The validity of the present model is examined by comparing the results from the numerical computation with experimental data obtained in a laboratory experiment and a strict solution for a rectangular submerged breakwater.

The experiments on the wave transformation over a submerged permeable breakwater were carried out in a laboratory wave flume as shown in Fig.6. The model breakwater composed of gravel with average diameter of 2.5 cm was placed on a 1/20 uniformly sloping bed. The offshore slope of the breakwater was 1/3. Tests were conducted for various wave conditions of regular and irregular waves with different values of the breakwater crown width. The water surface displacement was measured along the center line of the test section from offshore to onshore region. Sample of the experimental data for the distributions of root mean square value of water surface fluctuation are presented in Fig.7. In the figures, H_i and T represent the incident wave height and period for regular waves while $H_{1/3}$ and $T_{1/3}$ represent the significant wave height and period for irregular waves. The symbols X_t and X_c indicate the locations of the toe and crown of the breakwater, and X_{sh} the location of the shoreline. It is found that the wave amplitude considerably decreases over the breakwater which indicates a significant loss of the wave energy.

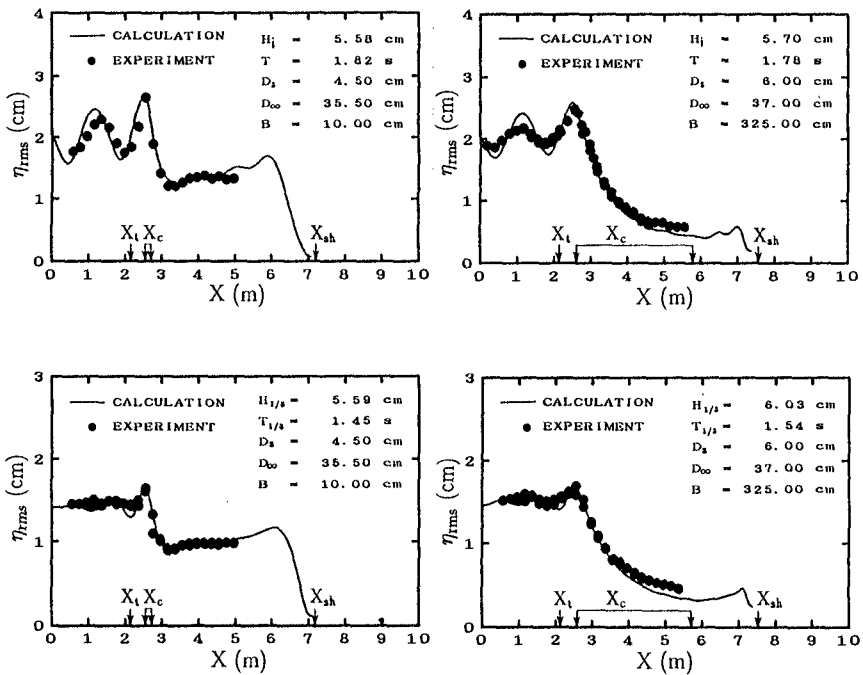

Fig.7 Distribution of root mean square value of water surface fluctuation.

The mathematical model based on the present mild-slope equation is applied to the computation of wave transformation over a submerged breakwater. Some important parameters are evaluated from given properties of the model breakwater; the porosity is 0.39. Values of the permeability K_p and turbulent friction coefficient C_f are interpolated from the results of laboratory tests under steady flow conditions which were presented by Sollitt and Cross (1972). In the present computation, the values of $K_p = 3.77 \cdot 10^{-7} \text{ m}^2$ and $C_f = 0.332$ are adopted. The inertia coefficient C_r is approximately regarded as unity after Sollitt and Cross (1972). The computation is performed by the iteration procedure. Results of the numerical computation are also shown in Fig.7 in comparison with the experimental data. The agreement between the model computation and experiment is generally good although the computation gives a transmitted wave component slightly smaller than the measured one. The computation also shows a slight overestimation of reflected wave due to the energy dissipation.

The present model is applied to a rectangular submerged breakwater and the reflection and transmission coefficients are compared with the strict solutions. A breakwater of width $B = 3 \text{ m}$ with the same physical properties as mentioned is considered. The amplitudes of reflected and transmitted waves are obtained from the potential in the offshore and onshore region of the breakwater. Then, the reflection and transmission coefficients are calculated. The computation was performed for various conditions. Sample results of the comparison are shown in Fig.8 as a function of relative water depth, h_0/L_0 . The agreement is fairly good in spite of the assumption of mild slope used in the derivation.

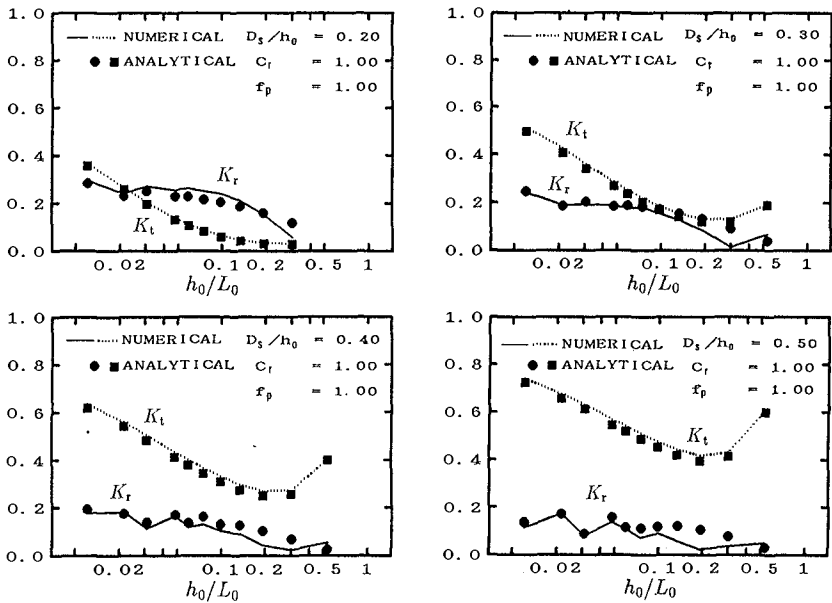

Fig.8 Reflection and transmission coefficients of rectangular submerged breakwater.

IV. CONCLUDING REMARKS

A mathematical model for the computation of wave transformation over a submerged permeable breakwater has been proposed on the basis of newly-derived mild-slope equation. The model equation is simple and helpful in understanding the physical behavior of the phenomenon. Its application was described by means of a numerical computation and the validity of the model was confirmed through comparisons with the experimental data and with a strict solution for a rectangular submerged breakwater. The present model is applicable for a wide range of breakwater configurations. However, the extension of the present model for a three-dimensional problem is essential to make the model more practical and useful for the prediction of wave field around the submerged breakwater.

CHAPTER 81

Wind-induced Cross-shore Water Flows

J B Crowley* and D H Swart**

1. Abstract

To cater for the effect of wind-driven nearshore processes on the prediction of nearshore onshore/offshore sediment transport a series of field experiments were carried out to establish a reference framework to be used as basis for the modelling of wind-driven cross-shore currents. The results indicate a clear relationship between bottom return current, wind speed and the water depth. This implies that a mathematical framework can be established using the conservation of mass and momentum and the similarity criterion.

2. Background

Nearshore sediment transport takes place as the combined action of wind, waves and tides. The processes are characterised by extreme turbulence under the action of breaking or near-breaking waves. Predictive techniques for the magnitude of the resulting nearshore transport rate, whether it be in the alongshore or the cross-shore direction, proliferate but they have all got but one commonality - the extreme simplifications and assumptions that have to be made. Typically what is done is that both wind and tide effects are neglected and only wave effects are considered. If we concentrate on cross-shore sediment transport, the best and/or most-used techniques today are those of Baillard (1981), Nairn (1988), Larson (1989), Stive (1987) and Swart (1974, 1986). Apart from the last technique, which has a broad theoretical basis with empirical coefficients which has proved extremely robust and accurate over a

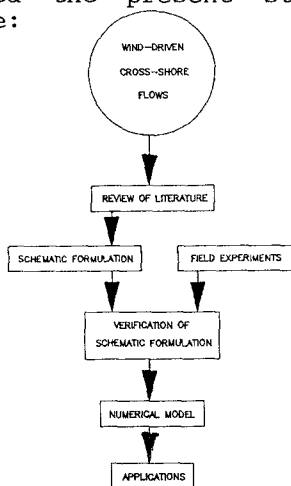

* CSIR, P O Box 320, Stellenbosch, 7600, South Africa.

** CSIR, P O Box 395, Pretoria, 0001, South Africa.

wide range of conditions, the other methods all utilise a momentum approach and are more theoretical of nature.

Experience has shown that these techniques are reasonably reliable (Seymour *et al.*, 1988, Möller *et al.*, 1988) but that specifically wind effects can totally upset the predicted results. Swart (1987) showed, e.g. that whereas all known predictors of the direction of cross-shore wave-driven transport would indicate offshore-directed sediment movement (beach erosion), the beach in the centre of a large bay of the south coast of South Africa accreted heavily whilst being attacked by normally-incident storm waves with a significant incident height of about 7 m and a deep-water steepness of 0,05. At the time a 20 m/s offshore wind was blowing, with presumably onshore return flow at the bed to compensate for water blown seawards.

This inspired the present study, which has the following outline:

The present paper concentrates on the field work and covers all aspects but the last two, namely, the numerical model and potential applications.

2. Review of Literature

A scan of the literature reveals a wide selection of papers dealing with the prediction of wind-driven water flow, e.g. Kranenburg (1987), Hubertz (1987), Kullenberg (1976), Winant (1980), Komen and Riepma (1981), Thomas (1975), Eidnes (1986), Bennett (1974, 1979), Birchfield (1972), Grant (1979), Madsen (1976), Kuzmic (1989) and Van Dorn (1953). However, although these papers contain valuable insights into the theoretical treatment of

wind-driven flows in general, they contain virtually nothing on cross-shore flows.

The only two papers with an applicable treatment of cross-shore flows are those by Kranenburg (1987) and Van Dorn (1953). In these two cases the following representation of the vertical flow profile was postulated on the basis of data:

a. Kranenburg (1987)

- Laboratory data
- Theoretical framework sketchy

b. Van Dorn (1953)

- Theoretical framework
- Sketchy data in pond

Figure 1. Postulated Wind-driven Flow Profile

Theoretical treatment. If one considers the various theoretical treatments in the whole body of the literature referred to above, it can be concluded that these are both numerous and varied. A short summary is included below.

The **basic equations** typically are

- the conservation of mass; and
- the equations of motion.

The **boundary conditions** used to solve these are then:

- the mean vertical surface flow is equal to zero; and/or
- the bottom shear stress is specified; and/or
- the surface shear stress is specified; and/or
- the surface drift velocity is related to the wind speed at some elevation above the water surface.

If one looks at the assumptions made by the various investigators, one sees the following spread:

- Direction of wind
 - on/offshore
 - longshore

- Water surface slope - horizontal
- sloping
- Homogeneous wind stress - all
- Coastal alignment - straight
- curved
- arbitrary
- Wave effects - included
- excluded
- Temporal variability - yes
- no
- Vertical averaging - yes
- no
- Hydrostatic pressure - yes
- no
- Dynamic pressure terms - included
- excluded
- Return flow - yes
- no
- Bed friction - neglected
- linear
- quadratic
- Geometry of water body - arbitrary
- rectangular
- two-dimensional

3. Schematic Formulation

On the basis of an analysis of the literature, the following first approximate approach is formulated.

Figure 2. Definition Sketch

The following assumptions are made:

- ♦ the rigid-lid approximation is used;

- ♦ wave effects are neglected;
- ♦ the water surface slope is horizontal;
- ♦ the pressure distribution is hydrostatic;
- ♦ turbulent pressures are neglected;
- ♦ shear stresses in the return flow area are disregarded;
- ♦ the velocity profiles in the boundary layer agree to similarity, that is, the surface drift is proportional to the shear velocity U_* .

With these assumptions as basis, the following formulation is found:

Equation of motion

$$U_r \frac{dU_r}{dx} + \frac{1}{\rho} \frac{\partial \bar{p}}{\partial x} = 0 \quad \dots (1)$$

Conservation of mass

$$- U_r d + \int_0^{\delta} U_b(x, z) dz = 0 \quad \dots (2)$$

Integral conservation of momentum

$$d \frac{\partial \bar{p}}{\partial x} + \frac{d}{dx} \left[\rho \int_0^{\delta} \left\{ -U_r + U_b(x, z) \right\}^2 dz \right] = \rho U_*^2 \quad \dots (3)$$

Similarity criterion

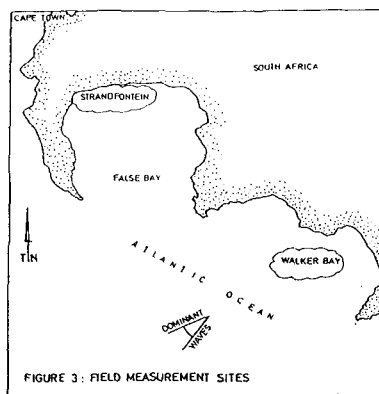

$$u_b(x, z) = U_* f(\zeta) \quad \text{where } \zeta = z/\delta \quad \dots (4)$$

The function $f(\zeta)$ determines the shape of the velocity profile inside the boundary layer. Kranenburg (1987) manipulated his data into a form where an expression could be found for $f(\zeta)$.

For the case where the bed slope is constant and with the surface shear velocity u_* proportional to the wind velocity W , it can be show that

$$\frac{U_r}{W} \propto d^{-1} \quad \dots (5)$$

This relationship will be used later as framework to plot the field data.

4. Field Experiments

The field measurements to quantify bottom return current as a result of a cross-shore wind were done at two sites on the south-western coast of South Africa. As can be seen on Figure 3, both of these bays face the predominant south-westerly swells although False Bay due to its dimensions is more protected than Walker Bay. Storm waves arrive at the latter nearly unabated.

In all three experiments were done, namely, in September 1986 and February 1990 in Walker Bay and in March 1990 in False Bay. The Walker Bay exercises were part of much bigger field measurement campaigns into nearshore coastal processes but the False Bay exercise was done solely for the purpose of determining wind-driven currents.

At Walker Bay the strongest wind events are from the north-west (May to August) and from the south-east during the rest of the year. Cross-shore wind events are therefore less prevalent. Nevertheless, a few useful blows in roughly the cross-shore direction did occur during the two exercises. The strongest wind events at False Bay occur from the same directions but due to the orientation of the bay and more specifically the prominent mountain ranges around it, the strong winds are nearly always roughly aligned in the cross-shore direction.

In doing the experiments during the three field programmes it was generally strived to deploy the equipment in the bottom 20 % of the water column and seaward of the dominant breaker line. Deployment water depth varied from 4 m to 20 m and in some of the shallower cases the current meters were at times inside the surf zone or very close to it, thus measuring wave-driven currents. It is easily visible on the plots of current velocity when this occurred.

As a result of the manner of deployment (location, depth, etc.) the results represent a breadth of varying influences, e.g. in incident waves (surface roughness), wave effects (rip currents, orbital velocity) and the bottom roughness (False Bay generally has a smoother bottom than Walker Bay).

Walker Bay : September 1986 Figure 4 gives an overview of the type of data gathered during this exercise. Figure 4c summarises all the available data points obtained with a vector-averaging current meter in 20 m water depth every 15 min. between 21 and 26 September 1986.

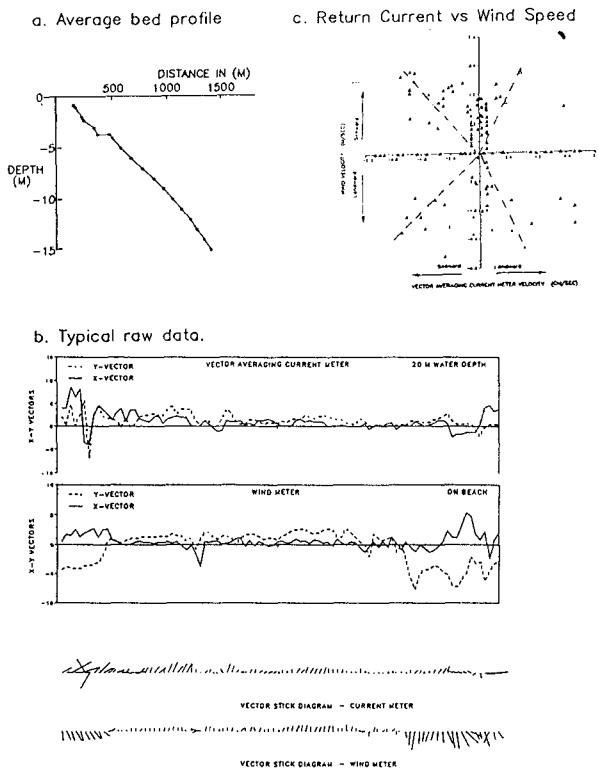

FIGURE 4: WALKER BAY DATA : September 1986

FIGURE 5 : WALKER BAY : February 1990

c. Return Current vs Wind Speed

a. Average bed profile

b. Typical raw data.

FIGURE 6 : STRANDFONTEIN : March 1990

During this period the incident, offshore wave climate varied as follows:

	Maximum	Mean	Minimum
* Significant height (m)	4,1	2,9	2,1
* Peak period (s)	15,5	12,3	7,5

The beachline was characterised by prominent cusps at 300 m centres, but the nearshore contours were nearly straight. As a result of the cusped shoreline rip currents occurred along the beach at 300 m intervals leading to breaches in the main breaker bar at 5 m water depth, also at 300 m centres. At the position of the meter, well outside the breaker line, the contours were nearly parallel.

Walker Bay : February 1990. During this exercise 'bottom' current meters were deployed in 4 m and 11 m water depth, in each case at 0,5 m and 1,5 m above the bed. Figure 5 gives an overview of the data for the 11 m depth, 1,5 m above the bed case. The duration of the measurement campaign was from 9 to 22 February 1990, for a period of 2 hours around each day time high and low tide. Electromagnetic current meters were used for all four deployments.

During this period the incident, offshore wave climate varied as follows:

	Maximum	Mean	Minimum
* Significant height (m)	3,8	2,1	1,2
* Peak period (s)	13,5	10,3	6,6

The nearshore topography was fairly complex with no clear, well-developed breaker bar. Thus the contours were also complex, characterised by rapidly changing bars, troughs and gullies in 4 m depth but with a reasonably stable, straight set of contours in 11 m depth. The location of the breaker bar in Figure 5a in relation to the measuring stand also shows the potential for variability.

False Bay : March 1990. During this exercise the configuration of the February 1990 Walker Bay experiment was repeated, except that the deeper stand now had current meters at 0,5 m, 1,5 m and 2,5 m above the bed. Unfortunately, the meter closest to the bed at this deep stand malfunctioned and no data was obtained for that elevation above the bed.

Measurements were obtained for 2 hours around each day time high and low tide for the period 11 March to

21 March 1990. During this period the incident wave climate varied as follows:

	Maximum	Mean	Minimum
* Significant height (m)	3,0	1,8	1,0
* Peak period (s)	13,5	10,3	5,5

Figure 6 shows an overview of the data for the meter at 2,5 m above the bed in 11 m water depth. Figure 6c clearly shows some predominant wave effects, associated with a macro-rip current occurrence in the area.

This site is characterised by a very much flatter bottom profile than at Walker Bay, a very straight beach with fine sand, a smooth calcareous surface offshore and nearly straight contours at both deployment stands.

5. Verification of Schematic Representation

It was shown earlier that for a constant bed slope, which is a realistic assumption for all cases as can be seen, in Figures 4 to 6, the ratio U_r/W is proportional to the inverse of the water depth. To test this hypothesis the data in figures like Figures 4 to 6, but for all instruments, were fitted with a best-fit straight line through the origin. It is important to note that the wind condition varied between onshore and offshore, thus giving two possible data points per graph. The data, given in Figure 7a, show clearly that the correct tendency is prevalent in the plot. The scatter is to be expected, since the experiments were done under very different wave conditions and with varying seabed configurations. It is interesting that ratios between approximately 0,01 and 0,02 are found for the return current, whereas earlier studies have shown that the surface drift velocity varies between 3 % and 7 % of the wind speed (Kullenberg, 1976).

What is interesting, however, is that not only do those cases conform where the bottom current is a return current when compared to the wind direction, but this is also the case for those situations when the bottom current is in the same direction as the wind direction (Figure 7b). Presumably this represents cases where the whole water column is moved by wind action and continuity is achieved through horizontal water circulation.

The problem with field observations of wind-induced drift, or for that matter with laboratory observations, is that the drift takes place in a part of the nearshore area characterised by fairly vigorous currents, to

mention but nearshore circulation with frequently stormy rip currents, orbital velocities and mass transport. All but the last are up to an order of magnitude higher than the wind-induced drift. Separation of the wind drift from the complex composite of currents in the nearshore area is at best a guesstimate. However, the analysis done herein is not intending to provide absolute values for the drift, but rather to indicate qualitative final estimates of what appears to be the wind drift. As was shown, some clear guidelines emerged, obviously keeping the above comments in mind.

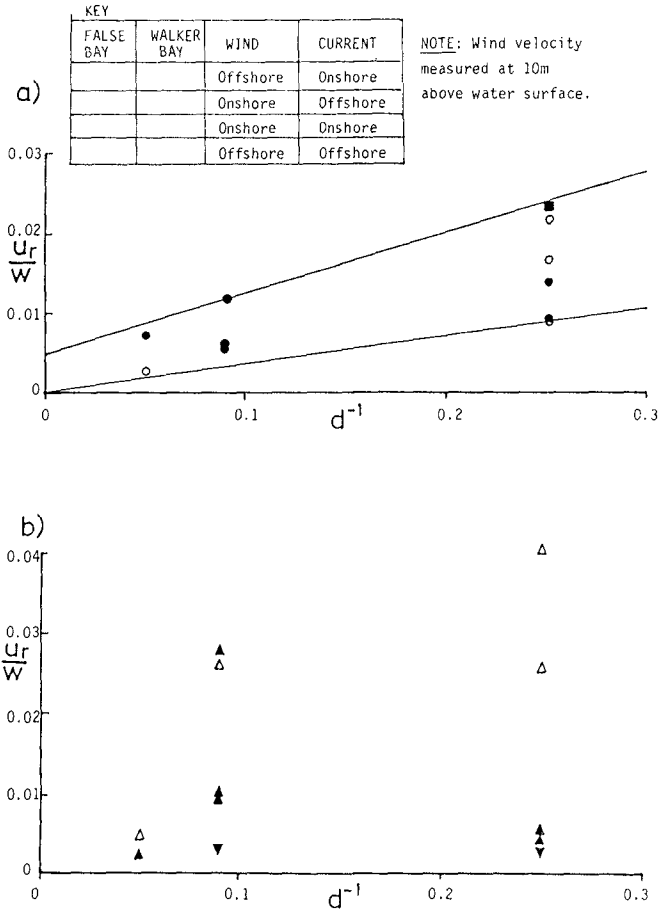

Figure 7. Schematic Framework for Prediction of Return Velocity U_r as a Function of Wind Velocity W and Water Depth d .

6. Conclusions and Recommendations

The main conclusions reached to date in this study on wind-induced cross-shore water flows are the following:

(1) The theoretical framework represented by Equations (1) to (4) is promising.

(2) The bottom 'return' layer concept seems reasonable, although the field data show that there are also cases where the return flow does not take place in the same cross-section. Presumably this latter case is strongly related to irregularities in the sea bottom and the obliqueness of the incident waves.

(3) The effect of bed slope on the results in Figure 7a and 7b appears to be fairly minimal.

(4) At present it is not sure to what extent waves will influence the results.

Therefore, with this as basis, we are taking the following approach:

♦ We are developing a numerical model for an arbitrary bottom profile; and

♦ We are further investigating the effect of varying surface roughness caused by variations in wave height.

Having made these advances, we hope to in time be in a position to predict the wind-driven cross-shore flows in a situation such as depicted below.

CHAPTER 82

Irregular Waves on a Current

H.-H. Prüser and W. Zielke ¹

1 Introduction

In coastal areas interacting currents and waves are quite frequent. The currents are generated by the tides or the discharge of a river; the waves are irregular short crested, generated by the wind. A suitable numerical wave model for this situation is presented in this paper. It is based on the Boussinesq-Wave-Equations (BWE) which were extended to simulate the influence of a current on a wave as well as the effects of nonlinear wave-wave interaction in a propagating wave spectrum.

An analytical approach to describe wave-current interaction was given by Longuet-Higgins/Steward (1960) [3]. They investigated linear small amplitude waves in a moving medium and introduced the concept of radiation stress to determine the change of wavelength and wave amplitude as a function of the current and the direction of wave propagation. Their fundamental work was the basis for the development of various numerical models, which were reviewed recently by Jonsson (1989) [2]. Most of these models are restricted to linear (small amplitude) wave theory.

The wave climate in shallow water is generated by the influence of bottom topography as well as by nonlinear wave-wave interaction in a propagating wave spectrum, which cannot be described by linear wave theory. Instead, such weakly nonlinear waves are frequently modeled using the BWE. The development of models based on these equations first began in the late 70's. Since then, a number of studies have been carried out to verify their capabilities. It has been shown that they are able to simulate accurately combined refraction, diffraction, reflection and shoaling (see for example Madsen/Warren (1984)[4] as well as the nonlinear wave-wave interaction in a wave spectrum propagating over an uneven bed (see for example Prüser/Schaper/Zielke (1986)[7]). Boussinesq wave models have now become a practical tool for engineering applications.

In this paper, a numerical model based on an extended form of the BWE which takes into account the influence of an ambient current on waves is used to investigate irregular waves propagating and refracting on an ambient current. After presenting the equations, a comparison based upon linear (small amplitude) wave theory is conducted to illustrate the range of application. The numerical model was used to simulate irregular waves with a current in a flume and in a basin. The results were in good agreement with the solution of Longuet-Higgins/Steward.

¹Institute of Fluid Mechanics, University of Hannover, Appelstr. 9A, 3000 Hannover, F.R.G.

2 The mathematical model

2.1 The Extended Boussinesq-Wave-Equations

Nonlinear wave behaviour in shallow water and in intermediate depth can be simulated using the BWE. These equations have been extended in order to include the effect of wave-current interaction, which is often necessary in coastal areas. *Mathematically, the general case of waves propagating through a current field over an arbitrary bottom topography is a complex initial boundary value problem. However, since the length and time scales of the wave motion are usually much smaller than those of the current, it is possible to solve the current field and the wave field in two separate steps*². Consequently, for the derivation of the extended BWE, it is assumed that the current field is known from numerical simulations or measurements. A step by step description is given by Prüser (1991)[6]. The extended BWE used in this paper and the equation of continuity are as follows (the index '0' refers to the ambient current and '*' to the combined flow of waves and currents. Variables without indices refer to waves only) :

$$\begin{aligned}
 u_{,t} + u^*u_{,x} + v^*u_{,y} + g\zeta_{,x} &= -\frac{D^2}{6}(u_{,xxt} + v_{,xyt}) + \frac{D}{2}((u_{,t}D)_{,xx} + (v_{,t}D)_{,xy}) \\
 &\quad + u_0\frac{D^2}{3}(u_{,xxx} + v_{,xxy}) + v_0\frac{D^2}{3}(u_{,xxy} + v_{,xyy}) \quad (1)
 \end{aligned}$$

$$\begin{aligned}
 v_{,t} + u^*v_{,x} + v^*v_{,y} + g\zeta_{,y} &= -\frac{D^2}{6}(u_{,xyt} + v_{,yyt}) + \frac{D}{2}((u_{,t}D)_{,xy} + (v_{,t}D)_{,yy}) \\
 &\quad + u_0\frac{D^2}{3}(u_{,xxy} + v_{,xyy}) + v_0\frac{D^2}{3}(u_{,xyy} + v_{,yyy}) \quad (2)
 \end{aligned}$$

$$(D + \eta)_{,t} + (u^*(D + \eta))_{,x} + (v^*(D + \eta))_{,y} = 0 \quad (3)$$

with: $u^* = u + u_0 \quad v^* = v + v_0$

The fluid velocities u^* , v^* are comprised of the ambient current field u_0 , v_0 and the wave flow field u , v . The current appears in the convective terms of the left hand side of the equations and also produces additional third order terms. The numerical BOUSSINESQ-WAVE-MODEL (BOWAM) which was available for the solution employs a formulation involving fluxes and surface elevations [8] [9]. Therefore, it was necessary to transform the equations by substituting $h = D + \zeta$, $p = uh$ and $q = vh$. The equations were solved by an implicit third order corrected finite difference method using two time levels and central differences.

2.2 Range of application, harmonic waves

The range of application depends on the wavelength to water depth ratio L/D . Shallow water is defined if the wavelength is larger than 20 times the water depth whilst deep water is defined if the wavelength is smaller than twice the

²cited from Jonsson[2]

wavelength; the region between these limits is referred to as intermediate depth. The BWE are limited to shallow water with an extension to include intermediate depth. In a nonlinear study with periodic waves, McCowan (1987)[5] has shown that the equations are valid provided the wavelength is at least 6 times the water depth. In this paper, the range of application for the extended BWE will be checked by a comparison with linear (small amplitude) wave theory. In a first step, the dispersion relations will be investigated. These results are necessary to subsequently verify the extended BWE using analytical solutions of wave-current interactions.

The wave profile is given by a harmonic function with amplitude a , wave number $k = 2\pi/L$ and frequency $\omega = 2\pi/T$.

$$\eta(x, t) = a \sin(\omega t - kx) \tag{4}$$

For simplicity, the investigation is limited to the one-dimensional case with constant water depth. The BWE and the equation of continuity reduce to:

$$u_{,t} + (u_0 + u)u_{,x} + g\eta_{,x} - \frac{1}{3}D^2u_{,xxt} - \frac{1}{3}D^2u_0u_{,xxx} = 0 \tag{5}$$

$$\eta_{,t} + u_0\eta_{,x} + Du_{,x} = 0 \tag{6}$$

The velocity u can be eliminated by differentiating (5) with respect to x and substituting (6) in (5). Finally, nonlinear terms of order $O(a^2)$ are neglected.

$$-\eta_{,tt} + (gD - u_0^2)\eta_{,xx} - 2u_0\eta_{,xt} + \frac{D^2}{3}(\eta_{,xxtt} + 2u_0\eta_{,xxxxt} + u_0^2\eta_{,xxxxx}) = 0$$

Inserting the wave profile (4) into the above equation gives Equ. (7). Nontrivial solutions for the frequency ω (8) are obtained if the first parenthesis is set to zero.

$$\left(\omega^2 - 2ku_0\omega + k^2u_0^2 - \frac{k^2gD}{1 + \frac{1}{3}D^2k^2}\right) a \sin(\omega t - kx) = 0 \tag{7}$$

$$\omega_{1,2} = ku_0 \pm \sqrt{\frac{k^2gD}{1 + \frac{1}{3}k^2D^2}} \tag{8}$$

The sign in front of the square root is chosen according to whether the wave is propagating in the direction of the current u_0 or in the opposite direction. The differentiation of ω with respect to the wave number k gives the group velocity:

$$c_g = \frac{\partial\omega}{\partial k} = \frac{1}{2}c^B(1 + G^B) + u_0$$

$$\text{mit: } G^B = \frac{1 - \frac{1}{3}k^2D^2}{1 + \frac{1}{3}k^2D^2} \tag{9}$$

Table 1 summarizes the analytical formulae for the dispersion relation of the linear theory and of the Boussinesq theory in the case of small amplitude waves.

and Steward. The wavelength in the presence of a current is given by an implicit function of the corresponding wave in still water (frequency ω ; phase velocity c) and the current u_0 :

$$L^c = 2\pi k^c \quad \text{with} \quad (\omega - k^c u_0)^2 = k^c \omega c \quad (10)$$

The change of wave amplitudes depends on the manner in which the ambient current is generated. Longuet-Higgins/Steward investigated two different situations, which were defined as *upwelling from below* and *inflow from the sides*. These definitions will be explained in the Chap. 3.1. In the case of *upwelling from below*, an adequate formula describing the situation with a current (a^c, L^c, G^c) and the situation in still water (a, L, G) is given by Brevik/Aas (1980)[1]. The change of amplitudes tends towards infinity as the Froude number tends towards $Fr \rightarrow -0.5$:

$$\frac{a^c}{a} = \sqrt{\frac{1 + G}{\left(\frac{L^c}{L} - \frac{u_0}{c}\right)(1 + G^c) + \frac{2u_0}{c}\left(1 - \frac{L}{L^c} \frac{u_0}{c}\right)}} \quad (11)$$

The parameters G, G^c, L^c and c can be substituted by the dispersion relations summarized in Table 1. Fig. 2 shows the change of wavelength L^c/L and Fig. 3 shows the change of wave amplitude a^c/a as a function of the Froude number $Fr = u_0/\sqrt{gD}$ for three different wavelengths ($L/D = 20, 10, 6$). The solid lines indicate the results obtained from the formulae (10) and (11) using linear theory whilst the dashed line indicate the results from Boussinesq theory. A negative Froude number indicates that the current and waves are propagating in opposite directions. The formulae are evaluated for Froude numbers $-0.3 < Fr < 0.5$. For most coastal engineering purposes, however, Froude numbers lie in the range of $-0.2 < Fr < 0.2$. With regard to the change of wavelength L^c/L , the following can be stated:

- The wavelength increases if the direction of wave propagation is the same as that of the current ($Fr > 0$) and decreases in the case of opposite directions. This effect is more pronounced in deeper water.
- The Boussinesq approximation is very good for the complete range of Froude numbers in Fig. (2) provided the wavelength is larger than 10 times the water depth.

With regard to the change of wave amplitude a^c/a , the following can be stated:

- The wave amplitude increases if the direction of wave propagation and that of the current are different ($Fr < 0$) and decreases when the directions are the same.
- The influence of the relative wavelength L/D on the change of amplitudes is very slight for Froude numbers greater than zero, but significant for Froude numbers less than zero.

	linear theory	Boussinesq theory
phase velocity $c^c = u_0 + c$	$c^L = \sqrt{gD} \sqrt{\frac{1}{kD} \tanh kD}$	$c^B = \sqrt{gD} \sqrt{\frac{1}{1 + \frac{1}{3} k^2 D^2}}$
group velocity $c_g^c = u_0 + \frac{1}{2} c(1 + G)$	$G^L = \frac{2kD}{\sinh 2kD}$	$G^B = \frac{1 - \frac{1}{3} k^2 D^2}{1 + \frac{1}{3} k^2 D^2}$

Table 1: Dispersion relation in linear and Boussinesq theory

The superscript *c* indicates currents, *L* indicates Linear theory, and *B* indicates Boussinesq theory. The comparison indicates a high degree of similarity between linear and Boussinesq theory. If an ambient current is present, then the phase velocity *c^c* and the group velocity *c_g^c* are superposed on the current *u₀* and the corresponding velocity in still water. For shallow water conditions (*kD* → 0), linear and Boussinesq theory are identical. In deeper water however, the solution obtained by Boussinesq theory is an approximation to linear theory.

Figure 1: Dispersion relation in linear and Boussinesq theory as a function of the parameter *kD*

Fig. 1 displays the relative errors of the phase velocity Δc (solid line) and the group velocity Δc_g (dashed line) as a function of the parameter *kD*. As expected, an excellent agreement is found between linear and Boussinesq theory for shallow water conditions ($L/D > 20, kD < 0.3$). Moving into deeper water ($kD > 0.3$), Boussinesq approximation for the phase velocity is much better than for the group velocity. A priori we will allow errors in phase and group velocity less than 5%, which gives a limit for the range of application of $kD < 1.0$ (see Fig. 1). This is in agreement with McCowan who indicated that the wavelength should be larger than 6 times the water depth.

The change of wavelength and wave amplitude due to the ambient current can be determined by analytical solutions based on the work of Longuet-Higgins

Figure 2: Change of wavelength due to an ambient current. Comparison with the corresponding wavelength in still water.

- For negative Froude numbers, the wavelength must be larger than 10 times the water depth.

In conclusion: Within limits of linear wave theory, extended BWE are valid for simulating the interaction of an ambient current on waves if the corresponding wavelength in still water is larger than 10 times the water depth and the Froude number is in the range of $-0.2 < Fr < 0.2$. If the corresponding wavelength in still water is smaller than 10 times the water depth and larger than 6 times the water depth, the extended BWE are applicable only if wave and current are in the same direction. If the waves are even shorter than 6 times the water depth, they are outside the range of Boussinesq theory, independent upon the current direction.

2.3 Range of application, irregular waves

The investigation on the basis of the dispersion relation, as presented in Chap. 2.2, is necessarily limited to harmonic waves with particular frequencies and wavelengths. The natural sea state, however, contains various interacting wave components. There is a need to define, which type of spectra and which frequency range can be modeled properly with BWE. Due to the nonlinear character of the waves there is no analytical theory available to define the range of validity. On the basis of experience, which has been obtained in a quite number of BOWAM-Simulations the following statements can nevertheless be made:

In irregular wave trains short waves are often related to longer waves. One ex-

Figure 3: Change of wave amplitude due to an ambient current. Comparison with the corresponding wave amplitude in still water.

ample is the behaviour of wave groups. Hydraulic measurements and the theory of biharmonic waves have shown, that bounded-long waves as well as bounded-short waves are generated. Another example is the propagation of a wave spectrum from deeper to shallower water. A transformation of energy towards higher harmonics can be observed. The centre-row of Fig. 6 demonstrates this quite clearly. In both cases, the high frequency components (short waves) which are created in the transformation may be outside of the range of validity of BWE as defined in Chap. 2.2. However, they can be properly modeled with BWE as long as the corresponding long waves are in the range of validity.

3 Waves on a current in a flume

3.1 Generation of the current

The current can be generated by pumping water into the flume through an inlet (or outlet) located at the bottom or in the walls. In the following it will be assumed that this volume flux is constant in time. The current velocity u_0 can be changed, however, by increasing or decreasing the cross-section of the flume. The change of wave amplitudes caused by the ambient current depends on *how* the current is generated. In the case of an upwelling of water from below (inlet at the bottom, varying water depth), it is larger than in case of inflow from the sides (inlet in the wall, narrowing of the width of the flume). Both cases will be investigated numerically. In Fig. 4, the corresponding analytical solutions for shallow water conditions and constant water depth are shown. A negative current with a Froude number of $Fr = -0.2$ shows an increase of the amplitudes of about

10% for the case of *inflow from the sides* and of about 25% for the case of *upwelling from below*. The change of wavelength is the same in both cases.

Figure 4: Change of amplitudes in shallow water. Comparison of the situations *upwelling from below*, *inflow from the sides* and BOWAM-Simulation.

3.2 Inflow from the sides

The behaviour of a wave spectrum propagating in a wave flume with constant water depth was investigated using the BWE. The upper part of Fig. 5 displays the experimental set-up: A numerical wave flume with a wave maker on the left hand side and three velocity/water elevation gauges A, B, C is shown. The water depth ($D = 0.5m$) as well as the width of the flume are constant. A number of inlets in the walls enable an ambient current to be generated between the gauges A and B by an *inflow from the sides*. The current u_0 is assumed to be zero at gauge A, increasing linearly to gauge B and remaining constant between gauges B, C.

Figure 5: Experimental set-up: Waves with an ambient current in a wave flume

Pierson–Moskowitz spectra are introduced into the flume by the wave maker. The simulated time series of the surface elevation η are recorded at the gauges. These were transformed by FFT into the frequency domain to investigate the change of the spectral shape along the flume. Fig. 6 displays the calculated wave spectra at the gauges A, B, C for different ambient currents. The total amount of energy is given by the spectral moment of zero order m_0 . Assuming a *Rayleigh* distribution, the significant wave height can be calculated from:

$$H_s = H_{m0} = 4\sqrt{m_0} \quad (12)$$

The spectra along the centre-row of Fig. 6 are the results of a simulation in still water ($Fr = 0.$). The significant wave height m_0 is the same for all gauges. For deep water conditions the incoming Pierson–Moskowitz spectrum is stable. In Fig. 6 the wavelength corresponding to the peak period of the spectrum ($T_p = 4.5s$) is about 20 times the water depth, which indicates shallow water conditions. Therefore, due to nonlinear wave–wave interaction in shallow water, the spectral shape changes considerably. Higher harmonics and low frequency components bounded to wave groups have been generated. This is visible in the spectral shape. A double peaked spectrum and lower frequency components not included in the input spectrum appear at gauge C. The numerical simulation without a current has been verified very successfully by hydraulic measurements for a number of different wave spectra (Prüser/Schaper/Zielke [7]). It can be used to estimate and compare the influence of the ambient current.

The first and third row of Fig. 6 display the influence of wave–current interactions. The Froude number of the ambient current was $Fr \pm 0.1$, i.e. the investigation deals with waves propagating in the direction of the current as well as in the opposite direction. The recorded time series at gauge A is equal in both cases because the current is zero at this location. The wave spectrum at gauge A is given in the centre-row. The influence of the ambient current on the wave spectrum can be separated into two phenomena:

The first one concerns the change of significant wave heights H_s between gauges A and B. If waves and currents are propagating in the same direction, the amplitudes i.e. the energy corresponding to the individual frequency components have decreased. The spectral moment of first order changes from $m_0 = 8.6 \cdot 10^{-5}$ to $7.8 \cdot 10^{-5}$ (the reverse effect occurs if waves and current are propagating in opposite directions $m_0 = 8.6 \cdot 10^{-5}$ to $9.6 \cdot 10^{-5}$). This gives significant wave height ratios of $H_s^c/H_s = 0.95$ and $H_s^c/H_s = 1.06$, respectively). Further investigations show, that these ratios are nearly independent upon the incoming wave height H_s , but they do depend on the peak–period of the spectrum. This is in agreement with Fig. 11. For shallow water conditions and a current, generated by an *inflow from the sides*, the results of BOWAM are very close to the analytical solution, as shown in in Fig. 4. The second phenomenon concerns nonlinear wave–wave and wave–current interactions. These can be obtained by comparing the wave spectra at the gauges B and C for the three test conditions displayed in Fig. 6. Double peaked spectra are generated and the total amount of energy

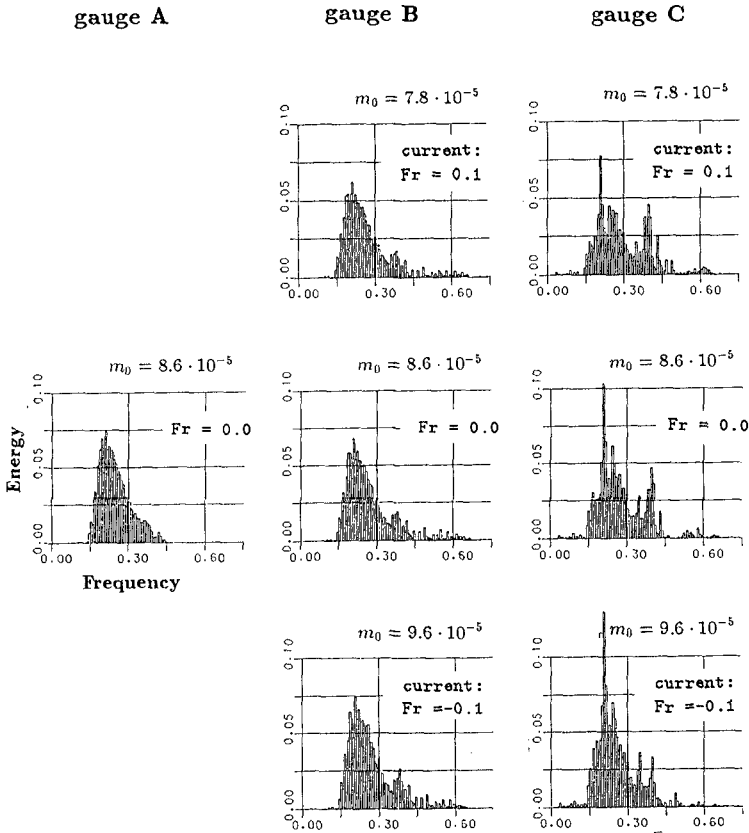

Figure 6: Wave-current interaction in the frequency domain

is constant for each test. However, the behaviour of the peaks at a frequency of $\approx 0.2Hz$ and $\approx 0.4Hz$ is different. The first peak decreases if waves and current are propagating in the same direction and increases otherwise. This is again in agreement with Fig. 4. The behaviour of the second peak is almost the reverse of the latter. It remains constant or increases if waves and current are in the same direction and decreases otherwise. This cannot be explained by the theory of Longuet-Higgins/Steward. Although the significant wave height of the spectrum is relatively small compared to the water depth ($H_s \approx 4.cm$ $D = 50.cm$), the nonlinear wave-wave interaction between the individual frequency components dominates the influence of wave-current interaction. Contrary to the first phenomenon there is a significant dependency on the incoming wave height, indicating the necessity of nonlinear numerical simulations.

3.2 Upwelling from below

The bottom picture of Fig. 5 displays the experimental set-up. This is almost the top picture, except that a slope is present between gauges **B** and **D** and the water depth reduces from 50.cm to 30.cm. Consequently, the wave transformation is even more complicated. Due to the different cross-sections, the ambient current is larger at gauge **D** than at gauge **A**. The change of the current takes place above the slope by an upwelling of water from below. In addition to this, the propagating wave spectrum shoals over the slope.

Assuming a linear, monochromatic wave, the change of its amplitude between gauges **B** and **D** can be calculated using the formula³

$$\frac{a^D}{a^B} = \sqrt{\frac{(u_{0,B} + \frac{1}{2}c_B(1 + G_B)L_B)c_D}{(u_{0,D} + \frac{1}{2}c_D(1 + G_D)L_D)c_B}} \quad (13)$$

If the ambient current is zero at both gauges ($u_{0,B} = u_{0,D} = 0$), then (13) gives the shoaling coefficient. If $u_{0,B} = 0$ and the water depths are equal at both gauges, then (13) is identical to Equ. (11). It is important to notice that the change of amplitudes results from a combination of wave-current interaction and shoaling.

As indicated in Chap. 3.2, the significant wave height of the spectrum H_s is affected by an ambient current as predicted by the analytical solution of Longuet-Higgins/Steward. This chapter is to investigate further changes in a combined current-shoaling situation. A suitable numerical model has to take into account that waves are transformed by an upwelling of water from below. In other words, it has to take into account a vertical component of the fluid velocity above the slope. Although the variables of the extended BWE are the depth-averaged horizontal velocities u, v , a vertical velocity w varying linearly from the bottom to the surface is assumed during the derivation. This enables the equations to simulate the wave behaviour above the slope which is influenced by water *upwelling from below*.

Several numerical simulations have been carried out using a Pierson-Moskowitz spectrum with different peak periods T_p and different significant wave heights H_s . Also, a comparison is made using Equ. (13), involving a monochromatic wave with a period equal to the peak period of the spectrum. Table 2 summarizes the results for a spectrum with $T_p = 4.5s$ and different current conditions: Column *BOWAM* displays the results of the numerical model whereas column *combined* shows the results of the analytical solution (13). It is common practice in simple linear wave modelling to approximate combined effects as a superposition of individual effects. For comparison, column k_s and column k_u are the results of separate shoaling and separate wave-current interaction, respectively. Column $k_{s,u} = k_s k_u$ displays the results of the linear superposition.

It can be stated that the results of BOWAM are in very good agreement with the analytical solution. The linear superposition of separate shoaling and

³This formula has been developed based on the concept of the *conservation of wave action*. For details, see Jonsson [2] and Prüser[6].

gauge B		gauge D		$H_{s,D}/H_{s,B}$				
u_0	Depth	u_0	Depth	BOWAM	combined	k_s	k_u	$k_{s,u}$
0.100	0.50	0.167	0.30	1.068	1.070	1.125	0.970	1.091
-.100	0.50	-.167	0.30	1.200	1.192	1.125	1.036	1.166
0.150	0.50	0.250	0.30	1.039	1.048	1.125	0.957	1.077
-.150	0.50	-.250	0.30	1.241	1.232	1.125	1.057	1.189

Table 2: Combined modelling of waves on a current and shoaling

separate wave current interaction is a relatively good approximation regarding wave heights. It should not be used, however, if one is interested in locating a breaker zone, which depends on the ratio of wave height to water depth; irregular wave trains will produce a time-varying breaker zone. This has to be simulated in nonlinear wave models.

4 Waves on a current in a basin

The corresponding two-dimensional extension of the test described in Chap. 3.2 will be investigated here. In a wave basin of constant water depth ($D = 50\text{cm}$), a Pierson-Moskowitz spectrum ($T_p = 4.5s$, $H_s \approx 4\text{cm}$) is generated by the wave maker and propagates from left to right. An ambient current with a Froude number of $Fr = \pm 0.1$ is assumed in a part of the computational domain.

The situations: a) waves and current propagating in the same direction; b) no current; c) waves and current propagating in opposite directions are displayed from top to bottom in Fig. 7.

The wave crests at a specific time step are given on the left hand side. The darker the wave crests, the higher is the surface elevation. A numerical, directional wave gauge is placed in the basin to obtain the spectral shape of the spectrum and the distribution of the mean direction as a function of the frequency. In the case of still water, the transformation is the same as displayed along the centre-row of Fig. 6. The mean direction is constant at $\Theta = 90^\circ$ and the spectral moment $m_0 = 8.6 \cdot 10^{-5}$.

In the presence of a current, the wave fronts change their direction. In the case of waves and current in the same direction, the waves are refracted with an average angle of $\Delta\Theta = 10^\circ$ at the gauge (For waves and current in opposite directions the angle of refraction is $\Delta\Theta = 12^\circ$). The quantity $\Delta\Theta$ depends on current and frequency. High components are refracted more than low components.

At the transition between still water and current, the crests are drawn apart. This produces a two-dimensional effect in which wave energy propagates along the crests. A decrease or increase of the spectral moment m_0 was recorded. This depends on the current condition and on the position in the computational domain. The change can be very much higher than predicted in the one-dimensional test (Chap. 3.2). Fig. 7 shows that in the case of waves and current in the same direction, the spectrum remains single-peaked ($m_0 = 5.1 \cdot 10^{-5}$) at the chosen

gauge. A double-peaked spectrum ($m_0 = 11.5 \cdot 10^{-5}$) is generated if waves and current are in opposite directions.

The numerical model was also used to simulate arbitrary angles between the current and the wave direction. Although, the results were very promising, they are not presented here because corresponding hydraulic measurements were not available for verification purposes.

5 Conclusions

A numerical model based on the extended Boussinesq-Wave-Equations (BWE) was applied to simulate irregular waves with an ambient current. The current alters wave height, wavelength and the direction of wave propagation. The equations may be used to simulate the generation or the change of a current by an *inflow from the sides* as well as by an *upwelling from below*.

The range of validity has been checked, comparing Boussinesq theory with linear wave theory. Regarding harmonic waves, the BWE are valid provided the wave length is at least 10 times the water depth and the Froude number of the current is smaller than ± 0.2 . Regarding irregular waves, even shorter waves of a spectrum can be simulated as long as they are related to long waves (bounded-short waves, the generation of higher harmonics).

The change of the significant wave height of a Pierson-Moskowitz spectrum can be predicted by the theory of Longuet-Higgins/Stewart using a monochromatic wave with the peak period of the spectrum. The change depends on the period of the wave, the strength of the current and the water depth. The wave amplitude itself has a minor effect. The results of the numerical model are in very good agreement with the theory. The numerical model also simulates the development of the spectral shape.

CHAPTER 83

WAVE SPECTRA TRANSFORMATIONS

Giancarlo Chiaia, Leonardo Damiani, Antonio Petrillo *

Abstract

In this paper the transformations of sea waves, reproduced by a JONSWAP spectrum in a laboratory channel, have been studied both in frequency and time domain. In frequency domain the occurrence of non-linearities producing energy transfers to high and low frequencies was studied. The reported experimental results enabled us to compare the two approaches and to define the limits within which they give the same results.

INTRODUCTION

The transformations of a sea state when moving from deep to shallow waters can be studied by analyzing how the values of its characteristic quantities vary in the time as well as in the frequency domain.

Although describing the same physical phenomenon, these two approaches are not always equivalent and often give quite different results, especially when great transformations have already occurred.

The study of the correlation between the results of the two methods is particularly important both for setting up and applying mathematical models to foresee the pattern of spectral shapes, as well as for application purposes, such as the estimate of the significant wave height for the design of sea works. Moreover, the knowledge of local sea states is indispensable for the study of solid transportation.

In this work the two types of analyses were made, referring to one-dimensional JONSWAP spectra generated in a wave channel with a sand bar-shaped bed, in order to define their applicability limits. We analyzed the occurrence of non-linearities by introducing first Ursell number and then a

*Hydraulics and Hydraulic Constructions Institute
Bari University - Via ReDavid, 200 - BARI (ITALY)

dimensionless depth and by establishing the limits of linear propagation (Thompson and Vincent, 1985).

Some singularities observed in the pattern of parameters calculated in the frequency domain led us to study the energy components at low frequencies, especially near the shore. These were studied according to the theory of reflection of small amplitude waves, which, despite the approximation due to the non-linearity of the problem, enabled us to identify the presence of an almost standing component (surf-beat) with remarkable energy quantities in the surf-zone.

Finally, the analysis in the time domain enabled us to establish the limits within which the knowledge of the energy spectrum can be applied to estimate the quantities of interest to engineers.

DESCRIPTION OF EXPERIMENTAL SET-UP AND FACILITIES

Experiments were carried out in the wave channel at the laboratory of the Hydraulics and Hydraulic Constructions Institute of Bari University.

The channel is about 45 m long and 1 m wide; its walls consist of 1.2 m high crystal glass sheets supported by iron frames with a center to center distance of about 0.44 m, resulting in 100 gauging cross-sections along the whole length of the channel (the 100th cross-section coincides with the wave generator paddle location). The channel bottom is covered with a sand layer of a pretty uniform size $d_{50}=0.15$ mm and with a corresponding fall velocity $\omega = 0.018$ m/s. Experiments are also being carried out to assess the performance of some submerged breakwaters (Lamberti et al., 1985); therefore, at a distance of 4.5m from the wave generator, the channel has been longitudinally subdivided into two parts in order to simulate the evolution of an unprotected beach, in one part, and the evolution of a protected beach under the same wave attack in the other. The experimental measurements reported in this paper were all made in the former. Two bars, whose crests were approximately located at cross-sections 60 and 30, were observed in the channel during the tests.

The wave generation system consists of a flat paddle which receives a rotatory-translational motion: the kinematic mechanism which drives the paddle is designed for the axis of rotation to be lower than the channel bottom, this being a better condition to generate waves at shallow depths. The paddle is set in motion by an oleo-dynamic system driven by an electrical valve which, through an electrical signal, sends pressurized oil to the two ends of the cylinder in which the piston moves. The piston displacements, measured by a transducer, control the system in a closed chain circuit and give it a good stability in the applied field of frequencies. The whole system is controlled by a processing computer.

The small water losses occurring in the channel, especially between the paddle and the channel walls, are compensated by an automatic supply system driven by an electrical water gauge equipped with a band-pass filter which eliminates wave-generated surface oscillations. During the tests, the water depth near the paddle was 0.8 m with level fluctuations of about 0.1 mm.

In Froude undistorted similarity with 1:10 length scale, the tests reproduce some meteomarine conditions of mid-Adriatic sea (Italy).

The sea states in the channel were represented by energy density JONSWAP spectra with amplification parameter $\gamma=3.3$ and shape factor $\omega=0.07$ for $f < f_p$ and $\omega=0.09$ for $f > f_p$. The wave attacks tested in the channel have off-shore significant heights (H_s) ranging from 8.34 to 24.17 cm and significant period (T_s) ranging from 1.49 to 2.13 s, corresponding to JONSWAP spectra with peak frequencies in the range $(0.44-0.63 s^{-1})$ and zero-th order moments m_0 of the spectra varying from 5 to 42 cm^2 .

In this study we analyzed the results referring to five wave attacks of the same peak frequency $(0.507 s^{-1})$ and m_0 (evaluated at the first monitoring cross-section) ranging between 5.20 and 36 cm^2 . For these attacks measurements are available at all the gauge stations of the channel, this being indispensable to describe a complete wave pattern.

The measurements in the channel were made through capacitive probes, calibrated before each experiment and connected to a processing computer through an analogue-digital converter. For each measurement the data acquisition was made simultaneously with three probes, for a time of 102,4 s and a sampling interval of 0.1 s. The three probes were also used to assess the incident and reflected spectra (Lamberti et al., 1986).

The probes could measure the wave state up to cross-section 8, since the low water depth near the shoreline makes the measurements poorly reliable because of the presence of air mixed with water.

Telecamera shots were used to measure the wave flow also in the area between cross-sections 8 and 5, where the swash-zone starts (Damiani and Ranieri, 1989), and to check the data obtained from the probes between cross-sections 13 and 8 where the presence of air bubbles can invalidate the probe measurements. The frame by frame shot enabled to have the time pattern of the free water level fluctuations.

The data taken by the probes or the telecamera were processed both in the time (up-zero-crossing method) and the frequency domain.

In the latter case, the n-th order spectral density moments were calculated through numerical integration; hence the average spectral periods ($T_{01} = m_0/m_1$ and $T_{02} = \sqrt{(m_0/m_2)}$) as well as the parameters of spectral width ($\epsilon_2 = (m_0 m_2/m_1^2 - 1)^{0.5}$ and $\epsilon_4 = (1 - m_2^2/(m_0 m_4))^{0.5}$) were obtained.

Through partial integration of the spectrum the energy content in the neighbourhood of the peak frequency and its two first harmonics (E_1, E_2, E_3) were calculated assuming, in agreement with other authors (Guza and Thornton, 1980), $0.9nf_p$ and $1.1nf_p$ with $n=1, 2, 3$ as integration limits.

The equivalent and significant wave heights $H_{rms} = \sqrt{8m_0}$ and $H_s = 4\sqrt{m_0}$ were calculated for an infinitely narrow spectrum.

For the study of low frequency waves (among which the surf-beat) the energy and the height H_{rms} of the examined frequencies were also calculated by integrating the spectrum on a $3\delta f$ large band, centered on the concerned frequency, with δf being the resolution frequency of the spectrum.

By applying the up-zero-crossing method for each cross-section all the statistical characteristics of the wave state were calculated. The water level rise distribution was also analyzed with respect of Gauss distribution by applying χ^2 test and calculating the skewness and the the kurtosis ($\beta_1, \sqrt{\beta_2}$).

The definitions and symbols of quantities were taken from the "List of Sea State Parameters" (I.A.H.R., 1987).

ANALYSIS OF EXPERIMENTAL RESULTS

Linear Propagation Field

In figure 1 the configuration of the sand bed of the channel with the two previously mentioned bars is illustrated. It also shows the energy spectra measured at some representative cross-sections and referred to a wave attack of a peak frequency equal to 0.507 s^{-1} and a zero-th order moment of the spectrum equal to

Figure 1. Beach profile and sample of spectra assessed in different cross-sections.

28 cm^2 at the first gauging cross-section.

This figure emphasizes the transformations of the spectrum in its propagation up to the shoreline. Already in the zone off-shore the first bar, where only shoaling is present (cross-section 67), the spectrum transformations result in an energy transfer to high frequencies; afterwards, flowing over the off-shore bar,

it is noticed a first wave breaking, which produces a decline of the energy content at the peak frequency and an increase of the above said transfers. It then follows a recombination phase in which the energy content at peak frequency grows up and energy quantities at low frequencies start being remarkable. The high energy dissipations, due to the wave breaking on the on-shore bar, cause a remarkable flattening of the spectrum at cross-section 31. The spectrum completely changes its initial shape at cross-section 13, so that it is no longer possible to detect any energy content at the peak frequency. Near the shoreline (cross-section 5) the only significant energy content is the one at low frequency (surf-beat): this points out that very slow oscillations of the mean sea level occur in this area.

Definitely, moving from off-shore to the shoreline, waves basically undergo three kinds of transformations: energy transfers towards high frequencies, breaking dissipations and energy transfers towards low frequencies. The energy transfer towards high frequencies shows that non-linearities occur in the propagation of spectra.

The non-linearities were studied by analyzing the ratios of the energy quantities around the first and the second harmonic to the peak frequency energy (Guza and Thornton, 1980; Petrillo, 1988). These ratios were taken as a function of Ursell number calculated through $Ur = H_{rms} L_p^2 / h^3$, where h is the local depth and L_p is the local wave length at the peak frequency (Figure 2).

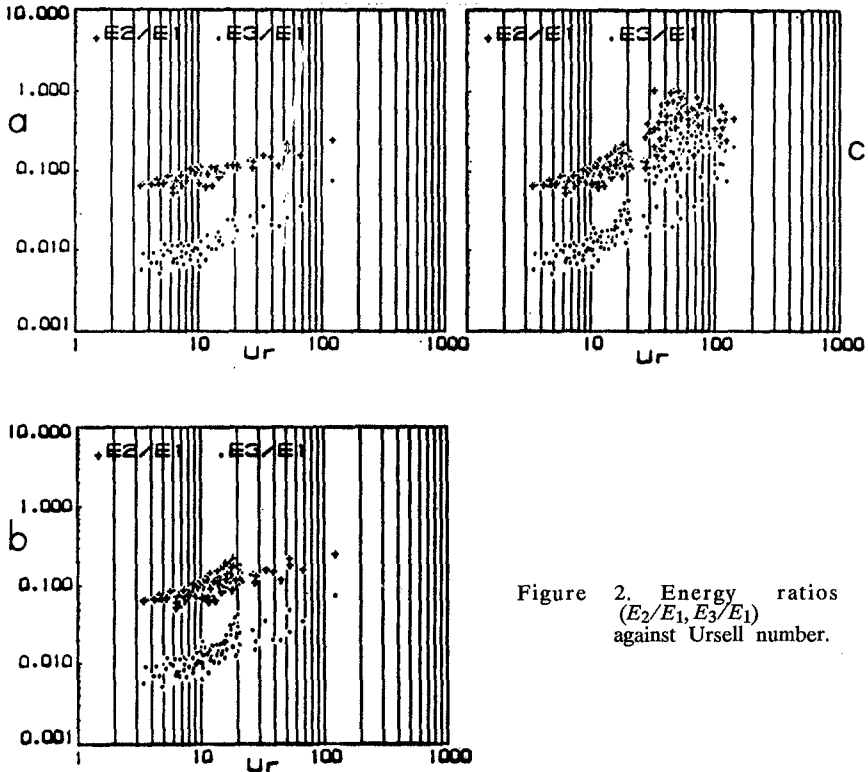

Figure 2. Energy ratios ($E_2/E_1, E_3/E_1$) against Ursell number.

In order to emphasize the shoaling, the breaking and the bar-effects, the pattern of these ratios was studied by plotting first the data off-shore the first bar (i.e. before breaking) (figure 2.a), then those before the on-shore bar (including the previous ones, but always excluding data of cross-sections where waves break) (figure 2.b) and, at last, the values of the ratios for all the cross-sections, including those of breaking (figure 2.c).

By comparing figures 2.a and 2.b it is noticed that the presence of bars locally creates some non-linearities. When flowing over the on-shore bar, wave breaking occurs and non linearities increase as shown in the figure 2.c.

From the analysis of the enclosed and examined diagrammes, considering that for a theoretical JONSWAP spectrum with $\gamma=3.3$ the E_2/E_1 and E_3/E_1 ratios are respectively equal to 0.083 and 0.008, it can be stated that the non-linearities on the first harmonic appear when Ursell number values are higher than 6, whereas the non-linearities on the second harmonic appear at higher Ur values (about $Ur > 10$). These results are in agreement with those found by Guza and Thornton (1980) and other authors.

Instead of Ursell number, the dimensionless depth $K_{p0}h$ (where $K_{p0}=2\pi/L_0$ is the wave number, calculated by referring to the peak frequency), which is easier to determine, can be applied to study the occurrence of non linearities at high frequencies.

Figure 3. Energy ratios ($E_2/E_1, E_3/E_1$) versus $K_{p0}h$.

From the analysis of figure 3, reporting the data for all the gauging cross-sections and all the wave attacks, it is shown that non-linearities occur both on the first and the second harmonic when $K_{p0}h$ is greater than 0.8.

It has to be observed that, since the examined attacks have all the same peak frequency, and so the same L_p , and since the non-linearity depends on the H/h and h/L_p ratios (Petrillo, 1988), h being equal, non-linearities increase with the increase in energy of the wave attack.

The pattern of ϵ_2 , and ϵ_4 as a function of Ursell number is reported in figure 4; for values of $Ur < 6$, the two parameters have values quite close to those

Figure 4. Spectral width parameter (narrowness parameter and broadness factor) against Ursell number.

of the undistorted JONSWAP spectrum ($\epsilon_2=0.329$ and $\epsilon_4=0.658$); they increase with the increase of Ursell number in a way qualitatively similar to that of the E_2/E_1 and E_3/E_1 ratios; the same behaviour is observed for ϵ_2 and ϵ_4 as a function of $K_p h$.

Figure 4 also shows that ϵ_2 , which has higher relative variations, is more significant than ϵ_4 in representing the phenomenon; this is in agreement with Thornton and Guza (1983).

Analysis in the Frequency Domain

Referring to the wave attack with $m_o=36 \text{ cm}^2$, figure 5 illustrates the pattern of H_{rms} calculated on the basis of the energy content of the whole spectrum and then of the spectrum around the surf-beat frequency (0.0781 s^{-1}); the figure also reports the pattern of the $T_{0.2}/T_p$ and $T_{0.1}/T_p$ ratios and the beach profile.

Figure 5. Beach profile; H_{rms} , $T_{0.2}/T_p$, $T_{0.1}/T_p$ values, assessed across the shore.

The pattern of H_{rms} of the whole spectrum is indicative of the kind of transformations which spectrum undergoes when approaching the shoreline: shoaling until reaching the off-shore bar; small wave breaking on the bar; then recomposition; shoaling again up to the on-shore bar; large wave breaking on it and, at last, spectrum reaches the shoreline with a saturated energy content in the wind-wave band.

The mean spectral periods decrease in the shoaling area and on the bar because of the energy contents increase on the second and the third harmonic; during recomposition, periods increase, go back to normal values, then they decrease again because of shoaling on the

on-shore bar and, at last, they become minimum in the area of highest wave breaking. Downstream of the on-shore bar (see figure 1), the spectrum is flat and so the values of average periods remain basically constant. Nevertheless the

Figure 6. Dimensionless mean spectral periods H_{rms} , $T_{0.2}/T_p$, $T_{0.1}/T_p$ across the shore, evaluated with different integral limits in n-th order moments calculation.

pattern of mean periods in this area shows an increase in the proximity of cross-sections 22 and 8 where the surf-beat energy values are maximum.

The influence of surf-beat at the cross-sections downstream of the on-shore bar on the the first and second order moments, and then on the mean spectral periods, can be observed in figure 6 which also illustrates the pattern of the mean spectral periods, calculated by integrating the spectrum starting from the frequencies $f_1=0$ and $f_1=0.5f_p$. It is noticed that the two quantities are the same up to the cross-section of maximum wave breaking (cross-section 34), whereas they greatly differ downstream the on-shore bar, where the surf-beat energy is greater. In this area the value of the $T_{0.2}/T_p$ ratio fluctuates, for the considered wave attack, in the range 0.62–0.67, and it decreases (about 10%) if the contribution due to low frequencies is omitted. Near

the shoreline, where the surf-beat reaches its absolute maximum value, such a ratio becomes equal to 0.72 and it reduces (15%) if the surf-beat contribution is omitted. The same pattern is observed for the parameter $T_{0.1}/T_p$.

The mean spectral periods, for all the examined wave attacks, are plotted in figures 7a and 7b, as a function of $k_p h$. It is noticed that for $k_p h > 0.6$, independently of the energy of attacks, the dimensionless periods remain rather constant ($T_{0.1}/T_p = 0.87$ and $T_{0.2}/T_p = 0.846$). These values are slightly different

Figure 7. Dimensionless mean spectral periods versus $K_p h$ for all the wave attacks.

from the theoretical ones of JONSWAP spectrum with $\gamma=3.3$, respectively equal to 0.844 and 0.801. These deviations, (3% for $T_{0.1}/T_p$ and 6% for $T_{0.2}/T_p$) are to be attributed to the inevitable errors produced in spectrum generation and survey. Nevertheless, the previous figures show the same trend found by other authors (Bendykowska, 1986; Liberatore and Petii, 1988).

For $K_{po}h > 0.6$, on the average, $T_{0.2}/T_p$ and $T_{0.1}/T_p$ tend to decrease with $k_{po}h$, but, differently from the results by other authors (Bendykowska, 1986), who found a monotone and always decreasing pattern, in the present experiments a high variability was observed as a function of the wave energy.

This behaviour is clearly linked to the non-linearities which occur during propagation (shoaling, bars, wave breaking) and to low frequency standing waves, both related to the wave energy and to the shape of the beach profile.

In order to show that surf-beat is really a standing wave produced by reflection from the beach, the small amplitude wave theory was applied (in spite of the approximations due to the non-linearity of the phenomenon). According this theory the resulting wave amplitude should be enveloped by the curves representing respectively the sum and the difference between the incoming and reflected waves. Figure 8 illustrates, for some frequencies, the heights of the resulting monochromatic waves, the sum of the incoming and reflected waves heights and their difference, along the channel. The above mentioned heights have been calculated by integrating around the considered frequency, respectively the spectrum surveied in the cross sections and the incoming and reflected spectra, assessed through the three probe method.

Figure 8. Envelope of monochromatic components according to small amplitude wave theory.

It can be observed that surf-beat component (at the frequency $0.0781s^{-1}$ in model scale) is a quasi pure standing wave because the progressive component (represented by the difference between the incoming and reflected waves) is very little if compared with the standing one (difference between the two lines representing the sum of the incoming and reflected wave heights and their difference): that means an almost complete reflection from the beach at the surf-beat frequency.

For the monochromatic components with frequencies higher than the surf-beat one, the progressive component is larger, but a standing component is still present: that means a partial reflection; the reflection lessens with frequency increasing and it becomes negligible near the peak frequency where monochromatic components can be represented by pure progressive waves.

Analysis in the Time Domain

The patterns of T_s/T_p and T_z/T_p (with T_s and T_z , respectively significant and average periods, both assessed in the time domain) for the attack with $m_o=36 cm^2$ and $f_p=0.507 s^{-1}$, as well as the beach profile are illustrated in figure 9.

Figure 9. Dimensionless wave periods (T_s/T_p and T_z/T_p), evaluated in time domain, across the shore.

In agreement with the results by other authors (Liberatore and Petti, 1988) T_z/T_p is not so much affected, at least up to the on-shore bar, by the transformations of the spectrum when passing from higher to lower depths. This ratio ranges around 0.9, higher than the theoretical value referred to JONSWAP spectrum with $\gamma=3.3$; such a difference is similar to the one observed in the analysis of the mean periods in frequency domain. The T_s/T_p ratio is, on the average, equal to 1.00 up to the on-shore bar, with a slightly decreasing trend. This enables to refer to the peak frequency of the

spectrum, rather than to the significant one, when using the models for studying the wave transformations. This is always true far from breaking; after breaking the T_s/T_p ratio is sensitive to the distortions of the spectrum, especially near the shoreline, where it is also affected by low frequency standing waves and the dimensionless significant period reaches the value 1.40.

Figures 10.a and 10.b report dimensionless wave periods, for all the examined wave attacks, as a function of $K_p h$. The two figures show quite the same behaviour.

For $K_p h > 0.6$, T_s/T_p is almost constant, with an average value equal to 0.975, whereas for $0.3 < K_p h < 0.6$, a dispersion of experimental data is observed with a slightly decreasing pattern. For values of $K_p h < 0.3$, the behaviour of different wave attacks greatly differs: the significant period increases with the increase of the attack energy and, hence, of the surf-beat it produces. In this area the data referring to the attacks with $m_o = 5; 10; 15 \text{ cm}^2$ fall below the straight line representative of the mean value off-shore, whereas, for higher energy, they fall above. These results are in agreement with those reported in figure 3. The same conclusions may be drawn from the analysis of the behaviour of T_s/T_p as a function of Ursell number: it is constant for $Ur < 10$; for $10 < Ur < 30$ the data are scattered around the mean value despite the presence of a band of variability; whereas for $Ur > 30$ the points form a cloud with increasing T_s/T_p values for the wave attacks of higher energy.

Figure 10. Dimensionless periods, evaluated in time domain, versus $K_p h$ for all waves attacks.

Figure 11. Beach profile and H_s/H_{rms} across the shore.

For the previously examined attack, figure 11 reports the pattern of H_s/H_{rms} ratio, calculated in the time domain. It is noticed that, except at some cross-sections, H_s/H_{rms} is not greatly influenced by the wave transformations: it decreases from 1.40 to 1.34 from off-shore to the shoreline, with lower values between cross-sections 24 and 32, where it reaches the minimum value 1.25. These results are partly in agreement with those found by Thornton and Guza (1983). In their experiments on gentle slope beaches, they found that the ratio H_s/H_{rms} is constant and equal to 1.42 for a sea state following wave heights Rayleigh distribution.

Figure 12 reports the ratio between the wave energy calculated in the time domain ($E_{td} = 1/8 \rho g H_{rms}^2$) and the energy assessed by integration of the spectrum (given by $E_{fd} = \rho g m_o$) and the skewness and kurtosis of elevations along the shore.

The figure shows that at the cross-sections off-shore the first bar, where the spectrum is not markedly affected by non-linearities, both the skewness and the kurtosis have values close to those of Gauss distribution and E_{td}/E_{fd} approaches to 1, that is the time and frequency domain analyses give the same results.

Figure 12. Beach profile, time domain energy rated to frequency domain energy, Skewness, and Kurtosis of surface elevations.

Figure 13. Comparison between significant wave height values calculated in the time domain and through the zero-th order moment of the spectrum.

When the spectrum is affected by non-linearities (produced by shoaling, bar-effect and breaking), both the kurtosis and the skewness increase: the former because of decreasing of maximum wave heights and hence of a greater probability around the average value, the latter because of energy transfers at high frequencies which makes the waves similar to cnoidal waves. In this case E_{td}/E_{fd} increases and reaches the maximum value of about 1.2.

In the inner surf-zone, the strong dissipations due to wave breaking produce a notable flattening of the spectrum, thus, as it is reported by other authors (Dally and Dean, 1988), the H_{rms} height, calculated in the time domain, declines and the E_{td}/E_{fd} ratio becomes lower than 1. Finally, from the figure it can be stated that the assumption $H_{rms} = \sqrt{8}m_o$, which links a quantity calculated in the time domain to a quantity obtained in the frequency domain, can be applied only when the non-linearities are far away. This is partly in disagreement with the results by other authors (Thornton and Guza, 1983), who noticed that the above said relationship can be applied also in the case of breaking waves.

Figure 13 illustrates the ratio between the significant height, H_s , calculated by the up-zero-crossing method and the significant height, H_{smo} , obtained from the spectrum which, in the case of JONSWAP spectrum with $\gamma=3.3$, is related to the zero-th order moment through the relationship $H_{smo} = 3.866\sqrt{m_o}$.

Figure 14. Behaviour of (H_s/H_{smo}) ratio for different wave attacks.

This ratio has a pattern qualitatively similar to that of E_{id}/E_{fd} illustrated in figure 12.

The pattern of H_s/H_{smo} , for three wave attacks of different energy (figure 14), shows that the deviations of the ratio from 1 depend on the attack energy. This is in agreement with the results found by Thompson and Vincent (1985) who relate the deviations of H_s/H_{smo} to the local steepness, which is a strictly increasing function of the energy for each cross section, since all the described wave attacks have the same peak frequency.

CONCLUSIONS

The analysis of the experimental results, confirms how difficult it is to establish a direct correlation between the characteristic quantities of a wave state in the frequency and in the time domain.

In fact, the results from the two types of analysis are well correlated only in a limited field of linear propagation with values of the parameter $k_p h > 0.6$, or $Ur < 10$.

Out of this field, the evaluation of the characteristic quantities in the time domain based on the knowledge of those in the frequency domain, entails big errors in that the spectrum, because of the great non-linearities occurring during propagation, can no longer represent the physical phenomenon correctly; in these zones it is better to refer to the time domain.

It was shown that, for values of $k_p h < 0.3$, a decreasing trend of the mean spectral periods $T_{0.1}$ and $T_{0.2}$ was observed, due to the presence in this zone of low frequency standing waves which greatly affect them, whereas the characteristic periods in time domain (T_s and T_c) are less affected by non-linearities.

Following on the lack of direct correlation of the results from the two methods, it is difficult to evaluate the significant wave height (needed to design sea structures) based on the knowledge of the spectrum.

The analysis in frequency domain pointed out some monochromatic components at low frequencies and, among them, the surf-beat ($f = 0.0781s^{-1}$ in model scale) with a great energy content in the surf-zone and a maximum value near the coast. Some authors (Bredshaw, 1980) assumed that the genesis of the phenomenon is related to the fact that, after breaking, the wave recomposes and generates new bigger waves which capture and incorporate smaller ones. This mechanism should produce a gradual change in the spectrum, passing from the

breaking point to the shoreline, in that going towards shallow waters a gradual absorption of smaller waves is supposed to occur. The present experiments, although not showing such a gradual absorption, showed, in the surf-zone, the presence of energy quantities at frequencies between the surf-beat and the peak one. It is thought, however, that although the above-said mechanism may contribute to the energy transfer to low frequencies, the presence of surf-beat is essentially due to the reflection of the beach (Guza and Thornton, 1985) which generates a standing wave at low frequency.

PART II

Long Waves and Storm Surges

CHAPTER 84

EVOLUTION OF INFRAGRAVITY VARIANCE DURING A STORM

Peter A. Howd¹, Joan Oltman-Shay^{1,2}, Rob Holman¹, and Paul D. Komar¹

Abstract

Data from an alongshore array of bidirectional current meters located in the surf zone were analyzed to provide estimates of the behavior of three bands of wave energy during the passage of a moderate storm. The variance in the incident wave band is found to be saturated, as is expected of depth-limited waves. The infragravity band variance is found to depend most strongly on the offshore wave height. Shear wave variance is found to be correlated with the magnitude of the measured longshore current. During a period of nearly constant high waves, the composition of the low frequency band motions ($f < 0.05$ Hz) changed dramatically. This change is thought to be related to the directional characteristics of the incident band wind waves.

Introduction

A primary interest in the study of nearshore processes has been the characterization of two frequency bands of surface gravity waves, incident wind waves ($0.05 < f < 0.33$ Hz) and infragravity waves ($f < 0.05$ Hz). The recent discovery of shear waves (Oltman-Shay, et al., 1989a; Bowen and Holman, 1989) has added additional complexity to the problem of quantifying coherent sources of energy in the nearshore.

The objective of this paper is to present data documenting the evolution of the low frequency waves during the passage of a moderate storm. The instruments used for this study were located in the trough of a nearshore bar system in approximately 1.5 m of water. In the next section we will briefly review previous work on

these low frequency waves, then move on to the data collection and analysis techniques used in this study. We then present our findings and some preliminary conclusions.

Background

Infragravity waves are traditionally considered to be the surface gravity waves which result from the second order interaction of incident wind waves. The free infragravity waves can be broken into two distinct groups, a set of discrete edge wave modes which are trapped to the shoreline, and a continuum of leaky waves which reflect from the shoreline and radiate energy back out of the nearshore zone. Bounded waves, the forced displacement of the free water surface by the structure of wave groups also contribute to infragravity wave energy. Edge waves on a plane sloping beach must have alongshore wavenumbers, k , in the range $\sigma^2/g \leq |k| \leq \sigma^2/g\beta$ (where $\sigma = 2\pi f$ and $k = 2\pi/L$) satisfying the relationship $\sigma^2 = g|k| (2n+1)\beta$ (Eckart, 1951), while for leaky waves there is a continuum of alongshore wavenumbers $|k| < \sigma^2/g$ (Suhayda, 1974; Guza and Bowen, 1976).

It is important to note that measurements of infragravity waves obtained in the surf zone underestimate the maximum variance of the infragravity band for two reasons. First, while incident waves decrease in height from breaking to the shore-

Figure 1. Cross-shore shape of the first three edge wave modes and the normally reflected leaky wave plotted versus dimensionless cross-shore distance.

line, infragravity waves have their maximum height at the shoreline and decay offshore (Figure 1). Secondly, infragravity waves have complicated cross-shore structures which contain zero crossings. Thus at any position seaward of the shore-

line, measurements are influenced not only by the offshore decay of the wave amplitudes, but by the nodal structure.

Shear waves, a new class of nearshore wave, are distinguished by large alongshore wavenumbers, well outside the range of surface gravity waves, $|k_{sw}| > \sigma^2/g\beta$ (Oltman-Shay, et al., 1989a). On the one beach studied to date, a typical energetic period is 200 s with an alongshore wavelength of 200 m. This distinctive signature permits their contribution to total current variance to be separated in alongshore wavenumber-frequency space. Bowen and Holman (1989) present a theoretical derivation of these waves as an instability of the mean longshore current which depends on the conservation of potential vorticity. The cross-shore shear of the mean longshore current provides background vorticity. Using a simple model they show there is a frequency range where a perturbation to the mean current (the shear wave) will grow exponentially at a rate which depends on the magnitude of the shear on the seaward face of the current.

Field Site and Methods

The data used for this study were collected as part of the SUPERDUCK experiment (Crowson, et al., 1988). This was a large multi-agency experiment hosted by the Coastal Engineering Research Center's Field Research Facility (FRF) in Duck, North Carolina during October, 1986. This beach is located on the mid-Atlantic coast of the United States in the center of a 100-km long barrier spit (Figure 2). The mean foreshore slope is approximately 1:10 and decreases offshore to 1:100.

Figure 2. Location of the Coastal Engineering Research Center's Field Research Facility.

Sand bars are common, are usually three-dimensional, but become linear during

storms (Lippmann and Holman, 1990). The extreme tide range during the experiment was 137 cm.

The primary source of data for this work was an array of bidirectional electromagnetic current meters deployed approximately 55 m seaward of the mean shoreline position (Figure 3). The sampled array length was 290 m, sufficient to resolve typical wavelengths at this site. Sensors were oriented such that +V currents (alongshore) flow 'north' parallel to the beach and +U (cross-shore) currents flow offshore. All gages remained submerged at low tide. The gages were hard wired to the computer and collected at 2 Hz for four hour periods surrounding high and low water. The incident wind wave climate was sampled in 8 m depth using a 255 m long array of 9 bottom mounted pressure sensors.

Figure 3. Plan view of the SUPERDUCK field site at CERC'S Field Research Facility in Duck, NC. Shown are the nearshore current meter array and the offshore wind wave directional array relative to the location of the pier.

A total of 37 4-hour data runs were recorded over the course of the experiment. From those, 21 were selected for further analysis on the basis of spatial homogeneity over the length of the arrays and stationarity over the 4 hour run duration. The current meter data were used to calculate the alongshore wavenumber-frequency spectra for both the cross-shore and alongshore components of flow. First each 4-hour time series was divided into 13 ensembles with 50% overlap, each 2048 s in length. The ensembles were demeaned and quadratically detrended and tapered with a Kaiser-Bessel data window. After application of an FFT, the cross-spectral constituents were calculated between all sensor pairs. Finally, alongshore wave-

number-frequency spectra were estimated using the Iterative Maximum Likelihood Estimator (IMLE) developed by Pawka (1983) and previously applied to surf zone data by Oltman-Shay and Guza (1987). The pressure sensor array in 8 m depth allowed similar alongshore wavenumber-frequency analysis.

Variance was then partitioned between the three bands in alongshore wavenumber-frequency space as shown in Figure 4. Integrated variances for each band were calculated using

$$s_{INC}^2 = \int_{0.05-k_{NY}}^{0.33 k_{NY}} \int (S(k, f)) dkdf$$

$$s_{IG}^2 = \int_0^{0.05 k_0} \int_{-k_0} (S(k, f)) dkdf$$

$$s_{SW}^2 = \int_0^{0.05 k_{NY}} \int_{-k_{NY}} (S(k, f)) dkdf - s_{IG}^2$$

where s^2 is the integrated variance for each of the bands, k_{NY} is the Nyquist alongshore wavenumber of the array, k_0 is the estimated mode zero wavenumber and $S(k, f)$ is the spectral density. The subscripts refer to **INC**ident, **Infra**Gravity, and **Shear** Waves, respectively.

Results

During the 14-day period of the experiment, the root mean square (rms) wave height $(8s^2)^{1/2}$ in 8 m water depth ranged from 50 cm to over 200 cm. During the peak of the storm the wave height remained very near 200 cm for a total of 18 hours. In the surf zone, the cross-shore component of the infragravity band reached a maximum rms value of 63 cm/s and averaged 32 cm/s for the 21 4-hour runs. The alongshore component of the infragravity band had a maximum rms flow of 33 cm/s and a mean of 20 cm/s. The shear wave band had maximum rms values of 41 and 35 cm/s with means of 25 and 20 cm/s for the cross-shore and alongshore components, respectively, for the 21 runs. First we will examine the general behavior of each of the wave bands (after Howd, et al., 1991), followed by a more careful examination of two data runs from the period of high waves.

Given the position of the current meter array in the inner surf-zone shoreward of the sand bar crest, we expect to observe that the incident band was limited

Figure 4. Cyclic alongshore wavenumber ($1/L$) vs. frequency spectrum with lines showing the bounds of each of the three wave types. The shaded boxes indicate peaks in $S(k,f)$ with the darkness indicating the higher variance. The width of the box indicates the half-power wavenumber bandwidth.

by the water depth, either at the array or further seaward at the bar crest. The strongest evidence for saturation of the incident band was the lack of statistically significant correlation (at the 95% level) between the incident wave heights at the array (calculated using linear theory) and the offshore wave height ($r^2 = 0.16$). There was however a significant correlation between the tide and the incident band wave height at the array ($r^2 = 0.80$) indicating the measurements were, as expected, a function of the water depth.

The infragravity wave motions were found to be significantly correlated with the offshore wave height ($r^2 = 0.73$ and 0.75 for the cross-shore and alongshore components, respectively). This finding is in agreement with current meter data from similar water depths on three other beaches (Holman, 1981; Guza and Thornton, 1985; Howd, et al., 1991).

Shear waves are expected to scale with the shear on the seaward face of the longshore current (Bowen and Holman, 1989), but because of the array design, no measurements of longshore current shear were available. Thus we have tested the absolute value of the mean longshore current $|\langle V \rangle|$, as a proxy for the shear. As expected from the preliminary observations of Oltman-Shay, et al. (1989a), significant correlations (95% level) were found ($r^2 = 0.25$ and 0.42 for the cross-shore and alongshore components respectively), but, as the low values suggest, considerable scatter exists in the data.

We will now compare two data runs taken during the storm. The first, taken just as the storm was reaching its peak, began at 1030 EST on October 10, 1986, and was characterized by an offshore rms wave height of 185 cm, peak period of 7.3 s and a 24.3 degree angle of incidence. The mean longshore current at the surf zone array was 160 cm/s to the south. The second run we will present was collected toward the end of the storm event and began at 1820 EST on October 11, 1986. The offshore wave height was 190 cm, the peak period was 10 s and the waves were near normally incident. The mean longshore current at the surf-zone array was 13 cm/s to the south.

Figure 5 shows the alongshore wavenumber-frequency spectra from the 8 m pressure sensor array for the two runs. To the right of each f - k spectrum is the more typical frequency spectrum (solid line). The different characteristics of the incident band are readily visible. The oblique approach of the wind waves on the 10th ($f \sim 0.125$ Hz) is clearly contrasted with the more shore-normal (at the variance peak, $f \sim 0.08$ Hz) approach on the 11th. Notice how the incident waves are clearly bounded by the line marking the relation $\sigma^2/g = k$, which is the cutoff for waves not trapped in the nearshore (i.e., they are either of deep water origin or are leaky waves reflected from the shoreline).

The infragravity band also shows surprising structure, despite the location of the sensors in 8 m of water nearly 1 km offshore. The distinctive linear trend of variance peaks from $f \sim 0.0$ to 0.10 Hz and k from 0. to 0.006 m^{-1} seen on the 10th has been shown to be the result of high mode edge waves, progressing in a southern direction (Elgar, et al., 1989; Oltman-Shay, et al., 1989b). While the high mode edge wave signature is still present on the 11th, the lowest frequencies ($f < 0.025$ Hz) appear to be more leaky in nature. There is a distinct lack of a shear wave signal at alongshore wavenumbers greater than the mode 0 dispersion curves as expected for pressure signals this far offshore (Bowen and Holman, 1989).

Figure 6 presents the alongshore wavenumber-frequency spectra computed from the alongshore component of flow in the surf-zone. As expected, the incident peaks are not visible. Most striking are the differences in the low frequency portion of the f - k spectra. On the 10th, the infragravity field was dominated by southward progressing edge waves and shear waves. The unique linear trend of the edge wave field which extends well into the incident band is unexplained, but was observed on

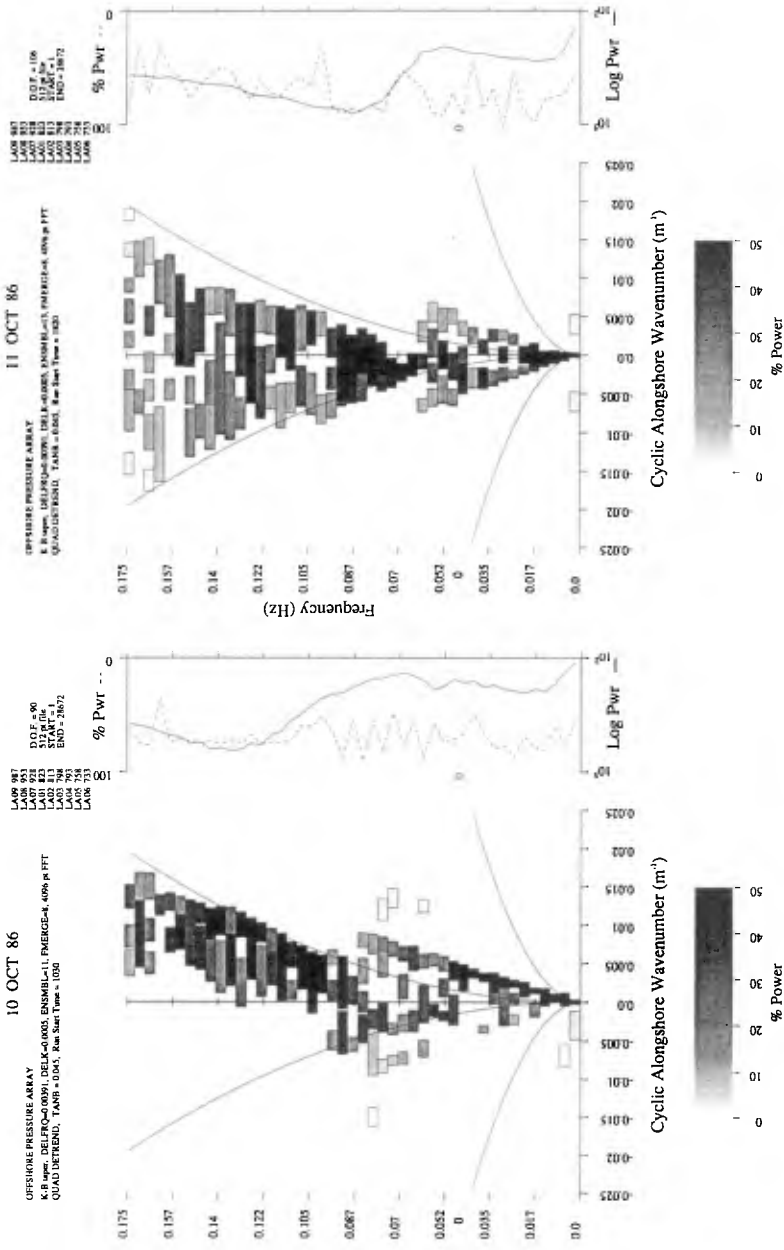

Figure 5. Frequency-alongshore wavenumber spectra from the pressure sensor array in 8 m depth. Positive wavenumbers indicate southward progressive waves. The height of the boxes indicates the frequency bandwidth, the width of the boxes indicates the half-power wavenumber bandwidth. The shading of the boxes indicates the percentage of that frequency band's variance contained in that peak. To the right of each $f-k$ spectrum is the frequency spectrum (solid line) and a representation of the percent of that frequency's variance contained in the identified peaks (dashed line). See text for interpretation of the data.

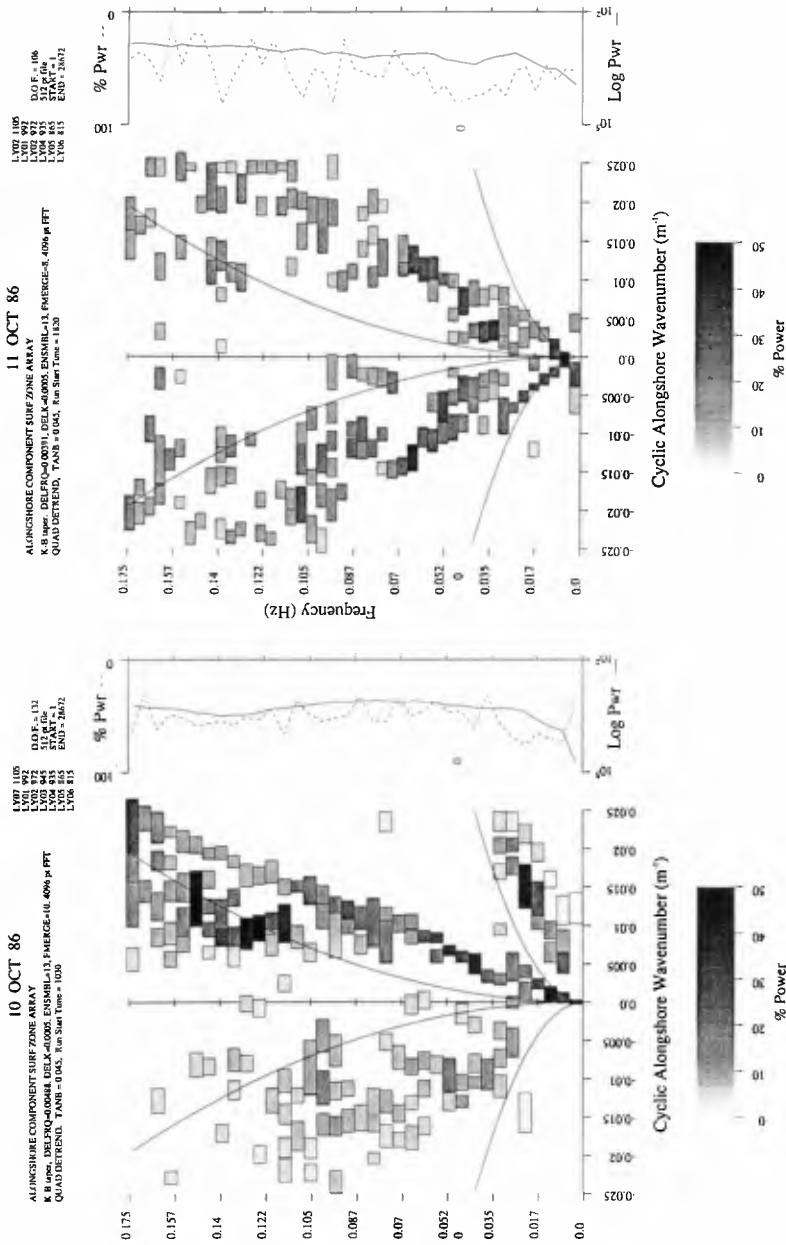

Figure 6. Frequency-wavenumber spectra calculated from the alongshore component of flow measured by the array of current meters in 1.5 m depth.

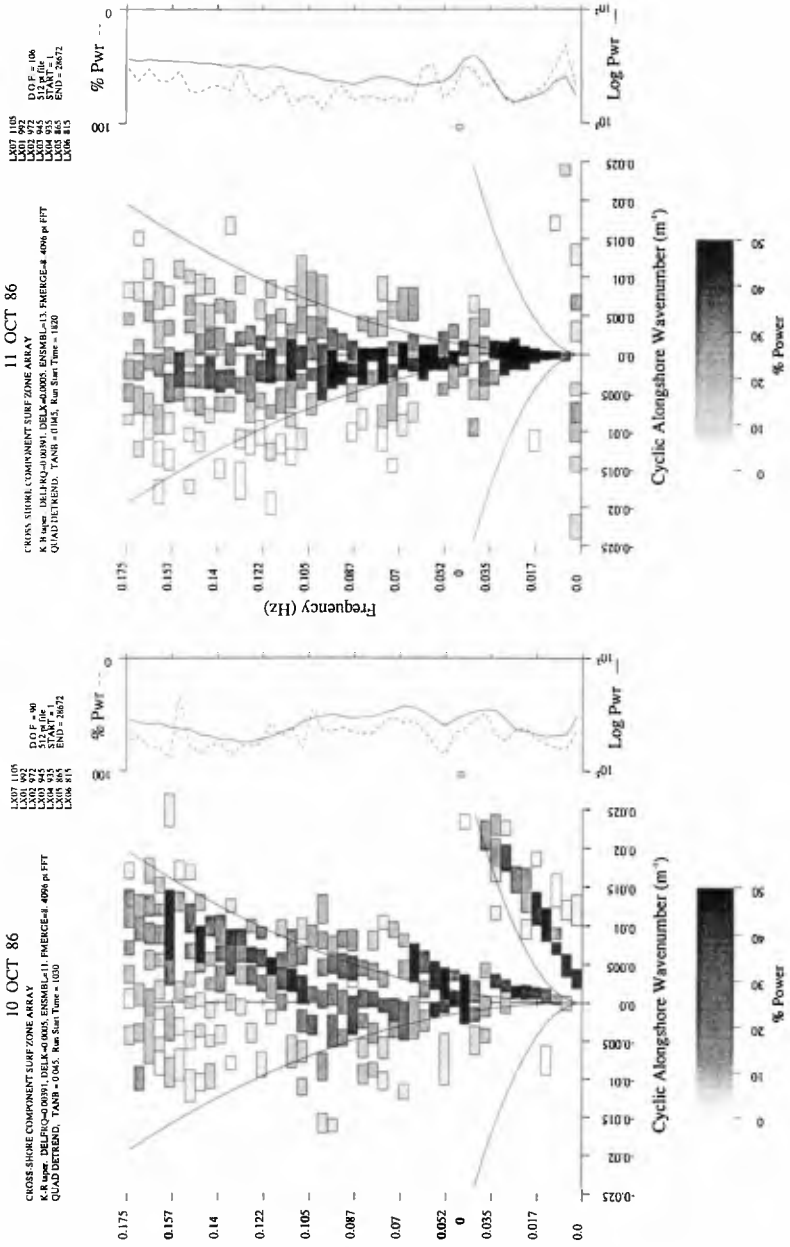

Figure 7. Frequency-wavenumber spectra calculated from the cross-shore component of flow measured by the array of current meters in 1.5 m depth.

other days with similar conditions. The rms infragravity oscillations measured 27 cm/s. The shear wave field was strong (rms oscillation of 28 cm/s) as would be expected in the presence of 160 cm/s mean currents. On the 11th, the infragravity wave field is again dominated by edge waves, but now with nearly equal contributions from the northward and southward progressive modes. The coherent structure of the shear wave band has vanished. The infragravity wave rms alongshore oscillation has remained steady at 29 cm/s while the shear wave rms value has dropped to 21 cm/s.

Figure 7 shows the equivalent spectra calculated using the cross-shore component of flow from the surf-zone sensors. The incident peaks are visible in the frequency spectra, but much less dominant than at the 8 m array (Figure 5). The differences between the low frequency motions on the two days are clear. On the 10th, not only is there a strong shear wave signal (rms oscillation of 38 cm/s), but the infragravity waves are dominated by low mode edge waves with an rms oscillation (as a band) of 36 cm/s. In contrast, on the 11th, the infragravity band is dominated by what appear to be either leaky waves or high mode edge waves. The rms oscillation of the infragravity band has nearly doubled from the 10th to 63 cm/s. As was also the case for the alongshore component of flow, the coherent structure has disappeared from the shear wave band.

While interpretation of the marked increase in the magnitude of cross-shore infragravity oscillations remains preliminary, it is safe to say that it is not due to an increase in the broad band forcing of low mode edge waves on the 11th. Oltman-Shay and Guza (1987) have shown that this should result in a simultaneous increase in the alongshore component of flow. Remembering that the alongshore rms oscillations for the two days were essentially unchanged, the increase in cross-shore oscillations is suspected to be due to an increase in the forcing of leaky waves or high mode edge waves, neither of which contribute greatly to alongshore velocity variance. A detailed study of the modal amplitudes of infragravity waves during this period is forthcoming.

Conclusions

We have used 21 4-hour data runs collected over a wide range of incident wave conditions to quantify the behavior of the alongshore and cross-shore components of wave motion for three different wave types. The incident band oscillations in the surf-zone were not significantly correlated with the offshore wave height, but were strongly correlated with the tide elevation indicating saturation due to depth limited breaking. The infragravity wave rms velocities were significantly correlated with the offshore wave height but the composition of the band appears to depend on the directional nature of the incident wind wave field. Shear waves were observed during times of strong longshore currents, but the magnitude of the current at the surf-zone array of instruments was found to be only a marginal predictor of the rms oscillations of the shear waves.

In addition there is significant evidence that the composition of the low frequency gravity wave field (edge, leaky and bound) changed considerably during the course of the storm. At the beginning of the storm when the incident waves approached the beach obliquely, the rms velocities of both components of flow in the infragravity band were nearly equal. As the angle of wave approach became nearly normal, the rms cross-shore velocity of the infragravity band grew, becoming a factor of two greater than the alongshore velocity.

Acknowledgements

We would like to thank the staff of CERC's Field Research Facility once again for the fine support they provided during the SUPERDUCK experiment. CERC also funded the deployment of the gages and the distribution of the data. The funding for the analysis of the data has been provided from grants to Oregon State University from the National Science Foundation (OCE87-11121) and the Office of Naval Research, Coastal Sciences Program (N00014-87-K0009).

CHAPTER 85

THEORY VERSUS EXPERIMENTS IN TWO-DIMENSIONAL SURF BEATS

Hemming A. Schäffer† and Ivar G. Jonsson‡

Abstract

Comparison is made between a deterministic infragravity-wave model and existing laboratory experiments. The theoretical model considers incident bichromatic waves including the effects of the accompanying incident long, bound wave, an oscillating position of the break point, and the intrusion of short-wave grouping into the surf zone, whereas frictional effects are neglected. A measure of the infragravity wave activity is the amplitude of a seaward progressing free, long wave. For this amplitude the qualitative agreement between theoretical results and experiments is excellent. Quantitatively the theory overestimates the infragravity waves by typically 50–100%. This may in part be attributed to the neglect of frictional effects.

1 Introduction

Numerous field experiments have shown that low frequency oscillations (periods of the order of several minutes) can account for a substantial part of the energy in a surf zone. The closer to the coastline, the more this feature is pronounced. These low frequency motions, which have been termed surf beats or infragravity waves have even been reported to exceed the magnitude of the breaking wind waves. It is widely recognized that surf beats are of major importance for the development of longshore bars in the two-dimensional case. Three-dimensional waves at infragravity frequencies account for more complicated ways of sediment transport and changes in coastal morphology.

Usually one distinguishes between the “trapped” and the “leaky” modes, where the trapped modes as opposed to the leaky ones are trapped to the coastline by refraction. In the present paper we confine ourselves to two dimensions so that only the leaky modes are considered. Three-dimensional results will be published elsewhere.

It is well known that groups of short waves induce long (low frequency) bound waves which are phase-locked to the short-wave envelope and travel with the group velocity. These bound waves are known to be a possible source of surf beats. Another effect of the modulation in the short waves is the resulting oscillations of the break point position. This further induces a time-varying

† Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark. The present work was conducted while H. A. Schäffer was a PhD-student at ISVA.

‡ Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Technical University of Denmark, DK-2800 Lyngby, Denmark

set-up which also contributes to the low frequency motion.

A theoretical model which takes both of these effects into account has been developed. In this paper we concentrate on the comparison of the model results with laboratory measurements by Kostense (1984), and the underlying theory is only briefly discussed. A short theoretical description is given in Schäffer et al. (1990), and for a full report on the theory we refer to Schäffer (1990).

2 Mathematical model

The phenomenon of infragravity waves forced by short waves involves two scales in time as well as in space. Typically the timescale of the short waves is $O(10s)$ and of the infragravity waves $O(100s)$. One way to treat this problem is to separate the two scales explicitly as in a WKB-expansion. Here we have used another approach, which is perhaps less stringent, but probably more transparent, physically as well as mathematically. Regardless of the approach the same equations evolve.

From the “narrow-minded” short-wave point of view the infragravity motion is merely a slowly varying current. In comparison with the large length scale of the infragravity wave, the water will be shallow and accordingly the current will be uniform over depth (we neglect bottom friction). Thus we can use the depth-integrated and time-averaged conservation equations of mass and momentum for waves on a slowly varying uniform current, where the time averaging is taken over one short wave period. Upon linearizing these equations, the current can be eliminated to get the equation governing the elevation of the mean water surface $\bar{\zeta}$

$$\frac{\partial}{\partial x} \left(gh \frac{\partial \bar{\zeta}}{\partial x} \right) - \frac{\partial^2 \bar{\zeta}}{\partial t^2} = -\frac{1}{\rho} \frac{\partial^2 S_{xx}}{\partial x^2} \quad (1)$$

(cf. Symonds et al., 1982, Mei and Benmoussa, 1984, and others). Here S_{xx} is the radiation stress associated with the incident short waves

$$\frac{1}{\rho g} S_{xx} = \frac{1}{2} |A|^2 \left\{ \frac{2c_g}{c} - \frac{1}{2} \right\} \quad (2)$$

where A is a complex amplitude allowed to have a slow variation in time as well as in space, c and c_g are phase and group velocities, respectively, h is depth, x is cross-shore coordinate, ρ is density and g is acceleration of gravity. The right hand side of (1) is responsible for the forcing of infragravity waves, and it is important how it is modelled. Thus a description of the radiation stress or essentially of the variation of A is needed. Given conservative circumstances of no dissipation, the forcing outside the surf zone follows from conservation of energy. After breaking sets in, assumptions concerning the variation of the break point position and the decay of the short waves are required.

2.1 The breaking of incident waves

The model used for the breaking and shoreward decay of modulated incident waves is a combination of two simple, but basically different models.

The first one is obtained by assuming that the short-wave modulation is totally destroyed by the breaking, so that the wave height in the surf zone is solely dependent on the local water depth. This implies an oscillation of the break point position which is essentially harmonic in time. This model was used

by Symonds et al. (1982) to study the effect of a time-varying position of the break point, neglecting the incident bound wave.

The second model postulates a fixed initial break point position letting the short-wave modulation be fully transmitted into the surf zone. This model was used by Schäffer and Svendsen (1988) when studying the nearshore behaviour of an incident long bound wave.

A hybrid model is now obtained by combining these two. After some manipulations the new model can be shown to correspond to a time-varying breaker depth given by

$$h_b(t) = \frac{\bar{a}_b}{\gamma_0} (1 + \kappa \mu \delta \cos \omega t + O(\delta^2)) \quad (3)$$

where $\delta = a^{(2)}/a^{(1)}$ is a small modulation parameter ($a^{(1)}$ and $a^{(2)}$ are the amplitudes of the two waves constituting the wave groups), \bar{a}_b is the mean amplitude at the mean break point, γ_0 is the amplitude to depth ratio for vanishing short-wave modulation ($\delta = 0$) and κ is a parameter at our disposal. Furthermore, μ is a factor which accounts for the short-wave shoaling within the region where the initial breaking takes place. This shoaling effect was disregarded by Symonds et al. (1982), Schäffer and Svendsen (1988), and Schäffer et al. (1990) corresponding to the assumption of $\mu \equiv 1$. However, we may as well include it, and after some manipulations we obtain

$$\mu \equiv \frac{1}{1 + \nu} \quad (4)$$

where

$$\begin{aligned} \nu &= - \left[h \sqrt{c_g} \frac{d}{dh} \frac{1}{\sqrt{c_g}} \right]_{h=\bar{h}_b} \\ &= \left[\frac{1}{2} \frac{h}{c_g} \frac{dc_g}{dh} \right]_{h=\bar{h}_b} \end{aligned} \quad (5)$$

so that $0 \lesssim \nu \leq \frac{1}{4}$ and thus $\frac{4}{5} \lesssim \mu \leq 1$. According to (5) ν can in principle be negative, but since this corresponds to breaking at intermediate water depth it will not happen in practice. The above two models appear for $\kappa = 1$ (short-wave modulation destroyed) and $\kappa = 0$ (fixed initial break point), respectively. The value of κ reflects the extent to which the modulation of the incident waves is "used" to produce an oscillating break point position and consequently the "amount" of grouping which is transmitted into the surf zone. On the basis on experimental results for monochromatic waves collected by Goda (1970), we have estimated κ to be in the range $1 < \kappa < 1.2$. From the empirical relations given by Hansen (1990), κ appears as a universal constant (i.e. independent of the steepness of the incident short waves) and we get $\kappa \equiv 1.09$, see Schäffer (1990). Results for γ_0 versus the deep water short-wave steepness $\hat{a}_\infty \equiv a_\infty k_\infty$ are adapted from Goda (1970) and Hansen (1990), and they are depicted in Fig. 1 for various beach slopes h_x . An estimate of the deviation from unity of the parameter κ can be shown to equal minus the slope of these curves in the double logarithmic plot, i.e. $\kappa = 1 - d(\log \gamma_0)/d(\log \hat{a}_\infty)$.

That $\kappa > 1$ actually means that the higher waves break so early that they end up being the lower ones inside the surf zone.

Figure 1 Index $\gamma_0 \equiv a_b/h_b$ versus deep water steepness \hat{a}_∞ for different bottom slopes $h_x = \tan \beta$. Results for monochromatic waves adapted from Goda (1970) (—) and from Hansen (1990) (---).

3 Method of solution

We restrict ourselves to a plane sloping beach $h = h_x x$ connected with an offshore shelf, and consider only periodic solutions. Fourier expansions of S_{xx} and ζ turn (1) into ordinary differential equations for the different regions, which are solved by the method of variation of parameters. Solutions of different regions are matched using standard conservation considerations with regard to mass, momentum, and energy. The boundary conditions are those of finite shoreline amplitudes and absence of incident free long waves — not to be confused with the incident bound long wave which is an important part of the solution.

Special action is taken in the region of initial breaking i.e. within the inner and outer limits of the initial break point. In this region substantial forcing of infragravity wave motion takes place as first shown by Symonds et al. (1982). The solution is developed to the leading order in the short-wave modulation parameter δ . To this order it can be shown that infragravity waves are only forced at the fundamental group frequency so that no higher harmonics appear. Furthermore, a large gradient of the infragravity wave surface elevation over the region of initial breaking is for convenience concentrated in a discontinuity at the mean break point depth \bar{h}_b as can be seen in the example shown in Fig. 2.

For a detailed description of the mathematical development we refer to Schäffer (1990).

4 Results and comparison with experiments

A sample of the model results is shown in Fig. 2. The figure shows the envelope of the infragravity wave (not to be confused with the envelope of the incident

Figure 2 Sample result for $\kappa = 1.1$ of the spatial variation of the infra-gravity wave elevation (normalized by the modulation of the short wave amplitude in deep water) versus depth (normalized by the (inverse value of the) deep water short-wave number ω_s^2/g). T is the group period, and the mean depth at the break point is \bar{h}_b . The abscissa is limited by the depth of the offshore shelf. The figure corresponds to the “•” at $\chi = 5.8$ in Fig. 6a.

short waves) and the elevation at $t = 0, -T/4$ where T is the group period. The discontinuity at the mean break point position at $t = 0$ is a consequence of the substantial forcing around the mean break point position mentioned above, together with a consistent development of the solution to the leading order in the short-wave modulation parameter. The latter can be shown to be consistent with letting the spatial extent of the region of initial breaking tend toward zero leaving a discontinuity behind.

The solution shows a gradual change from an almost standing wave in the vicinity of the shoreline to an almost purely seaward progressive wave some distance offshore.

A series of high quality laboratory experiments on long waves forced by short-wave groups, conducted at the Delft Hydraulics Laboratory, were reported by Kostense in 1984. Fortunately his experimental setup exactly meets the assumptions behind the present theoretical model. This applies to the bathymetry as well as the incident short-wave groups, and his measurements include the respective amplitudes of the incident, bound, long wave and the seaward progressive, free, long wave. The movement of the wave-maker paddle included second-order generation as well as active absorption of free, long waves returning to the wave maker. Consequently free, long, standing waves arising from the

Table 1 Short-wave characteristics for the experiments by Kostense (1984). The listed χ -values (based on $\gamma_o = 0.4$) differ a little from the ones used by Kostense, due to his neglect of short-wave shoaling.

reflection of free, long waves at the paddle were avoided, and the measurements provide an excellent test of the present theory.

Five series of experiments are reported, and the first four of these correspond to a short-wave modulation parameter of $\delta = 0.2$. This meets our assumptions of $\delta \ll 1$, considering the limited accuracy expected from the theoretical model due to the complicated physical mechanisms in question. The characteristics of the incident short waves for these four series (A–D) is given in Table 1. Here ($a_o^{(1)}, a_o^{(2)}$) and ($\omega^{(1)}, \omega^{(2)}$) are the amplitudes (over the shelf) and angular frequencies of the two wave trains, ω is the difference frequency (group frequency), and χ is a parameter defined by $\chi \equiv \omega^2 \bar{x}_b / (g h_x)$, \bar{x}_b being the position of the mean break point ($x = 0$ at the shoreline). In the fifth experimental run δ equals 0.8, and no comparison is made.

The relevant parameters describing the geometry of the experimental facility are the depth $h_o = 0.5m$ on the shelf and the beach slope $\bar{h}_x = 0.05$.

In series A and B the short-wave amplitudes are kept constant while the difference frequency ω is changed. The resulting amplitude of the incident, bound, long wave $|\xi_b|$ is compared with the theoretical values in Fig. 3a. The excellent agreement is indeed a manifestation of the thoroughness of the experiments. The theory of the bound, long wave is due to Longuet-Higgins and Stewart (1962, 1964). Kostense presents a comparison similar to that of Fig. 3 based on an equivalent formulation given by Ottesen Hansen (1978). Fig. 3b shows $|\xi_b|$ for series C and D for which the respective difference frequencies are

kept constant, while the amplitudes of the short-wave components are changed. Again the theory and the measurements compare very well.

We now turn to the results for the amplitude of the outgoing, free, long wave $|\xi_f|$, the generation of which is far more complex. The physical mechanisms of generation involve complicated surf zone dynamics, and thus the results of the mathematical model can hardly be expected to match the measurements as closely as the results for the incident bound, long wave. One aspect of the model can be expected to give a one-sided error, and that is the neglect of frictional effects. Thus, everything else being equal we can expect the model to overestimate the long-wave activity.

Fig. 4 compares $|\xi_f|$ (at the shelf) from the theory and measurements, and the qualitative agreement is seen to be excellent. Furthermore, we recognize the expected overestimation, which for most runs is approximately 50–100%. At least part of this mismatch may be attributed to the neglect of friction.

The results for $|\xi_f|$ are repeated in Fig. 5 with $\chi \equiv \omega^2 \bar{x}_b / (gh_x)$ as the abscissa. Note that the extraordinary trend of a straight line for the measurements of series D is reproduced by the theory. The measurements of series A, B, and C all show a convex trend as also given by the theoretical results.

In order to compare with the theory of Symonds et al. (1982) we have used Green's law to assign the computed as well as the measured values of $|\xi_f|$ to their values $|\xi_f(\bar{x}_b)|$ at the break point. Furthermore, $|\xi_f(\bar{x}_b)|$ was normalized by the variation about the mean of the stationary shoreline set-up for infinitely long groups, denoted $\Delta\zeta$. The results are shown in Fig. 6a together with the theoretical curve of Symonds et al., which is seen to be inadequate. Here $(\gamma_o, \kappa) = (0.4, 1.0)$ was used. Fig. 6b is equivalent to Fig. 6a, only the results are based on the dashed curve for $h_x = 1/20$ in Fig. 1, which gives γ_o -values ranging from 0.47 to 0.53 and $\kappa = 1.09$. The general picture is seen to be the same. (Note that the compression of the abscissa χ in Fig. 6b as compared with Fig. 6a (which is due to the larger γ_o -values used) affects the measured and computed results equally much, and it has nothing to do with how well they compare).

Fig. 7a is adapted from Kostense, and it shows $|\xi_f|$ versus $|\xi_b|$. As noted by Kostense, the correlation is very poor (as could be expected). This also applies to our theoretical results as shown in Fig. 7b.

The theoretical $|\xi_f|$ -values of this section were calculated with the assumptions of full long-wave reflection from the coastline. Corrections for partial reflection can be introduced by requiring the maximum shoreline amplitude of the elevation of the standing infragravity wave to be $|\xi_1(0)|_{max} = gh_x^2 / \omega^2$. This limit is valid for a free standing long wave on a plane sloping beach as indicated by the solution of the nonlinear shallow water equations by Carrier and Greenspan (1958) (see Meyer and Taylor, 1972). However, when these modifications are incorporated, the only correction is a 10% reduction of theoretical $|\xi_f|$ -value in the first run of series A, the rest of the runs being unchanged. Thus no conclusions are changed.

Kostense mentions three possible reasons for the limited validity of the theory by Symonds et al. These are the neglect of the incident, long, bound wave, the preclusion of short-wave grouping inside the surf zone, and the assumption of full long-wave reflection at the shoreline. The present model accounts for all these effects, and particularly inclusion of the incident, long, bound wave is of great importance. The next step towards a correct mathematical model should be the inclusion of frictional effects such as turbulence in the surf zone and bottom friction.

Figure 3 Amplitude of incident bound, long wave $|\xi_b|$ versus (a) the difference frequency ω (series A and B), and (b) the amplitude of the largest short-wave component $\alpha_o^{(1)}$ (series C and D).

Figure 4 Amplitude of outgoing free, long wave $|\xi_f|$ versus (a) the difference frequency ω (series A and B), and (b) the amplitude of the largest short-wave component $\alpha_o^{(1)}$ (series C and D). $(\gamma_o, \kappa) = (0.4, 1.0)$.

CHAPTER 86

BOTTOM PRESSURES DUE TO LONG WAVES: LABORATORY AND FIELD MEASUREMENTS

Fredric Raichlen¹, Jerald D. Ramsden², and James R. Walker³

1. INTRODUCTION

A convenient and attractive way of determining the nearshore wave environment is through the use of bottom (or near bottom) pressure measurements. However, it has been realized for some time that care must be taken in interpreting such pressure measurements and relating them to the local waves amplitudes in the region where the waves become highly nonlinear and shoal near the shore, e.g., see Grace (1978), Guza and Thornton (1980), Bishop and Donelan (1987), Lee and Wang (1984), Bodge and Dean (1984), and Nielsen (1989) among others. This study is directed to questions raised in connection with the interpretation of the water surface time-history from bottom pressure measurements for highly nonlinear long waves. In particular the waves which were primarily of interest were large solitary and cnoidal waves, i.e., non-periodic and periodic long waves.

The motivation for this work was the requirement to document the water surface-time histories of near breaking waves, nearly solitary in shape, with heights up to 2 m in a large fresh water wave basin. Wave staffs, either capacitance or resistance types, were not readily available for these measurements. In place of this technique, video recordings were made of the water surface at the location of surveyor's staff gages, but data reduction of these video recordings, except for a few cases, was estimated to be excessively time consuming. Hence, pressure transducers mounted near the bottom were installed at the wave staff locations to obtain simultaneous measurements which could be related to the variation of the water surface elevation with time.

To assist in defining the corrections to be used to convert the pressure measurements obtained in the large wave basin to wave heights, an experimental study in the laboratory and an analytical study were undertaken using solitary and cnoidal waves. For solitary waves pressure correction factors based on linear wave theory were not adequate to determine the wave amplitudes from the pressure measurements. Therefore, the correction factors were obtained first from theories

accurate to the second and third approximations as presented by Grimshaw (1971) and given in slightly different form by Fenton (1972). The pressure correction factors for nonlinear periodic long waves were obtained using stream function theory as presented by Dean (1965,1974), and higher order cnoidal wave theories presented by Isobe, Nishimura, and Horikawa (1978) and summarized by Horikawa (1988). The approach of Dean(1974) also was extended for use with solitary waves. This paper will compare the nonlinear theories mentioned for solitary and cnoidal waves to the results of laboratory experiments in addition to the limited field experiments conducted in a large fresh-water wave facility. Some discussion will be given herein regarding the use of pressure transducers for dynamic pressure measurements; this will be presented in Section 3.

As a convenience to the reader, expressions for the solitary wave from Fenton (1972) which are accurate through the third order are presented in this section; these will be compared with experimental results. The wave train is stationary in the x,y plane with the origin of the coordinates at a point on the bottom; x is measured in the direction of wave propagation. The amplitude of the solitary wave can be expressed as:

$$\eta = 1 + \epsilon s^2 - \frac{3}{4} \epsilon^2 s^2 t^2 + \epsilon^3 \left(\frac{5}{8} s^2 t^2 - \frac{101}{80} s^4 t^2 \right) + 0(\epsilon^4) \quad (1)$$

where η is the wave amplitude normalized with the depth, h , ϵ is the ratio of wave height to depth, H/h , $s = \text{sech } \alpha x$, $t = \tanh \alpha x$, and:

$$\alpha = \left(\frac{3}{4} \epsilon \right)^{1/2} \left(1 - \frac{5}{8} \epsilon + \frac{71}{128} \epsilon^2 \right) + 0(\epsilon^{7/2}) \quad (2)$$

The pressure measured on the bottom can be written as:

$$\frac{p}{\gamma h} = 1 + \epsilon s^2 + \epsilon^2 \left(\frac{3}{4} s^2 - \frac{3}{2} s^4 \right) + \epsilon^3 \left(-\frac{1}{2} s^2 - \frac{19}{20} s^4 + \frac{11}{5} s^6 \right) + 0(\epsilon^4) \quad (3)$$

where p is the total bottom pressure and γ is the specific weight of the fluid. The ratio of the wave height to the dynamic pressure head under the wave, accurate to second order, can be obtained from Eq 3 as:

$$\frac{H}{p_d / \gamma} = \frac{1}{1 - \frac{3}{4} \epsilon} \quad (4)$$

and to third order also from Eq 3 as:

$$\frac{H}{p_d / \gamma} = \frac{1}{1 - \frac{3}{4} \epsilon + \frac{3}{4} \epsilon^2} \quad (5)$$

For convenience, in the following, the subscript used in the dynamic pressure, p_d , will be dropped and the dynamic pressure will be denoted simply as: p . Experimental data obtained in a wave tank will be compared to Eqs. 4 and 5.

For the long periodic waves, cnoidal wave theory and stream function theory were used to describe the water surface-time history and the variation with time of the dynamic pressure. Due to the complexity of the resulting expressions, they will not be presented here. In lieu of that, the interested reader is referred to Horikawa (1988) and Dean (1974) for a presentation of the cnoidal wave theory and the stream function theory, respectively.

2. EXPERIMENTAL EQUIPMENT AND PROCEDURES

The laboratory experiments were conducted in a wave tank which is 15.24 m long, 0.38 m wide, and 0.61 m deep, with glass walls throughout and a programmable bulkhead wave generator located at one end. The trajectory of the wave generator was determined from the method described by Goring and Raichlen (1980). In this approach, used for long waves, the position of the vertical bulkhead with time is based on the condition that the velocity of the plate must be equal to the depthwise average of the water particle velocity under the wave at that instant. Thus, the plate trajectory includes nonlinear aspects of wave generation. Voltage-time histories were constructed with this approach and used in the electro-hydraulic servo system of the wave generator for both solitary and cnoidal waves. Resistance wave gages were used to determine the water surface-time history of the wave.

Pressures were measured in the laboratory using a variable reluctance pressure transducer (Pace Model P7D) with a pressure sensing diaphragm which was 0.0267 cm thick and 2.54 cm in diameter. The transducer pressure port was connected directly to the bottom of the wave tank by a 5.28 cm long and 0.46 cm inside diameter brass tube. In unsteady pressure measurements care must be taken to obtain as high a natural frequency of the instrument as is possible relative to the frequency content of the pressure signal while still maintaining adequate sensitivity to insure accuracy. Since air entrainment in a water filled pressure transducer can significantly lower its natural frequency, the pressure gage was filled carefully with water by flushing it for a substantial period of time. An analysis presented by Ippen and Raichlen (1957) showed that the internal dimensions of the tube which connected the transducer to the pressure source could have an important effect on the natural frequency of the gage. By careful attention to this feature of the gage-wave tank connection and to air entrainment, a measured natural frequency of the transducer of about 70 hz was attained.

As implied above, it is not the natural frequency of the gage alone which is important, but the magnitude of the natural frequency of the gage **relative** to the maximum frequency of the important portion of the pressure signal, (or the incident wave). It can be shown that the amplitude spectrum of a solitary wave when analyzed as a linear signal is:

$$\frac{S(\omega)}{S(0)} = \frac{\xi\omega}{\sinh \xi\omega} \quad (6)$$

where:

$$\xi = \frac{\pi}{\sqrt{3}} \sqrt{\frac{h}{g}} \frac{1}{\sqrt{\frac{H}{h} \left(1 + \frac{H}{h}\right)}}$$

and $S(\omega)$ is the amplitude of the frequency component ω , H is the wave height, and h is the water depth, see, e.g., Synolakis (1986). For the wave heights and water depths used in the laboratory experiments, the frequency at which $S(\omega)$ has decreased to about 1% of its value at zero frequency, i.e., $S(\omega)/S(0) = 0.01$, is about 4 hz. Thus, the natural frequency of the gage was significantly greater than the important frequencies in the wave. This resulted in relatively undistorted measurements.

Measurements of water waves were to be made in the field in a large fresh

water wave basin which consists of a wave channel 130 feet wide and 180 feet long with depths varying from 8 feet to approximately 5 feet, opening into a larger basin where the depth decreased uniformly to zero. The latter has a width of about 500 feet and a length in the direction of wave propagation of about 250 feet. The depth variations in the wave channel were as follows: a constant 8 ft depth extending 15 ft from the wave generator, followed by a 40 ft section with a 4.3% slope where the depth decreases from 8 ft to 6.28 ft, followed by 72 ft of constant depth, with the remaining 53 ft of the wave channel having a bottom slope of 2.2% reaching a final depth of 5.11 ft. Waves are generated at one end of the 130 foot wide channel by releasing a fixed volume of water into the channel during a short time interval.

Wave measurements were conducted at three locations in the wave channel; the location which is of interest in this study is in the constant depth region, 6.28 ft deep, about 90 ft from the wave generator. Thus, the position for which the wave measurements will be discussed here was about 35 ft, i.e., nearly six depths, from the beginning of the constant depth section. A pressure transducer was attached to the tripod at a distance from the bottom equal to 0.317 times the depth ($y/h = 0.317$). The pressure gage (Senso-Metric semiconductor pressure transducer Model SP91) had a natural frequency in air of approximately 30 KHz. For a near-breaking solitary wave in this region of the wave channel, 99% of the energy would be at frequencies less than approximately 2 Hz. Although the natural frequency of the transducer in water would be less than in air, little dynamic distortion would be expected using this gage. Simultaneous with the pressure measurements, video recordings were made of the wave as it passed the wave staff. In addition, visual observations were taken of the height of the first major wave as it propagated past the wave staff. In Section 3 theoretical results will be compared to the pressure measurements using the visual observations of the height of the first wave as it propagated past the pressure transducer.

3. RESULTS AND DISCUSSION OF RESULTS

Several theories for long waves will be compared to experimental results obtained in the laboratory and in the field. The variation of both the pressures and the amplitude-time histories of these waves will be presented.

It is useful, first, to look in a general way at the influence of non-linearities and vertical accelerations, i.e., frequency dispersion, on the pressures under solitary waves. (It should be remembered that if linear wave theory were applied to long waves such as solitary waves, the pressures under the waves would be distributed hydrostatically.) Evidence of these effects is shown in a qualitative fashion in Fig. 1. This three-dimensional plot was obtained from Eq. 3 and shows the variation of the wave amplitude normalized by the dynamic pressure head on the bottom, as a function of relative wave height and of relative distance measured from the crest for a solitary wave. The abscissal range of relative wave height is: $0 < H/h < 0.65$. In the ordinate, for convenience, only the value: $\eta/(p/\gamma) = 1$ is indicated. This corresponds to hydrostatic pressure conditions and it is seen to apply only for small relative wave heights independent of location, x/h . However, as the relative wave height increases, the effects of nonlinearities and vertical accelerations become apparent, and linear theory, i.e., a hydrostatic pressure distribution under the wave, is not applicable. For example, at $H/h = 0.65$, under the crest, the dynamic pressure head is less than the wave amplitude. Conversely, at $x/h \approx 2$, the dynamic pressure head is greater than the amplitude. If care were not taken in interpreting the pressure measurements properly for such large waves, the wave height would be significantly under-

Fig. 1 The Variation of Wave Amplitude Normalized by Dynamic Bottom Pressure with Relative Wave Height and Distance for a Solitary Wave

Fig. 2 Variation of Amplitude and Dynamic Bottom Pressure With Relative Distance for a Solitary Wave: $H/h = 0.54$

estimated and the wave shape distorted.

This variation is more clearly shown in Fig. 2 where the results of experiments conducted in the laboratory are presented. The ordinate corresponds to both the wave amplitude and the dynamic pressure head, each expressed in centimeters, and the abscissa is the distance from the crest normalized with respect to the depth. The depth for these experiments was 18.6 cm and the relative wave height was: $H/h = 0.538$. Theoretical pressures and amplitudes as obtained from Fenton (1972), Eqs. 1 and 3, are shown along with the experiments. It is seen that the dynamic pressure under the crest is approximately 75% of the amplitude. Therefore, if simple linear theory were used the wave height obtained from pressure measurements would be underestimated by approximately 25%. As distance from the crest increases, the correction factor becomes equal to unity at approximately $x/h = 1.5$, where the dynamic pressure is equal to the amplitude. For $x/h > 1.5$, because of the vertical water particle accelerations, the dynamic pressure becomes larger than hydrostatic.

The variation of the ratio of the wave height to the dynamic pressure head on the bottom with relative wave height for a solitary wave is shown in Fig. 3. Data are presented from two separate experiments. In Experiment A the pressure transducer used was as obtained from the manufacturer, and in Experiment C the internal pressure ports in the gage were enlarged as much as possible, limited only by the gage dimensions. It appears that the internal gage modifications did not affect the pressure measurements; thus, any change of the frequency response of the gage accomplished by the internal modifications were not important for these waves. No doubt one important reason for this is that for these solitary waves, as mentioned earlier, 99% of the energy was at frequencies less than approximately 4 hz whereas the natural frequency of the gage was about 70 hz.

Three analytical curves are shown in Fig. 3, corresponding to second and third order solitary wave theories and to the stream function theory. The analytical curves obtained from Eqs. 4 and 5 are shown as dotted and dashed, respectively. The solid curve which is labeled stream function theory was obtained from a numerical algorithm based on the development by Dean (1965) and from computations at higher orders than the results presented by Dean (1974). To use this method for solitary waves, first the variation of the ratio of wave height to dynamic pressure head with depth-to-wave length, h/L , was defined for long periodic waves. The curves corresponding to constant H/h so obtained were extrapolated to $h/L = 0$ to define a stream function result which might be applicable to solitary waves. (This will be discussed later in detail.) It is seen in Fig. 3 that the stream function theory agrees well with the experimental results for the full range of relative wave heights which were investigated.

These data have been replotted in Fig. 4 as the ratio of the dynamic pressure head on the bottom to the depth as a function of relative wave height. Experimental data shown in Fig. 4 compare well with the stream function theory and poorly with the linear theory except for $H/h < 0.1$. In essence Fig. 4 emphasizes problems which can occur when interpreting pressure gage measurements under long waves. For example, consider the case of a relatively large wave where the pressure has been measured and the wave height is to be determined. Fig. 4 shows that for solitary waves with $H/h > 0.7$ the dynamic pressure is essentially constant. This means that although the wave height is increasing, the vertical accelerations also change in such a way that the pressure remains relatively unchanged. Thus, for this range of relative wave heights it is difficult, if not impossible, to actually define the solitary wave

Fig. 3 Comparison of Theories to Experiments for Dynamic Bottom Pressures Under the Crest of a Solitary Wave: $H/(p/\gamma)$ vs. H/h

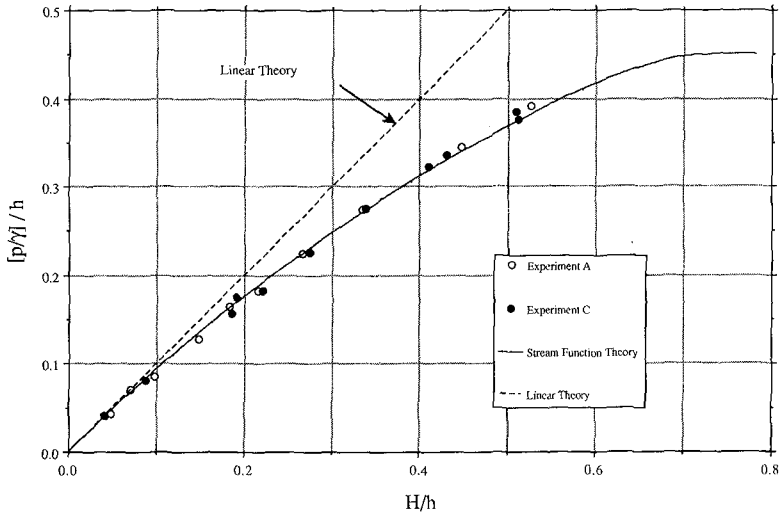

Fig. 4 Comparison of Theories to Experiments for Dynamic Bottom Pressures Under the Crest of a Solitary Wave: $(p/\gamma)/h$ vs. H/h

height from bottom pressure measurements. Unfortunately, at times, it is for just these large waves that one would like to obtain a good estimate of wave height. Thus, for such large long waves, bottom or near bottom pressure measurements may be inappropriate for accurate water surface time histories.

The pressures under large periodic long waves were also investigated in the laboratory and certain of these results are presented in Figs. 5a and 5b. The ordinate in Fig. 5a is the ratio of the wave amplitude to the depth. In Fig. 5b the ordinate is the dynamic pressure measured on the bottom normalized with respect to depth. For both Figs. 5a and 5b the abscissa is the relative distance in the direction of wave propagation. The depth for these experiments was 20.01 cm, the wave period was 1.98 seconds, $H/h = 0.565$, and the non-dimensional period parameter was: $gHT^2/h^2 = 108.6$. The cnoidal wave theory presented in Figs. 5a and 5b is a third-order long wave solution from Horikawa (1988). Included also is the result from the stream function theory carried out to the 21st order. It is seen that the two theories for the wave shape agree reasonably well with the experiments with some divergence in the trough region. The pressures measured are generally less than those predicted by the two theories although the stream function theory agrees better with the experiments near the crest than does the higher order cnoidal wave theory. This result is similar to that observed in the solitary wave phase of the study.

The theoretical and experimental variation of the wave height divided by the total dynamic pressure for periodic waves is shown in Fig. 6 as a function of depth to wave length for constant values of wave height-to-depth. The total pressure is defined in the ordinate as the difference between the pressure measured under the crest and that measured under the trough. The theoretical curves are determined from stream function theory computed to a high enough order so there is little variation in the ordinate value when the order of the computations is increased. For these computations the maximum order was 51 for the longer waves. (It is these curves, for given relative wave heights, which were extrapolated to $h/L = 0$ to define the stream function relationship for solitary waves presented in Fig. 3; the extrapolated curves are shown dashed.) The results from the linear theory, also presented in Fig. 6, appear to converge with the stream function theory for smaller wave height-to-depth ratios only as the depth-to-wave length becomes large. Included in Fig. 6 are the results of four experiments conducted with long cnoidal waves with the relative wave height for each experiment presented in brackets next to the data point. It is seen that the theory agrees reasonably with the experimental data.

The amplitude at the crest and the amplitude at the trough divided by the corresponding pressure head are plotted in Figs. 7 and 8, respectively, as a function of depth-to-wave length and relative wave height. The agreement of the theory with the experimental data appear to be reasonable with respect to the crest amplitude shown in Fig. 7, but appears to be less so for the trough measurements in Fig. 8. The primary reason for the latter is probably experimental error due to the relatively small pressures in the trough region. In both Figs. 7 and 8, the linear theory is shown for comparison, and it is seen, as expected, that for long waves the divergence from the linear theory increases significantly as the relative wave height increases. For example, for $h/L = 0.05$, the so-called limit of shallow water waves, the amplitude at the crest relative to the dynamic pressure head on the bottom for a wave with a relative wave height of: $H/h = 0.6$ predicted by the stream function theory is approximately 1.6 compared to a value of about unity for linear theory. This means that the pressure head under the crest is only about 60% of the amplitude. In Fig. 8 similar data are shown for the trough region where it is seen that, as the relative wave height increases for a given depth to wave length, the wave becomes

Fig. 5a Comparison of Theories to Experiments for Relative Amplitude of a Cnoidal Wave: $H/h = 0.57$, $gHT^2/h^2 = 108.6$

Fig. 5b Comparison of Theories to Experiments for Dynamic Bottom Pressures Under a Cnoidal Wave: $H/h = 0.57$, $gHT^2/h^2 = 108.6$

Fig. 6 The Ratio of Wave Height to Dynamic Bottom Pressure as a Function of Relative Depth and Height from Stream Function Theory

Fig. 7 The Ratio of Crest Amplitude to Dynamic Bottom Pressure as a Function of Relative Depth and Height from Stream Function Theory

Fig. 8 The Ratio of Trough Amplitude to Dynamic Bottom Pressure as a Function of Relative Depth and Height from Stream Function Theory

more solitary-like so that in the trough region the influence of vertical accelerations becomes less. Thus, contrary to the crest region, the correction factor for a large long wave is nearly unity in the trough region whereas linear theory indicates much larger factors due to the sinusoidal shape of the latter.

To some extent, these data can be summarized as shown in Fig. 9 where the ordinate is the dynamic pressure on the bottom normalized by depth and the abscissa is the wave height-to-depth. Theoretical results are shown for the solitary wave and for two long periodic waves with a relative depth to wave length of: $h/L = 0.05$ and 0.1 . Included also are curves labeled: "Linear (Solitary Wave)" and "Linear ($h/L = 0.1$)". These curves correspond to linear wave theory applied to a solitary wave and to a periodic wave ($h/L = 0.1$). The divergence of the nonlinear theories and the linear theories begins at about $H/h \approx 0.1$ for both the solitary and the periodic waves and increases thereafter. This indicates that care must be taken in applying linear theory to determine the wave height from pressure measurements for long periodic and non-periodic waves. As before, for large waves, the pressure becomes relatively insensitive to increasing wave heights. This again suggests the problem discussed earlier with regard to interpreting wave heights from pressure measurements for H/h greater than 0.6 to 0.7. It is interesting to note the similarity between the results for periodic waves with $h/L < 0.1$ and solitary waves.

Pressure measurements were made in the field in the large fresh water wave facility described in Section 2 at a distance from the bottom of $y/h = 0.317$. An example of pressure measurements for six different tests with an observed relative wave height of: $H/h = 0.79$ are shown in Fig. 10. The ordinate is the dynamic pressure in feet and the abscissa is the number of data points obtained when sampling at a rate of 16 samples per second. The reasonable agreement among the six runs demonstrates good wave generation reproducibility considering the scale of the waves being generated and the type of wave generator used. It should be recalled from Section 2 that these waves have propagated up a slope of about 4.3% before reaching the horizontal section where the pressure measurements were made. A distinctive solitary wave-like shape of the leading part of this wave is apparent as well as the shelf-like trailing part of the first wave. The latter has been found by others for solitary waves propagating up a slope in the laboratory, e.g., Skjelbreia (1987).

In Fig. 11 data are presented from field experiments conducted in the large wave channel on two different days. The ordinate is the wave height normalized by the dynamic pressure head and the abscissa is the relative wave height. (As mentioned earlier, the wave height which is used corresponds to the height which was observed on the wave staff as the wave propagated past the location of the pressure gage.) Included in this figure is a theoretical curve obtained from stream function theory for $y/h = 0.317$ and $h/L = 0$. Considering the shape of the waves as described by the pressure-time histories presented in Fig. 10, the agreement of the theory and the data are surprisingly good. Relative wave heights corresponding to $H/h > 0.8$ are realized due to the 4.3% slope which precedes the horizontal section where the measurements are made and the short distance from the beginning of that section to the location of the pressure transducer. Thus, to some extent, it appears that the leading portion of the wave can be described by a solitary wave reasonably well.

When the dynamic pressure head normalized by the depth is plotted as a function of relative wave height, as shown in Fig. 12, the variation is similar to that seen in Fig. 4. The field data for large relative wave heights appear to reach an asymptotic value of normalized pressure between 0.45 and 0.5. These data show, as

Fig. 9 Variation of Normalized Dynamic Bottom Pressure Under the Crest with Relative Wave Height: Stream Function and Linear Theories

Fig. 10 Field Measurements of Dynamic Bottom Pressure with Time (Data Rate = 16 Samples per sec)

Fig. 11 Comparison of Stream Function Theory as Extrapolated for Solitary Waves to Field Experiments: $H/(p/\gamma)$ vs H/h at $y/h = 0.317$

Fig. 12 Comparison of Stream Function Theory as Extrapolated for Solitary Waves to Field Experiments: $(p/\gamma)/h$ vs H/h at $y/h = 0.317$

before for the laboratory results, that for large, long, nonperiodic waves it is inaccurate to define the wave height from the pressure measurements alone.

4. CONCLUSIONS

The following major conclusions can be drawn from this study:

1. For solitary and cnoidal waves, nonlinear effects and vertical accelerations (frequency dispersion) are important in defining the pressures under the waves.
2. For $H/h > 0.1$ linear theory should not be used to evaluate the wave height from pressure measurements for long waves.
3. The extrapolated stream function theory appears to agree best with the experimental data for solitary waves. Solitary wave theories corresponding to the second and third orders in the parameter H/h agree reasonably well with the data only for small relative wave heights. For such non-periodic waves it is inaccurate to define the wave height from pressure measurements alone.
4. For relatively large solitary waves and cnoidal waves the ratio of the dynamic pressure under the wave crest, on or near the bottom, to the depth appears to approach a constant value of 0.45, or somewhat less.

CHAPTER 87

SEALEVEL RISE : A PROBABILISTIC DESIGN PROBLEM

prof. ir. drs. J.K. Vrijling ¹⁾
ir. I.J.C.A. Van Beurden

Abstract

An economic model is developed to calculate the optimal height of sea defences in case of sealevel rise. The optimal amount and the optimal period of heightening are found, for the single period as well as for the multi-period case. Finally the optimal strategy of heightening of sea defences in case of an uncertain sealevel rise is formulated.

1.0 Introduction

The relative sealevel rise is a well-known fact. In the period from 1682 to 1930, a rise has been measured at the official benchmarks in Amsterdam. The velocity of the rise however appeared to be a function of time. Initially the velocity was 0.04 m per century but after 1850, the sealevel rise increased up to 0.17 m per century. The Delta Committee therefore chose a value of 0.20 m per century for this phenomenon. During the last 20 years, measurements have confirmed this estimate.

However recently experts have come to doubt this figure. In studies several causes are mentioned that may increase the velocity of the sealevel rise :

- melting of the polar ice pack.
- thermal expansion of the oceans.
- tectonic movement of the crust of the earth.
- settlement of alluvial soils due to dewatering.

Estimates of the future sealevel rise based on these ranging from 0.20 to 1.20 m per century are mentioned.

1) Professor hydraulic engineering,
T.U Delft, Stevinweg 1, 2628 CN, Delft

facts differ considerably. For the year 2050 values However these extreme values have not yet been confirmed by observations.

If the sealevel starts to rise, it will pose a significant threat to the low lying countries. The question is when and to what extent should these countries strengthen their sea defences, considering the uncertainty in the relative sealevel rise.

2.0 An economic model

Although the question of the strengthening of sea defences allowing for sealevel rise is multi-faceted, it is readily schematised to an economic decision problem. Solutions for planning period and height are found by minimising the total costs TC consisting of the investment in heightening of the sea defences I and the present value of the expected loss in case of inundation R :

$$TC = I + R \quad (1)$$

figure 1
Optimisation of the
height of a sea
defence.

In this paper the problem as stated by Van Dantzig[1960] is used as a starting point for the analysis.

2.1 Base case

To allow for sealevel rise, it will be necessary to heighten the sea defence after a certain period. If only one planning period is considered the investment I is schematised by :

$$I = I_0 + I_1(H - H_0) \quad (2)$$

where I_0 = initial cost of heightening [DF1]

I_1 = cost per meter heightening [DF1]

H = height after heightening [m]

H_0 = initial height [m]

The present value of the expected loss in case of inundation R is given by :

$$R = \int_0^{T_p} W P_f(H) e^{-rT} dt = \frac{W P_f(H)}{\gamma} (1 - e^{-\gamma T_p}) \quad (3)$$

where W = damage by inundation [DF1]

T_p = planning period [year]

$P_f(H)$ = probability of failure, schematised by :

$$P_f(H) = e^{-\frac{H - \eta t - A}{B}} \quad (4)$$

η = sealevel rise [m/year]

A, B = parameters of the distribution [m]

γ = $r - \eta/B$

r = real rate of interest [/year]

It is assumed that the parameters A en B of the probability of failure, are not affected by the sealevel rise.

