig. 7).

The spatial distribution appears significantly correlated with sediment composition (especially mud content) and with water depth (Fig. 8) (Craeymeersch et al., 1990).

Fig.7 Characteristics of the six typical macrozoobenthos communities of the Voordelta

Spatial differences may be quite large. This is illustrated e.g. by observations of both hyperbenthos and macrozoobenthos. The Oosterschelde ebb tidal delta appears much poorer in this benthic fauna than the Grevelingen ebb tidal delta: the densities are about half, the total biomass about one third to one half of the Grevelingen values (Hamerlynck and Craeymeersch, 1990; Hamerlynck and Mees, 1990).

This difference is directly related to the changes in physical boundary conditions as induced by the Delta Project (see section 3). The Oosterschelde, which has remained partly open, only has known a relative small reduction in hydraulic energy conditions (current velocities ca. -30%); the hydrodynamic climate of the Grevelingen ebb tidal delta however, has become drastically calmer after closure of the estuary. This has induced large scale sedimentation of fine sediments especially in the tidal channels (see 5.1). Together with mud and silt sedimentation, organic material is deposited and several suspended juvenile stages of marine organisms are imported. Thus creating a very rich benthic fauna in this area (Hamerlynck and Craeymeersch, 1990).

The prognosis of future ecological changes indicates that, consistently with the expected, relatively small change in geomorphological characteristics for the next 10 - 30 years, also ecological changes most probably will be only gradual.

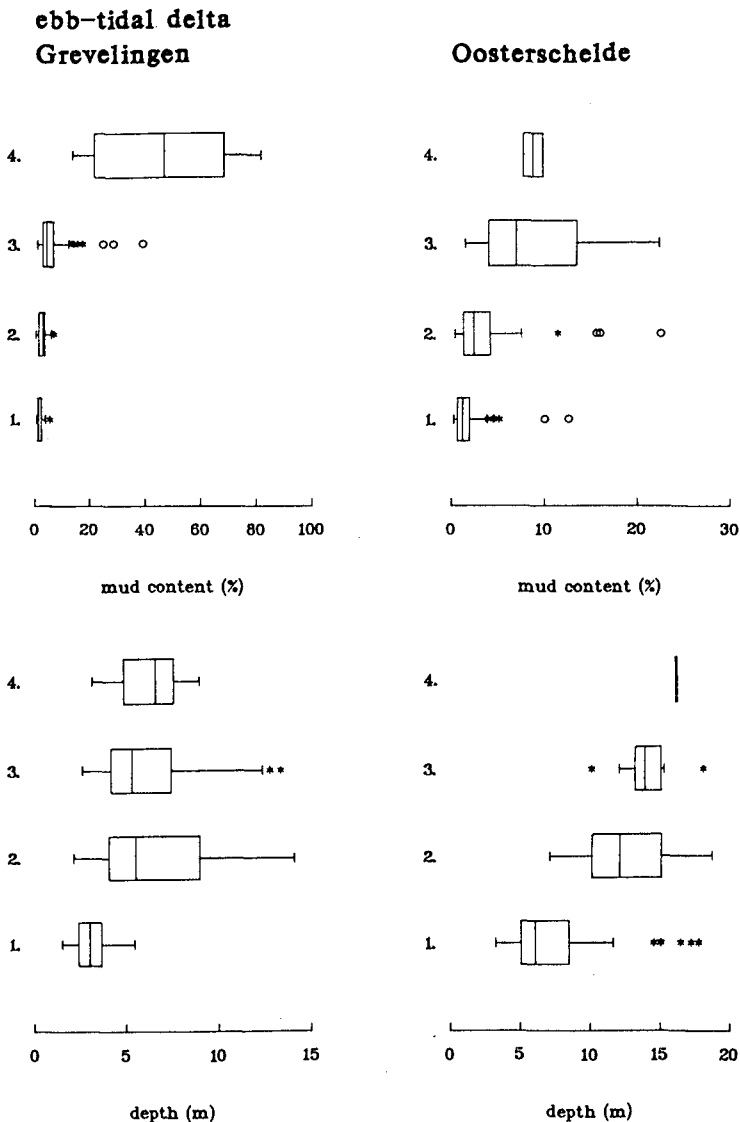

Fig. 8 Distributions of mud content and depth over the four typical macrozoobenthos communities of the Grevelingen - and Oosterschelde ebb tidal deltas, indicated by box-and-whisker plots. The median is marked by the central vertical line. The right and left edges of the box divide the distributions at the 25% and 75% level. The end of the whiskers denote the minimum and maximum values, unless there are outside values denoted by stars and circles.

6. CONSEQUENCES FOR WATER AND COASTAL MANAGEMENT

The observed and predicted changes in geomorphology and ecology of the Voordelta affect a series of (potential) human activities in the area. The main implications concern the following interests, each illustrated by an example (Hallie et al., 1990):

- shore protection; longshore bars and sand banks are reducing direct wave attacks on beaches and dunes, especially during storms. The resulting reduction in dune erosion has been calculated to amount locally 15 -25 percent.
- natural environment and landscape; the relative abundance of food, the extent of intertidal sand bars and shallow waters with a relatively mild hydraulic climate provide favourite conditions to several bird species and (potentially) to seals.
- recreational uses; enlargement of beaches has a positive, mud deposition around low water slack a negative effect on beach recreation. Shipping and surfing is stimulated by the attractive morphological variation and hydraulic conditions in the Voordelta.
- fisheries; the shallow, protected conditions make the area a potential nursery for some commercially interesting fish species (plaice, sole). Potentials for shellfish culture might develop.
- shipping; silting up of tidal channels and migrating sand bars affect shipping traffic towards local harbours.
- sand mining; the growth of sand bars near shore, provides a relatively cheap source of sands for several purposes (e.g. beach nourishments or land fills).

Obviously many of these interests are conflicting, at least potentially.

7. DISCUSSION, CONCLUSIONS AND RECOMMENDATIONS

Benthic fauna appears to be significantly correlated to abiotic variables. The distribution of macrozoobenthos of the Grevelingen area shows the highest correlation with mud content of the sediment top layer; on the other hand, macrobenthos of the Oosterschelde ebb tidal delta with water depth (Craeymeersch et al., 1990; also see Fig. 8). This illustrates that the established statistical correlations do not necessarily represent causal relationships. Possibly the variable water depth on the Oosterschelde ebb tidal delta, is a 'derived variable' from the driving variable current velocity.

In fact the ignorance of causal relationships between environmental variables and benthic fauna, poses a sincere problem once a prognosis of future developments is required. The statistical relation established for an open estuary (e.g. the Oosterschelde) does not necessarily have to be valid after the estuary has been closed (e.g. the Grevelingen).

This stresses the need of specific research of the driving processes in the relation between hydrodynamics - sediment (morphology and composition) - biota.

In this type of research, the level of detail (spatial and temporal)

in the geomorphological contributions, will have to be much higher than usual in current coastal morphological studies: for example, the need for hydrodynamic information near bottom, close to the benthos sampling locations, will eventually lead to hydrodynamical modelling at grid sizes of say 50 m or less. Another example is supplied by the statistical analyses of macrozoobenthos (Craeymeersch et al., 1990). As shown by the Grevelingen area (Fig. 8), 3 out of 4 macrozoobenthos communities (and among them the richest community) are correlated with mud contents between 2 and 10%. This indicates that in future research of this type, and in comparable environments, the distribution of mud content of the sediment has to be established at intervals between 2 - 5% ! These examples reveal the shortcomings of the applied integrated approach, and at the same time indicate possible ways of future progress in this field.

In general it may be concluded that the integrated geomorphological - ecological approach in coastal research as presented in this study, has appeared to be promising. The approach seems indispensable in view of the development of integrated coastal zone management.

ACKNOWLEDGEMENTS

By order of the Ministry of Transport and Public Works (Rijkswaterstaat) the present investigations have been carried out within the framework of a major multidisciplinary research project. Conducted by Rijkswaterstaat Tidal Waters Division, the following research institutes have participated: Rijksuniversiteit Utrecht Department of Physical Geography, Delft Hydraulics, Delta Institute of Hydrobiological Research and Rijksuniversiteit Gent, Institute of Zoology, Marine Biology Section.

CHAPTER 227

Numerical Simulations of Mud Transport by a Multi-Layered Nested Grid Model

Hiroichi Tsuruya¹
Kazuo Murakami¹
Isao Irie²

Abstract

A multi-layered model is developed for the prediction of mud transport in an estuary and ports to take into account the effects of submerged dikes and to reproduce the vertical distribution of suspended mud concentrations. A most remarkable result in the field observation in Kumamoto Port was the effect of a submerged dike on reducing the amount of deposition rate within the test trench.

It is predicted from the calculation that submerged dikes 1 m in height from the bottom will prevent siltation in the access channel and anchorages of Kumamoto Port by about 30% of the total deposition without submerged dikes.

1. Introduction

Extensive field measurements have been carried out in Kumamoto Port which is under construction to obtain detailed information on siltation mechanisms. Measured deposition rates within three trenches were used to calibrate the present model.

A nested grid model is adopted to treat the composite mesh arrangement of rough and fine meshes because the dimension of the trenches is so small, *i.e.*, 70m×50m in area.

The calculation is conducted with the supercomputer NEC SX-1E of the Port and Harbour Research Institute.

2. Mathematical Modeling of Mud Transport

For the treatment of the detailed configuration of the sea bed and construction such as submerged dikes, we adopted the multi-layered model with nested grid for the calculation of mud transport (Tsuruya et al., 1990). The present model consists of several horizontal layers as shown in Figure 1.

The water depth is vertically divided into seven layers as shown in Figure 2.

Tidal currents are calculated by a set of known equations: (1) continuity equations, and (2) equations of motion. Mud is transported in suspension and this process can be represented by diffusion equations.

Random wave deformations by refraction, wave breaking, diffraction, reflection are considered. Wave damping due to interaction between surface waves and a mud bed is also considered (Tsuruya et al., 1987b).

Figure 1. Multi-Layered Level Model

Figure 2. Division of Water Depth into Seven Layers

Figure 3. Vertical Distribution of SS and β

Erosion and Deposition

The rate of erosion of mud has been formulated by Partheniades (1965) as

$$E = M \left(\frac{\tau_b}{\tau_c} - 1 \right), \tag{1}$$

where τ_b (Pa) is the shear stress at the bottom by the combined action of waves and currents, τ_c (Pa) the critical shear stress for erosion, and M ($\text{kg/m}^2/\text{min}$) is the constant. The bottom shear stress τ_b is given by Tanaka and Shuto (1981).

Deposition rate D is estimated by a similar consideration by Sheng and Lick (1979) as

$$\begin{aligned} D &= w_s C_{bed} \\ &= \beta w_s C_{KMAX}, \end{aligned} \tag{2}$$

where w_s is the settling velocity, C_{bed} the concentration of mud at the bed, and β is the correction factor to estimate C_{bed} from the calculated mean concentration of the bottom layer (C_{KMAX}). The correction factor β is introduced to estimate the concentration near the bottom from the calculated mean concentration C_{KMAX} at the bottom layer. The factor β may depend on the wave conditions, turbulence, the type of bed materials, and the thickness of the bottom layer. We now estimate the value of β from the field observation data. Figure 3 shows the typical distributions of SS observed at the observation tower and the pipe pile on August 31st, 1987. Plotted data are the average values of SS measured by water samplers.

Fitted curves are exponential functions and the concentration at the bed is assumed to be the average value

Figure 4. Relation between Settling Velocity and Concentration of Mud

from the bed to the height of 5 cm. Estimated value of β for each observation station are also shown in the figure as a function of the thickness of the bottom layer. We assume that the value of β is given by the average value obtained at the observation station and the pipe pile, and β is constant if the thickness of the bottom layer is larger than 2.4 m. The thick solid line in Figure 3 shows the functional relationship between the thickness of the bottom layer and β , given by the following expression as

$$\begin{aligned} & 1.0, (z_b \leq 0.05\text{m}) \\ \beta &= 3.9z_b + 0.805, (0.05 < z_b \leq 2.4\text{m}) \\ & 10.0, (z_b > 2.4\text{m}) \end{aligned} \quad (3)$$

where z_b is the height from the bed and equal to the thickness of the bottom layer h_{KMAX} .

Settling Velocity

The settling velocity w_s for mud depends on the concentration. As the concentration increases, a probability of collision between mud particles increases and the settling velocity increases. Above some specific concentration, the settling velocity begins to decrease because of the hindered settling.

The relationship between the settling velocity w_s and mud concentration C is schematically shown in Figure 4. The broken line in the figure is given by Mehta (1986).

In the present model, hindered settling is not effectively applied because the erosion rate in this region will not be appropriately represented by Eq.(1). For the modeling of the process, more detailed research

Figure 5. Rate of Increase in Horizontal Diffusion Coefficient

is required. Here we assumed that the settling velocity is constant for the concentration greater than the critical value C_H . Two asterisks in the figure are obtained by solving the diffusion equation in which the convection and diffusion terms are neglected.

Diffusion Coefficients behind Submerged Dikes

Turbulence intensity in the region behind a submerged dike increases considerably. Vertical and horizontal diffusion coefficients also increase when compared with cases without submerged dikes. The rate of increase in the diffusion coefficients with and without submerged dikes is investigated experimentally (Tsuruya et al., 1987a).

If the velocity is larger than the reference velocity U_{ref} , horizontal and vertical diffusion coefficients are increased according to the following expression as

$$\frac{K_H}{K_{H_0}} = \left[\frac{U_m}{U_{ref}} (K_H' - 1.0) + 1.0 \right], \tag{4}$$

where K_H is the diffusion coefficient behind a submerged dike, K_{H_0} the diffusion coefficient without a submerged dike, U_m the mean velocity in the second layer, U_{ref} the reference velocity ($=25\text{cm/s}$), and K_H' is the rate of increase in the diffusion coefficient which is given by the experiment. An example of the increase in the horizontal diffusion coefficient is represented in Figure 5.

3. Field Observations at Kumamoto Port

Kumamoto Port is under construction as a new commercial port at a site off-Kumamoto City in Ariake Bay.

Figure 6 shows the final plan of Kumamoto Port. The observation tower and the pipe pile which are shown by open circles were built at 4 m and 2 m depth, respec-

Figure 6. Plan of Kumamoto Port and Field Observation Site

Figure 7. Time Variation of Deposition Heights at the Center of Three Trenches

tively, below the LWL to measure tides, waves, winds and turbidity of sea water.

Three trenches are constructed to investigate the relationship between the amount of sediment deposition and external forces such as waves and currents. The effect of a submerged dike to reduce the amount of deposition is also tested. Three trenches are shown in Figure 6. Trench No.1 is located at 4 m depth below LWL, and trenches No.2 and 3 are located at 2 m depth below LWL. Trench No.3 is surrounded by a submerged dike of 1m in height. On the other hand, trench No.2 is surrounded

by no facility. The dimension of the trenches is 70m×50m in area. Trenches No.2 and No.3 are located 100 m apart from each other. The depth of the trenches is 2 m from the bed level and the side slope is 20 %.

Siltation Rate in Trenches

Figure 7 shows the time variation of deposition heights at the center of each trench. In the figure, six arrows show the onset of large waves. The leftmost arrow shows the start of the observation. It is found from the figure that the severe and sudden deposition occurred at

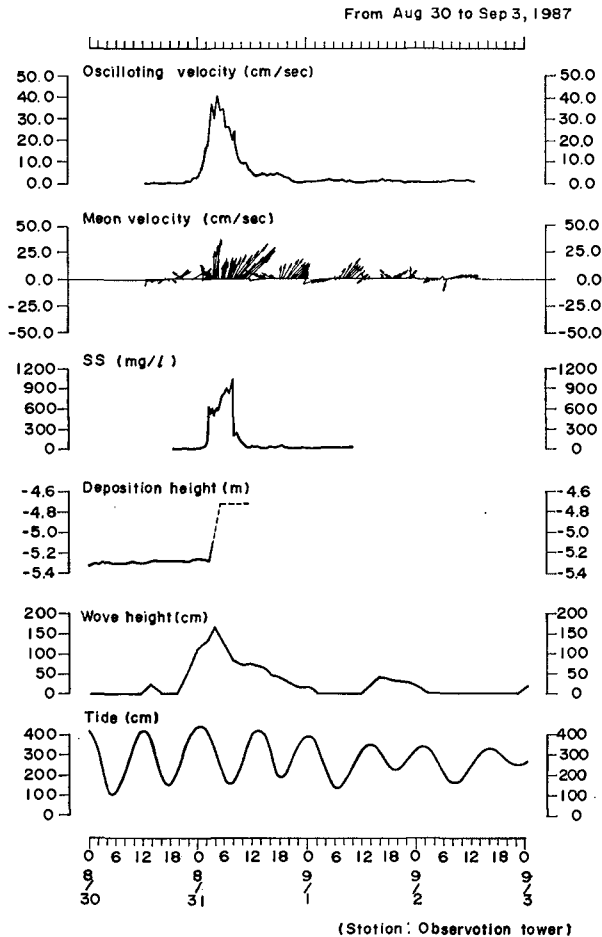

Figure 8. Example of Measured Time Series Data from Aug. 30 to Sept. 3, 1987 at Observation tower

trenches No.1 and No.2 during rough seas on February 3rd, 1987 and on August 31st, 1987. On the other hand, the deposition at trench No.3 was small. It is considered that the submerged dike has a considerable effect on reducing the deposition of mud. During gentle and calm seas, a small amount of deposition occurred in three trenches. This fact means that the tidal current has little effect on the deposition. Around the submerged dike, no extreme erosion and deposition could be observed.

The simultaneous measurements of tides, currents, turbidity, and bottom levels were carried out. Figure 8 shows the measured time series data of the oscillatory current velocity, averaged current vector, turbidity concentration, deposition height in trench No.1, wave height, and tidal level at the observation tower from August 30th to September 2nd, 1987. From the figure, it is found that there is a strong correlation between the oscillatory current velocity and the turbidity concentration. Moreover, increase of the bottom level starts when wave height is large and tidal level is low. It is suspected that the bottom sediments around Kumamoto Port are eroded mainly by wind waves. Also, the bottom sediments were eroded by stormy waves when the tidal level was low.

4. Calibration

Figure 7 shows the abrupt deposition occurred on February 6th and September 1st. We adopt the deposition on September 1st as the representative case for the

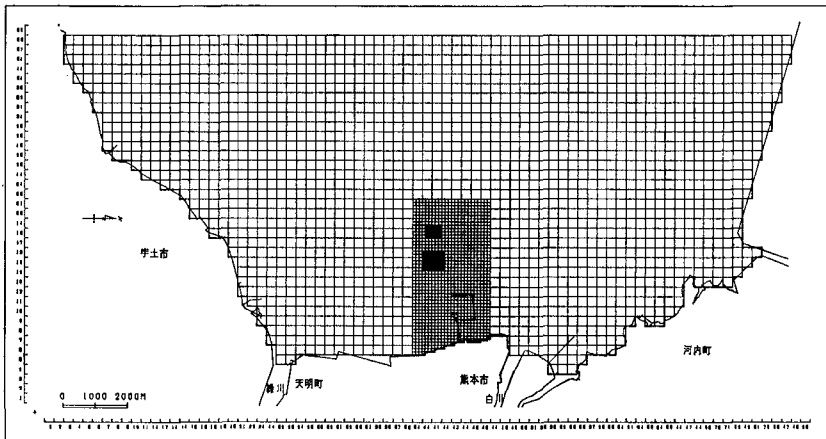

Figure 9. Mesh Map for the First Area

Figure 10. Mesh Map for the Second Area

calibration. Part of port facilities had been constructed at that time. The "Kumamoto Port Ohashi" bridge with a length of 872m, connecting the offshore port and the city, a wharf with a length of 300 m, and part of the revetment for a reclaimed land were completed.

The area for calculation is divided into five areas from the first to the fifth. Mesh sizes are 300m, 100m, and 100/3m for each area from the first to the third, respectively. For the fourth and the fifth area, the mesh size is 100/9m. Arrangement of the mesh for the first area is presented in Figure 9. Magnified meshes for the second area are shown in Figure 10. The third area is separated into two parts. Within them, there

exist the fourth and the fifth area. They are shown in Figure 10 as the solid rectangles because the mesh size is so fine (11.1m). The fourth area (the lower solid rectangle) includes No.2 and No.3 trenches. The present nested grid model can treat the composite mesh arrangement of rough and fine meshes. Therefore, calculation, which included the small area with special interest, can be efficiently conducted.

The predicted wave damping ratio of the pipe pile to the observation tower by the multi-layered viscous fluid model (Tsuruya et al., 1987b) was 0.56. This value agreed closely with the observation when wave heights are large, i.e., from 2:00 to 6:00 a.m., August 31st. In the calculation, the depth of the mud layer and water content are set to at 10 cm and 200 %, respectively.

From Figure 8, wave conditions are decided to be as follows: $H_{1/3} = 1.25$ m, $T_{1/3} = 4$ s, direction of the wave is WSW and their duration is 6 hours. When waves are large, the tidal level is low. Therefore waves are operated from 15:00 to 21:00 in the calculation as shown in Figure 11. Only tidal current is calculated from 0:00 to 15:00. Calculations of erosion, diffusion, and settlement are conducted from 15:00 to 27:00. All the calculations are finished at time 27:00.

Figure 11. Time Table of Calculation

Tidal Currents

An example of the calculated tidal current distribution is shown in Figure 12. Velocities in the second area where the mesh is three times smaller than that of the first area are expressed together with the velocities for the first area.

Measured deposition heights during rough seas from August 31st to September 1st within three trenches are listed in Table 1 together with the water content.

In the calculation of erosion, the critical shear stress τ_e was set at 0.1 (Pa) after Murakami et al. (1989) and the constant M was varied until the reasonable deposition heights are obtained. The calculated deposition heights are listed in Table 2. The upper row

Figure 12. Calculated Velocity Distribution for the First Layer at the Maximum Flood Tide

Table 1. Deposition Heights and Water Contents within Three Trenches (Aug. 29 - Sept. 2, 1987)

	Trench No. 1	Trench No. 2	Trench No. 3
Deposition Height (cm)	63	60	-2
Water Content (%)	231	189	192

Table 2. Calculated Result of Deposition Heights

	Trench No. 1	Trench No. 2	Trench No. 3
Deposition (cm)	63.4	39.8	4.0
Deposition + Mass Transport (cm)	74.6	53.4	4.0

shows the contribution from deposition only and the lower one shows the total amount by both deposition and mass transport of the mud layer due to wave action. Comparing with Table 1, the calculated total deposition heights agree with the measured one. The value of M thus estimated $1.2 \text{ kg/m}^2/\text{min}$. According to van Leussen and

Figure 13. Access Channel

Figure 14. Anchorage

Dronkers (1988), the range of M is $0.006-0.24 \text{ kg/m}^2/\text{min}$. We have a larger value of M for the present model than usual. However, as the model does not include every process in the field, we must finally calibrate the calculated value with the field data. Therefore, we concluded that the present model could reproduce the deposition heights in the field.

5. Application to Future Plan of Kumamoto Port

Figure 15. Amount of Deposition in Each Area

We show only the tentative plan that will be completed within a couple of years (Figures 13 and 14). In Figure 13, the access channel is 100m wide and 4.5m depth, and is shown as the inner parallel lines. The outer lines parallel to the access channel are submerged dikes which are 2,000m in length and 1m in height from the bottom. The calculated deposition heights inside the access channel are added together to get the volume of deposition for each area as shown in Figures 13 and 14. It is assumed that the water content of the deposited mud is 200%. The amount of deposition in each area is shown in Figure 15. The maximum deposition occurs at area E. The reducing effect of deposition by submerged dikes is about 23% for area E and 47% for area G. The calculated volume includes mass transport by waves. The amount of decrease in the volume of deposition owing to the submerged dike is about 30%.

6. Conclusions

Three-dimensional multi-layered level model with nested grid is developed for the calculation of siltation. After the calibration of deposition heights within three trenches, calculation for the future plan of Kumamoto Port is conducted. The amount of decrease in the volume of deposition due to submerged dikes was 30%.

Acknowledgements

We would like to express our appreciation to the Ministry of Transport and the Fourth District Port Construction Bureau for their support of the siltation research work project and for providing the field data.

We also thank Mr. Cao Zude, Chief Engineer of the Tianjin Research Institute of Water Transport Engineering, for analyzing the field data. Also, thanks are due to Mr. Hiroshi Yoshinaga, the member of Hydrodynamics Laboratory of the PHRI, for his assistance in typing the manuscript.

CHAPTER 228

Modelling of cohesive sediment transport.
A case study: the Western Scheldt Estuary

Herman P.J. Mulder¹ and Connie Udink¹

Abstract

A depth-averaged numerical model for the erosion, sedimentation and transport of cohesive sediment is applied to a mesotidal estuary. The transport model is coupled to a hydrodynamic and a wave model. First results are presented as part of the aim to predict year-averaged quantities. Comparisons with measured data of net sedimentation and suspended concentration are made. As the bed of the estuary consists mainly of non-cohesive sediments, the erosion formula is adapted to account for the local (non-)cohesive fraction in the bed. The effect of the spatial variation in this property of the bed is significant. Furthermore the influence of surface waves is investigated and showed to be of great importance in a qualitative and quantitative sense. The model can take into account the dumping of dredged material and gives reasonable results in case of the spreading and sedimentation of mud from one source, as shown by a simulation of the transport of fluvial mud.

Introduction

In the Western Scheldt Estuary (figure 1) in the south-western part of the Netherlands the input of severely contaminated fine sediments from the river Scheldt causes a considerable environmental problem. Especially in sedimentation dominated areas, like the great marsh land in the eastern part of the estuary, these sediments with cohesive properties accumulate in the bottom influencing the environment for many years to come. There is a need for models capable of simulating these processes and predicting the consequences of measures to reduce the pollution. Such models must

¹Rijkswaterstaat, Tidal Waters Division, P.O. Box 207, 9750 AE, Haren, The Netherlands

undoubtedly include the transport of cohesive sediments.

In the estuary the main channels are dredged frequently because of the shipping to the harbour of Antwerp up the river in Belgium. Also harbours along the estuary are regularly dredged. These activities involve not only high costs but also environmental problems in case the dredged material contains polluted sediments. A model for predicting the fate of dumped sediments is a powerful tool for decisions about the assessment of dump sites.

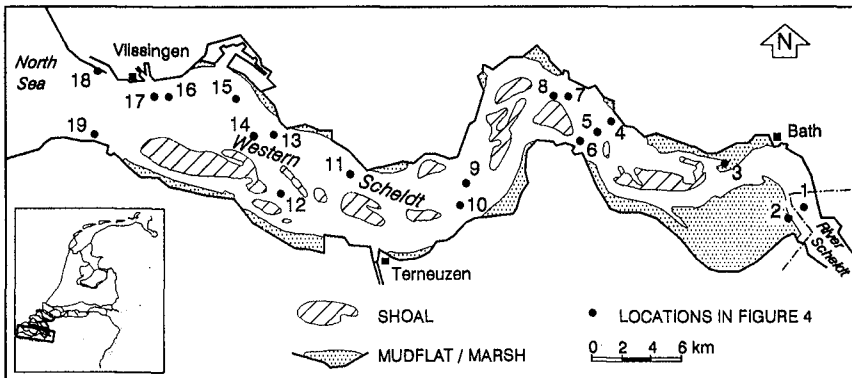

Figure 1. The Western Scheldt Estuary.

This paper presents some results of the numerical modelling of the transport of cohesive sediment or mud - here defined as the anorganic fraction finer than 63 micron - related to the problems in the Western Scheldt Estuary. The model involves hydrodynamics, surface waves and sediment transport. Descriptions of and experiences with models for estuaries (e.g. Hayter (1983), Sheng (1986), O'Connor and Nicholson (1988), Fritsch et al (1989)) showed that strongly empirical relations have to be used and that the incorporation of all relevant processes as well as the schematization of hydraulic and meteorological conditions form an enormous task. Therefore some processes are neglected in the present model while others are investigated, viz. the importance of the local mud fraction and the role of surface waves. Our final aim is a predictive model for long term behaviour of the cohesive sediment. Especially the spreading of fluvial mud is of interest and a simulation is presented.

Model description

Because of the considerable morphological variety in the lateral direction of the estuary (see figure 1) and the fact that the estuary is well mixed, two-dimensional

horizontal (depth-averaged) models are used: a hydrodynamic model, a surface wave model and a sediment transport model.

The hydrodynamic model (WAQUA) calculates the water flows, water levels and densities on a time scale much smaller than the tidal period (Stelling, 1983). Calibration of the model was carried out by others (Dekker, 1985). Wind induced currents appeared to be very small and are not taken into account in the calculations. Also the wind generated water level rise is neglected. The tidal range in the estuary varies between 3 and 4 m, while the average depth is 10 m. The simulation was carried out for a tidal cycle of 24.5 hrs of a semi-diurnal tide with a tidal range 5 % higher than the long term mean value. The grid is rectilinear and the element size is 400*400 m. The bottom schematization of the hydrodynamic model was used as input for both the wave model and the transport model, via different interface programs.

The wave model (HISWA) is suitable for shallow water waves and produces stationary wave fields. It solves a spectral action balance and takes into account the generation, dissipation, refraction and diffraction of waves (Booij et al, 1985). To restrict the computational costs a limited number of boundary conditions is used. As input for the wave calculation the mean values of wind speed (1983-1987) are used in four dominating wind directions: 220° (wind speed 10.3 m/s), 250° (9.7 m/s), 280° (9.3 m/s) and 310° (9.6 m/s; North=0°=360°), respectively representing 16%, 12%, 9% and 7% of time within a sector of 30°. The remaining 56% of time fair weather conditions are assumed. Because the model is stationary, an interpolation is performed between the calculated wave heights and wave periods at four different tidal stages: LW slack, maximum flood current, HW slack and maximum ebb current. The interpolated values are used to determine the orbital velocity and consequently the bottom shear stress component due to waves. Verification of the model at 6 locations throughout the estuary showed a systematic overestimation of the long term mean wave height of about 30% by the model. However, the available observations were made visually and exclude rough weather conditions. Therefore the wave model results are satisfying.

The dynamic model for the cohesive sediment transport, based on the program package DELWAQ (Delft Hydraulics, 1990), incorporates advection, diffusion and bottom exchange by sedimentation and erosion. The model solves the finite volume advection-diffusion equation with sink and source terms on the same grid as WAQUA. The tidal cycle can be repeated until a dynamic equilibrium is reached. The dispersion coefficients were chosen constant and equal in both horizontal directions. Although the bottom exchange processes are extremely complex and

influenced by physical, chemical and biological factors for practical reasons we adopted well-known empirical expressions for sedimentation (Krone, 1962) and erosion (Partheniades, 1962), in which the bottom exchange rates both linearly depend on the bottom shear stress with critical shear stresses of 0.2 and 0.4 Pa respectively. A constant settling velocity of 2 mm/s was used, based on indications from field measurements. The bottom shear stress can have three components: (i) the depth-averaged current velocity, assuming a logarithmic profile, (ii) the orbital velocity and (iii) the horizontal density gradient. The influence of the waves is restricted to the shear stress in the bottom exchange terms. The third component is omitted in this paper because of the relatively small effect on the presented results. The wave and current bottom shear stresses, τ_{bw} and τ_{bc} respectively are combined according $\tau_{bw} + \alpha_w \tau_{bc}$, in which α_w is a reduction factor related to the wave-current interaction (van Rijn and Meijer, 1986). The model takes into account one homogeneous bottom layer with a space and time dependent thickness although consolidation is neglected. In order to use the model to determine optimal dump sites for dredged material a special subgrid scale dumping routine is incorporated (van Heuvel, 1988). At first the dumped mud undergoes the process of transport on a detailed scale governed by the flow velocity and the slope of the bottom at the dump location. Then the location and the thickness of the layer after complete sedimentation in the neighbouring grid elements is determined by the dumping routine. Subsequently resuspension and transport can proceed under the proper hydrodynamic circumstances. Although simulations of the dumping and spreading of dredged material have been made the results could not be verified and are subject of further study.

Results

The results presented here concern the cohesive sediment transport only. A study of two influencing factors, the local mud fraction and the waves respectively, is performed. These factors are presumed to be very important for a reliable model result. Furthermore an application to the spreading of polluted mud from the river is made. Some verification of the model is made by comparison with measurements of net sedimentation and (suspended) concentrations. It is assumed that morphological changes in the estuary can be neglected.

The influence of a local mud fraction

The mud fraction in the bottom of the estuary shows a strong spatial variation (figure 2). In the channels

Figure 2. Silt content in the top layer (0 - 10 cm) of the bed (1980-1985).

the mud fraction is very low (<0.02) while the average fraction is about 0.15. This is partly the result of a morphodynamic process and it questions the applicability of a sediment transport model without the influence of the non-cohesive material. Because of the supposed effect on the availability of mud during erosion or resuspension, this influence is taken into account by putting the mud fraction $f_e(x,y)$ in the formula for the erosion rate E [$\text{kg}/\text{m}^2/\text{s}$]:

$$E(x,y,t) = f_e(x,y) M (\tau_b(x,y,t)/\tau_{ce} - 1) \quad \text{if } \tau_b > \tau_{ce}$$

$$E(x,y,t) = 0 \quad \text{if } \tau_b \leq \tau_{ce}$$

in which M [$\text{kg}/\text{m}^2/\text{s}$] is the erosion constant, τ_b the bottom shear stress and τ_{ce} the critical shear stress for erosion. Two calculations are made representing two extreme cases: (i) assuming a bed of pure mud, i.e. $f_e(x,y) = 1$ (with $M = 5 \cdot 10^{-5}$) and (ii) using values of $f_e(x,y)$ for each grid cell obtained from the measurements (with $M = 7 \cdot 10^{-4}$). For each case the value of M is found by calibration to obtain suspension concentrations of the same order of magnitude as the measured values in order to make a meaningful qualitative comparison. In both cases the bottom layer thickness is not a limiting factor and only fair weather conditions are applied. It appears that the tide-averaged sedimentation, see figure 3, and concentration, did not show important differences on a large scale. However in the channels with very low mud

Figure 3. Non-corresponding areas (black) of erosion or sedimentation for case 1 and 2.

fraction the sedimentation pattern can differ importantly, while the tide-averaged concentration in some areas can differ more than 30% (after correction for systematic difference). Comparison of the calculated and measured concentrations, corrected with respect to tidal and seasonal effects, at 19 locations, mainly located in the channels, shows reasonable agreement in both cases (see figure 4). Case 2 seems to be better than case 1 at locations 1-8. For one particular location with a water depth of 10 m and a low mud fraction the comparison of the time series is displayed in figure 5. Apart from a systematic deviation between the three time series, there are the following differences: a quick increase of concentration in case 1 directly after LW slack, which is absent in case 2. So the availability of mud in the bed influences the time series strongly. From the measured values it seems that in reality the availability of mud is high directly after slack tide, while afterwards it is low (other measurements show a similar pattern). This qualitative disagreement with the model is likely to be caused by the spatial variation in the presence of mud in both horizontal and vertical direction. Hence a more sophisticated model, including a sand transport model to account for fractional sorting in the bed, could be more appropriate. Due to tidal dynamics and the very small thickness of the active mud layer (in the order of 1 mm) consolidation may be excluded in case of sandy channels.

A consequence of the results above is that a spatial variation in other erosive bed properties, like biological activity or the composition of the mud, could have a similar impact.

Figure 4. Measured and calculated (case 1 and 2) tide-averaged concentration at 19 locations (see figure 1).

Figure 5. Calculated concentrations for case 1 (dashed) and case 2 (solid) and measured values (dots).

The influence of waves

From observations in several estuaries, the Eastern Scheldt e.g., it is clear that rough weather conditions lead to a resuspension of material in the intertidal zone of shoals and marshes and consequently to a transverse transport to the channels. During fair weather conditions this process is reversed resulting in a dynamic equilibrium on a time-scale of years. To verify this process and to examine the importance of it, some calculations are made assuming that the imposed tidal and wave conditions are representative for a yearly averaged situation. Figure 6 shows the tide-average sedimentation for the 4 different wind directions and the fair weather condition (current only). The area of the estuary between Vlissingen and the Belgian border is divided into five morphological units: tidal channels, shoals, i.e. the ones surrounded by channels, flats, i.e. muddy or sandy flats near the embankment, marshes and harbours. The differences between the wind directions is significant as well as the difference with currents only. In the simulation the superimposed waves cause extra transport from the shoals (more eroded with respect to currents only) and the marshes (more eroded) to the channels (less eroded). Whereas one part of the flats is more eroded, the other part, partly because of the sheltered position, shows more sedimentation leading to an overall increase of sedimentation on the flats. Because the channels form the interface between the other four units the increase in sedimentation of the flats and the harbours can be explained by the increase in concentration in the channels caused by extra erosion of shoals, marshes and some flats. Qualitatively this is in good agreement with observations. However, this result can be affected by some important limitations of the model, namely (i) the absence of water level set-up during storm events, by which more sedimentation can take place on marshes and flats, and (ii) the rough schematization of the marshes and harbours.

In a qualitative sense the yearly averaged sedimentation of the five morphological units (current+waves in figure 6), which is assumed equal to the tide-averaged value of the five schematized meteorological conditions combined by means of the percentage of occurrence, is in agreement with measured data. However, in a quantitative sense there is a disagreement of one order of magnitude, or even more in areas with a low mud fraction (channels 6%, shoals 7%). In areas with a high mud fraction (marshes and harbours up to 80%) the agreement is better. It should be noticed that the model was not calibrated again in the case of waves, which led to an important overestimation, and that the reliability of the measurement is not known. Nevertheless the result indicates that the

bottom exchange of mud is more easily simulated for sedimentation dominated regions than for erosion dominated ones, where bottom properties are more important.

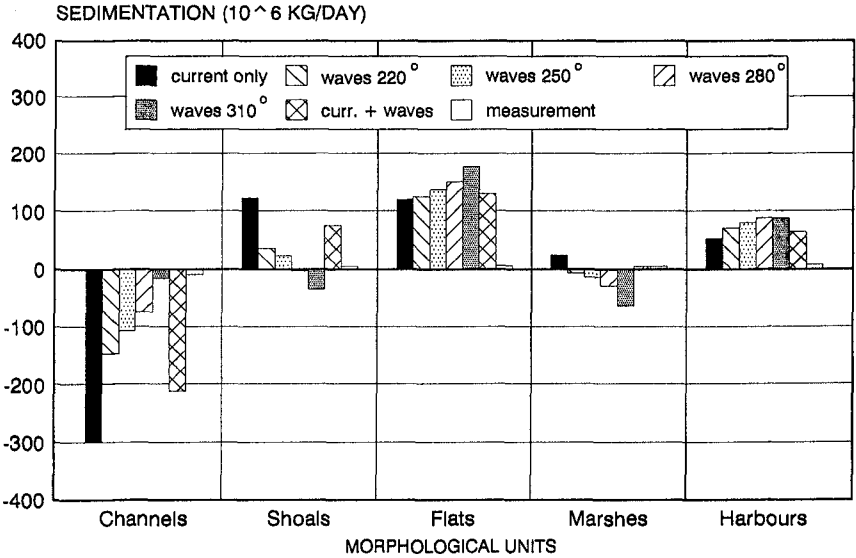

Figure 6. Tide-averaged sedimentation/erosion for each morphological unit calculated with and without wave influence (for 4 different wind directions and in total) and according to measurements.

The spreading of fluvial mud

One of our main purposes is the application of the model to the transport of the polluted fluvial mud. The fluvial and marine mud fraction can be distinguished by means of an analysis of carbon isotopes. Measurements of bottom level change (1980-1985) in combination with the observed mud fraction and correction for dredging and dumping quantities are used to estimate the year-averaged sedimentation or erosion. Verifying this with estimations of the river input has led to the fluvial mud sedimentation given in figure 7a, where the sedimentation of each grid element is related to the total input.

In the simulation only mud input from the river was allowed and the bottom layer started with zero-thickness. The result, see figure 7b, applies only to fair weather conditions and is presented in the same way as the measurements because of different the river inputs ($15 \cdot 10^5$ against $23 \cdot 10^5$ kg/day).

In both the simulation and the measurement the main

part of the river mud is deposited in the eastern part of the estuary. Areas with pronounced sedimentation are reproduced satisfactorily, although the agreement on a detailed scale can be poor.

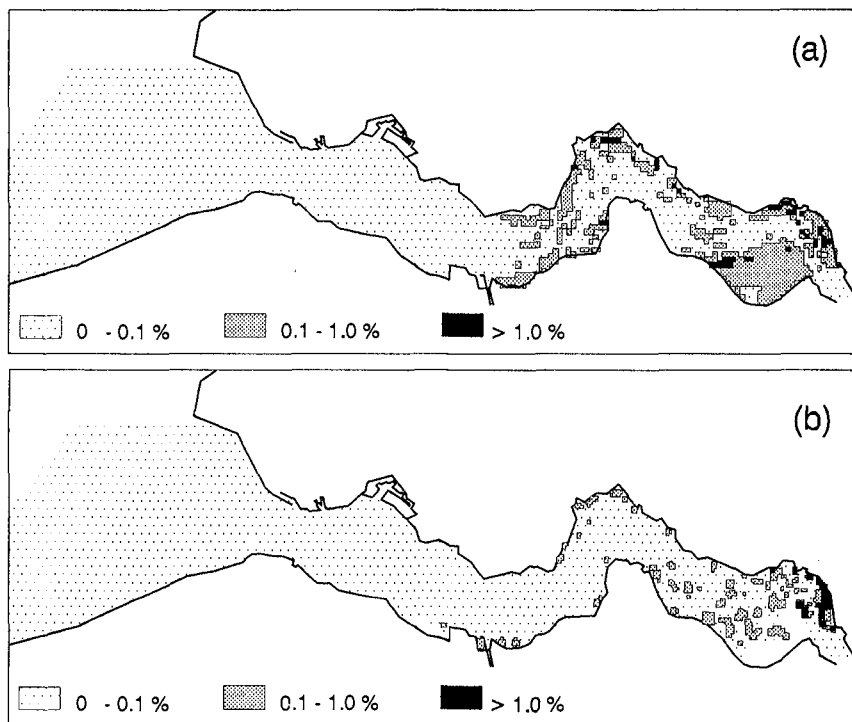

Figure 7. Measured (a) and calculated (b) fluvial mud sedimentation (relative to total river input).

Conclusions

First results of a numerical model, existing of a hydrodynamic, wave and sediment transport model, applied to the Western Scheldt Estuary are presented. Boundary conditions are roughly schematized in aiming at simulations of year-averaged quantities. Dumping of dredged material is modelled but needs verification. With the model the influence of the non-cohesive material in the bottom and the influence of surface waves is investigated. The results show that the spatial variation in erosive properties of the bed and the availability of mud have an important influence on the space and time depen-

dent distribution of concentration and sedimentation. The influence of waves according to the model is significant and qualitatively in reasonable agreement with reality. Waves redistribute the sediment from the wave-attacked shallow areas of shoals, flats and marshes to the deeper parts of channels and harbours and to the sheltered parts of flats. Spreading and sedimentation of the polluted fluvial mud can be simulated satisfactorily. It is believed that sedimentation can be modelled more easily than erosion, due to the strong influence on erosion of the usually poorly-known bed properties. For the present this justifies the use of the erosion constant as a tuning parameter.

CHAPTER 229

THE GREAT BELT LINK HOW TO ACHIEVE ZERO ENVIRONMENTAL IMPACT ON THE BALTIC SEA

Jacob Steen Møller¹ and Niels-Erik Ottesen Hansen²

Abstract

The Great Belt Link crosses the Great Belt (Denmark) which is the major strait connecting the Baltic Sea with the North Sea. A law passed by the Danish Parliament imposes an environmental design criteria of 'zero far field effect' on the Link. This paper describes how the challenge of zero effect is met by compensation dredging. The compensation dredging is designed by the use of highly sophisticated numerical models.

Introduction

The Great Belt is a channel approximately 18 km wide that divides Denmark into Jutland and Funen to the west and Zealand to the east. It is the largest of the three channels linking the Baltic to the Kattegat and North Sea (Figure 1). A major construction project (The Great Belt Link) is now underway to build a rail and road link across the strait and thus replace the busy cross-Belt ferry routes. The strategic location of the link and environmental concern about potential interference in the exchange of water between the Baltic and Kattegat have led to a comprehensive environmental plan.

² Ph.D., Director, LICEngineering A/S, Ehlersvej 24, DK-2900 Hellerup

The 'Zero Blocking Solution'

In general not much attention is given to the impact of bridges or causeways on the surrounding flow. However, the peculiar hydrography of the Danish Straits

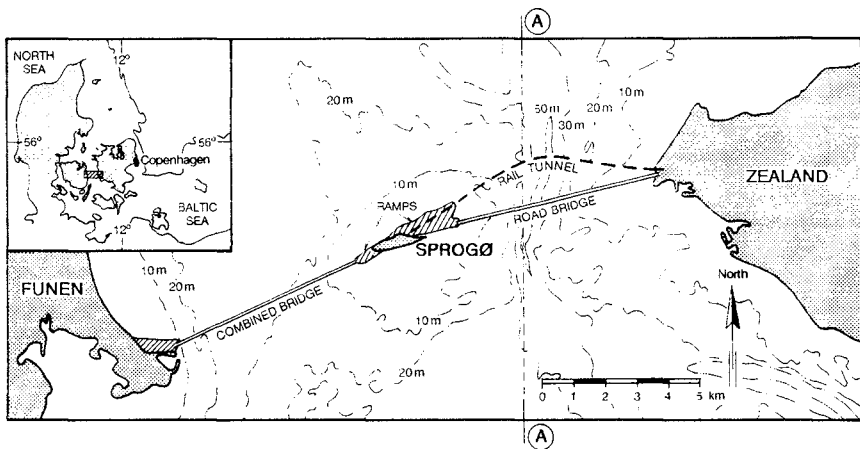

Fig. 1. The Great Belt Link

with a distinct layered flow, results in a flow with a very small hydraulic resistance. Therefore the total resistance may be sensitive to small changes in geometry. For instance, the hydraulic head difference between the Kattegat and the Baltic is normally only 0.2-0.6 m over a length of 300 km with a flow rate of 100,000 m³/s. Further, bridges built in the Straits will have to be designed for heavy ship impact and for ice loads which make the bridge abutments large, leading to increased blocking.

Most of the hydraulic loss in the Great Belt takes place through 4-5 narrows where the current becomes strong. The fixed link across the Great Belt will span the most constricted narrow of the Great Belt. Since a large part of the salt influx to the Baltic (60-70%) passes through this narrow, concern has been expressed that the construction of causeways, tunnels and bridges may exert a large flow resistance.

It is likely that the consequent reduction in the water exchange would significantly alter the hydrography and environment of the Baltic. A review of the hydrography of the Great Belt is given by Farmer and Møller (1990). To avoid such a change it has been specified in Paragraph 5 of the Danish law for contracting the link that "The work is to be carried out ... in such a way that the water flow through the Great Belt shall remain unchanged ... for the sake of the environment of the Baltic Sea". This somewhat unprecise design criterion has been interpreted by the authors to be understood as: "- The water discharge (m^3/s) through the Belt must not be changed by the crossing.

- The salt balance (kg salt/s) for the Baltic must not be changed by the crossing."

This so called "Zero Blocking Solution" ensures that no environmental impact on the Baltic, be it hydrographical or biological, will originate in the construction of the link.

It is cheaper to build causeways than heavy duty structures like suspension bridges or immersed tunnels. Therefore there is an economical demand for letting part of the Great Belt Link consist of causeways. This contradicts environmental interest which dictates as small a blocking of the flow as possible. A suitable compromise has been reached where causeways are only built in areas of water depth less than 6 metres and the blockage of these causeways and bridge piers has been compensated for by dredging.

Several proposals for compensation dredgings have been made. In the end it turned out that it would be most favourable to place the dredging on the reef East of Sprogø Island, Figure 2. This location was chosen because of high hydraulic efficiency of dredging and because materials from the area can be used for construction of causeways etc.

Designing the Compensation Dredging

The problem arises, how to determine the size and location of the compensation dredging. This engineering design work is carried out according to the following principle.

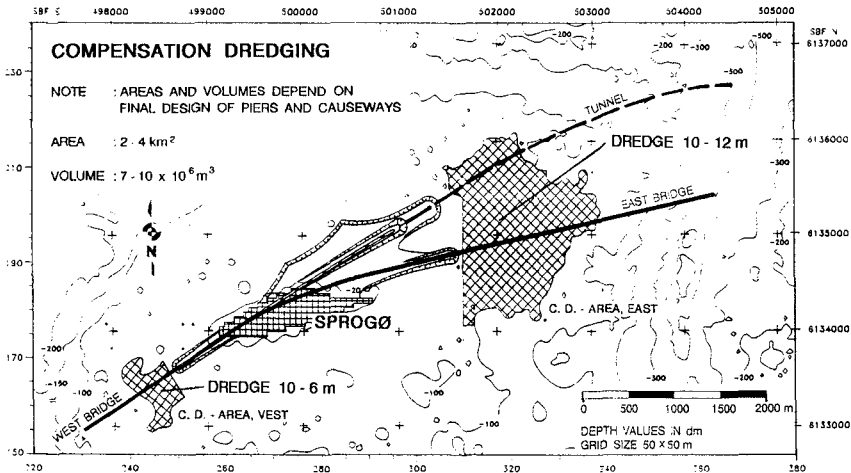

Fig. 2. Typical Compensation Dredging

Given the boundary condition for the flow through the Great Belt the surface current is calculated as it is without the Link, and as it will be with the Link. By calculating the deviation in surface water flow, we have defined a measure of deviation from the zero solution. This measure will depend on the geometry of the Link; large piers and long causeways will increase the deviation, see Figure 3.

Now for a given design of the Link we can introduce a dredging scheme and calculate the resulting deviation caused by the combined Link and dredging. If, for instance, the area to be dredged is kept constant the only parameter determining the efficiency of the dredging is the dredging elevation. By repeating the calculation of deviation for different dredging elevations the deviation is minimized, see Figure 4. The zero solution is reached for minimum deviation.

PRINCIPLE

$$\Delta q_i = \int_T |Q_o - Q_i| dt / \int_T |Q_o| dt$$

Fig. 3. Definition of Deviation in Water Flow

Fig. 4. Water Flow Deviation as a Function of Compensation Dredging Elevation

As demonstrated above not only the surface water flow but also the bottom water flow and the mixing must be kept unchanged by the Link. This is ensured by the use of a verified two layer numerical model.

Numerical Modelling

A comprehensive modelling and field study aimed at designing and controlling the compensation dredging has been carried out. For modelling the hydraulic effects the System 22 two layer numerical model developed by DHI is used, see e.g. Abbott (1979). The model is forced by meteorological data and measured water levels and interface levels at the model boundaries. Results are verified using field data from what is believed to be the most complete field data programme ever dedicated to numerical model verification. The verification includes the model's capability to describe the undisturbed flow field, the effect of ramps, piers and dredging all under baroclinic sub-critical as well as supercritical condition. The model area is shown in Figure 5.

The system 22 is a numerical modelling system for the simulation of two-layer stratified flows in two horizontal dimensions. The system computes the surface levels, interface levels and flows in both layers. The mixing between the layers is described in terms of entrainment between the layers. Entrainment rates are determined on the basis of turbulence production for each layer. (Bo Pedersen, 1986).

The equations solved by S22 are those of conservation of mass and momentum. The equations include the effects of:

- Non linear convective and cross momentum terms
- Coriolis forces
- Wind shear stress
- Bed shear stress
- Interfacial shear stress
- Flow resistance due to bridge piers
- Interfacial mixing
- Turbulent momentum dispersion
- Horizontal density gradients.

The Link and the Compensation Dredging are included in model by corresponding changes in model topography. Bridge piers are included by subgrid scaling methods, see Figure 6.

Fig. 5. Model Topography

DRAG FORCE ON BRIDGE PIER IN TWO LAYER FLOW.

DRAG FORCE IS CALCULATED FOR EACH SEGMENT OF THE PIER.

FORCE IS MODELLED AS "SUB-GRID" FRICTION TERM IN NUMERICAL MODEL S22.

Fig. 6. Subgrid Scaling of Flow Resistance due to Bridge Piers

Model Verification

The method needs verification; will the model describe:

1. The flow in nature ?
2. The effect of the link and dredging ?

These two questions are answered by comparing the model with field observations before beginning the dredging, and after 2/3 of the dredging is completed.

In practice model boundary data and verification data are assembled by a field monitoring programme. Simulations are carried out using measured boundary data. Modelled data are compared with measured data to check the performance of the model. Moreover a feedback mechanism is employed. If the results of the model verification show that the compensation dredging needs adjustment this may be done following the '2/3 through' verification of the hydraulic effect of the dredging.

A thorough description of the verification method is given by Farmer and Møller (1990).

Preliminary results of the verification have shown good agreement between modelled and measured data. Figures 7, 8 and 9.

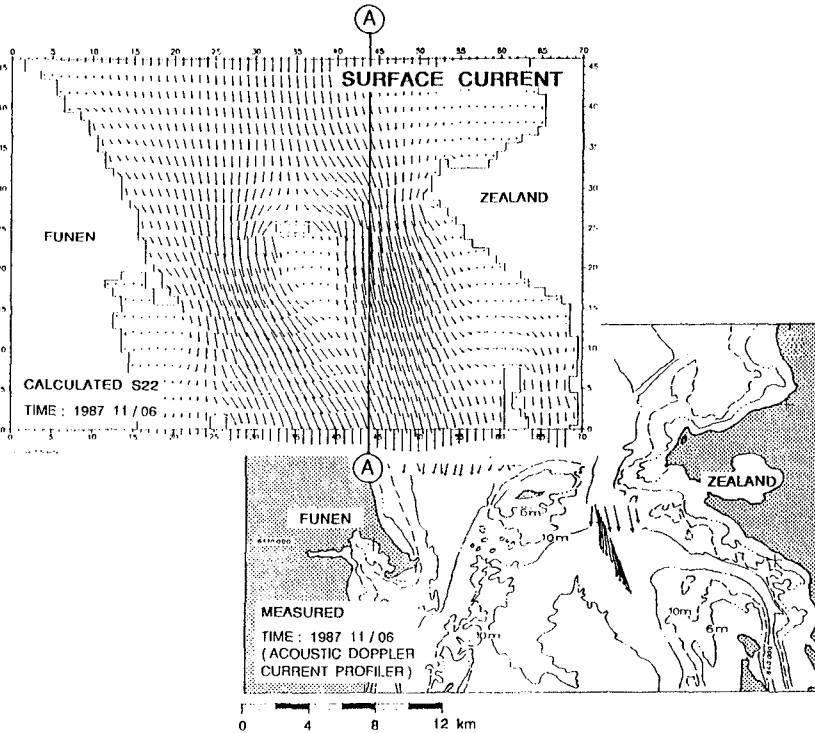

Fig. 7. Measured and Calculated Current Vectors. (Current Vectors in 500 m grid). Section A-A is shown on Figure 1. Synoptic Data from Nov. 6 1987. Measured Data from a Vessel Mounted Acoustic Doppler Profiler (ADCP) Operated by Danish Hydraulic Institute.

An interesting feature of the model is its capability to describe weak internal hydraulic jumps (hydraulically controlled flow), see Figure 8. The presence of hydraulic control has a dramatic influence on the interface position; this is seen both on Figures 8 and 9.

Fig. 8. Measured and Calculated Density Interface. Section A-A is shown in Figure 1. Measured Interface Based on Vessel Mounted Acoustic Interface Recorder developed by Danish Hydraulic Institute and on Conventional CTD-Instrument

Sensitivity Analysis

Based on a sensitivity analysis, where the compensation dredging design has been determined with varying model and boundary data input it is possible to evaluate the uncertainty of the zero solution dredging volume.

The uncertainty of the determined zero solution dredging volume has been found to be less than 10% of the total dredged volume. Given this uncertainty it is possible to evaluate the potential effects on the Baltic Sea due to uncertainty in the compensation dredging design.

In Farmer and Møller (1990) is described a model for the salinity and layering of the Baltic Sea. The LIC-Baltic-model developed by LIC-engineering A/S. By using the resistance of the Great Belt as input data the LIC-Baltic-model calculates the salinity and interface positions in the Baltic Sea. In Table 1 are shown the effects on the Baltic Sea due to various Link designs.

Fig. 9. Time Series of Measured and Calculated Density Interface at Measurement Station 'Østerrenden' shown in Figure 8. Note the Rapid Change in Position on Nov. 24. This Change is Associated with the Occurrence of Internal Hydraulic Control of the Two Layer Flow.

It is seen that when the zero blocking solution is exactly reached then by definition no changes will occur in the Baltic.

If the maximum expected uncertainty of the dredging amount is assumed then the effect of the Link measured as change in the Baltic salinity, is reduced by a factor of 10 compared with the case of the Link without dredging. In other words: Even if the maximum error in determining the dredging is assumed then the change in the Baltic salinity will be less than 10% of the change without compensation dredging.

Case	k	S	Y
	‰	o/oo	m
Undisturbed Storebælt	0.0	7.00	71.0
Link without dredging	+5.0	6.79	71.7
Link with correct dredging (by defin.)	0.0	7.00	71.0
Link with maximum overcompensation due to uncertainty	-0.5	7.02	70.9
Link with maximum undercompensation due to uncertainty	+0.5	6.98	71.1

Table 1 Calculated Change in Total Resistance, k, through the Model Area, see Figure 5. Surface Layer Mean Salinity of the Baltic, S, and Depth to Primary Interface in the Baltic, y.

Conclusions

The Great Belt Link project has initiated remarkable technical developments within hydraulics and environmental protection in association with major marine construction works.

The Great Belt Link project has introduced the concept of 'zero solution' meaning that any potential far field effect on the marine environment shall be compensated in such a way that no effects will occur. This policy is carried out in the Great Belt Link project by carefully compensating the hydraulic effect of the Link by dredging.

The dredging is designed by the use of advanced numerical models. These models are verified by comparison with field data from the Great Belt area.

CHAPTER 230

MUD TRANSPORT RATE IN MUD LAYER DUE TO WAVE ACTION

Tomoya Shibayama¹

Masakazu Okuno²

and

Shinji Sato³

ABSTRACT

In order to calculate mud transport rate, two forms of transport should be considered, which are (1) mud mass transport in mud layer, and (2) suspended mud transport in water layer. The first type of transport (mass transport in mud layer) is greater than the second one in quantity under soft mud or fluid mud condition, therefore the first type of transport is mainly considered. The previously proposed methods to calculate the first type of transport are summarized and discussed. Then a new transport model called visco-elastic-plastic model is derived and some of the results of the model are shown. The model is based on the assumption that the fluid mud layer can be assumed to be visco-elastic fluid and when the magnitude of stress in mud layer exceeds the value of yield stress, the mud layer is modeled as visco-plastic fluid. Results of the new numerical model are compared with laboratory results and some discussions are given.

1. INTRODUCTION

In coastal environment, a part of bottom surface is covered with soft mud. In estuaries, in river mouth area of large rivers

1 Associate Professor, Asian Institute of Technology, G.P.O. Box 2754, Bangkok 10501 Thailand

2 Engineer, Yokohama City Government

3 Associate Professor, Civil Engineering Department, Yokohama National University, Yokohama 240 Japan

such as Yangtze river in China or Ganges river in Bangladesh, or in large bay areas, most of the coastal bottom surface is covered with soft mud. In these areas, when surface water waves travel onto a bottom of soft mud, inter-surface wave between water layer and mud layer is generated. In the interface, fluid mud layer with high water content is formed under stormy conditions. The inter-surface wave causes mass transport in mud layer. This type of mud mass transport as well as suspended mud transport in water layer is considered to be the main mechanisms to transport mud in coastal environment. The former (mass transport in mud layer) is larger than the latter in quantity under many conditions of soft mud and therefore it is important. Behavior of suspended mud is also important when we analyze coastal environment problems or the effect of construction works to the environment.

As stated in the previous part of this paper, the mechanism of mud transport can be classified into two types which are (1) mud mass transport in mud layer, and (2) suspended mud transport in water layer. In the followings, the first transport type will be discussed mainly because the first one is greater than the second one in quantity.

Before we start to talk about mud behavior, mud characteristics should be considered. Otsubo and Muraoka (1986) classified mud into two groups according to their characteristics of settling form, flow curve (shear rate - shear stress curve) and resuspension behavior under unidirectional flow. The main factor to control these characteristics is the nature of cation attached to particle surface. The first group is represented by Kaolinite with Al^{3+} , Ca^{2+} or H^+ , and the second group by Bentonite which consist of Na^+ Montmorillonite. The first group forms apparent mid-surface between water layer and mud layer when mud particles settle down and it has yield value in flow curve. The second group does not form mid-surface and does not have yield value. Shibayama et al. (1986) suggested that both suspended load and mass transport in mud layer should be considered for the first group and suspended load alone should be considered for the second group. It is also suggested by Shibayama et al. (1986) that in the coastal environment, since the salinity of sea water supplies enough number of cation, major part of mud behaves like the first group. Therefore if we consider mud behavior in the coastal environment, we only consider the first group.

Figure 1 shows the diagram of a model for mud transport due to waves. In the figure, it is stated that mud behavior or mud transport rate is governed by mud characteristics and wave conditions. In order to calculate transport rate, mass transport in mud layer and suspended mud transport should be evaluated. The

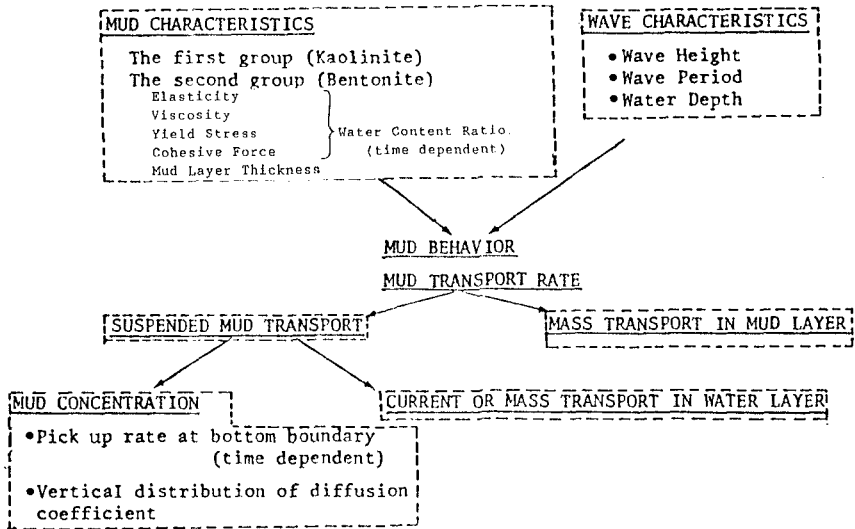

Figure 1: A diagram to evaluate mud transport rate.

suspended transport rate can be evaluated by the information of mud concentration distribution and current or mass transport in water layer. In the followings, mud mass transport in mud layer will be discussed.

2. GENERAL REVIEW OF PREVIOUS STUDIES

The study on the behavior of cohesive bed materials under wave action was started by Gade (1958). He treated mud as viscous fluid and estimated theoretically the decay rate of water surface waves propagating over mud bottom, under the assumption of long waves. Dalrymple and Liu (1978) derived "complete model" which models water layer and mud layer as viscous fluid. They also used boundary layer approximation and obtained an analytical solution of velocity field of mud layer. Recently, Hsiao and Shemdin (1980) and Mcpherson (1980) treated mud layer as visco-elastic fluid. The above four studies were carried out mainly to get the decay rate of water waves which travels over soft mud bottom.

In these five years, several attempts were carried out to estimate mud mass transport rate in mud layer. Nagai et al. (1984) performed experiments using wave flume and gave some qualitative descriptions for mud mass transport. Shibayama et al. (1986) used analytic solution of velocity field which was derived by Dalrymple and Liu (1978) using boundary-layer approximation and got formula to

calculate mass transport velocity. Mehta and Maa (1986) formulated multi-layered model with the assumption of visco-elastic fluid property and the results were compared with experiments. Tsuruya et al. (1986) extended the model of Dalrymple and Liu (1978) from Newtonian viscous fluid to Bingham fluid by using a technique of multi-layer model. They divided mud layer into several layers and applied different value of viscosity according to the velocity gradient in each layer. They also calculated mud mass transport rate. However, these two studies, Shibayama et al. and Tsuruya et al., calculated Lagrangean component of transport rate only, excluding Eulerian component. Shibayama et al. (1989) formulated visco-elastic model and calculated both Lagrangean and Eulerian components of mud mass transport velocity. Then they compared the model result of mass transport with the laboratory results and got good agreements.

3. THEORETICAL FORMULATION OF MUD BEHAVIOR

Dalrymple and Liu (1978) formulated two-layer viscous fluid model. In both water layer and mud layer, the Navier-Stokes equation with neglecting non-linear terms was given. For horizontal direction,

$$\frac{\partial u_j}{\partial t} = -\frac{1}{\rho_j} \frac{\partial p_j}{\partial x} + \nu_{ej} \left(\frac{\partial^2 u_j}{\partial x^2} + \frac{\partial^2 u_j}{\partial z^2} \right) \quad (1)$$

and for vertical direction,

$$\frac{\partial w_j}{\partial t} = -\frac{1}{\rho_j} \frac{\partial p_j}{\partial z} + \nu_{ej} \left(\frac{\partial^2 w_j}{\partial x^2} + \frac{\partial^2 w_j}{\partial z^2} \right) \quad (2)$$

The mass continuity equation is

$$\frac{\partial u_j}{\partial x} + \frac{\partial w_j}{\partial z} = 0 \quad (3)$$

Tsuruya et al. (1986) divided mud layer into n layers in order to incorporate the effect on non-Newtonian viscous fluid (multi-layer viscous fluid model). In each layer, the governing equations are given by (1), (2), and (3). Here we assume the solution as (in j -th layer)

$$u_j = \hat{u}_j e^{i(kx - \omega t)}, \quad w_j = \hat{w}_j e^{i(kx - \omega t)}, \quad p_j = \hat{p}_j e^{i(kx - \omega t)}, \quad \eta_j = \hat{\eta}_j e^{i(kx - \omega t)} \quad (4)$$

In mud layer, Mcpherson (1980) treated ν_{ej} as complex function. In j -th layer,

$$\nu_{ej} = \nu_j + i \frac{G_j}{\rho_j \sigma} \quad (5)$$

where G_j is elasticity, ρ_j is density, σ is radian frequency. Here the real part gives viscous effect and the imaginary part gives elastic effect. Shibayama et al. (1989a) incorporated the function (5) into equations (1) to (3), and determine the unsolved unknowns by using the following boundary conditions (which is the same as Tsuruya et al., 1986, for viscous fluid),

In water surface ($z = \eta_1 + h_1$)

$$\frac{\partial \eta_1}{\partial t} = w_1 \quad (6)$$

$$p_1 - 2\rho_1\nu_1 \frac{\partial w_1}{\partial z} = 0 \quad (7)$$

$$\rho_1\nu_1 \left(\frac{\partial u_1}{\partial z} + \frac{\partial w_1}{\partial x} \right) = 0 \quad (8)$$

In inter-surface ($z = -\sum_{i=2}^j h_i, z=0$)

$$\frac{\partial \eta_{j+1}}{\partial t} = w_j \quad (9)$$

$$u_j = u_{j+1} \quad (10)$$

$$w_j = w_{j+1} \quad (11)$$

$$p_j - 2\rho_j\nu_{ej} \frac{\partial w_j}{\partial z} - \rho_j g \eta_j = p_{j+1} - 2\rho_{j+1}\nu_{e(j+1)} \frac{\partial w_{j+1}}{\partial z} - \rho_{j+1} g \eta_{j+1} \quad (12)$$

$$\rho_j\nu_{ej} \left(\frac{\partial u_j}{\partial z} + \frac{\partial w_j}{\partial x} \right) = \rho_{j+1}\nu_{e(j+1)} \left(\frac{\partial u_{j+1}}{\partial z} + \frac{\partial w_{j+1}}{\partial x} \right) \quad (13)$$

In the bottom ($z = -\sum_{i=2}^n h_i$)

$$u_n = 0 \quad (14)$$

$$w_n = 0 \quad (15)$$

By using above conditions, simultaneous equations are obtained. Then we can calculate unknowns numerically by using computer.

In order to calculate, we have to give the values of elasticity and plasticity. A diagram to give viscosity is given by Tsuruya et al. (1987) as a function of water content ratio and velocity gradient. The way to give the value G , the elasticity is not yet established. However Shibayama et al. (1989b) used oscillating type viscous meter which is shown in Figure 2 and got the value of elasticity and viscosity simultaneously. Figure 3 shows some of the results of measured elasticity.

Figure 2: Apparatus of oscillating type visco-elastic meter.

Figure 3: Measured results of mud elasticity.

Here we formulate a model called visco-elastic-plastic model. In the model, we calculate magnitude of shear stress in mud layer by using the visco-elastic multi-layer model (Shibayama et al., 1989a). If the magnitude of stress exceeds the yield value of mud, the layer (in multi-layered mud layer) is assumed to be visco-plastic layer. In the visco-plastic layer, the value of elasticity, G , is given as 0 and instead of elastic term, a fixed value of yield stress is incorporated into governing equations and boundary conditions. In the real calculations, the following false elasticity G_y is used in order to left the effect of yield stress to the momentum conservation equation (Equation 1 and 2) in the visco-plastic assumption. The G_y is given as follows.

$$G_y = \frac{\tau_{y2} \sigma}{\left(\frac{\partial u_j}{\partial z} + \frac{\partial w_j}{\partial x}\right)_i} \quad (16)$$

Figure 4 shows the flow curve of Kaolinite mud which was given by Otsubo and Muraoka (1986) based on their measured results by using rotating type viscosity meter. In the figure, we will use τ_{y2} as the yield stress of the mud, that is the boundary between visco-elastic model and visco-plastic model.

Figure 4: Flow curve for Kaolinite mud. (Otsubo and Muraoka, 1985)

Figure 5: The relationship between the yield stress and the water content ratio. (Data from Otsubo and Muraoka, 1986)

Figure 5 shows the relation between water content ratio and the yield stress. The data for the yield stress is taken from the measured results of Otsubo and Muraoka (1986). From the figure, we will use the following formula for the yield stress based on the regression analysis.

$$\tau_y = 1.47 \times 10^8 \times W^{-2.83} \quad (\text{dyne/cm}^2) \quad (17)$$

Figure 6 shows some of the representative results of numerical model. In the figures, the following natures of mud layer are indicated. (1) All layers are modeled as visco-plastic, (2) upper layers are modeled as visco-plastic and lower layers are modeled as visco-elastic, (3) middle layers are visco-plastic and lower and upper layers are visco-elastic, (4) all layers are modeled as visco-elastic.

4. MUD MASS TRANSPORT RATE IN MUD LAYER

By using the above described method, we can evaluate the velocity field in both water layer and mud layer. The Lagrangean component of mass transport rate is given by ($\overline{\quad}$ gives time average over one wave period)

$$U_L = \overline{\frac{\partial u}{\partial x} \int_0^t u dt} + \overline{\frac{\partial u}{\partial z} \int_0^t w dt} \quad (18)$$

The Eulerian component of mass transport velocity is given by the

Period: T (s) Wave Height: H (cm)
 Water Depth: h (cm) Mud Depth: d (cm)

following momentum-conservation equation.

$$\overline{(uw)}_j - \overline{(uw)}_\infty = \nu_j \frac{dU_{Fj}}{dz} \quad (19)$$

where ∞ indicates the location of outer edge of boundary layer. The sum of Lagrangean and Eulerian components of mass transport velocity gives the total mass transport velocity.

Shibayama et al. (1989a) performed laboratory experiments in a wave flume. A number of tracers were inserted into the mud layer, and from the movement of tracers mud mass transport rate was quantitatively obtained. Figure 7 shows the comparison of laboratory results of mud particle excursion amplitude and calculated results by using visco-elastic-plastic model and viscous fluid model. It can be seen that the agreement of laboratory data and the visco-elastic-plastic model is better than that of viscous fluid model.

In Figure 8, the comparisons between the visco-elastic-plastic model and laboratory data are shown. The distributions of amplitude of vertical and horizontal excursion amplitude and mass transport velocity are shown in the figure. It can be observed that a good agreement is seen between laboratory results and model calculations.

5. CONCLUSIONS

A numerical model has been developed and used to predict mud mass transport rate in mud layer under the effect of water surface waves. In the model, the water layer was modeled as viscous fluid and the mud layer is modeled as visco-elastic or visco-plastic fluid. It was concluded that the present numerical model based on the assumption of visco-elastic or visco-plastic mud layer is useful to predict mud transport rate due to wave action.

CHAPTER 231

Estuary Geometry as a Function of Tidal Range

Brian O'Connor¹, John Nicholson² and Ralph Rayner³

Abstract

The tidal characteristics, and consequently the morphology, of an estuary can be altered substantially by engineering works. A method is suggested for estimating the magnitude and the time-scale of the resulting morphological changes. This method is then applied to the Welsh River Usk which will be affected by the construction of a planned tidal power barrage across the nearby Severn Estuary.

Introduction

Engineering works in an estuary, such as dredging, training walls, reclamation, storm surge barriers and tidal power barrages, can cause a marked change in the upstream tidal characteristics. This, in turn, can lead to changes in the geometry of the estuary and any sub-estuaries, provided that there are sources of mobile sediment. As these alterations have an impact on such factors as navigation and land drainage, there is a need to predict their magnitude and time-scale.

A method of predicting the new equilibrium shape of a disturbed estuary system containing fine sediment and the time needed to attain this shape is outlined herein. The proposed method is then applied to a real situation, namely the River Usk which is located in South Wales and is a tributary of the River Severn. The latter is the site of a planned tidal power barrage which will reduce the existing 12m spring tidal range to just over 4m.

³Director, Wimpey Environmental Ltd., Hargreaves Road, Groundwell Industrial Estate, Swindon SN2 5AZ, England.

Method

Two possible methods of determining the new geometry of a disturbed estuary are the detailed approach and the regime approach. The first method involves the use of two-dimensional, or even three-dimensional, numerical models of tidal motion and sediment transport. The second method, on the other hand, involves a simple one-dimensional tidal model in combination with empirical expressions which relate the flow field to the estuary geometry. The advantage of the detailed approach is the high level of accuracy but this is offset by appreciable running costs; the opposite holds true for the regime approach. Because of its simplicity and ease of operation, the regime approach is the basis for the proposed method.

The first empirical expression of the regime approach relates the estuary cross-sectional area to the tidal prism. If it is assumed that the tidal discharge at a given cross-section varies sinusoidally with time, then

$$P = \int_0^{T/2} Q_{MAX} \sin(2\pi t/T_T) dt$$

$$= Q_{MAX} T_T / \pi \quad \dots(1)$$

where P = tidal prism (m^3); Q_{MAX} = maximum discharge during a tidal period (m^3/s); t = time (s); T_T = tidal period (s). In addition,

$$Q_{MAX} = A_{MWL} U_{MAX} \quad \dots(2)$$

where A_{MWL} = cross-sectional area below mean water level (m^2); U_{MAX} = maximum cross-sectionally-averaged flow velocity during a tidal period (m/s). Hence, combining Eqs. 1 and 2 yields

$$A_{MWL} = (\pi / (U_{MAX} T_T)) P \quad \dots(3)$$

However, field studies (Bruun, 1967) have established that U_{MAX} is approximately constant along the length of a stable estuary, in which case Eq. 3 reduces to

$$A_{MWL} = a.P \quad \dots(4)$$

where a is a constant. In practice, work carried out by O'Brien (1931), and later modified by Jarrett (1976), indicated that for a stable estuary

$$A_{MWL} = a(P_s)^b \quad \dots(5)$$

where b is a constant; P_s = spring tidal prism (m^3).

The second empirical expression relates the centreline depth

at mean water level of a cross-section, H_{MWL} , to the spring tidal prism. In a study of North American inlets, Vincent and Corson (1981) found that H_{MWL} is directly related to A_{MWL} . Hence, from this information and from Eq. 5, it follows that

$$H_{MWL} = H_{MWL}(P_s) \quad \dots(6)$$

Also in a study of North American inlets, Bruun (1978) concluded that the mean water level width of a cross-section, W_{MWL} , is a function of H_{MWL} . This function, in combination with Eq. 6, therefore, yields the third empirical expression

$$W_{MWL} = W_{MWL}(P_s) \quad \dots(7)$$

It can also be shown that, under idealised flow conditions, W_{MWL} varies exponentially with distance downstream of the head of the estuary. Details are given in Appendix 1.

The fourth and final empirical expression concerns the shape of a cross-section, an idealised version of which is shown in Fig. 1. The cross-sectional shape is described by the relationship

$$W/W_{MWL} = (H/H_{MWL})^S \quad \dots(8)$$

where W = cross-sectional width (m) at any elevation H (m); S = side slope at the mean water level. It is argued that S is a function of the local sediment type which, in turn, is a function of the local flow conditions as represented by P_s . This line of reasoning leads to

$$S = S(P_s) \quad \dots(9)$$

Figure 1. Cross-Sectional Shape

The determination of the new estuary geometry is carried out using Eqs. 5 to 9 in conjunction with a one-dimensional tidal model. The sequence of operations is shown in Fig. 2. First of all, the tidal model is run for the original estuary geometry and the original hydrodynamic boundary conditions, the aim being to establish the exact form of the empirical relationships (Eqs. 5, 6, 7 and 9). The resulting $P_s - A_{MWL}$ relationship (Eq. 5) is then compared with the Jarrett version of this curve in order to check that the estuary was originally in a state of equilibrium. Assuming this to be so, the tidal model is then run again but this time for the original estuary geometry and the new hydrodynamic boundary conditions. This yields a new set of P_s values for various locations along the length of the estuary. Eqs. 5 to 9 are then used to give a first estimate for the new estuary geometry. The latter half of the above cycle of operations is then repeated until the $P_s - A_{MWL}$ relationship converges to the version associated with a stable estuary.

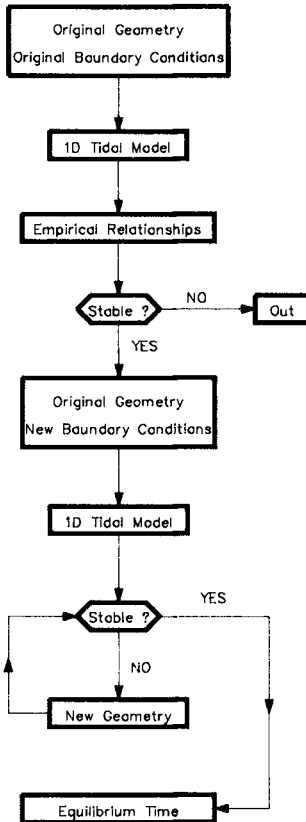

Figure 2. Sequence of Operations

The method used to compute the time taken by a disturbed estuary to attain a new state of equilibrium requires, firstly, that a relationship be established between mean sediment concentration and tidal range. This can only be done using available field data and makes it possible to derive the quantity of sediment carried into the estuary by any flood tide occurring during the lunar tidal cycle. Then, if an assumption is made regarding the fraction of the suspended sediment load deposited per tidal period, the rate of change in the estuary capacity immediately after the estuary is disturbed can be computed. Next, it is assumed that the rate of change of the estuary capacity varies exponentially with time until nominal equilibrium has been attained; a typical value for the latter is 95 per cent, say, of the capacity change. Finally, knowing the total quantity of siltation (from the difference between the original and the new estuary geometries), integration of the area under the curve describing the rate of change of the estuary capacity with time yields a solution for the total time required to reach equilibrium. Full details are given in Appendix 2.

Application

The proposed method of establishing the new equilibrium shape of a disturbed estuary was applied to the River Usk. This river, the location of which is shown in Fig. 3, discharges into the Severn Estuary and it is planned that a tidal power barrage be built across the latter. The River Usk is approximately 120 km long, of which the lower 27 km are tidal, and it has a mean spring tidal range at its mouth of just over 12 m. After construction of the barrage, the mean spring tidal range will be reduced to 4.3 m.

Figure 3. Location of the River Usk

The new estuary geometry was determined as described in Fig. 2. Following the running of a one-dimensional tidal model for the pre-barrage layout and hydrodynamic boundary conditions, the resulting relationships between P_s and A_{MWL} , H_{MWL} , W_{MWL} and S are as shown in Figs. 4 to 7 respectively. As can be seen, there is a strong correlation between the spring tidal prism and the first three variables but the situation is less clear for the fourth variable, S .

Figure 4. P_s versus A_{MWL}

Figure 5. P_s versus H_{MWL}

Figure 6. P_s versus W_{MWL}

Figure 7. P_s versus S

The stability of the existing layout was then checked by comparing the form of the $P_s - A_{MWL}$ curve with that obtained by Jarrett (1976) for stable estuaries. This comparison is contained in Fig. 8 which shows a close measure of agreement between the two curves. It was concluded, therefore, that the existing layout of the River Usk is in a state of equilibrium.

Figure 8. P_s versus A_{MWL}

The one-dimensional tidal model was then run again, this time for the pre-barrage estuary geometry but the post-barrage hydraulic boundary conditions. This yielded a first estimate for the new estuary geometry which, following one more circuit of the tidal model computational loop (see Fig. 2), resulted in a $P_s - A_{MWL}$ curve which closely matched that of Jarrett; the comparison is included in Fig. 8. The model output produced at this point, therefore, was considered to be an acceptable estimate for the final equilibrium geometry of the post-barrage estuary. An example of the pre-barrage and post-barrage shapes of a typical cross-section is shown in Fig. 9.

Figure 9. Typical Old and New Cross-Sections

The time required to attain a new state of equilibrium was computed as described in Appendix 2. Values adopted for the relevant independent variables were as follows:

$$\begin{aligned}
 F_E &= 0.95 & R_N &= 2.8 \text{ m} & \rho_D &= 1100 \text{ kg/m}^3 \\
 P_N &= 8 \cdot 10^6 \text{ m}^3 & R_s &= 4.3 \text{ m} \\
 P_s &= 12 \cdot 10^6 \text{ m}^3 & V_{TOT} &= 6.3 \cdot 10^6 \text{ m}^3
 \end{aligned}$$

where F_E = fraction of equilibrium attained; P_N = neap tidal prism at the estuary mouth (m^3); R_N and R_s = neap and spring tidal ranges at the estuary mouth (m) respectively; V_{TOT} = total estuary capacity change (m^3); ρ_D = dry density of the bed material (kg/m^3). The results of this exercise are set out in Fig. 10, the estuary-mean spring tidal concentration, C_s , and the fraction of the sediment load deposited, F_D , being treated as variables. If best estimates of 0.5 g/l and 0.10 are adopted for C_s and F_D respectively, then the computed equilibrium time, T_E is approximately 180 years.

Figure 10. T_E versus F_D

Conclusions

The suggested method for estimating the new morphology and the equilibrium time of a disturbed estuary has been applied to a real situation. The indications are that the suggested method can be operated without undue difficulty and that it yields meaningful results. It is necessary, however, that the method be checked against a situation for which both pre-disturbance and post-disturbance information is available.

Appendix 1 : Variation of W_{MWL} along the Length of the Estuary

Conservation of fluid mass, assuming a sinusoidal variation of tidal discharge with time, requires that

$$\partial Q_{MAX} / \partial x + W_{MWL} (\partial \eta / \partial t)_{MWL} = 0 \quad \dots(1.1)$$

where x = distance downstream of the head of the estuary (m); η = elevation of the water surface above some arbitrary datum (m); the other symbols are as defined in the text. However,

$$Q_{MAX} = A_{MWL} V_{MAX} \quad \dots(1.2)$$

where

$$A_{MWL} \approx H_{MWL} W_{MWL}/2 \quad \dots(1.3)$$

Hence, combining the above equations gives

$$\partial(H_{MWL} W_{MWL} V_{MAX})/\partial x + 2 W_{MWL} (\partial\eta/\partial t)_{MWL} = 0 \quad \dots(1.4)$$

If it is also assumed that H_{MWL} , V_{MAX} and $(\partial\eta/\partial t)_{MWL}$ are independent of x , then integrating the above equation with respect to x yields

$$W_{MWL} = (W_{MWL})_0 \exp(\alpha x) \quad \dots(1.5)$$

where $(W_{MWL})_0$ = mean water level width of a cross-section at the head of the estuary and α is a constant. Eq. 1.5 is the well known exponential shape of an 'ideal' estuary (McDowell and O'Connor, 1977).

Appendix 2 : Derivation of the Time to attain Equilibrium

Assume, for simplicity, that there is a linear relationship between suspended sediment concentration and tidal range, so that

$$C = \beta R \quad \dots(2.1)$$

where C = estuary-mean concentration (g/l); R = tidal range (m); β is a constant. Then, because R varies sinusoidally with time,

$$C = \beta((R_N + R_s)/2 + (R_s - R_N) \sin(2\pi t/T_L)/2) \quad \dots(2.2)$$

where R_N and R_s are the neap and spring tidal ranges, respectively, at the estuary mouth (m); t = time (s); T_L = lunar period (s). In addition,

$$P = (P_N + P_s)/2 + (P_s - P_N) \sin(2\pi t/T_L)/2 \quad \dots(2.3)$$

where P , P_N and P_s are the typical, neap and spring tidal prisms, respectively, at the estuary mouth (m^3). Furthermore, by definition,

$$M = (1/T_L) \int_0^{T_L} C P dt \quad \dots(2.4)$$

where M = mass of sediment entering the estuary per tidal period averaged over a lunar cycle (kg). Hence, combining Eqs. 2.1 to 2.4 yields

$$M = \beta((P_N + P_s)(R_N + R_s)/4 + (P_s - P_N)(R_s - R_N)/8) \quad \dots(2.5)$$

Next, the initial change in the estuary capacity per tidal period averaged over a lunar cycle, V_o , can be described by

$$V_o = D/\rho_D \quad \dots(2.6)$$

where D = deposition per tidal period averaged over a lunar cycle (kg); ρ_D = dry bed density (kg/m³). However,

$$D = F_D \cdot M \quad \dots(2.7)$$

where F_D = fraction of sediment load deposited and

$$\rho_D = \rho_s(\rho_B - \rho_F)/(\rho_s - \rho_F) \quad \dots(2.8)$$

where ρ_B = bulk bed density (kg/m³); ρ_F = fluid density (kg/m³); ρ_s = sediment density (kg/m³). Hence, combining Eqs. 2.5 to 2.8 results in an expression for V_o containing variables the values of which are known or can be estimated.

Assume that the variation of the capacity change with time is of the form

$$N = \exp(\gamma(1 - V/V_o)) - 1 \quad \dots(2.9)$$

where N = number of tidal periods; V = typical value of V_o (m³); γ is a constant. However, at equilibrium, Eq. 2.9 becomes

$$N_E = \exp(\gamma(1 - V_E/V_o)) - 1 \quad \dots(2.10)$$

where N_E and V_E are the equilibrium values of N and V , respectively. In addition, it is assumed that

$$V_E = (1 - F_E) V_o \quad \dots(2.11)$$

where F_E = nominal fraction of equilibrium attained. Combining Eqs. 2.9 to 2.11 then gives

$$V = V_o(1 - F_E \ln(1 + N)/\ln(1 + N_E)) \quad \dots(2.12)$$

However, by definition,

$$V_{TOT} = \int_0^{N_E} V \, dN \quad \dots(2.13)$$

where V_{TOT} = total change in the estuary capacity (m³). Hence, from Eqs. 2.12 and 2.13

$$V_{TOT} = V_o F_E N_E / \ln(1 + N_E) - V_o(F_E - N_E + F_E N_E) \quad \dots(2.14)$$

Eq. 2.14 is solved by trial and error for N_E , F_E being known or estimated, V_o being obtained from Eqs. 2.5 to 2.8 and V_{TOT} being derived from the known change in the estuary geometry.

CHAPTER 232

Flow Area Prediction of Tidal Inlets After Sea Level Rise

Hideo Kondo*

Abstract

An approach to predict flow area of constricted tidal inlets due to a mean sea level rise is developed. Increase of bay surface area is found to be the most dominant factor to increase the flow area due to SLR. A case study is conducted for an entrance channel of Lake Noto in the Okhotsk coast.

1 INTRODUCTION

The trend of excessive sea level rise (SLR) has brought several crucial problems to coastal engineers, above all the beach erosion due to it. Studies until now have been restricted to the problems at an open coast affected by waves and the resulting sediments (e.g. Bruun (1983), Everts (1985), Dean(1987)).

The problem at a shore along a tidal inlet is somewhat complex. The tidal amplitude in an inlet does not always coincide with that at sea, since the former is dominated essentially by the tidal discharge through the constricted entrance between sea and inlet. This means the effect of SLR on the flow area is a key problem to be solved in advance of estimating the inlet level rise. A change of the flow affects navigation, water quality, maintenance of coastal facilities, etc. besides beach erosion.

In the present study a prediction approach is proposed for the equilibrium flow area of tidal inlets after SLR in coasts with littoral drift.

2 EQUILIBRIUM FLOW AREA OF TIDAL INLETS

The minimum flow area of a stable or equilibrium tidal inlet (see Fig. 1) A_e has long been extensively studied by many researchers such as O'Brien (1931), Bruun (1958), Shigemura (1974) and Jarrett (1976). In 1975 the writer had proposed a relationship between the flow area A_e and the tidal prism P of inlet as in the following.

$$P / A_e = K_s \sqrt{a_s g} \cdot T \dots\dots\dots (1)$$

where a_s is the amplitude of tide at sea, T is the predominant tidal period and g is the gravitational acceleration. K_s is a dimensionless coefficient depending mainly on the littoral drift at sea M_l and entrance configuration. Eq. 1 had been deduced from an analysis of the maximum tidal current velocity of inlet and the data of P and A_e about inlets in US and Japan as shown in Fig. 2.

K_s had been given as;

$$\left. \begin{aligned} K_s &= 0.22, & \text{for } M_l/Q_m > 300 \\ &= 0.15, & \text{for } M_l/Q_m < 30 \end{aligned} \right\} \dots\dots\dots (2)$$

Fig. 1 Sketch of Tidal Inlet before and after SLR

Fig. 2 P/A_e versus $\sqrt{a_s g} T$ and M_l/Q_m for Prototype and Model Tidal Inlets

In Fig.2, computational results for the movable bed laboratory data by Mayor-Mora (1973) are added. They fit well with Eq.1.

In order to determine effect of M_L on Ae , K_s must be determined more quantitatively. A dimensionless parameter $P / (Ae \sqrt{\alpha_s g T})$ is plotted against M_L / Q_m as Fig. 3.

Fig. 3 $P / [Ae \sqrt{\alpha_s g T}]$ versus M_L / Q_m

The solid line drawn as an average in the figure brings a relationship as in the following :

$$P / (Ae \sqrt{\alpha_s g T}) = 0.1 [M_L / Q_m]^{0.1} \dots\dots\dots (3)$$

As far as a simple harmonic tides concerned, P is expressed

$$P = Q_m T / \pi = Ae U T / \pi \dots\dots\dots (4)$$

From Eqs. 3 and 4, Ae is derived as,

$$Ae = 1.02 Q_m^{1.1} \alpha_s^{-0.5} M_L^{-0.1} \dots\dots\dots (5)$$

a simplified analytical solution of the peak current velocity U and the tidal amplitude at bay a_b is (Kondo,1972),

$$U = \frac{1}{p} \sqrt{\frac{1}{2} [- \{ (\frac{\alpha}{\sigma^2}) - 1 \}^2 + \sqrt{ \{ (\frac{\alpha}{\sigma^2}) - 1 \}^4 + 4 \cdot (\frac{\beta p}{\sigma^2})^2 }]} \dots\dots\dots (6)$$

$$a_b = \alpha_s (\frac{\alpha}{\sigma^2}) \sqrt{\frac{1}{2} [\{ (\frac{\alpha}{\sigma^2}) - 1 \}^2 + \sqrt{ \{ (\frac{\alpha}{\sigma^2}) - 1 \}^4 + 4 \cdot (\frac{\beta p}{\sigma^2})^2 }]} \dots\dots\dots (7)$$

where

$$\alpha = Ag/lS \dots\dots (8) \quad n_p = n \sqrt{1 + (\int_0^L R^{4/3} / 2gl n^2)} \dots\dots (10)$$

$$\beta = \alpha_s g \sigma / l \dots\dots (9) \quad p = 4\pi n_p^2 g T \dots\dots\dots (11)$$

and l is channel length $\sigma = 2\pi/T$ and n is Manning roughness coefficient of it.

3 PREDICTION PROCEDURE

By making use of Eq. 4 we can estimate A_e after SLR with the procedure as shown in Fig. 4. Several cautions in the course of calculating procedure are:

- (1) Make use of a dominant simple harmonic tide to compute tidal discharge Q_m and P employing an analytical approach.
- (2) Initial value of bay surface area s and A inlet flow area are those at the MWL simply raised by $\bar{\eta}_s$ from the original one and neglecting effect of the other factors.
- (3) Neglect effect of SLR on M_l itself, as we have presently no substantial knowledge about it. The distribution of m_l only shifts due to SLR.
- (4) Due to the fact of (3), increment of trapped littoral drift by SLR ΔM_t may be evaluated as,

$$\Delta M_t = \int_h^{h+\bar{\eta}_s} m_l dh \dots (12)$$

referring to Fig. 1.

Thus the effective littoral drift rate M_l' is given as,

$$M_l' = M_l - \Delta M_t \dots\dots (13)$$

4 TREND OF CHANGE OF FLOW AREA

From Eq.4 the rate of change of the flow area is

$$\frac{\Delta A_e}{A_e} = 1.1 \left(\frac{\Delta Q_m}{Q_m} \right) - 0.5 \left(\frac{\Delta \alpha_s}{\alpha_s} \right) - 0.1 \left(\frac{\Delta M_l}{M_l} \right) \dots\dots\dots (14)$$

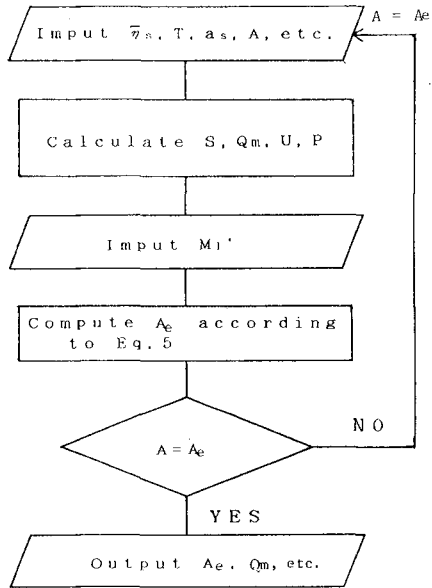

Fig. 4 Procedure to Estimate A_e after Sea Level Rise

This means the effect of change of discharge is much larger on the change of flow area. The discharge is approximated for common tidal entrances as,

$$Q_m = \alpha_s \sigma S \dots\dots\dots (15)$$

since they satisfy the following condition in Eq. 6,

$$\frac{\alpha}{\sigma^2} \gg \sqrt{\frac{Bp}{\sigma^2}} \gg 1 \dots\dots\dots (16)$$

Thus for those inlets, Eq.14 becomes

$$\frac{\Delta Ae}{Ae} = 1.1 \left(\frac{\Delta S}{S}\right) - 1.1 \left(\frac{\Delta T}{T}\right) + 0.6 \left(\frac{\Delta \alpha_s}{\alpha_s}\right) - 0.1 \left(\frac{\Delta M_L}{M_L}\right) \dots (17)$$

Applying the procedure above mentioned, it is found that the rate of variation of the flow area to SLR, $\Delta Ae/Ae$ behaves roughly as shown in Fig. 5 provided sea tide unchanged with SLR. Remarkable change of Ae which refers to $(\Delta Ae/Ae) > 0.5$ occurs for inlets of $\Delta S/S$ is larger than 0.4 due to SLR. It is deduced that those tidal entrances of inlet with low and flat beaches will suffer scouring troubles.

Fig. 5 Trend of Change of Stable Flow Area

4 A CASE STUDY

Lake Notoro in the Okhotsk coast, Japan has the surface area of 58 km^2 of an elliptic form. It had a shallow natural entrance with width of 100 m and the mean depth of 2 m below MWL as shown in Fig. 6. An analytical computation by Kondo (1978) had shown that the depth bringing the maximum tidal current was about 4 m for the width of 150 m . Since the entrance had had the depth less than 2 m , the flushing power of tidal current had been decreased with shoaling of the depth due to the drift sand by storm waves. An artificial entrance channel had been cut with a sheet piled side wall at the spring of 1974. After 16 years had passed, the entrance is 200 m wide between two side walls and protected with two long jetties (Kondo et.al, 1988) as shown with the broken line in the figure.

Estimation of A_e after SLR, has been performed for the present condition, and for the cases of $\bar{\eta}_s$ up to 2 m , according to the procedure explained in Chapter 3.

Computational conditions in the present case are;

- (1) Sea tide ; $T = 8.9410^4 \text{ (sec)}$, $a_s = 0.3 \text{ (m)}$
- (2) Channel ; $B = 200 \text{ (m)}$, $l = 200 \text{ (m)}$
 $n = 0.02$, $f_c = 1.5$

Estimation of A_e for case of each $\bar{\eta}_s$ is performed with the aid of topographical maps. M_l at the coast approximated to be about $100,000 \text{ m}^3$. At the present case which the entrance being protected with breakwaters as shown in the figure, the effective littoral drift rate M_l' is estimated to be $50,000 \text{ m}^3$. And it is assumed to decrease linearly with the value of $\bar{\eta}_s$.

A summary of the result is shown in Fig. 7. The bed scouring depth reaches approximately to 0.6 m for case of $\bar{\eta}_s = 1.5 \text{ m}$, and to 1 m for $\bar{\eta}_s = 2 \text{ m}$. The scouring depth become considerably large with the SLR value.

5 CONCLUSION

A sea level rise gives incidentally an excess tidal discharge and a decrease of effective littoral drift for inlets on sandy coasts. The flow area increases with increase of SLR from the present approach. Thus an entrance with vertical side wall will probably suffer severe bottom scouring trouble at inlets with ample low and flat shores.

J. Lundgren, Dr. Tech.⁵

Abstract

Knowledge of ship behaviour at berth is of fundamental importance for the design of harbours and marine terminals. To develop more precise data on acceptable ship movements than available in the literature, a joint research project was undertaken in cooperation between governmental and research institutions in the Nordic countries: Denmark, Faroe Islands, Iceland, Norway and Sweden. The purpose of the project was to establish criteria for acceptable ship movements in harbours for working and for safe mooring conditions.