The optimal probability of failure can be found by solving :

$$\frac{\partial TC(H, T_p)}{\partial H} = 0 \quad (5)$$

which yields :

$$P_{f_{opt}}(T_p) = e^{-\frac{H_{opt} - A}{B}} = \frac{I_1 B}{W} \frac{\gamma}{1 - e^{-\gamma T_p}} \quad (6)$$

In the following calculations values for the various parameters according to Van Dantzig have been used :

$I_0 = 40 \cdot 10^6$ [DF1]	$I_1 = 1 \cdot 10^6$ [DF1]
$H_0 = 3.00$ [m]	$W = 24 \cdot 10^9$ [DF1]
$A = 1.96$ [m]	$B = 0.33$ [m]
$r = 0.015$ [/year]	

figure 2
Optimal height of
for single period.

In figure 2 the optimal height derived from $P_{f,opt}(T)$ is shown.

The additional heightening ($H - H_{(n=0)}$) of the sea defence to allow for sealevel rise can also be expressed as a fraction of the occurring rise during the planning period ($\cdot T_p$). This is shown in figure 3. From this figure it can be seen that to allow for sealevel rise not the total occurring rise during the planning period has to be added to the height of the sea defence as should be expected, but only a part of it.

figure 3
Additional heightening
to allow for sealevel
rise as fraction of
occurring sealevel
rise

Additionally the condition for an economical solution is $TC_0 \geq TC$:

$$P_f(H_0) \geq \frac{\gamma}{W} \frac{(I_0 + I_1(H - H_0))}{1 - e^{-\gamma T_p}} + P_f(H) \tag{7}$$

Substitution of the optimal value of the height given by equation (6) yields :

$$P_f(H_0) \geq \frac{I_0 + I_1(H - H_0 + B)}{1 - e^{-\gamma T_p}} \frac{\gamma}{W} \quad (8)$$

2.2 Regular heightening

For a consistent solution of the optimal strategy however, not only the first heightening of the sea defence has to be taken into account, but also the subsequent future adaptations. In this case terms have to be added to I and R for future investments and risks. If all following planning periods are considered, this yields :

$$I = I_0 + I_1(H - H_0) + (I_0 + I_1\eta T_p) \frac{1}{e^{rT_p} - 1} \quad (9)$$

$$R = \frac{W}{\gamma} P_f(H) \frac{1 - e^{-\gamma T_p}}{1 - e^{-rT_p}} \quad (10)$$

The condition for an economical solution can be found by substitution of $T_p = \infty$ in equation (8) :

$$P_f(H_0) \geq (I_0 + I_1(H - H_0 + B)) \frac{\gamma}{W} \quad (11)$$

Optimum height

By solving equation (5), the optimal value for the probability of failure as a function of the planning period is found :

$$P_{f_{opt}} = \gamma \frac{BI_1}{W} \frac{1 - e^{-rT_p}}{1 - e^{-\gamma T_p}} \quad (12)$$

In figure 4 the optimal height computed from $P_{f_{opt}}$ and the optimal minimum height given by $H_{min} = H_{opt} - \eta T$ are shown for several values of η . From this figure it can be seen that for higher sealevel rises and longer planning periods, the optimal height increases and the optimal minimum height decreases. In figure 5 the relative extra-heightening to allow for sealevel rise is shown. The allowance factor is in the order of 0.5. Only for extreme values of the sealevel rise and long planning periods this factor is significantly exceeded.

figure 4
Optimal height and
optimal H_{\min}

figure 5
Additional heightening
as fraction of occur-
ring sealevel rise
(regular heightening)

Optimum planning period

Additionally total cost can be optimized by differentiating TC with respect to the planning period. Algebraically a solution cannot be found, however for the examples above, values for the optimal planning period $T_{p,opt}$ have been found numerically as shown by dots in figure 4 and figure 5.

In figure 6 total cost TC is shown as a function of the planning period. Early non-optimal adaptations appear to be more expensive than later non-optimal adaptations, especially for less severe sealevel rises.

As a result of the optimal height and the optimal planning period, the crest of the sea defence should be kept in a band between the optimal design level and a certain minimum. In figure 7 is shown an optimal scenario.

figure 6
Total cost as
function of the
planning period.

figure 7
Optimal scenario for
heightening.

2.3 Optimum waiting period

If the sea defence already has an non-optimal height or if some of the parameters change, the question arises, when and to what extent the sea defences should be heightened. To solve this problem, equations (9) and (10) have to be changed into:

$$I = [I_0 + I_1(H + \eta T_w - H_0) + (I_0 + I_1 \eta T_{opt}) \frac{1}{e^{rT_{opt}} - 1}] e^{-rT_w} \tag{13}$$

$$R = \frac{W}{Y} P_f(H_0) (1 - e^{-rT_w}) + \frac{W}{Y} P_f(H) \tag{14}$$

where T_w = waiting period

Again the optimal height can be solved by differentiating TC with respect to H. This leads to the same result as given before.

The optimal waiting period has not been solved

algebraically, but numerical solutions give the impression that a simple solution of the following form exists :

$$T_w = T_{p,opt} - \frac{H_{opt} - H_0}{\eta} \quad (15)$$

Optimal scenarios based on this equation are shown in figure 8. As for severe sealevel rises, optimal heights are higher and minimal heights are lower, in case of sudden increase of the sealevel rise immediate action will not be necessary. Only when the lower bound of the new regime is reached the sea defence should be heightened.

figure 8
Optimal action

2.4 Optimal design sealevel rise

So far the optimal scenario has been calculated for a certain known value of the sealevel rise. However as mentioned above, this value is uncertain. The occurring sealevel rise may vary from 0.20 to 1.20 meter per century according to various estimates. It will be clear that this will affect the total cost of the regular heightening.

In the following calculations the actual value of the occurring sealevel rise is supposed to be known at the moment the sea defences need to be heightened due to this sealevel rise.

Total cost in the case of a different assumed sealevel rise and occurring sealevel rise is given by :

$$TC(\eta_a, \eta_o) = I(\eta_a, \eta_o) + R(\eta_a, \eta_o) \quad (16)$$

where :

$$I(\eta_a, \eta_o) = I_0 + I_1(H_{opt\eta_a} - H_0) + (I_0 + I_1\eta_o T_{opt\eta_o}) \frac{1}{1 - e^{-rT_{opt\eta_o}}} e^{-rT_w} \quad (17)$$

$$R(\eta_a, \eta_o) = \frac{W}{\gamma} (P_f(H_{opt\eta_a}) (1 - e^{-\gamma T_w}) + P_f(H_{opt\eta_o}) \frac{1 - e^{-\gamma T_{opt\eta_o}}}{1 - e^{-rT_{opt\eta_o}}} e^{-rT_w}) \quad (18)$$

T_w is can be calculated using equation (15) :

$$T_w = T_{opt\eta_o} - \frac{H_{opt\eta_o} - H_{opt\eta_a}}{\eta_o} \quad (19)$$

In figure 9 the extra total cost due to different values for the design and occurring sealevel rise is shown for a design sealevel rise of 20 cm per century. As can be expected, the extra cost is higher for lower occurring sealevel rises.

figure 9
Extra total cost for
 $\eta_d = 0.006$ m/year

Assuming a certain probability density function for the occurring sealevel rise $f(\eta_o)$ the expected total cost for an assumed value of the sealevel rise can be calculated :

$$TC_{unc}(\eta_a) = \int_0^{\infty} TC(\eta_a, \eta) f(\eta) d\eta \quad (20)$$

In case of a discrete probability density function this equation can be written as:

$$TC_{unc}(\eta_a) = \sum_{i=1}^N TC(\eta_a, \eta_i) P(\eta_i) \quad (21)$$

The optimal design sealevel rise η_d can be found by minimising $TC_{unc}(\eta_d)$. Calculations have been made for three probability density functions (figure 10) :

- 1) : Uniform distribution
- 2) : Normal distribution :
- 3) : Gumbel distribution :

All distributions having $\mu = 0.006$ and $\sigma = 0.002$ m/year.

The value of the expected total cost as a function of the sealevel rises is shown in figure 11.

figure 10
The probability density functions of sealevel rise

figure 11
Expected value of the total cost.

The minimal value of the expected cost is approximately found at the average value of the sealevel rise. Further it is observed that the cost is less sensitive for an over-estimate of the occurring sealevel rise than for an under-estimate. It seems therefore advisable to choose a safe value for the design sealevel rise, if the sea defences have to be heightened.

3.0 Conclusions

The question when and to what extent the sea defences of low-lying countries should be strengthened in case of an increasing sealevel rise can be answered by an economic probabilistic model.

To allow for sealevel rise not the occurring sealevel rise has to be added to the height of the sea defence but only a part of it. This part is depending on the several parameters in the order of 0.5. Only in case of very high values of the sealevel rise this factor is significantly exceeded and approaches 0.7.

If the sea defences are well maintained, immediate action is not advised in case of an increase of sealevel rise. Action should be taken when the lower bound of the new regime as defined in this paper is reached.

In case of action under uncertainty of the future occurring sealevel rise, do not under-estimate this value, as the total cost of a sea defence that is constructed to low, exceeds the cost of a sea defence constructed sufficiently high.

Appendix 2 : Mathematical tools

The following formulas have been used in this paper :

Present value of a future amount A_T

$$PV(A_T) = A_T e^{-rT} \quad (22)$$

Present value of a flow F

$$PV(F) = \int_0^T F e^{-rt} dt = \frac{F}{r} (1 - e^{-rT}) \quad (23)$$

Present value of a future flow F_f

$$PV(F_T) = \int_T^{T+\Delta T} F_T e^{-rt} dt = \frac{F_T}{r} e^{-rT} (1 - e^{-r\Delta T}) \quad (24)$$

Present value of a returning future cost

$$PV(A, T) = \sum_{n=0}^{\infty} A e^{-rnT} = A \frac{1}{1 - e^{-rT}} \quad (25)$$

CHAPTER 88

NEARFIELD TSUNAMIS GENERATED BY THREE DIMENSIONAL BED MOTIONS

J.J. Lee* & J.J. Chang**

ABSTRACT

A theoretical and computer simulation has been conducted on near field tsunamis generated by three dimensional bed motion. Linear dispersive wave theory has been used. Nonlinear effect has been found to be negligible for nearfield tsunami generation problem, as nonlinear effect is significant primarily for propagation over long distances. The specified bed deformation takes into account many possible dipole dislocation patterns with different aspect ratio. Three dimensional pictures of the water surface elevation were constructed from the array of computer data.

For the nearfield tsunamis problem, the distance between the generation area and the shoreline is relatively short, thus the main generated wave quickly interact with the reflected leading wave from the coastal boundary to create an even more complicated wave profile. The coastal boundary can either focus or diffuse these waves, resulting in large variations in wave amplitude in the coastal region.

(I) PROBLEM FORMULATION

Let (x, y, z) constitute a Cartesian coordinate system with $z = 0$ as the undisturbed water surface as shown in Fig. 1. Initially, the fluid is at rest with the free surface and solid boundary defined by $z = 0$ and $z = h$ respectively, where h is a constant. For $t > 0$, the solid boundary is moved as prescribed by $\xi(x, y; t)$. The resulting deformation of the free surface is to be determined as $z = \eta(x, y; t)$. Assuming irrotational flow and an inviscid

Figure 1. Definition Sketch of General Dipole Bed Deformation

fluid, the fluid kinematics can be expressed in terms of a velocity potential $\varphi(x, y, z; t)$. The differential equation and the linearized boundary conditions that φ must satisfy can be listed as follows:

$$\Delta^2 \varphi = 0 \quad 0 < t < \infty, -\infty < x, y < \infty, -h < z < 0 \quad (1)$$

$$\varphi_{tt} + g\varphi_z = 0 \quad z = 0 \quad (2)$$

$$\varphi_z = \xi(x, y; t) \quad z = -h \quad (3)$$

In these equations, the subscripts denote partial derivatives and g denotes the gravitational acceleration.

The linearized relation between the water surface displacement, η , and the velocity potential, φ , is

$$\eta(x, y; t) = -\frac{1}{g}\varphi_t(x, y, 0; t) \quad (4)$$

The solution for φ (and hence, η) is obtained by using the Fourier transform for the spatial variables x, y and the Laplace transform for the time variable t defined by:

$$\hat{f}(K_1, K_2, s) = \int_0^\infty e^{-st} \int_{-\infty}^\infty e^{iK_2 y} \int_{-\infty}^\infty e^{iK_1 x} f(x, y; t) dx dy dt \quad (5)$$

By applying the transformation of equation (5) to the governing equation and boundary conditions with the subsequent inversion, one obtains the water surface elevation as:

$$\eta(x, y; t) = \frac{1}{(2\pi)^2} \int_{-\infty}^\infty \int_{-\infty}^\infty \left[\frac{1}{2\pi i} \int_{B_\gamma} \frac{s^2 e^{-iK_1 x} e^{-iK_2 y} e^{st} \hat{\xi}(K_1, K_2, s)}{(s^2 + \omega^2) \cosh \sqrt{K_1^2 + K_2^2} h} ds \right] dK_1 dK_2 \quad (6)$$

where $\omega^2 = g\sqrt{K_1^2 + K_2^2} \tanh \sqrt{K_1^2 + K_2^2} h$ and $\int_{B_\gamma} \equiv \lim_{\Gamma \rightarrow \infty} \int_{\mu - i\Gamma}^{\mu + i\Gamma}$ is the Bromwich constant, μ is a positive constant and Γ is a real number.

In order to obtain the specific wave profile as defined in equation (6), one must specify the bed deformation history $\xi(x, y; t)$. The bed deformation is assumed to be a rectangular block with a dipole type of deformation in x axis, and exponential variation in time:

$$\xi(x, y; t) = T(t)X(x)Y(y) \quad (7)$$

where

$$\begin{aligned}
 T(t) &= \xi_0(1 - e^{-\alpha t}) \quad t \geq 0 \\
 X(x) &= \begin{cases} M_1 x e^{-\beta_1 x} & x \geq 0 \\ M_2 x e^{\beta_2 x} & x < 0 \end{cases} \\
 Y(y) &= N e^{-\gamma|y|} H(A^2 - y^2)
 \end{aligned}$$

ξ_0 is the maximum amplitude of the vertical displacement, α is the time constant defined as $1.11/t_c$, and t_c is the characteristic time defined by $\xi/\xi_0 = 2/3$ at $t = t_c$. M_1 , M_2 , β_1 and β_2 , are real and positive constant, A is a half length of the rectangular block. The heavy side step function is defined as:

$$H(A^2 - y^2) = \begin{cases} 1, & A^2 - y^2 > 0 \\ 0, & A^2 - y^2 < 0. \end{cases}$$

The transformation of equation (7) yields:

$$\begin{aligned}
 \hat{\xi}(K_1, K_2; s) &= \left\{ M_1 \left[\frac{\beta_1^2 - K_1^2 + 2i\beta_1 K_1}{(\beta_1^2 + K_1^2)^2} \right] \right. \\
 &\quad \left. - M_2 \left[\frac{\beta_2^2 - K_1^2 + 2i\beta_2 K_2}{(\beta_2^2 + K_1^2)^2} \right] \right\} 2Ni. \tag{8} \\
 &\quad \left\{ \frac{e^{-\gamma A}}{\gamma^2 + K_2^2} [-\gamma \cos K_2 A + K_2 \sin K_2 A] + \frac{\gamma}{\gamma^2 + K_2^2} \right\} \cdot \\
 &\quad \xi_0 \left[\frac{\alpha}{s(s + \alpha)} \right]
 \end{aligned}$$

Substituting equation (8) into equation (6) and solving for the surface elevation one obtains:

$$\begin{aligned}
 \eta(x, y; t) &= \frac{-2\xi_0 Ni}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left\{ M_1 \left[\frac{\beta_1^2 - K_1^2 + 2i\beta_1 K_1}{(\beta_1^2 + K_1^2)^2} \right] \right. \\
 &\quad \left. - M_2 \left[\frac{\beta_2^2 - K_2^2 + 2i\beta_2 K_1}{(\beta_2^2 + K_1^2)^2} \right] \right\} \cdot \\
 &\quad e^{-iK_1 x} \cdot \left\{ \frac{e^{-\gamma A}}{\gamma^2 + K_2^2} [-\gamma \cos K_2 A + K_2 \sin K_2 A] + \frac{\gamma}{\gamma^2 + K_2^2} \right\} \cdot e^{-iK_2 y} \cdot \\
 &\quad \frac{1}{\cosh \sqrt{K_1^2 + K_2^2} h} \cdot \left[\frac{\alpha^2}{\alpha^2 + \omega^2} (e^{-\alpha t} - \cos \omega t - \frac{\omega}{\alpha} \sin \omega t) \right] dK_1 dK_2
 \end{aligned}$$

where

$$\omega^2 = g \sqrt{K_1^2 + K_2^2} \tanh \sqrt{K_1^2 + K_2^2} h \tag{9}$$

To obtain a simplified solution from equation (9) the bed deformation is assumed to be axially symmetrical. A sketch of such specific fluid domain is

set in Fig. 1 for the case of $M_1 = M_2 = M$, $\beta_1 = \beta_2 = \beta$, $\gamma = 0$ and $N = 1$. Thus, equation (9) becomes:

$$\eta(x, y; t) = \frac{2\xi_0\beta M}{\pi^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{\sin K_2 A}{K_2} \frac{K_1}{(\beta^2 + K_1^2)^2} \cdot e^{-iK_1 x} \cdot e^{-iK_2 y} \cdot \frac{1}{\cosh \sqrt{K_1^2 + K_2^2} h} \left[\frac{\alpha^2}{\alpha^2 + \omega^2} (e^{-\alpha t} - \cos \omega t - \frac{\omega}{\alpha} \sin \omega t) \right] dK_1 dK_2$$

where

$$\omega^2 = g\sqrt{K_1^2 + K_2^2} \tanh \sqrt{K_1^2 + K_2^2} h \quad (10)$$

Equation (10) contains poles at $K_2 = 0$. This singularity can be treated easily by L' Hospital's rule.

Introducing $K_1 = -2\pi k_1$ and $K_2 = -2\pi k_2$, equation (10) can be rewritten as:

$$\eta(x, y; t) = 8\beta M \xi_0 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{i2\pi k_1 x} e^{i2\pi k_2 y} f(k_1, k_2) dk_1 dk_2 \quad (11)$$

where

$$f(k_1, k_2) = \frac{-2\pi k_1}{[\beta^2 + (2\pi k_1)^2]^2} \cdot \frac{\sin 2\pi k_2 A}{2\pi k_2} \cdot \frac{1}{\cosh \sqrt{(2\pi k_1)^2 + (2\pi k_2)^2} h} \left[\frac{\alpha^2}{\alpha^2 + \omega^2} (e^{-\alpha t} - \cos \omega t - \frac{\omega}{\alpha} \sin \omega t) \right]$$

and

$$\omega^2 = g\sqrt{(2\pi k_1)^2 + (2\pi k_2)^2} \tanh \sqrt{(2\pi k_1)^2 + (2\pi k_2)^2} h$$

It should be recognized that equation (11) is a two dimensional Fourier transform of $f(k_1, k_2)$, and can be computed by using the fast Fourier transform (FFT).

(II) NUMERICAL IMPLEMENTATION

Suppose that $f(k_1, k_2)$ is defined in the interval of $-T/2 < k_1, k_2, \frac{T}{2}$ and is zero for $|k_1|, |k_2| > T/2$, equation (11) can then be written as:

$$\eta(x, y; t) = 8\beta M \xi_0 \int_{-\frac{T}{2}}^{\frac{T}{2}} \int_{-\frac{T}{2}}^{\frac{T}{2}} e^{i2\pi k_1 x} e^{i2\pi k_2 y} f(k_1, k_2) dk_1 dk_2 \quad (12)$$

It should be noted that the advantageous procedure of computing $\eta(x, y; t)$ in equation (12) is to fix a time $t = t_i$ and evaluate all possible x and y by recognizing equation (12) as a double Fourier transform of $f(k_1, k_2; t)$.

The integral in equation (12) can be approximated by Reimann sum. Thus, equation (12) became as two-dimensional discrete Fourier Transform form:

$$\eta(k_1, k_2; t) = 8\beta M \xi_0 \Delta k_1 \Delta k_2 \sum_{n_1 = -\frac{N_1}{2} + 1}^{N_1/2} \sum_{n_2 = -\frac{N_2}{2} + 1}^{N_2/2} f(n_1, n_2) \omega_1^{k_1 n_1} \omega_2^{k_2 n_2}$$

$$\text{for } \frac{-N_1}{2} + 1 \leq k_1 \leq \frac{N_1}{2}, \quad \frac{-N_2}{2} + 1 \leq k_2 \leq \frac{N_2}{2} \quad (13)$$

where

$$f(n_1, n_2) = \frac{-2\pi n_1 \Delta k_1}{[\beta^2 + (2\pi n_1 \Delta k_1)^2]^2} \cdot \frac{\sin 2\pi n_2 \Delta k_2 A}{2\pi n_2 \Delta k_2} \cdot \frac{1}{\cosh \sqrt{(2\pi n_1 \Delta k_1)^2 + (2\pi n_2 \Delta k_2)^2} h} \cdot \left[\frac{\alpha^2}{\alpha^2 + \omega^2} (e^{-\alpha t} - \cos \omega t - \frac{\omega}{\alpha} \sin \omega t) \right],$$

and

$$\omega^2 = g \sqrt{(2\pi n_1 \Delta k_1)^2 + (2\pi n_2 \Delta k_2)^2}$$

$$\tanh \sqrt{(2\pi n_1 \Delta k_1)^2 + (2\pi n_2 \Delta k_2)^2} h$$

N_1 and N_2 are the number of discrete points which correspond to the x and y axis, respectively; $n_i = -\frac{N_i}{2} + 1, -\frac{N_i}{2} + 2, \dots, \frac{N_i}{2}$ for $i = 1, 2$. The constant length, $\Delta k_i = 2T/N_i$ for $i = 1, 2$. This definition of Δk_i , implies that $\Delta x = \Delta y = \frac{1}{2T}$, and $x = k_1 \cdot \Delta x, y = k_2 \cdot \Delta y$.

It should be noted that $\omega_1 = e^{2\pi i/N_1}$ and $\omega_2 = e^{2\pi i/N_2}$ introduced in equation (13) are $N_1 - th$ and $N_2 - th$ roots of unity in the complex number field, respectively.

An array of 256×256 points was used to compute equation (13), i.e. $N_1 = N_2 = 256$ and $m = 8$. To avoid the spurious short-period oscillations, Δk should be kept small. However, a small Δk implies that the region of computation is also correspondingly limited. All numerical results presented in this study are obtained for $\Delta k = 0.03$. This value was arrived at through a series of numerical experiments.

In order to obtain the wave profile as defined in equation (13), one must specify the parameters M and β , for the comparison study, the results

obtained for the water wave generated by equation (13) will be compared with the previously published half-sine type dipole dislocation results (Chang (1981)). It should be noted that the bed deformation of half-sine type dipole dislocation is also assumed to be rectangular block with a dipole type of deformation in x -axis and exponential variation in time. This is specified as follows:

$$\xi(x, y; t) = \xi_0(1 - e^{-\alpha t})\left(\sin \frac{\pi x}{2B}\right)[H(B^2 - x^2)H(A^2 - y^2)]. \quad (14)$$

In order to set the resulting bed deformation specified by equation (7) and (14) to have the the same deformation energy as well as the same displacement volume the parameter M is equal to 5.8 and β is equal to 2.134.

(III) RESULTS AND DISCUSSION

Numerical results obtained from equation (13) for a general case dipole dislocation of a rectangular block have been obtained. A series of three-dimensional pictures of the wave surface elevation are presented in figure 2 for different dimensionless time parameters, $t\sqrt{g/h}$. The dimensionless parameters for this case are: $t_c\sqrt{g/h}/B = 0.069$, $B/h = 12.2$ (B is the effective half width of a rectangular block, let $B = \frac{1}{2}W = 2.0$ as shown in Fig. 1), $\xi_0/h = 0.2$. The time history of bed motion is an exponential form as seen in Equation (7) with a characteristic time parameter, $\alpha = 18.46$. These three-dimensional pictures were constructed from 256×256 pixel using image processing technique, and represent the overall pictorial view of the wave profile at $t\sqrt{g/h} = 4.20, 12.61, 21.02$ and 29.43 . The vertical viewing angle for these pictures is 60° and the horizontal angle is 60° . The wave amplitude, η , has been normalized by the total bed displacement, ξ_0 . By inspecting these three-dimensional pictures the wave along the x -axis are transformed from the original exponential form into waves of two opposite directions outward from the generation region. The waves along the y -axis disperse from the original wave form as time increase. Due to radiation of wave in every direction, the extent of the generated regions are presented as approximately elliptic region. The complex nature of generated wave patterns due to three-dimensional bottom dislocation is shown in these pictures.

In order to demonstrate the transformation of wave profile as a function of time, the water surface profile along any arbitrarily chosen coordinates by a generalized digital mathematical phantom is also obtained. Figure 3 show the water surface profile along x axis ($y = 0$ for $x > 0$). For convenient comparison of the results for the two different bed motion.

Figure 2. Three Dimensional Pictures Due to General Case Dipole Dislocation Bed Motion Showing the Wave Pattern Near the Generation Region for Specified Time Parameters (Viewing Angle: $\theta_h = 60^\circ$, $\theta_v = 60^\circ$)

The water profiles for a half-sine type dipole dislocation are also superimposed in Figures 3. These profiles are obtained by cutting the three-dimensional pictures such that shown in Figure 2. This series of water surface profiles shows how detailed waves are propagated from the origin of disturbance towards the surrounding region. By studying these wave profiles at different time parameters for both types of bed motion as shown in Figures 3, a number of observations can be made:

- (a) The limit of undisturbed water surface is consistent for all time parameters, even when the bottom disturbances differ.
- (b) The water surface profiles for both dipole bed motions obtained, show an asymmetric behavior due to the asymmetric bottom deformation. The wave amplitude along the y -axis is also zero at all the time. It should be noted that the present theoretical analysis does not treat the nonlinear effect, although the dispersive effect is allowed. Using these wave profiles, the propagation speed is also computed as 2.2 ft/sec, this is very close to the longwave celerity $c = \sqrt{gh} = 2.3$ ft/sec.
- (c) At a small time parameter, $t\sqrt{g/h} = 8.41$, the wave profiles due to general case dipole dislocation differ from the wave patterns due to the half-sine type dipole dislocation. This has provided an aspect showing the end effect of the generation region arriving at the x -axis. The generated wave profiles are dependent upon the shape of bed motion.
- (d) For the general type dipole dislocation, the wave amplitude decay rapidly in arbitrary direction (see Figures 3) the rate of decay is faster than the case of half-sine dipole dislocation the wave profiles exhibited larger negative wave trailing the positive leading wave.

The water surface profiles for two different bed deformations as a function of time at three locations away from the generated region are shown in Figure 4. The three locations are chosen along the minor axis ($y = 0$) at $x = 1.5B$, $2.0B$ and $2.5B$. It is seen that the wave profiles in these three locations shows the same time of arrival for different bed motion. The negative leading wave trailing the positive wave propagates away from the generation region, and oscillates in a manner which appears to be approaching the still water surface level as time increase. For the case of general dipole dislocation the negative leading wave trailing the positive wave occurs at a smaller value of $t\sqrt{g/h}$, than that for the case of half-sine bed motion.

To demonstrate the effect of coastal boundary on the nearfield tsunamis generated by the current bed motion models eight computer graphics are presented in Figure 5. These computer graphics show wave patterns for various time after the start of the bed motion as they approach the coastal boundary. The orientation of the coastal boundary is inserted in Figure 5. The computer graphics are generated by different viewing angles providing the

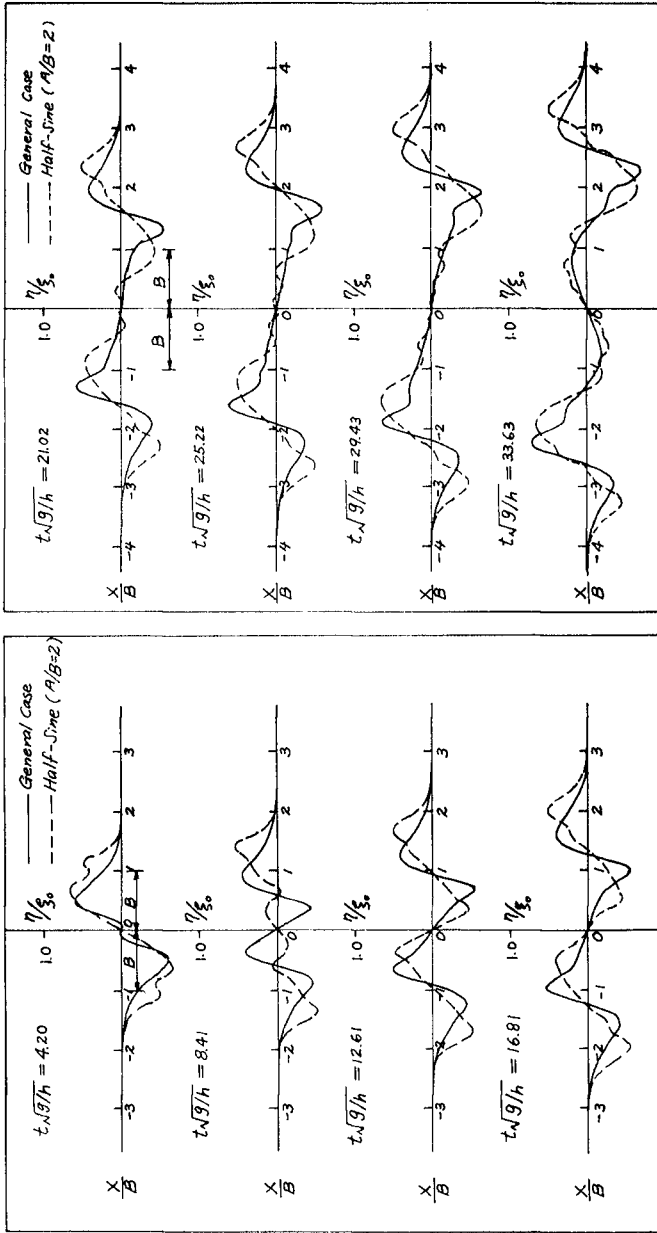

Figure 3. Water Surface Profile Along the x -Axis for Two Different Bed Deformation Models

Figure 4. Water Surface Profiles for Two Different Bed Deformation Models at $x = 1.5B, 2.0B$, and $2.5B; y = 0$

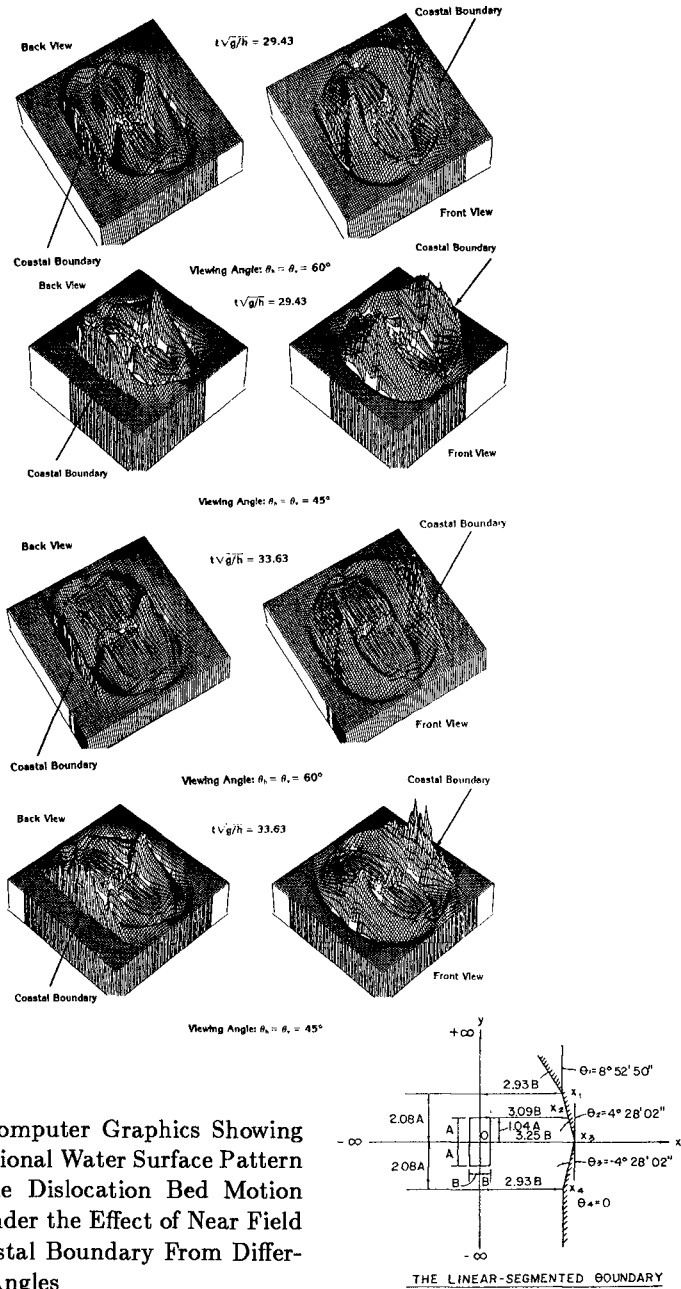

Figure 5. Computer Graphics Showing Three Dimensional Water Surface Pattern Due to Dipole Dislocation Bed Motion ($A/B = 2$) Under the Effect of Near Field Irregular Coastal Boundary From Different Viewing Angles

wave pattern from different perspective. From these, one can readily see the effect of the reflecting boundary and realize the variation of the transient wave amplitudes along the coastal boundary associated with nearfield tsunamis. This feature confirms the field experience which showed a great variation in wave amplitudes at nearby locations along the coastline. It should be noted that the water depth throughout the computational domain has been assumed constant. The resulting water surface profile for variable depth medium would even be more complicated than those shown.

CHAPTER 89

NUMERICAL 3-D CURRENT MODELLING OF STRATIFIED SEAS

Erland B. Rasmussen¹, Hans Jacob Vested¹
and Lars C. Ekebjærg¹

Abstract

A detailed knowledge of the velocity field is often needed, e.g. for environmental impact assessment and the presence of a continuously stratification often necessitate the use of three-dimensional models. The present paper describes such a three-dimensional numerical model. Its ability to model situations involving stratification is illustrated through two classical hydraulic problems and a practical application. The problems of boundary data in the three dimensions are discussed and a possible way of overcoming these problems is devised.

1. INTRODUCTION

The coastal sea will in many cases be stratified due to variations in temperature or salinity, and even very small differences in density may have a decisive influence upon the properties of the flow considered. During the last decade two dimensional layered models integrated over the layers have been developed to simulate stratified flow. These models typically describe two layers, and have been successfully applied in situations where a pronounced stratification exists. However, in practice the density varies often continuously and the mixing of the water can only be adequately described from a knowledge about the three-dimensional flow field. This has led to the development of three-dimensional numerical current

¹M.Sc. in Civil Engineering, Danish Society of Civil Engineers, Computational Hydraulics Centre, Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hoersholm, Denmark

models capable of calculating the three-dimensional velocity field and density differences in a continuously stratified sea.

In the present paper a three-dimensional numerical hydrodynamic and advection-diffusion flow model is described. The model takes into account density variations, bathymetry and external forcing from, for example, wind and hydrographic boundary conditions. The model is suitable for applications where a detailed description of the flow is necessary, such as water exchange in estuaries, and for environmental impact assessment.

An important aspect of three-dimensional modeling is the need for accurate boundary data that must be known a priori to the simulations. Often these are, however, not known or can only be poorly estimated in practice. Inconsistent boundary data will inherently lead to numerical instability in the model and this problem is more evident in the presence of density variations. A possible solution to this problem has been devised in the present paper.

2. DESCRIPTION OF A THREE-DIMENSIONAL MODEL

The mathematical model is based upon the equations for conservation of mass and momentum (the Reynolds-averaged Navier-Stokes equations) in three dimensions together with an advection-diffusion equation for the scalar quantities salt and temperature,

$$\frac{D\vec{u}}{Dt} + 2 \Omega \times \vec{u} = - \frac{1}{\rho} \nabla P - \vec{g} + \nabla \cdot \{\nu_e \nabla \vec{u}\} + \vec{F}_{\text{ext}} \quad (1)$$

$$\frac{D\rho}{Dt} + \rho \nabla \vec{u} = \nabla \cdot \{D_m \nabla \rho\} \quad (2)$$

$$\frac{D}{Dt} \{\rho S\} = \nabla \cdot \{D_s \nabla S\} \quad (3)$$

$$\frac{D}{Dt} \{\rho T\} = \nabla \cdot \{D_T \nabla T\} \quad (4)$$

where

\vec{u}	is the velocity vector,
P	is the fluid pressure,
ρ	is the density,
ν_e	is the effective viscosity,
\vec{F}_{ext}	is an external forcing such as wind shear,
D_m	is the dispersion coefficient due to fluctuations in density,
Ω	is the Coriolis tensor,
\vec{g}	is the gravitational vector,
S	is the salinity,
T	is the temperature,
D_s and D_T	are dispersion coefficients for salt and temperature, respectively, and
t	is time.

The conservation equations for mass and momentum are discretized with a second order accuracy into a finite difference formulation imposed on a space-staggered rectangular grid. The weak coupling between the fluid pressure and the three velocity components is solved by the artificial compressibility method which first was proposed by Chorin (1967).

The fractional step technique and a special handling of the convective terms allow for a non-iterative ADI (Alternating Directions Implicit) method to be applied for advancing the solution in time.

Simultaneously, the advection-diffusion equation is solved by an explicit quadratic upwind method, the so-called QUICKEST scheme proposed by Leonard (1979) and extended to two and three dimensions by Justesen et al. (1989).

3. MODELLING OF CLASSICAL HYDRAULIC PROBLEMS

Stratified seas are often characterized by migrating fronts of water with different density. The classical example of such flow is often referred to as the lock-exchange flow, as it is observed when a sluice gate separating saline and fresh water is opened. A numerical simulation of this test accentuates the properties of the model with respect to maintaining the density difference at the fronts and thereby the properties to simulate the flow correctly.

Consider a 4 km, 20 m deep channel. Initially the water is at rest, with the less dense water to the

left (salinity 20 ppt.) and the more dense to the right (salinity 32 ppt.), separated by a vertical wall. When the wall is suddenly removed, the two water bodies will start to move. A gridsize of $\Delta x = 100$ m and $\Delta z = 1$ m has been chosen. The time step is set equal to 2.5 sec. There is no wall friction applied and a constant eddy viscosity equal to 0.001 m/s² is used.

Fig. 3.1 shows the development in time of the flow. The very unsteady and complicated flow field at the two density fronts are clearly revealed. Due to the free surface, the flow is not symmetric.

Assuming a balance between the potential and kinetic energy the propagation speed, U_0 , of the density front can be expressed as

$$U_0 = 0.5 \sqrt{\Delta g H_0} \quad (5)$$

where H_0 is the water depth and $\Delta = \Delta \rho / \rho$.

The factor 0.5 in Eq. (5) refers to symmetrical flow and to non-viscid flow. In the presence of a free surface, laboratory experiments yield a deviation of the factor 0.5 in Eq. (5). According to Simpson (1987) the factor becomes 0.465 and 0.59 for the underflow and overflow, respectively.

A comparison between the model estimates and the empirical estimates has been listed in Table 1.

	Emp. Expression	Num. Model
Underflow	0.62	0.62
Overflow	0.66	0.78

TABLE 1 Propagation Speed (m/s) of Density Fronts Based on an Empirical Expression and the Present Model.

Fig. 3.1 Development of lock-exchange flow. Notice the characteristic head of the fronts which is also seen in laboratory experiments (cf. Simpson (1987)).

As seen from Table 1 there is an excellent agreement regarding the underflow whereas the model tends to overestimate the overflow compared to the empirical expression.

Another classical hydraulic problem in stratified seas is the wind-driven circulation and tilting of the interface. Consider again the 4 km and 20 m deep open channel; but with a stable, horizontal stratification at 10 m depth. The external force is a wind shear stress τ_w equal to 0.58 Pa. The wind causes a set-up in the wind direction and a set-down in the opposite. This tilting of the surface induces additional water movements, resulting in a reversed tilting of the interface, and a wind induced, clockwise rotating current in the upper layer. In the lower

Fig. 3.2 Wind driven circulation. Initial and steady state conditions.

layer a weaker, counter clockwise rotating current is generated. The steady state situation has along with the initial conditions been shown in Fig. 3.2. Assuming a static equilibrium between the wind set-up and the wind shear stress, the set-up can be determined from

$$\Delta\eta = \frac{\tau_{\omega} L}{\rho gh} \quad (6)$$

where L is the length of the channel and h the mean depth of the upper layer. The reversed tilting of the interface $\Delta\eta_i$ can be determined from

$$\Delta\eta_i = - \Delta\eta / \Delta \quad (7)$$

assuming the lower layer is at rest. Inserting the actual values gives $\Delta\eta = 30$ cm and $\Delta\eta_i = 3.18$ m. These values are to be compared with the model results $\Delta\eta = 2,6$ cm and $\Delta\eta_i = 2,76$ m. With the given approximation this is a reasonable agreement.

4. APPLICATION IN THE GREAT BELT AREA

The three-dimensional model briefly described in Section 2 has been set up for the Great Belt which connects the Baltic Sea with the Kattegat (see Fig. 4.1).

The flow in the Great Belt may be very unsteady due to the meteorological changes and the water masses are often stratified with less dense water from the Baltic Sea above the more dense water from the North Sea. In connection with the building of a link across the Great Belt between Funen and Zealand a large field measurement programme has been carried out, providing an excellent basis for comparing model results with field data.

On basis of the available field data a five days period in November 1987 has been selected for simulation. The three-dimensional model has been set up with a horizontal grid spacing of 500 m and with 4 m in the vertical. The time step has been set to 10 min. The relatively high velocities that are observed and the length scales present in the Great Belt imply a significant influence of the Coriolis force. Thus, the effect of Coriolis has been included in the model, also. For simplicity, a bed friction based on a

quadratic law with a constant bed friction coefficient has been applied.

Fig. 4.1 Bathymetry of the Great Belt area with the locations of the measuring stations. Horizontal grid spacing is 500 m.

To describe the turbulence a Smagorinsky formulation of the eddy viscosity (see e.g. Smagorinsky (1963); Aupoix et al. (1982)) has been used. A simple damping function dependent on the gradient Richardson number has been introduced to account for the reduction of the shear stress across a density interface,

$$\nu_e = \frac{\nu_e}{1 + \psi Ri} \quad , \quad Ri = - \frac{g \frac{\partial \rho}{\partial z}}{\rho \left(\frac{\partial \vec{u}}{\partial z} \right)^2} \quad (8)$$

where Ri is the gradient Richardson number and ψ is a calibration factor.

The boundary conditions for the three-dimensional model have in the present study been extracted from a two-layered model assuming hydrostatic pressure and uniform velocity and density profiles for each layer

at the boundaries. Although this approximation is relatively rude, the model will within few grid points from the boundaries adjust itself to a non-uniform velocity distribution. This technique is known to be reliable and will prevent any inaccuracy and contradiction in the prescription of the boundary data.

A total of five stations with between two and four current devices on each string have been deployed during the simulation period. Also, two water level stations near Funen and Zealand, respectively, have been available. The approximate locations of these stations have been shown in Fig. 4.1.

The simulation period begins at 00:00 November 1, and ends at 12:00 November 5, 1987 of which the first 12 hours are a spin-up period. Initially, the density interface is positioned horizontally at 16 m depth.

In Fig. 4.2 a time series of the measured and calculated water levels at the two water level stations have been shown. It is seen that the water level is dominated by the semi-diurnal tide and that the Coriolis effect causes a difference of approximately 10 cm across the Belt under conditions with southward flow. A persisting southerly wind direction throughout the simulation period prevents a northward flow in the upper water masses and hence, neutralizes the Coriolis effect under ebb-tide conditions. Due to the limited model area the water level is strongly influenced by the boundary data and evidently - as seen in Fig. 4.2 - there must be a good agreement between the measured and calculated water levels.

In Fig. 4.3 an example of the horizontal velocities at the surface, at 16 m depth and 24 m depth, have been shown. At this particular time a strong southward flow is present in the upper water masses yielding at a Coriolis tilting at the surface (cf. Fig. 4.2). The reversed tilting of the density interface approximately positioned at -16 m causes a westward flow of dense water through a narrow trench south of the small island Sprogø in the middle of the Great Belt. This feature is also observed in many of the measurements, taken from a research vessel, carried out in parallel to the fixed stations measuring programme.

Typical examples of time series of measured and calculated current speeds have been given in Fig. 4.4.

The discrepancies between the measured and calculated speeds are more pronounced compared with the water levels. Naturally this is to be expected, due to the complexity of the physical (and numerical) velocity fields.

Fig. 4.2 Time series of measured and calculated water levels in Slipshavn (upper) and Korsør (lower)

As a qualitative assessment of the model performance the 12 hourly peak values of the current speeds have been extracted from the time series of each current meter along with the corresponding model data. In Fig. 4.5 the calculated vs measured peak values have been shown for all stations and all levels.

Station AH, B and C are deployed on the hillside of a deep, narrow trench (see Fig. 4.1) and thus, provide difficulties in the calibration due to an often inadequate spatial resolution. Comparing these three stations it is seen that there is a reasonable

— 0.25 m/s

Fig. 4.3 Calculated horizontal velocities at the surface (A), -16 m (B) and -24 m (C) on November 4, 1987 at 12:00.

agreement for the upper levels except for station AH which seems to overpredict the current speed generally. At station B the model tends to underpredict the peak values at the lower levels which probably is due to a discrepancy in the actual and modelled density interface and the associated damping of the shear stress.

Fig. 4.4 Time series of measured and calculated current speed at Station C (upper) and Station W (lower)

The lower levels at station D show a fairly good agreement whereas the upper levels tend to overpredict. As station D is positioned close to the boundary the prescribed uniform velocity profile is a likely explanation for this behaviour. In nature the highest velocities are observed at the surface and decreasing downwards under the present meteorological and hydrographical conditions. At station W a good agreement is found at the upper level whereas the model overpredicts the peak values at the lower level. Similar to station B the likely explanation for this behaviour is the density interface.

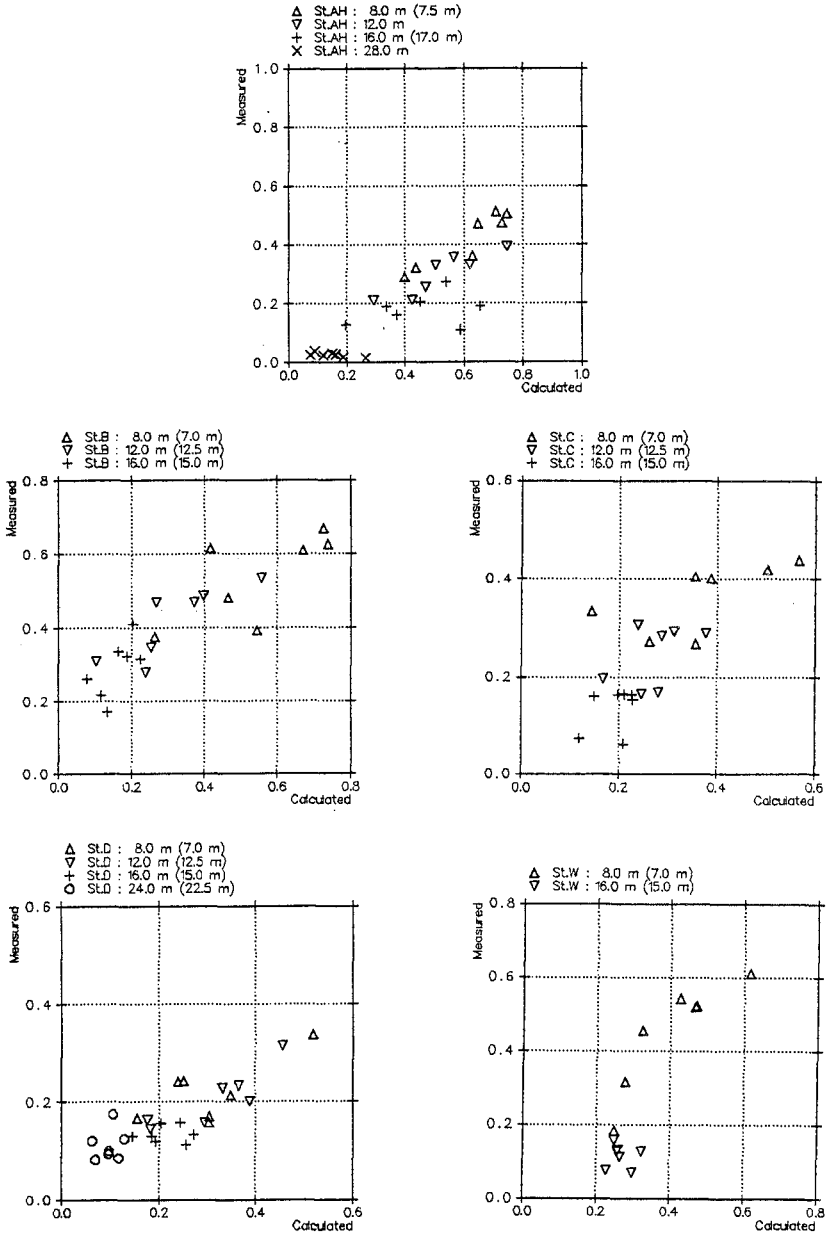

Fig. 4.5 Calculated vs measured 12 hourly peak values of current speeds (m/s) for all stations and all levels

The overall assessment of the model performance with respect to current modelling in stratified seas illustrates the importance of consistent boundary data and the ability of accurate modelling of stratification.

Although the present technique for establishing the boundary data for the three-dimensional model is not generally applicable and, furthermore, is time-consuming, it is a possible way out of the boundary data dilemma. On the other hand, this technique of utilizing results from layered models implies that only the area of interest needs to be modelled in detail and hence, often implies reduced computational costs. Alternatively, the three-dimensional model can be set up for so large an area that the open boundaries are better prescribed, e.g. so far away from the area of interest that the water masses can be regarded as homogeneous.

The problems associated with the boundaries may limit the practical applications of three-dimensional models seriously. Thus, further attention to these problems and especially those regarding the stratification is considered essential.

Long Wave Interaction with Steeply Sloping Structures

Stéphan T. Grilli ¹ and Ib A. Svendsen ², M. ASCE

Abstract : A fully nonlinear model for free surface potential flows is used to analyze the transformation of solitary waves above a mild slope, from intermediate to shallow water (shoaling, overturning), and to study the interaction of these waves with coastal structures located in the shallow area. Computations include wave runup, overturning and reflection from steep slopes or vertical wall, and from a combination of a slope and a submerged breakwater. Results are compared with other numerical, analytical and experimental results. Effects of the submerged breakwater, of making horizontal velocities more uniform over depth and of reducing wave runup on the slope, are further detailed.

Introduction

In this paper, the Boundary Element Model (BEM) for fully nonlinear waves developed by Grilli, *et al.* 1989, is used to analyze the runup and reflection of solitary waves from steep plane slopes and their transformation over a combination of a mild slope and coastal structures (submerged breakwater in front of a steep slope). The model solves two-dimensional free surface flows, in cases where potential flow is a good approximation. Under such conditions, Green's identity makes it possible to transform Laplace's equation into a Boundary Integral Equation (BIE). Instantaneous solution to this equation is then updated in time using the fully nonlinear kinematic and dynamic boundary conditions at the free surface. Along solid boundaries, no-flow conditions or conditions for generating or radiating waves can be imposed as well.

This approach to nonlinear wave flows has been very successful over the last decade. Particularly noteworthy for important steps in its development are contributions by Longuet-Higgins & Cokelet 1976, Vinje & Brevig 1981 and Dold & Peregrine 1986. Most of the applications so far, however, solved the problem in a transformed space or used complex variable formulations, and introduced the assumption that waves are periodic in space.

²Professor and Chairman (same address)

In our model, the equations are solved directly in the physical space (i.e., without any mapping). This yields a method which is capable of directly adapting to almost any geometry of the boundaries and to periodic as well as non-periodic wave conditions. The BIE is solved using a higher-order Boundary Element Method (first introduced by Brebbia 1978), and the time integration is explicit and of second-order accuracy in time, based on the method of Dold & Peregrine 1986. In the model, wave generation can be done by a wavemaker, by internal sources, or by imposing the potential on the free surface (see Grilli & Svendsen 1989b, 1990). In the present paper, only the numerical wavemaker is presented and used to generate solitary waves.

Mathematical formulation

Governing equations.— We consider an inviscid irrotational 2-D flow described by a velocity potential $\phi(\mathbf{x}, t)$, and the velocity field is given by $\mathbf{u} = \nabla\phi = (u, w)$. Thus, the continuity equation in the fluid domain $\Omega(t)$ with the boundary $\Gamma(t)$ becomes a Laplace equation for ϕ (Figure 1),

$$\nabla^2\phi = 0 \quad \text{in } \Omega(t) \tag{1}$$

Using the free space Green’s function $G(\mathbf{x}, \mathbf{x}_l) = -\frac{1}{2\pi} \log |\mathbf{x} - \mathbf{x}_l|$, (1) becomes the Boundary Integral Equation (BIE),

$$\alpha(\mathbf{x}_l)\phi(\mathbf{x}_l) = \int_{\Gamma(\mathbf{x})} \left[\frac{\partial\phi}{\partial n}(\mathbf{x})G(\mathbf{x}, \mathbf{x}_l) - \phi(\mathbf{x})\frac{\partial G(\mathbf{x}, \mathbf{x}_l)}{\partial n} \right] d\Gamma(\mathbf{x}) \tag{2}$$

where $\mathbf{x} = (x, z)$ and $\mathbf{x}_l = (x_l, z_l)$ are position vectors for points on the boundary, \mathbf{n} is the unit outward normal vector. and $\alpha(\mathbf{x}_l)$ is a geometric coefficient.

On the free surface $\Gamma_f(t)$, ϕ satisfies the kinematic and dynamic boundary conditions,

$$\frac{D\mathbf{r}}{Dt} = \left(\frac{\partial}{\partial t} + \mathbf{u} \cdot \nabla \right) \mathbf{r} = \mathbf{u} = \nabla\phi \quad \text{on } \Gamma_f(t) \tag{3}$$

$$\frac{D\phi}{Dt} = -gz + \frac{1}{2} |\nabla\phi|^2 - \frac{p_a - p_o}{\rho} \quad \text{on } \Gamma_f(t) \quad (4)$$

with \mathbf{r} , the position vector of a free surface fluid particle, g the acceleration due to gravity, z the vertical coordinate (positive upwards and $z = 0$ at the undisturbed free surface), p_a the pressure at the surface, p_o a reference pressure (e.g. at infinity) and ρ the fluid density.

General boundary conditions.— In the present applications waves are generated by simulating a plane wavemaker motion on the boundary $\Gamma_{r1}(t)$. In this case, the motion and normal velocity are specified over the paddle by,

$$\nabla\phi \cdot \mathbf{n} \equiv \overline{\frac{\partial\phi}{\partial n}} = \mathbf{u}_p(\mathbf{x}_p(t), t) \cdot \mathbf{n} \quad \text{on } \Gamma_{r1}(t) \quad (5)$$

where the overline denotes a specified value, and $(\mathbf{x}_p, \mathbf{u}_p)$ are prescribed wavemaker motion and velocity respectively. Along the stationary bottom Γ_b and the tank extremity Γ_{r2} representing a fixed structure (not necessarily vertical as in Figure 1), we have,

$$\nabla\phi \cdot \mathbf{n} \equiv \overline{\frac{\partial\phi}{\partial n}} = 0 \quad \text{on } \Gamma_b \text{ and } \Gamma_{r2} \quad (6)$$

Time stepping method.— The time stepping, described in detail in Grilli, *et al.* 1989, follows the Eulerian-Lagrangian approach used by Dold & Peregrine 1986. It consists of integrating the two nonlinear free surface conditions (3) and (4) at time t , to establish both the new position of the free surface $\Gamma_f(t)$ and the relevant boundary conditions of Laplace's problems at the next time step $t + \Delta t$. It uses Taylor expansions in terms of the Lagrangian time derivative (as defined in (3)) and the small time increment Δt , for both the position $\mathbf{r}(t)$ and the potential $\phi(t)$ on the free surface, which corresponds to following in time the pathline of a fluid particle, identical to a node of the discretization used for solving the BIE (2). We have so far limited the series to second order in Δt , which requires solving two Laplace problems at each time step (for ϕ and $\frac{\partial\phi}{\partial t}$), to get the coefficients in the series.

After solving a first Laplace problem for $(\phi, \frac{\partial\phi}{\partial n})$ at time t , boundary conditions of a second problem for $(\frac{\partial\phi}{\partial t}, \frac{\partial^2\phi}{\partial t\partial n})$ are determined. Along the free surface, Bernoulli's equation yields,

$$\overline{\frac{\partial\phi}{\partial t}} = -gz - \frac{1}{2} |\nabla\phi|^2 - \frac{p_a - p_o}{\rho} \quad \text{on } \Gamma_f(t) \quad (7)$$

and along the fixed boundaries, we get,

$$\overline{\frac{\partial^2\phi}{\partial t\partial n}} = 0 \quad \text{on } \Gamma_b \text{ and } \Gamma_{r2} \quad (8)$$

For a plane wavemaker, we have,

$$\overline{\frac{\partial^2 \phi}{\partial t \partial n}} = \left[\frac{d(\mathbf{u}_p \cdot \mathbf{n})}{dt} - \mathbf{u}_p \cdot \nabla(\mathbf{u}_p \cdot \mathbf{n}) \right] \quad \text{on } \Gamma_{r1}(t) \quad (9)$$

Boundary conditions for a plane wavemaker.— Development of (9) for a rigid body motion, with translation α and rotation θ yields (Cointe 1989),

$$\overline{\frac{\partial^2 \phi}{\partial t \partial n}} = (\ddot{\alpha} \cdot \mathbf{n}) + \dot{\theta}[(\dot{\alpha} \cdot \mathbf{s}) - \frac{\partial \phi}{\partial s}] - \frac{\partial^2 \phi}{\partial n \partial s}(\dot{\alpha} \cdot \mathbf{s}) + \frac{\partial^2 \phi}{\partial s^2}(\dot{\alpha} \cdot \mathbf{n}) \quad (10)$$

where the dots denote time derivatives ($\frac{d}{dt}$) following the body motion.

A *piston wavemaker* represents a flat vertical plate moving with horizontal displacement $x_p(t)$ and velocity $u_p(x_p(t), t) = \dot{x}_p(t)$. Hence from (5),(10), the boundary conditions read after some calculations,

$$\overline{\frac{\partial \phi}{\partial n}} = -u_p, \quad \overline{\frac{\partial^2 \phi}{\partial t \partial n}} = -\dot{u}_p - u_p \frac{\partial^2 \phi}{\partial s^2} \quad \text{on } \Gamma_{r1}(t) \quad (11)$$

A *Flap wavemaker* corresponds to a flat plate, hinged at the bottom at $\mathbf{x}_g = (0, -d)$ and rotating an angle $\theta(t) \in [\frac{\pi}{2}, 0]$ (negative clockwise). We define $x_p(t)$ and $u_p(x_p(t), t) = \dot{x}_p(t)$, the flap horizontal displacement and velocity respectively at the undisturbed free surface $z = 0$. Hence, from (5),(10), the boundary conditions read after some calculations,

$$\overline{\frac{\partial \phi}{\partial n}} = r_g \dot{\theta}, \quad \overline{\frac{\partial^2 \phi}{\partial t \partial n}} = r_g \ddot{\theta} + \dot{\theta} \left(r_g \frac{\partial^2 \phi}{\partial s^2} - \frac{\partial \phi}{\partial s} \right) \quad \text{on } \Gamma_{r1}(t)$$

$$\dot{\theta} = -R u_p, \quad \ddot{\theta} = -R \left[\dot{u}_p - 2u_p \frac{x_p}{d} \right], \quad r_g = R \sqrt{d^2 + x_p^2} \left[\alpha \frac{x_p}{d} + \beta + d \right] \quad (12)$$

where $R = d/(d^2 + x_p^2)$, and (α, β) represent points along the flap.

Numerical implementation

The BIE (2), equivalent to the Laplace's problems (1) for ϕ and the equivalent BIE problem for $\frac{\partial \phi}{\partial t}$, is solved by a Boundary Element Method (BEM, Brebbia 1978) using a set of collocation nodes on the boundary and higher-order elements to interpolate between the collocation nodes. Quasi-spline elements (Longuet-Higgins & Cokelet 1976) are used on the free surface, and isoparametric elements elsewhere (linear to quartic).

Each integral in (2) is transformed into a sum of integrals over each boundary element. Non-singular integrals are calculated by standard Gauss quadrature rules. A kernel transformation is applied to the weakly singular integrals, which are then integrated by a numerical quadrature exact for the logarithmic singularity. An adaptive numerical integration is used for improving the accuracy of the regular integrations near corners (A-D, Fig. 1) and other places, like the overturning jet in breakers (as, e.g., in Fig. 8c,d), where elements on different parts of the boundary get close to each other.

Details of the numerical implementation can be found in Grilli, *et al.* 1989, 1989b, 1990, along with a discussion of problems associated with surface piercing bodies, such as wavemakers.

Generation of a solitary wave

By a piston wavemaker.—In the following, primes denote dimensionless variables: lengths are non-dimensionalized by d , times by $\sqrt{\frac{d}{g}}$, velocities by \sqrt{gd} and accelerations by g .

For a wave of permanent form, Goring 1978 determined to the first-order, the motion required by a piston wavemaker to generate a specified water surface elevation η immediately in front of the wavemaker (see Grilli & Svendsen 1989a, for detail) as,

$$x_p(t) = \int_0^t \frac{c\eta(x, \tau)}{d + \eta(x, \tau)} d\tau \quad (13)$$

A *first-order* solitary wave profile of amplitude H' in water of constant depth $d' = 1$ is given by,

$$\eta'(x', t') = H' \operatorname{sech}^2[\kappa(x' - c't')] \quad (14)$$

where $\kappa = \frac{\sqrt{3H'}}{2}$ and the celerity $c' = \sqrt{1 + H'}$. Substituting (14) into (13) with $x' = x'_p(\tau')$ required throughout the integration gives the piston motion. The profile (14), however, is truncated at a distance $x' = \lambda'$ from the origin, before it is used in the computations. Setting $x' = x'_p + \lambda'$ in (14) and integrating (13) we get $x'_p(t')$ and, by derivation, $u'_p(t')$ and $\dot{u}'_p(t')$ (see Grilli & Svendsen 1990, for the complete expressions), which, introduced into (11), define the boundary conditions at the wavemaker.

Solitary waves of small amplitude ($H' < 0.2$) are well generated by this method. For such waves, the *first-order* profile (14) is indeed quite close to the exact solution. For steep waves ($H' \geq 0.2$), however, due to nonlinear effects, solitary waves generated by the piston adjust their shape as they propagate, and shed a tail of oscillation behind them (Grilli & Svendsen 1989a). In fact, this was already observed by Goring 1978, in his experiments.

Numerically exact solitary waves.—Solitary waves which are as close to being exact as the discretization allows—"numerically exact waves"—are also used in the computations. They are computed using the method developed by Tanaka 1986, and established as initial condition in the constant depth part of the computational domain.

Reflection from a vertical wall

Reflection of solitary waves from a vertical wall has been used to validate the numerical model, and to compare results with other numerical, analytical or experimental results. In this application, numerically exact solitary waves have also

Figure 2: Maximum runup $\frac{R_u}{d}$ for reflection from a vertical wall of solitary waves of height $\frac{H}{d}$. Results of : (—) spline fitting to BEM for the *exact* waves, (\square) BEM for the *first-order* waves, (\circ) Chan & Street 1970 Euler eq., (∇) Fenton & Rienecker 1982 Fourier Method, (\times) Camfield & Street 1969 exper., (- - -) Su & Mirie (1980) 3rd-order analytical solution and (— — —) linear solution.

been used along with the approximate waves generated by the piston wavemaker.

Runup.—In Figure 2, maximum runup values $\frac{R_u}{d}$ obtained with the BEM model for the exact and the approximate (1st-order) waves, are compared with a finite difference solution of Euler equations by Chan & Street 1970 (CH&S), a higher-order Fourier solution by Fenton & Rienecker 1982 (F&R), experimental results by Camfield & Street 1969 (CA&S), and a 3rd-order analytical solution by Su & Mirie 1980 (S&M). One sees that, up till about $\frac{H}{d}=0.45$, all theoretical methods predict similar runups. Above that value, the 3rd-order theory predicts smaller runups, implying that contributions of order higher than third are becoming important. For high waves, F&R's solution coincides closely with our results for the exact waves, and CH&S's solution agrees well with those of our 1st-order waves. This is likely due to the approximate way CH&S generated their initial waves, which makes them qualitatively closer to waves generated by a wavemaker. Finally, CA&S's experiments agree well with the higher-order results.

Pressure force.—Once the BEM solution for the wave motion has been computed, essentially all details of the flow pattern are known, including pressures. We can therefore also calculate the forces and moments exerted on the structure. We found that maximum forces and moments predicted by the BEM closely correspond to F&R and S&M results, up till $\frac{H}{d}=0.5$. For higher waves, a somewhat surprising result of the BEM is a double maximum found in the time variation of the force and moment (Figure 3).

Reflected wave.—A detailed analysis of the reflected waves shows that an os-

Figure 3: Development in time of total dimensionless pressure force F_x on a vertical wall during reflection of an *exact* solitary wave. $\frac{H}{d}$: (a) 0.2, (b) 0.3, (c) 0.4, (d) 0.5, (e) 0.55, (f) 0.6.

cillatory tail is created by the reflection process, along with negative rundown values on the wall (of about 10% $\frac{H}{d}$ for $\frac{H}{d}=0.5$). Energy is transmitted from the main leading wave to the tail, which results in a slight decrease in wave amplitude after reflection (of about 10% $\frac{H}{d}$ for $\frac{H}{d}=0.5$). These observations tie well in with the 5th-order analytical results by Byatt-Smith 1988. Right after reflection, the reflected wave is also found slightly faster than the incident wave, even though it is smaller (by about 0.5% for $\frac{H}{d}=0.5$). This is due to highly transient changes in shape, energy partition and celerity of the wave, which take place over large propagation distances.

Reflection from a steep slope

Reflection from steep slopes (45° and 70°) has been examined for solitary waves generated by a piston wavemaker, the same way as in the laboratory experiments by Losada, *et al.* 1986 (LVN). Comparison with the measurements shows that phenomena such as generation, propagation and runup on a steep slope of large amplitude waves can be accurately predicted by our model. Even small scale oscillations in the experiments (like the oscillatory tail after reflection) are reproduced quite accurately. An example is given below.

Runup and rundown.—Reflection is computed on both the 45° and 70° slopes for waves of $\frac{H}{d} \approx 0.26, 0.45$. Results show maximum runup values $\frac{R_u}{d}$ are in good agreement with LVN's experiments (within 2.5% for $\theta = 45^\circ$ and 2.0% for $\theta = 70^\circ$). The agreement for the rundown figures $\frac{R_d}{d}$ is somewhat less good but it should be noted that LVN found this quantity quite difficult to measure. Details

Figure 4: Comparison between computations (—) and measurements (- - -) by Losada, *et al.* 1986 for reflection from a 45° slope of a solitary wave of $\frac{H}{d}=0.269$. The symbols mark data points and the dotted curve is a spline fit to these points. (a) Instant of maximum runup. (b) 0.44 time unit before rundown. (c) Instant of lowest position of water surface. (d) Back of the reflected wave.

can be found in Grilli & Svendsen 1989a.

Free surface elevation.—Figure 4 shows results for the reflection of a wave of $\frac{H}{d}=0.269$ from a 45° slope. The computations are compared with the surface profiles measured by LVN at three different times, of which the first available is the instant of maximum runup (curves a) used for synchronization. In general, the agreement is considered good. Results, however, do not quite coincide at the time of rundown (curve c). The agreement is somewhat better with a profile computed at a time slightly before the instant of rundown (curve b). This shows that, as pointed out by LVN, both rundown and instant of rundown are quite difficult to measure since the surface motion along the slope is important over a very short time (the whole rundown process only lasts a small fraction of a second in the experiments).

Internal velocities.—Motivated by the accuracy of the computations the method has also been used to analyze flow properties such as velocity and pressure fields that have not been measured during the experiments. Water particle velocities have been computed above 30° and 45° slopes, during runup-rundown of a wave of $\frac{H}{d}=0.46$. Figure 5 shows quite complex flows above a 30° slope, with jet-like details (Fig. 5a,b) and a stagnation point (Fig. 5b) climbing up the slope during runup. It is found, the flow is never completely at rest at any moment of the wave reflection (even at the instant of runup in Fig. 5c). Finally, Figure 5d shows the initiation of breaking during the rundown process (backwash), at the rearside of

Figure 5: The internal velocity field during runup of a first-order solitary wave with $\frac{H}{d} = 0.46$ on a 30° slope, at time $t' - t'_a =$ (a) : 0, (b) : 0.40, (c) : 0.95 (maximum runup), (d) : 1.90.

and in the direction opposite to the propagation of the reflected wave.

Detailed analysis of the results (Svendsen & Grilli 1990) shows that, for both slopes, horizontal velocities are significantly non-uniform over the depth (with variations of 25-35%) and that, accordingly, important non-hydrostatic pressures are generated (up to 80% on a 45° slope and 180 % on a 30° slope). This invalidates the assumptions underlying the Nonlinear Shallow Water equations and makes their use questionable in these situations. The maximum runup, however, is found to compare reasonably well with the analytical results obtained by, e.g., Synolakis (1987) using those approximate equations.

Figure 6: Sketch of composite domain : The shoaling zone is defined for $x' \leq 84$, and the shallow zone for $x' > 84$. Solitary waves are generated by a piston wavemaker at the leftward boundary.

Shoaling and reflection over a complex geometry

Solitary waves are propagated from deep to shallow water, in a domain with the bottom configuration of Figure 6. Waves of $\frac{H_1}{h_1} = 0.05$ to 0.2 are generated by a piston wavemaker, at the left hand boundary, in water of depth $h_1 = 5$, and are propagated over a mild 1:20 slope towards a region of depth $h_2 = 1$. At the extremity of this region, there is a combination of a submerged breakwater and a 20° slope. The length of the domain is $100h_2$, and the regions with $x' = \frac{x}{h_2} < 84$ (the end of the mild slope), or > 84 are named the shoaling and the shallow zones, respectively.

Shoaling zone.—Shoaling of waves of $\frac{H_1}{h_1} = 0.05, 0.10, 0.15$ and 0.2 has been computed. In a logarithmic scale, results in Figure 7 show that, for $-\log\left(\frac{h}{h_1}\right) \leq 0.45$ (i.e., $x' \simeq 60$), the rate of shoaling is close to, but not quite, the one predicted by Green's law. The average slope of the 4 curves in Figure 7 actually is closer to 1:5 in this region. During shoaling, incident waves reflect on the 1:20 slope. Due to the finite length of the computational domain, however, reflected waves propagating backward in the domain also reflect on the wavemaker. This leads to a slight increase in water level in the shoaling zone. Since smaller solitary waves are longer, the relative increase in level is somewhat more pronounced for

Figure 7: Maximum wave amplitude $\frac{\eta_{max}}{H_1}$ in shoaling zone, as a function of relative depth $\frac{h}{h_1}$ for $\frac{H_1}{h_1}$: (—) 0.05, (- - -) 0.10, (- · -) 0.15, (— —) 0.20. The straight line represents theoretical Green's law: $\frac{\eta_{max}}{H_1} \propto \left(\frac{h}{h_1}\right)^{-\frac{1}{4}}$

the smallest waves. This is illustrated by the vertical shifts between the curves in Figure 7.

Further up the slope, for $-\log\left(\frac{h}{h_1}\right) > 0.45$ (i.e., $x > 60$), the rate of shoaling of the two smallest waves reduces, whereas the two largest waves shoal up even more and at an increasing rate. This is likely because the smallest waves, being longer, start earlier feeling the influence of the shallow water zone ($h = h_2$).

Shallow zone.—Figure 8c and d show that the largest waves of initial height $\frac{H_1}{h_1} = 0.15$ and 0.20 continue shoaling in the shallow zone, even though it is of constant depth. Their profile becomes more and more asymmetric, and their amplitude peaks up to $\frac{\eta_{max}}{h_2} \simeq 1.4$ and 1.6. They eventually become plunging breakers, somewhat before reaching the submerged breakwater. Hence, this shows, highly transient waves can reach breaking heights of more than twice the classical 0.78 times the local depth.

The two smallest waves of $\frac{H_1}{h_1} = 0.05$ and 0.1 (Figure 8a and b) shoal up to $\frac{\eta_{max}}{h_2} \simeq 0.55$ and 0.80 (at $x' \simeq 95$), respectively, propagate over the submerged breakwater and run on the slope up to heights of $\frac{R_w}{h_2} \simeq 0.90$ and 1.5 respectively. Even higher relative heights of $\frac{\eta_{max}}{h} = 1.26$ and 1.66 respectively, are locally reached above the submerged breakwater.

Figure 8b also shows the wave of $\frac{H_1}{h_1} = 0.1$, eventually, is similar to a collapsing breaker. Computations of internal velocities above the slope, for a time slightly before the collapsing, show that velocities are close to being uniform over the depth. This is unlike the results obtained (e.g., in Fig. 5) for wave runup on steep slopes without a submerged breakwater at their toe, where the non-uniformity of the horizontal velocity was as high as 35%. Computations

Figure 8: Free surface elevation $\frac{\eta(x)}{h_2}$ in the shallow zone for $\frac{H_1}{h_1}$: (a) 0.05, (b) 0.10, (c) 0.15, (d) 0.20. Profiles are plotted each 10 (varying) time steps.

made in the same domain, for the same wave as in Figure 8b, but without the submerged breakwater, give a maximum runup of more than twice the previous result ($\frac{R_u}{h_2} = 3.16$). This shows, the submerged breakwater has the effect, not only of making velocities more uniform (i.e., decreasing the maximum velocity), but also of reducing wave runup. Both these effects mean reduction of wave action on the steep slope.

Figure 9: Envelope of maximum surface elevation $\frac{\eta_{max}}{h_2}$ in the shallow zone : curves represent, from down to up, $\frac{H_1}{h_1}$: 0.05, 0.10, 0.105, 0.110, 0.115, 0.120, 0.125, 0.15, 0.20.

In order further to analyze the transition between situation (b) and (c) in Figure 8, computations have also been made for intermediate wave heights of $\frac{H_1}{h_1} = 0.105, 0.110, 0.115, 0.120$ and 0.125 . Figure 9 shows envelopes of the water elevations $\frac{\eta_{max}}{h_2}$ obtained for these waves, as well as for the waves used in Figure 8. When wave height is slightly increased above $\frac{H_1}{h_1} = 0.1$, results show, the breaking type changes from collapsing to surging and plunging. At the same time, the breaking point (i.e., the abscissa of the maximum amplitude of the last computed profile) moves slightly backward on the slope and the breaking height becomes slightly larger. For all waves, there is a trough in the envelope, slightly downstream of the submerged breakwater, corresponding to where velocities are becoming more uniform. Further downstream, about at the toe of the slope, wave height is building up again. This process corresponds to the transformation of kinetic energy into potential energy and seems to occur, here, at a faster rate than in the situation without the submerged breakwater. Hence, wave height builds up more and over a larger area above the slope, and runup values are reduced.

CHAPTER 91

NORTH SEA WIND WAVES ON TIDES AND STORM SURGES

Hendrik L. Tolman *

ABSTRACT

The influence of tide- and surge-induced currents and surface level variations on wind wave generation and propagation in the North Sea is investigated. The main interest is focussed on the shift of the absolute frequency due to time varying currents. For several North Sea storms calculations have been performed with a third-generation wave model, which includes all relevant effects of wave-current interactions and wave generation. Results of several hindcasts have been compared with data. The study shows that tides and surges result in relatively small but distinct modulations of mean wave parameters (5 - 10%), and large variations of spectral energy densities (50%). The tide-induced modulations of in particular wave periods are strongly influenced by the unsteadiness of depth and current. Observed modulations of mean wave parameters with periods comparable to that of the tide appear to be wind-induced for a significant part.

1 Introduction

In the present study effects of tides and storm surges on North Sea wind waves are assessed. Such effects have been recognized by people living of the sea for centuries; charts of shelf seas like the North Sea indicate that tidal races (e.g. severe current induced breaking) occur near many headlands and offshore shoals. Theoretically the interactions between (wind) waves and currents have also been recognized. The subject is treated in many textbooks and review papers (e.g., Whitham 1974; Peregrine 1976; Phillips 1977; Mei 1983; Peregrine and Jonsson 1983; Jonsson 1990).

The separate modeling of waves (and currents) is well developed; all relevant kinematic and dynamic aspects of waves (including sources and sinks of wave energy) can be accounted for explicitly (e.g. WAMDI group 1988). In models for waves on currents, however, only a limited part of this knowledge is used. Source terms for input and

* Department of Civil Engineering, Delft University of Technology. Presently: Code 911, NASA / Goddard Space Flight Center Greenbelt, MD 20771, USA

dissipation are usually not considered at all (e.g., Dobson and Irvine 1983; Gutshabash et al. 1986; Liu et al. 1989), or highly parameterized (e.g., Holthuijsen et al. 1989). Furthermore all these models assume quasi-stationary current fields.

In the present study two aspects are added to the scope of previous studies on wave-current interactions. First, the present study deals with unsteady currents, accounting for the corresponding shift of absolute frequency. As is indicated in previous papers (Tolman 1988, 1990b), this effect of unsteadiness should not be neglected if waves on tides are considered. Secondly both wave-current interactions *and* wave growth and decay are fully accounted for. For the scale of shelf seas such an approach seems necessary, since scales of wave-current interactions and of growth and dissipation of wave energy are approximately equal (i.e. of the order of 1000 km and 1 day). To obtain both qualitative and quantitative results, the present study deals with some practical storm cases in the (southern) North Sea.

This paper presents a selection of the results of the authors PhD study (1990a). Formulations and models are described briefly. For an extensive review of the governing equations, numerical models and results, reference is made to Tolman (1989, 1990a).

2 Wave-current interactions

Wind waves are usually described with a variance (or energy) density spectrum F as a function of wave phase parameters such as the wavenumber k , the intrinsic or relative frequency σ (as observed in a frame or reference moving with the mean current \mathbf{U}), the absolute frequency ω (as observed in a fixed frame) and the direction θ (normal to the wave crest of the component). In the linear theory for (quasi-) uniform surface gravity waves on slowly varying depths and currents (e.g., LeBlond and Mysak 1978; Phillips 1977; Whitham 1974), the wavenumber k is related to the frequencies σ and ω in the dispersion relation (surface tension neglected, d is the water depth averaged over the wave field):

$$\sigma = \sqrt{gk \tanh kd} = \omega - \mathbf{k} \cdot \mathbf{U} \quad (1)$$

Wind wave propagation in an unsteady and inhomogeneous medium is (within the linear wave theory) most conveniently described with the spectral action balance equation (e.g., Whitham 1965; Bretherton and Garrett 1968; Hasselmann et al. 1973; Willebrand 1975). In the present study, the following version of the action balance equation is used:

$$\frac{\partial N}{\partial t} + \nabla_x \cdot [(\mathbf{c}_g + \mathbf{U})N] + \frac{\partial}{\partial \omega} [c_\omega N] + \frac{\partial}{\partial \theta} [c_\theta N] = \frac{S}{\sigma} \quad (2)$$

$$N = \frac{F(\omega, \theta, \mathbf{x}, t)}{\sigma}$$

$$c_g = \frac{\sigma}{k} \left[\frac{1}{2} + \frac{kd}{\sinh 2kd} \right] \quad (3)$$

$$c_\omega = \frac{\partial \sigma}{\partial d} \frac{\partial d}{\partial t} + \mathbf{k} \cdot \frac{\partial \mathbf{U}}{\partial t} \quad (4)$$

$$c_\theta = -\frac{1}{k} \left[\frac{\partial \sigma}{\partial d} \frac{\partial d}{\partial m} + \mathbf{k} \cdot \frac{\partial \mathbf{U}}{\partial m} \right] \quad (5)$$

where N is the action density spectrum, the quantities c represent propagation velocities in several spaces (see below) and S represents the net source term for wave variance. The energy propagation velocity c_g has the direction θ and m is a coordinate perpendicular to θ .

The left hand side of (2) represents conservative action propagation. The first term of Eq. (2) is the local rate of change of the action density. The second term of Eq. (2) represents convection in the physical space due to the wave energy propagation velocity c_g and the mean current velocity U . This term includes straining of the wave field due to spatial variation of $c_g + U$ (which is usually called shoaling if depth variations are considered). The third term of Eq. (2) represents the change of absolute frequency due to the unsteadiness of depth and current (e.g., Barber 1948; Mei 1983 page 96). The fourth term of Eq. (2) represents refraction.

The right hand side of Eq. (2) describes non-conservative processes. A distinction is made here between four separate source terms: (i) wind input; (ii) nonlinear resonant wave-wave interactions; (iii) dissipation due to deep-water wave breaking (whitecapping) and (iv) dissipation due to bottom friction. Formulations for the first three terms are taken directly from the WAM model (WAMDI group 1988). The formulation for the fourth term is taken from Madsen et al. (1988). For slowly varying currents, these formulations are valid in a frame of reference moving with the mean current velocity. Expressions for a fixed frame of reference are obtained using a straightforward Jacobian transformation and some minor adaptations to the original expressions (see Tolman 1990a).

3 Method of investigation

Wind wave hindcasts for this study have been performed with the third-generation wave model WAVEWATCH (Tolman 1989, 1990a), which has been developed specially for this study. The model includes all relevant wave-current interactions and explicit formulations for all source terms for wave growth and dissipation as described in the previous section. The model utilizes second order accurate propagation schemes in all discrete spaces (x, ω, θ). The numerical treatment of source terms is taken from the WAM model (WAMDI group 1988). In the hindcasts the spectrum is described with 24 discrete directions ($\Delta\theta = 15^\circ$) and with 26 frequencies (0.041 Hz - 0.453 Hz, $f_{i+1}/f_i = 1.1, f = \omega/2\pi$). The spatial resolution $\Delta x = 24$ km and the time step $\Delta t = 15$ min. The bathymetry of the North Sea is shown in figure 1.

Wind fields for the hindcasts consist of UK6 wind fields of the British Meteorological Office (BMO). Input current and water level fields for WAVEWATCH have been calculated with the model DUCHESS (e.g. Wang 1989), which solves the depth integrated shallow water equations on a fixed grid. The current fields have been calculated using both tidal constituents and wind forcing, so that the current and water level fields consist of both tides and surges. Wave boundary conditions at the open northern model boundary have been calculated with the deep-water no-current ocean wave model DOLPHIN (Holthuijsen and De Boer 1988).

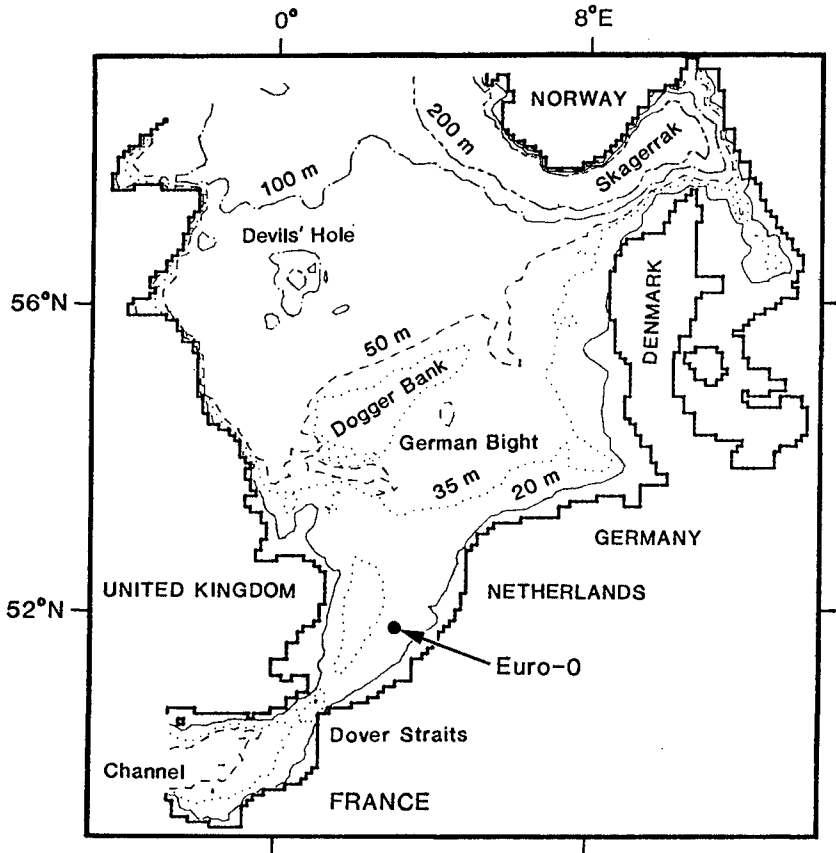

Fig. 1: The North Sea bathymetry.

Three storm cases on the North Sea are considered. Cases I (Jan. 1-4 1988) and II (Sept. 26-28 1987) consist of tide-dominated conditions with moderate SW and NW winds, respectively. For these cases wave observations were available. Case III consists of a surge-dominated case (Feb. 28-29 1988), for which no sufficient observations were available. The effects of the surge in this case are illustrated in Fig. 2 with water levels and the northerly current component U_N at location Euro-0 (see Fig. 1).

The tide- and surge-dominated cases are discussed separately below. In the discussion of the results for the tide-dominated cases the attention will be focussed on tide induced modulations of mean wave parameters and of parts of the spectrum, the specific effects of the unsteadiness of the tidal currents, the spatial distribution of tide-induced modulations of mean wave parameters and on a comparison of observed modulations of mean wave parameters with data. The results for the surge-dominated case will be

Fig. 2: Water levels $\bar{\eta}$ and northerly current components U_N for case III at location Euro-0. — : with wind forcing; ···· : without wind forcing.

discussed only for as far as they differ from the results of the tide-dominated cases. The mean wave parameters assessed here are the significant wave height H_s , the absolute period T_a and the mean wave direction $\bar{\theta}$:

$$H_s = 4\sqrt{\overline{\int \int F(\omega, \theta) d\omega d\theta}} \quad (6)$$

$$T_a = \overline{2\pi/\omega} \quad (7)$$

$$\bar{\theta} = \arctan \frac{b}{a} \quad (8)$$

The overbar notation at the right hand side of these equations denotes a straightforward average over the spectrum $F(\omega, \theta)$; a and b are the first two Fourier coefficients of the directional distribution (e.g., Kuik et al., 1988).

4 Results for tide-dominated cases

In the tide-dominated cases I and II, mean wave parameters show a small but distinct tide-induced modulation, as is illustrated in Fig. 3 with the significant wave height and the mean absolute period at Euro-0 for case I. In this figure, tide-induced modulations are observed as the difference between results of calculations in which tides are accounted for (solid lines) and where tides are neglected (dotted lines). As expected, the tide-induced modulations reflect the tidal period. The mean wave direction $\bar{\theta}$ is not presented in the figure, since it did not show significant tidal influences (tide-induced modulations less than 2°). The negligible tide-induced modulation of the mean wave direction suggest that current refraction has negligible influences on mean wave parameters. This is confirmed by practically identical results of repeated calculations, in which refraction is neglected altogether. Note that depth refraction is not relevant here, since waves are relative short (due to the moderate wind speeds) and are therefore not influenced by the bathymetry (e.g., deep water waves).

Fig. 3: Mean wave parameters at Euro-0 in case I (1988). — : with tides and surges; ···· : without tides and surges.

Fig. 4: Energy in fixed spectral bands (F_{band}) at Euro-0. (a) Case II, 0.1 - 0.2 Hz (b); case I, 0.3 - 0.5 Hz. — : with tides and surges; ···· : without tides and surges.

Modulations within the spectrum can be much larger than modulations of mean wave parameters, as is illustrated in Fig. 4 with the total energy in selected frequency bands at location Euro-0. Modulations of the order of 50% have been found in all frequency bands in the cases considered here. Since such large modulations have not been found in the significant wave height, modulations of different parts of the spectrum obviously have opposite signs and therefore largely cancel out in spectral averages.

The unsteadiness of tidal currents mainly manifests in modulations of the absolute period, since the unsteadiness explicitly causes a modulation of the absolute frequency (Eqs. (2) and (4), see also Tolman 1988, 1990b). The tide-dominated cases indeed show a significant modulation of the absolute period, as is illustrated in Fig. 3. The unsteadiness proved to have only a mild effect on the wave height modulation, as follows from results of repeated calculations in which the effects of unsteadiness are neglected (figures not presented here). The effects of unsteadiness are furthermore illustrated in Fig. 5 with the tide-induced modulations of the absolute period (ΔT_a , the difference between results of calculations with an without tides) for Euro-0 in case II, plotted as a function of the current velocity in the mean propagation direction of the waves, U_p (θ_U is the current direction).

$$U_p = |U| \cos(\theta_U - \bar{\theta}). \quad (9)$$

Plotted are both the results as obtained with a fully unsteady approach (solid line) and results as obtained with a quasi-stationary approach (dashed line) where $c_\omega \equiv 0$. In this case, the modulation of the absolute period completely disappears if depth and current unsteadiness are neglected. Apparently the entire modulation of the absolute period in this case is caused by the unsteadiness of depth and current. Figure 5 furthermore indicates, that the modulations of the wave parameters do not have a one-on-one relation with the local current velocity. Since the relation between modulations of wave parameters and the local current was found to vary with location and storm case, effects of wave-current interactions cannot be estimated from local parameters of tides only. This contrasts with the results of a analysis of effects of quasi-stationary currents, where many interaction effects can be estimated directly from the local current velocity.

Fig. 5: Modulations of the absolute period ΔT_a as a function of the current velocity in the propagation direction of the waves U_p at Euro-0 for case II.

— : unsteady [c_ω given by (4)] ; --- quasi-stationary ($c_\omega \equiv 0$).

The spatial distribution of effects of tides (and surges) on wind waves is assessed by considering the normalized rms modulation of wave parameters (i.e., the coefficient of variation CV). For example, the coefficient of variation of the wave height $CV(H_s)$ is defined as:

$$CV(H_s) = \frac{\sqrt{T^{-1} \int \Delta H_s^2 dt}}{T^{-1} \int H_s dt} \quad (10)$$

where T is the duration of the averaging period (typically several tidal periods). The largest effects of the tides occur in the southern North Sea, as was expected, since the largest current velocities also occur in this region. In fact, the spatial distribution of the coefficients of variation of the wave heights, periods and lengths is similar to that of the

Fig. 6: Spatial distribution of the coefficient of variation of the significant wave height ($CV(H_s)$, total effect of wave-current interactions) and the distribution of the maximum current velocities in the mean wave direction (U_p) for case I (Jan. 1-2 1988).

maximum current velocities in the mean wave direction U_p , as is illustrated in Fig. 6. This figure shows values of $CV(H_s)$ of up to 15 % in the southernmost North Sea. The absolute period, relative period and the wave length show coefficients of variation of up to 10 %, 5% and 10% respectively. In case II coefficients of variation and current velocities U_p are somewhat smaller, with maxima concentrated near the British coast (figures not shown here).

Observed data were available for both tide-dominated cases. To compare the relatively small observed modulations as found in the calculations with observations, the modulations have been isolated. In the calculations modulations are the difference between results of repeated calculations in which tides and surges are either incorporated or ignored; the modulations in the observations have been defined as modulations with periods between approximately 9 h and 15 h (obtained by filtering the observed data). Calculated tide-induced modulations of the significant wave height (ΔH_s) and of the mean absolute period (ΔT_a) show some agreement with observed modulations, but also significant differences. This is illustrated in Fig. 7 with observed and calculated modulations for Euro-0 in case I. However, the residual modulations of the significant wave height and the mean absolute period, defined as the difference between observed and calculated modulations, proved to be highly correlated with observed wind speed variations with periods between approximately 9 h and 15 h. This is illustrated in Fig. 8. The high correlation suggests that the differences between observed and calculated modulations of wave parameters in Fig. 7 are caused by wind speed variations, and are not due to model errors.

Fig. 7: Observed and calculated modulations (dashed and solid lines respectively) of the significant wave height and the mean absolute period at Euro-0 in case I (1988).

Fig. 8: Residual modulations of the significant wave height and the mean absolute period ($\Delta H_{s,r}$, dashed line and $\Delta T_{a,r}$, dotted line, respectively) and observed wind speed modulations (solid line) at Euro-0 in case I (1988).

5 Results for surge-dominated case

Results for the surge-dominated case III are presented, for as far as the results differ systematically from those of the tide-dominated cases (as mentioned above).

In the surge-dominated case, waves are essentially in shallow water, so that interactions can be caused by both surface level variations and currents. The numerical calculations indeed show effects of surface level variations and of currents on mean wave parameters; results of calculations with and without tides and surges, with surface level variations only and with currents only all show significant differences. This is illustrated in Fig. 9 with the corresponding wave heights at Euro-0. Since the time scale of computed interactions as presented in Fig. 9 is clearly larger than that of the tide, the interactions appear to be surge-dominated. For the effects of surface level variations this was expected, since surface level variation are surge dominated (see Fig. 2). For the effects of the currents this is somewhat surprising, since local currents are still tide dominated (see Fig. 2). It seems that the systematic nature of small wind driven currents results in more lasting (i.e. accumulated) effects than the larger, but oscillating tidal currents.

Fig. 9: Significant wave heights at Euro-0 in case III. — : with tides and surges; ···· : without tides and surges; - · - · : surface level variations only; - · - · - : currents only

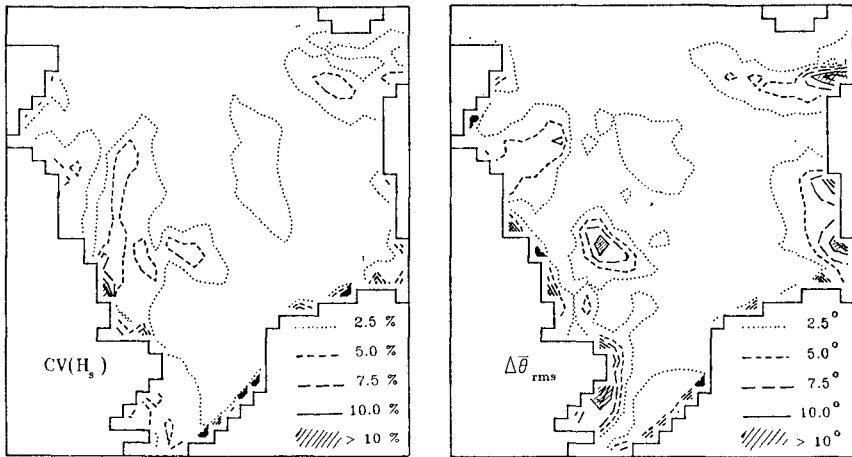

Fig. 10: Spatial distribution of the coefficient of variation of the significant wave height and rms differences of the mean wave direction due to refraction (case III, Feb. 28-29 1988).

The higher surface level and corresponding larger depth due to the surge result in higher waves (dash-dot lines versus dotted lines in Fig. 9), probably due to a reduced bottom-induced energy dissipation due to the increased water depths. On the other hand currents reduce wave heights and periods (dash-dot-dot lines versus dotted lines in Fig. 9). This might be explained from the wind-induced currents, which in the southern North sea are systematically in the propagation direction of the waves, reducing the effective

fetch and wind speed. The separate contributions of surface level variations and currents to the interactions are opposite and largely cancel out, resulting in a practically negligible total effect of all interactions.

Furthermore the surge-dominated case differs from the tide-dominated cases since depth refraction plays a distinct role in case III. This is illustrated in Fig. 10 with coefficients of variation for the significant wave height and rms differences of mean wave directions, obtained by comparing model results in which refraction was either incorporated or ignored. Effects of refraction are observed in areas with large gradients in the bottom level (compare Fig. 1), but do not spread over larger areas.

6 Discussion

The results of the North Sea hindcasts presented here show that the unsteadiness of tidal currents has a significant influence on wave-tide interactions. The relative importance of unsteadiness and inhomogeneity varies in space and time, so that effects of wave-tide interactions cannot be estimated from local depth and current parameters only, nor with a quasi-stationary or quasi-homogeneous approximation. Nevertheless effects of tides and surges seem to be restricted to areas with significant tide- and surge-induced currents and surface level variations.

The tidal currents result in modulations of mean wave parameters with an oscillating character (see e.g. Fig. 3), whereas currents and surface level variations of surges result in more monotonic variations (see e.g. Fig. 9). Wave-tide interactions seem to accumulate much less than wave-surge interactions, since case III shows that current-induced interactions appear to be surge dominated, although the local currents are clearly tide-dominated (as discussed in section 5). In the storm surge case considered here, effects of currents and surface level variations largely cancel out and resulting relative modulations of mean wave parameters are much smaller than in the moderate cases. It might therefore be concluded that the relative importance of wave-tide and wave-surge interactions decreases with increasing storm severity. However, the cancelling out of effects of currents and surface level variations cannot be expected to occur in any complex storm case. The potential magnitude of wave-surge interactions therefore is given by the potential magnitudes of effects of water level variations and currents separately, which are roughly of the same order of magnitude as the effects of tides in the tide-dominated conditions considered here. Consequently, it can not be concluded from the present results that the relative importance of interactions decreases with increasing storm severity.

This paper focuses on modulations of mean wave parameters. However, modulations of spectral densities or of energy in fixed frequency bands in general are much more pronounced than those of the mean wave parameters (modulations of 50% or more in all parts of the spectrum, e.g., Fig. 4). In particular the effects of the tides and surges on the low frequency variance (or energy) is striking, since wave-current interactions for monochromatic waves suggest a decreasing effect of currents with decreasing frequency due to decreasing Doppler shifts kU_p and relative current velocities U/c_g . This large impact is explained from the steep gradients in the low frequency flank of frequency spectra, where small shifts of the spectral peak frequency (or mean frequency) can cause large modulations of the total variance in fixed frequency bands. Like the

frequency shifts, these modulations of spectral densities are strongly influenced by the unsteadiness of depth and current and cannot be estimated from local depth and current parameters only, or with conventional quasi-stationary approaches (as discussed above). Considering the relatively small magnitude of effects of wave-tide and wave-surge interactions on the significant wave heights H_s and the mean wave period T_a (typically 5 to 10%), the implications for North Sea wave forecasting seem to be small. Such a conclusion is supported by the fact that observed modulations appear to be mainly wind-induced. However, the calculated modulations might be significant when assessing design wave heights for e.g. offshore platforms. Furthermore the large modulations of spectral densities due to tides has implications for e.g. the dynamic analysis of structures, as is illustrated by a study of the wave-induced movements and accelerations of the Euro-0 platform (tide-induced modulations of the order of 50%, Peters and Boonstra 1988).

7 Conclusions

This study on effects of tides and storm surges on wind waves in the North Sea has given rise to the following conclusions. Tides and storm surges in the North Sea should be treated as an unsteady medium for wind wave propagation. Both the unsteadiness and the inhomogeneity of depth and current play a significant role in the interactions so that neither a quasi-stationary nor a quasi-homogeneous approximation to wave-current interactions can be used. In moderate wind and wave conditions interactions are predominantly caused by (tidal) currents, whereas in severe conditions both currents and (mean) surface level variations contribute to the interactions. Due to accumulation of effects, relatively small currents of surges might have larger impacts on mean wave parameters than larger (but oscillating) tidal currents. Tide- and surge-induced modulations of mean wave parameters such as the significant wave height and the mean wave periods are relatively small (typically 5 to 10%). Tide-induced variations of spectral densities can be of the same order of magnitude as the average spectral density over a tidal period. Observed modulations of mean wave parameters (in particular the wave height) appear to be wind-dominated rather than tide-dominated.

Acknowledgements. The author acknowledges with pleasure that the Dutch Ministry of Public Works and Transportation (Rijkswaterstaat) has supplied the bottom schematization of the North Sea, the tidal boundary conditions and observed wind and wave data. The the Royal Netherlands Meteorological Institute (KNMI) has supplied the wind fields for this study. In this, the help of in particular J. de Ronde, R. van Dijk, A.J. van der Kerk, H. Ligtoet (Rijkswaterstaat), H.W. Riepma and E. Bouws (KNMI) was greatly appreciated. Permission to use the numerical wave model DOLPHIN of Digital Hydraulics Holland B.V. is highly valued. Furthermore, the support, suggestions and comments of colleagues at the Delft University of Technology, KNMI, Delft Hydraulics and Rijkswaterstaat, and of members of the WAM group, in particular L.H. Holthuisen, J.A. Battjes and N. Booij was of great help. This study has been performed

while the author was working at the Delft University of Technology. This paper has been written while the author held a National Research Council - NASA Research Associateship.

CHAPTER 92

DECOMPOSITION AND INTERCEPTION OF LONG WAVES BY A SUBMERGED HORIZONTAL PLATE

Haruyuki Kojima¹, Takeshi Ijima² and Akinori Yoshida³

Abstract

The results of two-dimensional hydraulic experiments are presented on the decomposition of regular and irregular surface waves by a fixed, submerged horizontal plate with a finite length. Nonlinear interactions, containing the near-resonant interaction as well as the self- and mutual-interactions, among the waves affected by the submerged plate are found to induce the generation of higher harmonic components which propagate independently in the lee side, and to result in appreciable disintegration of wave form. This wave decomposition may produce considerable modification of the spectrum of a transmitted-wave train through the nonlinear transfer of energy from primary wave components to higher frequency components and consequently reduce its significant wave period. With the above mechanism, thus, the submerged horizontal plate may serve as an effective interception device against waves, especially of long wave length.

1 Introduction

There are three conceivable mechanisms by which a submerged horizontal plate intercepts incoming waves: (1) linear interaction between surface waves passing over the plate and an oscillatory fluid motion beneath the plate, resulted from the phase differences between them; (2) wave breaking on it and turbulence around it which result in decreasing transmitted-wave height through energy loss; (3) wave decomposition due to nonlinear effects taking place in the shallow water region over the plate, which would cause the frequency band of transmitted waves to be diversified, thereby reducing the impact of individual waves. The first two mechanisms and their wave attenuation effects, which numerous researchers have studied theoretically and experimentally (for example, Ijima et al, 1970; Siew & Hurley, 1977; Patarapanich, 1984 and Tabuchi et al, 1987), are well known. Although the observation of wave disintegration by a submerged object like a submerged breakwater has been reported (Horikawa, 1960; Jolas, 1960), little attention has been placed on the third mechanism in the light of wave interception effects, nor extensive study has been performed to understand its phenomenon.

The purpose of this study is to examine the phenomenon of wave decomposition accompanied with the generation of higher harmonics by a submerged horizontal plate

and their propagation in the water region over the plate and in the transmitted-wave side in order to discover the conditions under which a significant energy transfer and shortening of wave length can take place. We also evaluate the effects of decomposing a wave into higher harmonic components on its statistical properties and attenuation.

2 Experimental Procedure and Analysis

A wave tank used is 29m long, 0.3m wide and 0.5m deep with the piston-type wave generator, which can generate both regular and irregular waves and absorb more than 90% of reflected waves. The tank ends in a very efficient wave absorber, the reflection coefficient of which is less than 10%. The water depth h is maintained constant at 0.38m. A horizontal plate was fixed at a certain depth h_s from the water surface. The length of the horizontal plate B was varied, and for a comparative purpose one plate was extended to the end of the tank, which plate was regarded to be infinitely long (hereafter referred to as the infinite plate).

The laboratory experiment has three phases:

- (1) The first phase involves regular wave tests where a monochromatic sinusoidal wave and a composite wave of two primary frequency components are used. To investigate the mechanism of wave decomposition by a submerged horizontal plate, we observed wave profile transformation in the regions over and past the plate of various lengths. Measurement of the wave profile was made with four capacitance wave gages at a number of stations along the tank, successive stations being 20cm apart. At each station the passage of the first 20 to 30 wave data was recorded, which were then converted at the sampling rate of 0.05sec. to digital data. The Fourier analysis was applied to the profile data to obtain the spatial distribution of harmonic component amplitudes.
- (2) The second phase is irregular wave tests where forced disintegration of random incident waves associated with real ocean waves is examined. The random waves generated in the experiments are based on the Bretschneider-Mitsuyasu spectrum. The range of significant wave periods $T_{1/3}$ used in the tests was 0.8 to 2.42 sec. ($h/L_{1/3} = 0.387$ to 0.085; $L_{1/3}$: the incident wave length associated with the significant wave period) and a significant wave height was 4.5cm ($H_{1/3}/h = 0.118$). Spectral densities for incident, transmitted and reflected waves were estimated from smoothing estimated periodgrams by the resolution technique (Goda and Suzuki, 1976). We also obtained statistical properties of the transmitted waves which may be modified by the nonlinear interactions.
- (3) The third phase deals with evaluation of the effects of wave disintegration on wave interception. The case where a vertically-slitted wall was placed behind a submerged horizontal plate was experimented and possible changes in wave transmission-reflection coefficients and wave force exerted on the permeable wall due to disintegration of incoming waves were studied.

3 Test Results and Discussions

3.1 Evolution of Wave Profiles

Figure 1 shows the evolution of wave profiles when a monochromatic wave of an infinitesimal amplitude ($H_I/L = 0.0066$) enters and travels over the infinite plate (Figure

1-(a)) and the finite plate of $B/h = 5.25$ (Figure 1-(b)). The wave profiles for two wave periods (T) are depicted from the data of every other station and each of the highest wave crest is aligned at zero on the abscissa for a comparative purpose. It is seen that waves propagating over the infinite plate will break down into multiple secondary peaks in their profiles, as observed by Multer and Galvin(1967) and Boczar-Karakiewicz(1972) in a wave tank of constant depth. Since the higher crest propagates faster than the smaller ones, the primary crest approaches the preceding secondary crest from behind. When the two crests encounter and interact each other, the large crest decreases in height while the smaller one increases, and the wave form is nearly identical with the initial wave form. Then they exchange roles in both amplitude and speed and start to separate each other. This event is repeated at a certain distance called the recurrence distance. The event clearly indicates that the well-known soliton effects occur in the shallow water region over the infinite plate.

Markedly different evolution of wave profiles is observed once waves passed over the finite plate and entered the original water depth(see Figure 1-(b)). One of the obvious features is that the wave profiles appear somewhat irregular so that it is difficult to follow a particular wave crest. Another is that as the wave train of a primary wave and secondary waves travels down the tank, some of the secondary waves grow as nearly great as the primary wave. A consequence of increase in the height of secondary waves would be apparent reduction in period of the wave train.

Figure 1 Wave profile transformation along the wave tank ($h/L = 0.100, H_I/L = 0.0066$).

3.2 Fourier Analysis

We study quantitatively wave profile data based on Fourier analysis. Applying this analysis to wave profile data yields the amplitude of any Fourier component, A_i ($i = 1, 2, 3, \dots$) associated with corresponding angular frequency σ_i at each measuring station. Figures 2 and 3 depict the spatial distribution of the amplitudes of the 1st, 2nd and 3rd harmonic components (A_1, A_2, A_3), normalized by the incident wave amplitude a_0 , for the case of the infinite and the finite plates, respectively. The heights of the two largest waves (primary and the largest secondary), Hm and Hs , normalized by the incident-wave height are also plotted versus distance from $x = 0$, the front end of the plate. The prominent difference between the results of the infinite and the finite plates lies in the variation of harmonic amplitudes in the region beyond the extent of the finite plate; the amplitude variation in the transmitted-wave side becomes nearly constant, independent of space, although small disturbances (or undulations) of spatial periodic manner is seen, while variation of the wave heights (Hm, Hs) is still spatially periodic. This implies that each of the harmonic component waves generated over the plate by nonlinear interactions should propagate independently and without mutual interactions in the water of the original depth with the phase speed corresponding to its own frequency. Thus the height of the primary wave would rise to the maximum when other harmonics are in phase with it; the height would decrease as phase is shifted.

Of interest here is the magnitude of harmonic component amplitudes in the lee side of the finite plate, because the increase in their amplitudes, comparable to the first harmonic one, indicates considerable transformation of surface wave form, which may consequently reduce an apparent wave period. As seen from the figures, the harmonic amplitudes are equivalent to those at the end of the plate, their magnitudes being related to the length of a submerged horizontal plate. It is then obvious that if the plate length is half of the recurrence distance, the amplitude of the first and third harmonics is minimum, while that of the second harmonic maximum. Similar results are discussed by Mei(1988) through the theory of nonlinear resonant interactions in water of constant depth.

3.3 Generation and Growth of Higher Harmonics

We examine factors affecting on the generation and growth of higher harmonics, which include fluid motion under the plate and water depth above the plate. In doing so, we introduce a parameter indicating the magnitude of the higher harmonics, namely, the square root of the ratio of the energy flux of harmonic components to the incident wave energy flux T_{p_i} ($i = 1$ through 3), referred to as the energy flux ratio. When $i = 1$, T_{p_1} is equivalent to a transmission coefficient of the first harmonic component.

The energy flux ratios versus relative water depth for the submerged horizontal plate and impermeable rectangular body are shown in Figure 4-(a) and Figure 4-(b), respectively. The solid line in the figure indicates the transmission coefficient obtained from the linearized computation of the boundary element method proposed by Ijima, Chou and Yoshida(1976). A distinct difference between the horizontal plate and rectangular body lies in the energy flux ratio of the first harmonic component, i.e., the transmission coefficient. The results of the horizontal plate show a strong tendency of selectively intercepting wave of a certain wave length, the measured value of T_{p_1} being

Figure 2 Spatial distribution of the amplitude of harmonic components for the infinite plate ($h/L = 0.100$).

Figure 3 Spatial distribution of the amplitude of harmonic components for the finite plate ($B/L = 10.50$, $h/L = 0.100$).

less than 0.4 at $h/L = 0.15$. In contrast, the rectangular body has no such tendencies and the measured value of T_{p1} appears to be around 0.75 in the entire range of h/L . The energy flux ratio of higher harmonics for the both cases has similar trends showing the maximum values of about 0.5 at around $h/L = 0.225$ for T_{p2} , except in the lower range of relative water depth where the energy of the higher harmonics generated by the rectangular body is relatively greater. Since the amplitude of the first harmonic component in that range is quite small for the horizontal plate, however, the relative magnitude of the second harmonic amplitude to the first is much larger in the case of the horizontal plate than the impermeable rectangular body. These results lead to

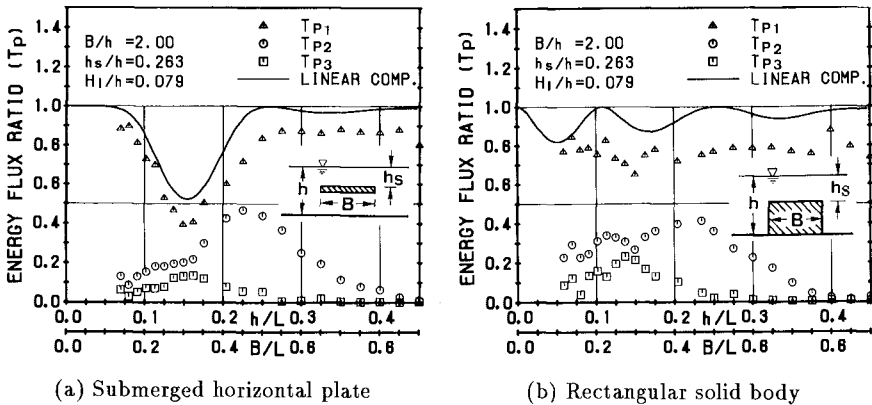

Figure 4 The magnitude of harmonic components in the transmitted waves.

conclusions that the fluid motion beneath the plate has little effect on the generation of higher harmonics and a submerged horizontal plate is more effective in reduction of wave period than a impermeable rectangular body.

The effects of a plate length B and water depth over the plate h_s on the generation and growth of higher harmonics are also studied. A brief summary is discussed here; detailed results can be seen elsewhere (Kojima and Ijima, 1989). Increase in the plate length results in heightening the maximum values of T_{p2} and T_{p3} as well as shifting these values to lower relative water depth. A horizontal plate of longer length will thus more effectively generate higher harmonics against waves of longer wave length. Decrease in the plate depth h_s results in augmenting the values of T_{p2} in the larger relative water depth and the maximum value of T_{p3} as well.

3.4 Decomposition of Two Primary Waves

Figure 5 shows an example of the normalized amplitude spectra of the incident waves of two primary frequencies $f_1 = 0.500_{Hz}$ and $f_2 = 0.667_{Hz}$ (upper) and those of the transmitted waves (lower). The amplitude spectra of the incident waves are measured at constant water depth without existence of a submerged plate and those of the transmitted waves are obtained from the data measured at the point $4.75h$ away from the rear end of the plate. It is obviously seen that many modes of harmonics are present in the transmitted waves, where the sum interaction components and the difference interaction components are generated other than the self-interaction modes, i.e., $2f_1, 2f_2, 3f_1$ and $3f_2$, the sum interactions being dominated. Secondary waves ($f_1 + f_2, f_2 - f_1$), the products of binary interactions between primary components, are evident together with tertiary waves ($2f_1 + f_2, f_1 + 2f_2$), the components arising from the interactions between primary and secondary wave; the sum interactions of these are appreciably larger than any of the components resulting from the self-interaction effects.

It has been shown in the theory of nonlinear resonant interactions by Phillips (1960)

Figure 5 Amplitude of spectra of the incident wave of two primary components(upper) and the transmitted wave (lower).

and Longuet-Higgins(1962) that in the case of deep water the secondary interactions will not occur since the phase velocity of the secondary components is always different from the phase velocity of a free infinitesimal wave of the same wave number, whereas the tertiary interaction will occur. In the case of waves transmitting over the submerged plate where the ratio of water depth to wave length becomes considerably small, however, the near-resonant interaction(Bryant, 1973) would give rise to secondary waves due to the fact that the wave dispersion relation approaches asymptotically a straight line as non-dimensional wave number kh becomes small. The harmonic modes present in the transmitted waves may thus be generated by the nonlinear interactions comprised of the near-resonant interaction as well as the self- and mutual-interactions among the waves affected by the submerged plate.

The amplitude of the harmonic components together with the amplitude of the two primary components is plotted versus distance from $x = 0$ in Figure 6. As the waves travel over the plate, the amplitudes of secondary and tertiary waves increase with decrease in the amplitudes of the two primary components. Once the waves passed the plate and entered the water of the original depth, however, amplitude variations appear to be independent of space, similar to the results of a monochromatic incident wave. Thus, disintegrated waves of all the harmonics in the transmitted-wave side are most likely to propagate at phase speeds corresponding to their own frequencies.

In order to examine changes in the magnitude of secondary and tertiary amplitudes generated by nonlinear interactions with varying the frequency ratio of two primary waves f_2/f_1 , the energy flux ratio of each harmonic component of the transmitted waves to the incident wave is obtained and depicted in Figure 7. One of the two fundamental frequencies f_1 is kept constant at $f_1 = 0.400$ Hz ($h/L_1 = 0.082$) for the upper figure and $f_1 = 0.667$ Hz ($h/L_1 = 0.148$) for the lower figure, while the other frequency f_2 is varied. Comparison of the two figures reveals an interesting result that when the frequency of one of the two primary waves is low, the frequency range of the other wave

Figure 6 Spatial distribution of harmonic component amplitudes, measured along the tank, for two primary waves.

that induces nonlinear interactions tends to become wider and the frequency range appears to be shifted to the higher range. Another noticeable point is that although a monochromatic wave of high frequency, say $f = 1.314_{Hz}$ ($h/L = 0.425$), striking the submerged plate alone produces hardly any harmonics (see Figure 4), coexistence of a low frequency wave with it could give rise to secondary and tertiary components (see in Figure 7 the energy flux ratio at $f_2/f_1 = 3.285$ for $f_1 = 0.40_{Hz}$ and at $f_2/f_1 = 1.970$ for $f_1 = 0.667_{Hz}$). These results can be taken as evidence that the decomposition of an incident wave by the submerged horizontal plate through the mechanism of nonlinear interactions is much more excited when multiple wave components exist in the incident wave field rather than a single component. It is concluded therefore that a submerged horizontal plate can be considered as a device that effectively transfers the energy of incident waves to higher components of transmitted waves, thereby reducing the impact of primary wave components.

3.5 Decomposition of Random Waves

3.5.1 Transformation of frequency spectrum

Forced wave disintegration by a submerged horizontal plate is examined for irregular incident waves associated with real ocean waves with a sharp spectral peak around a significant wave period. Figure 8 shows the transformation of frequency spectral shape, along the tank, for the random incident wave train with a significant wave frequency $f_{1/3} = 0.625_{Hz}$ ($h/L_{1/3} = 0.105$) and wave height $H_{1/3}/h = 0.118$. It is evident that the spectral shape differs from station to station over the plate. At the front end of the plate ($x = 0.1B$) the spectral shape is similar to that of the incident-wave train, and as the waves propagate further down the tank over the plate, its shape is modified in such manner that some part of the wave energy around the significant wave frequency is transferred to the higher frequency components, thereby flattening the spectral shape. However, little variation of spectral shape is observed when the waves propagate the

Figure 7 The magnitude of secondary and tertiary components for two primary waves.

Figure 8 Transformation of the spectral shape of random waves measured along the tank ($h/L_{1/3} = 0.105, H_{1/3}/h = 0.118$); --- target spectrum, ●●●● incident wave, ——— transmitted wave.

water of the original depth after passing the plate ($x > 1.0B$), the spectral shape of which holds the presence of large energy in the high frequency range. This significant energy transfer reflects the effects of the nonlinear interactions taking place over the plate, as discussed in Section 3.4.

3.5.2 Statistical properties of decomposed transmitted waves

We investigate statistical properties of a transmitted-wave train. Wave profile data taken from four wave probes situated 20 to 40cm apart are used. To define individual waves, we utilize the zero-upcrossing method. The number of individual waves sampled is between 400 and 600. All of the statistical values obtained from four probes are averaged to determine one representative value.

One of the main aims for the present research is to confirm the evidence of reduction in wave period of an incoming wave train by a submerged horizontal plate. The significant wave period of a transmitted-wave train $T_{T_{1/3}}$ is compared with that of an incident-wave train $T_{I_{1/3}}$ and their ratios for the cases of $B/h = 2.00, 3.00$ and 5.25 are plotted, in Figure 9, versus relative water depth $h/L_{I_{1/3}}$. Considerable reduction in wave period is seen; the lowest value of $T_{T_{1/3}}/T_{I_{1/3}}$ is about 60% for $B/h = 2.00$ and 45% for $B/h = 3.00$ within the range of relative water depth examined. The lowest value of the wave period ratio tends to be shifted toward the smaller value of relative water depth with increase in the plate length and the ratio comes close to one at the large value of relative water depth (say $h/L_{I_{1/3}} = 0.387$), where the amplitude of higher harmonics may be so small that the form of transmitted-wave profiles would barely alter. Of interest is that when considerable reduction in wave period occurs, the wave height distribution somewhat deviates from the Rayleigh distribution, similar to the wave height distribution for the case of wave transmission over a protruding vertical breakwater, which waves also have shorter periods than those of incident waves, as discussed by Goda and Suzuki(1976).

Figure 10 shows the relationship between the spectrum and the characteristic wave height of a transmitted-wave train and parameters indicating nonlinearity of waves, in which plotted versus relative water depth are the ratio of significant wave height to the square root of the total wave energy (equivalent to the root-mean-square value of the surface elevation) $H_{T_{1/3}}/\sqrt{m_0}$, the skewness $\sqrt{\beta_1}$, and the kurtosis β_2 . The skewness and kurtosis, indicating the extent of the distortion of the statistical distribution of the instantaneous surface elevation from the normal, are expressed as

$$\sqrt{\beta_1} = \frac{1}{\eta_{rms}^3} \frac{1}{N} \sum_{i=1}^N (\eta_i - \bar{\eta})^3, \quad \beta_2 = \frac{1}{\eta_{rms}^4} \frac{1}{N} \sum_{i=1}^N (\eta_i - \bar{\eta})^4 \quad (1)$$

where η_{rms} and $\bar{\eta}$ are the root-mean-square value and the mean value of the surface elevation, respectively.

The theoretical value based on the normal distribution is $\sqrt{\beta_1} = 0$ and $\beta_2 = 3.0$, the latter value of which is drawn with the chain line in the figure. The proportionality constant between $H_{T_{1/3}}$ and $\sqrt{m_0}$ is also plotted at 3.8, with the broken line, the value of which is determined from many wave observation data throughout the world(Goda, 1985). Two distinct trends are obvious: the proportionality constant tends to decrease to a value less than 3.5 in the range of relative water depth between 0.085 and 0.160,

Figure 9 Change in period of transmitted waves for different lengths of the submerged horizontal plate.

Figure 10 Relationship between the spectrum and the significant wave height and nonlinearity parameters for transmitted-wave trains.

where appreciable reduction in period of the transmitted-wave train occurs, as shown in Figure 9; in the same range the skewness value tends to become a larger value, being more than 0.2. With increase in relative water depth, both the values tend to approach the expected value of 3.8 for $H_{T_{1/3}} / \sqrt{m_0}$ and zero for $\sqrt{\beta_1}$. The value of the kurtosis β_2 has no clear tendencies with respect to relative water depth, but the value stays less than the theoretical value of 3.0 over the entire relative water depth examined, indicating the distribution shows lower peak than the corresponding normal distribution and long tails on both sides.

4 Wave Interception Effects

The disintegration of incoming waves by a submerged plate likely results in shortening of wave length in its shoreward side. We might thus anticipate that any structures located in the lee side of it would be exposed to less wave force and furthermore permeable structures which have a definite drawback in wave dissipation effectiveness against waves of long length would effectively intercept them once their lengths became shorter prior to striking the permeable structures. A schematical description of an experimental setup is shown in Figure 11, where a vertically-slitted wall with porosity $\varepsilon = 0.2$ and thickness $W/h = 0.171$ is placed in the lee side of the submerged horizontal plate. Figure 12 shows one of example of variation of transmission-reflection coefficients and non-dimensional wave force, F/F_s (F_s : standing wave force), acting on the permeable wall with the distance x_w between the plate center and the wall front along the wave channel. With the distance ratio x_w/h the values of a transmission coefficient K_T and wave force vary in a similar manner, while reflection coefficient values K_R vary in an opposite fashion, two peak locations of K_T and F/F_s being at about $x_w/L = 0.3$ and 0.85 where K_R indicates a minimum value.

Taking an average value of these fluctuations over the distance ratio and plotting the average value together with a vertical line indicating the maximum and minimum values of the fluctuations for K_T and F/F_s , with its top and bottom ends respectively, we have a representative value for wave transmission and force versus relative water depth in Figures 13 and 14. In these figures, the results for the case without a horizontal plate (Kojima, et al, 1988) are also plotted with a triangle mark for the measured and a solid line for the computed. It can be easily observed that the existence of the submerged horizontal plate considerably reduces both the wave transmission and force over the entire relative water depth tested. The experimental results for the case of the permeable wall plus the horizontal plate follow the same trend as the wave period changes shown in Figure 9; K_T and F/F_s tend to decrease with the relative water depth to a minimum value at about $h/L = 0.15$ and then increase. This trend can be taken as the evidence of the effects of wave disintegration on wave interception.

5 Conclusions

The major conclusions obtained are as follows:

- (1) Wave decomposition accompanied with the generation of higher harmonics by a submerged horizontal plate can be considered as a phenomenon that is induced by nonlinear interactions including the near-resonant interactions as well as the self- and mutual-interactions, which are much more excited when multiple wave components exist in the incident wave field. The non-spatial variation of harmonic component amplitudes in the lee side of the plate, different from the spatial variation above the plate, suggests that each component wave should propagate independently in that water region at its own phase speed without the self- and mutual-interactions.
- (2) By comparing the harmonic generation by the horizontal plate with that by the submerged rectangular body, the fluid motion beneath the plate was determined to have little effects on the wave decomposition.
- (3) A submerged horizontal plate induces a considerable modification in the ocean

wave spectrum, in such manner that the energy around significant wave frequency is transferred to higher frequency components due to the nonlinear interactions. This modification results in reducing significant wave period of the transmitted wave train by about 50%.

(4) When the significant wave period of a transmitted-wave train is reduced considerably compared with that of an incident wave train, interesting statistical properties of the transmitted-wave train are observed; namely, the wave height distribution somewhat deviates from the Rayleigh distribution, the ratio of the significant wave height to the root-mean-square value of surface elevation becomes about 3.3, and the skewness appears to be over 0.2.

(5) A submerged horizontal plate can serve as one of the effective wave interception devices against waves of long wave length, due to the fact that the energy of the long incident waves is disintegrated or dispersed into that of higher harmonic components

in the transmitted waves, thereby reducing the impact of the primary waves.

CHAPTER 93

Observations of the Swash Expression of Far Infragravity Wave Motions

Rob Holman¹, Peter Howd¹, Joan Oltman-Shay², and Paul Komar¹

Abstract

One of the important results from the recent SUPERDUCK experiment was the discovery of very low frequency motions (10^2 - 10^3 second periods) with anomalously short longshore wavelengths (10^2 meters). Subsequent analysis showed the motions to be shear waves, unstable perturbations of the mean longshore current that act to conserve potential vorticity. A specific prediction of the model is that these waves have negligible elevation signal (they are non-divergent), in contrast to gravity waves. Examination of simultaneous run-up data confirms the non-divergent nature of the solutions. While edge wave modes were detected, no significant swash energy was seen in the low frequency, high wavenumber region where shear wave energy was found in the current meter data. This apparently negative result adds support to the interpretation of these motions as shear waves.

Introduction

In September and October, 1986, a large field experiment called SUPERDUCK was held at the U.S. Army Corps of Engineers Field Research Facility (FRF) at Duck, North Carolina, USA. The site features a pronounced and frequently active nearshore sand bar system, and a primary objective of the October phase of the experiment was to study possible mechanisms of sand bar generation. Of particular interest to some participants was validation of models that depend on the presence of edge waves to account for dominant longshore lengthscales.

Detection of edge waves was accomplished using a longshore array of bi-directional electromagnetic current meters placed 50 m offshore, in the expected location of the trough, landward of the bar. Seven instruments were placed with lag spacings of 110, 20, 30, 10, 70, and 50 m, an optimal design for the subsequent maximum likelihood spectral analysis. Four hour time series were collected, and frequency-wave-number (f-k) spectra computed.

While edge wave modes were observed in the infragravity band, the highest energy densities occurred at lower frequencies with periods typically on the order of $10^2 - 10^3$ seconds (Oltman-Shay *et al*, 1989). To distinguish this frequency band, the name Far InfraGravity (or FIG) band was adopted, in analogy to the relationship of infrared and far infrared light in the optical spectrum. Most surprising, the wavenumbers of the FIG energy were substantially higher than $\sigma^2/g\beta$, the wavenumber of a mode 0 edge wave, the largest value allowable for gravity waves (σ is radial frequency, g the acceleration of gravity, and β the beach slope). Moreover, the observed motions were very coherent and were always progressive in the direction of the mean longshore current.

A theoretical explanation of these motions was provided by Bowen and Holman (1989). They showed that under some circumstances a strong mean longshore current is unstable to perturbations, such that the perturbation will grow and progress with the current. These motions are called shear waves since their existence depends on the cross-shore shear structure of the current. Using a simple example geometry, Bowen and Holman showed that typical time and length scales of shear waves would be in the FIG band, and at high wavenumber, as was observed in the data.

The underlying dynamics of shear waves depend on the conservation of the total potential vorticity. Thus, a perturbation of the vorticity (shear) of the mean longshore current will be compensated for by the relative vorticity, resulting in a meandering flow pattern. However, an explicit assumption of the theory is that the motions are non-divergent (the rigid lid assumption) so that the rate of change of sea surface elevation is negligible. Thus, the theory specifically predicts that, despite the large energies seen in the velocity data, the sea surface elevation signal of shear waves should be negligible.

Synchronous with the velocity data, run-up measurements were also collected during SUPERDUCK. These data represent sea surface elevation signals at a specific location (the shoreline), so they can be used to test the non-divergent assumption and hence whether the observed motions are, in fact, shear waves. Thus the objective of this paper is to examine swash data to determine the presence or absence of energy at the low frequencies and high wavenumbers seen by the current meter data. A negative result adds support to the interpretation of these waves as non-divergent shear waves.

Field Experiment

Run-up data were collected during SUPERDUCK using videotapes of near-shore wave motion (note that the terms run-up and swash are used interchangeably in this paper to indicate the time series of sea surface elevation at the shoreline). Three cameras were mounted on the top of a high tower on the crest of the sand dune, 43.2 m above mean sea level. Records were 1 hour 55 minutes long and, when possible, were timed to correspond to current meter runs.

Digitization of the swash time series was carried out with an Imaging Technology Series 150 image processing package using the following set of steps. As a

preliminary step, the geometry of the camera view was solved for by digitizing a representative frame and then locating the image coordinates of a set of known ground control points that fall in the field of view. The problem is generally over-determined (more known points than unknown parameters) so that the geometry variables can be solved for in a least squares sense. Then, for each sampling time, the video frame is digitized and the beach profile transects of interest placed on the image, based on the now-known geometry. Figure 1 shows an example frame. A total of 39 transects have been placed on the image at a longshore spacing of 10 m (for a total longshore beach length of 380 m being analyzed). For each transect, the intensities of image pixels are read into the host Sun 4/110 computer and a search algorithm implemented to find the water's edge (the selected run-up location is marked on the screen and in figure 1 with a small vertical tick). This selected horizontal location is then translated into a vertical elevation swash signal based on the measured beach profile, and the resulting value written into the computer file. This search is performed for each of the 39 transects before a new frame is digitized. The whole process is repeated every second for the length of the run. An operator monitors the performance of the system by observing the marked computer "picks" and can tune algorithm parameters for each individual transect during digitization.

Resolution of the technique depends on range from the camera and focal length of the individual lens. Typical horizontal resolutions range from 20 cm (swash elevation of 2.0 cm) for close ranges to 0.73 m (swash elevation of 7.3 cm) for the most distant cases. Worst case resolutions for each of the analyzed runs are listed in Table I.

Four data runs were selected for analysis. The first two were at times when no significant shear wave energy was observed in the current meter records and the second two when shear wave energy was obvious. Times of the runs and associated environmental conditions are listed in Table I.

Table I
Statistics for Selected Data Runs

1. peak period from 8 m depth pressure sensor
2. peak direction from 8 m depth linear pressure sensor array. Positive angles from south
3. significant wave height from 8 m depth pressure sensor, (periods from 3 - 20 sec)
4. significant swash height, averaged over entire longshore run-up array
5. horizontal resolution of swash data at farthest transect (worst case)

Figure 1. Example video frame showing waves in the nearshore and run-up. Lines across the beach represent surveyed beach profiles. For automatic digitization, the computer searches out along each line (starting with the left hand tick) until it finds the run-up (marked by the right-hand tick). 39 transects are shown.

General Swash Results

Figure 2 shows an example section of swash time series for 32 of the 39 transects, a total beach length of 310 m. The longshore structure of individual swashes is apparent to the eye; there is little discernible phase lag through the array, implying that the waves were approaching the shoreline at near normal incidence (nearby transects actually appear to lead distant ones slightly, implying a northward propagation, consistent with the observed angle of incidence). The visible coherence with longshore distance lends confidence to the digitization process; longshore variability appears to be a function of the observed wave field, not random noise in the sampling algorithm.

A further check on the believability of the results comes from plotting the longshore variability of the basic time series statistics. Figure 3 shows the significant swash height (calculated as $4 \times$ standard deviation) for each of the four runs. Longshore-averaged values are listed in Table I as dimensional values as well as normalized by the significant wave height measured by offshore pressure sensors. In general, the longshore variability shown in figure 3 is quite small, implying a stability in the digitization process. Most variability that does exist occurs on a number of transects, as would be expected for a natural phenomenon (as opposed to random scatter of the digitizing process). It should be noted that in none of these runs was the beach completely two dimensional. In each case, there was natural longshore variability in the bathymetry that undoubtedly contributed to the variability in the observed swash statistics.

SUPERDUCK Run-up

GD097, 01/12/86, 1135 EST
 (32 of 39 lines, 10 m spacing)

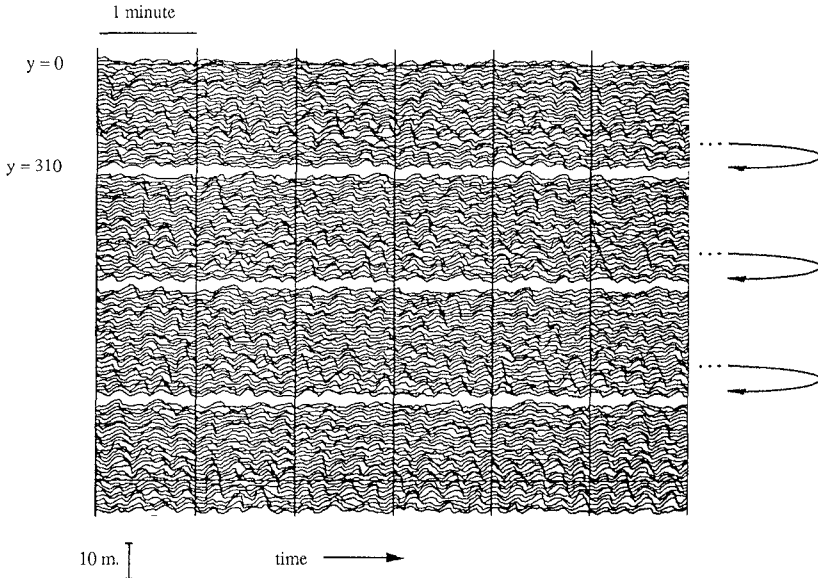

Figure 2. Example swash time series from one data run. Four non-contiguous segments are shown, each of six minute duration. For each segment, 32 adjacent transects are plotted. The longshore coherence and phase of incident wave motions is apparent. 10 m vertical swash scale is shown at bottom.

Spectra were calculated for all transects. Representative examples are shown in figure 4. In each case the peak period observed in 8 m depth is listed above the spectrum, and indicated by an arrow on the plot. For runs GD097 and GD105, there was significant energy at the incident peak. By contrast, for runs GM133 and GM143 (both near low tide) the high frequency incident waves are dissipated over the sand bar so that the spectral peak occurs at a period of about 15 seconds with some lower frequency energy present. GD097 and GD105 also show interesting (and statistically significant) peaks at lower frequency, with a representative period being 35-40 seconds. Intriguingly, this is roughly the period appropriate to an infragravity wave

Figure 3. Longshore variability of significant swash height for each of the four selected data runs.

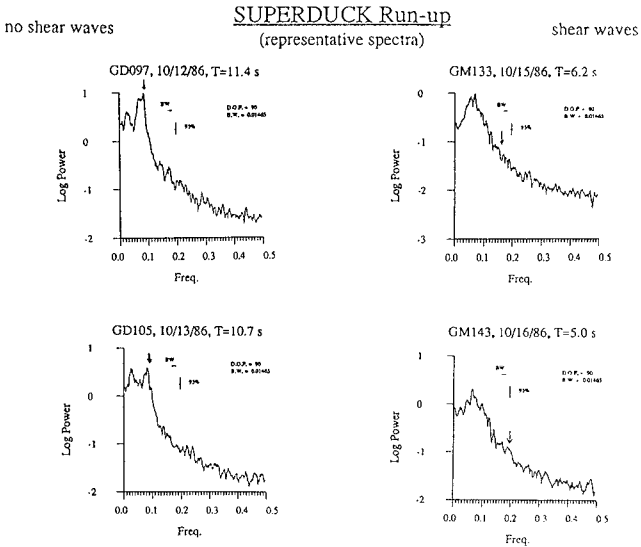

Figure 4. Spectra of swash for selected longshore transects, one for each of the four data runs. Peak periods from offshore pressure gauges are listed above each spectrum and are indicated by arrows on the plots. 90 degrees of freedom.

with a first node at the location of the observed sand bar. Examination of spectra over the length of the “array” shows a smooth variability in the lower frequency peak, suggesting some longshore standingness to this energy. This will be the subject of further work. In no case was the significant energy concentration in the very lowest frequencies associated with the FIG band.

Frequency-wavenumber results

In calculating f-k spectra from current meter measurements, a limited number of instruments (7) were deployed in a configuration optimized to the IMLE spectral analysis technique. In our case, adding “instruments” to the dataset simply involves specifying additional longshore transects to be digitized, and we have arbitrarily specified an array of 39 equally-spaced locations. However, due to technical aspect of the stability of the IMLE analysis, results are best if a subset of 7 transects are chosen, using the same lag spacing as was used for the current meter array. Of course, with so many transects, there are a number of potential choices. Figure 5 illustrates the

Figure 5. Schematic of “longshore array realizations” used in the analysis. The 39 available transects are shown equally-spaced at the bottom of the figure. Lines above indicate selected arrays for IMLE spectral analysis. Results from the 10 realizations are averaged to yield the final f-k spectra.

options, with the 7 sensor configuration shifted progressively in the longshore. When f-k spectra were calculated for each of these realizations, the basic structure of the spectra were similar, but there was also a great deal of noise that confused the interpretation. To combine the realizations and reduce the noise, the raw f-k spectral data were averaged for the 10 realizations shown in figure 5, yielding a much better result. (We note that many other array designs are also possible and could also be averaged into the result. The simplest of these would just be a reversal of the array. The independence of more and more permutations must gradually decrease, although, at this point, we have not pursued a rigorous quantification of the amount of averaging that is useful. Nor is it clear that averaging the wavenumber spectral results is preferred since IMLE calculations are nonlinear. Averaging of the cross-spectral matrix would be preferred and will be pursued in the future).

Figure 6b shows the resulting averaged f-k spectrum for run GM133, judged the highest quality of our data runs and also one for which shear waves were very clearly observed in the current meter records (figure 6a). Only the sub-incident frequencies are shown. The dispersion lines for modes 0, 1, 2 and cutoff mode edge waves, calculated to account for the true bathymetry as well as the presence of a mean longshore current, are shown to guide the eye.

Several features are seen. In general, there is a significant amount of energy at low wavenumbers, consistent with results from cross-shore velocity data shown in figure 6a. However, there are also clear suggestions of mode 0 edge wave energy propagating in both the southward (positive wavenumber) and northward (negative wavenumber) directions. Interestingly, the modes are asymmetric with respect to the zero wavenumber axis. This result is both predicted by the theoretical dispersion lines, and observed in the data. Identification of possible higher mode edge waves from this diagram is possible, but requires an active imagination.

Figure 7 is an alternate presentation of the same run-up spectrum. However, instead of relying on an algorithm to pick significant peaks in the spectrum, all data are shown with a shading linearly proportional to their energy density (note that each frequency band is still normalized to unit energy so that the shading density indicates relative concentration of energy within the frequency band). When viewed at a distance and with a partial squint, the concentrations of energy along curved dispersion lines are more apparent, with the two modes noted previously being relatively obvious and higher modes being somewhat distinguishable. The asymmetry due to the longshore current is quite obvious.

Figure 6a also clearly shows the region of shear wave energy from the cross-shore velocity data, as the linear feature on the positive wavenumber side of the spectrum. The concentration of energy in the shear waves is evident, particularly at the lower frequencies associated with the FIG band ($<10^{-2}$ Hz). By contrast, the same region, outlined in the run-up spectrum of figure 6b, shows no concentration of energy lying along this ridge. Some energy is observed in the lower frequency, higher wavenumber region (beyond mode 0 edge waves), but there is no correspondence between the f-k location of that energy and the location of the obvious shear waves in the current

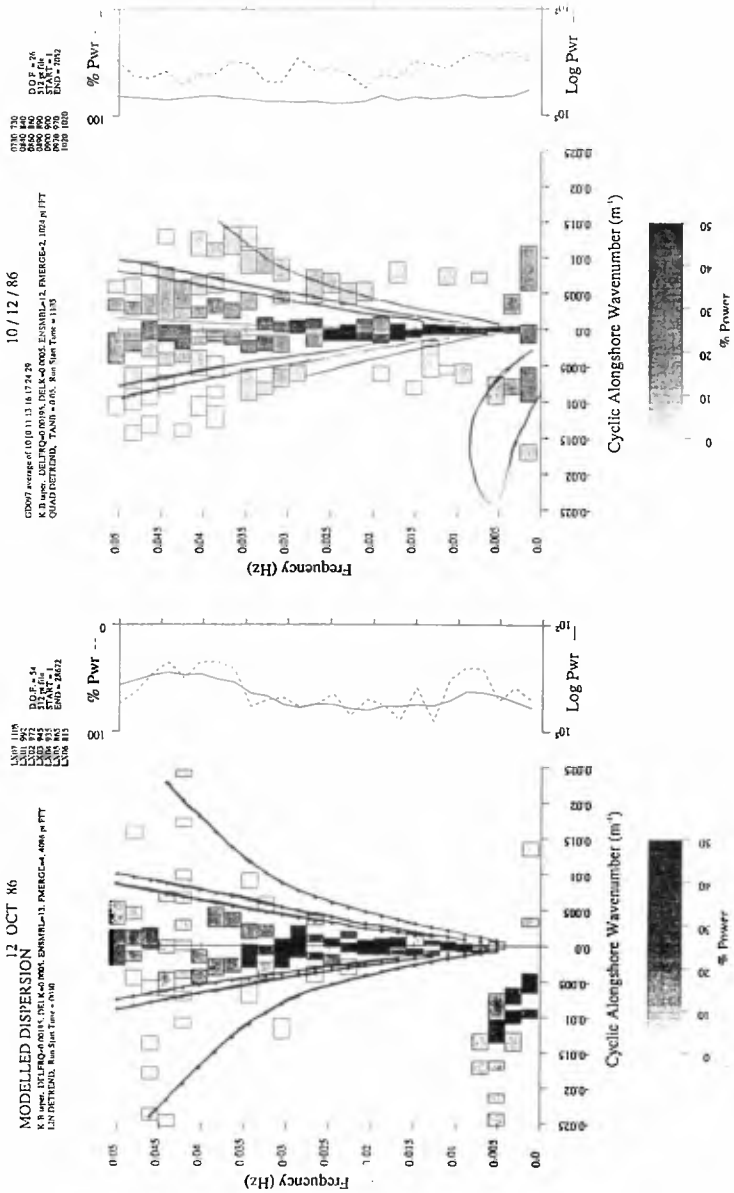

Figure 8. Frequency-wavenumber spectra for a) cross-shore velocity, and b) run-up for 10/12/86, a day for which little shear wave energy was observed in the velocity data. Edge wave mode lines are for modes 0, 1, and 2 and include effects of true bathymetry and mean longshore current. Run-up data clearly shows low mode edge wave energy, but little in the shear wave region.

meter data. At present, we do not know what the observed region of energy represents.

Figure 8 shows f - k spectra for October 12 (run GD097) for the cross-shore velocity data (figure 8a) and for run-up (figure 8b). Again, low mode edge waves are visible in the run-up data, even more than in the cross-shore velocity spectrum. While this run was specifically chosen as one for which shear wave energy was a minimum, we still see a slight concentration in the velocity data at very low frequencies and large negative wavenumber. Again, the same region, marked on the run-up spectrum, shows no particular concentration of energy.

The absence of low-frequency, high-wavenumber energy in the run-up data supports our hypothesis that shear waves are, in fact, just that; shear waves. These motions appear to obey the rigid lid assumption, showing no significant sea surface elevation signal despite large concentrations of energy in velocity time series.

Conclusions

Examination of the sea surface elevation signal (represented by swash time series) at sub-incident band frequencies has shown the presence of a variety of expected gravity wave motions including leaky modes (low wavenumber energy) and low mode edge waves. However, even under conditions when shear wave energy was extremely pronounced in velocity data taken 50 m offshore, there is no indication of such signals in the swash data. This supports the rigid lid assumption made in the theory; these low-frequency high-wavenumber motions appear to be vorticity signals with no significant sea surface elevation signal.

Acknowledgments

We would like to thank Paul O'Neill for the enormous amount of work he put into developing the image processing hardware and software, and in digitizing the data runs. Once again, we would like to acknowledge the excellent work of the Army Corps FRF staff during the SUPERDUCK experiment, and the efforts of Col. Grum in obtaining funding for the tower at Duck. Much of the theoretical and conceptual understanding of this problem has resulted from discussions with Tony Bowen. Funding for this work was from the Office of Naval Research, Coastal Sciences program under contract N00014-90-J-1118.

CHAPTER 94

Safety philosophy for dike design in The Netherlands

A.W.C.M. Vrouwenvelder¹, P. Struik²

Abstract

This paper describes the history and present state of the art with respect to safety philosophy for flood defence systems in the Netherlands. It is explained that present day philosophy is based on a so called dike-ring approach and on a probabilistic treatment of all load and strength parameters. Both target safety levels as well as verification procedures are discussed. Simplification rules for application in every day practice are given.

1. Introduction

In the past decades, the design of dikes and flood-defences has developed from a traditional craft to a scientific approach. Traditionally the crest of the dike was built 1 m above the highest water level known so far. In the late 1930's it was recognized that water levels are statistical quantities and that dike design should be based upon water level exceedence frequencies. The first step from a deterministic to a probabilistic design approach was taken. The next step is to extend this idea to other load and strength parameters, the so called full probabilistic design. This paper describes the main developments in this field and the present state of the art.

² Coordinating Engineer for the Technical Advisory Committee for Water Defences (TAW), Ministry of Transport and Public Works, Rijkswaterstaat, Hydraulics Section of the Road and Hydraulic Engineering Divison, P.O. Box 5044, 2600 GA Delft, The Netherlands.