Introduction

Modern maritime transport requires minimum time for loading and unloading in ports and at marine terminal. This requirement is in some ports restricted by ship movements at quay (operational conditions). If the ship movements are too large, damage to the ships and port installations may occur (safe mooring conditions).

⁵SSPA Marine Research Consulting, Chalmers Tvärgata 10, S-400 22 Göteborg, Sweden.

In recent years, changes in cargo-handling methods have resulted in changes of both ships and port installations. All these changes have large economic consequences, and the requirements to fast loading/unloading operations without delays due to ship movements are increasing. The above mentioned changes involve for example the containerization of general cargo and changes of methods of handling fish in fishing ports. The latter is of great importance in the Nordic countries which all have large fishing fleets.

As the new techniques are often more sensitive and vulnerable to ship movements than the conventional methods previously used, it is mandatory for cost benefit analyses of new ports or analysis of existing installations that pertinent criteria for acceptable ship movements be established for use in conjunction with the most modern investigation methods for determining ship movements at quay.

The present paper describes the methods applied and the results leading to recommendations for criteria for acceptable ship movements in harbours.

Aims and Objectives

The purpose of the project has been to determine criteria for acceptable movements of moored vessels in relation to:

- Efficiency of loading/unloading operations (denoted as working conditions)
- Safe stay at berth (denoted as safe mooring conditions).

The project has primarily concentrated on assessment of criteria for fishing vessels, ferries, coasters (freighters) and container vessels. The project involved the following four phases:

- Literature study.
- Pre-study to identify ports with ship movement problems that could be selected for prototype measurements of ship movements etc.
- Prototype measurements of ship movements and simultaneous interviews with captains and port personnel.
- Supplementary studies comprising interview with port masters and operators etc., and comparison with results from existing hydraulic investigations of the same ports. In two occasions, studies of container operations were also performed.

The prototype measurements of ship movements have been made in Denmark, Faroe Islands, Iceland, Norway and Sweden.

The supplementary study had the purpose of extracting as much information as possible from previous model studies from researchers, planners, port engineers and port users in the Nordic countries. By these interviews, critical situations have been described and compared with already existing knowledge of ship movements or wave agitation in the ports in question. In this way, it has in a number of cases been possible to procure more data on criteria for acceptable conditions in ports than obtained from the field measurements.

Fig. 1 shows the locations of prototype measurements and other studies in the five countries.

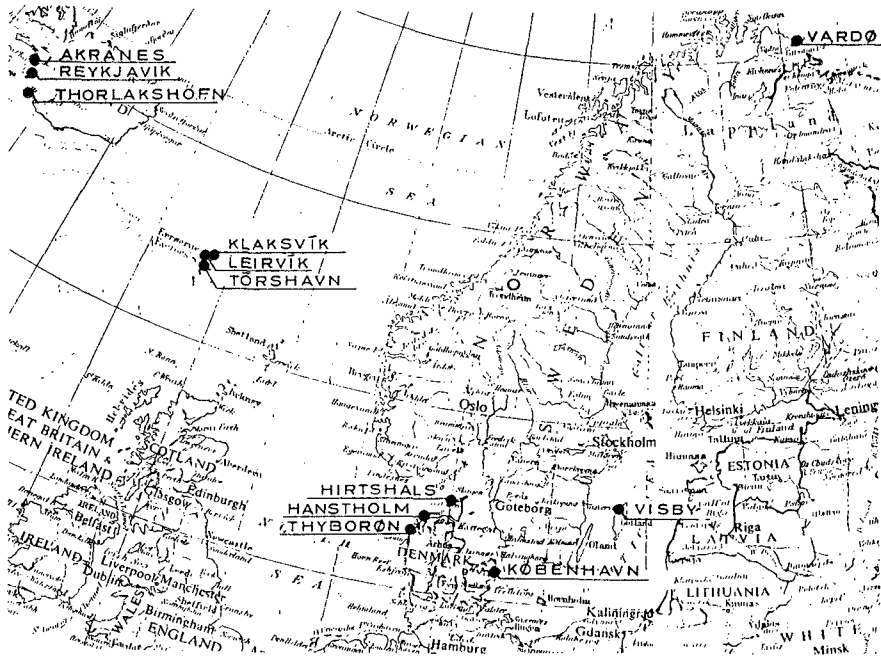

Figure 1. Locations of prototype measurements and other studies.

General on Ship Movements at Berth

The movements of a moored ship at berth can be described by the three translatory movements: surge, sway and heave, and the three movements of rotation: pitch, roll and yaw. The movements are defined in Fig. 2.

Figure 2. Definition of ship movements.

The movements of rotation, i.e. pitch, roll and yaw, are almost independent of the mooring system. They depend on the resonance period of the ship, the wave spectrum, the berth angle relative to the waves, the reflection pattern for the waves and the type of berth.

The translatory movements of a moored ship depend upon the type of ship, the mooring and fender system (geometry and stiffnesses), the type of berth, and the wave conditions (spectrum, direction of berth relative to the waves).

Typically, the natural periods of motion of the planar motions of a moored ship are for large vessels almost one order to magnitude larger than rotational movements, i.e. approximately 100 s to be compared with 10 s.

The various types of ship movements may, when they become excessive, cause different kinds of damages. Large surge movements may as an example cause breaking of mooring lines and collision with other ships aft or for. Yaw and sway movements may also cause breaking of mooring lines, but also in many cases damage to quay and fenders or to the ship itself.

It is, however, important to notice that ship movements are only one of several parameters influencing the conditions (ease and speed) of loading and unloading operations and safe stay at berth for a moored ship. Of major importance is also:

- Loading/unloading equipment and the level of skill and experience of the personnel,
- Type of goods to be handled,
- Type of vessel,
- Waiting time due to lacking capacity or efficiency at the quay front or for transport in the port,
- Wind,
- Snow, ice,
- Rain,
- Light.

The acceptable movements of a ship in a certain port are dependent on a number of factors:

- Local conditions,
- Loading/unloading methods, i.e. cranes on ship or quay, other devices for bulk or liquid products or Ro-Ro type operations,
- Movement pattern of the vessel, i.e. acceptable movement depends on not only the magnitude of movements but also on their composition,
- Mooring and fender system.

Possibility for Escape and Alternative Ports

Another very important factor to be considered for the safety of harbours is whether it is possible for a vessel experiencing excessive movements to leave the port and survive the storm either at sea or in an alternative harbour. In some ports, the manoeuvring conditions in the harbour entrance are so difficult that ships cannot enter or leave the port once a storm has reached the site. In such a port, the aspect of safe mooring at berth becomes even more important as the vessels have no other choice but to stay in the port.

Summary of Harbour Problems

The following Fig. 3 schematically presents an impression of the parameters which influence and might cause problems for mooring of vessels in a port.

Field Measurements

The measurements included ship movements, mooring forces, wind, waves off the port and inside the port and, in one occasion, fender deflections. The field measurements of ship movements were carried out with two different types of equipment developed in Iceland/Faroe Islands and Norway, respectively. Figs. 4 and 5 show the principles of the two different measuring systems. The Icelandic instrumentation was a further development of the Norwegian type to allow for measuring larger movements.

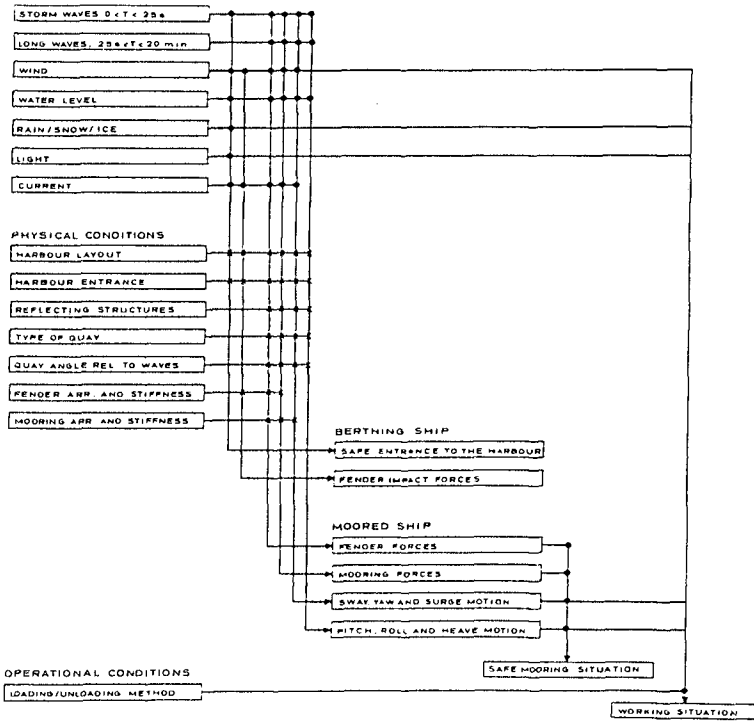

Figure 3. Parameters of importance for the conditions for a moored vessel.

- M: ROTATION (Pitch movement)
- 1: Angle in the horizontal plane
- 2: Angle in the vertical plane
- 3: Angle in the vertical plane
- 4: Angle in the vertical plane
- 5: Angle in the horizontal plane

Figure 4. Principle of Norwegian instrument.

Figure 5. Principle of Islandic instrument.

The measurements were analysed to determine representative parameters, such as:

- T^S : the significant period determined by Z-crossing
 T^m : the mean period determined by Z-crossing
 T_{mo2}^m : a characteristic period determined through spectral analysis. $T_{mo2}^m = 2\pi\sqrt{m_0/m_2}$
 T_P : the peak period determined through spectral analysis
 H_s : a significant value determined as the average of the highest third
 H^m : the mean value determined by Z-crossing
 H^{max} : the maximum value determined by Z-crossing
 H_o : 4 x the maximum-value determined through spectral analysis $H_o = 4\sqrt{m_0}$
 H_{rms} : 4 x the rms-value determined by Z-crossing.

Questionnaire

A questionnaire was used in parallel with the measurements in order to quantify the results of the measurements. However, the questionnaire was also used in situations where measurements did not take place. This was done in order to obtain more data and to obtain a more complete knowledge of conditions in certain ports.

The questionnaire contained four main items:

- Information on harbour, quay, ship (incl. moorings etc.),
- Evaluation by ship personnel of the situation during the measurements,
- Evaluation by ship personnel of whether it is necessary to interrupt the operations,
- Evaluation by ship personnel of critical mooring situations.

Results of Field Measurements

A total of 117 measurement sequences were carried out with 11 in Denmark (Hirtshals and Hanstholm), 22 at the Faroe Islands (Torshavn, Lervik and Klaksvik), 24 in Iceland (Reykjavik, Thorlakshöfn and Akranes), 43 in Sweden (Visby) and 17 in Norway (Vardö).

The measurements were carried out on different types of vessels: large passenger and car ferries, cargo vessels, trawlers, smaller fishing vessels and container vessels. In national reports, more detailed information on the ships, i.e. type and size of ships, loading/unloading equipment, mooring arrangement, etc., are presented.

Fig. 6 shows as an example results of measurements on a 27.4 m long vessel in Torshavn, Faroe Islands.

Fig. 7 shows the analyses of the same data.

In Fig. 8, results from nearly all the measurements of ship movements have been related to the length of the ship. It has been distinguished whether it was possible to load/unload or whether the movements were excessive for operations, but still allowed the ship to stay at berth.

Supplementary Investigations

Supplementary investigations were carried out including studies of the actual conditions in ports and harbours in which hydraulic model tests had been undertaken within the last 10-15 years using irregular natural waves for testing.

Fig. 9 shows an example from Visby in Sweden comparing field measurements of ship movements, mooring forces and wave disturbance with the results of hydraulic model tests of ship movements made at DHI.

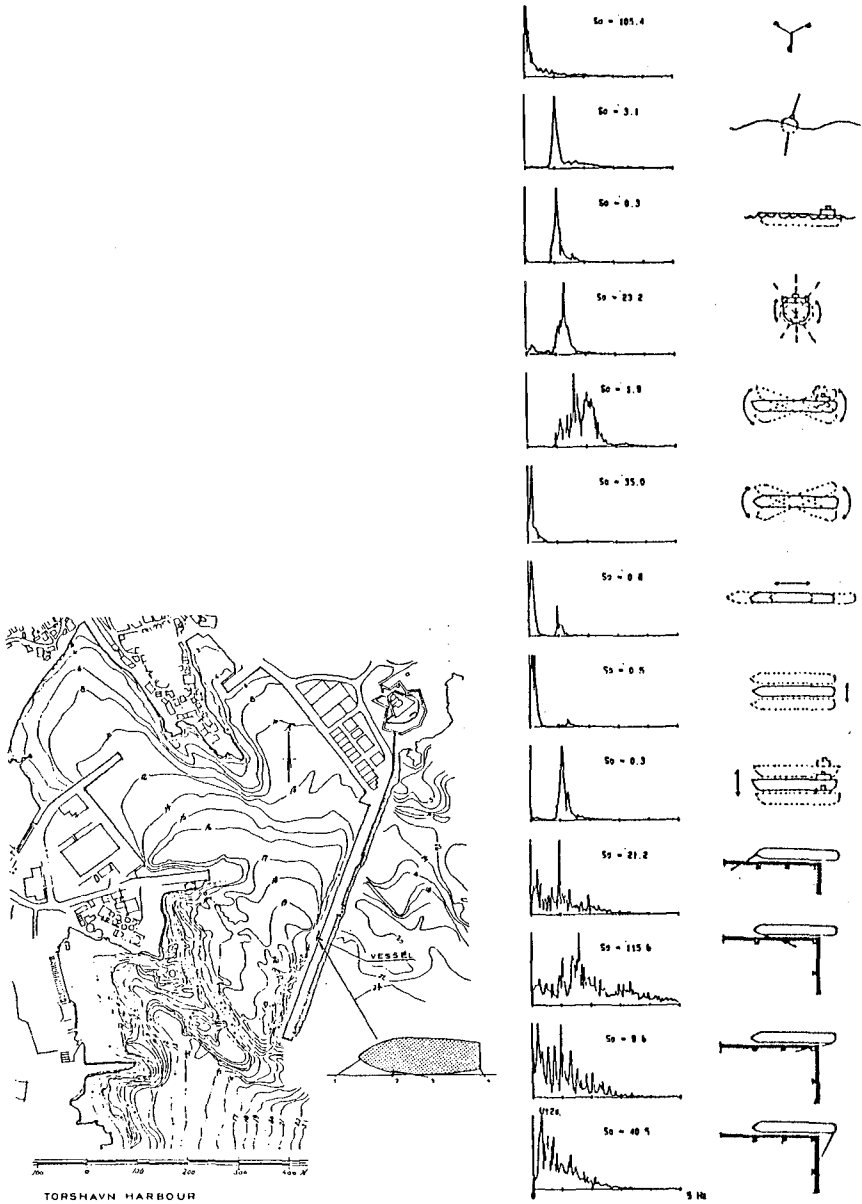

Figure 6. Example of field measurements in Torshavn, Faroe Islands.

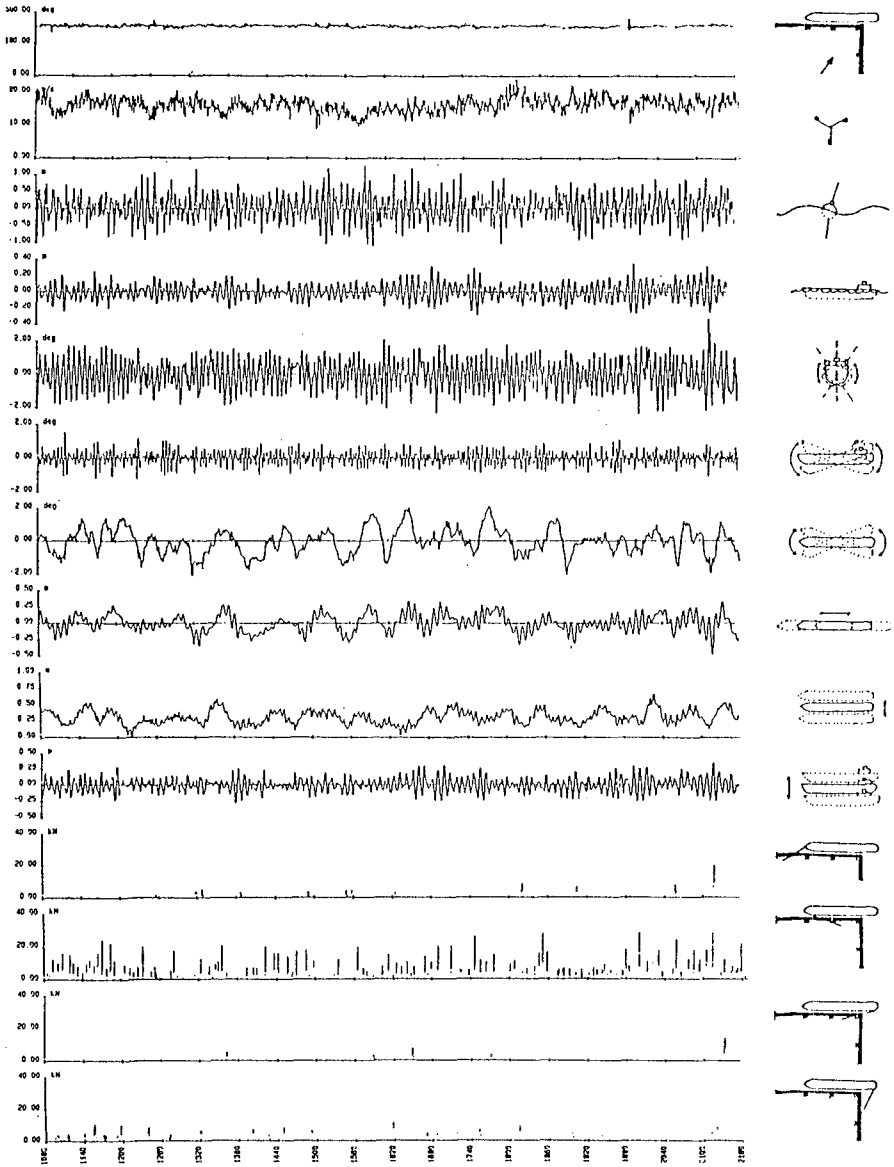

Figure 7. Results of field measurements in Torshavn, Faroe Islands.

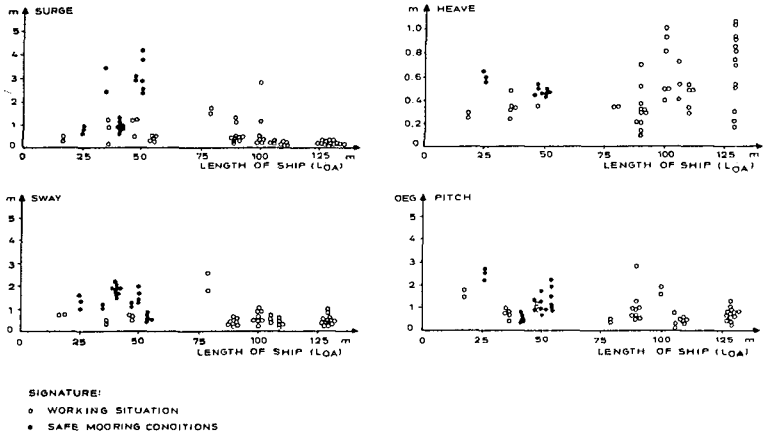

Figure 8. Ship movements in relation to the length of the ship.

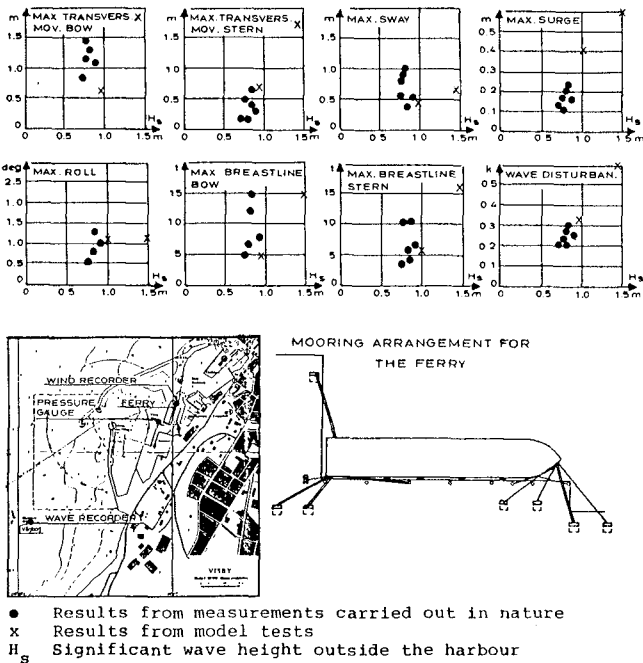

Figure 9. Example from Visby (Sweden).

It appears that there is a reasonable agreement between the field and model measurements. The differences found is believed to be caused by uncertainty about the stiffness and pretensioning of the mooring lines in nature.

Criteria for Acceptable Ship Movements

The following definitions have been adopted:

Interrupted Working Situation:

This situation is characterised by movements causing an interruption or a substantial reduction of the effectiveness of the loading/unloading operations. For this critical movement, analysis of the frequency of occurrence were undertaken. The results depend to a certain extent upon type of vessel and loading/unloading operations.

The investigations carried out have shown that on the average, a harbour in which operations have to be stopped for a total of up to 1 week/year may normally be regarded as having acceptable conditions for loading/unloading operations.

Safe Stay at Berth:

This condition is limited by the largest movements for which no damage occurs to vessel or quay, provided that the vessel is reasonably well moored and the quay is well equipped with fenders.

For acceptable condition in a harbour, attempts should be made to keep the frequency of occurrence of this situation less than once a year.

Criteria for Ship Movements

Tables 1 and 2 present the main results of the joint Nordic project in terms of criteria for acceptable ship movements for the working situation as well as for safe mooring conditions at berth.

The criteria for safe mooring conditions at berth are also given as critical velocities, as the velocity and the mass of the vessel are important parameters which determine the dynamic forces which may cause damage to the quay and/or the vessel.

Type of vessel	Surge (m)	Sway (m)	Heave (m)	Yaw (deg)	Pitch (deg)	Roll (deg)
<u>Fishing vessels</u> ¹⁾						
(L _{oa} = 25-60 m)						
LO-LO	1.0-1.5	1.0-1.5	0.4-0.6	3-5	4	3-5
Elevator crane	0.15	0.15				1.5
Suction pump	2.0-3.0	1.5-2.0				
<u>Freighters, Coasters</u> ¹⁾						
(L _{oa} = 60-130 m)						
Crane on the vess.	1.0-2.0	1.2-1.5	0.6-1.0	1-3	1-2	2-3
Crane on the quay	1.0-2.0	1.2-1.5	0.8-1.2	2-4	1-2	3-5
<u>Ferries</u> ²⁾						
(L _{oa} = 100-150 m)						
		0.8	1.0	1.0	1.0	2.0
<u>Container Vessels</u> ¹⁾						
(L _{oa} = 100-200 m)						
90-100% efficiency	0.6-1.0	0.6-0.8	0.6-0.9	0.5	1.5	3.0
50% efficiency	2.0	2.0	1.2	1.5	2.5	6.0

1) Frequency of these movements should be less than 1 week/year (2% of time)

2) Frequency of these movements should be less than 3 hours/year (0.03% of time).

Table 1. Criteria for ship movements (loading/unloading operations). The movements are maximum peak-peak.

Type of vessel	Surge (m)	Sway (m)	Heave (m)	Yaw (deg)	Pitch (deg)	Roll (deg)
<u>Fishing vessels</u>						
(L _{oa} = 25-60 m)						
Movement	1.2-1.5	1.0-2.0	0.6-1.0	6	4	8
<u>Freighters, Coasters</u>						
(L _{oa} = 60-120 m)						
Movement	1.0-2.0	1.5-2.0	1.0-1.5	3-5	2-3	6
<u>Velocity</u>						
Size of vessel						
about 1000 DWT	0.6 m/s	0.6 m/s		2.0 deg/s	2.0 deg/s	
about 2000 DWT	0.4 m/s	0.4 m/s		1.5 deg/s	1.5 deg/s	
about 5000 DWT	0.3 m/s	0.3 m/s		1.0 deg/s	1.0 deg/s	

Table 2. Criteria for vessel movements for safe mooring conditions at berth. The movements are peak-peak values. For the berth to be acceptable, the frequency of these movements should be less than 3 hours/year.

Criteria for Wave Height

Wave height criteria for safe mooring conditions at berth were also established. Table 3 presents the main result.

Ship type	L_{oa} (m)	H_s (m)
Open boats	5-12	0.20
Other boats	5-12	0.30
Small fishing vessels	15-30	0.30
Coasters (<2,000 DWT)		0.45

H_s is the significant wave height equal to the mean value of the highest one-third of the waves in a wave train. This criterion is valid only if wind waves are causing the disturbance. In harbours where seiching/long periodic waves are significant, the indicated wave height cannot be regarded as a criterion for acceptable conditions.

Table 3. Wave height criteria for safe mooring conditions.

Further Studies

PIANC decided upon review of the study report of the Nordic Research Project to set-up a new international working group for the study of Criteria for Ship Movements in Harbours and related problems. The group is chaired by the first author of this paper and three of the authors are members of the PIANC Working Group. Contributions and suggestions from firms, institutions and individuals on the subject of Ship Movements will be graciously acknowledged.

CHAPTER 234

NAVIGABILITY IN CHANNELS SUBJECT TO SILTATION

PHYSICAL SCALE MODEL EXPERIMENTS

C. BROSSARD 1, A. DELOUIS 2, P. GALICHON 3, J. GRANBOULAN 4,
P. MONADIER 5

ABSTRACT

The paper gives a brief description of the studies carried out in France during the last years, especially on scale models, in order to improve the knowledge of the behaviour of ships progressing in approach channels subject to siltation.

1 - INTRODUCTION

The French Ministry of the Sea and three French port authorities - Port Authority of Nantes - Saint-Nazaire, Port Authority of Bordeaux and the Maritime Service in French Guiana - have been working together over the past few years on studies with two main aims :

- to allow ships to use port approach channels subject to siltation, taking full advantage of potential while at the same time ensuring excellent navigability conditions,

- to ensure that technical conditions and maintenance dredging programmes are correctly adapted to the real requirements of port operations.

1 - Director of Approaches and Marine Environment, Port Authority of Nantes - Saint-Nazaire - Centre des Salorges - 18, Quai Ernest Renaud - B.P. 2199 - 44031 NANTES CEDEX 04 FRANCE

2 - Head of the Maritime Subdivision in French Guiana - Port of Degrad-des-Cannes - B.P. 338 - 97306 CAYENNE CEDEX FRANCE

3 - Head of Laboratory Division, SOGREA Consulting Engineers - B.P. 172 X - 38042 GRENOBLE CEDEX FRANCE

4 - Director of Development Works and Environment - Port Authority of Bordeaux - Palais de la Bourse - 2, Place Gabriel - 33075 BORDEAUX CEDEX FRANCE

5 - Head of Central Technical Department for Sea Ports and Inland Waterways - 2, Boulevard Gambetta - B.P. 53 - 60321 COMPIEGNE CEDEX FRANCE

These works cover three aspects :

- development of devices and methods for measuring the physical and chemical characteristics of fluid muds, such as the JTD 3 gamma densimetric probe (CEA - ORIS) working at fixed point, the JTT 4 gamma densimetric probe (CEA - ORIS) and the SD 105 ultrasonic densimetric probe (Port Authority of Bordeaux) working continuously and the SR 10 rheological probe (LCHF - SOGREAH), which are now fully operational, (ref. 1, C. BROSSARD and al, 1990, and ref. 2, C. MIGNIOT, 1984),
- physical scale model studies of the behaviour of ships in channels subject to siltation,
- observations and measurements taken from ships navigating in such areas.

This paper gives a brief summary of the exploratory work carried out by the Laboratoire Central d'Hydraulique de France (LCHF) in 1986 and then deals essentially with the systematic scale model tests carried out by SOGREAH in 1989.

2 - EXPLORATORY STAGE (ref. 3, LCHF, 1986)

This included :

- a preliminary bibliographical search that illustrated the interest of the study, but which also revealed that very few results were available from laboratory or in situ observations,
- theoretical considerations on the dimensional approach to ship displacement in clear water, the rheological problems connected with mud characteristics, the similitude applicable to scale model tests and the manoeuvrability of a ship moving over muddy beds,
- qualitative tests at a scale of the order of 1/100, enabling the measurement technology to be finalised and initial information to be obtained, giving an idea of the behaviour of a ship sailing over muddy beds.

3 - SIMULATION METHODS USED IN THE SYSTEMATIC TESTS (ref. 4, SOGREAH 1990)

This section deals successively with the problems of similitudes and scales, the experimental apparatus and the modelling of the mud.

3.1 - Similitudes and scales

Dimensional analysis of the factors constituting resistance to progress and ship behaviour led to the definition of dimensionless numbers enabling an accurate representation of the various phenomena involved.

Perfect modelling is impossible, as this would involve keeping many dimensionless parameters. Given the nature of the problem, the following choices were made :

- compliance with the Froude number and Froude densimetric number, which involves a velocity scale equal to the square root of the length scale and a mud density gradient increased in reverse proportion to the geometric scale,

- compliance with the ratio of inertia forces to rigidity forces and the ratio of densimetric forces to rigidity forces, which involves reducing the rigidity in the ratio of the geometric scales.

In contrast, neither the Reynolds numbers for water and for the mud medium nor the Grashov number (damping of internal waves) are retained. The medium in the model is therefore too viscous and forces are overevaluated.

The scales adopted after choosing the similitude rules and taking into consideration three geometric scales (1/100, 1/70 and 1/55) to represent different analysis situations are defined in the tables of figure 1.

Nature	Scale	Values		
Length	1/n	1/100	1/70	1/55
Area	1/n ²	1/10 ⁴	1/4 900	1/3025
Volume	1/n ³	1/10 ⁶	1/343 000	1/166 375
Speed	1/√n	1/10	1/8.37	1/7.41
Rigidity	1/n	1/100	1/70	1/55
Density	1	1	1	1
Theoretical tractive force	1/n ³	1/10 ⁶	1/343 000	1/166 375
Practical tractive force	-	1/3.310 ⁵	1/130 000	1/65 000
Power	1/n ^{3.5}	1/10 ⁷	1/2.87 10 ⁶	1/1.23 10 ⁶

1.1 - Chosen scales

Model		1/100	1/70	1/55
Speed	0.2 m/s	3.88 kn	3.25 kn	2.87 kn
	0.3 m/s	5.82 kn	4.87 kn	4.31 kn
	0.4 m/s	7.76 kn	6.50 kn	5.77 kn
	0.5 m/s	9.70 kn	8.12 kn	7.21 kn
	0.6 m/s	11.6 kn	9.71 kn	8.65 kn
Draught	15.6 cm	15.6 cm	10.9 m	8.58 m
	12.2 cm	12.2 cm	7.8 m	6.16 m

1.2 - Correspondences with full - scale speeds and draughts

Fig. 1 - Scales chosen for the tests and correspondences with some full scale parameters

3.2 - Experimental apparatus

The tests were run in the looped wave flume at SOGREAH in Grenoble. This flume is 50 m long and 3.2 m wide. It has a trolley that runs on rails, used for pulling the model and taking measurements (fig. 2)

The model used was that of a tanker of classic type, 2.56 m long, representing :

- at scale 1/100, a ship of the same type with a displacement of 120 000 t,
- at scale 1/70, a 25 000 - 30 000 t bulk carrier with a high block coefficient,
- at scale 1/55, a ship of the type calling in at French Guiana.

Fig. 2 - Plan of the looped flume

The model was equipped with sensors for measuring squat, trim and tractive force.

Four parameters were thus recorded simultaneously : foreward squat, trim, tractive force and speed (fig. 3).

The mud concentration was determined using an ultrasonic probe developed during the first stage of the study. Via two sensors, this measures the acoustic power transmitted through a layer of mud after direct immersion in the medium under study.

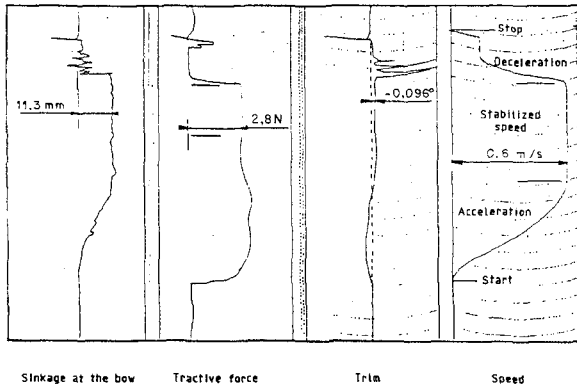

Fig. 3 - Examples of recordings

3.3 - Modelling of mud

In order to comply with the chosen rules of similitude, the mud had to be represented by a mixture which, at equal concentration, would have a rigidity value in proportion to the geometric scale, i.e. 1/100 for the basic configuration, and density gradients in similitude with those obtained in reality.

Following a review of the characteristics of mud deposits in the Loire, Gironde and Mahury (French Guiana), showing the variation of initial rigidity as a function of concentration and the density gradients in the deposits, it was decided to carry out tests with the following, in order to cover the entire range of possible situations :

- two types of mud : high rigidity and low rigidity,
- three concentration gradients as a function of depth : high, intermediate and low.

The techniques used to model the mud have allowed to respect, from the point of view of rheology and from the point of view of the density gradients, the conditions of similitude previously considered.

Figure 4 shows the gradients obtained on the model, for the mud of high rigidity, in conformity with those observed in situ and allowing profiles to be accurately repeated.

4 - TESTS IN CLEAR WATER

The aims of the tests carried out in clear water were :

- to check that the model behaved in conformity with the prototype,
- to gather information for comparing the results obtained with muddy beds.

4.1 - Programme of tests

The programme comprised 29 tests with :

- draughts of 15.6 cm and 11.2 cm with the ship at rest,
- speeds varying from 0.2 m/s to 0.6 m/s,
- under-keel clearances at rest varying from 8 cm to 0.5 cm.

The tests with large under-keel clearances at rest (6 and 8 cm) were carried out in order to appreciate the effect of reducing this parameter on the behaviour of the ship.

4.2 - Squat

The measurements were compared with the theoretical results obtained by applying the Barrass formula (1977) (ref. 5, L. Ribadeau-Dumas, 1982). The mean deviations observed were :

- 0.054 cm with a draught of 15.6 cm,
- 0.032 cm with a draught of 11.2 cm

i.e. about 0.3 % of the draught considered, which is less than the accuracy of the sensors.

4.3 - Trim

In the absence of known formulae, the measurements were compared only with the results of observations taken in the Netherlands Ship Model Basin (NSMB) and published by R. Sellmeijer and G. van Oortmerssen (ref. 6, 1983).

It appears that the results concur well for the narrow interval than can actually be plotted.

Fig. 4 - Density gradients on the model - Mud of high rigidity

4.4 - Tractive forces

4.4.1 - With the Froude similitude and a geometric scale of 1/100, the forces are theoretically in the scale of $1/10^6$ but on the model the viscous forces are actually increased owing to the fact that the Reynolds similitude is not respected, thus leading to a higher resistance than in reality.

Comparison of the in situ and model results indicates that the forces on the model are about three times too great with respect to the Froude similitude, which leads to the practical values shown on the table of figure 1.1, for example $1/3.3 \times 10^5$ for scale 1/100.

4.4.2 - The tests led to four types of conclusions :

- Forces increase when the under-keel clearance falls and forces are greater with a draught of 15.6 cm than with one of 11.2 cm.

- The difference between the tractive forces obtained for these two draughts is on average 5-10 % greater than could be expected from an increase in force based simply on the variation in hull area (+ 19 %).

- For both draughts, the force increases in an almost linear fashion as a function of the Froude number.

- A comparison of the forces measured on the model and those computed for the model shows that, overall, the forces measured are greater than those computed, though the differences are slight in the case of the lowest forces, increasing progressively with them. Given the lack of theoretical knowledge, uncertainties over the measurements, the methodology chosen and the aims pursued, it was considered that the model and sensors were adequate.

5 - TESTS WITH MUDDY BED AND NO CURRENTS

5.1 - Test programme

A programme of 99 tests was carried out.

The test or navigation conditions were characterised by five parameters, two linked to the mud :

- concentration-rigidity relation (type of mud used),
- concentration gradient of the mud deposit,

and three linked to the ship :

- draught at rest,
- under-keel clearance,
- speed.

5.2 - Squat

When the ship is above the top of the mud, the squat measured is of the same order of magnitude as with clear water when the keel is close to a hard bed, but when the keel is in the mud, the squat values differ according to navigation conditions.

- The type of mud has little effect on the squat values obtained.

- The draught has little effect on the squat values obtained, but, as in clear water, the squat values observed with a draught of 11.2 cm are very slightly higher than those obtained with a draught of 15.6 cm.

- Generally speaking, the greater the mud density gradient, the more the squat decreases algebraically.

- When the ship's keel is in the mud, the squat may be considered as the resultant of the hydrodynamic force connected with the speed and of the hydrostatic thrust.

. The observations made on the model at low speed, especially in the case of low and intermediate gradients, can be explained in this way.

. In the case of high gradients, in contrast, the ship is lifted more, as her trim is then positive, and this tends to cause the ship to climb on the top of the mud, all the more so as the speed increases.

. At high speeds (0.4 and 0.6 m/s), in the case of low gradients, there is an increase of the squat in comparison with the values obtained when the ship is above the mud.

- Considering the position of the keel when the vessel is at rest in comparison with density level 1.2, the squat values observed are greater than those obtained with clear water (with respect to the solid bed), even with under-keel clearances of the order of 10 % of the draught with low gradients and speeds of 0.4 to 0.6 m/s.

- The squat values vary in proportion to the square of the speed (fig. 5) :

. With low gradients, the squat values obtained in the presence of mud are higher than those observed in clear water, from about 0.5 m/s upwards.

. Independently of the density gradient, the positive squat values obtained with the under-keel clearances considered (vessel at rest) only appear with speeds above about 0.3 m/s.

All these various observations show that the density level is not, in fact, the only parameter to be taken into account, but that the density gradient is also an important factor.

5.3 - Trim

As far as manoeuvrability is concerned, a variation in trim is significant as soon as it corresponds to a difference of about 30 cm between fore and aft draught, i.e. an angle of the order of 0.068° . This phenomenon is significant especially in the case of a ship with a negative trim.

- The trim values obtained are very low with a mud of low rigidity, so that the effect of the other parameters may be examined only with rigid mud.

- Trim values increase with gradient, keeping the same speeds and under-keel clearances relative to the top of the mud, and, when the under-keel clearance decreases, the higher the gradient, the earlier the transition from a negative to a positive value.

- In the case of high gradients, the trim values remain lower for a draught of 11.2 cm than those observed, with the same under-keel clearance, for a ship with a draught of 15.6 cm.

Fig. 5 - Tests with mud bottom and without current - Variation of the value of the squat with the speed - Mud of high rigidity - Draught 15.6 cm

- Generally, the trim changes from a negative value to a positive value as the hull penetrates the mud. The lower the speed, the earlier the transition to a positive value.

- The trim varies in proportion to the square of the speed (fig. 6) :

. with the same under-keel clearance and the keel in the mud, the greater the speed, the more the trim decreases, to the extent where it may become negative ;

. the variation in trim resulting from an increase in speed is, however, less in the presence of mud than with clear water.

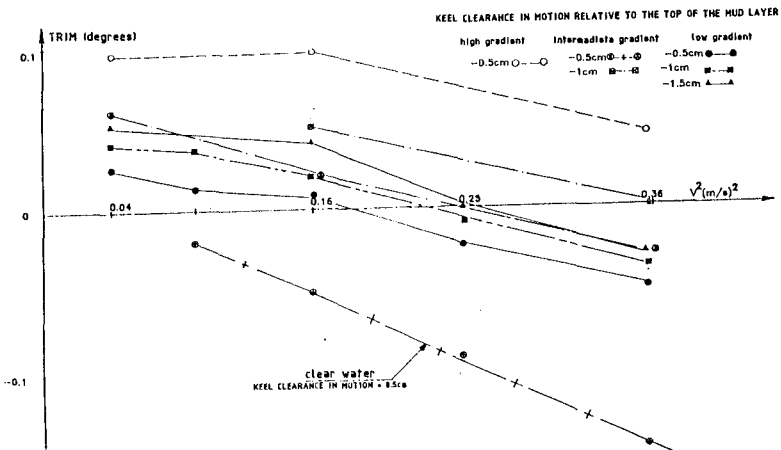

Fig. 6 - Tests with mud bottom and without current - Variation of the value of the trim with the speed - Mud of high rigidity - Draught 15.6 cm

5.4 - Tractive forces

Given scale effects, the forces involved should be mainly considered as relative.

Generally speaking, so long as the keel of the moving vessel is well above the top of the mud, forces are of the same order of magnitude as those observed in clear water. As the ship penetrates the mud, forces increase rapidly, but in a different way, however, depending on navigation conditions. In certain cases, a local maximum is observed when the ship's keel is just above the top of the mud.

- The effect of mud rigidity is felt particularly at low speed. The higher the speed and the less sinkage in the mud, the greater the relative proportion of the tractive force linked to the rigidity value. In areas where there may be differences in mud rigidity, this should be taken into especial account during periods of low-speed navigation and even more so during manoeuvring as, depending on the rigidity of the mud, the forces required may be very different.

- Low density gradients appear more favourable (less force with the same under-keel clearance during motion) than high gradients, considering the top of the mud as reference level. In contrast, low gradients appear less favourable if the 1.2 density level is taken as reference, because in this case and with the range of under-keel clearances used in the tests, the gentler the gradient, the greater the force appears to be with the same under-keel clearance.

- Tractive forces are generally higher with a draught of 15.6 cm than with one of 11.2 cm, and they vary in a relatively similar way depending on the under-keel clearance as the ship advances. The relative differences are of the order of 28 % for a speed of 0.4 m/s and 20 % for one of 0.6 m/s.

- Three types of variation in force may be distinguished, depending on the under-keel clearance during motion with respect to the top of the mud (fig. 7) :

. A variation as in clear water, when the ship's keel is distinctly above the top of the mud.

. A slight variation, when the ship's keel is close to the top of the mud. This type of change does not occur systematically.

. A very rapid increase with the sinkage of the ship in the mud. The speed at which this occurs increases with the gradient.

Fig. 7 - Tests with mud bottom and without current - Variation of the value of the tractive force - Mud of high rigidity - Draught 15.6 cm, $v = 0.4$ m/s

- An initial approximation of the variation in tractive force as a function of velocity may be written as follows (fig. 8) :

$$F = F^0 + k V^2$$

The values of F^0 and k depend on the under-keel clearance during motion relative to the top of the mud, the density gradient and the type of mud.

. The value of F^0 is nil when the keel is above the top of the mud and rises to 1.4 N for a high sinkage of the keel in the mud, with a rigid mud and a high density gradient.

. The values of k are higher by 20-50 % than that noted for clear water (10.5 N/m^2), depending on the type of mud deposit.

Fig. 8 - Tests with mud bottom and without current - Variation of the value of the tractive force with the speed - Mud of high rigidity - Low gradient - Draught 15.6 cm

5.5 - Internal waves

Internal waves were analysed on the basis of photographs taken through the flume observation window.

Internal waves are not visible with the most rigid mud, irrespective of speed, nor with the least rigid mud, with a speed of 0.2 m/s, but they appear with the least rigid mud and speeds of 0.4 and 0.6 m/s.

They generally occur in the form of a double-bump undulation above the top of the mud at rest, the first bump being less pronounced than the second one. The main characteristics are as follows :

- Distance between the two bumps, parallel to the keel centre line, of the order of 1 m, with the total wave length being of the order of 2 m.

- Wave crest making an angle of 30-50° with the centre line of the ship.

- Wave propagation speed perpendicular to the wave crest between 0.4 and 0.6 m/s.

- The amplitude of the internal wave depends little on the draught of the ship and on the density gradient. It increases with speed and reaches a maximum of 4-5 cm when the ship's keel during motion is close to the top of the mud and reaches a more or less constant value of 1.5-2 cm when the keel sinkage in the mud is of the order of 1 cm.

These observations concur, for the most part, with those published by R. Sellmeijer and G. van Oortmerssen (ref. 6).

6 - TESTS WITH CURRENTS

In order to assess the impact of a current on navigation in silted channels, some tests were also carried out with current in clear water and with muddy beds, using a ship with a draught of 15.6 cm.

The current speeds are denoted as positive when currents run in the same direction as the ship's motion, and negative in the opposite direction.

6.1 - Tests in clear water

Two series of three tests each have been performed, with an under-keel clearance of 1.6 cm (10 % of draught) at rest, with ship speeds in relation to the bed of 0.3 m/s and 0.4 m/s. Each series consisted of three tests : no current, a current of + 0.1 m/s and one of - 0.1 m/s.

The values obtained show that the results should be compared with those obtained under no-current conditions and with the same surface speed (i.e. in relation to the water).

With a current, squat is about 25 % greater and trim identical, irrespective of the current direction in relation to the ship's motion.

With the same surface speed, the tractive force is about 30 % greater than that observed in the absence of current when the current is in the same direction as the ship's motion and about 5 % less when it is in the opposite direction.

6.2 - Tests with muddy bed

Two series of three tests each were carried out, with the most rigid mud.

With the same surface speed and a muddy bed :

- squat decreases with a counter-current and is practically nil in the opposite situation,
- tractive forces are, as in clear water, slightly higher with a current.

With the same speed relative to the bottom and in the presence of a current, the tractive force is greater than in the absence of a current when it runs opposite to the direction of the ship's motion and is lower in the opposite situation. An initial approximation of the force may be obtained by considering that, with a given bottom speed and current, the force is close to that measured in the absence of a current considering the ship's speed to be equal to the bottom speed plus the current velocity.

7 - TENTATIVE APPLICATION OF TEST RESULTS TO REAL CASES

The study was completed by an attempt, suggested by ship's captains, to examine how the results obtained during the tests could be applied to real situations, in the form of nomographs.

The nomographs are formed by superimposing two families of curves (fig. 9).

- The first one, deduced from the tests, is taken from a set of ten figures corresponding to the ten categories of tests carried out (fixed rigidity, gradient and draught at rest). For known underkeel clearances at rest, this gives the force-speed curves (F-V), which can be transposed to real situations by applying the scales given in fig. 1.1.

Fig. 9 - Diagram giving the conditions of navigation - Mud of high rigidity - Low gradient - Draught 15.6 cm

- The second family of curves represents the characteristics of the ships. Isopower curves are defined in the plane F, V by the relation :

$$P = F V$$

with the curves being calibrated by the approximately verified relation for unconfined waters :

$$P = k V^3$$

in which k is a coefficient depending on the characteristics of the ship. A set of three figures represents the isopower curves of the three ships considered.

The ship's operating curve is represented schematically on these nomographs by successions of displacements along the isopower curves when the engine power can be maintained and along the curves of constant under-keel clearance at rest relative to the top of the mud when the engine power is reduced.

Three practical cases have been examined, concerning the ports of Nantes - Saint-Nazaire, Bordeaux and French Guiana.

8 - CONCLUSIONS

The scale model experiments enabled substantial progress to be made in understanding the behaviour of ships sailing in channels subject to siltation. The nature of the phenomena observed and the orders of magnitude of the parameters for characterising these phenomena were acknowledged to be quite valid by the mariners and pilots involved in the study.

The first attempts made to establish nomographs defining navigation conditions in real situations are encouraging, but they must of course be treated with great caution. Precise measurements under real navigation conditions should constitute the next stage of study, enabling the theoretical nomographs derived from the scale model studies to be adjusted to real navigation conditions.

CHAPTER 235

INTEGRATION OF MARINE SIMULATION IN HARBOUR DESIGN

Stig E. Sand ¹

Ole Juul Jensen ²

Abstract

The strong increase in the capabilities and efficiency of modern marine simulators are briefly outlined as the background for demonstrating the advantages of a much closer coordination of hydraulic and maritime oriented design work in relation to harbour planning and alteration. The interaction of the two disciplines and the implications on the final configuration of two different harbours are described.

Introduction

In the design of a harbour the two dominating engineering disciplines are hydraulic engineering and naval architecture. Just the fact that two different disciplines are involved brings about the inevitable risk of lack of coordination, which in turn may be the explanation for several far from well functioning harbours in the past.

Traditionally, the hydraulic engineer conducts environmental investigations, basic lay-out studies, sediment transport assessments, down time analyses, etc. Some of the key activities herein are numerical wave and current computations, wave disturbance model testing and stability tests of breakwaters.

In the design of a new harbour the naval architects have typically been consulted (separately) on assessment of space requirements, dredging limits, approach, berthing and departing strategy for a given class of ships, which are planned to call on the harbour. The most important tools in manoeuvring studies have traditionally been Planar Motion Mechanism (PMM) tests or free sailing model tests in combination with theoretical considerations. However, these tools cannot fully account for the great complexity and the large number of parameters inherent in the design of an optimal harbour from a maritime point of view. The development of computer based marine simulators has clearly filled a gap in this sense by increasing the number of combined

¹General Manager, Simulation of Marine Operations, Danish Maritime Institute, 99, Hjørtekaersvej, DK-2800 Lyngby, Denmark.

²Head, Ports and Marine Structures Division, Danish Hydraulic Institute, 5, Agern Alle, DK-2970 Hørsholm, Denmark

variables that can realistically be taken into account in the design process. One of the important additional capabilities of a simulator is the provision of the man-machine interaction. Furthermore, the unique flexibility of a marine simulator as regards description of environmental conditions, harbour lay-out, ship characteristics, etc. is the key to a closer coordination of hydraulic and naval architectural tasks in the design process.

As the background for a call for further integration of marine simulator services in the design of harbours the subsequent sections briefly outline the traditional hydraulic and maritime areas of work and examples of the benefits of integration.

Typical Hydraulic Investigations

The design of a harbour requires the definition of a long list of design parameters which relate to amongst other hydrographic conditions and various criteria for the different installations and structures. The hydraulic investigations for a harbour typically comprise:

- i) Definition of wind, water level, tide, wave parameters and statistics. These can be established by various methods ranging from analysis of existing data, performance of measurement programmes to different types of computations and modelling. The definition of design water levels, e.g. in hurricanes, may require mathematical modelling with the most advanced models available for computation of the highly complex influence of winds and barometric pressure on the flow (currents) and water level. The definition of offshore waves and the transformation of waves to the nearshore zone of the harbour also requires numerical modelling using the most advanced models for definition of the wave climate and related nearshore design waves.
- ii) The layout and general arrangement of a harbour is often determined by a combination of numerical and physical models using as input the above defined wave and water level statistics. It is further of importance for the interpretation of any model investigation, numerical or physical, that pertinent criteria are available for the harbour. Such criteria are related to wave disturbance, ship movements and mooring forces.
- iii) Equally important to the layout is the verification of the long term stability of the protecting structures. Such investigations are still today mainly carried out in physical models.
- iv) For almost any harbour on sandy beaches aspects of scour and sedimentation as well as the effect in general on the coastal morphology requires often detailed investigations. Such investigations are mostly performed by means of numerical models.

Typical Maritime Investigations

As mentioned earlier naval architects have traditionally been consulted on ship manoeuvring performance and the implications on operational strategies as well as on physical boundaries such as turning basins, entrance channel, etc. Because of the considerable difficulties inherent in assessing manoeuvring performance under specific environmental conditions, physical restraints, human (navigator, pilot) interaction, etc. a large part of the considerations in the past have been based on simplified rules of thumb. These are typically associated with the standard manoeuvres, e.g. turning circle, zig-zag, stopping, etc.

For illustrative purposes consider the determination of the diameter of a planned turning basin. Often it may be chosen to be equal to the tactical diameter of the ship(s). If tugs are available the diameter may alternatively be determined as 1.2 - 1.5 times the length of the ship(s) as a general rule of thumb. Similarly, the use of duc d'albe's or manoeuvring by means of the ship's anchor may be based on generalized rules.

In contrast to these simple rules it is worth recalling that manoeuvring performance is composed of the interaction between:

- hull
- propeller(s)
- thruster(s)
- rudder(s)

which, as described above, should be considered under environmental conditions such as:

- wind field, lee effects and gusts
- current conditions, incl. shear current
- wave action
- water depth variations (bathymetry)
- bank proximity

It is rather obvious that general considerations as opposed to a true representation of the complexity indicated above may have implications on the serviability and in turn the economics of the harbour.

It is therefore comprehensible that a reliable description of all the elements and their interaction together with an important feature such as real time man-in-the-loop operations are what make today's marine simulators attractive.

Marine Simulators

As an example of a marine simulator the one at DMI is described. DMI is a full member of the International Marine Simulator Forum (IMSF).

The mathematical models represented in the marine simulator cover all vessel characteristics and environmental elements so that design and training tasks related to ship manoeuvring, navigation, dredging, harbour lay-out, offshore operations, etc. can be undertaken.

The simulator was originally developed for two basic purposes, viz. training of navigators and evaluation of manoeuvring performance. However, as clear needs were identified for a more sophisticated simulator it was developed to encompass shallow water effects, limited channel boundaries (bank effects), ship-ship interactions, complex wind and current patterns, etc. DMI is presently developing its fifth generation simulator which amongst other includes first and second order wave effects in six degrees of freedom.

The present software consists of more than 30.000 Fortran statements organized in a general purpose computer. The latter communicates with three graphic computers and in turn three projectors for illustration of the view from the actual ship's bridge on a 6,6 m x 1,5 m screen. The computer is also connected to the ship's instruments such as machinery telegraph, rudder, thruster command, etc. One PC screen shows the actual speed, draught, underkeel clearance, wind, wave and current information as well as machinery characteristics and fender or tug forces. Another PC shows a "radar" picture in the form of a plane "birds-eye-view". Fig. 1 illustrates the DMI simulator.

Fig. 1 Illustration of the DMI simulator with instrument screen, steering stand, radar picture and visual screen in the background.

As regards the subjects discussed in section 2 and 3 in relation to the design of harbours the strong points of the simulator is:

- accurate hydrodynamic modelling of vessels
- space and time varying currents
- space and time varying winds including gusts

- wave spectrum modelling
- representation of actual bathymetry
- three-dimensional graphics of harbour
- real time man-in-the-loop operations.

in combination with high flexibility such that any of the items above can be easily changed in the search for optimal solutions.

To this end it should be mentioned that also fast-time simulations are available. These do not include a man-in-the-loop, but instead a deterministic rule bound autopilot. The advantage is, however, that a fast screening of various alternative solutions can be performed. A few of the most promising solutions can then be tested in real-time.

Examples of Integrated Designs

The first example of a harbour which has been subject to combined hydraulic design studies and maritime simulations is shown in Fig. 2. The harbour, which is located in the Far East, was planned at a rather open stretch of coast with considerable influence from wind, waves and current.

Fig. 2 Far East harbour.

The hydraulic investigations involved field measurements of waves and physical modelling of wave disturbance and currents. The wave disturbance study comprised a number of layouts and lengths of the main breakwater. It was found that the waves breaking over the shoal immediately to the west of the entrance channel caused considerable seiching in the channel and cross-currents in a certain area. These currents were expected to significantly affect the manoeuvring in the entrance channel.

The subsequent maritime investigations in the DMI simulator were based on the following plans:

- approach from north inside outer reef
- approach channel of width X m
- breakwater of length Y m
- turning basin of diameter Z m

After a series of simulations with amongst other a 130,000 DWT bulk carrier in loaded and in ballast conditions the maritime considerations led to the following solutions:

- a) The approach from north was too difficult in strong south-going current, because of the rather sharp starboard turn into the entrance channel. A better and cheaper solution was to dredge a channel through the outer reef. A much more appropriate alignment of the vessel when still in deep water had the advantage that the width of the approach channel could be reduced.
- b) Due to the shear current produced by the breakwater 1) in Fig. 2 the vessel had a tendency to turn starboard with the risk of colliding with the end of the quay 2). It was therefore recommended to lengthen the breakwater in order to separate the shear current zone and the deceleration area. Furthermore, the entrance channel 3) should be widened a bit to allow the vessel to keep away from the north bank and the quay.
- c) A detailed study of simulated tug boat and winch assisted manoeuvres led to a reduction of the turning basin 4) by about 75 m. The associated savings in dredging were not least important.

From the investigations and the results obtained, this example shows that simulations have a clear influence on the traditional hydraulic design objects and vice versa. The advantage of a coordinated work in the design phase is obvious. Site reports indicate that the harbour operates very well even in rather strong wind and current.

The second example focus on the design of a breakwater in a small ferry and fishing harbour, cf. Fig. 3, in the Faroe Islands.

Fig. 3 Harbour in the Faroe Island with
a) rather long 70 m outer breakwater and,
b) a short 40 m breakwater.

The harbour is located in a fiord open in both ends to the Atlantic Ocean. The wave climate is very rough with yearly waves of about, $H_s = 4.0$ m, and extreme waves exceeding $H_s = 6.0$ m. The conditions are further aggravated by the wave periods associated with these waves. For $H_s = 4.0$ m the peak period is in the order of 13-16 s, while in the extreme events the peak period approaches 20 s. The harbour has until recently been characterized by very unacceptable wave disturbances due to resonance oscillations. The size of the basin corresponds to natural periods of 12-14 s waves, which are very frequent in the North Atlantic and in the fiords of the Faroe Islands. Therefore the harbour authorities decided to change the layout of the harbour. Very detailed studies have been performed in physical models including alternative solutions with a new outer harbour in front of the existing harbour. This solution, however, requires the construction of breakwater in water depths up to between 25 m and 35 m and it was consequently given up due to excessive construction costs.

An alternative solution was developed. This solution appearing in Fig. 3 involved construction of a new outer harbour with absorbing rubble-slopes on all boundaries by blasting into the rocky shore. This solution had the advantage that all the stones blasted in the new outer harbour basin could be used for construction of a new reclamation with a berm breakwater as seaward protection. In this way both the quarry-run and the gradation of larger stones were used in an optimum manner.

Physical model tests at DHI showed that the length of the breakwater had the most significant influence on the wave disturbance in the harbour. Lengths from 0 to 100 m were studied.

Having investigated the length of the breakwater from a wave disturbance point of view the aim of DMI's manoeuvring simulations was to test the operational conditions.

First the new 38 m ferry calling on this harbour was mathematically modelled. It was planned to be fitted with two astern propellers, two astern rudders and a bow thruster. Three alternative harbour lay-outs were modelled with all associated land contours, marks, buoys, leading lines, bathymetry, currents (time varying), wind (incl. lee effects) and fenders. A total of 89 simulations were carried out. About one third of these concentrated on the length of the breakwater at the entrance.

Compared to the hydraulic investigations it appeared clearly that the length of the breakwater should be rather short, i.e. not exceeding 60-70 m. Especially in north-easterly winds the manoeuvres were rather complicated. A port or starboard turn was necessary in the outer basin as a part of the preparatory alignment before entering the narrow inner harbour, cf. Fig. 3a). Although an increasing length of the breakwater provided better lee for wind and waves the necessary manoeuvres became increasingly difficult. Compared to a shorter breakwater e.g. Fig. 3b) the one shown in Fig. 3a) causes the ship to

initiate the starboard turn earlier and it forces the ship towards the north-west boundary of the basin with the risk of grounding. The latter implies that there is a longer distance for the ship to pass with low speed in order to reach the inner harbour.

As in the preceding example the optimal solution was again a balance between the hydraulic design aspects and the maritime requirements, described above, thus leading to a final length of the breakwater of about 70 m.

Conclusions

A modern marine simulator provides several very important features which form the basis for further integration in the design process of harbours - some of these are:

- quantification of complex ship-environment and man-machine interactions in real time.
- large flexibility and hence an ideal forum for discussion among harbour authorities, consultants and navigators/pilots, of alternative solutions.
- low cost investigations as future harbour alterations, training of crews, call of larger ships, etc. can easily be studied once the graphics of the basic harbour, bathymetry, etc. are established.

The examples discussed in the preceding section clearly illustrate the advantages of carrying out combined hydraulic and maritime investigations as a careful balance of requirements have to be achieved. This is shown schematically in Fig. 4 in which a hydraulic and a maritime organization are illustrated by DHI and DML, respectively.

Marine simulators represent still a rather new technology, which, however, undoubtedly will be generally accepted as an important tool for developing safe, cost effective and well functioning harbours and waterways. The (fast-time) screening facility of simulator and the interaction with the hydraulic aspects clearly call for simulations at the design stage and not only for verification or testing of decided solutions. Fig. 4 indicates the principle in such an interaction, which is claimed here to result in a harbour where all parties - authorities, consultants, navigators, and pilots - their requirements and views have been taken seriously into account.

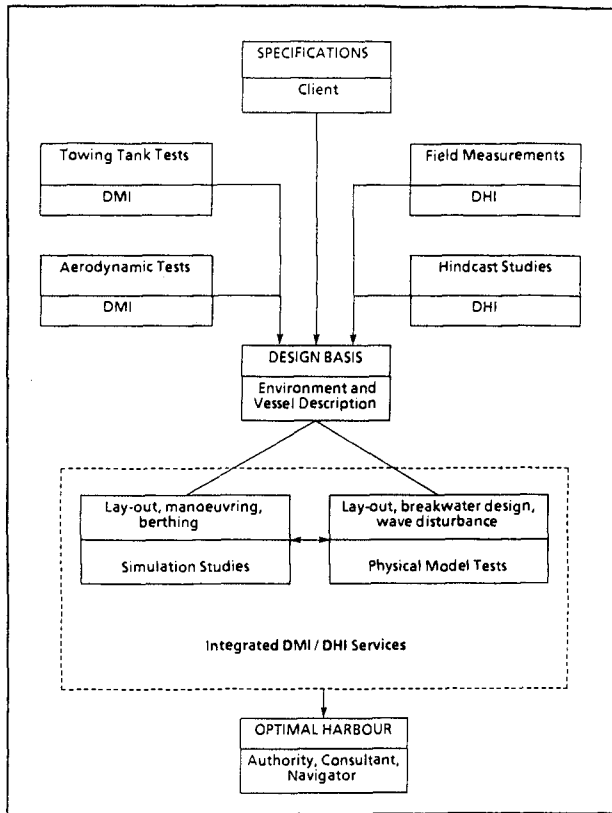

Fig. 4 Illustration of the integration of hydraulic and maritime services in optimal harbour design.

CHAPTER 236

EXTENSION OF THE BOUSSINESQ EQUATIONS TO INCLUDE WAVE PROPAGATION IN DEEPER WATER AND WAVE-SHIP INTERACTION IN SHALLOW WATER.

Per A. Madsen¹ and Ole R. Sørensen²

1. INTRODUCTION

Mathematical short wave models based on the Boussinesq equations have been shown to be capable of reproducing the combined effects of most of the wave phenomena of interest to the coastal engineer for a relatively low cost. Today, the following phenomena can be taken into account in the most advanced numerical wave models:

- Shoaling, refraction, diffraction
- Partial reflection from breakwaters
- Irregular wave trains
- Directional wave input
- Wave-wave and wave-current interaction.

In this presentation the standard Boussinesq equations will be extended for two different purposes:

- To simulate irregular wave propagation from deep to shallow water
- To simulate wave-ship interaction in shallow water.

Section 2 will cover the first topic. The depth limitation of the standard forms of the Boussinesq equations will be discussed. It is shown that the worst form of the equations breaks down for depth to deep water wave length ratios (h/L_0) larger than 0.12 while the best forms are limited to say 0.22, corre-

² M.Sc., Ph.D., Danish Hydraulic Institute, as above

sponding to a 5% celerity error. In order to improve these limitations a new form of the Boussinesq equations is presented. With the new equations it is possible to simulate the evolution of irregular wave trains propagating from deep water to shallow water. In deep water, the new equations become effectively linear and phase celerities agree with Stokes first-order theory. In more shallow water, the new equations converge towards the standard equations which are known to provide good results for waves up to at least 75% of their breaking height. The combination of a linear wave model in deep water and a non-linear wave model in shallow water is justified by the fact that waves which are non-breaking in shallow water will be only weakly non-linear in deeper water. More details can be found in Madsen et al. (1990).

In the second part of this paper (Section 3) a new solution method for calculating wave-ship interaction in shallow water is presented. The ship motion is represented by six degrees of freedom and roll and pitch angles are assumed to be small, while there is only physical limitations on the other four displacements of the ship. The model which is still under development has the potential of solving the following types of wave-ship interaction problems:

- a) Wave induced motion of ships moored in harbours or at unprotected installations, e.g. at single point moorings
- b) Wave generation and wave resistance due to ships sailing in calm water or in wave fields.

A general outline of the principles used in the development is given in Section 3 while details concerning theoretical formulations and numerical solution procedures can be found in Madsen (1990).

2. IMPROVEMENT OF THE DEPTH-LIMITATION OF THE BOUSSINESQ EQUATIONS

As discussed by McCowan (1987) a variety of different forms of the Boussinesq equations exists. Firstly the dependent variables can be chosen in different ways, and typical velocity variables are the surface velocity, the bottom velocity, the depth-averaged velocity or the depth-integrated velocity. Secondly the dispersive terms can be manipulated by invoking the long wave equation as a first approximation.

A natural starting point for the derivation of the different forms of Boussinesq equations is the depth-integrated continuity equation and the Bernoulli equation for the surface velocity (see e.g. Witting, 1984). In order to close the equations, a relation between the depth-averaged velocity and the surface velocity is necessary. The classical way to do this is to apply Taylor expansion about the bottom and to express the horizontal velocity in terms of the bottom velocity (see Svendsen, 1974 or Witting, 1984). As shown by Madsen et al. (1990) three different forms of the Boussinesq equations can be derived in this way.

The first form is expressed in terms of the bottom velocity, U_b :

$$S_t + h U_{b_x} - \frac{1}{6} h^3 U_{b_{xxx}} = 0 \quad (1)$$

$$U_{b_t} + gS_x - \frac{1}{2} h^2 U_{b_{xxt}} = 0$$

where S is the surface elevation and h the still water depth.

The second form is expressed in terms of the surface velocity, U_s :

$$S_t + h U_{s_x} + \frac{1}{3} h^3 U_{s_{xxx}} = 0 \quad (2)$$

$$U_{s_t} + gS_x = 0$$

The third form is expressed in terms of the depth-averaged velocity, \bar{U} :

$$S_t + h \bar{U}_x = 0 \quad (3)$$

$$\bar{U}_t + gS_x - \frac{1}{3} h^2 \bar{U}_{xxt} = 0$$

In principle, this is the form used by Abbott et al. (1984) and suggested by Whitham (1973).

The dispersion relation corresponding to a specific form of the equations can be obtained by considering solutions of constant form. It turns out that the resulting phase celerities can be expressed by

$$\frac{c^2}{gh} = \frac{1 + Bk^2h^2}{1 + (B + \frac{1}{3})k^2h^2} \quad (4)$$

where

$$B = \begin{cases} 1/6 & \text{for Eq. (1)} \\ -1/3 & \text{for Eq. (2)} \\ 0 & \text{for Eq. (3)} \end{cases}$$

Notice that each form of the equations leads to a different celerity expression, but for small wave numbers all the derived expressions converge towards the Stokes first-order theory for waves on arbitrary depth, which for this purpose will be considered as the exact solution. As the wave number increases, the various celerity expressions become more and more inaccurate relative to the Stokes theory.

The percentage errors of the phase celerities are shown in FIG 1 as a function of h/L_0 : Firstly, Eq. (1) appears to have the poorest phase properties, and for $h/L_0 > 0.12$ solutions to the dispersion relation cannot be found. As remarked by McCowan (1987), this corresponds to the depth limitation for cnoidal wave theory. Secondly, Eq. (3) has the best phase properties of the standard Boussinesq equations. This is the form recommended by Whitham (1973) and applied by most of the existing numerical models today. The absolute water depth limit beyond which solutions to the dispersion relation cannot be found is $h/L_0 = 0.48$. However, in order to restrict phase errors to, say, 5% the practical upper limit for h/L_0 reduces to 0.22,

which corresponds to the water depth limit determined numerically by McCowan (1981).

For many applications, a less restrictive water depth limitation is desirable. This requirement of an improved linear dispersion property in deeper water was addressed by Witting (1984), who presented a new set of equations valid for a single horizontal dimension. As shown by Madsen et al. (1990) the linear reduction of Witting's equations leads to a phase celerity on the form of Eq. (4) with $B = 1/15$. This leads to a significant improvement of the depth-limitation, and for h/L_0 as large as 0.50 celerity errors are still restricted to approximately 5% (FIG 1).

The group velocities corresponding to the various forms of the Boussinesq equations can easily be derived from Eq. (4), which yields

$$c_g = c \left[1 + \frac{Bk^2 h^2}{1 + Bk^2 h^2} - \frac{(B + \frac{1}{3})k^2 h^2}{1 + (B + \frac{1}{3})k^2 h^2} \right] \quad (5)$$

The percentage errors compared to Stokes first-order theory are shown in FIG 2. The errors are surprisingly large even for relatively shallow water. By restricting the percentage errors to, say, 6% the practical water depth limitations become

$$h/L_0 = \begin{cases} 0.055 & \text{for } B = -1/3 \\ 0.12 & \text{for } B = 1/6 \\ 0.13 & \text{for } B = 0 \\ 0.32 & \text{for } B = 1/15 \end{cases}$$

Again Witting's method is superior to the standard forms of the Boussinesq equations. Unfortunately, it turns out to be very difficult to generalize Witting's approach to two horizontal dimensions. Instead we have formulated a new set of Boussinesq equations which meet the following requirements:

- a) The equations should be expressed in two-horizontal dimensions in terms of the surface elevation and the depth-integrated velocity components.

Fig. 1 Percentage error of the phase celerity.

Fig. 2 Percentage error of the group velocity.

- b) The resulting linear dispersion characteristics should follow Eq. (4) where the coefficient B can be chosen explicitly to improve accuracy in deeper water.

The following equations meet these requirements:

$$S_t + P_x + Q_y = 0 \quad (6a)$$

$$P_t + \left(\frac{P^2}{d}\right)_x + \left(\frac{PQ}{d}\right)_y + gdS_x - (B+\frac{1}{3}) h^2 (P_{xxt} + Q_{xyt}) - Bgh^3 (S_{xxx} + S_{xyy}) = 0 \quad (6b)$$

$$Q_t + \left(\frac{Q^2}{d}\right)_y + \left(\frac{PQ}{d}\right)_x + gdS_y - (B+\frac{1}{3}) h^2 (Q_{yyt} + P_{xyt}) - Bgh^3 (S_{yyy} + S_{yxx}) = 0 \quad (6c)$$

where d is the total water depth, h is the still water depth, and P and Q are the depth-integrated velocity components (m^2/s). Notice that in extremely shallow water, where the long wave equations are valid as a first approximation, the new equations will converge towards the standard Boussinesq equations.

FIG 3 shows the effect of applying the new equations. The bichromatic wave considered is comprised by a 2.5 s wave ($h/L_0 = 0.43$) and a 3.0 s wave ($h/L_0 = 0.30$) each having an amplitude of 0.05 m. In the standard model (i.e. with $B = 0$) the group celerity errors are -90% for the 2.5 s wave and -44% for the 3.0 s wave. Hence, especially the 2.5 s wave is slowed down so much that the resulting time series taken at a position only 12 m down the channel almost looks like a monochromatic wave, at least until the 2.5 s wave eventually reaches the point and re-establishes the bichromatic wave pattern. In the new model with the coefficient $B = 1/21$, the wave train travels down the channel almost undisturbed.

More details, especially concerning the numerical solution procedure, are given by Madsen et al. (1990).

Fig. 3 Bichromatic wave test
a) Standard Boussinesq model (i.e. $B = 0$)
b) New model ($B = 1/21$)

3. SIMULATION OF WAVE-SHIP INTERACTION IN SHALLOW WATER

The second topic in this paper represents a natural step forward in the development of the Boussinesq type models by including the interaction between waves and moored or sailing ships in shallow water. Details concerning the theoretical formulations and the numerical solution procedure will not be given here but can be found in Madsen (1990). Instead a general outline of the general principles will be given below.

Depth-integrated flow equations in the time-domain are formulated to describe the free surface flow beside the ship as well as the pressurized flow under the ship. A slot-technique is used to combine the two flow regimes into a single set of equations expressed in terms of the depth-integrated velocity components and the local pressure height. This technique is similar to the one used by Preissmann and Cunge (1961) for modelling pressurized flow in conduits. The excess pressure, depth-averaged over the underkeel clearance, is used to determine the hydrodynamic forces and moments on the ship. This approximation is valid in shallow water and especially if the underkeel clearance is small. The local wave generation due to the moving ship is taken into account by distributing sources on the ship hull and including the effect in the continuity equation. The ship motion is represented by six degrees of freedom using one coordinate system, which is fixed relative to the moving ship and one, which is fixed relative to the surrounding bathymetry. Both systems are rectangular but the grid spacing can be different. First of all, the ship is described in the ship coordinate system by defining two-dimensional maps of ship draft and ship slot factors. A slot factor of 0.01 will indicate solid ship body, while a factor of 1.0 indicates an open water point. Normal vectors defining the ship elements will be determined in each ship grid point. When the ship moves around in the harbour coordinate system, the ship slot factors in this system will change from time step to time step indicating the new position of the ship. A simple interpolation routine is used to determine the successive ship configurations in the harbour coordinate system during the motion. This requires the roll and pitch angles to be small, while there is only physical limitations on the other four displacements of the ship.

The depth-integrated formulation makes the model very efficient and even though it is solved directly in the time-domain the computer economy is quite reasonable: The speed of the model is approximately 1200-1500 points/s on an IBM 4381 depending on the ratio of ship points to clear water points. A typical grid size will be from 1 to 5 m, depending on the beam of the ship, and a typical time step will be 0.1 to 0.2 s.

Fig. 4 Forced roll motion: Flux envelope.

One of the key problems in the model development has been the internal wave generation due to the motion of the ship. The resulting pressure and velocity distribution on the ship hull has to be accurate in order to take added mass and wave damping effects proper into account. In order to test this the forced

harmonic motion of a box shaped ship has been considered. Simple analytical solutions for this problem were derived by Svendsen & Madsen (1981) and Madsen et al. (1980) and they concluded that

- a) The forced sway motion leads to a linear pressure distribution and a constant flux distribution in space.
- b) The forced heave motion leads to a parabolic pressure distribution and a linear flux distribution in space.
- c) The forced roll motion leads to a cubic pressure distribution and a parabolic flux distribution in space.

The internal wave generation in the Boussinesq model has been verified against these analytical distributions. As an example the simulated flux envelope for forced roll motion is shown in FIG 4 comprising of sixteen instantaneous line plots covering one period in the forced motion.

CHAPTER 237

Safe Underkeel Allowances for Vessels in Navigation Channels

J M A Spencer, E C Bowers and G H Lean¹

Abstract

This paper describes methods used at Hydraulics Research to evaluate risks of ships grounding in navigation channels due to wave induced vertical motion. Risk assessments are then used as an aid to optimising channel depths with a view to minimising dredging. A mathematical model of ship response in waves in shallow water is presented and two case studies are considered to show how methods may be applied.

1. Introduction

Modern deep draught ships require long deeply dredged navigation channels for access to many ports. In many cases these are exposed to waves, and it is then necessary to ensure that sufficient allowance is made for vertical movement of any ship using the channel to prevent it damaging itself by bed contact (see Van Wyk and Zwamborn, 1988, for example).

At the same time, it is important not to design too deep a channel: each extra metre dredged in a channel 12 km long and 200m wide (Port Qasim, Pakistan) requires removal of at least an extra 2.4 million m³ of material. This sort of amount of dredging represents a considerable capital expenditure for any port, and more maintenance dredging may be necessitated to maintain the deeper channel as well - thus adding to the expense.

It is therefore important to design channels to be of optimum depth: deep enough for groundings to be acceptably infrequent, usable in most wave conditions at the site and all at minimum cost. Finding such an optimum channel depth is thus an integral part of port design.

Deciding on depths to which channels should be dredged is an area in which empirical procedures are commonly used: a 'marine expert' is engaged to give his advice based on past experience but

¹ Hydraulics Research, Wallingford, Oxon, OX10 8BA, UK

the complexity of ship response in waves makes this a difficult judgement to make with precision. It seems probable that some navigation channels are overdredged due to unnecessarily cautious expert advice, while others suffer excessive downtime because a little too much emphasis was put on saving construction costs. Where such subjective decisions have to be made, departures from the optimum are inevitable.

Physical models using radio-controlled ships underway in random or irregular waves can and should be used as design tools to assist in obtaining an optimum channel. They are the most reliable method for predicting vessel vertical motion, and thus form a reliable basis for assessing bed contact risks. But comprehensive physical model test programmes are expensive and time consuming because of the large number of variables involved: wave direction, wave spectrum, underkeel allowance, vessel type and speed being just some of the major parameters. The cost and time factors have dissuaded many port designers from using model tests in many cases and particularly at early stages in design when little money may be available to develop a fledgling project.

Mathematical models promise to overcome the drawbacks of using physical models in feasibility studies and of over-reliance on expert opinion. Because of this, mathematical models will be of increasing importance in the field in years to come. By making accurate estimates of vessel vertical response, a good mathematical model enables good quantitative estimates of the risk of a vessel grounding in a channel to be made; objectivity can thus be added to necessarily subjective expert opinions, and margins of error in design will be reduced. A mathematical model has the advantage over a physical model of being much quicker and cheaper to use. It therefore has applications in feasibility studies where large numbers of test conditions need to be examined in a short time. Having proved the feasibility of a particular project the physical model should be used to examine critical cases, etc in order to further reduce margins of error.

This paper describes a mathematical model of ship response in waves, called UNDERKEEL. The model has been developed at Hydraulics Research (HR) specifically for coastal engineering applications, and its use for assessing dredged depth requirements in navigation channels is described here. Two case studies will be examined: one considers VLCC safety in the Dover Strait, and another considers the use of the access channel to Port Qasim (Pakistan) by PANAMAX container vessels.

2. Description of the Ship Response Model

UNDERKEEL is a frequency domain model of ship response to waves using calculations of water flow derived from linear potential theory. It being linear, superposition principles are

applicable to its output and it can readily be used to compute ship response spectra for any given multi-directional wave spectrum.

The model is intended for use on ships in unprotected channels or moored at open quays; it is not appropriate to problems involving vessels close to wave reflecting obstacles like quay walls and canal banks. It does, however, model moving ship responses to waves as well as stationary ones.

UNDERKEEL has been developed specifically for coastal engineering applications in which the underkeel clearance between vessel hull and seabed is small compared to the vessel beam. Boundary element type models of ship response, commonly used in deep water applications, often have difficulty simulating flows in narrow gaps, and are thus not ideal for coastal usages. The difficulty is overcome in UNDERKEEL by using a semi-analytical approximate treatment of flow in the underkeel region. This gives an accurate model of ship response in shallow water, and has the further advantage of producing a model that is both quick to set up for a new ship and to run.

Standard output from the model is in the form of response functions: amplitudes of ship motion in response to unit amplitude regular waves of specified frequency and direction of propagation. Both horizontal ship movements (surge, sway, yaw) and vertical movements (heave, roll, pitch) can be simulated. As the vertical motions affect bed contact risks, this paper will focus on them although coupling between the various movements is taken into account.

There is a difficulty modelling roll response using any model, like UNDERKEEL, based on potential theory. The problem arises because most of roll damping in nature is due to eddy shedding and other viscous effects that are not present in the model. Adopting a conservative philosophy, we neglect all forms of viscous and eddy shedding roll damping in UNDERKEEL and include only the wave making damping predicted by potential theory; this course of action can be anticipated to lead to over-prediction of roll in nearly all circumstances.

But roll is often not a significant determinant of grounding risks. Most harbour entrance channels are aligned roughly perpendicular to the coastline and approximately colinearly with dominant directions of wave propagation after wave refraction is taken into account. Head and stern seas do not excite roll in ships. Thus, in these channels roll can be anticipated not to contribute to grounding risks.

2.1 Comparison with Experimental Results

Response functions calculated using UNDERKEEL may be compared

with physical model results. One such set of comparisons is shown in figure 1 for a VLCC sailing at 12 knots. Experimental results were obtained using a 1:100 scale model (radio controlled) of a 330m long, 22m draught VLCC. Details of the experiments are given by Bowers (1989).

The experimental results in figure 1 are for long crested random waves approaching the bow at an angle of 30°. Spectral peak periods are at 13s (significant wave height 5.0m representing storm conditions) and at 19.0s (significant wave height 1.5m representing swell conditions). It can be seen that response functions derived from the two different experimental spectra are similar despite the differing wave heights involved. This similarity of response is good evidence that heave and pitch response is linear which justifies the assumption of linearity made in UNDERKEEL. Comparison between UNDERKEEL and the experimental results show good correlation.

The full physical model programme involved testing the VLCC with a range of underkeel clearances. UNDERKEEL was found to predict the trends in the results very well as the following table shows (% changes in response are presented in going from a 4m to a 6m underkeel clearance).

Wave condition	Sea direction	% change in standard deviation response	
		Physical model	Mathematical model
$T_p = 19s$	Stern sea	-5	-5
$H_s = 1.5m$	Head sea	+33	+33
$T_p = 14.5s$	Stern sea	-16	-9
$H_s = 2.8m$	Head sea	+38	+24
$T_p = 13s$	Stern sea	-11	-5
$H_s = 5.0m$	Head sea	+25	+33
$T_p = 11s$	Stern sea	-12	-4
$H_s = 4.8m$	Head sea	+31	+40

2.2 Comparison with Boundary Element Model

Comparisons have also been made between responses computed using UNDERKEEL and NMI-WAVE developed by Standing (1978), a more conventional boundary element model of a type often used in offshore work. Figure 2 shows a comparison for heave and pitch. Responses in this case are computed for a 320m long hull with a 60m beam and 24m draught. No physical model data is available for comparison. Response functions are plotted as a function of wave direction for a fixed $0.06 H_z$ wave frequency. The hull was stationary. Underkeel clearance was 20% of draught.

UNDERKEEL agrees well with NMI-WAVE but UNDERKEEL requires a great deal less computer time and resources to run; the exact

Fig 2(a) Heave response of stationary ship at 0.06Hz Fig 2(b) Pitch response of stationary ship at 0.06Hz

difference will depend on the application, but ten times the speed of calculation should be easily achievable in practice. Perhaps more important, there are similar differences in ease and speed of setting up data describing any ship for calculation. UNDERKEEL is also more easily applicable in the limit of very small underkeel clearances.

3. Grounding Risk Calculations

Given a response function for the vertical motion of a point on a ship hull, $R(f,\theta)$, which is a function of wave frequency and direction, and which may be obtained using UNDERKEEL, and given also a directional wave spectrum, $S(f,\theta)$, (directions taken relative to the ship) then the spectrum $S_V(f)$ of vertical movement of the point may be computed:

$$S_V(f) = \int_{\theta=0}^{360} R^2(f,\theta) \cdot S(f,\theta) d\theta \quad (1)$$

The root mean square vertical movement amplitude, σ , is calculable from the response spectrum:

$$\sigma = m_0^{1/2} = \left(\int_{f=0}^{\infty} S_V(f) df \right)^{1/2} \quad (2)$$

The second spectral moment of response is:

$$m_2 = \int_{f=0}^{\infty} \int_{\theta=0}^{360} \frac{R^2(f,\theta)}{T_e^2(f,\theta)} S(f,\theta) d\theta df \quad (3)$$

Here, T_e is the ship's response period which contains a Doppler shift due to forward motion. This makes T_e different from the wave period $T = 1/f$.

$$T_e = \frac{\lambda T}{\lambda - TU \cos\theta} \quad (4)$$

where

λ = wavelength

U = ship speed

The zero up-crossing period of vessel motion - the average period between successive upwards movements through its equilibrium position - is defined as:

$$T_0 = \left(\frac{m_0}{m_2} \right)^{1/2} \quad (5)$$

The Gumbel probability distribution was found in experiments

(Bowers, 1989) to define the risk, of points at the bow and stern of the vessel, moving down from its mean position more than a distance d in a stationary sea state producing a root mean square vertical movement σ ,

$$p(\sigma, d) = 1 - \exp \left[- \frac{t}{T_0} \exp \left(- \frac{d^2}{2\sigma^2} \right) \right] \quad (6)$$

Here, t is the length of time the vessel is in a channel section,

$$t = \frac{\text{channel section length}}{\text{vessel speed}}$$

Such a distribution can be expected if the vessel response is linear, which appears to be the case for heave and pitch.

In general, and in the two applications that follow, navigation channels are aligned such that the vessels using them do not experience particularly beamy seas. In these cases rolling is not sufficient to cause quarter points on the keel to experience the largest downward movements. Therefore, we assume points on the vessel at the bow and stern experience the largest vertical movements. The probability p defined by equation (6) is simply the risk of grounding of a given point on the vessel if the mean underkeel clearance, when underway, is equal to d . We make the further assumption that risks at the bow (p_b) and stern (p_s) are independent (they typically have different average movements and periods) leading to a conservative estimate of the total risk of grounding (p_t)

$$p_t = p_b(\sigma_b, d) + p_s(\sigma_s, d) - p_b(\sigma_b, d) p_s(\sigma_s, d) \quad (7)$$

Thus, using UNDERKEEL we can calculate the risk of grounding in waves with a directional spectrum $S(f, \theta)$ using equations (1) to (7).

For determining design criteria for channels, figures such as the expected number of groundings in a year's (or century's) operation are required. This would depend on the volume of traffic through the port and on average bed contact risk to vessels in all wave conditions.

This average risk is found by weighting risks in different wave conditions according to the likelihood of those wave conditions occurring and then summing. In outline, wave prediction in a typical ship response application would involve parameterisation of offshore wave spectra. Using significant wave height, H_s , and mean wave direction, $\bar{\theta}$; a probability function (eg Weibull) is fitted to parameterised offshore wave data. A number of offshore wave spectra describing wave conditions of specified

return period from different directional sectors are constructed and then refracted inshore to positions along the navigation channel by mathematical modelling. Ship responses can then be computed in these inshore waves.

If $p_t(H_s, \bar{\theta}, d)$ is the risk of grounding in the channel in wave conditions with an offshore significant wave height H_s and mean direction $\bar{\theta}$, and $f(H_s, \bar{\theta})$ is the probability density function for those wave conditions, then the average risk of grounding in a transit through the channel with an underkeel clearance d is:

$$P(d) = \int_{\bar{\theta}=0}^{360} \int_{H_s=0}^{\infty} p_t(H_s, \bar{\theta}, d) \cdot f(H_s, \bar{\theta}) dH_s d\bar{\theta} \quad (8)$$

In the applications that follow two approaches to the calculation of safe underkeel allowances are used. In one approach the requirement is assumed to exist that safe passage must be possible in all weather. Having (subjectively) decided on an acceptable risk (P_{acc}) of grounding, equation (8) can be used to find the underkeel allowance (d) for vessel motion in waves that produces that risk

$$P(d) = P_{acc}$$

In an alternative approach a limit can be placed on the wave conditions in which it is safe to transit the channel. This limit must, of course, lead to an acceptable level of channel downtime. In this case the underkeel allowance (d) has to be chosen to satisfy

$$\int_{\bar{\theta}=0}^{360} \int_{H_s=0}^x p_t(H_s, \bar{\theta}, d) f(H_s, \bar{\theta}) dH_s d\bar{\theta} + \int_{\bar{\theta}=0}^{360} \int_{H_s=x}^{\infty} p_t(x, \bar{\theta}, d) f(H_s, \bar{\theta}) dH_s d\bar{\theta} = P_{acc} \quad (9)$$

In the above, the limiting H_s value is x and if the wave height exceeds x when a vessel arrives, passage is assumed to take place after waiting for the wave height to drop to the acceptable level.

In both the "all weather" and "weather window" approaches it is also important to ensure that individual risks to a vessel, as defined by (6) and (7) are acceptable in extreme conditions, eg the 100 year storm for an "all weather" channel and limiting conditions in the case of "weather windows".

4. Case Study I - Dover Strait

The Dover Strait is not a harbour navigation channel, but it poses similar problems for the transit of Very Large Crude Carriers (VLCCs) with draughts of up to 22m carrying oil to Rotterdam. On this north east (NE) bound route charted depths (at lowest astronomical tide) of 27.5m occur in known sand wave areas with a large uncertainty in seabed level.

The planning guide for the NE route (Deep Draught Planning Guide 1985) makes no use of the tide to aid passage (the passage takes about six hours in normal weather so delays due to fog could result in a vessel experiencing low water) and no particular restrictions are placed on weather conditions during passage. This guide recommends an underkeel allowance of 5.7m for a 22m draught VLCC in the central region of the Strait. Given all the factors to be taken into account: vessel movement in waves, vessel squat, negative tidal surges, seabed level uncertainties, the quoted allowances are not obviously safe. As a result the UK Department of Transport approached Hydraulics Research (HR) with a view to independently establishing safe allowances within the Strait. The work at HR involved both mathematical modelling (to predict wave climates and vessel response using UNDERKEEL) and physical modelling (to verify UNDERKEEL).

For wave prediction purposes the deep water NE bound route was divided into eight sections. In each section, storms with return periods of 3, 10, 30 and 100 years from all relevant directional sectors were predicted. Corresponding wave spectra were obtained taking into account local wave generation by winds and refraction around the many sand banks. Similarly, spectra were obtained for swell waves after taking into account refraction. The model used to make these predictions made use of extensive wind records after calibration against measured data from the Sandettie WSW buoy and the Dyck and Varne light vessels. The comparison between measurements and hindcasts from the prediction model showed good correlation provided wave refraction was taken into account.

It was then necessary to obtain ship responses. This was a two stage process. The first stage was done entirely by mathematical modelling using UNDERKEEL in the manner described earlier in this report. Grounding risks were estimated on the basis of these results and critical parameters identified.

In stage two physical model tests were performed to calibrate UNDERKEEL (see section 2.1 of this paper). This calibration showed good correlation between the physical model and UNDERKEEL and it was deemed better to base our definitive risk calculations on calibrated UNDERKEEL responses rather than on purely physical model results. This avoided a very large physical model test programme.

All risk calculations we did were based on a typical VLCC hull form: sensitivity tests carried out with UNDERKEEL having already been carried out in stage one of the study to quantify the effects of varying hull dimensions, ship speed and underkeel clearances.

A feature of the Dover Strait is that depth uncertainties are a greater factor in risk assessment there than they are likely to be in a normal navigation channel. They arise from several causes. Surveying inaccuracies, which are likely to be greater in the open sea. Bed mobility - at certain places sand waves and dunes encroach into the deep water channel, and these constantly move around. Storm surges can reduce grounding risks because those storms causing the greatest vessel movement in the Dover Strait will tend to raise water levels. However, some storms (producing little vessel movement in the Strait) can cause a negative surge and such surges could occur at the same time as swell in the Strait.

We had to modify equation (8) to take account of all these possible depth uncertainties by introducing a probability density function, $g(x)$, expressing the likelihood of depth variations. The probability calculation became:

$$P(d) = \int_{\bar{\theta}=0}^{360} \int_{H_s=0}^{\infty} \int_{x=-\infty}^{\infty} p_t(H_s, \bar{\theta}, d+x) f(H_s, \bar{\theta}) g(x) d\bar{\theta} dH_s dx \quad (10)$$

Using this probability calculation and ship responses from the calibrated model, and adding an allowance for vessel squat and trim underway, the following acceptably safe allowances were obtained:

<u>NE vessel route</u>	<u>HR allowance</u>	<u>Planning Guide</u> (Neth. Navy)
West of the Strait	6.2m	6.5m
	9.5m	6.5m
Central part of Strait	5.7m	5.7m
	5.3m	5.7m
	6.4m	5.7m
East of the Strait	6.4m	6.5m

On the whole, the HR results agree well with the Dutch allowances for the NE bound route. Only in two sections (one west of the Strait and one in the central part of the Strait) does HR suggest a larger allowance. In these sections tankers are exposed to quartering seas, which UNDERKEEL and physical model tests agree

are prone to cause particularly large pitch responses as well as rolling. However, these sections are deep enough not to affect vessel safety.

5. Case Study II - Port Qasim

Port Qasim is a developing port in Pakistan on the Indus Delta. Its approach is by a 12km long outer navigation channel with, until recently, a maintained depth (after allowing for siltation) of 12.4m CD through an offshore sand bar. This outer channel has experienced severe sedimentation problems due to combined wave and current action. Wave heights along the outer channel have been monitored using waverider buoys. Although primarily for sedimentation study purposes, this supply of high quality, frequently sampled wave data from several points along the channel was also of immense help in predicting waves at the site for use in estimating safe underkeel allowances.

In 1987, Port Qasim Authority (PQA) proposed a container facility at the port for handling PANAMAX vessels of up to 12m draught. Such ships would obviously require deepening of the approach channel, particularly for service during the months of the south west (SW) monsoon (May-September) when significant wave heights at the Fairway Buoy can reach over 3.5m which, with spectral peak periods of 13 seconds, will cause considerable vertical vessel movement. The question was how much deeper should the channel be? Hydraulics Research was commissioned to investigate.

Offshore wave predictions were based on visual observations of wave heights and directions by shipping in the Arabian Sea. This was necessary because waveriders do not record wave direction. Predicted wave spectra were then refracted inshore. The waverider records then formed an excellent check on the accuracy of these offshore predictions and the resulting refraction process after allowing for bottom friction. Bottom friction was found to be a significant factor in attenuating inshore wave energy. The calibration against measured data resulted in friction factors that were in the expected range (0.01 to 0.04). Good correlation was achieved between measured and predicted wave spectra at various points along the channel showing that wave height variation along the channel was well predicted.

Having predicted wave conditions, grounding risk calculations were as described in section 3 of this paper. To date, no physical model tests have been authorised for this study so responses are based solely on UNDERKEEL. The hull form used represented a third generation container vessel 207m long sailing at 11 knots. Sensitivity tests were performed to check the effects of underkeel clearance and of vessel speed and dimensions (including testing a 280m long, fourth generation hull, which proved far less vertically mobile than the much shorter version).

Our standard case was chosen for being the one that moved most in Port Qasim wave conditions.

Calculations indicated that, after taking into account allowances for vessel squat, set-down and vertical motion in waves, the maintained depth of the approach channel would need to be increased by at least 4.6m to allow acceptably risk-free all weather operation at high tide in June and July, at the peak of the monsoon. Dredging could be minimised by only deepening the more exposed outer 8km length of the approach channel but it was anticipated the costs involved would still make the scheme unviable.

Instead, the adoption of weather windows was suggested. PQA already had much successful experience of operating waverider buoys, and this experience could be utilised in monitoring wave heights at the seaward end of the channel (which is not visible from the port itself). The following table shows the percentage of time month by month we estimated the channel would be usable if a weather window were introduced for various underkeel allowances for vessel motion in waves (2m was available at high tide in the channel with a declared depth of 12.4m CD after allowing for vessel squat and trim).

Month	u/k allowance for vessel movement in waves (metres)				
	1	2	3	4	5
April	97	100	100	100	100
May	83	96	100	100	100
June	0	2	34	73	89
July	0	0	14	52	83
August	13	33	60	85	100
September	77	91	99	100	100

Thus, deepening the channel by 3m to give an underkeel allowance of 5m (instead of deepening by 4.6m for all weather operations) and using a weather window controlled by a standard waverider would allow almost uninterrupted port operations throughout the year except in June and July. In those months three to five days of disruption of container traffic is expected. This might be more acceptable than the cost of dredging and maintaining an all weather channel.

Also, one effect of deepening the channel would be to change wave refraction patterns; in general, a deeper channel would be expected to refract more waves away from itself, resulting in a calmer sea with less grounding risk and less channel downtime. In practice then, the 83% expected utilisation in July is probably an underestimate.

A further possibility, and one we recommend to PQA, is to measure wave direction as well as height at the channel entrance.

This can be done using a directional wave buoy. Vessel response is very sensitive to wave direction, so fairly high waves from some sectors generate less response than lower waves from other directions. This sensitivity can beneficially be built into weather windows. By allowing operation in higher waves from less sensitive directions, we estimate June-July channel usage can be greatly improved. For example, with just a 3m underkeel allowance and a directional weather window, the channel would be usable 58% of the time in June and July instead of an average usage of 24% for the two months with non-directional wave monitoring.

CHAPTER 238

NUMERICAL MODEL OF THE NONLINEAR INTERACTION OF WAVES AND FLOATING BODIES

Michael Brorsen ¹ Henrik I. Bundgaard ²

Abstract

A numerical model for the computation of the nonlinear interaction of water waves and floating large-volume bodies is described. The model works in the time domain and is based on the boundary element method (BEM) with internal generation of the incident waves and absorption of all outgoing waves (internally generated as well as reflected). This procedure makes it possible to simulate long time series of nonlinear wave forces even in case of irregular waves. Drift forces are extracted from the time series by filtering. Steady and slowly varying drift forces are computed in 2D and first order wave forces are computed in 3D.

Introduction

The need for an accurate description of the interaction of nonlinear water waves with floating large-volume bodies has been increasing during the last decade. The forces acting on a floating body are generally divided into three components:

- forces at wave frequencies.
- low-frequency forces caused by e.g. wave groups.
- steady components of the forces.

In most (if not all) commercial models today the wave-body interaction is based on linear theory in the frequency domain. This approach leads normally to accurate estimates of the forces at wave frequencies. The estimates of the two nonlinear components of the forces are, however, usually less accurate and only available up to second order.

Especially the low-frequency force is difficult to estimate from the linear theory. See e.g. Standing (1981). These forces are denoted slowly varying drift forces in this paper.

¹University of Aalborg, Sohngaardsholmsvej 57, DK-9000 Aalborg, Denmark

²Danish Hydraulic Institute, Agern Alle 5, DK-2970 Hørsholm, Denmark

All nonlinear effects which can be described by potential theory can be taken into account by the approach presented here. This is achieved by the fulfilment of the nonlinear boundary conditions at the free surface and integration of the nonlinear pressure forces up to the free surface.

Isaacson (1982) applied a very similar approach, but it was not possible to simulate long time series. Scattered waves were reflected back into the domain from that part of the boundary, where the incident waves were generated. In order to avoid this problem either a very long computational domain or a spatially periodic boundary condition has been applied.