2. Floods and flood defence strategies, a historical overview

In 1916 a storm surge flooded the land around the former Zuiderzee (see Figure 1). This inundation led to the decision to close the Zuiderzee, by means of a dam, the Afsluitdijk, and thus creating the IJssel-meer. The Afsluitdijk was completed in 1932. For the design only historical data were taken into account. The dike height was based on the rule that it should be able to withstand the highest known storm level in history.

For the next 20 years, Holland seemed to be safe. Then, on the first of February 1953, a severe storm surge struck the south western coast and drove the water into the delta of the Rhine, Schelde and Meuse, up to an unprecedented level. A great number of dikes collapsed, large parts of land were flooded and over 1800 people drowned.

After this disaster the so called Delta-committee was formed to prevent such a tragedy to ever happen again. The Delta-plan was developed and executed. This meant a 700 km shortening of the coastline, by the closure of all major estuaries, and strengthening of the dikes.

In the preceding decades it was discovered that the observed storm levels plotted on probability paper against their probability of exceedence formed nearly a straight line. Now it was possible to extrapolate this line and base the dike design on a storm level with a chosen probability of exceedence.

The acceptable return-period for the waterlevel that the dikes should still withstand was set by the Delta-committee on 10,000 years for central-Holland and 4,000 years for the other parts of Holland, with less inhabitants and less investments. Also a economical study was carried out, trying to balance the investments in flood defences against the probability of failure and the consequential damage. That study pointed in the same direction for the choice of the return period.

The Delta-plan was still under construction when the next event happened. In 1960 an inland polder dike failed and the polder Tuindorp-Oostzaan, an urban area near Amsterdam, was flooded. After the investigation of the cause of this event it was concluded that it would be better not to wait for the next disaster and then form an other committee of investigation, but to have a permanent committee to safeguard the safety against inundation.

This led to the formation of the Technical Advisory Committee on Water Defences (TAW) by the Minister of Transport and Public Works. The first task of this committee is to advise the minister on all technical-

scientific aspects of water defences and of the protected areas. To do so this committee coordinates research and publishes guides for the design and maintenance of water defence works.

In the early seventies the acceptable return period for river dikes became a matter of discussion. In this case the figures given by the Delta Committee seemed to be too strict. In 1975 the Becht Committee advised a return period of 1250 years for the design water level of the river dikes.

This recommendation was based on the following distinction between river and sea hazards:

- inundation by fresh water causes less damage than inundation by salt water;
- high water level on rivers can be predicted earlier and appropriate measures can be taken;
- the areas threatened by rivers are above mean water level, which means that after the flooding the water disappears and gaps can easily be closed.

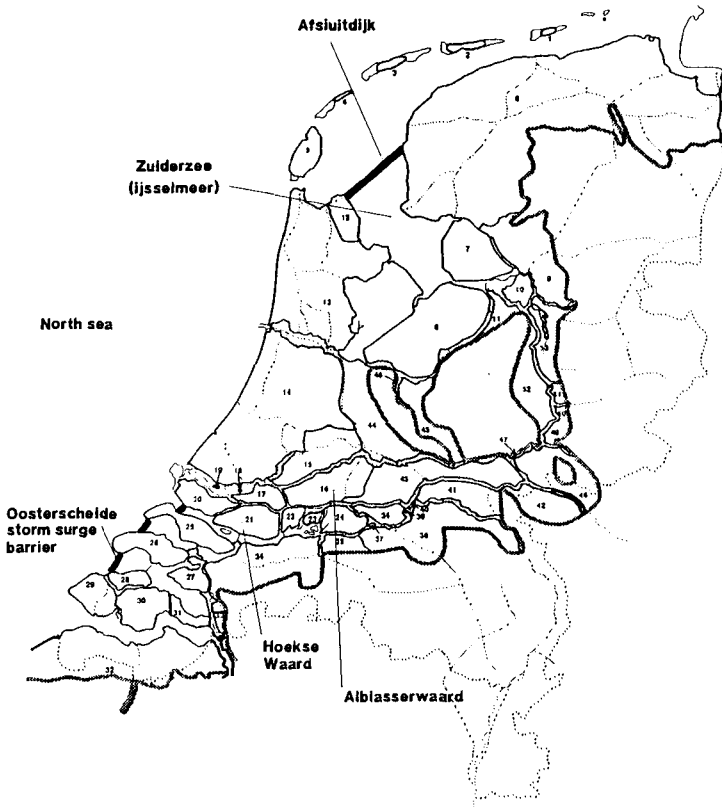

Figure 1: Map of the Netherlands

As a part of the Delta Plan the Eastern Schelde Storm Surge Barrier was build in the period 1980-1988 (see Figure 1). During design it was recognised that probabilistic treatment of the water level should be extended to other load parameters (wind, waves), but also to resistance parameters (soil) and operational factors (electric power, human factors). After this rather succesful introduction of probabilistic methods into practice, other applications followed.

Recently, in 1989, the TAW published the Guide for the Design of River Dikes, especially dealing with tidal-river dikes. This design guide is based on probabilistic starting points and the dike-ring concept (see section 3). It is however stressed that this does not imply that it is possible to actually calculate the probability of inundation.

In 1991 a new Law in Flood Protection is expected to pass the Dutch Houses of Parliament. Target of the new law is to maintain the safety that has been obtained by years of construction, consuming large sums of money. To do so a five-yearly check of the primary waterdefences has to be carried out and a report on the provided safety should be given. The TAW is now working on a guidance document how to carry out this safety-check.

3. Basic concepts of Probabilistic Design

In the Netherlands a polder is often bordered by water on many sides. Therefore the expression "dike-ring" is introduced for referring to the protecting ring of water retaining structures bordering the area (see Figure 2). An important point is that this protecting ring should be considered as a coherent system and not as an arbitrary set of individual elements. If for the time being equal consequences for the failure of all parts of the ring are assumed, the basic safety requirement for the dike-ring can be formulated as:

$$P\{F\} < P\{\text{target}\} \quad (1)$$

In here $P\{F\}$ is the failure probability or probability of inundation for the dike ring (per year) and $P\{\text{target}\}$ is the accepted value. The design problem now can be subdivided into two distinguished parts:

- (1) to determine the target failure probability;
- (2) to judge wether a given dike system (existing or designed) fulfils the basic requirement.

Item (1) is partly a technical matter and partly a matter of political decision. The technical part is related to questions as: what will be the consequences of a dike failure in terms of inundation, loss of property and loss

Figure 2: A dike-ring is an area surrounded by a system of water retaining elements as dunes, sheet walls, locks and so on.

of life. Politicians should answer questions as to what losses can be accepted.

Item (2) is a typical technical problem. It is effective to distinguish two different lines of approach. The first line of approach is bottom up: based on physical models for all failure mechanisms and based on statistical models for all random variables, one may calculate the failure probability for the complete system. The second line is top down: starting from a given target probability for the system, one derives targets for individual mechanisms and elements; from there on one derives requirements for the design variables.

As long as all mechanisms are known and full information on all statistical properties exists, both approaches are entirely equivalent. However, as this is not the case, the first approach is deemed to fail at present: the system failure probability for a complete dike-ring simply cannot be calculated. Taking the second approach however, it is possible to deal at least with a substantial part of the design problem, even if not all mechanisms can be treated. As research goes on, the part that can be dealt with using these techniques, will increase.

4. Target reliability

In Figure 3 the flow chart for a target reliability estimation has been indicated. Based on the hydraulic conditions at the river, sea or lake on one side and the gap growth characteristics for the failing dike element on the other, the discharge through the breach can be calculated. Given the resulting inundation pattern, the material losses and the losses of human lives must be estimated. An example is shown in Figure 4.

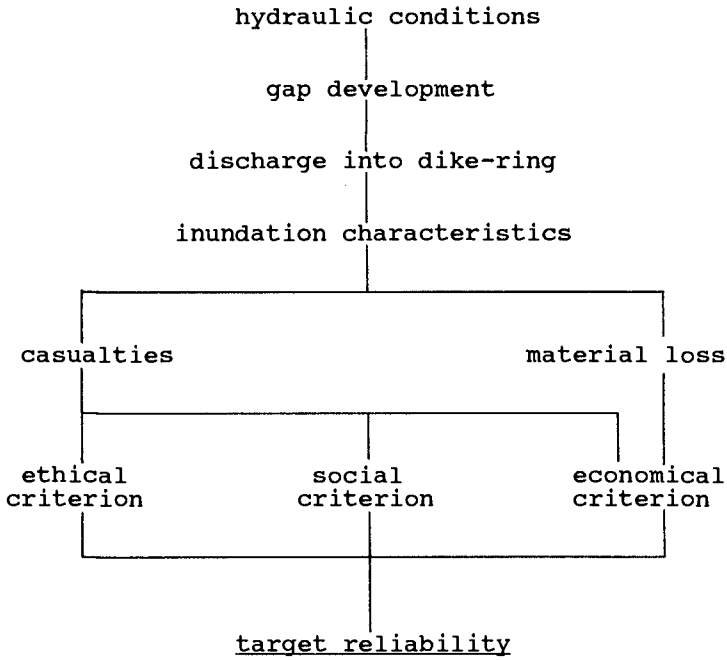

Figure 3: Determination of target reliability

Figure 4: Material loss and number of casualties as a function of the inundation depth (examples)

These losses should give indications for target reliabilities. In the Netherlands a three criterion system is under development:

1. An ethical or personal risk criterion. According to this criterion it is not allowed to let an arbitrary person run a risk for drowning which is substantially higher than the risk for an accident in normal life;
2. A socially accepted risk, which is concerned with the aversion a society has against large accidents including many casualties;
3. An economic criterion: the cost of improving a dike system should (at least) be balanced by the save of losses.

For further information the reader is referred to [TAW]. An interesting application, involving also time dependency and maintenance aspects is presented in [Vrijling]. If the three criteria give different answers, as they usually do, a possible strategy is to maintain the most severe requirement as the governing one. However, as said before, in matters of this kind the last word is to politicians.

Alblasserwaard case

In order to check the usefulness of the criteria mentioned and the adequacy of the calculation tools, one of the dike rings in the lower Rhine area has been analysed [Vrouwenvelder, Wubs]. The dike ring chosen was the Alblasserwaard which stretches from a river dominated regime at the east to a mixed sea river regime at the west side, see Figure 1. A more detailed map is presented in Figure 5. Figure 6 presents a schematic cross section.

For breaches on various locations along the dikes, the resulting water levels within the dike ring have been calculated (Figure 7). These water levels depend highly on the location of the breach: the most severe inundation occurs when the dike fails at Gorinchem. In that case the water level equals 3.70 m above average sea level, which means inundation depths varying from 1.70 m to 5.20 m. A breach at Alblasserdam, located at the most western point of the dike ring, leads to an inundation depth of no more than 1.5 m; parts of the dike ring even will remain dry.

These results show that it may be necessary to have a safety differentiation within one dike ring. At present this is not common practice. Following this line of thought, safety targets were derived for every location based on inundation depth versus loss diagrams (Figure 4) and the criteria presented before.

For Alblasserdam a target value for the inundation return period of 3,500 years resulted, which almost equals the present value. For Gorinchem this value varied from 8,000

Figure 5: Dike ring Alblasserwaard

Figure 6: Schematic cross section of Alblasserwaard

Figure 7: Inundation depth versus time curves for breaches on various locations

to 600,000 years, depending on the casualty-inundation depth relationship. It should be stressed that this relationship is highly uncertain. On the other hand, it is only necessary to oversize the dikes at Gorinchem slightly compared to other ones to reach a very high local safety level.

5. Assessment of a given dike-ring

As mentioned in section 3, a useful strategy is to start from the accepted general failure probability and break it down into acceptable failure probabilities for the various mechanisms and elements (top-down-approach). A demonstration of such a break down is presented in Figure 8. This failure tree shows the dominant failure modes and (by way of example) corresponding individual failure probabilities per mode. All modes have been assumed to be stochastically independent, which is conservative.

Within one mode one might continue the break down and split up the total failure probability for the mode under consideration between all elements of the dike-ring. As an alternative it is sometimes possible to use for one mechanism a bottom up procedure, and calculate the failure probability of the system. This depends on the characteristics of the failure mode, the elements involved and the system properties (serial system, parallel system or mixed). Both procedures will be discussed later on.

Special attention in the analysis of a dike-ring has to be given to structural components as locks and storm surge barriers. In the first place, these structures may give rise to additional mechanisms, resulting from discontinuities in the water retaining system. A second point is that these structures may contain moving parts, which may fail because of jamming, faults in electrical and hydraulic systems, human errors, and so on. The basic philosophy and assessment tools for these types of events can, however, be the same as for natural failure modes.

- Top Down procedures

For discrete elements forming a purely serial system, the break down within one mode can be performed in the same manner as for the break down between the modes; if necessary again independency between the elements or modes can be assumed. So in the case of N elements one has to fulfill:

$$\sum P(F_i) = P(F_1 \text{ or } F_2 \dots \text{ or } F_N) \geq P(F_{\text{system}}) \quad (2)$$

where $P\{F_i\}$ = Failure probability of element i for the failure mode under consideration (e.g. overtopping or sliding) and $P\{F_{\text{system}}\}$ = Target system failure probability for the mode under consideration.

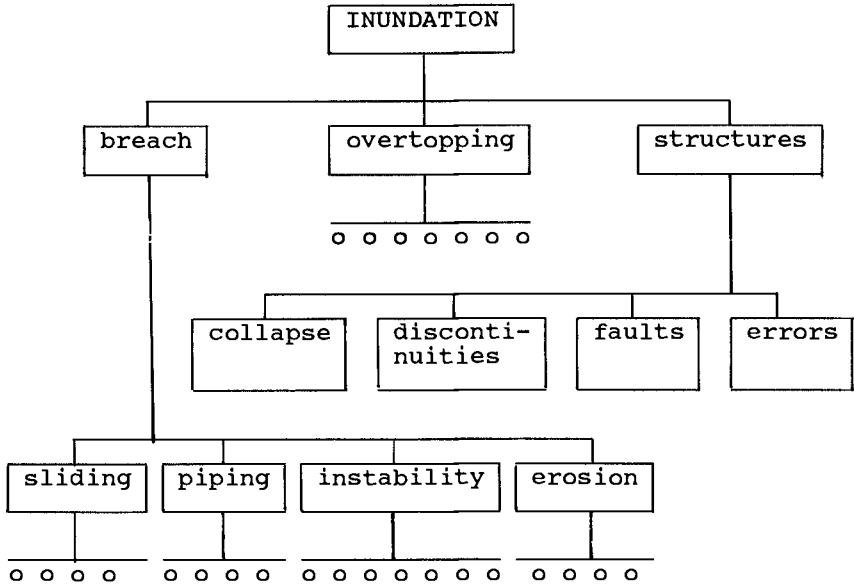

Figure 8: Failure Tree for a Dike-ring

Most straightforward of course is to take equal failure probabilities for all members. However, from the economical point of view some other distribution may be preferred. If there is correlation between the members, one might use some equivalent number of members (see [Vrouwenvelder]).

In the case of continuous elements the concept of the equivalent independent dike section can often be used. As an example consider the mechanism of slope instability. It can be proven [Calle] that the dike may be conceived as a system of independent sections, each section having a length of 30 - 100 m. This length coincides almost with the length of a sliding surface. The probability of failure for a single sliding surface can be found from a standard FORM analysis [TAW]. In the same way the mechanism of piping can be analysed [Calle].

- Bottom Up Procedures

It is sometimes possible to calculate the failure probability of the complete system for the specific mode. Three methods can be distinguished: (1) Monte Carlo, (2) Numerical Integration and (3) First Order Methods.

Monte Carlo may be considered as an appropriate for relatively simple systems. The point is that the number of simulations should be large in order to get a reliable result. However, there are promising developments going on into new techniques as for instance importance sampling and directional sampling [Bjerager].

Numerical integration is feasible as long as the number of random variables is small (say less than 5), or when some special structure of the mathematical problem makes it possible to break the multiple integral into a number of smaller integrals. The model defining the failure domain should not be too complicated.

An example where the technique of numerical integration has been applied with great success is the mechanism of wave overtopping: for all elements of a dike ring this mechanism may depend on the same sea water level, river discharge, wind velocity and wind direction. This enables the evaluation for the dike-ring failure probability by means of a multi dimensional integral. Based on this principle the computer program DIJKRING has been developed [Niemeijer, Volker, Vrouwenvelder]. Consider as an example the dike ring Hoekse Waard (Figure 9), which can be subdivided into 18 dike segments. DIJKRING needs a specification of the orientation, location and geometry for all dike segments. Next, for every combination of the four random variables DIJKRING checks all dike segments for overtopping failure. The resulting failure probability was calculated as once per 600 year. After the construction of a storm surge barrier near Rotterdam this number will be improved.

Figure 9: Dike ring Hoekse Waard, subdivision into 18 elements

Especially in structural engineering the method of First Order Methods is very popular. As a first step the individual failure modes are analysed using the FORM or level II procedures [TAW]. Next the combination of failure modes of failure sequences are evaluated using the first order approximation according to [Hohenbichler/Rackwitz], [Ditlevsen] or [Stevenson/Moses]. For this method the number of modes and the correlation between the failure modes should not be too large.

6. Every day practice/code development

Although the basic philosophy for the safety assessment should "always" be a probabilistic one, it is not desirable to perform detailed probabilistic analyses for all mechanisms and all dike-rings. There is a need for simple design methods for the every day practice. Standard procedures to derive simple rules from probabilistic considerations have been developed in the past decades and can be found in the international literature.

The basic idea is that one uses "design values" for the random variables. A design value X_d is the value that one uses in the safety check formulas, and corresponds to a probability of being lower (for strenght parameters) or higher (for load parameters) of:

$$P [X < X_d] = \Phi(-\alpha\beta) \quad (\text{for resistance}) \quad (3)$$

$$P [X > X_d] = \Phi(+\alpha\beta) \quad (\text{for load}) \quad (4)$$

Here β is the so called reliability index (corresponding roughly to $-\log P(\text{target})$) and the coefficient α ($0 < \alpha < 1$) indicates the relative importance of the variable and can be found from a FORM (First Order Reliability Method) or level II analysis. In many codes these α -values have been standardized in the following way:

- leading resistance parameter: $\alpha = 0.80$
- leading load parameter : $\alpha = 0.70$
- other resistance parameters : $\alpha = 0.32$
- other load parameters : $\alpha = 0.28$

In practice, design values are often calculated as the product of characteristic values and partial safety factors. Assuming the characteristic values to equal the mean value and a normal distribution, the partial safety factor is given by:

$$\gamma = 1 + \alpha \beta V \quad (5)$$

V is the coefficient of variation for the variable under consideration. For other distributions similar expressions are available. The concept of "design values", characteristic values and partial safety factors have also found its way into the TAW guides for river dike design and dune reliability assessment.

7. Conclusion

Based on the probabilistic principles and methods outlined in this paper, it is possible to judge in a rational manner the safety of a complete dike system. Consistent assessment on various levels of sophistication is possible. In practice the degree of refinement will depend on the state of the knowledge about the mechanisms under consideration and/or on the economic consequences of nonoptimal solutions.

In the present situation already many basic ideas of the probabilistic design philosophy have found their way into practice, either by design guides, or in the design of specific structures. There is a tendency towards more applications in specific projects. This has to do with the fact that the most difficult parts of the River dike construction works still have to be carried out. Especially the cases with conflicting interests have been postponed until the last stage. These are for instance dikes in cities or through valuable landscapes.

Problems of that type demand extra skills and ingenuity, to take all aspects in account and to find the best possible design. In these cases an integrated approach and an open discussion is necessary to achieve an optimal and generally accepted solution. For large projects, such as the Storm Surge Barrier in the Eastern Schelde, this is already good practice, but smaller projects may also demand the same approach. It may be necessary to change the historically approved opinion that only a water defence system consisting of sand and clay is a good one. Probabilistic methods will help to prove that other solutions can be considered as equivalent reliable alternatives.

CHAPTER 95

DYNAMIC STABILITY OF ARMOR UNITS - A BEM APPROACH

Chimin Chian(1) and Franciscus Gerritsen(2)

ABSTRACT

A method is presented for predicting primary stability of armor units on a breakwater exposed to solitary waves. A 2-D flow model is developed based on a boundary element method for simulating run-up of a nonbreaking solitary wave on an impermeable, smooth slope. Since Laplace equation subject to exact boundary conditions is solved by the model, the 'mild slope' restriction in using a 1-D long wave model is eliminated. Schemes including inductive wave generation, Lagrangian shoreline motion and free surface regridding are proposed. The run-up flow model is then coupled with an armor stability model to predict a stability number for armor units as function of time and location on the slope. Aspects such as applicability of Morison-type approach and selection of lift coefficient are examined. Results of computed wave run-up and armor stability are compared with experimental data.

1. INTRODUCTION

A solitary wave, described as a disturbance of water surface that travels at a supercritical phase speed with a permanent and symmetrical form completely above the still water line, propagates from offshore region shoreward towards a coastal structure which has a sloping seaward face. After the leading tip of the wave reaches the slope, the wave deforms, runs up to a maximum height, and then runs down before propagating seaward. In its passage, the wave generates an unsteady flow field which exerts hydrodynamic forces on the exposed part of the structure. The subject of this study is the primary stability of the protective layer of rocks, or armor units, on the sea-facing slope of the structure under such flow conditions.

Kobayashi et al. (1986, 1987) studied the problem for oscillatory waves with a flow model based on a finite-difference method. A stability model was developed for armor units which predicted a stability number as a function of time and location on the slope

1) Graduate Student University of Hawaii, presently M.I.T., R.M. Parsons Laboratory, Cambridge, MA 02139.

2) Professor of Ocean Engineering, University of Hawaii, Honolulu, Hawaii.

Since a one-dimensional long wave equation was used, their model is applicable only to mild slopes. When the slope is relatively steep, a two-dimensional model is desirable for adequate description of the flow condition along the sloping bed. For this purpose, an approach based on the boundary element method is deemed appropriate if we may assume the slope is, to a good approximation, smooth.

Run-up of solitary waves on a smooth slope has been studied, among a few others by Kim et al. (1983) using a boundary element method. To broaden the range of problems being treated and to reflect the development in our study of nonlinear wave simulation, we present in this paper a model based on the potential theory and a boundary element method (BEM) for evaluating the stability of armor units exposed to solitary waves on relatively steep, impermeable, smooth slopes.

Fig.1 Definition sketch.

2.PROCEDURE

For a problem defined in Fig.1 where potential theory is assumed valid, the appropriate governing equation and boundary conditions are

$$\nabla^2 \phi = 0 \quad \text{in } \Omega, \tag{1}$$

$$\frac{\partial \phi}{\partial n} = 0 \quad \text{on solid bed}, \tag{2}$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial \phi}{\partial x} \frac{\partial \eta}{\partial x} = \frac{\partial \phi}{\partial y} \quad \text{on } y = \eta, \tag{3}$$

$$\frac{\partial \phi}{\partial t} + \frac{1}{2} \left\{ \left(\frac{\partial \phi}{\partial x} \right)^2 + \left(\frac{\partial \phi}{\partial y} \right)^2 \right\} + g \eta = 0 \quad \text{on } y = \eta. \tag{4}$$

Nondimensionalizing variables such that

$$(x^*, y^*, \eta^*) = \frac{(x, y, \eta)}{h}, \quad t^* = t \sqrt{\frac{g}{h}}, \quad \phi^* = \frac{\phi}{\sqrt{gh^3}}, \quad (u^*, v^*) = \frac{(u, v)}{\sqrt{gh}}$$

dropping the stars, and expressing the free surface boundary conditions in surface-fitting coordinates (Liu, 1978), we have

$$\nabla^2 \phi = 0 \quad \text{in } \Omega, \quad (5)$$

$$\frac{\partial \phi}{\partial n} = 0 \quad \text{on solid bed}, \quad (6)$$

$$\frac{\partial \eta}{\partial t} = \frac{1}{\cos \beta} \frac{\partial \phi}{\partial n} \quad \text{on } y = \eta, \quad (7)$$

$$\frac{\partial \phi}{\partial t} + \frac{1}{2} \left\{ \left(\frac{\partial \phi}{\partial n} \right)^2 + \left(\frac{\partial \phi}{\partial s} \right)^2 \right\} + \eta = 0 \quad \text{on } y = \eta. \quad (8)$$

To specify the condition at the offshore (left) boundary, we differentiate between wave generation and run-up simulation. In wave generation, an inductive method is used (Chian, 1989) in which the wave field is generated by gradually introducing a known-a-priori wave form into the computational domain with other variables being solved stepwise in the process until the entire wave (cut at 0.1%H) is in the domain. For this procedure, the condition at the offshore boundary is

$$\frac{\partial \phi}{\partial n} = -u, \quad (9)$$

where u is the horizontal fluid particle velocity. In the ensuing run-up simulation, the generated wave field is taken as the initial condition and the offshore boundary is set open by using an Orlanski condition given by

$$\frac{\partial \bar{\phi}}{\partial t} + c \frac{\partial \bar{\phi}}{\partial n} = 0, \quad (10)$$

where c is the wave phase speed and overbars denote depth-averaged values, all being evaluated at each time step. The assumption underlying eq.(10) is that the shape of the outgoing wave keeps approximately unchanged.

At the shoreline, we write the dynamic free-surface boundary condition (8) as

$$\frac{d\phi}{dt} = \frac{1}{2} \left[\left(\frac{\partial \phi}{\partial n} \right)^2 + \left(\frac{\partial \phi}{\partial s} \right)^2 \right] - \eta \quad \text{on } y = \eta. \quad (11)$$

Assuming that the fluid element at the shoreline consists of the same fluid particles at all times, eq.(11) further reads

$$\frac{d\phi}{dt} = \frac{1}{2} u_s^2 - \eta \quad \text{on } y = \eta, \quad (12)$$

with u_s , the velocity of the fluid element at the shoreline, being evaluated using the boundary solutions of velocity potential along the slope. To match this scheme, Lagrangian nodes are used on the slope to follow fluid motion.

Applying Green's second identity to the boundary value problem governed by the Laplace equation, it may be shown that

$$\epsilon(\zeta)\phi(\zeta, t) = \int_{\Gamma} \left\{ G(\zeta, \omega, t) \frac{\partial \phi}{\partial n}(\omega, t) - \phi(\omega, t) \frac{\partial G}{\partial n}(\zeta, t) \right\} d\Gamma, \tag{13}$$

Where ζ, ω are field and source points, Γ is the boundary enclosing Ω , ϵ is the interior angle of the boundary at ζ , and G is a fundamental solution of the form

$$G(\zeta, \omega, z) = -1/r(z), \text{ with } r \text{ being the distance between } \zeta \text{ and } \omega.$$

Discretizing eq.(13) by dividing Γ into N linear elements, and differencing eqs. (7), (8), (10), (12) in time by a Crank-Nicholson implicit scheme, a set of simultaneous equations subject to boundary conditions may be obtained (Kim et al., 1983; Chian, 1989) and solved in time domain for ϕ and $\partial\phi/\partial n$ around Γ . Differentiating solutions of ϕ along the slope then yields a history of fluid particle velocities at various locations on the slope, which are used as input for the armor stability model as will be discussed later.

In implementing run-up simulation, a regridding scheme is used on the free surface at each time step, with which the size of projections on x of all elements are kept equal so as to avoid excessive elongation or shortening of certain elements and improve the accuracy of numerical differentiation along the free surface in evaluating $\frac{\partial\phi}{\partial s}$ and β . The scheme is given by

$$\begin{aligned} \left(\phi, \frac{\partial\phi}{\partial n}, \frac{\partial\phi}{\partial s} \right)_{i'} &= \xi_1^+ \left(\phi, \frac{\partial\phi}{\partial n}, \frac{\partial\phi}{\partial s} \right)_i + \xi_2^+ \left(\phi, \frac{\partial\phi}{\partial n}, \frac{\partial\phi}{\partial s} \right)_{i+1} && \text{(advancing wave)} \\ \left(\phi, \frac{\partial\phi}{\partial n}, \frac{\partial\phi}{\partial s} \right)_{i'} &= \xi_1^- \left(\phi, \frac{\partial\phi}{\partial n}, \frac{\partial\phi}{\partial s} \right)_i + \xi_2^- \left(\phi, \frac{\partial\phi}{\partial n}, \frac{\partial\phi}{\partial s} \right)_{i+1} && \text{(receding wave)} \end{aligned}$$

where

$$\begin{aligned} \xi_1^+ &= \frac{1}{2} \left(1 - \frac{dS - S_i/2}{S_i/2} \right), & \xi_2^+ &= \frac{1}{2} \left(1 + \frac{dS - S_i/2}{S_i/2} \right), \\ \xi_1^- &= \frac{1}{2} \left(1 - \frac{dS - S_{i-1}/2}{S_{i-1}/2} \right), & \xi_2^- &= \frac{1}{2} \left(1 + \frac{dS - S_{i-1}/2}{S_{i-1}/2} \right). \end{aligned}$$

In the above, S_i and S_{i-1} are the lengths of the i th and the $(i-1)$ th elements. dS is the difference in element length between two time steps. Primes for the subscripts denote the interpolated nodal points. Linear interpolation is chosen in this scheme for consistency with the linear elements used in this study.

To relate wave field with armor stability, Kobayashi et al. (1986) showed, based on analysis of forces acting on armor stones, that the commonly used stability number

could be dynamically represented by the one calculated from the threshold condition against sliding/rolling. Modified in this study, using the scaling relationships given previously, this number is given by

$$N_s = A \frac{H}{u_b^2} \left[\tan \phi \cos \alpha - \frac{u_b}{|u_b|} \left(B \frac{du_b}{dt} - \sin \alpha \right) \right], \quad (14)$$

$$A = \frac{2C_3^{2/3}}{C_2(C_D + C_L \tan \phi)}, \quad B = \frac{C_M}{s-1}, \quad s = \frac{\gamma_s}{\gamma_w},$$

in which u_b is the fluid velocity tangential to the slope, C_D, C_M, C_L are the drag, inertia and lift coefficients, respectively, and C_2, C_3 , , , are, respectively, area and volume coefficients of the stone, frictional angle of the stone, specific gravity of the stone and that of the water.

In this study, the same values for various coefficients in eq.(14) are adopted as in Kobayashi et al. (1986, 1987) except for C_L which is chosen to be 0.18. The value of 0.4 as used for some cases by Kobayashi et al. (1986, 1987) is close to the solution of Milne-Thomson (1960) for low Keulegan-Carpenter number flow and minor effect of wall proximity. These premises are apparently at odds with the present problem.

In coupling the BEM flow model with the stability model, special considerations are given to the fact that the Morison-type approach, on which eq.(14) is based, may be considered valid only when the depth of the flow is sufficiently large compared with the sizes of the stones. Since it is observed that a thin-water sheet trailing the down-running wave usually develops within a section near the shoreline, most obviously when the initial wave is relatively large, eq.(14) does not, and in fact should not be expected to, provide reasonable prediction of N_s . This difficulty is circumvented in this study by starting computing N_s from the location where the difference between the bed slope and the free surface slope becomes larger than 0.2, assuming this difference in slope increases monotonically within a certain distance from the shoreline at all times. This procedure, however, is found not necessary for waves of heights smaller than about 0.2 where no pronounced thin water sheet is observed.

3.RESULTS

Numerical experiments are run for solitary waves due to Boussinesq and Laitone on slopes steeper than 15° . The profile due to Boussinesq (1872) is given by

$$\eta = H \operatorname{sech}^2 \left\{ \left(\frac{3H}{4} \right)^{\frac{1}{2}} (x - ct) \right\}, \quad (15)$$

where

$$c = \sqrt{1 + H},$$

and the one due to Laitone (1960) is given by

$$\eta = H \operatorname{sech}^2[\sigma(x-ct)] \left\{ 1 - \frac{3}{4}H[1 - \operatorname{sech}^2\sigma(x-ct)] \right\} \tag{16}$$

where

$$c = 1 + \frac{1}{2}H - \frac{3}{20}H^2 + O(H^3),$$

$$\sigma = \sqrt{\frac{3}{4}H} \left(1 - \frac{5}{8}H \right) + O(H^{5/2}).$$

For eq.(14), we use $s = 2.71, C_2 = 0.9, C_3 = 0.66, C_D = 0.5, C_M = 1.5,$ and $C_L = 0.18.$

Fig.2 Sequences of free surface evolution during run-up (upper) and run-down (lower); $H=0.2, =15\%.$

Fig.2 shows typical sequences of the evolving free surface profiles during run-up and run-down of a wave of $H=0.2$ on a 15° slope. The deflected shape of the down-running wave with a thin tail near the shoreline when it approaches the still water line is clearly observed, which actually becomes more pronounced for higher waves.

Fig.3 Maximum run-up of two different solitary waves on a 25° slope compared with experimental data by Hall and Watts (1953).

Fig.3 presents the predicted maximum run-up on a 25° slope as compared with experimental data by Hall and Watts (1953). Fairly favorable agreement is achieved for both types of waves. The reflected wave formed after run-down is found to be around $3/4$ of the initial wave height. This reflected wave is observed to pass through the offshore open boundary with less than 3% increase in height and a phase speed agreeing well with the analytical value corresponding to its height. For waves higher than 0.38, backwash breaking is found to occur near the end of run-down, when fatal numerical instability occurs.

Computed stability numbers are compared with the experimental results by Ahrens (1975) where oscillatory waves are used. The reason for using this work for comparison is that no experimental work for the solitary wave has ever been done in this subject area. To seek a common reference parameter for comparison, we use an equivalent Iribarren number given by

$$\xi = \frac{\tan \alpha}{\left(\frac{H}{L_e}\right)^{\frac{1}{2}}}, \quad (17)$$

where L_e is the equivalent wave length defined by the length of the wave truncated at $\eta = 0.1\% H$ on both ends. Figs.4 and 5 present computed N_s as a function of ξ on 1:2.5 and 1:3.5 slopes, respectively. The trends of stability variation over the concerned

range of surf conditions are predicted satisfactorily with locations of minimum stability found at $2.0 < \xi < 3.0$ for cases tested. The value of minimum N_s , however, is somewhat underestimated in the case of 1:2.5 slope, which seems to be related to uncertainties in identifying regimes of applicability for a Morison-type approach in the present problem as mentioned earlier. For a particular wave, the minimum stability is always found to occur in the vicinity of the still water shoreline position during backwash.

Fig.4 Comparison of computed stability number with experimental data by Ahrens (1975) on a 1:2.5 slope.

Fig.5 Comparison of computed stability number with experimental data by Ahrens (1975) on a 1:3.5 slope.

4. CONCLUSIONS

The stability of armor units on a breakwater slope exposed to solitary waves can be favorably modelled using the wave field predicted by the procedure of boundary element method as presented in this study. No 'mild slope' assumption is needed.

The proposed schemes including inductive wave generation, Lagrangian shoreline condition and free surface regriding combined yield satisfactory results in run-up simulation. The Orlanski-type radiation condition also exhibits fair performance.

The formulation of stability number based on the Morison equation does not yield realistic results unless the local water depth is sufficiently larger than the characteristic stone size. The simple empirical criterion used in this study to exclude the region where the Morison-type approach does not apply yields reasonable results. Further study is needed to better determine regimes of applicability of the Morison-type approach in the present problem.

A reasonable range of lift coefficients of the armor stones should be close to the lower limit of the range used by Kobayashi et al. (1987), i.e. around 0.18.

5. ACKNOWLEDGEMENTS

Thanks are extended to Professors R.C. Ertekin, H. G. Loomis and J.A. Williams for helpful discussions. Financial support by the Hawaiian Natural Energy Institute, the Pacific Center for High Technology Research, and the National Science Foundation under Grant No. BCS-8958346 is also thankfully acknowledged.

1. Preface

Until now, offshore areas have rarely been utilized because of restrictions caused by waves. To utilize offshore areas more fully, it is necessary to develop technology for construction of offshore structures able to withstand large waves. To achieve this, C.E.R.I. of Hokkaido Development Bureau has carried out in situ offshore experiments to investigate structures in an area with large waves as part of studies funded by Funds for Science and Engineering Development: research on utilization of maritime zones by constructing offshore structures. This project has analysed data of wave forces against circular cylindrical members of offshore structures in a large wave area. This type of data has rarely been reported in the past.

2. Experimental structure and observation

The offshore experimental structure is 10mX5m and 18m high, and was constructed in 7.0m deep water off the Ohgon Cape at Rumoi in Hokkaido on the Japan Sea coast in 1984¹⁾.

Phot.1 shows the offshore experimental structure in winter, and Fig.1 shows the location of the omnidirectional wave force transducer, the ultrasonic wave gauge, the current meter, and the strain gauge.

The wave force transducer is shown in Phot.2, it was developed especially for this project and can measure the magnitude and direction of forces on cylindrical members (0.508m in diameter)²⁾. Fig.2 shows a sectional view of the wave force transducer.

Phot.2 Omnidirectional wave force transducer

Fig.2 Sectional view of wave force transducer

Wave induced forces were determined from the difference between the highest and the lowest shear forces obtained by measuring the strain along the axes of special alloy members at both the upper and lower ends of the wave force transducer.

Fig.3 shows the distribution of heights and periods of significant waves by the zero-down-cross method using data gathered in 1984-86. It shows some waves higher than 4 meters, and so the data can be used for wave force characteristics in the high Reynolds number range. The subject of the analyses are the largest 14 data sets (2,487 waves) of 48 sets from the winter of 1986: the waves are 2.47m - 4.52m and the periods 6.49sec - 9.64sec. Both total and local wave forces acting on the members were examined. Total wave forces were measured by the strain gauge set at the foot of the experimental structure in Fig.1. Local wave forces were measured by an omnidirectional wave force transducer set on a vertical circular cylindrical member at the center of the structure between 1.0m to 3.0m below the water.

Current velocities were measured by the current meter 2.0m under the water surface 2m from the wave force transducer perpendicular to the wave direction.

Fig.3 Distribution of heights and periods of significant waves by the zero-down-cross method

3. Drag coefficient and inertial force coefficient of vertical circular cylindrical members.

In general, wave forces acting on submerged cylindrical members can be calculated with Morrison's equation³⁾.

$$\frac{dF}{dz} = C_d \frac{\omega_o}{2g} Du|u| + C_m \frac{\omega_o \pi D^2}{4g} \frac{\partial u}{\partial t} \dots\dots\dots (1)$$

where, dF is the normal force action upon a length dz along the axis of member (tf); u is the water particle velocity acting normal to the member axis (m/s); Cd is the drag coefficient; Cm is the inertial force coefficient; D is the diameter of the member (m); ω_o is the weight of a unit volume of sea water (tf/m³); and g is the acceleration of gravity (m/s²)

The first term on the right side of Eq.(1) represents the drag force and the second the inertial force. The drag and inertial force coefficients are believed to be influenced by Reynolds number(uD/v), KC number(uT/D), and others. Widely deviating experimental data of these wave force coefficients have been reported, and data using Reynolds numbers in the range to 10⁶ are not adequate. There is also no standardized system for measuring wave force coefficients. This paper follows the procedure:

- ① Define each wave with the zero-up-cross time of the water surface-wave profile
- ② The direction of the resultant maximum wave force computed by combining the horizontal wave force components is to be considered the direction of each wave
- ③ The direction component of water particle velocity and its acceleration are derived for each wave
- ④ The Cd and Cm of each wave are derived by the least squares method
- ⑤ The Cd and Cm are corrected to restore peak values

When the residual sum of squares of measured and calculated wave forces is minimized in step ④, wave force coefficients can be given as:

$$C_d = \frac{2g}{\omega_o D} \frac{S_3 S_4 - S_5 S_2}{S_1 S_3 - S_2^2} \dots\dots\dots (2)$$

$$C_m = \frac{\omega_o \pi D^2}{4g} \frac{S_1 S_3 - S_2^2}{S_5 S_1 - S_2 S_4} \dots\dots\dots (3)$$

$$S_1 = \sum u_i^4, \quad S_2 = \sum (\partial u / \partial t)_i u_i |u_i|, \quad S_3 = \sum (\partial u / \partial t)_i^2 \dots\dots\dots$$

$$S_4 = \sum f_i u_i |u_i|, \quad S_5 = \sum f_i (\partial u / \partial t)_i \dots\dots\dots (4)$$

where, f_i and u_i shows the measured wave forces and water particle velocities at time i , and Σ means the sum total of the data of a wave at a particular time.

Fig.4 shows a time-series profile of representative wave forces calculated from measured wave forces and water particle velocities, and water particle accelerations and wave force coefficients calculated by the above equations. Despite its quasi-empirical nature Morrison's equation reproduces the wave force profile fairly accurately. However, since the above method is designed to compute wave force coefficients that on average agree to measured values, there is a danger that the peak values of wave forces - the most important in actual designs - will not always correctly correspond to the measured wave forces.

Fig.4 Time-series profile of measured and calculated wave forces

To observe this, a comparison of measured peak wave forces and computed peak wave forces of all analyzed data is made in Fig.5 where the relation between these two values is given by the least squares method. The results show that the calculated values tend to be only 87% of the measured values, and in the following, wave force coefficients are corrected by this factor (1/0.87).

Using the previous procedure, Figs.6 and 7 indicate the relation between the drag coefficient/inertia force coefficient of wave forces obtained by the omnidirectional wave force transducer, (effective measurement range above 0.07tf

(0.686kN)) and Reynolds number, using parameters derived from the KC numbers. The Reynolds and KC numbers are computed with the maximum water particle velocity of each wave.

Fig.5 Relation between peak values of measured and calculated wave forces

Fig.6 Relation between drag coefficient and Reynolds number

Fig.7 Relation between inertial force coefficient and Reynolds number

The omnidirectional wave force transducer in this experiment was painted to eliminate the growth of organisms, and none were found on the structure prior to the beginning of the measurements. Therefore, the data may be considered applicable for smooth circular cylindrical members.

As seen in Fig.7, there are correlations between wave height and period, and the Reynolds and KC numbers are related, which makes it difficult to determine the exact relation between wave force coefficients and the numbers. However it may be concluded that the drag coefficient will likely decrease with increases in Reynolds number, while the inertial force coefficient remains unaffected by Reynolds number. The dependence of the two wave force coefficients on the KC number is not shown explicitly. The drag coefficient becomes almost independent of Reynolds numbers above 7.0×10^5 . The average values of wave force coefficients of data in this range are $C_d = 0.60 \pm 0.17$ and $C_m = 1.23 \pm 0.34$ considerably less than the $C_d = 1.0$ and $C_m = 2.0$ commonly used.

Reported wave force coefficient measurements are given in Table 1^{4) 5) 6) 7)}. The results cannot simply be compared to these values because of the different Reynolds numbers involved, and the values in this study scatters less than other results. The data are relatively close to the results of Kim et al., but extend to higher Reynolds numbers.

Another point is that the drag coefficient in Kim et al. becomes constant at $Re > 2.0 \times 10^5$ ⁴⁾.

Table 1 Reported wave force coefficient measurements

Researcher	Re	KC	Cd	Cm
Kim	$1.5 \times 10^5 \sim 7.5 \times 10^5$	15 ~ 30	0.61 ± 0.15	1.20 ± 0.26
Bishop	$1.0 \times 10^5 \sim$		0.73	1.24
Yoshida	$2.5 \times 10^5 \sim 7.0 \times 10^5$	3 ~ 28	0.6 ± 1.8	1.7
Dean	$1.0 \times 10^4 \sim 1.0 \times 10^7$	10 ~ 50	0.5 ~ 1.2	1.33
Evan	$1.0 \times 10^5 \sim 5.0 \times 10^6$	10 ~ 80	0.58 ± 0.33	1.76 ± 1.06
Reid	$1.0 \times 10^5 \sim 2.0 \times 10^5$	10 ~ 20	0.53 ± 0.20	1.47 ± 0.36

4. Results of analyses of total wave force data

The values of the total wave force data measured by the strain gauges set at the foot of the experimental structure were compared with values computed by a three-dimensional static structural analysis program, and features of the wave induced forces were examined.

The experimental structure was analyzed by a structural analysis program for complex structures: ISAP-II of TOSBAC 600. Wave forces were calculated by Morrison's equation - wave direction designated by an arrow in Fig.1 - and water particle acceleration was determined by the small amplitude wave theory. Phase differences were not considered when computing wave forces because the structure is small compared with the wave length. Buoyancy acting against the members of the structure above the hydrostatic surface was also considered, buoyancy was applied to the entire cross section of the members on the assumption that the water level in the members was little affected by the waves. The range of wave forces and buoyancy was obtained from calculations of maximum wave heights ⁶⁾.

Fig.8 shows the relation between the measured axial forces and wave heights in six samples (1043 data) where the wave directions were relatively close to the calculations; the axial forces are the peak axial forces of each wave defined from the zero-up-cross time. The solid line (Fig.8) indicates axial force values computed by the typically used wave force coefficients - $C_d=1.0$ and $C_m=2.0$ - and the broken line presents values computed using the coefficients $C_d=0.6$ and $C_m=1.2$ obtained in the preceding section. In both cases, the wave period was assumed to be 10 seconds.

Fig.8 Relation between measured axial forces and wave height

The experimental structure has numerous horizontal members in addition to the vertical ones, and the calculated wave forces increase discontinuously with increases in wave height; however, the lines in Fig.8 are continuous because specific wave heights were chosen for the computation and the results were smoothed to a continuous curved line. This curve is approximately in proportion to the cube of the wave height.

Although the measured values are relatively dispersed as indicated in Fig.8, they tend to correspond well to the calculated values of the three-dimensional static structural analysis. However, even the values calculated with the coefficients $C_d=0.6$ and $C_m=1.2$ are greater than the measured values, especially at large wave heights. According to this figure, the present standard coefficient values ($C_d=1.0$ and $C_m=2.0$) are clearly in a safe range.

Furthermore, it was observed that the shock wave forces on structural members in this experiment were far larger than Morrison's wave forces above the hydrostatic plane⁹; however, no effect of these shock wave forces were found in the total wave force values.

Apparently, this resulted from the shock waves being so localized that there were phase differences among the members, and also because the duration of shock waves is so short that the structure as a whole, was unable to respond.

In the present project the experimental offshore structure was set in shallower water than actual offshore structures. However more members need not be considered when examining the overall stability of an actual offshore structure, except in particular cases.

5. Summary

This report examines features of wave induced forces on circular cylindrical structural members with data from an offshore experimental structure. The main results of the project are as follows:

① Data of wave induced forces on circular cylindrical members in an offshore area were obtained: some of the waves were large and in the high Reynolds number range. Wave induced forces on the members were examined for both total and local wave forces. Local wave forces were measured by an omnidirectional wave force transducer developed for this project.

② On the basis of wave forces (local wave forces) induced on the circular cylindrical members and the simultaneously measured water particle velocity data, the drag coefficient and inertial force coefficient were computed as $C_d=0.6\pm 0.17$ and $C_m=1.23\pm 0.34$, in the Reynolds numbers range above 7.0×10^5 . The drag coefficient decreases with increases in the Reynolds number, whereas the inertial force coefficient is unaffected by fluctuations in Reynolds number.

③ Measured values of total wave forces tended to agree with the three-dimensional static structural analysis calculations. However, the calculated values, even with wave force coefficients of $C_d=0.6$ and $C_m=1.2$, became larger than the measured values. There was no effect of shock wave forces in the measured values

CHAPTER 97

The Effect of Seawalls on Long-Term Shoreline Change Rates for the Southern Virginia Ocean Coastline

David R. Basco¹

Abstract

This paper examines the relationship between the off shore bathymetry, resulting wave climate, shore boundary conditions (i.e., seawalled versus dune/beach sections) and the shoreline response as represented by long-term shoreline change rates over 120 years for the southern Virginia ocean coastline in the United States. Along the tourist area of the City of Virginia Beach, the data supports the conclusion that a seawall's presence for over 50 years has produced no significant increase in the recession rate. The highest recession rate (3m/yr) occurs at the Sandbridge sector further south. Some now claim that the beach width is narrowing at Sandbridge as a result of recent seawall construction. This allegation completely ignores the root cause of the problem which is shown in this paper to be the steep offshore bathymetry and high wave energy in this region. If we neglect the offshore boundary conditions when making field studies of "hardfacing" versus dune/beach sections, we can reach completely erroneous results.

1.0 Introduction

Coastlines are either stable, accreting or receding when viewed on a long term basis relative to some *fixed* reference. For example, the City of Virginia Beach along the southern Virginia ocean coastline (Fig. 1) exhibits all three shoreline trends as described in detail below. There are numerous reasons for coastline recession, both natural and human-induced. Some form of shore protection

¹Professor of Civil Engineering and Director of the Coastal Engineering Institute, Old Dominion University, Norfolk, VA 23529.

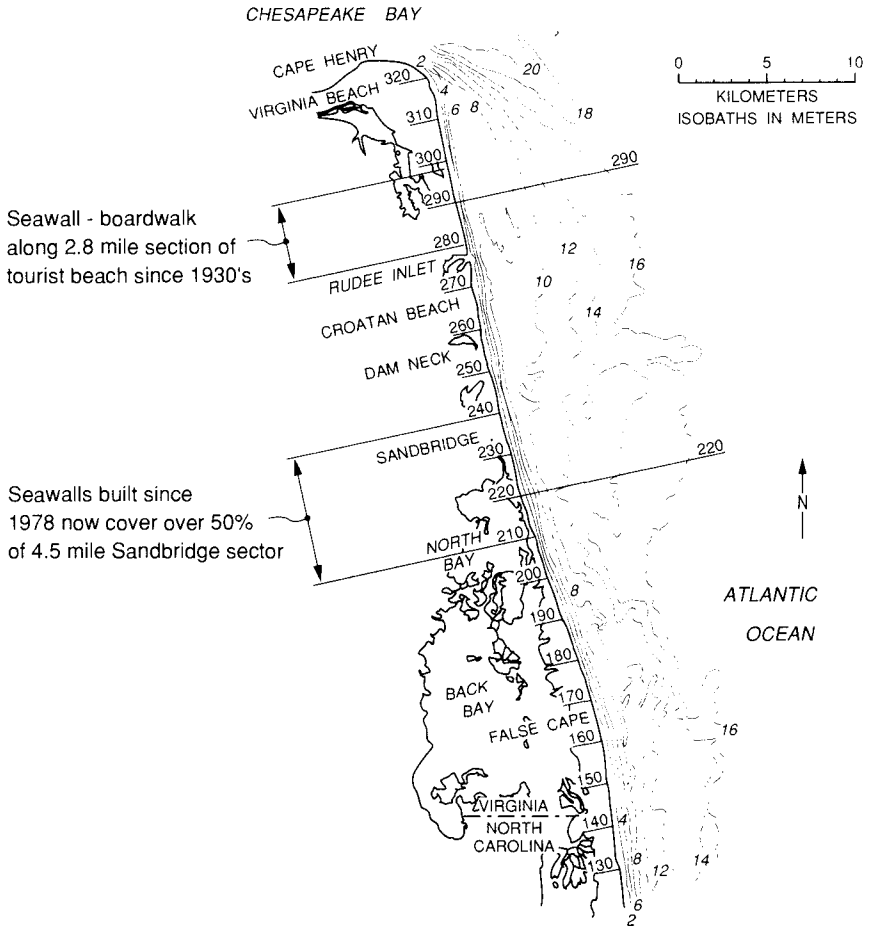

Fig. 1 Coastal Area and Bathymetry of the Study Region.
 (adapted from Wright et al., 1987)

measure is often undertaken when the shoreline recession threatens permanent resources (roads, bridges, buildings, etc.) and if the benefits exceed the costs over the design life of the project.

Three engineering options exist for shore protection: (1) natural defenses including strengthening dunes and beach nourishment; (2) sand trapping systems to widen beaches; and (3) coastal armoring; combinations are also possible. Coastal armoring includes seawalls, bulkheads and revetments, but all such coastal armoring structures will be referred to as "seawalls". Seawalls are usually constructed along developed shorelines experiencing a recessional trend and subject to storm-induced water level rise with accompanying wave energy. In many cases, recreational beaches are also present.

The degree to which a seawall affects the adjacent beach is the focus of much recent attention (e.g., Kraus and Pilkey, 1989, editors). Various allegations on the adverse effects of seawalls on beaches have been made and claimed as common knowledge (without reference). Statements such as "...the seawalls destroyed the beach"; "...bulkheads stir up wave action and increase erosion"; "...costly seawalls and jetties actually increase erosion"; "...bulkheading (does) more damage than it prevents"; "...bulkheads hasten the erosion of surrounding beaches"; etc. have been attributed to "coastal scientists". The most sweeping allegation of all is the claim that "...seawalls actually increase erosion and destroy the beach" (Pilkey and Wright, 1988). These allegations stem from an over emphasis on the land boundary conditions (i.e., "hardfacing" -vs- dune/beach "soft" boundaries) and consequently the almost total neglect of the offshore boundary conditions when discussing shoreline change. These allegations also stem from the "migration barrier beach paradigm" as discussed below.

In this paper, we examine the relationship between the offshore bathymetry, nearshore wave climate, type of landward boundary, and shoreline response as represented by long-term shoreline change rates based on over 127 years of survey records for the southern Virginia ocean coastline. Shoreline change rate data both before and after seawall construction are examined to determine if there is a discernable increase in long-term erosion rate in front of the seawalls. Shorter term variability and changes measured immediately after storms are also of concern but are not considered in this paper.

2.0 Boundary Conditions At Virginia Beach, Virginia

2.1 Offshore Boundary Conditions

The southern Virginia ocean coastline (Fig. 1) is all within the political jurisdiction of the City of Virginia Beach. It extends over 26 miles from Cape Henry at the north on the lower edge of the entrance to the Chesapeake Bay to the border of Virginia and North Carolina (latitude $36^{\circ} 33'$).

2.11 Bathymetry. A three-dimensional, perspective plot of the nearshore bathymetry for over 6000m seaward to depths beyond -15m (MSL) is presented as Fig. 2. The offshore bathymetry is irregular. A relatively broad, flat region is found adjacent to the tourist part of the City (labeled Virginia Beach) resulting in the -9m contour almost 4000m seaward. This -9m depth contour gradually moves closer to shore as the beach profile steepens further south. At the section labeled Sandbridge (a subdivision of the City) the profile is the steepest with -9m being found only about 1200m offshore. Continuing further south, the profile again flattens and a large, permanent offshore bar feature is found at False Cape. Putting sections A & B together reveals the continued variability in nearshore bathymetry along the study region.

The -9m depth is approximately the "closure depth" for the existing wave climate and sand gain size in this area. Beach profiles in the northern end (e.g. Section 290) are flatter and those at Sandbridge (e.g. Section 220) are steeper than the equilibrium shape for the representative sand grain size. Tidal currents through the entrance to Chesapeake Bay are an important factor in shaping local bathymetry as is the existing wave climate and its interaction with the tidal currents.

2.12 Wave Height Variation. The figures above are adapted from a recent report by the Virginia Institute of Marine Science (Wright et al., 1987) in which a computer model was used to transform ocean waves moving toward the shoreline from the northeast, east and southeasterly directions. The RCPWAVE code (Ebersole et al., 1986) was modified to include bottom friction, if desired. Fig. 3 is one example (Wright et al., 1987, p.61) for a deep water wave height of 2.1m and 8 sec period from the northeast and shows the three-dimensional perspective plot of wave height variation everywhere in the computational domain (60 x 160 grid with $\Delta x=100m$ offshore and $\Delta y=250m$ alongshore). The trends along the beach for

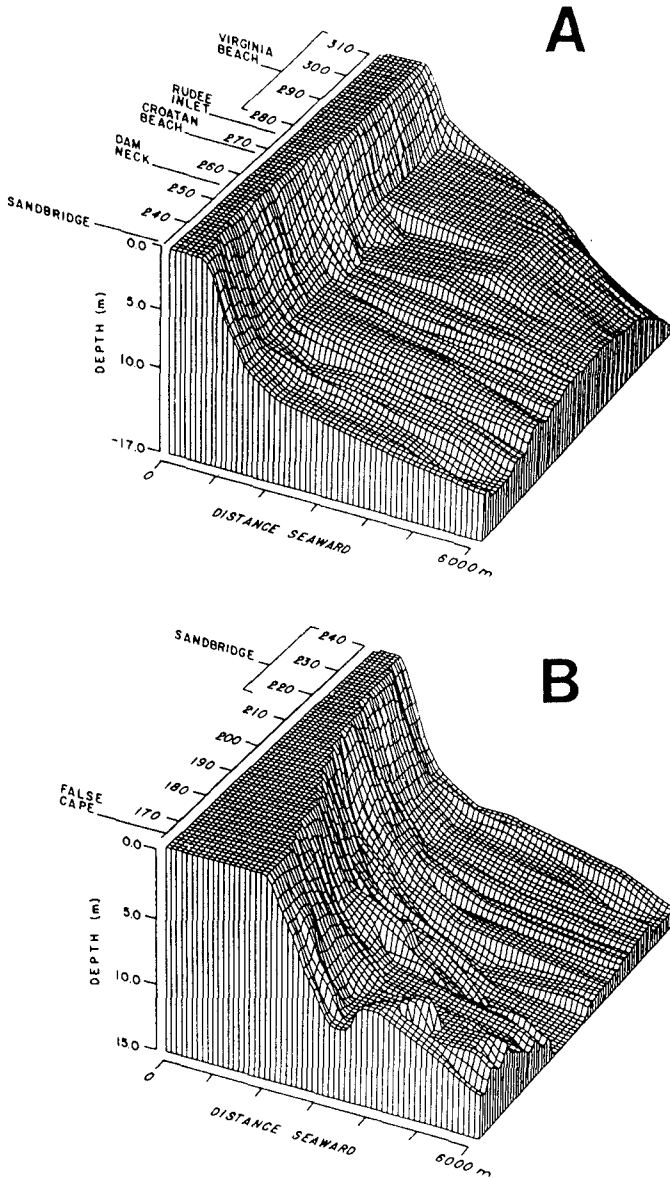

Fig. 2 The Study Region Bathymetry in 3-D Perspective and Split into a Northern (A) and Southern (B) Sector (adapted from Wright et al., 1987).

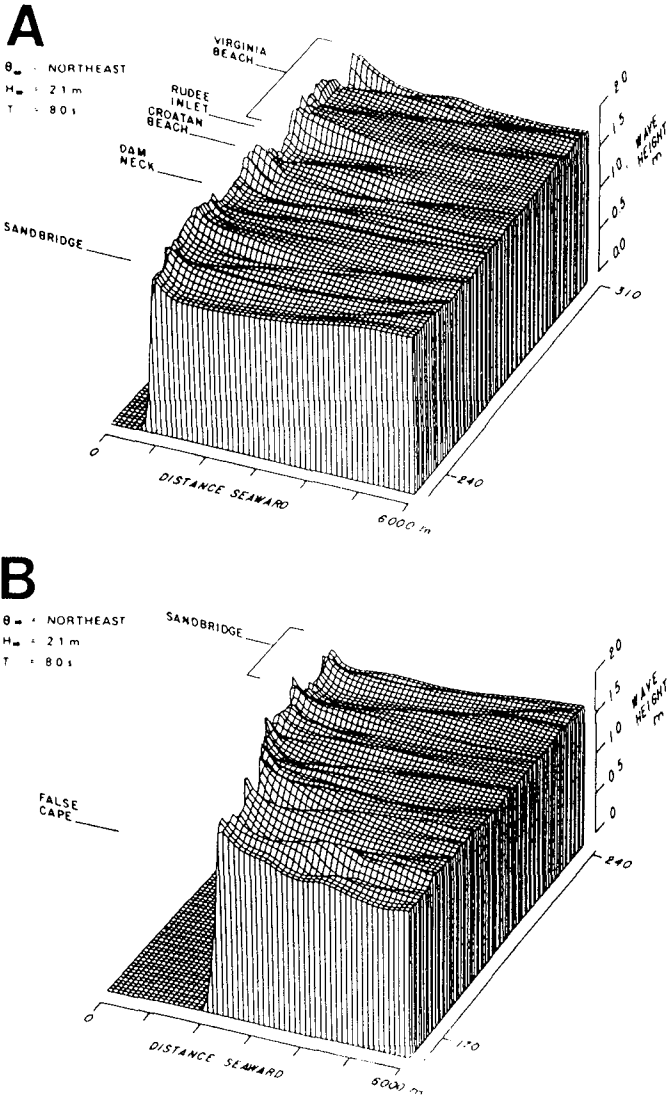

Fig. 3 Spatial Wave Height Variations for the Study Region As Predicted by the RCPWAVE Computer Code With No Bottom Friction. The Wave Conditions Are for a Typical Northeaster (adapted from Wright et al., 1987).

breaking wave height vary considerably but generally show H_b increasing along the Sandbridge sector relative to the northern and southern sectors. These results are with no bottom friction in the model.

Wright et al. (1987) considered the possibility for 55 different wave climate combinations (deepwater height, period, dominant direction) as measured in 1982 at the Corps of Engineers, Field Research Facility pier some 65 miles south of Virginia Beach. The computer model was run for these 55 cases, breaking wave height variations calculated along the coastline and then averaged together. The overall average breaking wave height calculated for the entire study region was 0.58m in 1982. The relative variation of breaking wave height along the shoreline from north(top) to south(bottom) when compared with the overall average is plotted in Fig. 4(rightside). These trends in breaker wave height are consistent with the variation in bathymetry. Higher wave energy at Sandbridge is expected because the deeper, offshore contours are closer to shore at Sandbridge.

2.2 Landward Boundary Conditions

The landward side of the shoreline consists of a sandy beach with natural and artificially created dunes, a small, stabilized tidal inlet and seawalls (with boardwalk) along some regions.

2.21 Seawalled Sections. Seawalls are found in two areas of Virginia Beach as shown in Fig. 1. Along the northern, tourist/resort beach, a seawall/boardwalk structure exists as illustrated in the Corps, Shore Protection Manual (1984), Vol II, p6-7) between Rudee Inlet and 49th Street. Private property seawalls further north extend the length of seawalled beach to about 2.8 miles. Some type of "hardfacing" structure with boardwalk has existed in this location since the 1930's*. Over 3 million people use this beach area during the three primary summer months of the tourist season.

Further south at Sandbridge, seawall construction began in 1978 to protect private property of individual lot owners as year-around residents or renters. Construction

*An 1887 photograph of the Princess Anne Hotel at the tourist beach location showed an extensive length of vertical pile seawall about 5-6ft in elevation above the beach face.

Fig. 4 Composite of Shoreline Change Rates(left), Bathymetry(center) and Breaking Wave Heights(right) and Their Variation Along the 25-mile Atlantic Ocean Coastline of the City of Virginia Beach, Virginia

has accelerated in recent years so that presently, over 50% of the 4.5 mile stretch has vertical, sheet-pile (steel, timber, concrete) bulkhead protection.

2.22 Rudee Inlet. An extremely small water body (Lakes' Rudee and Wesley) is open to the Atlantic Ocean through Rudee Inlet which was fixed in position by two, very short, rock jetties in 1953. Inlet bypassing from south to north and channel maintenance by fixed and floating dredging plant (hydraulic cutterhead and jet-pump systems) occurs each year averaging about 100,000cy per year. The short length of the jetties permits natural inlet bypassing in both directions and results in an accretional beach for less than 500 ft on both sides of the inlet. Consequently, these natural and artificial sand transport systems and the small scale of the tidal flows and jetties produce only local, minor changes along the landward boundary at this location.

2.23 Beach Renourishment. Since 1951, over 10.6 million cy of sandy material (including Rudee Inlet bypassing) has been deposited on the resort strip between Rudee Inlet and about 45th street. The average amount per year (0.27 M cy) is about 5 percent of the total active sand volume (envelope between erosional and accretioned profiles out to the closure depth) in this region. Net sediment transport to the north has changed the shoreline position in this region over the last 40 years as discussed below. Most references consider Sandbridge a nodal point for net sediment transport direction.

3.0 Shoreline Movements

3.1 Long-Term Average Shoreline Change Rates

3.11 Cartographic Information. Federal government surveys and resulting cartographic information has been used by Everts et al., (1983) to calculate the long-term average shoreline change rates in m/yr for 122 years of data as shown in Fig. 4 (far left side). The vertical scale (latitude) coincides with the shoreline location with Cape Henry at the top and the Virginia/NC border at the bottom. Accretion is to the right of zero and recession rates are shown to the left of zero (stable shoreline position) on the horizontal axis.

For a 67 year period between 1858-1925, the solid line reveals some accretion in the far north, a slightly receding shoreline along the tourist beach to Rudee Inlet, considerably recession exceeding 3 m/yr at Sandbridge and then the reverse trends with considerable

accretion (2m/yr) further south at False Cape and beyond the border.

For the next 55 year averaging period (1925-1980) as shown by the dashed line, the trends are very similar or less extreme in all locations. Further refinement by Everts et al., (1983) for the north end above Rudee Inlet using 10-15 years averaging intervals between 1925-1980 reveals increasing accretional rates with time and reflects the last 40 years of beach renourishment with net northerly drift.

3.12 Aerial Photographs. Dolan(1985) used historical aerial photographs between 1937 and 1984 (47 years) to determine long-term average change rates along this same coastline. These results are shown as the fine dotted line in Fig. 4 (far left side). The overall patterns are generally similar. Additional accretional reaches below Rudee Inlet and above Sandbridge may be due to some southerly movement of renourishment materials since 1952. The location and magnitude of the highest recessional rates at Sandbridge are confirmed by these results. The greatest differences in change rates between the mapped and photographically deduced data are found in the False Cape region. No explanation is offered for these discrepancies.

3.2 Short Term and Storm Effects

The results above are for average shoreline movement over very long time intervals. Shorter term "average" variability, seasonal changes and those occurring immediately after storms are also of concern. A study has recently begun at Sandbridge with the goal to investigate shorter term and storm term related effects of seawalls and beaches (Basco, 1990a).

4.0 Boundary Conditions and Shoreline Response

4.1 Virginia Beach, Virginia

Fig. 4 compares the (i)variability of offshore bathymetry and seawall locations (center)(ii)the variability in breaking wave height (far right) and the (iii)variability of long-term shoreline change rates (far left) on the same vertical scale. We must consider both the offshore and the landward boundary conditions when discussing shoreline change. For Virginia Beach, Virginia there exists a strong cause-effect relationship between offshore bathymetry (i.e., profile steepness), breaking wave height variation, and long-term shoreline response.

For the tourist section above Rudee Inlet, a comparison of pre-seawall recession rates (67 years, 1858-1925) and post-seawall recession rates (55 yrs, 1925-1980) allows us the opportunity to tentatively conclude that a seawall/boardwalk for over 50 years has produced no significant change in long term shoreline trends. This conclusion admits some shorter term variability in the data, accuracy of rate estimates and beach renourishment.

At Sandbridge, seawalls have only existed for a relatively short time period. About 90% of the total coverage (2.3 miles) had been constructed since 1986. One thing is clear, however. Seawalls are not responsible for over 130 years of steady shoreline recession of about 3m/yr. To argue now that the beach width is narrowing at Sandbridge as a result of the recent acceleration of seawall construction is to completely ignore the root cause of the problem.

4.2 General

Attempts to develop generalized boundary conditions landward, seaward and along the bottom that influence shoreline position and adjacent subaerial beach response are underway. Weggel has suggested a classification system (Weggel, 1988, p.36) involving six seawall "types" which depend on the location of the seawall with respect to the shoreline. During storm surge events on some coasts, all six "types" or locations could be realized when variable water levels are experienced.

The subsurface boundary is only of recent interest. Drain pipes to artificially lower the water table have produced stable or accretional shorelines in some locations that were previously recessional. More study is needed of the local water table effects on shoreline change rates.

5.0 Barrier Beaches and Adjacent Back Bay Systems

5.1 Barrier Beach Migration Paradigm

Barrier beaches are nature's mechanism for protecting the bays, lagoons, and estuaries that lie behind them. The reduced wave energy environment permits the retention of cohesive sediments and grasses to survive in the tidal marsh areas. Since the 1950's, coastal geologists have done a outstanding job of explaining the migrating nature of barrier beach systems. These educational efforts have influenced public policy regarding development on migrating barrier islands. In short, the beach migration paradigm says:

'Let the barriers migrate landward. All efforts to stabilize migration are "economically unsound" in the long run when *only* the value of property built on the barrier is considered. The government should not subsidize an "economically unsound" policy'.

The first road built on a migrating barrier island becomes a fixed reference line to measure shoreline movements. Barriers migrating landward (transgression) create recessional shoreline movements. Simply put, the distance from the shoreline to the reference line (e.g. road centerline) decreases each year. Efforts to maintain the road at its fixed position result in shrinking beach widths when the road gets close enough to the shoreline. Is the road "... increasing erosion and destroying the beach"?

The presence of the road permits easy access by car, development for commercial, residential and recreational use and when economical, seawall construction to protect upland resources including public facilities. The distance from the shoreline to the seawall (new reference line) continues to decrease each year. Is the "... seawall increasing erosion and destroying the beach"?

As shown in this paper, some coastlines are receding at some locations due to offshore boundary conditions causing wave energy focusing and excess erosional stress. Not all coastlines are protected by barrier islands. And, as conclude by Leatherman, 1988 (p.63):

" Overwash is *not* the dominant process by which *most* barriers move landward since the amount of sediment transported by this means is too small. Inlet formation, when tidal currents cut a channel below sea level, moves far greater quantities of sediment into a lagoon over the long term and is the major process for barrier migration" (p.63).

It is thus clear to the writer that much blame placed on seawalls for shrinking beach widths and disappearing beaches is ill-founded.

5.2 Loss of Tidal Marshes in Back Bay Systems

We need to consider the barrier island *and* the estuarine-bay-lagoon-system behind the migrating island as an

integrated whole. Since the 1950's a wetlands value paradigm for public policy has evolved that says in short:

'America's wetlands are diminishing. Alterations must be monitored and any losses mitigated to conserve existing wetlands. The government is opposed to all destruction of coastal marshes.'

Basco (1990b) discusses the conflict produced by migrating barrier islands that shrink wetlands and calls for an expanded, elevated and shifted new paradigm for public policy decisions that includes the total value of what's behind and on the moving barrier islands in the coastal zone.

6.0 Conclusions

No discernable increase in long-term average shoreline change rate has occurred over a 2.8 mile stretch of Virginia Beach when considering data prior to seawall construction (1858-1925) and in subsequent years (1925-1980) when seawalls have existed. The long-term average change rate in this tourist/resort strip area of the city is about 0.4m/yr recession.

At Sandbridge, fourteen miles south, the 127 year data average (all sources) is about 3m/yr recession. This is attributed to offshore boundary conditions producing an excess erosional stress and a nodal point for sediment transport at this location. Recent seawall construction at Sandbridge (since 1978) provides a new reference line to measure shrinking distances from the shoreline to the seawall. The presence of the seawall is not responsible for a long-term average shoreline change rate of -3m/yr. Only long-term data at this location will provide the necessary evidence to determine if the walls create a recession rate exceeding -3m/yr. Little is known about the proper averaging time necessary to remove short-term variability from the long-term trend.

If we neglect the offshore boundary conditions when making field studies of "hardfacing" sections of coastlines versus "soft" sections and erosion rates, we can reach completely misleading results. As a positive first step toward understanding how seawalls and beaches interact, the science and coastal engineering community must insist upon more complete documentation of field studies when reported in the literature and at conference proceedings.

CHAPTER 98

ROCK SLOPES UNDER IRREGULAR WAVE ATTACK

Nobuhisa Kobayashi¹, Andojo Wurjanto², and Daniel T. Cox³

ABSTRACT

The numerical model that was shown to be in fair agreement with six test runs of available data on the stability of rock units under irregular wave attack is used to examine the critical incident wave profile associated with the minimum rock stability for each run. The minimum rock stability computed for the runs with dominant plunging waves on gentler slopes is caused by the large wave with the maximum crest elevation during its uprush on the slope. The minimum rock stability computed for the runs with dominant surging waves on steeper slopes is caused by the downrushing water with high velocities resulted from a large zero-upcrossing wave with a high crest followed by a deep trough. In addition, a simplified model is proposed to predict the eroded area due to the movement and dislodgement of rock units using the probability of armor movement computed by the numerical model. This model is shown to be in qualitative agreement with the empirical formula of Van der Meer (1988).

INTRODUCTION

Kobayashi and Wurjanto (1989a) synthesized their numerical models and presented a computer program called IBREAK, which may be used for the design of rough or smooth impermeable coastal structures of arbitrary geometry against normally incident waves. Kobayashi and Wurjanto (1989c) showed that IBREAK could be calibrated and applied to predict the hydrodynamic forces and sliding motion of dolos units at the Crescent City breakwater. Kobayashi, Cox and Wurjanto (1990) conducted irregular wave tests and showed that IBREAK could be extended to predict irregular wave reflection and runup on a 1:3 rough impermeable slope. On the other hand, Kobayashi and Wurjanto (1989b, 1990) extended IBREAK to predict the flow and armor response on a rough permeable slope as well as the flow in a thin permeable underlayer. Kobayashi, Wurjanto and Cox (1990) applied the extended numerical model and showed that the computed critical stability number for initiation of rock movement under the computed irregular wave motion was in good agreement with the stability number corresponding to the start of damage measured by Van der Meer (1988).

In this paper, the temporal and spatial variations of the stability of rock units computed by Kobayashi, Wurjanto and Cox (1990) are analyzed in detail to examine what wave conditions may cause the minimum stability of rock units. Gunbak and Bruun (1979) described the various sequences of waves which may cause severe conditions on a breakwater. Their descriptions were qualitative since it is very difficult to measure the flow and armor response simultaneously.

COMPARISON BETWEEN MEASURED AND COMPUTED STABILITY NUMBERS

In the following, the comparison made by Kobayashi, Wurjanto and Cox (1990) is summarized. They expressed the hydraulic stability condition against sliding or rolling of an armor unit on a rough permeable slope in the form

$$N_s = H'(s - 1)^{-1}(\rho s/W')^{1/3} \leq N_R(t, x) \quad (1)$$

where N_s = stability number; H' = incident wave height used for the normalization of dimensional variables indicated by the prime; s = specific density of the armor unit; ρ = fluid density; W' = median mass of the armor units; and N_R = armor stability function. The dimensionless function N_R varies with the normalized time, $t = t'/T'$, and the normalized horizontal distance from the toe of the slope, $x = x'/[T'(gH')^{1/2}]$, where T' = incident wave period used for the normalization; and g = gravitational acceleration. The expression of N_R as a function of the normalized fluid velocity and acceleration was given in the paper of Kobayashi and Wurjanto (1990) where the input parameters for the computation of the armor stability were specified.

Computation was made for six test runs selected from the test results with the dimensionless damage level, $S=2$, and the number of incident waves, $N = 1000$, listed in Appendix II of the thesis of Van der Meer (1988). These runs corresponded to the start of damage. The incident irregular waves for the six runs were generated using the Pierson-Moskowitz spectrum. The significant wave height, H'_s , and the average period of the zero upcrossings, T'_m , of the incident wave train were used by Van der Meer to characterize the incident irregular waves. As a result, use was made of $H' = H'_s$ and $T' = T'_m$ for the normalization of the dimensional variables. The normalized incident wave train, $\eta_i(t) = \eta'_i/H'$, at the toe of the $1 : \cot \theta'$ slope required as input to the numerical model was generated numerically for the specified spectral density with assumed random phases. Since different sets of the random phases yield different temporal variations of $\eta_i(t)$, the incident irregular wave train specified for each run was not the same as that generated in a wave flume by Van der Meer (1988). In order to reduce the computation time, the duration of the computation was limited to $0 \leq t \leq 256$, corresponding to $N = 256$ instead of $N = 1000$.

Table 1 lists the values of $\cot \theta'$, $H' = H'_s$, $T' = T'_m$, $\xi = T' \tan \theta' / (2\pi H' / g)^{1/2}$ and N_s for each of the six test runs, where ξ = surf similarity parameter based on H'_s and T'_m . The six runs with $\xi = 1.72 - 6.88$ were selected to represent dominant breaker types of plunging, collapsing and surging waves on uniform slopes. Runs R2a and R2b corresponded to run R2 and were based on the same spectral density with given values of H'_s and T'_m . The time series $\eta_i(t)$ for runs R2a and R2b were generated numerically using different sets of the random phases.

Table 1 also lists the computed value of the critical stability number N_{sc} for each run. The value of N_{sc} for each run was taken as the minimum value

Table 1: Six Test Runs Compared with Numerical Model

Run No.	$\cot \theta'$	H' (cm)	T' (sec)	ξ	Measured N_s	Computed N_{sc}
R1	6	10.09	2.63	1.72	1.72	1.56
R2a	6	7.75	3.15	2.36	1.32	1.75
R2b	6	7.75	3.15	2.36	1.32	1.63
R3	4	8.16	3.22	3.52	1.39	1.15
R4	3	8.92	3.13	4.37	1.52	1.36
R5	2	7.98	2.69	5.95	1.36	1.01
R6	2	7.98	3.11	6.88	1.36	1.47

of $N_R(t, x)$ for the ranges of $x \geq 0$ and $8 \leq t \leq 256$ where the normalized horizontal coordinate x was taken to be positive landward with $x = 0$ at the toe of the slope and the duration $0 \leq t < 8$ was excluded to account for the initial transient waves in the computation starting from the initial conditions of no wave action in the region $x \geq 0$ at $t = 0$. The computed critical stability number N_{sc} and the measured stability number N_s are in fair agreement as shown in Table 1 where the values of N_{sc}/N_s are in the range 0.74-1.33. The small difference between the computed values of N_{sc} for runs R2a and R2b indicates the variability caused by the random phases, although a much larger number of simulated runs are required to perform a statistical analysis of the variability. The comparison between N_s and N_{sc} shown in Table 1 is not really rigorous because of the inherent differences between these stability numbers as discussed by Kobayashi, Wurjanto and Cox (1990).

WAVE CONDITIONS FOR CRITICAL ARMOR STABILITY

The wave conditions corresponding to the computed minimum stability of rock units for each run are examined in this paper to identify the wave conditions which are critical to the stability of rock units. In the following, runs R1 and R4 may be regarded as representative runs for dominant plunging and surging waves, respectively, whereas run R3 happens to include an exceptionally large wave.

The free surface displacement above the still water level (SWL) and the depth-averaged horizontal fluid velocity are normalized as $\eta = \eta'/H'$ and $u = u'/(gH')^{1/2}$, respectively, where u is taken to be positive landward. Fig. 1 shows the computed variations of η , u and N_R with respect to x at the time, $t = t_{sc}$, when the minimum value of N_R in the range $x \geq 0$ corresponds to the critical stability number N_{sc} . The values of t_{sc} for runs R1, R3 and R4 are 164.75, 156.38 and 161.55, respectively. The shaded area shown in the figure for η corresponds to the permeable underlayer for each test where the numerical model is presently limited to the case of a thin permeable underlayer (Kobayashi and Wurjanto, 1990). Fig. 1 also shows the computed variation of the local stability number N_{sx} with respect to x where N_{sx} was defined as the minimum value of $N_R(t, x)$ at the specified location during $8 \leq t \leq 256$. The minimum value of N_{sx} with respect to x equals the critical stability number N_{sc} .

The critical stability number for run R1 with $\xi = 1.72$ occurs slightly behind the steep front of the uprushing water with large upslope velocities and accel-

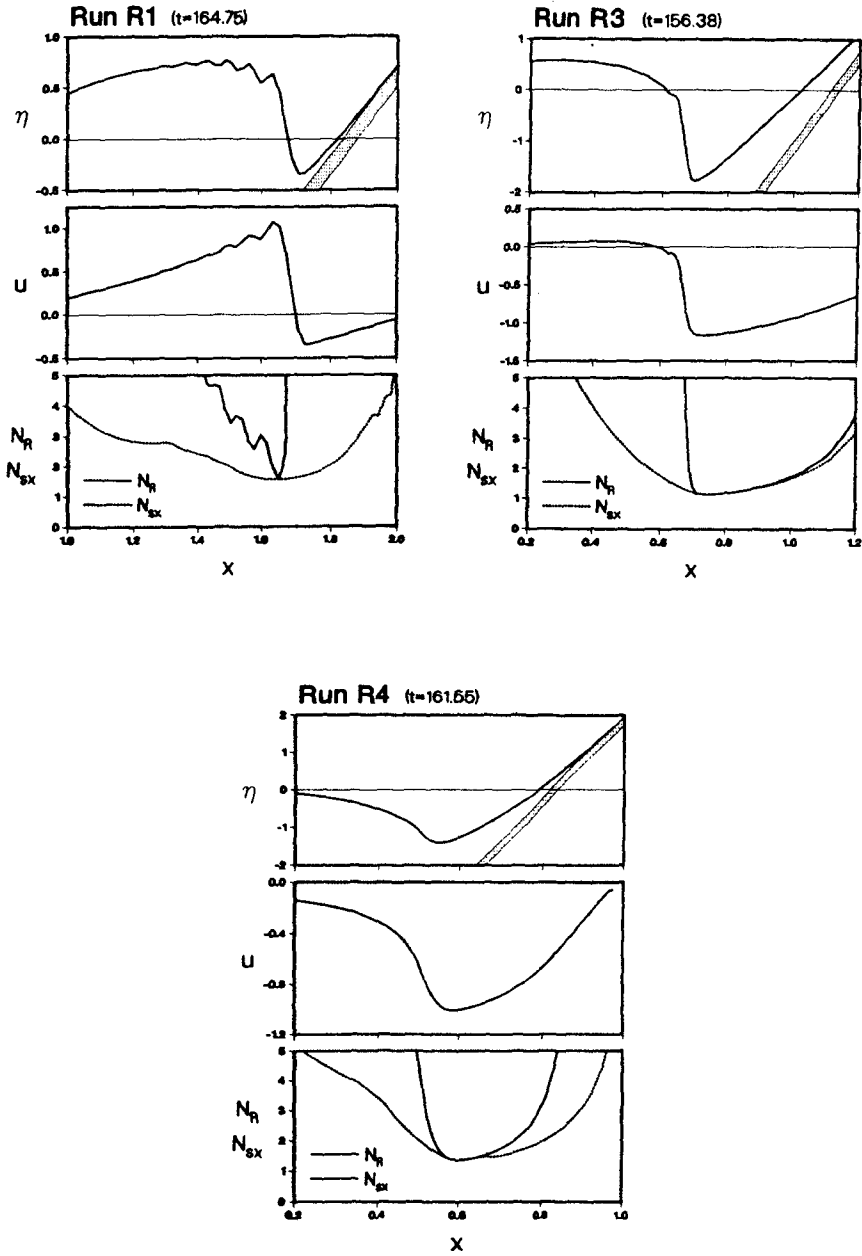

Figure 1: Variations of η , u and N_R with Respect to x at Time of Minimum Stability for Runs 1, 3 and 4

Figure 2: Definition Sketch for Critical Incident Wave Profile

erations. The local stability number in the range $1.5 \leq x \leq 1.9$ is computed to occur when this steep front moves upslope. On the other hand, the critical stability number for run R4 with $\xi = 4.37$ is caused by the downrushing water with large downslope velocities. For the exceptional case of run R3, the downrushing water flows extremely deep below SWL and encounters the uprushing water. The corresponding incident wave profile for run R3 will be shown to exhibit a very high crest followed by a very deep trough. This is one of the dangerous wave conditions identified by Gunbak and Bruun (1979).

The incident wave profile associated with the critical stability number N_{sc} for each run is examined to identify the incident wave profiles which may cause the critical uprushing or downrushing flow on uniform slopes. Fig. 2 shows the incident wave profile $\eta_i(t)$ at the toe of the slope normalized by the zero-upcrossing significant wave height H'_s slightly before the time $t = t_{sc}$ when $N_R(t, x) = N_{sc}$ at the certain location on the slope. The crest elevation η_c above SWL associated with the critical incident wave profile is obtained. The trough elevations η_{td} and η_{tu} adjacent to the crest elevation η_c are then found using the zero-downcrossing and zero-upcrossing methods, respectively. The corresponding wave heights H_d and H_u are given by $H_d = (\eta_c - \eta_{td})$ and $H_u = (\eta_c - \eta_{tu})$.

The values of η_c , η_{td} and η_{tu} for each run are listed in Table 2. These values are compared with the maximum crest elevation η_{cm} and the minimum trough elevation η_{tm} for $\eta_i(t)$ during $0 \leq t \leq 256$. Table 2 shows that $\eta_c = \eta_{cm}$ for runs R1, R2a, R2b and R3 while $\eta_{tu} = \eta_{tm}$ for runs R3 and R4. For runs R5 and R6, η_c is somewhat smaller than η_{cm} and η_{tu} is somewhat larger than η_{tm} .

Table 3 lists the values of H_d , T_d , H_u and T_u for each run where T_d and T_u are the zero-downcrossing and zero-upcrossing periods, respectively, of the individual wave whose crest elevation is η_c . The wave periods are normalized by the average zero-upcrossing period T'_m . Table 3 also lists the ranks of H_d and H_u among the 256 zero-downcrossing and zero-upcrossing individual wave heights, respectively, which are ranked in the descending order. Table 3 suggests that the critical incident wave profile is more related to the zero-upcrossing wave than the zero-downcrossing wave for runs R4, R5 and R6. The zero-upcrossing wave with $\eta_c = 1.052$, $\eta_{tu} = -1.126$ and $H_u = 2.178$ for run R3 appears to be exceptional, although the computed critical stability number N_{sc} for run R3 listed in Table 1 is not exceptionally small.

Table 2: Crest and Trough Elevations of Critical Wave Profile

Run	Crest		Trough		
No.	η_c	η_{cm}	η_{td}	η_{tu}	η_{tm}
R1	0.905	0.905	-0.527	-0.669	-0.934
R2a	0.822	0.822	-0.602	-0.459	-0.833
R2b	0.969	0.969	-0.877	-0.648	-0.933
R3	1.052	1.052	-0.673	-1.126	-1.126

R6	1.219	17	1.066	1.484	4	1.235

Figs. 3-5 show the temporal variations of $\eta_i(t)$ and $Z_r(t)$ in the vicinity of $t = t_{sc}$ for runs R1, R3 and R4, respectively, where $Z_r = Z'_r/H'$ is the normalized waterline elevation on the slope above SWL corresponding to the instantaneous water depth $\delta'_r = 1$ cm (Kobayashi et al. 1990). Figs. 3-5 also show the zero-upcrossing and zero-downcrossing wave height distributions of the specified incident wave train $\eta_i(t)$ for each run as compared with the Rayleigh distribution given by $P = \exp[-2(H_p/H_s)^2]$ where P is the exceedance probability associated with the normalized wave height H_p and H_s is the normalized significant wave height.

The value of P for give H_p is estimated by $P = n/(N_o + 1)$ where $n =$ rank of H_p and $N_o =$ number of individual waves, which is 256 for these runs. Since the zero-upcrossing significant wave height H'_s is used for the normalization, $H_s = 1$ for the zero-upcrossing wave height distribution. The values of H_s for the zero-downcrossing wave height distribution are found to be essentially unity for all runs. Figs. 3-5 also point out the exceedance probability P for H_u and H_d for each of the three runs to indicate the values of H_u and H_d as compared with the rest of the individual wave heights.

Figs. 3-5 together with Figs. 1-2 and Tables 1-3 elucidate the critical wave conditions corresponding to the minimum stability of rock units for each run. For run R1 with $\cot \theta' = 6$ and $\xi = 1.72$, the critical stability number occurs at the time t_{sc} when the large wave with the maximum crest elevation $\eta_c = \eta_{cm}$ uprushes on the slope and encounters the trough of the waterline oscillation on the slope as shown in Fig. 3. The computed results for runs R2a and R2b with

Figure 3: Analysis of Critical Wave Profile for Run R1

Run R3

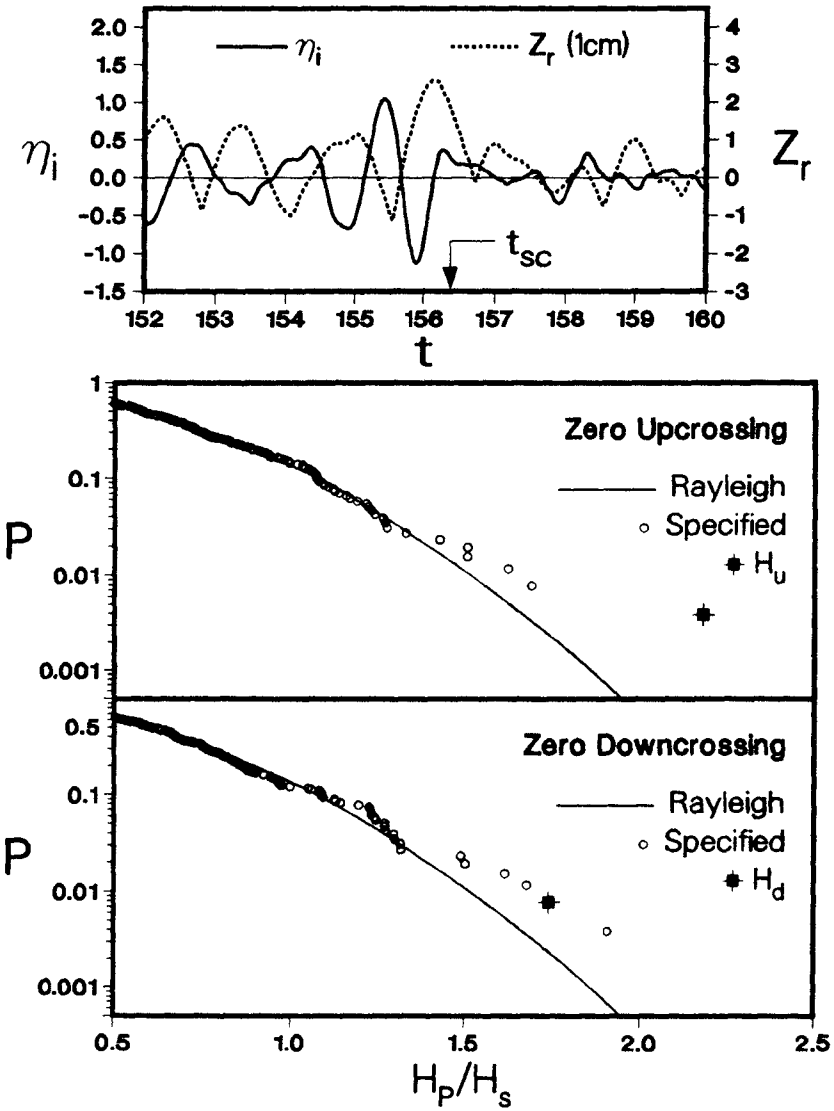

Figure 4: Analysis of Critical Wave Profile for Run R3

Run R4

Figure 5: Analysis of Critical Wave Profile for Run R4

$\cot \theta' = 6$ and $\xi = 2.36$ are very similar to those for run R1. Additional runs are required to determine whether these critical wave conditions are limited to relatively gentle slopes such as $\cot \theta' = 6$ or can occur for steeper slopes as long as the surf similarity parameter is roughly two. For run R3 with $\cot \theta' = 4$ and $\xi = 3.52$, the critical stability number occurs at the time t_{sc} when the extremely large wave with the maximum crest elevation $\eta_c = \eta_{cm}$ and the minimum trough elevation $\eta_{tu} = \eta_{tm}$ causes the downrushing water with large velocities following large runup as shown in Fig. 4. For run R4 with $\cot \theta' = 3$ and $\xi = 4.37$, the critical stability number occurs at the time t_{sc} when the relatively large zero-upcrossing wave with the high crest followed by the deep trough causes the downrushing water with large velocities with the waterline on the slope being near SWL as shown in Fig. 5. The computed results for run R5 with $\cot \theta' = 2$ and $\xi = 5.95$ and run R6 with $\cot \theta' = 2$ and $\xi = 6.88$ are similar to those for run R4.

PROBABILITY OF ARMOR MOVEMENT AND DAMAGE LEVEL

The critical incident wave profile and resulting critical stability number N_{sc} is useful for the design of armor units in which $N_s < N_{sc}$ so that armor units will not move under the action of design waves. If the mass of armor units is reduced such that $N_s > N_{sc}$, the degree of armor movement and resulting profile change will need to be predicted.

The computed armor stability function $N_R(t, x)$ depends on the normalized incident wave train $\eta_i(t)$ and the slope and armor characteristics specified as input to the numerical model. In the numerical model, the constant friction factor f' is used to account for the roughness effects of the primary cover layer on the flow over the rough permeable slope, while the effects of the permeable underlayer are taken into account by the volume and momentum fluxes into or out of the permeable underlayer. Since the computed flow field is not very sensitive to the assumed value of f' , the computed temporal and spatial variations of $N_R(t, x)$ for each run in Table 1 may be assumed to remain essentially the same even if the stability number N_s defined in Eq. 1 is increased somewhat by decreasing only the median mass W' of the armor units.

In the following, the probability of armor movement based on the movement duration, P_t , and the probability of armor movement per unit normalized time, P_m , are predicted as a function of the stability number $N_s > N_{sc}$ and the location x of the armor unit along the uniform slope. For given N_s and x , armor movement will occur during the time when $N_s > N_R$. The duration of each event of armor movement is denoted by t_j with $j = 1, 2, \dots, J$ where $J =$ number of armor movement events during the specified duration $t_{min} \leq t \leq t_{max}$. In this paper $t_{min} = 8$ and $t_{max} = 256$. From the computed armor movement statistics, the probabilities P_t and P_m may be defined as

$$P_t = (t_{max} - t_{min})^{-1} \sum_{j=1}^J t_j ; P_m = \frac{J}{(t_{max} - t_{min})} \tag{2}$$

For example, Fig. 6 shows the computed probabilities P_t and P_m for $N_s/N_{sc} = 1.1, 1.3$ and 1.5 for run R1 where the normalized elevation, $z = z'/H'$, of the armor unit on the slope relative to SWL located at $z = 0$ is used instead of x . The computed probabilities of the armor movement occurring mostly below SWL increase with the increase of N_s . For run R1, the computed value of N_{sc} is 1.56 and the measured value of N_s corresponding to the start of the damage was 1.72 as listed in Table 1. This implies that the numerical model predicts the

Figure 6: Computed Probabilities for Given N_s of Rock Movement for Run R1

movement of the armor units with $N_s = 1.72$, that is, $N_s/N_{sc} = 1.10$. However, the predicted probabilities for $N_s/N_{sc} = 1.1$ are very small as shown in Fig. 6.

The probability of armor dislodgement per unit normalized time, P_d , is expected to be less than P_m . As a first attempt, it is simply assumed that $P_d = C_d P_m$ where $C_d =$ empirical parameter. The rate of vertical erosion of the primary cover layer may be given by

$$\frac{\partial \eta'_e}{\partial t'} = \frac{C_3(d')^3}{1 - n_a} \frac{1 - n_a}{C_2(d')^2} \frac{P_d}{T'} = \frac{C_3 d' P_d}{C_2 T'} \tag{3}$$

where $\eta'_e =$ vertical erosion depth of the primary cover layer taken positive downward; $t' =$ time associated with the profile change; $d' =$ characteristic length of the armor unit; $C_3 =$ armor volume coefficient; $C_2 =$ armor area coefficient; $n_a =$ porosity of the primary cover layer; and $(P_d/T') =$ probability of dislodgement of a single unit per unit time. In Eq. 3, $C_3(d')^3/(1 - n_a)$ is the volume occupied by a single unit, while $(1 - n_a)/C_2(d')^2$ is the number of armor units per unit area along the slope. Eq. 3 predicts the erosion only since the dislodged armor units are assumed to be deposited in the region where P_d is essentially zero.

In the following, the profile change is assumed to be so small that P_d may be assumed to be independent of t' . Then, Eq. 3 yields $\eta'_e = (C_3 d' P_d t)/C_2$ where $\eta'_e = 0$ at $t' = 0$ and $t = t'/T'$ is the normalized time which is equal to the number of individual waves. Integration of η'_e along the slope in the region $\eta'_e > 0$ yields the eroded area A'_e . Van der Meer (1988) defined the damage level S by $S = A'_e/(W'/\rho_s)^{2/3}$. The present analysis can be shown to yield

$$S = \frac{C_d C_3^{2/3} (s - 1) N_s t}{C_2 \sin \theta'} \int P_m dz \tag{4}$$

where the stability number N_s is defined in Eq. 1 and the integration of P_m with respect to z can be performed for given $N_s > N_{sc}$ using the computed variation of P_m such as those shown in Fig. 6. For the runs listed in Table 1, use was made of $C_3 = 0.66$, $C_2 = 0.90$ and $s = 2.63$ by Kobayashi and Wurjanto (1990). In the following computation, the number of individual waves is taken to be $t = 1000$ and the value of N_s is varied such that $N_s/N_{sc} = 1.1, 1.2, \dots, 2.0$.

Fig. 7 shows the computed damage level S as a function of N_s for runs R1, R3 and R4. The empirical parameter C_d is taken as $C_d = 0.005, 0.01$ and 0.02 so that the computed values of S are of the order of the values of S based on the empirical formula of Van der Meer (1988) which is also plotted for each run in Fig. 7. The computed variations of S with respect to N_s for the other runs are also in qualitative agreement with the empirical formula. Eq. 4 will overestimate the value of S if S becomes so large that the profile change will result in the decrease in P_m and P_d . The major difference between Eq. 4 and the empirical formula is that the probability of armor movement P_m in Eq. 4 is computed for the specified incident wave train $\eta_i(t)$ for each run. It is hence possible to examine the sensitivity of P_m to various incident wave trains.

CONCLUSIONS

The computed results presented herein is not extensive and need to be verified. The numerical model is used to examine the detailed armor response to the specified incident wave trains since the detailed quantitative understanding

Figure 7: Computed Damage Level S as a Function of N_s for Runs R1, R3 and R4

is essential for improving the design of rock slopes for specified design waves as well as determining the design wave conditions more specifically than those based on the representative wave height and period. Generally, the scatter of data points about an empirical curve used for the design of a coastal structure against irregular waves is fairly large. Some of the scatter appears to be caused by the use of the representative wave height and period.

CHAPTER 99

DYNAMIC ANALYSIS OF FLOATING BREAKWATER MOORING SYSTEMS

John R. Headland¹ and Limberios Vallianos²

Abstract

This paper presents a numerical model for computation of floating breakwater mooring forces. The model is based on time domain mooring analysis techniques which permit simulation of: (1) nonlinear mooring line load characteristics and (2) mooring line loads associated with second order wave drift forces. Numerical model results are compared to physical model tests (Torum, 1989) and prototype measurements (Nelson and Broderick, 1986). These comparisons demonstrate that the numerical model provides good estimates of floating breakwater mooring line forces. Accordingly, it is concluded that the numerical model serves as a useful engineering tool for analysis and design of floating breakwater mooring systems.

Introduction

Floating breakwaters have been the subject of research for many years. Much of this research, however, has focused on breakwater wave transmission characteristics. Although wave transmission is an important functional design consideration, floating breakwaters and their moorings must also withstand survival environmental loadings. This paper presents a systematic and practical procedure for analysis of floating breakwater mooring systems.

Previous Investigations

Floating breakwater performance can be evaluated using numerical and physical models. Physical models provide the most reliable estimates of floating breakwater performance, but are generally expensive. Numerical models provide a relatively inexpensive means of assessing floating breakwater performance and are particularly useful in feasibility level analyses which can be used to refine designs prior to physical model testing. Numerical modeling of moored floating breakwaters has most often been performed using frequency domain techniques. Examples of frequency domain numerical models may be found in Adee et al (1976) and Tekmarine Inc. (1986) which can be used to estimate floating breakwater wave transmission characteristics and mooring line forces. Georgiadis and Hartz (1982) developed a numerical model to evaluate the internal loads of a floating breakwater module using both frequency and time domain techniques.

Laboratory and field studies of various floating breakwater installations (Adee et al, 1976) have shown that frequency domain analysis provides a good engineering estimate of floating breakwater wave transmission characteristics. However, as will be discussed below, frequency domain analyses often do not adequately predict breakwater motions and attendant mooring line forces.

Miller et al (1984) found that the frequency domain approach adequately predicted floating breakwater motions in heave and roll, but could not predict the low frequency sway motions which generally dominated mooring forces. Similarly, Adee et al (1976) concluded that mooring forces developed from frequency domain analysis must be increased substantially in order to provide an estimate of actual mooring forces. Figure 1 presents an example force time history reported by Adee et al (1976) for floating breakwater installation at Tenakee, Alaska. Incident waves had periods ranging from 1 to 2 seconds, however, mooring line forces were dominated by long period oscillations with periods of approximately 55-60 seconds. A review of the dynamic characteristics of the floating breakwater mooring system indicated that the recorded sway motion of the floating breakwater was very close to the sway natural period. Similar prototype measurements were reported by the Japanese Ministry of Transport at site near Kumamoto, Japan (see Tekmarine (1986)). Clearly, any numerical analysis of floating breakwater mooring line forces must account for both high and low frequency motions.

Figure 1. Typical Mooring Force Time History

Low frequency motions of moored structures result from second order wave drift forces (Pinkster, 1980). Such forces are neglected in a first order frequency domain analysis such as that reported in Adey et al (1976) and Tekmarine Inc. (1986) which assume applied hydrodynamic loading and attendant breakwater response are sinusoidal at a frequency equal to the incident wave frequency. As a result, such frequency domain analyses do not account for the "second order" wave drift forces which can dominate mooring line forces. The following paragraphs outline a time domain numerical model capable of estimating first and second order floating breakwater motions and mooring line forces.

Numerical Model Theory

Equations of Motion. Research on the behavior of moored vessels has shown that mooring systems are best modeled in the time domain using the impulse-response method (Van Oortmerssen, 1976). The time domain approach can be used to simulate nonlinear mooring line behavior as well as arbitrary applied loadings. Because an arbitrary applied loading can be specified, the time domain approach can be used to assess first and second order wave forces. The governing equations of motion, which account for time domain motion in six degrees of freedom, are as follows:

$$\sum_{j=1}^6 [(M_{kj}+m_{kj})\ddot{x}_j + \int_{-\infty}^t K_{kj}(t-\tau)\dot{x}_j(\tau) d\tau + C_{kj}x_j] = F_k(t) \tag{1}$$

$$k = 1, 2, \dots, 6$$

Where:

- x_j = motion in the j-th mode
- M_{kj} = inertia matrix
- C_{kj} = hydrostatic restoring force matrix
- K_{kj} = impulse response function matrix
- m_{kj} = constant added mass matrix
- $F_k(t)$ = arbitrary external force in k-th mode due to waves, mooring line reactions, viscous damping, winds, currents, etc.
- k = denotes mode of motion, (i.e. 1 (surge), 2 (sway), 3 (heave), 4 (roll), 5 (pitch), 6 (yaw))

The left hand side of equation (1) contains linear hydrodynamic reaction forces while the right hand side represents an arbitrary forcing function which may include linear terms (e.g. first order wave forces) and nonlinear terms (e.g. second order wave drift forces, mooring line forces, viscous damping, etc.). The primary advantage of the impulse-response function approach is that arbitrary motion over a range of motion frequencies can be simulated correctly. Other time domain methods, such as that used by Georgiadis and Hartz (1982), assume constant values of added mass and damping at a single frequency even though breakwater motion may occur over a range of frequencies.

Hydrodynamic Coefficients. The inertia matrix, M_{kj} , and hydrostatic restoring force matrix, C_{kj} , are computed using standard methods of naval architecture. The impulse-response function matrix, K_{kj} , and the constant added mass coefficient, m_{kj} , are computed as follows (Van Oortmerssen, 1962):

$$K_{kj} = \frac{2}{\pi} \int_0^{\infty} b_{kj}(\omega) \cos \omega t d\omega \tag{2}$$

$$m_{kj} = a_{kj}(\omega^*) + \frac{1}{\omega^*} \int_0^{\infty} K_{kj}(t) \sin \omega^* \tau d\tau \quad (3)$$

Where:

- a_{kj} = frequency-dependent added mass
 b_{kj} = frequency-dependent damping coefficient

The above frequency dependent added mass and damping coefficients may be computed using either strip-theory or diffraction theory hydrodynamic analysis. The Frank Close-Fit strip theory approach, as documented by Kaplan (1989), was used in the present analysis.

Wave Forces. The applied force resulting from waves, $F_{kw}(t)$, can be written as:

$$F_{kw}(t) = \sum_0^n f_k^{(1)}(\omega_n) a_n \cos(\omega_n t + \epsilon_n + \epsilon_k) \quad (4)$$

$$+ \sum_0^n \sum_0^m f_k^{(2)}(\omega_n) a_n a_m \cos((\omega_n t + \epsilon_n) - (\omega_m t + \epsilon_m))$$

Where:

- $f_k^{(1)}(\omega_n)$ = first order wave transfer function in k-th mode for n-th wave component
 $f_k^{(2)}(\omega_n)$ = second order wave transfer function in k-th mode for n-th wave component
 ϵ_k = phase of first order wave transfer function in k-th mode for n-th wave component
 a_n = wave amplitude of n-th wave component
 ϵ_n = phase of n-th wave component
 ω_n = frequency of n-th wave component

The above formula is used to simulate first and second order wave force time-histories resulting from an incident wave spectrum composed of n-waves. The incident wave spectrum is represented in the above formulation by

the wave amplitudes and phases (i.e. a_n and ϵ_n) which correspond to wave frequencies, ω_n . Wave amplitudes and frequencies are determined from an incident wave spectrum using the "equal area" method described by Borgman (1969).

It should be noted that the wave force formulation presented in equation (4) is only valid for long-crested, uni-directional wave conditions. The present version of the model cannot be used to assess mooring loads from directional spectra. Fortunately, the results of Torum et al (1989) indicate that directional spreading has little influence on mooring line forces.

The first order wave transfer functions were also computed using the Frank-Close Fit method documented by Kaplan (1989). The second order wave transfer functions were computed from the first order wave analysis using methods based on the work of Gerritsma and Beukelman (1972) and Newman (1967). As will be discussed later, mooring simulations using these computed drift forces over estimated the sway motions and attendant mooring line forces of scale model and prototype floating breakwaters. This overprediction was believed to be due to the fact that both the physical model and prototype breakwaters were heavily overtopped by waves. In an effort to account for overtopping, wave drift forces were computed using the following expression derived by Longuet-Higgins (1977):

$$f_2^{(2)} = \frac{1}{4} \rho g (a^2 + a_R^2 - a_T^2) \left(1 + \frac{2kh}{\sinh(2kh)} \right) \quad (5)$$

Where:

- a = incident wave amplitude
- a_R = reflected wave amplitude
- a_T = transmitted wave amplitude
- k = wave number
- h = water depth

The reflected wave amplitude can be estimated from the incident and transmitted wave amplitudes as follows:

$$a^2 \sim a_R^2 + a_T^2 \quad (6)$$

Given measured values of the incident, reflected and transmitted wave amplitudes, equation (5) can be used to estimate second wave drift forces. Wave overtopping conditions are taken into account implicitly through the measured incident, reflected and transmitted wave amplitudes.

Viscous Damping Coefficients. Numerous studies (e.g. Wichers, 1988) have shown that potential theory damping terms for surge, sway and yaw motions of moored structures are negligible in comparison to viscous damping terms at low frequency. Accordingly, an additional term is added to the time-varying applied force, $F_k(t)$, to account for viscous damping effects. Both nonlinear and linear viscous sway damping formulations were investigated. In accordance with the findings of Wichers (1988), initial efforts were directed towards evaluation of a quadratic damping term formulated as follows:

$$F_{2D}(t) = -\frac{1}{2} \rho C_{2D} |\dot{x}_2| \dot{x}_2 A_2 \quad (7)$$

Where:

- $F_{2D}(t)$ = nonlinear damping force in sway
- ρ = water density
- A_2 = lateral wetted area of breakwater
- C_{2D} = viscous drag coefficient in sway

After considerable analyses, it was concluded that the above nonlinear damping formulation provided very little damping for typical floating breakwater sway motion velocities and was abandoned in favor of a linear damping formulation as follows:

$$F_{2D}(t) = -B_{2D} \dot{x}_2 \quad (8)$$

Where:

- B_{2D} = linear viscous damping coefficient

A similar formulation has been shown to successfully predict surge damping characteristics of vessels secured to single point moorings in still water (Wichers, 1988). Using the results of a prototype extinction tests, Seelig (1990) demonstrated that the above linear formulation could be used to estimate the sway motions of a spread-moored vessel in still water. Seelig's prototype measurements were used to estimate linear damping coefficient, B_{2D} .

Mooring Forces. Mooring line restoring forces in the numerical model are computed using static catenary theory. Mooring line loads are determined from the instantaneous position of mooring attachment point on the breakwater and from static load deflection curves for each line. The total mooring restoring forces and moments acting on the center of gravity of the breakwater in each mode of motion are computed by summing the force (and moment) contributions from each mooring line. These forces are then added to the $F_k(t)$ term on the right hand side of equation (1). Although Torum et al (1989) suggest that such effects may be important at high frequency, no attempt has been made to incorporate dynamic oscillations of the mooring lines in the numerical model.

MODEL APPLICATION

The U.S. Army Corps of Engineers initiated the Floating Breakwater Prototype Test Program in 1981. A concrete box or caisson-type floating breakwater was constructed, installed and monitored an exposed site in the Puget Sound as part of this program. Results of this study are presented in Nelson and Broderick (1986). The general arrangement of the floating breakwater installation is shown in Figure 2. The particulars of the floating breakwater unit are summarized in Table 1.

Figure 2. Layout of Puget Sound Floating Breakwater

Table 1
 Characteristics of Puget Sound Floating Breakwater

Length=150 ft (46m)	Natural Period-Sway = 20 sec
Beam =16 ft (4.9m)	Natural Period-Heave = 3.2 sec
Draft=3.5 ft (1.1m)	Natural Period-Roll = 2.4 sec
Mass=16,696 slugs (244,022 kg)	Natural Period-Pitch = 3.4 sec
C.G = 1 ft (.31m)	Natural Period-Yaw = 14 sec
GM = 5.35 ft (1.6m)	

Table 1 also summarizes the natural period for each mode of motion of the breakwater. The natural periods were determined by performing extinction tests with the numerical model for mid-tide conditions. As can be seen in Table 1, the natural periods of motion in sway and yaw are much longer than: (1) heave, roll and pitch natural periods and (2) typical floating breakwater design waves periods.

The U.S. Army Corps of Engineers, Waterways Experiment Station, Coastal Engineering Research Center recently sponsored a series of 1:10 scale physical model tests to evaluate the performance of the prototype structure. The tests are given in Torum et al (1989).

In order to validate the numerical model presented in this paper, the predictions of the numerical model were compared to measurements obtained in the prototype experiment and physical model tests. Results of this comparison are described below.

Physical Model Tests. Torum et al (1989) present physical model test results for both a continuous breakwater structure (i.e. "stiff" model) and a discontinuous series of breakwater pontoons separated by fenders (i.e. "fendered") model. Only the "stiff" model results were used in the evaluation of the time domain numerical model. The linear hydrodynamic coefficients and wave transfer functions for the caisson-type floating breakwater were computed in the frequency domain and converted to time domain functions using the techniques described above. It would be highly desirable to measure these parameters directly with the results of physical model tests. Unfortunately, given the nature of physical modeling program described by Torum et al (1989), there is no way to validate these quantities directly. A systematic series of physical model tests would be

required to evaluate the added mass, damping and wave transfer functions separately. At this juncture, one can only compare the final output of the physical model (i.e. breakwater motions and mooring line forces) to that simulated by the numerical model.

Mooring analyses were prepared for a variety of the wave conditions tested in the physical model. As previously mentioned, second order wave transfer functions were initially computed without accounting for wave overtopping. The resulting mooring dynamic simulations significantly overpredicted breakwater motions and attendant mooring line forces. A systematic variation of the second order wave transfer functions and viscous damping coefficients demonstrated that the floating breakwater response was relatively sensitive to the second order wave transfer functions and less sensitive to the viscous damping coefficient as long as the linear damping formulation was used. Hence, the original method for computing the second order drift forces was abandoned in favor of the method of Longuet-Higgins (1977) presented in Equation (5). In order to apply equation (5) it was necessary to know the incident, reflected and transmitted wave amplitudes for each wave frequency. Fortunately, breakwater transmission characteristics were presented in Torum et al (1989). Hence, the second order wave transfer functions could be estimated directly from equations (5) and (6). Mooring line load deflection curves were estimated from plots presented in Torum et al (1989).

Example numerical model results are presented in Figure 3 which presents time histories of water surface elevation, sway, heave, and roll motions and mooring line forces for beam-on waves with a significant wave height of 1.43 meters and a peak spectral wave period of 4.3 seconds. Figure 3 is actually a portion of the predicted time history as the numerical model was run for a total time of 960 seconds. With the exception of roll, the numerical model provided a good prediction of the breakwater motions. Specifically, the peak values of sway, heave, and roll measured in the physical model were 3.029 meters, .7022 meters, and 10.04 degrees, respectively, while the peak values of sway, heave, and roll predicted by the numerical model were 2.8 meters, 0.65 meters, and 25 degrees, respectively. The maximum mooring line load predicted by the numerical model (31.8 kilonewtons) was comparable to that measured in the physical model tests (32.97 kilonewtons). Figure 3 indicates several facets of the breakwater response, namely: (1) heave and roll response are at the incident wave frequency, (2) sway response and mooring line forces

are dominated by low frequency motion near the natural period of sway motion, and (3) roll motion is overpredicted by the numerical model. Similar results were obtained for other comparisons of the numerical model results with that measured in the physical model.

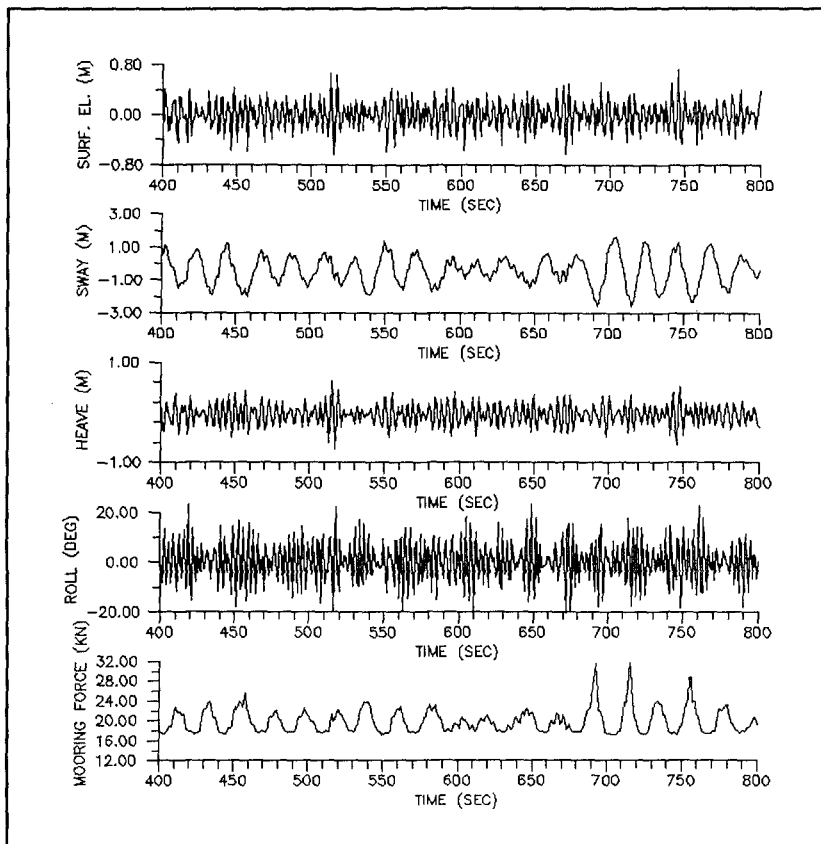

Figure 3. Example Numerical Model Results.

The numerical model results described above are generally consistent with the conclusions presented by Torum et al (1989) who concluded that: (1) floating breakwater sway response was dominated by low frequency motions and (2) mooring line forces were governed by low frequency sway motion and wave frequency roll and heave motions. However, spectral plots of mooring line forces presented in Torum et al (1989) indicate peak spectral energy at or near the wave frequency with a secondary

peak at low frequency. This led Stansberg et al (1990), in a summary of the Torum et al (1989) report, to conclude that mooring line forces were on the average governed by heave and roll motions with extreme events strongly influenced by low frequency sway peaks. The numerical model presented in this paper indicates that mooring line loads are dominated by horizontal sway motions. Additional analyses will be required to evaluate the apparent discrepancies between the sway motion and mooring line force spectra presented in Torum et al (1989).

Prototype Measurements. The numerical model was used to estimate the mooring line loads recorded during the Floating Breakwater Prototype Test Program. Hydrodynamic coefficients and wave transfer functions were computed in the same manner as described above for the physical model. Wave transmission coefficients measured in the physical model tests of Torum et al (1989) were used to estimate the second order wave transfer functions for the prototype structure. Mooring line load-deflection characteristics were estimated on the basis of the field pull tests described in Nelson and Broderick (1986).

Example numerical model results are presented in Figure 4 for an incident significant wave height of 1.29 feet and a peak spectral period of 2.75 seconds. Numerical computations were performed for a total simulation time of 540 seconds to correspond with the results presented in Nelson and Broderick (1986). The results presented in Figure 4 for the prototype breakwater are similar to those presented in Figure 3 for the scale model breakwater. Specifically, breakwater sway response and attendant mooring line force is primarily at low frequency near the natural period of sway motion while the breakwater response in heave and roll is at a frequency corresponding to the incident wave. The maximum mooring line load measured for these wave conditions was 6,346 pounds (28.3 kilonewtons) while the numerical model prediction was 6070 pounds (27.0 kilonewtons). Similar results were found for other numerical model-prototype measurement comparisons.

CONCLUSIONS

A numerical model for dynamic analysis of floating breakwater mooring systems has been presented. Comparisons of numerical model results with physical model and prototype measurements indicate that the numerical model provides reasonable estimates of floating

Figure 4. Example Numerical Model Results

breakwater mooring line forces for planning and design use. Moreover, the numerical model can be used as a planning tool prior to physical model studies of final floating breakwater mooring configurations. Additional studies, involving systematic physical model tests, will be necessary to reduce uncertainties associated with: (1) computation of the hydrodynamic coefficients, wave transfer functions, and applied wave force time histories, and (2) importance of roll and heave motions on mooring line loads.

CHAPTER 100

WAVE-INDUCED PORE PRESSURE IN RUBBLE MOUND BREAKWATERS

Oumeraci, H.; Partenscky, H.W.¹

Abstract

Experimental results from large scale tests are presented for the distribution of wave-induced pore pressure within rubble mound breakwaters, for the reflection coefficients and the damping of wave motion through the armour and under-layer. The results are then discussed with respect to application and further research.

1. Introduction

Previously, the effects of the internal flow field on the armour and geotechnical stability of rubble mound breakwaters were largely ignored. A brief literature review /3/ as well as recent hydraulic and numerical model investigations /14; 7; 1/ highlighted the importance of the motion of pore water for a better understanding of the geotechnical behaviour and of the external flow on and in the armour layer.

At present, numerical modelling efforts appear to be directed towards the elaboration of an integrated code which should describe wave action on and within the breakwater as well as its effect on armour stability.

Considering the present knowledge of scale effects /8; 13; 4/ and owing to the fact that the loading parameters are not controllable under prototype conditions, measurements from large scale model tests at present represent the most suitable data for calibration and verification. Thus, it is one of the main objectives of this paper to provide the necessary information for this purpose.

¹Franzius-Institute, University of Hannover, Germany

2. Oscillatory Flow in Porous Media-Theory

When a wave approaches a non-overtopped rubble mound breakwater, part of the incident energy E_i is dissipated on and within the structure (E_d), part is reflected (E_r) and the rest is transmitted (E_t) through the breakwater:

$$E_i = E_d + E_r + E_t, \quad (1)$$

The dissipated energy (E_d) can in turn be divided in three distinct parts: the energy dissipated on and in the armour layer (E_{da}), the energy dissipated in the under layer filter (E_{df}) and the energy dissipated within the core (E_{dc}):

$$E_d = E_{da} + E_{df} + E_{dc} \quad (2)$$

Most of the studies available on waves in rubble mound breakwaters are directed more toward the determination of averaged transmission and reflection coefficients than toward the understanding of the internal wave motion; i.e. the porous structure is often considered as a kind of a black box system.

Theoretical work which actually deals with the internal oscillatory flow induced by waves was mostly related to the study of permeable wave absorbers and wave filters /2; 9; 11/. In this respect, BIESEL /2/ was the first to identify the form of the spatial and temporal relationships which describe a linearly damped, oscillatory flow. LE MEHAUTE /10/ continued BIESEL's work and applied it to rubble mound breakwaters.

The investigations of BIESEL /2/ and LE MEHAUTE /10/ are considered here because a) they constitute the first attempts to describe wave motion in porous media and b) almost no significant advances on their fundamental approach have been made since then.

A general linearized BERNOULLI equation for an oscillatory flow in a wave filter based on the NAVIER-STOKES equation has been derived by BIESEL /2/.

A parameter $k_v = D/n$ was introduced in this equation by LE MEHAUTE /10/ to account for the porosity n and inertia effects (D) of the porous material:

$$\frac{p}{\rho} + k_v \frac{\partial \phi}{\partial t} + g y + c_f \phi = \text{const.} \quad (3)$$

The time derivative of equ. (3), together with $\frac{\partial y}{\partial t} = \frac{1}{n} \frac{\partial \phi}{\partial y}$ and $p = \text{const.}$ at the free surface $y = f(x,t)$ yields:

$$k_v \frac{\partial^2 \phi}{\partial t^2} + \frac{g}{n} \frac{\partial \phi}{\partial y} + c_f \frac{\partial \phi}{\partial t} = 0 \quad (4)$$

where:

- g = acceleration of gravity
 p = pore pressure
 ρ = water density
 c_f = linearized friction coefficient
 ϕ = potential function of a 2D-wave travelling through a porous medium with a porosity n and subject to a friction force $\vec{F}_R = -c_f \cdot g \vec{\text{grad}} \phi$
 t = time
 x, y = coordinates (Ox-axis is at SWL and Oy-axis is positive upward)

Considering the continuity equation $\Delta \phi = 0$ and the boundary condition at the depth $y = -h$, the following particular solution of equ. (4) is obtained.

$$\phi = \frac{H_w}{2} e^{-\beta k x} \frac{\omega}{k \sinh k h} \left| \cos \beta k (h+y) \cosh k (h+y) \sin (kx - \omega t) + \sin \beta k (h+y) \sinh k (h+y) \cos (kx - \omega t) \right| \quad (5)$$

where:

- H_w = incident wave height at the outer boundary of the porous medium ($x = 0$)
 h = water depth
 k = $2\pi/L'$: wave number
 L' = wave length within the breakwater
 ω = $2\pi/T$: angular wave frequency
 T = wave period
 β = damping coefficient

The wave length L' within the rubble mound breakwater is related to the length L of the incident wave as follows /10/:

$$L' = L/\sqrt{D} \text{ for } h/L < 0,5 \quad (6)$$

where:

$$L = \frac{gT^2}{2\pi} \tanh \frac{2\pi h}{L} \quad (7)$$

- D : Coefficient characterising the relative increase of the seepage length as a result of the deviation of the flow path caused by the presence of the grains. An empirical value $D \approx 1.4$ was given by LE MEHAUTE /10/, whereas a value $D = 1.5$ was determined theoretically by MICHE /12/.

It follows from equ. (5) and (6) that the height of the pressure oscillation $p(x)$ of a wave travelling through a rubble mound breakwater in the x -direction will decrease exponentially according to the following expression:

$$p(x) = p_0 \cdot e^{-\beta \frac{2\pi}{L'} x} \quad (8)$$

where p_0 = pore pressure at $x = 0$

3. Experimental Set-up and Test Procedure

3.1 Description of the breakwater model

The rubble mound breakwater model tested and the experimental set-up have already been described in a previous paper /3/. The cross-section of the large scale model with the position of the pressure cells and the run-up gauges is shown in Fig. 1.

Figure 1. Large scale model of the investigated breakwater

The grain size distribution of the core material used in the model is given in /3/.

The mean diameter is $d_{50} \approx 4$ cm and the uniformity coefficient $U = \frac{d_{60}}{d_{10}} \approx 2.2$. For the wave heights tested the REYNOLDS number related to the grain size is in the range $Re = 5 \cdot 10^4$ to 10^5 ; i.e. scale effects due to viscous flow within the core material can be neglected /13/.

3.2 Test programme and procedure

For each test series the wave period was kept constant, whereas the wave height was increased after each test.

Monochromatic waves with heights up to 2.0 m and periods $T = 3 - 8$ s, as well as irregular waves with significant heights up to 1.0 m and peak periods $T_p = 3 - 8$ s have been used. In addition, 4 test series with the most critical peak period ($T_p = 4.5$ s) were carried out for groupiness factors $GF = 0.6, 0.7, 0.8$ and 0.9 in order to investigate the effect of wave grouping on wave run-up, internal pressure build-up and armour stability.

During the tests, attention has been placed on observations of armour stability as well as on simultaneous measurements of incident waves, pore pressure distribution and wave run-up on the slope of the armour, filter layer and core material.

4. Experimental Results

4.1 Wave reflection

The incident and reflected waves have been determined by means of the commonly used 3-wave gauge procedure. For the range of wave conditions tested, the reflection coefficient K_R is given in Fig. 2 as a function of the surf similarity parameter ξ .

Figure 2. Reflection coefficient K_R vs. surf similarity parameter ξ

The reflection coefficients obtained ($K_R = 0.20 - 0.45$) correspond to the values given by SOFREMÉR and SOGREAH for tetrapods, but are comparatively lower than those given by the empirical relationship derived by CERC /14/ for natural stone armours. The latter appears to rather describe the envelope of the maximum values for the tetrapod armour (Fig. 2).

4.2 Wave damping by the armour and under-layer

The incident waves penetrating into the armour and under-layer as well as into the core are followed by means of 3 wave run-up gauges. They have been specially developed for this purpose and were installed along the slope of the tetrapod armour, of the under-layer and of the core material, respectively ((Fig. 1).

The analysis of the results shows that a considerable part of the incident wave energy is dissipated not only by the armour but also by the under-layer. The degree of dissipation is strongly dependent on the magnitude of the similarity parameter ξ . The smaller this parameter, the more pronounced is the energy dissipation. For instance, the drop of the relative wave height when the wave passes through the armour layer varies from about 30 % to 60 % for surf similarity parameters $\xi = 5$ and $\xi = 2$, respectively. Considering the total attenuation of wave motion taking place within both the armour and the under-layer, the corresponding values become 60 % to 90 %, respectively (Fig. 3).

Figure 3. Wave damping by the armour and under-layer vs. surf similarity parameter ξ

The dependence of the energy dissipation on the surf similarity parameter ξ results from the shape of breakers on the outer slope; i.e. spilling and plunging breakers ($\xi \leq 2$) which are associated with a high degree of air entrainment and high impact velocities give the largest damping values, whereas collapsing and surging breakers ($\xi > 2$) yield the lowest ones.

A further result emerging from Fig. 3 is the much lower value of the run-up and run-down heights on the core slope compared to that at the outer slope. This is of importance for the design of the crest level of the core material. However, a set-up of the mean water level inside the breakwater, which may range from 10 to 20 % of the incident local wave height, should be additionally considered.

5. Wave-Induced Pore Pressure

For the measurement of the pore pressure inside the rubble mound breakwater model twenty piezoresistive pressure gauges (Type PDCR NATEC SCHULTHEISS) were installed at different locations (Fig. 1). These locations were selected in such a way that the pore pressure distribution and the boundary values required for the implementation and calibration of numerical models can be gained with sufficient accuracy.

The designation "pore pressure" used in the following is related to the excess pore water pressure which is solely induced by wave action; i.e. all the twenty pressure gauges record zero pressure at still water level (no wave action). Thus, the corresponding hydrostatic pressure head should be added to the recorded pressure values to obtain the total pore water pressure. The terms "pore pressure height" and "pore pressure amplitude" are used on the analogy with waves to designate the height and the amplitude of the pressure fluctuations, respectively.

5.1 Influence of incident wave parameters on pore pressure

5.1.1 Effect of wave height

The effect of the incident wave height on the magnitude of the pore pressure is illustrated for one location in Fig. 4.

Given a wave period and with increasing wave heights the pore pressures first increase rapidly, then at a lower rate, due to higher friction losses associated with larger hydraulic gradients. The pore pressure - wave height curves appear to have a similar shape for the locations and wave periods investigated.

Figure 4. Effect of wave height on pore pressure

5.1.2 Effect of wave period

The effect of the incident wave period on the magnitude of the pore pressure is shown in Fig. 5.

Figure 5. Effect of wave period on pore pressure

Given a wave height and with increasing wave period the pore pressure first increases very slightly, then rapidly and finally at a lower rate.

Similar shapes of pore pressure - wave period curves have been obtained for further locations and various wave heights.

5.2 Spatial distribution of pore pressure

In the following, only the spatial distribution of time averaged values of pore pressure heights is considered. In this respect and for simplification, the horizontal and the vertical distributions are treated separately.

5.2.1 Horizontal pore pressure distribution

In order to verify whether the waves are damped within the breakwater according to the theory outlined in chapter 2, the horizontal plane containing the pressure cells PC 15 to PC 19 is considered (Fig. 1). For this purpose, the ratio between pore pressure $p(x')$ at a distance x' from the origin located at PC 15 ($x' = 0$) and pore pressure p_0 measured at $x' = 0$ is plotted against the relative distance x'/L' .

Figure 6. Pore pressure dissipation within the breakwater

For the elevation of the horizontal plane considered, the pore pressure decreases exponentially in the direction of wave propagation according to the following relationship:

$$p(x') = p_0 \cdot e^{-2 \cdot \frac{2\pi}{L'} x'} \tag{9}$$

However, the magnitude of the damping factor β in equ. (8) depends on the elevation of the horizontal plane considered with respect to the still water level (SWL). Further results which will be published in the near future suggest that the lower the location under SWL, the smaller the damping factor β becomes. This can be explained by the friction losses which become smaller as the degree of turbulence decreases, i.e. as the distance from SWL increases.

5.2.2 Vertical pore pressure distribution

The pore pressure does not vary hydrostatically with depth, even in the centre of the breakwater. This may be explained by the dynamic effects which are more pronounced near the front face and just under SWL. In order to identify the relevant parameters which influence the degree of attenuation with depth, the relative pore pressure height $p(y)/H_w$ is plotted against the relative elevation (y/L) under SWL in Fig. 7 for different relative water

Figure 7. Pore pressure attenuation with depth

depths (h/L). Departing from SWL the pore pressure first increases up to a maximum value with increasing depth, then slightly decreases. The smaller the relative water depth (h/L), i.e. the longer the waves, the higher is the induced pore pressure and the less pronounced is the pressure attenuation.

6. Discussion and Application of the Results

6.1 Reflection coefficient

An accurate evaluation of the reflection coefficient $K_R = \sqrt{E_r/E_i}$ is important, since it is the remaining energy $E_{dt} = E_d - E_t$ (see equ. (1)) which represents the input for the study of energy dissipation on and in the breakwater. Thus rewriting equ. (1) as:

$$E_{dt} = E_d + E_t = (1 - K_R^2)E_i, \quad (10)$$

it follows from the relationship obtained in Fig. 2 that E_{dt} may amount to 80 - 96 %, depending on the surf similarity parameter ξ . For the range of common ξ -values this relationship can be used for tetrapod armours. It is suggested, however, that future work should focus upon the development of more suitable measuring techniques and methods for the determination of reflection coefficients, since the 3 wave gauge procedure commonly used is still not satisfactory.

6.2 Energy dissipation through armour and under-layer

The results shown in Fig. 3 represent the first attempts to follow the wave motion from the sea-structure interface to the core. For this kind of investigation, small-scale model tests are not suitable because of the dissimilarity of air entrainment resulting from breaking waves and flow separation. For the importance of air content for energy dissipation on and in the breakwater see chapt. 6.4. A reliable evaluation of the rate of energy dissipation through the first layers does not only provide the necessary boundary conditions for resolving the equations of motion in numerical codes, but also helps in assessing the forces on armour units.

Together with the relationship given in Fig. 2, the results presented in Fig. 3 allows the evaluation of the different energy components involved in equ. (1) and (2). For instance, given a surf similarity parameter $\xi = 4$, the reflected energy is $E_r = 12$ %, the energy dissipated on and in the armour layer $E_{da} = 54$ %, the part dissipated in the under-layer $E_{df} = 23$ % and the remaining part which

is finally transmitted into the breakwater core is only 11 % of the total incident wave energy.

These results implicitly highlight the importance of the armour and the under-layer for energy dissipation and the question which may arise if a single armour layer is used or an under-layer is omitted.

6.3 Attenuation of pore pressure within the breakwater

The experimental results presented here generally give much higher pressure values when compared to the results from available numerical codes /1; 5; 6/. This is mainly due to the fact that the dynamic component of the pore pressure has not been well accounted for. The latter, however, represents an important part of the total wave-induced pore pressure, particularly in the region under SWL and near the front face where it is more dominant.

6.4 Some remarks on scale effects

The limitations of common small scale model tests when investigating wave energy dissipation on and within rubble mound breakwaters are due to the impossibility of simultaneously fulfilling the similitude criteria of FROUDE, WEBER and REYNOLDS.

a) Scale effects due to the dissimilarity of WEBER's number

The rate of air entrainment into the armour and under-layer resulting essentially from wave breaking, and to a lesser extent from flow separation, is generally higher in prototype; i.e. the rate of wave energy dissipation through the armour and under-layer is lower in the model. The relationship between air entrainment and energy dissipation in breaking waves has already been treated by FÜHRBÖTER /4/. In addition, it has been observed (video records) that a large amount of air bubbles are often driven into the core by breaking waves. The effect of air content α in the two-phase internal flow, however, is known to cause a reduction of the effective hydraulic conductivity of the porous medium /6; 5/:

$$K_{aw} = K_w (1 - \alpha)^3 \quad (11)$$

where K_{aw} , K_w : two-phase and single-phase hydraulic conductivity, respectively.

This means that an air fraction α of only 10 % may cause a reduction of more than 25 % in the hydraulic conductivity. This in turn will considerably reduce the rate of pore pressure attenuation.

- b) Scale effects due to the dissimilarity of REYNOLDS' number

The use of small-scale models generally results in a lower permeability of the core material. This effect is additionally reinforced by the afore mentioned dissimilarity in air entrainment, thus leading to too high viscous forces in the model and affecting the flow regime within the breakwater. A lower rate of energy dissipation will result. This subject has been treated by OUMERACI /13/ and JENSEN et al. /8/.

7. Concluding Remarks and Perspectives

The present results may be used to estimate reflection, run-up and run-down heights as well as the rate of attenuation of a wave as it propagates into a tetrapod armoured breakwater. However, it should be kept in mind that these results present only a small part of a considerable set of data obtained from systematic tests in large and small-scale models which are now being analysed.

Evaluating in a more systematic and fundamental manner the different energy components in equ. (1) and (2) in order to better understand the complex processes of wave energy dissipation on and in rubble mound breakwaters will be the topic of a forthcoming paper. In addition, an attempt will be made to improve the theory presented in chapter 2. However, in view of the variety and complexity of the interrelated processes involved, like wave breaking and air entrainment, virtual mass effects, non-linearity and unsteadiness of the flow together with the uncertainties in the hydraulic properties of the different breakwater layers, it seems obvious that reliable analytical solutions cannot be developed in a straightforward manner. Therefore, the research strategy adopted at the University of Hannover consists in the development of a reliable integrated numerical code which will be calibrated by the data from the large-scale tests and then used as a research tool, the ultimate objective being the development of analytical solutions.

8. Acknowledgements

This investigation is part of an extensive basic research programme in coastal engineering (SONDERFORSCHUNGSBEREICH 205) which is supported by the German Research Council (DFG).

CHAPTER 101

REDUCTION OF WAVE FORCES AND OVERTOPPING BY SUBMERGED STRUCTURES IN FRONT OF A VERTICAL BREAKWATER.

B. González Madrigal (1)
J. Olivares Prud'Homme (2)

1.- ABSTRACT:

This paper describes some of the results obtained from a series of model tests to measure wave forces and overtopping in a vertical breakwater located in a surf zone. The aim of the tests was to better design conditions using submerged structures. With the sections proposed in this study, it is possible to achieve a considerable reduction in wave forces and overtopping on vertical breakwaters.

2.- INTRODUCTION

Most vertical breakwaters in Spain have been constructed at depths where breaking does not occur. It is a well known fact that the wave pressure to which a vertical breakwater is subject in breaking conditions, is much greater than when such conditions are absent, so the design conditions vary considerably. As a result of this, some solutions, including vertical breakwaters with block mounds, have been developed with a view to dissipating energy. Nevertheless, these solutions have not taken into account their possible use for recreational purposes, such as Marinas; in these cases, the question of aesthetics is fundamental as regards the impact that they might have on the coastal environment.

Recently, the C.E.P.Y.C. has carried out tests on a series of sections subject to irregular waves, with a view to improving design conditions for a vertical breakwater situated in a surf zone. The various options studied, are

(1) Head of Maritime Structures Division, Centro de Estudios de Puertos y Costas, (CEPYC-CEDEX), Antonio Lopez 81, Madrid 28026, Spain.

(2) Research Engineer, Centro de Estudios de Puertos y Costas, (CEPYC-CEDEX), Antonio Lopez 81, Madrid 28026, Spain.

based on the geometrical variation that crowns the caisson and on the inclusion of submerged elements in front of the vertical face breakwater, which modify the conditions of the incident wave. These elements consist of a submerged breakwater and rubble toe protection with a small rubble fill between them.

These tests were made for the Marina breakwater at the Olympic Village in Barcelona, whose technical engineers proposed different test solutions. In addition to this work, a series of complementary tests were carried out in order to obtain further information concerning the overtopping rate.

3.- TEST CONDITIONS

The tests took place in a tank with an overall length of 45 m, 6.5 m wide and 0.80 m deep, at the C.E.P.Y.C. laboratories in Madrid.

A channel 1.3 m wide was placed inside the tank, into which the test section was located, facing the normal direction of the wave propagation generated by the paddle.

The depth of the water at the foot of the paddle was 0.70 m, so as to guarantee wave generation in acceptable conditions, and the depth at the foot of the test section was 0.225 m, with a 1:30 gradient at the bottom. A 1:40 scale was used in the tests.

A dynamometer was used for measuring the wave forces, whose ranges of measurement were:

F_x and F_y : 40 Kp (Model units)
 M : 600 Kp.cm (Model units)

As regards the measurement of the overtopping, which included: the amount of these expressed in terms of the number of waves contained in the wave recording, the height reached by the "sheet" of water above the crown and the volume of water that overtopped, we would say that, the recordings of the first two cases were carried out using a device designed in the C.E.P.Y.C., consisting of a transducer made up of a fibreglass plate on which a printed circuit was attached, this being connected to a series of electrodes 1 cm apart. As the water flowed over them, the circuit closed and thus provided the overtopping height (in centimetres) as a sum of the wet electrodes, the abovementioned overtopping also being counted in the overall calculation. The measurement of the volume of water which overtopped was achieved, by a tray attached to the

rear part of the section. The results of this volume are given per linear metre of section of breakwater and per second ($m^3/m/s$).

The output of the analogical signals from the dynamometer and the overtopping gauge are conditioned afterwards, by means of an A/D convertor and digitalized so that they can be read by a computer. A description of of this process is shown in Figure 1.

Figure 1. Measures diagram

The tests were carried out in three types of storm conditions, adjusted to a theoretical spectrum of the J.O.N.S.W.A.P. kind, whose characteristics are similar to those that occur in the Spanish Mediterranean; the wave conditions of these storms, are shown in table 1.

Where:

Gamma is the peak enhancement factor of the Jonswap spectrum, T_p is the peak period of the wave spectrum in seconds and H_s is the significant wave height in metres. The calibrated test waves correspond to records of 300 to 325 waves.

STORM	T_p (s)	H_s (m)	GAMMA
I	10	6, 7.5	3.3
II	12	6, 7.5	3.3
III	14	6, 7.5	3.3

Table 1.

On considering the depth of the toe of the structure $d = 10.20$ m, the bed slope $m = 0.033$ and the three peak periods of the storms, it could be concluded that the structure under the different wave calculations, would be subjected to unbroken waves, broken waves and breaking waves, critical conditions being given for waves that break or which are at breaking point over the vertical facing.

4.- PROCEDURE

The sequence of tests was developed in four distinct stages, each one constituting an approximation to the optimization of the section for the design wave conditions

The First Stage, consisted of testing three vertical breakwaters with the same crown height $h_c = 8.4$ m (which did not vary during the different test stages), but having different crown shapes, these included solutions 1,2,3. Figure 2.

The storms that these structures were subjected to were storms I and III, shown in Table 1.

Figure 2. First stage solutions

The second stage consisted of placing a submerged breakwater that would serve as a filter to the incident wave, causing it to break, so that the wave forces and overtopping at the vertical breakwater would be reduced, Figure 3. Initially, the solutions tested were 4, 5 and 6, that vary as regards the distance between the transversal axis of the submerged breakwater and the wall of the vertical breakwater (L) and the crown height of the submerged breakwater (C_c). After this, and with a view to observing the degree of operativity of the combination vertical breakwater - submerged breakwater, complementary overtopping measurements were carried out with the solutions 4a, 4b, 4c, 5a and 6a, whose characteristics can be seen in Table 2.

The wave conditions tested, corresponded to storms II and III in Table 1, with steps for significant waves of 4, 5, 6 and 7.5 metres.

TABLE 2.

The Third stage was made up by solutions 7 to 15, and consisted of placing rubble toe protection at the base of the vertical breakwater. As regards the submerged breakwater, the geometrical parameters were varied: Cc, L and B, as well as considering rubble of 8 Tons and different parallelepiped concrete block weights on the crown. Fillings of different depths (dr) were tested between the submerged breakwater and the attached rubble, Figure 4 and Table 2.

The test storms were those referred to as II and III in Table 1.

Figure 4. Third stage solutions

The Fourth Stage, comprised solutions 16 and 17. It consisted of testing a tiered superstructure of the type used in solution 2, but occupying the whole width of the caisson. Likewise, the protective rubble attached to the vertical breakwater was removed, one sole thickness of

filling being considered, the variation between the two solutions referred to being determined by the crown width of the submerged breakwater, B, Figure 6 and Table 2.

The test waves at this stage, were storms II and III from Table 1 with step heights for significant waves of 4, 5, 6 and 7.5 metres.

Figure 5. Fourth stage solutions

5.- WAVE FORCE ANALYSIS

The analysis of the results as far as the wave forces is concerned, will only be carried out for the maximum horizontal force recorded by the dynamometer throughout the length of each one of the tests, these being characterized by significant wave height and a specific peak period.

The analysis will be made for the solutions included in each one of the stages outlined in section 4. and, finally all the solutions will be compared as a whole.

The maximum horizontal forces of the first group of tests, corresponding to the first three solutions, can be seen in Figure 6.

The results clearly show, a reduction in the resulting force, undergone in solutions 2 and 3, that at the height +2 present a sloping and tiered surface at the crown of the section, by contrast to solution 1, which has a totally vertical surface. At the same time, the influence of the peak period in the value of the wave force, is clearly shown.

The reduction referred to, as is known, is a result of the lag that exists between the wave action on the two surfaces of the structure; i.e.: that of the caisson, totally vertical, and the tiered sloping surface of the crown. Likewise, the discontinuity that is implied in the sloping plane, also prevents high pressures, known as impulsive breaking wave pressures, from being brought to bear, because they occur slightly above the still water level (S.W.L.); however, this kind of pressure does feature in solution 1, as all the necessary conditions are present.

Figure 6. Results from first stage.

Mitsuyatsu (2) demonstrated, on the basis of a series of systematic experiments that, where there is no rubble mound breakwater foundation and as long as the breaking of the wave occurs in front of a vertical wall, impulsive breaking wave pressure could be brought to bear if the sea bed were equal to or greater than 3% and the wave incidence angle were below 20° , as is the case in solution 1.

Nevertheless, in spite of the considerable reduction in the wave force in solutions 2 and 3, as compared to solution 1, neither of the two can be considered acceptable from the viewpoint of values of the safety factors required for the sliding and overturning of a particular caisson, this having been previously designed. So various options were designed in front of the breakwater and this gave rise to the subsequent stages that were commented upon in section 4.

Solutions 4, 5 and 6 made up the second stage of the present work. The results, as far as the maximum horizontal force is concerned, are shown in Figure 7.

The differences that exist between the results, are determined by the variation in depth of the crown of the submerged breakwater (C_c) and by the length (L) between the vertical face of the caisson and the axis of the submerged breakwater.

It can be observed from the comparison of results, how length (L) is the most influential of the abovementioned parameters, while C_c , at least as regards the experimented values (a difference of 1 m), hardly undergoes any variation, if the respective values of solutions 5 and 6 are observed.

Figure 7. Results from second stage

The reduction in the maximum horizontal force, as a result of the submerged breakwater, in the three solutions, with respect to solution three in the first stage, this serving as a reference, is 8.3 %, solution 4, 18 %, solution 5 and solution 6, 22.75 %. In spite of the reduction in two of the cases being significant when compared to solution 3, it still does not meet the safety factor values that are required for the specific caisson.

The analysis of the next group of tests, belongs to the third stage, and the different solutions are characterized, as was mentioned in section 4, by the variation in some of the geometrical parameters of the submerged breakwater, as a result of a rubble toe protection at the vertical breakwater and by a filling between both breakwaters: vertical and submerged.

The results of this stage can be seen in Figure 8. It can be said that the filling at height -6 m , barely influenced the dissipation of the incident wave energy, once this passed over the submerged breakwater, which can be seen from the values of the figures that correspond to solutions 7 and 8; nevertheless, the same filling, increasing the crown height by 2 m to -4 m , brought about a reduction that lies in a range that goes from 8.5 % to 14 % (compare with solutions 8-9, 13-14 and 12-15).

Solutions 10, 11, 13 and 14 were tested by placing one single layer of parallelepiped elements of concrete blocks of different weights on the crown of the submerged breakwater; as regards this, it could be said that solutions 10 and 11, with respective weights of 20 Tn and 25 Tn , gave worse results than those others where 8 Tn quarry stone units were used on the crown, through the absence of interlocking between the concrete units and, as a result, there was an increase in damage once the first.

test waves attacked: this caused a reduction in the crown height.

45 Tn elements were placed for solutions 13 and 14. Such a great weight difference gave rise to a decrease in the damage and caused an improvement in behaviour, as far as the recording of maximum horizontal force was concerned, and when compared to solutions 10 and 11, although the crown height width went up from $B = 18$ m to $B = 30$ m.

The influence of parameter B in the stretches being tested, can also be seen when comparing the results of solution 8 and solution 12, the latter undergoing a reduction in wave force of 16.6 %.

$H_s = 7.5$ m

Figure 8. Results from third stage

In the last solutions to be tested, 16 and 17, the configuration of the caisson superstructure was changed, its profile being completely tiered, as can be seen in Figure 5. In addition to this, the rubble attached to the caisson toe was removed, the filling being retained.

The results of these solutions can be seen in Figure 9. The result of solution 2, that corresponds only to the caisson with tiered superstructure, is also shown. The reduction of the maximum horizontal force exceeds that of solution 2 in both, and by more than 50 %. The different crown widths of the submerged breakwater, $B = 18$ m and $B = 30$ m that were tested, determine the variation in the results of solutions 16 and 17.

In the light of these results, solution 16 was chosen as the definitive one, that on the basis of the maximum simultaneous wave forces recorded on the dynamometer, complied with the advisable and authorised safety factors in the practice, in accordance with the caisson width that had been previously adopted.

Finally, Figure 10 shows all the results of each one of the solutions tested, corresponding to the maximum horizontal force reached in every one of them.

By mere observation, the reduction that occurs when comparing solution 1 with solution 16, can be considered spectacular, to say the least.

$H_s = 7.5m$

$H_s = 7.5m$

Figures 9 and 10

6.- WAVE OVERTOPPING ANALYSIS

The measures that were taken as regards wave overtopping were; firstly the number of waves that overtopped the breakwater (N), with respect to the total number of waves in the recording (Overtopping %). Secondly, the height of the sheet of water that overtopped the crown of the breakwater, to which, if we add the distance from the water level of the design to the crown height, can be called "overflow wave run-up", from whose values the parameters $R1/3$, R and R_{max} are obtained, through the statistical analysis of the recordings. Finally, the total volume of overtopping during the test storm, expressed in terms of

one m³/s per running metre of vertical breakwater, (average overtopping rate (Q)).

The most important factor for the design engineer concerns the value of Q, because this parameter is the one that determines the flood level behind the breakwater, the capacity that the structure's drainage system requires or the degree of operativity during the storms, of the installations, behind the breakwater.

Making an overall analysis of the overtopping rate obtained for the different solutions tested, we could say that the inclusion, in front of the breakwater, of the different submerged elements, with their respective test sizes, has proved to be effective, as regards the reduction of the overtopping rate; this can be observed in Figure 11, which refers to the most unfavourable wave conditions.

Figure 11. Overtopping comparative graphic, Hs=7.5m

It is not possible to give design recommendations in this work, because in order to do this, it would be necessary to take the geometrical variables of the different element into account, together with a greater number of tests, but, on making an analysis by stages, it is possible to talk of the different effects that could be observed under test conditions.

The first stage of the tests had as main aim to observe the effects, in the wave run-up and overtopping, of the three shapes of crown that were chosen. In figure 12, it can be seen that the least favourable crown was the one used in solution 2. As regards the wave run-up, it can be clearly stated that there are no great differences between the solutions, it turning out to be a very uniform phenomenon for the two test storms (Tp = 10s and Tp = 14s), nevertheless, the final difference in the results is marked by the overtopping percentage that is found in line with the overtopping rate.

Of the different solutions tested at the second stage complementary tests, i.e. solutions 4, 4a, 4b, 4c, 5, 5a, 6 and 6a, see Table 2, firstly it can be said that, compared to the previous stage, reductions have been obtained in the wave run-up and overtopping through the use of the submerged breakwater, Figure 11, and secondly, that for the two phenomena, the least favourable storms were those characterized as $T_p = 14s$, Figures 13 and 14.

$H_s = 7.5m$

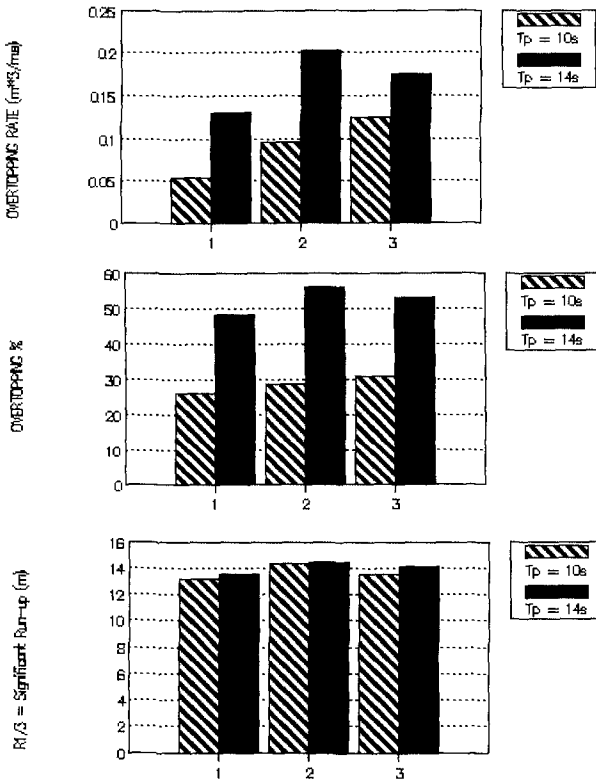

Figure 12. Results from solutions 1,2,3 with $H_s=7.5m$

Thirdly, that, within the magnitude of the values tested in variables L , C_c and B , the run-up phenomenon still shows very uniform behaviour, the best results being observed at this stage for $L = 60 m$ and $B = 12 m$. However, in the case of the overtopping rate, it can be seen that parameters C_c and L do not influence very much, and that it is parameter B , for the solutions that have a greater value ($B = 18 m$), which gives the best results both for $T_p = 12s$ and $T_p = 14s$. Figures 13 and 14.

At the third stage, owing to the fact that the run-up phenomenon is still fairly uniform and unhelpful in the evaluation of the various solutions, it will not be taken into account in this analysis.

On studying the results of the different solutions at this stage (7 to 15) with respect to the overtopping rate, we can say that, simply by including the protection at the toe of the vertical breakwater acting together with the submerged breakwater, solution 7, Figure 15, reductions are obtained in the overtopping with respect to the two previous stages, and then, on reducing the existing depth in the space formed between the two breakwaters using a rubble filling, we continue to obtain improvements the lesser the depth ($dR = -10.2, -6, -4$). Nevertheless, the most influential variable is still the width of the berm (B) of the submerged breakwater, a considerable improvement being observed when it is increased to 30 m.

Finally, of the solutions taken at the 4th stage, it can be seen from Figure 11, how the omitting of the wall protection influences the results, and, also the influence of the width of the berm (B) between 18 m and 30 m.

Figure 13. Wave Run-up

$H_s = 7.5m$

Figure 15. Results from third stage solutions

7.-CONCLUSIONS

The different activity, carried out in front of the vertical designed breakwater, have been shown, at the Marina of the Olympic Village for Barcelona-92, they were designed to optimize the abovementioned breakwater from the point of view of its stability and functionality.

In the light of the tests performed, it is not possible to establish any design criteria to determine the optimum geometrical characteristics of the submerged breakwater situated in front of the vertical one; it would only be possible by the realizing of a larger number of more systematic tests carried out in order to detect the sensitivity of each of the parameters involved in the wave attack (C_c , B , L and dr).

Nevertheless, it can be said that, within the range of values experimented for the above-cited parameters, the crown width of the submerged breakwater, B , turned out to be the most sensitive to both the wave force and the overtopping.

As far as the "overtopping/run-up" is concerned, it can be said that the statistical parameter $R_{1/3}$, used in its analysis, hardly showed significant variations for the different situations tested.

8.-ACKNOWLEDGEMENTS

The authors would like to acknowledge the help given by the persons in charge of the Olympic Village, who provided us with the slides showing the situation of the Marina at the time. These slides made the presentation at the I.C.C.E.'90 easier.

CHAPTER 102

STABILITY OF BREAKWATERS CONSTRUCTED ON DREDGED SAND MOUND

Kenji Yano, Yuzo Mizuno, Nobutoshi Umezawa and
Tomoyuki Yanase¹

ABSTRACT

The possibility for the construction of "sand mound breakwater", which is a caisson type breakwater on a artificial sand mound, has been studied. First the wave force characteristics acting on the composite sand mound breakwater model are described, to identify the conditions where impulsive breaking wave pressures are generated. Second, the scouring of the toes of rubble mounds is discussed. Finally there is an outline of field experiments, scouring of sand mounds, and the status of the deposits. The results of experiments provide useful information for the design of breakwater constructed on the artificial sand mound or on a similar double-sectioned sea bottom.

1. INTRODUCTION

The construction of composite breakwaters in relatively deep sea areas requires a large rubble mound foundation that takes up a considerable proportion of the total construction cost. This is due to limitations imposed on the capacity of the caisson plant, which force an increase in the height of the rubble mound. In harbors where dredging of waterways and anchorages yields large quantities of good sand, the construction costs of breakwaters and the cost incurred in disposing the dredged sand may be reduced if the sand is used in the breakwater mound.

¹ Port and Harbor Section, Civil Engineering Research Institute, Hokkaido Development Bureau, 1-3 Hiragishi, Toyohira-ku, Sapporo, 062, Japan.

The construction of "Sand Mound Composite Breakwaters" requires a solution to the technical problems with wave force characteristics, scouring, bearing capacity, liquefaction characteristics, all of which are important in breakwaters on the artificial sand mound. Since 1986, the Hokkaido Development Bureau has been conducting experiments with hydraulic models and field demonstration tests at Tomakomai East Port to help solve these problems.

This report presents an evaluation of tests with the hydraulic model, with partial results of the field tests. First the wave force characteristics acting on the composite sand mound breakwater model are described, to identify the conditions where impulsive breaking wave pressures are generated. A number of studies on impulsive breaking pressures (e.g. Tanimoto, 1976) acting on normal composite breakwaters have been carried out, but studies relative to the breakwater on a double-sectioned sea bottom are virtually non-existent.

Second, the scouring of the toes of rubble mounds is discussed. Much effort has been made to avoid the scouring of toes of rubble mound, however, no generally applicable countermeasures have been established to meet particular local requirements. This presents a design method for effective countermeasure work based on tests with hydraulic models: (i) determining the scouring positions of breakwaters by structural types, and (ii) determining the length of effective counter-scouring work.

Finally there is an outline of field experiments, scouring of sand mounds, and the status of the deposits.

2. WAVE FORCE CHARACTERISTICS ACTING ON BREAKWATER

2-1 Testing Equipment and Method

The tests were conducted in a two-dimensional wave tank equipped with an irregular wave generator (24m long, 80cm wide, 1m high). Dimensions were 1/75, with the channel bed slope 1/100. The wave spectrum employed was the modified Bretschneider-Mitsuyasu frequency spectrum. The measurement time was set at the significant wave period $\times 200$ sec., to ensure measurements of more than 200 waves. The data was transformed to digital at the sampling frequency of 100Hz. Figure 1 shows a typical section of the test model.

Fig. 1 Typical section of test model

The wave pressures were defined as the maximum average pressures of individual waves, and the representative wave pressures were defined with a same way for the wave heights such as the maximum wave pressure, the 1/10 maximum one-tenth wave pressure, and the maximum one-third wave pressure or significant wave pressure, expressed as p_{max} , $p_{1/10}$, and $p_{1/3}$ respectively.

There are two major types of tests. Test 1 on a fixed bed with the sand mound slope, and thickness and the depth varied. The rubble mound had a standard width of front berm F_m of a minimum 14cm (in-situ size 10.5m) assuming the foot protection concrete block and the armor concrete block as paired. For reasons of economy the thickness was kept as low as possible, 4cm (3m in-situ) including the thickness of the armor concrete block. The breakwaters were then evaluated with significant waves of 6 wave heights \times 3 periods.

Test 2 was performed on a movable bed and the variation in wave pressures after scouring was investigated. A movable bed was prepared in the same section as the fixed bed by replacing the sand mound and seabed with fine sand (median particle size $d_{50}=0.16\text{mm}$). Considering characteristics of littoral drift, this was equivalent to a median particle size of $d_{50}=1\text{mm}$ in-situ. The slope of the sand mound and the width of the counter-scouring works were varied. After measuring the sand surface after scouring by the precision bottom gauge with wave motion for 4 hours, the wave pressures were measured at similar conditions as in Test 1.

2-2 Results and Discussion

(a) The Effect of Slope of Sand Mound

Figure 2 shows variations in the coefficient of wave pressure intensity with the slope of the sand mound

at 1/15, 1/30, and 1/50 and with $t=6\text{cm}$, and $h=24\text{cm}$. The figure indicates that the coefficients often become large when the steepest slope is $a=1/15$, and it also indicates that there are cases where coefficients become greater with the longer periods and flatter slopes. This shows that impulsive breaking wave pressures are possibly generated more commonly with flat sloped sand mounds of moderate slope length.

(b) Shock Wave Pressure Generation

The above confirmed that very strong shockwave pressures could act on the sand mound composite breakwater under various conditions. Figure 3 graphically shows the possibility of shock pressures leading to breaking waves. It uses two sets of nondimensional quantities, and the ratio of significant wave height ($H_{1/3}$) to own depth of mound (d) on the ordinate and mound slope length (l) to wavelength (L) on the abscissa and the coefficients of the maximum cotidal average intensity of wave pressure ($\bar{P}_{\text{max}}/w_0H_{\text{max}}$). The broken and chained lines indicate boundaries where the coefficients exceed 1.5 and 2.0 suggesting the possibility of shock pressure from breaking waves to be significant above these boundaries.

The design of conventional composite breakwaters for sea areas with bedrock and cross sections similar to sand mounds, require special attention to the possibility of producing similar wave pressure characteristics.

(c) The Effect of Scouring of Sand Mound

The wave pressure tests above were all on fixed beds, and relate to the problems of the effect of various conditions of wave on the stabilization of the breakwaters immediately after completion. Another important problem in the stability of sand mound breakwaters is scouring and the possible effects of wave pressures when the shape of the sand mound changes due to scouring in front of breakwaters.

Figure 4 shows results with $h=24\text{cm}$ and $t=6\text{cm}$ as in Table 2, when $H_{1/3}=8.5\text{cm}$, and $T_{1/3}=1.3\text{s}$ was active for 4 hours. The scouring is greater with $a=1/15$ than with 1/50. It is evident that the face of the narrower anti-scouring installations suffers more from scouring. This indicates problems with actual breakwaters as the maximum scouring depth with the model can be assumed to be 1 to 1.5m.

In $\bar{P}_{1/3}$ there are no appreciable changes among the values before and after scouring for different wave pressure intensities. For \bar{P}_{max} , the intensities before

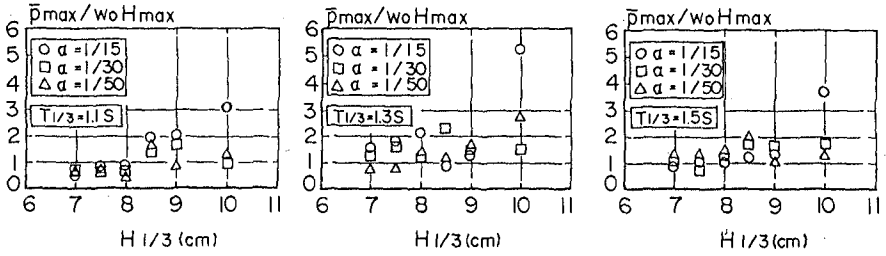

Fig. 2 Differences of wave pressures by sand mound slopes

Fig. 3 Possibility of shock pressure

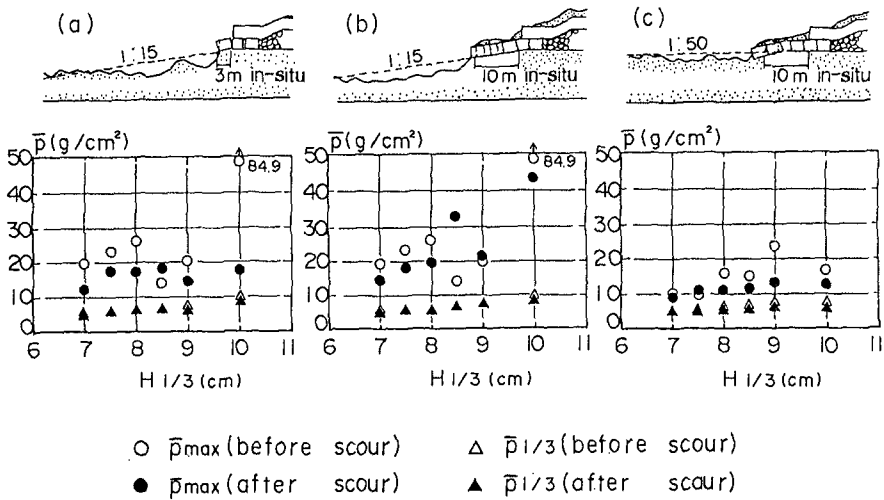

Fig. 4 Differences of wave pressures due to before and after scours

scouring was greater. Other periods show similar results, and it is assumed that there are no significant differences in the characteristics of wave pressures with different scouring configurations.

3. SCOURING IN FRONT OF BREAKWATERS AND ITS PREVENTION

3-1 Test Method

The tests were carried out in the two-dimensional wave tank used for the wave pressure tests. The scale, except for the bottom materials, were based on the Froude Model Law of 1/40 without distortion. The bottom materials were the same as used in the previous wave pressure tests. The particle size of the sand equal a $d_{50}=0.5\text{mm}$ size of bottom materials. The rubble-filled wire cross baskets for the scour prevention were 1/40 of the regular baskets (2.0m x 3.0m x 1.0m) with the weight adjusted to equal 10 tons in-situ. With regular waves as test waves scouring was studied on 3 kinds of wave periods $T=7, 10, \text{ and } 13$ sec.

3-2 Test Results and Discussion

(a) Structural Type of Breakwater and Place of Scouring

Irie (1984) pointed out that because of standing

waves bottom is scoured at nodes and accumulated at loops in front of the actual breakwaters. A remarkable damage of rubble mound would take place when the first node of standing waves $L/4$ comes near the toe of rubble mound where L is the length of a progressing wave.

Introducing this into a design poses problems: (i) establishing a basis for depth determination when calculating L of a composite breakwater, and (ii) determination of the location of the reflection face (the origin for $L/4$) for breakwater armored with wave dissipating blocks or slit caisson breakwater. To evaluate (i) and (ii), these 3 types of breakwater were examined. Figure 5 shows the models of wave dissipating type breakwater. The height of the crown was set so the breakwater would be non-overtopping.

Figure 6 shows an example of the scouring location where: $h=37.5\text{cm}$ (15m in-situ), and $T=2.06\text{sec}$ (13 sec). The \circ mark in the figure indicates the use of (h) as the depth when determining the wave length and Δ indicates when (d) was used. K_r is the reflection coefficient. The locations of $L/4$, $L/2$, and $3L/4$ are shown on the structures. Hence, black indicates the scouring locations and white the deposition. Based on this, the conversion into $L/4$ shows only differences of a few meters with long $T=13$ sec periods, which indicates that it is relevant to the pickup (h) as the depth to determine the wavelength.

Figure 7 shows the scouring locations of the wave dissipating armor block structure and the 2-stage slit breakwater. The \circ and \square in the figure show the locations of $L/4$, $L/2$, and $3L/4$ seen from structures using (h) to calculate the wavelength as with the composite breakwater. The \circ mark indicates upright wall reflection of the wave dissipating armor block structure and the \square mark indicates the intersection between the slope face of the wave dissipating blocks and the still water level.

For the slit caisson breakwater, \circ indicates the offshore side slit wall face and \square indicates the rear upright wall. In wave dissipating armor block breakwaters, visual inspection was considered necessary to establish the upright wall face as a reflector, based on the reflected waves around the structure and the scouring location shown in the figure.

With the slit caisson breakwater, the reflecting face was set on the offshore side of the upright face up to $T=10\text{sec}$. However, for periods of $T=13\text{sec}$, the reflection face of the scouring location is thought to be located somewhere between the offshore side slit wall face and the rear upright wall. In practice it is

Fig. 5 Models of wave dissipating type breakwater

Fig. 6 Scouring location in front of composite breakwater

strongly recommended to set all on the offshore side of the slit wall face.

Comparing the scouring of common composite breakwaters with low-reflection type breakwaters shows that the absolute quantities of scouring and deposition are smaller with the low-reflection type, suggesting that the reduction in reflected waves is more effective to control the scouring.

(b) Length of Scour Prevention Works

The experiments with the composite breakwater used the wavelength as the parameter to attempt to determine the length of rubble-filled wire cross baskets for the scour prevention. Wavelength L was determined with the installation depth, and the scouring conditions were compared by successively increasing the length of the wire crosses from the offshore side (i) $L/4$ ($3L/12$), (ii) $L/3$ ($4L/12$), and (iii) $5L/12$, with the upright wall face as the origin (face of reflection). Two sea bottom slopes were studied $1/100$ and $1/15$.

Figure 8 shows one set of results. The bottom slope did not affect moving the wire crosses nor cause scouring when the basket length was $5L/12$, and these dimensions was considered effective for scour control. Scour control with $L/3$ were also generally effective although there was a slight dipping of one basket at the end. With $L/4$ baskets, the movement of baskets in the front row was significant, and particularly with steep bottom slopes, and the scour quantity at the toe of the slope was the largest. These results showed that using only the wave length parameter L in designs was adequate for scour prevention. There were good results with $L/3$ from the upright wall of the structure as the effective length of scour prevention works.

4. FIELD TESTING

4-1 Construction of Sand Mound

The tests were conducted in a 16m deep sea area at Tomakomai East Port on the Pacific coast by Tomakomai Port and Harbor Construction Office. Figure 9 shows schematic diagram of sand mound breakwater at Tomakomai Port. Figure 10 shows a model of the breakwater with two 12.5m (L) x 20m (W) x 12m (H) caissons installed on the sand and rubble mound. The construction started in November 1986 and was complete in October of the following year.

Fig. 8 Scouring shapes in front of breakwater under various length of scour protections.

Fig. 9 Schematic diagram of sand mound breakwater for field test at Tomakomai Port

Fig. 10 Test breakwater at Tomakomai Port

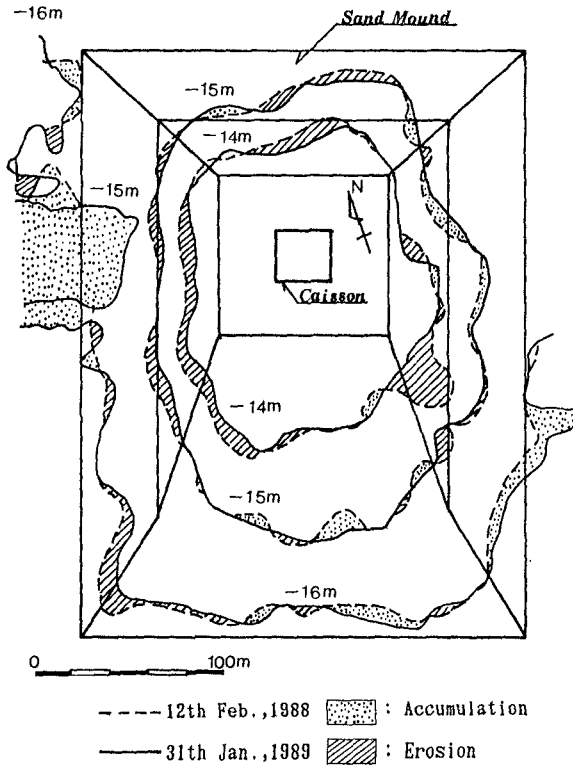

Fig. 11 Comparison of contours

The sand mound used dredged sediment from waterways (the median particle size $d_{50}=0.8\text{mm}$) and other fill material (the median particle size $d_{50}=1.7\text{mm}$, pump dredged and pile-stored on land for several years during which the fine particles were washed out leaving stones as main component). The materials for the sand mound were transported by bottom door hopper barges installed canvas curtain for dispersion prevention, and approximately 1,000,000 cubic meters were dumped for a maximum mound thickness of 3m.

4-2 Stability Against Scouring

Figure 11 shows sounding surveys conducted between the caissons half a year after the initial installation (February, 1988) together with sounding survey of January 1989. The largest significant waves observed during this time was 4.0m, and the variation in the subbase heights lower than 0.5m, indicating that the sand mound remained stable.

5. SUMMARY

The results obtained from the study may be summarized as follows:

(1) The relation between the slope of the sand mound and the generation of shock pressure breaking waves is affected by the angle of the slope, and also particular slopes of sand mounds and lengths of slope are susceptible to the wave conditions generating shock pressure breaking waves.

(2) The nondimensional ratios: significant wave height ($H1/3$) to crown depth of rubble mound (d), and slope length of sand mound (l) to wave length related to the significant wave period in Figure 3, and indicates the possibility of shock pressure breaking wave generation.

(3) There were no significant differences in the intensities of wave pressure before and after scouring.

(4) Comparing the scouring of common composite breakwaters with low-reflection type breakwaters shows that the absolute quantities of scouring and deposition are smaller with the low-reflection type, suggesting that the reduction in reflected waves is more effective to control the scouring.

(5) It is recommended that the effective length of scour prevention work is $L/3$ from the upright wall of the structure.

CHAPTER 103

STABILITY OF LOW-CRESTED AND REEF BREAKWATERS

Jentsje W. van der Meer¹⁾ and Krystian W. Pilarczyk²⁾

Abstract

Low-crested structures are designed for some or even severe overtopping. The stability of these structures is sometimes higher than the non-overtopped structures, due to the fact that wave energy can pass over the crest, giving lower wave forces on the armour layer of the seaward slope.

Low-crested structures can be classified into three categories: dynamically stable reef breakwaters, statically stable low-crested structures with the crest above swl and statically stable submerged structures. Well described investigations at various institutes (in total about 275 tests) were re-analysed and this has led to practical design formulas and graphs for each of the three classes mentioned above.

Introduction

As long as structures are high enough to prevent overtopping, the armour on the crest and rear can be (much) smaller than on the front face. The dimensions of the rock in that case will be determined by practical matters as available rock, etc.

Most structures, however, are designed to have some or even severe overtopping under design conditions. Other structures are so low that also under daily conditions the structure is overtopped. Structures with the crest level around swl and sometimes far below swl will always have overtopping and transmission.

It is obvious that when the crest level of a structure is low, wave energy can pass over it. This has two effects. First the armour on the front side can be smaller than on a non-overtopped structure, due to the fact that energy is lost on the front side.

The second effect is that the crest and rear should be armoured with rock which can withstand the attack by overtopping waves. For rock structures the same armour on front face, crest and rear is

1) Delft Hydraulics, PO Box 152, 8300 AD Emmeloord, The Netherlands
2) Rijkswaterstaat, PO box 5044, 2600 GA Delft, The Netherlands

often applied. The methods to establish the armour size for these structures will be given here. They may not yield for structures with an armour layer of concrete units. For those structures physical model investigations may give an acceptable solution.

Classification of low-crested structures

Low-crested rock structures can be divided into three categories, see also Figs. 1-3.

Dynamically stable reef breakwaters

A reef breakwater is a low-crested homogeneous pile of stones without a filter layer or core and is allowed to be reshaped by wave attack (Fig. 1). The equilibrium crest height, with corresponding transmission, are the main design parameters. The transmission will not be treated in this paper (one is referred to Van der Meer (1990b)).

Figure 1 Example of reef type breakwater (Ahrens (1987))

Statically stable low-crested breakwaters ($R_c > 0$)

These structures are close to non-overtopped structures, but are more stable due to the fact that a (large) part of the wave energy can pass over the breakwater (Fig. 2).

Figure 2 Example of low-crested breakwater (Powell and Allsop (1985))

Statically stable submerged breakwaters ($R_c < 0$)

All waves overtop these structures and the stability increases remarkably if the crest height decreases (Fig. 3).

Figure 3 Example of submerged breakwater Givler and Sørensen (1986))

Description of data sets

Ahrens (1987) described the stability of reef type breakwaters. This type of breakwater is little more than a homogeneous pile of stones with individual stone weights similar to those ordinarily used in the armour and first underlayer of conventional breakwaters. The initial crest height is just above the water level. Under severe wave conditions it is allowed that the crest height decreases to a certain equilibrium crest height. Ahrens performed about 15 tests on stability of these structures and gave a formula for the equilibrium crest height.

Allsop (1983) and Powell and Allsop (1985) described about 45 tests on the stability of breakwaters with the crest above swl and which were conventional breakwaters. Only small damage (displacement of stones) was allowed during design conditions.

Givler and Sørensen (1986) described about 45 tests on the stability of submerged breakwaters. The tests were performed with regular waves and included a large range of wave heights, but also wave periods. The damage at the crest was measured and the design criteria are similar to the conventional breakwaters (no or only small damage allowed).

Finally Van der Meer (1988) performed about 45 tests during his very extensive model investigation (in total about 500 tests) on structures with a low crest. These tests cover all three structure types described above (reef type, low-crested above swl and submerged) and were used as a connection between the various structures and data sets.

A more extensive description of the above described data sets together with the complete re-analysis of the data can be found in Van der Meer (1990a).

Reef breakwaters

The analyses of stability by Ahrens (1987, 1989) and Van der Meer (1990a) was concentrated on the change in crest height due to wave attack, see Fig. 1. Ahrens defined a number of dimensionless parameters which described the behaviour of the structure. The main one is the relative crest height reduction factor h_c/h_c' . The crest height reduction factor h_c/h_c' is the ratio of the crest height at the completion of a test, h_c , to the height at the beginning of the test, h_c' . The natural limiting values of h_c/h_c' are 1.0 and 0.0 respectively.

The wave height can be characterised by $H_s/\Delta D_{n50}$ (Van der Meer (1988)) or N_s (stability number: Ahrens (1987, 1989)).

$$H_s/\Delta D_{n50} = N_s \quad (1)$$

where:

H_s = significant wave height, H_s or H_{m0} (H_{m0} was used in this study)

Δ = relative mass density; $\Delta = \rho_a/\rho_w - 1$

ρ_a = mass density of armour rock

ρ_w = mass density of water

D_{n50} = nominal diameter of rock; $D_{n50} = (M_{50}/\rho_a)^{1/3}$

M_{50} = average mass (50% value on mass distribution curve)

Ahrens found for the reef breakwater that a longer wave period gave more displacement of material than a shorter period. Therefore he introduced the spectral (or modified) stability number, N_s^* , defined by:

$$N_s^* = H_s^{2/3} L_p^{1/3} / \Delta D_{n50} \quad (2)$$

where: L_p = the Airy wave length calculated using T_p and the water depth at the toe of the structure h . In fact a local wave steepness is introduced in Eq. 2 and the relationship between the stability number N_s and the spectral stability number N_s^* can simply be given by:

$$N_s^* = N_s \times s_p^{-1/3} = H_s/\Delta D_{n50} \times s_p^{-1/3} \quad (3)$$

where: s_p = the local wave steepness; $s_p = H_s/L_p$

That a longer wave period gives more damage than a shorter period is not always true. Ahrens concluded that it was true for reef breakwaters where the crest height lowered substantially. It is however not true for non-overtopped breakwaters (Van der Meer (1987 or 1988)). The influence of the wave period in that case is much more complex than suggested by Eq. 3.

The crest height (reduction) of a reef type breakwater can be described by:

$$h_c = \sqrt{A_t / \exp(aN_s^*)} \tag{4}$$

where "a" = a coefficient and A_t = area of structure cross-section. Ahrens gave various equations for the coefficient a. The most recent and refined one is given by Ahrens (1989):

$$"a" = 0.046(h_c' - h_c) / h + 0.2083(h_c / h)^{1.5} - 0.144(h_c / h)^2 + 0.4317 / \sqrt{B_n} \tag{5}$$

where:

h = water depth at structure toe and
 $B_n = A_t / D_n^2$ (bulk number)

The structures of Van der Meer (1988) had other crest heights, water depths, bulk numbers and slope angles than Ahrens' structures. A first fit of Eqs. 4 and 5 with these data is shown in Fig. 4. The breakwater response slope is shown on the vertical axis and is defined by:

$$C = A_t / h_c^2 \tag{6}$$

The graph shows the data sets with different bulk numbers B_n and response slopes C . Where Ahrens' data were nicely located around the curve (Eqs. 4 and 5), the data of Van der Meer did not. It is clear from Fig. 4 that the average slope "as built", C' , has also influence on the crest height, besides the parameters h_c' / h and B_n .

Figure 4 Data of Van der Meer (1988) with Eqs. 4 and 5

Therefore all the data of Ahrens (1987) were re-analysed together with the data of Van der Meer (1988). The complete analysis is given by Van der Meer (1990a), the basis of this paper. It will not be given here.

The final equation that was derived from the analysis is given by:

$$h_c = \sqrt{A_c / \exp(aN_s^*)} \quad (4)$$

$$\text{with "a"} = -0.028 + 0.045C' + 0.034h'_c/h - 6.10^{-9} B_n^2 \quad (7)$$

and $h_c = h'_c$ if h_c in Eq. 4 $>$ h'_c .

The same data as shown in Fig. 4 are given in Fig. 5, but now with the new equations 4 and 7, and with on the vertical axis the relative crest height h'_c/h in stead of the response slope C. The agreement is good. Eq. 7 gives almost the same results for Ahrens' test range as Eq. 5. Eq. 7 is, therefore, valid for a wider range of conditions.

Figure 5 Data of Van der Meer (1988) with Eqs. 4 and 7

The lowering of the crest height of reef type structures as shown in Fig. 1, can be calculated with Eqs. 4 and 7. It is possible to draw design curves from these equations which give the crest height as a function of N_s^* or even H_s . An example of h_c versus H_s (produced by Delft Hydraulic's program BREAKWAT) is shown in Fig. 6. The reliability of Eq. 4 can be described by giving 90% confidence bands. The 90% confidence bands are given by $h_c \pm 10\%$.

Statically stable low-crested breakwaters above swl

The stability of a low-crested conventional breakwater can be related to the stability of a non-overtopped structure. Stability formulas as the Hudson formula or more advanced formulas (Van der Meer (1987, 1988)) can be used for example. The required stone diameter for an overtopped breakwater can then be determined by a reduction factor for the mass of the armour, compared to the mass for a non-overtopped structure.

Figure 6 Design graph of reef type breakwater

Data sets that could be used for analysis were a part of Ahrens data (with small damage to the crest), Powell and Allsop (1985) and Van der Meer (1988). Fig. 7 gives the damage curves of a part of Van der Meer's tests with four crest heights, R_c , and for a constant wave period of 1.7 s. From this figure it is obvious that a decrease in structure crest height results in an increase in stability.

Furthermore, from the tests it could be concluded that a longer period of 2.2 s gave an increase in stability for $R_c/H_c \leq 1.3$ and the shorter period of 1.7 s for a lower value of $R_c/H_c \leq 0.8$. This can also be explained in a physical way. A long period gives higher run-up on a slope than a short period. Therefore more energy is lost by overtopping for a long period at the same crest level as for a short period.

The transition height where the increase in stability starts (given as a R_c/H_c value) should in fact be a function of the wave period (or wave steepness) too. From the mentioned data sets the following transition heights R_c/H_c were derived and the corresponding (average) wave steepness $S_{op} = 2\pi H_s/gT_p^2$ was taken from the original data.

Author	transition	
	R_c/H_s	s_{op}
Van der Meer ($T_p = 2.0$ s)	0.8	0.025
Van der Meer ($T_p^D = 2.6$ s)	1.3	0.015
Ahrens	1.3	0.010
Allsop (long wave)	2.0	0.006
Allsop (short wave)	0.7	0.027

Figure 7 Influence of crest height on damage curves (from Van der Meer (1988))

These data points are shown in Figure 8. Although the points are only a rough estimate, they show a consistent trend: a decreasing transition crest height with increasing wave steepness. The possible maximum steepness in nature will be in the order of $s_{op} = 0.04 - 0.045$, which in fact was not tested by one of the authors. Although not the best fit, the following equation (also shown in Figure 8) gives a good fit with the data:

$$\text{transition crest height: } R_c/H_s = 0.13 s_{op}^{-0.5} \tag{8}$$

In Powell and Allsop (1985) a dimensionless crest height R_p^* was introduced which was used to describe overtopping and which included the wave steepness. The definition is given by:

$$R_p^* = R_c/H_s \sqrt{s_{op}/2\pi} \tag{9}$$

Comparison and rewriting of Eqs. 8 and 9 shows that the transition crest height can simply be described by:

$$R_p^* = 0.052 \tag{10}$$

The average increase in stability ($H_s/\Delta D_{n50}$ or N_s^*) for a structure with the crest at the water level, in comparison with a non-overtopped structure, is in the order of 20-30%. If the increase in stability is set at 25%, independent of wave steepness, and if a linear increase in stability is assumed between $R_p^* = 0.052$ and $R_p^* = 0$, the increase in stability can be described as a function of R_p^* only. Furthermore, if not the increase in stability is taken as a measure, but the reduction in required nominal diameter D_{n50} , the final equation becomes:

$$\text{Reduction factor for } D_{n50} = 1/(1.25 - 4.8 R_p^*) \tag{11}$$

for $0 < R_p^* < 0.052$

Figure 8 Transition crest height where the influence of a low crest starts, as a function of wave steepness

This final equation 11 describes the stability of a statically stable low-crested breakwater with the crest above swl in comparison with a non-overtopped structure. Eq. 11 is shown in Fig. 9, for various wave steepnesses, and can be used as a design graph. The reduction factor for the required nominal diameter can be read from this graph (or calculated by Eq. 11) in comparison with a non-overtopped structure.

An average reduction of 0.8 in diameter is obtained for a structure with the crest height at the water level. The required mass in

that case is a factor $(1/1.25)^3 = 0.51$ of that required for a non-overtopped structure.

Figure 9 Design graph with the reduction factor for the stone diameter of a low-crested structure ($R_c < 0$) as a function of relative crest height and wave steepness

Submerged breakwaters

The tests of Ahrens (1987, 1989) and Allsop (1983) and Powell and Allsop (1985) had always an initial crest level at or above the water level. Only Van der Meer (1988) and Givler and Sørensen (1986) had initial crest heights below the water level. The total amount of data is limited, however. Van der Meer (1988) tested only a slope angle of 1:2 and Givler and Sørensen (1986) tested only a slope of 1:1.5. The seaward slope angle might have some influence on the stability of the submerged structure. Therefore the analysis of submerged structures here will be only valid for rather steep slopes, say about 1:1.5 to 1:2.5.

The slope angle has large influence on non-overtopped structures. In the case of submerged structures the wave attack is concentrated on the crest and less on the seaward slope. Therefore it might be allowed to exclude the slope angle of submerged structures as being a governing parameter for stability.

The relationship between relative crest height h'/h and spectral or modified stability number N_s^* (Eq. 2) for a fixed damage level of $S = 5$, where S is defined by Van der Meer (1988), is shown in Fig. 10. It is noted again that the tests of Givler and Sørensen were

performed with monochromatic waves and that therefore, differences in results between Van der Meer's tests and Givler and Sørensen's tests might be due to this effect.

The N_s^* values of Givler and Sørensen for $h'_c/h = 0$ are a little smaller than those of Van der Meer. This might be caused by the above described difference in wave testing, but also by a less accurate measuring technique for the damage.

The N_s^* values for $h'_c/h = 0.75$, however, are lower in Van der Meer's tests, see Figure 10. The data points of Van der Meer for this crest height are very close which means that for statically stable submerged structures stability might better be described by N_s^* instead of $H/\Delta D_{n50}$. That this is not the case for low-crested structures with the crest above swl, can also be concluded from Figure 10, where for $h'_c/h > 0$ substantial difference is found for the two wave periods tested by Van der Meer.

Figure 10 Spectral stability number as a function of relative crest height for submerged structures and for a fixed damage level of $S = 5$

For structures with the crest above swl it was concluded that a reduction of 0.8 in nominal diameter (or an increase of 25% in N_s^*) value can be expected for breakwaters with the crest at the water level, in comparison with non-overtopped structures. This factor is also present in Figure 10. For submerged structures, however, the increase in stability is much larger. The difference in N_s^* between $h'_c/h = 1.0$ and 0.5 is about a factor 2.

Moreover, if $h'_c/h < 0.45$ a remarkable increase in stability is present (the right points in Figure 10). This might be due to a change in phenomenon considered. If the structure becomes too low (and too small) the wave does not "feel" the structure anymore.

Figure 10 can be used to develop a design formula for submerged structures. As the difference between testing with monochromatic or random waves is not known for this type of structure, a design curve

should be at the safe side of the data of Givler and Sørensen. According to the description of the crest height for a reef breakwater (see Eq. 4) the following equation can be fitted to the data:

$$h'_c/h = a \exp(bN_s^*) \quad (12)$$

where "a" and "b" are coefficients. The coefficient "b" was found to be the same for all three damage levels of $S = 2, 5,$ and 12 which were considered, and amounted to $b = -0.14$. The coefficients "a" were respectively 2.33, 2.68 and 3.11 for $S = 2, 5$ and 12 . A linear relationship between "a" and S gives the following equation:

$$a = 2.1 + 0.1 S \quad (13)$$

Eqs. 12 and 13 together give the final stability formula:

$$h'_c/h = (2.1 + 0.1 S) \exp(-0.14 N_s^*) \quad (14)$$

The stability of submerged breakwaters is only a function of the relative crest height, the damage level and the spectral stability number. Eq. 14 is shown in Figure 10 and gives good agreement with the test results.

Figure 11 Design curves for a submerged structure

For fixed crest height, water level, damage level, and wave height and period, the required ΔD_{n50} can be calculated, giving finally the required stone weight. Also wave height versus damage curves can be derived from Eq. 14.

Eq. 14 is shown as a design graph in Fig. 11 for four damage levels. Here $S = 2$ is start of damage, $S = 5-8$ is moderate damage and $S = 12$ severe damage (more than one layer removed from the crest).

Conclusions

Low-crested rubble mound structures can be divided into three categories: dynamically stable reef breakwaters; statically stable low-crested breakwaters ($R_c/H_c > 0$) and statically stable submerged breakwaters. All waves overtop these structures and the stability increases remarkably if the crest height decreases.

The stability of reef breakwaters is described by Eqs. 4 and 7. Design curves can be drawn with the aid of these equations and an example is given in Fig. 6.

The stability of a low-crested breakwater with the crest above swl is first established as being a non-overtopped structure. Stability formulas derived by Van der Meer (1987, 1988) can be used. The required stone diameter for an overtopped breakwater can then be determined by multiplying the derived stone diameter for a non-overtopped structure with a reduction factor, given by Eq. 11. Design curves are shown in Fig. 9.

The stability of submerged breakwaters depends on the relative crest height, the damage level and the spectral stability number. The stability is described by Eq. 14 and a design graph is given in Fig. 11.

CHAPTER 104

FORCES ON AND PARTICLE MOTIONS AROUND SUBMERGED STRUCTURES IN STEEP WAVES

JESPER SKOURUP ¹ and IVAR G. JONSSON ²

Abstract

A boundary integral equation method combined with a non-linear time stepping procedure for the free water surface is developed for simulations of the interaction between highly non-linear water waves and fixed submerged horizontal cylinders.

The wave forces on the cylinders are computed and a good correspondence is found with other computed results for low Keulegan-Carpenter numbers.

A new method for tracing the orbits of water particles in the fluid domain is developed, and the influence from submerged structures on the orbits is visualized through some computational examples.

Introduction

The numerical modelling of the interaction between highly non-linear water waves and large structures has been a field of growing interest during the last decade. These studies are motivated by the desire to obtain a numerical model in which simulations of wave/structure interactions can be performed, and hence establish an alternative to physical model tests. Among the numerical models based on a potential theory formulation the Boundary Integral Equation Method (BIEM) turns out to be one of the most efficient ones.

The first contribution where the BIEM was used for the modelling of steep and overturning waves was given by Longuet-Higgins & Cokelet (1976). They used a formulation based on Green's 2nd identity, but in a conformably map-

-

 - 2) Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Technical University of Denmark, DK-2800 Lyngby. DENMARK

ped space, and the computations were thus restricted to two spatial dimensions (2-D).

Use of a BIEM based on the Cauchy integral theorem was made by Brevig et al. (1981), and they computed the wave forces on a submerged horizontal circular cylinder (pipeline) caused by breaking waves.

Stansby and Slaouti (1984) also used a formulation based on the Cauchy integral theorem in their computations of wave forces on a horizontal circular cylinder, and they obtained results which were in good agreement with the analytic results of Ogilvie (1963).

An efficient method for the temporal updating of the free water surface was developed by Dold & Peregrine (1984). In this method the influence of the higher order derivatives along the free water surface was taken into account, and this permitted the use of large time-steps with a good accuracy, and the method became very efficient for the modelling of e.g. overturning waves. In their model a conformably mapped space and Cauchy's integral theorem were used, and hence their computations (as in the previous models) were restricted to 2-D problems.

In the present paper a 2-D physical-space, non-linear BIEM is used for the modelling of steep water waves and for wave-structure interactions, and contrary to the 2-D models described above, there are in principle no restrictions for this model to be extended to 3-D.

A simple method (based on the BIEM) for a time-stepping of water particles within the fluid domain is developed and used for tracing particle orbits in time. Fixed structures are incorporated into the model, and the flow field around them are evaluated by use of the time-stepping of interior points.

Furthermore the wave forces on the structures are computed, and the "shielding" and "blockage" effects are shown for the case of two parallel cylinders.

Mathematical Formulation

The irrotational flow of an incompressible fluid with a free surface is considered. Within the frame of potential theory the flow can be described by a velocity potential $\phi(x,t)$, and the fluid velocity is then given by $u = (u,w) = (\phi_x, \phi_z) = \nabla\phi$ where $x = (x,z)$ is a position vector of an "observation point" and t is the time. By use of the mass conservation equation in the fluid domain $\Omega(t)$ (depicted in Fig. 1) we find that ϕ satisfies the Laplace equation throughout the fluid domain, i.e.

$$\nabla^2\phi = 0. \quad (1)$$

The boundary conditions for ϕ on the free surface $\Gamma_f(t)$ are the kinematic condition

$$\frac{D\vec{r}}{Dt} = \left(\frac{\partial}{\partial t} + \vec{u} \cdot \nabla\right)\vec{r} = \vec{u} = \nabla\phi, \quad z = \eta \tag{2}$$

where \vec{r} is a position vector of a water particle at the free surface, and the dynamic condition (Bernoulli's equation)

$$\frac{D\phi}{Dt} = -gz + \frac{1}{2} |\nabla\phi|^2 - \frac{p_a}{\rho}, \quad z = \eta \tag{3}$$

($D\phi/Dt = \phi_t + |\nabla\phi|^2$ is a particle following (Lagrangian) operator, and ϕ_t is an abbreviation of $\partial\phi/\partial t$). In (3), g is the acceleration due to gravity, p_a is the atmospheric pressure, and ρ is the density of water (here taken as 10^3 kg/m^3).

Fig. 1 Calculation domain and definition of boundaries. The x-axis is at the mean water level (MWL).

On the stationary bottom Γ_b (which is horizontal and impermeable) the boundary condition is

$$\phi_n = 0, \quad z = -h \tag{4}$$

where n is the coordinate along the unit normal vector \vec{n} pointing outwards from the fluid domain (and ϕ_n is an abbreviation of $\partial\phi/\partial n$).

When a structure is situated in the computational domain, the boundary condition on its surface $\Gamma_s(t)$ is

$$\phi_n = \nabla\phi \cdot \vec{n} = V_s \tag{5}$$

where V_s is a function describing the velocity of the body surface in the direction of the unit normal vector n . In the case of a fixed structure $V_s = 0$.

Boundary conditions at the lateral boundaries $\Gamma_{r1}(t)$ and $\Gamma_{r2}(t)$ are needed for a closure of the boundary value problem for ϕ . By assuming space periodicity (but not necessarily time periodicity) and no net current

below wave trough level, periodicity conditions can be imposed on the vertical boundaries $\Gamma_{r1}(t)$ and $\Gamma_{r2}(t)$

$$\phi_n[\Gamma_{r1}(t)] = -\phi_n[\Gamma_{r2}(t)], \quad \phi[\Gamma_{r2}(t)] = \phi[\Gamma_{r1}(t)] \quad (6)$$

for the same z-values at the two boundaries. The horizontal distance between $\Gamma_{r1}(t)$ and $\Gamma_{r2}(t)$ has to be an integer number of wave lengths. Periodicity conditions at the lateral boundaries were also used by Brevig et al. (1981) and by Stansby and Slaouti (1984) in their studies of wave/structure interaction by use of the BIEM.

In order to solve the Laplace problem (1) with the fully non-linear boundary conditions we use an integral equation method based on Green's 2nd identity

$$\alpha(\vec{x})\phi(\vec{x}, t) = \int_{\Gamma(t)} \phi(\vec{\xi}, t)G_n(\vec{x}, \vec{\xi}) - G(\vec{x}, \vec{\xi})\phi_n(\vec{\xi}, t) d\Gamma \quad (7)$$

where $\vec{\xi}$ is the position vector of an "integration point" situated at the boundary $\Gamma(t)$.

The kernel function $G(\vec{x}, \vec{\xi})$ is the free space Green's function which in two dimensions is:

$$G(\vec{x}, \vec{\xi}) = \ln|\vec{\xi} - \vec{x}| \quad (8)$$

The factor $\alpha(\vec{x})$ depends on the boundary geometry ($\alpha(\vec{x}) = \pi$ for \vec{x} at a smooth part of the boundary, and $\alpha(\vec{x}) = 2\pi$ for \vec{x} inside $\Omega(t)$).

The derivative of G in the direction of the outwards unit normal vector \vec{n} is

$$G_n(\vec{x}, \vec{\xi}) = \frac{(\vec{\xi} - \vec{x}) \cdot \vec{n}}{|\vec{\xi} - \vec{x}|^2} \quad (9)$$

Following the solution of the Laplace problem for ϕ an updating in time of the computational domain and related boundary conditions to a subsequent time level must be performed. Using the Lagrangian approach developed by Dold & Peregrine (1984), truncated Taylor series in time for the position vector \vec{r} of a free surface particle and for the velocity potential ϕ provide

$$\vec{r}(t+\Delta t) = \vec{r}(t) + \sum_{k=1}^n \frac{(\Delta t)^k}{k!} \frac{D^k \vec{r}(t)}{Dt^k} + O[(\Delta t)^{n+1}] \quad (10)$$

$$\begin{aligned} \phi(\vec{r}(t+\Delta t), t+\Delta t) &= \phi(\vec{r}(t), t) \\ &+ \sum_{k=1}^n \frac{(\Delta t)^k}{k!} \frac{D^k \phi(\vec{r}(t), t)}{Dt^k} + O[(\Delta t)^{n+1}] \end{aligned} \quad (11)$$

where Δt is the time increment, and the Lagrangian (particle following) operator D/Dt is defined in (2).

The expansion coefficients in (10) and (11) are obtained by successive solutions of the Laplace equation for the velocity potential ϕ and its time derivatives, where the solution of one Laplace problem provides the non-linear boundary conditions for the next.

The solution of the Laplace problem for ϕ by use of Green's 2nd identity (7) gives as result ϕ and ϕ_n at the whole boundary of the computational domain. Hence the gradient of the velocity potential can be evaluated, and thereby the first order expansion coefficients in (10) and (11) by use of the free surface boundary conditions (2) and (3).

The boundary condition at the free surface for the Laplace problem involving the first order time derivative is obtained from the Eulerian form of the dynamic condition at the free surface (cf. (3)).

$$\phi_t = -gz - \frac{1}{2}|\nabla\phi|^2 - \frac{p_a}{\rho}, \quad z = \eta \quad (12)$$

The conditions at the remaining part of the boundary are obtained by differentiating (4), (5), and (6) with respect to t .

Just as the governing differential equation (1) and the integral equation (7) are valid for ϕ , these may also be written for time derivatives of any order of ϕ . Hence we have a mathematical problem formulated in the same geometry as before, but now with ϕ_t and ϕ_{tn} as solution at the boundary of the computational domain. The numerical solution of the second (and of subsequent) Laplace problems is computationally very fast compared to the solution of the first Laplace problem since the kernel functions (G, G_n) of the governing integral equation only are functions of the boundary geometry which is unchanged, since all derivatives are computed at the same time level. In the present work the series (10) and (11) are truncated after $n=2$, but it is mentioned that the expansion coefficients are obtained from the fully non-linear boundary conditions at the free surface.

The lateral boundaries of the computational domain are updated by following the horizontal motion of the intersections with the free surface.

After the solutions of the Laplace problems for ϕ and ϕ_t have been found by use of the BIEM, all variables of interest at the boundary of the computational domain are determined. By use of (7) it is thus possible to determine the values of the velocity potential ϕ and its time derivative ϕ_t at any point inside the computational domain $\Omega(t)$. Furthermore, analytical differentiations of (7) provide integral equations to determine the values of $\phi_x, \phi_z, \phi_{xt}, \phi_{zt}, \phi_{xx}$ and ϕ_{xz} at the observation point x .

These functions only appear as unknowns outside the relevant integrals (since G and its derivatives are functions of the geometry, which is known), and the numerical evaluation of them is therefore very fast. From the results we may deduce the particle velocity components u and w , the acceleration components a_x and a_z , and the dynamic pressure p^+ ($= p + \rho gz$) at the interior point given by the position vector \vec{x} as:

$$u(\vec{x}) = \phi_x(\vec{x}) \quad (13)$$

$$w(\vec{x}) = \phi_z(\vec{x}) \quad (14)$$

$$a_x(\vec{x}) = \phi_{xt}(\vec{x}) + \phi_{xx}(\vec{x})\phi_x(\vec{x}) + \phi_{xz}(\vec{x})\phi_z(\vec{x}) \quad (15)$$

$$a_z(\vec{x}) = \phi_{zt}(\vec{x}) + \phi_{xz}(\vec{x})\phi_x(\vec{x}) - \phi_{xx}(\vec{x})\phi_z(\vec{x}) \quad (16)$$

$$p^+(\vec{x}) = -\rho \left[\phi_t(\vec{x}) + \frac{1}{2} \{ (\phi_x(\vec{x}))^2 + (\phi_z(\vec{x}))^2 \} \right] \quad (17)$$

where in (16) $\phi_{zz}(\vec{x})$ has been replaced by $-\phi_{xx}(\vec{x})$.

A time-stepping method for water particles in the fluid domain $\Omega(t)$ similar to the one for updating of particles at the free water surface (i.e. based on truncated Taylor series) may then be written as:

$$x_i(t+\Delta t) = x_i(t) + u(\vec{x})\Delta t + a_x(\vec{x}) \frac{(\Delta t)^2}{2} + O[(\Delta t)^3] \quad (18)$$

$$z_i(t+\Delta t) = z_i(t) + w(\vec{x})\Delta t + a_z(\vec{x}) \frac{(\Delta t)^2}{2} + O[(\Delta t)^3] \quad (19)$$

where the position vector of the water particle is $\vec{x} = (x_i, z_i)$. Hence we have established a visualization technique that enables us to follow the traces of water particles in the fluid domain in time.

Numerical Solution Method

The boundary of the computational domain is subdivided into a finite number of small segments, each segment connecting two adjacent discretization points situated at the boundary curve. By representing the geometry as well as the boundary functions ϕ and ϕ_n at each segment by a prescribed variation, the governing integral equation can be formulated in terms of the values of the variables ϕ and ϕ_n (or ϕ_t and ϕ_{tn}) in the discretization points. Hence we may form a linear algebraic system of equations, in which each element only is a function of the geometry of the boundary and of the interpolation functions used.

In order to model the variation of boundary functions between the discretization points, we use a Hermite

cubic spline representation along each boundary element at the free surface (i.e. between two adjacent discretization points) and a linear variation elsewhere. By this method a continuity up to and including 2nd order derivatives of the free surface representation is kept, and all boundary nodes there are treated equally in the numerical solution of the governing integral equation.

The numerical integration over each regular boundary element (i.e. an element where the integration point does not coincide with the observation point) is performed by use of a standard Gauss-Legendre quadrature. At the singular boundary elements special methods must be used (see Skourup (1989) for details).

Results

During recent years, particular attention has been paid to numerical simulations of the interaction between waves and submerged floating structures with large dimensions. Especially a new concept for crossing of deep fjords and straits with submerged tunnels (which e.g. has been proposed for a strait crossing at Høgsfjord, Norway) has inspired to the work presented in this paper.

In all the following computations the Keulegan-Carpenter number K is smaller than 2 and the predominant contribution to the force on the structure is thus inertial and can be computed by the BIEM.

The total wave force vector \vec{F} on the structure, which is cylindrical, is obtained by integrating the excess pressure p^+ (due to the waves) over the whole surface of the structure.

$$\vec{F} = - \int_{\Gamma_s} p^+ \vec{n} d\Gamma \quad (20)$$

where \vec{n} is the outward normal unit vector from the surface of the cylinder. The excess pressure p^+ is determined from the Bernoulli equation as

$$p^+ = - \rho \left[\phi_t + \frac{1}{2} (\phi_s^2 + \phi_n^2) \right] \quad (21)$$

where ϕ_n vanishes at the surface of the cylinder (since it is fixed and impermeable). The term ϕ_s is found from the spatial derivatives of ϕ at Γ_s .

One Circular Cylinder

The special reference case with computation of the interaction between waves and a submerged horizontal circular cylinder with its axis parallel to the wave crests has been treated widely in the literature, beginning with Dean (1948), who showed that linear deep water waves un-

dergo a phase shift as they pass over a cylinder, and further that there is no reflection from the cylinder. Ursell (1950) used a multipole method, and derived expressions for the first-order forces on the cylinder. Ogilvie (1963) extended Ursell's method and provided expressions for the mean second order ("drift") force at the cylinder. Chaplin (1984a,b) performed experiments to determine the non-linear forces and mass transport around a horizontal submerged cylinder, and experimentally verified that there is a mass-transport around the cylinder, as it could be predicted by use of Milne-Thomson's (1968) circle theorem.

A fluid domain with a horizontal dimension of one wave length L is considered. In this domain we situate a fixed horizontal circular cylinder with diameter $D = 2a$ (a being the radius of the cylinder) and a submergence d of its centre axis as depicted in Fig. 2.

Fig. 2 Definition sketch of submergence d and radius a of horizontal circular cylinder.

The diameter of the cylinder is $D = 10.0$ m and the submergence is $d = 20.0$ m. The wave data are: $H = 10.0$ m, $T = 8.78$ s, at a depth $h = 100$ m and an initial profile given by the stream function wave theory by Rienecker & Fenton (1981). This gives a wave length $L = 128$ m and hence a steepness of the wave of 7.8%, and the Keulegan-Carpenter number $K = 1.2$. Computations are carried out covering 6 wave periods with time steps of $T/100$, and the resulting wave force variation in time on the cylinder is depicted in Fig. 3. The total force on the cylinder is computed as the modulus of the two force components F_x and F_z .

Fig. 3 Wave force on a horizontal cylinder during 6 wave periods. Domain length is L .

By regarding Fig. 3 it is readily seen that the oscillations of the total force tend to decrease as the computations proceed in time. In order to investigate if this is an effect arising from using the periodicity conditions at the lateral boundaries with a distance of just one wave length, the same computation is carried out with identical wave and structure data, but now with the horizontal dimension of the computational domain of either three or five wave lengths (i.e. the spacing of the cylinders is either $3L$ or $5L$).

In Fig. 4 the total force on the cylinder is compared for the horizontal dimension of the computational domain being either one or three wave lengths.

Fig. 4 Total wave forces on a cylinder during 6 wave periods. Domain length is either L or $3L$.

During the first three wave periods the difference between the two results is less than 1.5% of the mean total force on the cylinder. The larger deviation hereafter is probably an effect of the proximity of other cylinders. Extending the horizontal dimension of the computational domain further to five wave lengths provides almost identical results as obtained from the domain, which was three wave lengths long, when the first three wave periods are considered.

From these computational results we conclude that a horizontal dimension of one wave length is sufficient

for computations covering a time span less than three wave periods. It is mentioned that the computational time is proportional to N^3 for large values of N (where N is the number of computational nodes at the boundary), and the desired accuracy of the results therefore must be assessed against the computational time necessary to provide the results.

Numerical results for the interaction between non-linear waves and a submerged horizontal, circular cylinder at low Keulegan-Carpenter numbers, are found in Stansby & Slaouti (1984), in Vada (1987), and in Isaacson & Cheung (1990), and in all cases the inertia coefficients are in the same range as the present results.

Experimental results are also available, and for deeply submerged cylinders Cheong et al. (1989) found the inertia coefficients to be in the vicinity of 2 for low Keulegan-Carpenter numbers. For a cylinder close to the free surface, Chaplin (1984b) and Miyata & Lee (1990) found the inertia coefficients to be much smaller than 2 in their experiments with Keulegan-Carpenter numbers in the range 1-3. Chaplin (1984b) explained this decrease as associated with the circulation generated by steady streaming in the oscillatory boundary layer on the cylinder. It has not been possible in the present work to reproduce these low inertia coefficients. This indicates that the large reduction of the inertia coefficients is an effect due to viscosity, which is omitted in the present work. Miyata & Lee (1990) obtained this large decrease of the inertia coefficient in their computations where they solved the Navier-Stokes equations in a finite difference formulation for Reynolds numbers $1.69 \cdot 10^4$ and $3.87 \cdot 10^4$.

Tracing of the orbits of water particles in the vicinity of the cylinder is performed by use of the time stepping method for particles in the fluid domain (i.e. eqs. (18) and (19)).

In Fig. 5 the particle motion during one (Eulerian) wave period is followed. It is seen that the water particles tend to follow the cylinder contour and that they have all moved to new positions in the clockwise direction around the cylinder after one wave period. This circulation of water particles around a horizontal cylinder is also showed analytically by e.g. Ogilvie (1963), and verified experimentally by Chaplin (1984a). The amplitudes (both in the horizontal and the vertical directions) are by linear wave theory found to be 2.77 m for a water particle at $z = -12.0$ m, and this corresponds quite well with the orbits shown in Fig. 5.

Particle orbits in the vicinity of the cylinder are also computed using the circle theorem (cf. Milne-Thomson, 1968) combined with a time-stepping procedure (as (18) and (19)) for water particles and good agreement was found with orbits computed by the BIEM.

Fig. 5 Traces of the particle motions during one period in the vicinity of a submerged, circular cylinder with diameter $D = 10.0$ m. Wave data: $T = 8.78$ s, $H = 10.0$ m, $L = 128$ m at $h = 100$ m. ●: initial position, ▶: orbital direction. Domain length L .

Two Circular Cylinders

Computations with more than one cylinder in the fluid domain are also performed.

Two parallel horizontal circular cylinders are considered, and the dimensions of the cylinders are kept the same as in the previous case, i.e. with a diameter $D=10.0$ m, and a submergence of their centre lines at $d=20.0$ m. The wave data are also the same as before. The length of the computational domain equals L . In order to investigate the shielding and blockage effects between the two cylinders, computations with different distances between the centre lines have been carried out covering three wave periods. The distances have been chosen as $1.5D$, $2D$ and $3D$ and the main results are given in Table I. Here also the reference-numbers corresponding to an "infinite" distance between the cylinders are given. These reference numbers are computed during the second and third wave period for the case with one cylinder in a domain with length $5L$.

From Table I two different effects from the interaction between the two cylinders appear. Regarding the horizontal force F_x on each of the two cylinders it is seen that the amplitudes are decreasing as the cylinders are approached to each other, and that the force amplitude is larger on the upstream cylinder than on the downstream cylinder. This is due to a shielding effect between the two cylinders.

Cylinder	Centre	$F_{x,max}$	$F_{x,min}$	$F_{z,max}$	$F_{z,min}$	$F_{t,max}$	$F_{t,min}$
	axis dist.						
1 (upstream)	1.5D	138.1	-123.2	160.3	-142.9	162.0	116.4
	2D	139.9	-129.5	151.6	-134.1	154.5	122.3
	3D	142.4	-134.0	145.4	-128.4	149.1	122.8
2 (downstream)	1.5D	126.1	-122.7	155.0	-146.4	155.6	116.9
	2D	131.7	-125.6	145.0	-137.5	146.5	119.9
	3D	134.4	-130.4	138.7	-132.8	141.3	121.7
	"∞"	137.6	-134.2	142.9	-128.4	143.0	128.1

Table I Extreme wave force amplitudes (in kN/m) at two parallel cylinders as function of centre axes distance. The computations cover 3 wave periods.

Regarding the vertical force F_z on each of the two cylinders it is seen that the amplitudes are increasing as they are approached to each other. This result shows that there is a blockage effect between the two cylinders. The maximum force amplitude is slightly larger on the upstream cylinder than on the downstream cylinder.

The sum of the shielding and the blockage effects between the two cylinders appear in the total force variation at the two cylinders, and it is seen that the effect from blockage influences the total force, since the maximum values of the total force on each of the two cylinders increase as the they are approached to each other.

Fig. 6 Particle orbits in the vicinity of two parallel horizontal circular cylinders with centre axis distance 1.5D. Other data as in Fig. 5.

The shielding effect between the two cylinders is seen only to have a small influence on the maximum value of the total force on the two cylinders.

Particle orbits in the vicinity of the cylinders are shown in Fig. 6 for a centre axis distance 1.5D.

Conclusion

It has been demonstrated that a fully non-linear boundary element model with periodicity conditions at the lateral boundaries of the computational domain provides good results for wave forces on and particle orbits around submerged horizontal cylindrical structures (2-D) for small Keulegan-Carpenter numbers. The effects from shielding and blockage between two cylinders are shown by computational examples, and the cylinder distances are found to have some effect on the forces.

There are, in principle, no restrictions in the mathematical formulation that prevent the present model from being extended to 3-D. However, appropriate conditions at the lateral boundaries of the computational domain must be developed in order to be able to perform computations with 3-D waves of not permanent form. Furthermore, faster and more efficient computers than those of today must be developed before an accurate non-linear 3-D model can be developed and used for application as a "numerical wave tank".

A more detailed account of the present study will be published subsequently (Skourup & Jonsson, 1990).

CHAPTER 105

Reliability Analysis of Composite Breakwaters Protected with Armor Blocks

Masato Yamamoto*
Kazumasa Mizumura**
Taiji Endo***
and
Naofumi Shiraishi****

Abstract

The subject of this present research is to study probabilistic design of caissons of composite breakwaters, rubble-mounds and foundations protected with armor blocks. Concerning caissons, sliding, rocking and overturning motions are considered to be the failure modes. Wave forces acting on a caisson can be calculated using Goda's formulas(1974). The stability of the rubble-mound is estimated by means of Bishop's method while geotechnical problems employ a simplified equation as a reliability function in accordance with the Japanese Standards for Coastal Structures.

Since distribution for occurrence for each failure mode is unknown, Monte Carlo simulation was applied to calculate the risk of each failure. The probability of geotechnical failure was greatest among the failure modes but the rubble-mound was not in danger of collapse.

Introduction

In Japan, breakwaters of the type shown in Fig.1 are the most commonly designed and constructed. They consist of caisson, concrete cap, rubble-mound and armor blocks. Such a breakwater is referred to as "a composite breakwater protected with armor blocks". It has several advan-

tages, i.e.

- (1)The construction period is short.
- (2)A large sea area within the breakwater is conserved.
- (3)The crest elevation is low.
- (4)Ships are easily moored inside the upright section.
- (5)etc.

Fig.1 Typical Composite Breakwater Protected with Armor Blocks

In recent years, breakwaters have been constructed in deeper and deeper areas so the armor blocks and upright sections receive large wave forces. As a result, blocks receive damage and caissons slide or overturn. In addition, foundations receive such high pressure from caissons that they collapse.

Engineers in Japan design composite breakwaters protected with armor blocks using a deterministic method introducing a safety factor. The method is based on experiences from construction of breakwaters over many years. However if a new type structure is designed or constructed or conventional breakwaters are placed in a deep sea area where no structure has existed before, the deterministic or safety factor approach is not easily applicable.

Recently, new methodology based on probabilistic and statistical theory has been the subject of study for application to coastal structures e.g. Burcharth(1985), Van der Meer et al(1987), Mizumura et al(1988) and PIANC(1990). In this new design method, ranks of safety between breakwaters can be balanced and structures designed taking into account economical conditions (Yamamoto et al(1988)).

In this paper, the authors applied the probabilistic method to a composite breakwater protected with armor blocks taking wave breaking and retaining wave after breaking into account.

Reliability Analysis

If the external force is represented by S and the resistant force by R in a certain failure mode, the reliability function Z is given by eq.(1).

$$Z = R - S \tag{1}$$

In this case, as Z is greater than 0, failure does not occur. However, if Z is less than 0, failure does occur. In eq.(1) the variables R and S are generally uncertain or probabilistic ones therefore Z is also a probabilistic variable. So if the probabilistic density function of Z is known, the probability where the failure occurs can be calculated as follows;

$$P = \int_{-\infty}^0 f(Z) dZ \tag{2}$$

in which f(Z) is the probabilistic function of probabilistic variable Z.

If m failure modes exist for a breakwater, the total failure probability for the breakwater is obtained as eq.(3).

$$P_f = \text{Prob} \{ (Z_1 < 0) \cup (Z_2 < 0) \cup \dots \cup (Z_m < 0) \} \tag{3}$$

Assuming all m failure modes are independent of each other, the probability for the risk is simply rewritten by eq.(4).

$$P_f = 1 - \prod_{i=1}^m \{ (1 - P_{fi}) \} \tag{4}$$

Concerning the failure modes for the composite breakwater protected with armor blocks as shown in Fig.1, the main modes are (1) movement of armor blocks, (2) slide of the upright section, (3) overturning of the upright section, (4) slide of the rubble-mound and (5) collapse of the foundation that is geotechnical instability shown in Fig.2.

Fig.2 Failure Mode for Composite Breakwater protected with Armor Blocks

The block movement for these failure modes was already discussed by Mizumura et al(1988) and Yamamoto et al (1988) in a previous ICCE in Spain. Therefore in this paper the authors dealt with (2)-(5) as the failure modes of the composite breakwater. The failure modes above were selected as representative, however because the proba-

bility density functions of the failure occurrence, $f(Z)$ was not unknown, Monte Carlo simulation was conducted to calculate the functions.

Wave Forces Acting on Caisson Wall

Fig.3 Distribution of Wave Pressure

Fig.3 shows a sketch of a wave pressure distribution along the upright section. Wave pressures acting on the upright section are expressed as below (Tanimoto et al(1976));

$$p_1 = \lambda \alpha_1 w_0 H \tag{5}$$

$$p_3 = p_u = \lambda \alpha_1 \alpha_3 w_0 H \tag{6}$$

$$\eta^* = 1.5 \lambda H \tag{7}$$

where λ is the wave pressure reducing ratio due to the armor block protection, and

$$\alpha_1 = 0.6 + \frac{1}{2} \left[\frac{4\pi h/L}{\sinh(4\pi h/L)} \right]^2 \tag{8}$$

$$\alpha_3 = 1 - \frac{h'}{h} \left[1 - \frac{1}{\cosh(2\pi h/L)} \right]$$

λ refers to the ratio of the wave force in the case of protection as opposed to that without protection. When λ equals to 1, no protection exists in front of the caisson. In the case where λ is less than 1, that indicates that there is the armor block protection. The value of λ is taken to be 0.8 in the case of the composite breakwater protected with armor units according to the Japanese Standards of design of breakwaters based on hydraulic model tests. The total horizontal wave force acting on the vertical wall, up-lift force and moment around the heel

Goda(1974) proposed formulas representing wave forces acting on an upright section of a composite breakwater without armor protection. Tanimoto et al(1976) modified Goda's formulas to apply a composite breakwater protected with armor blocks introducing a wave pressure reducing ratio due to armor blocks.

of the caisson are obtained by eq.(9)-(12).

The horizontal wave force;

$$F = \frac{1}{2} (p_1 + p_3)h' + \frac{1}{2} (p_1 + p_4)h_c^* \quad (9)$$

The moment around the corner of the base due to the horizontal wave force;

$$M_p = \frac{1}{2} (2p_1 + p_3)h'^2 + \frac{1}{2} (p_1 + p_4)h'h_c^{*2} \\ + \frac{1}{6}(p_1 + 2p_4)h_c^{*2} \quad (10)$$

in which

$$p_4 = \begin{cases} p_1 (1 - h_c/\eta^*) & : \eta \geq h_c \\ 0 & : \eta^* < h_c \end{cases}$$

$$h_c^* = \min (\eta, h_c)$$

$\min(a,b)$: smaller of a and b.

The total up-lift force:

$$U = \frac{1}{2} p_u B \quad (11)$$

The moment around the hcel due to the up-lift force:

$$M_u = \frac{2}{3} UB \quad (12)$$

Reliability Functions for Each Failure Mode

When the wave forces F and U operate on the caisson, the resistant force against slide is due to friction represented by eq.(13) and the resistant moment is given by eq.(14).

$$F_r = \mu (W - U) \quad (13)$$

$$M_r = Wt \quad (14)$$

in which W is the weight of the upright section in water, μ indicates a frictional coefficient between the caisson base and the surface of the rubble-mound and t refers to the distance between the caisson heel and the centroid of

the upright section.
So the reliability functions for slide and overturning of the upright section are expressed by

$$Z_S = \mu (W - U) F \tag{15}$$

and

$$Z_O = Wt - M_u - M_p \tag{16}$$

respectively.

Concerning the collapse of rubble-mound slope, the mound slope is assumed to be destroyed by a circular arc of which the center is located at point O as shown in Fig.4.

Fig.4 Selection of Center of Circular Arc

The computational method is as proposed by Bishop. The forces exerted on the *i*-th soil element are described in Fig.4. Assuming that $T_i = T_{i+1}$ and $P_i = P_{i+1}$, the sliding and resistant moment with respect to point O are written as;

$$M_S = \sum_{i=1}^n (W_i + u_i) R_o \sin \beta_i \tag{17}$$

$$M_b = \sum_{i=1}^n \tau_{fi} l_{bi} R_o \tag{18}$$

in which W_i is the weight of the *i*-th soil element, β_i is an angle of the sliding arc of the *i*-th soil element to the horizontal, R_o refers to the radius of the circular arc, τ_{fi} indicates the shear stress exerted on the circular arc of the *i*-th soil element, l_{bi} is the length of the circular arc and u_i is the vertical force due to wave action. If the normal force exerted on the circular arc is given by N_i , the shear stress becomes

$$\tau_{fi} = \frac{N_i}{l_{bi}} \tan \phi \tag{19}$$

where ϕ is the friction angle. The balance of the verti-

cal forces exerted on the i -th element gives the normal force as eq.(20).

$$N_i = \frac{W_i + u_i}{\cos\beta_i + \tan\phi \sin\beta_i / F_s} \quad (20)$$

F_s is obtained as follows.

$$F_s = \frac{1}{\sum_{i=1}^n (W_i + u_i) \sin\beta_i} \sum_{i=1}^n \frac{(W_i + u_i) \tan\phi}{\cos\beta_i + \tan\phi \sin\beta_i / F_s} \quad (21)$$

Therefore the reliability function is given by

$$Z_b = M_b - M_s \quad (22)$$

This equation is tantamount to F_s . If $Z_b < 0$ or $F_s < 1$, the rubble-mound slope collapses. F_s should be obtained by iteration in eq.(21).

Concerning the geotechnical instability, the bearing capacity of the foundation engineering for eccentric inclined load. However in this study a simplified technique was employed in order to examine the magnitude of the heel pressure. According to Goda(1985), the largest bearing pressure at the heel P_e is obtained as below;

$$P_e = \begin{cases} \frac{2W_e}{3t_e} & : t_e \leq \frac{1}{3} \\ \frac{2W_e}{B} \left(2 - 3 \frac{t_e}{B} \right) & : t_e > \frac{1}{3} \end{cases} \quad (23)$$

in which $t_e = M_e / W_e$, $M_e = Wt - M_u - M_p$ and $W_e = W - U$. If the allowance for heel pressure is τ , the reliability function for the geotechnical stability is represented by the following equation.

$$Z_g = \tau - P_e \quad (24)$$

The value of τ is usually taken to be 40ton/m²-50ton/m².

Wave Transformation from Offshore to Breakwater Site

The wave force acting on the upright section can be obtained from eqs.(5)-(12) if the wave height at the breakwater is given. The distribution of the wave height in deep water can be regarded as Rayleigh distribution. However, that at the breakwater in shallow water or the surf zone is generally not known. Goda(1975) proposed the numerical method to calculate the wave height of random waves in the surf zone. In this study, the method was

applied to obtain the wave height distribution at the breakwater site. This method is as follows;
 A random wave train of which the height distribution is given in deep water is separated into individual waves defined by the zero-up crossing and deformation of each individual wave due to shoaling or breaking is estimated applying monochromatic wave theory including non-linearity. Goda obtained the wave height distribution in the surf zone taking retaining waves after breaking and surf beat into consideration.

Risk Analysis and Illustrative Examples

In this study, failure probability for the composite breakwater protected with armor blocks was calculated on the basis of the following assumptions.

(1) Uncertain variables are wave heights in deep water, wave periods, frictional coefficients (μ) and wave force reducing ratio (λ). Other variables are deterministic ones.

(2) The distribution of wave heights follows the Rayleigh distribution in deep water. The distribution of wave period of the 2nd power is also Rayleigh distribution.

(3) A frictional coefficient between the caisson base and rubble-mound is distributed in accordance with the normal distribution of which the mean value is 0.57 and the standard deviation is 0.05. This is decided under a condition where 10cm sliding distance of the upright section is allowed (Toyama(1985)).

(4) The wave force reducing ratio is uniformly distributed from 0.4 to 1.0 with reference to the results of hydraulic model tests conducted by Tanimoto et al(1976).

The procedure for risk analysis was as follows;

The distribution of wave height at the site of the breakwater was calculated employing the numerical method described previously. Next, we sampled a wave height coupled with a wave period from their distribution at the breakwater site. In this sampling, the distribution of the wave periods was assumed not to change at the site of the breakwater. The wave force and moment acting on the upright section could be calculated substituting the sampled wave height and period into eq.(5)-(12). We judged whether the failure for each mode occurred or not utilizing the reliability function. This procedure was repeated 5000 times (Monte Carlo simulation). Eventually, the failure probability for each failure mode could be estimated. Total risk of the breakwater is obtained by eq.(25).

$$\begin{aligned}
 P &= P_s + P_o + P_b + P_g \\
 &- P_s P_o - P_o P_b - P_b P_g - P_g P_s \\
 &+ P_s P_o P_b + P_o P_b P_g + P_b P_g P_s + P_g P_s P_o
 \end{aligned}$$

- PsPoPbPg

(25)

in which P:the total failure probability, Ps:the failure probability of slide, Po:the failure probability of over- turn, Pb:the failure probability of mound slip and Pg:the failure probability of geotechnical instability. In the computation, the value 45 ton/m² was taken as the limitation of the heel pressure. Fig.5 shows the model of the breakwater used in this analysis.

Fig.5 Model of Breakwater

Fig.6 shows variations of the total and each failure probability versus the equivalent deep water wave heights when the wave period(T) is 8.0sec, the water depth(h) is 6.0m, the caisson width(B) is 4.0m, the clearance(a distance between the still water and the top elevation of the upright section hc) is 2.0m and the water depth on the mound(d)is 4.0m.

Fig.6 Effect of Wave Height on Failure Probability

The value of the individual and total failure probabilities increases the wave height becomes larger. The risk to the rubble-mound slope is not seen in the figure because that the probability was zero through all computation cases in our simulation. In other words, the rubble-mound is strongest against wave force. In the range where the wave height is smaller than 5m, the geotechnical and total

failure probabilities increase significantly. However when the wave height exceeds 5m, the increment of this risk decreases. This is one reason why the number of the incident wave breaking between the offshore and the site of the breakwater increases when H_o' becomes larger than 5m. Among the failure modes, geotechnical risk is the greatest problem followed by slide of the upright section. Therefore if an incident wave height became large, the foundation would collapse before the upright section slide or overturned.

Change in the failure probability versus the wave period is shown in Fig.7 in the case where the equivalent deep water wave height(H_o') is fixed at 6.0m, $h=6.0m$, $B=4.0m$, $h_c=2.0m$ and $d=4.0m$.

Fig.7 Effect of Wave Period on Failure Probability

The failure probability linearly increases as the wave period becomes long. In this case, the risk for geotechnical instability is greatest, but that for slide of the upright section becomes the same as the risk for geotechnical when the wave period increases. As the wave length becomes large, α_1 and α_3 in eq.(8) increase, therefore the wave force also become large. In addition, when h/L_o (L_o : a wave length in deep water) is small, waves tend not to break. So the wave force becomes large and the failure probability increases as the wave period is large.

Fig.8 indicates the influences of the water depth on a breakwater when $H_o'=6.0m$, $T=8.0sec$, $B=4.0m$, $h_c=2.0m$ and $d=4.0m$.

As the water depth increases, each as well as the total failure probability increases. When the water depth is large, wave heights hitting the breakwater becomes large and their wave lengths also increase. The wave forces acting on the breakwater therefore increase because the number of breaking waves decreases and because of the effects of wave length from the formulae for wave forces. In this case also, in the range where the water depth is greater than 8m, the difference between the risk for foundation collapse and caisson slide is close.

Fig. 8 Effect of Water Depth on Failure Probability

Fig. 9 Effect of Upright Section Width on Failure Probability

The relationship between the width of the upright section and failure probability is shown in Fig. 9 in the case of $H_o' = 6.0m$, $T = 8.0sec$, $h = 6.0m$, $h_c = 2.0m$ and $d = 4.0m$. When the caisson width is narrow, the risk of overturn is greatest. From this figure, it can be seen that in order to reduce risk increase of the upright section is the best way. In particular, the wide caisson effect to decrease the risk of overturning.

Fig. 10 shows the variation of the failure probability as the gradient of the sea bottom slope is changed from 0.01 (1/100) to 0.1 (1/10). The failure probability increases as the sea bottom becomes steeper. The breaking wave height becomes large if the wave period and water depth are fixed. As a result, the incident wave height becomes is so large that the great wave force can lead the breakwater to collapse. Failure probabilities of slide and overturn increase with the steepness of the sea bottom.

Geotechnical risk increases until the gradient of the sea bottom slope is 0.08. This is the plateau and is less than the probability for the slide and overturn when the gradient is greater than 0.08.

From Fig. 6 - Fig. 10, the wave period and gradient of the sea bottom affect the failure probability more significantly than the wave height. The longer the wave period and the steeper the sea bottom, the greater the failure probability for the composite breakwater protected with armor blocks is. In most cases, the probability of geotechnical instability is larger than the slide and over-

turn of the upright section of the composite breakwater protected with armor blocks.

Fig.10 Effect of Gradient of Sea Bottom Slope on Failure Probability

Comparison with Risk for Armor Protection

Mizumura et al(1988) calculated the failure probability for displacement of armor blocks whose weights were obtained using the Hudson formula under the conditions where $H_o'=4.0m$ with all other previous conditions remaining the same.

Fig.11 is a comparison of the failure probability of an upright section with that of motion from armor blocks as obtained by Mizumura et al(1988) versus the wave height and period respectively.

In the figure, the solid lines show the failure probability of the composite breakwater protected with armor blocks designed with a safety factor of one unit concerning slide of the upright section.

The failure probability of the armor units is greater than that of the composite breakwater in the total range of wave height. When the wave period is less than approximately 15sec, the risk to the armor blocks is also greater than that of the composite breakwater protected with armor blocks. This implies that when high waves attack a composite breakwater protected with armor blocks, armor

Fig.11 Comparison of Failure Probability of Protection with Upright Section

units collapse sooner than the upright section. However if armor blocks move sooner than the composite breakwater with protection, the width of the protection decreases, the wave force acting on the upright section through the protection increases (Hattori et al). Therefore the risk for motion of the upright section or geotechnical instability of the composite breakwater would become larger. It is therefore necessary to take into account the correlation between the armor blocks and upright section of the breakwater protected with armor blocks.

Conclusions

The following conclusions have been derived from this study.

1. Wave transformation, i.e. wave shoaling, breaking and retaining wave energy after breaking are acceptable for inclusion in simulations from offshore to the site of a breakwater.
2. Wave height is not as significant as wave period, water depth, caisson width and gradient of the sea bottom slope in failure probability of a composite breakwater protected with armor blocks. In particular, it can be seen that wave period is most significant.
3. In order to decrease risk to a breakwater, increases of caisson width proved effective because failure probability is reduced remarkably as the caisson width increases.
4. Geotechnical failure is potentially more dangerous than other failure modes.
5. Comparing the failure probability of armor unit displacement with that of the composite breakwater protected with armor blocks, the former is greater than the latter even when the wave height is increased. The risk of the former is less than that of the latter in the case of

short period waves, while when the wave period becomes longer, the former is greater than the latter. However correlation between collapse of the upright section and blocks should be taken into consideration in the case of a composite breakwater protected with armor blocks.

CHAPTER 106

Stresses in Dolosse

H.F. Burcharth¹ Liu Zhou² Gary L. Howell³ W.G. McDougal⁴

Abstract

Failures of rubble mound breakwaters armoured with complex types of unreinforced concrete armour units are often due to breakage. This happens when the stresses exceed the material strength. Sufficient parametric studies of the stresses are not yet available to produce design diagrams for structural integrity.

The paper presents the results and the analyses of model tests with 200 kg and 200 g load-cell instrumented Dolosse. Static stresses and wave generated stresses were studied as well as model and scale effects. A preliminary design diagram for Dolosse is presented as well.

Introduction

Many of the recent dramatic failures of a number of large rubble mound breakwaters armoured with Dolosse and Tetrapods were caused by breakage of the concrete armour units. Breakage took place before the hydraulic stability of intact units in the armour layers expired. Thus there was an imbalance between the strength (structural integrity) of the units and the hydraulic stability (resistance to displacements) of the armour layer.

While the hydraulic stability can be roughly estimated by formulae and further evaluated in conventional hydraulic model tests, it is much more complicated to assess the structural integrity of the armour units. The increased research activity in this field has not yet resulted in generally applicable design diagrams or formulae by which the armour units can be designed as is the case for other civil engineering structural members.

For dealing with the problem the different types of loads on armour units and their origins might be listed as shown in Fig. 1.

TYPES OF LOADS		ORIGIN OF LOADS	
STATIC		Weight of units	
		Prestressing due to: Settlement of underlayers Wedge effect and arching due to movements under dynamic loads	
DYNAMIC	Impact	Rocking/rolling of units Missiles of broken units Placing during construction	} impacting solid bodies
	Pulsating	Gradually varying wave force including slamming Earthquake	
ABRASION		} Suspended material	
THERMAL		} Stresses due to temperature differences during hardening processes Freeze — thaw	
CHEMICAL		} Corrosion of reinforcement Sulfate reactions etc.	

Fig. 1. Types and origin of loads on armour units (from Burcharth, 1981).

It is characteristic for both static and dynamic load conditions that a deterministic calculation of the stresses in the units is practically impossible, mainly because of the stochastic nature of the wave loads, the complex shape of armour units and their random placements.

It is also characteristic of these stresses that they do not scale in the same way. Generally speaking the stresses due to non-impact loads increase linearly with the characteristic length of armour units, while impact-induced stress increases with the square root of the characteristic length. The relative importance of these stresses depends on the size and geometry of the units, their position on the slope and so on.

In this paper only static and pulsating stresses are considered.

Dolos static stress experiments in the dry (ramp tests)

Description of the experiment

With the purpose of studying the characteristics of static stresses in Dolosse and the related model and scale effects, a large field experiment programme was started in 1986 in Aalborg Hydraulic Laboratory (AHL) at Aalborg University. It includes comparative compaction experiments with 200 kg and 200 g Dolosse placed on ramps with various slope angles. The geometries of the Dolosse are given in Fig. 2.

		app. 200 kg	app. 200 g
Height H_D	(cm)	80	8
Waist width a	(cm)	26	2.6
Head width b	(cm)	16	1.6
Height of fillet c	(cm)	4.0	0.46
Waist ratio		0.325	0.325

Fig. 2. Geometry of Dolosse.

200 kg strain-gauged Dolosse

Based on the structural consideration and practical experience, it is now generally accepted that Dolos fractures tend to occur in or near the shank-fluke interfaces. Consequently, two shank and two leg cross sections near the shank-fluke interfaces of 200 kg Dolosse were chosen as strain-gauged sections. Because the signals from the surface mounted strain gauges turned out to be too weak a load-cell solution was adopted. Four strain-gauge rosettes were mounted on the surfaces of steel tubes inserted as load cells in each of the chosen sections, cf. Fig. 3.

Fig. 3. Instrumented sections. 200 kg concrete Dolosse, Aalborg Hydraulic Laboratory (AHL).

The load cells allowed the following component forces/moments to be recorded, cf. Fig. 4, where the octahedral cross section is the correct one, and the circular cross section is an approximation (Burcharth et al., 1988).

The instrumentation made it possible to verify the relative importance of shear and axial forces.

Fig. 4. Component forces/moments recorded in the instrumented sections.

200 g strain-gauged Dolosse

The applied units were developed by CERC and lent to the University of Aalborg (Markle, 1990). One shank cross section in the shank-fluke corner was strain-gauged to obtain two orthogonal bending moments and the torque. The stress contributions from axial and shear forces, which were believed to be of minor importance, were neglected.

The applied signal analysis, i.e. the transformation of the recorded load cell strains to armour unit stresses, is described in Burcharth et al., 1988. The first step in the signal analysis is to calculate the component forces/moments in the steel tube sections according to the recordings of strains. The next step is to transform these component forces into the stresses in the corresponding Dolos sections, and finally to calculate the maximum principal tensile stress, which is chosen as the critical parameter for the structural integrity of the armour units.

A large ramp (5 x 4 m) and a small ramp (0.5 x 0.4 m) with changeable slope angles were built. 72 Dolosse (200 kg or 200 g), including the instrumented ones, were randomly placed in two layers on the ramp. Every experiment involved the following 4 steps and corresponding recordings.

- (i) Zeroing of strain gauges while the two instrumented Dolosse were in a specified position resting unloaded on ground.
- (ii) Placement of the Dolosse on the ramp.
- (iii) Vibration of the ramp.
- (iv) Removal of Dolosse from the ramp and placement of the two instrumented Dolosse in the position described under (i).

Three pre-determined slopes were used: 1 : 0.9, 1 : 1.38 and 1 : 2. The instrumented Dolosse were 'randomly' placed at positions 1 and 2 in the bottom layer, as shown in Fig. 5.

Fig. 5. Dolos compaction experiment set-up, Aalborg Hydraulic Laboratory (AHL).

Results from the static stress experiments (ramp tests)

Comparison of stresses in the shank and fluke cross sections

Because the small scale units cannot for practical reasons be instrumented in the fluke sections it is important to investigate if this implies a model error of any significance. From the tests with the 200 kg Dolosse it is clearly demonstrated in Table 1 that the max principal tensile stresses in the shank cross sections generally are bigger than those in the fluke cross sections.

Table 1. 200 kg Dolos compaction experiment results.

Group	1	2	3	4
Slope	1 : 0.9	1 : 1.38	1 : 1.38	1 : 2
Instrumented Dolos position	1	1	2	1
Average of σ_T in shank (MPa)	0.336	0.167	0.151	0.166
Average of σ_T in fluke (MPa)	0.181	0.157	0.088	0.12
No. of tests	28	40	36	20

σ_T denotes the max principal tensile stress in strain-gauged sections.

It is also seen that when dealing with results based on stresses only measured in the shank section it is necessary to compensate for the influence of fluke failures.

If it is assumed that the only relevant failure modes are fracture in the type of sections shown in Fig. 3, i.e. 2 shank sections and 4 fluke sections, then it is possible to calculate the probability of failure for the Dolos, P_{Dolos} , from the probability of failure in the fluke section, P_{fluke} , and the probability of failure in the shank section, P_{shank} if the correlations between the various failure modes are known. If the Dolos is modelled as a series system, consisting of n elements $i = 1, 2, \dots, n$, i.e. the failure of the Dolos takes place when any one of the element fails, then the probability of failure for the Dolos can be estimated as

$$P_{Dolos}(\sigma_T) \simeq 1 - \Phi_n(\bar{\beta}; \bar{\rho})$$

where $\bar{\beta} = (\beta_1, \dots, \beta_n)$ and $\beta_i(\sigma_T) = -\Phi^{-1}(P_i(\sigma_T))$ is the generalized reliability index corresponding to failure mode i . Each failure mode is approximated by a linear failure function in independent standard normal variables.

$\bar{\rho} = [\rho_{ij}]$ is the correlation matrix for the linear failure functions.

$\Phi_n = n$ -dimensional standardized normal distribution.

Generally calculation of $\Phi_n(\bar{\beta}; \bar{\rho})$ for $n \geq 3$ cannot be performed exactly but the Hohenbichler approximation can be used (Thoft-Christensen et al. 1986). $n = 6$ in the proposed model for a Dolos. Alternatively reliability bounds can be calculated. A simple lower bound is the maximum probability of failure of any element, in this case corresponding to P_{shank} . This lower bound corresponds to full correlation between all elements, i.e. $\rho_{ij} = 1$ for all i and j . A simple upper bound can be found by assuming non-correlated elements in which case we get

$$P_{Dolos}(\sigma_T) = 1 - (1 - P_{shank}(\sigma_T))^2 (1 - P_{fluke}(\sigma_T))^4$$

The assumption of non-correlated elements gives the highest possible probability of failure. More narrow bounds can be found if the correlations are known. The simple lower and upper bounds are shown in Fig. 6 together with an estimate of the real failure probability based on a Hohenbichler approximation. The high stress levels shown in the Figure are due to the inclusion of test results from the very steep 1 : 0.9 slope.

Influence of Dolos position and slope angle

The results in Table 1 show as expected that the dolosse situated in lower positions of the bottom layer have greater stresses than those situated in the higher positions, and the dolos stress increases with steeper slopes, other conditions being equal.

Fig. 6. Failure probability of Dolosse based on recorded static stresses in ramp tests in the dry, AHL experiments.

The stress distribution

The measured maximum principal tensile stresses σ_T followed the log-normal distribution both in the shank and the fluke cross sections. The density function is given by

$$f(\ln \sigma_T) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\ln \sigma_T - \mu}{\sigma}\right)^2}$$

$$\mu = \frac{1}{N} \sum_{i=1}^N \ln(\sigma_T)_i \quad \sigma^2 = \frac{1}{N-1} \sum_{i=1}^N (\ln(\sigma_T)_i - \mu)^2$$

where μ and σ are average and standard deviation respectively.

The conclusion on stress distribution is consistent with results from small scale tests conducted by D. Turke, Canada (private communication), see also Anglin et al., 1990.

Stress contribution from shear and axial forces

In small scale tests it is difficult or even impossible to mount a sufficient number of strain gauges inside small Dolosse to determine all component forces/moments in a cross section. Generally the stress contributions from axial and shear forces are regarded of minor importance. To check this hypothesis the distribution of $(\sigma_T - \sigma'_T/\sigma_T)$, where σ'_T represents the corresponding maximum principal tensile stress without axial and shear forces, is plotted in Fig. 7. The results are from the fully instrumented 200 kg Dolosse and represent only the conditions in the instrumented shank sections. From this Figure the following can be concluded:

- (i) the bigger σ_T , the smaller $(\sigma_T - \sigma'_T/\sigma_T)$, i.e. reduced influence from axial and shear forces.
- (ii) The negligence of axial and shear forces most likely results in overestimation of the max principal tensile stress. In other words, it is on the safe side.

 — : 200 kg concrete Dolos (without shear and axial forces)

Figure 8. Comparison of stress distributions in shank cross sections of 200 kg and 200 g concrete Dolosse. Influence from shear and axial forces are neglected. AHL experiments.

Influence of compaction and surface roughness

Comparative tests with smooth (polyester) and rough (concrete) Dolosse revealed that the amount of compaction (settlement) and the surface roughness influenced the stresses significantly. The effects should be considered in the model test analysis.

Hydraulic flume tests

The object of the flume tests at AHL is to study the armour unit stresses as functions of the structural and the sea state parameters.

Although a comprehensive parametric study has not yet been completed, enough tests have been made to present some conclusions related to a range of problems. The set-up and procedure for the tests are coordinated with tests at CERC, Vicksburg, in order to establish a more complete parametric study.

Model test set-up and description of the experiments

All tests were conducted in a 1.2 m wide and 1.5 m deep flume with the model situated app. 17 m from the wave paddle, Fig. 9. The flume was divided into two parts with width of 0.75 m and 0.45 m, respectively. The breakwater model was placed in the 0.75 m wide part of the flume at the top end of a 1 : 20 foreshore slope. The water depth at the toe of the breakwater was 23 cm. The 0.45 m wide part of the flume was fitted with an effective non-reflecting array of perforated metal sheets. Fig. 9 also shows the cross section of the breakwater.

Measures and levels in meter

Fig. 9. Set-up of the wave flume and the cross section of the breakwater. Aalborg Hydraulic Laboratory (AHL) experiments.

To compensate for reflected waves two arrays of three wave gauges were installed. The incident wave spectrum was calculated by the least square method presented by Mansard et al., 1980.

The irregular waves were generated by a piston type paddle according to the five parameter JONSWAP spectrum with the peak enhancement coefficient being 4.

Table 2 lists the characteristics of the applied waves propagating towards the breakwater at the paddle and at the toe of the breakwater. L_p is wave length

corresponding to the spectral peak period and $\zeta = T_p \left(\frac{2\pi}{gH_{m0}} \right)^{0.5} \tan\alpha$.

Table 2. H_{m0} and T_p at the wave paddle and at the toe of the structure.

H_{m0}^p	at the paddle (cm)	5	10	15
T_p	at the paddle (sec)	1.5	2	2
H_{m0}^p/L_p	at the paddle	0.016	0.022	0.032
H_{m0}^t	at the toe (cm)	5.7	11.8	17.9
T_p	at the toe (sec)	1.5	2	2
ζ	with H_{m0}^p and $\tan\alpha = \frac{1}{20}$	0.27	0.25	0.21
ζ	with H_{m0}^t and $\tan\alpha = \frac{1}{1.5}$	3.3	3.1	2.5

Definition of peaks of static plus pulsating stresses

In the statistical analyses of the stress peaks presented in the paper a definition of the peaks by zero down crossing identification has been adopted, Fig. 10. This definition is applied due to the fact that static and pulsating stresses scale the same way.

Figure 10. Definition of peaks of stress in time series.

Results from the flume tests

Distribution of static stresses

The distribution of the static stresses which are defined as the average of the Dolos stresses before and after wave attacks is shown in Fig. 11. As is seen the distribution closely follows the log-normal distribution as also found from the ramp tests.

Figure 11. Distribution of static stresses in flume tests with 200 g Dolosse as recorded in one shank cross section.

Distribution of stress peaks for static plus pulsating loads

Fig. 12 shows for three different sea states the stress distributions obtained from the flume tests with 200 g Dolosse only instrumented in one shank cross section. Results are for 6 positions of Dolosse within the area between levels SWL \pm app. 1.5 times the Dolos height.

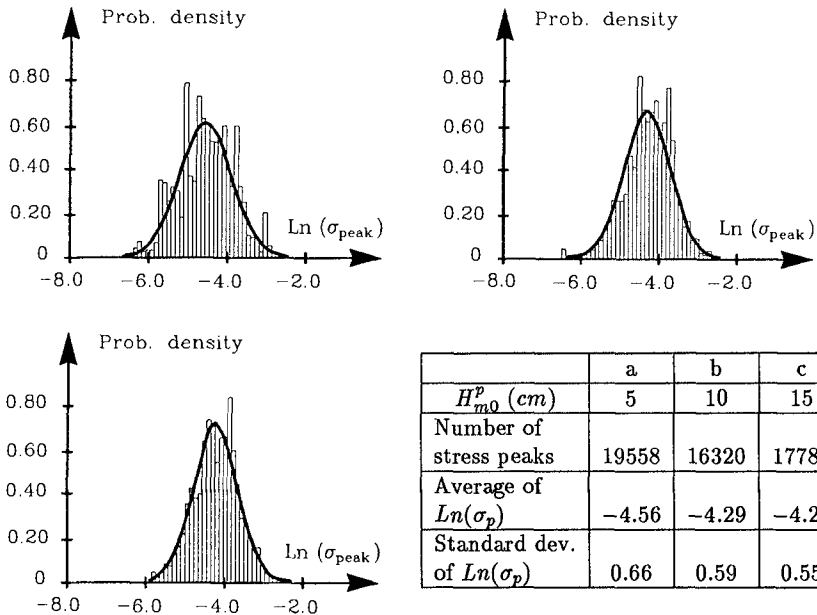

Figure 12. Distribution of peaks of static and pulsating stresses (in MPa).

It is seen that the mean values (mean of \ln) increase with the wave height, but at the same time the standard deviation decreases. Consequently, the stress corresponding to higher exceedence probability levels are found to be almost invariant to the wave height for waves higher than a certain level, cf. also Fig. 12. This tendency can also be seen in model test results with Tetrapods, Bürger et al., 1990.

Preliminary design chart

Fig. 13 is an example of a preliminary design chart. Note that the static stresses (corresponding to zero wave height) are large compared with the total stresses under wave action.

Figure 13. Preliminary design chart for Dolos with waist ratio 0.32. The design chart covers the area between levels SWL \pm app. 1.5 times the Dolos height. The exceedence probabilities are obtained from the fitted log-normal distribution of peaks of static and pulsating stresses. Impact stress, fatigue, failure contribution from flukes and surface roughness correction are not included.

Within the tested range it was found that the wave generated pulsating stresses, in terms of the average of the significant stress wave height, increase almost linearly with the significant wave height.

Acknowledgement

The valuable assistance of Dr. L. Pilegaard-Hansen, Institute of Building Technology, University of Aalborg, in the early phase of the ramp tests is very much appreciated. The work reported here was part of a cooperative effort between the Crescent City Prototype Dolosse Study of the Coastal Engineering Research Center and the University of Aalborg. Permission to publish this paper has been granted by the US Army Corps of Engineers, Office, Chief of Engineers.

CHAPTER 107

VERIFICATION AND PRACTICAL USE OF
METHOD

BLOCK REVETMENT DESIGN

A.M.Burger*, A.Bezuijen**, K.W.Pilarczyk*** and M.Klein Breteler****

ABSTRACT

The research into the physical processes in concrete block revetments under wave attack resulted in three separate design methods. A resume is given of the numerical, analytical and black-box methods and their respective fields of application have been indicated. Special attention is given to the verification of the analytical model with large scale model tests.

INTRODUCTION

Since 1980 Delft Hydraulics and Delft Geotechnics have been involved in a research project for the Dutch Rijkswaterstaat (Ministry of Transport and Public Works). The aim of this research project was to develop a sophisticated design method for placed concrete block revetments under wave attack. This type of block revetments is used throughout the Netherlands for the slope protection of water retaining structures. Separate parts of the design method have been published by Den Boer et al (1983, 1984), Bezuijen et al (1987, 1988), Klein Breteler et al (1987, 1988), Pilarczyk (1990) and Burger et al (1983, 1988, 1990). The present paper gives a resume of the results and a comparison of the results of computations with the results of large scale verification tests. The development of the design method has presently been finished and the ongoing research on block revetments is aimed at developing the probabilistic concept of safety and the residual strength of block revetments after initial failure.

A summary of the results of the entire research project has recently been published by Bezuijen et al (1990-1). The design method covers the schematization and calculation of the external and the internal wave induced loads, on the various structure elements and enables the design of a stable top layer and stable filter and base layers, including stable interfaces between successive layers. The design of the sublayers will not be dealt with in this paper, but has been covered by Bakker et al (1990) and earlier by Van der Knaap et al (1986) and Bezuijen et al (1987).

RESUME OF DESIGN METHOD

The design method has been developed for revetments that are founded on a granular filter layer. A typical cross section is given in fig.1.

The principle of the design is based on a specific perception of the course of events that endanger the structure's stability: Wind waves running on a slope induce time dependent pressures on the top layer of a revetment; these pressures are transmitted through the top layer to the filter layer and influence the ground water flow in the filter layer, causing time and place dependent pressure differences across the top layer, that tend to lift individual blocks from the revetment.

Figure 1 Definition sketch

From the results of large scale model investigations (Burger 1983, 1984) it has been concluded that this failure mechanism can only occur when the relative percentage of openings in or between the blocks is smaller than approximately 10% of the top surface of the blocks.

This covers most of the concrete block revetments in the Netherlands, but excludes all kind of block mats, with mostly perforated blocks or large interspaces between the blocks. Also the stability (or failure) of placed block revetments on a more or less impermeable core is not covered by the perception of the failure mechanism on which the calculation method of the physical processes has been based. For those situations empirical results from mostly large scale model investigations and field experience have been used to develop an empirical extension of the design method.

The design method, based on a mathematical description of the physical hydraulic processes, has been divided into two main parts: the computation of the loads on the various parts of the structure and the computation of the strength of these parts.

For the determination of the hydraulic loads the following steps have been distinguished:

- Transformation of the wave conditions in front of the revetment to the external hydraulic loads on the structure's surface. For this transformation a data base of systematic pressure recordings from model tests has been established to be used in conjunction with numerical models to calculate the time dependent internal pressures and the structure's response (Bezuijen et al 1987, 1988). An empirical simplified description for the wave induced pressures has been developed to be used in an analytical model (Burger et al, 1990).
- Transformation of the external hydraulic loads on the structure's surface to the hydraulic loads in the sublayers of the structure. For the computation of the pore pressures, the hydraulic gradients and the internal water flow in the granular sublayers, a detailed numerical and a schematised analytical method have been developed.

For the computation of the internal hydraulic loads the permeabilities of the different layers of the revetment proved to be essential. For the permeability of granular layers use can be made of existing relations, but for the determination of the permeability of the concrete block top layer an analytical method has been developed and verified. This method has been described by Klein Breteler et al (1998) and enables the calculation of the permeability of a new top layer. It fails, however, for the calculation of the time dependent changes in permeability due to siltation, vegetation and such that have turned out to be decisive for the top layer stability in practical situations.

For the determination of the strength of the relevant parts of the revetment structure the following separation can be made:

- The strength of the placed blocks top layer, that is composed of the weight of the block and the different interaction forces between adjacent blocks. For the latter strength factors a conservative 'common sense' approach has been developed, that accounts for the fact that through friction and clamping forces a top layer of individual blocks may act as an interlocked system. It should be emphasized, however, that this additional strength is mobilized only after that the internal pressures, acting from the filter on the block, tend to lift the block.
- The strength of the granular sublayers of the revetment, which is the resistance to hydraulic loads. For the evaluation of this filter strength a new set of filter rules has been developed and verified by means of model testing. In this way the internal stability of a filter and the stability of granular interfaces can be determined. The development of this method and the final results have been presented by Bezuijen et al (1987) and Bakker et al (1990).

The combination of the methods mentioned above for the determination of loading and strength of different parts of a revetment enables the design of a safe stable structure.

LARGE SCALE VERIFICATION

During the development of the predictive models for loading and strength of the various structure elements each model has been verified by means of schematized, mostly full scale model investigations. Small scale models have been used only for the predictive models for hydraulic external wave induced loads, as it appeared that conflicting scale rules for wave action and ground-water flow (in the sublayers) prohibit the application of small scale models for stability investigations.

Finally, the model as a whole has been thoroughly checked and verified in a full scale model investigation in the large wave flume of Delft Hydraulics. In this model investigation 12 different placed concrete block revetments were exposed to varying wave conditions. The slope angle was kept constant at, $\cotg \alpha = 3$. The core of the structure consisted of well compacted, fine sand. Table 1 indicates the characteristics of the 12 different slope revetment structures.

Table 1 Slope revetments for large scale verification tests

Figure 2 shows a typical model structure, covering the eastern half of the 5 m wide wave flume. The model was equipped with instruments to measure the external wave loads (pressures and water velocities) and the wave induced internal water pressures in the sublayers and acting on the underside of the toplayer. In a special measuring frame the upward motion of a selected block was measured. In this way the loads and the response of the revetment were measured simultaneously. On the interface of base and granular filter layer the hydraulic gradients have been measured to verify the filter rules (Bakker et al, 1990).

Figure 2 Cross section and plan-view of slope II, east

Figure 3 shows an example of the output of the physical model tests. The figure shows the recording of the pressures on top and underneath a free moving block together with the recorded block motion for two almost identical tests. The only difference between the tests was that in one test (P208) the block was free to move (the recording shows a periodic lift of some 2.5 cm) and in the other test (P213) the block was fixed. The influence of block motion on the pressures is clear.

Figure 3 Influence of block movement on internal load

The top part of the figure shows the exact reproduction of the external wave pressures for the two tests; the lower part shows the successive block jumps with a duration of some 1.5 seconds. The central part of figure 3 shows the load reduction during upward block motion, and the pressure increase during downward motion. This confirms qualitatively the phenomenon that the upward motion of a free block reduces the pressures underneath that block. When the resultant upward load on the block exceeds the critical value of potential instability the block starts moving upwards, inducing water flow in the filter towards the space created by the upward motion. Consequently, the pressure difference across the top layer is reduced. This potentially important load reduction can be quantified with the numerical and analytical design methods that have been developed. Bezuijen et al (1990-2) deals with the verification of the numerical model.

The remarkable negative pressure peaks in figure 3 are due to water hammer just after the moment that the block falls back in its initial position. This dynamical phenomenon is neither dealt with in the analytical nor in the numerical model as inertia effects of the revetment are assumed to minimize the effect of impacts. In this specific situation it is considered to be a model effect related to the situation that the block can move up and down almost frictionless; a situation that will never occur in practical situations.

Figure 4 shows the result of a quantitative comparison between the physical model results and the analytical design method presented by Burger et al (1990).

Figure 4 Comparison of analytical model with large scale model results

The figure shows an H-T diagram for one of the tested slopes in which each symbol represents a test. The type of symbol indicates the recorded maximum block displacement (\square = 0-10 mm; \times = 10-20 mm; ∇ = 20-30 mm). The connected solid symbols are the result of calculations with the analytical method for different acceptable block movements (\blacksquare = 0 mm; \bullet = 30 mm).

The general agreement is good and indicates that the analytical design method yields somewhat conservative (= safe) results. Given the fairly rough schematisations of the physical processes involved this result is considered to be quite satisfactory.

PRACTICAL APPLICATION OF THE METHODS

In fact the design method as a whole consists of a number of separate methods to design a block revetment from the first stage of the feasibility study to the stage of detailed engineering. In the following the practical application of those methods will be outlined. The following models will be dealt with:

- analytical model;
- numerical model;
- black box model;
- initial design model.

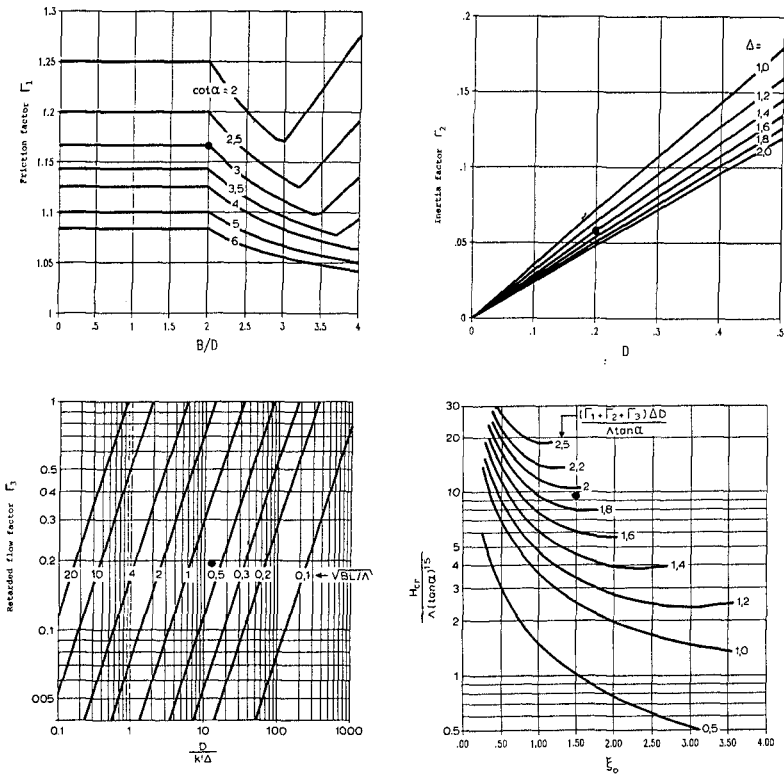

Next, some attention will be given to the general tendencies of the consequences of adaptations to the structure's design.

Analytical model

The analytical model consists of a set of large formulae that discourage their use in stages of preliminary design (see Burger et al, 1990). Those formulae, however, are the results of only a simplified description of only the most relevant physical phenomena of a block revetment under wave attack. To encourage the use of the method the formulae have been presented in figure 5 in the form of a set of graphs.

In the following some remarks to the figure will be made:

- the graphs do not yield a design, but only determine the limit state wave conditions for a given design;
- the input consists of the block dimensions (B,L,D, Δ), the slope steepness (α), the wave steepness (H/Lo) and the permeabilities of top layer and filter, which are incorporated in the leakage factor (λ);
- the upper left figure accounts for the friction between individual blocks, the upper right figure accounts for the inertia of a moving block, the lower left figure accounts for the pressure fall underneath a moving block and the lower right figure integrates those three correction factors and leads to the critical wave height (H_{cr}) for the structure;
- this critical wave height should be larger than the design wave height for the structure.

Example (•): $B = L = 0.4 \text{ m}$ $D = 0.2 \text{ m}$ $\Rightarrow \begin{cases} \Gamma_1 = 1.17 \\ \Gamma_2 = 0.06 \\ \Gamma_3 = 0.19 \end{cases}$ with block motion: $H_{cr} = 1.1 \text{ m}$
 $\cot \alpha = 3$ $\Delta = 1.4 \text{ m}$
 $\Lambda = 0.6 \text{ m}$ $k' = 0.01 \text{ m/s}$ (without block motion:
 $\xi_0 = 1.5$ choose $\Gamma_2 = \Gamma_3 = 0 \Rightarrow H_{cr} = 0.65 \text{ m}$)

Figure 5 Design graphs for analytical model

This analytical model is also very suitable for transformation into a PC-model as has been done for one of the manufacturers of block-mat systems (see figure 6).

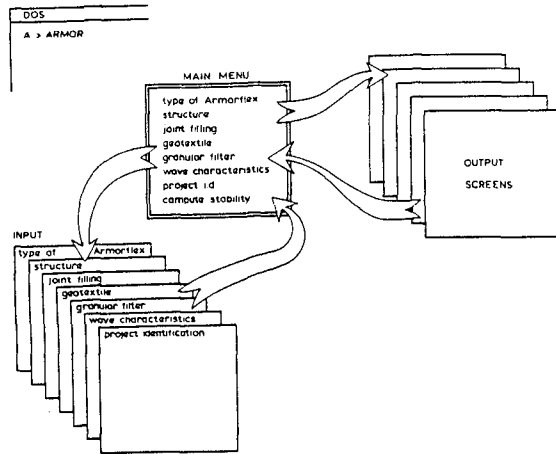

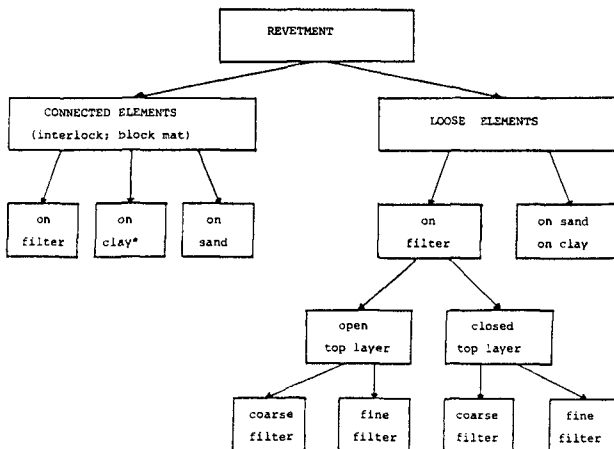

Figure 6 Set-up of Amorflex model

Numerical model

The numerical model can be considered as a specialist's tool. It will be used during the stage of detailed engineering of a revetment structure. It gives the time dependent loads and the structure's response. The average designer will need specialist's assistance to make an optimum use of this sophisticated design aid (see Bezuijen et al 1987, 1988, 1990-2).

Black-box model

* no model data available

Figure 7: Flow diagram for block-box model

This model consists of a system of purely empirical model test results of block revetment failure. In fact the box is not completely black but it is rather a grey-box. The acquired knowledge of the decisive parameters for block revetment stability have led to a division in eight combinations of top layer and sublayer (figure 7). The black-box model is very valuable for situations where the schematisations of the numerical and analytical models are not acceptable; for example for impermeable filter layers.

Initial design model

Finally an attempt has been made to combine all information from analytical, numerical and black-box models with field experience. This attempt has led to a consistent set of graphs to get a first impression of the critical wave height for a given structure.

Figure 8 Simple design graph for top layer thickness

Even when using those methods the designer must still be aware of the consequences of his design freedom, also beyond the design of a stable top layer. Adaptation of one structural element may have strong effects on other parts of the structure as will be illustrated by a description of the possible consequences of steepening of an initially flat slope:

The aim of the designer will be to reduce the costs of the revetment by a reduction of the slope length. However, the wave run-up on a steep slope will increase and consequently the length of the revetment or even the volume of the dike will increase. The wave run-down will also increase, due to the higher value of the breaker parameter ξ . This generally will necessitate thicker blocks. Steepening the slope will also reduce the effective block weight but will on the other hand increase the friction between the blocks. For a steeper slope the soil mechanical stability will be more critical and the design of the granular filter and the interfaces between successive layers should be adapted and may even necessitate the application of a geotextile. Steepening the slope may also necessitate a stronger toe structure to support the revetment, and an extension of the toe structure to compensate for additional toe scour. Finally it is expected that an initial small damage will grow faster on a steep slope than on a gentle slope.

Some of the consequences mentioned are covered by the design methods that have been presented, but others are not. The designer himself is finally responsible for the quality of his design.

SAFETY CONSIDERATIONS

Correct application of the design methods lead to a 'safe' concrete block revetment. However, in the following some ideas about safety will be presented, showing the designer that safety is not an absolute and strict design consideration. The functional requirements of the revetment, the statistics of the boundary conditions, the residual strength of the structure and the acceptability of occasional (or even intensive) maintenance influence the selection of the hydraulic design conditions and the structural design itself.

In a very general way a safety consideration for a designer is: a reference for dealing with the possibility of a failing structure. It is the awareness of the designer that the same block revetment can be applied as a channel bank protection and as a protection of a dike surrounding a low lying polder area. The consequences of failure can be completely different and vary from the necessity of some repair measures to the loss of many lives, as will be illustrated in the following:

A revetment along an inland waterway will regularly meet its design conditions, maybe even daily, consisting of the waves induced by a ship sailing at maximum speed. From a maintenance point of view this means that no damage under design conditions is acceptable. Consequently, all attention from the designer is focussed on the initial strength of the structure; the residual strength does not play a role.

But a revetment on a dike enclosing a low laying polder will only at very rare occasions meet its design conditions. In the Netherlands such structures are designed for average storm recurrence frequencies of 1/4,000 or 1/10,000 times per year, because of the enormous potential losses resulting from a dike break-through.

Under such very rare conditions some damage to the top layer might be acceptable when the residual strength of the revetment is sufficient to guarantee the safety of the protected land. Consequently, the designer will explicitly incorporate the residual strength in his design.

A safety consideration is also: dealing with uncertainties. Uncertainties in material performance, construction methods and maintenance discipline.

For given boundary conditions and estimated uncertainties in the design parameters a revetment has been designed and the chance of failure has been calculated, using the three different design procedures: black-box model, analytical model and numerical model. The results of these probabilistic calculations (see table 2) confirm that more advanced design models requiring more detailed input, lead to a more reliable structure.

However, because of the many uncertainties in even the estimates of the parameter uncertainties, the calculated chance of failure will have little or no relation with the frequency of damage to the structure. But, for the comparison of different structures a probabilistic safety analysis may be very valuable.

Applied model	Chance of failure per 100 yr
Black-box	0.16
Analytical model	0.04
Numerical model	0.01

Table 2 Chances of failure for a specific structure

It will be clear that with the present state of the art a safety consideration for a revetment must be much more than the application of a probabilistic design method. The following example, however, will demonstrate that the use of a probabilistic calculation may contribute to the knowledge of the sensitivity of a structure design and is therefore a valuable tool.

Example: the resultant load on the top layer of a revetment is governed by the value of the leakage factor λ that can be calculated from the permeabilities and thicknesses of top layer and filter layer and the slope angle. In a deterministic approach a reduction of the leakage factor yields an increased top layer stability. In a probabilistic approach, however, not only the median leakage factor is taken into account, but also the statistical deviation of this value, based on the statistical deviation of the forementioned constituents. In the case of a reduction of the leakage factor it appears that for a smaller leakage factor the sensitivity of top layer stability for variations in the leakage factor is much greater than for larger values of the leakage factor. For a given acceptable chance of failure for the top layer much of the profit obtained by reducing the leakage factor is lost due to the increased sensibility of the stability for variations in the leakage factor!

This example reveals the validity of the concept of probabilistic design for placed block revetments.

Summarising it can be stated that at present, and probably also during the next decade, the role of probabilistic design for placed block revetments is essential for the analysis of the weaknesses of a design, but is of very limited value for a prediction of the chance of failure.

For the time being those elements of a structure that contribute for a large part to the total uncertainty of its performance should be avoided as much as possible.

The present research on safety aspects of block revetments is therefore focussed at:

- better estimates for the partial safety coefficients for the various parameters of the design models
- and at
- determination of the residual strength of the block revetment after an initial failure.

CONCLUSIONS

The research on placed block revetments has resulted in three design procedures: a black-box model, an analytical model and a numerical model. The models have been verified thoroughly and have been integrated in a set of simple graphs for initial design purposes. A start has been made to include probabilistic concepts in a safety consideration for block revetments. The following conclusions can be drawn from the research so far:

- The presented methods provide a powerful design tool for placed block revetments, based on thorough understanding of the physical processes in the revetment.
- Stochastic phenomena have proved to dominate the actual behaviour of a realised structure. Current research is therefore focussed on gaining knowledge of the statistical distribution of the structure's parameters.
- The effect of time dependent changes in structure parameters is still ignored in the design model. The gradual decrease of the permeabilities of top layer and filter layer in combination with a gradual increase of the friction between individual blocks may lead to a completely different behaviour of the structure than perceived in the design.
- For an optimum design the separate parts of the revetment should be treated completely integrated.
- For the time being the most profitable way to design a good revetment is to reduce the statistical dispersion of the input parameters for the design model.

ACKNOWLEDGEMENT

The development of this design model has been performed by order of the Technical Advisory Committee on Water Retaining Structures of the Dutch Ministry of Transport and Public Works. Their co-operation and permission to publish these results is gratefully acknowledged.

CHAPTER 108

Rock Armour Stability Formulae-Influence of Stone Shape and Layer Thickness

Bradbury AP¹, Latham J-P² & Allsop NWH³

Abstract

A series of hydraulic model tests of armour rock stability have been carried out on a 1:2 slope armoured with rock of each of 5 different shape types. Results of these tests have been compared with damage predicted by van der Meer's stability formulae. Coefficients are suggested to describe the influence of armour shape and layer thickness in revised stability formulae.

1. Introduction

Coastal structures may be protected from the effects of wave action using rock armour with a variety of rock types, each of different grades and shape properties. The shape characteristics of quarried rock are governed largely by natural jointing and fracturing, and by production techniques. Many quarries can only produce flat slabby armourstone due to the limitations of the bedding. Under circumstances where the bedding and joint characteristics of the source permit, and where special production techniques are used, near equant blocks of armour can be produced.

During service, rock armour may suffer changes to both its shape and size. Previous research by Queen Mary College, and Hydraulics Research (Refs 1,2,3) has demonstrated the importance of rock quality and shown that degradation of armour in service constitutes a major problem for many coastal structures worldwide. Degradation of the armour may occur by fracturing, spalling or abrasion. These may be particularly important in severe wave climates, where there are abrasive sediments, or where the rock is of low grade, or where the rock is too small for the incident wave

³Coastal Structures Section, Hydraulics Research, Wallingford, OX10 8BA, UK

conditions. Recently some structures have been designed for dynamic stability. In such cases the armour will also be more susceptible to degradation due to its movement under wave action.

2. Previous Work

Recent work in the UK and the Netherlands has highlighted the shortcomings of the Hudson formula (Ref 4), traditionally used for the design of rock armour for static stability. The omission of several fundamental hydraulic parameters in the Hudson formula has been addressed by van der Meer (Refs 5,6). These studies included the data from Thompson & Shuttler's work on rip-rap stability (Ref 7), in addition to the results from many other irregular wave tests. The new design formulae are based upon a more comprehensive empirical framework, and allow the designer to explore the influence of mound permeability, storm duration and acceptable damage levels. These formulae do not give quantitative advice on the effects of armour shape stability. Neither do they allow for variations in construction which may result in loose interlock, or armour layers of variable thickness.

The influence of armour shape and placement on stability has been discussed by a number of researchers. The Shore Protection Manual (Ref 4) suggests different stability coefficients for smooth and angular rock. Jensen (Ref 8) and Bergh (Ref 9) have tested rock armour of various shapes, and identified significant influence of armour shape on stability.

Van der Meer did not consider gross shape and roundness as variables in his static stability programme. However, a number of interesting observations arose during his tests which may be related to armour shape. Rounding of material during the extensive testing programme seems to give a likely explanation of some anomalous results. Two repeat tests at the beginning and end of the test programme resulted in 2.5 times more damage in the second test. Tests to investigate the effects of relative mass density identified a systematic effect, apparently uncorrelated to rock density. These differences may have arisen from variations in roundness and surface texture.

These suggest that gross shape and roundness, together with placement technique, have an important effect on stability, but no clear guidance is given to the designer on these effects. This study sought therefore to identify the influence of rock shape on armour stability, for inclusion in empirical design methods.

3. Test Programme

The framework of this study was based on the parameters defined in van der Meer's design formulae. A systematic series of random wave stability tests were carried out on each armour shape, including the effects of wave period, significant wave height and mean wave steepness, for a range of surging and plunging wave

conditions. A number of variables were kept constant throughout these tests:

Median armour weight $W_{50} = 323\text{g} \pm 2\%$
 Relative mass density of rock = 1.73
 Armour slope $\cot \alpha = 2$
 Armour grading (D_{85}/D_{15}) = 1.25
 Spectral shape = JONSWAP
 Approach beach slope = 1:52
 Filter size $D_{50} = 11\text{mm}$
 Construction method, crest level, wave angle
 Water depth at the toe of the structure, $h_s = 0.5\text{m}$

Measurements were made of the armour slope profiles, using a computer driven bed profiler, sampling at intervals of approximately $0.5 D_{n50}$ along each of 10 profiles across the test section. Damage to the test sections was expressed by the dimensionless damage parameter, S , defined:

$$S = A_e / D_{n50}^2 \quad (1)$$

An important variation between this study and previous work was the method of construction of the armour layers. Studies by both van der Meer and Thompson & Shuttler used armour layers constructed to a thickness of $2 - 2.4 D_{n50}$, with bulk placement of rock. Whilst bulk placement is common for rip-rap with a wide armour grading, this study used armour with a narrow grading ratio of $D_{85}/D_{15} = 1.25$. This study therefore used individual placement of the armour blocks to give two layers. The effect of this placement method was that the measured armour layer thickness was about $1.5 - 1.7 D_{n50}$.

Five contrasting shapes of rock were selected to represent the full range of armour shapes. Categories of rock defined in this study are: fresh, equant, tabular, semi-round, and very round. Fresh, crushed rock is used in many model tests and is generally typical of much quarried rock. This shape was initially selected as a base condition for comparison with van der Meer's work. Flat or slabby rock was excluded from this category. Equant or nearly cubic rock was selected as the second armour shape. Flat, slabby or tabular rock, with maximum to minimum lengths in excess of 2, was selected as a third shape, typical of much quarried limestone presently excluded from many design specifications. The effects of changing shape whilst in service were also examined by testing two grades of rounded rock, prepared by tumbling in a concrete mixer. Rounding to a weight loss of 5-10% and 20-25% represented materials subject to varying degrees of abrasion.

4. Shape Analysis

A study has been carried out at Queen Mary College to develop methods for the description of particle shape (Ref 3, 11), and

this has allowed a number of shape parameters to be examined. The median value of the X/Z ratio (maximum and minimum dimensions of the enclosing cuboid) has been used in the past to give a basis for comparing the gross shape of the samples. Recently Latham et al (Ref 11) have developed shape descriptors based on Fourier and/or Fractal analysis of particle outlines and armour slope profiles. These include the Fourier shape factor, P_C , which describes gross shape, and the Fourier asperity roughness, P_R , which is sensitive to roughness, but is also influenced by gross shape. The most useful of these shape descriptors was the Fourier asperity roughness factor, P_R . Blocks that have not undergone rounding but are tabular and elongate will give higher values of P_R than ones that are equant.

5. Test Results

For each test, values of the damage parameter were calculated from the profile data. In the preliminary analysis, damage was compared directly with that predicted by Van der Meer's formulae with a permeability coefficient of $P = 0.1$. For the purposes of further analysis, van der Meer's formulae were re-arranged, replacing the fixed coefficients in the original formulae by variables. The plunging wave formula was rewritten:

$$S^* = H^* / C_{p1} \quad (2)$$

where

$$S^* = (S/\sqrt{N})^{0.2} \quad \text{and} \quad H^* = H_s/\Delta D_{n50} \sqrt{\xi_m} P^{-0.13}$$

where C_{p1} replaces 6.2 in the original.

The surging wave formula was rewritten :

$$S^* = H^{**} / C_{su} \quad (3)$$

where

$$H^{**} = H_s/\Delta D_{n50} \sqrt{\tan \alpha} P^{0.13} \xi_m^{-P}$$

where C_{su} replaces 1.0 in the original equation.

Curve fitting regression coefficients for C_{p1} and C_{su} were calculated, for a permeability of $P = 0.1$ and are given in Table 1. Results from this study for plunging waves are compared with predicted damage from van der Meer's equation in Figure 1. Comparisons with van der Meer's equations indicated that very round rock performed worse than predicted, as did the partially rounded rock. However, equant and fresh rock also performed somewhat worse than predicted. Tabular rock surprisingly performed better than any other shape. Throughout the test programme, the threshold of damage for virtually all conditions was lower than that predicted by van der Meer's formulae. There

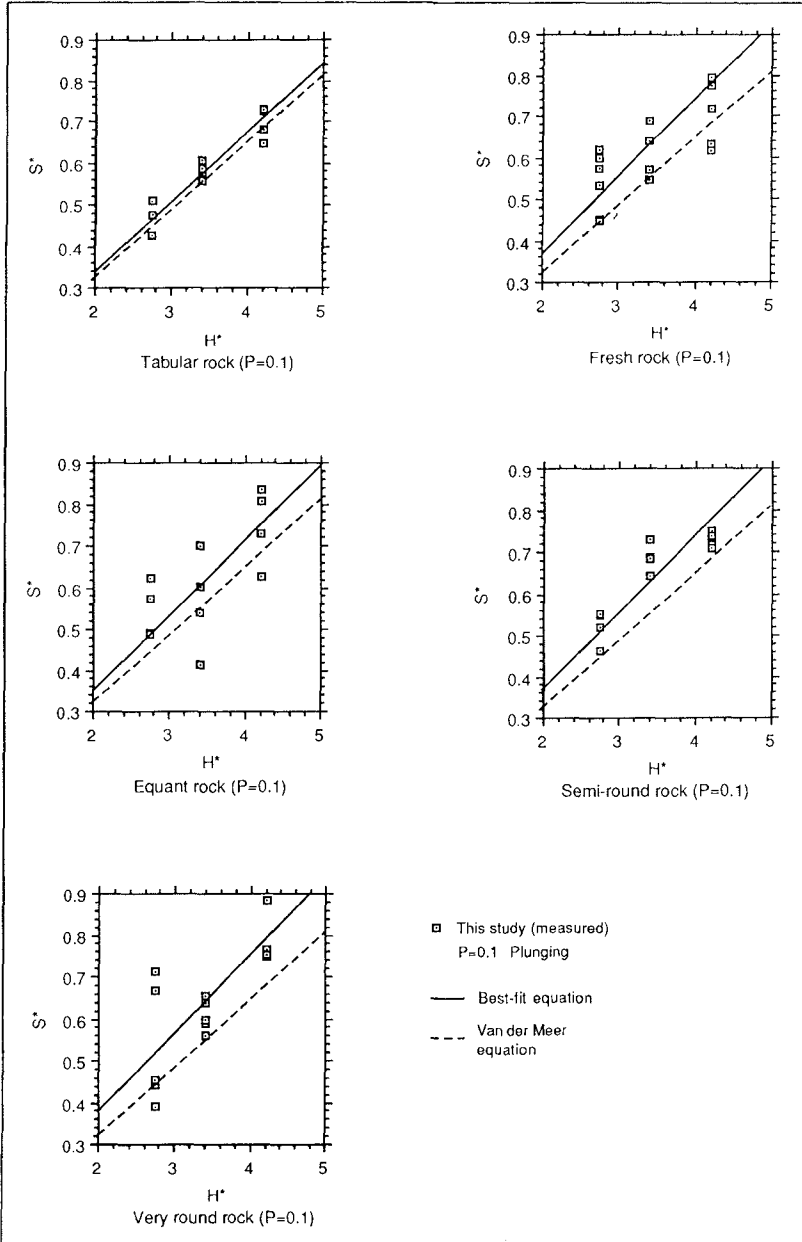

Figure 1 Van der Meer's predictions for plunging waves and curve fitting regression results for C_{p1}

was also noticeable scatter outside of Van der Meers 90% confidence bands, mostly at higher damage levels.

Table 1 Curve fitting regression results for C_{pl} and C_{su} in eqs. (2) and (3) for $P = 0.1$

Shape classes	Plunging C_{pl}	Surging C_{su}
Tabular	5.93	0.999
Fresh	5.63	0.711
Equant	5.61	0.894
Semi-round	5.39	0.830
Very round	5.35	0.713
Van der Meer	6.20	1.000

Initially it was felt that the consistently higher damage observed in this study could have resulted from the lower layer thickness, perhaps giving a lower value of P than the 0.1 limit given by Van der Meer. Subsequent analysis of this variable in the equations given by van der Meer indicated that substitution of a lower value of P cannot give satisfactory results for both surging and plunging formulae. A more reasonable explanation of this anomaly was derived after more detailed analysis and comparison of the results of this study with previous work. Samples of material from the previous studies were analysed using Latham's shape descriptor techniques.

This showed that the bulk of van der Meer's tests were performed with material similar in roughness and degree of rounding to the semi-round rock of this study, but with more equant gross shape. The material used by Thompson & Shuttler had characteristics similar to the equant rock of this study. It was concluded therefore that van der Meer's equations represent the stability of equant and semi-round rock.

6. Effects of Layer Thickness and Particle Shape

For armour with a narrow grading, the procedure most often adopted is to build a two layer system with random block orientation and individual placement of armour. A layer thickness of less than $2D_{n50}$ may therefore be common. Differences in the layer thickness achieved in this study and those in van der Meer's study represent a 30% reduction in layer thickness. It was suspected that this comparative reduction in layer thickness alone gave the increase in damage from that predicted by van der Meer for equant and semi-round materials.

This increase can be explained by replacing some coefficients in the van der Meer equations by variables. Analysis of the results by least squares non-linear regression gave acceptable explanations for the influence of both shape and layer thickness. The shape effects were best described by using the coefficients

C_{pl} and C_{su} . To fix these values at 6.2 and 1.0 for equant and semi-round materials required either that:

- (i) the power coefficients of P, 0.18 and 0.13 must be adjusted to be functions of layer thickness; or
- (ii) the power coefficient of S/\sqrt{N} , must be adjusted.

Both (i) and (ii) were tested, but the most satisfactory results were achieved by adjustment of the power coefficients of S/\sqrt{N} . Conveniently a single adjustment of this coefficient can account for both surging and plunging results as shown in Table 2.

These revised equations may be given:

$$\text{Plunging waves: } S^{*'} = H^*/C_{pl}' \quad (4)$$

$$\text{Surging waves: } S^{*'} = H^{**}/C_{su}' \quad (5)$$

$$S^{*'} = (S/\sqrt{N})^{x(1)} \quad \text{for plunging} \quad (4a)$$

$$S^{*'} = (S/\sqrt{N})^{x(2)} \quad \text{for surging} \quad (5a)$$

Table 2. Derivation of curve fitting power coefficients for S/\sqrt{N} by least squares non linear regression

	Plunging	Surging
	$C_{pl}' = 6.2$	$C_{su}' = 1.0$
Equant	$x(1)=0.236$	$x(2)=0.249$
Round	$x(1)=0.269$	$x(2)=0.260$
Equant & semi-round	$x(1)=0.252$	$x(2)=0.254$

The coefficients $x(i)$ and $x(ii)$ may therefore be reasonably assigned the same value of 0.25. The only difference in the formulae needed to describe the effects of layer thickness on damage for equant and semi-round rock was therefore a change in the power coefficient from 0.2 to 0.25. Thus S in eqn.(4a) and eqn.(5a) can be replaced by:

$$S^{*'} = (S/\sqrt{N})^{0.25} \quad (6)$$

Further curve fitting to establish best fit values of C_{pl}' and C_{su}' in equations (4) and (5), assuming equation (6), was then carried out to quantify the effects of armour shape on stability. The regression results for C_{pl}' and C_{su}' for each armour shape are presented in Figures 2 and 3, and Table 3.

It is important to emphasise that this analysis is only valid for the range of conditions used in this study [i.e 1:2 slope, impermeable core, layer thickness $t_a = 1.5-1.7 D_{n50}$].

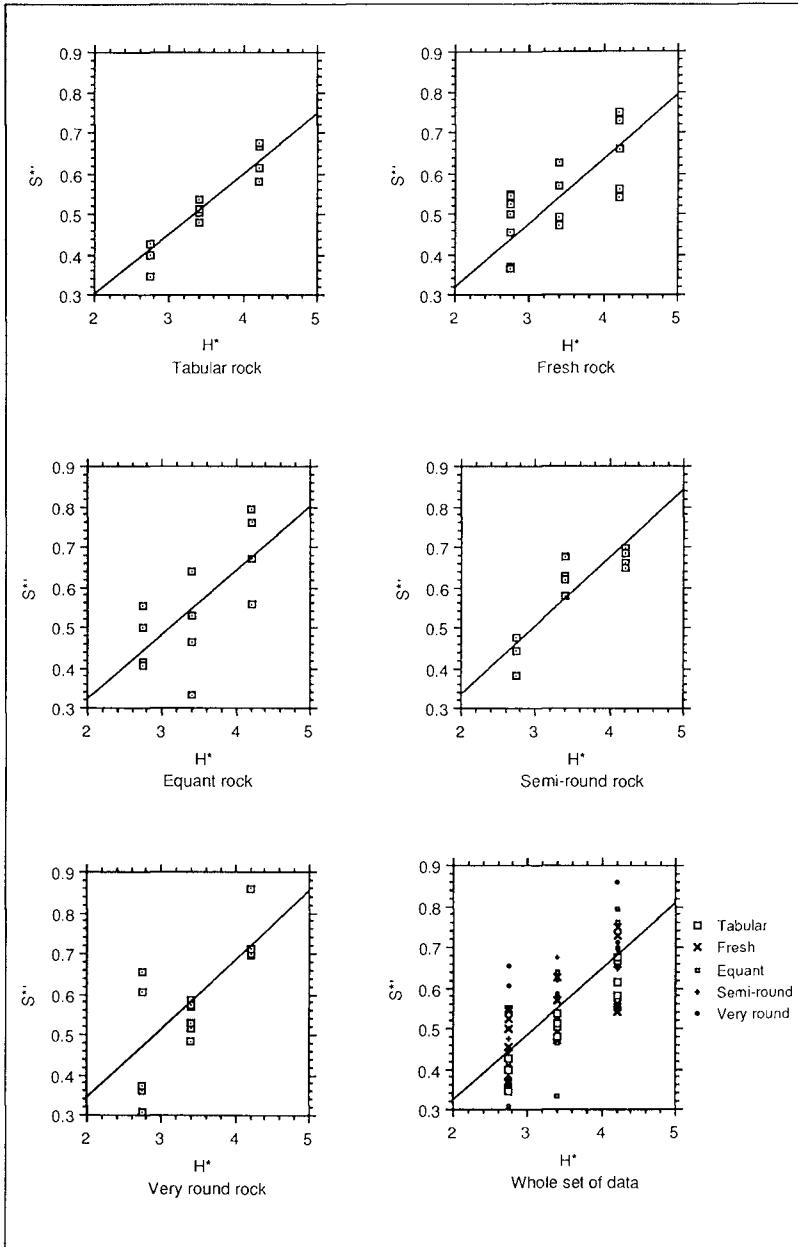

Figure 2 Curve fitting regression results for C_{pl} , plunging wave formula

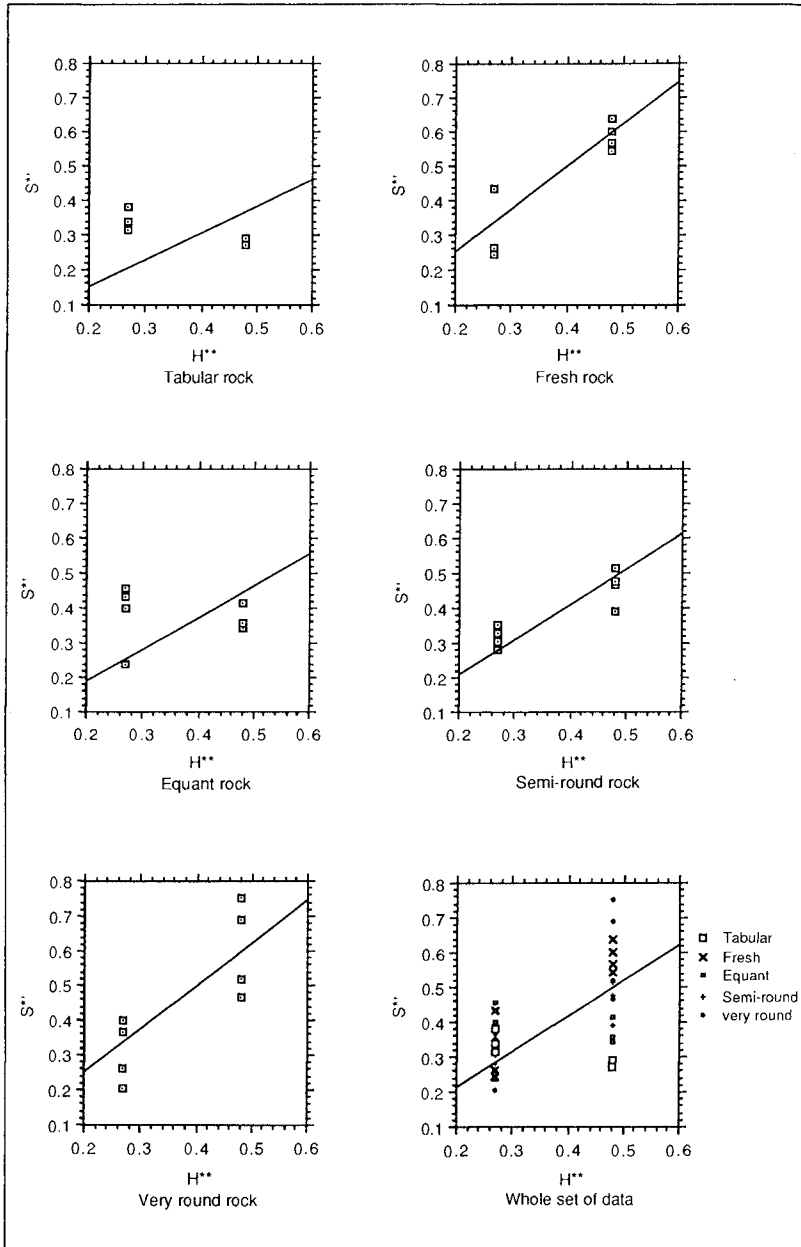

Figure 3 Curve fitting regression results for C_{su}^1 , surging wave formula

Table 3 Curve fitting regression results for C'_{pl} and C'_{su} in eqs. (9) and (10)

Shape classes	Plunging	Surging
	C'_{pl}	C'_{su}
Tabular	6.72	1.301
Fresh	6.32	0.811
Equant	6.24	1.087
Semi-round	5.96	0.989
Very round	5.88	0.810

The results of shape analysis of the armour determined during the test programme can be compared with the stability coefficients C'_{pl} and C'_{su} . From a simple regression of C'_{pl} and C'_{su} on P_R , the following summary equations were derived:

$$C'_{pl} = 5.4 + 70.0 P_R \quad (7)$$

$$C'_{su} = 0.6 + 40.0 P_R \quad (8)$$

Figures 4 and 5 show the results of this analysis including data derived from the original tests carried out by van der Meer, for which values of 6.2 and 1.0 can be assumed for C'_{pl} and C'_{su} .