The application of a long domain is very costly as it generates a large system of equations and the spatially periodic boundary condition is only an approximation in most cases with a body of arbitrary shape.

If the incident waves are generated inside the computational domain all waves reaching the domain boundaries are per definition outgoing waves. At the open boundaries these waves can be absorbed and the wave field inside the domain is not corrupted by scattered waves reflected at the boundaries. This approach was introduced for the BEM method by Brorsen and Larsen (1987) and it makes it possible to simulate time series as long as necessary to determine the slowly varying drift forces as well as the steady drift force.

It should be stressed that this approach is applicable in both 2D and 3D models.

The 2D version of the model is used to calculate the drift forces on a rectangular body in case of regular waves and beating waves.

The 1. order wave forces on a barge are calculated by the 3D version of the model.

Theoretical formulation

Fluid flow

Irrotational flow of an incompressible and inviscid fluid is considered. Therefore a velocity potential φ exists, giving the fluid velocity \vec{v} as

$$\vec{v} = \nabla\varphi \quad (1)$$

The incident waves are generated by a vertical source distribution situated between the floating body and the open boundary of the domain.

The time varying volume flux density of the source distribution is denoted q^* , and the velocity potential φ must satisfy the Poisson equation

$$\nabla^2\varphi = q^*(\vec{\zeta}, t) \quad (2)$$

where $\vec{\zeta}$ is the position vector of the source and t is the time.

Brorsen and Larsen (1987) has described how q^* should be varied in space and time in order to generate a specified incident wave field.

On the free surface the nonlinear kinematic and dynamic boundary conditions are fulfilled, i. e.

$$\frac{\partial \varphi}{\partial n} \cdot \frac{1}{\cos \beta} = \frac{\partial \eta}{\partial t} \quad \text{at } z = \eta \tag{3}$$

$$\frac{\partial \varphi}{\partial t} + gz + \frac{1}{2} (\nabla \varphi)^2 = 0 \quad \text{at } z = \eta \tag{4}$$

where β is the angle between the outward normal to the free surface and the vertical direction, g is the gravitational acceleration, z is the level of the point.

On the sea bed the no flow condition is used,

$$v_n = \frac{\partial \varphi}{\partial n} = 0 \quad \text{at } z = -h \tag{5}$$

On the surface of the floating body it is assumed that the body and the fluid have the same velocity component in the direction of the normal to the body, i.e.

$$\frac{\partial \varphi}{\partial n} = \vec{v}_b \cdot \vec{n} \quad \text{on } S_b \tag{6}$$

where \vec{v}_b is the velocity of a point on the surface of the body and S_b denotes the instantaneous wetted surface of the body.

Figure 1. Sketch of 2D wave channel and floating body. Still water.

The domain is enclosed by vertical open boundaries, see Fig 1., where all outgoing waves are absorbed. The absorption is modelled with the radiation condition:

$$\frac{\partial \varphi}{\partial t} = -c \frac{\partial \varphi}{\partial n} \tag{7}$$

where c is the phase velocity. The radiation condition is nonreflecting in case of waves of constant form propagating out of the domain. This boundary condition is, however, found to be adequate also in case of beating waves provided that the wave periods do not deviate substantially from each other, i.e. the rate of change in form is rather small.

The forces from the fluid on the body is found by integration,

$$\vec{F}_p = \int_{S_b} p \vec{n} dS \tag{8}$$

where S_b denotes the instantaneous wetted surface of the body and p the pressure. The pressure is obtained from the nonlinear Bernoulli's equation:

$$\frac{\partial \varphi}{\partial t} + gz + \frac{1}{2} (\nabla \varphi)^2 + \frac{p}{\rho} = 0 \tag{9}$$

where ρ is the density of the fluid.

We need to calculate the pressure at points moving with the velocity \vec{v}_{point} . In that case, see e.g. Brorsen (1989), equation (9) reads:

$$p = -\rho gz + \rho \frac{d\varphi}{dt} + \rho \vec{v}_{point} \cdot \nabla \varphi - \frac{1}{2} \rho (\nabla \varphi)^2 \tag{10}$$

The boundary value problem is transformed into an integral equation by the application of Green's 2. identity.

Thus the potential at point P positioned at \vec{x} is given by

$$\alpha \cdot \varphi(\vec{x}) = \int_S \left(\varphi(\vec{\xi}) \frac{\partial G(\vec{x}, \vec{\xi})}{\partial n} - G(\vec{x}, \vec{\xi}) \frac{\partial \varphi(\vec{\xi})}{\partial n} \right) dS + \int_A q^*(\vec{\zeta}, t) G(\vec{x}, \vec{\xi}) dA \tag{11}$$

where S is the boundary of the domain A , $\vec{\xi}$ denotes the position vector of a point on the boundary, $G(\vec{x}, \vec{\xi})$ is a Green function and α is a constant.

In case of constant water depth and \vec{x} is situated on the boundary of the domain, we use the following Green function:

$$\text{2D model : } \alpha = \pi \text{ and } G(\vec{x}, \vec{\xi}) = \ln |\vec{\xi} - \vec{x}| + \ln |\vec{\xi} - \vec{x}_r|$$

$$\text{3D model : } \alpha = -2\pi \text{ and } G(\vec{x}, \vec{\xi}) = \frac{1}{|\vec{\xi} - \vec{x}|} + \frac{1}{|\vec{\xi} - \vec{x}_r|}$$

where \vec{x}_r is the position vector of the point which is the reflection of point P into the sea bed.

Motions of the body

In 3D the body has the 6 degrees of freedom shown in Fig. 2. Only 3 degrees of freedom are present in 2D, namely sway, heave, and roll.

The motions of the body are found from the equations of motion expressed in a coordinate system with origo at the center of gravity (CG) and fixed to the body, i.e.:

$$\sum \vec{F}_{external} = m(\vec{v}_G + \vec{\omega} \times \vec{v}_G) \tag{12}$$

$$\sum \vec{M}_{external} = \bar{I} \frac{d\vec{\omega}}{dt} + \vec{\omega} \times (\bar{I} \vec{\omega}) \tag{13}$$

where \vec{v}_G is the velocity of CG and $\vec{\omega}$ is the angular velocity of the body. \bar{I} is the matrix of moment of inertia and m the mass of the body. $\vec{F}_{external}$ and $\vec{M}_{external}$ denote external force and moment with respect to CG, respectively.

The external forces are pressure forces from the fluid, see equation (8), and e.g. forces from moorings, fenders and wind.

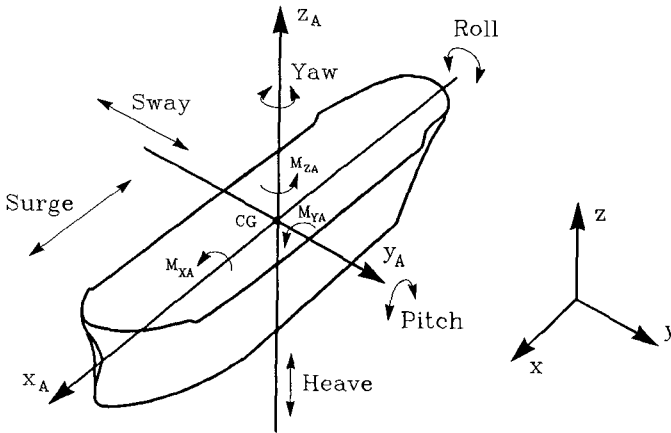

Figure 2. Definition sketch of surge, heave, roll, sway, pitch and yaw.

Numerical formulation

A time-stepping technique is used, where the flow problem is solved at each time level. Time-dependent terms are discretized as finite differences, and time step k is indicated with k as a superscript, i.e. φ^k denotes the velocity potential at the time $t = k\Delta t$, where Δt is the time step.

The boundary is discretized into N linear (in 2D) or plane (in 3D) elements and the variables φ , $\partial\varphi/\partial n$, p and η are calculated at points situated at the centroid (the node) of each element. It is, furthermore, assumed that the variables are constant over each element.

The pressure force on the body is calculated by the discretized version of equation (8), i.e.

$$\vec{F}_p = \sum_{j=1}^N p_j \vec{n}_j dA \tag{14}$$

where index j refers to a element on the body, p is the pressure at node j and \vec{n} is the unit, outward normal to the body.

Note that equation (14) is exact if the pressure distribution over each element is linear.

It is now assumed that the flow, the velocity of the body and the position of the boundary are known at time step k . The unknown shape of the boundary at

time step $k + 1$ is estimated by a linear extrapolation, see Isaacson (1982). The first estimate of the flow at time step $k + 1$ is found by application of equation (11) at each node. This gives N equations, which can be solved together with the discretized boundary conditions, see Brorsen and Larsen (1987). After the solution φ^{k+1} and $(\partial\varphi/\partial n)^{k+1}$ are known at all nodes. The pressure $p^{k+\frac{1}{2}}$ and the elevation η^{k+1} are known at the nodes on the body and the free surface, respectively.

When the values of $p^{k+\frac{1}{2}}$ are known, updated values of forces and moments from the fluid are calculated. This leads to the calculation of improved estimates of the position and velocity of the body by use of the discretized versions of equation (12) and (13).

Hereafter the free surface is updated according to the η^{k+1} -values, and the N equations are set up and solved once more. In this study only insignificant changes were observed if the procedure was repeated a 3. time.

In all simulations the fluid is at rest at time $t = 0$.

Numerical example, 2D

The objective of this section is to show that it is possible to calculate the nonlinear wave forces on both fixed and floating bodies so accurately that the drift forces can be obtained by filtering of the raw force time series.

Rectangular body exposed to nonlinear regular waves

In this example a rectangular body with beam $b = 20$ m and draft $d = 8.0$ m is exposed to regular waves generated at $y = 32.5$ m.

The drift forces on both a fixed body and a freely floating body are calculated.

The incident wave height H is varied between 0.2 m and 0.9 m and the applied wave period is constant $T = 8.0$ sec corresponding to a 1. order wave length $L = 69.8$ m.

The water depth is 9.6 m and the two open boundaries are radiation boundaries. See Fig. 1. The boundary is discretized into 41 elements, where the element length near the open boundaries is 5.0 m decreasing to 2.0 m on the body. The time step is $\Delta t = 0.5$ sec corresponding to only 16 steps per wave period.

The steady drift force on the body is calculated by a low pass filtering of the total lateral force found by equation (14). The numerical results are in Fig. 3 compared with the theoretical second order drift force derived by Longuet-Higgins (1977):

$$F_{drift} = \frac{1}{16} \rho g \left(1 + \frac{2kh}{\sinh 2kh} \right) (H_i^2 + H_r^2 - H_t^2) \quad (15)$$

where $k = 2\pi/L$ and H_i, H_r, H_t are the incident, reflected, and transmitted wave heights, respectively.

H_r and H_t are estimated by Fourier analysis, and it is found that the numerical damping is insignificant, i.e. $H_i^2 \approx H_r^2 + H_t^2$.

Figure 3. Comparison of calculated and theoretical steady drift force, 2D model.

From Fig. 3 is seen that the agreement between the numerical results and the theoretical solutions are excellent even though a steady drift force is only a few percent of the amplitude of the total lateral force (0.6% if $H_i = 0.20$ m in case of fixed body). Note that the floating body is more transparent to the waves than the fixed body.

Rectangular body exposed to a pair of nonlinear, beating waves

The mean drift force and the slowly varying drift force on a fixed body are calculated.

The domain and the body are the same as described in the preceding example. The two beating waves have each a wave height of 0.4 m and the periods are 8 and 10 sec, respectively. This gives a wave group period of 80 sec and the length between the nodes of the group is 302 m. The corresponding slowly varying drift force has a period of 40 sec.

In case of beating waves one must be careful to generate the correct bounded long wave in order to avoid spurious free long waves, see Stig Sand (1982). In this study this is done by including the velocities corresponding to the bounded long wave when the source distribution is calculated.

Initially it was checked that the correct bounded long wave (amplitude and phase) was created and that only insignificant reflection took place at the radiation boundary. This was done by calculation of the beating waves in a domain without the body. The bounded wave amplitude and phase were found by filtering of the elevation time series at several stations. Excellent agreement was found with the theoretical results, probably because the phase velocities of the short and long waves do not deviate to much in case of shallow water.

Note, however, that in a deep water situation, the larger deviations in phase velocities are expected to create a significant reflection on the radiation boundary. This will result in both wrong amplitude and phase of the long wave.

The slowly varying drift force on the body and the corresponding surface elevation 1.5 m upstream of the body are shown in Fig. 4. This drift force is found by application of a filter with a cut-off frequency of 0.04 Hz .

The mean value of the drift force is calculated to -0.59 kN/m . Note that the mean value of the drift force only deviates 2% from the theoretical value, -0.60 kN/m , which is the sum of the steady drift forces corresponding to the individual regular waves.

Figure 4. Slowly varying drift force on a fixed body. 2D model.

From Fig.4 is seen that the maximum drift force (negative) appears later than the maximum elevations in the wave group.

According to Newman's approximation the maximum drift force (negative) should appear at the same time as the max. elevations in the wave group. However, when the effect of the surface gradient of the bounded long wave is taken into account, it must be expected that the maximum drift force appears later than the maximum surface elevations and increase in magnitude.

The amplitude of the slowly varying drift force is seen to be approx. 30% bigger than the corresponding value according to Newman's approximation, which in this case is equal to the mean drift force.

A full verification of the computed results, e.g. by comparing the result with results from a theoretical 2. order model, see Faltinsen (1979), has not been made so far.

Linear 3D-Model (BEMSHIP)

At the Danish Hydraulic Institute a 3D model has been developed. This model calculates the motions in six degrees of freedom of a floating body. So far this model is based on the linearized equations, but non-linear mooring forces and fender forces can easily be included.

3D ship movements calculated by BEMSHIP are in the following compared to some test values, see Östergaard (1987).

The 'ship' selected is a rectangular barge representative for a vessel frequently used by the offshore industry as a lay barge or crane vessel. The main particulars for the barge are listed in Table No. 1 below.

Length	(m)	150
Beam	(m)	50
Draft	(m ³)	10
Displaced volume	(m)	73750
C.G. above base	(m)	10
Transverse gyradius	(m)	20
Longitudinal gyradius	(m)	39
Vertical gyradius	(m)	39
Natural heave period	(sec)	10.4
Natural pitch period	(sec)	12.1
Natural roll period	(sec)	9.4

Table 1. Particulars of rectangular barge.

The discretization of the barge can be seen in Fig. 5.

Figure 5. Sketch of wetted surface of the barge. xy -plane situated in SWL.

In the following calculations the barge is floating freely in all six degrees of freedom and it is exposed to regular, linear beam waves. The incident waves are generated within the calculation domain.

The sway, heave and roll motion transfer functions are plotted in Fig. 6-8, where they are compared to the experimental values obtained by Östergaard.

Legend:
 Δ Experiment
 \blacktriangle Bemship

Figure 6. Comparison of calculated and experimental sway motions of the barge in beam waves. a_y and a_i are the amplitude of sway and the incident wave, respectively.

Figure 7. Comparison of calculated and experimental heave motions of the barge in beam waves. a_z and a_i are the amplitude of heave and the incident wave, respectively.

Figure 8. Comparison of calculations and experimental roll motions of the barge in beam waves. a_{wx} and a_i are the amplitude of roll and the incident wave, respectively, k is the wave number $k = 2\pi/L$.

The barge is again floating freely, but is now exposed to regular, linear head waves.

The surge, heave and pitch motion transfer functions are plotted in Fig. 9-11, where they again are compared to the experimental values obtained by Östergaard.

Legend:

- \triangle Experiment
- \blacktriangle Bemship

Figure 9. Comparison of calculated and experimental surge motions of the barge in head waves. a_x and a_i are the amplitude of surge and the incident wave, respectively.

Figure 10. Comparison of calculated and experimental heave motions of the barge in head waves. a_z and a_i are the amplitude of heave and the incident wave, respectively.

Figure 11. Comparison of calculated and experimental pitch motions of the barge in head waves. a_{wy} and a_i are the amplitude of pitch and the incident wave, respectively, k is the wave number $k = 2\pi/L$.

When looking at the calculated and experimental measured barge motions in Figs. 6-11, a good agreement is found despite the rather low spatial resolution ($10 \cdot 10 \text{ m}^2$) of the body. Wave periods lower than 11 sec. are not used, as a spatial resolution of at least 16-18 elements per wave length is needed.

Conclusion

A new approach to the calculation of nonlinear drift forces on large bodies is reported. The numerical model is working in the time domain and the drift forces are calculated by filtering of long time series of the nonlinear lateral wave force acting on the body.

The nonlinear 2D version of the model is used to calculate steady drift forces as well as slowly varying drift forces.

Excellent agreement is found between the numerical results and the corresponding analytical solutions when the steady drift force (regular waves) and the mean drift force (beating waves) are considered.

In case of beating waves the preliminary results indicates that the amplitude of the slowly varying drift force may be somewhat underestimated by Newman's approximation.

An improved modelling of the absorption of the wave energy at the open boundaries is, however, probably required if the forces corresponding to deep water, irregular waves are to be calculated satisfactorily.

The linear version of the 3D model BEMSHIP is shown to yield good estimates of the motions of a freely floating barge exposed to head or beam waves.

RIA DE FOZ: WORKS BEHAVIOUR

DIEZ, J.J. Catedrático de Oceanografía en la E.T.S.I. Caminos C. P. Universidad Politécnica de Madrid
ESCOBAR, V.A. Ingeniero de Caminos C. y P. Responsable de proyectos en el Centro de Estudios de Puertos y Costas C.E.D.E.X. Madrid.

INTRODUCTION

When, in the previous Conference, a paper was presented and published (1) aboarding the problems and solutions in a ria of the West End of the Spanish Cantabrian coast, the works of the solution project had just been finished (JUN 1988), so that very few data had been obtained about their behaviour. Additionally, the systematic survey of the dynamics in the ria had been initiated but not finished, not even in the field data collecting, therefore the hydrodynamic and morphodynamic model obtained to implement the project, having explained rather satisfactory all the known coastal and estuary process and changes, only was a qualitative approximation. Nevertheless it was in agreement with a very complete methodology of coastal processes analysis (2) and good enough to justify some singular circumstances: one of them refers to the increasing sandy filling of the ria what, like in all Cantabrian ones and probably like in many other bights -glaciars, like in New England, U.S.A., and Scotland, or structural, like in the rest of the Cantabrian and Bretagne (France),- has been principally filled with littoral materials, without any significant contribution of the respective rivers, whichever its size; other one, to the spit nature and genesis of the barriers of all the Cantabrian rias; they have been generated by the longshore transport through a "negative geometric singularity" (3) more than by onshore-offshore equilibrium and, consequently the migration of the tidal inlets is downdrift, but respect to the local drift, though it could appear to be updrift.

As the rias practically are the only shelter areas in the Spanish Cantabrian coast, the harbours have been initially established in them and even one or more small fishing harbours remain in each of them at present, so that the sandy filling processes, together with the increasing size and draught of the ships has become a meaningful problem in them. In the case of the Foz ria the problem had become even more acute because

Fig. 1
Location

Fig. 2
designed project

it affected extremely the stability of the channel entrance, so that a jetty had to be constructed, but, being a unique jetty facing the spit end, when it was extended landward at the other side of the gorge, the fast erosion of the spit (just in the winter of 1977-78) was induced, the problem has both extended to the beaches around, which have begun to suffer erosion, and accentuated in the ria, which has increased several times the rate of filling.

The project, described two years ago, tried to be a solution for both aspects of the problem: the regeneration and protection of the beaches and the lessening of the process of filling of the interior of the ria, but subordinating the later to the former.

The aim of this paper is to analyze the data obtained since then to check the initial hypothesis and the behaviour of the works.

2. DESCRIPTION OF THE WORKS

The construction of the project defined two different kind of works: one of them, the basic one, was the artificial nourishment of the eroded beaches and spit up to about 275.000 m³, the minimum volume was supposed to guarantee the posterior stability of the system; the other, the construction of a jetty to support the spit-sand and to lead the interior channel, this jetty might, likely have not been necessary if the nourishment had been developed during the summer and accomplished in a short term; nevertheless this last condition would have been very unlikely to happen.

The sands for the designed nourishment had to be obtained exclusively from the interior of the ria, from a delimited area, which was supposed to have been overfilled since the erosion of the spit-barrier and whose sands were not only compatible but equal to the remaining sands of the beaches; our previous sedimentological surveys show the identity not only in the grain-size distribution but in the minerals content too. and it had been projected to be laid down adequately distributed along all the eroded area to obtain the best effect, taking into account the direction of the local transport (westward) and trying to minimize it. The bulk of sand was determined from the designed final form of the beaches and barrier so that the sand had to be laid rather homogeneously down, half about along the beaches (Altar and Anquieira) to partially replenish them, and half about in the spit, to regenerate it.

The jetty was designed shorter than the supposed necessary one to keep the channel clean, trying more to behave like a hook-groin than to constitute a real jetty, and being only the initial stretch of the final

likely necessary complet jetty, whose seaward stretch was not considered at that moment nor was designed. A mere arc of circle, ending the designed jetty was considered enough to behave like a suport-groin. The first strait section was designed aproximately parallel to the longshore transport from the Angueira point towards the channel; and it was short designed too, leaving so a wider than the adequate gorge for the channel. Two kind of reasons have imposed this design: the first and principal one was that no sufficient previous research had been developed to accurately determine the most convenient width for the channel (distance between jetties). The second one was derived from the different but convergent responsibilities of several administrative authorities; Coastal authorities (central) has the responsibility of shore protection, had assumed the regeneration of the beaches and financed the project and other studies in the ria; harbour (authonomic) authority has the responsibility of the harbour facilities; and township (local) authority was afraid that the project could affect the opposite beach of the "Rapadoira". Being urgent the regeneration of the beaches, this solution was assumed to guarantee none administrative delay was going to be produced. And, at the same time, it compatibilized its efficiency with a minor foreseeable destruction when the posterior extention and adaptation of the jetty ought to be decided, once the most adequate width between jetties could be defined for the outlet.

During constructions (September 86-June 88), coastal authorities decided to enlarge the hook stretch of the jetty 30 meters aproximately and to increase the volume of nourishment up to 350.000 m³; some differences between the project bathymetry (Aug. 1985) and the one for planning work (Nov 86) seemed to justify the last decission, supposing mistake in the former.

Nearly all the sands obtained from the interior of the ria have been pumped down by the jetty and, later, distributed on land by means of dumpers, bulldozers, etc. The accretion of the upper part of the beaches seemed to be minor than the theoretically pumped sand; so the constructor decided to take the sands of the tidal plane (fig 3). They supposed that part of the pumped sand was moved by water. The authors of this paper claimed against this practice without any possitive result.

3. SURVEYS AND MONITORING.

A complete series of compaigns of observation has been developed since August-86 to Spring-89 as surveying the dynamics of the ria, but the analysis of

some of the data has not been completed yet.

On other hand, a monitoring program of cross profiles has been developed during and after the construction of the works. Related to the first program, the maritim weather of this area permits to stablish four annual seasons but the storms are randomly distributed along winter and springtime, in such a way that spring equinox happens at the end of the stormy period and the fall-equinox happens before it begins; therefore the two annual survey compaigns have been developed around equinoccial terms, just before and during the spring and fall tides, which happen here in the later relative maxima immediately anterior to every equinoccial date; just before every maximum, a minimum of the astronomical tide happens, so that the largest and the smallest annual tides have been surveyed with this schedule. The data obtained in every campaign have been the following:

- a. Flood and ebb currents (maximum and minimum) have been measured in different cross-sections of the interior channels and in the gorge, and in several pints of each cross-sections.
- b. Tide levels have been continuously registred in two meaningfull points of the inner part of the ria and in a third one close to the gorge of the inlet (formerly in the closest basin of the harbour and lately by the Rapadoira jetty); the two former points are respectively around the middle and the end of the ria and coincident with two narrowness caused by embankments and bridges built for railway and the highway crossing the ria.
- c. the bathymetries of both the inner and outer (here not always extended under low tide) areas of the ria and the long cross-profiles in front of the beaches, have been as accurately surveyed as possible every season and compared to the previous references.
- d. Sedimentological analysis including organic material containt, percentage of carbonats and grain size distribution have been surveyed in all the shoals and beaches.

Besides: 1. Once and for all a more complete sedimentological survey, including mineralogical analysis has been done afecting to the ria and the rest of the shore between the rias of Vivero and Ribadeo. 2. An ecological survey, completed with a more ambitious research (4) have been developed before the construction (1984-1986), but no posterior observation could be done because of the lack of financial support. 3. And a very frequent survey of the beaches and spit cross-profiles has been developed by the coastal authorities as a monitoring work during the priod of construction (1986-88) though unfortunately these profiles were short, not having been extented farer

Fig. 3, 4, 5, 6 y 7
Tides and currents

than the low see level.

For this paper not all these data were equally outstanding and, unfortunately, not all the relevant ones could be completely analysed. On the other hand study of littoral dynamics developed for the project and described in (1) has been assumed in the following discussion as related to the winds, wind-waves and littoral transport. But some few considerations must be done:

a) Wave regimes estimated from the visual observations seem to be only roughly accurate and has some unacceptable distribution of the calms. b) Hindcasting wave regimes seem to be much more accurate but their use in estimating the littoral transport appears very problematic here because of the extreme high power of the storms (at least using the C.E.R.C. formule). It has been realized that above a certain value of the wave energy (or height) the estimated longshore transport rate became roughly high, as under a certain value they are too low. c). In any case, the littoral drift is much less than the potential littoral transport because of the lack of materials and the steepness of the platform. d) Whatever the estimation method the net littoral transport and drift are eastward seaside in front of the mouth headlands (Escairo and San Bartolome points), but both of them are westward in front of the Altar and Angueira beaches, landside between the points, over all with high tide levels of the sea. And the mouth is extremely short and narrow to permit an accurate reflection-refraction-diffraction model.

3.1 Tides

Between March and July 1987 a mareograph was located in the harbour of Foz. Continuous data was registered in this point, being the most relevant results these that follow: The maximum amplitude registered was 3.9 m. faced to 3.67 m. in the same date, calculated by the Tables of Tides published by the "Centro Hidrografico Nacional" related to Gijon harbour and corrected to Foz.

The maxima negative differences (bigger in the mareograph than in the Tables) and positive are shown in the next table:

	MAX. DAILY DIFFERENCE		MAX. MONTHLY AMPLITUDE
	+ DIF	-DIF GAUGE	TABLE GIJON
March	0.33	-0.42 3.9	3.83
April	0.26	-0.44 3.65	3.64
May	0.14	-0.43 3.5	3.58
June	0.18	-0.42 3.5	3.47
July	0.09	-0.31 3.7	3.62

An estadistical analysis of the data shows that the probability of a tide-amplitude differing of the one calculated by the Tables in less than 10 cm. is about 65 %, between 10 and 20 cm. 21 % and more than 20 cm. 14 % being the difference bigger than 30 cm only in 4 % of the tides. Considering a posible measuring error of about 10 cm. (the mareograph is graphic), the correlation between the meassures and the Table calculations can be defined as good. The observed differences can be attributed to the meteorological tide and the interferences principally caused by the flow of the river Masma. A maximum of about 50-60 cm. has been estimated for the meteorological tide. The two other mareographs mentioned in a paragraph above were located in two sections in the inner part of the ria (in the railway and the highway bridges), both were registrering tide-levels between February 1987 and July 1988. figs 3,4

The relationships between tide amplitudes in gauges 1 and 2 are very stable when the amplitude in the mouth of the ria is higher than 1.75 m. and do not vary too much with minor amplitudes, this relationship is not bigger than 1 in any case. However, between the gauge 2 and 3 (or the tables) the mentioned relationship is higher than 1 for amplitudes minor than 1.75 m. in the exterior, that means that there is a noticeable steepness of the tide in some special cases (Mehta, Mc. Manus). The tidal prism is in these circunstances bigger than the one calculated without any level-gradient along the ria. The opposite occurs when the amplitudes are bigger; so the tidal prism is more delimited than the prism calculated in previous phases of the study, (aproximately 15 % bigger for little amplitudes and 10 % minor for the higher ones).

3.2 Currents

Since 1986 some campaigns has been made; currents has been measured in several points of the ria, especially in the gorge cross-section, in the railway and highway bridges, and in the main ebb-channel. The velocities in the gorge have had a maximum of about 170 cm/s in ebb equinoctial tide and a minimum of 75 cm/s in neap tide. After the construction of the jetty the velocities have increased in about 30 cm/s for the maxima and 10 cm/s for the minima. The other sections have practicaly maintained the maxima and minima after the contructions (60 cm/s and 30 cm/s respectively for the highway and, 50 cm/s 30 for the railway).

3.3 Several bathymetries of the ria were used: 1967, March 1985, September 1986, March 1987, September 1987, September 1988 (partial) and September 1989 (partial).

Fig. 8, 9, 10, 11, 12, 13, 14
BATHYMETRIES

in the inner part of the ria and: 1967, August 1985, September 1988 and September 1989. From 1985 to 1989 in the outer part, 22 cross profiles has been taken 17 times.

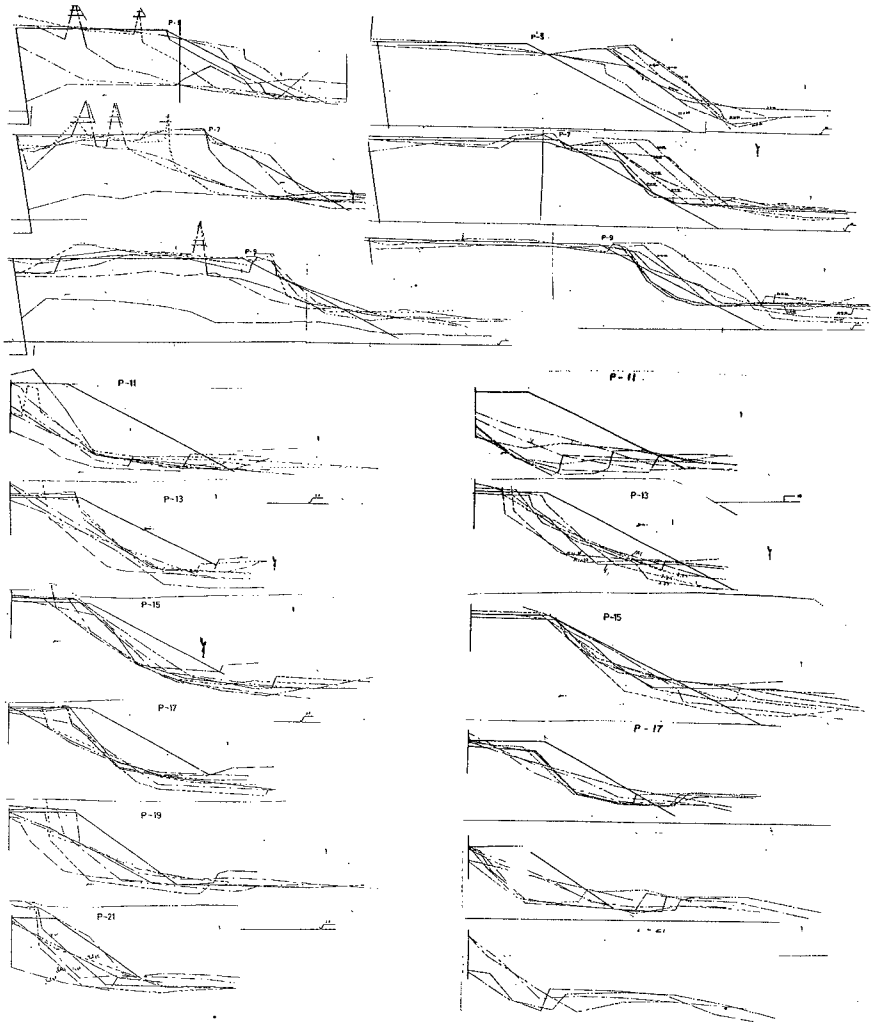

Comparing the inner bathymetries (figs 8-11) it may be noticed that the rate of filling of this area has increased after the erosion of the old natural spit (barrier); during the construction a local reduction of sand is noticeable, undoubtedly related to the sand dredged for nourishment. After the construction of the artificial barrier the rate of filling is unnoticeable from the bathymetries and may be estimated in about 12.000 m³/year, locally by the end of the jetty, part of the filling seems to have passed in front of the end of the jetty and the rest through it because its impermeability has not been appropriately got. Comparative analysis as a calcul permit estimate in about 10.000 m³/yr and in about 80.000 m³/yr the rates of filling respetively before and after the destruction of the natural barrier in March 1978.

Comparing quantitatively outer bathymetries (figs 12-14) it may be shown: 1. A strong erosion has been produced from 1967 to 1985 (it has been visually observed that the process began after 1978), of at least 420.000 m³. 2. The bathimetrie of the project (Aug. 1985) was allright, the difference of 75.000 m³ mentionedd before likely being product of the erosion. 3. The rate of erosion after desapearing the natural barrier was about 67.000 m³/year, consistent to the anterior datum; and before 1978 the rate of accretion of the outer part of the ria was of about 37.000 m³/yr.

During the period of erosion not less than 135.000 m³ have been dredged from the inner part of the ria, in agreement with all the bathymetries, but the bathymetry of March 1985 (5).

The analysis of the profiles fig (15-16) shows that a permanent, or quasi-permanent, tranport of sand from the eastbound westward nas been happening along all period of monitoring. A continuous erosion was detected from August 1985 to May 1987, when the jetty began to behave as a barrier, and a continuous accretion may be noticed later.

3.4 The mineralogical analysis of the samples of the banks from the interior of the ria are completely similar to the samples of the beaches around the ria. Only the samples from the beaches westward of the Fazouro ria show a meaning difference. It means a general littoral transport eastward, some kind of sink in front of Fazouro mouth and a unique origine for all sands of the beaches and the ria banks. In its turn the ecological study shows: a) The maritime origin of all the materials (sands) of the banks and its recent

increasing. b) The reduction of the land materials at the marshes of the inner ends of the different lobes of the ria.

4. DISCUSSION AND CONCLUSIONS

Tides in the ria of Foz have an acceptable correlation with the tides of Gijon harbour, but some differences are very noticeable, over all by the effect of the storm surges (frequently up to 50 cm) and by the steepness in the interior basin of the ria (weaker the tides, more meanings the local differences the water level). These discord may explain the disagreement of some bathymetry (5) analyzed above.

Inlet currents have increased a little bit after the construction of the jetty because of the small increasing of the tidal prism and mostly because the better estabilization of the channel. Nevertheless, currents still are less than admisible what, together with the sediments laid backside by the jetty end, show that the aim of designing a short barrier was got, but that the cleaning capability of the currents has improved also.

As it has previously said, nearly all the sands obtained from the interior of the ria have been pumped by the jetty and later distributed by land means. But the periodic visual observations of the works permit to question the accuracy of the nourishment operations: an overview to the bulk of the materials accumulated in front of the jetty supports that the real nourished volume was rather minor than the bulk theoretically pumped; and the way in which sand was fetched up to the berm (upper part) of the Angueira and, over all, Altar beaches to get the designed profiles, that nearly all of sand was obtained from the tidal plain in frot of both beaches; so it would be happening that very few sand from outside of the beach system was actually being used in the regeneration of the berms and that most of it was merely transported from the lower to the upper part of the emerged profile during low tide (that is to say, from the emerged tidal plain towards the permanent berm), it would be like trying to accelerate the natural process of nourishment of these beaches, which had been foreseen in the project to happen when the jetty had been finished and the spit rebuilt. Nevertheless the rate of fetching up sand was undoubtely excesive because an immediate strong and very noticeable steepness of the berm profile was produced after every high tide; the sand so applied obviously formed already part of the beach and, consequently, it was put immediately back in the tidal platform by the onshore-offshore dynamics. Some of the
in this paper in

observations described and analysed in this paper in the previous items permit to support this explanation which is particularly consistent with the different bathymetries of the ria: March 87, Sept 87 and Sept 88 in the inner part, showing the effects of the extraction and Aug 85, Sept 88 (showing the effects of the dragging from the tidal plain) and Sept 89 (showing the deferred consequences) of the outer part of it.

The immediate answer of the system shows an insufficient volume of nourishment: the tombolo and most of berm in Altar and Anguleira beaches, just where the sand was brought from the tidal plain vanished. The slow recovery up to the natural rebuilt of the tombolo was favoured by the delay of the storms in the 1988-1989 winter. Nevertheless, the insufficiency of sands permitted the new disappearance of the tombolo (Feb-Mar 89). As a consequence, in both occasions part of the mobilized sand has been transported westward, and it has passed to the backside of the jetty, laying aside just by it, approximately in a volume of 12.000 m³/yr, and, in both occasions it happened in a very short time (Mar-May) following the disappearance of the tombolo; in May the new natural accretion from the seaside permitted the regeneration of the tombolo and the restabilization of the system.

All these processes could be continuously followed by visual observations, besides the monitoring here shown. And they are consistent with the continuous westward potential transport and with the necessity of a certain minimum threshold of sand to set firmly the tombolo; also with the hypotheses of the project that this is necessary to estabilize the system and to reduce at a minimum the sand entering and filling the ria.

The winter 1989-1990 was anomalously quite in storms and the natural nourishment permitted the tombolo to remain all the year: it was enough to permit a beautiful recovery of all the beaches (fig 19) in the summer of 1990. What shows that, in any case, the natural nourishment exceeds the volume entering into the ria, and it is consistent with the rough calculs from bathimetries. As a consequence the volume of sand overpassing and laying aside by the jetty in this year (1990) was unnoticeable (less than 5000 m³/yr roughly).

From the ecological point of view, the fishing had vanished from the ria since the erosion of the natural barrier in 1978. Though many opinions supposed this phenomenon to be caused by washing aggregates of a next quarry, in the memorandum of the project was assumed to be caused by the biotopic changes so suddently produced, in such a way that regenerating the barrier, a recuperation of the catch could be expected. In fact fishing has been recovered in the inner part of the ria since 1989, and specially since 1990, when the

Fig. 17
1.978

Fig. 18
1.985

Fig. 19 1.990

the ria since 1989, and specially since 1990, when the movements of sands in the outer part of the ria have begun to be reduced.

Consequently with all these analysis and discussion several conclusions may be established.

1. The natural barrier had been generated as a spit, that is to say, as a consequence of a longshore littoral drift, instead as a bar, consequence of the onshore-offshore equilibrium. The question was not obvious because the general net littoral transport in all Spanish Cantabrian coast is eastward, but it is in agreement with the remake of the project about the permanent westward local littoral drift in the outer basin of the ria. And the conclusion is not trivial because most of the barriers of the Cantabrian rias and other analogous estuaries and bights behave in the same way; also because it shows that many tidal inlets, if not all of them, described as "updrift" migrating inlets, really migrate "downdrift", taking into account the local nearshore drift and not the direction of the net littoral transport along a more general and extensive coastal stretch. In this case, the headlands of Escario and St. Bartolome and the bathymetry of the Gulf of Masma may justify, as it was exposed in the project (1) this local change on the transport direction. But in many inlets, their ebb-shoals may be cause enough to produce an analogous change. In the ria of Foz, the role of the shoals at both sides of the Rapadoira jetty may explain the unsuitability of some numerical models to explain the actual permanent westward transport along the Altar and Angueira beaches; that is likely right because this area was not taken into account in the refraction model.

2. Nevertheless the littoral transport off-shore of both the Peña do Altar, and the Rapadoira jetty is dominantly eastward, justifying the submerged spit starting in the end of the Rapadoira beach eastward; this spit is noticeable in the bathymetry of Sept 88, when the channel was very dangerous at strong low tides, but it nearly disappeared in Sept 89. It may be explained by the process of recovery of the tidal plain after the undue (wrongful) extraction to nourish the berm; and may be noticed comparing both bathymetries each other and with the design's (figs 13-14).

3. Also the real volume of sand obtained from the inner part of the ria likely was less than projected having been substituted by the sand previously accumulated on the tidal plain of the outer part of the ria, but not accrued from the pumped sands. That explain the immediate erosion of Altar and Angueira beaches just after the construction of the designed profiles, and the differed partial recovery of the profiles once the tidal plain was reacrued from both the berm and the

submerged spit.

4. The behaviours of the artificial barrier has been successful in spite of the defects of construction: it has permitted the natural renourishment of the beaches and, secondary improved the conditions of the harbour channel. Nevertheless this improving situation must be considered only transitory because an increasing of the outer ebb-shoals must be expected. Therefore the complementary actions foreseen in the project must be put forward.

4.bis. It has also been successful decreasing the filling rate of the inner basin of the ria, from about 70.000 m³/yr to about 12.000 m³/yr as a maximum (or transitory) and likely to less than 5.000 m³/yr. But the present situation of the ria corresponds to a very high degree of filling.

5. The behaviour of the ria as a sink of sands has been checked, so that the beaches seaward of it obviously suffer now a deficit of material. Therefore dredging the ria to nourish this beaches and to increase its tidal prism up to at least the bulk of filling since 1978 seems to be previous to the construction of the eastern jetty of the inlet.

Taking sand from the tidal plane.

ACKNOWLEDGEMENTS

The study of the ria and the project have been financed by the General Direction of Ports and Coast of the Ministry of Public Works. The monitoring of profiles has been developed by the Service of Coast of Lugo. The rest of the monitoring works has been financed by the author. The topographers J.M. Olmo and Isabel Olmo, the civil Engineers J.M. Perez-Pozuelo and J.M. Silvestre and different students sporadically as a crew have decisively to the long development of the surveys.

CHAPTER 240

EMERGENCY SITUATION IN THE SHORELINE REACH OF AN OFFSHORE OILFIELD PIPELINE AND REMEDIAL MEASURES

Jefferson V. Bandeira¹ Luiz C. Araújo² and Antonio B. do Valle²

Abstract

This paper describes the critical situation experienced in the northeast coast of Brazil by an oil and a gas pipeline, in their shoreline reach, due to the growth of a spit, and the remedial measures adopted, which avoided an environmental and economical disaster.

Introduction

For the exploitation of the offshore gas and oil fields of "Agulha" and "Ubarana", in the coast of Rio Grande do Norte State in Brazil (Fig. 1), PETROBRÁS, the Brazilian Petroleum Company, has installed a group of six steel pipelines linking the offshore to the mainland facilities.

The region is a flat sand beach, with a mean slope 1/1360 between 0 and -10m depth contour, in a coast with an E-W alignment (Fig. 2) and subjected to the action of waves coming from the NE quadrant and winds blowing from N to SE. The currents outside the breaker zone, with velocities up to 0,5m/s, have a westward resultant and are also influenced by the tide which is semi-diurnal and has amplitudes ranging from 1.0 to 3.1m (INPH 1981) (Moreira et al. 1987). In consequence, there is a westwards littoral drift which promotes the growth of spits in the region (Fig. 3).

The bottom is active with respect to sediment movement down to depths of 12 to 13m, as observed comparing successive bathymetric surveys made in the pipelines region, which also revealed the existence of sand banks (Fig. 4).

Figure 4. Sand Banks in the Coastal Region of Guamaré

When the pipelines were buried, the shoreline presented no problems. Nevertheless, there existed eastwards a spit, almost parallel to the shoreline, originating in a nearshore island situated in front of Guamaré village. With the growth of this spit (Fig. 5), which defines, between it and the mainland, a double-entrance estuary, the pipelines region, in the shoreline, was submitted to a tidal current that eroded severely the seabottom under the two western pipelines, due to a narrowing of the tidal channel right in their placement, leaving in suspension an extension of about 40m of both lines (Fig. 6, 7, 8 and 9). One of them is a gas and the other an oil pipeline, both with an outside diameter of 0.66m and lined with a concrete coating, 7.6cm thick.

Figure 9. Channel Cross Section at Oil Pipeline Placement. Date: March 1988

Statement of the Problem

The influence of the strong crossing tidal currents, with measured values of 2.5 knots (1.3m/s), could produce rupture of the pipelines through a vortex shedding, prompt to happen for conditions nearly those the pipelines were subjected, as pointed out in a simulation study (Carvalho 1988):

a) the oil pipeline was in a situation dangerously close to resonance conditions because: for a free length of the order of 50m its natural frequency of vibration would coincide with the vortex frequency caused by a current of 2.8 knots (1.4m/s) flowing in its surroundings. Indeed, the extremities of the suspended portion of the oil pipeline had already presented deep fissures in the concrete lining;

b) the gas pipeline, lighter than the oil pipeline and with a higher natural frequency would be in resonance for a free length of 70m and then it was in a situation of lesser risk than the oil pipeline.

The real free length of both pipelines were greater than the measured ones, as the pipelines would find effective support, only some metres inside the margins of the channel.

Remedial Measures

In order to cope with this situation, three alternatives were considered as remedial measures (Bandeira 1988) (Santos 1988):

I - burying the two pipelines deeper underneath the eroded bed;

II - holding the suspended portion of the pipelines by means of piles until, due to the westwards displacement of the spit extremity, the channel sections in the pipelines region might be naturally shoaled;

III - closing the tidal channel entrance by construction of two sand dikes, the first (E dike) as near as possible the region where the tidal waves, entering the channel at both entrances meet each other, and the second (W dike) in the western entrance, where the pipelines cross the shoreline.

Considerations about the Remedial Measures

The first remedial measure considered was abandoned due to the risks of rupture of the pipelines, during the process of burying, as they were already dangerously stressed and submitted to the action of strong crossing tidal currents.

The second one could avoid the imminent vortex shedding by diminishing the free length of the pipelines, but still the pipelines would be submitted to the strong crossing tidal currents until the channel sections in

the pipelines region might be naturally shoaled. But this natural shoaling could not be assured and then, another intervention could be required.

Solution Adopted and Further Reaction of the Coastline

Having in mind the possible drawbacks of the first two considered remedial measures, PETROBRAS has decided to implement the third one, which seemed the most convenient and proved to be successful.

For the construction of the sand dikes, PETROBRAS made use of two bulldozers which piled sand in the two sides of the dike sections, and plastic bags filled with sand. Shortly before the low water of a neap tide, the plastic bags were placed in the deepest part of the channel section and, after that, the bulldozers, simultaneously from both sides, pushed the piled sand over the section, completing the closure.

The E dike (Fig. 10 and 11) was built on March 22, 1988 and the W dike (Fig. 12) three days after. There was a strong sediment deposition westwards of the western dike as expected (Fig. 12, 13 and 14) and on March, 1989, a rupture in the spit portion between the two dikes occurred during an equinoctial tide and is presently being monitored.

The E dike was not constructed in the region where the tidal waves, entering the channel by both entrance, meet each other (mangrove region in Figure 10)

Figure 10. East Dike and Mangrove Region
Date: 04/07/88 Hour: 08:25 W.L. = +2.2m

but, for environmental reasons and ease of construction it was situated at the narrowest section of the channel, near the mangrove region and west of it, as indicated in Figure 5, which was taken at the high water of a spring tide. In this way there was an increase in the tidal prism flowing through the eastern entrance.

Figure 11. East Dike (Closer View)
Date: 04/07/88 Hour: 14:23 W.L. = +0.8m

Figure 12. West Dike (13 Days After Closure)
Date: 04/07/88 Hour: 14:27 W.L. = +0.8m

Figure 13. West Dike (10 Months After Closure)
Date: 01/25/89 Hour: 13:50 W.L.= + 1.1m

Figure 14. West Dike (27.6 Months After Closure)
Date: 06/14/90 Hour: 14:00 W.L.= +0,6m

Then, when the rupture of the spit occurred (Fig. 15 and 16), PETROBRAS decided to open the E dike in order to re-establish the original tidal circulation in the mangrove area and in the eastern entrance (e.g. a decrease in the tidal prism flowing through this entrance). This action caused a correspondent increase in the tidal volume flowing through the new western entrance.

Figure 15. Disrupted Spit with the E Dike Opened
Date: 12/27/89 Hour: 9:55 W.L.= +0.7m

Figure 16. New Western Entrance
Date: 12/27/89 Hour: 10:00 W.L.= +0.7m

This new western entrance has now a greater tidal volume flowing through it than the original one (which is estimated in $425,000\text{m}^3$ relatively to the average tide amplitude), when the extremity of the spit was situated in the same region as the entrance. Now, there is a contribution of the tidal prism western of the mouth (in the channel between this mouth and the W dike) which is estimated in $326,000\text{m}^3$, giving a total tidal prism of the order of $751,000\text{m}^3$. This increased tidal volume flowing through the mouth added to the fact that now the flood flow branches E and W after crossing the mouth and the ebb flow coming from these two directions converges upon the entrance, may have an influence in the rate of advance of the mouth to W, compared to the velocity of migration of the spit when its extremity occupied the same region of the present mouth, from which there is no record.

Presently the mouth is situated about 1920m east of the section of the W dike, and its migration to W due to the unidirectional littoral drift is being monitored. In Figure 17, the contours of the two margins relatively to the MSL, are pictured for four surveys made in the interval February - May 1990. Geometrical calculations considering the portions of the shoreline contours limited by horizontal lines passing by A and B (E side) and C and D (W side), indicated an average rate of migration of the mouth to W:

$$V = 10.5\text{m/month (E side)}$$

and

$$V = 24.9\text{m/month (W side)}$$

Figure 17. Surveys in the New Western Entrance

Conservatively assuming the rate of migration to W of the W side of the mouth as constant, in $1920 / (24.9 * 12) = 6.4$ years the problem could happen again, unless some preventive measures are taken, such as: to bury the pipelines deeper underneath the level of the eroded bed, before they are exposed to the strong crossing tidal currents again. In this way the spit can migrate freely, and it will not be necessary to construct dikes and alter the tidal circulation in the mangrove area.