Van der Meer's equations can now be modified to account for different shaped armour and layer thicknesses. Substituting the new coefficients for 2 layers of armour on an impermeable core at a slope of 1:2, the proposed modifications to van der Meer's equations are given by:

$$H_s/\Delta D_{n50} \sqrt{\xi'_m} = C'_{pl} P^{0.18} (S/\sqrt{N})^{0.25} \quad (9)$$

$$H_s/\Delta D_{n50} = C'_{su} P^{-0.13} (S/\sqrt{N})^{0.25} \sqrt{\cot \alpha} \xi'_m P \quad (10)$$

where C'_{pl} and C'_{su} are shape coefficients given in equations (7) and (8) by the Fourier asperity roughness parameter P_R .

C'_{pl} and C'_{su} have been set to be coincident with C_{pl} and C_{su} respectively for flume tests results from all studies using Equant and Semi-round type test material. However C_{pl} and C_{su} in the general equations (2) and (3) may not have the same influence on stability as eqns. (7) and (8) since, for example permeability in the core may greatly influence the effect of shape on damage.

The implications of these equations are now summarized. The change in damage S as a result of using tabular or very round rock by comparison with equant rock has the following influence.

Damage, S Plunging : Tabular = 0.81 Equant
Very round=1.40 Equant

Figure 4 Best fit for shape coefficient C'_{pl} in Equation (7) versus block shape parameter P_R

Figure 5 Best fit for shape effect coefficient C'_{su} in Equation (8) versus block shape parameter P_R

Surging : Tabular =0.52 Equant
 Very round=3.44 Equant

This simple summary of the shape effects given by equations (7) and (8) may be an over-simplification of the complexity of shape effects but indicates the potential dangers of underdesign if the effects of shape are ignored.

The surging wave data gave more scatter than the plunging data and gave large standard errors for the curve fitting, whilst the fresh rock results did not conform to summary trends at all, casting some doubts on this simple interpretation of the surging waves results.

10. Conclusions

The results of the study gave consistently higher damage levels than predicted by van der Meers equations for shape classes of material of similar shape characteristics to those from which the formulae were derived.

These differences have been attributed to the lower layer thickness achieved by placing armour in a two layer thickness resulting in a total layer thickness, of $t_a \approx 1.6 D_{n50}$. Such increased damage for thinner armour layers can be predicted by assuming that the power 0.2 for (S/\sqrt{N}) in both surging and plunging equations is replaced by 0.25.

For different armour shapes and conditions represented in the model test series van der Meer's equations can be simply modified, assuming the 0.25 power correction for double armour layers with the introduction of two shape coefficients.

$$C'_{pl} = 5.4 + 70.0 P_R$$

$$C'_{su} = 0.6 + 40.0 P_R$$

into the equations:

$$H_s/\Delta D_{n50} \sqrt{\xi_m} = C'_{pl} P^{0.18} (S/\sqrt{N})^{0.25}$$

$$H_s/\Delta D_{n50} = C'_{su} P^{-0.13} (S/\sqrt{N})^{0.25} \sqrt{\cot \alpha} \xi_m^P$$

11. Acknowledgements

This paper describes the results of model tests funded by the Department of the Environment, the Ministry of Agriculture Fisheries and Food, and the Science and Engineering Research Council. Additional work has been supported by Queen Mary and Westfield College, Hydraulics Research, and New Forest District Council.

The authors are grateful for helpful advice from Dr van der Meer of Delft Hydraulics during the model studies, and for the assistance of Mr H Wang at Queen Mary and Westfield College in the further analysis.

Summary of notation

ξ_m	Iribarren or surf similarity number
P	Notional Permeability factor
S	Dimensionless damage to a mean profile
N	Number of waves in a storm or test
H_s	Significant wave height
Δ	Relative density
D_n	Nominal particle diameter
C_{su}	Surging wave shape coefficient, defined in equation (2)
C_{pl}	Plunging wave shape coefficient, defined in equation (3)
C'_{su}	Surging wave shape coefficient defined in equation (4)
C'_{pl}	Plunging wave shape coefficient defined in equation (5)
A_e	Cross section area eroded

CHAPTER 109

Reflection Performance of Rock Armoured Slopes in Random Waves

N W H Allsop¹

Abstract

Waves reflected from breakwaters and sea walls may cause navigation or mooring problems in or near harbours, and may increase beach erosion or local scour.

This paper gives results of hydraulic model tests on the reflection characteristics of idealised rock armoured slopes. Examples of the performance of a number of practical structures are also discussed.

1. Wave Reflections

The importance of wave reflections from coastal and harbour structures has historically been given relatively little weight in the design process. Recently it has been appreciated that local problems may often arise due to cumulative increases in wave energy, particularly within harbours. Typically, increased wave reflections may lead to:

- (a) Danger to vessels, often close to the harbour entrance.
- (b) Disruption to handling operations in the harbour due to excessive vessel motions.
- (c) Damage to vessel or mooring systems.
- (d) Local bed scour.
- (e) General increases in erosion at adjoining sites.

Recent studies at Hydraulics Research on wave reflections were prompted by problems experienced in harbours in the Caribbean. Changing wave patterns within these harbours arose from increased reflections from new structures, and from the refraction effects of dredging, (Refs 1, 2). A detailed review of the data available on the wave reflection performance of coastal structures was conducted (Ref 3), and was summarised at the 1988 ICCE (Ref 4). The review noted that data on the reflection performance of rock armoured slopes was sparse, and was restricted

¹Manager, Coastal Structures Section, Hydraulics Research, Wallingford, OX10 8BA, UK)

to regular waves only. It was therefore agreed that a short series of random wave flume tests would be conducted to provide data of general application, and to be used in the numerical modelling of the harbours of interests. This paper presents results from those tests on simple and bermed rock armoured slopes (Ref 5). The paper also presents results from tests on some practical example structures.

2. Measurements and Definitions

In each of the tests considered in this paper, reflections have been measured in a random wave flume. Three wave probes were placed in a constant water depth in front of the test section. Incident and reflected spectra were calculated from the wave probe output by a program developed by Gilbert & Thompson (Ref 6), based on the method of Kajima (Ref 7). This method calculates the reflection coefficient function $C_r(f)$ over the frequency range $0.5f_p < f < 2.0f_p$, where f_p is the frequency at peak energy density for the generated wave spectrum. The reflection coefficient function gives information on the reflection performance with frequency, and is often used in cases where it may be assumed that reflection is a linear process.

At coastal structures wave breaking will have a significant influence on the reflection performance. For this work a total energy approach has therefore been adopted. The reflection coefficient, C_r , is defined in terms of the total reflected and incident energies, E_r and E_i respectively, each parameter measured over the same frequency range:

$$C_r = (E_r / E_i)^{1/2} \quad (1)$$

3. Reflections from Simple and Bermed Slopes

Figure 1 Simple slopes tested

A total of 19 cross-sections were used in these tests to explore the effects of:

- (a) front face slope angle, α ;
- (b) smooth or armoured facing;
- (c) armour layer thickness, t_a ;
- (d) armour unit size, M_{50} , D_{n50} ;
- (e) berm length, B .

For the simple slopes, 3 slope angles were used, $\cot \alpha = 1.5$, 2.0 and 2.5. Smooth and armoured slopes were tested at each angle, Figure 1. A further series of tests explored the influence of 3 berm widths, Figure 2. Armoured slopes were tested with single or double layer armour placement.

Figure 2 Bermed slopes tested

A set of 9 sea states were used with mean sea steepness, $s_m = H_s/L_m$, from 0.0043 to 0.52. Relative mean local wave lengths, L_{ms}/h_s , varied from 6.2 to 14.8. Values of the Iribarren number for the simple slopes, $I_{r_m} = \tan \alpha / s_m^{1/2}$, varied between 1.7 and 10.2.

4. Test Results

Simple slopes

The results of the tests were presented as graphs of C_r against I_r for the simple slopes. To these results have been fitted simple empirical equations of the form used by Seelig (Ref 8):

$$C_r = \frac{a I_{r_m}^2}{b + I_{r_m}^2} \quad (2)$$

This equation was preferred as it is well-known and simple to use, and has been found to give a good description of the reflection coefficient over most of the range of practical interest, see Reference 4. Values of the empirical coefficient a and b were derived for each of the simple slopes tested, both smooth and armoured.

In the preliminary analysis it was noted that the curves calculated by simple regression did not give a good fit over the full range of values tested, and tended to under-estimate C_r at higher values of I_{rm} for the rock armoured slopes. A revised analysis was therefore attempted in which a weighting was applied at the larger values of I_{rm} . This is not a fully satisfactory approach, it did however give consistently better descriptions of much of the data for smooth and armoured slopes. Examples of the test results are shown in Figures 3 to 6 and values of the empirical coefficients are summarised below:

Test section	a	b
Smooth	0.96	4.80
Rock armour, 2 layer	0.64	8.85
Rock armour, 1 layer	0.64	7.22
Large rock, 2 layer	0.64	9.64
Large rock, 1 layer	0.67	7.87

Figure 3 Reflections, smooth and armoured slopes

The results in Figures 3-5 are presented as values of C_r against I_{rm} , where the calculation of I_{rm} is based upon the deep water wave length of the mean wave period, T_m :

$$L_m = g T_m^2 / 2\pi$$

Figure 4 Reflections, large rock, 2 layer

Figure 5 Reflections, large rock, 1 layer

The use of L_m in the calculation of I_r intended to represent the local wave breaking may seem somewhat obstruse. It might be the water depth local to the structure, L_{ms} , would give a more reliable description. The results shown in Figure 3 were therefore re-plotted as C_r against $I_{r_{ms}}$, where $I_{r_{ms}}$ was calculated using the wavelength of the mean period in the water depth at the test section, L_{ms} . These results are shown in Figure 6. Surprisingly there appears to be no improvement through the use of L_{ms} which, being less easy to calculate, complicates the use of any prediction formula based upon it.

This conclusion is similar to one drawn by Yoo (cited by Southgate, Ref 11), who noted the paradox of using an offshore wave parameter to described an inshore process, but found that the use of L_{m0} gave a clearer classification of wave breaking.

Figure 6 Simple slopes, effect of $I_{r_{ms}}$

Bermed slopes

It is difficult to justify the use of the Iribarren number in analysing the performance of bermed slopes. The dimensionless parameter that has been found most useful for such structures is the ratio of berm length to wave length, B/L . The use of this parameter is however complicated by the choice of which wavelength best represents random wave conditions. In this study the wavelength was calculated for the mean wave period both in deep water and in the test water depth, giving L_{m0} and L_{ms} respectively. No clear difference in the fit of the data emerged, and L_{m0} is used in the results shown in Figure 7.

Figure 7 Effect of berm width

Careful consideration of the results shown in Figure 7 suggests that the effect of increasing B on the reflection performance is negligible over the berm widths tested. The separation of the curves for different berm lengths is due primarily to the effect of B in the parameter B/L_{ms} . The data does however suggest that for values of $B/L > 0.05$, the reflections will be reduced to about 50-65% of those from the equivalent simple slope.

5. Comparisons with Other Data

Practical examples of coastal or harbour structures often differ from those for which the test data is used to derive empirical design methods. It is instructive therefore to compare the results of the simple prediction methods available with those measured for realistic structures. Three such examples will be considered here.

Seawall at Blue Anchor Bay

Vertical or slightly battered walls are known to reflect at around 90-100%. These reflections frequently increase local scour, often undermining the wall. Increasingly refurbishment of such seawalls has involved the construction of a rock armoured slope against the wall, reducing wave impacts on the wall, and reducing the level of reflections. Such protection may also improve the wave overtopping performance of the seawall, although some configurations may make matters worse!

In an example described previously (Ref 4), the engineer considered two rock armoured slopes as alternatives to an asphalt grouted toe. The site is subject to a large tidal range, and the wall only experiences significant wave action above about neap high water level, Figure 8.

Figure 8 Blue Anchor Bay, sea wall reflections

For the existing structure, C_r reduced from around 0.85 at $h_s = 4.7\text{m}$, to about 0.65 at $h_s = 2.4\text{m}$, principally due to the increasing influence of the (relatively) smooth asphalt slope. Even at the lower test level the rear wall greatly influenced the reflections. A continuous smooth slope at the 1:2.86 angle of the asphalt would reflect at $C_r = 0.30$ using the data in Section 4.1 above. Two protection schemes were considered, each using rock placed at 1:2.5, to crest levels at 3.3m or 5.0m above the toe. Both schemes reduced the reflections significantly, and in the prototype considerable beach material has built up against the rock. Of interest here however is the comparison of the reflections measured, and those predicted for a continuous armoured slope. For the wave conditions tested, the idealised slope would give $C_r = 0.16$, but those measured generally exceeded 0.3.

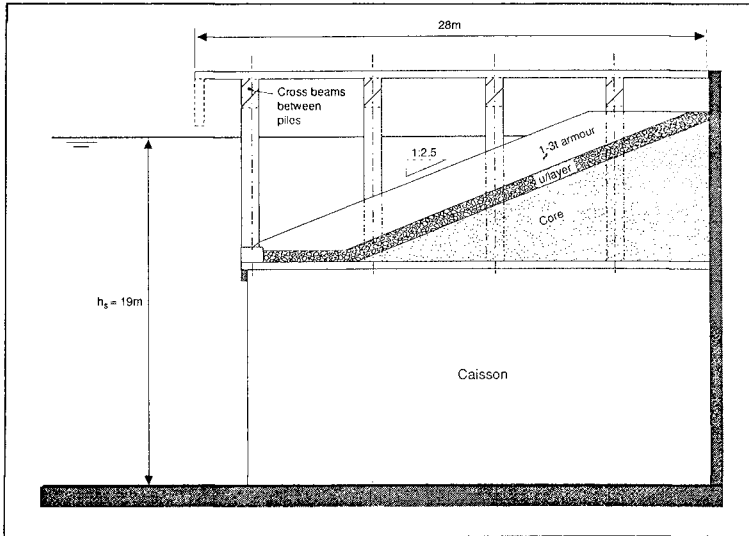

Figure 9 Coal berth quay, option A1/A2

Figure 10 Coal berth quay, option B

Coal berth armoured slopes

Reflections from two alternative harbour structures were compared in a recent study. Both structures were formed by an armoured slope beneath a piled deck. In the first instance, models A1-A3, the rock armoured slope at 1:2.5 was to be constructed on a part-depth caisson, see Figure 9. Models A1 and A2 were very similar, differing only in fine details of the underlayer construction. In both sections waves were able to ride over the crest of the armour. The seaward edge of the armoured slope was about 7m from the impermeable rear wall. Section A3 differed in the crest detail only. For this section the void behind the 4th row of piles was filled, in prototype by a service duct laid on fine fill and concrete footing.

The alternative structure, model B, used a full depth slope at 1:1.75 with a small berm at half water depth, Figure 10. The crest of the armour was very close to the water surface, as was the impermeable rear wall.

Figure 11 Coal berth quay, reflection performance

The results of the tests may be compared with values of C_r predicted by Seelig's equation with $a = 0.64$ and $b = 8.85$. The results are shown in Figure 11. Somewhat to the designer's surprise, model A reflected least, with values below the prediction. The reflections from model A3 were more severe, due to the proximity of the rear wall. The reflections from model B were significantly greater than for A, but when plotted against Ir_m again lie only slightly above the prediction line.

Analysis of other data by Postma

Reflection data measured by van der Meer (Ref 10) on simple armoured slopes have been analysed by Postma (Ref 9), using the surf similarity parameter, or Iribarren number, defined using the steepness of peak period in deep water, $s_{op} = 2\pi H_s/g T_p^2$. For all of van der Meer's data, Postma derived a simple prediction equation:

$$C_r = 0.14 Ir_p^{0.73} \quad \text{where} \quad Ir_p = \tan \alpha / s_{op}^{1/2} \quad (3)$$

Postma also fitted an equation of the form of (3) to the data in Reference 5:

Figure 12 Simple slopes, comparison with Equation 4

$$C_r = 0.125 Ir_p^{0.73} \quad (4)$$

Equation 4 is compared with the smooth and armoured slope results in Figure 12. Postma's simple curve gives a good fit to the data for simple rock armoured slopes over the range $2 < Ir_p < 9$.

6. Conclusions and Recommendations

Tests with random waves on idealised simple slopes have given new values for the empirical prediction equation for C_r derived by Seelig. Comparisons of the performance of practical examples have shown that their reflection performance may be strongly influenced by small geometric variations around the water line. Where the structural geometry departs from the idealised structures tested, particularly close to the water level, hydraulic model tests will be required to quantify the reflections.

CHAPTER 110

A Model for Breaking Wave Impact Pressures

M.J. Cooker* and D.H. Peregrine[†]

Abstract

This paper discusses a mathematical model of the large, short-lived pressures brought about by waves breaking against coastal structures. The idea of pressure impulse, P (the integral of pressure with respect to time from the start to the finish of the impact) is used to simplify the equations of ideal incompressible fluid motion. P satisfies Laplace's equation in a domain which is the mean position of the wave during the very short time of impact. We solve analytically a two-dimensional boundary-value problem, which models an idealized wave striking a vertical wall. Expressions are derived for the impulse on the wall, the peak pressure distribution, and the change in fluid velocity due to impact. The results are insensitive to the shape of the wave far from the wall. The results agree with some experimental measurements, from the literature.

Introduction

This paper is concerned with the very large and sudden pressures exerted by a breaking wave when it slams into a solid surface.

Winter storms in February 1990 caused great damage to sea walls on the UK coast, and there is a long-standing need to understand how breaking waves are able to exert loads on vertical walls, and other structures. Many field measurements and experimental studies since Bagnold (1939) have shown the existence of peak pressures exceeding 10 times the hydrostatic head and which last for periods between 0.1 and 10 milli-seconds (depending on the size of the wave). Figure 1 shows a typical pressure-time curve, for a point on a vertical wall. Blackmore and Hewson (1984) measured impact pressures in the field and high, short-lived loadings have been recorded on sloping beaches (Richert, 1968; Grüne, 1988).

Figure 1.

Figure 2. Sketch of wave steepening in shoaling water. A vertical face at the moment of impact, gives the highest peak impact pressures.

A full review of the literature is given by Cooker (1990, chap.6), and here we highlight the laboratory studies of Bagnold (1939), Nagai (1960) and Weggel and Maxwell (1970), all concerned with vertical walls. Current empirical engineering rules for peak pressure distribution p_{PK} at a vertical wall are summarized by Partensky (1988). All these studies suggest that p_{PK} varies up and down the wall with a clear maximum near the water-line and a decrease toward the bed. Computations by Cooker and Peregrine (1990) reproduce these pressure distributions.

This paper puts these empirical rules on a rational basis by using the theory of pressure impulse, (Lagrange 1783),

$$P(x,y) = \int_{t_b}^{t_a} p(x,y,t)dt \quad (1)$$

where t_b and t_a are the start and finish times of the impact. See figure 1.

Many experimenters have noted that under fixed wave conditions there is wide scatter in peak pressure. Bagnold (1939) pointed out that, despite the variations in p_{PK} (and in the impact time, $\Delta t \simeq$ twice pressure rise time), the product $p_{PK} \Delta t$ remains roughly constant;

$$P = p_{PK} \frac{\Delta t}{2} \quad (2)$$

is an approximation to the definition of P in equation (1). Given the unavoidable difficulty of predicting p_{PK} , in this paper we suggest that pressure impulse is a more convenient concept, especially from a mathematical viewpoint. Below we show that $P(x,y)$ satisfies Laplace's equation within a fluid domain which is the mean position of the fluid during the short time of impact. Armed with an analytic expression for P , and an estimate of the impact time Δt , we can use (2) to arrive at reasonable predictions for peak pressure distribution.

An advantage of this approach is that it allows us to model impact pressures due to even turbulent waves and, so far as P is concerned, the fluid can even be slightly aerated. The method can also be applied to more complex and three-dimensional wave impacts such as waves hitting a vertical cylinder. This is the subject of further work in progress.

Mathematical Model

We consider a wave in shoaling water approaching the shore from deeper water, and we expect typically the wave to steepen and break with a height possibly greater than the local still water depth, and with a speed greater than the maximum local wave speed

(gh)^{1/2}. Experiments show that the highest impact pressures occur when the wave face is vertical at the instant it strikes the wall. See figure 2.

We return to this specific problem below, but first consider a body of water striking a rigid surface. Let the impact speed be typically U_0 , and the length-scale of the body of water be L_0 . Let Δt be the impact time. Let $U_0, L_0, \Delta t, p_0$ be independent velocity, length, time and pressure scales for the variables in Euler's equations, for two dimensional inviscid, incompressible flow. After some manipulation we arrive at an equation in dimensionless variables $\underline{U}, t, p, x, y$

$$\frac{\partial \underline{U}}{\partial t} + \frac{\Delta t U_0}{L_0} (\underline{U} \cdot \nabla) \underline{U} = \frac{-\Delta t p_0}{\rho U_0 L_0} \nabla p \quad (3)$$

where $\nabla = (\partial/\partial x, \partial/\partial y)$.

Typically $\Delta t U_0/L_0$ is very small (~ 0.03 in the computations of Cooker and Peregrine, 1990). The smallness of this dimensionless group enables us to discriminate between events which are "impact" and those which are not. If $\Delta t p_0/\rho U_0 L$ is $O(1)$ then we have a balance between the first and last terms in equation (3), and the nonlinear 2nd term can be neglected.

We now integrate (3) with respect to time from $t = t_b$ to $t = t_a$, the duration of the impact. Returning to dimensional variables in (3) this gives us

$$\int_{t_b}^{t_a} \frac{\partial U}{\partial t} dt = \frac{-1}{\rho} \nabla \left\{ \int_{t_b}^{t_a} p dt \right\}.$$

From (1) this reduces to

$$\underline{U}_a - \underline{U}_b = \frac{-1}{\rho} \nabla P \quad (4)$$

where \underline{U}_b and \underline{U}_a are the fluid velocities at times immediately before and after the impact, respectively.

We will also assume that the flow is incompressible so that both $\nabla \cdot \underline{U}_b$ and $\nabla \cdot \underline{U}_a$ vanish. Taking the divergence of (4) we arrive at Laplace's equation in the pressure impulse P

$$\nabla^2 P(x, y) = 0. \quad (5)$$

Note that (5) does not involve time so we must solve boundary-value problems in a fixed domain which is a mean position for the fluid during impact. Finally note this theory admits arbitrary

vorticity and can be extended to 3 dimensions.

Boundary-Value Problem.

Let us turn to the 2 dimensional problem in figure 3 for water wave impact on a vertical wall. Given U_b we want to know $P(x,y)$ by solving (5) with appropriate boundary conditions, and then use (2) to find the peak pressure distribution. Also equation (4) gives us U_a , the flow immediately after impact; once we know P .

The boundary condition at the free surface is $P = 0$ because the pressure is a constant (zero) there. At the bed the vertical component of velocity $V = 0$ throughout the impact, so $V_a = V_b = 0$, hence from the vertical component of (4) we have $\partial P / \partial y = 0$. At the wall, we have chosen an upper region occupying a fraction of the wetted length, called the impact zone. Here the horizontal component of fluid velocity U changes from $U = U_b = -U_o$ before impact, to $U = 0$ after impact. From (4) this gives the boundary condition $\partial P / \partial x = -\rho U_o$ where $U_o > 0$ is a constant. Also $\partial P / \partial x = 0$ on the rest of the wall. Towards infinity $P \rightarrow 0$. Figure 3 summarises the boundary value problem, and we can solve using Fourier analysis. A solution which satisfies the bed, free-surface and infinity boundary conditions is

$$P = \sum_{n=0}^{\infty} a_n \sin(\lambda_n y) e^{-\lambda_n x} \tag{6}$$

where $\lambda_n = (n + \frac{1}{2}) \pi / H$.

The constants a_n are determined by the known values of $\partial P / \partial x$ at $x = 0$, the wall

$$\left. \frac{\partial P}{\partial x} \right|_{x=0} = \sum_{n=0}^{\infty} -a_n \lambda_n \sin \lambda_n y$$

$$\left(\begin{array}{ll} = -\rho U_o & y: -\mu H \leq y \leq 0 \\ = 0 & y: -H \leq y \leq \mu H \end{array} \right)$$

which give
$$a_n = \frac{-2\rho U_o}{H} \frac{(1 - \cos \mu \lambda_n)}{\lambda_n^2} \tag{7}$$

and
$$P(x,y) = \frac{-2\rho U_o}{H} \sum_{n=0}^{\infty} \frac{(1 - \cos \mu \lambda_n)}{\lambda_n^2} \sin(\lambda_n y) e^{-\lambda_n x}. \tag{8}$$

Note that for points $x > 0$ (away from the wall) the series in (8) is rapidly convergent because of the exponential terms. At the wall ($x = 0$) the distribution of pressure impulse is as shown in figure 4, for several values of μ .

Now from (2) we have

Figure 3. Semi-infinite rectangle geometry. Boundary-value

problem for pressure impulse $P = \int_{t_b}^{t_a} p(x,y,t)dt$.

Note the impact zone occupying the fraction μ of the wall.

Figure 4. Pressure impulse P from equation (3) at the wall ($x = 0$) for several values of μ . Note that P is directly proportional to the peak pressure.

$$p_{PK} = 2P/\Delta t .$$

The impact time, Δt , is difficult to model because it depends critically on the exact type of breaking at the wall, the air content of the fluid, and the inherent random qualities of impact under "fixed" wave conditions. Following experience from computations in Cooker and Peregrine 1990 it seems reasonable to take $\Delta t \propto \mu H$ e.g. $2\mu H/C_a$ where C_a is the sound speed in aerated water. The authors wish to make it clear that the above theory does not depend on any particular model or choice of Δt (so long as Δt is small, in the sense $\Delta t U_o/L_o \ll 1$). A designer may wish to use values of Δt gleaned from experience or which are related to the resonant frequency of the structure under wave attack.

The peak pressure distribution corresponding to a simple model: $\Delta t = \frac{1}{2}\mu H/U_o$ is shown in figure 5. Small values of μ are of particular interest, and the curves bear a striking resemblance to the empirical diagrams reported in Partensky (1988). Note that the pressure does not decay to zero at the bed and that for $\mu = 1$ the maximum peak pressure lies at the bed.

The impulse on the whole wall, I_w , is the integral of (8) with respect to y , at $x = 0$, over the wall.

$$I_w = \frac{2\rho U_o}{H} \sum_{n=0}^{\infty} \frac{(1 - \cos \mu \lambda_n)}{\lambda_n^3} . \quad (9)$$

See figure 6. In addition the impulse due to a finite triangular wave is shown. This result can also be found analytically. This comparison shows that the impulse is mainly due to the loss of momentum from fluid near the wall. We calculate the significant thickness of fluid L_m (momentum length) for the semi-infinite wave by equating I_w with the momentum of a rectangle of fluid of height μH , speed U_o , density ρ and length L_m . Then

$$L_m = \frac{2}{\mu H^2} \sum_{n=0}^{\infty} \frac{(1 - \cos \mu \lambda_n)}{\lambda_n^3} . \quad (10)$$

Surprisingly L_m is at most $0.543H$ (when $\mu = 1$). This explains why the triangle and the infinite rectangle in figure 6 give impulses which are the same order of magnitude.

Last in this section of theoretical results we can use eqⁿ (4) to predict the fluid velocity after impact, U_a . This is most interesting to evaluate at the free surface. Suppose $V_b = 0$ (i.e. the top of the wave is in horizontal translation before impact) then taking the vertical component of (4) we have

Figure 5. Peak pressure p_{PK} at the wall $p_{PK} = 2P/\Delta t$. Here Δt is modelled by $\frac{1}{2}\mu H/U_0$. Note the non-zero values of p_{PK} at the bed ($y/H = -1$).

Force impulse $\rho U_0 H^3$.

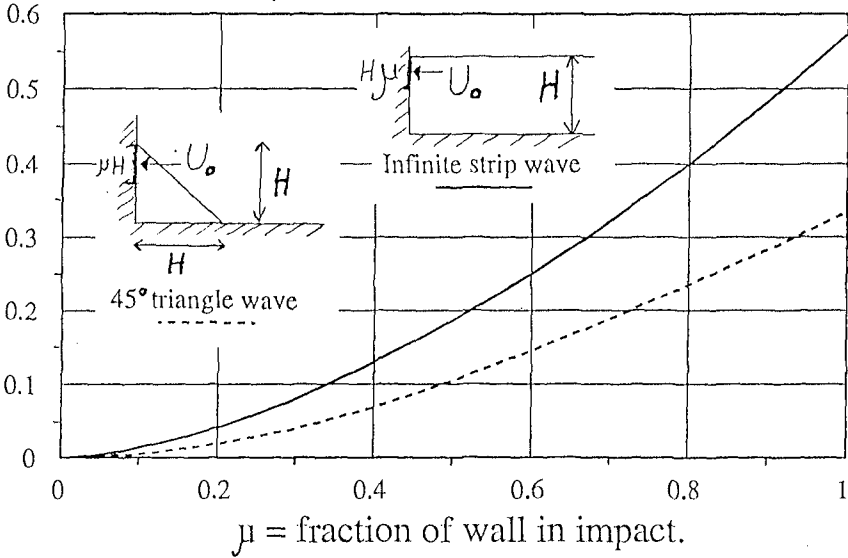

Figure 6. The impulse, I_w , on the wall from equation (9). The impulse due to a triangular wave (see sketch) is also plotted for comparison. The two waves are very different in shape but exert the same order of magnitude of impulse on the wall.

Figure 7. The vertical velocity at the free surface immediately after impact, V_a (with $V_b = 0$) from equation (11) Note these curves are proportional to surface elevation a small time after impact. The velocity near $x = 0$ resembles $\frac{-2U_0}{\pi} \ln(x)$.

$$V_a \Big|_{y=0} = \frac{-1}{\rho} \frac{\partial P}{\partial y} \Big|_{y=0} = \frac{2U_o}{\Pi} \sum_{n=0}^{\infty} \frac{(1 - \cos \mu \lambda_n)}{\lambda_n} e^{-\lambda_n x} \quad (11)$$

$$= \frac{2U_o}{\pi} \ell n \left| \frac{\operatorname{cosech} \pi z / 2 + \operatorname{coth} \pi z / 2}{\operatorname{cosech} \pi x / 2 + \operatorname{coth} \pi x / 2} \right|$$

where $z = x + i\mu$.

At $x = 0$, V_a is infinite, but the vertical flux of fluid between $x = 0$ and any station $x = X$ is finite. V_a is plotted for several values of μ in figure 7. Note that the surface elevation, η , some small time T after impact is given by $\eta(x) = V_a(x) \cdot T$, so that the curves in figure 7 show possible *shapes* of the free surface after impact when the incident wave has a flat top, as in figure 2.

Comparison with Experiment

Figure 8 shows a comparison between the current theory and the peak pressure distributions for two small wave impacts, measured by Weggel and Maxwell (1970). Note that the pressure axis is dimensionless and that we are here comparing shapes of distribution of peak pressure. Our choice of μ accords with that chosen by the experimenters in their own mathematical model.

Figure 9 compares theory with large-scale experiments (Partenscky and Tounsi, (1989): peak values from figure 5). Here we have chosen $\mu = 0.24$, in agreement with the experimenters' choice for their comparison with theory. $\Pi = 2.45\text{m}$, breaker height = 1.5m , so $U_o \approx 3.8 \text{ m/s}$. $\Delta t = 0.015$ (measured) which if $\Delta t = 2\mu\Pi/C_a$ implies $C_a = 230 \text{ m/s}$, (this corresponds to an air volume content of only 0.2%.

These comparisons encourage belief that pressure impulse theory captures the essential fluid mechanics of wave impact.

Conclusions

The theory of fluid pressure impulse has been used to model wave impact on a vertical wall. The results give spatial distributions of peak pressure which agree well with measurements. The theory predicts that the impulse on the wall is similar for two widely differing geometries (semi-infinite rectangle and 45° triangle). This is because the momentum lost from a wave of any shape comes from a narrow zone close to the wall (whose width is the momentum length). An important advantage of this theory is that it can be applied to waves with arbitrary vorticity. Further work is in progress to calculate pressure impulses due to three-dimensional waves.

CHAPTER 111

Overtopping of Solitary Waves at Model Sea Dikes

Erdal Özhan ¹ and Ahmet Cevdet Yalçmer ²

Abstract

This paper discusses an analytical model for solitary wave overtopping at sea dikes. The model is based on the "weir flow analogy" of Kikkawa et al.(1968). Results of laboratory test on smooth and impermeable model dikes with angles of 45°, 60° and 90° are utilized in constructing the model. Results for solitary waves are compared with those for regular oscillatory waves for the case of vertical dike.

Introduction

Coastal structures are being constructed often low-crested due to economical and/or aesthetic considerations. An important design criterion for such structures is the allowable discharge of wave overtopping. The problem of wave overtopping by oscillatory waves has been studied by various researchers since 1960's. The initial investigations were basically based on laboratory experiments. An analytical model was developed by Kikkawa et al(1968), by following an analogy with the flow over sharp crested weirs. In recent years, following advances on mathematical treatment on wave propagation on steep slopes, some researchers concentrated on numerical modelling of wave deformation on the dike slope and the subsequent overtopping (i.e. Kobayashi and Wurjanto,1989).

¹Prof. Dr. Middle East Technical University, Coastal and Harbor Engg. Res. Cent. 06531 Ankara, Turkey

²Assist. Prof. Dr. Middle East Technical University, Coastal and Harbor Engg. Res. Cent. 06531 Ankara, Turkey

To the knowledge of authors, the problem of solitary wave overtopping at coastal structures has not been studied before. Investigation of this problem is useful for at least two reasons. Firstly findings may contribute to the understanding of the basic mechanism of wave overtopping. Secondly, the results obtained may be used for practical purposes in situations where solitary-like waves interfere with coastal structures.

In this paper, the analogy proposed by Kikkawa et al(1968) is extended and applied to solitary wave overtopping to derive a closed form analytical model. Laboratory experiments are carried out to provide the empirical information required by the model. Solitary overtopping rates at vertical dikes are compared with those of regular oscillatory waves.

Theory

By considering analogy with steady flow over a sharp crested weir, wave overtopping rate at a sea dike may be equated to :

$$q(t) = \frac{2}{3} m (2g)^{\frac{1}{2}} \{z(t) - z_0\}^{\frac{3}{2}} \quad (1)$$

where $q(t)$ = unsteady overtopping rate per unit dike width; $z(t)$ = changing water level elevation measured from still water level; z_0 = crown elevation of the dike; g = gravitational acceleration; m = the weir coefficient which is equal to 0.611 in steady flow. The change of water level elevation during overtopping is written as:

$$z(t) = z_{max} F(t) \quad (2)$$

where z_{max} = maximum rise of the water level; and $F(t)$ = a function having the range of 0 and 1. It is assumed that the maximum water level rise is related to the incident solitary wave height (Fig. 1) as:

$$z_{max} = K H \quad (3)$$

where the maximum rise coefficient K may be a function of wave height-to-water depth ratio ($\frac{H}{d}$), dike angle (α), and wave height-to-crown elevation ratio ($\frac{H}{z_0}$). The water level elevation prior to overtopping is assumed to change in the same way as a deformed solitary wave profile (symmetrical) and the function $F(t)$ is taken as:

$$F(t) = \text{sech}^2(\epsilon \lambda C t) \quad (4)$$

2 nd STORAGE TANK Figure 1: Experimental set-up and parameters

where; $\lambda = (\frac{3H}{4d^3})^{\frac{1}{2}}$, pulse width (phase) parameter; $C = (gd)^{\frac{1}{2}}(1 + \frac{H}{2d})$, celerity of the incident solitary wave; ϵ = an empirical coefficient (called the profile coefficient) which may account for deformation of the wave profile prior to overtopping and nonlinearity in the superposition of incident and reflected waves.

Substitution of Eqns. (2), (3) and (4) into (1) leads to:

$$q(t) = \frac{2}{3}m(2g)^{\frac{1}{2}}K^{\frac{2}{3}}H^{\frac{2}{3}}[Sech^2(\epsilon\lambda Ct) - (\frac{z_0}{KH})^{\frac{2}{3}}] \quad \text{for } |t| \leq \frac{1}{\epsilon\lambda C}Sech^{-1}(\frac{z_0}{KH})^{\frac{1}{2}}$$

$$q(t) = 0 \quad \text{otherwise} \quad (5)$$

Integration of Eq.(5) with respect to time gives the overtopping volume of a solitary wave as:

$$Q = \frac{4}{3}m(2g)^{\frac{1}{2}}K^{\frac{2}{3}}H^{\frac{2}{3}}\frac{I}{\epsilon\lambda C} \quad (6)$$

where Q = overtopping volume of a solitary wave per unit dike width;

$$I = \int_0^{\tau^*} (Sech^2\tau - \frac{z_0}{KH})^{\frac{2}{3}}d\tau$$

and $\tau^* = Sech^{-1}(\frac{z_0}{KH})^{\frac{1}{2}}$. It has been shown that the integral I is approximately equal to (Özhan, 1975):

$$I = \frac{1}{2}sech^{-1}(\frac{z_0}{KH})^{\frac{1}{2}}(1 - \frac{z_0}{KH})^{\frac{2}{3}} \quad (7)$$

Then, the final result giving the overtopping volume of a solitary wave per unit dike width is obtained from (6) and (7) as:

$$\frac{Q(1 + \frac{H}{2d})}{Hd} = \frac{0.6652}{\epsilon}(K)^{\frac{2}{3}}(1 - \frac{z_0}{KH})^{\frac{2}{3}}sech^{-1}(\frac{z_0}{KH})^{\frac{1}{2}} \quad (8)$$

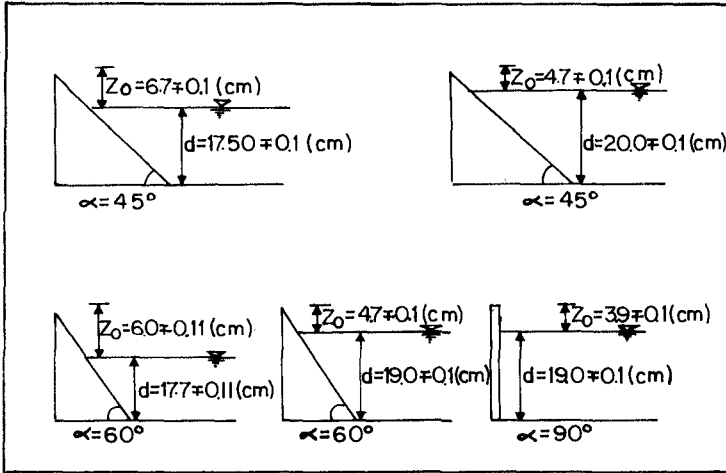

Figure 2: The geometries of model dikes and the water depths used in each experimental group

where $m = 0.611$ is used. This equation includes two empirical coefficients ϵ and K . Laboratory experiments were designed to investigate the values of these coefficients together with their dependence on various parameters.

Laboratory Experiments

The experimental set up is shown in Fig.(1). The solitary waves were generated by a sluice gate operation through introducing suddenly a volume of water into the wave flume. As this deformation evolved into a solitary wave, the trailing disturbances were cut off by closing the vertical gate 1, right after the passage of the solitary wave. The solitary wave moved over a constant water depth up to the dike. Incident solitary wave profiles and water level changes near the dike crown (3 cm in front) just prior to overtopping were measured. The overtopped volume of water was collected successively by two storage tanks. In order to eliminate the possibility of overtopping for a second time by the reflected wave, the gate 2 was closed after the reflected wave moved away from the dike.

The geometries of model dikes and the water depths used in each experimental group are shown in Fig. (2).

Results

In the evaluation of the experimental results, the first consideration was given to the incident solitary wave profile. The measured wave profile was compared with the theoretical Boussinesq profile. The runs which did not show close agreement were disregarded. The experimental data were first used to derive the values of two empirical coefficients, ϵ and K , which appeared in the theoretical model developed in section 2, and then to check the validity of the theoretical model to predict the overtopped wave volume. Finally, the solitary wave overtopping rates were compared with the data available for regular oscillatory waves.

The shape coefficient, ϵ

The shape coefficient, can be written as:

$$\epsilon = \frac{\text{Sech}^{-1}\left(\frac{z(t)}{z_{\max}}\right)^{\frac{1}{2}}}{\left(\frac{3H}{4d^3}\right)^{\frac{1}{2}} Ct}$$

The measured values of $z(t)$ at the location 3 cm in front of the dike crown were used to determine the value of the shape coefficient which provides the best fit to the measured profile. For this purpose, only the water level elevations in excess of the crown elevation (i.e. $z(t) > z_0$) were utilized. The procedure followed minimized the square error in the value of $\text{sech}^{-1}\left(\frac{z(t)}{z_{\max}}\right)^{\frac{1}{2}}$.

The values of ϵ for all three dike slopes are plotted in Fig. (3) against $\frac{H}{z_0}$ ratio. Also shown are the least square lines for each slope. The values of profile coefficient is seen to decrease with increasing $\frac{H}{z_0}$ value for all dike slopes. The least square lines for 60° and 90° dike angles are comparable. However, the slope for the dike with the angle of 45° is somewhat steeper.

The correlation coefficients between ϵ and $\frac{H}{z_0}$ ratio are computed as -0.84, -0.49 and -0.54 respectively for the dike angles of 45°, 60° and 90°. These rather low correlation coefficients indicate the importance of other parameters as well (such as $\frac{H}{d}$ ratio). In the present study however, the least square relationships shown in Fig.(3) were used for the computation of volume of overtopping as it will be discussed later. The intercept and slope (a_1 and b_1) of the linear relationship $\epsilon = a_1 + b_1\left(\frac{H}{z_0}\right)$ for three dike slopes tested are given in Table 1.

Figure 3: The values of shape coefficient for all three dike slopes

Table 1. The intercept and slope of the linear relationship between ϵ and $\frac{H}{z_0}$

Dike Angle	Intercept, a_1	Slope, b_1
45°	.994	-0.179
60°	.834	-0.076
90°	.839	-0.080

The maximum rise coefficient, K

The maximum rise coefficient defined in Eq.(3) was determined for each experimental run from the water level elevation measured near the dike crown. However, due to the horizontal distance of 3 cm. between the probe location and the dike crown, this value K_m obtained from the maximum recorded water level would be somewhat lower than the actual value corresponding to the maximum level to be reached at the dike crown. Alternatively, the actual value of K could be determined from Eq.8 by using the measured values of overtopped volume and the respective ϵ

Figure 4: Comparison of theoretical (K) and measured (K_m) values of maximum rise coefficient

value corresponding to the $\frac{H}{z_0}$ ratio of the test. The implicit equation in terms of K which forms after substitution of Q and ϵ for a test, was solved numerically. The maximum rise coefficient, thus obtained are compared with the respective K_m values corresponding to the maximum recorded level in Fig. (4). It is observed that two values are correlated reasonably well. In line with expectations, the maximum rise coefficients computed from the theoretical model by using the measured overtopped volume are larger by 9 % on the average than the respective K_m values. As it was mentioned earlier, this is due to 3 cm. distance between the measurement location and the dike crown.

The maximum rise coefficient K correlates better with $\frac{H}{z_0}$ ratio than the shape coefficient ϵ (Fig. 5). The correlation coefficients were found as (-0.79) to (0.85) for three dike angles tested. For use in conjunction with the theoretical model of overtopping, the least square linear relationships between K and $\frac{H}{z_0}$ ratio were found. These are also shown in Fig. 5. The intercepts and slopes of these equations for 3 dike slopes are given in Table 2.

Figure 5: The values of maximum rise coefficient (K) for all three dike slopes

Table 2. The intercept and slope of the linear relationship between K and $(\frac{H}{Z_0})$

Dike Angle	Intercept, a_2	Slope, b_2
45°	2.63	-0.534
60°	2.27	-0.383
90°	2.07	-0.243

The values of maximum rise coefficient K should approach the respective run up coefficients for small values of $\frac{H}{Z_0}$.

Volume of Overtopping

The least square lines for ϵ and K were used in the analytical expression (Eq. 8.) to compute the dimensionless volume of overtopping as a function of $\frac{H}{Z_0}$ ratio. The resulting curves for three dike slopes tested are compared with the experimental data in Fig.(6)- (8). The theoretical model developed together with the empirical

Figure 6: Comparison of measured and calculated overtopping volume $\alpha = 45^\circ$

relationships for ϵ and K are observed to provide reasonable agreement with experimental data for all three dike slopes. For the dikes with 45° and 60° slope angles, the dimensionless overtopping volume is seen to decrease with increasing $\frac{H}{z_0}$ ratio after a critical value of $\frac{H}{z_0}$ 2.0 to 2.1 is exceeded. Within the experimental range covered ($\frac{H}{z_0}$ ratio less than 2.5), such a change of trend is not observed for the vertical dike.

Comparison of the predictions of the presented theoretical model for different dike slopes reveals that the overtopping volume is greater for $\alpha = 45^\circ$ than the other two slopes for $\frac{H}{z_0} \leq 1.9$. The results for 60° and 90° dikes are very similar up to $\frac{H}{z_0} \leq 1.4$. For larger values, the overtopping volume for the vertical dike becomes greater than the respective value for the 60° dike.

Comparison with regular wave overtopping

For comparison of solitary wave overtopping with that of regular waves, it is necessary to define a practical wave period for the solitary wave. This may be done as the time length over which a certain percentage of solitary wave volume passes a fixed point. The resulting expression reads as:

$$T_p = \frac{\sqrt{\frac{g}{d}} \tanh^{-1}(\rho)}{\frac{\sqrt{3}}{4} (\frac{H}{d})^{\frac{1}{2}} (1 + \frac{H}{2d})} \tag{9}$$

Figure 7: Comparison of measured and calculated overtopping volume $\alpha = 60^\circ$

Figure 8: Comparison of measured and calculated overtopping volume $\alpha = 90^\circ$

Figure 9: Comparison of solitary and oscillatory wave overtopping rates for a vertical dike

where T_p = the practical wave period; g = gravitational acceleration; and ρ = the percentage of wave volume. Furthermore, the series of solitary waves were treated as a cnoidal wave terrain, and the water depth of the experimental runs was increased by adding the trough amplitude of the respective cnoidal wave. The reanalyzed experimental data in this manner for the vertical dike is compared in Fig.(9) with the curve for regular oscillatory waves given by Tsuruta and Goda (1968). In this comparison, q is the average overtopping discharge over a wave period. The experimental data for solitary waves are plotted twice by using practical wave periods determined from two volume percentages, namely 95 % and 99 %. The presentation in Fig.(9) reveals that the solitary wave overtopping rates are significantly in excess of the respective oscillatory wave discharges.

Conclusions

The results of the present paper can be summarized as follows

1. An analytical expression is derived for the solitary wave overtopping, based on the analogy with sharp-crested weir flow.
2. Empirical data obtained from model dikes with $\alpha = 45^\circ, 60^\circ, 90^\circ$ slope angles is fed into the derived expression.

3. The analogy is shown to be successful for steep dike slopes ($\alpha \geq 45^\circ$).
4. Solitary wave overtopping rates are significantly greater than those for oscillatory waves.

CHAPTER 112

Permeability characteristics of rubble material - New formulae

Robert W K Shih¹

1 Introduction

Rubble mound structures have been used extensively to protect coastal areas of human interest. These include breakwaters, seawalls and related structures. To be successful, a rubble mound structure should absorb most of the energy from the incident waves and be able to withstand the pore pressures generated during the process. These are determined by the geometry of the structure and the hydraulic properties of rubble.

Advances in computer resources enable the interaction between waves and rubble structures to be simulated numerically (Ref 1, 2 and 7). The general approach is to describe the porous medium as a continuum, having properties of dimension, porosity and permeability. The flow of water into and through such a porous continuum may then be described, depending upon the velocities and pore pressures induced. In physical hydraulic modelling of coastal structures various researchers (Ref 5) have considered the importance of permeability characteristics on the scaling of porous rubble core material. Similitude is usually achieved by selecting a model material, of prototype porosity, which yields a comparable hydraulic gradient to the prototype when subjected to an equivalent Froude scaled flow velocity. Both the numerical and physical methods of modelling, however, require a good description of the energy dissipation process which is related to the permeability of the structure. At present, most modellers use formulae which were originally developed for flows in sand. That proposed by Engelund (Ref 4) has been most widely used.

Engelund's formula is expressed in the Forchheimer form which describes the hydraulic gradient (i) in laminar, transitional and turbulent conditions by: $i = au + bu^2$ (Eqn 1) where u is the superficial velocity. The dimensional coefficients a and b are generally referred as the laminar and turbulent coefficients respectively, and are given in terms of particle diameter (D) and

¹Engineer, Coastal Structures Section, Hydraulics Research, Wallingford, Oxfordshire, OX10 8BA, UK

sample porosity (n):

$$a = \alpha_o (1-n)^3 \frac{v}{gn^2D^2}, \quad b = \beta_o \frac{(1-n)}{gn^3D} \quad (\text{Eqn } 2)$$

with appropriate coefficient values:

- (i) uniform spherical particles $\alpha_o = 780$, $\beta_o = 1.8$;
- (ii) uniform rounded sand grains $\alpha_o = 1000$, $\beta_o = 2.8$;
- (iii) irregular angular grains α_o up to 1500 or more, β_o up to 3.6 or more

It should be noted values have been derived for α_o and β_o for materials with diameters much less than 10mm. Large uncertainties are involved when applying these values to rubble materials which have diameters up to or greater than 1m.

The research work presented in this paper is part of a comprehensive study on the hydrogeotechnical performance of rubble mound breakwater. It aims at providing a better insight into the permeability properties of porous media, particularly as they influence the wave/structure interactions. Extensive literature review on previous experimental works and methods of analysis and implementation has been carried out and presented in Ref 8. Based on the review, a new permeameter has been designed, and used to test samples with wide ranges of size and grading under a wide range of flow conditions. Analysis on the results have indicated the inadequacy of the existing formulae and new formulae are proposed in this paper. Results from this study will be implemented in the numerical models which are being developed in parallel.

2 Permeameter design

During the design of the permeameter which was constructed especially for the present study, the following points were considered:

- (i) The main body should be sufficiently large to test material of characteristic diameters up to 50mm. It has been suggested that the permeameter diameter should be at least ten times the diameter of the largest material to be tested (Ref 3).
- (ii) The design should minimise the potential of air entrainment in the material sample.
- (iii) The water supply should be capable of generating a flow velocity through the sample of at least 0.1 m/s.
- (iv) The measured pressure head loss should be representative of the complete sample cross-section.
- (v) The sample should be constrained to retain constant porosity throughout a test without significant dilation or loss of fines.
- (vi) The inflow velocity should be measured precisely.
- (vii) The system should be capable of reproducing and measuring hydraulic gradients in the range 0.01 to 5.

It was decided that a bottom water entry would be most appropriate. This would allow the majority of air entrained in voids between particles to be eliminated by running water through the system for a few minutes before commencement of the test.

The final design solution is presented in Figure 1. The permeameter is cylindrical in shape with overall height and internal diameter equal to 1.45m and 0.6m respectively. Flexible PVC tubes 9mm in diameter were used to allow measurement of a representative pressure head loss at a separation of 0.5m across the entire sample cross-section. Rigid perforated steel plates were incorporated to contain the sample at top and bottom. Water was pumped through the permeameter, initially through a 0.3 metre baffled inlet section, and allowed to flow freely over the upper rim. The system was operated up to a flow velocity of approximately 0.1 m/s. The pumped water was flow gauged using an orifice plate meter in the supply pipe. The discharge water from the permeameter was allowed to drain back freely into the reservoir, within which the pump intake was located, thus providing continuous water cycling.

Fig.1 Schematic sectional plan of the present permeameter

3 Testing procedure

The testing procedure is represented by a flow chart in Figure 2. Details of each process are given below.

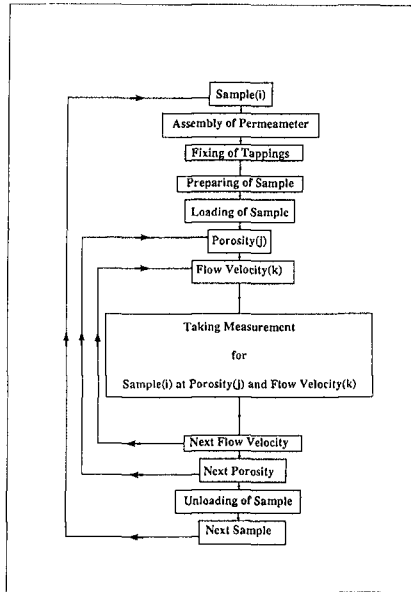

Fig.2 Flow chart for the test procedures

Assembly of the permeameter

Before the permeameter was assembled, it was necessary to ensure that areas such as the flanges, gaskets and bolt holes at the interfaces among the chamber, the perforated base plate, and the base stand, were free from particles.

The perforated base plate was first connected to the chamber hoisted by a gantry. This was done with four 15mm diameter bolts passing from the bottom flange of the chamber into threaded holes in the base plate. This partly assembled permeameter was then hoisted over the top of the base stand. It was lowered down such that the four prefabricated holes on the flange of the chamber, the base plate, and the base stand all lined up with one another. Four 15mm diameters bolts were used to pass through these holes and tighten the three different parts together. The permeameter was then filled with water to check for leakage.

Fixing the tappings

Pressures were measured at two levels, 0.5m apart, inside the permeameter. At each level, the measurement arrangement consisted of a pair of tapping tubes running perpendicularly across the inside diameters of the permeameter. These tubes were made of flexible PVC tubes 9mm in diameter, with perforations at 40mm

intervals. The open ends of these two tapping tubes were connected outside the permeameter via a looped PVC tube. The single outlet from this looped tube was connected to a manometer to provide a representative measurement of pressure at that particular level.

Preparing of samples

The main samples used in the tests were generally limestone with density equal to 2.76 gm/cm^3 . Before use each samples was sieved to produce the required size bands. They were then washed to eliminate fine material which might be washed away during the test, and hence affect the porosity.

Loading of samples

Samples, in small quantities, were carefully loaded into the permeameter. The weight of each sack was recorded so that the total quantity in the permeameter could be determined.

Porosity of the test specimen

Before starting a new series of tests, water was pumped through the sample for 10 minutes at the highest discharge to allow natural settlement to take place. The porosity obtained at the end of this period was defined as the highest porosity that the sample could achieve.

Lower porosities were obtained by compacting the sample with a vibrating poker. This was done by following the procedure below.

- (i) The permeameter was filled with water up to the top surface of the sample.
- (ii) A fixed amount of material was added onto the surface and smoothed by hand.
- (iii) The vibrating poker was used until the water surface just covered the samples.

In cases of high porosities, the poker was only required to be inserted to a depth of about 150mm at two locations. As the samples became more compact, the poker had to be inserted to a greater depth and at more locations. In general, six to eight different porosities were achieved in a series of tests.

Porosity measurements

Porosity was calculated from the weight of the samples loaded, the gross volume of the samples when stabilised, and the specific gravity of the samples.

Flow conditions

For each porosity, up to nine different flow rates were used, increasing regularly from approximately 0.01 m/s to 0.10 m/s .

4 Test conducted

The test samples were produced as a range of single size classes and mixtures derived from them. Each single size class was initially referred to by its nominal upper sieve size, generally significantly greater than either D_{15} or D_{50} which are the diameters of the sample that 15% and 50% of the sample exceed (see Table 1).

Nominal Size (mm)	D_{15} (mm)	D_{50} (mm)	D_{85} (mm)
4	1.49	2.13	2.76
6	4.94	5.42	6.26
10	7.22	8.65	9.74
14	9.35	10.87	12.40
20	12.72	14.65	17.39
28	19.28	21.77	24.58
40	27.61	33.23	37.77
61	54.50	63.00	73.80

Table 1 Single size samples

As quarried rock is more likely to exhibit a "gradual" size grading curve. This is illustrated by Kobayashi et al based on available field data (Ref 6) who describe prototype gradings falling in:

$$1.24 < (D_{50}/D_{15}) < 2.0$$

$$1.24 < (D_{85}/D_{50}) < 1.8$$

$$1.54 < (D_{85}/D_{15}) < 3.6$$

To study the effect due to both the 'size' and 'distribution' of samples within the mixture, a series of tests were carried out on graded samples (see Table 2).

Mixtures (Nominal dia. in mm)	D_{15} (mm)	D_{50} (mm)	D_{85} (mm)	D_{50}/D_{15}	D_{85}/D_{50}	D_{85}/D_{15}
6,10,14	4.09	8.20	11.77	2.00	1.44	2.88
6,10,14,20	4.43	9.77	16.70	2.21	1.71	3.77
6,10,14,20,28	4.76	11.59	22.50	2.43	1.94	4.73
6,10,14,20,28,40	5.70	14.02	29.24	2.46	2.09	5.13
10,14,20	8.04	11.59	17.60	1.44	1.52	2.19
10,14,20,28	8.50	14.02	23.62	1.65	1.68	2.78
10,14,20,28,40	8.97	17.29	30.17	1.93	1.75	3.36
14,20,28	10.66	17.29	24.75	1.62	1.43	2.32
14,20,28,40	11.51	20.59	31.10	1.79	1.51	2.70
20,28,40	16.99	24.38	32.10	1.43	1.32	1.89

Table 2 Wide graded samples

The gradings of the graded sample were chosen based on the following criteria.

- (i) Each mixture should contain at least three different sizes of materials.
- (ii) Sizes of materials should be increased gradually.
- (iii) Ratios of (D_{50}/D_{15}) , (D_{85}/D_{50}) and (D_{85}/D_{15}) should cover the ranges observed in the field data.

5 Analysis of test results

5.1 Single size samples

In considering the large amounts of data produced, it proved to be convenient to describe the flow/resistance relationship for each test in terms of the Forchheimer equation (Eqn 1) with coefficients a and b initially represented by the expressions proposed by Engelund (Eqn 2). A simple assessment of the dependence of coefficients α_0 and β_0 on the particle sizes was carried out. Regression analysis was performed depending on the particle sizes (Eqn 3).

$$\frac{i}{u} \frac{gD_{15}}{u} \frac{n^2}{(1-n)^3} = \alpha_0 + \beta_0 \frac{1}{n(1-n)^2} \left(\frac{uD_{15}}{u} \right) \quad (\text{Eqn 3})$$

Good linear relation was observed (see Figs 3a to 3g).

The laminar constant (α_0) was found to increase in proportion to D_{15} . Its lower limit coincided with the upper limit suggested by Engelund (see Fig 4a). The turbulent constant (β_0) was found to decrease exponentially with D_{15} (see Fig 4b). These results suggest that Engelund's expressions for a and b will need to be modified to represent flow in material larger than 10mm. At its simplest this may be given for formulae for α_0 and β_0 .

The permeability relationship for single size materials is therefore given by $i = au + bu^2$, where i = hydraulic gradient, u = superficial velocity and

$$\begin{aligned} a &= \left[\alpha_1 + \alpha_2 \left(\frac{g}{u^2} \right)^{2/3} D_{15}^2 \right] \frac{(1-n)^2}{n^2} \frac{u}{g} \frac{1}{D_{15}^2} \\ b &= \left\{ \beta_1 + \beta_2 \exp \left[\beta_3 \left(\frac{g}{u^2} \right)^{1/3} D_{15} \right] \right\} \frac{(1-n)}{n^3} \frac{1}{gD_{15}} \end{aligned}$$

where

n = porosity

$\alpha_1 = 1683.71$, $\alpha_2 = 3.12 \times 10^{-3}$

$\beta_1 = 1.72$, $\beta_2 = 1.57$, $\beta_3 = -5.10 \times 10^{-3}$

u = kinematic viscosity of water = $1.14 \times 10^{-6} \text{ m}^2/\text{s}$

g = gravitational acceleration = 9.81 m/s^2

(Eqn 4)

Good agreement was obtained between observed and predicted hydraulic gradients, Fig 5.

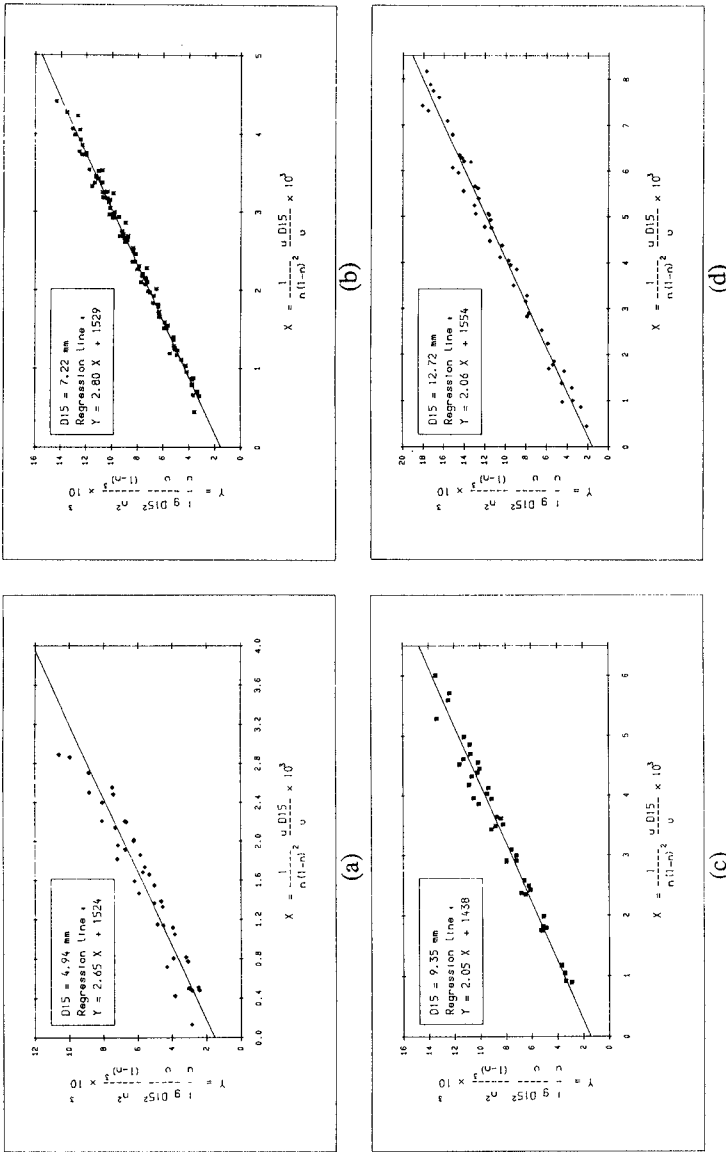

Fig.3 Regression analysis on results of single size materials

(e)

(f)

(g)

Fig.3 cont.

Fig.4 Dependence of α_0 and β_0 on particle diameter D_{15} for single size materials

Fig.5 Comparison between $i(\text{obs})$ and $i(\text{pred})$ for single size materials

Number of data points = 392

5.2 Wide graded samples

For wide graded samples, same permeability relationship for single size samples was adopted with D_{15} replaced by D_* where

$$D_* = D_{15} \left(\frac{D_{15}}{D_{50}} \right)^{c1} \left(\frac{D_{50}}{D_{85}} \right)^{c2} \quad (\text{Eqn 5})$$

so as to include the effect due to the grading of the material. Coefficients $c1$ and $c2$ were determined such that the total square errors in hydraulic gradient, $(i_{\text{predicted}} - i_{\text{observed}})^2$, was minimum. This gave $c1 = -1.11$ and $c2 = 0.52$ (see Fig 6).

Fig.6 Least square analysis on results of wide graded materials

The permeability relationship for wide graded materials is therefore given by:

$$i = au + bu^2$$

where

i = hydraulic gradient, u = superficial velocity

and

$$a = \left[\alpha_1 + \alpha_2 \left(\frac{g}{U^2} \right)^{2.73} D_*^2 \right] \frac{(1-n^3)}{n^2} \frac{u}{g} \frac{1}{D_*^2}$$

$$b = \left\{ \beta_1 + \beta_2 \exp \left[\beta_3 \left(\frac{g}{U^2} \right)^{1.73} D_* \right] \right\} \frac{(1-n)}{n^3} \frac{1}{gD_*}$$

$$D_* = D_{15} \left(\frac{D_{15}}{D_{50}} \right)^{-1.11} \left(\frac{D_{50}}{D_{85}} \right)^{0.52}$$
(Eqn 6)

where

n = porosity

$\alpha_1 = 1683.71, \alpha_2 = 3.12 \times 10^{-3}$

$\beta_1 = 1.72, \beta_2 = 1.57, \beta_3 = -5.10 \times 10^{-3}$

u = kinematic viscosity of water = $1.14 \times 10^{-6} \text{ m}^2/\text{s}$

g = gravitational acceleration = 9.81 m/s^2

Good agreement was obtained between observed and predicted hydraulic gradients Figure 7.

6 Conclusions and recommendations for future work

6.1 Conclusions

A permeameter (Fig 8) with diameter equal to 0.6m was used in the present study. Materials with size varying from 2 mm to 61 mm were tested as single size and wide graded samples. Hydraulic gradients varying from 0.1 to 5.0 were used. New formulae (Eqn 4) and (Eqn 6) for the permeability of rubble materials were proposed to update the existing formulae proposed by Englelund which were originally derived for sand. It should be noted that the newly proposed formulae were based on experimental results carried out in steady state.

6.2 Recommendations for future work

It is recommended that future work should cover the following areas:

- (i) Unsteady/cyclic flows
 - Influence on inertia forces
- (ii) Air entrainment effects
 - External and internal waves breaking
- (iii) Interface loss between different rubble layers
 - Real breakwater composition

7 Acknowledgements

The work on which this paper is based has been funded by the Department of the Environment.

The permeability tests were designed primarily by R V Stephens and conducted by A R Channel. The work was carried out in the Coastal Structures Section managed by N W H Allsop, in the Maritime Engineering Department of Hydraulics Research Limited, Wallingford.

CHAPTER 113

MORISON EQUATION COEFFICIENTS AND DATA CONDITION

R.T. Hudspeth¹
Member, ASCE

Abstract

Identification of the Morison equation force coefficients C_m & C_d depends on the condition of the wave force/kinematic data. For simple harmonic kinematics, the data are equally conditioned for identifying C_m & C_d at the critical value of the period parameter ($K = U_m T/D$) defined by Keulegan and Carpenter (1958). Critical values for K are = 11.4 from geometric interpretations and = 13.16 from numerical interpretations. Stable transverse lift forces may also be shown to correlate with the critical values of K from the physical interpretation of the period parameter given by Keulegan and Carpenter (1958). Data from three different types of physical experiments are used to demonstrate the importance of the condition of the data.

Introduction

The Reynolds parameter ($R = U_m D/\nu$) and the Keulegan-Carpenter parameter ($K = U_m T/D$) are the two parameters that are most often used to parameterize the two empirical force coefficients C_m and C_d used in the Morison equation (Dean and Dalrymple, 1981 & 1984). Dean (1976) recognized the importance of the condition of the data when identifying these two empirical force coefficients from wave force data; but he did not correlate the condition of the data with these two parameters. The Dean error ellipse demonstrates geometrically the condition of data for identifying C_m and C_d by the alignment of the axes of the error ellipse as illustrated in Fig. 1.

¹Professor, Ocean Engineering Program, Oregon State University, Corvallis, OR USA 97331

Fig. 1 Dependency of Dean Error Ellipses on $W = |f_d|/|f_m|$

The data are relatively better-conditioned for identifying the empirical force coefficient C_m or C_d on the axis that is parallel to the semi-minor axis of the error ellipse. Dean (1976) correlated the alignment of the axes of these error ellipses with the dimensionless O'Brien force ratio (1952) $W = |f_d|/|f_m|$; but not with either the Reynolds or Keulegan-Carpenter parameters. Hudspeth and Nath (1990) demonstrated that the Dean eccentricity parameter E is proportional to the Keulegan-Carpenter parameter K for kinematic data that are simple harmonic. Consequently, the Dean eccentricity parameter E connects the alignment of the semi-minor axis of the error ellipse to the parametric dependency of C_m and C_d on K . When $E = 1.0$, then $K = 11.40$ and the error ellipse is a circle with zero eccentricity.

The Dean error ellipse (1976) may be extended to include errors in the amplitudes/phases of the kinematics. This extension to include errors in amplitudes/phases demonstrates geometrically the parametric dependency of C_m and C_d on the parameter K (or E) by the magnitude of the slope of the contours of the dimensionless O'Brien force ratio

$W = |f_d|/|f_m|$ passing through the origin for zero error in phase. The advantage of the amplitude/phase error method is that the separate plots required by the Dean error ellipse method for each constant value of $W = |f_d|/|f_m|$ shown in Fig. 1 may be replaced by a single graph with contours of constant values of W . Comparisons of the amplitude/phase analysis with synthetically phase-shifted laboratory data for $E < 1.0$ or $K < 11.40$ and for $E > 1.0$ or $K > 11.40$ are excellent for phase shifts in the range of $|\omega\tau| < \pi/8$.

Data condition is defined as the ability of a least-squares algorithm to locate a global minimum on an error surface for given wave kinematic/force data (cf. Marquardt, 1963). This geometric definition is related to the numerical matrix condition number (cf. Atkinson, 1989). The matrix condition number is computed by four standard measures for the Morison equation. The matrix condition number is identically equal to unity when $K = 13.16$ and $E = 1.15$.

Geometric Interpretations

1) Dean error ellipses: The mean squared error ϵ^2 between the "true" force per unit length (denoted by upper case unprimed letters) $F(\theta)$ and the "computed" force per unit length (denoted by lower case primed letters) $f'(\theta)$ may be estimated from

$$\epsilon^2 = \langle [F(\theta) - f'(\theta)]^2 \rangle \quad (1)$$

where $\theta = 2\pi t/T$; T = wave period; and the temporal averaging operator $\langle (\cdot) \rangle$ is

$$\langle (\cdot) \rangle = \frac{1}{2\pi} \int_0^{2\pi} (\cdot) d\theta$$

If the "computed" force per unit length is given by the Morison equation

$$\begin{aligned} f'(\theta) &= f'_m(\theta) + f'_d(\theta) \\ &= k'_m \dot{u}(\theta) + k'_d u(\theta) |u(\theta)| \quad (2a) \end{aligned}$$

then the "computed" inertia and drag constants are, respectively

$$k'_m = C'_m [\rho \pi D^2 / 4] ; \quad k'_d = C'_d [\rho D / 2] \quad (2b)$$

When simple harmonic kinematics are used in Eq.(2a), Eq.(1) becomes a conic section equation for an ellipse whose origin has been translated and axes rotated (Hudspeth and Nath, 1990; and Thomas, 1965)

$$(\alpha X)^2 + 2HXY + (\beta Y)^2 + 2GX + 2JY + C = 0 \quad (3)$$

where $X = C'_d$ and $Y = C'_m$.

Equation (3) may be written in a form that is more familiar for an ellipse according to (Dean and Dalrymple, 1984)

$$\frac{(X - X_o)^2}{(R/\alpha)^2} + \frac{(Y - Y_o)^2}{(R/\beta)^2} = 1 \quad (4)$$

The eccentricity of the error ellipse may be expressed in terms of the Dean eccentricity parameter E or the Keulegan-Carpenter parameter K or the O'Brien force ratio W by (Hudspeth and Nath, 1990)

$$E = \frac{\alpha}{\beta} = \frac{\sqrt{3}}{2\pi^2} K = \frac{C_m \sqrt{3}}{C_d} W \quad (5)$$

When $K = 2\pi^2/\sqrt{3} \approx 11.40$ then $E = 1.0$ and the error ellipse is a circle and the data are equally conditioned for identifying both C_m & C_d . The eccentricity e^2 of the error ellipse determines geometrically the condition of the data for identifying C_m & C_d . The eccentricity e^2 may be expressed by

$$e^2 = 1.0 - E^{(\pm)^2} \quad (6a, b)$$

where +2 is to be used when $E < 1.0$ and -2 is to be used when $E > 1.0$. Equations (6) imply that a separate error ellipse plot will be required for each constant value of the O'Brien force ratio W (vide Fig. 1 and Dean, 1976).

Specifically, when $E < 1.0$, then $K < 11.40$ and the semi-minor axis of the error ellipse is parallel to the C_m axis. Conversely, when $E > 1.0$, then $K > 11.40$ and the semi-minor axis is parallel to the C_d axis. Note that a value of $K \approx 11.40$ is approximately the value of K at which the peak in C_d and the trough in C_m occur in the replotted Keulegan-Carpenter data shown in Fig. 2 (cf. Sarpkaya and Isaacson, 1981 and Chakrabarti, 1987).

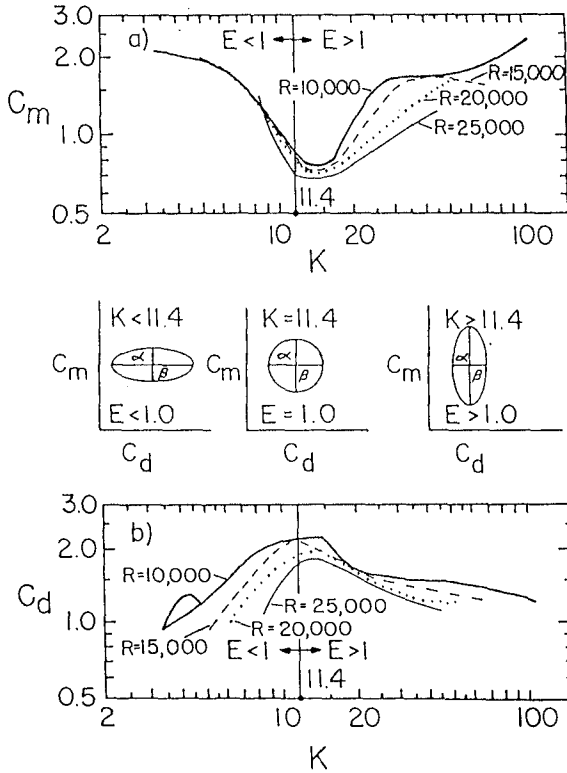

Fig. 2 Correlation of Replotted Keulegan-Carpenter Data with Dean Error Ellipses

2) Amplitude/phase analysis: Hudspeth, et.al. (1988) extended the Dean error ellipse method to include the effects of errors in amplitudes and phases of the wave force/kinematic data. This extension eliminated the need for separate error ellipses for each constant value of the O'Brien force ratio W .

Minimizing Eq.(1) with respect to the computed coefficients C_m and C_d yields 2 equations which may be rearranged to give the following dimensionless inertia coefficient ϵ_m and drag coefficient ϵ_d ratios for small values of the phase shifts $|\omega\tau| \approx 0$:

$$\epsilon_m \approx V[1 - (8W/3\pi)\omega\tau] \tag{7a}$$

$$\epsilon_d \approx V^2[1 + (32/9\pi)(\omega\tau/W)] \tag{7b}$$

with slopes near the origin given by (approximately)

$$S_m = \frac{\partial \epsilon_m}{\partial (\omega\tau)} \approx -\left(\frac{8WV}{3\pi}\right) \tag{8a}$$

$$S_d = \frac{\partial \epsilon_d}{\partial (\omega\tau)} \approx \left(\frac{32}{9\pi}\right)\left(\frac{V^2}{W}\right) \tag{8b}$$

where V = dimensionless velocity amplitude ratio. Note that it is not necessary to construct a separate error ellipse for each constant value of the O'Brien force ratio W .

Figure 3 compares Eqs. (7&8) with synthetically phase-shifted experimental data for $W = 0.49$ (or $E < 1.0$) and for $W = 2.32$ (or $E > 1.0$).

Fig. 3 Comparisons of ϵ_m & ϵ_d with Synthetically Phase-Shifted Laboratory Data (Hudspeth and Nath, 1990)

Numerical Interpretations

Scaling the variables in Eq. (1) by the following:

$$F = \frac{F}{\rho D a^2} \quad u = \frac{u}{a} \quad \dot{u} = \frac{\dot{u}}{a \omega}$$

where a = amplitude of the "computed" velocity; $\omega = 2\pi/T$; and minimizing Eq. (1) with respect to C'_m and C'_d gives the following scaled (or nondimensional) matrix equation :

$$AX = B \tag{9}$$

where the scaled matrices are

$$A = \begin{bmatrix} \frac{4\pi^2}{3K} & 0 \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} \frac{2}{E\sqrt{3}} & 0 \\ 0 & 1 \end{bmatrix}$$

$$X = \begin{bmatrix} C'_m \\ C'_d \end{bmatrix} \quad B = \frac{16}{3} \begin{bmatrix} \langle F\dot{u} \rangle \\ \langle Fu|u| \rangle \end{bmatrix}$$

Matrix A is Hermitian and unitary. It becomes a unit matrix with matrix condition numbers identically equal to unity when $K = 4\pi^2/3 \approx 13.16$ and $E = 2/\sqrt{3} \approx 1.15$.

Table 1. Summary of Matrix Condition Numbers.

Matrix Condition Number (1)	$K < 13.16$ $E < 1.15$ (2)	$K = 13.16$ $E = 1.15$ (3)	$K > 13.16$ $E > 1.15$ (4)	$K = 11.40$ $E = 1.0$ (5)
Cond(A) ₁		1.0		
Cond(A) _∞	$\frac{4\pi^2}{3K} = \frac{2}{E\sqrt{3}}$		$\frac{3K}{4\pi^2} = \frac{E\sqrt{3}}{2}$	1.15
Cond(A) ₂				
Cond(A) _*				

The four standard matrix condition numbers listed in column 1 of Table 1 are defined as follows (Atkinson, 1989):

$$\text{Cond}(A)_1 = \text{Cond}(A)_\infty = \|A\| \cdot \|A^{-1}\|$$

$$\text{Cond}(A)_2 = \left[\frac{\text{Max}|\lambda|}{\text{Min}|\lambda|} \right]^{1/2} ; \quad \text{Cond}(A)_F = \left[\frac{\lambda \in \sigma[A]}{\lambda \in \sigma[A^*A]} \right]$$

where $\|\cdot\|$ = a matrix norm; A^{-1} = matrix inverse; λ = eigenvalue of the matrix A ; $\sigma[\cdot]$ = spectral radius of the matrix $[\cdot]$; and A^* = complex conjugate transpose.

Stable Transverse Lift Forces

Keulegan and Carpenter (p. 439, 1958) gave a physical interpretation of their period parameter in terms of the distance traveled in one direction by a fluid particle in the absence of the cylinder. Accordingly, this definition lead to the ratio between the wave period T and the eddy shedding period T_s being equal to the product between the Strouhal parameter S and the Keulegan-Carpenter parameter K ; or

$$\frac{T}{T_s} = S \cdot K \quad (10)$$

When this ratio is exactly equal to two, then exactly two vortices will be shed during one wave period and the transverse lift force will be stable (Keulegan and Carpenter, 1958). For normal wave conditions, $0.18 < S < 0.20$ and $K \approx 11$ when the ratio $T/T_s \approx 2$.

Data are available that correlate with the critical values of the Keulegan-Carpenter parameter K computed from both the geometric and the numerical interpretations. The only stable transverse lift force seen in the Hayashi and Takenouchi data (1979) shown in Fig. 4 occurs when $K = 11.8$ which is approximately the critical value of K determined from geometric considerations.

Fig. 4 Transverse Lift Forces on Vertical Circular Cylinders (Hayashi and Takenouchi, 1979)

The only stable transverse lift force seen in the Maull and Milliner data (1979) shown in Fig. 5 occurs in Run 145 when $K = 13.02$ which is approximately the critical value of K determined from numerical considerations.

Fig. 5 Forced In-Line Motions and Transverse Lift Forces on a Vertical Circular Cylinder Oscillated in Still Water (Maull and Milliner, 1979)

Conclusions

The critical values of the period parameter $K = U_m T/D$ identified by Keulegan-Carpenter (1958) are shown to correlate with: 1) wave force/kinematic data that are equally conditioned for identifying C_m & C_d ; and 2) stable transverse lift forces. The effects of the condition of the data on the inertia and drag coefficients C_m & C_d are evaluated from two geometric and one numerical interpretations. The two geometric interpretations of the condition of the data proposed by Dean demonstrate that when the Dean eccentricity parameter E equals unity, the data are equally conditioned for determining C_m & C_d . For simple harmonic data, the Dean eccentricity parameter may be shown to be proportional to the Keulegan-Carpenter parameter; i.e., $E = \sqrt{3}K/2\pi^2$. When $E = 1.0$, then $K = 11.40$ and the Dean error ellipse is a circle with zero eccentricity. The numerical interpretation of the condition of the data demonstrates that when the matrix condition number of the 2×2 matrix used to compute C_m & C_d in a best least-squares sense becomes identically equal to unity then $K \approx 13.16$ and $E \approx 1.15$. Stable transverse lift forces occur when the ratio of the wave period T to the period of eddy shedding T_s is exactly equal to two. For a Strouhal parameter $0.18 < S < 0.20$ and $T/T_s = 2$, $K \approx 11$. Three sets of experimental data are compared with the two geometric and one numerical analyses and with the stable transverse force hypothesis. These experimental data represent three very different physical conditions; viz., 1) a horizontal circular cylinder located at the node of standing surface gravity waves, 2) a vertical circular cylinder in propagating surface gravity waves, and 3) a vertical circular cylinder forced to oscillate in otherwise still water.

CHAPTER 114

NEW CRITERIA FOR GRANULAR FILTERS AND GEOTEXTILE FILTERS UNDER REVETMENTS

K.J. Bakker¹, M. Klein Breteler²
and Dr. H. den Adel³

Abstract

New criteria for the design of filters under revetments are introduced and verification tests are described. These criteria are based on a hydrodynamic limit instead of the usual geometric limit, assuming a similarity between the flow in open channels and flow in the pores at an interface between filter and base. First a theory was developed for a granular filter only, and later this theory was extended to include the influence of a geotextile. The verification experiments are outlined, and the applicability of the derived formulae is discussed.

Introduction

For the design of coastal structures, such as dike revetments or a breakwater, several aspects have to be considered. Not only the stability of the cover layer is important, but also the stability of the foundation layers, i.e. the filter layers has to be assured. In this paper we restrict ourselves to the filter layers. Until recently the design of these filter layers was based on strict rules demanding geometrically tight filters: the pores in the filter material have to be smaller than the particles of the subsoil to be protected.

The geography of the Netherlands with vast area's of its surface beneath sea level urge a major infrastructure in order to protect its population against flooding hazards. Many dike revetments are necessary, so it is of

Fig 1. Wave attack on revetments

vital interest to be able to dimension these structures both as safe and as economic as possible. Mainly they can be outlined as in Fig. 1.

For the case we are concerned with, e.g. filter layers between cover layer and base, under a revetment, damage to the filter layer leads to inadmissible settlements of blocks in the cover layer. As a result of research concerning revetments, it was found that the hydraulic gradients in this type of construction are related to the slope gradient. These gradients are relatively small except within the direct vicinity of the surface of the structure.

For transport of grains, forces to activate particle movement have to be present, such as water flowing through the soil skeleton. When hydraulic gradients are small, the "no transport" demand can thus be achieved as well by controlling the pore water velocity; i.e. limiting the permeability of the filter material. In the Netherlands much effort has been put in research to derive new filter rules, based on a combination of geometric and hydrodynamic effects. This has led to filter criteria which might be a factor four less

stringent concerning the ratio of filter to base grain size. After verification of these filter criteria for granular material, the theory was extended to incorporate the influence of a geotextile, at the interface between filter and base material. Assuming that the geotextile has a damping effect on the hydraulic load on the base material, an extended design formula was derived and calibrated with experimental research.

Theory for granular filter interface

Traditionally filter criteria are based on geometric considerations which yield criteria which are based on limiting the diameter of the pore-channels connecting the pore holes in the soil skeleton. These constrictions in the filter must be that small, that the characteristic grain size of the base material is larger, so that base particles cannot pass these constrictions.

Figure 2 The characteristic constriction size is a function of grain size, and packing of the soil skeleton

In this paper we will distinguish between filter and base material by using D for the diameter of the filter material and d for that of the base material.

According to Kenney (1985), the characteristic constriction in the filter material is

$$D_c^* \leq 0.2 D_{15} \quad (1)$$

and the characteristic grain size of the base material is d_{85} . This leads to a design rule which was conducted first by Terzaghi which says that the ratio D_{15}/d_{85} must be smaller than 4 or 5.

Figure 3 Hydraulic gradients

Yielding;
$$\frac{D_{15}}{d_{85}} < 5 \tag{2}$$

Though later researchers like Thanikachalam (1974) and others have conducted criteria including effects of the grain size distribution, geometric filter criteria are generally tight.

In order to introduce hydraulic criteria we have to classify the loading conditions, see Fig. 3. Traditionally filter experiments to verify for geometric penetration where performed applying flow perpendicular to the filter interface. However, in practical circumstances, the hydraulic loading is often dominated by the hydraulic gradient parallel to the filter interface. As the pore water velocity is determined by the higher permeability in the coarser filter, the hydraulic gradient parallel will lead to higher velocities in the filter than in the base material. On the contrary with perpendicular loading the velocities are approximately the same since continuity must hold.

If the diameter of the pore holes in the filter is large with respect to the grain size of the base-material, the hydraulic loading on the base material can be related to the loading of a sand bottom in an open channel. It is assumed that, given a granular filter with pores much wider than the grains in the base layer, the critical shear over the sand interface is equal to the critical shear in a channel with the same bed material.

Shields related the critical shear stress to the diameter of the base material. As the critical shear stress is related to the water velocity, a relation between the filter velocity and the diameter of base material can be derived, adding corrections for hydraulic conditions in a filter. The threshold of sediment motion

Figure 4 Shields parameter.

in open channels according to Shields is;

$$\tau_{cr} = \psi_s \Delta g D_{50} \rho \tag{3}$$

Where;

τ_{cr} = critical shear stress

ψ_s = Shields parameter

Δ = relative density of sand grains ($\frac{\rho_s - \rho}{\rho}$)

g = acceleration of gravity

D_{50} = grain size corresponding to 50% by weight of finer particles

ρ = mass density of water

ρ_s = mass density of sand

By introduction of the shear velocity $V_* = \sqrt{\tau/\rho}$, equation (1) can be rearranged to yield;

$$V_{*cr} = \sqrt{\psi_s \Delta g D_{b50}} \tag{4}$$

Where V_{*cr} = the critical shear velocity.

Formula (4) was extended in order to calculate the water velocity at threshold of sediment transport for steady flow parallel to a horizontal interface between a filter layer and a base layer, assuming a ratio between the shear velocity and the pore water velocity;

$$q_{cr} = n V_{pcr} = \frac{n}{\kappa} \sqrt{\psi_s \Delta g d_{50}} \tag{5}$$

Where κ is the ratio V_*/V_p between shear velocity, and pore water velocity, and q is the filter velocity. The magnitude of coefficient κ was determined experimentally; κ will be discussed in the next section.

For as far as the inclination concerns, assuming that at threshold of particle motion, there is an

Figure 5 Equilibrium of forces

equilibrium of three forces, see Fig. 5, this leads to:

$$F_p + F_g \sin \alpha = \tan \phi \left\{ F_g \cos \alpha - F_{\perp} \right\} \quad (6)$$

With ϕ : natural angle of repose of single grains of the base material
 α : slope angle

Furthermore the gravitational force, F_g is virtually neutralized when fluidisation occurs:

$$i_f = \Delta(1 - n_b) \quad (7)$$

Where n_b is the porosity of the base material.

Since the shear forces are proportional to v^2 , the critical filter velocity q_{cr} can be written as:

$$q_{cr} = \frac{n}{\kappa} \sqrt{s \Delta g d_{50} \left(\frac{\sin(\phi - \alpha)}{\sin \phi} \right) - \frac{i_{\perp}}{\Delta(1 - n_b)}} \quad (8)$$

where one can identify a part that is related with the hydraulic conditions, a part that accounts for the slope angle, and a part which accounts for the perpendicular hydraulic gradient. A more detailed derivation is given in Bezuijen, Klein Breteler and Bakker (1987)

Finally a permeability relation is needed to relate the filter velocity to the grain size of the filter material. As this filter material is relatively coarse,

we do have to account for the turbulence intensity. Therefore we suggest a non linear permeability relation such as proposed by Forchheimer:

$$i = a q + b q^2 = a q \left(1 + \frac{b}{a} q \right) \tag{9}$$

with;

$$a = 160 \frac{\nu}{g} \frac{(1-n)^2}{n^3 D_{15}^2}$$

$$b = \frac{2.2}{g n^2 D_{15}}$$

where;

$$\nu = \text{kin. visc. of water: } 1.2 \cdot 10^{-6} [\text{m}^2/\text{s}] \quad (13^\circ)$$

This relation which is a quadratic equation in the filter velocity, can be solved directly, and this gives a secant linear expansion in the permeability

$$k^s = \frac{-a + \sqrt{a^2 + 4bi}}{2bi} = \frac{a}{2bi} \left\{ \sqrt{\left(1 + \frac{4bi}{a^2} \right)} - 1 \right\} \tag{10}$$

if $4bi/a^2 \ll 1$ than $\sqrt{1 + 4bi/a^2}$ can be approximated by $1 + 1/2 (4bi/a^2)$; the secant permeability becomes than $1/a$; The Darcy result.

If $4bi/a^2 \gg 1$, than $\left\{ \sqrt{1 + 4bi/a^2} - 1 \right\} \approx (2/a) \sqrt{bi}$

Figure 6 Loading conditions

So than $K^S = 1/\sqrt{bi}$, the result for turbulent flow.

Also experimentally, by measurement it is relatively simple to identify a laminar part, and a turbulent part. Dividing the filter velocity by the hydraulic gradient, one gets;

$$i/q = a + b q \tag{11}$$

By measuring the hydraulic gradient for two values of the hydraulic discharge, a and b can be derived relatively simple.

Verification by model tests for granular filters

The formulae (5) and (8) have been verified by means of laboratory experiments, using non cohesive base materials with steep sieve curves.

In order to verify formula (8), it was tested for the different load components. First stationary flow was verified, both on a horizontal bed, and on sloping beds. Then test were carried out with a perpendicular gradient added to the horizontal flow, and finally the effect of cyclic flow was tested.

Figure 7 Delft Hydraulics Filter-box, with inclined interface

All these tests were performed in facilities where the sand transport could be measured and where the stability of the interface could be observed visually, except the tests with cyclic flow (visual observation only). The hydraulic loading was increased until there was particle transport. For the stationary flow, both on a horizontal bed, as well as for the inclined beds, the

Figure 8 Filter-box test results for stationary flow parallel to a horizontal interface

filter box of Delft Hydraulics was used. see Fig 7. Tests were performed using different base materials with diameters ranging from 0.10 mm up to 0.82 mm and different ratio's D/d . The hydraulic gradient was increased step by step until considerable erosion took place. Sand transport of 0.2 gr/s/m² of dry sand was considered to be critical.

In Fig. 8 some results of the experiments in the filter box are given. The values for the coefficient κ where determined from this figure. As κ becomes constant for larger diameters of the base material the critical filter velocity becomes constant. For the finer base material the critical filter velocity is still a function of the filter material, as this material determines the turbulency conditions. This yielded the following relations for κ ;

$$\kappa = \frac{v^*}{v_p} = 0.8 Re_{cr}^{-0.2} \quad \text{for } 0.1 < d_{50} < 0.3 \text{ mm}$$

$$\kappa = 0.20 \quad \text{for } 0.5 < d_{50} < 1.0 \text{ mm}$$

$$\kappa = 0.35 \quad \text{for } d_{50} > 2 \text{ mm}$$

For $0.1 < d_{50} < 0.3 \text{ mm}$ in formula (8) q_{cr} is a function of Re_{cr} . and therefore a function of q_{cr} , so formula (8) is an implicit relation, however by rearranging q_{cr} , an explicit relation can easily be found.

From tests where a perpendicular gradient was added it was concluded, that though there is a lot of scatter in the results, the proposed formula gives a safe estimate of the critical horizontal filter velocity.

Under practical circumstances the stationary perpendicular gradient is often small, and can than be neglected. For the non stationary component, especially for smaller particles, the stability is enhanced. Since if a particle would move perpendicular to the interface, the removal of the particle from the bed would create an under pressure between particle and subsoil, reducing the gradient, thus giving a greater stability than suggested by the fluidisation gradient.

In order to investigate the influence of a cyclic component in the water velocity, tests were performed in the pulsating water tunnel of Delft Hydraulics. Tests were performed with a wave period of 2 s. which is relatively small compared to wave periods experienced on dikes and bank protection. The experimental results indicated, that for a wave period of at least 2 s. the critical velocity does not differ significantly from the stationary result. The experimental results where discussed in more detail by Bezuijen, Klein Breteler and Bakker (1987)

Figure 9 Design diagram for granular filter interface

Finally wave loading tests on a revetment in the Scheldt flume of Delft Hydraulics was performed. In these tests the combination of all loading aspects were present, and the filter was build based on the afore mentioned filter criteria for a critical design. The tests were used to derive wave loading characteristics

too. The verification was both visually, and by measurements of particle transport. No transport of base material was noticed.

Based on the derived theory a design diagram was made. Assuming that hydraulic conditions are known, one can use this, either to find the admissible hydraulic conditions for a given base material, and ratio between filter and base material, as is indicated in Fig. 9, or one can use it the other way round, and derive the filter ratio, when hydraulic conditions are given.

Extension of theory to geotextile interfaces

Once thus far the question arose whether the theory could be extended to include the influence of a geotextile. In comparison to an interface without one, the geotextile reduces the hydraulic loading because the boundary layer of the water flow cannot reach the grains of the base material, so a damping effect will exist. Apart from that, the geotextile, even when it is not geometrically tight, will provide an obstacle for transporting particles.

Figure 10 Principle of erosion at interface

Relevant parameters for the stability of particles underneath a geotextile might be;

- the characteristic opening size 0_{90} of the geotextile.
- the permeability k_g of the geotextile, as this

determines whether turbulences in the pore holes in the filter can penetrate to the base material surface, and

- the thickness T_g of the geotextile, which is related to this damping and has a geometric effect too.

The water partly flows just along the geotextile, and gives less shear on the underlying particles. As we assume that the pore water velocity gives the driving force for particle transport, the presence of a geotextile will reduce this pore water velocity. This reduction is a function of the opening size distribution, the permeability, and the thickness of the geotextile, see Fig. 10.

In order to derive a unified theory, the earlier proposed formula for a horizontal bed (without the effect of perpendicular flow) was extended using dimension analysis. An extended formula was derived, see Klein Breteler (1990), where three dimensionless coefficients were introduced in order to quantify these results;

$$q_{cr} = \left(c_1 \left(\frac{T_g}{d_{90}} \right) c_2 \left(\frac{d_{90}}{O_{90}} \right) c_3 \left(\frac{w}{k_g} \right) c_4^{1/m} + \frac{n}{\kappa} \right) \sqrt{\psi_s \Delta g d_{50}} \quad (12)$$

Where c_i are positive coefficients

The geotextile/soil geometry is characterized by the dimensionless thickness of the geotextile, T_g/d_{90} . The critical filter velocity q_{cr} increases with decreasing O_{90}/d_{90} ratio, or with increasing T_g/d_{90} , leading to T_g/d_{90} as a parameter. The geometric effect is characterized by the ratio d_{90}/O_{90} . The ratio w/k_g , where w is the fall velocity of a base particle, is characteristic for flow damping at the threshold of sand motion.

The formula was arranged in such a way, that all parameters will be zero, if no geotextile is present. The formula reduces than to that for granular material (5).

Geotextile interface experiments

Formula (12) was calibrated with experimental testing, quantifying the coefficients c_i . Tests were performed with mesh netting, tape fabric geotextile, and the thicker mat alike geotextile. In these tests base materials ranging from 100 μm up to 200 μm were used under the condition of horizontal flow through a rock layer on a horizontal geotextile.

Figure 11 Test results and empirical formula

Since the number of tests performed is relatively small, it is not possible to determine more definite values for the coefficients C_i . Using trial and error methods, acceptable values for C_i were established; $C_1 = 12$, $C_2 = 1$, $C_3 = 4$ and $C_4 = 1/2$, with the test results. This yielded the following formula;

$$q_{cr} = \left(12 \left(\frac{T_g}{d_{90}} \right) \left(\frac{d_{90}}{O_{90}} \right)^4 \left(\frac{w}{kg} \right)^{1/2m} + \frac{n}{\kappa} \right) \sqrt{\psi_s \Delta g d_{50}} \quad (13)$$

In Fig. 11 the test results are gathered in such a way that one can judge the overall behavior of the derived formula. The experiments were described in more detail by Klein Breteler (1990).

Concluding Remarks

The derived formulae give a large extension to the range of applicability for filter materials, because the ratio of filter material and base material can be extended considerably.

The extension of the derived formulae to include the presence and influence of a geotextile filter makes them

more generally applicable. The extended formula can, for example be applied to the design of bottom protections. As the feasible extension to include the influence of the inclination, such as included in the formula for granular filters only, has not been been verified yet.

For other types of structures such as breakwaters, with large elements at the surface structure the use of the criteria should be restricted to that part of the structure for which the interface is not in the direct vicinity of the surface of the structure. Since in the large "pores" between these elements, the dynamic effects of the water flow are not negligible.

A limiting factor to the applicability is that hydraulic loading conditions have to be known, or need to be established, thus for the further introduction of the derived filter criteria a parallel development of design tools to predict the hydraulic loading, in various constructions, is needed.

CHAPTER 115

WAVE FORCES ON BREAKWATER ARMOUR UNITS

Jørgen Juhl¹ and Ole Juul Jensen²

Abstract

The authors have carried out a research project for investigation of the wave forces acting on breakwater armour units. The project included a literature study, hydraulic model testing and analysis of the test results. The hydraulic model testing was made in a wave flume on a 2-dimensional idealised breakwater structure with an armour layer consisting of two rows of horizontal pipes.

Introduction

Many researchers have for many years looked into the question of wave forces on breakwater armour units. Most of the research has concentrated on studying the stability of breakwater slopes armoured with various types of armour units.

Only a few researchers have directly studied the wave forces on armour units by making measurements on idealised armour units in a hydraulic model. Sigurdsson (1962) and Sandström (1974) have made measurements on idealised breakwaters consisting of spherical balls exposed to regular waves.

The present work is of the same nature, but is a pure 2-dimensional case and included testing with irregular waves.

The maximum measured forces on an armour unit, both during run-up and run-down, has been studied as function of wave height, wave period, and position of the unit on the breakwater slope.

¹Senior Hydraulic Engineer, Danish Hydraulic Institute

²Head, Ports and Marine Structures Division, Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark.

In order to make a simplified representation of the acting forces, stability calculations including both measured force components have been carried out.

During run-up large forces in the direction into the breakwater have been measured. These slamming forces were measured both for regular and irregular waves, but are generally more pronounced for irregular waves. The slamming forces are characterised by a rapid growth and a short duration, and occur when the water hits onto the units. This type of forces is not considered to be dangerous for the stability of armour units, but may be dangerous for breakage of slender and fragile concrete armour units.

Results of the study have been published by the authors in Refs. /1/ and /2/.

The Model

The model tests were conducted in a 23 m long and 0.6 m wide wave flume. The flume set-up is shown in Fig. 1.

Fig. 1 Set-up of wave flume.

The model tests were conducted on a 2-D breakwater model with a slope of 1:2 of the armour layer. The crest height was chosen not to allow for wave overtopping. The armour layer consisted of two layers of horizontal steel pipes with diameter 50 mm to form an idealised and purely 2-dimensional representation of a breakwater armour layer. The porosity of the armour layer was selected to $p = 0.40$. Details of the model are shown in Fig. 2.

Fig. 2 Details of test set-up.

The wave forces on three of the pipes in the upper layer were measured simultaneously by use of strain gauge transducers giving two force components, i.e. vertically and horizontally. Nine of the pipes in the upper layer were prepared for force measurements. The forces were measured on the 0.2 m wide middle section of the horizontal pipes.

Waves

Regular and irregular waves were used for model testing. The wave combinations covered both non-breaking and breaking waves.

The tests with irregular waves covered a range of wave combinations: Peak periods, T_p , from approximately 1.0 to 3.0 s and significant wave heights, H_s , from approximately 0.05 m to 0.20 m.

The wave heights for the irregular waves were determined as $H_s = 4 \times h_{rms}$, where h_{rms} is calculated as

$$h_{rms} = \sqrt{\frac{1}{m} \sum_{i=1}^m h_i^2}$$

m being the total number of samples and h_i being the surface elevation.

Wave Measurements

The waves in the flume were measured in 5 points by resistance type wave gauges as shown in Fig. 1.

The coefficient of reflection, R , has been determined for each test by a standard three gauge method, wave gauges Nos. 1, 2, and 3.

The measured wave heights have been corrected by a factor of $\sqrt{1+R^2}$ to take into account waves reflected from the breakwater.

The wave height measured 1.5 m in front of the breakwater (wave gauge No. 4) has been used as reference wave height for all test runs.

Measurements of the run-up/run-down was carried out with a wave gauge placed parallel to the breakwater slope and in a distance of 50 mm (one pipe diameter) to ensure no effect from the steel pipes.

Force Measurements

Strain gauge transducers were used for measurements of two force components, i.e. vertically and horizontally.

The natural periods for the 0.2 m test section of the pipes fixed to the strain gauge transducers have been determined:

(a) In air	100 Hz
(b) In water	55 Hz
(c) In half air/half water (pipe No. 5)	60 Hz

It should be noted that the transducers were calibrated to zero-force for still water level. This means that the buoyancy acting vertically upwards has been subtracted for pipes Nos. 1-5 being either totally or partly submerged.

The buoyancy for a totally submerged pipe was 19.30 N/m and for the partly submerged pipe No. 5 the buoyancy was 9.65 N/m. This fact is important in the interpretation and comparison of the test results for the different pipes.

Test Conditions

All tests were carried out with fixed wave conditions, i.e. stationary wave height (H , H_s) and wave period (T , T_s). The water level was identical during all test runs, i.e. a water level of 0.38 m at the toe of the breakwater.

The test runs with regular waves had a duration of 300 s, while the test runs with irregular waves had a duration corresponding to approximately 500 zero-crossing waves.

The signals from the wave gauges and the strain gauge transducers were recorded (with a logging frequency of 40 Hz) and stored by a micro computer.

Wave Forces on a Two-Dimensional Breakwater

The determination of forces acting on the idealised armour units can be compared with forces acting on a pipeline located on or close to the seabed. The following points indicate the complexity for the present model set-up.

- (a) The flow pattern around the pipes is very complex, each individual pipe is influenced by the presence of neighbouring pipes.
- (b) Air entrainment occurs which makes the velocity field uncertain and decreases the density of the fluid.
- (c) The buoyancy varies with time as a result of run-up/run-down. This means that it is impossible to separate the hydrostatic force and hydrodynamic forces.
- (d) Wave breaking results in wave slamming forces.

The positive orientation of the measured forces is shown in Fig. 3.

Fig. 3 Definition sketch of the used coordinate system, and simplified stability calculations.

Velocity and Acceleration in Run-up/Run-down

The wave gauge for measuring run-up/run-down was installed 0.05 m above the slope and calibrated so that the run-up/run-down was measured vertically in agreement with the standard procedure for reporting of run-up heights.

The velocity and acceleration of the water in the run-up/run-down front has been calculated by a filter technique as described by Hamming (1977). The filters represented single and double differentiation of the measured time series of run-up/run-down.

It should be noted that the calculated velocity and acceleration refers to the run-up/run-down and not to the flow conditions around the individual pipes.

Stability Calculations

Stability calculations including both force components have been carried out with the aim of making a simplified representation of the acting forces. It is assumed that the armour unit is supported in two contact points as shown in Fig. 3. Only symmetric contact points have been used for the calculations, i.e. $\theta = \theta_A = \theta_B$.

An example of the measured run-up/run-down and measured horizontal and vertical forces is shown in Fig. 4 together with the calculated required weight for no movements. The required effective weight to withstand roll-down, W'_d , is positive whereas the required effective weight to withstand roll-up, W'_u , is plotted as negative values. The required weights presented throughout the paper have been calculated for $\theta = 60$ deg.

Fig. 4 Recorded and calculated time series for a regular wave with $H = 0.07$ m and $T = 2.0$ s.

Test results for Regular Waves

The following paragraphs include results from testing with regular waves.

Required Weights in Relation to Pipe Position

For regular waves with a wave period of 2.0 s, a series of tests has been carried out for studying the effect of pipe position.

Fig. 5 shows the calculated required weights to withstand roll-up and roll-down, respectively. W'_u and W'_d are presented for the nine pipes on which wave forces have been measured.

The calculated required weights to withstand roll-down shows that a maximum of W'_d is reached at pipes Nos. 1, 2, or 3 depending on the wave height. Also for roll-up, a maximum in required weight is found at pipe No. 1, 2 or 3 and further, a local maximum is found at pipe No. 5. The test results show that the required calculated weights to withstand roll-up are generally less than the required weights to withstand roll-down. This is in good agreement with the experience from physical model tests of rubble mound breakwaters, i.e. the major part of damage occurs during run-down for a slope of 1:2.0.

Fig. 5 Required weights to withstand roll-up/roll-down for the nine pipes. Wave period $T = 2.0$ s.

Influence of Wave Period

The calculated required weights to withstand roll-down, W'_d , for pipes Nos. 2 and 5 are shown in Fig. 6 as function of the wave period. The results show that for pipe No. 2, the largest required weight occurs for $T = 1.5$ s, whereas a minimum is found for $T = 2.5$ s. For pipe No. 5, the required weight only varies slightly with the wave period, whereas for pipe No. 8, an increase with the wave period is found, which is due to increasing wave run-up for increasing wave periods. Similar dependencies of the wave period are found for the required weights to withstand roll-up.

Fig. 6 Required weights as function of the wave period. Regular waves.

The measurements show that it is a rough simplification to aim for one stability formula for description of the stability of the entire seaward armour layer of a rubble mound breakwater.

Influence of Surf Similarity Parameter, $\xi = \tan \alpha_0 \sqrt{H/L_0}$

The influence of the surf similarity parameter on stability has been studied. For fixed values of the required weights to withstand roll-up and roll-down, the corresponding wave heights have been found and the results are for pipe No. 2 presented in Fig. 7. It was found that a minimum in stability occurs for a surf similarity parameter in the order of 2 to 4, which corresponds to peak wave periods in the order of 1.5 s to 2.0 s. It is very important to notice that this range of the ξ -factor corresponds approximately to the transition between plunging and surging wave breaking.

Fig. 7 Relationship between wave height and surf similarity parameter, ξ , for fixed required weights to withstand roll-up and roll-down. Pipe No. 2.

Test Results for Irregular Waves

All results presented in this section are based on model tests with irregular waves generated on basis of a JONSWAP spectrum. The forces were during all tests measured on pipes Nos. 2, 3, and 5.

Analysis of Results

The measured forces and calculated required weights have been analysed statistically by plotting the results on semi-logarithmic paper as shown in Fig. 8. From these plots, the most probable forces and required weights have been found and used for further analyses.

Influence of Wave Height

The calculated required weights to withstand roll-up and roll-down have been plotted for each wave period as function of the wave height. It was found that the relationship between the required weights and the wave height to a high degree depends on the peak wave period and location on the slope.

Influence of Wave Period

The test results for irregular waves show the same tendency, but less pronounced as for regular waves, i.e. a maximum in required weight for $T_p = 1.5$ s for pipe No. 2,

whereas the required weight for pipe No. 5 is almost independent of the wave period.

Fig. 8 Distribution of maximum forces and required weights on pipe No. 3. $H_s = 0.13$ m, $T_p = 2.0$ s.

Influence of Surf Similarity Parameter, $\xi = \tan \alpha_o \sqrt{H_s} / L_{op}$

In Fig. 9, the influence of the surf similarity parameter on the stability is shown for pipe No. 2. For fixed values of the required weights to withstand roll-up and roll-down, the corresponding wave heights have been found.

Fig. 9 Relationship between significant wave height and surf similarity parameter, ξ , for fixed required weights to withstand roll-up and roll-down. Pipe No. 2.

For roll-up, a minimum in stability is found for a surf similarity parameter in the order of 2 to 4.

For roll-down, the minimum in stability is not so pronounced as for roll-up or as was the case for regular waves. A minimum in stability was found for a surf similarity parameter of 3-5.

Wave Slamming Forces

The wave slamming forces on the pipes have been analysed by studying the horizontal forces acting into the breakwater, i.e. when $F_{hor} < 0$. The advantage of this method is elimination of the varying buoyancy. It can, however, not be excluded that small buoyancy effects occur due to asymmetrical buoyancy and air entrainment. The duration of the measured slamming forces was approximately 0.1 s with a rising time of approximately half, i.e. 0.05 s. This is significantly longer than slamming forces on a vertical wall, most probably due to the circular shape of the pipe.

Maximum Horizontal Force in Relation to Pipe Position

For regular waves with a period of 2.0 s, a series of tests has been carried out for studying the relationship between the maximum inwards acting horizontal force ($-F_{hor}$) and the pipe position. Fig. 10 shows the results for the nine pipes on which wave forces have been measured.

Fig. 10 Maximum inwards acting horizontal forces in relation to pipe position. $T = 2.0$ s. Regular waves.

The results show that for $H = 0.10$ m the largest force is acting on pipe No. 5. When the wave height is

increasing, the wave run-up is increasing and thus the largest force is acting on a pipe further up the slope. For $H = 0.20$ m, the largest force is found to act on pipe No. 8, but this force is only slightly larger than the largest forces acting on pipes Nos. 5, 6, and 7.

For all three wave heights, it was found that the maximum forces acting on pipes Nos. 1, 2, and 3 are approximately half the largest maximum force.

Slamming Forces as Function of Run-Up Velocity

In order to analyse if the run-up velocity is the dominant factor for the horizontal wave impact on the pipes, the maximum measured horizontal force during each run-up period has been determined.

A scatter diagram of the correlation between run-up velocity and maximum inwards acting horizontal force, $-F_{hor}$, on pipe No. 5 is shown in Fig. 11.

The results show that the maximum horizontal force increases almost linearly with the run-up velocity. This result is very surprising as $-F_{hor}$ is expected to be proportional to U^2 .

Fig. 11 Scatter diagram of run-up velocity and maximum inwards acting horizontal force on pipe No. 5. $H_s = 0.18$ m, $T_p = 2.0$ m. JONSWAP spectrum.

Summary and Conclusion

Calculations of the required weights to withstand roll-up and roll-down showed that the maximum required weights occur for pipes Nos. 1, 2 or 3 (below SWL), depending on the wave height.

For roll-down, a maximum in required weight for pipe No. 2 is found for a wave period of 1.5 s, whereas the required weight for pipe No. 5 is almost independent of the wave period.

For roll-up, a minimum in stability was found for a surf similarity parameter, ξ , of 2 to 4 for both regular and irregular waves. For roll-down, a minimum in stability was found for a ξ of 2 to 4 for regular waves, whereas the minimum is less pronounced for irregular waves and occurs for a ξ of 3 to 5.

The results show that the slamming forces acting on the pipes vary to a high degree with the wave period resulting in different types of wave breaking and on the position of the pipe relative to SWL.

The largest horizontal slamming forces were measured at the pipes from still water and upwards on the slope. There was a tendency that waves with a period of 1.5 s to 2.0 s caused the largest forces which corresponds to a surf similarity parameter in the order of 2 to 4. This range of the ξ -factor corresponds approximately to the transition between plunging and surging wave breaking.

Analyses have shown that the measured horizontal slamming forces are increasing almost linearly with the run-up velocity.

Acknowledgement

The research study of wave forces on idealised breakwater armour units was partly financed by the Danish Technical Research Council. The support is graciously acknowledged.

Appendix 2 - Notation

The following symbols are used in this paper:

g	=	acceleration due to gravity
F_{hor}	=	horizontal force component (outwards from the breakwater)
$-F_{hor}$	=	horizontal force component (inwards the breakwater)
F_{ver}	=	vertical force component (upwards)
$-F_{ver}$	=	vertical force component (downwards)
F_t	=	total force. Negative when acting into the breakwater
H	=	wave height at wave gauge No. 4
H_s	=	significant wave height at wave gauge No. 4
h^s	=	water depth
h_i	=	surface elevation
h_i^{rms}	=	rms-value of the water surface elevation
L_o	=	deep water wave length, $L_o = g/2\pi \cdot T^2$
L_{op}	=	deep water wave length, $L_{op} = g/2\pi \cdot T_p^2$
m^{op}	=	number of samples
p	=	porosity of armour layer
R	=	reflection coefficient
T	=	wave period
T_p	=	spectral peak wave period
W^p_d	=	required weight to withstand roll-down
W^u_d	=	required weight to withstand roll-up
α	=	slope of breakwater, $\tan \alpha_o = \frac{1}{2}$
θ	=	angle for contact points
ξ	=	surf similarity parameter

CHAPTER 116

EFFECTS OF WAVE GROUPS ON THE STABILITY OF RUBBLE MOUND BREAKWATERS

by

Josep R. Medina¹, Claudio Fassardi²,
and Robert T. Hudspeth³

ABSTRACT

The stability of the armor layer of rubble mound breakwaters has been shown to be highly influenced by some wave grouping characteristics. The measured damage functions are dependent on the Envelope Exceedance Coefficient, α , and also on the Groupiness Factor defined as: $GF = \sigma[H^2(t)]/8m_0$.

INTRODUCTION

Wave groups have been identified as playing an important role in a variety of coastal problems. Medina and Hudspeth (1990) reviewed most of the parameters and methodologies commonly used, as well as the engineering problems associated with wave groupiness. Although the effects of wave groups on the stability of the armor layer of mound breakwaters have been considered by many, a rational method for incorporating wave groups into the design of mound breakwaters has yet to be developed.

Current design methods for armor layers follow the design methodology proposed by the Shore Protection Manual (SPM, 1984) which relates the design of the armor layer to a single representative wave height, H_{10} , which corresponds to a design sea state. The SPM methodology does not incorporate the effects of

storm duration, wave period or wave groupiness from the design sea state.

Bruun (1985) reviewed the design of mound breakwaters and emphasized that the stability of these structures is sensitive to wave groups; and, therefore, wave grouping characteristics should be incorporated into their design. On the contrary, Van der Meer (1988) proposed new formulae which considered the influence of duration and wave periods; however, he concluded that wave grouping characteristics and spectral shape have only a minor influence on the stability. Recently, Medina and McDougal (1990) reanalyzed the experimental data from Van der Meer and Pilarczyk (1988); and found that rubble mound breakwaters were more stable against sea states with long wave groups, which appears to be contrary to intuition.

As noted above, there is an apparent contradiction regarding the effects of wave grouping on the stability of rubble mound breakwaters. In order to evaluate the influence of wave grouping on the stability of rubble mound breakwaters and revetments, a series of large scale experiments were conducted at the O.H. Hindsdale Wave Research Facility (OHH-WRF) at Oregon State University. The main goal of these experiments was to resolve the controversy regarding the dependence of damage on the spectral shape and/or the characteristics of wave groups.

ENVELOPE AND WAVE HEIGHT FUNCTIONS

Rye (1982) reviewed the methods for analyzing wave groups and concluded that wave groups measured from field data compared quite well with those obtained from numerical simulations using linear algorithms. The validity of the linear hypothesis was also obtained by Goda (1983) and by Battjes and Vledder (1984) for wave groups in non-shallow waters.

In his classic treatise on random noise, Rice (1954) developed an extensive theory that may also be applied to linear surface gravity waves where the envelope theory appears to be appropriate for analyzing wave groups. Medina and Hudspeth (1987) and Hudspeth and Medina (1988) used the envelope theory of Rice and focused their attention on only some of the more important aspects for analyzing wave groups. The envelope theory, originally applied to 1-D wave analyses, may also be extended rather easily to 2-D and 3-D waves and to wave groups.

Assuming that the sea surface elevation at a point is an ergodic Gaussian stochastic process having a variance spectrum $S_{\eta}(f)$, a realization may be approximated by

$$\eta(t) = \sum_{m=1}^M R_m \cos(2\pi f_m t + \theta_m) \quad (1)$$

where M = the total number of wave components in the realization; R_m , f_m , and

θ_m = the amplitude, the frequency, and a random phase angle, respectively, of the m^{th} wave component. The random phase angle is uniformly distributed in the interval $U[0, 2\pi]$. The Hilbert transform, $\hat{\eta}(t)$, of $\eta(t)$ is given by

$$\hat{\eta}(t) = \sum_{m=1}^M R_m \sin(2\pi f_m t + \theta_m) \quad (2)$$

and the analytical function, $AF(t)$, by

$$AF(t) = \eta(t) + j\hat{\eta}(t) = A(t)\exp(j[\theta(t) + \phi]) \quad (3)$$

where $j = \sqrt{-1}$; $A(t)$ = the envelope function; and $[\theta(t) + \phi]$ = the instantaneous phase angle defined by

$$A(t) = \sqrt{\eta^2(t) + \hat{\eta}^2(t)} \quad (4)$$

$$\theta(t) + \phi = \text{ARCTAN} \left[\frac{\hat{\eta}(t)}{\eta(t)} \right] \quad (5)$$

In the complex plane, Hudspeth and Medina (1988) identified $AF(t)$ as an orbital movement consisting of a vertical displacement of a point floating in the sea surface $\eta(t)$ and a horizontal displacement $\hat{\eta}(t)$. An instantaneous wave height, $H(t) = 2A(t)$, and a local radian frequency, $\Omega(t) = d\theta(t)/dt$, were defined. The statistical properties of these two functions were evaluated and related to the characteristics of wave groups.

The envelope theory may be extended to 2-D experiments in wave flumes using space (x) and time (t) as the independent variables. The water surface elevation in a wave flume may be expressed as

$$\eta(x, t) = \sum_{m=1}^M R_m \cos[2\pi(\lambda_m x - f_m t) + \phi_m] \quad (6)$$

where ϕ_m is a random phase uniformly distributed in the interval $U[0, 2\pi]$; and λ_m is the inverse of the m^{th} wave length computed from by

$$f_m^2 = \left(\frac{g}{2\pi}\right) \lambda_m \tanh(2\pi \lambda_m h) \quad (7)$$

where h is the water depth, and g is the acceleration due to gravity. The Hilbert transform of $\eta(x, t)$ in the space and time domains may be defined as

$$\hat{\eta}(x, t) = \sum_{m=1}^M R_m \sin[2\pi(\lambda_m x - f_m t) + \phi_m] \quad (8)$$

where x and t are considered to be space and time parameters for time and space domain calculations, respectively. The envelope and wave height functions in the wave flume are given by

$$H(x,t) = 2 A(x,t) = 2 \sqrt{\eta^2(x,t) + \hat{\eta}^2(x,t)} \quad (9)$$

The variance spectrum in the space domain, $S_\eta(\lambda)$, may be related to the variance spectrum in the time domain, $S_\eta(f)$, according to the linear dispersion relationship and

$$S_\eta(f) df = S_\eta(\lambda) d\lambda \quad (10)$$

The properties of waves and envelopes in the time domain may be projected to the space domain to obtain

$$4 S_A(\lambda) = S_H(\lambda) \sim (8-2\pi)m_0\Gamma_\eta(\lambda) \quad (11a)$$

$$S_{H^2}(\lambda) \sim 64m_0^2\Gamma_\eta(\lambda) \quad (11b)$$

$$\Gamma_\eta(\lambda) = \frac{2}{m_0^2} \int_0^\infty S_\eta(x+\lambda) S_\eta(x) dx \quad (12)$$

where $S_{H^2}(\lambda)$ and $S_H(\lambda)$ are the variance spectra of $H^2(x,t)$ and $H(x,t)$ in the space domain (t fixed); and $\Gamma_\eta(\lambda)$ is the corresponding spectral density function (unit variance). The envelope spectral density functions in space and time are not related by the linear dispersion relationship.

The spectral density functions for waves and envelopes in space and time may be used to estimate the mean wave velocity and mean group celerity for irregular waves. The flux of energy in a wave flume is approximately proportional to $C_g H^2(x,t)$, where C_g is the mean group celerity. Therefore, it is reasonable to test if $H^2(t)$ at the toe of a rubble mound breakwater affects stability.

Realizations of different discrete waves with the same flux of energy and local wave height and period characteristics may be expressed by

$$\eta_\psi(x,t) = \sum_{m=1}^M R_m \cos[2\pi(\lambda_m x - f_m t) + (\phi_m - \psi)]; 0 \leq \psi \leq 2\pi \quad (13)$$

where ψ is a constant phase shift given to each component. Digital-to-analog simulations make it possible to simulate a desired wave train at the toe of the structure.

DESCRIPTION OF EXPERIMENTS

The effects of wave groupiness on the stability of the armor layer of rubble mound breakwaters do not appear to have been treated in a consistent manner in previous studies. The published results of these experiments do not always give a

precise indication of the wave grouping characteristic that significantly affected the stability. Johnson et al.(1978) indicated that wave trains with long wave runs and high GF are more damaging. However, Burchart (1979) suggested that sea states with short wave runs are the most damaging. Finally, Van der Meer(1988) could not identify any significant differences between wave trains with high GF, long wave runs and narrow spectra and wave trains with low GF, short wave runs and broad spectra.

The apparent contradiction from these published experimental results may possibly be resolved by the wave grouping characterization model proposed by Mase and Iwagaki (1986). They considered two independent characteristics: a) a wave groupiness factor and b) a run length. Our experiments exploit the model of Mase and Iwagaki (1986) using linear wave theory. Our final results will demonstrate those wave grouping characteristics that significantly influence the stability of the armor layer of rubble mound breakwaters.

In order to analyze the influence of wave groups on the stability of the armor layer, two different design methodologies were considered as being representative of the state-of-the-art methods for design: 1) the S.P.M. method (1984); and 2) the highly elaborated Van der Meer method (1988). In both of these two methods, the stability of the armor layer is controlled mainly by

$$N_s = \left[\frac{\rho_r H_s^3}{W \left(\frac{\rho_r}{\rho_w} - 1 \right)^3} \right]^{\frac{1}{3}} \quad (14)$$

where N_s is a stability number; H_s is the significant wave height; W is the median value of the mass distribution of rocks in the armor; and ρ_r and ρ_w are the mass densities of the rocks and water, respectively.

The following secondary factors also affect the stability (or damage function): slope, thickness of armor layer, permeability of the structure, number of waves in a run, surf similarity parameter or mean period, roughness and placement of the armor rocks, and wave groupiness. In our experiments, most of these secondary factors were held constant in order to compare the stability number and the wave grouping characteristics of wave runs with damage (or erosion of the armor layer). The 3.7 m. wide wave channel was divided into two equal halves in order to test simultaneously the same rubble mound breakwater profile but with two different armor layer rock sizes (viz., $W_L=13$ kg. and $W_S=10$ kg.). Consequently, each run provided two different surf similarity parameters in order to evaluate the influence of wave period on stability.

Fig. 1. Schematic of Wave Channel Used for Experiments.

Profiles of the armor layer were recorded after each run in order to measure damage (erosion). A surveying rod with an articulated foot (1 ft. diameter) was used to measure the armor layer profile at every foot. Two hydrophones and nine pressure transducers were placed inside the structure in order to detect rock movement and to measure pressures in the secondary layer.

Two fundamental wave grouping characteristics were considered: 1) the spectral shape related to the mean run length and 2) the energy flux exceedance pattern related to the groupiness factor. The spectral shape and mean run lengths were evaluated using random waves simulated from a Goda-JONSWAP spectra having the same H_s and T_{01} parameters but different peak enhancement factors; viz., $\gamma=1$ and $\gamma=10$. Because breakwaters are subject to damage only from wave heights above a certain threshold level, our experiments were designed to attack the breakwater structure with energy levels above a specified threshold level. Irregular wave trains with envelopes having different energy flux exceedance parameters (related to the groupiness factor) were selected from Monte Carlo realizations of random waves.

Two different realizations of $H^2(x,t)$ were selected for each spectral shape (viz., $\gamma=1$ & $\gamma=10$). These two realizations had relatively high and low envelope exceedance coefficients, α , computed from

$$\alpha = \frac{\alpha'}{E[\alpha']} ; \alpha' = \frac{1}{N} \sum_{n=1}^N \left[\frac{H(n\Delta t) - H_{10}}{H_{10}} \right]^2 \delta(n) \tag{15}$$

where $\delta(n)=1$, if $H(n\Delta t) > H_{10}$ and $\delta(n)=0$, if $H(n\Delta t) < H_{10}$; N is the number of data points in the time series; Δt is the discretization time interval; $H(t)$ is the wave height function measured at the toe of the structure; and $H_{10}=1.27 H_{m0}$. The low and high values for α were selected from one-hundred DSA random wave realizations simulated from two Goda-JONSWAP spectra ($\gamma=1$ & $\gamma=10$), with $T_{01}=3.0$ sec., $f_{min}=0.7 f_p$, and $f_{max}=2.5 f_p$. Four simulations with the maximum and minimum values of α for each spectral shape were selected for the experiment. Initially, a threshold level of H_{10} was used in Eq. 15; however, changing H_{10} to H_s did not change the statistics of α significantly.

For each of the four envelopes, the constant phase shift used in Eq. 13 was $\psi=0, 2\pi/3, 4\pi/3,$ and 2π . Because wave trains having $\psi=0$ & $=2\pi$ are identical, the differences in the measured damage for $\psi=2\pi/3$ & for $\psi=4\pi/3$ means that only the wave height and wave period functions are controlling the stability. Therefore, sixteen wave trains (unit variance) of 650 waves were simulated corresponding to: 1) two spectral shapes ($\gamma=1$ & $=10$); 2) two envelope exceedance coefficients (high and low α); and 3) four phase shifts (viz., $\psi=0, 2\pi/3, 4\pi/3,$ and 2π). The levels of energy in the physical simulations were increased in discrete increments in order to make the stability numbers for the small and large rocks equal in consecutive runs. Seven runs of sixteen wave trains were simulated with significant wave heights determined from

$$H_s(k) = 0.43 \left(\frac{W_L}{W_S} \right)^{\frac{k-1}{3}} ; k=1,2,\dots,7 \quad (16)$$

where $H_s(k)$ is the significant wave height in meters corresponding to the k^{th} run.

Three ultrasonic wave gauges were placed 10 m. from the toe of the structure in order to obtain two records of the incident and reflected wave trains (vide Fig. 1). The wave board did not have direct-digital-control in order to cancel the waves reflected from the structure. Consequently, the measured incident wave trains contained some multi-reflected waves. The method used to separate the incident and reflected wave trains is a modification of the method proposed by Goda and Suzuki (1976).

EXPERIMENTAL OBSERVATIONS

Rock profiles, wave records, video records of run-up, and visual observations of rock movements were recorded during the experiments. The rock profiles were used to calculate the damage defined as the normalized erosion of the armor. The wave records obtained from the three ultrasonic wave gauges located 10 m. in front of the structure were used to measure the waves incident on the structure.

The armor damage was calculated from the eroded area of the mean measured profiles corrected for small errors in measurements and for settlement. Distances along the profiles were normalized by the equivalent cube size (Iribarren) or nominal diameter (Van der Meer), $D_n = (W/\rho_r)^{1/3}$. The Eroded Volume Function (EVF) is defined as the corrected cumulative sum of the differences between the eroded profiles and the original profile. The damage is defined as the maximum value of the EVF.

Two spectral shapes ($\gamma=1$ & $=10$); two envelope exceedance coefficients (high & low α); four phase shifts ($\psi=0, 2\pi/3, 4\pi/3,$ & 2π); two rock sizes ($W_L=13$ kg. and $W_S=10$ kg.); and seven wave runs of increasing energy (Eq. 16)

gave a total number of 512 rock profiles and 224 values of damage. Damage observations from runs $\psi=0$ & $=2\pi$ were used as replicates in order to estimate the statistical variability of the experiments. A comparison between the results obtained from $\psi=2\pi/3$ & $=4\pi/3$ demonstrated that no significant difference was observed by changing the phase shift, ψ . Therefore, the experiments contain four replicates for each of the seven runs with the values of the parameters γ , α , & W held constant.

Measurements of damage at different levels of wave energy were recorded. In order to compare with the definition of damage in the S.P.M. (1984), the breakwater crest elevation was assumed to be equal to the design wave height. The active zone of damage for the experiment ($K_D=4$, $\cot \beta=2$, and $\rho_r/\rho_w=2.74$) was about $31D_n^2$. The data for damage given in the S.P.M. (1984) may then be reasonably approximated by

$$\frac{H_s}{\left[\frac{\rho_r}{\rho_w} - 1 \right] D_n} = N_s = 1.15 [\cot \beta]^{\frac{1}{3}} \sqrt{D} \quad (17)$$

where D is the damage or normalized eroded armor; β is the slope; N_s is the stability number; and $D_n=(W/\rho_r)^{1/3}$ is the nominal diameter. We note that Van der Meer and Pilarczyk (1987) have proposed a different equation.

It would be possible to compare the damage function proposed by Van der Meer (1988) using values for $P=0.2$ (low permeability), $\xi_z=2.2$, and $M=1100$ waves with the damage function estimated from Eq. 17. However, the Van der Meer formulae (1988) were not used for comparisons because they depend critically on the value of the permeability parameter which is too difficult to estimate for design. Van der Meer and Pilarczyk (1987) suggest typical values for P for typical cross sections. However, the two cross sections used in our experiments have values for $0.1 < P < 0.4$. Consequently, estimates of damage may vary by as much as 50% about the average value of $P=0.2$. Because the selection of the parameter P is too subjective to use for design, we have not included the Van der Meer formulae in our comparisons.

Both Eq. 17 and the Van der Meer formulae (1988) suggest a fifth power relationship between damage and the significant wave height. Figure 2 compares the following experimental data for the small size rock: a) envelopes E1 ($\gamma=10$, $\alpha=1.8$) and E3 ($\gamma=10$, $\alpha=0.5$); b) envelopes E2 ($\gamma=1$, $\alpha=1.6$) and E4 ($\gamma=1$, $\alpha=0.5$); c) envelopes E1 and E2; and d) envelopes E3 and E4. The damage function estimated by Eq. 17 and 95% confidence intervals for the experimental data are also included in Fig. 2. Comparisons for the large size rock were similar.

Figure 2 demonstrates that damage produced by envelopes E1 and E2 were similar and clearly higher than damages produced by envelopes E3 and E4. This implies that the mean run length and spectral shape are not relevant for estimating armor stability. On the contrary, the envelope exceedance pattern significantly affects the stability. In addition, the surf similarity parameter significantly affected the stability because all of the damage functions for small size rocks gave systematically higher values than those for large size rocks (with a ξ_z 4.5% lower).

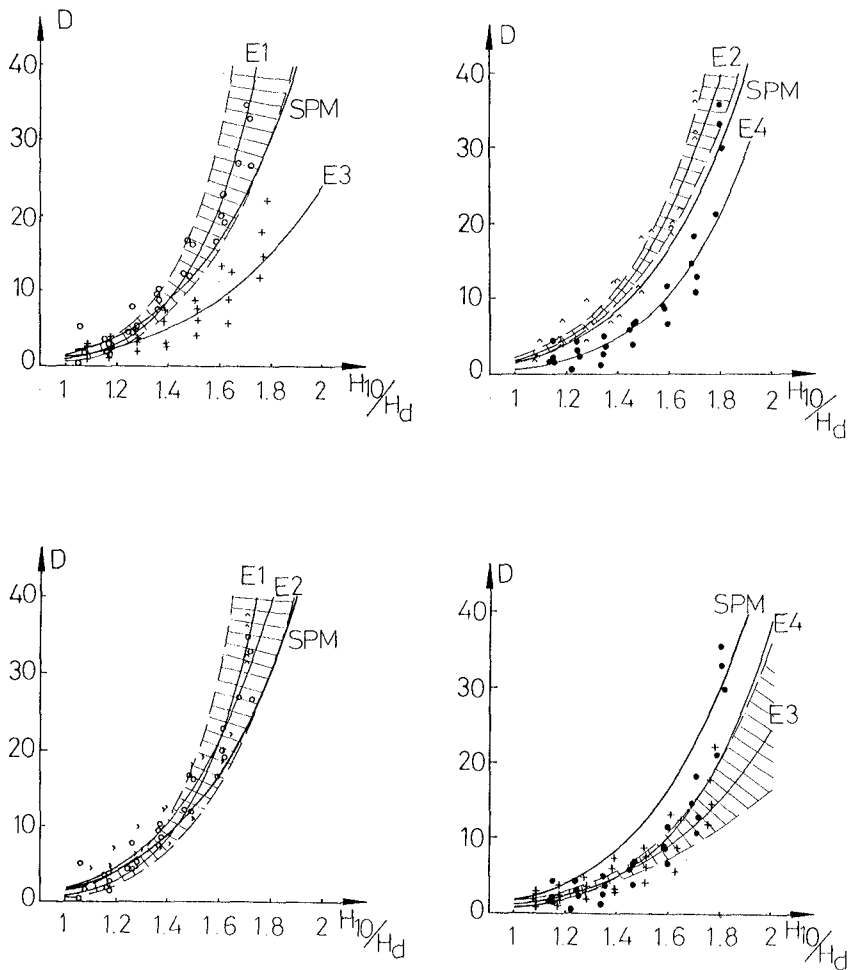

Fig. 2. Comparison of Damage to Small Rocks: a) Narrow & b) Broad Spectra; c) High & d) Low α .

In the past, characteristics of wave groups have only been correlated with spectral peakedness, with mean run lengths, or with other related groupiness parameters. These groupiness parameters have not proven to be completely satisfactory for determining the stability of the armor layers. However, our experimental data demonstrate that wave envelopes may be correlated with stability. Two wave trains incident at the toe of a structure, having exactly the same spectral shape and Rice groupiness parameter, may have significantly different wave envelope functions. By analyzing the wave envelope function as a measure of wave groupiness, it is possible to determine the one that will cause the more damage.

The envelope exceedance coefficient, α , may be related to a groupiness factor, not as defined by Rice, but by $GF = \sigma[H^2(t)]/8m_0$. This definition may not be calculated by the SIWEH as proposed by Funke and Mansard (1979). If the GF were calculated by the SIWEH, it would be biased and would depend on the spectral shape in a way similar to the Rice definition. Our definition for a GF was found to be highly correlated with the envelope exceedance coefficient α computed from analyses of 1000 DSA random simulations for the two spectral shapes used in the experiments (viz., $\gamma=1$ & $=10$). For both of these values of γ , a linear relationship given by $GF=(9+\alpha)/10$ was found to correlate with the simulated data at the 90% confidence level. The mean value of α is $E[\alpha]=1$ by definition and the standard deviation depends on the spectral shape; e.g., $\sigma[\alpha] \approx 0.45$ if $\gamma=10$ & $\sigma[\alpha] \approx 0.30$ if $\gamma=1$.

CONCLUSIONS

The envelope exceedance coefficient, α , defined by Eq. 15 and correlated with the groupiness factor, $GF = \sigma[H^2(t)]$, is a groupiness parameter which controls the stability. Random wave trains in wave flumes may have exactly the same spectral shape, but cause different levels of damage to the armor. The groupiness parameters α or GF may be able to resolve as much as 50% of the variability of the mean damage for a given design sea state and storm duration.

The spectral shape and the number of waves alone are not sufficient to describe the characteristics of wave groups and amount of armor erosion. Wave groups are more appropriately described by the parameters given for the envelope exceedance coefficient, α , or for the groupiness factor defined by $GF = \sigma[H^2(t)]/8m_0$. The spectral peakedness parameter and the mean run lengths are incomplete parameters for analyzing armor stability.

The influence of wave groupiness on armor stability may be of the same order of magnitude as the storm duration. The statistical variability of the observations, and the limited number of cases analyzed in these experiments do not permit a more precise description of the effects of wave groups on the stability of rubble mound breakwaters. However, for a preliminary design, it appears to be

reasonable to modify existing formulae for damage functions by a factor of $(\alpha)^{1/2}$. The envelope exceedance coefficient, α , in random seas demonstrated a log-normal distribution having $E[\alpha]=1$ and $\sigma[\alpha]$ ranging from $[0.30 < \alpha < 0.45]$ depending on the spectral shape.

CHAPTER 117

Monitoring hydraulic loads on the Eastern Scheldt Storm Surge Barrier

Leo Klatter¹, Jan Konter² and Tom Jongeling³

1. Abstract

The paper describes the monitoring program that has been set up for the hydraulic loads on the Eastern Scheldt Barrier. The strategy for the measurements will be discussed in detail. The results of the measurements, that have been performed yet, will be presented. These results are discussed only briefly, because the evaluation of the results has not been completed yet.

2. Introduction

The Eastern Scheldt Barrier is located in the mouth of the Eastern Scheldt and is built across the three main channels; Hammen and Schaar both one kilometer wide and Roompot two kilometers wide (See figure 1). The barrier consists of 62 basic sections. Such a basic section is 45 m wide and is built up as following (See figure 2):

The sandbed is covered by a filtermat. On these mat concrete piers are placed. The final flow opening is framed by a concrete sill beam and an concrete upper beam. A steel gate driven by hydraulic cylinders can close the flow opening. On top of the piers a motorway bridge is located. The piers and sill beams are packed in by a rubble sill structure.

All structural elements were prefabricated at a remote construction site, and have been placed by heavy floating equipment.

Figure 2: Elements in the Eastern Scheldt Barrier

3. The monitoring system

In an early stage of the design of the barrier it was decided to set up a monitoring program for the entire barrier project (See van Westen, 1990 for the effects of the barrier on environmental aspects).

This paper describes the monitoring system for the hydraulic loads on the barrier itself.

The need for this monitoring system is dictated by the following reasons:

- The innovative design concept called for extrapolation of existing techniques and development of new techniques.
- The probabilistic design coupled the design loads and the rules for operating the barrier. Incertainties in the design are "balanced" against each other.
- The design concept with large prefabricated elements placed on a sand bed foundation made construction tolerances and later deformations critical items.
- The design lifetime of the barrier of 200 years made evaluation of subjects as fatigue of the steel gates and life time expection of geotextiles necessary.

A monitoring system has been designed by the Dutch Rijkswaterstaat and its contractors, in close cooperation with Delft Hydraulics and Delft Geotechnics.

The following items are monitored:

- The hydraulic boundary conditions; waves, waterlevels and currents.
- The loads on the structural elements with special attention for:
 - steel gates; effect of wave impacts, stress variations and response of the gates.
 - upper beam; wave impacts and the response of the beam.
- Foundation aspects (van Heteren et al, 1988). The measurement system is set up to enable a trace back of the forces (by waves and waterlevel difference) through the structure and the response of the foundation; pore pressures and deformations of the subsoil.
- Concrete technological items.
- The behaviour of the rubble sill, bedprotection and scour holes.

It is obvious that it is impossible to measure every item at every pier location. The following strategy has been chosen: extensive measurements are performed at selected locations. In the Schaar-channel at gate S13 and pier S9, in the Roompot-channel around pier R22, gate R21 and upper beam R20 (See figure 3).

Figure 3: Measurement locations

At all pier locations the overall displacements are measured once a year. Most of the measurements are concentrated during storm closures the of the barrier, with additional campaigns for example to determine natural frequencies of the gates.

All measured data are gathered by a data acquisition system (DAS). The large number of sensors, over 250, with frequencies ranging from 10 - 1000 Hz made a powerful computer system necessary. The DAS is located in the operating post (figure 3).

Before results of the measurements will be presented, attention will be paid to the difference between field measurements and model tests:

- In model tests the boundary conditions that are applied, are mostly even more extreme than the design conditions. Field measurements however are likely to take place under rather moderate conditions.
- Model tests are these days performed in conditioned, sheltered areas while field conditions are relatively rough.
- This is important for the selection of the instruments.
- Model tests are planned operations. Field measurements are occasional operations and the conditions for the measurements are more or less a surprise.
- Model tests are relatively cheap compared to field measurements.
- Model tests can be repeated. In field measurements, of say once a 10 years conditions, failure, one has to wait for another 10 years (statistically) before these measurements can be repeated.

Because of the items mentioned above, translation problems will occur when interpreting field measurements: To evaluate the design, the level of the field measurements has to be translated to the design level, with the complication that the design level of the structure, as built, may differ from the theoretical design level.

The results of the measurements are valid at the measuring locations only. So the results have to be translated to other locations or well, for a complete evaluation of the design of the barrier.

When one compares the results of the field measurements with those from model tests, again a translation to another level and/or other location has to be performed. The translation problems, related to the evaluation of the design with results of field measurements have to be considered thoroughly for the design of a monitoring system.

4. Measurements performed

Since the barrier has been completed in 1986, it still took some time to overcome problems encountered, mainly with the data acquisition system. By the end of 1988 the system became operational.

In december 1988 the first real measurements were performed. These were measuring campaigns were the single gates, R21 and S13 were closed to measure wave impacts and the response of the gates.

In February 1989 the first storm closure of the barrier was performed, and a complete measurement campaign has been performed then (see figure 4).

Figure 4: Storm report 13th - 14th February 1989

Westerly winds, with windspeeds between 15 and 20 m/s, caused a maximum waterlevel of 3.08 m above mean sea

level. The maximum waterlevel difference, with the barrier closed was 2 m, with wave heights of over 2 m (significant wave height).

In Oktober 1989 a special measuring campaign was performed to measure the natural frequencies of the gate S13. These are important for the interpretation of the dynamic response of the gates.

February 1990 a heavy storm occurred. This most recent storm was a succesfull one from monitoring point of view; westerly winds, with wind speeds over 20 m/s lasted for more than two days (see figure 5).

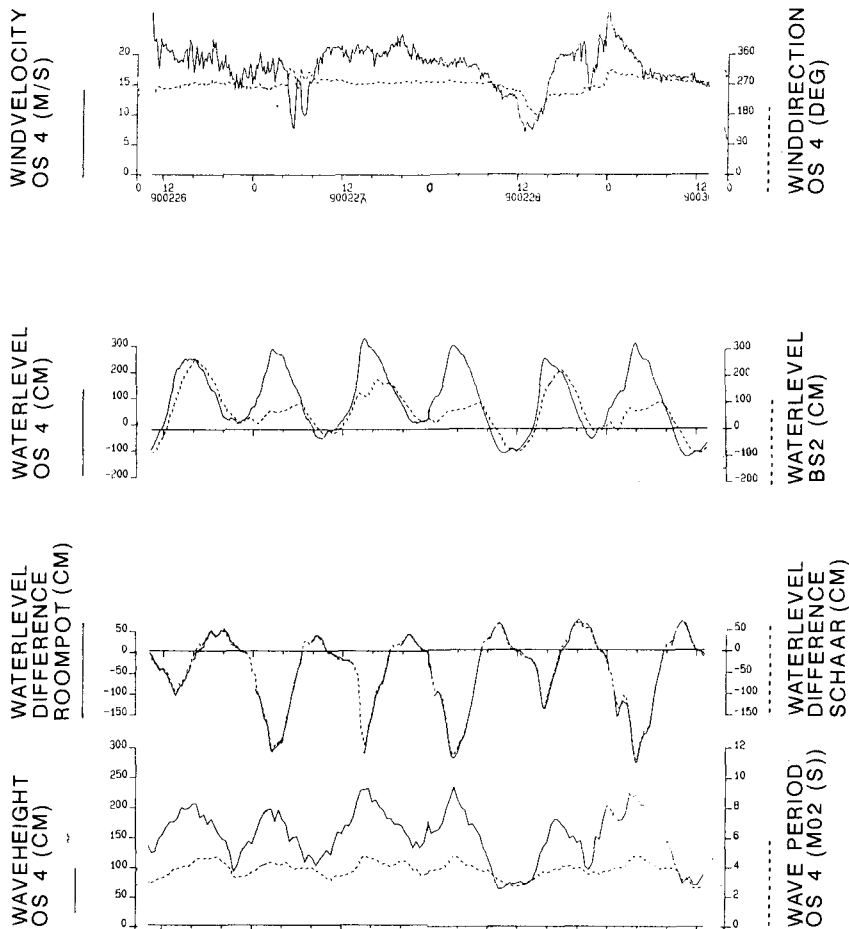

Figure 5: Storm report 26th February - 1st March 1990

The barrier has been closed four times. A maximum water level of 3.61 above MSL was reached. The maximum waterlevel difference was approx 2.4 m with the barrier closed. The significant waveheight reached almost 2.5 m.

Figure 6: Registration WAVEC buoy

Figure 6 gives the spectral registration of the directional WAVEC buoy. The wave frequencies are in the range of 10 to 3 seconds. The average wave period is 5 seconds.

Rather rough conditions with caused a lot of damage to the Dutch coast. However compared with the design conditions the storm conditions were rather moderate; see table below:

design values	February 1990
waterlevel 5.4 , above MSL	3.6 m
waterlevel difference 5 - 6 m (*)	2.4 m
wave height 5 - 6 m (*)	2.5 m

(*) Due to the probabilistic design an exact design level cannot be given

Until now most of the 1989 data have been processed. The 1990 data are still being processed. Interpretation is planned together for all data.

5. Results

The following paragraph gives an overview of the results of the measurements that were analysed until now. Most of the results are based on the 1989 data.

5.1 Wave impacts on upper beam

Figure 7: Instrumentation upper beam

When the gate is open, wave impacts against the bottom of the beam can be expected when the water level is in the vicinity of the bottom of the beam, which is at 1 m above MSL. The prestressed concrete beam is relatively light and is sensitive to these loads.

The upper beam is instrumented with pressure gauges, accelerometers, a force gauge in one of the supports and a waterlevel gauge (See figure 7).

As an example of the results, the registration of four pressure gauges are presented in figure 8.

The maximum pressure in this registrations is approx. 30 kN/m^2 with 1 m significant wave height.

Figure 8: Registrations pressure gauges upper beam.

Figure 9 shows the registration the accelerometers in the middle of the beam and at the support, the registration of the force gauge in the support of the beam and the registration of the waterlevel under the beam. The interpretation and the evaluation of the design still have to be completed. Especially the area opposed to an impact is of importance here.