The monitoring of the migration of the entrance will be continued at four months interval.

A great deal of information on the features of this unstable coast has been gained by the study of this emergency situation.

CHAPTER 241

SAND BYPASSING TO "PLAYA DE CASTILLA" (HUELVA SPAIN)

José Fernández (1)
Gregorio Gómez Pina (2)
Angel Muñoz (3)

Abstract

The "Sand bypassing to Playa de Castilla" project consists of a sand bypassing from the zone behind Huelva Harbour dike to "Playa de Castilla" beach, situated in the downdrift direction of littoral transport.

The objective of this project is to artificially nourish a 25 Km eroded beach ("Playa de Castilla") as well as to check some coastal engineering theories.

The total volume of sand has been transferred to the updrift extreme of the beach, forming a 2 Km protrusion. The high rate of littoral transport guaranties its quick distribution along the whole beach, following the downdrift direction.

Introduction

The "Sand bypassing to Playa de Castilla" is a recently finished work in the Southwest Coast of Spain (Province of Huelva) (Refer.1).

-
- (1) Head of "Demarcación de Costas de Canarias"
(M.O.P.U., Ministry of Public Works).

 - (3) Head of "Servicio de Costas de Alicante" (M.O.P.U.)
Plaza de la Montañeta, 9 03001 ALICANTE (SPAIN)

The Southwest coast of Spain, between the Guadiana and the Guadalquivir rivers, was created by the large sand sediment supplies coming from those rivers during the last thousand years.

Fig.1.- Situation

This portion of the coastline has been exposed to the oblique incidence of predominant swell.

There are several coastal formations that indicate very clearly the net result direction of littoral transport.

In fact, one can find some important sandy spits along Huelva coastline, like "El Rompido", "Punta Umbría" and "Doñana", all of them associated with wide tidal marshes systems.

This kind of formations provides an idea of the

strength of the littoral processes in the Huelva coastline.

As indicated in the scheme, there is a very clear littoral drift direction from West to East along the whole coastline.

Fig.2.- Huelva Coastline Scheme

Figure 2 shows the coastline is divided into two parts by the Tinto-Odiel Estuary, also called "Ria de Huelva".

The tidal flow along this Estuary has almost acted as an integral barrier to the longshore sand transport.

The rates of the net result for littoral drift are evaluated around 190,000 m³/yr. on the west side (between the Gadiana river and the Tinto-Odiel Estuary), and around 390,000 m³/yr. on the east side (from Tinto-Odiel to Guadalquivir river).

Up to a few hundred years ago, the volume of sand brought to the coast, mainly by the Gadiana river, was enough to determine its progressive shape, but now there is an important shortage of sediment supplies, and this is due to several causes:

- Climatic variations (less rain)

- Physical factors (smoother river profiles)
- Human actions (constructions of dams, littoral barriers, etc...)

So the Huelva coastline is, at present, strongly recessive, and specially on its eastern side.

Firstly, because the coastal alignment makes it more exposed to the oblique incident waves attack.

And secondly, because the natural barrier effect due to the Tinto-Odiel Estuary has been recently reinforced by the construction of the sand contention dike for Huelva Harbour.

Description of the Sand Bypassing Project

The "Playa de Castilla" beach, that extends for 25 Km between Mazagón and Matalascañas tourist resorts, is situated on this part of the coast.

Field data obtained during the last 30 years indicate that the coastline recession has reached a mean of 1.5 m/year.

Through the sand bypassing project, an artificial nourishment of that eroded beach was carried out nearly a year ago.

Fig.3.- Sand Bypassing Scheme

The work consisted of a sand bypassing from the zone behind Huelva Harbour dike to the "Playa de Castilla", situated on the other side of the Tinto-Odiel Estuary.

As mentioned before, the increasing of the barrier effect of the Tinto-Odiel Estuary (that it is due to the construction of the sand contention dike) has produced a large sand accumulation on the beach formed on its west side.

Figure 4 shows the sand contention dike for Huelva Harbour. The photograph was taken in 1.985, a few years after the construction of the dike. As one can see, there is a large sand accumulation in the beach formed on the updrift side of the dike:

Fig.4.- Beach Behind the Sand Contention Dike (Huelva Harbour)

The volume of sand moved from the accumulative area to the eroded beach was 1,690,000 m³, and the cost was \$5,800,000, what means \$3.4 per m³.

The sand was dredged by a trailing suction hopper dredger, then transported to the fill zone, that is situated out of the dike's shadow area, and pumped to the beach through a 2 Km long steel submerged pipeline.

The nourishment length is 25 Km.

The total volume of sand was transferred to the updrift extreme of the beach, forming a protruding area of about 2 Km length by 115 m width (Fig.5):

Fig.5.- Aerial View of the Protruding Area

The high rate of littoral transport guaranties the nourishment of the whole beach by the borrowed sand, that it is moved along it following the downdrift direction.

The chosen system to keep the beach stable was a "complete artificial nourishment", without any other kind of works and constructions.

This system implies that only periodic beach filling has to be carried out.

Another system could have been to built groynes, detached breakwaters, etc..., together with the beach nourishment.

Using this system it would not be necessary to make regular filling, but the coastline would have too many groynes and other hard coastal constructions.

It is hoped that the right decision was made regarding the system chosen, as the preliminary studies have indicated it was cheaper, more effective and clearly softer alternative.

It has been calculated that a sand bypassing like this would be needed every 4-5 years. However, more precise data will be available once the field investigation is finished.

Some of the First Results

In order to show the beach behaviour in the protruding area, in the next figures we can see some of the first data and results obtained after the sand bypassing works.

Several samples of the native sand were taken along many profiles of the beach, each one from a certain depth. As it is shown, the expected sand sorting along the beach profile is clearly indicated by the native sand lines.

Characteristics samples of borrowed sand were taken on the dredger during the works.

As one can see in Fig.6, the borrowed sand is coarser than the native sand.

Fig.6.- Native and Borrow Sand

Fig.7 shows the evolution of the bathimetric line +2m:

Fig.7 Evolution of Bathimetric Line +2 m

Fig.8 indicates the evolution of the bathimetric line 0 m:

Fig.8.- Evolution of Bathimetric Line 0 m

As was expected, the recession of bathimetric +2 m in the protruding area after the sand fill, is clearer than the recession of bathimetric 0 m.

As is indicated the recession in the protruding area is made in benefit of the downdrift beach.

Fig.9 shows the beach transect AA in the middle of the protruding area:

Fig.9.- Cross Section of the Beach in Transect AA

Fig.10 shows the beach transect BB at the downdrift extreme of the protruding area:

Fig.10.- Cross Section of the Beach in Transect BB

As one can see, the evolution of the beach shape after the sand fill seems to follow the behaviour described by Hallermeier.

Field Measurement Program

After having finished the works a field measurement program is being carried out in order to obtain the needed data to check different coastal engineering theories related to sediment transport, shaping of active profiles, planform of beach fill, sediment sorting and distribution, etc...

The main objective of this checking of theories is to obtain applicable results for beach improvement policy, particularly in the Huelva coastline.

The scheduled field measurement program has only recently started. Therefore, any kinds of results or conclusions would not be able to be presented at this point.

Interesting results are expected in the space of one year, in time to present them at the 23rd ICCE in Venice.

The main parameters that are being taken are:

Daily:

- * Visual observations: Two measurements.
 - Wave direction in shallow water.
 - Breaking width.
 - Wave period and wave height within the surf zone.
- * Wave recording by a buoy gauge.

Monthly:

- * Beach transects each 500 m along "Playa de Castilla" beach.
- * Sand samples at different depths in each transect.
- * Sand analysis.

Since the results of the definitive current field measurement program are not available, conclusions about the scheduled checking of some coastal engineering theories cannot be presented.

However, visual observations of the beach platform evolution, have so far indicated a positive benefit of the downdrift adjacent coastline, which was the main goal.

Acknowledgements

We would like to thank Mr. F. Palao, General Director of Ports and Coasts, and Mr. F. Osorio, Director of Coasts, for their interest shown in this study and also for their anticipated support for future investigations.

CHAPTER 242

BERM BREAKWATER CONTAMINATION STUDY SERGIPE MARINE TERMINAL, BRAZIL

Charles P. Fournier ¹, Otavio J. Sayao ¹, M.ASCE and Felipe Caldas ².

ABSTRACT

A physical modelling programme was undertaken to investigate the contamination of a berm breakwater armour stone layer with fines. For construction purposes, it became necessary to significantly increase the berm breakwater core crest width (construction roadway) beyond the design value. Thus, contamination of the armour material by fines, much beyond the specified tolerance, immediately adjacent to the core section resulted. As the original design did not consider the influence of this contamination on the armouring stability, the present modelling study was carried out, in response to the above construction limitation. The implications of a contaminated berm armour section was investigated. The results showed that for a high crested breakwater structure, the contamination of the armouring close to the core did not influence the breakwater stability and, profile reshaping was virtually the same for the contaminated and the original structure. This is due to the fact that the contaminated section was not placed in the active berm area. However, for a low crested structure, the contaminated section was less stable than the uncontaminated counterpart, due to the increased volume of water which overtopped the structure resulting in back slope instability.

1.0 INTRODUCTION

The berm breakwater under investigation is presently under construction for the Sergipe Marine Terminal in Brazil (see Figure 1). The terminal (Terminal Portuário de Sergipe, TPS) consists of a 2.4 km long trestle way connecting the berthing pier to shore. The pier is protected from wave attack by an offshore berm breakwater 543 m long, located in about 10 m depth at low water (see Figure 2).

The alternative design for the berm breakwater was developed by Construtora Norberto Odebrecht S.A. (CNO) in 1988 (Sayao and Hall, 1988). The final design specified an 11 m berm width and a 4 m core crest width both at 0.75 m above the Design High Water Level (see Figure 3). The contractor, CNO, was interested in constructing the structure by widening the core crest to 8 m, resulting in contamination of 4 m of armour material adjacent to the core. The

TRUNK CROSS-SECTION

Figure 3 - Original Berm Cross Section

Figure 4 - Queen's University Model Layout Profile Reshaping Measurement Lines

berm breakwater stability depends on a porous berm of armour stones to dissipate wave energy. It is, therefore, essential that the expected prototype armour stone gradation and structure cross-section geometry be modelled correctly. The original design did not consider a contaminated section during the modelling programme. Thus, a physical modelling programme was undertaken at the National Research Council Canada (NRC) Hydraulics Laboratory to investigate the contamination of a berm breakwater armour stone layer with fines adjacent to the core crest. The purpose of the testing programme was to compare profile reshaping which occurred in the original (uncontaminated) design tests to those with a high percentage of fines (contamination) adjacent to the core.

2.0 MODEL STUDIES

This paper draws on information obtained from three separate model studies undertaken over the past couple of years (for details, see Murray and Sayao, 1990). The first, the original berm breakwater design conducted at Queen's University (Sayao and Hall, 1988), is referred to as the Queen's 3D tests. The second model study was dedicated to the investigation of armour contamination by fines and is the subject of the present paper. This model study is referred to as the NRC 2D tests. Finally, a redesign of the structure was carried out for geotechnical reasons (Murray and Sayao, 1990) and is referred to as the NRC 3D tests.

Queen's University 3D Design Model Tests (Queen's 3D tests)

The design of the berm breakwater for Sergipe Marine Terminal was achieved by means of a series of three dimensional hydraulic model studies at a geometric scale of 1:35. The tests were undertaken in a wave basin at the Queen's University Coastal Engineering Laboratory in Kingston, Canada. The modelling programme consisted of a total of 24 tests, all conducted using irregular waves. Variables in the test included design water levels, wave direction, geometry of the structure and the occurrence of single and multiple design storms (Sayao and Hall, 1988). Profile reshaping measurements were taken after each storm at the 5 locations shown in Figure 4.

NRC 2D Contamination Model Tests (NRC 2D tests)

A berm breakwater contamination study was conducted at the National Research Council Canada with the aid of two-dimensional physical hydraulic model tests at a geometric scale of 1:42.5 (Atria, 1989). The purpose of the testing programme was to assess the influence of a contaminated armour layer on structural stability by comparing the contaminated profile reshaping results with the ones obtained for the original design section. The design storm and prototype armour stone gradation for the present study were virtually the same as the Queen's 3D tests described above (for comparative purposes).

NRC 3D Redesign Model Tests (NRC 3D tests)

In November 1989, CNO commissioned the coastal engineering redesign of the offshore breakwater, due to the weak bearing capacity of the sub-soil (Atria, 1990). The redesign breakwater was a low crested structure which allowed overtopping. The objective of the design process was to achieve a modified berm breakwater structure founded on soft clays ensuring its safe performance for both the geotechnical and the hydraulic aspects of the site.

The 3D physical model studies carried out for the redesign of the breakwater were undertaken in the National Research Council

Hydraulics Laboratory at a geometric scale of 1:35. The modelling programme consisted of hydraulic stability tests which lead to the development of the breakwater redesign for the TPS. Included in this modelling programme was a series of tests to assess the influence of the contaminated armour material immediately adjacent to the core. In fact, the approach to modelling contamination during this series of tests was conceptually identical to that used previously in the NRC 2D contamination tests discussed here.

INPH Design Storm

Details of the environmental conditions which were utilized throughout the course of the design and modelling programme are given in Sayao and Hall (1988) and Atria (1990). However, a brief review of the specific storm used for the NRC 2D tests is presented.

This design storm utilized in all three model studies was developed at the Instituto Nacional de Pesquisas Hidroviárias (INPH) in Rio de Janeiro for the original conventional breakwater design (Murray and Sayao, 1990). The individual wave train characteristics were based on prototype measurements. Table 1 illustrates the 12 segments of the INPH design storm representative of the 100 year return event (Hidroservice, 1987). Irregular waves were used throughout the course of the NRC 2D modelling programme and the influence of different sequences of water levels were considered analogous to the Queen's 3D tests. The peak significant wave height of the design storm was 4.0 m.

The maximum design high water level was specified as elevation +2.5 m above chart datum. The design low water level was specified as -0.15 m below chart datum. To achieve a comparison with the Queen's 3D tests, a low water, high water storm sequence was necessary to reproduce the test conditions in the Queen's 3D tests (Sayao and Hall, 1988).

TABLE 1: INPH DESIGN STORM

Segment	Duration (hrs)	Cumulative Duration (hrs)	Significant Wave Ht. (metres)	Peak Wave Period (sec)
1	3	3	2.5	9.3
2	3	6	3.0	9.3
3	3	9	3.5	9.3
4	3	12	4.0	9.3
5	3	15	2.5	11.5
6	3	18	3.0	11.5
7	3	21	3.5	11.5
8	3	24	4.0	11.5
9	3	27	2.5	14.3
10	3	30	3.0	14.3
11	3	33	3.5	14.3
12	3	36	4.0	14.3

Armour Stone

The model stones used for the berm armour at the Queen's 3D tests were not available for the NRC 2D tests. Thus, the geometric scale of 1:42.5 was chosen such that the armour stone distribution of the berm armour material matched (reasonably well) the armour stone distribution from the Queen's 3D tests. Figure 5 shows the comparison of the armour stone distributions for both the 2D contamination study and the original Queen's 3D tests. At this

Figure 5 - Berm Armour Stone Gradation Curves

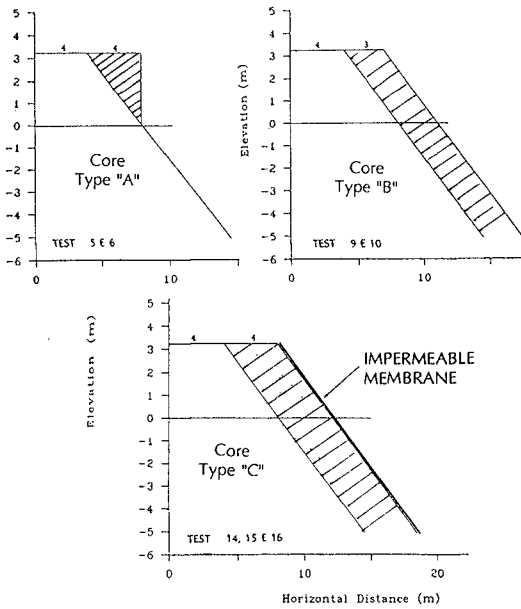

Figure 6 - Contamination Core Types

scale, the Reynolds number in the armour layer is maintained at a value exceeding 5×10^4 , which is sufficient to minimize scale effects resulting from the inability to simultaneously model both Reynolds and Froude criteria (Dai and Kamel, 1969, U.S. Army Corps of Engineers, 1984). As can be seen from Figure 5, the armour stone gradation ranged from 300 kg to 4 tonnes. This resulted in the determination of the following parameters:

$$\frac{D_{60}}{D_{10}} = 1.65; \frac{D_{85}}{D_{15}} = 1.86; \frac{H_s}{\Delta D_{n50}} = 3.1$$

where D_{85} , D_{60} , D_{n50} , D_{15} and D_{10} are the armour stone diameters exceeded by 15%, 40%, 50%, 85% and 90% of the armour stone distribution respectively, H_s is the (maximum) significant wave height and Δ is the submerged relative density of the armour stone.

3.0 INFLUENCE OF ARMOUR STONE CONTAMINATION

The approach adopted for the contamination study (NRC 2D tests) was to compare the reshaping characteristics of the contaminated structure versus the uncontaminated breakwater cross section. For this, profiles 1 and 2 from the Queen's Tests (see Figure 4) were used for comparative purposes. Firstly, a calibration procedure was necessary to ensure that the reshaping of the NRC 2D structure was (practically) identical to that of the Queen's 3D structure. That is, the reshaped profile after the design storm in the NRC 2D tests should be comparable to the reshaped profile after the same design storm from the Queen's 3D tests. This calibration technique therefore addresses the issue of the 2D versus 3D modelling effects, i.e. the 2D berm width is not the same as the 3D berm width to achieve the same profile reshaping. Having achieved an acceptable calibration, contamination of the breakwater was considered by comparison of contaminated versus uncontaminated reshaped profiles.

Simulation of Contamination

The simulation of contamination immediately adjacent to the core crest was achieved by constructing (in the model) various core extensions as shown in Figure 6. Core type "A" perhaps represented a physically realistic geometry of a contaminated armour layer given a construction roadway extension of 4 m over already placed armour. Core type "B" adopted a narrower contaminated section than core type "A" with a more extensive degree of contamination over the front slope. Finally, Core type "C", considered a worst case scenario for the simulation of contamination in the physical model study. This section utilized an additional 4 m of core material extended to the base of the structure over the entire front slope of the core. Furthermore, an impermeable membrane was placed over the entire front slope of the (new) core to eliminate any permeability effects into the core.

Summary of NRC 2D Tests and Results

A summary of the 2D tests conducted at the National Research Council Canada to study the contamination of a berm armour layer is given in Table 2.

TABLE 2: TEST SUMMARY - NRC 2D CONTAMINATION STUDY

Calibration of 2D Contamination Tests

The calibration phase of the modelling programme consisted of modelling in the 2D flume various berm widths until the reshaped profile from the 2D tests matched those from the Queen's 3D tests. It is important to note that the same prototype armour stone distribution and design storm (wave climate) was utilized in both model studies, and therefore a 2D berm width existed which produced the same reshaped profile as in the 3D tests.

Tests 1 and 2 (low water, high water storm sequence) started with an 11 m berm width identical to the Queen's 3D tests. As expected, the berm reshaped less in the 2D testing than measured in the 3D Queen's tests. For tests 3 and 4, an 8 m berm width was used which yielded a reshaped profile very similar to that obtained in the 3D Queen's test. Tests 5 and 6 tested the same structure with contamination defined by core type "A".

Tests 7 and 8 tested a 9 m berm width which reshaped somewhat less than the 3D tests. Comparison of tests 7 and 8 results with the Queen's reshaped profile after low and high water respectively showed inadequate agreement in 2D versus 3D reshaped profiles, particularly after the high water test. It was therefore concluded that a 9 m berm in the 2D tests had more reserve capacity than the 11 m berm in the Queen's 3D tests. Nevertheless, contamination tests using core type "B" were conducted for comparative purposes between an uncontaminated structure with a contaminated structure (tests 7 with 9, 8 with 10). Although not shown in this paper, the profile reshaping for contaminated versus uncontaminated sections was (practically) identical. These tests provided a preliminary indication that contamination of the berm armour stone adjacent to the core did not influence the reshaping of the structure.

Due to the inability to model permeability in the core, it was decided to proceed testing (subsequent to test 11) with an impermeable membrane over the outer edge of the core and/or contaminated section. This effectively eliminated any debate with respect to the correct scaling of flow through the core since flow was not permitted, and thus it was guaranteed that the contamination had a maximum impact on stability.

Tests 12 and 13 represented the "calibrated test section" in that the profile reshaping after low water (test 12) and high water (test 13) were very similar to the Queen's 3D tests. Figures 7 and 8 illustrate the 2D versus 3D comparison of reshaped profiles after low water (test 12) and high water (test 13) respectively. A comparison of tests 12 and 13 results with the Queen's reshaped profiles showed acceptable agreement which lead to the conclusion that an 8 m berm width in the 2D model was equivalent to an 11 m berm width in the 3D model from a stability (reshaped profile) point of view, and for the tests boundary conditions.

Contaminated versus Uncontaminated Profile Reshaping

Having achieved a reasonable calibration of the 2D reshaped profile to that of the 3D Queen's tests, i.e., having considered the 2D versus 3D modelling effects, a valid assessment of contamination was achieved. Tests 14 and 15 were conducted using the same structure geometry as tests 12 and 13 with the contaminated core type "C" as shown in Figure 6. A comparison of low water and high water uncontaminated versus contaminated profile reshaping (test 12 with 14 and 13 with 15) are shown in Figures 9 and 10 respectively. It can be seen from these figures that very similar reshaped profiles resulted in both the uncontaminated and contaminated test sections, particularly at the water line. Some additional onshore transport of material towards the berm crest is visible for the contaminated section which is not an unrealistic result. Therefore, the results of the study indicate that contamination of the armour material immediately adjacent to the core as shown in core type "C" (Figure 6) does not significantly affect profile reshaping for the given structure and wave climate.

NRC 3D Contamination Tests

As mentioned in Section 2.0, a redesign of the breakwater was required due to geotechnical restrictions. To meet these restrictions, a low crested structure was adopted (crest 1.5 m above high water) which utilized heavier armour material (ranging from 1 to 4 tonnes) in the berm and conventionally placed armour stone over the core crest and backslope. During the course of the modelling programme, contaminated structures were tested using the core type "C" shown in Figure 6. For the redesigned structure, very little profile reshaping occurred for either the uncontaminated or contaminated structures. Figure 11 shows a typical plot of profile reshaping of the contaminated structure after a low water, high water and a second high water storm sequence. However, the contamination had a pronounced effect on the stability of the crest and backslope stones. Localized zones of damage were quite apparent (by eye) on the crest and backslope of the contaminated structure which were not present during testing of the identical uncontaminated structure. The displacement of crest and backslope stones occurred for a direction of wave attack perpendicular to the structure centerline. The effect of varying direction of wave attack was not considered during the contamination component of the structure redesign because the contamination option for construction was immediately ruled out.

4.0 CONCLUSIONS

The results of the present study showed that for a high crested breakwater structure where overtopping is minimum, increasing the core dimensions to facilitate construction resulting in the contamination of the armouring close to the core did not influence the breakwater stability. In this case, profile reshaping was virtually the same for the contaminated and the original (uncontaminated) structure. This was due to the fact that the contaminated section was not placed in the active berm area. However, for a low crested structure where overtopping is significant, increasing the core dimensions to facilitate construction could have a significant effect on the stability of the crest and backslope stones. During tests of this nature, the contaminated section was less stable than the uncontaminated counterpart, due to the increased volume of water which overtopped the structure resulting in back slope instability.

If the construction methodology is changed after any breakwater design, rather than investigating the increase of core width and the contamination of the adjacent armouring, an alternative armouring design could be considered. This may consist of a heavier gradation resulting in a reduced berm width and an increased core width, thus making effective use of quarry materials.

It should be realized that this study was site specific and thus more research is required to determine the permissible dimensions of core and armour extremities.

CHAPTER 243

OFFSHORE BREAKWATER FOR THE SERGIPE MARINE TERMINAL, BRAZIL

MALCOLM MURRAY¹, MICE and OTAVIO J. SAYAO², M.ASCE

ABSTRACT

This paper describes the development of an alternative design for the offshore breakwater of the Sergipe Marine Terminal (Terminal Portuário de Sergipe, TPS), in northeast Brazil. Earlier alternative designs for the breakwater are presented and the chosen solution, a berm breakwater design, is described. Details of the hydraulic model testing carried out during the designing stages are given and the construction methods are explained together with a brief overview of construction controls and organization. In order to accommodate the unfavourable subsoil conditions which were found to be worse than initially expected, a redesign of the offshore breakwater was carried out. The new redesign is presently under construction. The TPS breakwater is the first berm type structure to be constructed in Brazil and one of the few in the world to be constructed over a soft marine clay layer.

1. INTRODUCTION

The growing industrialization of the state of Sergipe led to the need for the construction of a port to handle solid and liquid bulk cargo near the industrial pole to be established to the north of Aracaju, the state capital. Engineering feasibility studies (e.g. Sondotécnica, 1978) comparing an estuarine port on the Sergipe River and an offshore terminal located 17 km north of the river led to the adoption of the latter. With a total forecast investment of US\$ 110 million, the implementation of the new port was started in 1986 and is due to be concluded in 1991.

A contract was signed between Petróleo Brasileiro S.A. (Petrobrás) and Construtora Norberto Odebrecht S.A. in March 1987 for the construction of the marine civil works. Figure 1 shows the TPS location and layout. The terminal consists of a pier located in 10 m of water (below chart datum), connected to the port area by an access bridge 2,400 m long and protected by a breakwater 543 m long. The 332 m quay is designed for two 15,000 DWT vessels.

² Principal; ATRIA ENGINEERING HYDRAULICS INC., 8 Stavebank Rd. N., Suite 301, Mississauga, Ontario, L5G 2T4, Canada.

The sea bed at the breakwater site consists of a 4 m layer of fine sand overlaying an extremely soft layer of marine clay about 8 m thick which in turn overlays another sand layer (Figure 2).

2. TENDER DESIGN AND ALTERNATIVE SOLUTIONS

Figure 3 shows the tender design (Hidroservice, 1987), a conventional design adapted to the unfavourable subsoil conditions (Lundgren and Jacobsen, 1987). It involved placing of eight grades of stones during 17 distinct construction phases. These included the placing of a sand layer within the geotechnical berm. Construction of the geotechnical berm is done with floating plant while the superstructure of the breakwater is constructed by land-based equipment using the access trestle.

According to the tender planning, within the contractual period of 24 months construction would proceed with the use of marine equipment such as split barges and floating cranes, as well as land-based equipment. Even though the tender design was subsequently trimmed by the client, it would still involve the use of marine equipment during the winter of 1989. Thus, alternative solutions were sought which would simplify construction, also by maintaining marine operations within the summer months only. A number of structural and mixed solutions were developed in-house by CNO. Here, the structural solutions would require extremely heavy elements to resist hydraulic impacts of the order of 100 t/m (Danish Hydraulics Institute, 1987).

The classic solutions of substituting the marine clay by sand drains to accelerate the dissipation of pore pressures were already eliminated by the client on economical grounds. The alternative solution chosen and developed was a berm breakwater (Figure 3). It consisted of a geotechnical berm designed to distribute loads over the subsoil (as in the tender design) and a hydraulic berm to dissipate wave energy. Table 1 summarizes the comparison between the conventional tendered design and the alternative berm design.

3. BERM BREAKWATER SOLUTION

DESIGN CONCEPT

The design concept for the offshore breakwater, known as berm breakwater, has been reported in a number of references (Willis et al., 1987; Foster and Hall, 1987; Van der Meer, 1988). Figure 4 shows examples of recent berm breakwater projects. The features and advantages of this type of structures can be summarized as follows:

- The main armour can be constructed using lighter stones than those required for a comparable design using a conventional double layer armour.
- The structure can be constructed using relatively simple procedures which allow the relaxation of tolerances leading to better control during construction.
- The berm structure exhibits greater stability than a conventional double layer armour breakwater for a number of reasons. The berm has a high bulk porosity which allows the waves to propagate into it, dissipating their energy over a large volume. This does not occur in a conventional design since the flow into the filter and core layers is restricted due to reduced permeability, causing energy reflection and consequent instability of the armour due to down-rush.
- The berm breakwater also increases its stability as a result of wave action which tends to move stones about in the outer layers of armour. This leads to stabilized slopes of about 1:5 inclination as well as consolidation of the mound due to interlocking between the stones. As a result a stable profile is developed which is very resilient to wave action.

The adopted berm breakwater design is shown in Figures 3 and 5. The final structure dimensions was designed after carrying out hydraulic tests and geotechnical stability analyses.

Core is composed of stones in the range of 0 to 500 kg while armour stones range from 300 kg to 4,000 kg. With this simplified design, consisting of only two types of stones, the construction period was reduced from 24 to 15 months.

Table 1 Breakwater Design Quantities

Item	Unit	Conventional	Berm
Sand fill	m ³	344,000	0
Rock quantities	m ³	735,000	587,000
No. of material grades	-	8	2
No. of construction phases	-	17	4
Width of geotechnical berm	m	169	123
Acceptable percentage of damage	%	4	0
Maximum settlement	cm	150	120

Figure 3 shows cross-sections of both alternatives.

 ARACAJU BREAKWATER STUDY

HYDRAULIC MODEL TESTING

The berm design was model tested at the Coastal Engineering Laboratory, Queen's University, Canada (Murray, 1989; Sayao and Hall, 1988). The model structure was subjected to a wide range of wave conditions including two different design storms (DS1 and INPH, see Table 2). Testing was undertaken using the notion of a design storm which had wave characteristics during the peak segment of the storm corresponding to the 100 year wave event. Waves from 2 directions, orthogonal and 35° oblique attack, were tested with both high and low water levels. A summary of the design parameters is given in Table 3.

The structure was also tested to assess its performance when subjected to multiple consecutive design storms. The most intensive testing involved subjecting the breakwater to three consecutive design storms undertaken at low water, high-water and low-water respectively or to the following sequence: 100 years storm at low water; two consecutive 100 year storms at high water; 24 hours (prototype) of waves having a height equal to the 100 year height. The final design was successful in surviving these events, both along the trunk and at the heads of the structure. Figure 6 shows a typical profile development after physical model testing (Murray, 1989).

4. CONSTRUCTION

TEMPORARY LOADING FACILITY

One of the first activities to be carried out during the construction phase of the project was the construction of the temporary loading facility (Porto de Embarque Provisório, PEP) which was accomplished during the winter of 1988 (Figure 7). This facility was constructed alongside the access trestle, at 800 m from its abutment, in 5 m of water at low tide. Its breakwater was designed for waves with a recurrence period of 5 years and a significant wave height of 3.2 m. The PEP layout and a typical cross-section of the temporary breakwater are shown in Figure 8.

Table 3: Summary of Design Parameters

• Deepwater Design Wave	≈ 6.0 m
• Highest Recorded H_s at the Structure	3.0 m
• Mean Water Depth at Structure	11.5 m
• Tidal Range at Structure	≈ 2.5 m
• Foundation Conditions	poor (soft clay)
• Design Wave at Structure	4.0 m
• Design Wave Periods (T_p)	6.5; 8; 10 s
• Dimensionless Wave Height ($H_s/AD_{0.50}$)	≈ 3
• Dimensionless Wave Period ($\sqrt{g/D_{0.50}}T_p$)	22; 27; 34
• Length of Structure	543 m
• Berm Width	11.0/13.0 m
• Crest Height	+ 6.0 m
• Berm Armouring Gradation	300 kg - 4t
• Mean Stone Weight (W_{50})	1.5 t

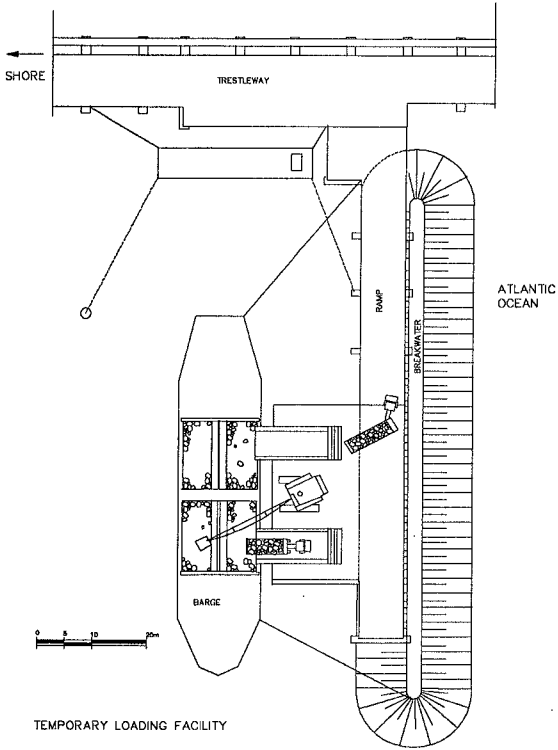

FIGURE 8: PEP PLAN AND CROSS SECTION

QUARRY

The quarry is situated 73 km from the terminal site. Rock extraction is obtained by conventional methods with bench heights of 10 m. The rock is gneiss and granite of sound quality. Fines are separated at the quarry by a simple grizzly operation and transported to the site by 40 t lorries. A buffer stock pile is maintained at the terminal site to smooth out loading peaks. With the berm design and a suitable blasting pattern it was found possible to utilize nearly all of the quarry production, with the obvious exception of the fines and overburden material.

CONSTRUCTION SEQUENCE

The first main construction activity to be carried out in October 1988, following the winter season was to place the stones of the geotechnical berm. This task involved dumping 340,000 m³ over an area of 124 m by 669 m, with a depth of water over the berm of 5.10 m.

Dumping was to be carried out in the open sea under waves and littoral currents. In order to conclude the operation in five months before the winter of 1989, weekly productions of 30,000 t would be necessary. After examining various solutions, including the use of locally available split barges, it was decided to charter a side dumping vessel of 1,100 t capacity which loaded down stone carpets on the sea bed in areas of approximately 30 m by 60 m and 0.30 m thickness. As this vessel was equipped with a dynamic positioning system, Schottel driven screws and bow thrusters, it was possible to achieve tolerances on the geotechnical berm construction of plus or minus 0.30 m vertically and plus or minus 1.0 m horizontally, leading to a substantial reduction of wastage. Figure 9 shows the phases of marine construction. The land based construction sequence is shown in Figures 5 and 9. It consists of dumping of the core and placing the armour stone by a combination of lorry tipping and skips handled by cranes. Production during these phases was expected to be about 40,000 m³ per month.

CONSTRUCTION ORGANIZATION AND CONTROL

Construction falls under the responsibility of a Construction Manager reporting to the Contract Manager, while design coordination and macro-planning are the responsibility of a specialized Engineer Manager. In order to maximise production, double shifts have been worked, with Saturday nights off and Sundays reserved for equipment maintenance. Quality control is carried out by members of the contractors staff, with a Quality Control Manager reporting directly to the Contract Manager as well as liaising with the client's supervisory staff.

Control of breakwater construction includes periodic checking of project geometry and construction tolerances, rock quality, and gradation curves for core and berm armour materials. It should be mentioned here that the design gradation curves were based on pilot curves prepared after experimental blasting had been carried out on opening up of the quarry, with the intention of optimizing quarry production.

During the design stage several experimental methods for gradation control were tried, including curves based on computer analysis of photographs of rock samples (Maerz et al., 1987). In most cases, however, gradation curves are carried out simply by weighing randomly chosen samples and ensuring that the measured curve falls within the specified gradation tolerance intervals.

FIGURE 9: CONSTRUCTION SEQUENCE

5. REDESIGN

While under construction, evidence that the soft clay layers were much weaker than expected was obtained through subsidence of the breakwater foundation. Subsequently, the breakwater project was reviewed to adapt to the new soils situation. Both hydraulic and geotechnical engineering redesigns were carried out (Atria, 1990a; Geoprojetos, 1990). In order to decrease the loading on the subsoil the hydraulic design has evolved to a low crested berm design, overtopping being reduced by a suitable increase in the hydraulic berm width as indicated in Figures 10 and 11.

The wave climate for the TPS used in the CNO original design (Sayao and Hall, 1988) was the same as given in Hidroservice (1986). Site measurements of the wave climate are still underway. Since more data are collected near the study site, more work has been carried out to examine the given design wave climate (Atria, 1990b). Even though there is evidence that the wave climate for the TPS has changed since Hidroservice (1986) work, the decision was made by Petrobrás to redesign the breakwater structure for the same wave climate as used in the original design.

Physical model studies for the redesign of the breakwater were carried out in the National Research Council Hydraulics Laboratory (NRC), Ottawa, Canada. The modelling programme included hydraulic stability tests for the breakwater structure as well as wave agitation measurements in the lee of the breakwater. Several model structures were tested under 2 different design storms (INPH and DS3, see Table 2), leading to the development of the breakwater redesign for the TPS. A typical section of the final redesign is shown in Figure 10 and a comparison with the original berm design is shown in Figure 11.

The rubble-mound redesign structure consists of an outer berm placed at a slope of 1:3 (due to geotechnical constraints), extending from the geotechnical berm elevation to the crest elevation. The berm armouring material consists of stones weighing between 1 and 4 tonnes; crest and backslope are armoured with stones of 4 to 8 tonnes, providing for protection against wave overtopping. A description of the model testing programme and test results leading to the final redesign of the TPS offshore breakwater are given in Atria (1990a).

In order to avoid the need to contaminate the hydraulic berm by the widening of the temporary access road, it has been decided to advance the cranes over the berm on a system of leap-frogging girders. Contamination of the armouring due to fines is discussed in Fournier et al., (1990).

6. CONCLUSION

The design phases for the offshore breakwater of the Sergipe Marine Terminal were presented. The TPS breakwater is one of the few in the world to be constructed over a soft marine clay layer and to accommodate for unfavourable subsoil conditions an extensive redesign was carried out. The new redesign is presently under construction.

The advantages of the adaptation of the tender breakwater design from a contractors point of view can be summarised as follows: elimination of the sand layer in the geotechnical berm, reduction of rock quantities, reduction of the number of stone gradations, simplification of the construction methods, execution of the marine phases during the summer months only and finally, reduction of the overall construction period.

FIGURE 10: TYPICAL SECTION THROUGH SUPERSTRUCTURE TRUNK

FIGURE 11: TRUNK CROSS-SECTIONS

There is also the philosophical aspect that for the conventional design a certain percentage of damage of the armour layers is acceptable, whereas the berm design does not suffer 'damage' for the design conditions, thus eliminating the need for maintenance.

Thanks are due to Petrobrás - Petróleo Brasileiro S.A. and Construtora Norberto Odebrecht S.A. for authorizing and motivating the preparation of this paper, respectively. Also, the authors would like to thank Dr. Kevin R. Hall, Queen's University, for supervision of hydraulic model testing. The tender design was developed by Hidroservice Engenharia de Projetos Ltda., Brazil. The alternative berm design was carried out by Dolfim Engenharia S.A., Brazil and F.J. Reinders and Associates, Canada. Placing of the geotechnical berm was accomplished by ACZ Marine

CHAPTER 244

ST. PAUL BREAKWATER, PHASE 1

The Project, the Failure and the Subsequent Investigations

Torben Sørensen¹ and Ole Juul Jensen²

Abstract

The St. Paul Phase 1 berm breakwater was destroyed by two storms within approximately two months of its completion. Investigations made after the failure demonstrate that the cause of the failure was that the breakwater was built from material that was vastly undersized as compared to the recommended minimum rock gradation, and heavily contaminated by fines and overburden from the quarry.

Original Design and Hydraulic Studies

In 1982, the City of St. Paul, Alaska commissioned an American consulting engineering firm (the Consultant) to design a fishing harbour on St. Paul Island, one of the Pribilof Islands in the Bering Sea approximately 450 km north of the Aleutian Islands. The Consultant subcontracted the Danish Hydraulic Institute (DHI) to perform scale model tests and other hydraulic studies to support the design of the project. These studies resulted in the recommendation of a conventional rubble-mound breakwater to be constructed from locally available quarry rock material.

Construction and Revised Design

Construction of the breakwater started early May 1984 under the supervision of the Consultant. Soon after commencement of construction, it became clear that the contractor was unable to produce the stones required for the breakwater armour as designed.

¹ Director and ² Head, Ports and Marine Structures Division, Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark.

On the basis of detailed information of quarry yield reported to have been obtained DHI, in response to an inquiry from the Consultant, suggested consideration of a berm type breakwater, including suggestions for a trunk cross-section that might be used with the available stone sizes.

On 20 July 1984, DHI was authorized to perform a model test programme to be executed during the first two weeks of August 1984. This is to be seen on the background that Phase 1 of the breakwater, i.e. the first approximately 900 ft of a 2050 ft long breakwater, should be completed before the start of the winter, presumably before November 1984. The revised breakwater design (Fig. 1) involved only two stone gradations, called A and B-stones. The A-stones, also called the "1-8 t" gradation, were the armouring with a prescribed minimum gradation curve and the B-stones were 0 to 0.5 t quarry run. DHI's final report of September 1984 states the following with respect to the A-stones: "It is recommended that the coarse "1-8 t" gradation used in the tests is made a minimum requirement for construction, understood so that the material built into the breakwater should at no point have a gradation curve below (with smaller stones) than the "1-8" t stones".

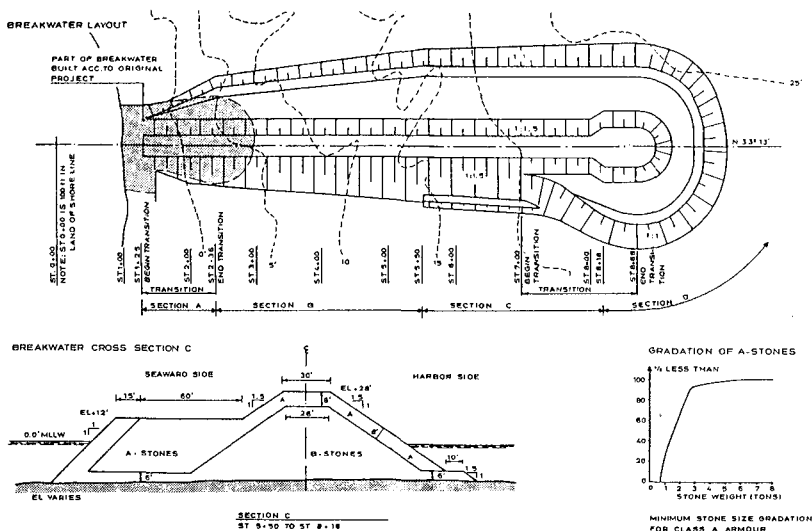

Figure 1. Plan and Cross-Section of St. Paul Breakwater Redesign, Phase 1.

Due to the planned interruption of construction during the winter 1984/85, a temporary protection of the outer end of the Phase 1 breakwater was required.

Having been informed that large armour stones were not available for the temporary breakwater head, DHI suggested the use of a berm type roundhead as a temporary protection using the same "1-8 t" A-stones as used on the trunk of the breakwater. However, DHI cautioned the Consultant that "it is expected that the provisional roundhead will suffer severe damage in the coming winter, but that the damage will not hamper the progression of construction work on Stage II in the spring of 1985, since the stones displaced from the roundhead will be deposited on the harbour side where the inner breakwater is to be constructed. It is thus expected that the stones can be directly incorporated in the inner breakwater" (which formed part of the envisaged construction under Phase 2 of the project). For reasons of time and costs, no three-dimensional model tests with the temporary breakwater head were made prior to construction.

During construction, the Consultant's "Construction Manager" on the site repeatedly complained that the contractor was deviating from the specifications using too small stones and stone material mixed with overburden and fines. However, neither the Consultant nor the contractor apparently ever made any measurements by weighing or by any other means to determine the actual gradation of material being placed in the breakwater profile. At least, no such measurements were ever presented or found during the subsequent litigation. Similarly, it appears that none of the undersized rocks was ever removed from the breakwater.

The Breakwater Failure

The Phase 1 breakwater was completed 2 October 1984 and was severely damaged during two storms in November and December the same year. At the end of the December storm, the length of intact crest of the breakwater was reduced from its original approximately 800 ft to less than 300 ft (Fig. 2).

Various surveys of the A-stone gradations used for construction were made after the damage. Fig. 3 shows the results of all of these surveys. It appears clearly from the various surveys that the average weight of the A-stones used for construction was generally very much smaller than what was recommended by DHI.

Model Tests

During "discovery" under the subsequent litigation, model tests were made both by DHI (defendant) and by ARCTEC for plaintiffs (the Consultant and its insurance company). These tests were three-dimensional model

tests with a structure modelled in compliance with DHI's recommendations regarding profiles and stone material. The wave conditions used in these tests represented those of the two storms that destroyed the breakwater built at St. Paul and were determined by numerical hindcasting made in-house by DHI and by OCTI on behalf of plaintiffs.

Figure 2. Comparison of Model Test Results and In-Situ Damage.

Figure 3. Estimates of A-Stone Gradations As-Built.

In spite of a number of differences between the two sets of model tests, both in the hindcast wave conditions and in the physical modelling, the results of the two sets of tests were remarkably similar. In both tests, the damage observed in the models had no resemblance whatsoever to that experienced in nature. In the models, the damage was limited to the temporary breakwater head proper and fell well within what was predicted in DHI's final report of September 1984, whereas in the nature the breakwater had suffered virtually total destruction (Fig. 2), chiefly through the process of crest erosion caused by excessive overtopping.

In both sets of model tests, overtopping was insignificant and did not at any point cause damage to the crest of the breakwater. This is in sharp contrast to what was observed in nature where photographs taken during the storms show violent overtopping, and photos taken after the storms show extensive damage in the form of crest erosion over the entire outer portion of the breakwater.

The difference in overtopping between models and nature is entirely consistent with the assumption that the rocks used for construction were much smaller (and contaminated with fines and overburden) than corresponding to those used in the model tests and recommended by DHI. This assumption is also supported by numerous photographs taken during and immediately after construction.

Conclusion

DHI considers the identical results of the two sets of model tests as conclusive engineering proof that the St. Paul Phase 1 breakwater was built from stones that were generally very much smaller than those recommended by DHI. Smaller stones combined with extensive contamination with fine material would cause both highly accelerated erosion from the end and drastically increased overtopping resulting in heavy damage to the crest and the rear side - i.e. exactly those processes that destroyed the breakwater in nature as seen from the surveys and the photographs.

CHAPTER 245

The Durban Beach Restoration Scheme after 30 years

W I Laubscher*, D H Swart*, J S Schoonees*, W M Pfaff** and A B Davis**

1. Abstract

The harbour breakwaters at Durban in conjunction with the dredging of the harbour entrance cut off the sediment supply to the important bathing beaches of the city, necessitating a beach restoration scheme. This paper reviews this scheme. Before 1977, the measures to restore the beaches included an underwater mound, beachfill and rock groynes. After 1977 and following a previous review, it was recommended not to complete the mound, to place initial beachfill, regularly nourish the beaches and to build low-level groynes. Implementation started with a sand pumping scheme and 600 000 m³ of beachfill followed by the building of three multi-functional pier/groynes. Monitoring of the beach restoration scheme enabled valuable experience to be gained on aspects such as the loss rate of sand from the beaches, beach profile and scour levels alongside the pier/groynes and on the determination of a potential erosion line and building control zone. This paper concludes with some important lessons learned from the scheme.

2. Introduction

Durban, situated on the South African East Coast, is one of the oldest South African harbour cities and a popular holiday resort renowned for its golden beaches and subtropical climate. Since construction of the harbour started in 1857, the natural northbound littoral drift was cut off from the bathing beaches in the Durban Bight north of the harbour entrance. Figure 1 shows the position of the harbour and the beaches along the Durban Bight.

The state of the beaches deteriorated progressively over the years and this led to the local council, the Durban Corporation, to consider and implement measures to prevent the increasing erosion. Beach replenishment in the form of various sand pumping schemes had been implemented over the years and two rubble-mound groynes, known as the Paterson groynes, were constructed in a critical area to retain longshore sediment transport. However,

* CSIR, P O Box 320, Stellenbosch, 7600, South Africa.

** The City Engineer's Department, P O Box 680, Durban, 4000, South Africa.

these measures did not cope sufficiently with the erosion problem and the Durban Corporation was forced to take further action.

The Council for Scientific and Industrial Research (now CSIR) became involved in 1957 when it was contracted by the Durban Corporation and the then South African Railways and Harbours (now Portnet) to investigate the whole beach erosion problem and to devise a strategy for beach improvement and restoration. The investigation consisted of field studies to collect environmental data (e.g. on wave and current characteristics, sedimentological and morphological conditions) and various model studies to investigate the effect of present and proposed structures on the sediment movement around the harbour entrance and the beaches to the north. This extensive investigation was undertaken over a period of 20 years during which numerous reports were published regarding the results of the different investigations. All the work done over this period was summarised in a *status quo* report (CSIR, 1976) which also described various alternative schemes to improve the condition of the beaches and presented proposals for prototype monitoring.