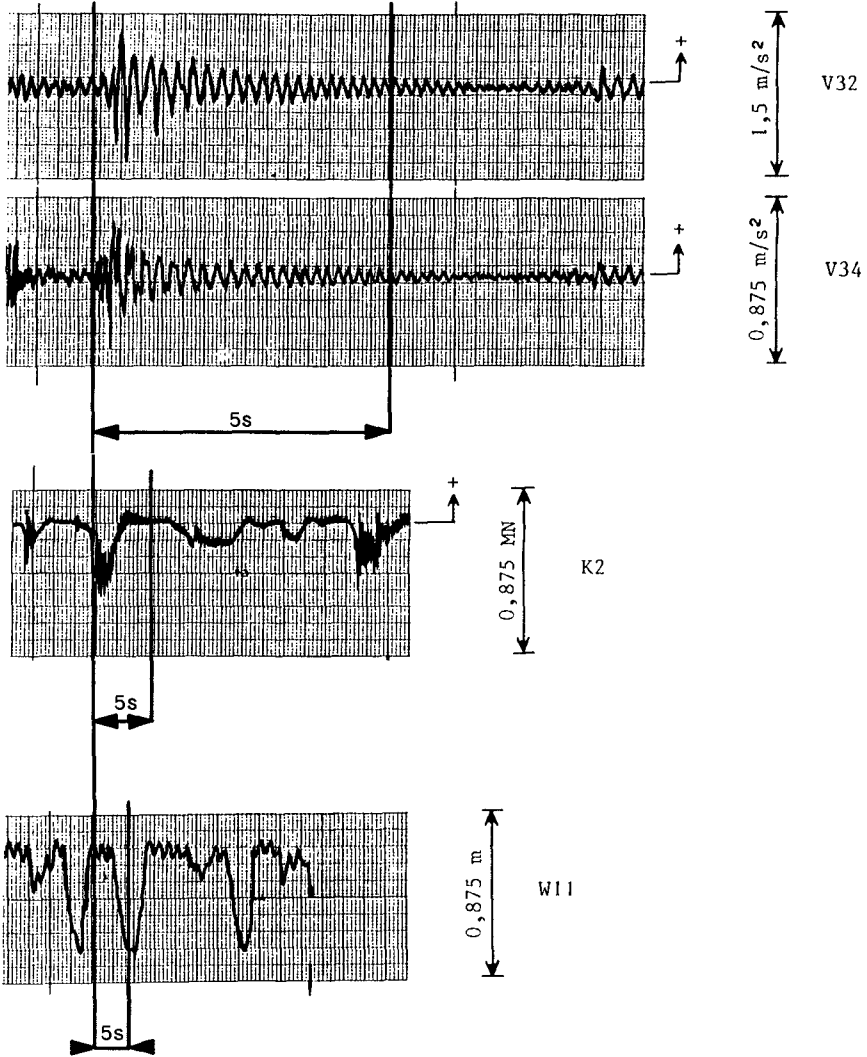

Figure 9: Registrations accelerometers, force gauge and water level gauge upper beam.

5.2 Wave forces on steel gates

The forces in the girder system of the gate are measured by strain gauges attached to the tubes of the girder system.

In this way the force distribution in a single node is measured by instrumenting all five connecting tubes. The horizontal and vertical lateral forces on the gate are measured indirectly by instrumenting six thross girders close to the supports of the gate.

Figure 10 gives an example of one of stress signals related to the lateral force in the gate. The figure gives the stress signal and the exceeding percentage of the stress amplitude.

Figure 10: Registration stress signal (below) and exceeding percentage stress amplitude (top) of "lateral force gauge", gate S13.

Evaluation of these results is important, because the gates are constructed of a high strength type of steel that must be inspected on fatigue cracks. The results will be used to evaluate the inspection strategy of the gates.

Wave impacts on the girder system of the gates occur when the girders cross the waterlevel. Impacts have been recorded during the 1990 storms and are under evaluation.

5.3 Boundary conditions

The evaluation of the boundary conditions has been concentrated on waterlevels en flow parameters, and the validation of the flow models that were used for the design (Klatter et al, 1989).

Further the discharge coefficients of the barrier were determined.

Still under evaluation are the result of wave models for reflection coefficient and effects of crest length of the waves.

5.4 Foundation aspects

To evaluate the geotechnical aspects, measurements were performed of pore pressure generation and dynamic deformation of the subsoil. To evaluate these aspects much more measuring data will be needed. The relatively low level of the loads, compared to the design conditions makes an evaluation of the results, especially of the accelerometer data very difficult.

5.5 Bed protection

The bed protection has been monitored by acoustic and visual inspections. These inspections were mainly used to trace damages in the bed protection due to the construction activities of the barrier. Additional field measurements were performed to determine the design load of the critical part of the bed protection close to the barrier. Herefore pilot locations were fitted up with relatively light stones. These locations were carefully monitored and in this way the critical waterlevel difference for initial damage to the bed protection could be determined effectively.

6. Conclusions

The items that have been evaluated so far showed that a monitoring program is highly valuable for:

- optimization of the rules for the barrier operations, the closure and opening strategies of the gates.
- optimization of the inspection program.
- evaluation of the design tools, for example the flow models that were used for the design of the barrier.

Setting up a monitoring system requires much more than just rebuilding a scale model instrumentation at full scale.

- Certain phenomena can better be determined in model tests than in field measurements (eg. stability of rubble stone, liquefaction of the subsoil).
- A selection of a limited number of signals that are representative for the design problems is of vital importance.
- The measuring system should be redundant, critical sensors should be installed double.
- The translation of the measured signals to design conditions must be possible. One has to account for the relatively moderate conditions that can be expected in field measurements.
- The system must be an operational system. The latest high-tech, state of the art systems are likely to fail.
- Optimization is necessary, because the costs of a field monitoring system are extremely high. Not only the construction costs should be considered but also the maintenance costs and operational costs.

The experience is, that it is much easier to record a few giga-bytes of data than to retrieve, analyse and interpret these data.

CHAPTER 118

Stresses in Tetrapods: Results of Large Scale Model Tests

Bürger, W.W.^{*)}; Oumeraci, H.^{**)}; Partenscky, H.W.^{***)}

Abstract

This paper intends to review the experimental research work performed at the University of Hannover on the structural stability of tetrapods. It presents particularly the first results from the hydraulic and pendulum tests which suggest that:

- the most critical location of the armour units with respect to structural stability has been found at and slightly above still water level;
- for regular waves a well defined relationship can be found between incident wave parameters and the induced dynamic and quasi-static stresses. In the case of irregular waves, however a clear relationship appears to exist only for quasi-static loads;
- the critical IRIBAREN-Parameter with respect to structural stability is in the same range as the one found for hydraulic stability;
- a linear relationship has been found between impact bending stress and impact velocity for the tested tetrapods 50 kg - 1.8 t.

1. Introduction

It is now widely accepted that not only the hydraulic stability but also the structural integrity of concrete armour units should be considered in the design of rubble mound breakwaters. Due to a number of diffi-

^{*)} Dipl.-Ing., Research Engineer

^{**)} Dr.-Ing., Senior Research Engineer

all University of Hannover, SFB 205, Franzius-Institut,
Nienburger Str. 4, 3000 Hannover 1, FRGermany

culties, no generally applicable criteria and procedures accounting for the breakage of the units and its effect on the whole armour stability are yet available. One of the difficulties is the determination of the actual load history for armour units in a breakwater environment.

The main objective of this paper is to contribute to a better understanding of the actual single impact loads and the subsequent impact stresses.

2. Description of the Research Program

The investigations on the structural behaviour of concrete armour units constitutes a part of an extensive basic research program on rubble mound breakwaters conducted at the University of Hannover and supported by the German Research Council (DFG) within the scope of the "Sonderforschungsbereich 205" (SFB 205). Aside from the research program on structural behaviour of concrete armour units, a number of aspects like hydraulic stability, internal and external flow field as well as geotechnical stability are also being investigated (BÜRGER et al., 1988). The different tests which has been performed on structural stability of the units are given in Fig. 1.

The main purpose of the hydraulic tests with respect to structural stability of the units was to determine the actual response of the units in a breakwater environment as a function of the incident waves and of the location of the units on the slope.

The static tests were primarily destined to calibration as well as to verification purposes related to the sensitivity of the measuring techniques used.

The pendulum tests have been performed, aside from other objectives (BÜRGER et al., 1989), in order to:

- a) compare the impact strain history of tetrapods with full cross section and of the same tetrapods with a reduced cross section,
- b) develop a correlation between the recorded response of the units in the hydraulic model and that in the pendulum tests,
- c) determine impact strain-time functions for instrumented model and prototype tetrapods.

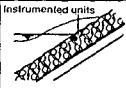

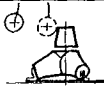

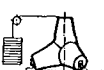

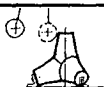

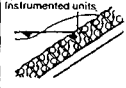

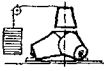

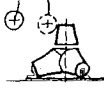

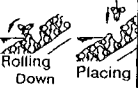

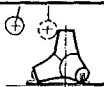

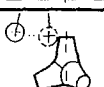

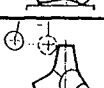

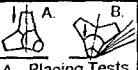

Units	Hydraulic Tests	Static Tests	Pendulum Tests	Drop Tests	Additional Tests
Tetrapods 1 kg (reduced cross section)					
Tetrapods 1 kg (full cross section)					
Tetrapods 50 kg (reduced cross section)					
Tetrapods 50 kg (full cross section)					
Tetrapods 250 kg (full cross section)					
Tetrapods 1.8 t (full cross section)					

Fig. 1 Review of performed tests on structural stability at the University of Hannover

The results of the aforementioned experimental investigations, together with available results from basic research on impact and cyclic loading of concrete are intended to be used for the development of design criteria for the structural stability of the units.

Although a reliable design of concrete armour units with respect to their mechanical strength requires the consideration of all loads and environmental impacts (BÜRGER et al., 1989), the most relevant loads, however, are induced by the combined action of waves and the weight of the units.

3. Large Scale Hydraulic Model Tests

3.1 Description of the Breakwater Model and the Instrumented Units

Fig. 2 shows the cross section of the model in the Large Wave Channel, Hannover.

Fig. 2 Cross section in the Large Wave Channel (GWK)

The instrumented tetrapods used in the hydraulic tests had a reduced cross-section in order to measure the wave-induced static loads, quasi-static loads and to a certain extent also dynamic loads (Fig. 3).

Each of the oppositely applied strain gauges on the square steel bar was assigned to one recorder channel. Two signals are thus obtained on channels 1 and 2, respectively, when the tetrapod leg is subjected to load.

3.2 Calibration of the Instrumented 50 kg-Tetrapods

The sensitivity of the measuring instruments and the necessary amplification factor for the tests can be determined by calibration.

By increasing the load, the linearity of the measured values can be checked and both hysteresis and creep effects may be detected.

Fig. 3 50 kg-tetrapod with reduced cross section

On the test rig (Fig. 4) the tetrapod is centrally fixed and the load is transferred horizontally to the upwards directed leg by hanging on calibrated weights up to 100 kg in increments of 10 kg.

Fig. 4 Set-up for static tests

Strain and bending moments for both axes were recorded at each stage of loading. Thereafter, the leg was unloaded, the steel plate was rotated and the instrumented leg loaded once again.

To check the long-term behaviour of the strain gauge applications and also to determine whether a single calibration value was valid for all tests, a calibration was performed after each series of the hydraulic tests.

3.3 Testing and Recording Procedures for the Hydraulic Tests

3.3.1 Testing Procedure

Since the forces acting on a unit will show a large variability based on the units location and the wave climate, the tests covered up all critical locations on the breakwater (Fig. 5) and were performed with both regular and irregular waves, started with low wave conditions and increased in steps of 10 - 20 cm until a significant unit movement was observed.

After every test series, the cover layer was completely removed and reconstructed by the same persons, to ensure as far as possible similar positions of all tetrapods and similar porosity in all tests.

Fig. 5 Positions of the instrumented tetrapods

3.3.2 Data Collection and Recording Procedure

The measured data were recorded at a sampling frequency of 400 Hz. At the same time, the measured values were also registered at a sampling frequency of 11000 Hz by a Video Pulse Code Modulator (Video PCM).

All tests were recorded using two video cameras, one recording the whole armour layer, and the other one the instrumented units. So the movements, rocking or displacement, can be compared with the measured strain data.

Before and after every test, photographs were taken in order to determine the changes which occur in the whole armour layer and the instrumented units.

3.4 Data Reduction

Among the more recent results of hydraulic model tests using instrumented armour units only those of ANGLIN et. al. (1988) are related to the analysis of quasi-static load data. High frequency signals related to impact loading are not measured or are filtered out. However, only regular waves are used for the tests. Therefore, only an averaging procedure for the analysis of the results is adopted; i.e. the average load is determined for each test and then correlated to the wave parameters tested.

In contrast to this approach the tests performed in the Large Wave Channel at the University of Hannover are based on regular and irregular waves and consider all types of loads: static, pulsating and impact loads as well as slamming.

For the irregular wave tests, however, it is necessary to analyse the correlation between the single wave and the induced load. For the tests with more than one thousand waves the interaction between wave parameters and resulting load has to be described individually; i.e. separately for each wave.

The results of the static and dynamic calibration are two calibration factors, one for the static load, pulsating load and slamming (all together called quasi-static load), and the other for the dynamic load. Since the quasi-static and the dynamic load could not be measured separately, the recorded load signal should be splitted into a quasi-static and a dynamic part by a

computer program developed for this purpose. This computer program provides a table containing the wave parameters and the resulting quasi-static and dynamic load for both channels of each tetrapod.

The steps of the program may be described as follows:

1. Identification of the wave occurrence and calculation of the wave duration by analysing the time series of the run-up gauge placed along the slope;
2. Determination of the wave height by analysing the time series of the wave gauge installed in front of the breakwater;
3. Step by step analysis of the measured strain-history for each instrumented tetrapod and both channels;
 - a) Adjustment to zero separately for every time window;
 - b) Calculation of the quasi-static strain by filtering the high-frequency signals;
 - c) Determination of the resulting maximum quasi-static strain according to the following formula:

$$\epsilon_{qs} = \sqrt{\epsilon_{qs1}^2 + \epsilon_{qs2}^2} \quad (1)$$

- d) Evaluation of the dynamic strain by determining the difference between the zero-adjusted raw data and the quasi-static strain;
- e) Determination of the maximum impact strain according to the following formula:

$$\epsilon_d = \sqrt{\epsilon_{d1}^2 + \epsilon_{d2}^2} \quad (2)$$

- f) Print out of the values in a table for each test.

Fig. 6 a) and b) show the separated signals in the same test for both dynamic and quasi-static load and for two different positions of the instrumented tetrapods.

3.5 First Results

The position of each individual tetrapod is of a stochastic nature. When installing the instrumented tetrapods, it is not possible to position the instrumented legs in such a way that the pre-loading

a) Tetrapod D Position 1

b) Tetrapod F Position 7

Fig. 6 Strain records (Wave conditions: JONSWAP-Spectrum, $H_g = 0.90$ m, $T_p = 4.5$ s)

(static loading) is the same from one test series to the next. This also means that the point of contact between an instrumented tetrapod and its neighbouring one is not reproducible. Each reinstallation therefore represents a new loading variant.

Although the tetrapods occupy the same positions shown in Fig. 5 for various periods in the test series, the points of contact, and thus the strain or bending moments, are not directly comparable. As a rule, each test with new wave parameters and settlement during the running tests implies new bearing conditions.

Therefore, a first attempt to determine a relationship between strain and corresponding incident wave parameters resulted in a large scatter of the data, particularly for large wave heights (BÜRGER et al., 1989). Linear regression analysis led to correlation coefficients in the same range as found by ANGLIN et.al. (1988). However, a better correlation could be obtained by considering only the maximum strain-values (BÜRGER et al., 1989).

From the analysis of the data related to the location of the instrumented tetrapods, the highest wave-induced stresses within the tetrapods generally occur at and slightly above the still water level.

Some results from the tests with irregular waves are shown below.

Selected are the locations 1 and 7. The results of one tetrapod with position 1 and those of one tetrapod with position 7 are presented.

Fig. 7 a) & 7 b) show the wave induced strain vs. the IRIBARREN-Parameter for position 1 and for quasi-static and dynamic load, respectively. The same relationship is shown in Fig. 7 c) & 7 d) for position 7. It appears that the maximum dynamic strain is an order of magnitude higher than the quasi-static one. However, both occur at the same IRIBARREN-parameter ($I = 3.0$).

4. First Results of Pendulum Tests

As shown in Fig. 1, pendulum tests have been performed on 1 kg- and 50 kg-Tetrapods with a reduced and a full cross-section, as well as on 250 kg - and 1.8 t - tetrapods with full cross-section.

A detailed description of the tests and some results have already been published (BÜRGER et al., 1989).

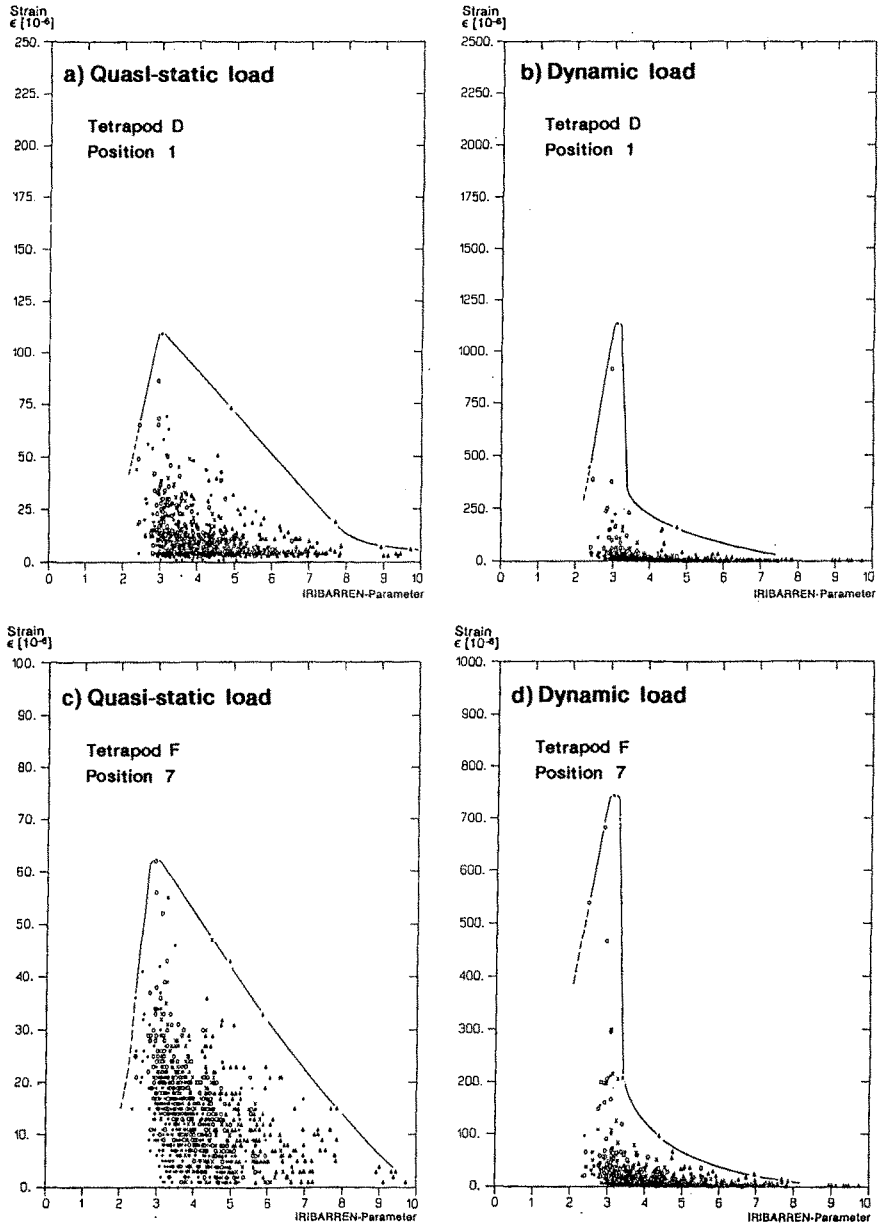

Fig. 7 Quasi-static and dynamic strain vs. IRIBARREN - Parameter (JONSWAP-Spectrum, $H_S = 0.90$ m, $T_p = 4.5$ s)

Considering the range of accuracy of the measurements and the range of the strain rate investigated ($\dot{\epsilon} = 0.061$ to 1.0 s^{-1}) Fig. 8 suggests that a linear relationship between dynamic bending stress σ and impact velocity v appears to exist for the tested tetrapods (50 kg to 1.8 t); i.e. the following relationship holds:

$$\frac{\sigma_{T1.8}}{v_{T1.8}} = \frac{\sigma_{T250}}{v_{T250}} = \frac{\sigma_{T50}}{v_{T50}} \quad (3)$$

where the indices T1.8, T250 and T50 refer to the 1.8 t, 250 kg- and 50 kg-tetrapods, respectively.

Fig. 8 Bending stress vs. impact velocity for the tested tetrapods

This supports the similitude criterium derived by NISHIGORI, et al. (1985) which suggests that the impact stress in the model (σ_m) is related to that in the prototype (σ_p) by:

$$\frac{\sigma_m}{\sigma_p} = \sqrt{\lambda} \quad (4)$$

where λ is the linear scale factor.

5. Perspectives

Within the scope of the ongoing analysis of the data it is planned to:

- . clarify the similitude problems related to the transfer of the measured impact strains to prototype conditions;
- . include the data related to static loading of the tetrapods in the analysis, so that the total loading can be assessed;
- . elaborate a design procedure with respect to the structural stability of tetrapods based on the experimental results and on an extensive literature study.

CHAPTER 119

EXPERIMENTS ON COASTAL PROTECTION SUBMERGED BREAKWATERS: A WAY TO LOOK AT THE RESULTS

Gregorio Gómez Pina¹
J.M. Valdés Fernández de Alarcón²

1. ABSTRACT

In this paper, various damping action on submerged breakwater test results will be analyzed, in order to improve the methodology for future analysis. Experimental data from the authors and other researchers will be analyzed.

2. INTRODUCTION

The use of submerged detached breakwaters has become very attractive in beach restoration projects. The knowledge of how these breakwaters can affect coastal dynamics is necessary for almost any study.

Even though two-dimensional experiments on wave transmission on submerged breakwaters have been carried out by several authors, the application of the results to particular coastal protection projects is difficult and inapplicable in many cases.

Very often, relatively highly sophisticated wave propagation or coastal evolution models consider the influence of the submerged breakwater in a rather simplistic way: by a particular value of the transmission coefficient (K_t).

Furthermore, the application of the coefficient might not respond to realistic situations, depending on model test conditions, data analysis, wave evolution characteristics in the area between the submerged breakwater and the beach, etc.

¹ Coastal Project Manager, MOPU, Dirección General de Puertos y Costas, Paseo de la Castellana 67, Madrid 28046 SPAIN.

² Civil Engineer, Centro de Estudios de Puertos y Costas, (CEPYC-CEDEX), Antonio López 81, Madrid 28026, SPAIN.

3. OBJECTIVE OF THIS STUDY

The purpose of this study is to analyze various damping action on submerged breakwater test results, in order to improve the methodology for future analysis. Due to the breadth of this topic as well as the space limitation, the two following aspects are emphasized in this paper: A) Why it is too simplistic to model all processes by the parameter K_t (normally measured in one position behind the breakwater). B) The potential for mis-interpreting data when analyzing K_t .

4. ANALYSIS OF PHENOMENA INDUCED BY A SUBMERGED BREAKWATER

4.1. Characteristic zones of study

For analyzing hydrodynamic phenomena induced by a submerged breakwater or barrier, five characteristic zones are considered by the authors. This zones are schematized in Fig. 1.

Fig. 1.- Scheme of Characteristic Zones of Study.

Fig. 2 tries to emphasize the two following concepts (which are sometimes ignored or not considered relevant):

- A) Most of experimental data are measured in zone III (near the breakwater) while practical application is needed in zone IV-V (near the beach).

- B) Some hydrodynamic phenomena induced in zones IV-V (difficult to be separated for practical applications) can affect data acquisition in zone III (i.e. wave reflection at the beach).

Fig.2.- Interrelation between Characteristic Zones.

4.2. Summary of Hydrodynamic Phenomena

In the authors' opinion, an attempt to show the complexity of the hydrodynamic phenomena induced by a submerged breakwater would help in understanding the existing shortcomings in data acquisition and application. Some of this hydrodynamic phenomena found in the area between the breakwater and the beach were corroborated from some of the experimental results carried out at CEPYC (CEDEX) by the authors (Ref.6, 7, 8 and 15). This will be shown in a very simple, schematic and "descriptive" way (including a few "liberties" with the drawings).

ZONE I

Phenomena: shoaling; wave reflection; breaking (or not) in front of breakwater.

Dimensionless Parameters

$$K_r = H_r / H_i$$

$$I_r = \tan \alpha / \sqrt{H_i / L_i}$$

$$X_B / L_i$$

Fig. 3.- Zone I

ZONE II

Phenomena: wave breaking (possible); wave energy losses; long wave pulsative amplification; on/off-shore flow.

Dimensionless Parameters

$$C_L \text{ (breaking, friction, turbulence, percolation)}$$

$$B / L_i \text{ (or } B / gT^2, B / H_i, B / d)$$

$$F / L_i \text{ (or } F / gT^2, F / H_i, F / d)$$

Fig. 4.- Zone II

ZONE III

Phenomena: wave transmission and damping; shifting of transmitted wave periods; wave set-up; periodic on/off-shore flow; possible standing wave patterns; possible longwave oscillations.

Dimensionless Parameters

$K_t = H_t/H_i$
 T_t/T_i
 ξ/H_i

Fig. 5.- Zone III

ZONE IV-V

Phenomena: wave height and period evolution; wave reshaping and possible wave breaking, interference with waves reflected from the beach.

Dimensionless Parameters

Evolution of K_t , T_t/T_i , ξ/H_i
 Influence of (K_r) beach.

Fig. 6.- Zone IV-V

5. LOOKING AT THE RESULTS IN CHARACTERISTIC ZONES

The two aforementioned concepts (A and B) derived from Fig. 2, should be kept in mind by Coastal Engineers when analyzing experimental data on wave damping action on submerged breakwaters as well as for future model tests. Model tests carried out at CEPYC (CEDEX) (Ref.6, 7 and 8) have shown that in certain

cases, it is not so simple to draw conclusions on wave damping by only analyzing K_t (generally in zone III). In other words: submerged breakwaters could (under certain conditions) be not as "efficient" as one might think, when the evolution of the transmitted wave parameters are compared in the characteristic zones (especially in zone IV-V).

Fig. 7 schematizes the CEPYC model set-up and parameters of study. Notice that waves were measured in 13 points past the breakwater. Also, breaking wave conditions (induced or not by the submerged breakwater) were investigated.

Fig. 7.- Scheme of Transmitted Wave Evolution Model Set-Up.

The two following figures, from the above mentioned model tests, have been chosen as a "reflexion" on the importance of measuring wave characteristics (H , T , ξ) in more than one or two points behind the breakwater.

The first figure is an example of the "relative efficiency" in crest width increment: in zone III (where most of measurements were taken) the increment seems to be very favorable in decreasing transmitted wave height (H_t) while the efficiency is not as clear for zone IV-V (close to the beach).

The second figure remarks the importance of wave reshaping and possible new breaking once the submerged breakwater has induced waves breaking on the breakwater (notice also the set-down points outlined on this figure).

Fig.8.- Example of Wave Transmitted Height (Ht) Evolution

Fig.9.- Example of Wave Set-Up (ξ) Evolution

For a thorough understanding of the main hydrodynamic phenomena induced after wave breaking, including undertow, the authors would like to point out the elegant work carried out by Prof. Svendsen (i.e. Refer.14). New studies trying to "link" the main submerged breakwater parameters and wave evolution in characteristic zones would be very beneficial for coastal engineering applications.

6. LOOKING AT THE RESULTS OF K_t IN ZONE III

The potential for mis-interpreting data, even in the simplest cases of analyzing K_t in zone III will be discussed.

6.1. Transmission Coefficient (K_t) versus relative crest width (B/L)

For coastal engineering applications it is important to know which is the optimum breakwater crest width (B) which gives the minimum transmission coefficient (K_t). From dimensional analysis, the following expression can be derived as one possibility:

$$K_t = f(B/L, H_i/d) \quad (1)$$

To accurately plot the results it is important to note the fact that a change of crest width will also alter the reflection coefficient (K_r) and thus the incident wave height (H_i), according, for instance, to the method of Goda and Suzuki (Ref.5). Therefore, it is not so easy to get the exact values of the term H_i/d unless a large number of model tests are performed. In other words: the plot of K_t versus B/L (Eq. 1) should include the mean value and also the standard deviation of the relative incident wave height term (H_i/d), due to the difficulties in obtaining "exact values" of (H_i/d). This fact, in the authors' opinion, has not been considered in the existing literature.

Even though different authors (Ref.3, 4, 10 and 13) have shown the existence of distinctive maximum and minimum values of K_t in Eq. 1, it has not been remarked whether these curves respond to the spreading characteristics of the results themselves or to the real hydrodynamic problem, according to the equations involved in that modelling.

This fact is important when analyzing experimental results, since one could think (at first) that the obtained results, for instance, might not be valuable due to the large data spread, even when this spread is inherent to the mathematics involved in modelling (i.e. matching conditions).

6.2. Poble Nou Wave Transmission Study

This study, carried out at the CEPYC (Ref.6 and 7), was part of a large project to greatly improve the sea front in Poble Nou, in Barcelona (Spain), for the '92 Olympic Games. Basically, the aim of the model tests was to investigate the efficiency of increasing crest

width on wave damping action.

For that, three crest widths ($B = 34.50$ m. and $\pm 15\%$ on this value), and three wave periods ($T=7, 9$ and 11 secs) were tested, for a crest freeboard $F=0.00$ m. Also a mean water elevation of 0.50 m., associated to the largest wave period was considered.

There were 108 model tests (a relatively large number, in our opinion), in order to get well defined maximum and minimum values in the curves K_t versus B/L , as explained in 6.1. Fig 10 is a typical example of a curve representing Eq. (1):

Fig. 10.- A Typical Example of K_t versus B/L_o , for $\bar{H}_i/d=0.306$ (Crest Freeboard $F=0.00$ m.).

From Fig. 10 one could ask the following reasonable questions:

A) Are the results valuable due to the apparently large data spreading shown in Fig. 10 ?

B) Should a fitting curve be used ?

C) Could a figure obtained by connecting all points, and showing distinctive maximum and minimum points, be a real response of the wave transmission phenomenon ?

D) Supposing the above mentioned questions were known, which should be the design value for the relative crest width B/L ?

And, before giving any answer to all these questions, one could also make the following logical reasoning: Which is really the most simple mathematical

answer to these questions?

In Fig. 11, the geometric parameters and also the reflected (R and D) and transmitted (C and T) waves are shown for the three regions in an impervious submerged obstacle. The four variables R, C, D and T are calculated using the four known matching conditions related to velocities and pressure.

A graphic solution is shown in Fig. 12, using the most simple case of short waves, linear theory and no dissipation. Also a crest freeboard of 0.50 m. is adopted, to greatly simplify the problem.

Fig. 11.- Geometric and Wave Parameters for a Submerged Obstacle.

Fig. 12.- A Typical Solution of K_t versus B/L_0 for an Impervious Submerged Obstacle ($F=0.50$ m) Using Linear Theory and Short Waves.

In Fig. 12 it can be seen that in the analysis for the most simple case of short waves, linear theory, and no wave dissipation, the solution for K_t (and also for K_r) shows distinctive maximum and minimum values, as found in other works on submerged obstacles.

However, the theoretical transmission coefficient of linear waves propagating over a submerged porous step decays monotonously with the relative crest width (B/L), but reflection coefficient does oscillate (Losada, personal communication, 1990). This distinct

behaviour is worthy of further research.

Fig. 13 summarizes the results obtained in Ref.6, related to wave transmission (K_t) versus relative crest width (B/L_0) for different relative incident wave height (H_i/d) and zero freeboard ($F=0$) values.

Fig. 13.- K_t versus B/L_0 for Different (H_i/d) and Zero Freeboard ($F=0$).

The following conclusions could be drawn from Fig.13:

- The wave transmission coefficient shows a decreasing oscillatory trend when plotted against the relative crest width (B/L_0) with distinctive maximum and minimum values.

- The relative incident wave height (H_i/d) seems to have influence only on the amplitude of K_t , but not in the values of (B/L_0) corresponding to the maximum and minimum values of K_t .

- Small variations of B/L_0 , corresponding to the minimum values of K_t , gives rise to relatively high values of K_t . Thus, design criteria based on minimum K_t values might be too risky due to the joint appearance of all the complex hydrodynamic phenomena involved and model scale effects in two-dimensional tests.

Unfortunately, the relative small number of model tests considering a freeboard $F=0.50$ m. make the authors unable to compare the results with those obtained applying the most simple theoretical cases of impervious and porous submerged steps, as obtained in Losada's work (Ref.11).

6.3. Influence of Breaking Conditions

The influence of taking into account different breaking conditions (i.e. breaking in front of the breakwater, breaking induced by the breakwater or not breaking) on wave transmission is investigated.

6.3.1. Plotting of Results

The plotting of different dimensionless coefficients versus a new parameter $Ir*(B/F)$, provided a reasonably good fitting in general, as well as a good physical understanding of the results, including the influence of breaking (Ir = the known Iribarren's parameter = $\text{tg}\alpha/\sqrt{H/gT^2}$; $\text{tg}\alpha$ = bottom slope in front of the breakwater; B = crest width; F = crest freeboard).

Space limitations have prevented the authors from presenting some of the results obtained in References 1, 2, 9, 13 and 15, using the above mentioned parameter. However, figure below is the result of analyzing some specific data from Dattatri et al (Ref.3) using the condition of breaking over the breakwater, presented in Nakamura et al (Ref.12).

Fig. 14.- Influence of Breaking Conditions on Kt

The following conclusions could be drawn from Fig.14:

- Large data spreading occurs if breaking conditions are not separated adequately.

- The fitting of Kt versus the parameter $Ir*(B/F)$, both for breaking and non-breaking conditions (using Nakamura's criteria), seems to be quite

reasonable: the fitting for breaking condition should show a quasi-asymptotic decreasing curve as expected ($K_t \rightarrow 1$ for relatively small values of B/F and $K_t \rightarrow 0$ for large values of B/F). On the other hand, the pattern for non-breaking condition shows a definitely different shape. This could be also expected since values of $K_t > 1$ are reported for non-breaking conditions (i.e. Ref.12 and 15).

7.-CONCLUSIONS

1) Most of the practical data obtained by different authors is measured in zone III. Thus, one should be aware of this when they are used in zone IV-V for beach application.

2) Since various transmitted wave parameters evolve in different zones as wave propagates landwards, more detailed information should be provided in model tests. In particular, several wave gauges, appropriately separated, should be used for measurements of wave transmitted parameters. Also, reflective beach characteristics and distance from the beach to the breakwater should be reproduced as reliably as possible.

3) When analyzing data in one particular zone, the different processes affecting that zone should, if possible, be separated, for a proper interpretation and application of this data. In particular, breaking conditions (such as breaking induced by the breakwater, breaking in front of the breakwater, or not breaking at all) should be adequately distinguished. This observation should be kept in mind when simple formulae for combined wave transmission data are tried for general design purposes.

4) The use of the parameter $(B/F) \cdot I_r$ versus the other dimensionless parameters (transmission, reflection and losses coefficients, ratio between transmitted and incident wave period and relative wave set-up) seems to improve the fitting of results, especially if the above-mentioned breaking conditions are separated.

5) Experimental studies on wave transmission on submerged breakwaters and zero crest freeboard, as the one explained about Poble Nou, have shown that curves representing transmission coefficients (K_t) versus relative crest width (B/L), for various relative incident wave heights (H_i/d) show, in general, distinctive maximum and minimum values.

Since theoretical studies, with negative crest freeboard, also show in general oscillatory patterns, experimental data should not at first be treated as though they were presenting a large spreading (as is sometimes reported).

6) Even though the above mentioned experimental curves show in general, distinctive maximum and minimum values, the joint appearance of all the complex hydrodynamic phenomena, explained at the beginning of this paper, together with possible model scale effects, make design criteria based on minimum K_t values too risky.

8.-ACKNOWLEDGEMENTS

We would like to thank the Director of CEPYC (CEDEX) for giving permission to publish this paper which has mainly been based on the experimental results carried out by the authors there.

This piece of work could not have been written without the help of most of the people working at the Experimental Division of CEPYC. Space limitation prevents us from writing their names individually. Also the draftsman Mr. Carlos Redondo helped us make the presentation at the ICCE'90 quite enjoyable.

Finally, we would like to thank Professor Miguel Losada and Dr. Raúl Medina, from the University of Santander, for the many helpful discussions we have had with them while writing this paper.

CHAPTER 120

NUMERICAL SIMULATION OF THE MOTION OF A LOOSE REVETMENT BLOCK

A. Bezuijen¹
J. Wouters ²
H. den Adel³

Abstract

The movement of a block lying loose in a placed block revetment under wave loading was simulated numerically. The results have been compared with the results of large scale model tests in which the motion of a block and the pressure distribution in the filter layer underneath was measured. It appeared that the mechanism concerning the pore pressure distribution and the block movement are described well in the numerical program. The block movement as calculated in the program is higher than measured. The reason for this is described in this paper.

Introduction

A research programme on placed block revetments has led to design rules for the cover layer and filter layer of this type of revetment (Bezuijen et al, 1987, Burger et al, 1990a, Bezuijen et al, 1988). Large scale model test have been performed to verify the design rules. The research programme was commissioned by the Public Works Department of the Ministry of Transport and Public Works in the Netherlands (Rijkswaterstaat) and performed by Delft Hydraulics and Delft Geotechnics.

In this paper the experimental verification of the computer program STEENZET/1+ will be treated. This program is used to calculate the stability of the blocks in a placed block revetment. The program calculates the pore pressures in the filter layer as a function of the geometry, the permeability of both cover layer and filter layer and the wave pressures. For fixed blocks it was shown before that the calculated pore pressures correspond with the measured pore pressures in large scale model tests (Bezuijen et al, 1987). However the displacement of a block will influence the

¹ Research engineer, Delft Geotechnics, P.O. Box 69, 2600 AB Delft, the Netherlands

² Research engineer, Delft Hydraulics, P.O. Box 152, 8300 AD Emmeloord, the Netherlands

³ Research engineer, Delft Geotechnics

pressure distribution below that block, leading to smaller pore pressures underneath the blocks (Burger et al, 1990a). In the model tests described in this paper block motion as well as the pressure underneath a moving block were measured and therefore it is possible to compare measured (and calculated) pore pressures underneath a moving block and its motion.

Model tests

The model tests have been performed in the 230 m long, 7 m deep and 5 m wide wave flume of DELFT HYDRAULICS. All tests were carried out on a slope 1 : 3 and with a water depth of approximately 5 m. Two revetments were tested simultaneously. Hereto the 5 m wide slope at the end of the flume was divided into two sections each 2.5 m wide; these two sections were called East and West, respectively. In total 2 * 6 types of revetments were tested. For the present paper the following 3 revetments are of importance:

	D	B	L	s	b	D _{f15}	n
	[m]	[m]	[m]	[mm]	[m]	[mm]	[%]
I West	.15	.25	.30	1.5	0.25	3.6	38

VI West	.30	.50	.50	3.8	0.35	17.3	38

in which: D is the thickness of the blocks, B is the width of the blocks, L is the length of the blocks, s is the width of the joints between the blocks, b is the thickness of the filter layer, D_{f15} is the grain size of the filter material material that is exceeded by 85% of the mass of the grains and n is the porosity of the filter.

An example of two revetments in the Delta flume is shown in photograph 1, a cross-section in figure 1.

With revetment I West as a starting-point the following parameters have been varied: the thickness of the filter layer, the size of the blocks, the grain size of the filter material, and the thickness of the blocks.

In each section there is one block that is completely loose from the adjacent blocks. By means of a displacement gauge the movement of the loose block was measured, see Photograph 2. The wave pressure distribution on top of the revetment as well as the pressure distribution underneath the blocks are of primary importance for the stability of the block revetment and resulting block motion. In order to measure these pressure distributions 19 pressure gauges were placed on top of the revetment and 24 pressure gauges underneath the blocks, viz. 12 on the East and 12 on the West side. The loose blocks and two adjacent blocks, one higher and one lower were provided with both a pressure gauge on top of the block and a pressure gauge under the block. In this way the resulting uplift pressure over these blocks could be measured during the tests.

Three H-T combinations at a constant ξ were tested: a combination for which no block motion was expected, one for the start of block motion and one for a large block motion. H is the wave height, T is the wave period, ξ is the breaker parameter: $\xi = \tan(\alpha)\sqrt{H/L}$, α is the slope angle and L is the wave length.

The following ξ values were used for the tests: $\xi = 1.0, 1.5, 2.0, 3.0$ and 4.0 . The tests used in the simulations were run with regular waves.

Before the actual test, the water level in the flume was adjusted to the level, where the loose block is maximally loaded, providing a maximum block displacement in the actual test.

Photograph 1. Example of two revetment sections

STEENZET/1+

The basic assumptions of STEENZET/1+ are the same as described for STEENZET/1 (Bezuijen et al, 1988). Both models calculate the pore pressures in a granular filter layer below a cover layer of placed blocks.

The permeability of the subsoil is assumed to be much lower than the permeability of the filter layer and therefore the flow in the subsoil has no significant influence on the flow in the filter

layer. The permeability of the cover layer is also lower than the permeability of the filter layer, resulting in a flow parallel to the slope in the filter layer and perpendicular to the slope in the cover layer.

Photograph 2. Displacement gauges in instrumented blocks next to the moving block

Without any block movement the flow can be described with a finite difference scheme that is shown in figure 2, allowing for flow parallel to the slope in the filter layer and perpendicular to the slope in the joints.

Darcy's equation combined with conservation of mass leads to a description for the potential in each node.

$$\phi_i = \frac{1}{1 + 2 \frac{kbD}{k'L^2}} \left\{ \frac{kbD}{k'L^2} (\phi_{i-1} + \phi_{i+1}) + \phi_{t,i} \right\} \quad [1]$$

where: ϕ_i = piezometric head in the filter layer near joint i (m)

$\phi_{t,i}$ = piezometric head on the revetment near joint i (m)

b = the thickness of the filter layer (m)

D = the thickness of the blocks (m)

k = the permeability of the filter layer (m)

k' = the permeability of the cover layer (m).

At the phreatic surface the piezometric head in the filter layer is equal to the position of the phreatic surface. At the lower end of the revetment the condition $\phi_{i+1} = \phi_{i-1}$ is assumed. If there is no phreatic surface then $\phi_{i-1} = \phi_{i+1}$ for the highest position in the revetment. The potential distribution in the filter layer can be solved if the potential ($\phi_{t,i}$) on the revetment is known. The solution obeys equation [1] for all joints.

Figure 2. Finite difference scheme of STEENZET/1+

Until now the situation without block movement is described. With block movement the equations change.

In the calculations it is assumed that there is only one loose block. The revetment in the experiments is constructed similarly. This seems to be in contradiction with reality where all blocks might move. However pull-out tests have shown that in a block revetment there are only a few really loose blocks, since clamping forces are high between most blocks.

When a block starts to move, water will flow towards the block from the filter layer underneath the moving block. The water will flow from all sides underneath the block. Far away from the moving block nothing will change and the solution as described by equation [1] can be used. This solution can be used to find the solution with block movement.

The finite difference scheme of figure 3 is applied. This scheme allows for horizontal flow along the slope as well. The solution of equation [1] is used as the solution for the side rows. The row in the middle of the filter layer represents the potential distribution underneath a moving block.

The distance between the side rows and the middle row can be determined from an analytical calculation. It was determined (Bezuijen, 1986) that the right distance equals the leakage factor:

$$\Lambda = \sqrt{\{(k/k')bd\}} \quad [2]$$

This value was used for the horizontal distance in figure 3.

The finite difference scheme of figure 3 allows the flow from 8 directions to the point $\phi_{b,i}$, see figure 4. This flow is assumed to be symmetrical around the moving block which means that only 5 different terms remain. The contributions 3 and 5 are added to the finite difference scheme to describe the more or less radial flow to the moving block. However these terms depend the other

terms and so a correction term on the flow direction 3, 4 and 5 in figure 4 is necessary. By performing a calculation with sheer horizontal flow it was found that this term has to be:

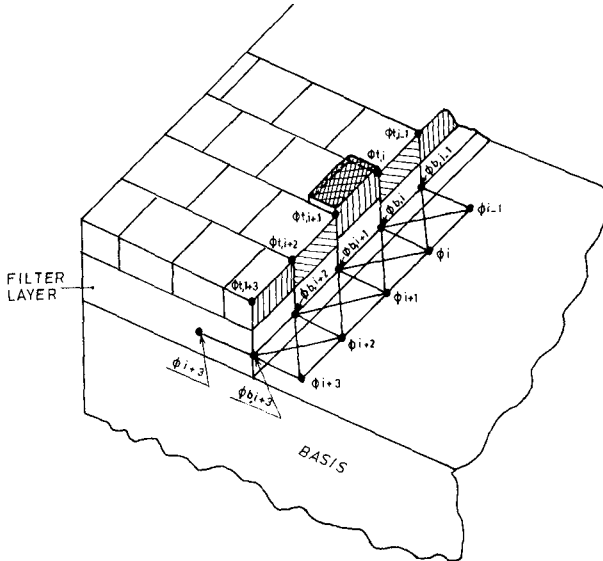

Figure 3. Finite difference scheme of STEENZET/1+

$$c = \left[\frac{2\Delta}{\sqrt{(L^2 + \Delta^2)} + 1} \right]^{-1} \quad [3]$$

The discharge for each contribution in figure 4 can again be determined from Darcy's law. Continuity demands that the sum of all discharges is zero, leading to the set of equations:

$$\begin{aligned}
 kb \frac{\phi_{b,i-1} - \phi_{b,i}}{L} - kb \frac{\phi_{b,i} - \phi_{b,i+1}}{L} + 2kbc \frac{\phi_{i-1} - \phi_{b,i}}{\Delta s [1 - \frac{1}{2} \frac{\Delta L}{\Delta}]} \\
 + 2kbc \frac{\phi_{i-1} - \phi_{b,i}}{\Delta - \frac{1}{2}l} + 2kbc \frac{\phi_{b,i} - \phi_{i+1}}{\Delta s [1 - \frac{1}{2} \frac{l}{\Delta}]} + qb = k' \Delta x \frac{\phi_{b,i} - \phi_d}{\phi} \quad [4]
 \end{aligned}$$

where: $\phi_{b,i}$ = the piezometric head in the column of blocks with the moving block

$s = \sqrt{(\Delta^2 + L^2)}$, the diagonal distance (m) between two different points

$l = L$ for the points of the moving block (otherwise $l = 0$)

This incorporates the fact that underneath the moving block the potential gradient is zero.

Below the non moving blocks $qb = 0$ and the equation (4) can be used to solve $\phi_{b,i}$ for all finite difference points.

Figure 4. Flow direction towards moving block as schemed in STEENZET/1+

Only directly underneath the moving block the situation is different; the amount of pore water may vary due to the block movement. The piezometric head is not the result of a groundwater flow calculation. Neglecting inertia forces, the piezometric head is determined by the piezometric head on the block, the weight of the block and the friction force:

$$\phi_i = \phi_{t,i} + \Delta D (1 \pm f_c \sin \alpha) \quad [5]$$

where:

$$\Delta = (\rho_c - \rho_w) / \rho_w \text{ the relative density} \quad (-)$$

$$\rho_w = \text{the density of water} \quad (\text{kg/m}^3)$$

$$\rho_c = \text{the density of concrete} \quad (\text{kg/m}^3)$$

$$f_c = \text{the friction coefficient} \quad (-)$$

$$\alpha = \text{the slope angle} \quad (^\circ)$$

\pm means + if the block moves up

means - if the block moves down.

In STEENZET/1+ also the effect of inertia is included, but this is omitted here because the influence of inertia is usually small and including inertia leads to more complex formulae. Substitution of equation [5] in equation [4] for the points underneath the moving block leads to a value for q which determines the block movement for one time step. The remaining difficulty is the term $\pm f_c \sin \alpha$ in equation [4]. It is not known in advance in which direction the block will move. In the STEENZET/1+ program this problem is solved by trial and error. One direction of movement is assumed and equation [4] is solved. If the discharge does not fit with that direction, the other one is tried. It is possible that both do not fit; in that case the piezometric head in the filter layer is too small to push a block further-out of the revetment, but too high to let the block move downwards; this means that the block does not move at all. After some displacement it stops temporarily due to the friction with adjacent blocks and although it is not in contact with the filter layer the solution for non moving blocks equation [1] can be used.

The block starts to move as soon as the difference in piezometric head is larger than the difference that corresponds with the weight of the block, or more mathematically if $\phi_{t,i}$

underneath the possible moving block, calculated with equation [1] is larger than calculated with equation [4]. The block movement is calculated by accumulation of the block displacements during each time step. The calculation of block movement stops if the accumulated displacements lead to a negative block movement, which means inwards the filter layer.

Simulation of tests

The results of the experiments were simulated with STEENZET/1+. In the first simulation test SZ 208 was used. This test was run on revetment II-West, a revetment with a long leakage factor, loaded with a wave with a low steepness. Block movement was measured over 1.5 s in this test. Figure 5 shows the measured pressures in this test together with the pressures measured in test SZ 213. This was exactly the same test, only in test SZ 213 the block was fixed.

Figure 5 shows that when a block starts to move, the pore pressure is reduced as long as the block moves out of the revetment. When the block is pushed backwards to its original position, the pore pressure below the block is higher than for the fixed block. The reason for this is that during the outward directed movement of the block, there is a waterflow towards this block. The water partly flows through the joints around the block and partly pushes the block upwards. When the block drops back to

Figure 5. Example of measured pressures and block motion. Pressures with respect to still water. Arrows indicate positive pressure and motion

its original position, the water below the block is 'pushed' into the filter layer, leading to higher pore pressures than in case of no block movement.

Test SZ 208 was used to calibrate the numerical program. It appeared that the friction coefficient between the blocks (see equation [5]) has to be kept zero. This result can be obtained from the test directly by comparing the uplift pressure at which a block starts to move with the pressure corresponding to the weight of the block. The leakage factor see equation [2] of this revetment was also calibrated by means of this test. First the leakage factor was calculated using the results of Den Adel (1987) for the filter layer and of Klein Breteler and Bezuijen (1988) for the cover layer. Thereafter the leakage factor was determined by fitting the results of the calculations with the results of the measurements for test SZ 208. The calculated and 'fitted' leakage factors are shown in table 1.

Test section	Calculated leakage factor (Λ) from literature (m)	by STEENZET/1+ (m)
I	0.67	0.57
II	1.22	1.30
VI	1.13	1.56

Table 1. Leakage factor for the simulated sections, calculated from literature and "fitted" with STEENZET/1+

Figure 6. Test SZ 208, measured and calculated pore pressures below the moving revetment block due to wave attack and resulting block motion ($H = 0.25$ m, $T = 3.7$ s, $\xi = 3.11$)

The results of the simulation show good agreement between the measured and calculated pore pressures, see figure 6.

However the simulated block movement is higher than measured (25 mm measured, 120 mm calculated), due to simplifications that have been used to describe the flow directly underneath a moving block. In the simulations it is assumed that the filter layer below the moving block has a very high permeability (due to fluidisation of that part of the filter layer). In the tests fluidisation was prevented by a geotextile that was placed between the blocks and the filter layer.

With the same values of the input parameters (the leakage factor and friction) test SZ210 on the same revetment was simulated. The result is shown in figure 7.

Figure 7. Test SZ 210, measured and calculated pore pressures below the moving revetment block due to wave attack and resulting block motion ($H = 0.49$ m, $T = 2.7$ s, $\xi = 1.6$)

Again the pore pressures agree quite well, but the calculated block movement is too high (15 mm measured, 75 mm calculated).

Figure 8 shows the measured and calculated pore pressures for test SZ152. This test was run on the revetment I-West with a much shorter leakage factor. Again the results of the simulation are the same: good agreement for the pore pressures, but a calculated block movement that is too high (2 mm measured, 10 mm calculated). The results of the measurements as well as the simulations for this revetment can be compared with the results obtained for the revetment II-West with the longer leakage factor.

This shows that in a revetment with a shorter leakage factor the duration of the block movement is much shorter. For the two tests on revetment II-West it was more than a second. For the test on revetment I it was less than 0.5 s.

Figure 8. Test SZ 152, measured and calculated pore pressures below the moving revetment block due to wave attack ($H = 1.19$ m, $T = 5.15$, $\xi = 1.94$)

Furthermore the moment of maximum uplift pressure appears to be different. In the test on revetment II-West the maximum uplift pressure was found at the time the wave pressure on the block is at minimum. In the test on revetment I-West it was found that the maximum uplift pressure occurs during the pressure rise of the new incoming wave.

A remarkable result was found when analysing experiment SZ617 on revetment VI-West. The measured and calculated pore pressure are in good agreement as long as the block does not move. However when the block starts to move, a discrepancy was found between measured and calculated pore pressures, see figure 9. The reason for this discrepancy was found by re-analysing the measured pressures. It appeared that the block starts to move before the uplift pressure is larger than corresponding to the weight of the block, see figure 10 where the uplift pressure as measured is plotted together with the block movement. The revetment VI-West consists of relatively large blocks of $0.5 * 0.5 * 0.3$ m, with respect to the wave height. Measuring the uplift pressure over these large blocks on only one position leads to an under-estimation of the pressure. The STEENZET/1+ program uses a linear interpolation over one block. In this case this also leads to a slight under-estimation of the uplift pressure and is probably the reason for the discrepancy between calculated and fitted leakage factor (see table 1).

Influence of cover layer permeability

Since good agreement is found between simulations using

STEENZET/1+ and the tests, we are confident that the program can be used to calculate the effect of changes in parameters on the pressure distribution in the filter layer and the block movement.

As an example the influence of the cover layer permeability was calculated. This example is not purely theoretical but has practical implications. When a block revetment is newly constructed the joints between the block will be clean, leading to a relatively large cover layer permeability. However after some time the wave action will transport sand, silt and shells to the revetment and into the joints causing a decrease in the cover layer permeability.

Figure 9. Test SZ 617, measured and calculated pore pressures below the moving revetment block due to wave attack ($H = 0.64$ m, $T = 4.1$ s, $\xi = 2.14$)

Figure 10. Measured uplift pressure compared with block movement

Recent measurements on a 28 years old revetment have shown a decrease in the cover layer permeability from 10^{-3} m/s to 10^{-6} m/s. It was known from earlier calculations (Bezuijen et al, 1987) that a low cover layer permeability leads to high uplift pressures over the revetment, which can possibly damage the revetment. With the model described in this paper it is possible to investigate what will be the influence of a low cover layer permeability on the block movement. Calculations were performed using the wave loading that was measured by wave SZ208. All calculations were carried out with the same revetment geometry, only the permeability of the cover layer was changed.

The results are presented in figure 11. A very permeable coverlayer results in small uplift pressures, too small to cause any block motion. Decreasing the cover layer permeability leads to higher uplift pressures and in an increase of the block motion, but this block motion has a maximum. For very low values of the cover layer permeability the block motion again decreases. This is caused by the fact that the flow in the filter layer towards the moving block is restricted by these very low values of the cover layer permeability. The calculations also show that the permeabilities that are reached right after construction (between 10^{-3} and 10^{-2} m/s) are most dangerous for the stability of the revetment (the block displacement is then at maximum).

Figure 11. Block displacement as function of the cover layer permeability

Conclusions

The numerical simulations of the large scale model tests lead to the following conclusions:

- It is possible to simulate the motion of a loose revetment block under wave attack with STEENZET/1+. The calculated pore pressures

agree well with the measurements. The calculated block movement is somewhat higher for the structures simulated. This can partly be explained by the presence of a geotextile which prevented fluidisation of the filter layer between the blocks and the filter layer in the model tests and partly by some simplifications in the computer program.

- The influence of friction as well as inertia forces on the results of the calculations is negligible.
- The moment of maximum loading depends on the leakage factor. For a revetment with a long leakage factor (much longer than the wave height) the loading is maximum when the wave pressure on the loaded block is minimum. In case the leakage factor is shorter than the wave height, the maximum uplift pressure is present during the increase in the wave pressure caused by the new incoming wave.
- Measuring the pressure at one location on the block can be insufficient when experiments are performed with block dimensions that are of the same order of the wave height, for example test SZ 617 (wave height 0.64 m and block length = 0.5 m). In this test the inaccuracy in the determined uplift pressure became clear since the block started to move before the uplift pressure was larger than the pressure corresponding with the weight of the loose block.
- Simulation of the block movement for a revetment with different values for the cover layer permeability showed that the block displacement as function of the cover layer permeability has a maximum. Although a revetment with a very low cover layer permeability will be loaded with large uplift pressures, the block movement remains limited because the amount of water that can flow underneath the moving block is restricted by the low cover layer permeability.

CHAPTER 121

WAVE PRESSURE ATTENUATION IN BREAKWATER ARMOUR LAYERS

Kevin R. Hall¹

Abstract

An experimental investigation was conducted to examine the change in fluid pressure through a breakwater armour layer as a function of the incident wave characteristics, breakwater geometry, armour unit type, number of layers of armour and core permeability. Values of internal pressure were found to decrease with the number of layers of armour. The largest percentage decrease occurred within the first few layers; although this trend was somewhat influenced by armour type.

Introduction

A set of experimental studies were undertaken primarily to investigate the mechanism of wave energy dissipation that occurs throughout the various zones (core, filter and armour) of a rubblemound breakwater subjected to monochromatic wave attack. In addition, information regarding the phreatic surface motion within the various zones of the structure was collected. The influence of the armour unit type, relative geometry of the armour layer, breakwater slope and the material used to construct the various layers of the structure on wave energy dissipation, wave runup and rundown on the outer surface of the structure and the internal flow generated within the structure was assessed.

These studies were undertaken in a two dimensional wave flume in which a rubblemound breakwater, instrumented with pressure transducers and capacitance gauges, was subjected to monochromatic wave attack. The rubblemound structure consisted of a core (constructed using either 3.5 mm angular, 16 mm angular or 14 mm rounded stone), a filter layer (constructed using either 16 mm angular or 14 mm rounded stone), and an armour layer (consisting of 1 to 5 layers of either 50 mm stone, 50 mm steel spheres or 60 mm cubes).

Preliminary work was required to determine the flow resistance characteristics of the porous media used in the study. This work was undertaken in a steady flow parameter.

Dept. of Civil Engineering, Queen's Univ., Kingston,
Ontario CANADA K7L 3N6

Test Conditions

The basic geometry of the test section is shown in Figure 1. The outer slope of the breakwater was tested at 1:3, 1:2, and 1:1.5. The slopes of the core and filter layers were made the same as the outer slope. The structure was instrumented with 10 pressure transducers, five on the outer slope of the structure at elevations of -20, -10, two at 0 and +10 cm (all elevations referenced to the still water level) and five on the outer slope of the core at elevations of -20, -10, -5, 0 and +10 cm placed along the centreline of the breakwater. Miniature stainless steel diaphragm pressure transducers (Data Instruments AB-15psig) capable of measuring gauge pressures ranging from 0 - 100 kPa were used. Five capacitance gauges for measuring the internal water surface movement were located along the centreline of the structure.

All tests were undertaken with the still water level located 30 cm above the flume bottom. Eighteen combinations of wave height and wave period were used for each test structure and are summarized in Table 1.

The wave height, H , is the wave height measured at the location of the rubblemound structure in the flume with no structure present. The surf similarity parameter, ξ , uses the breakwater slope, θ , the wave height at the structure, H , and the deep water wave length, L_0 .

Model Materials

(i) Core and Filter Materials

Three types of core material were used during the experimental studies; 3.5 mm river gravel, 14 mm river gravel and 16mm crushed river gravel. Table 2 lists the characteristic geometric properties and the relative density of each material. A filter layer was used in conjunction with the 3.5 mm core material and consisted of the 16 mm crushed river gravel described in Table 2.

(ii) Armour Units

Three types of armour units were utilized during the course of the experimental studies. These are summarized in Table 3.

(iii) Permeability

The flow characteristics of the core and filter materials were tested in a down-flow permeameter connected to a constant head tank. The results are given in Table 3 which lists the porosity and the Forchheimer constants, a and b , for each material.

During each test, the pressures and internal phreatic surface conditions were

ET - EXTERNAL PRESSURE TRANSDUCER
 IT - INTERNAL PRESSURE TRANSDUCER
 SG - PHREATIC SURFACE MONITORING GAUGE

monitored until steady state conditions were obtained. Time series records of pressure fluctuation at each gauge location were recorded. Post processing was incorporated to decrease the requirement for data storage.

The pressure was measured at a sampling rate of 50 Hz for a total recording length of ten wave periods. Earlier trials in which pressure was sampled at rates of 20 to 50,000 Hz provided sufficient evidence that a sampling rate of 50 Hz would enable determination of peak pressure. The data were subsequently phase-averaged so that each test segment (wave height-wave period combination) was characterized by a time series having a record length equal to the wave period. For the purpose of further analysis, each phase-averaged time series was characterized by a maximum differential pressure head, ΔP , which describes the maximum variation in recorded pressure over the period of the wave divided by ρg , where ρ is the fluid density and g is gravitational acceleration. Therefore, all pressure measurements were reported in terms of the equivalent head of water. The ratio of maximum differential pressure head, ΔP , to wave height, H , was used to provide a non-dimensional expression.

Results

In order to compare the attenuation of pressure between the various layers as a function of the test variables, the percent attenuation of pressure relative to one layer of armour, $\% \Delta P_1$, was calculated where

$$\% \Delta P_1 = \frac{\left(\frac{\Delta P}{H} \right)_n}{\left(\frac{\Delta P}{H} \right)_1} = \frac{\frac{\Delta P}{H} \text{ for } n \text{ layers}}{\frac{\Delta P}{H} \text{ for } 1 \text{ layer}}$$

Values of $\% \Delta P_1$ were calculated for each wave height-period combination. Table 4 shows values of the average and standard deviation of $\% \Delta P_1$ as a function of the number of layers of armour and elevation of the pressure recording.

In order to reduce the number of variables, the data was refined one step further. For each test series, the differential pressure head for a specified number of layers is presented as a percentage of differential pressure head for one layers, that is

$$\overline{\Delta P / \Delta P_1} = \sum_{i=1}^J \left(\frac{\Delta P_{nj}}{\Delta P_{1j}} \right) / J$$

* the y-l column represents the difference between tests with y layers and l layer.

where $\Delta P/\Delta P_1$	=	average value of ratio of differential pressure head for n layers to differential pressure head for one layer.
ΔP_{ij}	=	differential pressure head for one layer
ΔP_{nj}	=	differential pressure head for n layers
n	=	number of layers
j	=	test segment number
J	=	total number of test segments

Thus plots of $\overline{\Delta P/\Delta P_1}$ provide a graphical representation of the data in Table 4.

Influence of Elevation

The largest reduction in internal pressure as the number of layers was increased occurred at the still water level, whereas the pressure measured at an elevation of -20 cm showed the smallest reduction as the number of layers of armour was increased. This is illustrated in Figure 2.

Influence of Core Type

The influence of the type of core material on the internal differential pressure head was assessed only for a structure with 50 mm stones in the armour layer and a front slope of 1:2.

Figure 3 provides an example of the variation of $\overline{\Delta P/\Delta P_1}$ with the number of layers of armour as a function of core type. At all elevations, the internal pressure measured in core type A ($D_{50} = 3.5$ mm) were the highest. At all elevations, the internal pressures measured in core type B were approximately 15-20 percent lower than those measured in core type A. The internal pressures measured in core type C varied from being equal to those measured in core type A at elevations of the still water level and -20 cm to a 30 percent reduction at elevation -5 cm and a 15 percent reduction at elevation -10 cm. The reason for this variation with elevation is not quite clear, although it may be a consequence of non-homogeneity in core type C. It was suspected that core material C was non-homogeneous because two separate loads of material were used and these may have had slightly differing characteristics.

The influence of core type was found to be relatively linear with the number of layers of armour.

FIGURE 2 INFLUENCE OF ELEVATION ON % ΔP_1

FIGURE 3 INFLUENCE OF CORE TYPE ON % ΔP_1

Influence of Armour Type

The influence of the type of armour unit used in the armour layer on the internal pressure field at the four internal gauge locations is shown in Figure 4 which shows the variation of $\overline{\Delta P / \Delta P_1}$ with the number of layers for a given breakwater slope and pressure gauge elevation.

In general it appears that randomly placed cubes provided the greatest reduction in internal pressures at all elevations on all slopes (with the exception of a few instances). The internal pressures measured for armour layers consisting of stones and spheres exhibited fairly similar trends. Typically cubes provided an additional 10-30 percent reduction in internal pressure, although this usually occurred across the second layer. The rate of change of $\overline{\Delta P / \Delta P_1}$ with the number of layers of armour was similar for all three unit types.

For a breakwater slope of 1:1.5, armour stones exhibited the greatest ability to dissipate internal pressure at the still water level. Cubes exhibited the same trend at all other gauge locations (-20, -10 and -5 cm), with a typical average internal pressure reduction 25-50 percent greater than that of stones, depending upon the number of layers of armour.

For a breakwater slope of 1:2 the greatest internal pressure reduction at all elevations was achieved by using cubes in the armour layer.

As the slope became flatter (1:3), stones and cubes exhibited similar capabilities in providing a reduction in internal pressure, particularly with decreasing gauge elevation.

Influence of Breakwater Slope

Examples of the influence of breakwater slope on the variation of $\overline{\Delta P / \Delta P_1}$ with the number of layers of armour is shown in Figures 5 to 7. One graph is presented for each type of armour unit. An elevation of -10 cm was chosen as representative.

The variation in $\overline{\Delta P / \Delta P_1}$ as a result of slope change was not significant in tests undertaken with armour layers comprised of stones, except at the still water level. A slope of 1:3 consistently provided the greatest internal pressure reduction, although this was only of the order of 5-10 percent greater than that for the other slopes.

This was also true for tests in which the armour layer was constructed of spheres.

FIGURE 4 INFLUENCE OF ARMOUR TYPE ON $\frac{\Delta P}{\Delta P_1}$

FIGURE 5 INFLUENCE OF SLOPE ON $\frac{\Delta P}{\Delta P_1}$ (Stones)

FIGURE 6 INFLUENCE OF SLOPE ON $\overline{\Delta P}_1$ (Spheres)

FIGURE 7 INFLUENCE OF SLOPE ON $\overline{\Delta P}_1$ (Cubes)

For these tests, the variation of $\overline{\Delta P/\Delta P_1}$ with slope was not significant at any gauge location. This trend was also observed in tests in which the armour layer was constructed with cubes, except at the still water level.

There were two cases in which the trend described above did not occur. These cases were for measurements made at the still water level. Since the internal pressure at this elevation will be influenced by local variations in the phreatic surface, this may provide an explanation for this effect. The phreatic surface elevation for given test conditions was typically much higher for spheres than for stones or cubes. In tests undertaken with spheres, minor fluctuations in the phreatic surface creates a dynamic pressure component which makes up only a small percentage of the total internal pressure at the still water level. The hydrostatic component was far more significant since the phreatic surface elevation was consistently well above the still water level. However, for tests undertaken with stones and cubes, the local variations in phreatic surface often had a magnitude equal to the average set-up of the phreatic surface. Thus the local variations in phreatic surface elevation became quite significant. These variations were a function of breakwater slope and may indicate why a large variation in

$\overline{\Delta P/\Delta P_1}$ with slope occurred at the still water level in tests undertaken using stones and cubes.

Summary of Findings

- the external pressure response curves were characterized by sharp peaks and rapid rise times whereas internal pressure response was somewhat smooth and gradual as a result of damping within the armour.
- the elevation at which the maximum $\Delta P/H$ on the external slope of the breakwater occurred was found to vary with wave period
- the rate of change of pressure during wave uprush was found to increase with increasing wave height at all gauge elevations
- the core material type had no significant influence on the external pressures but had a marked influence on the internal pressure field. As the number of layers of armour was increased, the magnitude of the peak pressure decreased while the rise time between trough and peak pressures increased
- the number of layers of armour had no influence on the external pressures but had a marked influence on the internal pressure field. As the number of layers of armour was increased, the magnitude of the peak pressure decreased while the rise time between trough and peak pressures increased.

- the type of armour unit used in the armour layer was found to have a small influence on the external pressure field. Using cubes produced the highest value of $\Delta P/H$.
- the maximum $\Delta P/H$ was found to increase with decreasing wave steepness.
- values of internal maximum $\Delta P/H$ were found to decrease with increasing armour layer thickness. The largest percentage decrease was found within the first few layers of armour. This trend was more evident with tests undertaken with stones and cubes in the armour layer. (this is primarily a permeability effect)
- a net downward propagation of wave energy and pressure was found by analyzing phase and elevation relationships between gauge locations
- internal pressures were found to be the highest for tests undertaken using spheres and lowest for tests undertaken using cubes.

CHAPTER 122

CONCRETE ARMOR UNIT STRUCTURAL DESIGN CRITERIA

C.D. Anglin, AM and R.D. Scott, AM ASCE¹
D.J. Turcke²

ABSTRACT

A comprehensive examination of the structural response of breakwater armor units to static and wave-induced loads has been completed using a dolos armor unit load cell in a physical breakwater model. Three extensive test series were completed to assess the influence of a wide range of breakwater and sea state parameters, and data reduction and analyses techniques were developed to estimate the structural response as a function of the critical independent parameters.

Using these data, improved design criteria, which consider both the hydraulic and structural aspects of breakwater design, have been developed for the dolos unit. Perhaps even more significant is the fact that the basic instrumentation scheme, model testing program, and data reduction and analysis procedures could be utilized to develop improved design procedures for other armor units, or to assist in the development of a new armor unit.

INTRODUCTION

Concrete armor units are used to protect rubblemound breakwaters when quarried stone of sufficient size to resist the incident wave climate is not available. The design of these breakwaters considers the hydraulic stability of the armor layer, but does not generally consider the structural integrity of the armor units themselves. The resultant limitations in these design approaches were clearly demonstrated by a number of damages and failures of rubblemound breakwaters in the late 1970's and early 1980's.

A co-operative effort between W.F. Baird and Associates, the Department of Civil Engineering at Queen's University, and the Hydraulics Laboratory of the National Research Council of Canada was initiated in 1980 to investigate the nature and magnitude of the forces acting on breakwater armor units. This effort led to the development of an armor unit "load cell" (Scott, 1986) which could accurately measure static and wave-induced (quasi-static) loads in a hydraulic breakwater model. This instrumentation was used in several extensive test

series to provide the structural response data required to develop structural design criteria for the dolos armor unit, as discussed in this paper.

INSTRUMENTATION - THE DOLOS LOAD CELL

In this study, the structural response of the dolos armor unit to static and wave-induced (quasi-static) loads was measured in a breakwater model using the armor unit load cell developed by Scott (1986). The load cell utilizes the concept of geometric distortion, and consists of a thin-walled aluminum tube instrumented with strain gauges and inserted into the shank of a hollowed out dolos unit, as shown in Figure 1. Three full strain gauge bridges measure two orthogonal bending moments and the torque at the mid-shank section; instrumentation to measure other load components, such as axial and shear forces, was not provided, as a review of prototype damages and previous analyses for the dolos unit indicated that bending and torsional stresses were dominant. The accuracy and sensitivity of the load cell instrumentation were investigated during calibration by comparing the measured moments and torques to theoretical values.

The original load cell design utilized in the first parametric study (wave-induced loads) was instrumented at the mid-shank section. For the subsequent investigations of static forces and the combined effects of static and wave-induced forces, four improved load cells were constructed, two instrumented at the mid-shank (MS) section and two at the fluke-shank (FS) section. These improvements are discussed in detail in W.F. Baird and Associates (1989b). Details of the two designs were identical except for the location of the split in the dolos shank. In general, all of the load cells utilized in the various testing programs performed well in the harsh environment of a hydraulic breakwater model.

TESTING PROGRAMS

Approximately 2000 tests were undertaken in three separate test series using the dolos load cell in a physical breakwater model in order to measure static and wave-induced (quasi-static) forces in the armor units, and to provide structural response data from which preliminary design criteria could be developed. All tests were undertaken using a "conventional" breakwater cross-section, with a primary armor layer of dolos units (mass of 482 g and density of 2500 kg/m³) placed over a filter layer of crushed stone (mass of 30 to 100 g), as shown in Figure 2. The dolos units had a waist ratio (shank width/overall length) of 0.32 and were randomly placed in two layers with a packing density, ϕ (as defined by Zwamborn, 1978), of 0.8 to 0.9.

The first parametric study of quasi-static (wave-induced) loads was completed using a two-dimensional wave flume at the Hydraulics Laboratory of the National Research Council of Canada (Baird and Associates, 1989a). Over 1000 tests were run with regular waves and approximately 140 tests with irregular waves to assess the effects of breakwater slope, armor unit location, wave period and wave height on armor unit structural response.

After placing two load cells (mid-shank units only) at selected locations in the armor layer, the breakwater was subjected to a short of waves, and the wave gauge and amplified load cell responses (M_1 , M_2 , T) were sampled at 500 Hz for 30 s (regular waves) or 60 seconds (irregular waves). This sample length covered from 10 to 34 wave periods depending on the incident wave period.

Figure 1. The Dolos Armor Unit Load Cell

Figure 2. Model Breakwater Cross-Section

The next set of tests, a parametric study of static loads, was completed in a dry environment, with the armor and filter layers constructed on a 0.7 m wide by 1.3 m long plywood ramp. Over 400 tests were run to assess the effects of breakwater slope, load cell location (relative to the "crest" of the breakwater), vibration, and the location of the force measurements (mid-shank section or fluke-shank section).

An additional series of flume tests was then undertaken, using the improved mid-shank and fluke-shank armor unit load cells, in order to measure the combined effects of both static and quasi-static (wave-induced) forces. The primary objective of this test series was to obtain data to allow an assessment of the interaction of the two force components (static and quasi-static). Consequently, a procedure could be developed to combine the results of the two independent parametric studies of these force components to estimate the overall response of the dolos unit to the combined loading conditions. The breakwater cross-section was the same as that used in the earlier flume study (see Figure 2), but the range of parameters tested was reduced as there was no need to repeat all the previous tests to assess the interaction of these forces.

DATA REDUCTION

An initial review of the structural response of the armor unit load cell to wave-induced forces was undertaken using the time series and spectral density plots. An example of these presentations for a selected regular wave test are shown in Figures 3 and 4. The time series plot (Figure 3) shows the repeatability of the response with the wave period, but shows considerable variation between the magnitude and shape of the "response profile" for the three measured load components (M_1 , M_2 and T). The spectral density plot (Figure 4), which shows the energy in the signal as a function of frequency, reveals the presence of an energy peak in the response at the incident wave frequency (f), and also at second and higher harmonic frequencies (i.e. nf , where $n = 1, 2, 3 \dots$). The largest peak in the response was normally located at the incident wave frequency or at the second harmonic frequency. The presence of second and higher harmonics in the response indicates a non-linear interaction between the response and the incident waves. Harmonic peaks in the response signals were observed to occur under the full range of wave conditions and load cell locations tested, although not in every test.

Similar observations were made in reviewing the response of the dolos load cell to irregular waves. The time series plots demonstrated the grouping effect of the incident wave train, with groups of large waves generating a large response in the armor units. The spectral density plots showed that the armor unit response typically had a peak frequency equal to that of the incident wave train (f_p); however, as with the regular wave tests, higher order harmonic peaks were observed in many of the tests.

In order to undertake the various analyses on the load cell response data necessary to develop design criteria, it was desirable to combine the effects of the three measured load components into a single quantity that could be related to a relevant failure criterion for concrete armor units. For unreinforced concrete structures, the exceedance of the tensile cracking strength at any point in the structure is a well accepted failure criterion. Consequently, the measured moment and torque time series (or simply values for the static tests) were used to calculate the time series (or value) of the maximum principal stress (σ) at the measurement location (mid-shank or fluke-shank). This calculation was undertaken using standard structural engineering equations, as summarized below:

Figure 3. Load Cell Response Time Series

Figure 4. Energy Spectra for Load Cell Response

$$\sigma = 0.5(\sigma_x) + \sqrt{(0.5\sigma_x)^2 + \tau^2} \quad (1)$$

where $\sigma_x = Mc/I$ (longitudinal stress due to resultant bending moment, M) (2)

$\tau = Tc/J$ (shear stress due to torque, T) (3)

with $M = \sqrt{M_1^2 + M_2^2}$ (resultant bending moment calculated from measured moments M_1 and M_2) (4)

T = measured torque

c = distance from neutral axis to surface of dolos shank

I = moment of inertia of dolos shank section

J = polar moment of inertia of dolos shank section

For the static tests, the calculated maximum principal stress value, after scaling to prototype, could simply be compared to the tensile strength of the concrete (ft) to assess the structural integrity of the unit under specified conditions. However, in the case of the quasi-static tests, where the wave-induced principal stress consists of a 30 or 60 s time series rather than a single value, it was desirable to derive a characteristic value of the principal stress time series. Preliminary data analyses were undertaken using the "average stress height" ($\sigma_{avg ht}$) for regular waves and the "one third stress height" ($\sigma_{1/3 ht}$) for irregular waves.

For the development of design criteria, it seemed more appropriate to select an extreme value from the time series with a specific probability of exceedance. Statistical analyses of the regular wave results were undertaken which showed that the distribution of the response peaks within any given sample could be described by a normal distribution. Thus, by calculating the mean (\bar{x}) and standard deviation (s) of the principal stress peaks within a particular sample, a characteristic large value with a specified probability of exceedance could be calculated.

DATA ANALYSES

Initial parametric analyses of the static and quasi-static test data were completed by producing a series of scatter plots for the dependent variable (a characteristic value of the principal stress response) plotted as a function of selected independent variables. The effects of other independent variables was shown by sorting the data into specific ranges for a selected variable and calculating regression lines for the various data subsets.

For example, the principal stress measured in the static armor layer tests was plotted as a function of the vertical distance below the breakwater crest for sixteen data subsets, defined by mid-shank (MS) or fluke-shank (FS) instrumentation, top or bottom layer, before or after vibration, and 1:1.5 or 1:2.5 slope. Figure 5 shows a plot of the full data set for a 1:1.5 slope. In general, the measured stresses tended to be higher on the steeper slope, at locations further down the slope, and in the bottom layer. However, no consistent trend was observed in the results for MS or FS instrumentation location or vibration.

For the quasi-static (wave-induced) test results, the average stress height (for regular waves) or one-third stress height (for irregular waves) was plotted as a function of wave height (H), wave steepness (H/L) and surf similarity parameter ($\xi = \tan \alpha / \sqrt{H/L}$). These plots were produced for selected armor unit locations and periods, as well as for all the data sorted by these parameters, for each breakwater slope tested. A typical plot is shown in Figure 6, which shows $\sigma_{avg ht}$ vs H for all test locations plotted with the different wave periods identified.

Figure 5. Static Stress as a Function of Vertical Distance (1:1.5 slope, bottom layer)

Figure 6. Average Stress vs Wave Height (1:1.5 slope)

In general, wave-induced stresses for both regular and irregular waves were observed to increase with wave height, wave period and wave steepness, while the effects of breakwater slope, armor unit location [top or bottom layer, and position relative to the still water level (swl)] were not as consistent. Wave-induced stresses under regular waves tended to be greatest on a slope of 1:2.0 and lowest on a slope of 1:2.5, with 1:1.5 falling in between; the effect of slope was not investigated in the irregular wave tests. Plots of the average stress height versus the surf similarity parameter (Figure 7) showed that the maximum stresses tend to occur for ξ between approximately 2 and 3.5, which is consistent with earlier literature concerning armor unit stability [for example, Van der Meer and Pilarczyk (1987)].

Multiple regression analyses were undertaken independently on the test results from the static and quasi-static (wave-induced) parametric studies in order to systematically assess the influence of the various independent parameters and to develop a mathematical expression defining the structural response (principal stress) of the dolos unit as a function of the critical parameters. A multiple regression analysis serves to identify three factors: a regression equation; standard error of estimate (s) and coefficient of multiple determination (R^2).

Linear combinations of the independent parameters were tested as an initial model for both the static and quasi-static test results. For the quasi-static test results, the regular and irregular tests were treated separately. In all three cases, it was found necessary to transform the dependent variable (principal stress) by taking its logarithm in order to satisfy the assumption of constant variance in the regression model. This transformation is consistent with the exponential relationship observed between the average stress height and the wave height in the regular wave tests, as mentioned earlier. The resulting regression equations for the three data bases, and their associated standard errors and coefficients of multiple determination, are summarized below:

Static Tests:

$$\log(\sigma_s)_{est} = -2.28 + 0.91(m) + 0.30(D_v - 0.45) + 0.34(layer) \quad (5)$$

$$s = 0.31, R^2 = 0.31$$

Note: the effects of instrumentation location (MS or FS) and vibration (before or after) were found to be insignificant.

Quasi-Static Regular Wave Tests:

$$\log(\sigma_{avg} h)_{est} = -2.70 + 0.18(m) + 0.31(D_{swl}) + 0.13(T) + 2.70(H) \quad (6)$$

$$s = 0.20, R^2 = 0.48$$

Note: the effect of layer (top or bottom) was found to be insignificant.

Quasi-Static Irregular Wave Tests:

$$\log(\sigma_{1/3} h)_{est} = -2.33 - 0.20(D_{swl}) + 0.07(T_p) + 1.91(H_s) \quad (7)$$

$$s = 0.20, R^2 = 0.48$$

Note: the effect of layer (top or bottom) was found to be insignificant.

The parameters in these equations are defined below:

$(\sigma_s)_{est}$	= estimated principal stress from static tests (MPa)
$(\sigma_{avg ht})_{est}$	= estimated average principal stress height, regular wave tests (MPa)
$(\sigma_{1/3 ht})_{est}$	= estimated one-third principal stress height, irregular wave tests (MPa)
m	= tangent of breakwater slope angle (for a 1:2.0 slope, m = 0.5)
D_v	= vertical distance of load cell test location below breakwater crest (m)
D_{swl}	= vertical distance of load cell location from still water level (m) (positive is above the swl)
layer	= categorical variable for layer, top = 0, bottom = 1
T	= average wave period for regular wave tests (s)
H	= average wave height for regular wave tests (m)
T_p	= peak wave period for irregular wave tests (s)
H_s	= significant wave height for irregular wave tests (m)

The standard error of the estimate, which provides a measure of the scatter of the data, can be used to define confidence or exceedance limits for the data if one knows the distribution of the data. Preliminary statistical analyses of the regular wave test results demonstrated that the distribution of the $\log(\sigma_{avg ht})$ values about the regression hyperplane could be described by a normal distribution. Thus, an exceedance limit for the average stress height can be established at any specified probability level using the results of the multiple regression analysis, as shown below:

$$\log(\sigma_{avg ht})_{\alpha} = \log(\sigma_{avg ht})_{est} + \Phi^{-1}(\alpha)s \quad (8)$$

where $(\sigma_{avg ht})_{\alpha}$	= average stress height with a probability of exceedance of α
$(\sigma_{avg ht})_{est}$	= average stress height estimated by the regression equation
$\Phi^{-1}(\alpha)$	= standard normal variate evaluated at probability level α
s	= standard error of the regression equation estimate

This probabilistic approach was incorporated in the development of structural design criteria for the dolos armor unit, as described later in this paper. However, the design criterion for wave-induced loads was developed using a peak stress value with a specified probability of exceedance from each test time series, rather than the average stress height from the time series.

The coefficients of multiple determination were 0.3 for the static tests and approximately 0.5 for the quasi-static tests. This implies that the respective regression models account for only 30 and 50% of the observed variation in the logarithm of the stress value. Some of this variation may be attributed to experimental error; however, a significant portion of this scatter may be explained by the effects of random orientation and boundary conditions of the armor units in the complex armor layer. Quantification of these variables was not attempted in this study. More complex regression models incorporating non-linear terms of the independent variables were investigated, but did not provide any significant improvements over the log-linear models discussed above.

DEVELOPMENT OF DESIGN CRITERIA

Introduction

Design stress level relationships have been derived from the results of the extensive testing programs described earlier for the following loading conditions:

- Static Loads - stresses induced by armor unit self-weight and inter-unit contact
- Quasi-Static Loads - fluctuating stresses induced by wave action
- Total Loads - the total stress due to the combined effects of static and quasi-static (wave-induced) loading

These relationships were derived on a statistical basis such that the designer can select the exceedance probability for the design stress level estimated for a particular set of design conditions. The development of these structural design criteria is presented in detail in Baird and Associates (1989b). Due to space limitations, the following section of this paper summarizes the results for only the total load condition.

Design Equation for Total Loads

A design equation was developed for the total stress occurring in a dolos armor unit due to the combined effects of static and quasi-static loads. The design equation for the combined loading condition is based on a statistical combination of predictive equations for estimating the static and quasi-static stresses. The predictive equations for the static and quasi-static stresses were derived from detailed parametric model studies of the two independent loading conditions using multiple regression analyses, while the statistical combination of these two equations was based on a third model study which investigated the combined effects of the two loading conditions. The resulting design equation for the combined loading condition is presented below.

From a design perspective, we require that:

$$n(\sigma_{tsp})_{\alpha} \leq f_t \quad \text{or} \quad \frac{n(\sigma_{tsp})_{\alpha}}{f_t} \leq 1 \tag{9}$$

where:

- $(\sigma_{tsp})_{\alpha}$ = design total stress level in model armor unit (MPa) with a probability of exceedance of α
- n = model scale factor
- f_t = prototype tensile strength of concrete (MPa)

The design total stress level in the model (MPa) is given by:

$$(\sigma_{tsp})_{\alpha} = (\sigma_{tsp})_{est} + [\Phi^{-1}(\alpha)]s \tag{10}$$

where:

$$(\sigma_{tsp})_{est} = 0.905(\sigma_s)_{est} + 0.639(\sigma_{qsp})_{est} \tag{11}$$

$$(\sigma_s)_{est} = 10^{**}[-2.28 + 0.91(m) + 0.30(D_v/n - 0.45) + 0.34(\text{layer})] \tag{12}$$

$$(\sigma_{qsp})_{est} = 10^{**}[-2.36 + 0.15(m) + 0.10(T/\sqrt{n}) + 0.29(D_{swl}/n) + 2.20(H/n)] \tag{13}$$

s = 0.001 (standard error of the estimate)

$(\sigma_{tsp})_{est}$ is the estimated peak value (5% exceedance) of the principal stress time series for the total loading condition, while $(\sigma_s)_{est}$ is the multiple regression equation estimate of the principal stress due to static loads and $(\sigma_{qsp})_{est}$ is the estimate of the peak value (5% exceedance) of the principal stress time series due to wave-induced loads.

The breakwater geometry parameters in equation 11 have been defined earlier. The representative model scale factor, n , is calculated using the following expression:

$$n = 9.43 \sqrt[3]{\frac{W}{.1549 w_r}} \quad (14)$$

where: W = armor unit mass (tonnes)
 w_r = unit mass of concrete (tonnes/m³)

The design equation presented above can be used to determine the maximum dolos size that is structurally sound, given various breakwater and sea state parameters. For example, given a particular armor unit size (mass) in a specific location, the unit mass of concrete, the breakwater slope, the tensile strength of concrete and the wave height and period, the structural capacity of the unit may be directly computed for different levels of exceedance probability.

For example, Figure 8 presents the maximum permissible dolos mass as given by both the structural capacity criterion (described above) and the hydraulic stability criterion (Hudson's formula) for specified conditions. The design equation for structural capacity was solved for the location within the breakwater producing the highest total stress (i.e.: bottom layer, $D_v/n = 0.6$, $D_{swl}/n = 0.1$).

In a typical breakwater design, the dolos units may be sized initially by means of a hydraulic model study or through use of a stability formula such as Hudson's formula. The structural performance of the armor unit may then be checked by means of the structural design equation for the specified breakwater geometry and sea-state conditions. An appropriate minimum concrete strength may then be selected that ensures the structural integrity of the individual armor units. In addition, the capacity of the dolos unit could be increased by increasing the waist ratio, or by specifying reinforcement as necessary to resist the applied loads. It should be noted that although the design equation is based on dolos load cell data for a waist ratio of 0.32, it is expected that small changes in this variable would not significantly affect the loads acting on the units, but could significantly reduce the stresses in the units due to the increased capacity of the section.

Limitations in the Design Equation

It is important to recognize that in developing this design equation, there are, as in any design equation, a general set of limitations. The general limitations in the application of these results to the structural design of armor units include the following:

- All tests were undertaken in a two-dimensional wave flume; therefore, the results can not be used to assess the influence of three-dimensional effects such as oblique wave action and breakwater layout features (such as heads, corners and transitions).

Figure 7. 5% Exceedance Average Stress Envelopes vs Surf Similarity Parameter

Figure 8. Dolos Hydraulic/Structural Failure Criteria
 ($w_r = 2.4 \text{ t/m}^3$, $K_D = 16$, 1:1.5 slope, $T = 12 \text{ s}$, 5% exceedance limit)

- All tests were completed using non-breaking waves ($H/d < 0.35$); therefore, shallow water effects, most importantly wave breaking, have not been considered.
- The design equation is based on regular waves tests; a limited test series was completed using irregular waves, but was insufficient to develop detailed design criteria. A detailed comparison between the response to regular and irregular waves should be undertaken and incorporated into the design equation.
- The tests were completed using a "no-overtopping" breakwater cross-section. Consequently, the effect of wave overtopping on the structural response of the armor units cannot be assessed.
- The tests were conducted at a single scale; thus, no quantitative assessment of scale effects can be obtained from the test results.
- Stresses derived from the model results are located at the surface of the mid-shank section of the dolos; the stress distribution throughout the dolos unit, in particular stress concentrations at the fluke-shank interface, have not been considered.
- Fatigue effects have not been considered.

Specific limitations on use of the design equations, based on the range of parameters tested, are summarized below:

Location	-with respect to the still water level:	$-0.1 \text{ m} < D_{sw}/n < +0.1 \text{ m}$
	-with respect to the breakwater crest:	$0.3 \text{ m} < D_v/n < 0.6 \text{ m}$
Wave Height:		$0.05 \text{ m} < H/n < 0.25 \text{ m}$
Wave Period:		$1.25 \text{ s} < T/\sqrt{n} < 2.50 \text{ s}$
Breakwater Slope:		$0.4 < m < 0.67$

If any of these quantities are outside these limits, the standard error of the predicted stress will increase, thus decreasing the reliability of the prediction.

So long as one is aware of these limitations, the design equation presented above can be used to provide an initial assessment of the structural integrity of the dolos unit under specified design conditions. However, these limitations must be addressed in future research work, which clearly represents a significant level of effort requiring global co-operation.

Application of the Design Procedure for Other Types of Armor Units

The load cell technology and analyses procedures developed in this study may be readily applied to other types of armor units, particularly those of a slender shape such as the tetrapod, quadripod, etc. As was described in this paper, general design equations may be developed, or it may be desirable to simply verify a preliminary design which has been based on hydraulic stability criteria.

The use of the load cell concept in a physical modelling environment also provides a tool for the development of new types of armor units. This procedure allows one to readily investigate the effects of changes to armor unit shape on both hydraulic stability and structural capacity.

CONCLUSIONS

A comprehensive examination of the structural response of armor units to static and quasi-static (wave-induced) loads has been completed using a dolos armor unit load cell in a physical breakwater model. Predictive equations have been derived which define the stress as a function of the critical breakwater geometry and sea state parameters, and a preliminary structural failure criterion for dolos

armor units has been developed for the first time. In addition, a design chart incorporating both the structural integrity and the hydraulic stability of the dolos unit has been presented. Limitations in the application of these results to the design of armor units have been extensively discussed to ensure that the results are not misused, and to provide guidance for future research. Finally, the procedures and methodologies developed in this study, including the instrumentation, model testing program, and data reduction and analyses techniques, can be readily applied to develop improved design procedures for other armor units, or to assist in the development of new armor units.

ACKNOWLEDGEMENTS

The financial support of the Marine Research and Development Branch of the Canadian Coast Guard, the Natural Sciences and Engineering Research Council of Canada, and W.F. Baird and Associates Ltd. is gratefully acknowledged.

The time and facilities support provided by the Department of Civil Engineering at Queen's University and the Hydraulics Laboratory of the National Research Council of Canada were critical to the successful completion of this work. In particular, Dr. E. Mansard of NRC must be thanked for his contribution to this work. The assistance of Dr. T. Smith of the Queen's STATLAB in overseeing the statistical analyses of the data was an essential element of this study.

CHAPTER 123

A Fundamental Study on Construction Scheme for Rubble Foundation of Deep Water Breakwater from Hopper Barges

Yoshiharu Matsumi*

ABSTRACT

This study aims to establish the effective construction scheme of the rubble mounds which are constructed by discharging a large amount of rubble from hopper barges. The numerical simulation technique is developed to estimate the spatial geometry of individual rubble mound discharged from a hopper barge. The effective distance between the discharge sites of the barge which makes the uneven property of the mound surface a minimum is discussed in connection with the change in the spatial geometry of the discharged rubble, the water depth and the direction of barge allocation.

1. INTRODUCTION

In general, deep water breakwaters are caisson type structures. The caissons are placed on a rubble foundation which is constructed by discharging a large amount of rubble from a hopper barge. An advantage of this construction method exists in its rapid "executability", since a volume of rubble at one discharge time is extremely large. However, since the rubble landing on the sea floor widely distributes from the discharge point of the barge, the rubble mounds by individual discharges usually form uneven surface foundations. Fig. 1 shows the illustration of the uneven surface of the rubble foundation, the elliptical lines show the plane profile of the individual rubble mound discharged from a hopper barge. When the distance between the discharge sites of the barge becomes larger, the size of the gap between mounds by individual discharges becomes larger. These are the drawbacks of this method of construction.

* Associate Prof. Dept. of Social Systems Engg. Faculty of Engineering, Tottori University, Tottori, Japan.

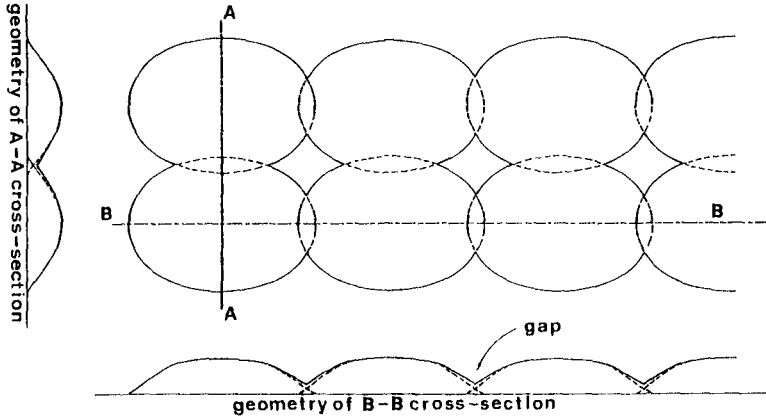

Fig. 1 Illustration of the uneven surface of the rubble foundation.

Recently, the design water depth of breakwaters is becoming deeper and the size of the rubble mound is greater. The portion of the rubble foundation work to the total process of breakwater construction is increasing. Therefore, the technique to construct a mound for breakwaters effectively and economically has become very important. To establish effective construction schemes of the rubble mounds which are constructed by the mentioned techniques, this study investigates the fundamental properties of the rubbles discharged from the barge with numerical techniques. The aim of this study is to make clear the optimal distance between the discharge sites of the barge which makes the uneven property of the rubble mound a minimum.

2. NUMERICAL SIMULATION TECHNIQUE

The spatial geometry of individual rubble mound discharged from a hopper barge can be evaluated by combining the volume of rubble at one discharge with a probability distribution of the plane scatter for the landing rubble on the sea floor. This probability distribution is obtained by analyzing numerically the stochastic differential equations of three dimensional motions for the settling rubble.

2-1 THE EQUATIONS OF MOTION FOR THE SETTLING RUBBLE

The equations of three dimensional motion for one piece of settling rubble are given as

$$M \frac{du}{dt} = -\frac{\rho}{2} C_D A u^2 - C_{Am} \frac{du}{dt} + F_x(t) \quad (1)$$

$$M \frac{dv}{dt} = -\frac{\rho}{2} C_D A v^2 - C_{Am} \frac{dv}{dt} + F_y(t) \quad (2)$$

$$M \frac{dw}{dt} = -\frac{\rho}{2} C_D A w^2 - C_{Am} \frac{dw}{dt} + (M-m)g + F_z(t) \quad (3)$$

where u , v and w are the x , y and z components of the velocity of one piece of settling rubble, A is the projected area of the rubble, M and m are the mass of the rubble and the liquid displaced by the rubble, C_D is the drag coefficient, C_M is the added-mass coefficient, ρ is the fluid density, g is the gravity acceleration. In these equations, the first and second terms on the right-hand side are the drag force and the inertia force exerted on the settling rubble, respectively. The last terms, $F_x(t)$, $F_y(t)$ and $F_z(t)$ indicate the x , y and z components of the drift force exerted on the settling rubble. These drift forces are random external forces. This study focus on the scatter range of the landing rubble on the sea floor. Therefore, in this simulation technique, the z component of the drift force exerted on the settling rubble is neglected.

$$\frac{du}{dt} = -\alpha u^2 + \beta F_x(t) \quad (4)$$

$$\frac{dv}{dt} = -\alpha v^2 + \beta F_y(t) \quad (5)$$

where

$$\alpha = \rho C_D A / \{2(M+C_{Am})\} \quad , \quad \beta = 1/(M+C_{Am}).$$

Eqs. (4) and (5) are non-linear stochastic differential equations (i.e. Langevin equation type). Therefore, in this study, these equations are linearized by using the following equations

$$u^2 = Uu \quad (6)$$

$$v^2 = Vv \quad (7)$$

where U and V are assumed to be of constant value in every time step of the numerical calculation. In this simulation technique, the random drifts, $F_x(t)$ and $F_y(t)$, are expressed by Gaussian random forces with zero mean.

Therefore, the variances (σ_x^2 , σ_y^2) for the x and y components of the landing position on the sea bottom can be obtained as the solution of the linearized stochastic differential equations.

$$\sigma_x^2 = \frac{\gamma\beta^2}{(\alpha U)^3} \left\{ \alpha U t - \frac{3}{2} + 2 \exp(-\alpha U t) - \frac{1}{2} \exp(-2\alpha U t) \right\} \quad (8)$$

$$\sigma_y^2 = \frac{\gamma\beta^2}{(\alpha V)^3} \left\{ \alpha V t - \frac{3}{2} + 2 \exp(-\alpha V t) - \frac{1}{2} \exp(-2\alpha V t) \right\} \quad (9)$$

where γ is the intensity of the white noise which directly influences the scatter range of the settling rubble. The probability distributions of plane scatter for the landing rubble on the sea bottom are given as follows lastly

$$p(x) = \frac{1}{\sqrt{2\pi\sigma_x^2}} \exp\left(-\frac{x^2}{2\sigma_x^2}\right) \quad (10)$$

$$p(y) = \frac{1}{\sqrt{2\pi\sigma_y^2}} \exp\left(-\frac{y^2}{2\sigma_y^2}\right) \quad (11)$$

in which $p(x)$ and $p(y)$ are the x and y components of the probability for one piece of settling rubble.

2-2 SPEED OF THE SETTLING RUBBLE (U,V)

In Eqs. (8) and (9), U and V must be given in consideration of the random drift force acting on the settling rubble. In this study, therefore, U and V are evaluated as the standard deviations (σ_u , σ_v) for the speed of settling rubble at any position. Eqs. (4) and (5) are rearranged in term of x and y, respectively, as

$$u \frac{du}{dx} + \alpha u^2 = \beta f_u(x) \quad (12)$$

$$v \frac{dv}{dy} + \alpha v^2 = \beta f_v(y) \quad (13)$$

where $f_u(x)$ and $f_v(y)$ are assumed to be expressed in the Gaussian random force with zero mean and the intensity of the white noise (γ'). The variances (σ_u^2 , σ_v^2) for the x and y components of the speed of the settling rubble at any position become from Eqs. (12) and (13) as

$$\sigma_u^2 = \beta \left(\frac{\gamma'}{\alpha} \right)^{1/2} \{ 1 - \exp(-4\alpha x) \}^{1/2} \quad (14)$$

$$\sigma_v^2 = \beta \left(\frac{\gamma'}{\alpha} \right)^{1/2} \{ 1 - \exp(-4\alpha y) \}^{1/2} \quad (15)$$

On the other hand, the intensities of the white noise, γ and γ' are included as unknown variables in Eqs. (8), (9), (14) and (15). Basing on the Langevin equation (Hori, 1977), the γ and γ' are related to the mean square of the drift force as following equations

$$2\gamma = \langle F(t)^2 \rangle dt \quad (16)$$

$$2\gamma' = \langle f(\ell)^2 \rangle d\ell \quad (17)$$

where $\langle \rangle$ indicates the expected value, ℓ is the moving distance of the settling rubble. Since $f_u(x)$ and $f_v(y)$ in Eqs. (12) and (13) are assumed to be equivalent to $F_x(t)$ and $F_y(t)$ respectively, γ' becomes from Eqs. (16) and (17) as

$$\gamma' = U\gamma \quad (18)$$

$$\gamma' = V\gamma \quad (19)$$

Therefore, U and V are given as follows lastly

$$U_i = \left[\beta \left(\frac{\gamma U_{i-1}}{\alpha} \right)^{1/2} \{ 1 - \exp(-4\alpha x) \}^{1/2} \right]^{1/2} \quad (20)$$

$$V_i = \left[\beta \left(\frac{\gamma V_{i-1}}{\alpha} \right)^{1/2} \{ 1 - \exp(-4\alpha y) \}^{1/2} \right]^{1/2} \quad (21)$$

in which U_i and V_i are the x and y components of the speed of the settling rubble in the i-th step of the numerical calculation.

2-3 SPATIAL GEOMETRY OF RUBBLE MOUND DISCHARGED FROM HOPPER BARGE

The probability distribution of plane scatter for the landing position of rubbles discharged from a hopper barge can be evaluated as

$$P(j) = \left\{ \sum_{i=1}^N p_i(j) \right\} / N \quad (22)$$

in which $p_i(j)$ is a probability that the rubble which is fallen from the i-th discrete portion in the hopper mouth lands to the j-th discrete portion on the sea floor as shown in Fig. 2. The probability, $p_i(j)$, can be calculated from the probability distribution functions, $p(x)$ and $p(y)$ in Eqs. (10) and (11). Therefore, the spatial geometry of rubble mound discharged from a hopper barge can be simulated by combining this probability with the volume of rubble at one discharge.

Fig. 2 Mathematical model of hopper barge.

3. OPTIMUM VALUE OF THE INTENSITY OF THE WHITE NOISE

The choice of the value for the intensity of the white noise used in this simulation technique is a problem, because the intensity of the white noise directly influences the scatter range of the settling rubble. In this study, the optimum value of the intensity of the white noise was investigated by comparing the calculated results with the experiments for the probability distribution of the plane scatter of the landing rubble on the sea bottom.

Fig. 3 shows examples of the experimental and calculated probability distribution of the plane scatter for the landing position of rubbles, in which every piece is dropped from the same position. In these cases, the representative size of rubble $d=2.64\text{cm}$ is applied. The upper figures are experiments for three kinds of water depth (i.e. $h=75\text{cm}$, $h=1\text{m}$ and $h=1.5\text{m}$). These experiments were carried out by Okude et al.(1982). P of the ordinate is the amount of the landing rubbles on unit area divided by the total amount of fallen rubbles. In the calculations, figures (A), (B) and (C) are the case for $\gamma=100000$, $\gamma=250000$ and $\gamma=400000$, respectively. All other parameter but γ are the same in these figures. In the

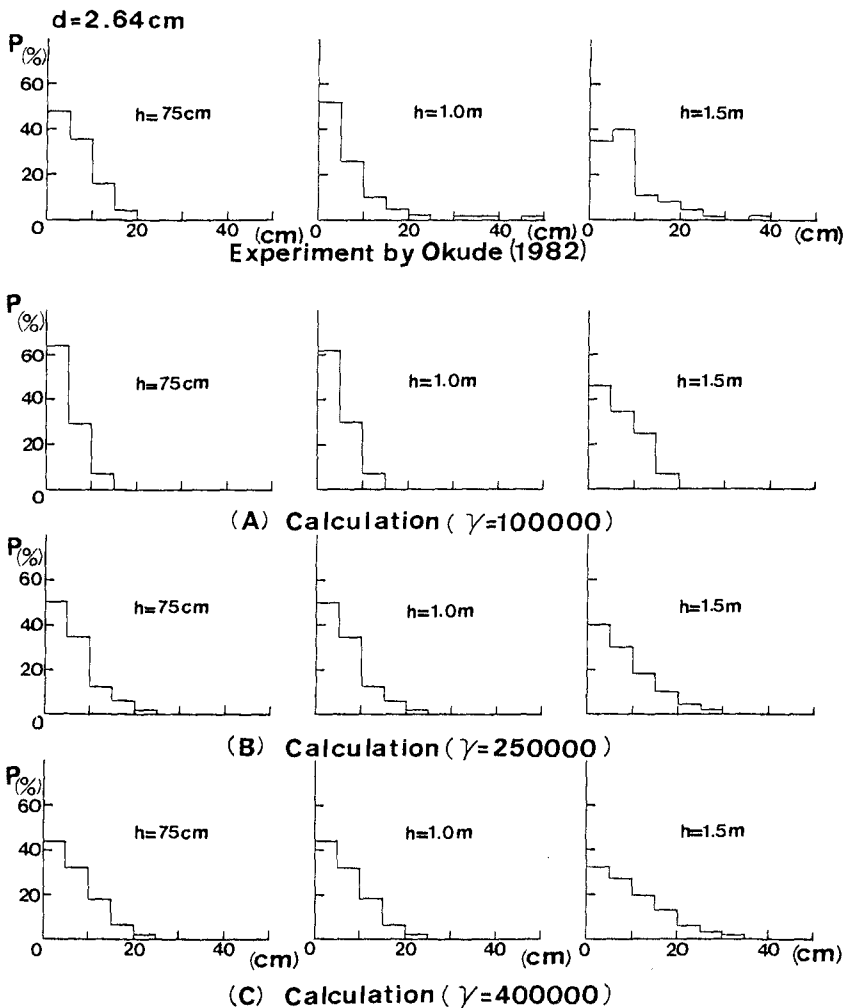

Fig. 3 Experimental and calculated probability distribution of the plane scatter for the landing position of rubbles ($d=2.64\text{cm}$).

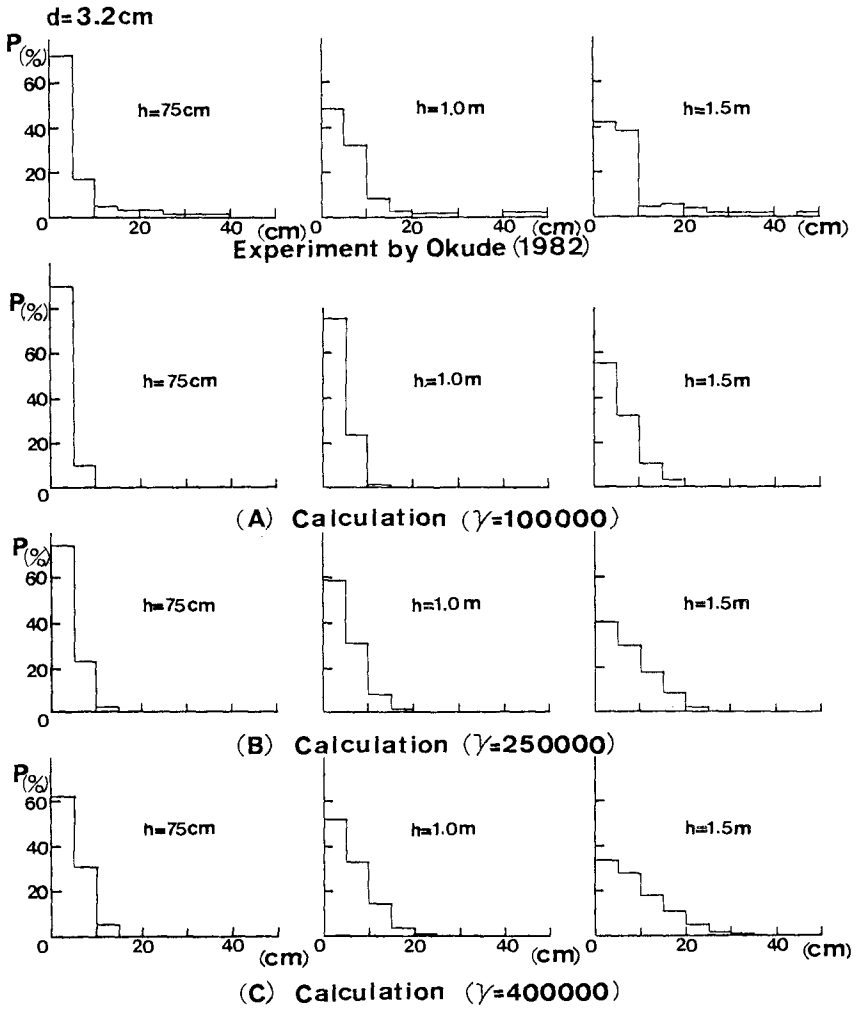

Fig. 4 Experimental and calculated probability distribution of the plane scatter for the landing position of rubbles (d=3.2cm).

calculations, when the value of γ becomes greater, the scatter range for the landing position becomes wider. Comparing these calculated results and the experimental results, it can be found that the calculations of the case for $\gamma=250000$ (Fig. 3 (B)) agree well with the experiments.

Furthermore, Fig. 4 shows the experimental and calculated probability distribution of the plane scatter for the landing position of rubbles in the case of $d=3.2\text{cm}$. The calculations for $\gamma=250000$ (Fig. 4 (B)) agree well with the experiments again. Therefore, from these investigations, it can be concluded that $\gamma=250000$ is the optimum value for the intensity of the white noise in the case of these rubble size. The scale effect of γ is not made clear yet in this study.

4. APPLICATION OF THE NUMERICAL SIMULATION TECHNIQUE

The application of the present simulation technique for the spatial geometry of the rubble mound discharged from a hopper barge was investigated by comparing the calculated results and the experimented results which were carried out by Okude et al.. In their experiment, a 1/20 scale model hopper barge with 100m^3 hopper volume was employed as shown in Fig. 5. The length of the hopper L is 77.3cm , the width W is 24.4cm . In the numerical calculations, the hopper mouth is divided into small panels as shown in Fig. 2. Size of the panel is d times d , d is the representative size of rubble.

Fig. 5 Definition sketch for the model barge.

Fig. 6 Calculated spatial geometry of the discharged rubble mound, ($h/d=57.2$)

Fig. 6 shows an example of the calculated spatial geometry of the discharged rubble mound, in which the x and y are taken to be the direction of width and length of the hopper barge, respectively. This calculation is the case for the relative water depth h/d of 57.2. Next, the application of this simulation technique for the spatial geometry of rubble mound was investigated by comparing these calculations with the experimented results by Okude et al..

Fig. 7 shows a comparison between the shape of the calculated cross sections of rubble mound and those obtained in the experiments, figures (A) and (B) are the cases for $h/d=27.2$ and $h/d=57.2$, respectively. The left side from the ordinate in figures shows $x-x$ cross section of the rubble mound (key sketch : top right) and right side shows corresponding $y-y$ cross section. When h/d is 27.2 (Fig. 7 (A)), the simulated results overestimate the experimental results. This simulation technique cannot simulate the rubble sliding down the slope of the mound, which is recognized in the experiments. This overestimate may hence come from this reason. On the other hand, when the water depth becomes deeper, the slope of the mound becomes more mild, therefore the rubble sliding down the slope may hardly occur. In the case of $h/d=57.2$ (Fig. 7 (B)), the calculated and the experimented results agree reasonably well. From these investigations, it can be concluded that the present technique simulates the spatial geometry of the discharged rubble mound for the deeper water depth with sufficient accuracy. However, the applicable limitation of this simulation technique for the shallow water is not made clear in this study.

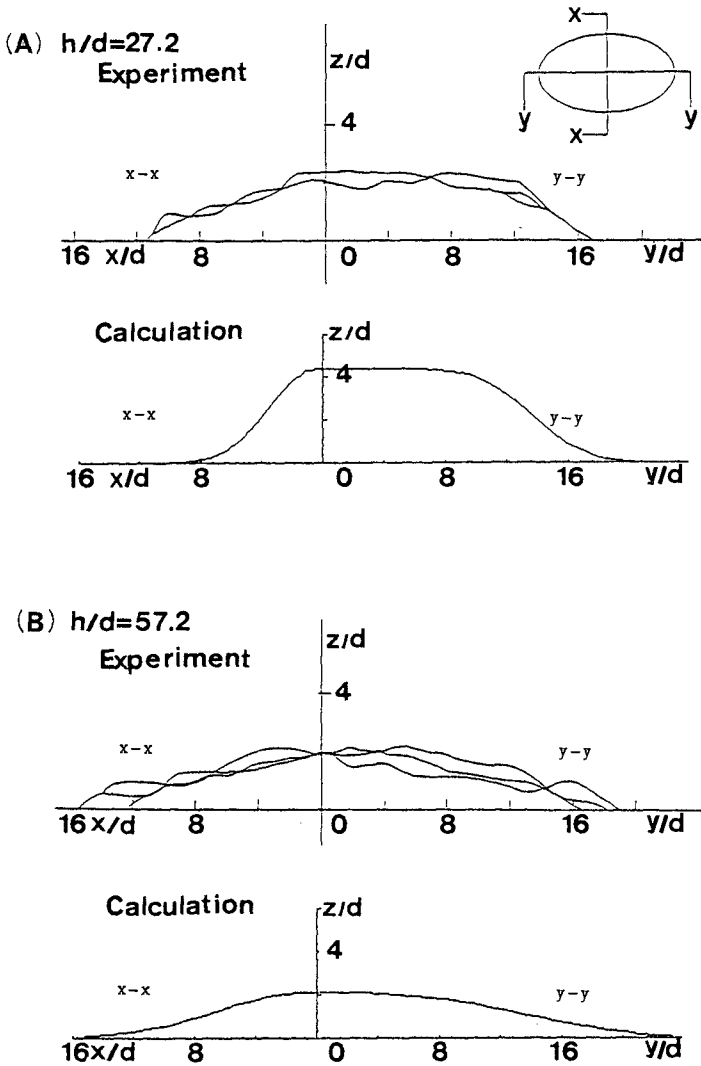

Fig. 7 Comparison between the shape of calculated rubble and experiments.

5. OPTIMAL DISTANCE BETWEEN THE DISCHARGE SITES OF THE BARGE

Fig. 8 shows the change of the calculated spatial geometry of the discharged rubble mound by two barges with respect to the water depth, a is the distance between the discharge sites of the barge. Figure (A) is the case of which the distance a is two times as long as the rubble size d , figure (B) is the case for $a/d=12$. When the distance between two barges is small (Fig. 8 (A)), the mounds by individual discharges form relatively even surfaces in shallow water. On the other hand, when the distance is larger (Fig. 8 (B)), the mounds form remarkably uneven surfaces in deep water. Therefore, it may be concluded that when deciding the distance between the discharge sites of the barge, the design water depth of breakwater becomes an important parameter.

Fig. 8 Change of the discharged rubble mound by two barges with changing water depth.

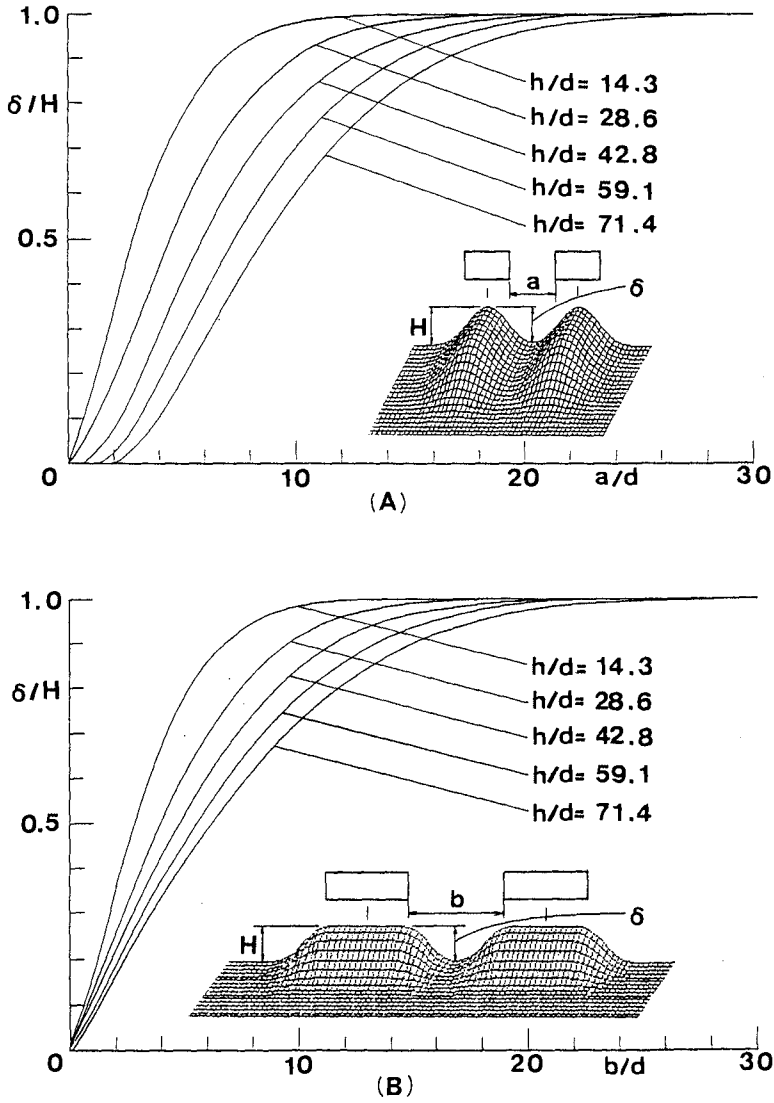

Fig. 9 Change in the size of the gap between the mounds with respect to the distance between the discharge sites of the barge.

Fig. 9 shows the change in the size of the gap between the mounds with respect to the relative distance between the discharge sites of the barge, in which δ is the gap size between individual mounds, H is the representative height of the mound. Figure (A) is the case of which two barges are allocated in the barge width direction, figure (B) is the case for the barge length direction. By using these figures, the effective distance between the discharge sites of the barge which makes the uneven property of the mound surface a minimum can be determined. Comparing the value of δ/H in figure (A) with that in the figure (B), in the region of small distance between the discharge sites of the barge, it is found that a change in the direction of barge allocation gives difference in both values of δ/H , (e.g. focusing the line of $h/d=71.4$, δ/H is equal to about 0.1 at $a/d=4$ in figure (A), on the other hand, at $b/d=4$ in figure (B), δ/H is equal to about 0.3). These extreme difference are caused by the direction of barge allocation. Therefore, it can be concluded that when deciding the distance between the discharge sites of the barge, the direction of barge allocation becomes an important parameter also.

6. CONCLUSION

Concluding remarks are as follows:

- (1) The present technique can successfully simulate the spatial geometry of the discharged rubble mound from the hopper barge in the deep water with sufficient accuracy.
- (2) The effective distance between the discharge sites of the barge which makes the uneven property of the mound surface a minimum is made clear in connection with the change in the spatial geometry of the discharged rubble, the water depth and the direction of barge allocation.
- (3) Applying this simulation technique for the case of the shallow water, the problem of how to deal with the rubbles sliding down the slope of the mound still remains.

CHAPTER 124

RESISTANCE OF GRASSMAT TO WAVE ATTACK

Jan Willem Seijffert¹ and Leo Philipse²

1. SUMMARY

The Dutch dikes along the North Sea and the tidal inlets need protection against erosion by wave attack. In 1983 two tests on full scale were carried out, concerning the resistance of large grass sods taken from Dutch sea-dikes, against wave attack.

For both tests in two different ways grass sods of 7500 to 9000 kg were dug from se-dike slopes, transported and placed in test facilities. In Test 1. the hydraulic load was performed by irregular waves up to $H_s = 1.85$ m, in Test 2. the hydraulic load was a simulated regular wave run-up with velocities until 4 m/s. Test 1. affirmed the possibility of a grassmat to withstand a design storm surge on a dike slope of 1:8 without severe damage. Test 2. showed the limits of erosion resistance and affirmed that the erosion resistance of a grassmat on sandy clay is concentrated in the upper layer of soil and roots.

2. TEST 1.

2.1 The motive of Test 1.

As a part of the realization of the so called Deltaworks in the Netherlands a section of 12 kilometers of the Frisian sea-dike in the northern part of the country should be enlarged (fig. 1).

The dike is situated on the south eastern side of the Waddenzee, a tidal flat of at medium 0.5 to 1 m below Ordnance Datum (O.D.) and a semi-diurnal tidal rise of about 2 m. The foreshore of the dike is a marsh situated about 1.5 m above O.D., that is some decimeters above

¹ J.W. Seijffert, Road and Hydraulic Engineering Division of the Rijkswaterstaat, P.O. Box 5044, 2600 GA Delft;

² L.A. Philipse, Waterschap Fryslân, P.O.Box 147, 8860 AC Harlingen; The Netherlands.

Figure 1. Plan of the Frisian sea-dike to be enlarged

the normal spring tide. Therefore only at storm surge tide a hydraulic load attacks the dike. The design water level is O.D. + 5.50 m, 1.80 m higher than the highest level that appeared in the past, with according wind waves of height $H_s = 1.85$ m, much higher than experienced in situ. The enlarged dike was designed with a relative flat outer slope from 1 : 12 up to 1 : 8 at design water level. Such a wide and rather voluminous cross section was possible because of the local available amount of clay as building material (fig. 2). This raised the question whether or not a non-reinforced grass revetment could be sufficient for the future. Under design conditions the erosive effect of breaking wind waves will be the representative event. In the large wave flume of Delft Hydraulics it is possible to generate

Figure 2. Cross section of enlarged dike

Figure 3. The sod cutting machine

Figure 4. A grass sod being transported

fully realistic the representative hydraulic load, related to water-level and irregular wind waves. The remaining question was the possibility of building a representative and full scale cross section of the outer slope and grass revetment.

2.2 Experimental set-up

As a representative grass revetment the grass of an outer slope angle from 1:5 to 1:6 of about ten years old at a comparable sea-dike was available in the vicinity. To utilize this opportunity a sod cutting machine was designed, and sods of $2.25 \times 5 \times 0.45 \text{ m}^3$ were dug out, transported and placed in the large wave flume.

The cutting machine consisted of a horizontal knife, 2.25 m wide, being pulled underneath the grass at a depth of 0.45 m, followed by a steel plate of 5 m length. Simultaneously two circular steel knives cut the vertical sides of the sods (fig. 3). The steel plate bearded the sod while raising it and during the transport by truck to the large wave flume (fig. 4). For reducing the tractive forces on the horizontal knife and steel plate (and so minimizing the distortion of the grass sod) it was necessary to use some water.

The grass sods were placed in a wave flume of 200 m length, 5 m wide and 7 m depth, under a fixed slope angle of 1:8. The slope reached from the bottom of the flume (Ordnance Datum (O.D.) + 0.5 m) along 55 m up to

Figure 5. Realized loading conditions (water level and significant wave height) in course of time

O.D. + 7.3 m = crestheight. The grass sods were placed on a clay layer of 1 m thick, with underneath sand with $D_{50} = 225 \mu\text{m}$.

The hydraulic loading was realized by generating irregular waves with a Pierson-Moskowitz spectrum, with varying water level and wave height (fig. 5), with a peak wave period between 5.2 and 5.6 s. This stands for a plunging breaker type, falling on water cushion. The variation of the water level reproduced a storm surge superimposed on a tidal cycle, during 29 hours, reaching a maximum level of O.D.+ 5.50 m and a maximum significant wave height $H_s = 1.85 \text{ m}$. In total the experiment lasted 48 hours, because of two stops between times for lowering the water-level, visual inspection and measuring the erosion level.

The test was executed with fresh water, while in nature the heaviest loading appears with seawater. The clay minerals in the Netherlands are mostly of the illite type (and therefore not very sensitive for dispersion). From experiences in the past with storm surges in the cold season no special effects in respect to dispersion can be derived. Therefore it is assumed that the tests with fresh water are sufficiently reliable.

The water velocities, measured at 0.05 m above the surface, were at maximum 2.2 m/s, at 4% of the waves a speed of 2.00 m/s was exceeded and the mean of the peak velocities was $\pm 1.00 \text{ m/s}$, upward as well as downward, appearing at $H_s = 1.85 \text{ m}$. Run-up and overtopping were measured and were in good accordance with the design values.

Special care has been taken for avoiding erosion due to rim-effects on the grass sods along the walls of the test flume.

Table 1. Vegetational species (percentage)

	Test 1	Test 2	
		sample 1	sample 2
Poa Pratensis (%) (Smooth-Stalked Meadow- or Kentucky Blue Grass)	65	2	2
Festuca Rubra (%) (Red Fescue)	12	20	64
Lolium Perenne (%) (Perennial Ryegrass)	6	76	29
other grasses (%)	7	0	1
other herbs(not grass), (%) among which Trifolium (Clover)	10	2	4
Total	100	100	100

2.3 Description of the grassmat

The grass was in good condition, due to 10 years of treatment, mostly by grazing sheep. The vegetation afforded initially a coverage of the soil of 50 to 80 %, which decreased to 40 to 50 % in the weeks just before the execution of the test. This was due to a lack of direct sunlight by the coverage of the roof on top of the construction hall of the wave flume, in combination with outdoor temperatures up to 25°C. Nevertheless it is not very likely that the root system has weakened significantly in this period. One week before the execution of the test the grass was cut to a length of 0.05 m. A determination of the vegetational species is presented in table 1. Some soil parameters are given in table 2.

Table 2. Soil characteristics

	Test 1	Test 2

Liquid Limit (%)	36	42
Specific Weight (dried) (kN/m ³)	14.8	13.9
Sand underneath:		
D ₅₀ (μm)	225	-

2.4 Results

Besides the still water level and wave characteristics being measured during the experiment, the amount of surface erosion was measured during breaks of the execution, by sounding the surface of the turf with a vertical rod in a fixed pattern. Because of the standard deviation of 0.005 m in measuring a single point, the results are presented as a difference between before and after wave loading, of the mean of 30 points in an area of 5 x 5 m (fig. 6). In this way the largest erosion, of about 0.005 to 0.010 m, was measured at levels of about O.D. + 2.45 m and O.D. + 4.25 m as well. In the first mentioned area a wave height of $H_s = 0.85$ m (as a mean) has worked out during 18 hours approx. (fig. 5) and in the second one $H_s = 1.65$ m (as a mean) lasted during 6 hours. Although most of the grass leaves had vanished, the turf was in exceptional good condition without any

visual holes or cracks, caused by erosion. In general it was found that the erosion resistance originated from the upper layer of soil and roots, much more than from the grass leaves. The erosion of the clay surface occurred in a rather even way, without forming obvious cracks or holes. While eroding, a fine root structure of the grass remained on top of the clay. This root structure reduced further erosion rather effectively.

It was remarkable that at the horizontal seams between the successive sods no extra damage occurred, in spite of the presence of little differences in surface height, up to a few centimeters.

Because of the minute erosion after the storm surge simulation during 29 hours, it was decided to restart the experiment after cutting 4 holes in the grass surface. The dimensions of the holes were 0.50 m (width) x 0.20 m (length) x 0.07 m (depth). The wave height was established at $H_s = 1.57$ m and the water level at O.D. + 5.00 m. In the vicinity of the breaker impact the holes eroded progressively, by scouring the soil underneath the upper layer of the turf. The first visible erosion appeared after 5½ hours of loading. After 7 hours two holes were scoured out to the depth of the underlaying, very resistive, clay layer. Conclusive can be stated that the soil material of the grass sods itself was not very resistive to erosion, in contrast to the top layer with roots (of 0.03 m to, at maximum, 0.10 m) which appeared very resistive to erosion under the given loading.

Figure 6. Averaged drop of surface, due to erosion

3. TEST 2.

3.1 The motive of Test 2.

The main objective of test 2. was the development of a quantitative and reproducible full scale test of erosion of vegetation on clayey soil under realistic hydraulic load by run-up, caused by breaking wind waves. This situation is very common on Dutch sea-dikes with a vegetational revetment on top of an armored revetment until the storm surge design water level. In that case the waves brake on the rigid revetment while the grass is only loaded by run-up and run-down.

Therefore 4 problems had to be solved:

1. Cutting and transporting large scale grass sods to a testing location.
2. Generating realistic and reproducible hydraulic loads.
3. To control rim effects and other shortcomings that distorted former experiments in laboratory conditions.
4. Defining a measurable erosion rate parameter.

Only if the conditions mentioned could be satisfied, it would be meaningful to establish an erosion/loading rate on a given grass/soil sample of a well defined condition. Two samples have been taken and tested, under the same conditions, to determine the reproducibility of the test. The two samples originated from the same sea-dike slope in the north of the Netherlands.

Figure 7. Two grass sods for Test 2. being dug out

3.2 Experimental set-up

In Test 2, a grass sod of 0.5 m thick, 1 m wide and 10 m length was dug out as a whole from a sea-dike as follows. An I-girder of 10 m long and 1 m high with one flange cut off was placed with its web horizontally, in a groove, dug out next to the sod to be taken out. The sharp edge of the web was pressed horizontally by hydraulic pistons at 0.5 m below the grass surface underneath the sod. Then the other side of the 1 m wide sod was dug free and the I-girder functioned as a bearer during the take up, the transport as well as during the whole test (fig. 7).

After transport it was put in a test flume with slope angle 1:4. Before starting the experiment, the flange first taken off, and elongating steel plates forming the sides of the flume, were welded on the I-girder. So the test was carried out on an almost undisturbed sample within the steel flume of 1 m wide.

Special care was given to the filling of the slot between the soil and the vertical wall of the steel flume. It was filled by a clay-bentonite mixture and covered by coarse stone-chipping and a strip of Enkamat, a non woven fabric of course filaments. This fabric protects the underlying vulnerable rim, with a roughness according to that of grass, without introducing renewed rim-effects on the transition to the plain grass.

The steel flume described before was placed in a larger (2 m wide) concrete flume next to a weir in the river Meuse. Over this weir a falling water head of about 5 m was available for generating the demanded hydraulic loading. Wave run-up and run-down were generated by simulating a breaking wave. Wave breaking was simulated

Figure 8. Experimental set-up of TEST 2 with simulation of wave run-up

by periodically (once in 7 seconds) intermitting a water jet of $2.2 \text{ m}^3/\text{s}$, streaming out of a rectangular nozzle (0.7 m high, 1 m wide) at the end of a horizontal pipe (fig. 8).

Designing the set-up for the hydraulic loading, a small scale model was built for testing the lay-out. After building in full scale and placing the grass sod in situ the hydraulic loading was calibrated on a temporary (for some hours only) wooden board, placed 0.10 m above the grass to be tested. For simulating the roughness of grass the board was roughened by placing (and glueing) small wooden cubes of $0.03 \times 0.03 \times 0.03 \text{ m}^3$ in a diamond-shaped pattern with edges of 0.9 m. In this way 3 usable hydraulic conditions were tuned in, each of heavier hydraulic load.

Starting the experiment with sample 1, at first the two lightest conditions were used, each during one hour. After coming out that only the heaviest possible loading should give a significant erosion within reasonable time, only the latter was used.

Free falling (3 s approx.) the water plunged on a roughened wooden board, 0.75 m before the downward rim of the turf, so creating an upward streaming parallel to the grass surface. Before starting the next "wave" the time remaining was enough for all the water running down. The maximum up and down velocities parallel to the grass surface came to 4.0 m/s, and the maximum thickness of the water layer was at maximum 0.70 m at the downward rim of the turf, decreasing uniformly along the grass surface up to the point of maximum run-up, 8 m upward along the slope. This equals, according to the theory of Battjes and Roos (1975), a wave with height $H = 3.6 \text{ m}$ and period $T = 6.8 \text{ s}$.

3.3 Description of the grassmat

The grass was in good shape before starting the tests. The soil coverage by the vegetation was 70-85 % for sample 1 and 70-95% for sample 2. A determination of the vegetational species is presented in table 1.

In the winter before the test the root content as a function of depth was determined at the dike location the grass was taken from. Two samples were taken. The total weight of roots over 0.50 m depth was $29 \text{ g}/\text{dm}^2$ (sample 1) and $35 \text{ g}/\text{dm}^2$ (sample 2), of which 10 and $18 \text{ g}/\text{dm}^2$ (35 and 51 %) in the upper 0.05 m, and 94 and 95 % in the upper 0.40 m.

The most significant difference between the two large sods was the somewhat better condition of the second one at starting the test, and some difference in the dominating grass species in the turf (see table 1).

Some soil parameters of the turf are given in table 2. It

is noticeable that the soil of the samples was not homogeneous, but there were several patches of sand present.

3.4 Results

The amount of erosion was gauged by vertical rods touching the surface in a fixed pattern, during breaks of the simulated wave loading. The erosion at the point of maximum damage at the end of the test of each sample is given in fig. 9. During the first 3 hours of loading hardly any erosion was visible. In the next period from 3 to 10 hours, in the lower 5 m along the slope the grass leaves eroded away. In general it was established that the upper 0.03 m of the turf eroded in a rather even way, without obvious cracks or holes. Thereafter, (between 10 to 15 hours with sample 1, 15 to 25 hours with sample 2) cracks developed.

In sample 1 after 16 hours the rate of erosion increased. After 18 hours, when at 0.6 m from the lower rim the erosion is 0.08 m deep and 0.60 m long, lumps of soil started breaking away and after 22 hours the bottom of the turf was reached.

In sample 2 the increase of the erosion rate appeared after 25 hours at 2.5 m from the lower rim of the turf. After 40 hours the hole was 0.20 m deep and 0.40 m long and the bottom was reached after 41 hours.

As said sample 2 hold out longer than sample 1. Partly this may have been caused by a somewhat better condition of the grassmat as a whole, but it is important to

Figure 9. Maximum erosion depth in course of time

mention that sample 1 had a bold patch in the heaviest loaded zone, caused by lack of sunlight during the two months before test by a wall sustaining wooden lath at 0.20 m above the grass. Although 20 hours for sample 1 is significantly shorter than the 40 hours lifetime of sample 2, the top layer caused mainly the total resistivity, even at the bold patch. This confirms the lesser importance of the grass leaves, and shows that the resistivity of the upper root layer can sustain a period of weak growth of the grass, which is likely to be important for the condition of the sea-dike grass in the winter and early spring.

During the process of erosion it was clear that small unevenness of the soil nor small holes such as wormhole were harmful at all. The thick tap-roots such as from the *Taraxacum Officinale* (Dandelion) caused some extra erosion, but not in such a way that the damage that occurred was influenced significantly.

Beyond the detrition of the grass leaves, in general two types of erosion could be distinguished:

1. Areas where the clay remained rather bare behind (up to an erosion of 2 to 3 cm) and
2. Areas where a fine network of roots stayed behind after the soil washed out. This network retards further erosion.

In the first mentioned areas the *Lolium Perenne* (Perennial Ryegrass) dominated, while in the second case *Festuca Rubra* (Red Fescue) dominated. From botanical descriptions it is well known that the *Festuca Rubra* has a wider and finer root system than the *Lolium Perenne*.

From the areas where the grass top layer was eroded 1 to 3 cm, without final distortion, it was hardly possible to grow up the grass in the laboratory from the remaining roots. This means that the grass, after withstanding such a heavy attack, will need one or more growing-seasons for recovery.

Parallel to the full scale test described, laboratory tests were carried out on small cores ($\phi = 66$ mm) taken from the dike location in the winter, from the upper 0.05 m as well as from a depth of about 0.40 m. These erosion test by a rotational water apparatus confirmed qualitatively the large difference between the erosive resistance of the turf at the two depths.

4. CONCLUSIONS

- 4.1 In two different ways the digging out of grass sods of about 0.50 m thick and an area of 10 to 12 m², transporting and placing them as a whole was possible.

- 4.2 Successful simulation was possible of wave attack by direct impact of breaking irregular waves up to $H_s = 1.85$ m and by wave run-up and run-down equivalent to regular waves of about $H = 3.6$ m.
- 4.3 The measures to overcome the influences of rim-effects along the grass sods on the test results were successful.
- 4.4 A general insight and a quantitative description were obtained of the erosion process of the tested grass from real sea-dikes under rather realistic boundary conditions.
- 4.5 It was affirmed that a proper quality grass on sea-dikes can have a high resistance against erosion by storm surges. Thus was decided to enlarge the sea-dike described in paragraph 2.1 as designed, without reinforcement of the grass revetment.
- 4.6 In the two cases with soil of rather sandy clay, the resistance was concentrated in the top layer of 0.03 up to (at maximum) 0.10 m, composed of soil and roots.
- 4.7 The type of erosion depends on the type of grass, particularly the root structure. A wide and fine root-structure (such as *Festuca Rubra*) leaves a fine root-structure behind while eroding, which retards further erosion. Other grasses, such as *Lolium Perenne*, omit this property, which causes a lower erosion resistance.
- 4.8 In two specific cases a quantitative erosion resistance is determined.

CHAPTER 125

Practical Study on Larger-Scale Cylindrical Caisson Breakwater in Port of Kaohsiung

Kuo, Shih-Duenn

ABSTRACT:

Using cylindrical caisson for a large-scale breakwater is not popular so far in the world. Never-the-less with the completion of Port of Kaohsiung's 2nd Harbor Entrance Project, the engineers in Taiwan has encouraged by the successful experience in this field due to its simple construction method and low cost consideration.

1. INTRODUCTION

Taiwan is an island, most of the economic activities with foreign countries rely on seaport's operation. Therefore, at least 4 international seaports were built successively in last 3 decades. Among them, Port of Kaohsiung is the most important one in terms of cargo handling and foreign trade as a result of the construction of 2nd harbor entrance as shown in Fig. 1.

Although there are many types of breakwaters can be selected for harbor entrance construction project, rectangular caisson breakwater is one of the most popular types in Taiwan, R.O.C. For Kaohsiung 2nd harbor entrance project due to tight schedule, limitative budget and shortage of material, the Harbor Bureau bravely and cautiously used cylindrical caissons as main structure of breakwater to replace the traditional rectangular shape to meet the development of heavy industrial zone surrounding the harbor area. This not only encouraged the engineers in Taiwan, but also set a record in R.O.C.'s harbor engineering.

Perhaps, cylindrical caisson used for breakwater in Kaohsiung was not the first one, but, I think it would be the largest one in the world so far. Kaohsiung's 2nd harbor entrance, navigable by ships up to 125,000 D.W.T. is protected by 2189-meter southern breakwater and 1322-meter northern breakwater, to keep the main channel to a min. depth of 16 meters as shown in Fig. 2. This project, took 8 years to complete from 1967-1975, totally used 136 units of cylindrical caissons including 37 units of $\phi 17^m$ and 99 units of $\phi 24^m$ at a cost of about US\$35 millions at that time.

Breakwater (by using cylindrical caisson)

2. PRACTICAL EVALUATION

In view of practical evaluation of cylindrical caisson breakwater, it will be compared its project cost, construction period, construction method, technical problem, damage rehabilitation during construction and maintenance after operation etc. with those of the rectangular type in Taiwan's conditions.

2.1. Initial cost

As conservative evaluation, the construction cost of the cylindrical caisson breakwater could save about 15-20% than that of the rectangular one due to simple construction method and short construction period etc.,

For diver demand, from beginning to the end, divers needed for placing cylindrical caissons in Port of Kaohsiung were only 2-3 teams in comparison with about 50 teams which needed for rectangular types of the same size in doing foundation works and so on in Taiwan's experience. This implied that the cost could reduce in a large amount for cylindrical caisson breakwater.

For rock requirement, due to foundation free, the volumes of rock need for cylindrical caisson breakwater was only half as much as rectangular type. This meant it could save much more money and time in comparing cylindrical caisson breakwater with rectangular one.

For others, it could save about 20% of the budget for equipments and other kinds of material in cylindrical caisson breakwater.

2.2. Construction period:

Using very simple and mass-produced methods for fabricating cylindrical caissons and for the sake of no necessity placing rock base, foundation screed and other sophisticated under-water-works for caissons etc., the construction progress of cylindrical caisson breakwater was much faster than that of the rectangular type. Normally, under the same manpower to complete a same size breakwater, the construction period taken by cylindrical caissons was only half as long as the rectangular one. Taking Port of Kaohsiung's 2nd harbor entrance breakwater into account, placing about 24 units of cylindrical caissons a year were a very high through-put regardless of bad weather in the region lasting for more than 5 months annually.

2.3. Construction method:

Taking average, 2-dozen of cylindrical caissons were needed per year in Port of Kaohsiung's 2nd harbor entrance breakwater construction project. Hence, many possible approaches were used in fabricating works simultaneously to meet the annual demand. At the same time, some other construction methods were also simplified to cope with the actual requirements which were quite different from the rectangular type.

For fabricating works, cylindrical caissons were built either on shore bank, quay side or inside the dock simultaneously to catch the schedule.

2.3.1 Fabricated on shore bank:

Some caissons of 17-meter in diameter were built to complete on the shore bank. After completion, they were launched and floated by cutter dredger, and then, grounded before towing & sinking to prevent them from hitting each other in typhoon season as shown in Fig. 3. Some 20 units of $\phi 24^m$ cylindrical caissons were done in the same way before fabricating dock was available. Simplification and low cost were the advantages, but they needed a lot of land areas and coastal fronts for using.

Fig. 3. Cylindrical Caissons fabricated on shore area.

2.3.2 Fabricated inside the dock:

A total of 81 units of $\phi 24^m$ cylindrical caissons were fabricated inside the dock to the height of 4-meter (draught 3.7^m , freeboard 0.3^m) as shown in Fig. 4, and then, built continuously outside the dock, also in water, till completion and grounded for temporarily setting. This case cost more and took a long time to complete with no other better solution.

Fig. 4. Cylindrical caisson fabricated inside the dock.

2.3.3 Fabricated on quay side:

Some caissons of 17-meter in diameter were constructed to the height of 1.57 meters (draught 0.86^m, free board 0.71^m) on the apron of quay side, and then, hoisted by 200-ton capacity floating crane down to the water to continue the rest part as shown in Fig.5. Being completed, they were grounded temporarily as well. Quay was the requisition for this case.

Fig. 5. Cylindrical caisson fabricated on quay apron.

For foundation built-up, due to caissons being put directly on sea bed of slope ranging from 1:100-1:50 or so, natural sea bed was just the foundation of cylindrical caissons to make the cutting wall to cut through it. Placing rocks or armour units for this kind breakwater aimed at giving appropriate protection to the toes of cylindrical caissons rather than to the foundation, as shown in Fig. 6.

As to the towing & sinking of cylindrical caissons, It's a key point for breakwater construction. The temporarily grounded caissons were refloated before towing. Towing & sinking was done in a continuous process to put the caisson in the right position. Then, the following works, such as sandfill, rock-placing and capping etc. followed up till the caisson come to the absolutely stable condition.

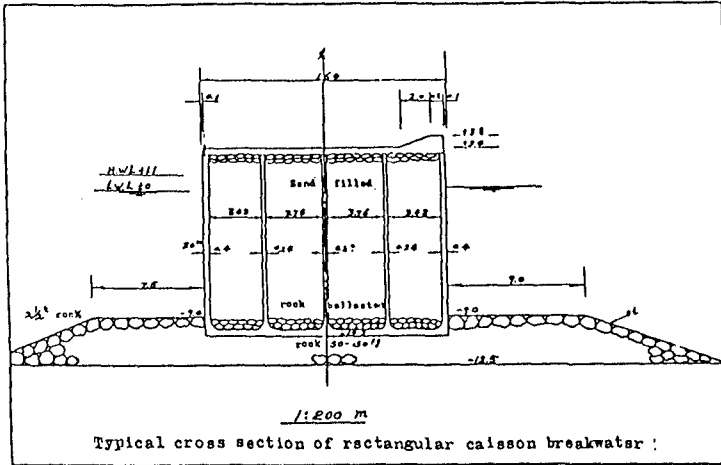

Fig. 6. Different Foundation Methods between cylindrical caisson and rectangular shape breakwaters

2.4. Technical problem:

Some technical problems which play a very important role referring to the cylindrical caisson breakwater were cutting wall installation, gap control, design criteria and so on.

2.4.1 Cutting wall installation:

Cutting wall's design was a very important breakthrough to the cylindrical caisson breakwater. It's installed along the bottom wall with a height of 1.25-1.50 meters as shown in Fig. 7. When cylindrical caissons placed directly on the sea bed, it cut into the sand layer by its self-weight and weight of sand-fill etc. to increase the horizontal resistance forces against sliding. At the same time, it could protect the sand under the caisson from scouring during constructing in monsoon season (wave height under 2 meters). The later was more important than the former due to caisson being placed in monsoon season rather than in typhoon season.

2.4.2 Gap control:

Gaps between each two caissons should be controlled in a proper limit, designed for 40cm in Kaohsiung's case, to avoid wave transmission packing sand from outside the breakwater to silt the channel. Furthermore, the unsuitable arrangement of the gaps could induce wave momentum to wash away the rock or armour units placed in between the gaps. In Kaohsiung's case, we should do routine maintenance by placing about US\$300,000 equivalent armour units (Used 15-20 ton modified tetrapods) annually due to bad control of gaps.