After an intensive review of the information contained in the *status quo* report an amended beach management strategy was proposed in 1977. This strategy was published in CSIR (1977). The Durban Corporation accepted the strategy outlined in this report and in 1980 embarked on an extensive restoration and replenishment scheme for the beaches south of Somtseu Road (Figure 1). The CSIR was again involved in the implementation of the scheme through model studies of proposed structures and through prototype monitoring. At present the CSIR is involved in the scheme as specialist advisor on beach improvement and management by means of interpretation of the monitoring data. A second *status quo* report compiled in 1989 (CSIR, 1989), summarised all work done and the conclusions reached over the years and also made recommendations for further work.

The beach improvement scheme over the last 30 years can therefore be divided into two distinct periods, namely, (1) the original beach restoration scheme implemented before 1977, and (2) following the intensive review in 1977, the new restoration and management strategy after 1977. The purpose of this paper is to review the beach restoration and management scheme and to share with others some of the important lessons learned over a period of 30 years.

3. Beach Restoration Before 1977

3.1 Strategy

The original beach restoration strategy proposed in the early 1960s, was based on various model studies and prototype monitoring and consisted of:

- (i) Construction of an offshore underwater mound designed to reduce storm-wave energy in order to reduce longshore sediment transport along the beaches.
- (ii) Provision of an initial beachfill to restore the beaches along the sediment starved section of the Bight.

- (iii) A renourishment scheme to replenish material as compensation for the natural losses from the Bight. (These natural losses were calculated then to be about 70 000 m³/year (CSIR, 1963, 1974 and 1976) and it was therefore recommended that this volume of material be placed annually on the beaches).
- (iv) Replacement of the old dilapidated Paterson groynes by a number of groynes to retain sediment transported along the Bight.

3.2 Implementation

Implementation of the above-mentioned strategy started in 1966 and was initially centred around the construction of the underwater mound. The position of the mound is shown in Figure 1. The mound was constructed by placing dredged sand on the line indicated on Figure 1 according to a design profile. It was found that the mound naturally reached a stable profile such that the ratio of the height of the mound to the original water depth was approximately 0,4. An effort was also made to place an initial fill on the southern Bight beaches. Replenishment of the beaches was done through a simple sand pumping scheme which delivered sand at two locations immediately north of the northern harbour breakwater. However, construction of the proposed new groynes to replace the Paterson groynes were then not attempted due to concentration on the mound construction.

In 1976, after 20 years of involvement in the project, the CSIR compiled an overview of all the work done up to that point. Conclusions were drawn from all the information available and recommendations were made concerning future work with respect to beach improvement and management. These can be summarised as follows (see Figure 1 for the different locations referred to):

- (i) Due to progressive lengthening of the harbour breakwaters, the northward directed longshore transport was cut off at the harbour entrance. This, together with the focusing effect of the old dredger spoil dump situated offshore from the harbour entrance, led to the coastline in the Bight realigning itself to a new long-term equilibrium shape which was more concave than that which existed before harbour construction.
- (ii) Development between Somtseu Road and West Street encroached into the dynamic beach area and was, therefore, subjected to extensive storm erosion.
- (iii) The beaches between Mgeni River mouth and Somtseu Road appeared to be in a state of long-term equilibrium while the beaches south of Somtseu Road were subjected to gradual long-term erosion at a rate of 70 000 m³.
- (iv) The underwater mound, which had by 1976 not been completed to the design dimensions, offers some protection against extreme conditions in the area north of Somtseu Road, while little or no protection is provided in the area south of Somtseu Road.
- (v) The underwater mound could be extended in a northerly direction which would provide better protection for the area immediately south of the Mgeni River. This would result in a reduction of the loss rate from the beaches in the

Bight. However, this would mean that erosion of the beaches immediately north of the Mgeni River mouth would increase with an amount equal to the reduction in the Bight loss rate.

The above conclusions indicated that beach restoration and improvement should be concentrated on the Bight beaches south of Somtseu Road. It was recommended that, should additional protection against storm erosion be required, the underwater mound should be extended to the north and completed to its design dimensions. Additional erosion north of the Mgeni River would then have had to be accepted. An estimated 2,5 million m³ of sand would have been required to complete the mound. It was further advised that a sufficiently wide buffer be provided along the beaches south of Somtseu Road and that an estimated 200 000 m³ of sand would be needed for this purpose. A combined beachfill and low-level groyne scheme was considered the most feasible alternative of the possible beach restoration schemes. However, it was necessary for the Durban Corporation to define their specific requirements for the Bight area and to decide on the level of improvement necessary to meet these. Besides the restoration measures, it was recommended that some prototype monitoring be carried out to gain more knowledge of the complex system and to ensure optimization of the improvement measures.

4. Beach Restoration After 1977

4.1 Strategy

Shortly after the appearance of the 1976 *status quo* report, the conclusions and recommendations of which were summarised in the previous paragraph, an extensive re-evaluation of the functioning and effectiveness of the underwater mound was carried out. The results indicated that the mound was not as effective as was first thought and that the actual loss rate from the Bight was higher than estimated previously. A detailed report (CSIR, 1977) addressed the problem of how the Bight beaches should be managed and outlined firm recommendations and guidelines for a beach restoration scheme. These recommendations, which built on but superseded previous recommendations, can be summarised as follows:

- (i) The mound should not be completed to its design dimensions.
- (ii) A control zone, where building should not be permitted due to potential erosion, should be established 40 m landwards of the 1977 high-water line.
- (iii) An initial fill should be placed in the area south of where the Paterson groynes then were, so as to provide sufficient buffer width.
- (iv) Renourishment should be carried out to compensate for the loss rate from the Bight, the rate of which at the time had been determined to be between 70 000 m³/yr and 90 000 m³/yr. Renourishment of 60 000 m³/yr on the Addington and South Beaches and another 30 000 m³/yr on the North Beach was recommended, assuming that compatible borrow material was available.
- (v) The Paterson groynes, being dilapidated and of a high level design, should be replaced with new low-level groynes.

These firm proposals were accepted by the Durban Corporation and they embarked on the implementation of the revised scheme in 1978/79.

4.2 Implementation

The implementation of the proposals started in 1978/79 with the design of a sand pumping scheme to deliver replenishment material along the eroding beaches (Barnett, 1982).

The scheme consisted of a hopper station (into which sand is delivered from a dredger) with four booster pump stations and a number of outlets along the pipeline. To allow for losses, the required replenishment rate was calculated to be 100 000 m³/yr. The system was designed with a capacity of being able to pump 4 000 m³ of sand per day (2 dredger loads) on anticipation of dredgers working 100 days per year. The overall limiting factor on the operational capacity of the scheme was, at that time, the supply of dredger sand for pumping on the beaches which was made available from the harbour authorities (Portnet) routine dredging operations. However, a supplementary agreement between the Durban Corporation and Portnet now provides for the charter hire of the dredger when necessary to win sand solely for the purpose of supplying the sand pumping scheme. With good co-operation between Portnet and the Durban Corporation, the replenishment scheme has, over the last few years, been operated at approximately 230 000 m³/yr, thus achieving some beach-building as well.

In 1982 an initial bulk placement of 600 000 m³ was carried out on Addington and South beaches (between Survey Stations 13 and 16 - Figures 1 and 2) in addition to the renourishment scheme.

A further component of the restoration scheme consisted of the replacement of the old Paterson groynes by two low-level groynes. The position of the groynes are shown on Figure 2. The basic design concept for the new structures was that of a low-level groyne which allows sand to pass over it once the design beach profile, and therefore the desired beach width, have been attained. Both the feasibility study and the subsequent design and construct contract were awarded to a contractor who came forward with several alternative designs based on performance requirements laid down by the Durban Corporation. The resulting design was that of a combined pier/groyne structure, the pier consisting of a deck and two rows of piles with the groyne comprising rock placed between the piles to form a low-level obstruction. The hydraulic design of these two new groynes was carried out by the CSIR on the basis of small-scale physical model tests. Construction of the piers, known as the North Beach Pier and the Bay of Plenty Pier respectively, started in September 1983 and both piers were completed in June 1985. Removal of the Paterson groynes followed and was completed by October 1985.

In 1987 the Durban Corporation decided to construct a third pier/groyne, named the Dairy Beach Pier, with a design similar to of the older two piers (see Figure 2 for the location).

This pier was needed to provide a usable recreation beach adjacent to West Street jetty (Figure 2) in an area where encroachment into the dynamic

beach area had occurred (Section 3.2). Again the CSIR was involved in supplying design information such as the design beach profile, permeability of the rock core, predicted scour adjacent to the pier and orientation of the pier. Construction of the pier has since been completed.

Both during and following the implementation of the above measures, the initial field studies were continued and expanded into an extensive ongoing prototype monitoring programme which includes:

- (i) Beach and bathymetric surveys (see Figure 2 for an example as well as for the position of the survey sections).
- (ii) Sedimentological surveys and computation of volumes of sand lost and gained from the beaches as well as the volumes of sand pumped onto the beaches. In total, 1 175 000 m³ of sand has been placed on the beaches between 1984 and 1988.
- (iii) Monitoring of the nearshore wave climate by means of Waverider and clinometer measurements. The median peak wave period was found to be about 10 s within a range from 5 s to 15 s. At the Waverider position (landwards of the mound in about 13 m of water (to mean sea level)) the 1 in 1 year and 1 in 100 year significant wave heights were found to be respectively 3,6 m and 5,3 m. The mean spring tidal range is 1,72 m.
- (iv) Monitoring the profile behaviour adjacent to the new piers to determine the extent of scour. Because of the large rocks used for the cores of the pier/groynes, the permeability of the structures was found to be too high. Grouting was carried out to rectify this. Generally speaking, it was found that the beach profile (sand) levels on the updrift side of the pier/groyne were about 1 m to 1,5 m and on the downdrift side, approximately 2 m below the rock level in the core. The scour alongside the structures was found to exceed the design values considerably. This is presently the subject of a detailed investigation.

The monitored data provide valuable information on the physical processes in the Durban Bight. The following work resulted directly from the analysis and interpretation of the monitored data:

- (i) A computer data bank was developed where all monitored data are stored. Reports on the interpretation and analysis of these data are published annually.
- (ii) A representative nearshore wave climate for the Central Beaches was determined from the wave measurements.
- (iii) The functioning of the North Beach and Bay of Plenty piers continue to be closely monitored, especially with respect to scour adjacent to the seaward ends. Estimates of the expected scour were calculated for the piers and are updated as more information becomes available. Design parameters for the new Dairy Beach Pier were also determined through these analyses.
- (iv) The average loss rate from the Bight was further revised through a detailed study which included theoretical and empirical calculations and which

used as input wave data from voluntary observing ships, dredging data from Cave Rock Bight (the harbour sand trap - see Figure 2) and beach surveys. The dredger records cover a 60-year period - see Campbell *et al.* (1985). A combined estimate of the loss rate, based on the theoretical and empirical results, was made. It was found to be about 200 000 m³/yr with a corresponding replenishment rate of 210 000 m³/yr to cater for additional losses caused by a steepening of beach profiles as a result of a seaward advancement of the shoreline. Long-term changes in the deep-sea wave climate, especially the wave direction, caused the loss rate to vary significantly over time.

(v) The long-term stability (over a 15-year period) of the Bight beaches was determined using the beach surveys since 1973. This study indicated as had been stated previously, that the beaches between the Mgeni River and Somtseu Road are in equilibrium. Figure 3 shows the variation in the shoreline position at Section 14 over time. It is clear from this and other similar figures that the beaches south of Somtseu Road are at present in the best state since 1973.

(vi) A new potential erosion line for the Bight was determined through a combined numerical and empirical method. A building control zone for the Bight has also been defined. It was found that by specifying the potential erosion line as simply a fixed distance behind the median position of a certain beach profile level (for example +1 m to mean sea level) can be misleading if the slope of the lower limit beach profile is rather flat. Figure 4, taken from CSIR (1990), illustrates this point.

It can therefore be stated that all the measures which were proposed in the 1977 beach restoration and management strategy have been carried out to the substantial benefit of the bathers in the Durban Bight.

5. Conclusions

5.1 General

Following a 30-year period during which various different beach improvement and restoration methods and schemes were proposed and some also implemented, the beaches in the Durban Bight are at present in a better state than at any time since 1959. The combination of experience gained over the years, valuable information gained from prototype monitoring, theoretical and empirical studies, construction of hard structures and the implementation of a sound beach management policy have lead to the present good state of the beaches. The wealth of information which has over the years become available on the specific problem experienced in Durban can now be applied to similar situations elsewhere.

It is anticipated that pressure will increase for further development along the Bight beaches as a result of an increasing demand for recreational facilities.

5.2 Lessons Learned

The following lessons have been learned:

- (i) The initial position of the dredger spoil dump caused wave focusing on the beach, which aggravated the erosion due to the harbour cutting off the sand supply.
- (ii) The loss rate of sand from the beach was found to vary significantly with the deep-sea wave climate, especially with the wave direction.
- (iii) The height of the underwater mound stabilised naturally at about 0,4 times the original water depth. With this equilibrium crest level, the mound offered only limited protection from wave action to the beaches.
- (iv) Development in the dynamic beach zone should be avoided and must be controlled by designating a potential erosion line and a building control zone where strict controls of development proposals have to be done.
- (v) Specifying the potential erosion line as a fixed distance behind the median position of a certain beach profile level can be misleading if the slope of the lower-limit beach profile is rather flat.
- (vi) The pier/groyne combination provides a multi-functional structure. Sand levels on the beach on the updrift side adjacent to the structure are generally about 1 m to 1,5 m, and approximately 2 m on the downdrift side, below the rock core level. The permeability of the rock core and the scour alongside the piles are very important design considerations.

DESIGN AND CONSTRUCTION OF PLEASURE CRAFT HARBOUR - CLUB MYKONOS LANGEBAAN

Bosman D E*, Retief G de F*, Kapp J F* Kloos M*
Ridge A B†

1. ABSTRACT

A description of the pre-design investigation, design and construction of a pleasure craft harbour is given. The influence of the breakwaters on the sedimentation pattern in the direct vicinity of the harbour during construction and after completion of the harbour is described. Adaption of the design of some of the harbour components due to unforeseen circumstances revealed during the construction period is also discussed.

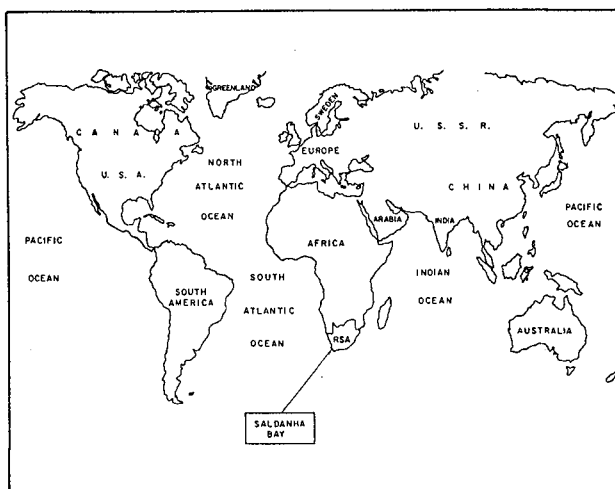

FIGURE 1 : LOCALITY MAP OF CLUB MYKONOS LANGEBAAN SMALL CRAFT HARBOUR AT SALDANHA BAY

2. INTRODUCTION

The Club Mykonos Langebaan Pleasure Craft Harbour Development is situated to the east of and in line with the entrance to Saldanha Bay on the West Coast of South Africa.

* Kapp Prestedge Retief, Consulting Coastal & Environmental Engineers, P O Box 523, Stellenbosch 7600, South Africa

+ Geustyn Forsyth & Joubert Inc, Consulting Civil and Structural Engineers, P O Box 413, Stellenbosch 7600, South Africa.

In view of the similarity in climate and scenery of the South African West Coast and that of the Greek Island settlements in the Aegean Sea, the architectural and aesthetic model of the development was drawn from the latter - therefore the Greek name: Club Mykonos Langebaan.

It is the first privately owned pleasure craft harbour on the open coast of South Africa and forms the nucleus of an ultimately planned 100 million US Dollar private resort. The development includes a commercial centre (restaurants and shops), accommodation (single residential, timeshare, share block and sectional title), recreational, hotel and conference facilities. Figure 2 illustrates the proposed ultimate project.

FIGURE 2 : ILLUSTRATION OF ULTIMATE SCHEME

The harbour works were completed in 14 months during 1988/89 at a cost of about 4 million US Dollars. Figure 3 presents the layout and components of the harbour.

The harbour can accommodate yachts with draft up to 3 m and provides floating walk-on moorings for about 130 vessels. A boat ramp, launching jetty, fuelling and sewage pump-out facilities are also provided.

The basin size is approximately 4 ha of which a part had to be dredged to the required depth. Spoil from dredging has been used to create approximately 1,4 ha reclaimed land adjacent to the harbour basin.

The size of the harbour was determined mainly by the size of the land development from which the funds for it had to be generated. The layout of the harbour breakwaters was designed such that the harbour could be expanded towards the south if required in future.

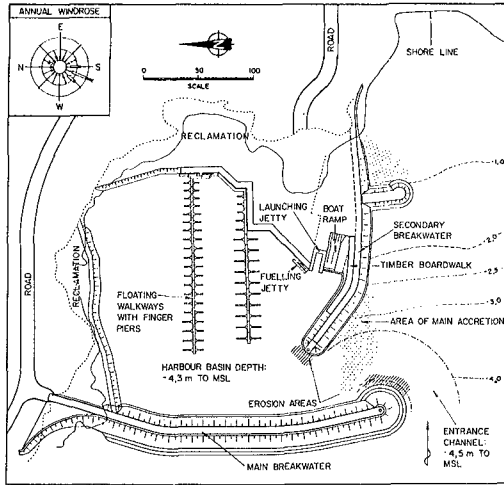

FIGURE 3 : HARBOUR LAYOUT AND COMPONENTS

For marketing reasons and since the harbour forms the nucleus of the development, creating a focal attraction point and therefore increases the market value of the adjacent land, it had to be completed before the land development.

To minimize time for which bridging capital had to be provided (i.e. the time during which expenditure exceeds income), selling of accommodation units on land had to commence soon after expenditure on construction of the harbour had started. This requirement from the developer's side necessitated a fast track programme for the design and construction of the harbour. The predesign investigations and design were done in about 4 months followed by a two months tender and contract adjudication period. The contract was completed in 14 months.

3. ENVIRONMENTAL CONDITIONS

Figure 4 indicates the location of the development in Saldanha Bay as well as the macro scale bathymetry, wind and wave conditions. The wind direction is predominantly from the South-Southwest sector.

The spring tidal range at the site is about 1,5 m.

Waves that directly penetrate Saldanha Bay in the direction of the pleasure craft harbour are reduced in height due to refraction to about 60% of their deepsea height. The 1:10 year deepsea significant wave height in the area is about 7 m which will therefore reduce to a significant wave height of 4,2 m at the harbour site. Peak wave periods vary between 11s and 13s.

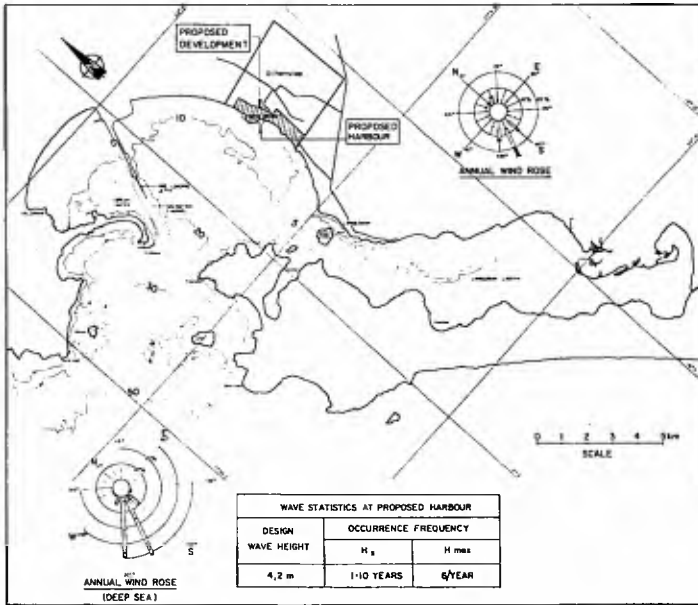

FIGURE 4 : ENVIRONMENTAL CONDITIONS

Figure 5 indicates the wave crest patterns in Saldanha Bay which is practically unidirection at the harbour site. Because of the latter, negligible longshore sediment transport due to wave action was expected. Tidal currents are reasonably high in the entrance to Langebaan lagoon (maximum of about 0,5 m/s) however the tidal current velocities at the Mykonos harbour site are very small.

FIGURE 5 : WAVE REFRACTION PATTERNS IN SALDANHA BAY

The sediment on the seabed in the vicinity of Mykonos harbour is fine (D50 = 140 micron) and sediment movement due to wind-driven currents is possible.

Figure 6 indicates the hydrographic survey of the harbour site. Water jet probings were also done to establish rock depths. From the latter the landward limit of the harbour mooring area (after sand dredging) was derived.

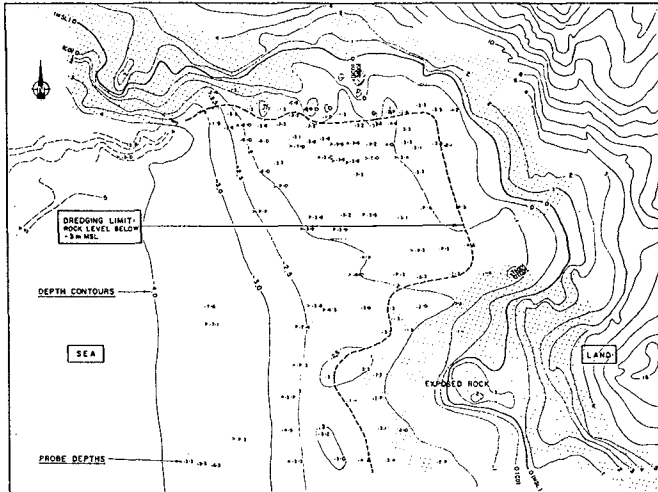

FIGURE 6 : HYDROGRAPHIC SURVEY OF HARBOUR SITE

Good quality granite rock was available from an existing quarry about 2 km from the harbour site.

4. DESIGN AND CONSTRUCTION OF HARBOUR

4.1 Breakwaters

4.1.1 Layout of Breakwaters:

A survey of existing yacht population on the South African coastline indicated the distribution of sizes as indicated in Table 4.1 below. The required mooring water depth for these sizes are also indicated in Table 4.1.

**TABLE 4.1 : LENGTH DISTRIBUTION OF YACHTS AND
REQUIRED MOORING WATER DEPTH**

Length	Percentage Distribution %	Required Mooring Depth below Mean Sea Level m
Up to 8 m	17	2,9
8 m - 11 m	40	3,9
11 m - 15 m	37	4,2
Longer than 15 m	6	

Based on the above boat size distribution, provision was made for 180 moorings of the walk-on floating jetty type anchored to concrete piles.

The following facilities were also needed:

Boat launching jetty

Boat ramp

Fuelling and sewage pump-out jetty

To provide for the above needs, a water area (including access channel and fairways) of about 4 ha was required.

The required water area together with the following factors determined the basic breakwater layout:

- o Landward limit of mooring area that could be dredged to the required depths as determined from the rock depth survey.
- o Required minimum depth at harbour entrance = 4,5 m below Mean Sea Level and entrance width of 45 m.
- o Provision for expansion of harbour towards the south.

The Phase I breakwater layout as optimised by means of three-dimensional hydraulic model tests together with a possible layout of an extended harbour (Phase II) is illustrated in Figure 7.

FIGURE 7 : BREAKWATER LAYOUT, PHASE I, WITH POSSIBLE EXTENSIONS, PHASE II

4.1.2 Main Breakwater:

The design conditions for the main breakwater were:

- Design water depth = 5,4 m
- Design wave height = 4,2 m (breaking wave)

The occurrence frequency of a significant wave of 4,2 m is 1:10 years, however considering the maximum wave in the wave spectra, breaking waves can occur approximately 6 times per year at the location of the main breakwater.

- Wave period = 11s to 13s.

Two basic alternative breakwater designs for the main breakwater (as indicated in Figure 8) were included in the tender to establish the cheapest solution. Stability tests on these were done in both two- and three-dimensional model tests.

The two alternatives were (refer Figure 8):

Alternative 1 : Berm type breakwater

Alternative 2a: Conventional rubble mound protected with Dolos armour units

Alternative 2b: Conventional rubble mound protected with Accropode units

FIGURE 8 : ALTERNATIVE BREAKWATER DESIGNS

Alternative 2b protected with 9.6 t Accropodes was finally selected based on both cost and stability considerations. This design was also checked by Sogreah who holds the patent rights on the Accropode units. Although Alternative 1 proved to be the cheapest, it was not chosen because of the remote possibility of crest damage under extreme storm events. The latter problem could not be investigated in more depth due to the limited time available for the design period.

Some of the characteristics of the finally selected main breakwater design (Alternative 2b) are:

- o The crest level at +5,1 m above Mean Sea Level allowed some overtopping and the leeward armour slope is thus protected by means of a secondary wave wall.
- o The main breakwater comprises of 45 000 cub metres of rock, 1 400 Accropodes and 3 000 cub. metres of concrete capping and wave walls.

The main works on the main breakwater were completed in 5 months. It was subjected to breaking waves (i.e. the design wave height) for a number of times during the construction period. The wave action during one of these occasions are shown in Figure 9.

FIGURE 9 : BREAKING WAVES ON MAIN BREAKWATER DURING CONSTRUCTION

A precast and placed cut-off wall designed to be finally part of the concrete capping, rendered significant protection to the structure against breaking wave attack during the vulnerable construction stages. Figure 10 shows the effectiveness of the cut-off wall protecting the vulnerable crest during construction against breaching. The completed main breakwater with concrete capping, wave walls and Accropode protection is shown in Figure 11.

FIGURE 10 : ILLUSTRATION OF PROTECTION PROVIDED BY CUT-OFF WALL DURING CONSTRUCTION

FIGURE 11 : COMPLETED HARBOUR WITH MAIN BREAKWATER ON LEFT SIDE

4.1.3 Secondary Breakwater:

The secondary breakwater is also of the conventional rubble mound type with 1 to 3 t primary armour on the seaward side (see Figure 12).

FIGURE 12 : SECTION THROUGH SECONDARY BREAKWATER

At commencement of construction of this breakwater it was found that the construction level (i.e. level at crest of rubble core at which the crane and trucks operated) had to be raised from the designed +1,4 m to +2,0 m above Mean Sea Level due to excessive damage experienced at the construction face.

Due to sediment accretion at the position of the secondary breakwater from the original -2,5 m contour and deeper (refer Section 4.1.4), the breakwater had to be founded on a higher level than the original seabed level. To prevent future undermining of the breakwater due to possible scour, a special toe protection on the seaward side was provided (see Figure 12).

The end of the breakwater comprises a 12 m caisson section built up of concrete box units filled with concrete after placement. The units were founded on a 1,3 m thick stone bed based at a dredged level of -5,8 m. The concrete box units were placed on aligned and levelled concrete pads with the void between the rubble foundation and concrete boxes being filled by tremie concrete contained in a filter cloth bag as shown in Figure 13.

FIGURE 13 : CROSS SECTION THROUGH SECONDARY BREAKWATER CAISSON END

4.1.4 Local Sediment Accretion and Erosion Patterns during and after Construction of Breakwaters:

The main breakwater was constructed first to provide protection to construction operations of other components in its lee. The construction progress (in months) of the breakwaters is indicated in Figure 14; the main breakwater was completed in 4 months after which construction of the secondary breakwater commenced.

Construction of the secondary breakwater was delayed when about half of its length was constructed (at month 7 of breakwater construction - Figure 14) due to a significant amount of sediment accretion encountered at the construction face. An attempt to remove the sediment by grab crane so that the breakwater could be founded on the original seabed level was not successful since accretion took place at the same rate as removal.

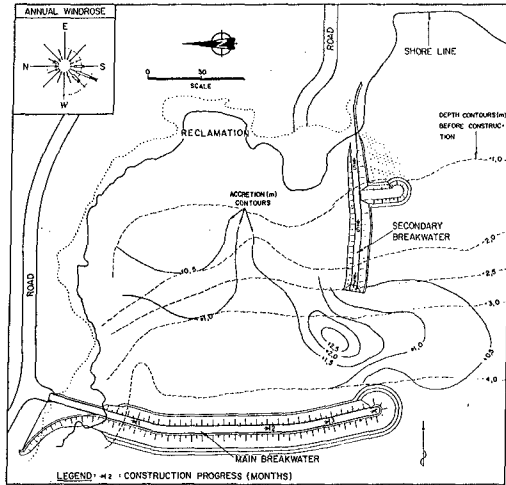

FIGURE 14 : CONSTRUCTION PROGRESS AND SEDIMENT ACCRETION DURING CONSTRUCTION

A hydrographic survey of the harbour area during this stage of construction indicated sand accretion that took place during construction as shown in Figure 14. Current measurements in the prototype during this stage indicated a rip current along the seaward side of the secondary breakwater causing sediment accretion in the area of the construction face.

Based on current measurements in the 3-D model of the harbour, it was decided to build a spur breakwater as indicated in Figure 14 to deviate the rip current so that the sediment accretion problem in the construction area as well as in the harbour mouth area could be limited.

The sediment accretion/erosion pattern 12 months after completion of the breakwaters is indicated in Figure 15. Erosion areas occurred at the end of both main and secondary breakwaters. Accretion occurred in the lee of the spur breakwater as well as in the harbour mouth area. The latter will necessitate periodic maintenance dredging estimated at about 15 000 m³/year.

4.2 Reclamation and Revetment

The reclaimed area (1,3 ha) as shown in Figure 3, was formed from 43 000 cub metres sand dredged from the harbour basin. The reclaimed area is edged with stone revetment at a 1:1,5 slope to reduce undesirable wave reflection. Where required, timber boardwalks mounted on concrete columns were provided for public access to the water's edges. Vertical guides fitted to these columns restrain the floating jetties installed next to the boardwalk. Figure 16 illustrates the revetment, boardwalk and floating walkways.

FIGURE 15 : SEDIMENT ACCRETION/EROSION AFTER CONSTRUCTION

FIGURE 16 : REVTMENT, BOARDWALK AND FLOATING WALKWAY

To prevent settlement of buildings founded on the reclaimed area, steep foundations of the buildings were founded on gravel piles (520 mm diameter; 19 mm stone; hammer compacted and spaced at 2 m intervals).

The timber boardwalk deck was constructed of untreated hardwood (Keruing) fixed with hot-dipped galvanized bolts and brass screws.

4.3 Floating Jetties

A floating walk-on jetty system comprised steelframed timber decking on polyethylene floats held by concrete gravity piles, was provided for boat moorings. The floats under the walkways were filled with polyurethane foam. The steel is protected after sandblasting with two zinc-rich base coats followed by two coats of polyachrothane paint. The floating jetty system is illustrated in Figure 17.

FIGURE 17 : FLOATING JETTY SYSTEM

Due to shallow rock substrata, concrete gravity anchor piles for the jetties had to be used. Three precast concrete rings, placed concentrically and the spaces between filled in situ, with tremie concrete, formed the gravity footing for the anchor piles (see Figure 18).

4.4 Launching Jetty, Boat Ramp

The yacht launching facility consists of two piers providing access for a mobile straddle carrier capable of launching yachts with a dry mass of up to 20 t. The two vertical walled parallel piers are constructed from precast concrete blocks on a rubble foundation.

A boat ramp is provided to enable the launching of motor boats on trailers with sufficient width to launch two craft simultaneously. The boat ramp consists of precast slabs on rubble fill below Mean Sea Level and in situ cast slabs above this level. The boat ramp slope is 1:8 and terminates at 2 m below Mean Sea Level.

FIGURE 18 : CONCRETE ANCHOR PILES FOR FLOATING JETTIES

Figure 19 shows the launching facility, boat ramp and fuelling/sewage pump-out jettie.

5. ACKNOWLEDGEMENTS

The authors would like to acknowledge the co-operation of the Client (Club Mykonos Langebaan Ltd) and the Contractor (Marine Civil (Pty) Ltd) during the execution of the project. This made it possible to successfully complete the project from design commissioning to completion of the works in 20 months.

CHAPTER 247

ARTIFICIAL BEACH NOURISHMENT ON NORDERNEY, A CASE STUDY

H. KUNZ

Coastal Research Station/NLWA-Forschungsstelle Küste
Norderney, Federal Republic of Germany

ABSTRACT

Norderney is one of the East Frisian Barrier Islands that extend along the western part of the German North Sea coastline (Fig. 1). Severe dune erosion jeopardized the health resort settlement on the west end of Norderney and necessitated the construction of solid coastal protection structures since 1857. These structures were successful in stopping the migration of the inlet and in preventing further dune erosion; but they were not able to maintain stable beaches. To protect the existing structures against damage artificial beach restoration was initiated on Norderney in 1951. Since then five further beach fills were necessary to affect an active protection by shifting the zone of wave attack seawards. The scouring from the groyne fields had been monitored. Based on these data the sand budget has been investigated. It has been proved, that on Norderney beach nourishment is an appropriate solution to protect the existing structures from failure during severe storm-floods. If we want to lower the amount of losses, we have to nourish the beach not higher than necessary to achieve the protection goals. Above a 'critical beach profile' in certain areas losses of nourished material increase considerably with height. Especially for the Norderney-case we should develop a 'low-cost-technique' for a 'low-rate-beach-nourishment'.

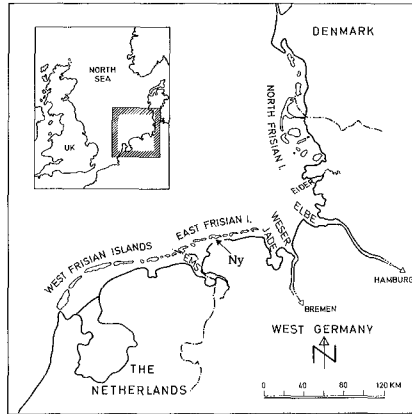

Fig. 1: Location map of the German North Sea Coast with Norderney-island (Ny)

INTRODUCTION

Like the other East Frisian Islands, the barrier-island of Norderney is formed by the coincidence of current, surf, wind (LÜDERS 1953). The migration of the islands has been well documented for the last three hundred years (FORSCHUNGSSTELLE 1964). During the two centuries, 1850 ago, the situation between Norderney and the island to its west had changed from two hydraulically equivalent inlets, separated by a small middle island, into a single inlet. This inlet shifted to the east, eroding the core of the west end of Norderney (HOMER 1964, LUCK 1975). In accordance with the changed hydraulic conditions the offshore sandbars were forced seawards and therefore the west end of Norderney was no longer sufficiently supplied with sand. The development can be explained by the connection between the tidal inlet and the tidal prism; the eastward migration of the affiliated catchment area located on the tidal flat has to be considered (O'BRIEN 1969, FITZGERALD et al. 1984a/b, BRUUN 1978, LUCK 1976).

In 1857, people started to construct a combined system of shore-parallel structures and groynes on Norderney to prevent further erosion. It was necessary to extend the groynes into deep water to a depth of almost twenty meters to prevent the ongoing shifting of the inlet channel. During one century the system of protective structures was extended to a length of six kilometers. Descriptions are given by FÜLSCHER (1905), BACKHAUS (1938), PEPER (1956), KUNZ (1987). The development of the city of Norderney into a seaside health resort provided economical justification for the investment.

Even the shoreparallel structures were successful in preventing further dune erosion and the groynes were able to keep away the strong tidal currents from the core of the island, they could not stop the scouring from the beach. As the beach level progressively fell, the toe-protection of seawalls and groynes had to be extended and strengthened several times. Because of World War II the structures were not well maintained during the nineteen-forties. The classical approach of toe protection had been reviewed by a special task group. As an alternative they recommended a restoration of the beach (ARBEITSGRUPPE NORDERNEY 1952). Thus the first artificial beach nourishment in EUROPE was implemented on Norderney in 1951/52. For the same reason five further beach fills were necessary up to now. This paper focuses on the development of the sand volume in groyne fields that ensure the safety of the structures. Results of volumetric calculations based on field data shall be presented and the question shall be discussed what we might learn from a feed-back to the monitored information concerning the technique of beach restoration on Norderney.

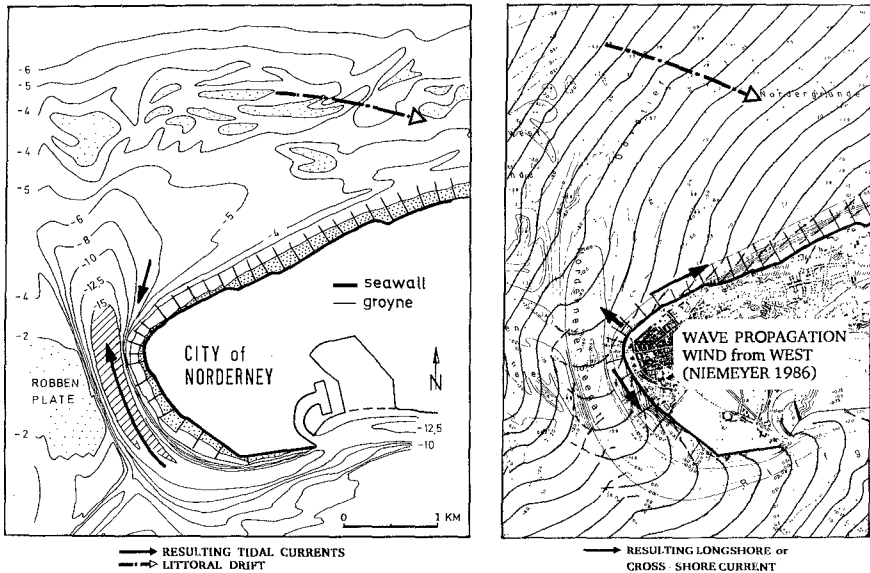

Fig. 2: Depth-contourlines, resulting currents and littoral drift (left); Wave propagation, resulting wave-induced currents (right) - Western spit of Norderney

BEACH RESTORATION SINCE 1951/52

The western spit of Norderney is displayed on Fig. 2. The left picture shows the depth-contour lines. The crescent shaped reefbow is dotted. The net littoral drift runs within the reef-bow from West to East. From time to time bars merge with the island, but only far from the western spit. For this reason there is barely sand naturally supplied to the western area. The hedged part of the tidal channel is more than fifteen meters deep. The groynes facing this part of the inlet are essential to govern the strong tidal currents. The MTR of 2,40 m leads to velocities of more than 1,50 m/s. There is a strong wave action predominantly from the west to northwest sector. An example for the wave propagation is shown in the right hand picture. The resultant longshore currents run bidirectional from an area located near the very western part. We address it as 'area of divergence'. This is the stretch where we have to face the greatest losses of sand and the strongest wave attack. Breaking waves generate high velocities in the groyne fields (NIEMEYER, 1990). The groynes which cover the easterly beach part as well as the other groynes, diminish the effects of longshore currents in the nearshore area. They are less effective the higher the water level is. The highest water level measured during storm flood (HHW) is three meters above MHW-level.

Fig. 3: Combined Protection System on Norderney-island

The combined protection system on Norderney is described by Fig. 3. Only the first artificial beach nourishment in 1951/52 covered the whole stretch.

The Fig. 4 gives some information on nourished volumes, on grain size and on literature. For the first nourishment the sand had been dredged from the tidal flat, where only fine material with a medium d_{50} of about 0,1 mm

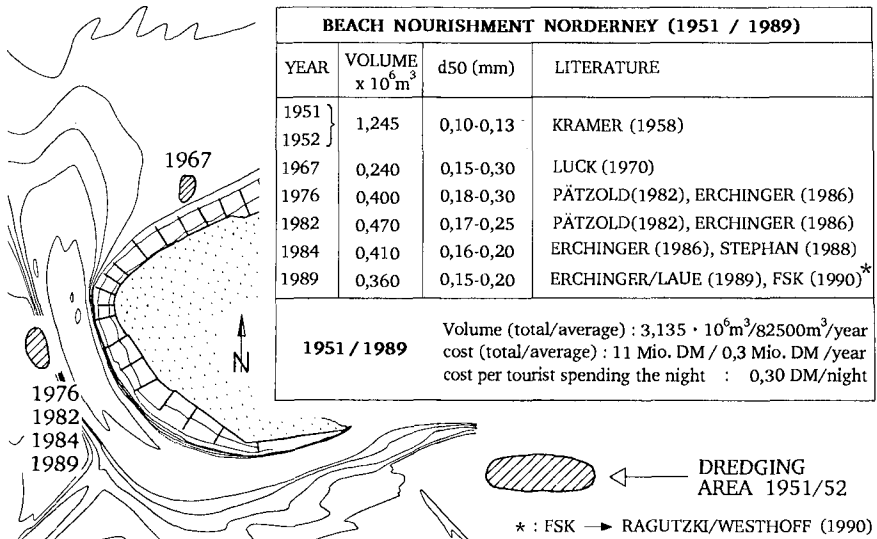

Fig. 4: Beach nourishments on Norderney (1951 to 1989)

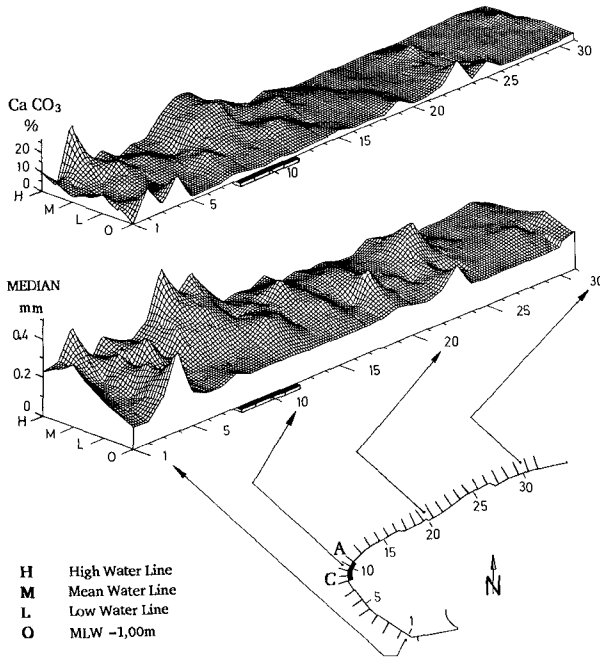

Fig. 5: Shell material and grain size in the groyne-fields of Norderney, Sept. 1987 - WESTHOFF (1990)

is available (KRAMER 1960, 1972). In 1967 the dredging of a relatively small amount of material with a medium d_{50} of about 0,25 mm was accomplished from a foreshore area (LUCK 1970). Since 1976, when the technique was available to cross the deep channel by submerged pipe-line, the sand was taken from an ebb shoal across the inlet. The material was less coarse, especially in 1989 with a medium d_{50} of about 0,17 mm (RAGUTZKI/WESTHOFF 1990). Since 1951 an average volume of 82500 m³ per year had been nourished.

The grain-size of the sand in the groyne-fields varies quite a bit. Fig. 5 pictures the situation in Sept. 1987. The convergence area (C-A) is marked by the solid line. The effects of sorting are obvious. The coarse material contains relatively more parts of broken shells, indicated by CaCO₃ (WESTHOFF 1990).

VOLUMETRIC CALCULATIONS AND LOSSES (1951 TO 1990)

As mentioned before, the paper is restricted to volumes to give an idea of the losses out of the vulnerable part of the groyne fields with time. The calculation focuses on the beach area where we definitely do need beach restoration for the purpose of securing groynes and shoreparallel

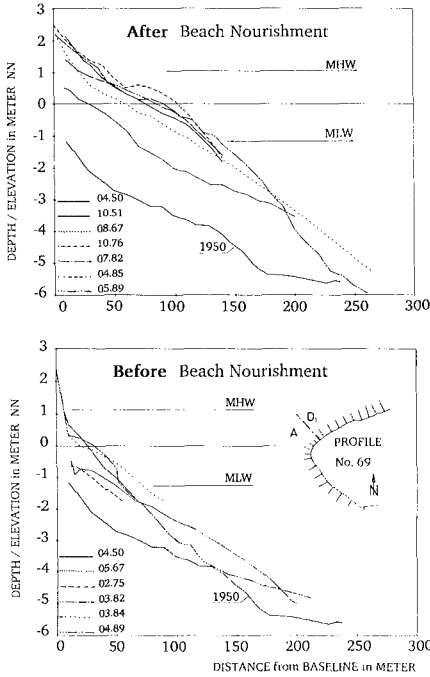

Fig. 6: Beach-Profiles in the groyne-field (A-D₁)

Fig. 7: Volumes above the 1950-Reference-Profile and the NN -1,50 m -level (ΔV) of five selected groyne-fields - Western spit of Norderney, 1951 to 1990

structures against failure during storm floods. To meet this target the volume calculation can be restricted to the beach part above NN -1,50 m - level, that's about MLW. This practical engineering approach is appropriate. There will be no discussion on the complicated cross- and longshore processes within enlarged boundaries.

An example for the monitored beach profiles is mapped on Fig. 6. Since the preliminary aim of the survey has been to monitor the vulnerable part of the seawall - and groyne - system, only some of the profiles extend deeper than MLW (STEPHAN 1988). The lowest profile is that of 1950, just before the first beach-restoration. We use the 1950-profile, specifically for each groyne field, as a 'reference profile' for the volumetric calculation. A restored beach would at least reach this profile if we would'nt nourish. From the lower picture we can see that the beach nourishments started off from different heights. The upper one depicts the different profiles just after the beach restoration. If we would plot the shape of the groyne into the picture, it almost would envelope the highest profiles (type of low lying groynes).

In the following, the volume-data always will be addressed as ΔV with unit cubic-meter per meter shoreline

(m^3/m). The accuracy of the volume calculations has errors within the range of $\pm 7,5\%$. The used field data for the profiles have been provided by STAIK (agency for island and coastal protection, Norden) and FORSCHUNGSSTELLE KÜSTE (research station, Norderney).

We can not expect to define a groyne-field that provides representative conditions for the whole six-kilometer stretch. The development of the volume (ΔV) over time is to be seen from Fig. 7. The field A-D₁, discussed above, is placed almost in the middle. Since it is located near the 'divergence area', each beach-nourishment indicated by the vertical solid lines, is to be recognized clearly. The deviation from the rectangular line in 1976 is an exception: the profiles after the nourishment had been monitored six month later. With greater distance from the 'divergence-area' the ΔV -graph is less immediate determined by the nourishment. The picture for the groyne-field P₁-Q₁ shows effects of sand supply from the reef-bow-bars that merged further to the East. The picture for groyne-field N-M displays an almost constant ΔV -curve, whereas the nearby-lying groyne-field G-F is obviously impacted by sand arriving from nourished parts. In general it seems to be justified to distinguish the period before 1976 with relatively moderate beach-volumes and the time after 1976 with comparably higher rates of beach nourishments. The 1967-restoration was weak and had almost no impact on the ΔV -curves. This contrast to data published by ERCHINGER (1986) can be explained by different boundaries fixed for the volumetric calculations.

1951 to 1976 is the only long-time period we can look at. The beach-nourishment of 1967 can be neglected, since it had almost no effect, that would interfere. Fig. 8 indicates how the volume (ΔV) of the divergence-area A-C decreases rapidly after the 1951-beach-nourishment. The curve does not seem to follow a kind of exponential-function (AUSSCHUSS KÜSTENSCHUTZWERKE 1977, 1988, FÜHRBÖTER et al. 1976, PÄTZOLD 1982). There are ups and downs in the ΔV -graph that might be caused by storm-surges. To prove this expectation, the storm-surge-duration and the number

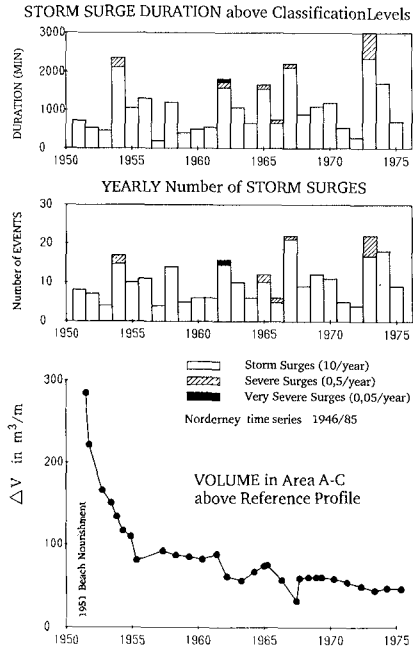

Fig. 8: Storm Duration, Number of Storm Surges, Volumes in area (A-C)

Fig. 9: Volume (ΔV) plotted over time and approximation by exponential functions. Left: 1951 to 1976. Right: periods after the nourishments of 1951, 1976, 1984, 1989

of storm-surges per year are plotted above. If we look at it carefully, we hardly will find a significant correlation; investigations on a much smaller time-scale are needed, if we want to describe the impact of storm-surge and wave action on profiles and on volumes (HOMEIER 1975). However, if we calculate and integrate wave-energy over time, we can get a relationship to the losses (PÄTZOLD 1982).