2.4.3 Design criteria

Besides the sand-fill and the weight of caisson itself, the stability design of cylindrical caisson for bearing, sliding and overturning was also controlled by constructing caisson as a hollow type with 1.25-1.5m cutting wall to cut through the sand layer. For the 6 meters designed wave height, the factor of safety of $\phi 24^m$ cylindrical caisson were:

$$F_b = 2.25$$

$$F_s = 1.84$$

$$F_o = 5.40$$

Which were all larger than the standard value 1.2 set for the design criteria.

2.5. Damage rehabilitation during construction

During construction, already placed cylindrical caissons would be declined to about 9 degree or sunk down to the sand bed some 1.5 meters deep, but wouldn't be moved out of the position as hit by big wave forces in case that protection works had not yet completed. If so, the repair and rehabilitation works could be done by mounting precast concrete frame on the top of caisson to the design elevation. This procedure was quite different to the rectangular type which would be damaged in a different way-slide away from its position as shown in Fig. 8. Other damages, such as wall fracture, also could be repaired in a easy way.

2.6. Maintenance after operation:

Although there were many advantages using cylindrical caisson for breakwater, maintenance was the big problem to be solved in comparison with the rectangular one.

For regular maintenance, placing 7.5-20 ton of armour units should be made annually to protect the toes of cylindrical caissons from scouring before typhoon season.

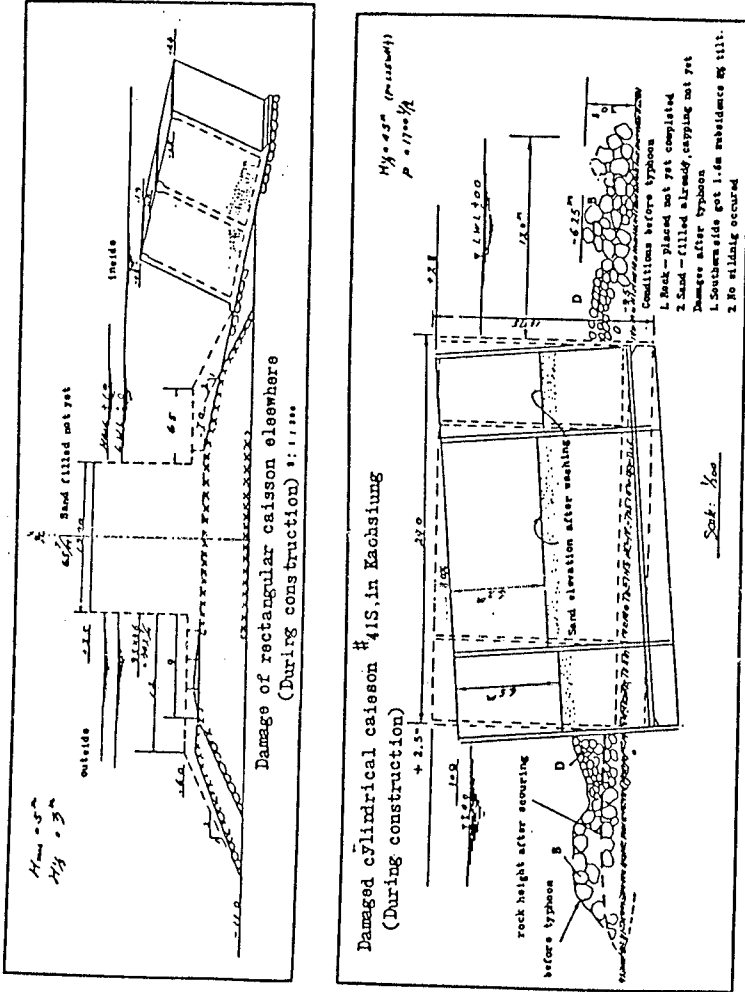

Fig. 8. Different damages for cylindrical and rectangular caissons during construction.

Fig. 9. Repair method... for serious damaged cylindrical caisson breakwater

For emergent disposal, repair works should be carried out as soon as typhoon passed in case of serious damages occurred as shown in Fig. 9.

3. CONCLUSIONS:

(1) Using cylindrical caisson for a large-scale breakwater is encouraged as Port of Kaohsiung's 2nd harbor entrance breakwater has successfully experienced in many typhoon attack (the peak wind speed reached 63 m/sec or 227 km/hour) since it was completed in 1975.

(2) Cutting wall was a key point in cylindrical caisson breakwater design, from which a very good horizontal resistance force against sliding could be given to reduce the damage to the least during/after construction.

(3) Gap design of cylindrical caisson breakwater gave a very close relation with maintenance, Therefore, laboratory model test and mathematics model analysis should be done to find the suitable armor units for long-term stability consideration.

(4) No matter what disadvantages during/after construction are, using cylindrical caisson for the large-scale breakwater project is worthwhile to recommend as it could shorten construction period, simplify construction method and reduce construction cost under the consideration of security and safety. Especially, it will provide a valuable experience for developing countries which run short of funds and need seaport urgently.

CHAPTER 126

ARCTIC SLOPE PROTECTION METHODS

Craig B. Leidersdorf, M. ASCE¹

Peter E. Gadd, M. ASCE¹

William G. McDougal, M. ASCE²

ABSTRACT

This paper reviews knowledge acquired in the Alaskan Beaufort Sea pertaining to three methods of Arctic slope protection: (1) sacrificial beaches, (2) "soft" (geotextile based) armor, and (3) linked concrete mats. Design considerations and performance evaluations are presented for each method, along with recommendations for future use. It is concluded that the existing technology is capable of providing reliable protection for structures located in coastal and nearshore areas, and that more durable systems will be required to withstand the extreme wave and ice loads which can occur at exposed sites in deeper waters.

INTRODUCTION

Since 1976, more than twenty man-made islands, causeways, and coastal pads have been constructed in the Alaskan Beaufort Sea in response to the needs of the petroleum industry. The initial facilities were sited along the coast or at nearshore locations where wave heights and ice forces were limited by the water depth. By the mid-1980's, however, slope protection methods and construction techniques had advanced to the point where islands were installed in exposed locations with water depths to 15 m. Although the rate of new construction decreased in the 1980's with the decline in oil prices,

¹ Principal, Coastal Frontiers Corporation, 9424 Eton Ave., Suite H, Chatsworth, CA 91311, U.S.A.

² Professor, Department of Civil Engineering, Oregon State University, Corvallis, OR 97331, U.S.A.

performance monitoring of many of the facilities has continued through the present date.

The objective of this paper is to review the knowledge of Arctic slope protection which has been acquired from the past fifteen years' experience in the Alaskan Beaufort Sea. Emphasis will be placed upon the three methods which have been most widely employed: (1) sacrificial beaches, (2) "soft" (geotextile-based) armor, and (3) linked concrete mats.

SITE CONDITIONS

The most distinguishing feature of the Arctic offshore environment is the presence of sea ice. First-year ice typically attains a thickness approaching 2 m during the long winter season. When the ice is deformed by pressure, its thickness can increase to 30 m or more, and the resulting pressure ridge can often survive one or more summer melt seasons. Such multi-year floes pose a particular threat to offshore structures, not only because of their great mass, but also because of the drift velocities they can attain during the period of open-water.

Design ice loads generally are based on the crushing strength of the ice (American Petroleum Institute, 1988). Global loads in shallow water are of order 700 to 1000 kPA, while those in deeper water (to 15 m) are of order 1400 to 1700 kPA. Local loads, as might occur on piles or protruding armor units, can exceed the corresponding global load for the entire structure by a factor of three. Damage can also result from the shear forces exerted when ice moves up or along the structure slope, and from ice abrasion.

Hydraulic loads are moderate in the Beaufort Sea due to the limited fetch which results from the proximity of the polar ice pack. At an exposed, deep-water site, representative wave conditions for the 10-year return period storm might consist of a maximum significant wave height of 4-5 m and a peak period of 8-10 sec. Storm surges can significantly increase the water depths and the resulting depth-limited wave heights in nearshore areas.

Experience to date suggests that the most severe damage to slope protection systems often results from a combination of ice and wave loads. Drift ice impacts can damage and displace armor units below the waterline, for example, after which the slope is predisposed to rapid degradation under even moderate wave loads.

Conversely, deformations in the slope profile caused by wave impacts can create local protrusions which serve as focal points for ice forces.

In addition to ice and wave loads, the following factors must be considered in designing slope protection systems for Arctic service: (1) low temperatures (-50°C), (2) a brief open-water season during which construction can be performed (typically 60 to 90 days), (3) a lack of native construction materials (including quarystone and cement in the Alaskan Beaufort Sea), (4) a paucity of environmental data from which to predict extreme events, (5) a lack of specialized construction equipment, and (6) the high cost of importing equipment and non-native construction materials. As a result of these limitations, the slope protection methods which have evolved in the Alaskan Arctic have tended to emphasize simple construction techniques, maximum use of locally available materials, and non-catastrophic modes of failure (in the event that the design conditions have been underestimated).

SACRIFICIAL BEACHES

Sacrificial beach slope protection consists of providing a buffer zone of expendable beach material around the area to be protected (Plate 1). The width of the buffer zone should be sufficient to accommodate the

Plate 1. Sacrificial Beach on Niakuk 4 Island

erosion anticipated from both daily conditions and design storm events. The obvious advantages of such an approach include a low capital cost, ease of construction, and low susceptibility to ice damage. The primary disadvantages are the need for frequent maintenance, and the fact that the degree of protection provided by the system depends not only upon the incident wave heights, but also upon storm duration. Because erosion rates tend to become unacceptably high in exposed locations, sacrificial beaches are most appropriate for coastal or nearshore sites in which the wave heights are depth-limited.

Design Considerations

Of particular benefit in the design of sacrificial beach protection has been the availability of gravel and coarse sand in relict river deposits along the Alaskan coast. To date, all of the sacrificial beaches in the Alaskan Arctic have been constructed from this material rather than from the fine sands and silts found on the sea bottom. The median grain size (D_{50}) has typically ranged from 4 to 8 mm, with a maximum cobble size of 80 mm and a fines content ($D_{50} < 0.075$ mm) of less than 10%. As discussed below, the coarse nature of the sediment has resulted in lower longshore transport rates, and consequently more stable beaches, than those associated with the sand-sized material.

Both cross-shore and longshore transport must be taken into account in determining the required width of the sacrificial buffer zone. To obtain a first approximation of the former, successive profiles were obtained on the slopes of Niakuk 4, a man-made island located in a water depth of 1.4 m, during the three-year period between 1985 and 1988. The change in the configuration of the island which occurred during the monitoring period is illustrated in Fig. 1; representative profile data from the exposed northeast side are presented in Fig. 2.

The data suggest that the gravel tends to assume an equilibrium profile analogous to that reported for sand beaches by a number of investigators (for example, Bruun, 1954; Dean, 1977). The characteristic concave-upward shape of the below-water portion of the profile can be described by the relationship:

$$h = ax^m \quad (1)$$

where h is the depth (m), x is the distance offshore (m), and a and m are empirical constants which provide a best fit to the data with values of 0.39 and $2/3$, respectively.

Figure 1. Evolution of Niakuk 4 Island, 1985-88

Figure 2. Beach Profiles on Niakuk 4 Island, 1985-88

As reported by Komar (1988), data regarding longshore transport rates for gravel-sized material are extremely sparse. To develop a first order predictive capability for the sacrificial beach material available in the Alaskan Arctic, the average annual net transport rates for the exposed northeast and northwest sides of Niakuk 4 Island (Fig. 1) were calculated from the survey data for the 1985-88 monitoring period. These results were combined with the wave measurements available from a single open-water season prior to the monitoring period (1982) to determine the transport coefficient K in the relationship proposed by Komar and Inman (1970):

$$I_s = KP_1 \quad (2)$$

where I_s is the immersed-weight transport rate and P_1 is the longshore component of wave power based upon the root-mean-square wave height. Values of 0.08 and 0.12 were obtained for the transport coefficient on the northeast and northwest sides, respectively. In view of the limitations of the data set, this range is not surprising. The mean value of 0.10 was therefore adopted as a first approximation of the transport coefficient.

It is noteworthy that the foregoing result, obtained for material with a D_{50} of 4 mm, is substantially lower than the transport coefficient of 0.77 reported for sand (CERC, 1984; note that the value of $K = 0.39$ presented by CERC has been modified to 0.77 to reflect the use of the root-mean-square wave height rather than the significant wave height in calculating P_1 in Eq. 2.) It therefore appears that the use of coarse sediment can significantly improve the performance of sacrificial beaches by reducing the rate of longshore transport.

Performance Evaluation

Four man-made islands and two shore-connected causeways using sacrificial beach slope protection have been constructed in the Alaskan Beaufort Sea to date. Water depths have ranged from 0 to 3 m. The most extensive application has been on the Endicott Oil Production Facility (Munday and Bricker, 1988), where 8 km of causeway in water depths to 2 m are protected by gravel beaches placed at an initial slope of 7H:1V. Fill losses and scarp formation have been modest, and no replenishment has been required since the facility was completed in 1986.

The most thorough documentation of beach performance has been obtained for Niakuk 4 Island (Plate 1; Fig. 1). Constructed in 1984 in 1.4 m of water as a 122 x

107 m rectangle, the island experienced moderate erosion during the 1985 open-water season. It was re-graded to its original configuration during the fall of 1985, at which time the monitoring program referred to previously was undertaken.

During the ensuing three open-water seasons (1986-88), the gravel losses from the exposed northeast and northwest sides of the island averaged only 2,200 m³/yr. More than 75% of this material accumulated in spits which formed at the east and west corners (Fig. 1). During the 1989 open-water season, the spit material was excavated and used to restore the width of the buffer zone on the northeast and northwest beaches. Initial concerns that the gravel would remain frozen during the summer months proved to be unfounded, allowing the backpasing operation to proceed at a rate of 2,900 m³/day.

In contrast to the relative stability evidenced by sacrificial beaches in water depths of 2 m or less, substantial erosion rates have been observed on beaches in deeper water. Such observations encompass islands from which the original armor has been removed (Anderson and Leidersdorf, 1988), as well as purpose-built beaches. Based upon both the rates of erosion and the cost of transporting gravel offshore for beach replenishment, it appears that the 2-m isobath represents a practical limit for the application of sacrificial beach slope protection methods in the Alaskan Arctic.

SOFT ARMOR

"Soft armor" refers the use of geotextile containers filled with sediment as a means of providing slope protection. Although the concept embodies a wide range of devices, the Alaskan experience has indicated that massive units such as tubes and mats are susceptible to rapid deflation when punctured by ice (Leidersdorf, et al., 1981). Large gravel-filled bags (Plate 2) have proven to be best-suited for Arctic service, and are therefore the focus of the discussion which follows.

The advantages of gravel bag slope protection include a moderate capital cost, the ease of performing repairs, and the relative simplicity of the installation procedure. The primary disadvantages are a susceptibility to ice damage, resulting in the need for maintenance, and the environmental nuisance which is created when damaged bags drift away from the slope.

Plate 2. Gravel Bag Armor on Resolution Island

Design Considerations

The central issues to be addressed in the design of gravel bag slope protection are the characteristics of the bags themselves, the placement configuration, and the characteristics of the underlying filter fabric. In the case of the bag characteristics, two sizes, representing capacities of 1.5 and 3.0 m³, have been adopted for most Arctic applications to date. The 3.0 m³ size, with a weight of approximately 5.5 tonnes, has proven to be the largest unit which can be easily handled by conventional construction equipment. It is typically used in exposed locations with relatively energetic wave regimes, while the 1.5 m³ size is applied in cases of more limited wave exposure.

Based on the performance of prototype test sections (Leidersdorf, et al., 1981), bags constructed of a single layer of high-strength fabric are more durable than those comprised of multiple layers of lower-strength material. Woven polypropylene with a grab tensile strength of 700 N/cm has been used to construct the majority of the bags in Arctic service; specifications for this material are provided by Gadd (1988).

Representative placement configurations for gravel bag armor are illustrated in Fig. 3. An inclination of 3H:1V has proven to be the steepest grade at which the

Figure 3. Gravel Bag Placement Configurations

bags are not prone to sliding failure, and has therefore been adopted for most gravel bag installations in Alaska. Maximum stability is achieved by orienting the longitudinal axis of each bag in the on-offshore direction, and by providing a measure of overlap between the bags. A minimum overlap of 10% of the bag length is recommended to insure that the closure end of the bag is protected from direct wave impact by the next bag upslope. Increasing the overlap to 50% requires additional bags, but offers the advantages of greater stability, redundant coverage in the event that bags are damaged, and reduced wave runup elevations.

Based on the results of large-scale model testing, the hydraulic stability of gravel bags in the 50% overlap configuration can be estimated using Hudson's Equation (CERC, 1984) with a stability coefficient K_D of 3.0 (Gadd, 1988). Fig. 4 displays the computed threshold wave heights for bag instability as a function of the cotangent of the slope angle. For the 3H:1V slopes in common use, instability is predicted to occur at a wave height of 1.9 m for 1.5 m³ bags, and 2.4 m for 3.0 m³ bags.

A permeable filter fabric must underlie the gravel bag armor layer to retain the slope fill material (Fig. 3). The experience to date indicates that if the slope is composed of coarse sand and gravel with a low fines content, non-woven material with a grab tensile strength of 525 N/cm provides acceptable performance.

Performance Evaluation

Gravel bags have been used as the primary means of slope protection on nine man-made islands and two coastal pads in the Alaskan Beaufort Sea. Four of the islands were constructed in exposed locations with water depths of 12 to 15 m; the remainder were located in partially sheltered sites with depths to 7 m.

Resolution and Mukluk Islands illustrate the range of performance which has been observed for gravel bag armor systems. Resolution, located in a partially

Figure 4. Threshold Wave Heights for Gravel Bag Instability

sheltered location with a water depth of 2.3 m, has sustained damage to its 3,140 1.5 m³ gravel bags at an average rate of about 5% per year since it was constructed in 1980. The primary causes of the damage have been the impacts of drift ice during the summer months, and movements of the ice sheet during the winter months. Repairs have been performed on two occasions to restore the integrity of the armor.

Mukluk Island was constructed in 1983 at an exposed location in 14.6 m of water. During the following two open-water seasons, drift ice impacts ruptured a majority of the 3.0 m³ bags from the waterline to a depth of 8 m. Because the island was no longer needed for oil exploration, the damage was not repaired, leading to an extensive failure of the armor and loss of island fill material in response to two severe storms in 1986 (Anderson and Leidersdorf, 1988).

The foregoing observations, as well as those from other facilities, suggest that gravel bag armor is best suited for applications in shallow and intermediate water depths where wave heights seldom exceed 3 m, and where frequent impacts from large, drifting ice floes are not anticipated. Because ice damage can predispose the armor to failure under wave conditions which are well below the threshold level for hydraulic instability, periodic inspections and repairs are essential to maintaining its functional effectiveness.

LINKED CONCRETE MATS

Linked concrete mat armor consists of concrete blocks which are joined by flexible linkages to form a continuous, articulated cover on the slope to be protected (Plate 3). Rather than depending upon mass alone, the mat derives a significant portion of its stability from the connections between adjacent blocks.

Plate 3. Concrete Mat Armor on the Endicott Project

The primary advantages of the mat concept are a reduced susceptibility to ice damage, a suitability for modular installation, and the ability to accommodate changes in the subgrade without permitting catastrophic fill losses. Disadvantages include a relatively high capital cost, and the difficulty in effecting repairs if significant damage is sustained.

Design Considerations

In recognition of the need to withstand both severe ice loads and the cyclic impact loads resulting from wave-induced uplift, relatively large, reinforced blocks with chain-and-shackle linkages have been selected for most Arctic offshore applications. A representative example of the block design, in which the blocks are 1.2 m square and 230 mm thick, is provided in Figure 5.

A filtration medium is required under the blocks to retain the slope fill material. Permeable geotextiles

(AFTER HAYLEY ET AL., 1987)

Figure 5. Representative Concrete Block Design

have been used for the Arctic projects to date, but graded stone or manufactured concrete rubble may be warranted for projects with a long design life or at exposed locations where the fabric might be damaged by uplift-related abrasion.

Although a semi-analytical model has recently been developed for evaluating the hydraulic stability of unlinked mat systems (Burger, et al., 1990), a comparable design tool for linked mats does not presently exist. Hydraulic model testing is therefore recommended as the most reliable means of refining and confirming the design of linked mat systems for major projects.

The relatively smooth surface of concrete mat armor, although advantageous from the standpoint of reducing ice forces, is ineffective in deterring wave runup. As illustrated in Plate 3, this potential problem can be addressed by restricting the use of the mat to the zone of severe ice and wave impacts, and placing overlapped gravel bags on the upper portion of the slope.

Performance Evaluation

Linked concrete mat armor was tested on a limited scale on two nearshore islands in the early 1980's. Based on the successful performance of these prototype test sections, it has been selected for use in a coastal revetment, and as the primary means of protection for three islands: Northstar, constructed in 1985 in a water depth of 13.7 m (Hayley, et al., 1987), and the two

islands of the Endicott Project, constructed in 1985-6 in depths of 1.8 to 3.6 m (Munday and Bricker, 1987).

At the Endicott site, where the wave and ice conditions are moderated by the water depth, the mat has sustained no significant damage and required no maintenance since it was installed. It is noteworthy that this performance has been achieved despite the occurrence of wave and ice events with sufficient energies to displace 4 m^3 gravel bags on the upper slopes.

Wave and ice conditions have been more extreme at the Northstar Island site, and have included storm waves with heights of 3 to 4 m, and numerous impacts from large multi-year ice floes. Although the mat performed significantly better than the gravel bag armor systems on nearby islands, it nevertheless sustained appreciable damage. As discussed by Gadd and Leidersdorf (1990), wave-induced uplift was of a sufficient magnitude to cause deformation of the subgrade, abrasion of the filter fabric, and localized fill losses. These irregularities in the slope served to intensify the loads imparted by ice impacts, resulting in the breakage of both concrete blocks and steel linkages, and the displacement of groups of blocks in the vicinity of the waterline.

The foregoing observations suggest that the mat systems currently in use are capable of withstanding the wave and ice forces in partially sheltered environments with little or no damage. They are particularly appropriate for projects in such locations with extended service lives, in that their relatively high capital cost will be offset by low maintenance costs. In exposed locations, the existing mat technology is susceptible to damage from the wave and ice forces associated with extreme events. Possible alternatives for improving the armor performance in this regard include increasing the thickness of the blocks and the strength of the linkage system in the vicinity of the waterline, and providing a near-horizontal bench in the slope just below the waterline to dissipate the energy of arriving waves and ice floes (Leidersdorf, et al., 1994).

SUMMARY AND CONCLUSIONS

The experience of the past 15 years indicates that the existing slope protection methods are capable of resisting the hydraulic and ice forces encountered in the coastal and nearshore waters of the Alaskan Arctic. The most cost-effective method of protection for a particular project depends upon the water depth, the degree of exposure to wave and ice impacts, and the project

design life. Sacrificial beaches are well-suited for applications in depths of 2 m or less. Gravel bag armor can withstand more severe wave conditions, but is susceptible to ice damage and requires regular maintenance. Linked concrete mat armor is capable of resisting both the ice and wave impacts commonly encountered in nearshore areas, and is therefore recommended for projects requiring secure protection over an extended period.

Gravel bags and linked concrete mats have also demonstrated the ability to protect facilities at exposed sites in deeper water, but have sustained damage from extreme wave and ice events. Frequent inspection and repair activities are necessary at such locations to prevent catastrophic slope failures.

In order to develop more durable slope protection systems suitable for long-term service at exposed sites, it will be necessary to provide an improved resistance to the impacts of large ice floes, and to the combined effects of wave and ice loads. At the present time, the most promising approach appears to be through modifications to the existing mat technology.

CHAPTER 127

Bragg Reflection Breakwater: A New Shore Protection Method?

James A. Bailard¹, Jack DeVries², James T. Kirby³
and Robert T. Guza⁴

ABSTRACT

The feasibility of a new type of breakwater is explored through a combined program of theoretical analysis, laboratory experiments and a prototype field test. The breakwater consists of a series of low height, shore-parallel bars which are placed just outside the surf-zone. The incident wave field is strongly reflected when the incident wave length is equal to twice the distance between adjacent bars. The breakwater acts to shelter the beach against storm wave attack and to build a tombolo sand deposit behind the breakwater. Theoretical and laboratory studies indicated that the Bragg reflection breakwater concept may have considerable merit, however, a small scale field test served to demonstrate the many practical difficulties in implementing the concept.

INTRODUCTION

The Naval Civil Engineering Laboratory (NCEL) has been involved in a multi-institutional program to explore low cost, rapidly deployable techniques for reducing beach erosion during storms. One concept under consideration is the Bragg reflection breakwater. Theoretical and

¹ Principal, Bailard Jenkins Technologies, Carpinteria, CA

² Engineer, Naval Civil Engineering Lab, Port Hueneme, CA

³ Professor, University of Delaware, Newark, DE

⁴ Professor, Scripps Institution of Oceanography, La Jolla, CA

laboratory studies have shown that a series of periodically spaced, low height bars, oriented parallel to the beach, can produce a strong reflection of the incident wave field. A resonant condition (termed Bragg reflection) occurs when the incident wave length is equal to twice the separation distance between bars.

The Bragg reflection breakwater concept involves placing a series of artificial bars just outside the surfzone. Referring to Figure 1, the effect of the bar field is two-fold: to shelter the beach from storm wave attack; and, to create a large sand volume behind the breakwater by way of the induced nearshore circulation. Both effects serve to protect the beach against storm wave attack: the first by reducing the rate of offshore sand transport, the second by increasing the erodable sand volume.

The objective of the research program was to explore the feasibility of the Bragg reflection breakwater concept through a combined program of numerical and laboratory modeling and a prototype field test. The present paper presents an overview of the program with an emphasis on the planning and results of a small scale field experiment.

BACKGROUND

Theoretical and Experimental Basis

Davies and Heathershaw (1984), Mei (1985) and others have shown that a series of low amplitude sinusoidal undulations on the seabed can be an effective reflector of surface gravity waves. The reflected wave energy varies as a function of the ratio of the incident wave length to the spacing between bottom undulations. A resonant condition, termed Bragg reflection, occurs when the incident wave length is equal to twice the distance between undulations. When resonance occurs, a small number of bars can reflect a substantial portion of the incident wave energy.

Technical Issues

At the onset of the research program, there were a number of unresolved technical issues relating to the feasibility of the Bragg reflection breakwater concept. These included: the response characteristics of non-sinusoidal bars on a sloping beach; the effects of finite bar length and the resulting wave-induced circulation; the morphological response of the beach in the presence

Figure 1. Schematic drawing of Bragg reflection breakwater concept.

Figure 2. Beach profile response model results.

of the breakwater; the practical design, installation and recovery of a breakwater; and, the effects of waves on bar stability and scour. An additional issue was how to measure spectral wave reflection in the field.

PRELIMINARY ASSESSMENT

As a means of exploring the feasibility of the Bragg reflection breakwater concept, a series of preliminary studies were conducted. These studies were to culminate in a small scale field test of the concept. The results of the preliminary studies can be summarized as follows.

Wave and Current Modeling

Numerical and laboratory modeling studies were conducted at the University of Florida to examine the effects of bar shape, bar placement, beach slope and bar length on the reflection characteristics of a Bragg reflection breakwater. Details of these studies may be found in Anton et al. (1990). Specific results included:

- o The primary effect of beach slope is to require an adjustment in the spacing between each bars to accommodate the change in incident wave length.
- o The reflection from a non-sinusoidal bar field can be calculated by expanding the bottom shape function as a fourier series and linearly summing the response characteristics for each component of the series.
- o Finite bar length causes a longshore variation in the wave-induced setup leading to the formation of a rip current flowing outward over the bar field. The rip current acts to broaden the resonant peak.

These studies indicated that a Bragg reflection breakwater, constructed from a small number of practical-shaped (i.e. non-sinusoidal) bars, could be expected to generate a reflection coefficient in the range of 0.2 to 0.4.

Beach Response Modeling

A Bragg reflection breakwater protects a beach from storm wave attack by reducing the rate of offshore sand transport via decreased wave height and increasing the erodable sand volume via creation of a tombolo behind the breakwater. The former is a two-dimensional effect which is independent of breakwater length. The latter is a three-dimensional effect which results from the formation of a nearshore circulation cell with a rip current flowing outward over the top of the breakwater.

NCEL conducted a numerical model study to determine the impact of a Bragg reflection breakwater on the two-dimensional response of a beach profile during a simulated storm. The model study utilized an energetics-based beach profile response model developed by DeVries and Bailard (1988). The model was run for a simulated 5 day storm assuming varying wave reflection coefficients. The effectiveness of the breakwater was expressed in terms of the normalized erosion volume. This was defined as the ratio of the eroded sand volume in the presence of the breakwater divided by the eroded sand volume without the breakwater.

Model inputs were as follows:

- o Initial equilibrium beach slope = 0.03
- o Grain size = 0.4 mm
- o Storm duration = 72 hr
- o Peak wave height = 2 m
- o Peak wave period = 9 sec

Without the breakwater, the beach eroded approximately 205 cubic meters per meter of beach. Referring to Figure 2, the breakwater reduced the storm erosion volume by an amount which was inversely proportional to the wave reflection coefficient, K_r . The degree of reduction is quite significant, amounting to 35% for a reflection coefficient of 0.2.

A movable bed physical model study was conducted at the University of Florida to qualitatively examine the three-dimensional beach changes induced by a Bragg reflection breakwater. The model confirmed the presence of a nearshore circulation cell with a rip current flowing outward over the bar field. The circulation cell caused a tombolo to form behind the breakwater, with the outer edge of the tombolo perched on the shoreward-most bar.

Bar Module Tests

It was anticipated that developing a practical breakwater would be a significant design challenge. Our limited budget necessitated coming up with a breakwater which could be rapidly assembled, installed and recovered using a minimum of people and equipment. In order to explore various design and installation concepts, NCEL conducted field tests of two bar designs at a Port Hueneme beach. Both designs featured modular constructions consisting of skid-mounted bar modules which could be assembled on the beach and dragged offshore.

Referring to Figure 3, the first design consisted of a geotextile bag attached to a skid-mounted steel frame. The concept was to drag the modules into place with the bags empty, and then fill the bags with sand using a small dredge pump. When the breakwater was no longer needed, the bags could be slit, allowing the sand to disperse and the bars dragged back ashore. The advantage of this design was that the bar modules would be light and easy to move when empty, but heavy and difficult to move when full.

An attempted field test of the geotextile bar design ended in failure. Although assembling and positioning the bar module proved simple, filling the geotextile bag with a small dredge pump proved difficult. The pump was mounted on an amphibious LARC vehicle, parked in the surfzone. The principal difficulties were maintaining an adequate supply of sand to the pump and handling the intake and discharge hoses. When, after a few hours of filling, little sand had been pumped into the bag, the test was abandoned. In retrospect, the test might have been more successful had a larger, perhaps land-based dredge pump had been used. Nevertheless, the installation procedure was judged to be too cumbersome for the planned field experiment.

Referring to Figure 4, the second bar module design consisted of a corrugated steel arch attached to a skid-mounted steel frame. The concept was to assemble the modules on the beach and drag then into position. When the breakwater was no longer needed, the modules would be dragged back onto the beach and removed. The advantage of this design was that the modules were ready to go once they were moved into position. The main drawback was that the modules were relatively light weight and could be moved about by large waves. Although pinning the modules with uplift resisting anchors was considered, it was judged unnecessary for the anticipated wave climate.

The field test demonstrated that the arch module design could be rapidly assembled and installed. Provided wave heights were less than 1 m (rms), the module tended to remain in place. The primary problem was a scouring of the seabed underneath the bar module. This was caused by wave-induced flow passing through the narrow gap between the leading and trailing edges of the bar and the sand bottom. The scour depression acted to further enhance the venting flow, reducing the reflectivity of the bar module.

Figure 3. Geotextile bar module design.

Figure 4. Steel arch bar module design used in the field test.

The venting/scour problem was solved by adding steel plates to the leading and trailing edges of the bar. The plates were attached to the bar by hinges, effectively sealing off the gap underneath the bar. Although some scour continued to occur around the bar module, the plates continued to function by dropping down into the scour depressions. After a period of two days, the scour depressions appeared to stabilize at a depth of about 0.3 m. A few days later, a significant storm passed through the area destroying the bar modules. However, the successful performance of the module prior to the storm convinced us to that the steel arch design would be suitable for the planned field test.

Detection Method

An inverse method was developed to estimate the directional spectrum of the reflected wave field (see Herbers and Guza, 1990). The method requires simultaneous measurement of the incident wave field at a point offshore and the reflected wave field at a point immediately in front of the Bragg reflection breakwater. The procedure is as follows:

- o The incident wave field is estimated using the offshore wave measurements.
- o The incident wave field is transformed to shallow water using linear refraction.
- o The reflected wave field is estimated using the inshore wave measurements and subject to maximum compatibility with the refracted incident wave field.

PROTOTYPE FIELD TEST

Site Selection

In order to maximize the detectable reflected wave energy, we wanted to construct a breakwater that was significantly longer than the incident wave length and which produced a reflection coefficient of about 0.4. To minimize the size of the breakwater and therefore its cost, we decided to carry out our experiment in "super laboratory" conditions. These can be defined as significant wave heights less than 0.25 m, a wave period of about 5 seconds and an installation depth of about 1.5 meters.

A number of sites were considered for the field experiment. The desired site required small amplitude, short period waves, a long planar beach, limited public access

and good logistical support. Based on these criteria, Cape Canaveral Beach, Florida, was selected as the preferred site for the field experiment. The site was located within the confines of Cape Canaveral Air Force Base, limiting public access and providing the necessary logistical support. Two years of wave data from the site indicated that during the month of July, we could expect significant wave heights of about 0.2 m with a 5 second period.

Breakwater Design

Referring to Figure 5, the prototype Bragg reflection breakwater was composed of three bars, 90 meters long. The offshore and middle bars were 0.7 meters high and 2.2 meters wide. The inner bar was 0.6 meters high and 2.4 meters wide. The spacing between the outer and middle bar was 9 meters versus 8 meters between the middle and inner bars. The breakwater was designed to be installed in a water depth of about 0.76 meters MLW.

Referring to Figure 5, each bar module was 7.3 meters long. The modules were fabricated from a pair of corrugated steel arches attached to a steel skid-mounted frame. The frame was composed of a pair of steel angle members attached to two steel skid beams. The angle members served as attachment points for the edges of the corrugated steel arches and the a series of steel scour plates hinged to the front and rear edges of the bar. The bar modules were designed to be assembled by a small crew using a crane and hand tools. Assembly was facilitated by prefabricating the components off-site and using nuts and bolts for fasteners.

The total weight of the bar modules was approximately 3300 lb. An stability analysis indicated that the modules would remain in place without anchoring if rms wave heights were less than 1 m (assuming a wave period of 5 to 6 sec).

Anticipated Performance

Figure 6 shows a plot of the estimated reflection characteristics for the prototype breakwater. These characteristics were estimated using a computer program developed by Kirby (1987). The response function shows a broad peak centered at about 6 seconds with a reflection coefficient value of 0.4. The adjacent narrower peak is the first harmonic resulting from the non-sinusoidal shape of the bar field (i.e. discrete bars resting on a planar bottom).

Figure 5. Bragg reflection breakwater design used in the field test.

Figure 6. Estimated reflection characteristics for the field tested breakwater.

Installation and Recovery

The bar modules were assembled in a staging area located about 200 meters from the beach. After assembly, the modules were carried to the beach with a large front-end loader. The loader placed the modules on the upper beach face in groups of three, with their skids oriented perpendicular to the shore. Scour plates were attached to each module and tied up out of the way to facilitate module dragging.

Referring to Figure 7, the original installation plan called for dragging the modules into position in groups of three using a shore-based winch and a movable sheave and anchor assembly. In practice, we found that the waves at the site were too large to allow this method of installation. In particular, the LARC vehicle found it difficult to negotiate the surfzone while pulling a heavy anchor and cable. As a result, only one group of modules was installed using this technique. The rest of the modules were installed individually at extreme low tide using the front-end loader. Although rapid (all of the modules were installed in a single low tide), this alternative technique required placing the breakwater approximately 15 meters closer to shore. As a result, the breakwater was situated inside the surfzone for a substantial portion of the tidal cycle.

Monitoring Plan

A survey grid was established in the area of the breakwater and in an adjacent control area. Daily wading profiles were to be conducted in the test and control areas. These were to be supplemented by combined wading and fathometer surveys at the start and end of the experiment.

The incident directional wave spectrum was measured at a depth of 6 meters using a linear array of pressure sensors. A second array of pressure sensors and current meters was to measure the reflected wave field and the induced nearshore circulation field around the breakwater. The offshore array was constructed prior to the installation of the breakwater. The inshore array was to be constructed once the breakwater was in place. Unfortunately, this never occurred due to problems described below.

RESULTS

The Bragg reflection breakwater was deployed on 11 July 1988. During the week prior to installation, the significant wave height at the site averaged about 0.4 m.

Figure 7. Planned installation method.

Figure 8. Observed scour pattern in field test.

This was approximately twice the anticipated wave height based on two years of measured wave data and essentially equal to the maximum design wave height for bar stability.

Immediately following breakwater installation, the significant wave height increased to about 0.6 m and remained at this level for the next 36 hours. These waves were significantly greater than the maximum design wave, causing the bar modules to slowly shift their positions. The modules rotated towards the direction of wave attack and moved shoreward about 1 to 2 m. The movement began with the outer-most bar and progressed inward through the middle and inner bars.

Another problem which developed almost immediately after installation of the breakwater was an intense scouring around the bar modules. As the tide rose, the bars were observed to be generating a significant degree of turbidity. On the following day we discovered large scour holes had formed in front of and behind the bars (see Figure 8). The scour holes slowly grew, becoming deeper and wider. Eventually they reached more than 2 meters deep, threatening the stability of the bar modules.

The observed scour was approximately an order of magnitude greater than the scour observed in the Port Hueneme tests. Since wave conditions were similar, we believe that the increased scour was attributable to the different properties of the two beach sands. At Port Hueneme, the sand was well sorted, having a median diameter of 0.25 mm and quartz and feldspar composition. At Cape Canaveral, the sand was poorly sorted, having a medium diameter of 0.14 mm and calcium carbonate composition. Apparently the lighter specific gravity of the Cape Canaveral sand, coupled with its smaller size and higher percentage of fines, resulted in increased sand suspension and enhanced scour.

After two days, the bar modules had become badly scattered. Some of the modules had shifted into their scour holes and begun to become buried. With bar burial becoming a growing problem, the decision was made to terminate the experiment and recover the bar modules while it was still possible. A bulldozer was used to pull the individual modules out of the surfzone and back up the beach face. From there, a front-end loader transported the modules back to the staging area where they were disassembled.

Because of the short duration of the breakwater deployment, the nearshore sensor array was never installed. As a result, no quantitative measurements were obtained.

Visual observations during the first few hours of deployment indicated that some wave reflection was occurring as evidenced by a standing wave pattern in front of the breakwater.

CONCLUSIONS

Theoretical and laboratory studies have indicated that the Bragg reflection breakwater concept may have merit as an expedient shore protection method. The wave sheltering produced by a small number of bars was found to significantly reduce the estimated erosion volume due to a model storm. The small scale field test, however, served to demonstrate many of the difficulties that will need to be overcome before the Bragg reflection breakwater concept becomes practical. Bar stability and sea bed scour appear to be the most troubling problems. Further tests are needed to determine the overall merit of the concept.

CHAPTER 128

Scale Effect of Wave Force on Armor Units

Tsutomu Sakakiyama¹ and Ryoichi Kajima²

ABSTRACT

This paper describes the scale effect in experiments on the stability of armor units from the point of view of the wave forces. The relationship between the drag coefficient C_D and the stability coefficient K_D of Hudson formula is theoretically derived to be that $K_D \propto C_D^{-3}$ on the condition that the inertia force is negligible. Three kinds experiments were performed by using various sizes of Tetrapods ranging from 16 g to 6800 g according to the Froude law for scaling, 1) to measure wave force on an armor unit placed in an armor layer of a breakwater, 2) to determine the drag and inertia coefficients in wave fields, and 3) to determine the drag coefficient in a steady flow. It is found that the wave force in the small-scale experiments is relatively larger than that in the large-scale experiments. As the wave height increases, the drag force becomes predominant in comparison with the inertia force. It is concluded that the scale effect of the wave force on armor units is mainly due to the change of the relative drag force number as a function of Reynolds number.

1. INTRODUCTION

The weight of armor units in breakwaters and sea walls are usually determined by laboratory experiments or stability formulae. Hudson formula (1959) is prevalently used as a stability formula for its simplicity. In order to apply the experimental results to prototype designs, the scale effect of the experiments on armor units should be taken into account. Thomsen et al.

1 Senior Research Engineer, Central Research Institute of Electric Power Industry, 1646 Abiko, Abiko-city, Chiba, 270-11, Japan.

2 Senior Research Fellow, ditto.

(1972) and Shimada et al. (1986) investigated the scale effect of the stability of armor units by using the large-scale models. Both researches showed that small-scale models were less stable than large-scale models.

In other words, the experimental coefficient in Hudson formula, K_D , at a certain constant damage rate depends on a model scale. As a result, small-scale experiments give conservative stability criteria. The weights of armor units are overestimated when the results are directly applied to prototype designs by the Froude law for scaling. On the other hand, van der Meer (1988) showed that the stability of an armor layer of rock was not influenced by Reynolds number ranging from 4×10^4 up to 7×10^5 .

It was reported that the transmission and reflection coefficients in small-scale tests become smaller than those in large-scale tests (Johnson et al., 1966; Shuto and Hashimoto, 1970; Delmonte, 1972; Wilson and Cross, 1972; Shimada et al., 1986). It means that the energy dissipation in small-scale tests is relatively larger than that in large-scale tests. It also implies that the drag force in small tests is relatively larger than that in large-scale tests. As long as tests are performed by using the Froude law the similarity of the viscosity is neglected.

Although the experimental results of the scale effects were presented in the previous papers and the quantitative evaluation was described, the mechanism of the scale effects has not adequately explained so far.

For the purpose, we focus our attention on the wave forces acting on a single armor unit. This paper firstly aims to theoretically interpret the scale effects of the stability of armor units. Secondly, three kinds of experiments were performed to show that relative wave force depends on the model scales and to approve the theoretically presented relationship between the parameters relevant to the scale effect.

2. THEORETICAL CONSIDERATION

Hudson formula (1959) was derived from the balance between the wave force and the resisting force. The process of the derivation of Hudson formula was reviewed here from the point of view of the scale effect of the wave force. Fig. 1 shows the definition sketch. A wave force is given by Morison equation as shown by eq.(1).

$$F = \frac{1}{2} \rho C_D A u |u| + \rho C_M V \dot{u} \quad (1)$$

where ρ is the fluid density, C_D , C_M the drag and inertia coefficients, A and V the projected area and volume of an armor unit and u , \dot{u} the velocity and acceleration of water particle.

The resisting force is expressed by eq.(2).

Fig. 1 Definition sketch

$$F_r = \pm fW' \cos \theta - W' \sin \theta \quad (2)$$

where f is the friction coefficient, W' the buoyant weight of the armor unit and θ the angle of the breakwater slope. The signs of "+" and "-" are applied for wave run-down and wave run-up, respectively. For incipient instability of armor units, the wave force is equal to the resisting force. After letting $F=F_r$, the following equation was obtained to describe the relationship between the weight of an armor unit, W , and other parameters.

$$W = \frac{k_a^3 \gamma_r C_D^3 (u | u |)^3}{8 k_v^2 ((\pm f \cos \theta - \sin \theta) (S_r - 1) g - C_M \dot{u})^3} \quad (3)$$

where k_a , k_v are the shape coefficients defined as $A=k_a q^2$, $V=k_v q^3$ and $q=(W/\gamma_r k_v)^{1/3}$ as defined in Hudson (1959).

Hudson formula was derived on some assumptions as follows.

- 1) The inertia force is neglected.
- 2) The velocity u is substituted by that of the linear long wave theory, $u=\alpha \sqrt{gh}$, where α is a proportional coefficient.
- 3) Wave height is assumed as $H=\gamma h$, where γ is a function of the wave steepness. Together with assumption 2), the velocity is given by $u=\alpha \sqrt{gH/\gamma}$.

These assumptions are also introduced into eq.(1). Eq.(1) becomes eq.(2) as follows.

$$W = \frac{k_a^3 \alpha^6 \gamma_r C_D^3 H^3}{8 k_v^2 \gamma^3 ((\pm f \cos \theta - \sin \theta) (S_r - 1) g)^3} \quad (4)$$

In order to investigate the mechanism of the scale effect, the parameters which are functions of Reynolds number should be kept in the formula.

On the other hand, Hudson formula is expressed by eq.(5).

$$W = \frac{\gamma_r H^3}{K_D \cot \theta (S_r - 1)^3} \quad (5)$$

where K_D is the experimentally determined coefficient which is a function of various parameters as mentioned in Hudson (1959).

Hudson (1959) assumed that the resisting force was equal to the buoyant weight of the armor units because an armor unit is isolated for incipient instability. The difference of the term of θ is $\cot \theta$ instead of $\pm f \cos \theta - \sin \theta$ which is equivalent to the term in Iribarren's formula. Hudson introduced the slope of the breakwater θ by the stability number $N_s = (K_D \cot \theta)^{1/3}$.

The rest of the differences are the coefficients which are not related to the scale effects. Comparison between eq.(4) and eq.(5) gives the following relationship between K_D and C_D .

$$K_D \propto C_D^{-3} \quad (6)$$

So far, for the design a value of K_D of a specific kind of armor unit has been considered as a constant at a fixed damage rate. Eq.(6), however, implies that K_D depends on the model scale because the drag coefficient C_D is a function of Reynolds number. It is necessary to ascertain experimentally the relationship between K_D and C_D given by eq.(6). It is also important to check the assumptions which were introduced to the derivation of eq.(4) and Hudson formula. From among them, assumption 1) which is related to the scale effect will be investigated in section 3.2.

3. EXPERIMENTS AND RESULTS

In previous researches the experiments of the stability of armor units were done in the ways of counting the numbers of armor units which rolled down an armor layer of the breakwater and measuring the damaged area due to wave attack. The experimental results might be subjected to the handling of the armor units in the individual experiments. However, it is more accurate to measure wave forces directly than to investigate the damage rate.

3.1 Wave Force on Armor Unit

The first series of experiments was performed in order to measure wave forces acting on an armor unit in an armor layer. Wave force were obtained by using load-cell type wave force gages for various sizes of Tetrapods. Fig. 2

shows the experimental setup which was constructed in a wave flume 51 m long, 0.9 m wide and 1.2 m deep. Wave forces were measured by using the strain gages transducers which transform displacement of armor unit to wave force. The armor unit installed to the wave force gage was protected not to have contact with armor units surrounding it. By the present measuring system, wave force acting on a cylinder which connected the armor unit and the force gage was also included in the data. In order to reduce the wave force acting on the cylinder, as shown by Picture 1 in section 3.2, a pair of wave force gages were used. One force gage was used for the armor unit and the cylinder and the other for the cylinder. Table 1 shows the experimental conditions. According to the Froude law for scaling, the geometric parameters of breakwater model and water depth etc. were determined. Wave heights were chosen by the capacity of the wave generator.

Table 1 Experimental conditions (wave force)

CASE	Tetrapod		breakwater depth h(cm)	period T (s)	wave height H (cm)
	weight W (g)	height b (cm)			
F4	2200	15.0	68.2	2.32	16.9~33.3
F3	570	9.6	43.6	1.85	11.6~27.7
F2	120	5.8	26.4	1.44	6.9~17.6
F1	60	4.6	20.9	1.27	5.7~14.3

Fig. 2 Experimental setup to measure wave force acting on armor unit in breakwater

Fig. 3 shows an example of time histories of wave run-up, ξ , the wave force F_b in the direction along the breakwater slope and the uplift force F_u . It is observed that the uplift is negative at the moment when a wave hits the

armor unit. It means that wave force works in the direction into the break-water body.

Fig. 4 shows the relationship between the relative wave force F_b/W' and the deep-water wave steepness H_o/L_o for four different sizes of model scales. As this figure shows, the relative wave force increases as model scale becomes small. It means that an armor unit in small-scale experiments becomes unstable under relatively smaller wave action than large-scale experiments.

Fig. 3 Time histories of wave forces and wave run-up

Fig. 4. Relative wave force depending on model scale

Fig. 5 Hodograph of wave forces

The result of $W=570$ g shows a different tendency. The armor unit of $W=570$ g was set at a different level from the others. Fig.5 shows the hodograph of the wave force. The pattern of $W=570$ g shows acutely different change from the others. When a wave runs down, the wave force is equal to the weight of a part of the armor unit which is under the still water level. The values for $W=60, 120, 2200$ g were about -0.4 but -0.2 for $W=570$ g.

From the above investigation, it is confirmed that the wave force in smallscale experiments is relatively large compared to that in large-scale experiments.

3.2 Drag and Inertia Forces

The second series of experiments was performed in order to check assumption 1), that is, to measure the magnitude of the drag and inertia forces

Picture 1 Experimental setup to determine drag and inertia coefficients

by using five different sizes of Tetrapods. Picture 1 shows the experimental setup. Surface displacement was also measured by using a capacitance-type wave gage. The drag and inertia coefficients were determined by Fourier analysis of the measured wave forces, the estimated wave velocities and accelerations based on Morison equation (Sarpkaya, 1976). Wave velocities and accelerations at the position of Tetrapod were estimated by the fifth order solution of Stokes wave theory (Isobe et al., 1978). The projected area of the armor unit in Picture 1 is $0.59 \times b^2$. Table 2 shows the experimental conditions. The scale of armor units and wave period were determined by the Froude law.

Table 2 Experimental conditions
(drag and inertia coefficients)

CASE	Tetrapod		uniform depth h(cm)	period T (s)	wave height H (cm)
	weight W (g)	height b (cm)			
C5	6800	22.0	92.5	2.87	6.2 ~ 31.8
C4	2200	15.0	90.8	2.36	7.0 ~ 34.3
C3	570	9.6	89.9	1.87	7.3 ~ 35.9
C2	120	5.8	57.3	1.45	4.2 ~ 21.4
C1	60	4.6	49.7	1.28	4.4 ~ 20.9

Fig. 6 shows the comparison between the measured and calculated results of the surface displacement and of the wave forces. At top, the measured surface displacements were in good agreement with the calculated ones. The measured wave force is also in good agreement with the calculated total wave force which consists of the drag and inertia forces as shown by Morison equation.

Fig. 7 shows the ratio of the drag force F_D to the inertia force F_I . Reynolds number Re is defined as $Re = u_c b / \nu$, where u_c is the velocity under the wave crest. As Reynolds number increases, the ratio F_D / F_I increases for each scale model. Since a wave height is large at the incipient instability of armor units, the drag force becomes predominant compared to the inertia force.

Fig. 8 shows the inertia and drag coefficients as functions of Reynolds number and KC number where KC is defined as $KC = u_c T / b$. Since KC number is a ratio of the drag force to the inertia force, as shown in Fig. 7(a), as KC decreases, C_M increases. As Re increases, C_M increases at a certain KC number; on the other hand, C_D decreases. At a constant KC number, Froude number is also constant. It is necessary to concentrate on the changes of C_M and C_D at a constant KC in order to investigate the scale effect of wave force. C_M and C_D are non-dimensional inertia and drag forces, respectively. At a certain constant Froude number, C_M and C_D change depending on Reynolds number.

Fig. 6 Surface displacement and wave forces

Fig. 7 Ratio of drag force to inertia force

(a) Inertia coefficient C_M

(b) Drag coefficient C_D

Fig. 8 Inertia and drag coefficients depending on model scale

The ratio of the gravity to the inertia force is constant but that of the inertia force to the viscous force changes. The similarity of the dynamics is not kept constant. The inertia force is proportional to wave acceleration and the drag force proportional to the velocity squared. As a result, as wave height increases, the drag force becomes predominant to the inertia force as shown in Fig. 7.

3.3 Scale Effects of Drag Force and Stability

The drag coefficients of various sizes of Tetrapods in a steady flow were obtained by measuring the fall velocities in still water. The weight of Tetrapod ranged from 16 g to 6800 g. A 4-m deep and 2-m by 2-m section water tank as shown in Fig. 9 and a set of video recording system were used to measure fall velocities. Fall velocities were obtained by measuring the falling time for the distance of 1.0 m at three levels ($z = -2.5, -3.0, -3.5$ m). Measurements were repeated from five to ten times for each size of Tetrapod.

By this series of experiments, the determined drag coefficients were obtained on the condition that no inertia force worked and the relative drag force was a constant. It means that the drag force is equal to the buoyant force ($F_D/W'=1.0$) for each size of Tetrapod. If the drag coefficient, which is the relative drag force, is constant, there will be no scale effect due to the viscosity.

Fig. 10 shows vertical changes of the fall velocities of Tetrapods. It was observed that there was no significant change vertically. It is confirmed that the fall velocities were obtained on the condition that no inertia force worked. Maximum fall velocity is up to about 2 m/s at $W=6800$ g on the ex-

Fig. 9 Water tank to measure drag coefficient in steady flow

Fig. 10 Fall velocity of Tetrapod

perimental conditions. Vertically averaged values of the fall velocities in Fig. 10 were used in the following analysis. The drag coefficient C_D was calculated with the formula $C_D = 2(S_r - 1)gV/(w^2 A)$, where w is the fall velocity and the projected area $A = 0.65 \times b^2$ was chosen as an averaged value.

Fig. 11(a) shows the normalized drag coefficient C_{Dm}/C_{Dp} depending on Reynolds number, R_b , where C_{Dp} is the prototype drag coefficient and is assumed as 0.6 which is the value of the drag coefficient at $R_b = 10^8$. Reynolds number R_b is defined as $R_b = wb/\nu$. As Reynolds number decreases, C_{Dm}/C_{Dp} increases. It means the relative drag force increases, as a model scale decreases.

The drag coefficient is dependent on conditions of the environment of the armor units. When armor units in an armor layer are attacked by waves, an upper half side of the armor units is exposed to waves. It seems that an armor unit is isolated for incipient instability. It is possible to substitute the drag coefficient of a single armor unit for that in an armor layer in order to discuss the scale effect of the wave force.

Fig. 11(b) shows the scale effect of the stability of armor units (Shimada et al., 1986). This result agrees with that by Thomsen et al. (1972). Although definitions of Reynolds number for R_b and R_N are not exactly same, values of R_b and R_N for a same size of Tetrapod is almost equal. As Reynolds numbers increase from 10^4 to 10^8 , both C_{Dm}/C_{Dp} in Fig. 11(a) and $(K_{Dp}/K_{Dm})^{1/3}$ in Fig. 11(b) reduce roughly to a half. As presented in section 3.2, at large wave height, the drag force becomes predominant compared to the inertia force. However, the inertia force works under wave action. The slight difference between Fig. 11(a) and Fig. 11(B) may be due to the inertia force.

Although the resisting force was not measured in the present study, the result of the scale effect of the stability on the armor units in Fig. 11(b) include both the wave force and the resisting force. The resisting force may be not significantly contribute to the scale effect because an armor unit is isolated when it is unstable.

From the comparison of Fig. 11(a) and (b), eq.(6) which presents that K_D is inversely proportional to C_D cubed, is approved by the experiments.

4. CONCLUSION

This paper presented the interpretation of the scale effect of the stability of armor units from the point of view of the wave forces. It is concluded from the results of the theoretical consideration and of the experiments that:

- 1) The relationship between the drag coefficient and the stability coefficient K_D of Hudson formula is theoretically derived to be that K_D is inversely proportional to the drag coefficient cubed on the condition that the inertia force is negligible. That relationship was approved by the experiments.
- 2) Wave force acting on an armor unit in small-scale model tests is relatively large compared with that in the large-scale model tests.

(a) Scale effect of drag force of armor unit

(b) Scale effect of stability of armor units

Fig. 11 Scale effect in experiments on armor units

- 3) For incipient instability of armor units, the drag force is predominant to the inertia force.
- 4) The scale effects of the wave force and of the stability of armor units can be interpreted as the scale-dependent change of the relative drag force because of the neglect of the similarity of the viscosity.

CHAPTER 129

Trends in Stability of Dynamically Stable Breakwaters by Joseph S. Kao¹ and Kevin R. Hall²

Abstract

The reshaping of dynamically stable breakwaters was studied subject to variations in armour stone, (gradation and shape), wave characteristics and duration of wave attack from head on waves in a two dimensional wave flume. Tests were undertaken at the Coastal Engineering Research Laboratory of Queen's University, Kingston, Canada using irregular waves. Profiles of the structure during the various stages of reshaping were measured using a semi-automatic profiler developed for this study.

The volume of stones and the initial berm width required for development of a stable profile along with the extent to which the toe of the structure progressed seaward were chosen as the characteristic parameters of the reshaped breakwater. The results indicated that the toe width formed as a result of reshaping and the area of stones required for reshaping were dependent on the wave height, gradation of the armour stone and duration of the storm. The initial berm width required for reshaping was also found to be dependent on the wave height, armour stone gradation, percentage of rounded stones in the armour and the duration of the storm.

Introduction

Dynamically stable breakwaters are formed as a result of reshaping by wave action. Priest et al. (1964), Moutzouris (1978), Kogami (1978), Naheer and Buslov (1983), Hall et al. (1983) and Bruun (1985) reported the formation of S-shaped profiles to be superior in performance to statically stable breakwaters. Van der

Meer and Pilarczyk (1987) provided design formulae for rock slopes and gravel beaches and extended them to apply to dynamically stable breakwaters. Breakwaters studied and reported here cover a range of instability number, $H_s/((S_r-1)D_{50})$, from 2 to 5, and utilize the total yield from quarries.

Present Tests

The studies were undertaken in a 1.4 m wide channel located within a 2 m wide wave flume, further details are provided in Hall and Kao (1990).

The rubble mound structure consisted of a core having a D_{50} of 1.2 cm and an armour layer having a D_{50} of 1.9 cm, where D_{50} is the diameter exceeded by 50% of the gradation. Four different gradations of the armour stones were used with D_{85}/D_{15} ratios ranging from 1.35 to 5.4 where D_{85} is the diameter of stone, that is larger by weight, than 85% of the sample and D_{15} is the diameter of stone, that is larger by weight, than 15% of the sample. In particular, gradation 2 has characteristics of quarries used for many previous breakwater projects (Hall et al. (1983), Baird and Hall (1984a, 1984b) and Hall (1987)).

Two other gradations of armour stones having a D_{50} of 1.9 cm and D_{85}/D_{15} ratio of 1.9 that were similar to gradation 2 but with differing percentages of rounded stones were also used in the tests, so that the percentage of rounded stones was varied from 0% to 30%. The characteristics of the armour stones used in the study are summarized in Table 1.

Tests were undertaken on a dynamically stable breakwater whose initial configuration is shown in figure 1. The basic geometry of the test structure was selected based on previous experience and taking into consideration practical aspects which make construction simpler.

Parameters Studied

Three parameters describing various aspects of the profile reshaping were chosen as dependent parameters. The three parameters, illustrated in figure 2, are the volume per unit length of armour stone required on the front slope, (A), the width of berm eroded, (B), and the distance from the control point to the outer extent of the toe following reshaping, (L), formed after the attack of 3000 waves. These parameters were made into

Figure 1 Layout of test breakwater

Figure 2 Definition of parameters

dimensionless quantities, A/D_{50}^2 , L/D_{50} and B/D_{50} .

Test Results

Effect of uniformity of stones

Figure 3 shows the relationship between L/D_{50} and the instability number, $H_s / ((S_r - 1)D_{50})$, (where H_s is the significant wave height and S_r is the specific density of armour stone) for the four gradation of stones having a D_{50} of 1.9 cm, and all containing 30% rounded stones. It is seen that gradation 1 is least susceptible to movement offshore indicating that the presence of substantial voids in the armour layer contributes to an efficient wave energy dissipation system. As the relative width of the gradation is increased, there are effectively less voids in the armour stone matrix. Figure 3 shows that the toe width developed increases for gradations 2 and 3. This trend, however, reverses for gradation 4. It appears that as the width of the gradation and thus the maximum stone size increases, the large quantity of stones exceeding a certain upper threshold size has a more dominant effect on stability than does the presence of voids. In gradation 4, a sizeable proportion (20%) of the armour stones exceed 100 gm in weight. The presence of these large stones no doubt had a considerable influence over the stability of the armour layer. Similar trends are observed parameters A/D_{50}^2 and B/D_{50} .

Effect of rounded stones in the gradation

No significant difference was observed regarding the influence of the percentage of rounded stones in the armour layer on L/D_{50} and A/D_{50}^2 following reshaping. Burcharth and Thompson (1983) indicated that in oscillatory flow, there was no appreciable difference in hydraulic stability between rock armour units and dolosse, that is for submerged units, the shape does not significantly influence stability. In the present case, although the berm width, B , of the structure was reduced as a result of wave action, the parameters A and L which are dominated by the underwater profile did not vary with shape. Such behaviour seems to confirm the results of Burcharth and Thompson that when the armour units are completely submerged the shape of the armour unit does not significantly affect the hydraulic stability. However, B/D_{50} was found to depend on the percentages of rounded stones in the armour. Gradation 2A (0% rounded) was found to be more resistant to erosion than gradation 2B (30% rounded), and gradation 2B more resistant to erosion than gradation 2 indicating that the proportion

Figure 3 Dimensionless toe width versus instability number, with fitted curves, gradations 1, 2, 3 and 4

Figure 4 Dimensionless width of berm eroded versus instability number, with fitted curves, gradations 2, 2A and 2B

of rounded stones in the gradation affects initial movement, (stability decreases with increasing "rounding" of stones). Figure 4 shows the influence of the percentage of rounded stones on B/D_{50} .

Effect of duration of storm

Several sets of data were collected for storm durations ranging from 500 to 3600 waves. Such results would be important if there was uncertainty over the expected duration of the design storm. In analyzing these data, the respective areas, A , toe width, L , and width of berm eroded, B ; at any number of waves were divided by the corresponding values formed after the attack of 3000 waves and were called relative area, A_R , relative toe width, L_R , and relative width of berm eroded, B_R , respectively. The number of waves was also divided by 3000 to give the relative number of waves, N_r , (number of waves / 3000). Since relative values are involved, they are independent of wave height, wave period, wave groupiness, gradation and shape.

The relative toe width, $(L/D_{50})_R$, is plotted against the relative number of waves, N_r , in figure 5. The first 500 waves caused most of the reshaping (about 90 % of that of 3000 waves). After 3000 waves, the process of reshaping was found to slow down considerably, but actually never stopped. After the attack of 36000 waves, additional reshaping of about 10 % more than the total toe width formed after 3000 waves attack was observed.

The same trends were observed for A/D_{50}^2 and B/D_{50} .

Effect of other parameters

Wave period and groupiness factor were found to have no significant influence on the three dependent parameters under study. A typical diagram showing the relationship between L/D_{50} and peak spectral wave period T_p is shown in Figure 6. The relationship between L/D_{50} and groupiness factor $g.F.$ is shown in Figure 7.

Derived Relationships for A , B and L .

A multiregression analysis was undertaken using minimization techniques in order to determine the relationship between the three parameters of the reshaped profiles and characteristics of the stone gradations including D_{85}/D_{15} and the percentage of rounded stones (P_R), instability number and number of relative waves, N_R .

Figure 6 Dimensionless toe width versus spectral peak period, gradation 2

Figure 5 Relative toe width versus relative number of waves, with fitted curves, gradations 2 and 3, all waves

Figure 7 Dimensionless width of berm eroded versus groupiness factor, gradation 2

The relationship between $(L/D_{50})_N$, $(A/D_{50}^2)_N$ and $(B/D_{50})_N$ and N_R are given by

$$\left(\frac{L}{D_{50}}\right)_N = \left[26 + 1.15\left(\frac{H_s}{(S_r-1)D_{50}}\right)^{2.2} + 11\frac{D_{85}}{D_{15}} - 1.5\left(\frac{D_{85}}{D_{15}}\right)^2\right] N_R^{0.042}$$

$$\left(\frac{A}{D_{50}^2}\right)_N = \left[148 + 30\left(\frac{H}{(S_r-1)D_{50}}\right)^{1.9} + 194\frac{D_{85}}{D_{15}} - 27\left(\frac{D_{85}}{D_{15}}\right)^2\right] N_R^{0.043}$$

$$\left(\frac{B}{D_{50}}\right)_N = \left[-10 + 0.51\left(\frac{H}{(S_r-1)D_{50}}\right)^{2.5} + 7.5\frac{D_{85}}{D_{15}} - 1.1\left(\frac{D_{85}}{D_{15}}\right)^2 + 6.1P_R\right] [1 + \ln N_R^{0.11}]$$

where,

- $(A/D_{50}^2)_N$ = dimensionless reshaping area of breakwater after N waves attack
- $(B/D_{50})_N$ = dimensionless width of berm eroded after N waves attack
- $(L/D_{50})_N$ = dimensionless toe width after N waves attack

Conclusions

The present series of tests indicate that for armour stones having the same D_{50} values, the wave height is the single most important factor affecting the reshaping process. Both the porosity of the armour and the fraction of heavy stones in a gradation influence the reshaping of dynamically stable breakwaters. It appeared when the gradation of stones is not very wide ($D_{85}/D_{15} < 3$) narrowly graded armour stones are less prone to reshaping; however, when the gradation of the armour stones is sufficiently wide, the effect of the very large stones start to dominate the effect of the voids inside the armour stone layer. The percentage of rounded stones was found to have an influence only on the width of berm eroded. The other dependent parameters, A and L , are dominated by the submerged section of the structure, where it appears stone mass not shape is more significant. Wave period and wave groupiness were found to have no significant effect on either A , B , or L .

CHAPTER 130

FORCES ON VERTICAL WALLS DUE TO OBLIQUELY-INCIDENT WAVES

Ching-Piao Tsai * and Dong-Sheng Jeng **

Abstract

The force exerted on a vertical wall due to obliquely-incident waves has been analyzed in this paper from the calculation of short-crested waves system by a numerical scheme. The numerical model preserves the wave elevation in an implicit function form for the dynamic and kinematic boundary equations on water surface, the accuracy is then improved. It is found that the maximum loading in onshore direction may be caused by obliquely-incident waves as the water is greater than intermediate depth. However, the onshore loading does not necessarily be the greatest force for such instance. The greatest force could be produced by the offshore loading under steeper normal standing waves. While the wall is in the shallow water region, the greatest force is occurred in onshore loading at crest by normal standing waves. This research also shows good comparisons from some experimental results.

1. Introduction

Wave forces exerted on vertical walls play a very important role in coastal engineering. The forces produced by standing waves, whose crest parallel to the wall, are usually considered as the maximum loads. However, some evidences have shown that the forces due to obliquely-incident waves, called short-crested waves, could exceed those from waves normal approach to the wall (Silvester 1974, Fenton 1985). The surface of short-crested wave is defined as having a doubly-periodic diamond-shaped crest pattern. Two dimensional progressive and standing waves are physically two limiting cases of short-crested waves as the incident waves are traveling parallel and normal to the wall respectively.

Short-crested waves have been investigated theoretically since Fuchs (1952). The systematic analysis by a third-order approximation in a non-dimensional form was proposed by Hsu et al (1979). While the detailed analysis for the force on vertical walls due to such wave system was first studied by Fenton (1985), with a third-order expansion in wave height. Fenton's solutions showed a number of unusual features which can further be found in this study. Nevertheless, it is found that the third-order

* Associate Professor, Department of Civil Engineering, National Chung-Hsing University, Taiwan 40227, Republic of China

** Master of Engineering, Department of Civil Engineering, National Chung-Hsing University, Taiwan 40227, Republic of China

approximation could produce moderately residual pressures on free surface, which has an influence on the distribution of wave pressures, as the wave is in shallow water, or steeper in intermediate depth in which coastal structures are always located.

To improve the accuracy, the force exerted on a vertical wall is obtained in the study from calculation short-crested waves by a numerical scheme. The numerical model using Fourier series approximation was proposed to calculate the highest periodic short-crested waves on deep water by Tsai et al (1990). Unlike Roberts and Schwartz (1983), the present numerical model preserves the wave elevation function in an implicit form, in analogy to the exact nonlinear nature for the dynamic and kinematic boundary conditions on water surface. Basic formulations are outlined in section 2, and the main procedures for numerical calculations given in section 3. Section 4 demonstrates the results of the force exerted on the wall. The experimental data of standing waves (Goda 1967), one of limiting cases of short-crested waves, are also quoted to compare with the calculation results.

2. Formulations

A sketch diagram of the short-crested wave motion produced by full oblique reflection from a vertical wall is shown in Fig. 1. Assume the fluid to be inviscid, incompressible and of uniform finite depth. The velocity potential ϕ for irrotational motion gives rise to the Eulerian water particle velocity components as

$$u=\phi_x, v=\phi_y, w=\phi_z \tag{1}$$

where the velocity potential $\phi(x,y,z,t)$ satisfies Laplace equation

$$\nabla^2\phi = \phi_{xx} + \phi_{yy} + \phi_{zz} = 0 \tag{2}$$

The dynamic boundary condition at the free surface (DFSBC) is

Fig. 1 Sketch diagram of short-crested waves

$$\phi_t + g\eta + \frac{1}{2}(\phi_x^2 + \phi_y^2 + \phi_z^2) = C, \quad \text{at } z = \eta \quad (3)$$

and the kinematic boundary condition at the free surface (KFSBC) is

$$\eta_t - \phi_z + \phi_x \eta_x + \phi_y \eta_y = 0, \quad \text{at } z = \eta \quad (4)$$

while the bottom and wall boundary conditions are

$$\phi_z = 0 \quad \text{at } z = -d; \quad \phi_y = 0 \quad \text{at } y = 0 \quad (5)$$

in which $\eta = \eta(x, y, t)$ is the water surface elevation, g is the acceleration due to gravity, and the subscripts (x, y, z, t) designate differentiation with respect to the Cartesian co-ordinates (see Fig.1) and the time, and C is an arbitrary constant.

Taking the material derivative, D/Dt , of (3) and subtracting g times (4) gives

$$\begin{aligned} \phi_{tt} + g\phi_z + 2(\phi_x\phi_{xt} + \phi_y\phi_{yt} + \phi_z\phi_{zt}) + 2(\phi_x\phi_y\phi_{xy} + \phi_x\phi_z\phi_{xz} + \phi_y\phi_z\phi_{yz}) \\ + (\phi_{xx}\phi_x^2 + \phi_{yy}\phi_y^2 + \phi_{zz}\phi_z^2) = 0 \quad \text{at } z = \eta \end{aligned} \quad (6)$$

The unknown time derivative of η_t in (4) can thus be eliminated, in which η is a priori unknown itself yet to be determined.

As shown in Fig. 1, let L be the wavelength of the incident and reflected waves and L_x and L_y the distances between crests in the x and y directions respectively. The corresponding components of the wavenumber k in these two directions may be defined as

$$k_x = 2\pi / L_x = k \sin\theta = pk, \quad k_y = 2\pi / L_y = k \cos\theta = qk \quad (7)$$

in which $k = 2\pi / L$. By using a reference length $1/k$ and reference time $1/\sqrt{gk}$, the following set of non-dimensional parameters may be introduced,

$$\begin{aligned} \hat{x} = pkx - \sigma t, \quad \hat{y} = qky, \quad \hat{z} = kz \\ \hat{\phi} = \frac{k^2}{\sqrt{gk}}\phi, \quad \hat{\eta} = k\eta, \quad \omega = \frac{\sigma}{\sqrt{gk}} \end{aligned} \quad (8)$$

in which σ is the angular frequency of the incident and reflected wave (i.e. $\sigma = 2\pi / T$ where T is the wave period in seconds).

The carets denoting dimensionless quantities will now be omitted for the sake simplicity, unless otherwise specified. The governing equations may now be transformed in terms of these dimensionless quantities.

$$p^2\phi_{xx} + q^2\phi_{yy} + \phi_{zz} = 0 \quad (9)$$

$$-\omega\phi_x + \eta + \frac{1}{2}(p^2\phi_x^2 + q^2\phi_y^2 + \phi_z^2) = Q, \quad \text{at } z = \eta \tag{10}$$

$$\begin{aligned} &\omega^2\phi_{xx} + \phi_z - 2\omega(p^2\phi_x\phi_{xx} + q^2\phi_y\phi_{xy} + \phi_z\phi_{xz}) \\ &+ 2(p^2q^2\phi_x\phi_y\phi_{xy} + p^2\phi_x\phi_z\phi_{xz} + q^2\phi_y\phi_z\phi_{yz}) \\ &+ (p^4\phi_{xx}\phi_x^2 + q^4\phi_{yy}\phi_y^2 + \phi_{zz}\phi_z^2) = 0, \quad \text{at } z = \eta \end{aligned} \tag{11}$$

$$\phi_z = 0 \quad \text{at } z = -d \tag{12}$$

$$\phi_y = 0 \quad \text{at } y = 0 \tag{13}$$

in which Q is a dimensionless constant.

3. Numerical procedures

A truncated double Fourier series which satisfies both Laplace equation (9) and the bottom and wall boundary conditions (12) and (13) can be given by

$$\phi = \sum_{m=1}^{M-1} \sum_{n=0}^{2N} B_{mn} \frac{\cosh \alpha_{mn} (z + d)}{\cosh \alpha_{mn} d} \sin mx \cos ny \tag{14}$$

in which $\alpha_{mn}^2 = p^2m^2 + q^2n^2$. As (m+n) is odd, then B_{mn} is equal to zero for satisfying the symmetry condition required for the wave motion. The equation (14) yields the appropriate two-dimensional limiting cases of a progressive wave as $p=1$ and $q=0$, and a normal standing wave when $p=0$ and $q=1$. Substituting (14) into DFSBC (10) and KFSBC (11), yields

$$-\omega u + \eta + \frac{1}{2}(p^2u^2 + q^2v^2 + w^2) = Q \tag{15}$$

and

$$\begin{aligned} &\omega^2u_x + w - 2\omega(p^2u_xu + q^2u_yv + u_zw) + 2(p^2uu_zw + p^2q^2uu_yv + q^2vv_zw) \\ &+ (p^4u_xu + q^4v_yv^2 + w_zw^2) = 0 \end{aligned} \tag{16}$$

where

$$\begin{aligned} u &= \sum_{m=1}^{M-1} \sum_{n=0}^{2N} mB_{mn}F_{mn}(\eta) \cos mx \cos ny, & v &= \sum_{m=1}^{M-1} \sum_{n=0}^{2N} -nB_{mn}F_{mn}(\eta) \sin mx \sin ny \\ w &= \sum_{m=1}^{M-1} \sum_{n=0}^{2N} \alpha_{mn}B_{mn}G_{mn}(\eta) \sin mx \cos ny, & u_x &= \sum_{m=1}^{M-1} \sum_{n=0}^{2N} -m^2B_{mn}F_{mn}(\eta) \sin mx \cos ny \end{aligned}$$

$$\begin{aligned}
 u_y &= \sum_{m=1}^{M-1} \sum_{n=0}^{2N} -mnB_{mn}F_{mn}(\eta) \cos mx \sin ny & , & & u_z &= \sum_{m=1}^{M-1} \sum_{n=0}^{2N} m\alpha_{mn}B_{mn}G_{mn}(\eta) \cos mx \cos ny \\
 v_y &= \sum_{m=1}^{M-1} \sum_{n=0}^{2N} -n^2B_{mn}F_{mn}(\eta) \sin mx \cos ny & , & & v_z &= \sum_{m=1}^{M-1} \sum_{n=0}^{2N} -n\alpha_{mn}B_{mn}G_{mn}(\eta) \sin mx \sin ny \\
 w_z &= \sum_{m=1}^{M-1} \sum_{n=0}^{2N} \alpha_{mn}^2 B_{mn} F_{mn}(\eta) \sin mx \cos ny & , & & & \\
 F_{mn}(\eta) &= \frac{\cosh \alpha_{mn}(\eta+d)}{\cosh \alpha_{mnd}} & , & & G_{mn}(\eta) &= \frac{\sinh \alpha_{mn}(\eta+d)}{\cosh \alpha_{mnd}} \tag{17}
 \end{aligned}$$

It is noted that the water surface elevation $\eta(x,y)$ is preserved in an implicit form, instead of a straight double Fourier series by Roberts and Schwartz (1983). This approach is similar to that of Rienecker and Fenton (1981) in solving the problem of two-dimensional progressive waves.

For the purpose of numerical computations, the discretized mesh points (x_i,y_j) are chosen by even symmetric properties given by

$$\begin{aligned}
 x_i &= i \pi / M , & \text{for } i &= 0,1,2,\dots,M \\
 y_j &= j \pi / 2N , & \text{for } j &= 0,1,2,\dots,N
 \end{aligned} \tag{18}$$

For all the mesh points required in (18), the DFSBC of (15) provides $(M+1)(N+1)$ algebraic equations. While (16) is automatically satisfied at points $(x_{M/2},y_N)$, (x_0,y_j) , and (x_M,y_j) for all j , and the value of (16) at points (x_{M-i},y_N) are equal to that of (x_i,y_N) (for $i=1,2,\dots,M/2-1$) from trigonometric symmetry. Then satisfied (16) at remaining points lead to $(M-1)N+M/2-1$ equations. Furthermore, there are two additional equations should be specified, firstly, a wave height relationship ensures that,

$$\eta_{00} - \eta_{M0} - H = 0 \tag{19}$$

where η_{ij} represents $\eta(x_i,y_j)$, H is the waveheight of the short-crested wave. Secondly, the mean water level can be chosen at the coordinate origin, using the simple trapezoidal rule then

$$\frac{\pi^2}{8MN} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} (\eta_{ij} + \eta_{i+1,j} + \eta_{i,j+1} + \eta_{i+1,j+1}) = 0 \tag{20}$$

Consequently, there are $2MN+3M/2+2$ nonlinear algebraic equations for the same number of unknowns $B_{mn}, \eta_{ij}, \omega, Q$. The system equations can be solved by Newton's iteration scheme. It is noted that M should be taken to be an even integer.

4. Numerical results

Through the numerical scheme stated above, the velocity potential ϕ and wave elevation η of short-crested waves can be calculated completely as both the waveheight and water depth are given. The force exerted on the wall by short-crested waves, produced by obliquely-incident waves reflection from a vertical wall, then may be estimated by integrating the pressure over depth per unit of the wall. The pressure in the wave motion is given by Bernoulli's theorem in terms of dimensionless quantities as

$$\hat{P} = -z - \omega\phi_x - \frac{1}{2}(p^2\phi_x^2 + q^2\phi_y^2 + \phi_z^2) + Q \quad (21)$$

where $\hat{P} = (k/\rho g)P$ is the departure of the wave pressure from that of the atmosphere, ρ being the water density. The force on the wall per unit length due to the wave then performed by

$$F = \int_{-d}^{\eta} P(x, 0, z, t) dz \quad (22)$$

Considering the hydrostatic contribution of the undisturbed water back of the wall, the net force on the wall per unit length then given by

$$[F] = \int_{-d}^{\eta} P(x, 0, z, t) dz - \frac{1}{2} \rho g d^2 \quad (23)$$

In the following results, the term $M=2N=8$ is taken to calculate. Since the wave elevation is preserved in an implicit form in the numerical model, the accuracy can be improved. The accuracy could be measured from the order of residual pressures (the non-zero value of pressures) on the water surface. Although the solution by traditional perturbation method was also obtained from satisfying the conditions of zero-pressure and continuity at the water surface, the pressure computed with the final solution does not necessarily become null at the surface due to the influence of higher order terms neglected in the calculation (Goda 1967). The error is especially occurred in the case of steeper wave in shallow water. In the numerical calculation of present model, however, the error less than 10^{-12} can be under control. Fig. 2 and Fig. 3 show that comparisons of the residual surface pressure / waveheight, in dimensionless \hat{P}_r / \hat{H} , of the steeper wave in the shallow water depth.

The variation of forces in each phase with different angle of incidence are shown in Fig. 4 and Fig. 5, the double peaks appear in small incident angle, such as 0° , 5° . But the phenomenon can not be found in the cases of shallow water and the small steepness in intermediate water depth, which are shown in Fig. 6 and Fig. 7 respectively. From the results, the maximum onshore force does not at the crest but at the intermediate maximum as the wave is small angles of incidence in deep water or larger steepness in intermediate water.

 (L_a : wavelength of linear approximation)

Fig. 8 to Fig. 11 show the variation of forces per unit length with angle of incidence for each of the wave crest, the trough and the intermediate maximum. Analogous to Fenton (1985), the maximum force for onshore loading may be caused by obliquely-incident waves rather than standing waves. But this behavior is only found to be in water greater than intermediate depth, and opposite in shallow water. These figures also show the greatest net force exerted on vertical walls is occurred in offshore direction under the wave trough, as the water depth is greater than intermediate. And the maximum offshore loading is always produced by normal standing waves. Fig. 12 is the comparison from experimental data of the maximum onshore wave force of standing waves obtained by Goda (1967). The present research shows good agreement with experimental results even though the case of shallow water.

5. Conclusions

Through the calculation of short-crested waves by a numerical model, the force exerted on a vertical wall due to obliquely-incident waves has been obtained. Analogous to Fenton (1985), a number of unfeatures are also found in this paper. Because the wave elevation is preserved in an implicit function form for the dynamic and kinematic boundary equations on water surface, the results in this research show better agreement with some experimental data. Some conclusions can be drawn as the following. As the wave is in the water greater than intermediate depth, the double peaks appear on the time histories of forces in the cases of small incident angle. It is shown that the maximum loading in onshore direction does not be at the crest. From the analysis, it is also investigated that the maximum onshore loading may be caused by obliquely-incident waves rather than those of normal standing waves. Nevertheless, the maximum onshore loading does not necessarily be the greatest force for such instance. The greatest force is always produced by the offshore loading under the wave trough for normal standing waves as waves are steeper. While for shallow water waves, the greatest force is found in onshore loading at crest for normal standing waves.

CHAPTER 131

STATIC AND DYNAMIC LOADING TESTS ON THE HARO ARMOUR UNIT

J. Degrieck⁵

1. ABSTRACT

During the harbour extension works at Zeebrugge a new armour unit has been developed : the HARO. Tests in wave flume and wave tank showed a very good hydraulic stability, comparable to that of the dolos. Static and dynamic loading tests in the laboratory and pendulum tests on site confirm the HARO's excellent structural performance, comparable to that of the cube. Based on the results of exhaustive investigations one can state that the HARO is a safe and economical solution for the protection of maritime structures.

2. INTRODUCTION

The HARO is a plain concrete block for the protection of maritime structures (breakwaters, sea walls, groynes ...) against wave attack. It found an extensive application in the harbour extension works at Zeebrugge. It is also currently being used for the Gwadar Port in Pakistan. The name HARO is registered by HAECON N.V.

The HARO is a compact concrete block with a large central opening (fig. 1). Both short sides are made wider at the base. The corners are asymmetrically tapered in plan. Thanks to the large central opening, the protuberances at the short sides and

Figure 1. Geometry of the HARO armour unit

conform an appropriate placement pattern, a porosity as high as 51-53 % can be achieved.

An exhaustive laboratory investigation conducted at the Hydraulic Research Laboratory in Borgerhout (Antwerp) showed a very good hydraulic stability which is comparable to that of the dolos (De Rouck et al., 1987; Wens et al., 1990). However, the reliability of the armour layer and thus the whole rubble mound breakwater, not only depends on the hydraulic stability of the armour units but also to a large extent on their structural strength. Unfortunately, failures in the late seventies and in the early eighties showed this point all too clearly. In order to verify the structural strength of the HARO, static and dynamic loading tests were carried out in the Magnel Laboratory of Ghent State University and on the site.

3. STATIC LOADING TEST

The test set-up for the static loading test on a 150 kN HARO is shown in fig. 2. The block was turned on its side and placed on two supporting concrete beams with variable depth. On the upper surface, a circular steel disc (300 mm \varnothing), on which the load P was applied, was placed. This load application point is located on the axis passing through the centroid of cross-section BB (fig. 1). During the test, the total load P was

Figure 2. Test set-up for the static loading test

increased by increments of 200 kN. At each load level the deformation of the concrete surface was measured at 10 different points by means of strain gauges with a gauge length of 60 mm. The strain gauges were positioned parallel to the original upper and lower faces of the block. The shortening of the minor axis of the central hole was measured along three verticals.

Rupture of the block occurred at a load level of 2400 kN which corresponds to 16 times the weight of the block itself. Fig. 3 shows the HARO after failure.

Figure 3. Block after the static loading test

The shortening of the short central axis BM-OM in relation to the applied load P is shown in fig. 4. From this figure it appears that the elastic state extends to about 1600 kN. Beyond this value the shortening of the axis BM-OM increases at a higher rate. This non-linear behaviour is confirmed by the strain gauge readings. Measured strains and strains found in a supporting 3-dimensional linear elastic finite element analysis correspond reasonably well for loads up to $P = 1600$ kN, as is shown in fig. 5 for strain gauge LA. From this load level on, the course of the measured strain signals varies rather widely depending on the location of the strain gauges. This is due to the fact that during the loading process the internal stress distribution gradually changes and that only local strains are measured. The maximum measured (tensile) strain equals $190 \cdot 10^{-6}$ (strain gauge BV).

As the static loading test concerns, the total input energy is obtained as the surface under the load-displacement curve. Associating the decrease Δd of the axis BM-OM with the displacement at the point load, one can obtain from fig. 4 the energy values mentioned in table 1.

Figure 4. Shortening of the axis BM-OM as function of the load P

Figure 5. Comparison of measured and calculated strain at LA

TABLE 1 - Static loading test

P (kN)	Δd (mm)	E_i (kJ)
1600	0.21	0.252
2400	0.5	0.800
2400	0.7	1.280

After the test, cores were drilled at the upper and lower face of the block. On the cores (113 mm in diameter and 100 mm in height) compression and splitting tests were performed. Compressive strengths equal to 43.4 MPa and 48.7 MPa were found respectively for the upper and lower surface. Values of 3.08 MPa (upper surface) and 3.67 MPa (lower surface) were obtained for the splitting tensile strength. Each value represents the mean of three test results.

4. DYNAMIC LOADING TEST IN THE LABORATORY

The test set-up for the dynamic loading test is essentially the same as for the static one. The impact is performed by means of a falling steel block, having a mass of 516 kg. The vertical movement of the block is guided by two steel laths which fit, with some margin, in vertical notches at two opposite side faces of the steel block. The lifting hook is designed in such a way that delocking takes place almost instantaneously.

Figure 6. Block after the dynamic loading test

The height of fall, being equal to 50 mm the first time, was successively increased by 50 mm increments until complete failure of the HARO took place. The following cracking sequence could be observed by the naked eye :

- drop height of 650 mm : vertical crack at the upper inner face, extending to the front and back face.
- drop height of 700 mm : vertical crack at the lower inner face.
- drop height of 750 mm : horizontal crack at the left inner face.
- drop height of 800 mm : extension of the vertical cracks and rupture of the block into two parts (fig. 6).

In fig. 7, the maximum tensile strain, recorded during the impact at the locations RA, BM, LA and OM is plotted. It follows that after the impact from 550 mm height, cracking already occurred at the lower inner face (OM). The maximum strain at the upper inner face appears to remain almost constant at a value of 180 microstrain from the impact from 250 mm height on. Noteworthy is that the maximum concrete strain, again corresponds to the usual range i.e. 150-200 10^{-6} , as encountered in the static loading test.

Figure 7. Measured peak strains during impact

The energy input corresponding to the potential energy of the impactor is obtained from

$$E_i = m_i g \Delta h \tag{1}$$

where m_i : mass of the impactor (516 kg)
 g : gravitational acceleration
 Δh : drop height.

For Δh equal to 550 mm (onset of damage) and 800 mm (complete rupture) the values E_i , mentioned in table 2, are obtained. As it was observed that rebound of the impactor

TABLE 2 - Dynamic test in the laboratory

Δh	E_i (kJ)
550 mm	2.784
800 mm	4.050

remained very limited, these values can reasonably be considered as the energy absorbed by the HARO block. The values mentioned in table 1 are considerably smaller than those given in table 2.

From the dynamic measurements, the impact time was calculated as 0.7 ms.

5. PENDULUM TESTS ON THE SITE

5.1. General description

Armour units should be able to withstand impacts from adjacent units. These impacts can occur while placing the units on the slope or under wave attack. In order to simulate these impacts, pendulum tests were carried out on site.

A 150 kN HARO suspended by a cable at the top of a crane jib was first given a horizontal deviation d from its equilibrium position and then swung against other blocks at rest on a rock bed (fig. 8). Two different impact situations were envisaged (fig. 8). In the first test, the impact block hits two blocks of an adjacent row. In the second test, an edge of the impact block hits another block on its weakest side. The first situation results from the design placement pattern (a block of an upper row rests against two blocks of the lower row). The second is deemed to correspond to an exceptional event.

5.2. First test series

The first series of tests is performed according to the first impact situation. The horizontal deviation d before release was progressively increased by 0.50 m. The final deviation amounted to 7.00 m. No further increment was possible due to technical limitations imposed by the crane. None of the blocks was broken. Only the three directly involved blocks were locally damaged at the protuberances.

In table 3, values of the maximum accelerations measured at different locations on the back side of the impact block are mentioned. No reliable strain measurements were obtained during the test series.

Figure 8. Test set-up for pendulum test on site

The input energy E_i corresponding to the potential energy of the impact block, calculated by (1) is also indicated in table 3. Also indicated is the value $0.5 E_i$, which will be useful for the evaluation of the second and third test series (see sections 5.3 and 5.4). The energy values mentioned in table 3 are considerably larger than those mentioned in tables 1 and 2. However, the impact phenomenon is quite different and obviously the bending stresses are much lower for this first site configuration.

5.3. Second test series

The second series of tests was performed according to the second impact situation envisaged in 5.1. This situation is rather similar to the dynamic loading test performed in the Laboratory (section 4).

TABLE 3 - First test series : accelerations and potential energies E_i

Horizontal deviation d (m)	Δh (m)	Accelerations (m/s^2)				E_i (kJ)	$0.5 E_i$ (kJ)
		A1	A2	A3	Mean		
3.0	0.174	510	220	180	300	25.6	12.8
4.0	0.310	530	340	400	400	45.6	22.8
4.5	0.392	110	30	20	50	57.7	28.8
5.0	0.485	620	270	360	420	71.4	35.7
5.5	0.588	420	370	300	360	86.5	43.3
6.0	0.702	280	200	310	260	103.2	51.6
6.5	0.826	830	1010	750	860	121.5	60.8
7.0	0.960	1000	1020	780	930	141.2	70.6

The deviation was progressively increased by steps of 1 m. The target block showed severe transverse cracks after the impact out from the 4 m deviation. In table 4, peak values of accelerations and strains are mentioned. The locations of the accelerometers A and the strain gauges R are as follows :

- A1 and A2 : back side of target block (opposite to the impact face)
- A3 : front side of impact block (opposite to the impact face)
- R1 : inner back face of target block
- R2 : inner side face of target block
- R3 : inner front face of target block
- R5 : inner back face of impact block
- R6 : inner side face of impact block.

TABLE 4 - Second test series

Deviation d (m)	Peak accelerations (m/s^2)			Peak strains (10^{-6}) (↗ indicates strain gauge failure)				
	A1	A2	A3	R1	R2	R3	R5	R6
1	200	190	210	9	2	3	-	-
2	360	220	140	140	6	14	50	-
3	450	880	330	160	10	25	12	2
4	730	1590	850	↗	41	↗	8	16

The maximum peak strain, before rupture of strain gauge R1, is equal to $160 \cdot 10^{-6}$ which indicates that for the three tests considered so far, the maximum concrete strain could be considered as a useful failure criterion. In fig. 9, the recorded strain signal from strain gauge R3 is shown for the impact from $d = 3$ m. It follows that the impact time is about 12 ms. Fig. 10 shows the acceleration signal A3 for the same impact situation. The second impact at about 295 msec is caused by the rotation of the impact block after the first contact at one of the edges. It has to be noted that the time scales of figs. 9 and 10 are different.

Only in a very limited zone of the front face of the target block, local crushing of the concrete occurred during the first few impacts. This indicates that the energy release in the contact zone remained small. This locally damaged zone had a diameter of about 0.25 m and was located at a height of about 0.50 m.

5.4. Third test series

The third test series was also performed according to the second impact situation. The target block was replaced by a new one but the impact block was the same as in the second test series. Only deviations equal to 1 and 4 m were realized. At the latter impact, severe transverse cracks occurred this time in the impact block. Measured peak accelerations of the impact block are given in table 5.

TABLE 5 - Third test series : accelerations (m/s²)

Deviation d (m)	A1	A2	A3
1	90	20	60
4	720	1350	410

5.5. General remarks

- The results of the tests according to the first impact situation, which could occur during regular placing of the blocks, indicate that under these circumstances no rupture of the blocks seems possible in practice.
- The second, accidental impact situation, appears to be more critical. Comparison of the second and third test series indicates that the stress fields generated both in the impact and the target block, cause damage of comparable magnitude. Hence the mention of $0.5 E_j$ in table 3.
- The input energy at $\Delta h = 800$ mm in the laboratory test equals 4.05 kJ whereas at $d = 4$ m, a value of 22.8 kJ is obtained for the pendulum test. A comparison only based on energy values, appears not to be appropriate.
- Interpretation of the dynamic behaviour on the basis of the acceleration measurements

Figure 9. Strain signal R3 during impact from $d = 3$ m (second test series)

Figure 10. Acceleration signal A3 during impact from $d = 3$ m (second test series)

is not straightforward. Regarding the first impact situation, contact with the two adjacent blocks at rest never occurs simultaneously and hence the energy distribution between the different blocks turns out to be quite complex. In the second impact situation considered, the impact block starts to rotate during the edge contact. This results in a contribution of rotations to the measured total acceleration signal which cannot be separated from the acceleration due to the main pendulum movement.

6. FURTHER CONSIDERATIONS WITH REGARD TO STRENGTH

For plain concrete armour units, structural integrity depends to a large extent on the absence of significant cracks, and thus on the concrete tensile strength. A major problem in this respect is cracking due to thermal stresses caused by the hydration process. Temperature measurements in both grooved cubes and HAROs were carried out during the first days after casting (Van Damme et al., 1988). Due to the central opening in the HARO the temperature increase remained small and resulted in a considerable reduction of the thermal stresses at early age. No thermal cracks are observed in the approximately 11000 HARO units manufactured in Zeebrugge.

7. CONCLUSIONS

- During a static loading test in the laboratory, the HARO block failed at a load of 2400 kN, which represents 16 times its own weight.
- During a dynamic loading test in the laboratory, rupture of a block took place after the impact of a steel block with a mass of 516 kg from a drop height of 800 mm.
- Pendulum tests on the site were performed according to two different configurations (lower part of figure 8). When the impact block was swung in between two other blocks, up from a horizontal deviation of 7 m, only local damage of the blocks occurred. When the impact block hit an adjacent block at its weakest side, failure of the blocks occurred for a horizontal deviation of 4 m.
- Although the general structural shape of the HARO is less robust than a massive cube, the results of static and dynamic loading tests on a 150 kN block confirm the adequate structural performance. Indeed, the tests prove that during regular placing of the individual armour elements no rupture of the blocks seems possible in practice. Even in case of an accident, e.g. dropping of a block during placement, the chance for damage of the blocks remains negligible.
- From a structural point of view the maximum concrete strain can be considered as a useful failure criterion both in static and dynamic loading conditions. Further research on concrete to concrete impact with large-scale tests would provide a better understanding of the failure mechanism.
- It can be stated that all investigations (hydraulic stability, run up, structural strength, durability), the experience on site (fabrication and placement on the slope) and the favourable cost price show that the HARO perfectly fulfils all performance criteria required for armour units.

8. ACKNOWLEDGMENT

The authors gratefully acknowledge the assistance of J. Vyncke (formerly with the Magnel Laboratory, now with the Scientific and Technical Centre for the Building Industry at Brussels) during the dynamic test in the laboratory.

DETERMINATION OF COEFFICIENTS IN MORISON FORMULA BY A KALMAN FILTER

P. Wilde* E. Sobierajski[†]

W. Romańczyk[‡]

Institute of Hydroengineering, Polish Academy of Sciences,
Kościerska 7 Str., 80-953 Gdańsk, Poland

1 INTRODUCTION

In engineering practice semi-empirical formulae are used for the determination of hydrodynamical loads on vertical cylinders due to water waves. The most popular is the Morison formula

$$\frac{dP}{dz} = C_M \rho \frac{\pi d^2}{4} \frac{\partial u}{\partial t} + C_D \frac{\rho d}{2} u |u| \quad (1)$$

where dP is the resultant horizontal force, ρ – the density of the fluid, d – diameter of the cylinder, u – the horizontal component of the orbital velocity in wave motion calculated at the axis of the cylinder. The drag coefficient C_D and inertia coefficient C_M for uniform oscillating flow were determined experimentally by Sarpkaya (1975). The value of these coefficients depend upon the Reynolds and Keulegan – Carpenter numbers. The experiments for the determination of the hydrodynamical forces due to water waves were performed by Chakrabarti (1983), Cotter (1984), Bearman (1985), Sparboom (1987). There are not many data available for this case of loading. A few procedures are established for the determination of the drag and inertia coefficients from the measurements. Some authors claim that the coefficients should be variable in the period of the wave to obtain a good approximation of the real behavior.

*Professor of Civil Engineering

[†]Dr. Eng.

[‡]Research assistant

Figure 1: Scheme of dynamical system in one plane.

In the wave flume of the Institute of Hydroengineering in Gdańsk experiments were performed with a vertical rigid cylinder of diameters $d = 76.6 \text{ [mm]}$ and $d = 46.7 \text{ [mm]}$ supported by elastic springs at the bottom and top in the inline and transverse directions (four degrees of freedom). The investigated dynamical system is shown in Figure 1. The water depth was 0.80 [m] , and the wave heights $H = 12, 20, 25 \text{ [cm]}$ were investigated. The displacements at the positions of the springs were measured. Details are given by Wilde and Sobierajski (in print).

A Kalman filter of the type as presented by Wilde and Kozakiewicz (1984) and by Wilde and Romańczyk (1989) were used to decompose the measurements in components with frequencies equal to the multiple of the wave dominant frequency.

2 THE OUTLINE OF THE PROCEDURE

Let us point to some details of the proposed methods of estimation of the C_M and C_D coefficients in the Morison formula. It is necessary to construct a mathematical model for the decomposition of the elevation of the free surface. Let us define two independent stationary random functions $A_1(t)$, $D_1(t)$ defined by the following ITO

stochastic differential equation

$$d \begin{bmatrix} A_0(t) \\ A_1(t) \end{bmatrix} + \eta \begin{bmatrix} 1 & 0 \\ -1 & 1 \end{bmatrix} \begin{bmatrix} A_0(t) \\ A_1(t) \end{bmatrix} = 2\sqrt{\eta P} \begin{bmatrix} 1 \\ 0 \end{bmatrix} dB(u) \tag{2}$$

where η is a parameter with dimension $[s^{-1}]$, P is the asymptotic value of the variance and $dB(u)$ is a Brownian motion process with the variance equal to one. Two random functions $X(t), Y(t)$ are defined by the matrix equation

$$\begin{bmatrix} X(t) \\ Y(t) \end{bmatrix} = \begin{bmatrix} \cos \omega t & \sin \omega t \\ -\sin \omega t & \cos \omega t \end{bmatrix} \begin{bmatrix} A_1(t) \\ D_1(t) \end{bmatrix} \tag{3}$$

where ω is the dominant angular frequency. The mean values of the processes $X(t)$ and $Y(t)$ is equal to zero and the covariance functions are for the stationary case are

$$c_{xx}(\tau) = c_{yy}(\tau) = Pe^{-\eta\tau} [1 + \eta\tau] \cos \omega\tau \tag{4}$$

where $\tau = |t_2 - t_1|$.

Let us define a complex signal

$$Z(t) = X(t) + iY(t) = W(t)e^{-i[\omega t - \psi(t)]} \tag{5}$$

where

$$W(t) = \sqrt{X^2(t) + Y^2(t)} = \sqrt{A_1^2(t) + D_1^2(t)} \tag{6}$$

is the random amplitude and $\psi(t)$ is the random phase shift. Let us assume that the process $X(t)$ has a narrow - band spectral density, such that the amplitude $W(t)$ and phase shift change very little in the wave period.

Two finite sequences of stochastic processes $X_n(t), Y_n(t)$ for $n = 1, 2, \dots$ are defined by the formula

$$X_n(t) + iY_n(t) = Z^n(t) = W^n(t)e^{in[\omega t - \psi(t)]} \tag{7}$$

which have dominant frequencies equal to $n\omega$. It follows from equations (6) and (7) that the function $W^n(t)$ are envelopes for both functions $X^n(t)$ and $Y^n(t)$. If the expression in the square brackets is equal to $r\pi$, where r is an integer then $Y_n(t)$ and $X_n(t)$ touches the envelope for all n . If in the mathematical model (2) the parameter η is equal to zero then the solutions correspond to constant in time functions and the amplitudes and phase shifts are random variables and the real parts correspond to cos and imaginary parts to sin functions. In the stochastic case when η is not equal to zero but is small compared to ω there is a similar behaviour for the sample functions.

From equations (5) and (7) it follows that $X_n(t)$ is the real and $Y_n(t)$ the imaginary part of $Z(t)$ to the power n and thus it is possible to express them as polynomials in $X(t)$ and $Y(t)$ of order n . For example

$$\begin{aligned} X_2(t) &= X^2(t) - Y^2(t) \\ Y_2(t) &= 2X(t)Y(t). \end{aligned}$$

The inverse problem is to express $X^r(t)$ and $Y^r(t)$ as a series in terms of $X_p(t)$ and $Y_s(t)$ where p and s are smaller or equal to r . It may be easily seen that such a

representation is possible with coefficients which depend upon $W^q(t)$ where $q + p = r$ and $q + s = r$. For example

$$\begin{aligned} X^2(t) &= 0.5W^2(t) + 0.5X_2(t) \\ X^4(t) &= 0.375W^4(t) + 0.5W^2(t)X_2(t) + 0.125X_4(t). \end{aligned}$$

In general any polynomial function in $X_r(t)Y_q(t)$ may be expressed as a linear combination of terms of the type $X_p(t)$ and $Y_s(t)$ with coefficients which depend upon $W(t)$.

The surface elevation for the second order Stokes' wave $\zeta(t)$ is described by the formula

$$\zeta(t) = \frac{H}{2} \{ \cos(kx - \omega t) + \frac{2\gamma}{h} \cos[2(kx - \omega t)] \} \quad (8)$$

where

$$\gamma = \frac{kh}{2} \coth(kh) \left[1 + \frac{3}{2\sinh^2(kh)} \right],$$

H is the wave height, h the water depth, ω the angular frequency and k is the wave number. When the wave height and phase shift change very little in the wave period for a fixed position in space $x = 0$, the relation (8) may be generalized for random waves by assuming

$$\zeta = X(t) + \frac{\gamma}{h} X_2(t) \quad (9)$$

where the wave number k is assumed constant and calculated from the dispersion relation for the peak frequency. When the process has very narrow-band spectral density the relations for the regular waves may be used as a first approximation to find the horizontal components $u(t)$ of the velocity vectors and the accelerations. For example the accelerations are

$$\frac{\partial u}{\partial t} = \omega^2 \frac{\cosh[k(h+z)]}{\sinh(kh)} Y(t) + \frac{3}{2} \omega^2 k \frac{\cosh[2k(h+z)]}{\sinh^4(kh)} Y_2(t) \quad (10)$$

where z is the vertical coordinate measured from the still water level.

According to the Morison formula it is necessary to calculate the values of the function $|u|$. It is desirable to express this random function as a sum of random functions with dominant frequencies equal to $n\omega$ and coefficients which are varying slowly in time. Thus we want to approximate a random function $g(X, Y)$ by the following series

$$g(X, Y) = a_0(W) + \sum_{p=1}^n a_p(W) X_p + \sum_{r=1}^n b_r(W) Y_r \quad (11)$$

in the sense that the squared difference J between the left and right side in (11) is minimum. From (7) it follows

$$\begin{aligned} X_p(t) &= W^p(t) \cos[p(\omega t + \psi)] \\ Y_p(t) &= W^p(t) \sin[p(\omega t + \psi)]. \end{aligned} \quad (12)$$

When these functions are substituted it follows that the function J is a function of the random amplitude $W(t)$ and random phase shift $\psi(t)$, and for a fixed time t is a random variable. It is easy to see that when $A_1(t)$ and $D_1(t)$ are independent random variables with Gaussian distributions then $W(t)$ has a Rayleigh distribution

and $\psi(t)$ has a uniform distribution in any interval of length 2π and that they are statistically independent. We may substitute

$$U(t) = -\omega t + \psi(t) \tag{13}$$

and for a fixed t the random variable U has a uniform distribution in the interval $-\pi, \pi$. Thus as a criterion of approximation for a fixed t , in the random formulation we may take that the expected value with respect to the phase

$$I = \int_{-\pi}^{\pi} J(W, u) \frac{1}{2\pi} du \tag{14}$$

is minimized, where the integral is a Riemann integral and $W(t)$ is a fixed value and u is dummy variable.

Similar as in the case of Fourier series, when the necessary condition and the orthogonality properties of the trigonometric functions are used the following expressions for the coefficients are obtained

$$\begin{aligned} a_0(W) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} g(W, u) du \\ a_s(W) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} g(W, u) \cos(su) du \\ b_s(W) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} g(W, u) \sin(su) du. \end{aligned} \tag{15}$$

When these formulas are used for the polynomial functions the same expressions result as before by a direct calculation. For the case $|X|X$ it follows

$$|X|X \simeq \frac{8}{3\pi}WX + \frac{8}{15\pi}W^{-1}X_3 - \frac{8}{105\pi}W^{-3}X_5 + \dots + \tag{16}$$

In Figure 2 a realization of a random function $|X|X$ calculated by a computer is shown and an approximation by two terms. It may be seen that the difference are very small.

With the same approximations as in the expression for the acceleration (10), the horizontal components of the orbital velocities are given by the formula

$$u = \omega \frac{\cosh[k(h+z)]}{\sinh(kh)} X(t) + \frac{3}{4}\omega k \frac{\cosh[2k(h+z)]}{\sinh^4(kh)} X_2(t). \tag{17}$$

Thus the function $|u|u$ depends upon the values of $X(t)$ and $X_2(t)$ and when the integrals according to the expressions (16) are calculated the interval of integration has to be split into parts (absolute value) which depend upon the values of W and the values of z , where the velocity is determined. The coefficients may be determined by numerical methods and the final result is that the expansion in terms is useful and only a few terms are sufficient to obtain a good approximation.

To obtain the resultant force and moment the loads given by the Morison formula (1) have to be integrated along the pile from the bottom to the free surface which changes in time. This is an approximate procedure because the real velocity field in the neighbourhood of the free surface is not very well described by the Stokes' second order approximation. It should be however mentioned that such a procedure is used in an engineering approach and the differences in resultant forces and moments are not great. Due to the integration to the time-dependent free-surface, terms with the double frequency are generated even when the second term

Figure 2: Example of $|X|X$ process and its decomposition

in the Stokes' approximation is very small and the position of the free surface is well described by linear theory of waves.

To avoid complicated algebraic formulae the integrals corresponding to the resultant forces and moments were not expanded in series with the help of the relations (16) but a numerical procedure was applied. From the measured surface elevations by a Kalman filter the functions $X(t)$ and $Y(t)$ with the dominant frequency equal to the peak frequency of the wave were determined. By the relations (10) and (17) the accelerations and velocities as function of z for the times of measurement were calculated and then according to the Morison formula separately for the inertia forces and drag forces. These functions of z were integrated from the bottom of the pile to the free surface to obtain the following relations

$$\begin{bmatrix} R(k) \\ M(k) \end{bmatrix} = \begin{bmatrix} R^M(k) & R^D(k) \\ M^M(k) & M^D(k) \end{bmatrix} \begin{bmatrix} C_M \\ C_D \end{bmatrix} \tag{18}$$

where $R^M(k)$ is the resultant force due to the term with $C_M = 1$, and $R^D(k)$ due to the drag term with $C_D = 1$, $M^M(k)$, $M^D(k)$ denotes moments due to the inertia and drag terms with $C_M = 1$, $C_D = 1$ and k denotes the time step t_k .

When the resultant forces and moments are known the displacements as functions of time may be calculated. In the plane of propagation of water waves the dynamical system has two degrees of freedom. The position of the rigid cylinder is determined by the measured horizontal displacements $x_g(t)$ and $x_d(t)$ at the levels of upper and lower spring respectively. The damping is very small and the natural frequencies are high compared to the peak wave frequency. In the determination of displacements

it is possible to assume the equation for undamped vibrations

$$\begin{bmatrix} M & 0 \\ 0 & J \end{bmatrix} \begin{bmatrix} \ddot{x}(t) \\ \ddot{\varphi}(t) \end{bmatrix} + \begin{bmatrix} k_g + k_d & k_g z_g - k_d z_d \\ k_g z_g - k_g z_d & k_g z_g^2 + k_d z_d^2 \end{bmatrix} = \begin{bmatrix} R(t) \\ M(t) \end{bmatrix} \quad (19)$$

where $x(t)$ is the horizontal displacements of the center of mass, $\varphi(t)$ is the angle of rotation around the center of mass, k_g, k_d are the spring constants of the upper and lower springs, z_g, z_d are the distances from the center of mass to the upper and lower springs, $R(t), M(t)$ are the resultant force and moment of the hydrodynamic forces with respect to the center of mass. The position of center of mass and the mass matrix were calculated with added mass of water and the spring constants were obtained from static loads. The dynamic equation was verified by measuring free vibrations in still water.

The measured displacements $x_g(t), x_d(t)$ are related to the displacements $x(t), \varphi(t)$ by the equation

$$\begin{bmatrix} x_g(t) \\ x_d(t) \end{bmatrix} = \begin{bmatrix} 1 & z_g \\ 1 & -z_d \end{bmatrix} \begin{bmatrix} x(t) \\ \varphi(t) \end{bmatrix}. \quad (20)$$

When the equation of undamped vibrations (19) is used the measured vibrations can not be determined by the solution of this equation because the initial conditions will never be forgotten. The steady - state solution for harmonic vibrations will be used. The hydrodynamic loads (18) are decomposed into components with dominant frequencies corresponding to the multiples of the wave peak frequency and for each component the steady - state harmonic response is calculated. Thus, after simple manipulations the observations model for the time t_k assume the following form

$$\begin{bmatrix} x_g(k) \\ x_d(k) \end{bmatrix} = \begin{bmatrix} H_g^M(k) & H_g^D(k) \\ H_d^M(k) & H_d^D(k) \end{bmatrix} \begin{bmatrix} C_M \\ C_D \end{bmatrix} + \sigma_0 \begin{bmatrix} v_g(k) \\ v_d(k) \end{bmatrix} \quad (21)$$

where $H_g^M(k)$ and $H_d^M(k)$ are the calculated displacements due to the inertia term in the Morison formula for $C_M = 1$, and $H_g^D(k), H_d^D(k)$ due to the drag term for $C_D = 1$, $v_g(k), v_d(k)$ are independent sequences of gaussian white noise with distribution $N(0, 1)$ and σ_0 is the standard deviation of the observation noise.

In the mathematical models for the coefficients C_M and C_D it is assumed that they are statistically independent have constant mean values and fluctuations which are described by the $IT\hat{O}$ stochastic differential equation (2).

The standard Kalman filter procedure is used to estimate the values $C_M(k), C_D(k)$ on the basis of the measured values $x_g(k), x_d(k)$. The procedure was written in the form of an IBM PC computer program.

3 THE EXPERIMENTAL RESULTS

The water depth was 0.80 [m]. Different waves were considered. In Figure 3 the the results for a wave with a small wave height are shown. In this case the wave period was $T = 1.4$ [s] the amplitude of the wave was $\frac{H}{2} = 0.0596$ [m], the horizontal component of the velocity at the still water level calculated on basis of Stockes' theory was $u_{max} = 0.2915$ [$m \cdot s^{-1}$], the corresponding KC number 5.327 and the Reynolds number 1.96×10^4 . According to the data shown in Figure 3 the second term in the Stockes' approximation is negligible. The measured displacements are

Figure 3: The measured and estimated wave and displacements and the estimated C_M and C_D coefficients for test db1.dat.

very close to trigonometric functions. The estimated coefficients C_M , C_D are very close to constant functions. The average values are $C_M = 1.99$ $C_D = 0.23$. It may be seen that the fluctuations are very small and not regular. Thus the assumption of constant values for the coefficients is justified.

In Figure 4 the data for a steeper wave are shown. In this case the wave period was $T = 1.9$ [s], the amplitude $\frac{H}{2} = 0.113$ [m], the horizontal velocity $u_{max} = 0.527$ [ms⁻¹], the KC number 13.08 the Reynolds number 3.54×10^4 . The wave is a second order Stokes' wave. The measured displacements are not symmetric and the influence of the double frequency of the peak wave is large. It may be seen that also in this case the estimated coefficients C_M , C_D are very close to constant functions. The average values are $C_M = 1.60$, $C_D = 0.70$. It should be stressed however that in this case there are differences between the measured values and the values calculated on the basis of the estimated coefficients. It may be seen from the graph that there are higher harmonics which are neglected in the analysis. The Morison formula introduces approximations, the determination of the velocity and acceleration fields from the Stokes' second order approximation does not correspond exactly to the real behaviour. The description of the dynamical system is simplified because damping is neglected and steady - state harmonic solutions are assumed. It is surprising that with such rude approximation the constant coefficients C_M , C_D may be so adjusted that the calculated solution gives the the basic features of the real behaviour.

The results of all experiments are presented in Figure 5. It should be mentioned that in all experiments the Reynolds numbers are in the range of 10^4 and thus only the relationship with respect of the Keulegan - Carpenter number KC may be shown. If one compares the results with previous investigations they are within the range of the published values. It should be noted that the coefficients C_D are smaller than the values usually used for $Re < 10^5$. As a crude recommendation the results show that for $KC \leq 5$ $C_M = 2$ and it drops to $C_M = 1.5$ for $KC \sim 20$, the values for C_D are $C_D = 0.25$ for $KC = 5$ and they grow up to $C_D = 0.8$ for $KC = 15$ (there are points $C_D = 1.0$). One can not expect to obtain exact values for the considered dynamical system because measurements have a small range in Reynolds numbers.

4 CONCLUSIONS

1. The investigations shown that the Kalman filter procedure is a suitable tool for the analysis of the problem.
2. In the mathematical models it is enough to assume once differentiable random functions described by the $IT\hat{O}$ stochastic differential equation (2).
3. The nonlinear term due to the drag force in Morison formula may be included in the observation model which becomes nonstationary.
4. The simplifying assumptions introduced in the analysis of the dynamical system are justified for practical applications.
5. The results of experiments shown that constant values for the C_M and C_D coefficients may be taken.
6. The procedure may be refined by considering the influence of damping but it looks like it is not possible to expect much better results and the scattering of results must be considerable in view of the complicated physics of the problem.

CHAPTER 133

Wave forces on vertical breakwater on Reef Coasts

Eizo Nakaza¹⁾, Seikoh Tsukayama²⁾ and Mikio Hino³⁾

Abstract

The characteristics of the "Bore-like surf beat", one of long wave phenomena occurred on the reef coasts, are clarified by the field observations and experiments. And also, wave forces on breakwaters in the reef coasts are verified through the experiments.

A new pressure formula, taking into account of the wave force due to "Bore-like (Tsunami-like) surf beat", is suggested, and it is shown that the calculations by the formula show good agreement with results of experiments.

1. Introduction

There are a number of wave pressure formula on vertical breakwaters. But, they are derived for the cases of usual breakwaters constructed in sea area having monotonously sloping sea bed, and the accuracy has not been verified when they are applied to the case of breakwater in coasts with reef or multiple topography. As for the waves on the reefs, it is discovered by the authors (1988 (a), (b), (c)), after field observation and experiment, that the "Tsunami-like surf beats" occur when the period of incoming wave groups close to the period corresponding to the resonant frequency of water oscillation in the coastal zone. And this phenomenon may influence to the wave forces.

In this study, first of all, the discussion is made on the main reason of the disaster of coastal structures on the reef coasts due to Typhoon, and the relation between surf beat and fluid forces acting on the vertical breakwater in the reef coasts is clarified. Finally, a new pressure formula taking into account of the wave force due to the surf beat is proposed.

2. Damages of Coastal Structures and Feature of Tsunami-like Surf beat

In this section, some examples of damaged breakwaters are shown firstly, and then the Tsunami-like surf beat just attacking a sea coast is introduced by photographs.

Photograph 1 shows a damaged breakwater by waves due to Typhoon. The caisson of the breakwater was dragged and declined, and armor blocks of tetrapods about 2 tons of weight on harbor side of the breakwater were drawn by fluid forces and dragged about 100 meter from its ordinal position. Photograph 2 shows a destroyed mound breakwaters due to Typhoon. As shown in the photograph, two tons weighted tetrapods were scattered by fluid forces accompanied by the Typhoon. As for the waves conditions on occasion at these site, the wave heights on the places where these breakwater were constructed could not exceed 1.0 meter, because the water depths at the sites are about 2 meters. And significant wave height in offshore at the time, when these disaster were happened, was about 9 meters. Therefore it cannot be supposed that such waves having almost 1.0 meter of height could cause the disasters shown in these photographs.

What was happened on there ?. The answer to this question was discovered by Nakaza. He disclosed that main reason of these damage of break-water is strong flood like currents accompanied by a surf beat, such as Tsunami waves. Nakaza and Hino named this phenomenon as "bore-like surf beat" or "Tsunami-like surf beat", for analogous of its phenomenon to one of Tsunami.

Photograph 3 shows the such " bore-like surf beat" just coming to reef coast, on a occasion of the Typhoon on 6th Oct. 1988. Photograph (a) shows the state when the Bore-like surf beat was outgoing to offshore, and photograph (b) shows coming bore-like surf beat to the shore line, and photograph (c) shows the surf beat just attacking the coastal cliff, after 12 seconds from the time of photograph (b) was taken.

For the existence of such violent phenomenon of bore-like surf beat, wave forces acting on the breakwater or seawall may be different from ones on the same coastal structures built in the usual sea coast having monotonous slope of sea bed. So, ordinal wave pressure formula could not be applied to estimate the wave force in reef zone.

This study devote to clarify the characteristics of wave forces acting on the breakwater on the reef coast under existence of bore-like surf beat by experiments, and suggest a new wave pressure formula taking into account of the wave forces due to the surf beat.

3. Experiment

Two series of experiments were conducted. The first series of the experiments was carried out to grasp the characteristics of hydraulic phenomena when the bore-like surf beat is attacking the breakwater. The second series of the experiments was conducted for the purpose of characterizing quantitatively the wave forces acting on the breakwaters in relation with the width of the reef flat, and consequently to suggest a new formula for wave pressure under the circumstances above mentioned.

3.1) Experimental equipments and method

Figure 1 shows the arrangement of experimental equipments used in the first series of the experiment. The wave channel shown in the figure, is 22m long, 0.8m wide and 1.0m deep. At the one end of the channel, a flap-type wave generator is installed, which can make regular waves.

Fig. 1 Experimental equipments (quasi-three dimensional)

The experiments were carried out with two-type of incident waves, one was a continually incoming regular wave groups with constant interval, and the other one was monochromatic wave. The regular wave groups can cause the bore-like surf beat on the model reef as mentioned above, whereas the monochromatic waves cannot excite the surf beat on the reef model.

The method of experiment is as follows; after setting the model, wave generator was started. The wave profiles were recorded by wave gauges, as shown in the Fig. 1, at the suitable points on the reef model. And simultaneously, the wave force acting on the model breakwater was recorded.

Second series of the experiments were conducted utilizing random waves. Figure 2 shows the apparatus used in the experiment. Wave generator for irregular waves are mounted on the wave channel in the figure.

Fig. 2 Experimental equipments (two dimensional)

The experiment was carried out with the method as follows. After setting the model breakwater in the channel, the wave generator was started and the wave profiles and wave forces acting on the breakwater was observed. In the experiment, irregular waves with the spectrum of Bretschneider-Mitsuyasu type was used as

the incident wave. And the distance from the reef front to the breakwater was changed from 0m to 400m .

3.2) Results of first series of the experiments

Photograph 4 shows the vortex shedding from the end of the breakwater. Comparing to dimension of the breakwater, the diameter of the vortex is estimated as more than 30m in prototype scale. Therefore, we cannot ignore the influence of the vortex to the characteristics of the waves transmitted to the sea side of the breakwater, and so as to the wave forces.

(a) in flood stage of the surf beat
(at the time indicated by the arrow A in Fig. 3)

(b) in ebb stage of surf beat
(at the time indicated by the arrow B in Fig. 3)

Photo. 4 Vortex shedding from the edge of a vertical breakwater

Figure 3 shows the profiles of water surfaces and wave forces recorded in the experiment. Figures (a) and (b) show the water surfaces traced by the wave meters, and figure (c) corresponds to the record of wave forces acting on the breakwater. It can be seen, in the figure, the bore-like surf beat results impulsive forces on the breakwater when its incident and reflected wave front struck on the breakwater. The profile of wave force is analogous to one of the water surface in front of the breakwater.

Fig. 3 Profiles of water surface and wave force (in case with surf beat; T_{wg} is the period of incident wave groups)

Figure 4 is similar one to the Figure 2, obtained in the case of experiment with monochromatic incident waves. So there are no occurrence of surf beat such as in the case of upper mentioned. From comparison of figure 2 and figure 3, the difference between these two cases is evident. We can not see in the Fig. 3 the impulsive forces such as seen in the Fig. 2, as though the incident wave heights are equal in both cases.

In estimation of wave forces acting on the breakwaters in the reef areas, therefore, we should take into account such phenomenon mentioned above.

Fig. 4 Profiles of water surface and wave force (in case without surf beat)

3.3) Results of second series of the experiments

Figure 5 shows the profiles of water surfaces, wave pressure and wave forces recorded in second series of the experiments. In this figure, the oscillations with short periods correspond to the elements of irregular waves, which are usually called as individual waves, and the undulating solid curves with long period represent the surf beat. It can be seen, in the figure, that the contribution of the surf beat to the wave pressures or wave forces is so large to compare with one of the individual waves.

To clarify the difference between wave forces in cases with and without bore-like surf beat, the experimental results were analyzed in relation with the coefficient of wave pressure $K_{1/3}$, which corresponds to the ratio of wave pressure to static hydraulic pressure expressed as wH , where w represents unit weight of water and H is the wave height. The experimental results were shown in the Fig. 6. In this figure, it can be seen that the coefficient $K_{1/3}$ may be constant on the axis of wave steepness $K_{1/3}/L$. And in the figure, open circles correspond to the individual wave forces, and filled circles represent the coefficient of the wave forces with bore-like surf beat.

Fig. 5 Profiles of water surfaces, wave pressure and wave force

Fig. 6 Coefficient of wave pressure acting on a breakwater (for significant wave)

The results calculated from traditional formula of wave force agree with only that of individual waves, so the traditional wave force formula could not apply to the case with bore-like surf beat. Figure 7 shows the

changes of the amplitude of surf beat and the coefficient of wave forces in relation with the width of the reef flat. It can be said, from the fig.7(a) and (b), that the amplitude of the surf beat enlarge with distance from the edge of reef flat. And the other hand, coefficient $K_{1/3}$ become larger with distance X , and take its maximum value at $x=300m$ and then decrease. The reason of this result can be considered as effect of resonant oscillation of water in the reef basin due to incident wave groups.

(a) distribution of amplitude of waves and surf beat

(b) changes of amplitude of surf beat

(c) change of coefficient of wave pressure

Fig. 7 Changes of amplitude of surf beat and wave force coefficient in relation with the width of reef flat
 (η'_0 , η' , $\etã'$ are the root mean square amplitudes of incident wave, individual waves and surf beat on the reef)

4. Suggestion of a New Pressure Formula

After the experiment, it is found that the water stage in front of the breakwater under existence of bore-like surf beat becomes as Fig. 8(a). Therefore, it can be assumed that the wave pressure distribution on the breakwater as shown in the Fig. 8(b). And, upon this assumption, a new pressure formula taking into account of surf beat have been derived as follows,

$$P = w A$$

$$A = \frac{1}{2}(KH)^2 + (h+dh)KH \quad \text{--- (1)}$$

where, w is the specific weight of sea water, h is the still water level in front of the breakwater and dh represents the wave set-up on the reef.

(a) sketch of water stage in front of breakwater

(b) distribution of wave pressure

Fig. 8 Definition sketch of wave pressure acting on the vertical breakwater

To test the applicability of newly suggested formula, the wave forces calculated by eq. (1) were compared with experimental results of horizontal wave forces acting on a unit span of the breakwater as in the Figure 9. In the figure, the filled circles represent the wave forces with bore-like surf beat, and the open circles correspond to one of the individual waves only, and it can be seen in this figure that the calculated result by new formula shows good agreement with the experiments under existence of the surf beat,

Fig. 9 Wave force distribution in relation with relative water depth $H1/3/h$

Fig. 10 Comparison of calculated wave forces with results of experiment

whereas the result by the former formula correspond to the wave pressures due to individual waves only. Therefore, the former formula for the wave force can not be applied to a case with the surf beat which has the same order of the wave height as one of individual waves.

Figure 10 shows the comparison of the calculated wave pressures by the equation (1) with experimental ones. Where the representative wave heights of one tenth highest high wave $H1/10$ and significant wave height $H1/3$. Both results from the calculation and the experiment show good agreement with each other. So it can be concluded as the newly suggested wave pressure formula is applicable to the case that the bore-like surf beat exist.

5. Conclusions

Main conclusions of this study are summarized as follows, "Bore-like surf beat" occurs on the reef coast as a result of resonant oscillation of the mean sea-level on the reef flat by incoming wave groups. This "Bore-like surf beat" acts as violent Tsunami, and strongly affects to the wave forces on the breakwater. A new wave pressure formula taking into account of the wave force³ due to the surf beat on the reef is derived and suggested as equation (1).

The new formula is tested by the experiments. The results from this formula show good agreement with the experimental results.

CHAPTER 134

LOCAL SCOUR AROUND A LARGE CIRCULAR CYLINDER DUE TO WAVE ACTION

Eiichi Saito

Research Engineer, Tech. Res. Inst., Hazama-Gumi Ltd.

Shinji Sato and Tomoya Shibayama

Associate Professor, Yokohama National University
156 Tokiwadai, Hodogaya-ku, Yokohama 240, JAPAN

1. Introduction

In the construction of large-scale maritime structures, the prediction of scouring around the foundation is essential to examine the stability of the structures. The local scour around a large circular cylinder is closely related to problems encountered in the construction of offshore artificial island and large-scale piers and is thus very important from engineering point of view.

The mechanism of local scours at the base of breakwaters as well as small circular cylinders has been investigated mainly by laboratory experiments [*e.g.* Irie and Nadaoka(1984), Bijker and Bruyn (1988)]. The mechanism of sand movement around a large circular cylinder was also investigated experimentally by Katsui and Toue(1988). However, there seems to be no model to predict bottom profile change around large-scale structures, the dimension of which is comparable to the wavelength, since the wave field around them is complicated owing to the presence of diffracted waves.

The aim of the present study is to propose a numerical model to estimate the topographical change around a large circular cylinder installed in the wave field. The validity of the model will be confirmed with laboratory experiments.

2. Experimental Procedures

Experiments were performed in a 9 x 9 m wave basin as shown in Fig. 1. A 2 x 2 m test section enclosed with a wooden frame was installed in the basin. Well-sorted sand of 0.2 mm in median diameter was filled in the test bed on which a circular cylinder of 52.2 cm in diameter was installed. The water depth at the test bed was 16.5cm. A continuous-type bottom profiler and capacitance-type

Fig. 1 Experimental Equipment

wave gages were installed on a measurement carriage as shown in Fig. 1. The wave and current field as well as bottom profile change were measured in detail for two monochromatic wave conditions listed in Table 1, where H represents incident wave height and T the wave period.

(1) Distribution of Wave Height

The distribution of wave height was measured systematically at grid points situated with a horizontal spacing of 10 cm. The measurements were carried out from 0 to 1 hour and from 4 to 6 hours upon the initiation of wave action.

(2) Test Bed Topography

The bottom profile in the test bed was measured by using a bottom profiler installed on the measurement carriage. The carriage was allowed to move in

Table 1 Experimental Conditions

case	1	2
T (sec)	0.94	0.94
H (cm)	6.7	7.9
h (cm)	16.5	16.5

parallel to the wave incidence so that the bottom profile along the measuring line was measured. The measuring line interval was set to be 5 cm near the circular cylinder and 10 cm for the other areas. The measurements were carried out at 1, 2, 4 and 6 hours after wave generation. The scouring depth along the cylinder surface was also measured.

(3) Current

The direction and the magnitude of the current developed around the cylinder were measured by tracing the movement of dye particles.

(4) Sand Movement Mechanism

The sand in front of the cylinder was replaced with sand colored with white paint so that the sand movement and suspension were easily observed.

3. Numerical Model

A numerical model was developed for the bottom topography change around a large circular cylinder. The model consisted of three submodels, that is, wave model, current model and sand transport model. In the present study, the model was developed on the assumption that the change of sand surface level was small compared with the initial water depth so that the wave and current field were not changed drastically even after bottom deformation. The present model is therefore applicable only to the sand movement in early stages, where the change in the topography around the circular cylinder was small compared to the water depth.

(1) Wave model

The wave field was evaluated by using the linear diffraction theory presented by McCamy Fuchs(1954). The velocity potential ϕ expressed in the cylindrical coordinate defined in Fig. 2 was given by

$$\phi = -\frac{igH}{2\omega} \frac{\cosh k(h+z)}{\cosh kh} \left[\sum_m \varepsilon_m i^m \left\{ J_m(kr) - \frac{J'_m(kr_0)}{H_m^{(1)}(kr_0)} H_m^{(1)}(kr) \right\} \cos m\theta \right] \quad (1)$$

where ω denotes the angular frequency, k the wave number, h the water depth, r_0 the diameter of the cylinder and $J_m(kr)$ and $H_m^{(1)}(kr)$ are the Bessel and the Hankel function of the first kind respectively. The symbol i represents the imaginary number unit and ε_m is unity for $m = 0$ and 2 for otherwise. Near-bottom velocity and the radiation stress were evaluated analytically by using the theoretical wave field.

(2) Current model

The net movement of sand is influenced by the two current velocities, that is, the depth-integrated current induced by the spatial variation of the radiation stress and the mass transport velocity in the vicinity of the bed. The mass transport velocity $\vec{U}_m = (U_{mr}, U_{m\theta})$ at the edge of the bottom boundary layer was evaluated by the following equation which was converted from the laminar

Fig. 2 Definition of Coordinates

solution for compound waves in the Cartesian coordinate presented by Carter et al. (1973) to the cylindrical coordinate (r, θ) :

$$U_{mr} = -\frac{1}{4\omega} [F_5 u_r \frac{\partial u_r^*}{\partial r} + F_6 u_\theta \frac{1}{r} (\frac{\partial u_r}{\partial \theta} - u_\theta)^* + F_7 \frac{u_r}{r} (\frac{\partial u_\theta}{\partial \theta} + u_r)^*] \quad (2)$$

$$U_{m\theta} = -\frac{1}{4\omega} [F_5 \frac{u_\theta}{r} (\frac{\partial u_\theta}{\partial \theta} + u_r)^* + F_6 u_r \frac{\partial u_\theta^*}{\partial r} + F_7 u_\theta \frac{\partial u_r^*}{\partial r}] \quad (3)$$

where u_r and u_θ represents the amplitude of the radial and the tangential components of the orbital velocity and the symbol * denotes complex conjugate. The symbols F_5 , F_6 and F_7 are complex constants such that $F_5 = -3 + 5i$, $F_6 = -1 + 2i$ and $F_7 = -2 + 3i$.

A compound wave field with a complex wave height distribution was observed around the large circular cylinder. The spatial variation of the radiation stress therefore seemed to induce a stationary current field around the cylinder. This stationary current velocity $\vec{U} = (U_r, U_\theta)$ was determined through numerical calculation using depth integrated conservation equation of mass and momentum, expressed by the cylindrical coordinates as follows:

$$\frac{\partial \bar{\zeta}}{\partial t} + \frac{1}{r} \frac{\partial}{\partial r} [r U_r (h + \bar{\zeta})] + \frac{1}{r} \frac{\partial}{\partial \theta} [U_\theta (h + \bar{\zeta})] = 0 \quad (4)$$

$$\frac{\partial U_r}{\partial t} + U_r \frac{\partial U_r}{\partial r} + \frac{U_\theta}{r} \frac{\partial U_r}{\partial \theta} + F_r - M_r + R_r + g \frac{\partial \bar{\zeta}}{\partial r} = 0 \quad (5)$$

$$\frac{\partial U_\theta}{\partial t} + U_r \frac{\partial U_\theta}{\partial r} + \frac{U_\theta}{r} \frac{\partial U_\theta}{\partial \theta} + F_\theta - M_\theta + R_\theta + \frac{g}{r} \frac{\partial \bar{\zeta}}{\partial \theta} = 0 \quad (6)$$

where $\bar{\zeta}$ denotes the mean water level and t the time. The symbols F_r and F_θ

denote the friction term given by the following equation respectively:

$$F_r = \frac{f}{\rho(h + \zeta)} U_r \quad (7)$$

$$F_\theta = \frac{f}{\rho(h + \zeta)} U_\theta \quad (8)$$

where f is the friction coefficient expressed by

$$f = \frac{2}{\pi} \rho C_f u_b \quad (9)$$

where C_f denotes the bottom friction coefficient, u_b the orbital velocity amplitude near the bottom and ρ the density of fluid.

Terms M_r and M_θ represent lateral diffusion expressed by

$$M_r = \frac{1}{r} \frac{\partial}{\partial r} (\varepsilon r \frac{\partial U_r}{\partial r}) + \frac{1}{r^2} (\varepsilon \frac{\partial^2 U_r}{\partial \theta^2}) \quad (10)$$

$$M_\theta = \frac{1}{r} \frac{\partial}{\partial r} (\varepsilon r \frac{\partial U_\theta}{\partial r}) + \frac{1}{r^2} (\varepsilon \frac{\partial^2 U_\theta}{\partial \theta^2}) \quad (11)$$

where ε denotes the diffusion coefficient. The value of ε was assumed to be $100 \text{ cm}^2/\text{s}$ in the present study.

The symbols R_r and R_θ represent the gradient of radiation stress expressed by

$$R_r = \frac{1}{\rho(h + \zeta)} \left(\frac{\partial S_{rr}}{\partial r} + \frac{1}{r} \frac{\partial S_{r\theta}}{\partial \theta} \right) \quad (12)$$

$$R_\theta = \frac{1}{\rho(h + \zeta)} \left(\frac{\partial S_{\theta r}}{\partial r} + \frac{1}{r} \frac{\partial S_{\theta\theta}}{\partial \theta} \right) \quad (13)$$

where S_{rr} , $S_{\theta\theta}$, $S_{r\theta}$ and $S_{\theta r}$ represent components of the radiation stress tensor.

(3) Sand transport model

The sand transport rate was modeled in terms of the bottom shear stress and near-bottom current velocity. The Shields parameter ψ_m was expressed by

$$\psi_m = \frac{1}{2} \frac{f_w u_b^2}{sgd} \quad (14)$$

where f_w denotes the friction coefficient proposed by Jonsson (1966), s ($=1.65$) the specific gravity of sand in water and d the diameter of sand particle. Water particles near the bottom move in general in elliptic orbits under compound wave field and there are many unknown factors involved in the estimation of the friction factor. The friction factor was estimated in the present study by using maximum wave orbital velocity.

Using the mass transport velocity \vec{U}_m , stationary current velocity \vec{U} and the Shields parameter ψ_m , the volumetric net sand transport rate \vec{q} per unit width was assumed to be estimated by the following equation:

$$\vec{q} = A(\psi_m - \psi_c)(\vec{U}_m + \alpha\vec{U})d\frac{1}{1 - \lambda_v} \quad (15)$$

where ψ_c represents the critical Shields parameter for the general movement of sand particles, λ_v the void ratio of sediment and the symbols A and α denote non-dimensional coefficients. The coefficient α is a parameter which represents the ratio of the contribution to \vec{q} of \vec{U} to that of \vec{U}_m . The mass transport velocity \vec{U}_m represents the steady drift velocity at the edge of the bottom boundary layer while the stationary current velocity \vec{U} is depth-integrated velocity calculated assuming that the velocity is uniform over entire water depth. In reality, the current profile is not uniform and therefore the velocity near the bottom is considered to be smaller than that of the averaged velocity. It is thus considered that the influence on the sand movement by the mass transport is greater than that of the stationary current and therefore the value of α is expected to be smaller than unity.

The net sand transport rate was considered to be also affected by local sea bed gradient. The net sand transport rate \vec{Q} was expressed by the following equation by introducing the influence of the sea bed gradient in the same way as proposed by Watanabe et al.(1986):

$$\vec{Q} = \vec{q} - \epsilon_s |\vec{q}| \nabla z_b \quad (16)$$

where z_b denotes the bed level and ϵ_s , a non-dimensional coefficient.

The change of bottom topography was calculated by using the mass conservation equation of the sediment.

$$\frac{\partial z_b}{\partial t} = -\nabla \vec{Q} \quad (17)$$

The numerical calculation was carried out by using a finite difference method with a calculation grid as shown in Fig. 3. Every derivative in the governing equations was replaced with a central difference in the computation.

4. Results

(1) Wave Field

Figure 4 shows the distribution of relative wave height which was the ratio of local wave height to the incident wave height. Figure 4 (a) was measured from 0 to 1 hour after the initiation of wave action and Fig. 4(b) from 4 to 6 hours. The wave field by the linear diffraction theory is shown in Fig. 4(c). No great difference is noticed in Fig.4 (a) and Fig.4 (b), which means that no great

Fig. 3 Calculation Grid

variation in the wave field was developed even when the bed topography varies with time. This implies that the assumption made in the numerical models was almost completely satisfied for the condition of present experiments. The overall agreement between the measurement and the theory supports the validity of the wave model.

(2) Current Field

Since the current field around the circular cylinder was very complicated, it was very difficult to quantitatively measure the current velocity by tracing injected dye. However, it was observed that there existed a stationary current field as shown in Fig. 5(a). In Fig. 5(a), the large arrow represents the current direction and the arrow given by the continuous line represents the displacement of water particles near the bottom due to wave orbital motion. Figure 5(b) shows the computation of the mass transport velocity and Fig. 5(c) gives the computation of the stationary current velocity. According to these figures, the calculated stationary current velocities agree well with the observed velocity field.

(3) Test Section Topography

Figure 6 shows a comparison of the calculated bottom topography with the measurement. The hatched areas in the figure indicate the scoured area. Since it took approximately 4 hours for bottom topography to reach equilibrium for the condition shown in this figure, the numerical computation were carried out for 4 hours. The coefficient A was set at 0.07, ϵ_s at 0.03 and the critical Shields parameter ψ_c at 0.06. Figure 6 (a) shows the measurement, Fig. 6(b) the calculation assuming that α be unity and Fig. 6(c) the calculation when α is 0.2.

Since the influence of the stationary current is overestimated in Fig. 6(b), the calculation shows a considerably different topographical variation. Compared Fig. 6(b) and (c) with Fig. 6(a), we can conclude that the numerical model can predict the local scour pattern when α was fixed at 0.2. However, some discrepancies are noticed especially in the area just in front of the circular cylinder. The reasons for the discrepancy will be discussed in the below.

Firstly, there seems to be a problem in the estimation of the Shields parameter. The wave field around the circular cylinder is so complicated that water particles near the bottom move in two-dimensional orbits shaped circle, ellipse and straight line. Therefore, there seems to be inadequacy in estimating the Shields parameter ψ_m and critical Shields parameter ψ_c in an analogy to one dimensional oscillatory flow.

Fig. 6 Bottom Topographies (Case 2, 4 hours after wave action)

Second reason for the discrepancy is due to the use of the linear wave theory. The effect of wave asymmetry was not involved in the model since the near-bottom velocity was estimated by using the linear theory. Remarkable discrepancy is noticed just in front of the cylinder where standing waves were formed. According to Irie and Nadaoka(1984), which investigated the sea bed deformation in front of a breakwater, the direction of sand movement under standing waves was determined by the mass transport velocity and the asymmetry in near-bottom velocity variation. Waves observed in the experiments were relatively high so that the nonlinearity of wave is another factor which should be involved in the model.

5. Concluding remarks

Laboratory experiments were performed in a wave basin to reproduce the local sea bed scour around large-scale maritime structures. Experiments suggested that the mass transport velocity and wave-induced steady currents were essential in modeling sand transport. Based on experimental observations, a numerical model was presented for the local scour around a large circular cylinder. The applicability of the model was confirmed with experiments. Although some discrepancies are still present between experiments and computation, the model seems to provide a basic framework for the local scour around large-scale structures. Future studies are expected on the three-dimensional boundary layer flow as well as on the wave nonlinearity.

CHAPTER 135

Stability of Dolosse with Different Waist Thicknesses for Irregular Waves

A H Holtzhausen¹ and J A Zwamborn²

Abstract

Model tests were done to investigate the effect of waist thickness on the stability of dolosse under irregular wave attack. A comprehensive test programme resulted in a better understanding of dolos behaviour under a wide range of different conditions.

Irregular waves with Jonswap and Pierson-Moskowitz spectra were generated using a total of four different peak wave periods. Dolosse with five different waist ratios were tested. All the dolosse had a mass of about 80 g and were placed at a "normal" packing density of $\phi = 1,00$. Tests were done on three different slopes namely 1:1,33, 1:1,5 and 1:2.

The test results showed that the stability of dolosse decreases as the waist ratio is increased. On average, K_D -values for 2 per cent displacement of dolosse with waist ratios of 0,36 0,38, 0,40 and 0,43 were approximately 22, 51, 49 and 69 per cent respectively smaller than the K_D -value of dolosse with a waist ratio of 0,33.

It was found that irregular waves cause more damage than regular waves. In the 2 per cent displacement range, regular waves ($T=1,75$ s) with wave height H , cause the same degree of damage to dolosse with waist ratios of

1 Research Engineer and 2 Programme Manager, Maritime and Hydraulic Structures, Division of Earth, Marine and Atmospheric Science and Technology, CSIR, P O Box 320, Stellenbosch, 7600, South Africa.

0,33, 0,38 and 0,43 as waves with a Jonswap spectrum ($T_p=1,75$ s) with wave heights $H_{mo} \approx 0,9 H$, $H_{mo} \approx 0,8 H$ and $H_{mo} \approx 0,75 H$ respectively. It was also found that the stability factor obtained with the Pierson-Moskowitz Spectrum ($T_p=1,75$ s) is on the average 16 per cent lower than that obtained with the Jonswap Spectrum.

There was a noticeable decrease in stability for shorter wave periods and the shortest wave period ($\xi \approx 3$) produced the lowest stability values.

Dolos stability appeared to decrease as the slope was increased from 1:2 to 1:1,33. This was more pronounced with the $r = 0,33$ dolosse than with the $r = 0,38$ dolosse. The difference in behaviour of these units can be ascribed to differences in their interlocking characteristics.

Introduction

A previous report on the effect of waist thickness on the stability of dolosse (Scholtz and Zwamborn, 1983) contained the results of model tests done with regular waves.

In that report, the results of tests with three different waist-to-height ratios, namely, 0,33, 0,38 and 0,43 were presented. Only regular waves which were produced by a translatory wave board were used. The wave period was kept constant at 1,75 s. The results showed a marked decrease in stability, especially when the waist-to-height ratio was increased to above 0,38.

Although the increased waist-to-height ratio showed a general decrease in stability, it was considered necessary to also test with units having waist-to-height ratios between 0,33 and 0,38 and between 0,38 and 0,43 to confirm this trend. It was also decided to use more realistic irregular waves instead of regular waves for these additional tests.

In addition, the effects of wave period and armour slope on dolos stability were tested to obtain a more comprehensive picture of dolos stability.

Description of Tests

Model layout and Dolos Characteristics

The tests were done in the 127 m long (effective length), 3 m wide and 1,1 m deep wind-wave flume in Stellenbosch.

A total of 538 dolosse were placed in each $750 \times 750 \text{ mm}^2$ test area. Additional 80 g dolosse were placed above and below the 'test area' as shown in Figure 1, but these were not taken into account in assessing damage.

The underlayer consisted of 16,5 g selected stone and was 43 mm thick. The breakwater core was built of loose bricks covered with an approximately 200 mm thick layer of 1 to 5 g gravel.

Test Wave Conditions and Measurements

Waves were generated by Seasim irregular wavemakers placed near to the one end of the flume in 1,0 m deep water. The wavemaker is equipped with a wave absorption control unit which makes it possible to absorb reflections from the breakwater structure, thus minimizing unwanted re-reflections off the wavemaker paddles.

The following wave conditions were used for the tests: Jonswap spectrum with T_p -values of 1,25, 1,5, 1,75 and 2,0 s and Pierson-Moskowitz spectrum with $T_p = 1,75 \text{ s}$.

Waves were measured by means of twin-wire resistance type probes coupled to the CSIR's model hall data acquisition system.

Three probes were positioned in each of the three channels at distances of 5,55, 5,80 and 6,20 m from the model slope. These three sets of three probes each were used to separate the incident from the reflected spectra. A three-point method using a least squares technique for decomposing the measured spectra from three known probe positions, developed by Mansard and Funke (1980), was used.