Plotting the volume ΔV against time in a semi-logarithmic scale, we come up with the results shown in Fig. 9. The elapsed time after beach-nourishment (first volumetric data) is indicated by 't'. Left hand again we have the period from 1951 to 1976. We have to distinguish at least two periods if we want to approximate by e-functions: a first one over 5 years from 1951 to 1956 and a second one for the following years. The two solid lines give the approximations (ΔV_I and ΔV_{II}). The exponent of the e-functions lead to 'half-times' of 6 years, respectively 37 years. After these time periods we have lost 50% of the nourished volumes through the fixed boundaries: in cross-shore-direction into deeper parts of the beach and in long-shore-direction across the groynes.

For a time-period of 60 months we adjusted data of different nourishment-periods to a fixed scale representing the average conditions of the used periods. The results can not be compared directly with those published by PÄTZOLD (1982). The data from the 1982 beach-nourishment have been skipped; there are only two years to the nourishment and the losses are not well documented. Instead of this, the much better data from the 1989-nourishment have been used; the ΔV -function seems to behave quite similar to that one after 1982. The weak 1967-nourishment had only little impact on the ΔV -curve, as mentioned earlier. Again, the linear approximation is given in the semi-logarithmic scale. The exponent stays for a 'half-time' of 29 months. There is a substantial scattering but taking into account the different conditions (nourished material, profiles, tides, waves) we should not expect more.

From Fig. 9 we learn, that we can't describe properly the volume ΔV over the whole time-period by only one exponential function: If we use several different e-functions, the 'half-time (t_h)' of those would increase with the elapsed time (t). This leads to the non-exponential approximation as shown in the upper part of Fig. 10. The exponent of ΔV_{III} is a function of the elapsed time (t) after beach-nourishment: $t_h(\Delta V_{III})$. From this we come to the 'half-period' as function of 't' - shown below. The e-functions, as described before, are plotted into the distinguished time-periods for comparison-purpose: for the first 60 months this is $t_h(\Delta V_I)$ and $t_h(\Delta V_{60})$; the graph $t_h(\Delta V_{II})$ is representative for the time beyond the 60 months. Again, the graphs highlight that we face substantial errors, if we extrapolate a constant 'half-time' - for example from the fixed time boundaries in Fig. 10 (dotted vertical line).

We can convert the elapsed time into volume ΔV and come up with a curve as shown in Fig. 11. On the vertical axis again the 'half period t_h ' in months; on the horizontal axis the volume ΔV . We can take this volume as nourished volume above the reference profile, landwards the fixed NN -1,50 m boundary. The curve (1) points out, how sensitive the 'half-period' reacts on the volume placed above the reference

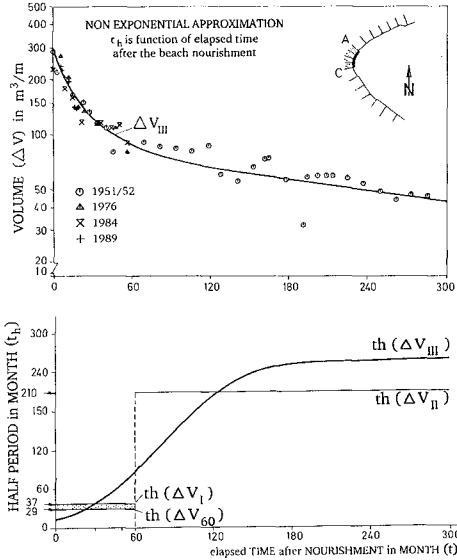

Fig. 10: Non exponential Approximation for ΔV versus time in semi-logarithmic scale (ΔV_{III}) Half-Period as function of elapsed time $t_h(\Delta V_{III})$ - Norderney (A-C)

Fig. 11: Half Period and Rate of Erosion as function of nourished Volumes - Norderney, divergence-area (A-C)

profile. The rate of erosion (2) increases with decreasing half-period.

We draw as results:

If possible, we should nourish the divergent area, which determines the beach restoration-procedure, not more than 70 m³/m. In other words: we should stay in the 'L-area'. If we exceed out of the L-area the 'half time' decreases substantially with volume. This area is indicated as J. Beyond 120 m³/m the half-time gets almost constant; losses increase linear with volume.

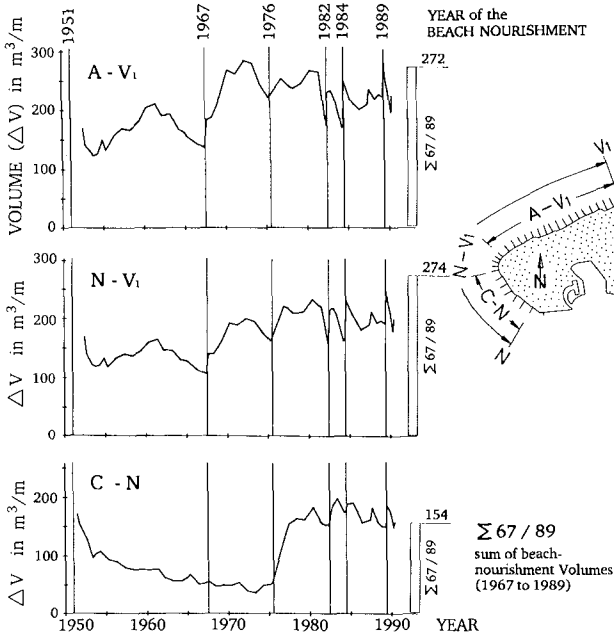

Fig. 12: Volumes (ΔV) - Norderney 1951 to 1990

Figure. 12 leads back from the 'convergence area' to the whole armoured stretch, to get an idea, how the volumes of groyne-fields on both sides of the 'convergence-area' change and how they benefit from the losses out of that area. The upper curve indicates the volume in m³/m in area 'A-V₁'. We use the same seaward boundary conditions as described earlier. The graph on the bottom is for the area 'C-N'. The curve in the middle stands for the whole stretch - that is 'N-V₁'. The beam on the right side of each picture indicates the total volume of sand in m³/m placed into the groyne fields after the first beach nourishment. If we compare the sum of nourished volumes (Σ67/89) with the difference between the 'actual ΔV' and the 'ΔV before the 1967-nourishment' we can conclude, that

almost none of the material is left. The upper picture indicates, that from 1968 to 1973 substantial sand supply must have been provided by sandbars that arrived at the beach eastwards of the groyne-fields. To address the impact of beach nourishment on the ΔV it is favorable to brake the time into two distinct periods: one 'from 1951 to 1976' and another one 'from 1976 to 1990'. Comparing the areas it is obvious, that since 1976 the average volume-level is significant higher than it had been before. With the effort of beach nourishment every 2 to 6 years a kind of volume-equilibrium is obtained, that seems to range on a higher level than needed. This encourages to look into the addressed problems, to answer the question whether we can go along with a lower volume-level, which would us enable to decrease beach nourishment-volumes substantially.

FINAL REMARKS AND CONCLUSION

The western spit of Norderney is endangered because: there is a natural tendency of the inlet to shift eastwards to the island, there is a negative sand budget, there are storm surges up to more than 3 meters above MHW-level and strong wave-induced currents.

To protect Norderney, a combined system has been established since 1857. It consists of three components
shoreparallel structures
groynes with two different purposes
groynes to keep away the strong tidal currents from the core of the island
groynes to stabilize the beaches
artificial beach nourishment.

By storm surges in combination with waves the beach-profiles on Norderney are lowered, especially in front of the shoreparallel structures and groynes. Artificial beach nourishment is an appropriate solution to protect the existing structures against damage.

To achieve the protection goals we must ensure, that the beach area above MLW-level is considerably higher than the 'natural beach' would be without beach-restoration. Calculations of the beach volumes above the dynamic natural equilibrium profiles (approximated by 'reference profiles') on a long term time-period (1951 to 1990) led to relationships between the losses of nourished sand and beach volume. Above a 'critical beach profile' the losses of fulfilled material increase considerably with height (divergence area). The losses over a long time period can be calculated by an exponential function, if we use an exponent that itself depends on volume, respectively time. The function represents the average conditions that be-

sides the volume-parameter have an impact on the losses; different diameter and shape of the nourished sand and the initial profiles of the beach restoration as well as wave-energy lead to random scattering or temporary to different tendencies compared to the approximation-function. However, if we look at a long term time scale the losses out of the most vulnerable part of the Norderney-protection-system mainly depend on the calculated volumes within the fixed boundaries. If we want to lower the amount of losses, we should nourish the beach not higher than necessary to achieve the protection goals.

The efficiency of the groyne in the 'extended divergence area' against wave-induced longshore currents seems to account for one of the major reasons of this result.

We should try to approximate the natural beach slopes; however it seems to be essential that we nourish sand not finer than the natural beach.

It appears advantageous to nourish only the area from which the longshore currents are bidirectional (area of divergence) with a limited extension to the East. From the nourished area sand will be moved naturally to both directions (feeder beach).

We should try to get experience with a deposit of sand in the foreshore-area of the easterly part of the 'extended divergence area' in combination with lower beach profiles in the area above MLW-level.

We have to look after a 'low-cost-technique' for a 'low-rate-beach-nourishment' on Norderney (KRAMER 1960). The comparison of low- and high-rate beach-nourishments will bring us to the cost-benefit-optimum.

Since the beach restoration on Norderney is part of the 'Coastline Defence System', the costs are paid by Federal and State. The enhancement of the recreational features of the beach is a welcome side-effect. Because Norderney is a highly frequented recreational beach area, there is an immediate demand for beach restoration after severe storm floods. However, we have learned that there can be a substantial amount of natural beach replenishment. There may be major savings in the cost of beach nourishment by postponing the decision on the design and quantity of sand to be placed on the beach, until the major quantity of the natural replenishment has occurred.

ACKNOWLEDGEMENT

This study is part of an interdisciplinary research-programme sponsored by the GERMAN FEDERAL MINISTRY FOR SCIENCE AND TECHNOLOGY (BMFT). The author is grateful for the support he got from his colleagues at the COASTAL RESEARCH STATION, NORDERNEY.

CHAPTER 248

DESIGN AND INSTALLATION OF SCOUR PROTECTION FOR THE ACOSTA BRIDGE

Billy L. Edge¹, David K. Crapps²,
J. Sterling Jones³ and William L. Dean⁴

ABSTRACT

The Acosta Bridge is located in a bend at a natural constriction of the tidally influenced St. Johns River. This natural constriction has resulted over time in scour of the river bottom resulting in present water depths up to 80 feet. The Acosta Bridge is presently being replaced with a new bridge. The existing bridge is located immediately adjacent to a railroad bridge and both bridges are on caisson foundations. Divers have reported that penetration of the foundations for one of these existing bridges is as little as two feet. Construction of the replacement bridge will increase the scour potential. Therefore, scour protection had to be provided not only for the replacement bridge but the two existing bridges. The scour protection for the existing bridges was completed in 1990. The replacement bridge is under construction and scour protection is being installed as the piers are constructed.

INTRODUCTION

The Acosta Bridge, as shown in Figure 1, is located in a bend of the St. Johns River at a natural constriction of the flow. This natural constriction has resulted in scour of the river bottom which is considerably deeper than at other sites in this part of the river. Another important aspect is the proximity of the existing Acosta Bridge piers to the piers of the railroad bridge. It is obvious that the proximity of the two sets of bridge piers in this tidal area creates local scour beyond that which would normally be encountered were there only one set of bridge piers. The bridge piers in the center of the river of the existing Acosta and railroad bridges and the new Acosta bridge are shown in Figure 2. It is noted that the bottom topography and the bend in the river causes the stream flow to be helical and therefore it is difficult to define the flows in this part of the river accurately.

The St. Johns River is very flat and the tidal prism extends over 100 miles upstream from the

Figure 2. Plan View of the Acosta and Railroad Bridge Piers

bridges. The most severe storm conditions of record were during Hurricane Dora in September 1964. At that time there was an estimated flow of approximately 244,000 cfs downstream and 204,000 cfs upstream with a maximum stage at about elevation 5.2 MSL. The adjacent stream banks are at about elevation 6 MSL.

In the shallow water area of the site there is a sand layer varying in thickness from about 2 to 10 feet. This thin upper sand layer is highly erodable. The sand layer is underlain by a layer of lime rock varying in thickness from about 10 to 20 feet. Below the lime rock is marl that extends to great depth below the bottom of the channel. The marl erodes more easily than the lime rock. When the marl erodes it eventually leaves an overhang of lime rock which subsequently falls to reform a smooth channel slope. Figure 3 shows a survey that was made in 1924 and a recent survey of the area made in 1986. This figure shows that there has been approximately 20 feet of scour during this 62 year period. The largest amounts of scour occurred in the deeper parts of the river cross section. It also appears that geomorphologically the channel is migrating to outside of the bend in the river at the site. Similar scour has been observed at other bridges in the area.

ANALYSIS OF SCOUR

The scour which occurs in this part of the river can be considered as the cumulative effect of general scour and local scour. "General scour" results from a net reduction in the cross-sectional area of the river when additional bridge piers are added. The addition of obstructions or piers in this case results in an increase in the velocity of flow. This increased velocity in turn causes scour. The general trend is for erosion to continue until a stable channel is established. General scour usually increases with an increase in water depth according to Christensen and Bush (1971).

To determine general scour the procedure referenced in Christensen and Bush (1971) was followed. Dr. Christensen used this approach to provide the necessary general scour coefficient for the Acosta Bridge site which is shown in Figure 4. The existing Acosta Bridge as well as the range of pier widths considered during the preliminary design phase are also shown in Figure 4. To obtain the ultimate general scour the following relationship was used:

$$d_{gs} = c_{gs} (d^2)$$

where d_{gs} = depth of ultimate general scour in feet
 c_{gs} = coefficient of ultimate general scour from
 Figure 4
 d = water depth in feet

The construction of additional piers in the river for the new Acosta Bridge will create general scour that will adversely impact the existing Acosta and railroad bridges unless proper precautions are taken. This is particularly true for the deep water piers located in the marl (Acosta Bridge Piers 6, 7, and 8 and railroad piers 8, 9 and 10). Assuming that the total sum of pier widths added is about 200 ft, the general scour coefficient from Figure 4 is .0028. For different water depths, Table 1 summarizes the estimated general ultimate scour, estimated scour after three years (the time expected for construction of the new bridge and removal of the old bridge) and the minimum present footing depth below the river bottom.

Figure 3. Profiles Across the St. Johns River in 1924 and 1986 at the Acosta Bridge

Figure 4. General Scour Coefficient for Acosta Bridge Site on St. Johns River

TABLE 1
SCOUR SUMMARY FOR DEEPWATER PIERS IN MARL

Pier #	Average Width ft	Shape ft	Original Water Depth ft	Actual Scour ft	Estimated Ultimate Scour ft	Estimated Time To Ultimate Scour years
6	12.0	circular	54.2	15.8	31.2	32,700
7	12.0	circular	60.0	26.0	32.8	330
8	12.0	circular	52.2	16.6	30.7	14,600
9 (RR)	17.8	rectangular	61.5	23.3	55.5	448,100

The table shows that the estimated scour after three years is below the foundations for the Acosta piers 6 and 7 and railroad pier 9. These data predict likely pier failure for both bridges due to general scour alone if steps are not taken to protect the deep water piers. Similarly it can be shown that the construction of new foundations for the replacement bridge will cause local scour and most likely cause pier failure for both bridges if adequate steps are not taken for protection.

Addition of bridge piers in the cross-section creates a local obstruction to flow as well. The flow divides in front of the pier and the velocity increases as it flows around the pier. A system of vortices develop around the pier which are generally described as a horse-shoe vortex (Breusers, Nicollet and Shen, 1977). The combination of increased velocity plus the vortices form to create an environment for scour in the vicinity of the pier which is commonly termed "local scour". The local scour depth and the width to the affected area increases both with the width of the pier and with the depth of the water. It has been determined that the shape of the pier is also very important in determining the depth and extent of the local scour. Likewise the presence of other piers or structures have a very important role in local scour.

The total amount of scour is the sum of the general scour and local scour. In this analysis it was assumed that general scour is complete and that the local scour is superimposed for the ultimate conditions.

To determine local scour several procedures were considered. One procedure used a complete set of velocity profiles taken in 1962. These raw data taken by the USGS at the Main Street Bridge were analyzed to develop a velocity profile at the Acosta Bridge site. The Main Street Bridge is approximately one-half mile downstream from the Acosta Bridge. Based on all the analyses it was decided that the maximum flow during the 100-year storm would have an average velocity of 6.2 fps on both flood and ebb conditions.

Initially, it was decided that stone riprap should be used for general and local scour protection. The method of Isbash as reported in Bruesser, Nicollet and Shen (1977), Blodgett and McCaughy (1983) and ASCE (1975) was used to calculate the minimum stone size. The formula was originally proposed by Isbash in 1936 for the construction of dams by dropping rock into a flowing stream. The size of the stone was then modified to take into account the slope of the bank and the curvature of the channel. The Isbash equation is frequently given in the following form:

$$W = \frac{4.1 \times 10^{-5} G_s V^6}{(G_s - 1)^2 \cos^3 \phi}$$

in which W = the weight of the stone in pounds
 G_s = the specific gravity of the stone
 V = velocity
 ϕ = angle of the bank

Typical results with this approach yielded stone size for general scour protection on the flat slopes of 0.4 feet in diameter. On the steeper slope of 1.3h:1v, the required stone diameter increased to 1.5 ft. For local scour, required stone sizes varied from 1.2 ft in water depths of 30 ft to 4.5 ft in water depths of 80 ft. Considering a minimum protection of two layers of stone plus bedding stone the thickness of the bottom scour protection is such that in itself it will cause an increase in the general scour and possibly increase flooding in Jacksonville during design conditions.

PHYSICAL MODEL

Since there was not time to develop a full three dimensional tidal model a unidirectional movable bed model was done for this project by the Federal Highway Administration. The purpose of the model was to develop further confidence in the analytical results and to further understand the interrelationship of the pier structures on the local scour. Undistorted wooden scale models of the pier configurations were placed in a sump filled with sand within the flume. The model scale was restricted by the size of the flume. The scale of 1:50 was based on a maximum flume flow depth of about 1.25 ft and a river depth of 70 ft. The actual bathymetry in the river was not reproduced in the model. The appropriate model ratios are listed below:

<u>Parameter</u>	<u>Ratio</u>
length	50:1
velocity	7.1:1
unit flow	354:1
riprap size	50:1

Since the flume was only 6 ft wide the full river could not be modeled at any given time. The available sand at the laboratory was used as the movable bed material. However, no specific specifications were given to the sand to insure that it would quantitatively model the depth, time rate or extent of scour. The approach to the sump in the flume was plywood with sand glued to the surface to provide continuity of bottom roughness. There was no mechanism for recirculating sand therefore the bed shear stress, t_o , was kept near the critical shear stress value, t_c . For higher values of shear stress, sand would wash out of the sump. With an upstream supply of sand, the scour holes would fill as fast as scouring occurred once equilibrium was reached. The flow rate used in the experiments was determined from the minimum flow at which sand particles began to move under the maximum depth of flow. After the threshold flow was determined a pier was placed into the sand and the time for full development of the scour hole was measured.

Flow in the flume was unidirectional unlike the flow in the prototype. The model bridge piers

were therefore placed so that the flow traveled in the tidal flood direction. The bridge piers were also altered so they could be aligned with a flow approach direction of 15 degrees from normal to account for the bend in the St. Johns River at this location. Results from the model gave upstream and adjacent velocity profiles as well as the extent of scour. Results from these model tests showed that generally the maximum velocity by the bridge piers was approximately 1.4 times the approach velocity. The hydraulic model study also concluded that stone riprap with 1.5 ft diameter and a specific gravity of 2.65 would be satisfactory with a stability factor of 1.2 for local scour protection.

DESIGN

Since the St. Johns River is tidal at the Acosta site, scour protection design had to consider both upstream and downstream bridge piers. Initially riprap protection from general scour and local scour was considered. The size of stone was calculated using an approach velocity of 6.2 fps for the design conditions of a 100 year storm. These calculations indicated a stone size of approximately 4.0 feet. The steep side slopes of the channel which approached 1:1 would require even larger stone. The stone would need to be placed upon an appropriate filter which would be difficult to install considering the deep water, high currents, poor visibility and limited bridge clearance at the site.

Because of the large sizes of stone required for traditional riprap protection around the bridge piers it was decided that an alternative form of construction should be considered. The selected alternative was gabion wire baskets. These baskets when tied together form a blanket which holds smaller stone in place and which can have a filter integral to the installation. Individual gabion baskets can be wired together into large units to be placed on the bottom. These units can then in turn be laced (wired) to other units to create a continuous layer of protection across the bottom in the areas where local scour protection is required.

The final gabion design was developed based on Agostini et al. (1985). The structure included two layers of 9 inch mattresses. The baskets were filled with stone with the following gradation:

<u>Weight</u>	<u>% Finer Than</u>
11 lb	100
6.2 lb	50
1.3 lb	0

Filter fabric was in the bottom of the upper mattress layer. The layout for the existing Acosta and railroad bridges is shown in Figure 5. This layout will be connected to and become part of the scour protection for the new Acosta Bridge which is under construction. To minimize the effects of corrosion the wire mesh baskets were first galvanized and then coated with PVC. All tie wire was also galvanized and coated with PVC.

Two other bridges have also used similar techniques as alternatives to armor stone. The most recent was the Kalamazoo River Bridge in Michigan (personal communication with David Parsh of C-Way Construction, 1989). A very similar project was completed at the Vendee Bridge which crosses Loire River in Nantes, France. Although the conditions were not tidal on the Loire River, the combination of general and local scour posed a serious threat to the safety of the bridge (Officine MacCaferri S.p.A., 1983). Soon after construction was completed in 1982 a 100-year flood occurred on the Loire River and the scour protection performed satisfactorily.

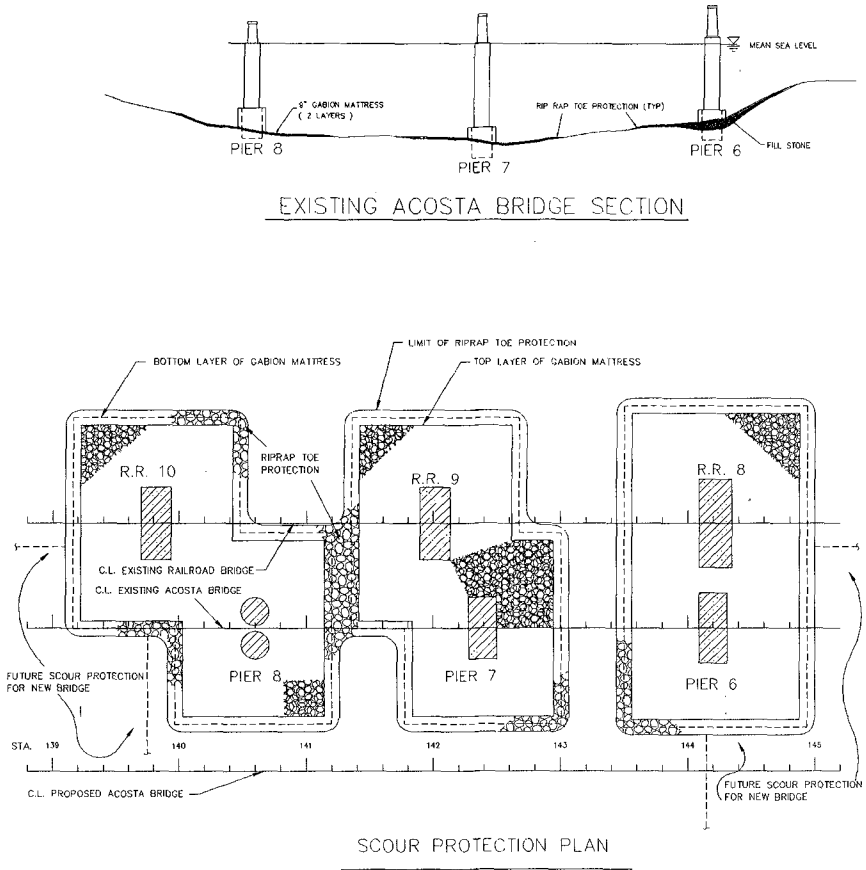

Figure 5. Plan of Scour Protection for Existing Acosta and Railroad Bridges

CONSTRUCTION

The individual mattresses of 6 feet by 18 feet were laced together on land and filled with stone on a barge before being placed. Special placement barges were fabricated by the Contractor to handle large sections of mattresses placed together to form a single unit 18 feet by 36 feet. Figure 6 shows the mattresses on the support barge and Figure 7 shows the special placement barge and the 18 ft by 36 ft unit being transferred from the support barge to the special placement barge. Note that the placement barge had to be partly submerged to maneuver and place the mattress assembly beneath the low railroad bridge. This was accomplished by transferring the assembly from the crane to the placement barge which was then winched by anchor cables to the proper location. In order to secure an adequate foundation for the mattresses side scan sonar and detailed bathymetric surveys were made to identify areas which were too steep to support the mattresses, to identify debris on the bottom which would have to be removed and to identify other obstructions which the mattresses would have to accommodate through construction or modification of design. In areas that were too steep for the mattresses to lay properly, stone fill was added to bring the slope up to at least 1v:1.5h and generally 1v:2.0h. Placement of the mattress assemblies and subsequent lacing underwater was made doubly difficult by the high tidal currents which although generally less than 2 feet per second occasionally exceeded 4 feet per second and the turbid water which limited visibility to a maximum of 4 feet and generally 12 inches with occasions of zero visibility. The placement was completed in August 1990 in time for construction of the new bridge piers.

SUMMARY

Scour protection was designed and installation completed for two existing bridges on the St. Johns River. Scour protection was designed to accommodate a 100 year design storm with a flood elevation of approximately 6.0 feet. This is the largest known tidal deep water installation for this type of protection. Coordination of the design and execution of the construction in adverse conditions was a challenge to all concerned.

CHAPTER 249

Influence functions

H.G. Wind¹

Abstract

Influence functions combine part of the strong body of coastal engineering knowledge, the one-line theory, with the most reliable sources of data: position of the shoreline and geological information about the evolution of the shoreline. Influence functions yield a model of the shoreline erosion or -accretion, which is based upon the characteristic length $\sqrt{4at}$. This model can be used to reproduce the present shoreline and predict the changes of the shoreline after human interference. Examples are given of the Petrace delta in Italy and the port construction near the Kelantan Delta in Malaysia.

1. Introduction

Engineers must provide reliable answers based upon unreliable data. Coastal engineers are no exception to this rule. At the start of a project they are faced with scanty wave data, unreliably or lacking bathymetric data and hardly any information on sediment yield of rivers. They have knowledge about the processes which take care of the longshore distribution of sediment. Clients however often have restricted time and money for the required advice. On these cross-roads the influence functions were born.

The first step on the mathematical modeling of curved shorelines has been made by Pelnard Considère (1956). He showed that the shoreline evolution could be described by the diffusion equation. This theme has been elaborated by various investigators e.g. Walton (1979), Grym (1960,1964) and Bakker and Edelman (1964).

¹Professor of civil engineering, University of Twente, P.O. Box 217, 7500 AE Enschede, The Netherlands, Scientific advisor of Delft Hydraulics.

The application of the diffusion equation in engineering practice is often hampered by the fact that at the initial stage of the project the wave data is not available and in a later stage of the project that both wave data and sediment transport formulae appear to be somewhat unreliable. In the present study therefore a slightly different approach has been taken. A framework of analysis has been set up in which various sources of geological and geophysical information can be combined in the morphological study.

In chapter 2 the theory behind the diffusion equation is explained. Influence functions and some applications are worked out in chapter 3. A large scale study, dealing with the Kelantan delta, is presented in chapter 4, followed by a summary and conclusions.

2. Theory

Consider a stretch of beach as shown in Figure 1.

Figure 1: Definitions

It will be assumed that the time scale of changes in the beach profile in the direction normal to the shore is either much shorter or much longer than the time scale of changes in the direction parallel to the coast. This allows for the approximation of a parallel displacement of the beach profile. Furthermore it will be assumed that in all profiles similar sediment transport processes are taking place. Along the beach this leads to parallel depth contours allowing for simple refraction computations. The erosion or accretion depth h is assumed to be constant along the beach. The continuity equation for the sediment transport S then reads:

$$\frac{\partial S_x}{\partial x} + \frac{\partial S_y}{\partial y} + h \frac{\partial y}{\partial t} = 0 \quad 2.1$$

In this study only sedimenttransport induced by wave driven longshore currents will be regarded. The effects of tidal currents on the sediment transport will be ignored. A similar restriction can be found in the work of M. Blosset (1935), where he presents the original conclusions, which form the basis of the famous 1956 Pelnard Considère study. The conclusions of Blosset were obtained from the morphological model studies of the port of Abidjan in Delft Hydraulics.

An important parameter in wave driven longshore transport is the angle ϕ_b between the wavecrest at the breakerline and the local depth contour (see Figure 1). The angle ϕ_b can be expressed in terms of the angle ϕ_o , (angle between the wavecrest and the positive x-axis) and $\partial y/\partial x$, (the angle between the shoreline and the positive x-axis) by:

$$\phi_b = \phi_o - \partial y/\partial x \quad 2.2$$

In the present study it will be assumed that ϕ_o and $\partial y/\partial x$ are sufficient small, such that the longshore transport S may assumed to be equal to S_x and that S_y can be neglected ($S_y \ll S_x \approx S$). In the discussion in chapter 5 this point will be taken up again.

Noting that with the chain rule $\partial S/\partial x$ can be expressed as $\partial S/\partial \phi_b = \partial S/\partial \phi_b \cdot \partial \phi_b/\partial x$ it follows from formulae 2.1 and 2.2 that:

$$a \frac{\partial^2 y}{\partial x^2} - \frac{\partial y}{\partial t} = 0 \quad 2.3$$

in wich

$$a = \frac{1}{h} \frac{\partial S}{\partial \phi_b} \quad 2.4$$

3. Influence functions and applications

3.1 Influence functions

Pelnard Considère (1956) has presented solutions of the diffusion equation 2.3 for the accretion near a breakwater and sediment passing a breakwater. Furthermore Pelnard Considère obtained a solution describing the behaviour of

a replenishment. These solutions are reproduced in Table 1 (see also Bakker, 1964).

	accretion near breakwater river delta 	sediment passing a breakwater 	sand replenishments 	definitions
y	$\text{tg } \phi \sqrt{\frac{4at}{\pi}} F(u)$	L G(u)	$\frac{1}{\sqrt{\pi}} \frac{Q}{\sqrt{4at}} H(u)$	$F(u) = e^{-u^2} \cdot u \sqrt{\pi} G(u)$
$\frac{\partial y}{\partial x}$	$\text{tg } \phi G(u)$	$\frac{2}{\sqrt{\pi}} \frac{L}{\sqrt{4at}} H(u)$	$\frac{2}{\sqrt{\pi}} Q u H(u)$	$G(u) = 1 - \frac{2}{\sqrt{\pi}} \int_0^u e^{-u^2} du$
$\frac{\partial y}{\partial t}$	$\text{tg } \phi \frac{1}{2t} \sqrt{\frac{4at}{\pi}} H(u)$	$\frac{1}{\sqrt{\pi}} \frac{L}{t} u H(u)$	$\frac{1}{\sqrt{\pi}} \frac{Q}{\sqrt{4at}} \frac{1}{t} (-\frac{1}{2} u^2) H(u)$	$H(u) = e^{-u^2}$

Boundary conditions $x = 0 \quad S = \text{constant}$ $x = 0 \quad S = 0$ $x = 0 \quad S = \text{constant}$
 $x = \infty \quad S = 0$ $x = \infty \quad S = \text{constant}$ $x = \infty \quad S = \text{constant}$

Table 1: Influence functions

As shown in Table 1 the solutions of the diffusion equation can be regarded as representing the influence in longshore direction of sources and sinks on respectively the shoreline displacements y, shoreline rotation $\partial y/\partial x$ and rate of displacement of the shoreline $\partial y/\partial t$.

It will be shown that complex morphological systems can rather simply be expressed in terms of influence functions. This expression can then be used to obtain an estimate of the parameter $\sqrt{4at}$, describing the shape of the shoreline, based upon a characteristic dimension of the existing shoreline.

The approach is based upon the property of the linear diffusion equation, that the superposition of two solutions of the diffusion equation forms a new solution of the diffusion equation. However this is only true if the boundary conditions for both initial solutions are also satisfied by the superposed solution.

3.2 The riverdelta consisting of one river

The evolution of a river delta, dominated by wave driven longshore transport, can according to the solutions given in Table 1, be described by

$$y = \text{tg } \phi \sqrt{\frac{4at}{\pi}} F(u) \tag{3.2.1}$$

where ϕ is the angle between the incoming averaged wave field and the shoreline. The influence of the individual source on the displacement y of the shoreline at a distance x can be expressed in dimensionless terms, by

rearranging 3.2.1, dividing by the distance x and noting that $u = x / \sqrt{4at}$.

$$\frac{y}{x \operatorname{tg} \phi} = \frac{1}{\sqrt{\pi}} \frac{1}{u} F(u) \tag{3.2.2}$$

The expression 3.2.2 is shown in Figure 2.

Figure 2: Influence functions

As can be seen from Figure 2 the influence of the source on the shoreline displacement is reduced to 10% of the displacement at the source at a distance of about $0,85 \sqrt{4at}$. It is interesting to note that a similar influence on $\partial y / \partial x$, represented by $G(u)$ in Figure 1, extends upto $1,2 \sqrt{4at}$.

3.3 The riverdelta consisting of two rivers

3.3.1 Introduction

The second example is related to a coastal plain near Gioia Tauro in the South of Italy. This coastal plain is formed by two rivers: the Petrace and the Mesima. The Petrace and the Mesima will be represent by two sources with a sediment yield of $\gamma Q \text{ m}^3/\text{yr}$ and $Q \text{ m}^3/\text{yr}$ respectively.

3.3.2 Determination of the value of $\sqrt{4at}$ if the baseline is known.

The evolution of the riverdelta due to a single source is

described by 3.3.1. In case of two sources the contributions of the two rivers will be linearly superposed. The width of the delta respectively at the Petrace ($x = 0$) and the Mesima ($x = L$) becomes in that case respectively

$$y(0,t) = \operatorname{tg} \phi \sqrt{\frac{4at}{\pi}} \{ 1 + \gamma F(u_1) \} \quad 3.3.1$$

$$y(L,t) = \operatorname{tg} \phi \sqrt{\frac{4at}{\pi}} \{ \gamma + F(u_1) \} \quad 3.3.2$$

$$\text{where } u_1 = \frac{L}{\sqrt{4at}} \quad 3.3.3$$

and L is the distance in meters between both rivers.

From a map the angle ϕ_0 between the shoreline at the mouth of the Mesima with a line parallel to the baseline can be obtained. This angle ϕ_0 is formed by superposition of the angle ϕ in absence of the Petrace and the value of $\partial y/\partial x$ at the Mesima due to the Petrace alone or

$$\operatorname{tg} \phi_0 = \{ 1 + \gamma G(u_1) \} \operatorname{tg} \phi \quad 3.3.4$$

The maximum width of the delta at $x = L$ can be expressed in terms of u_1 and known parameters, by combining 3.3.1, 3.3.3 and 3.3.4 rearranging and dividing by L .

$$\frac{y(L,t)}{L \operatorname{tg} \phi} = \frac{1 + \gamma F(u_1)}{\sqrt{\pi} u_1 (1 + \gamma G(u_1))} \quad 3.3.5$$

For the application of Figure 3.3.5 it is essential that $y(L,t)$, e.g. the distance between the baseline and the mouth of the river, is known. In the next example the baseline is unknown and in that case use will be made of a characteristic length of the shape of the shoreline in order to obtain an estimate of $\sqrt{4at}$.

4. Kelantan Minor Port Project

4.1 Introduction

The Kelantan Minor Port will be located in the north-eastern part of Malaysia, along the coast in between the mouths of Kemasin and Pengkalan Datu rivers (see Figure 3). The first part of the study was focussed upon the general morphology followed by an assessment of the

morphological consequences of the projected harbour.

4.2 Description of the morphological system

The proposed harbour is located along the border of the delta of the Kelantan. This delta can be traced back upto 18 km inwards. The sediment yield of the remaining rivers on the delta is small relative to that of the Kelantan. West of the mouth of the Kelantan a spit is growing in N.W. direction, pointing towards a predominantly SE-NW sanddrift. East of the Kelantan, at a distance of about 50 km, an ondulation in the delta can be observed. This ondulation is caused by the presence of the offshore Perhentian islands leading to a kind of tombolo formation on the delta. At some stage of the delta formation, probably around 1700, the Kelantan has shifted its course, cutting off the sediment yield to the delta. Parts of the delta are presently eroding.

Figure 3: Before (A) and after (B) the change of the Kelantan.

4.3 Mathematical schematisation of the sediment balance

The delta formation has been represented by means of three rivers (Figure 3). The first river is the Kelantan with a sediment yield of $Q \text{ m}^3/\text{yr}$. The second and third river are jointly representing the ondulation of the delta. Due to

the Perhentian islands part of the coast is protected against the incoming wavefield, resulting along the shoreline in a reduced transport capacity of the waves behind the islands. In order to allow for the continuous SE - NW sandtransport, an increased angle between coastline and incoming wave field in the area has resulted. This feature has been represented by two rivers, which together do not affect the overall sediment balance. The second river is located at a distance of $L_2 = 36,1$ km from the Kelantan and acts like a sink with a negative sediment yield of γQ m³/yr, where γ is a constant. The third river is located at $L_3 = 50,1$ km from the Kelantan and has a sediment yield of γQ . In the mathematical formulation superposition of a continuous sanddrift from SE to NW does not change the shape of the delta and has therefore not been included. Loss of sediment in offshore direction, out of sediment balance, is not envisaged.

In the mathematical representation of the formation of the Kelantan delta, each point of the delta experiences the influence of the three rivers. These contributions can be expressed in terms of $y_1(x,t)$, $y_2(x,t)$ and $y_3(x,t)$, where the numbers refer to the numbers of the rivers. In terms of the influence functions of chapter 2 these contributions are:

$$y_1(x,t) = \text{tg } \phi \sqrt{\frac{4at}{\pi}} F(u_1); u_1 = |x|/\sqrt{4at} \quad 4.3.1$$

$$y_2(x,t) = -\gamma \text{tg } \phi \sqrt{\frac{4at}{\pi}} F(u_2); u_2 = |x - L_2|/\sqrt{4at} \quad 4.3.2$$

$$y_3(x,t) = \gamma \text{tg } \phi \sqrt{\frac{4at}{\pi}} F(u_3); u_3 = |x - L_3|/\sqrt{4at} \quad 4.3.3$$

The resulting delta is formed by superposition of these three contributions. For practical reasons use will be made of one parameter for instance u_2 instead of the three parameters u_1 , u_2 and u_3 . This can be achieved by simple algebra. The formation of the delta in dimensionless form follows from superposition of y_1 , y_2 , y_3 , dividing by a length scale, say L_2 , and rearranging:

$$\frac{y(x,t)}{\text{tg } \phi L_2} = \frac{1}{\sqrt{\pi}} \frac{1}{u_{22}} \left\{ F\left(\frac{|x|}{L_2} u_{22}\right) - \gamma F\left(\frac{|x-L_2|}{L_2} u_{22}\right) + \gamma F\left(\frac{|x-L_3|}{L_2} u_{22}\right) \right\}$$

$$\text{where } u_{22} = L_2/\sqrt{4at} \quad 4.3.5$$

In this representation of the Kelantan delta $tg\phi$ is the angle between the baseline and the shoreline near the mouth of the Kelantan in absence of rivers 2 and 3. The combined effects of the three rivers on $tg\phi$ results in $tg\phi_0$, where ϕ_0 can be measured from a map near the mouth of the Kelantan.

$$tg \phi_0 = tg \phi \left\{ 1 - \gamma G(u_{22}) + \gamma G\left(\frac{L3}{L2} u_{22}\right) \right\} \tag{4.3.6}$$

In this formulation the first term between brackets represents the influence of the Kelantan on $tg\phi_0$ (note that $G(0) = 1$), the second term refers to river 2. The third term refers to river 3, but has been expressed in terms of 4.2.2.

Introducing 4.3.6 in 4.3.4 leads to expression 4.3.7.:

$$y(x,t) = \frac{1}{tg_0 \phi L2} \frac{1}{\sqrt{\pi}} \frac{1}{u_{22}} \frac{\left\{ F\left(\frac{|x|}{L2} u_{22}\right) - \gamma F\left(\frac{|x-L2|}{L2} u_{22}\right) + \gamma F\left(\frac{|x-L3|}{L2} u_{22}\right) \right\}}{\left\{ 1 - \gamma G(u_{22}) + \gamma G\left(\frac{L3}{L2} u_{22}\right) \right\}} \tag{4.3.7}$$

representing the shape of the delta in terms of known variables and one parameter u_{22} . In the next paragraph the value of u_{22} or in fact the value of $\sqrt{4at}$ will be determined from a characteristic dimension of the shape of the delta.

4.4 Determination of the value of $\sqrt{4at}$ and γ from the shape of the delta.

As a characteristic dimension of the shape of the delta in Figure 5 the distance CD has been selected. Obviously the width of the delta AB could also have been selected, however at the beginning of the project the position of the baseline was not known and the influence of river 2 and 3 is rather small for a large range values of $\sqrt{4at}$.

Figure 4: Characteristic dimension CD, expressed in terms of $\sqrt{4at}$.

The distance CD in Figure 4 can be expressed in geometrical dimensions of the delta as follows:

$$CD + DE = AB - (AB - FG) L2/L3 \tag{4.4.1}$$

In terms of x, y and t, equation 4.4.1 can be expressed as:

$$CD + y(L2,t) = y(0,t) - \{ y(0,t) - y(L3,t) \} L2/L3 \tag{4.4.2}$$

Taking the angle near the mouth of the Kelantan as the reference angle, the following expression of CD in terms of u^2 can be obtained:

$$\frac{CD}{L2 \text{ tg } \phi_0} = \frac{1}{L2 \text{ tg } \phi_0} \{ y(0,t) - y(L2,t) - (y(0,t) - y(L3,t)) L2/L3 \} \tag{4.4.3}$$

where the displacement of the delta $y(x,t)$ is described by 4.3.7.

The functional relation between CD, u^2 and γ , as represented by equation 4.4.3, is shown in Figure 4.

The following geometrical parameters have been selected for the Kelantan delta: $CD = 5,900m$, $L_2 = 36,100m$, $L_3 = 50,100m$ and $\phi_0 = 22,5^\circ$. The value of parameter $CD/(L_2 \text{ tg } \phi_0)$ equals $0,395$. According to Figure 4 both $u = 0,47$ and $u = 1,07$ satisfy 4.4.3 for $\gamma = 0,5$. It is interesting to note that there are two values of u ($u_1 = 0,47$ and $u_2 = 1,07$) which satisfy $CD = 5,900m$. This implies that both at time t_1 and t_2 after the start of the build up of the delta, that $CD/(L_2 \text{ tg}_0) = 0,395$. For a constant value of a and L , it follows from the definition of u that:

$$\frac{t_2}{t_1} + \left(\frac{u_1}{u_2} \right)^2 \quad 4.4.4$$

If the present shoreline is the result of a continuous process of $t_1 = 6000$ years, that at $t_2 = 1150$ years after the start of the build up of the delta CD reached also the present value. This is an example of many valuedness in the analysis of shoreline evolution.

In the next paragraph the selected values of γ and $\sqrt{4at}$ will be validated.

4.5 Validation of the values of $\sqrt{4at}$ and γ . The shoreline

A fair reconstruction of the shoreline by means of influence functions is shown in Figure 3. The following values of the parameters have been used: $\sqrt{4at} = 75,790m$, $\gamma = 0,5$, $\phi_0 = 22.5^\circ$.

The base line

On basis of a LANDSAT image of the Kelantan delta the alignment of the various series of beach ridges could be reconstructed. In Figure 3 a tentative line is drawn to indicate the delta growth over the last 6000 years. The distance between baseline and the mouth of the Kelantan is roughly $18,000m$. A theoretical estimate of the position of the baseline, using 3.2.1 and realising that $x = 0$ or $F(u) = 1$ at the origin of the river, than 3.2.1 leads to a value of $y = 17,711m$. The fact that the effect of the rivers 2 and 3 on the width of the delta near the Kelantan is small, is due to the fact that the location of both rivers is of the same order of magnitude as the length scale $\sqrt{4at}$ in the diffusion equation, and that both rivers are of equal magnitude, but of opposite sign.

Sediment yield of the river.

The natural geological rate of erosion in the Kelantan delta is in the order of $100m^3/km^2/yr$ from the totally

undisturbed catchment area. The yearly sediment yield of the Kelantan would be in the order of 1,300,000 m³/yr. In the last century, due to human activities, this figure has increased to 1,700,000 m³/yr. Only the bedload will contribute to the growth of delta. From measurements the bedload appeared to be 50% of the total load, leading to a sediment yield of the Kelantan in the order of 700.000 m³/yr to 800,000 m³/yr.

A numerical estimate of the sediment yield Q_t of the Kelantan can be obtained from the continuity equation. Near the mouth of the river this formula leads to:

$$Q_t = 2St = 2at h \text{tg } \phi \quad 4.5.2$$

Assuming an accretion depth of 4 m. to 5 m., this leads to a total sediment yield of $4,8 * 10^9 \text{ m}^3$ to $5,9 * 10^9 \text{ m}^3$. According to the geological study the present delta formation has continued over the last 6000 years, leading to an annual sediment yield of the Kelantan of 790.000 m³/yr to 991.000m³/yr.

The conclusion is that on all three aspects: the shape of the shoreline, the position of the baseline and the total sediment the theoretical approximation and the selected parameters yield a reasonable approximation.

5. Summary and remarks

The approach presented in this paper has been tested in various coastal morphological projects, where wave drive longshore sediment transport played a dominant role. In the analysis the morphological project is placed within a larger framework, allowing for various disciplines to contribute. The experience is that application of the approach is rather straightforward, highlighting the important aspects and conflicting sources of data and theory for a specific site.

The use of influence functions requires a clear perception of the large scale morphology. The set up of the equations such as shown in paragraph 4.3. and 4.4 is rather straightforward. Personal Computers are particularly suitable for the construction of the dimensionless graphs as shown in Figures 2 and 4. Reconstruction of the present coastline using the obtained values of $\sqrt{4at}$ requires a similar approach as for the construction of the dimensionless graphs. For the verification of the longterm morphology, information can be used from geological and geophysical sources. For calibration of recent developments particularly use is made of the rate of accretion in recent decades.

The framework of analysis allows for highlighting

conflicting data sources and the resulting effects on the large scale morphology if either of the data sources would be true. Equally important however is that influence functions can be used to form a test for the basic hypothesis that the longshore transport process related to ϕ_{br} is the dominant process for the coast under consideration. If this is not the case a different approach than the one-line theory should be devised. An example is the offshore transport term S_y . However the concept of influence functions remains applicable for those beaches where offshore transport can be represented as : $S_y = \text{constant}$ or $S_y = \text{constant}$ fraction of the longshore transport gradient $\partial S/\partial x$. The effect on the shape of this offshore transport on the present shoreline in that case is nil. Obviously the effect can be noted in the large scale delta evolution and in the total volume of longshore transport.

In some morphological projects it appeared that long term trends in beach evolution differed considerably from recent trends in beach evolution. In that case the values of the parameters for the recent evolution were used for prediction of future changes. Within the realm of the projects it was not possible to find the cause for the changing trends on different time scales. It may be that if experience from more sites are combined a coherent picture may emerge, for instance the effects of a rise of mean sea level.

Acknowledgement

The theory of influence functions has been developed by the author in the period 1976 - 1987. In this period the author was employed as an project engineer of Delft Hydraulics. The theoretical development was initiated by the investigations for the Gioia Tauro Port project. The Kelantan Minor Port project, carried out by mr. W. Tilmans led to a further elaboration and illustration of the theory. The author acknowledges the permission of colleagues, Delft Hydraulics and the clients of the Gioia Tauro Port project and the Kelantan Minor Port project to allow publication of the results.

Notation

a	diffusion coefficient
A	constant
C	characteristic dimension of a beach plan
c_0	deep water wave celerity
F	influence function for shoreline displacement
G	influence function for shoreline rotation
h	depth of accretion
H_0	significant deep water wave height
H	influence function for rate of accretion of the shoreline
L, L_2, L_3	distance between two rivers

Q	sediment yield of the river
S	sediment transport rate
t	time
u	$x/\sqrt{4at}$; parameter
u1	idem $L/\sqrt{4at}$
u2	idem $ x - L2 /\sqrt{4at}$
u3	idem $ x - L3 /\sqrt{4at}$
u22	idem $L2/\sqrt{4at}$
x	co-ordinate axis
y	co-ordinate axis
γ	ratio of the sediment yield of two rivers
η	reduction factor of the sediment yield of the river
ϕ_b, ϕ_o	angle between deep water wave crest respectively the breakerline and the positive x-axis
subscripts	
b	breakerline, y
x,y	parallel to x,y-axis
pet., mes.	Petrace, Mesima
1,2,3	referring to river 1,2 or 3
0	deep waterwave characteristics