The wave data calculated from the recordings made during the actual tests at the three probes in each channel (9 probes altogether) were used to calculate the mean incident wave height for each test.

Test Procedures

After the underlayer stones had been smoothed out, the test area was profiled using the standard sounding technique on a 50 mm grid (Zwamborn, 1980). The dolosse were then placed in one operation, from the bottom upwards, and the surface was profiled on the same grid as the underlayer. The profiling of the underlayer

grid as the underlayer. The profiling of the underlayer and the dolosse surface was done for a number of tests only. The mean difference between the two soundings provided the average layer thickness, $t_{n=2}$ while the 'fictitious' porosity, P_f , was calculated using the following two equations:

$$t_n = r_n V^{1/3}$$

$$\text{and } \phi_n = n C_n (1 - P_f/100)$$

where

t = layer thickness

n = number of layers

$r_n = n C_n$ = 'relative' armour thickness

C_n = shape factor

$$= \phi_n/n (1 - P_f/100)$$

P_f = 'fictitious' porosity

Table 1 shows the average values of P_f , and $C_{n=2}$ that were determined for dolosse of five different waist ratios (r).

Waist ratio	$r=0,33$	$r=0,36$	$r=0,38$	$r=0,40$	$r=0,43$
P_f (%)	54,9	52,7	50,5	49,3	47,0
$C_{n=2}$	1,18	1,09	1,05	1,03	1,01

Table 1. Measured values of P_f (%) and $C_{n=2}$

A test series consisted of 60 minutes of wave action for each wave height starting from the smallest wave height and increasing the wave height in steps of about 20 mm until failure occurred or until the biggest wave was reached (normally about 5 to 8 steps).

The return period (55 to 80 minutes) of the input wave sequence used was mostly longer than the actual test period (60 minutes) used, with the result that the wave conditions varied throughout a test. All the repeat tests were started at the same position in the wave sequence, therefore the same section of the wave sequence was used for the different tests. Three 1,8 to 2,9 minute-long wave recordings were made in each test channel during each one-hour test.

Displacement of units were recorded by visual observation after each 60 minute test. Photographs were also taken at the start of a test series and after each 60 minute test. Rocking movements were recorded by

A test series was repeated from 3 to 8 times using the same wave sequence. The sublayer and the dolos cover were replaced after each test series.

Dolosse of different waist-to-height ratios were tested side by side in the flume. To eliminate the effect of small differences in wave conditions in the three channels, the positions of the test dolosse were alternated in the three channels.

Damage Criteria

In the analysis of the test results, the following damage criteria were used:

- (1) displacement, movement of at least h
- (2) continuous rocking or full roll-over (no displacement)
- (3) intermittent rocking (about two-thirds) of the time
- (4) occasional rocking (about one-third of the time)

At least three repeat tests were done for each test condition and the average damage was obtained for the different wave heights from these data.

Test Results and Interpretation

Effect of Irregular Waves

A comparison of the results obtained with regular waves and the results obtained with irregular waves are shown in Figure 2.

The results indicate that dolosse are less stable with irregular waves than with regular waves of height H_{mo} . For the $r = 0,33$, $r = 0,38$ and $r = 0,43$ dolosse, it is found that in the 2 per cent displacement range, regular waves with wave height H cause the same degree of damage as irregular waves with $H_{mo} \approx 0,9 H$, $H_{mo} \approx 0,8 H$ and $H_{mo} \approx 0,75 H$.

Ouellet (1972) concluded from his model test results that "... the use of the significant wave height, $H_{1/3}$ for the design wave height of a rubble-mound breakwater is comparable to a constant periodic wave height ...", which contradicts the above results.

Brorsen *et al.* (1974) concluded from their model test results that irregular waves of H_s cause the same degree of damage as regular waves with the height $H \approx 0,8 H_s$. After checking the results presented by Brorsen, however, it was found that $H_s \approx 0,8 H$ and not

$H \approx 0,8 H_s$ as given in the paper (the same error is carried through in Burcharth *et al.* (1986)). Thus, after making this correction, these results are similar to the above ones.

Figure 2. Irregular versus Regular Wave Results for Different Waist Ratios

Effect of Waist-to-Height Ratio

The 'relative' stability factor was used to describe the effect of waist ratio on stability. This is defined as the K_D value for a specific waist ratio divided by the K_D value of a waist ratio of 0,33 i.e. $K_D/K_D(r=0,33)$, where K_D is the Hudson stability coefficient:

$$K_D = \frac{\gamma_s H^3}{W \Delta^3 \cot \alpha}$$

where

W = weight of dolos
 H = wave height

$$\Delta = \frac{\gamma_s}{\gamma} - 1$$

γ = specific density of water
 γ_s = specific density of dolos
 α = breakwater slope angle

Figure 3 shows the relative stability factor against waist ratio for a range of different test conditions including one condition tested by Burchart *et al.* (1986). All the results of the present tests show a very definite trend of decreasing stability with increase in waist thickness. This result is to be expected, considering the reduction of interlocking capability and decrease in porosity (Table 1) for the thicker-waist dolosse.

Surprisingly, the results of Burcharth show no clear influence of waist ratio on stability. Figure 3 shows that Burcharth's results are rather scattered and follow no clear trend with change in waist thickness. The reason for this is probably that the units tested were rather small (30,7 g). Also, the packing density was increased with increasing waist ratios, therefore variation in test results can not be attributed to waist ratio only.

Figure 3. Effect of Waist Ratio on Stability

Effect of Wave-period and Wave Spectrum

The effect of wave period and spectrum shape on stability is shown in Figure 4. There is a noticeable decrease in stability with shorter wave periods except for $T_p = 1,5$ s when K_D is about equal to that for $T_p = 1,75$ s with $r = 0,36$, $r = 0,40$ and $r = 0,43$ dolosse.

- JONSWAP SPECTRUM, $T_p = 2,0$ s
- X JONSWAP SPECTRUM, $T_p = 1,75$ s
- JONSWAP SPECTRUM, $T_p = 1,5$ s
- △ JONSWAP SPECTRUM, $T_p = 1,25$ s
- PIERSON - MOSKOWITZ, $T_p = 1,75$ s
- ▽ REGULAR WAVE, $T = 1,75$ s

Figure 4. Effect of Wave Period and Spectrum Shape on Stability

For a displacement of 2 per cent for dolosse with $r = 0,33$; $r = 0,36$ and $r = 0,40$ respectively, waves with a Jonswap spectrum were approximately 9 per cent, 6 per cent and 4 per cent larger than waves with a Pierson-Moskowitz spectrum. Therefore the average stability factor obtained with the Pierson-Moskowitz Spectrum, $T_p = 1,75$ s is 16 per cent lower than that obtained with the Jonswap Spectrum, $T_p = 1,75$ s.

Effect of Armour Slope

For comparing the stability of units on different slopes, the stability number $N_s = H_s / (\Delta(W/\gamma_s)^{1/3})$ which equals $(K_D \cot \alpha)^{1/3}$, was used since (unlike K_D) it gives a direct indication of armour weight independent of the slope angle. Another important aspect of stability comparisons between different slopes, is the definition of wave attack. Comparison should be done when the destabilising forces produced by waves on different slopes are the same. Günbak (1979) showed that the Iribarren number $\xi = \tan \alpha / (H/L_0)^{1/2}$ may be used to describe the wave attack on a rubble mound structure. In this formula α is the slope angle, H is the wave height and L_0 is the deep water wave-length.

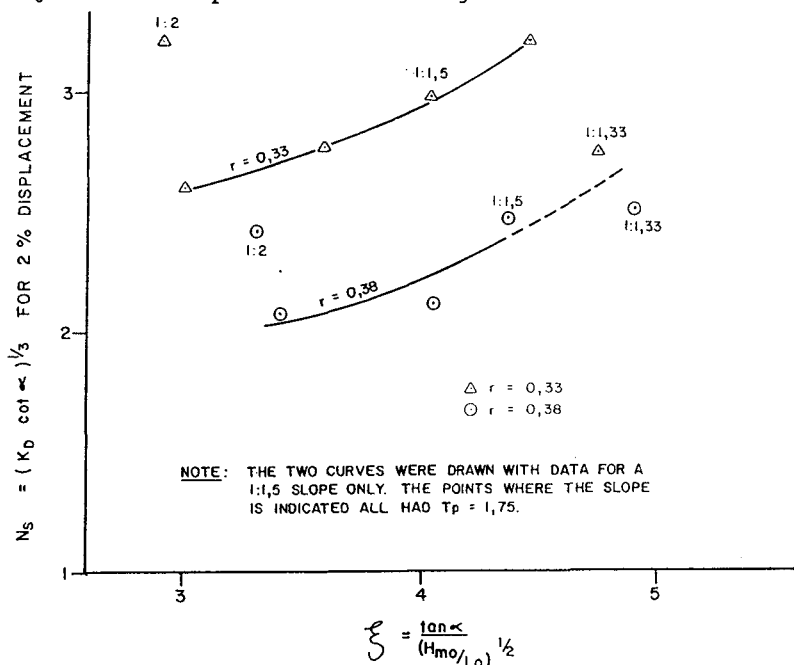

Figure 5. Effect of Armour Slope on Stability

Figure 5 shows the stability (defined by N_s) against the wave attack (defined by ξ) for three different slopes for dolosse with $r = 0,33$ and $r = 0,38$. For calculating ξ , the wave height was taken as H_{m0} just in front of the start of the dolos slope and L_0 was calculated as: $L_0 = (g/2\pi) T_p^2$ where T_p is the peak wave period. The 1:2 and 1:1,33 slopes were tested with

$T_p = 1,75$ s while the 1:1,5 slope was tested with four different peak wave periods.

From Figure 5 it is clear that the stability decreases as the slope is increased from 1:2 to 1:1,33 for both types of dolosse. However, this comparison was done at only one wave period and can therefore not be assumed to apply in general. The decrease in stability was more pronounced for the $r = 0,33$ dolosse than for the $r = 0,38$ dolosse. This seems to indicate that thicker units have better stability (for low displacement values) than more slender units on steep slopes. A possible explanation for this is that steep slopes cause the thicker units to pack close enough to utilize most of their interlocking capacity, while the slender units (with their higher porosity) require some initial settlement before optimum interlocking is achieved.

Design Curves

Based on the present test results, the relationships between the stability factor and the Iribarren number are as shown in Figures 6 and 7. For the range of Iribarren numbers used in the present tests (ξ approximately 3 to 5) the most critical wave conditions for the stability of dolosse have Iribarren numbers of approximately 3.

For the $r = 0,38$ dolosse all the data points (including the 1:1,33 and 1:2,0 slopes) fitted the design curve reasonably well. If the data points for the 1:1,33 and 1:2,0 slopes are included as data for the $r = 0,33$ dolosse, a very bad fit is achieved. These two data points were therefore excluded for the design curve of the $r = 0,33$ dolosse, and this curve is therefore strictly valid only for an armour slope of 1:1,5.

It is clear from the wide spread of data points in Figures 6 and 7 that the two parameters, K_0 and ξ , do not fully describe the stability of dolosse under the various test conditions. However, these design curves can be used as a guide for a first design using Figure 6 for high quality strength-improved dolos projects while Figure 7 should be used for lower quality projects.

Figure 6. Design Curve for 2 per cent Displacement

Figure 7. Design Curve for 2 per cent 'Total Damage' (displacement + continuous rocking + intermittent rocking)

Conclusions

Test results showed that the stability of dolosse decreases as the waist-to-height ratio increases. The results also showed that, for 2 per cent displacement, there is a noticeable decrease in stability with shorter wave periods down to $\xi \approx 3$ (minimum ξ value of tests).

It was also found that dolosse are on average 16 per cent less stable with Pierson-Moskowitz Spectra waves than with Jonswap Spectra waves of the same peak period.

It can further be concluded from the test results that irregular waves with a significant wave height equal to the wave height of regular waves, cause significantly more damage than the regular waves. The stability factors for dolosse with $r = 0,33$, $r = 0,38$ and $r = 0,43$, determined with irregular waves are respectively 23, 45 and 55 per cent smaller than the stability factors determined for regular waves. Although regular waves can be used to determine the relative stability of different types of dolos armouring, it is better to use irregular waves in tests where the stability of the armouring for a specific project is to be determined. If only regular waves can be used for these tests, allowance must be made for the expected greater damage by using a regular wave height, $H = 1,1 H_{m0}$ for dolosse with $r = 0,33$, $H = 1,2 H_{m0}$ for dolosse with $r = 0,38$, and $H = 1,3 H_{m0}$ for dolosse with $r = 0,43$.

Tests with different breakwater slopes showed a decrease in stability as the slope was increased from 1:2 to 1:1,33. This decrease was less pronounced for dolosse with $r = 0,38$ than for the $r = 0,33$ dolosse.

Design curves are included in Figures 6 and 7 which show the dolos stability as a function of the Iribarren number and the waist ratio for two different damage levels. The data points in these figures show considerable scatter, indicating that these parameters do not fully describe the stability of the dolos armouring, particularly with regard to armour slope. However, the curves can be used as a guide for a preliminary design, taking into account the above limitations.

CHAPTER 136

ESTIMATION OF PEAK WAVE STRESSES IN SLENDER COMPLEX CONCRETE ARMOR UNITS

*Gary L. Howell*¹
*Hans F. Burcharth*²
*Joon P. Rhee*³

1 INTRODUCTION

Recent methods for the structural design of concrete armor units divide the forces into static loads, impact loads, and wave or pulsating loads. Physical model technology is being developed at several laboratories to measure wave loads on model armor units. While this technology represents significant progress, structural designers require a maximum stress value to design armor units. Rubble mound breakwaters are structures with both random loading and random boundary conditions, such that a single set of stress measurements cannot characterize the loading. This paper presents a method to determine a design stress for wave induced loads based on the design wave height, a designer specified exceedance probability, and a site specific parameter, k_s , which can be empirically determined from physical model measurements. The methodology was developed from analysis of many field measurements of wave loads on 38-tonne dolosse armor units at Crescent City, California.

2 PROTOTYPE MEASUREMENTS

Steel bars with strain gages were cast at the shank-fluke interface of the dolosse during construction. The bars were sized and arranged so the strains could be used to estimate the gross structural moments and torque about the shank-fluke section. Strains were sampled and converted to digital data at a 500 Hz rate and later reduced to 50 Hz. Details of the instrumentation can be found in Howell (1986).

The measurements were made during the winters of 1987 and 1988. The experimental design and examples of the prototype data are shown in Howell (1988). The dolos records during storms which occurred March 12-15, November 29-30, and December 1, 5, 6, 1987, and January 9-11, 14-16, 1988 were selected for this analysis. Low wave conditions were represented by data from December 11-14, 1987. The significant wave

Figure 1: Time Series of Moments and Principal Stress

height for the data set ranged from 0.9 *m*. to 5.0 *m*. and the maximum wave height was 9 *m*. The water depth at the toe of the structure is 10 *m*. with a typical tidal range of 2 *m*. The structure has an average slope of 1:5. More than 1600 records of 30-minute dolosse response were analyzed from 14 dolosse. The sample dolosse were grouped on the top layer from approximately 1 unit length downslope from the mean water line to 3 unit lengths above the mean water line.

3 ANALYSIS

Define σ_1 as the principal tensile stress, at the shank-fluke interface of the dolos armor unit, which can be computed from measurements of moments and torques as shown by Burcharth and Howell (1988). For the wave induced portion of the total load, the required value for design is the maximum principal stress measured from the mean or static stress.

$$\sigma_{max} = Max|\sigma_1 - \sigma_{1,static}|$$

σ_{max} can be interpreted as the maximum tensile stress, due to waves, at any point on the surface of the shank-fluke cross-section. Figure 1 shows example time series of moments, torque and the computed σ_1 . σ_{max} is the maximum of this time series occurring in the half-hour interval. In general σ_{max} will vary over a wide range depending upon breakwater characteristics, dolos boundary conditions, and sea state. The variability due to all but breakwater characteristics was examined statistically.

Consider σ_{max} for all dolosse and all storms grouped into bins of constant $H_{1/10}$. Within each bin, the distribution of σ_{max} was found to be well described by a Rayleigh distribution using the mean σ_{max} , $\bar{\sigma}_{max}$ as the single parameter. Figure 2 shows an exceedance probability distribution plot for measured values together with the Rayleigh exceedance probability for $H_{1/10}$ in the range 3.5 to 4.5 m. Figure 3 shows the range 4.5 to 5.5 m. The distribution of maximum stress for other ranges of wave height were similarly represented by a Rayleigh distribution of $\bar{\sigma}_{max}$.

Figure 4 shows a plot of $\bar{\sigma}_{max}$ computed from measured data vs. the $H_{1/10}$ bin used for the computation. The best fit linear correlation coefficient is 0.976. The best fit linear line passing through the origin has a slope within 10% of the best fit line. Assuming a zero intercept constraint based on physics the slope is defined as k_s , the wave stress constant, such that

$$\bar{\sigma}_{max} = k_s H_{1/10}$$

Note that since both σ and H ideally scale by length, k_s should be model scale invariant. A non-dimensionalized form of k_s can be given by

$$\frac{\bar{\sigma}_{max}}{hg(\rho - \rho_w)} = \frac{k_s H_{1/10}}{h}$$

where h is the dolosse length, ρ is the dolos density, ρ_w is the density of water, and g is the acceleration of gravity.

4 Comparison to Physical Model Measurements

The results from the prototype data indicate that the wave induced stresses for an individual dolos may vary due to many factors. The variation results from the random boundary conditions and random nature of the waves. However, the empirical analysis presented above indicates that for a population of dolosse, the statistical description of the response may be well defined, at least for the case of a site specific prototype breakwater. This possibility has potential for simplifying the use of a hydraulic breakwater model to estimate wave induced stresses on armor units.

Two problems have limited the use of hydraulic models for this task. First the development and verification of a model dolos unit which accurately measures stresses at small scale has required considerable effort due to the very small strains which must be measured. Second, the best method of applying the model scale measurements to the

Figure 2: Cumulative Exceedance Probability of σ_{max} for $H_{1/10} = 3.5 - 4.5m$

Figure 3: Cumulative Exceedance Probability of σ_{max} for $H_{1/10} = 4.5 - 5.5 m$

Figure 4: $\bar{\sigma}_{max}$ vs. $H_{1/10}$. The dashed line is the best line through the origin and the solid line is the best fit line.

Figure 5: Scatter Plot of σ_{max} from the model test of Crescent City breakwater. The mean values for each bin are shown along with the corresponding prototype values. (Markle, 1990).

prototype has not been determined. Stresses measured for a dolos in the model, may not be applicable to units placed in different positions during prototype construction.

It was therefore proposed that intercomparison of model and prototype be made based on the empirical parameter k_s , rather than deterministic comparison of the stresses from individual units. To test the validity of this approach a physical model of the *as built* Crescent City Breakwater was constructed and tested with instrumented model dolos armor units at CERC by Markle (1990).

The model was exposed to the same storms as used for the above analysis of prototype data. Data from the model were analyzed using the same procedure as described above. Figure 5 shows a scatter plot of σ_{max} from the model along with the $\bar{\sigma}_{max}$ values from the prototype. The $\bar{\sigma}_{max}$ values from the model data exhibit good agreement with the prototype values. Figure 6 shows an exceedance probability distribution plot for measured values together with the Rayleigh exceedance probability for $H_{1/10}$ in the range 5 to 6m. It can be seen that like the prototype, the model data are well described by the Rayleigh distribution.

5 RESULT

These results suggest that a physical model can be used to measure wave induced stresses without considering boundary conditions of units in a deterministic way. Also if the linear relationship between k_s and $H_{1/10}$ is confirmed by additional tests, it may

Figure 6: Cumulative Exceedance Probability of σ_{max} from the model tests for $H_{1/10} = 5 - 6 \text{ m}$. (Markle, 1990)

be possible to limit tests in the future to the minimum required to estimate a linear function with zero intercept.

If for a given breakwater model, k_s can be determined by measurements from model dolosse for a range of dolos boundary conditions and wave heights, then a σ_{max} can be determined for the wave load portion by substitution into the Rayleigh p.d.f. to obtain

$$\sigma_{max} = 1.13\sqrt{-\ln P(\sigma_{max})}k_s H_{1/10}$$

where the designer specifies $P(\sigma_{max})$ the probability of exceedance. This σ_{max} can then be combined with the static stress design value for input into the structural design process.

CHAPTER 137

RESEARCH OF WAVE FORCES OF BREAKWATER IN DEEP WATER AREA

Ho-Shong Hou, Ph. D. , P.E.
Director, Transportation Engineering Dept.
Institute of Transportation
240, Tunhua North Road
Taipei, Taiwan, Rep. of China

ABSTRACT

The design of breakwater in deep water requires a reliable assessment of the forces, it will be subjected to and full understanding of the behaviour of the structure. Wave forces on a vertical wall caisson of composite breakwater vary with the configuration of the rubble mound foundation as well as the condition of incident waves. If the conditions are very unfavorable, powerful impact breaking-wave forces may act on the vertical wall caisson. It is an important subject to clarify the generation conditions of impact breaking wave forces, so that the breakwater under design would not be exposed to a very strong breaking wave force.

The present study points out on the basis of the experimental results for the typical example of slided caisson that careful attention should be paid to the possibility of the generation of impact breaking wave forces in the design of composite breakwater. The generation conditions are investigated by the two dimensional experiments on the variation of wave forces due to the configuration of rubble mound and the three-dimensional experiments on the effect incident wave angle to the breakwater. The impact breaking wave forces are easily be produced on the vertical-wall caisson, where the mound is relatively high and has an appropriately broad crest width.

If the generation of impact breaking wave forces are unavoidable owing to the breakwater configuration, provision of an appropriate wave dissipating work in front of the caisson is recommended to alleviate the method of calculation of design wave forces on the caisson covered with wave dissipating concrete blocks and the wave dissipating caisson with a permeable front wall.

In the study, problems are highlighted with respect to wave climate range that will induce breaking wave pressure, model test is conducted to measure the wave pressure and the sliding effect. Then the current formula for calculated wave pressure is

discussed. The factor of experiment considered in the test flume is depth of composite breakwater, height, width and slope of rubble mound, etc.

1. Introduction

For dealing with the construction problems of the deep water breakwater, as for the caisson-composite type breakwater, the foundation work is the problem as the breakwater goes to deeper due to the limit of operation of diver in the deep water, the pavement of mattress, the leveling of the mound, etc. will cause much problem. Since the body of caisson is larger in the deep water, constructing, tawing and replacing caisson work will be more difficult than those of shallower water part. For flow chart of deep breakwater construction, planning and design of the structure need to be further considered.

For planning aspect, the huge deep breakwater that need to be made sure it is necessary. Since (1) invest benefit: due to expensive cost of engineering fee of deep breakwater, the after construction, its benefit is not larger than the invest cost, then it is unnecessary. (2) alternative plan: due to the elongation of existing breakwater to the deeper position, the construction fee is expected much higher, therefore, to find out the alternative plan such as, to construct one shallow breakwater could be also obtained the same harbor function; or if the breakwater was not prolonged, then to enlarge and repair some wharves could be also reached the same effect, etc. (3) calm wave sheltering area: due to high cost of breakwater, it is naturally to cut down the elongation of breakwater however, the harbor basin need to be calm. Therefore it is necessary to study the relationship between the elongation of breakwater and the calm wave sheltering area of basin. The criteria of the calm basin is necessitated to determine.

2. Test Results and Analyses of Deep Breakwater of Caisson-Composite Type

Around the Taiwan coast, especially the international trade port, breakwater of the caisson-composite type is commonly used. Deep outer breakwaters of the 2nd entrance of Keelung Harbor are tested for impact pressure analyses. The typical design section of -35M deep is shown in Fig.1; while

impact pressure (Fig.2c) is about triple of the normal wave pressure, its period is about 1/7 to 1/20 sec. In addition to the breakwater of 2nd entrance of Keelung Harbor, the varying mound shape, mound height of caisson-composite breakwater are tested and analyzed for further new information.

Fig.3 and Fig.4 are many cases of test results, the results show that, the higher mound of caisson-composite breakwater ($d/h=1/3$), wave pressure increases as the wave height becomes large; therefore the mound height has obvious effect on the wave pressure. The varying transverse width of the mound also shows that wave pressure has the different degree for increasing. Since the test results indicate that the wave pressure is larger as the transverse width of mound is wider, the wave pressure is bigger as the mound height is higher.

Fig.5 shows that the impact wave pressure occurring range of deepwater breakwater has the same tendency as that of shallower depth. That is as d/h smaller (or higher mound), the occurrence of the impact pressure is very often. The case of no wave overtopping is easier to occur than that of wave overtopping. The impact pressure occurring range is indicated by the dot line of Fig.5.

3. Results and Discussion

For caisson-composite breakwater, it is designed that the armour concrete block such as dolos, hollowtripod, etc. to prevent wave acting directly toward the caisson from forming shock pressure (one form of impact pressure). By using porosity of armour concrete block to increase turbulence for dissipating wave energy therefore wave pressure should be minimized. Based on the previous test results, it is considered that in front of composite type, the covering layer of armour unit on the mound could reduce the wave pressure about 60% in the shallower water area. However, reducing of wave pressure depends on water depth, wave condition, mound height, mound slope and mound shape, etc. For the present test results (test section of -35M deep or more) show that the portion of caisson (vertical wall) is subjected to standing wave or part of breaking pattern, the cover layer of armour unit is easily happened that the wave acting on the slope forms the breaking wave and produces shock pressure (strong impact pressure) in a short time, the impact pressure is quite huge. Therefore, the placement of armour concrete unit is inefficient to the wave action and will be a negative effect;

therefore, it is suggested the design section be changed to the section as shown in Fig.6

4. Failure of Deep Water Breakwaters

Failures to deep water breakwaters have occurred over the past decade, are due to the following (main) reasons:

Rubble Mound Type: the increase of depth and related increase of design wave heights led to designs with very steep slopes and protected by concrete armour units of weights and sizes far in excess of previous experience. The strength of these concrete blocks appeared in many cases to be insufficient due to the high peak forces, which occur on the blocks during a storm. The blocks broke and were subsequently easily removed from the slope. The great steepness of the slopes may also have contributed to failure, since the geotechnical stability of the mound becomes critical under wave loading.

Vertical Wall Type: failures to this type of breakwater occurred mainly due to high impact forces of breaking waves at the vertical front, leading to horizontal displacements of the caissons and in some cases to geotechnical instability of the foundation and tilting. The author has been invited in many cases of breakwater failure to investigate the failure and make a design for repairing, e.g. Su Ao Harbor Breakwater and Hualian Harbor Breakwaters in the east coast of Taiwan, R.O.C.

The solution to the problems mentioned above lies primarily in following the proper design procedures, as applied by Hou ('78 '80) throughout its breakwater projects. The main features of this procedure are systematic failure analysis of each design and an integral approach, including hydraulic-, geotechnical- and concrete strength aspects in a balanced way.

5. Conclusion

- 1) For the deep water breakwater construction, the field measurement of deep water wave, geological, oceanographic data, foundation and earthquake problem, etc. need to be further studied.
- 2) For the caisson-composite deep breakwater, the higher mound is easily to subject to occur the impact pressure, the lower mound has little such phenomena.

CHAPTER 138

Dynamic Revetments

John P. Ahrens¹

Abstract

The concept of a stone revetment where rock movement is expected is relatively new. For people familiar with gravel and shingle beaches, the idea is an easily accepted extension of the traditional statically stable revetment. However, for engineers familiar with classic breakwater design, the idea that a dynamic structure can provide suitable shoreline protection raises many doubts. Recent research in the Netherlands by van der Meer (1988) and colleagues has gone a long way toward answering difficult questions regarding the development of sound design criteria for dynamic revetments. This paper discusses progress in quantifying the problem and defining solutions. Laboratory model tests were conducted at the Coastal Engineering Research Center (CERC) to confirm and extend Dutch research. These tests are described and important findings presented, including a simple quantitative method to predict the amount of stone required to protect a bulkhead, i.e. critical mass. The method to protect a bulkhead appears to have more general implications which could lead to extensive application to a wide range of shoreline erosion problems. Analysis of data is continuing.

Introduction and Background

The concept of a rubble structure having a dynamic response to wave attack has been around for quite some time. Per Bruun has commented frequently about the high stability of "S" shape profiles of some very old breakwaters in Plymouth, England, and Cherbourg, France (Bruun and Johannesson, 1976). An adaption of the "S" profile is the berm breakwater concept developed by William Baird (see Baird and Hall, (1984) for a discussion of design considerations, or Hall (1987) for background information. The basic strategy is to build an extensive stone berm which can adjust and deform in response to severe wave action. A berm is effective because a large mass of rubble near the water line is capable of

¹Research Oceanographer, U.S. Army Engineer Waterways Experiment Station's Coastal Engineering Research Center, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199

disrupting wave action and dissipating wave energy. Stone size may be smaller than required for traditional armor, and placement does not require special care. The advantages appear to be, berm breakwaters have less expensive construction equipment requirements, are simple to construct, and use smaller stone, which is usually less expensive than conventional heavier armor stone. However, conventional breakwaters have a smaller cross section than berm breakwaters and smaller stone does not always cost less than conventional armor stone, so a berm breakwater is not always cost effective.

The idea of a dynamic revetment seems to be of more recent origin than dynamic breakwaters. van Hijum and Pilarczyk (1982) and Pilarczyk and den Boer (1983) present data and summarize some of the Dutch experience with gravel beaches and cobble-sized revetments. Recently, research has been initiated in England on the response of shingle beaches to wave action (Powell, 1988). Recent research in the Netherlands and England is motivated by a need for fundamental understanding of shingle beaches, how they might be nourished, and if shingle beaches could be used in some situations instead of a traditional statically stable riprap revetment.

With increasing interest in both dynamic breakwaters and revetments, there has been an acknowledgement that not enough was known about the durability of stone. Considerable effort has been directed in the United Kingdom towards understanding rock durability in the marine environment under dynamic conditions, (see e.g. Allsop and Latham, 1987 and Latham and Poole, 1988).

In the United States, Johnson (1987) found that gravel beaches and dumped rubble are frequently cost effective alternatives to using sand for beach nourishment and placed stone for revetments, respectively. Johnson's findings were obtained from extensive experience on Lakes Michigan and Superior where fluctuating water levels created enormous problems for conventional shoreline protection. This experience shows dynamic revetments are not vulnerable to toe scour, overtopping, or flanking. Advantages cited by Johnson for coarse material include a long residence time and an ability to stay in the vicinity of the water line. Other advantages are similar to those noted by Baird and Hall (1984), i.e., ease of placement and lower unit cost.

Comprehensive research efforts conducted recently in the Netherlands resulted in detailed and quantitative findings on dynamic stability (van der Meer, 1988). Findings are based on a very extensive amount of laboratory work and data analysis. One problem in applying van der Meer's results is that his tests were conducted in relatively deep water, and most problems in the United States involving shoreline erosion and protection are in shallow water. One goal of this study is to utilize the Dutch research to the greatest possible extent to help design dynamic revetments.

This paper provides information on laboratory tests conducted to gain familiarity with the concept of dynamic revetments and their use in shallow water. Specifically, this study was initiated to determine how dumped stone might protect a vertical bulkhead.

Test Setup, Conditions and Procedures

The model tests were conducted in CERC's 0.46x0.91x45.73 meter long glass walled wave tank (Figure 1), using an undistorted Froude scale of 1:16 (model : prototype). Irregular waves representing JONSWAP spectra were generated by a hydraulically actuated piston type wave maker. The test sections were placed approximately 35.4 meters from the wave board. Wave data were collected for each run using two Goda Arrays each consisting of three electronically driven resistance-type wave gages. Incident and reflected spectra were resolved using the method of Goda and Suzuki (1976). Wave signal generation and data acquisition were controlled using a DEC MicroVAX I computer. Data analysis was performed on a DEC VAX 11/750.

Figure 1. Profile view of wave tank setup.

Figure 2 shows a typical initial and equilibrium profile for a dynamic revetment. All initial profiles, except for Test 4, had a horizontal berm and a seaward face on a slope of 1 on 1, (vertical to horizontal). Test 4 used the equilibrium profile from Test 3 as a starting profile to determine how sensitive the equilibrium profile was to initial conditions. The influence of the initial berm width and berm height above the still water level (SWL) are two of the major variables investigated in this study. One goal of the study was to determine how much stone was required to protect a vertical bulkhead from direct wave attack. The bulkhead was simulated in the model using a plywood board to terminate the rubble on the landward side, located at 0.0 on the horizontal axis in the profile figures. Profiles shown in the figures are the average of five profile surveys along the length of the tank. There was very little across-tank variation in the profile observed during these tests. Surveys were made using a rod attached to a disc with a ball and socket connection. The disc had a diameter of 15 mm.

Figure 2a, Typical equilibrium profile.

Figure 2b. Definition Sketch

Initial test conditions were first generated to simulate wave action similar to that found on Lake Michigan near a site in Chicago at Devon Avenue. The initial berm width was chosen by substituting these initial test conditions into a simplified version of the Dutch equations (van der Meer, 1988). As testing progressed, more severe wave conditions were run in the wave tank to fully test the range of circumstances for which a dynamic revetment would be suitable. Later tests examined a shorter wave period which may better represent the conditions for a structure on a body of water smaller than Lake Michigan.

Table 1 summarizes the gradations and specific gravity of the stone used in this study. Specifically the stone is a dense limestone.

Cumulative Percent Passing	Tests	Tests
	1-22 Sieve size (mm)	23-26 Sieve size (mm)
2	4.8	3.1
15	5.6	4.3
50	8.1	5.6
85	11.2	7.3
98	12.7	9.3
specific gravity	$\rho(r) = 2.68$	$\rho(r) = 2.72$

Table 1. Characteristics of stone used in this study

Table 2 gives some of the basic data collected during this study. Number of waves is the total number of waves generated during a test based on the period of peak energy density, T_p , of the incident spectrum. T_p and H_{m0} , the incident zero-moment wave height, were measured at Goda Array 2 which is the shallow water array shown in Figure 1. Array 2 depth is the water depth at the middle gage in the three gage array. It was found that the initial profile adjusts rapidly to the incident wave conditions. For tests with $T_p = 2.5$ there was little change in the profile between 3000 and 5000 waves and for tests where $T_p = 1.75$, there was little change between 4245 and 7080 waves.

Berm width, W_B , is the horizontal length of the berm as it was constructed at the beginning of a test. Berm height, h_B , is the average vertical distance from the still water level (SWL) to the almost horizontal berm surface at the beginning of a test. Berm crest height, h_C , and berm crest length, l_B , are the vertical and horizontal distances respectively from the still water line to the conspicuous berm crest formed by the wave runup. Toe water depth, d_s , is the depth at the toe of the revetment at the beginning of a test. Erosion depth, h_e , and erosion length, l_e , are the depth and horizontal distance respectively of the toe of

Table 2. Basic Data

the revetment from the still water line for the indicated number of waves. Water depth at the wave generator is the depth in the deepest part of the tank (Figure 1). Revetment Response Category (RRC) is a simple evaluation of the performance of the revetment during a test where "F" indicates the revetment failed, "S" indicates the revetment was safe, and "I" indicates an intermediate condition. The RRC and the dimensionless revetment size will be discussed further in the next section. K_r is the reflection coefficient which is defined by Goda and Suzuki (1976) as the square root of the ratio of reflected to incident wave energy.

Critical Mass Analysis

One of the goals of this study was to provide guidance on the quantity of stone, critical mass, necessary to protect a structure, such as a bulkhead, from wave attack. To accomplish this goal, all of the test results were classified into one of three categories. When wave conditions are severe in relation to the quantity of stone in the revetment wave action will erode the rubble, usually by carrying it over the bulkhead, until waves can impact directly against the bulkhead; this category was designated failure, denoted "F" in Table 2 and illustrated by Figure 3a. When the amount of stone in a revetment is large in relation to the wave conditions the development of the berm crest will have enough room so that neither stone or water will be carried over the bulkhead; this category is designated safe, denoted "S" in Table 2, and illustrated by Figure 3b. The third category fell between safe and failure and occurs when the berm crest buildup extends far enough landward to reach the bulkhead and there is at least some overtopping of the bulkhead by both water and stone; this category was designated intermediate, denoted "I" in Table 2, and illustrated by Figure 3c. The ability of a dynamic revetment to protect a bulkhead is a function of the volume of stone per unit length and the incident wave conditions.

In order to calculate the critical mass it is necessary to estimate three characteristic dimensions of a dynamic revetment, i.e., berm crest height, h_c , berm crest length, l_c , and erosion length, l_e . Regression analysis was employed to determine the following equations which are used to estimate, h_c , l_c , and l_e :

$$h_c/H_{mo} = 0.270*(H_{mo}/L_p)^{-0.645}, R^2 = 0.96 \quad (1)$$

$$l_c/H_{mo} = 0.677*(H_{mo}/L_p)^{-0.521}, R^2 = 0.92 \quad (2)$$

$$l_e/d_s = \exp(2.24*(H_{mo}/L_p)^{0.143}), R^2 = 0.64 \quad (3)$$

Equations 1, 2, and 3 are based on analysis of Tests 1 through 22. R^2 values give the portion of the variance explained by the regression analysis. Tests 23, 24, 25, and 26 were conducted with somewhat smaller stone (see Table 1) and were withheld from analysis. Figures 4 shows observed data with regression trends for Equations 1, 2, and 3, respectively. Stone sizes are denoted by

3a. FAILURE PROFILE RESPONSE

3b. SAFE PROFILE RESPONSE

3c. INTERMEDIATE PROFILE RESPONSE

Figure 3. Dynamic Revetment Response Categories.

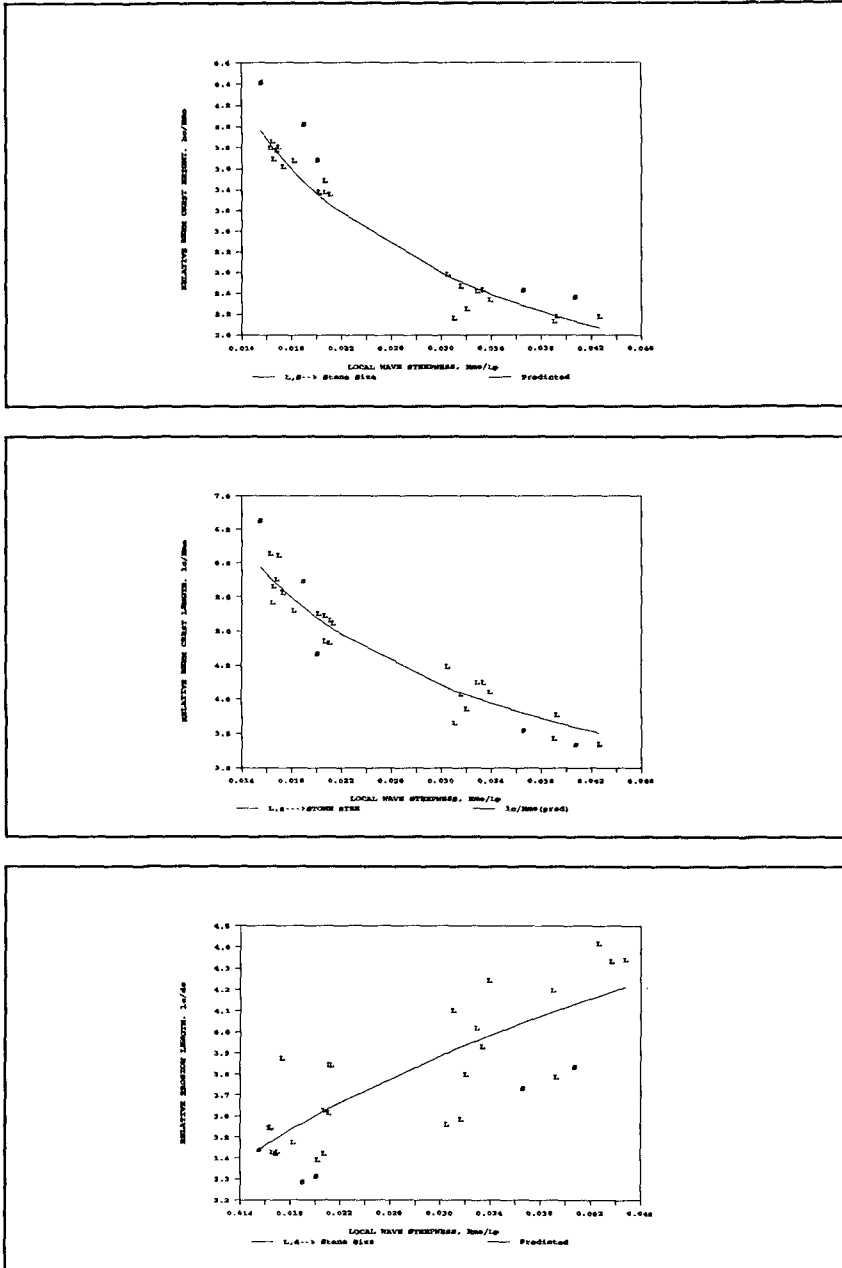

Figure 4, Characteristic dynamic revetment dimensions as a function of local wave steepness.

symbol in these figures so that the suitability of regression curves for the smaller sized stone withheld from analysis can be judged.

To specify the scale of the revetment response to wave attack it is useful to define a scale parameter, $A_s(c_m^3/c_m)$, where

$$A_s = (d_s + h_c) * (l_e + l_c) \tag{4}$$

and where h_c , l_c , and l_e are estimated using Equation 1, 2, and 3, respectively. The water depth at the toe of the revetment d_s is selected based on design considerations. The total volume of the revetment per unit length is denoted $A_t(c_m^3/c_m)$ and includes the void space of about 45 percent. Figure 5 shows the response category versus the ratio of A_t to A_s . For convenience let $A_t'(s) = A_t/A_s$. It can be seen that $A_t'(s)$ is able to properly categorize all tests including those with smaller stone withheld from analysis.

Figure 5, Dynamic revetment response categories as a function of two dimensionless revetment size variables.

A slightly easier but less accurate way to estimate the amount of stone required for a stable dynamic revetment can be obtained using the wave severity parameter, $H_{mo} * L_p$, where L_p is the Airy wave length calculated using d_s and T_p . Let $A_t'(w_s) = A_t / (H_{mo} * L_p)$. In Figure 5 it can be seen that $A_t'(s)$ is somewhat better than $A_t'(w_s)$ at predicting the proper revetment response category. The purpose of considering $A_t'(ws)$ is that it is quite simple and can provide some additional insight. It was found from the study of reef breakwaters that when wave conditions were quite severe in relation to the size of a reef, the reef could not dissipate wave energy effectively. For reefs it was found that for $(A_t / (H_{mo} * L_p)) < 0.5$, energy dissipation was largely a function of the relative size of the structure such that the percent energy dissipation = $(A_t / (H_{mo} * L_p)) * 100$.

From the analysis given above there appears to be at least two ways to interpret the critical mass for a dynamic revetment: (1) It is a supply and demand relation to determine if A_t is large enough to supply the demand, characterized by A_s . (2) It is an energy dissipation relation to determine if there is enough stone A_t available to dissipate the wave energy characterized by $H_{mo} * L_p$.

Wave Reflection and Energy Dissipation

After Coda Suzuki (1976) the reflection coefficient is defined as the square root of the ratio of the reflected wave energy to the total incident wave energy. Wave reflection from dynamic revetments appears to be a function of two variables, wave steepness and relative void size. Reflection coefficients can be predicted with the following equation:

$$K_r = 1 / (1.0 + (C_o * (d_{50} / L_o)^{C_1} * \exp(C_2 / H_{mo} / L_o))) \quad (5)$$

where d_{50} is the median stone size and L_o is the deep water wave length given by, $L_o = (g * (T_p^2)) / 2 * \pi$. The dimensionless regression coefficients are given by,

$$\begin{aligned} C_o &= 23.4 \\ C_1 &= 0.312 \\ C_2 &= -0.00374 \end{aligned}$$

Equation 5 explains about 97 percent of the variance in a sample size of 30, i.e. $R^2 = 0.97$ and $N = 30$. Tests in the failure response category were not included in the above analysis since at failure a substantial part of the reflection is from the vertical bulkhead. Percent of incident wave energy dissipated by a dynamic revetment can be estimated by using Equation 5 and the relation,

$$\%D = (1.0 - (K_r^2)) * 100$$

where %D is the percent energy dissipation. Observed data gives reflection coefficients between 0.27 and 0.50, indicating that dynamic revetments dissipate between 75 and 92 percent of the

incident wave energy. By dissipating over three-quarters of the incident wave energy dynamic revetments would make good wave absorbers.

Summary and Conclusions

A series of laboratory tests were conducted to investigate the response of dynamic revetments to shallow waver wave conditions. No more laboratory tests are planned at this time but data analysis is continuing. Most tests from this study fall into the category "dynamically stable rock slopes" based on the Dutch classification system (van der Meer and Pilarczyk, 1987). For this study, the ratio of the wave height to stone dimension is in the range of roughly 5 to 16. Typically zero-damage on a conventional riprap revetment occurs when the wave is about two and a half times larger than the stone dimension.

It was found the equilibrium dynamic revetment profile was not sensitive to the initial profile. This means that construction costs can be lowered because special care is not required in the placement of the stone. The berm crest is a conspicuous feature of the profile and the crest height is strongly dependent on the product of the zeroth moment wave height and local wave length.

The concept of a critical mass for a dynamic revetment is introduced. Critical mass is the quantity of stone required to protect a unit length of a vertical bulkhead for a given water depth at the toe and given wave conditions. This quantity is found to increase with increasing water depth, and zeroth moment wave height and period of peak energy density. Two methods to calculate the critical mass are introduced and discussed.

Future work includes more analysis and greater familiarity with the extensive Dutch research (van der Meer, 1988). Surprisingly, most of the Dutch laboratory work was conducted in relatively deep water at the toe of the revetment. Part of the effort in this study involves determining to what extent the Dutch findings can be applied to shoreline erosion in the United States. A related study being conducted in England can also provide valuable information to this study (Powell, 1988).

Acknowledgements

The author wishes to thank Mr. Donald L. Ward, Hydraulic Engineer, for contributing valuable insight on the conduct of this study. Mr. Willie Dubose conducted the laboratory work in a careful and professional manner. Mr. John Heggins, Computer Specialist, provided expert assistance in manipulating data files and analyzing the data. Ms. Myra Willis, Secretary, very capably put text, figures, and tables together to produce a paper.

The tests described, unless otherwise noted, were conducted under the Coastal Structures Evaluation and Design program of the

United States Army Corps of Engineers by the Coastal Engineering Research Center. Permission was granted by the Chief of Engineers to publish this information.

CHAPTER 139

STATISTICAL APPROACH OF DURATION OF EXTREME STORMS : CONSEQUENCES ON BREAKWATER DAMAGES

Charles Teisson¹

Abstract

A statistical model of storm duration has been developed and successfully applied to wave records on various French sites. Distribution of storm durations at various significant wave-height levels are fitted to Weibull curves. Extrapolation of these distributions to rarer storm events is presented, and enables the estimation of return period of any storm as a function of the exceeded wave height and the duration of this exceedance.

These results on storm duration have been applied to breakwater design, with the help of laboratory tests displaying the influence of duration on breakwater damages.

1. INTRODUCTION

Actions of waves on natural shores or artificial structures are at first described by the height of incident waves. Observations of phenomena of littoral transport, or damages caused on breakwater also display the importance of duration of the action of this incident wave. This point of view of persistence of sea state is usually disregarded : analysis of waves records is most often carried out without taking interest in information about duration, however implicitly contained in the sampling, equally or irregularly time-spaced.

It is only in the 1970's that the first "mathematical persistence models" were developed, under the impulse of oil industry, for effective planning of offshore activities (HOUMB and VIK, 1975 ; GRAHAM, 1983).

In the same way, we developed a statistical method of analysis of the couple height/duration of storm from available waves record, successfully applied to various French sites, allowing to estimate distribution of storm duration for extreme events (TEISSON, 1984).

¹ Research Engineer

EDF - Laboratoire National d'Hydraulique, 6, quai Watier 78400 Chatou, France.

Fig. 1: Definition of the duration of a storm at a selected wave height threshold from waves records

Fig. 2: Statistical adjustment of durations for storms $H_s > 1.50$ m.

These results on storm duration have been applied to breakwater design, in order to judge their influence on the determination of the armour unit size. Previous tests conducted in laboratory enabled to check that storm duration clearly influence the damages : when using stability formulae, as Hudson type, the design wave height producing similar damages lies between $H_{1/10}$ and $H_{1/20}$.

These practical information, combined with the results of the statistical method lead to a more comprehensive use of waves records and a promising approach for breakwater design.

2. THE STATISTICAL METHOD

2.1. Return interval of storm including height and duration

When dealing only with wave height statistics, the definition of storm is reduced to storm peak. We tried to develop a statistical method saving more information and we immediately had to answer some puzzling questions : what is an occurrence of a storm and its duration ? Following LAWSON and YOULL (1977), we defined the occurrence of a storm when wave height passes, in an upward direction, a selected wave height level. The duration of the storm corresponds to the time exceedance of the wave height level, i.e., the duration of the uninterrupted sequence of significant wave height greater than the selected level (fig. 1). Therefore the same storm can be represented by various durations associated to different wave height levels.

For a selected wave height threshold, i.e. $H_{1/3} = 1.5$ m, the set of storm durations observed in the 5 years records was fitted to various distribution laws to estimate the 1 in a year, 1 in 10 years durations ; the best adjustment was obtained for Weibull laws (fig. 2) :

$$P(t) = e^{-\left(\frac{t}{\alpha}\right)^\beta}$$

where $P(t)$ is the probability that a storm duration exceeds t hours, above the selected wave height level of 1.5 m.

The same methodology was reproduced for higher wave height level H , i.e 2 m, 2.5 m, 3 m ..., leading to new values of $P(t)$ at each level. Following the variations of α and β as a function of H enables to extrapolate α and β for extreme H . Thus, on Antifer harbour site :

$$\alpha(H) = 11.4 H^{-0.42}$$

$$\beta(H) = e^{\frac{H - 3.3}{5.4}}$$

Finally this method enables to estimate the distribution of storm duration for extreme events. Returns period R of any storm is thus known not only from the exceeded wave height, but also from the duration of this exceedance (fig.3) :

$$\frac{1}{R} = n(H) \times P(t) \quad (1)$$

where $n(H)$ is the classical distribution of extreme wave height and $P(t)$ is the conditional distribution of the duration, for a given threshold H in wave height. $n(H)$ and $P(t)$ are in general Weibull laws, adjusted by the renewal method developed previously at LNH.

Fig.3: 1 a year, 1 in 10 years, 1 in 100 years storms defined from height and duration parameters
 Ex: A storm with a wave height exceeding 3 m. during 34 hours is a 1 in 10 year storm

Fig.4: Return interval for the storm of november, 7, 1982 (Marseille site)

2.2. Severity of a storm

As seen above, a storm is a complex event, which cannot be reduced to the maximum wave height reached, or even a duration in hours above a single wave height threshold. In our method, a storm cannot be represented by a single event, and therefore its return interval is not unique. Nevertheless, it is possible to calculate the return interval for various wave height thresholds within the storm from (1), and the greatest return interval will symbolize the "severity" of the storm, and will be selected as the return interval of the storm. This return interval can be visualized by plotting, in the height-duration plan of fig. 3, the various couples wave height-duration of exceedance of any observed storm.

On fig. 4, the storm of november, 7, 1982 in Marseille is plotted in thick line with this value of duration at each level. With classical analysis carried out only on wave height, this storm would be a 1 in a year storm, according to its peak height. Information on duration shows that this storm, at lower height level was a more severe storm, with a return period of 13 years.

3. INFLUENCE OF STORM DURATION ON BREAKWATER DAMAGES

Results on storm duration have been applied to breakwater design, in order to judge their influence on the determination of the armour unit size. Previous tests conducted in a flume (LEPETIT and FEUILLET, 1979) enabled to evaluate the damages as a function of the duration of the action of random waves represented by significant wave height $H_{1/3}$ (fig. 5):

$$D = a H_{1/3}^b t^c \quad (2)$$

D : Cumulative damage at instant t, expressed in number of displaced blocks of the armour ; a, b, c, constants depending on type of blocks (for rubblemound beakwater a = 0.706, b = 3.9, c = 0.37).

A design wave height H_D , producing similar damages in regular waves can be expressed as :

$$H_D = 1.18 H_{1/3} t^{0.095}$$

On fig. 3, for a given return period, R = 10 years for instance, different values of height and durations as design conditions can be selected, leading to damages according to (2) :

1 in 10 year design condition	$H_{1/3}$	1,50m	2m	2,50m	3m	3,50m	4m	4,50m	5m	5,50m
	t (hours)	101,8	72,6	51,02	33,24	22,17	14,89	9,77	5,80	1,83
	H_D (m)	2,36	3,10	3,82	4,50	5,17	5,81	6,42	6,99	7,33

Table 1 : Influence of storm duration in stability formulae - "Equivalent design height H_D "

Duration clearly influence the damages : when using stability formulae, as Hudson type, the design wave height H_D producing similar damages lies between $H_{1/10}$ and $H_{1/20}$, compared with information only on wave height.

Fig.5: Evolution of damages as a function of duration of storms

Fig.6: Damages and equivalent dimensional height for storms with same peak height but various durations

Recent developments relate to a better description of sea states, especially storm. The complete information of an occurrence of a storm is tentatively saved : not only the peak height, as in classical long term statistic waves, neither duration at some reference waves level, as stated in the method above, but the complete cycle of waves height growing and then decreasing.

By an integrated theoretical approach from (2), we calculated damage all along the storms. Let us suppose that a storm can be described by a sequence of significant wave height $H_i, i = 1, \dots, n$, the duration of each height being $\Delta t_i, i = 1, \dots, n$. The first wave height reaching the breakwater will produce damages according to (2) :

$$D_1 = 0.706 (H_1)^{3.9} \Delta t^{0.37}$$

The next wave height H_2 , lasting Δt_2 , arrive on a breakwater which has already suffered from damages D_1 . We can calculate the equivalent duration $\Delta t'$ which would have produced similar damages with H_2 (fig. 5) :

$$\Delta t' = \Delta t_1 \left(\frac{H_1}{H_2} \right)^{0.37}$$

Therefore, it looks like if H_2 has played during $\Delta t' + \Delta t_2$, producing damages :

$$D_2 = 0.706 H_2 (\Delta t' + \Delta t_2)^{0.37}$$

Replacing $\Delta t'$, it comes :

$$D_2 = 0.706 \left[\Delta t_1 H_1^{10.54} + \Delta t_2 H_2^{10.54} \right]^{0.37}$$

Reproducing the reasoning step by step, one can write, if we assume that the wave is known in a continuous way :

$$D_{(t)} = 0.706 \left[\int_0^t H_{1/\beta}(\tau)^{10.54} d\tau \right]^{0.37}$$

To see the net influence of duration, this formula has been applied to two storms which appeared in the records, reaching nearly the same peak height of 3.5 m, but with very different durations (fig. 6), the first storm persisting 35 hours above 3 m, the second one only 3 hours. Damages are almost three times greater in the longer storm. Speaking in terms of equivalent design wave height, using $H_D = 1.29 D_{1/3.9}^{1/3.9}$, we found :

$$\begin{aligned} H_D &= 5.63 \text{ m} && \text{for the longest storm} \\ H_D &= 4.46 \text{ m} && \text{for the shortest one} \end{aligned}$$

Reminding that H_D plays at a power 3 in Hudson formula, for instance, the weight of the blocs of the armour layer would be in a factor of 2 between the two storms, if we have to design a breakwater for each of this storm condition. In this particular case, the duration of storm is as important as the reached wave height, for breakwater design.

Fig. 7 exhibits that for a quasi-symmetric storm with respect to duration of growing and decreasing phase, 80 % of damages occur during growing height phase. From another point of view, 80 % of the damages are concentrated near the peak ; this remark pleas for accurate recording of waves height, instead of time step of 4 hours as on fig. 7.

Fig.7: Storm of January, 3 1978
 . Time evolution of cumulative damages
 (in % of the damages at the end of the storm)

Fig.8: Influence of time sampling.
 Storm of 22 March 1981 at PENLY

4. INFLUENCE OF TIME SAMPLING

Usually wave data acquisition is performed in the following manner : the significant wave height is calculated from records of length 20 minutes, every 4 hours. But what does happen in between ? In fact :

- the persistence of waves at the peak cannot be precised in the range 20 minutes - 4 hours,
- the true peak reached is unknown.

Now these missing information are of major importance. From (2) :

- a storm persisting 4 hours at a given level is 3 times more damageable than a storm of 15 minutes (influence of duration),
- for a given duration, a wave of 6 m is 2 times more damageable than a wave of 5 m (influence of true peak).

What does really happen is shown on fig. 8, on a site where classical records every 4 hours were available, together with another record every 15 minutes in case of storm.

When available, recording every 15 minutes leads to strong influence on design conditions, as a consequence of better description of sea state (TEISSON, 1986). On the same data base, 1 in 10 years extreme significant wave height can be increased by 25 % when changing the time step from 4 hours to 15 minutes.

5. PRACTICAL CONCLUSIONS AND FURTHER DEVELOPMENTS

The synthesis of the theoretical statistical developments and laboratory tests lead to some practical information on storm duration and breakwater damages :

- a storm persisting 4 hours at a wave height level is three times more damageable than a storm persisting only 15 minutes at the same level (influence of storm duration),
- to select $H_{1/3}$ as design wave height in Hudson formulae assumes that the associated storm will last for only 10 minutes : this choice could lead to an under estimation of breakwater design,
- to speak of 1 in 10 years wave estimate has no significance without referring to the time sampling of the records.

On going developments try to treat the waves records, and especially storms, with respect to their specific final aim : each storm is transformed into cumulative potential damages on rubblemound breakwater (see fig. 7). These damages are then expressed in an equivalent dimensional height, by an inverse transformation, which could be extrapolated to extreme event. This theoretical approach, which is now under verification in flume tests, could lead to complete new definitions of design conditions, closer and more adequate for breakwater layout.

All these researches, aiming at a better description of sea state including persistency, may help in a more precise evaluation of design conditions for coastal activities.

ACKNOWLEDGEMENTS

This study was performed as part of a joint research program between EDF-LNH and the French Sea State Secretary.

CHAPTER 140

COASTAL DEFENCE ALTERNATIVES IN THE NETHERLANDS

The Dutch Coast : Paper No. 1

Cees (C) J.Louisse*) and Ton (A) J. Kuik *)

Abstract

Coastal defence is an important issue in the Netherlands since more than half of its territory is situated below sea-level. Coastal erosion causes a permanent threat for this largely natural system. As a consequence flood-protection of the polderland may not everywhere be sufficiently guaranteed in the future. Besides dune area with valuable interests may be lost. These problems will worsen due to sea-level rise.

In 1987 the minister of public works instructed to perform a study to identify these problems and to develop alternatives for an overall coastal defence strategy in the Netherlands and to determine the effects of implementation of the alternatives over a time interval of several decades. The impacts of 4 alternatives have been determined with a policy analysis model, which has been especially developed for this purpose.

Model calculations indicate that the more (structural) measures for coastal defence are taken the less are the losses of dune area and the higher the costs. As time proceeds (up to 2090) the differences in costs between the alternatives decrease, while losses for some of the alternatives rise highly. Acceleration of sea-level rise results in an increase of costs and losses of dune area. A remarkable increase of impacts shows up when a change in wind climate is introduced.

Introduction

About one third of the Netherlands is situated below sea-level and would be flooded if it was not protected by the coastal defence system. This defence system is composed of three major units: in the south the Delta coast, consisting of (former) delta's and islands; between Hoek van Holland and Den Helder a stretch of coast not interrupted by tidal inlets (the Holland coast) and in the north the Wadden Island coast, consisting of a series of coastal barrier islands with tidal inlets in between (Figure 1). The defence system consists of dunes and dikes protecting the polders, and dams closing off large tributaries (Delta coast). The last have been constructed during the last decades (Delta works). In this period, which ends in 1990, also the defence system of the dunes has been improved. This leads everywhere along the coast to an accepted level of flood-protection. This flood-protection level is expressed as the frequency of exceedance of a storm surge

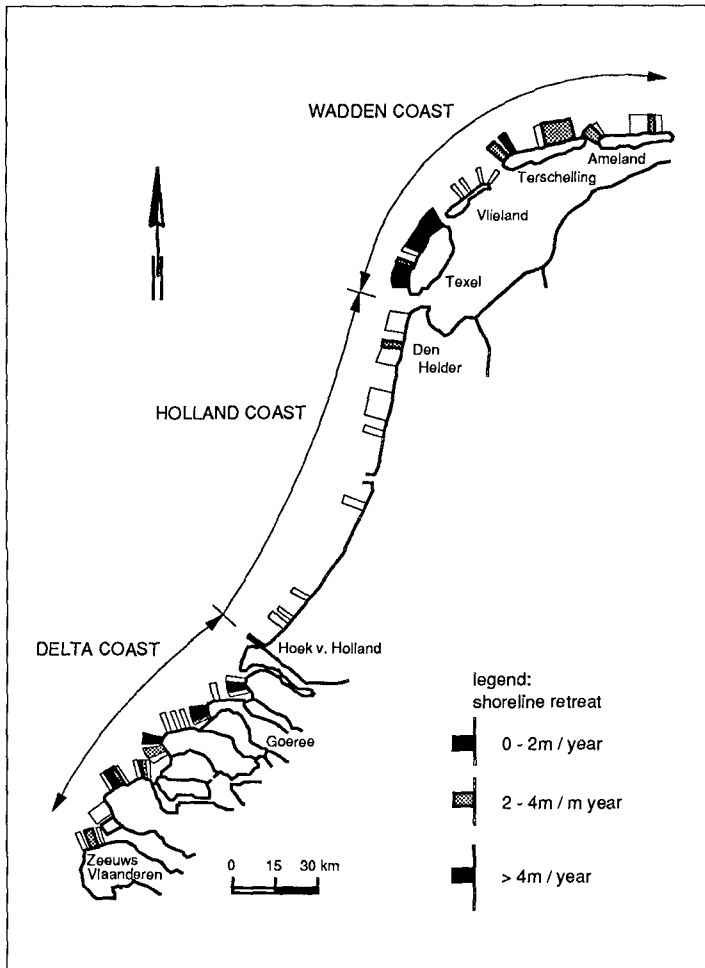

Figure 1. Pattern of erosion and erosion rates along the Dutch coast.

water-level (see Figure 2); dune dimensions are designed in such a way that collapse in these conditions may occur once of a hundred times.

Apart from flood-protection which up till now is the most important function of the dunecoast, the dune area covers a number of communal functions and interests, which also are worthwhile maintaining: drinking water supply, recreation, housing, and such like. Moreover the dune area as a whole is being considered as a very valuable natural landscape. It is one of the largest more or less continuous dune areas of Europe with a specific status of protected nature area.

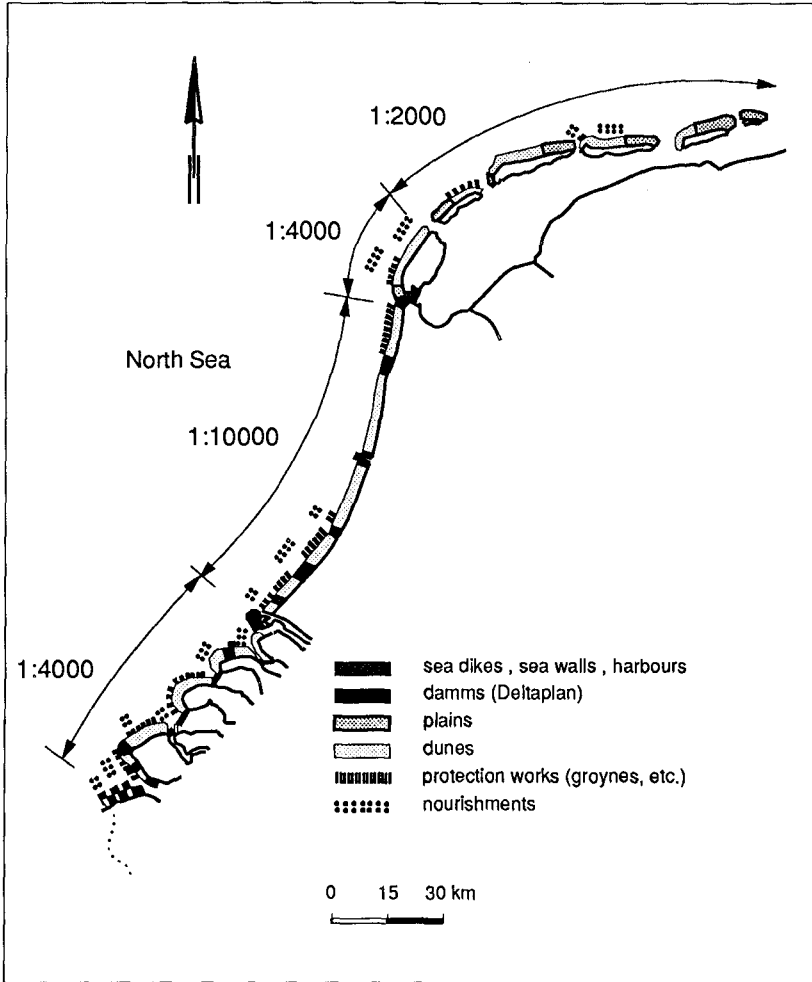

Figure 2. Coastal defence along the Dutch coast and the level of flood-protection along the coast expressed as the frequency of exceedance of a storm surge water-level

However, shoreline retreat due to coastal erosion at various areas along the coast constantly threatens the defensive force of the dunecoast and leads to a loss of valuable dune area. Figure 1 shows the main erosion areas to be situated in Delta and Wadden coast. With the present-day coastal defence policy this process is not being prevented or stopped. The present-day policy is confined to regular maintenance and reinforcement of coastal stretches with a weak defence with sand nourishments. As a consequence at many places shoreline retreat proceeds. Besides, climate changes due to the Greenhouse-effect may worsen or speed up this process.

The major question concerning coastal defence is how to guarantee the level of flood-protection in the future under conditions of continuing shoreline retreat and the threat of an accelerating sea-level rise and climate change. Coastal defence efforts must also as much as possible prevent further loss of dune area and the interests in this area. To investigate precisely the problems of forthcoming coastal erosion under the present-day coastal defence policy and to develop and evaluate new approaches for a coastal defence policy, a policy analysis study of the Dutch coast was performed. In this study three scenarios of sea-level rise are considered: the present-day sea-level rise (20 cm/century), the expected scenario (60 cm/century) and the pessimistic scenario (85 cm/century). The pessimistic scenario also includes a change in wind- and wave-climate (10 % increase of wind force, 10 degrees change of wind direction)

This paper describes the method of the study and presents the results. The study results in a comparison of 4 alternatives for coastal defence.

The policy analysis study has been described in a final report (Rijkswaterstaat, 1989) and in 20 technical documents. Some of these technical studies are presented on this Conference in the session "The Dutch coast". The state-of-the-art of knowledge of coastal development in the Netherlands is described by Zitman et al. (1990), Hoozemans (1990) and Van Vessem et al. (1990). Model analyses and studies on coastal prediction are described by Roelvink et al (1990), Steetzel (1990), Dijkman et al. (1990), Eysink (1990) and Stive et al. (1990). Techniques and strategies for coastal defence are described by Roelse (1990), Van Alphen et al (1990) and Pluym (1990); Terwindt et al. (1990) conclude with a description of implications for future coastal research. Thanks to former and recent coastal research programs like Coastal Genesis and TOW, data and models needed for this study, could be adequately obtained.

Analysis method

The study focuses upon the part of the coast which protects hinterland; dams in the tributaries of the Rhine-Meuse delta are not considered. This part of the coast with a total length of 353 kilometer shows various types of defence against the sea (Figure 2). The dunecoast covers a length of 252 kilometer, 34 kilometer consists of dikes and 27 of other constructions (boulevards, sluices, etc.). The remaining 38 kilometer concern beach plains, located at the extreme ends of the barrier islands of the Wadden coast. These plains do not protect polderland and are merely nature areas.

Since dikes and other constructions are considered as fairly immobile, representing coastal stretches with a fixed coastal defence system at a sufficient level, they are just of marginal importance in this study. From the point of view of flood-protection beach plains are not interesting as well: they do not protect polderland. Concerning nature these plains are most interesting when they can freely develop, thus when coastal management is not too strict. The most interesting part of the coast in this study is therefore the dunecoast.

The main characteristics of the policy analysis study of the dunecoast are on the one hand the sand economy of the coastal morphologic system and on the other the use of the coastal area for communal functions. Both are depicted in the scheme of figure 3. The sand economy describes the movement of sand at large spatial (and temporal) scales and identifies the areas of accretion and erosion and the resulting shoreline movement.

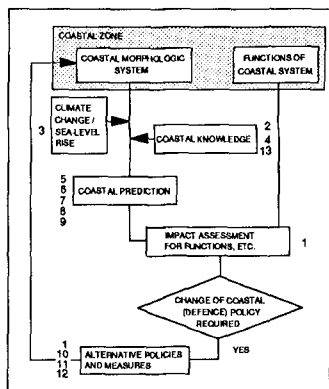

Figure 3. Policy analysis scheme

Evaluation of this shoreline movement (prediction) provides information on future shoreline positions and enables the assessment of the impact on functions of the dunecoast: flood-protection and dune interests. Confronting “autonomous” shoreline behaviour with functions of the dunecoast results in a quantification of the problems, that can be expected when no measures against shoreline retreat are taken (problem analysis).

When this confrontation leads to an undesired number of potential problem’s solutions must be developed. For each problem observed, different solutions can be considered, but this leads to ad hoc approaches. A structural approach was needed and led to a process of development of alternative strategies. These strategies were transferred into a

coherent set of measures for coastal defence along the entire coast: alternatives.

Given the alternative policies, next step in the analysis is to run through the scheme again to evaluate the impacts (benefits and costs) of these alternatives. Now the position of the shoreline as a function of time is not just determined by the prediction of the “autonomous” displacement of the shoreline, but also by shoreline behaviour imposed by the coastal defence alternatives. This identifies the places along the coast where measures are needed. The costs of these measures are computed. Where measures are not necessary, while the shore retreats losses of dune area are calculated.

Both for identification of the problems, and especially for the assessment of the impacts, the need for a policy-analysis model was felt. This model, KUSTBEL, enabled analysis of a variety of alternatives with a high resolution along the coast (1 kilometer) for different scenarios of sea-level rise and met the need for sensitivity-analyses for a number of parameters that greatly influence the final results.

In the scheme of figure 3 the technical studies, that have been performed to support the policy analysis study, are indicated by the numbers, which have been given to the papers in the session “The Dutch coast”.

The main cause of problems: coastal erosion

Shoreline retreat is caused by coastal erosion. Coastal erosion shows up in two ways, which are clearly related to each other: the sudden, fairly local event of storm erosion and the more gradual chronic erosion. In the first case high water level and waves during storm surges can locally result in a sudden loss of sand from the duneface. The storm erosion will result in a structural loss of sand from the coast on a stretch of coast suffering chronic erosion, because the dune sand will (partly) be used to replenish the sand deficit of the shoreface. Accreting coastal stretches may initially show a serious damage due to storm erosion, but this will be followed by a gradual restoration of the original dune profile in course of time.

Although more gradual and global, chronic erosion at the long run is much more threatening for the dunecoast than loss of sand from the dunes due to storm surges. Due to an often very subtle mixture of hydraulic processes residual transport of sand bodies from one place to another takes place and results in accretion at one place and erosion at others. Long-periodic changes in erosional and accretional processes also occur and result in periodic fluctuations of the shoreline with periods of tens of decades (Verhagen, 1988).

Procedure for problem identification

The problems which arise as a consequence of shoreline retreat are twofold: the threat for flood-protection and for loss of valuable dune area. Problems with flood-protection are concentrated on coastal stretches with a relatively narrow dune area; problems concerning loss of valuable dune area mainly concern wide dune areas.

Flood-protection

The entire coastal profile from shoreface to the landward boundary of the dunes is of interest for the safety of land behind the dunecoast; this whole area determines the strength of the coastal defence system. Mostly the main defence is formed by shoreface, beach and the first dune row, the front dune. The strength of this defence-system can be calculated for each profile and compared with the required strength, derived from design instructions (Vellinga, 1986). The strength is expressed as a dune-width, the storm erosion width A in figure 4. A is the distance from the dunefoot to the point O to where, due to the design storm surge sand from the front dune has been removed (see figure 4). This width A is determined by the assumption that the loss of sand from the duneface during a design storm surge equals the amount of sand that (according to the local geometry) can be placed on the profile of beach and upper shoreface (Vellinga, 1986). Besides some additional loss must be anticipated, leading to an increase of A to AT (point P). Connecting all points P along the coast leads to the 'storm erosion-line'. The minimum width in a selected profile must at least equal AT plus a residual width (and height) of the "residual profile". When due to shoreline retreat the front dune has become too narrow to contain AT plus the residual profile, reinforcement of the front

Figure 4 Schematic cross-section of the coastal defence area with definition of the procedure for evaluating problems with flood-protection.

dune is necessary. At present this is often realised by adding sand to the landward side of the front dune, either by activating the natural process of sand blowing or by mechanically replacing sand to the backside. This process results in a narrowing of the dune area. Eventually the dune area may be narrowed to a minimal defence system, consisting of just one row of marginal dunes (AT plus residual profile) at the landward edge of the dune area. Since further landward movement of this row of dunes into the polder is not admitted, potential problems for flood-protection arise when this situation is reached.

In fact at many places along the coast shifting of the defence up to the landward boundary of the dune area is not possible, simply because there is no sufficient volume of sand to contain the residual profile (a height of 2-3 m above the design storm surge level and a width of approximately 25 m). Therefore the ultimate point in the profile to where the backside of the coastal defence (point P) may be retreated is defined as the point (Q) at the landward side of which just the residual profile (related to the local storm surge design level) can be 'constructed' (figure 4). Connecting these points Q along the coast results in a 'most landward residual profile-line', the Q-line. There may be no gaps in this line along the coast. Given this Q-line and the P-line of potential storm erosion damage, the reserve-width for shoreline retreat with respect to flood protection is defined as the distance Q - P. This distance is known for every kilometer of coast.

To evaluate the conditions of flood-protection of the coast it is assumed that the shape of the front dune does not alter in time, even not when the shoreline retreats. When shoreline development as a function of time is known (Stive, et al., 1990), the evolution of the reserve-width due to shoreline development can be identified for every kilometer of coast. Potential flood-protection problems (when the reserve-width equals 0) can now be determined.

Loss of dune area with interests and nature

The economic interests and the nature values of the dune area are presented in table 1. Both economic interests and nature are partitioned to enable a distinction in appraisal within the interests (see table 1). This enabled a more refined analysis. For instance, various levels of appraisal of nature areas are distinguished, so that not just potential

Figure 5. Schematic picture of the effects of shoreline retreat on interests in the dune area.

loss of nature area in general can be determined (which in fact is nearly the entire dune area), but also more specific potential losses of nature values.

Table 1. Sensitiveness of the (sub)functions of the dunes for effects of shoreline retreat (+ = sensitive; - = not sensitive).

Shoreline retreat can threaten the interests of the dune area in different ways. Direct and indirect effects are distinguished. Direct effects of shoreline retreat are directly caused by coastal defence management and concern (see figure 5):

- a loss of land and the interests accommodated on this land due to displacement of the shoreline (**disappearing**).
- due to shoreline retreat the backside of the front dune must be reinforced to keep the front dune at strength; as a consequence interests located at the backside of the front dune will be covered with sand (**covering**). This may lead to a loss for some interests as for instance housing, recreation, etc.
- shoreline retreat leads to a lowering of the groundwater-table. This may cause damage to nature areas and to groundwater-reserves.

Indirect effects of shoreline retreat are caused by the displacement of the front dune due to coastal defence management measures:

- extra blowing of sand caused by damage of the vegetation of the front dune.
- landward shifting of the zone of salt spray.
- inundation of the dune area when a weak front dune collapses.

In the analysis just 'disappearing' and 'covering' are taken into account. For the other effects supporting information for quantification of the impacts lacked, so they were ignored in the analysis.

The front of the area of potential loss is determined by the two lines which indicate the character of the potential loss: the line-of-disappearance and the line-of-covering.

Identification of the potential losses takes place for every kilometer of coast. To obtain a sufficiently refined analysis each unit of one kilometer of coast is split up in crossshore direction in grids with a width of 50 meter. All interests that are found in a grid are identified. This identification is closely related to the way they suffer loss due to shoreline behaviour.

The problems identified

Shoreline retreat may result in a problem concerning flood-protection of the polderland when safety requirements are no longer met. For interests in the dune area a problem has been defined as a situation of loss of area for these interests either due to disappearing or to covering. The analysis for both issues has been performed at each of the 252 cells (of 1 kilometer length) and results in an expression of the length of coast (\approx number of cells) where potentially problems may occur. In figure 6A the length of coast where the flood-protection can not longer be guaranteed is depicted for the whole prediction period and for the three scenario's of sea-level rise. For the present-day value of sea-level rise in the year 2000 already more than 20 kilometer are 'unsafe'; this increases to about 40 kilometer in 2090. For the pessimistic scenario an increase with about a factor 2 must be anticipated. The expected sea-level rise causes intermediate effects.

Figure 6. Length of coast where problems for flood-protection (A) and drinking water supply (B) may occur when no measures against shoreline retreat are taken.

The effects of shoreline retreat on the dune area and functions accommodated here can not all be presented here. Just the (potential) loss of area for water supply is shown (figure 6B). In the year 2000 for the present-day value of sea-level rise along about 10 kilometer of coast area for drinking water supply may be lost. In 2090 this is increased to about 15 kilometer. In the pessimistic scenario an increase of about 50 percent may be expected.

Solutions

With the present-day coastal defence policy a gradual increase of places where measures are needed to guarantee safety will occur. Besides due to the absence of a structural approach for protection of dune interests and nature an ever-increasing loss must be anticipated.

A structural approach for coastal defence must mainly be focused on protection of dune interests. Safety of the polderland has already been secured by norms, which vary along the coast (see figure 2). The policy margin here is determined by the distance in cross shore direction along which the defensive front dune can be displaced before the ultimate position has been reached: the reserve width for shoreline retreat (see figure 4). This is also the space within which (extra) protection of dune area and interests can be claimed. The strategies on coastal defence therefore give utterance to the level of protection of the dune area. It will be clear that guarantee of safety against flooding of the low country behind the dunes is a common feature of all strategies. The strategies lead to "alternatives" when they are completed with measures for coastal defence. Four alternatives are distinguished each of which describing the conditions with respect to the initial situation of 1990:

- **Withdrawal W:** admission of further retreat of the shoreline, except for the places where safety can just be guaranteed at the minimum level (norms according to figure 2) and where the reserve width has become zero.
- **Selective erosion control S:** counteract further shoreline retreat at places where dune area with nature and/or functions in this area are threatened; admit shoreline retreat at the other places. Since there is a fair number of interests which all could be separately and in combinations protected, a nearly endless number of alternatives could be defined, which would all fit into Selective erosion control. Just a small selection has been investigated, and the most representative is being presented in this paper. In this alternative the most valuable elements of nature and interests are protected:
 - * Housing: concentrations of houses (villages, residential quarters)
 - * Nature: wet dune, moors, etc.
 - * Drinking water supply: production plants and infiltration works
 - * Recreation: campings and recreation parks
 - * Industries
- **Full erosion control F:** counteract further shoreline retreat everywhere along the coast. Measures for coastal defence for these three alternatives consist of solutions with sand. In this way the natural character of the coast is not irreversibly affected and there is much experience with this type of defence measures (Roelse, 1990). Except for coastal stretches with a tidal gully close to the coast, groynes and pile-rows, which have been frequently applied in the past, are not considered as promising measures. A study on the effectiveness of these measures indicated a low effectivity for coastal defence objectives.

For Full erosion control, for Selective erosion control at those places where interests of the dune area may not be abandoned, and for Withdrawal at those places where the reserve width has become zero, counteraction of shoreline retreat is prescribed. This is realised by beach nourishments. In specific situations reinforcement of the dunes by supply of sand at the landward side of the front dunes is performed.

The fourth alternative is:

- **Seaward expansion E:** seaward expansion of the shoreline at places where the coastal defence is relatively weak with the objective of improving the coastal defence. At those places where seaward expansion measures are not projected, shoreline retreat will be counteracted just like for alternative Full erosion control.

In this alternative structures of hard material, like groins and dams are chosen (Pluijm, 1990). This alternative has just been worked out for the present-day scenario of sea-level rise.

For all alternatives the need for regular maintenance (maintenance of groynes and sea dikes, prevention of sand blowing from the dunefront, etc.) of the coastal defence is discerned. It is clear that the costs for maintenance will differ for the various alternatives: counteracting shoreline retreat will result in a decrease of efforts for maintenance of groynes and other constructions.

Comparison of the alternatives

The various alternatives have different implications for a series of aspects. These aspects are:

- length of coast where measures need to be taken to guarantee safety;
- loss of dune area with economic functions or valuable nature area;
- amount of sand needed for coastal defence;
- costs for coastal defence measures (maintenance and counteraction of shoreline retreat).

The impact of the alternatives on these aspects have been determined. Although regional and local (sectors) variation may be interesting, presentation of the comparison will be focused upon results on a national scale. The present-day scenario of sea-level rise will be discussed first.

Present-day scenario of sea-level rise

In the year 2000 already about 20 km of coast length requires counteraction of shoreline retreat for alternative W (see figure 7). The bars indicate the uncertainties in the estimates due to uncertainties in shoreline predictions and analysis method. The coast length where measures are needed to prevent further shoreline retreat for alternative S is substantially longer than for alternative W: about 60 kilometer. For alternative F and E an increase to about 140 kilometer is observed.

Figure 7. Length of coast where measures against further shoreline retreat must be taken for the 4 alternatives.

As a function of time there is an increase of coast length that needs to be protected for alternatives W and S (Figure 7). For alternatives F and E a slow decrease of this parameter is observed. The explanation for this effect is that the length of coast that suffers erosion has been predicted to be slightly smaller in the far future than in the first decades. This is mainly due to expected favourable periodic behaviour. The increase for the other alternatives has apparently been caused by an increase of coastal places where shoreline retreat leads to 'problems'.

The diagram of the cumulative loss of area shows the same pattern of increase as a function of time for alternatives W and S (Figure 8). For alternative W the loss of dune area amounts to about 3,5 km in 2000 and increases to more than 20 km in 2090. As

Figure 8. Cumulative loss of dune area for the 4 alternatives

housing about 0.06 km, and for valuable nature about 1.5 km. For alternative S these values respectively amount to: 0.1, 0.02 and 0 km. Obviously these interests are better protected with this alternative. As a function of time an increase comparable to the loss of dune area in general is observed.

Figure 9. Total costs for coastal defence

could be expected, for alternative S losses of area are considerably smaller: 1,5 km in 2000 rising to about 6 km in 2090. A choice for alternative F or E does not lead to any loss of dune area. Considering the yearly loss of dune area, a decrease as a function of time is observed (W and S). This is caused by the fact that in course of time at an ever increasing length of coast (see Figure 7) further shoreline retreat must be counteracted. At these places further loss of dune area does not occur. The loss of area for economic interests in the dunes is just a fraction of the total loss of dune area. For alternative W the loss for Drinking water supply for the year 2000 is about 0.15 km, for

The costs show a pattern which is more or less in agreement with the coast length where measures against shoreline retreat must be taken (Figure 9). For the year 2000 they rise from about 35 million guilders per year for alternative W to about 60 million guilders per year for alternative F. This rise is caused by the fact that for the consecutive alternatives more sand that erodes from the coast must be replaced. Alternative E is somewhat more costly, about 80 million guilders per year. Here the construction costs have been roughly estimated (large uncertainties). 20 to 25 million guilders of these amounts are allocated for maintenance (higher costs for maintenance for the alternatives where shoreline retreat is less counteracted). In course of time costs for W and S have increased and fro

F and E decreased. Obviously the differences between the costs for the alternatives decrease in course of time. At the longer term F will just be slightly more expensive than W. However, with alternative W a considerable loss of dune area (about 20 km, Figure 8) must be anticipated, while the loss for F is zero.

More severe scenarios of sea-level rise

Acceleration of sea level rise from 20 to 60 cm/century results in an increase of the impacts for the various alternatives. If instead of the present-day scenario the pessimistic scenario (85 cm sea-level rise per century, including a change in wave climate) should be reckoned with, a more severe rise of the impacts must be anticipated. Figure 10 gives an overview of these effects for costs and area loss. For the expected scenario (60 cm/century) costs will increase with 10-20 percent, while losses increase with 20-30 percent. The impacts for a more rapid rate of sea-level rise (pessimistic scenario) are more drastically: 25-35 percent increase of costs and more than 75 percent increase of area loss. Here mainly the effect of a change in wind climate (and as a consequence wave climate) is responsible for the extra increase.

One may conclude that acceleration of sea-level rise and especially climate changes will result in a considerable increase of costs for coastal defence and losses of dune interests.

Expected scenario	increase of costs	increase of area loss
	%	%
Withdrawal	10	20
Selective erosion control	15	30
Full erosion control	20	—
Pessimistic scenario	increase of costs	increase of area loss
	%	%
Withdrawal	25	75
Selective erosion control	35	90
Full erosion control	30	—

Figure 10. Effects of sea level rise

Political choice

In June 1990 the government took the decision on the coastal defence policy for the next 5 years. Erosion will be fully controlled in the near future. This means that yearly on the average 6-10 million cubic meters will be placed upon the coast.

CHAPTER 141

RECONSTRUCTION OF THE HOLOCENE EVOLUTION OF THE DUTCH COAST

The Dutch Coast: Paper No. 2

Tjerk J. Zitman¹, Marcel J.F. Stive¹ and Hans (J.) Wiersma²

Abstract

In 1986 the TOW Coastal Engineering Research Programme was merged with the Coastal Genesis Research Programme. Rijkswaterstaat, the financier and initiator of these programmes, concluded that the growing interest in the longer term development of the coast in relation to sea-level rise and other climatic changes made it necessary to approach the research questions from a wider perspective than just the coastal engineering discipline. Geology, historical geography and physical geography were included as disciplines, and a multidisciplinary approach to a holistic understanding of the Dutch coast was undertaken. The results of the first phase of the Coastal Genesis Programme became available in 1987, comprising a reconstruction of the Holocene evolution of the Dutch coast, and a view on the available knowledge regarding the physical processes responsible for this evolution. A summary of the reported conclusions is given here.

1. Introduction

Since the early 1970's Rijkswaterstaat stimulated Dutch coastal research at Rijkswaterstaat, Delft University of Technology and Delft Hydraulics with the TOW Coastal Research Programme. This programme was mainly devoted to the study of coastal processes from the coastal engineering perspective.

Around 1985, initiated by coastal erosion management questions, an interest grew into larger scale, longer term coastal evolution processes and it was realized that the TOW Programme as such (i.e. focussing on coastal evolution processes of typical time- and length-scales of a year and a kilometer) was too limited in scope. In order to gain an understanding of large-scale, long-term coastal evolution, a variety of geo-morphological processes with a diversity of time- and length-scales needs to be considered, which, in turn, calls for the deployment of many specialisms. This approach has been applied in a new research programme, called Kustgenese (Coastal Genesis). In this programme, the fields of geo-morphology, hydro- and

1 DELFT HYDRAULICS, P.O. Box 152, 8300 AD Emmeloord, The Netherlands

2 Ministry of Transport and Public Works, North Sea Directorate,
P.O. Box 5807, 2280 HV Rijswijk, The Netherlands

morphodynamics, physical and historical geography and geology have been linked in order to study and understand coastal evolution at the scales of interest and, subsequently, to arrive at a (physical-mathematical) tool for coastal erosion and eventually coastal zone management.

The present paper deals with the first phase of the Coastal Genesis Programme, which resulted in a reconstruction of the Holocene evolution of the Dutch coast and a view on the available knowledge regarding the physical processes responsible for this evolution. Based on this, the main research items for the second phase of Coastal Genesis were identified (Terwindt and Battjes, Paper No. 10, these proceedings).

2. Research strategy

The Dutch coast is a complex morphological system with a length-scale of hundreds of kilometers. Since length-scales and time-scales are coupled in the sense that the larger the length-scale, the larger the time-scale (De Vriend, 1988), it immediately follows that in order to unravel this system, a large time-scale has to be considered. Against this background, it was decided to focus the first phase of the Coastal Genesis Programme on the evolution of the entire Dutch coast over the past 5000 years.

In fact, 'typical' time-scales of 100, 1000 and 5000 years were distinguished. For each of these time-scales, a working-group was formed and given the task to identify the physical processes dominating the coastal evolution at the given scale. The fields of geomorphology, hydrodynamics and physical geography took a leading position in the Working Group 100 and the activities in this group were mainly concerned with coastal modelling and gathering field data. Central in the Working Group 1000 were the fields of geology and historical geography and for the Working Group 5000 this position was taken by the field of geology.

The research strategy, applied in each of these working groups, is based on the rationale that the physical processes to be identified, form the link between the external conditions or constraints that influence coastal evolution (wave climate, currents, availability of sediment) and the corresponding morphological response in the coastal zone. In this respect, reconstructions of the external conditions and the actual coastal evolution have been made. These aspects, called Input and Output, respectively, were determined first. The natural link between the Input and the Output is formed by the (geo-)morphological processes and their interactions, shortly denoted as the System. Put together, this approach is called the ISO-method. Correlating the Input and the Output has led to hypotheses regarding the (potential) relevance of various morphological processes which fit in the System. In the description hereafter, the distinction between Input, System and Output is maintained.

3. Output: Reconstruction of the actual coastal evolution

A summary calendar of the Dutch Coastal evolution in the Holocene is given in Table 1. A more detailed description is as follows.

geological time	years BP	years AD	sea level (m)	event in coastol evolution
Pleistocene				
H O L O C E N E	10000			
	Preboreal			
	9000		- 25	8700 BP: Southern North Sea is formed
	Boreal			8300 BP: Connection between southern and northern North Sea
	8000	5500 BC	- 15	7800 BP: Coastline oppr. 25 km west of present locotion
	Atlantic			On average, the coastline retreats and barrier islands are formed in the eastern part of the country
	7000			
	6000			
	5000	3850 BC	- 4.5	5000 BP: Interconnection of borrier islands in the east; formation of old dunes; mouth of river Rhine becomes active; coastline 8 km east of present position and odvncing
	Subboreal			
4000		- 3.0		
3000	1100 BC	- 1.7	3200 BP: Closure of the inlet near Bergen	
2000			Coastal advance comes to an end and retreat begins; the mouth of the river Rhine becomes inactive	
Sublantic				
1000				
0	1987		NAP	+ 500 AD: Break-through of dunes in the south +1100 AD: Break-through of dunes in the north-west 1000-1600 AD: Formation of the young dunes

Table 1 Time table with the main events in the development of the Dutch coast (after Stive, 1987)

At the end of the last Glacial (Pleistocene), some 10,000 years ago, the area presently known as the southern North Sea was completely dry. It took about 2000 years before this area started to flood (Fig. 1). At first, the water came in from the south, through the English Channel. In the meantime, the northern North Sea was formed immediately south of the retreating polar ice. The separation between the southern and northern parts of the North Sea extended from

the present Dutch Wadden island Texel in western direction. It flooded approximately 8300 BP (BP stands for carbon-14 years before present). As the icecaps continued to melt, the sea transgraded. About 7500 BP, the Dutch coastline was situated some 25 kilometers west of its present position and migrated in eastern direction.

Figure 1 Four stages in the formation of the North Sea (after Zagwijn, 1986) at 9000 BP (a), 8700 BP (b), 8300 BP (c) and 7800 BP (d).

During the first 3000 years since the beginning of the Holocene, the rate of sea-level rise amounted approximately 1 meter/century.

This rate slightly decreased in the following 2000 years. A drastic decrease of this rate occurred around 5000 BP. Within a period of only a few centuries, the rate of sea-level rise almost decimated (Zagwijn, 1986).

These changes in the sea-level rise coincide with and are probably the cause of a turning point in the evolution of the Holland coast (Beets et al., 1990). When the rate of sea-level rise started to decrease significantly, the various tidal inlet systems were suppressed due to siltation processes in the direct vicinity of the main channel systems. As a result, barrier islands were formed originating from the sand reservoirs contained in the underwater deltas (from 7300 BP onwards). Interconnection of these islands took place around 5000 BP and led to a closed coastline at which, during the following 4000 years, the so-called old dunes were formed. In the meantime, the coastline advanced seaward, although the sea-level continued to rise.

The typical shape of a cross-section of these old dunes is low and wide. The amount of sediment contained in these dunes is approx. 62,000 m³ per meter along the coast. The period between 3000 and 1800 BP is characterized by an inversion of the coastline migration. Since that period, the Dutch west-coast has retreated almost continuously and from 1000 to 400 BP the so-called young dunes were formed on top of the old ones. These young dunes are higher than the old dunes, but much narrower. They contain about 14,000 m³ of sediment per meter in long-shore direction.

Before the interconnection of the barrier islands (i.e. before 5000 BP), the area behind these islands flooded with the tide (salt water) and with high river output (fresh water from the Rhine and Meuse). In this wet, brackish environment, peat started to grow and managed to keep pace with the rising sea-level. After the closure of the coastline, the brackish water was entirely replaced by fresh river water. This did not stop the growth of peat but merely caused a change in the type of peat (Van der Valk, 1990).

The retreat of the coastline (from 3000 BP onward) in combination with a continuously rising sea-level caused an increasing number of break-throughs in the dune coast. This initiated a chain of mutually intensifying processes. The first break-throughs caused the drainage of the peat area's behind the dunes. The allied subsidence gave way to extensive flooding and, thus, erosion of the peat. This occurred primarily in the north and in the south-west of the Netherlands and resulted in the Waddensea (north) and the Zeeland estuaries (south-west). The excavation and burning of peat, performed by our ancestors, have intensified this process.

The resulting coastal system has not shown any dramatic changes during the past few centuries. Especially since approximately 1850, the coastline has been intensely regulated by man. The coastal system can roughly be divided into three sub-systems: the estuaries in the south-west (the Delta-coast), the closed dune coast in the west (the Holland coast) and the barrier islands in the north (the Waddensea coast). The estuaries at the Delta-coast have been closed off almost completely after the flooding of 1953. The concave-shaped Holland-coast is slowly eroding at its outer ends, whereas the centre maintains a fairly stable position. However, the shoreface at

the centre of this part of the coast is steepening, so that there is effectively a loss of sediment. The erosion at the northern end of the Holland-coast is related to a vast accretion in the near-by part of the Waddensea, which becomes gradually shallower. These sub-systems of the Dutch coast are indicated in Figure 2.

Human interventions have influenced the coastal evolution since the early middle ages, when the first dykes were built. Especially during the past century this effect is noticeable.

Figure 2 Subsystems of the Dutch Coast

4. Input: Reconstruction of the external conditions

Figure 3 Supposed average summer and winter temperatures (after Lamb, 1982)

The end of the Pleistocene (appr. 10,000 BP) is marked by a sudden (on a geological time-scale) rise in the average winter temperature. Within a period of 2000 years, this temperature rose from appr. -8°C to appr. $+3^{\circ}\text{C}$ (Lamb, 1982; see Fig. 3). This change gave way to the melting of icecaps and, hence, to the formation of the North Sea.

The rise of the sea-level interacts with a number of supposedly important factors in coastal evolution. The horizontal sizes of the sea in combination with the bottom geometry and the water level clearly affects the propagation of the tidal wave and it

has a vast influence on the generation and propagation of wind-waves in the (relatively shallow) coastal area.

The relation between various characteristics of the wind-wave field on the one hand and the sea-level on the other hand has been indicated by Stive (1987; see Fig. 4). Apparently, the significant wave height and the wave period have stabilised after the decrease in the sea-level rise (5000 BP) whereas the wave skewness, an important measure for wave-driven sediment transport, has increased continuously. Furthermore, model computations have been carried out to reconstruct the changes in the tidal conditions due to a rising level of the North Sea (Franken, 1987; see Fig. 5 for an example).

With the rising (average) air temperature, the atmospheric conditions have changed. The dominant wind direction as well as the distribution of the wind speed over time and directions has changed over the years (Kollen, 1987; Hoozemans, Paper No. 3, these proceedings). This has a direct effect on the transport of sediment (aeolic transport), but it has also an indirect effect (wind-induced waves and currents).

5. Input-Output correlation

The purpose of correlating the reconstructed external conditions and the observed coastal evolution is to gain insight in the relevance of processes which determine the large-scale coastal evolution. In the long run, the morphological changes in the coastal zone are obviously determined by the availability of sediment. Hence, it is important to localize the potential sediment sources and sinks. Additionally, the intensity of the mechanisms that transport the sediment to and from these sources and sinks have to be determined.

Figure 4 Changes in wave parameters in relation to the sea-level rise (after Stive, 1987).

Figure 5 Iso-amplitude lines and amphidromic points cooresponding to the semi-diurnal tide (after Franken, 1987).

One of these sources or sinks may be formed by a seaward boundary of the coastal system. For example, such a boundary could act as a sink if sediment can only be transported across this boundary in offshore direction. Van Vessem and Stolk (Paper No. 4, these proceedings) have searched for such a boundary, but could not find clear indications for the existence of one.

Tidal basins can act as a sink, for instance if a near equilibrium situation is disturbed by sea-level rise (Eysink, Paper No. 8, these proceedings). These basins appear to strive for an equilibrium ratio of their wet surface and their wet volume. A rising sea-level continuously disturbs this equilibrium in the sense that the basin becomes too deep in relation to its horizontal sizes. This results in accretion inside the basin at the expense of the nearby coastal area.

An important source is formed by sediment contained in river discharge. This way, material is brought into the coastal system at the river mouth and is distributed along the coast by longshore transport mechanisms. Before 5000 BP, the relatively high output of sediment from the rivers Rhine and Scheldt in combination with a transport of sediment from deeper towards the coast, has led to the formation of a delta. Later on, the sediment supply from these rivers decreased and the delta slowly eroded due to gradients in the longshore transport. This erosion process has also acted as a source of sediment.

An important item in the correlation of Input and Output was to gain insight into the relative importance of cross-shore and longshore transport of sediment. A survey has shown that a considerable part of the observed coastal evolution cannot be explained if only longshore transport is taken into account (Zitman, 1987). From this it was concluded that cross-shore transport is at least as important as long-shore transport. However, this survey did not yield any indications regarding the relevance of the involved physical processes. This has been investigated later (Roelvink and Stive, Paper No. 5; Steetzel, Paper No. 6; Stive et al., Paper No. 9; all in these proceedings).

6. Summary of hypotheses

The correlation of the external conditions and the reconstructed (observed) coastal evolution (input and output, respectively) has led to hypotheses regarding the relative importance of physical processes that have played a dominant role in the coastal evolution. This relative importance is dependent on the considered time-scale. Stive (1987) has given an overview of the hypotheses and their relevance in relation to the various time-scales. A summary of this overview is given hereafter.

Exchange of sediment between the nearshore and the inner shelf is a process of which the physics are not fully understood. Nevertheless, it is believed to explain much of the observed coastal evolution. There are no hard indications that there is a seaward boundary to this exchange on a time-scale of 100 years. This cross-shore transport is believed to have provided a considerable part of the material needed in the building up of the coast since the beginning

of the Holocene. Up to 5000 BP this building up kept pace with the rising sea-level. However, at that time the sea-level rise decreased. This, in combination with the earlier described closure of the tidal inlet system on the central Holland coast, yielded a sediment surplus in the nearshore which, eventually, resulted in the formation of barrier islands and the old dunes. Furthermore, cross-shore sediment transport is also believed to have played an important role in the formation of the young dunes, which started approximately 1000 years ago.

In contrast with the cross-shore sediment exchange, there is a good understanding of the physics behind the longshore transport of sediment in the nearshore zone. This type of transport is mainly wave-driven and takes place inside a comparatively narrow band along the coast. In this case, there is a closed system in which the sediment is redistributed along the coast due to gradients in the longshore transport. Examples of this process are the coastal retreat at the outer ends of the Holland coast (time-scale of 100 years) and the interrelation of the coastal advance and the erosion of the Rhine-Scheldt delta (from 5000 BP onwards).

On a time-scale of 1000 years, changes in the sea-level rise appear to be highly correlated with the formation of dunes. However, the understanding of this relation is insufficient to estimate its importance with respect to the observed coastal evolution.

The importance of (changes in) the tidal amplitude is even harder to estimate. The changes themselves can be roughly determined, but the knowledge regarding the physics behind the influence on coastal evolution is insufficient to determine its significance in this respect.

Human interventions in the coastal system are well-known. About 1000 years ago the peat areas behind the dunes were brought under cultivation. This has intensified the process of break-throughs of the dunes, especially in the northern and southern parts of the Dutch coast. This has contributed to the formation of the Wadden Sea (north) and the Zeeland estuaries (south). The effects of human interventions are also noticeable at a shorter time-scale. During the last 100 years, the Dutch coastline has been intensely regulated. Obviously, erosion control measures, the construction of defensive structures as dikes and dams have, at least locally, directed the coastal evolution.

7. Relation with subsequent phases of the coastal genesis programme

The first phase of the Coastal Genesis Project was completed at the end of 1987. It was concerned with a reconstruction of the Holocene evolution of the Dutch coast, the formulation of hypotheses on the physical processes behind this evolution and the, mainly qualitative, testing of these hypotheses. The research activities in this first phase have resulted in an overview of missing knowledge on relevant physical processes. Furthermore, an inventory was made of supplemental historical information required for understanding the observed coastal evolution. Phase I is reported in a main report (Stive, 1987) and five supporting reports (Kollen, 1987; Wind, 1987; Stolk et al. 1987; Keinalda, 1987; Zitman, 1987).

The second phase of the programme is in progress now. It was started around mid 1989 with a consultation of the international scientific world in the form of a Colloquium (Terwindt and Battjes, Paper No. 10, these proceedings). Consensus about the missing knowledge resulting from Phase I and this Colloquium has led to a research strategy for Phase II. Implementation of the gathered knowledge in partly conceptual physical-mathematical models, as well as the verification and testing of these models, is planned to be carried out in a third phase of the programme.

CHAPTER 142

LONG TERM CHANGES IN WIND AND WAVE CLIMATE ON THE NORTH SEA

The Dutch Coast: Paper No. 3

Frank M.J. Hoozemans¹

Introduction

This paper presents the first results of a study on the wind and wave climate along the Dutch coast of the North Sea. The analysis of time series of wind force, wave height, wind direction, etc, identifies the occurrence of long term changes in wind and (wind)wave climate. In the Dutch Coastal Defence Study, the results of these climate analyses were used to develop the so called "unfavourable hydro-meteorological scenario" with which an evaluation was made of the extreme impact of the shore line retreat of the Dutch coast. The wind and wave climate study is part of a project that examines the relation between changes in the regional wind and wave climate and the long term and large scale morphological development of the Dutch coast.

Method

For the study concerning coastal behaviour in relation with climatic changes, continuous time series of meteorologic and oceanographic data are of paramount importance. The available time series of wind waves in the Dutch part of the North Sea, cover a rather short period. To gather information over longer periods supplementary sources have to be found (for the period that wind wave data is lacking). Wind data of light vessels off the Dutch coast confirm to the requirements.

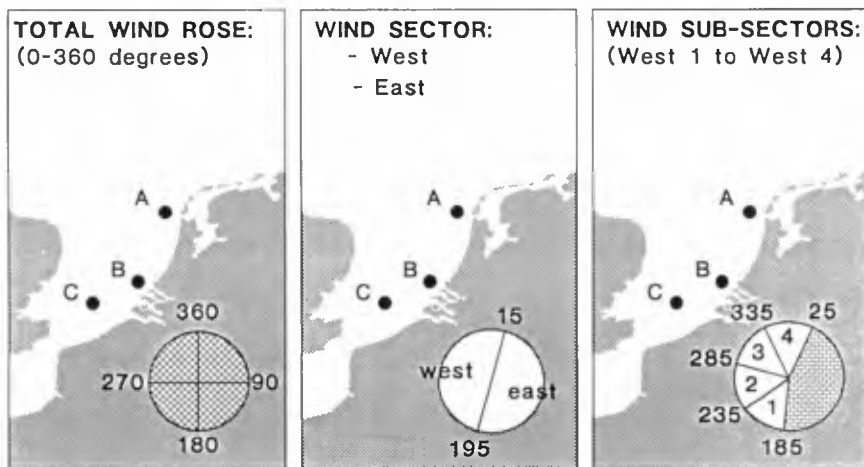

Between 1859 and 1982 various light vessels were stationed off the Dutch coast (Figure 1) to collect meteorological data such as; temperature, wind force and wind direction. As from 1926, the data collected included details of wave conditions and as from 1949 sea-state as well as swell (far field effect) were recorded separately. From that year onwards wave direction, wave period and wave height are available. The climate analysis of this study covers the period 1907-1980 and is in the first part of the project concentrated on wind data.

Analysis of this meteorologic and oceanographic data is concentrated on the time series of mean annual values of wind velocity,

¹ DELFT HYDRAULICS, P.O. Box 152, 8300 AD Emmeloord, The Netherlands

wind percentage and wind direction. Trends in the mean climatologic data indicate long term changes. To identify these trends linear regression techniques were applied. Apart from these trends the time series also seem to contain periodic changes. Since the period of these changes is rather large with respect to the length of the time series, determination of this feature is difficult. Since data of more than one light vessel is available for the same registration period, variations along the coast can be determined. The wind climate analysis is executed for several wind fields (see Figure 1):

1. The total wind rose which covers 360 degrees.
2. A division of the wind rose in two wind sectors WEST and EAST.
3. A subdivision of sector WEST into 4 sub sectors WEST-1 to WEST-4.

Results

Wind direction:

Changes in wind and wave climate of sector WEST [195-015°] in the Dutch part of the North Sea do occur. Figure 2 shows the mean annual wind direction measured at three Dutch light vessels of wind sector WEST. The figure shows a backing of the wind for period 1907-1924, a veering of the wind for period 1925-1938 (no high registration density between 1939-1948) and a more or less steady wind direction for the period from 1949 onwards.

Wind velocity:

Analysis of the mean wind velocity shows an increasing wind velocity when period 1907-1940 is compared with period 1950-1980.

Figure 2 Mean wind direction

Figure 3 shows the mean annual wind velocity measured at three Dutch light vessels supplied with wind data of coast station Den Helder (situated in the north of Holland near light vessels Haaks/ Texel) and a German light vessel/-station Scharhorn and Elbe-1 (situated in the estuary of the river Elbe).

Figure 3 Mean wind velocity

Figure 4 shows the mean annual wind velocity of light vessels Haaks & Texel for the four sub sectors separately. The diagram shows an identical increase in time as figure 3, but far more important are the differences between the sub sectors. Sector West-4 contains

the lowest mean wind vector increase and the three other sub sectors, especially sub sector West-3, contain the highest increase.

Figure 4 Mean wind velocity

Figure 5 shows the percentage of each Beaufort class of the total wind field for two periods: from 1922 to 1933 and from 1950 to 1980. The histogram shows an increasing force when the two periods are compared. Beaufort class three shows the highest percentage for the period between 1922 and 1933, but this mode has changed into Beaufort class four for the period between 1950 and 1980.

Source : Dutch light vessels
 Wind field: 0 - 360 degrees

Figure 5 Frequency distribution scale numbers of Beaufort

Frequency of wind:

A third wind parameter, the frequency of wind in a sector, shows a decreasing frequency of wind in sector WEST.

Conclusions based on wind analyses:

It can be concluded that the wind climate along the Dutch coast has changed in the period 1960-1980: a veering of the wind direction, an increasing wind velocity and a decreasing wind percentage in sector WEST. Significant spatial differences in wind climate between the several light vessels along the coast could not be found.

Wave height:

Parallel to wind observations, the visual wave height ($H_v \approx H_s$) has been estimated between 1949 and 1982. These observations are less reliable than the time series of wind parameters. Figure 6 shows the mean annual significant wave height measured at three Dutch light vessels. For comparison this figure also shows the series of light vessel Seven Stones (south-west England).

Figure 6 Mean annual significant wave height measured at Dutch and English light vessels

In the Coastal Defence Study the effects of three hydro-meteorologic scenarios have been investigated. The major factor in these scenarios is a sea level rise. The first two scenarios only concern a sea level rise (the present-day sea level rise of 20 cm/century, the expected scenario of 60 cm/century). In the third scenario, which was supposed to present an unfavourable development of hydro-meteorologic conditions, also changes in wind and wave climate were included (a veering of the wind direction of 10° in the most unfavourable direction and an increasing wind velocity of 10%). An indication of the magnitude of these changes expressed in this unfavourable scenario was derived from rough wind data analyses. In the present study the wind parameters are statistically determined. The related values of the wave climate and wave and wind setup are derived by model analysis. Since the Dutch coast is mainly exposed to the west this analysis is focused on the sector West. The results are presented in Figure 7. The values in the centre column present

the mean climate of the period 1907-1980. Column "DEVIATION + 2σ " corresponds to the unfavourable scenario.

PARAMETERS	DEVIATION (-2 σ)	HYDRAULIC SCENARIO	DEVIATION (+2 σ)	DIM
Mean Wind Velocity	6.6	8.0	9.4	m/s
Mean Wind Direction	250	265	281	°
Mean Wave Height	1.0	1.3	1.7	m

Mean Wave Direction	250	265	281	°
Mean Wave Setup	3	10	13	cm
Mean Wind Setup	5	11	21	cm

Figure 7 Effect of variations in westerly winds (195-015 degrees) on hydraulic parameters

Further research

Time series of the above mentioned wind parameters will be used as input variables for wave and transport models. With these models the effect of climatic changes on the hydraulic conditions can be analyzed as well as the impact on the large scale development of the Dutch coast (e.g. coastal erosion or accretion).

There is a relation between the regional climate on the North Sea and the mondial climate of the Northern hemisphere. Changes in the mondial climate have a direct (e.g. displacement of depressions to the north) as well an indirect effect (e.g. far field effect on height of swell). If possible, a simple relation has to be found between the mondial and regional climate in which the far field effect will play an important role.

In the course of time, several authors have given a relation between changes in wind direction, seasonal temperature amplitudes, stability of air masses on sea level, coastal behaviour, etc. The above mentioned meteorologic, oceanographic and morphometric time series will certainly contribute to the knowledge of coastal behaviour as a response to changes in climate.

CHAPTER 143

SAND BUDGET OF THE DUTCH COAST

The Dutch Coast: Paper No. 4

P. van Vessem 1) A. Stolk 1)

1. Introduction

About 255 kilometer (70%) of the Dutch coast is protected against flooding and storm surges by dunes. Another 43 kilometer is defended by dikes with a sandy nearshore. The sand is transported by physical processes in alongshore and onshore-offshore direction. As a result the coast shows continuous alternations. A detailed sand budget is very useful to gain insight into the dynamics of the coast and of different morphological zones. Within the framework of the Coastal Defence Study in the Netherlands recent advances in modelling of large scale coastal development were made (Louisse and Kuik, 1990; Stive, Roelvink and De Vriend, 1990). Verification and calibration of these models is possible by comparing the model results with the sand budget of the coast. According to the Shore Protection Manual (1984) the sediment budget is defined as a sediment transport volume balance for a selected segment of the coast. The elements of the budget are processes that increase (sources) or decrease (sinks) the quantity of sand in a defined control volume. Usually a sand budget analysis is made to calculate an unknown erosion or deposition rate by estimating the different elements of the budget like for instance longshore transport, on- and offshore sand movement and the building or erosion of dunes. The method is clearly described by Bowen and Inman (1966) and Chapman (1981).

The balance itself is defined by Bowen and Inman (1966) and Komar (1983) as the component of the budget that gives the net gain or loss of sand in a control volume. This balance is obtained by monitoring the erosion or deposition rate over a number of years. This paper is concerned with the sand balance of the Dutch coast over the years 1965 - 1986. A method for calculating the balance based on yearly measured profiles is described. Besides the more general results for the Dutch coast a more detailed example of the Schouwen peninsula is given.

2. Measurements

Along the Dutch coast in the second half of the 19th century a monitoring system was set up to observe the coastal development. Therefore along the whole Dutch North Sea coast poles were placed on the beach at a distance of 1000 m. The line connecting these poles is the reference line for coastal monitoring. The beach poles were placed between the mean high water line and the foot of the dune.

The position of the mean low water line, the mean high water line and location of the foot of the dune is measured yearly with respect to the reference line. In this way a detailed picture of the development of the coastline during the last 100 to 140 years is obtained.

Since 1964 the morphological monitoring is considerably enhanced. A system of about 2000 fixed measuring lines perpendicular to the coastline has been established. The distance between the lines is 200 - 250 meter, less where the coastline is curved.

The height and depth are determined in respect to Dutch Ordnance Datum (NAP) which is about mean sea level. To define the horizontal position in the profiles the original reference line is maintained. Because of the coastline changes since the poles were placed there is no relation between the location of the reference line and the present morphology.

Until 1975 the measurements of the dry part of the profiles were carried out by levelling from the mean low water line to the top of the first dune row. From 1975 onwards the heights are determined by aerialphotography and were extended to at least 200 meter inland from the top of the first dune row.

The measurements of the underwater part of the profiles are carried out by echo-sounding from the low water line to at least 800 m out of the reference line. In several parts of the coast, especially in the Wadden Area the profiles reach much further seaward, up to about 1500 meter.

The survey area includes the first dune row, the beach and the surfzone. Some tidal channels in front of the Delta en Wadden Islands are situated within the reach of the measurements. The tidal deltas and inlets are not included in the data set.

The profiles are measured annually in the non-storm period from April to September and are not equidistant in time. Apart from normal measurement inaccuracy the dataset still contains systematic and random errors due to wrong individual height or depth values or to faults in the distance to the reference line or reference height. To correct for these errors a visual validation is executed by plotting all the yearly profiles of a measuring line together and remove or correct the unreliable values. This procedure can lead to the elimination of yearly profiles or to total elimination of a measuring line from the data set.

In the years before 1975 the levelling was not executed far enough inland to reach a more or less closed boundary in the dunes. The photogrammetrical height measurements do come up to this requirement. For the coast of Holland it was possible to lengthen the earlier profiles by complementary investigations of detailed maps of the dune area (De Ruig, 1987). The dunes in the Wadden Area and the Delta Area are too dynamic to allow such a procedure.

In addition to the yearly measurements every 5 year 2500 m long profiles are measured with an interval of 1000 m along the coast. This has resulted in a dataset of 3 to 4 profiles for each measuring line, what is not yet sufficient for a reliable trend analysis.

3. Method

To make a useful sand balance the following main conditions are specified:

- the relation between the transport processes and the morphological changes must be well connected
- the balance must describe the natural development of the coast (as far as possible on the Dutch coast with dikes, revetments, groynes and harbour moles)
- the control volume only consists of those parts of the nearshore from which the sediment transport is directly related to the safety of the coast.

The first condition means that the changes in volumetric content between predefined upper and lower boundaries must be calculated. Every part of the profile within such a layer accounts for the content (figure 1).

Optionally the upper boundary coincides with the maximum height measured in a yearly profile. This option is used if one wishes to calculate the yearly loss or gain of sediment due to storm surges and eolian sand transport. The other option is to choose a relevant height, for instance mean low-water level.

The lower boundary is formed by the maximum depth within the reach of all measured depths of a specific profile or by an other suitable depth.

It is obvious that the position of the horizontal boundaries determines which of the morphological processes account for the calculated changes.

The already mentioned landward boundary is situated landward of the first dune row. It is preferable that inland of this point the elevation of the profile is more or less constant. In this case there is no net transport through the boundary. Otherwise the transport rate has to be estimated.

All the boundaries are determined for each profile and are time independent, except for the optional "free" upper boundary.

To calculate the volumetric content between two adjacent profiles it is assumed that a profile is representative for the area between the profile and the bisector (figure 1). Given a horizontal distance of less than 200 - 250 m this seems a realistic assumption. Only for small-scale safety problems this assumption must be checked. The first calculated area between two profiles coincides with the lower boundary. This area is multiplied by a given height of 0.1 meter and the procedure is repeated until the upper boundary is reached. The content of the control volume is calculated.

From 1952 onwards beach nourishment projects have been carried out at several locations. Because the sand balance must give insight in the "natural" development of the Dutch coast (second mentioned limiting condition) the calculated contents are corrected with the amount of supplied sand brought into the control volume (Roelse, 1990). There is no correction made for the possible loss of supplied material out of the control volume due to the redistribution of sediment.

Also activities to restore the dune profile after storm surges can influence the amount of sand in the control volume. Other examples of artificial displacement of sand are the building and conservation of elevated beach sections against the dunes to protect recreational facilities on the beach. It is assumed that the involved quantities are small compared with natural sand transport rates. Usually there is only a redistribution of sand within the control volume.

Given the corrected yearly sand content, the net gain or loss of sand in a given period

is calculated by a linear regression analysis.

To gain insight in the annual variations the mean, minimum and maximum value of the difference in sand volumes of the successive years are calculated. Short-term events, such as storm surges, are averaged out.

figure 1. Sketch to define the calculation procedure.

4. Results Dutch coast sections

As a first approach the changes in volumetric content of 13 coast sections are calculated. These sections are separated from each other by ebb tidal deltas (Wadden), harbour moles (coast of Holland) and estuaries and tidal basins (Delta). These interruptions are the cause of a more or less independent development of adjacent sections. All sections have specific control volumes from which the balance is calculated.

The length of a section is determined by the first and last measuring line.

The vertical dimension depends, besides on the length of the measured profiles, on the

local morphology. The lower boundary varies from 3 - 10 m along the central parts of the islands and the coast of Holland. The depth of the tidal channels within reach of the measurements varies from 10 - 30 meter. The upper boundary coincides with the maximum height of the profile. This means that sedimentation or erosion in the first dune row are accounted for.

The measurements on the coast of Holland are far enough inland to reach a more or less closed boundary (de Ruig, 1987) The transport rate across the landward boundary in the Wadden and Delta Area are not yet estimated.

It is certain that the lower boundary do not reach the closure depth for cross-shore sand transport at de Dutch coast. This is indicated by the 5 yearly measurements and other, more local, repeated profiling which extended to a greater depth. Roelvink (1990) calculated an onshore transport across the -10 meter line in the order of 10 m³/m/year. This is an important source term in the sand budget.

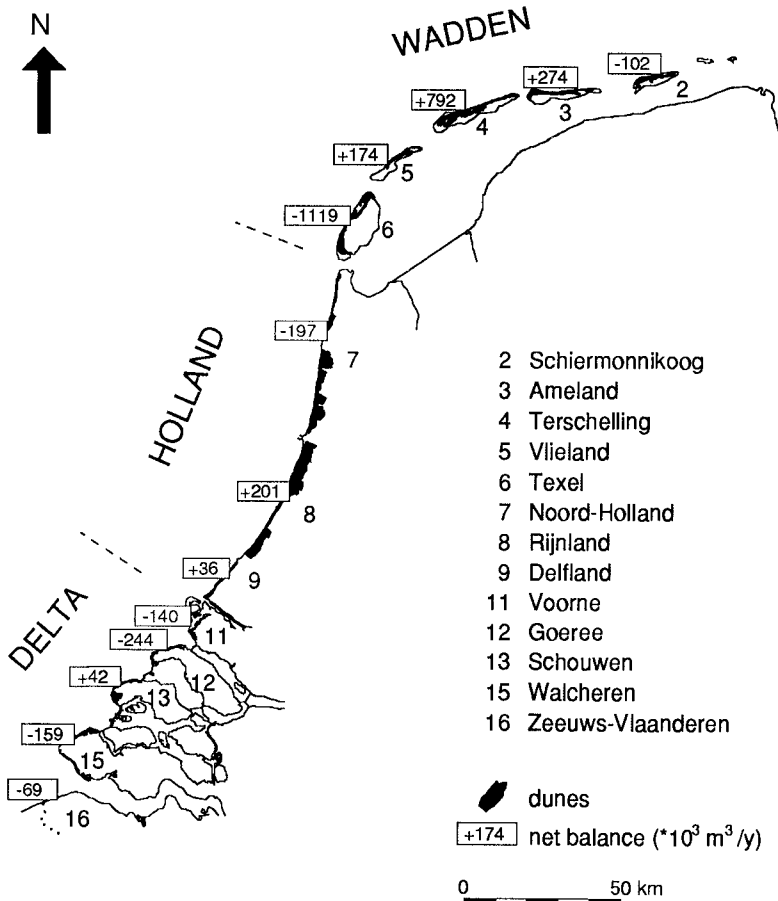

figure 2. Calculated sand balance of the Dutch coast.

Despite of the above mentioned uncertainties the sand balance is calculated (figure 2). The total sum of $-511 \cdot 10^3 \text{ m}^3/\text{y}$ indicates that over the specified period of 20 years and a length of about 302 km the Dutch coast is very slowly eroding ($-2 \text{ m}^3/\text{m}/\text{y}$). On the scale of separate coast sections, 8 - 53 km, the variability is much greater. Trends normalized to coast length of -41 up to $+28 \text{ m}^3/\text{m}/\text{y}$ are calculated (table 1). The difference between the coastal sections are great in respect to the total sum.

The dynamic of a sandy coast is best illustrated by the yearly fluctuations. The mean value varies from 19 to $68 \text{ m}^3/\text{m}/\text{y}$. The minimum and maximum yearly difference amount to respectively 0 and $369 \text{ m}^3/\text{m}/\text{y}$. Due to this large time variability the reliability of the calculated trends depends strongly on the number of validated measured years.

5 Result Schouwen

5.1 Introduction

The peninsula of Schouwen is situated in the Delta Area between the tidal basins "Grevelingen" in the north and "Oosterschelde" in the south (figure 3). The tidal channel "Brouwershavense Gat" in front of the north coast of Schouwen is silting up now, due to the closure of the Grevelingen basin in 1972. A branch of this tidal channel, the "Schaar van Renesse" is situated very close to the coastline (figure 4). In the south the "Westgat" is one of the main tidal channels at the entry of the Oosterschelde. There is another tidal channel, "Krabbengat", around the west coast (figure 4). The tidal range is 2.5 meter.

The human interference with the about 17 km long North Sea coast of Schouwen is restricted to the construction of groyne on the northern part and pile rows on the western

part. Furthermore, there is the usual maintenance of the first dune row like planting of beach grass. The groynes were placed in the middle of the 19th century and were very effective in preventing coastline erosion by the Schaar van Renesse (Verhagen, 1989a). The coastal development in this coastal stretch is not complicated by beach or dune nourishment in the period (1968 - 1983).

figure 3. The Delta Area with the peninsula of Schouwen.

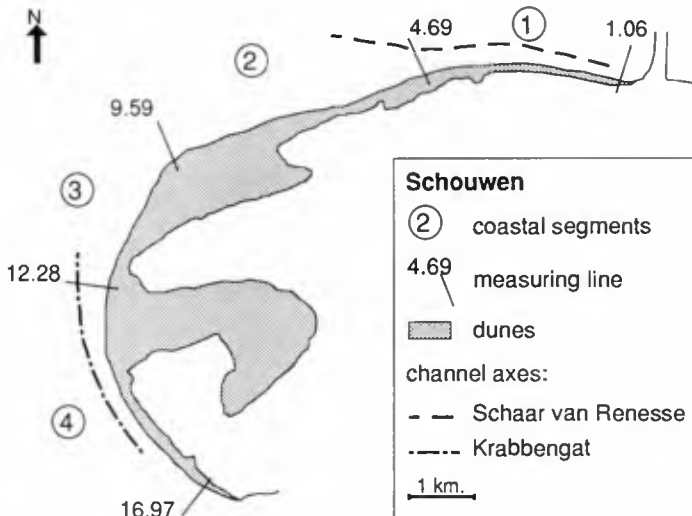

figure 4. Dune coast of Schouwen with channel axes within reach of measurements.

5.2 Profiles

The measuring lines along the part of the coast considered in this case study are numbered from beach pole 1.06 to beach pole 16.97 (figure 4). The numbering of the poles is related to a kilometer scale so the length of coast along the reference line is 15.9 km. In this area 91 measuring lines are situated.

The profile along the coast of Schouwen is not uniform but shows spatial and temporal variations. There is an obvious morphological difference between the northernmost and western coastal stretches, where tidal channels are situated close to the coastline, and the central part where the nearshore profile is more gentle. In the central part the beach is wide and in front of the first dune row some primary dunes have been formed.

There is also a temporal variation in profile morphology. In general the coastal development from 1965 - 1986 does not show a parallel retreat or a parallel progradation over the whole profile.

The coast of Schouwen shows different types of profile development. In a first approximation we divide the profile in an upper part, the dunes, and a lower part, the (upper) shoreface and make a visual estimation of the profile development in three classes; sedimentation, stability and erosion.

A matrix of this kind of two classes gives nine possibilities for profile development. When we group the profiles in the matrix we see that the coast of Schouwen shows all possibilities except a total stable profile (table 2).

table 2. Different classes of profile development, Schouwen.

dunes	(upper) shoreface		
	sedimentation	stable	erosion
sedimentation	4.1 km (25.2%)	0.4 km (2.5%)	1.8 km (11.0%)
stable	3.1 km (19.0%)	-	1.2 km (7.4%)
erosion	1.2 km (7.4%)	1.0 km (6.1%)	3,5 km (21.5%)

figure 5. Coastal profiles along measuring line 9.59 at Schouwen.

The profiles that show either total sedimentation or total erosion are well represented (25.2 and 21.5% of the coast length). In more than half of the coastal stretch (51.6%) there is a net sedimentation on the shoreface. About forty percent is eroding. In the dunes the classes are more equally represented; 38.7% of the dunes show sedimentation, 35.0% erosion, and 26.4% is stable in the period 1965 - 1986.

An example of profile development is given in figure 5, where some profiles are drawn for measuring line no. 9.59, situated at the very west of the peninsula. This example illustrates the steepening of a dune profile to a certain maximal gradient. The dunefront migrates seaward in the period 1965 - 1979. A landward migration of a small branch of the Krabbengat caused a shifting of the nearshore profile in a landward direction. Therefore the seaward movement of the dune is interrupted and inverted to a landward movement from 1980 onwards because of undermining of the dunefront. Over the period 1965 - 1986 there still is a net sedimentation in the dunes, but when the process goes on the sediment volume in the dunes will soon come down to the value of 1965. On the basis of the different categories of profile development four coastal segments can be distinguished (table 3; figure 4).

table 3. Coastal segments Schouwen.

segment (measuring lines)	profile development
1 (1.06 - 4.69)	stable or eroding dunes and sedimentation in the nearshore
2 (4.69 - 9.59)	sedimentation in the dunes and mainly sedimentation in the nearshore
3 (9.59 - 12.28)	strongly varying profile development in both the dunes and the nearshore
4 (12.28 - 16.97)	mainly erosion in the dunes and nearshore

table 4. Migration mean low-water line (m/y) at Schouwen (+ progradation - recession)

segment	1900-1984 (*1880-1984)	1964-1984

4	-1.91	-2.29

5.3 Sand balance

The sand balance is calculated for the North Sea coast of Schouwen between measuring line 1.06 and 16.97 as well as for the four segments separately. The landward and seaward boundaries of the control volume are selected according to the procedure described in section 3. So a control volume is defined for which the calculated trends are reliable. The area for which the sand balance is calculated is not uniform in distance to the coastline and in maximum height and depth of the profiles (figure 6). On the landward side always the first dune row is included, except in segment 4. In segment 4 the landward side of the control volume was chosen at the end of the profiles of the first years of the monitoring. These profiles were too short to cover the position of the dune top in later years. So the top of the first dune row moves out of the control volume in this area.

Because of the variation in height of the dunes the maximum height of the control volume varies along the coast. Because of the variation of the seaward boundary along the coast and the variation in local morphology the depth of the seaward boundary is also varying. Figure 7 shows the volumetric contents of the control volume for the period 1968 - 1983. Some years are not included in the calculation, because there were no reliable data for the whole coast of Schouwen. There is a considerable variation in the sand content from year to year, with a minimum of $4 \cdot 10^3$ m³ between 1979 and 1980, and a maximum of $841 \cdot 10^3$ m³ between 1970 and 1971. The fluctuations demonstrate that the coast is highly dynamic and sensitive to changes in e.g. meteorological conditions. Also the fact that the measurements were not carried out with exact twelve month intervals can be of influence.

figure 6. Maximum height and depth of control volume of Schouwen.

In the control volume along the coast of Schouwen there is a net gain of $41.7 \cdot 10^3$ m³/year. When we look at the contribution of the various segments to the total amount,

figure 7. Volume change coast of Schouwen; linear trend and yearly fluctuations.

figure 8. Change in volumetric content, Schouwen. For locations see figure 4.

we see that the three northern segments (1,2 and 3) together gain sand to a total of $282 \cdot 10^3 \text{ m}^3/\text{year}$, and the southernmost segment (4) loose sand ($240 \cdot 10^3 \text{ m}^3/\text{year}$). The volume changes normalized to coast length are given in table 5.

The overall impression of the results of the sand balance is not fundamentally different from the one based on shoreline records (table 4); accretion in segments 1, 2 and 3, and erosion in segment 4.

To get an insight in what processes are responsible for the volume changes we divide the control volume in three morphological zones :

- a supratidal zone, which is mainly influenced by storm surges and eolian processes
- an intertidal zone, which is influenced by eolian processes and wave action
- a subtidal zone, which is influenced by wave-, wind- and tide-related processes

The tidal range at Schouwen is 2.5 meter, with MLW at -1.18 m and MHW at +1.35 m NAP. The boundaries of the morphological zones are chosen at -1 m and +1 m NAP. In table 5 the normalized volume changes in the four segments are given, both the total

change and the change in the different morphological zones.

The normalized volume changes are also given in figure 8. This figure clearly shows the contribution of the different morphological zones to the total volume change.

Segment 1 is visually characterized (see section 5.2) by profiles who are stable or eroding in the dunes and gain volume in the nearshore. The sand balance shows the quantitative volume changes. The supratidal zone shows almost no net volume change. In the intertidal zone very little sedimentation took place. For the major part the net sedimentation in segment 1 is due to the sedimentation in the subtidal zone.

table 5. Volume change (m³/m/y) Schouwen.

segment	total	supratidal >+1 m NAP	intertidal -1 to +1 m NAP	subtidal <-1 m NAP
1	+19.2	-0.1	+2.2	+17.1
2	+41.2	+15.3	+10.5	+15.4
3	+4.1	+1.1	+0.2	+2.8
4	-51.4	-21.9	-4.7	-24.8
total	+2.6	-1.6	+2.5	+1.7

The subtidal zone within the control volume reaches depths of 13 meter and includes parts of the Schaar van Renesse. The sedimentation in the tidal channel caused by the decrease of the tidal currents after the closure of the Grevelingen is responsible for the major part of the net sedimentation in this coastal segment.

Segment 2 is characterized by profiles with sedimentation in the dunes and nearshore. The sand balance shows that the contribution of the three morphological zones to the total net sedimentation is quite the same. This means that all kinds of processes are involved with the volume change in this coastal stretch. The depth of the control volume is for the major part between 2 and 5 meter and hardly any influence of the silting up of the tidal channel can be expected here. However, the changed tidal patterns can have influenced the sediment transport pattern e.g. by a relative increase of wave influence. Segment 3 is characterized by its non-uniform profile development in alongshore direction. The depth of the control volume varies from 3.5 to 5.5 meter (locally 9 m). There is no deep tidal channel included. But there is a shallow gully in the subtidal zone in this segment. In the north it migrates landward (see figure 5) and causes erosion in the intertidal and supratidal zone. This is attended by a coastline retreat in this part of the segment. For the segment as a whole the overall coastline development shows progradation, also the overall volume change is positive. The net volume change is positive in all morphological zones (figure 8). Two thirds of the sedimentation takes place in the subtidal zone.

The erosion and sedimentation pattern in this segment can be explained by the lateral migration of the gully, both in an alongshore and crossshore direction. The sandwave that can be seen in the displacement of the mean low water line represents the impact

of this process on the coastline (Verhagen, 1989b).

Segment 4 is characterized by profiles with erosion in the dunes and nearshore. The depth of the control volume is about 9 meter. The landward part of the Krabbengat tidal channel is included in the sand balance. The sand balance shows that the amounts of erosion in the supra- and intertidal zones are about the same. There is less erosion in the intertidal zone. The decrease in volume in the supratidal zone is due to a retreat of the dunefront, rather than a lowering of the dune. As mentioned before the first dune row moves out of the control volume. The decrease of volume in the subtidal zone is due to the landward migration of the Krabbengat tidal channel.

The coast of Schouwen shows a variation in the sand balance in an alongshore direction; negative volume change in the south changing to positive volume change in the north over the period 1968 to 1983.

In every segment the sand balance of the various morphological zones shows the same qualitative trend as the total sand balance for that segment. Their relative contribution to the total sand balance of the segment varies in alongshore direction (figure 8).

Oertel et al. (1989) suggested a classification for volume changes in terms of $m^3/m/month$. According to this classification the coast of Schouwen with a gain of sediment of $2.6 m^3/m/year$ is stable over the period 1968 - 1983.

The length of the coastal stretch (15.9 km) and the long period tend to average out the spatial and temporal variations in erosion and accretion. When we focus on the coastal segments we see that segment 3 is stable, segment 1 has a mild accretion rate, segment 2 has a moderate accretion rate and segment 4 has a strong erosion rate.

However, the classification mentioned is based on data from the microtidal Atlantic and Gulf coasts of the U.S.A. In these areas the sediment transport is concentrated between the upper backshore and the breaking waves at low water, with the foreshore as the major element affecting the volume change (Oertel et al., 1989).

The data from Schouwen shows that the relative small intertidal foreshore is of less influence on the sand balance, especially where tidal channels are close to the coast like in segments 1 and 4. Most of the volume changes occur in the supratidal and subtidal parts of the coast.

It can be concluded that not the normal wave-driven longshore transport is the main process affecting the sand balance of Schouwen, but the eolian- and storm surge related processes (including wave-driven longshore transport at high levels) in the supratidal zone, and the wave- wind- and tide-related processes in the subtidal zone.

6. Conclusions

The results clearly shows the advantage of the horizontal approach in calculating the sand balance for a better understanding of the coastal behaviour. The division of the coast of Schouwen in alongshore segments and cross-shore morphological zones shows how the sand balance is composed and gives insight in the processes that are responsible for the sand transport.

A question is of the dynamic of the Dutch coast is underestimated until now. This can be checked by coastal models with different length and time scales.

On the basis of nine categories of profile development, more or less uniform coastal segments can be distinguished. It is recommended to calculate a separate sand balance for each segment.

Because of the difference in zones where the major net transport take place, it is questionable if the classification as proposed by Oertel et al. (1989) can be used without change for the Dutch coast.

CHAPTER 144

SAND TRANSPORT ON THE SHOREFACE OF THE HOLLAND COAST

The Dutch Coast: Paper No. 5

J.A. Roelvink¹ and M.J.F. Stive¹

Summary

Yearly averaged transport vectors have been computed along a number of rays, perpendicular to the coast, on the shoreface of the Holland coast. Variation in time and space of wave conditions, tidal flow and long-term average near-bottom flows are considered in fine detail. Special attention is paid to various correlations, both between different velocity components and between velocity and water level, as these correlations play a major role in determining direction and magnitude of net transports. Calibration is performed against both long-term and short-term observations of developments. The resulting transport pattern helps to explain some observed large-scale developments of the Dutch coast.

1. Introduction

The Coastal Genesis Research Programma of Rijkswaterstaat aims to identify geomorphological processes that determine the long-term, large-scale development of the Dutch coast. To this end a collection of interdisciplinary projects has been set up among geologists, geographers and civil engineers of Rijkswaterstaat, National Geology Department, DELFT HYDRAULICS and several universities. In 1988 and 1989 Rijkswaterstaat asked the researchers involved to contribute to supporting studies for a Coastal Defence Study, aiming to develop an overall coastal defence strategy for the Netherlands (Louisse and Kuik, Paper No. 1, these proceedings). The results presented here were generated for this study.

The goal of this study is to provide backing for conceptual large scale evolution models of the Dutch coast, developed in the framework of the Coastal Genesis Programme (see Stive et al, 1990). These models can then be used to improve predictions of the coastal developments, required by the Coastal Management Study. More specifically, this study should provide an estimate of the large-scale net transport pattern on the shoreface, and identify the relative importance of the mechanisms contributing to this pattern.

¹ DELFT HYDRAULICS, P.O. Box 152, 8300 AD Emmeloord, The Netherlands

The general approach followed in this study is, to estimate hydraulic conditions in a number of points, and to analyze the resulting transport vectors in these points. As the interest is focussed on large-scale trends, estimates of the variation of hydraulic conditions along the coast can be based on the data from existing measuring stations. The variation of conditions perpendicular to the coast can be computed (on this large scale) with ray models or empirical formulations. Special care must be given to correlations between variables and non-linear effects; the importance of many of these aspects has been shown, among others, by Roelvink and Stive (1989). As the net transport in the area of interest is generally small compared to the amplitudes of the tidal and orbital contributions, second-order effects are of major importance.

2. Model assumptions

The basic assumptions which are made are, that the deep water (approx. 20 m water depth) wave and current conditions vary slowly along the Holland coast, and that on a longshore scale of tens of kilometres the depth contours are approximately parallel. Under these conditions, the problem is reduced to a one-dimensional problem which is solved for a limited number of cross-shore sections. The spatial resolution is thus limited, in accordance with the large-scale concept that the model is a part of.

In such a large-scale model, the relevant time-scale is at least in the order of years. However, in order to arrive at estimates of yearly-averaged transports, the transport at a given point must be correctly integrated over a number of shorter time-scales: the short-wave time-scale, the wave-group scale, the tidal-scale, the storm-scale and the seasonal variations. The variations on all these time-scales and the interactions between some of them potentially cause net transports. This means that we have to go back some time-scales in order to produce the long-term parameter: 'yearly-averaged transport'.

3. Analysis of relevant interactions

For the computations of sediment transport due to a combination of waves and currents, in both wave- and current direction, one of the few (practically suitable) available formulations is that of Bailard (1981) after the concept by Bagnold (1966). This formulation has proved reasonably accurate in the case of cross-shore transport (Roelvink & Stive, 1988; Ribberink & Al Salem, 1990). It is conceptually simple and is able to combine transport contributions from different directions and on different time-scales.

The formulation describes the transport as a function of the instantaneous near-bottom velocity at a certain reference level:

$$\begin{aligned} \langle \vec{q}_x \rangle = & \frac{c_f}{\Delta g N} \frac{\epsilon_B}{\tan \phi} \left[\langle |\vec{u}|^2 \vec{u}_x \rangle - \frac{\tan \beta_x}{\tan \phi} \langle |\vec{u}|^3 \rangle \right] + \\ & + \frac{c_f}{\Delta g N} \frac{\epsilon_S}{w} \left[\langle |\vec{u}|^3 \vec{u}_x \rangle - \frac{\epsilon_S}{w} \tan \beta_x \langle |\vec{u}|^5 \rangle \right] \end{aligned} \quad (1)$$

$$\begin{aligned} \langle \vec{q}_y \rangle &= \frac{c_f}{\Delta g N} \frac{\epsilon_B}{\tan \phi} \left[\langle |\vec{u}|^2 \vec{u}_y \rangle - \frac{\tan \beta}{\tan \phi} \langle |\vec{u}|^3 \rangle \right] + \\ &+ \frac{c_f}{\Delta g N} \frac{\epsilon_S}{w} \left[\langle |\vec{u}|^3 \vec{u}_y \rangle - \frac{\epsilon_S}{w} \tan \beta_y \langle |\vec{u}|^3 \rangle \right] \end{aligned}$$

where x, y are two arbitrary directions perpendicular to each other, q is the total volume transport, \vec{u} is the instantaneous total velocity vector, c_f a roughness coefficient, Δ the relative density, g the acceleration of gravity, N the fraction of sediment relative to total volume, w the fall velocity, ϵ_B and ϵ_S efficiency factors (calibration constants) and $\tan \beta$ the bottom slope. The $\langle \rangle$ indicate averaging over time, the averaged powers of the velocity are also called 'velocity moments'.

From flume and wave tunnel experiments (Ribberink & Al Salem, 1990) it follows that the term with the power of 3 is the dominant term in the equation. For a first analysis we can therefore use:

$$\langle \vec{q} \rangle = A \langle |\vec{u}|^3 \vec{u} \rangle \quad (2)$$

Now we can estimate the relative importance of contributions to the transport on different time-scales, by decomposing the velocity vector into components which act on the time-scales from short waves to storm periods.

$$\vec{u} = \vec{u}_{nL} + \vec{u}_{nC} + \vec{u}_t + \vec{u}_l + \vec{u}_s \quad (3)$$

where:

$$\vec{u}_{nL} = u_{nL} \begin{bmatrix} 1 \\ 0 \end{bmatrix} = \text{net longshore current,}$$

$$\vec{u}_{nC} = u_{nC} \begin{bmatrix} 1 \\ 0 \end{bmatrix} = \text{net cross-shore current,}$$

$$\vec{u}_t = u_t \begin{bmatrix} 1 \\ 0 \end{bmatrix} = \text{tidal current,}$$

$$\vec{u}_l = u_l \begin{bmatrix} \cos \alpha \\ \sin \alpha_w \end{bmatrix} = \text{long-wave motion,}$$

$$\vec{u}_s = u_s \begin{bmatrix} \cos \alpha \\ \sin \alpha_w \end{bmatrix} = \text{short-wave motion.}$$

All velocities are taken here at a near bottom reference level; the x -direction is taken alongshore, and the y -direction onshore, α_w is the angle between the longshore direction and the direction of wave propagation. Both long waves and short waves are assumed to have the same dominant direction.

The term \vec{u} in equation (2) can be substituted by equation (3); after some simple algebraic manipulations and neglecting what we estimate to be small terms, we then find:

$$\begin{aligned}
 \langle \vec{u} |^2 \vec{u} \rangle = & \langle u_{nL} u_t^2 \rangle \begin{bmatrix} 3 \\ 0 \end{bmatrix} & + & \text{net longshore - tidal current} \\
 & + \langle u_{nC} u_t^2 \rangle \begin{bmatrix} 0 \\ 1 \end{bmatrix} & + & \text{net cross-shore - tidal current} \\
 & + \langle u_{nL} u_s^2 \rangle \begin{bmatrix} \cos 2\alpha + 2 \\ \sin 2\alpha \end{bmatrix} & + & \text{net longshore - short wave} \\
 & + \langle u_{nC} u_s^2 \rangle \begin{bmatrix} \sin 2\alpha \\ 2 - \cos \alpha_w \end{bmatrix} & + & \text{net cross-shore - short wave} \\
 & + \langle u_t^3 \rangle \begin{bmatrix} 1 \\ 0 \end{bmatrix} & + & \text{tidal current asymmetry} \\
 & + \langle u_t u_s^2 \rangle \begin{bmatrix} \cos 2\alpha_w + 2 \\ \sin 2\alpha_w \end{bmatrix} & + & \text{tide - short wave interaction} \\
 & + \langle u_l u_s^2 \rangle \begin{bmatrix} 3 \cos \alpha_w \\ 3 \sin \alpha_w \end{bmatrix} & + & \text{long - short wave interaction} \\
 & + \langle u_s^3 \rangle \begin{bmatrix} \cos \alpha_w \\ \sin \alpha_w \end{bmatrix} & + & \text{short wave asymmetry} \quad (4)
 \end{aligned}$$

The relative importance and some characteristics of these terms are described below.

Net longshore-tidal current interaction

The two components are generally uncorrelated. As the variance of the tidal velocity is relatively high, a small net current can cause significant transport: the tide stirs up sediment which is advected by the net current.

Net cross-shore-tidal current interaction

This term is similar to the previous one. Even though the net cross-shore current may be small, it may give an important contribution in combination with the stirring up due to the tidal velocity.

Net longshore - short wave interaction

The components in this term are highly correlated. Two mechanisms are responsible for this: during storms the wind drives both currents and waves, and, more directly, the waves drive a net longshore current.

An interesting side-effect of the interaction term is, that it is not directed in longshore direction, but has a deviation which for angles $< 90^\circ$ (which is generally the case) is directed onshore.

Net cross-shore - short wave interaction

These components are also highly correlated. During storms, wind- and wave-driven cross-shore currents occur near the bottom, which are generally directed offshore; during calm weather these currents tend to be directed onshore.

Tidal current asymmetry

Along the Holland coast, the tide manifests itself as a northward propagating wave, where the M2 and M4 components are more or

less in phase. This causes an asymmetric velocity; the highest velocity occurs in northward direction. Due to this, the term causes a net northward transport component.

Tide - short wave interaction

The tide and the short waves interact through the water level variation. Two mechanisms play a role. The most important one is, that the water level influences the orbital velocities: the greater the water depth, the smaller the orbital velocity. As the lowest water level occurs during South flowing current, this mechanism causes a net southward effect. On the other hand, a lower water level implies more wave dissipation due to friction and breaking, which reduces the wave height and thus the orbital velocity. This effect reduces the net southward effect somewhat.

Long - short wave interaction

In groupy waves variations in radiation stress occur which drive long waves ('bound long waves', Lonquet-Higgins & Stewart, 1964). Outside the breaker-zone these long waves are generally in counter-phase with the varying wave energy, thus, when the highest waves occur, the long-wave velocity is directed offshore. Due to this, a net offshore interaction term arises (Shi and Larsen, 1984).

Short wave asymmetry

Due to non-linearity, the orbital velocity under short waves is asymmetric in time; the velocities under wave crests are higher than those under the troughs. This leads to a large transport term directed onshore.

4. Model formulation

Based upon the above analysis of the important terms that contribute to the yearly averaged transport, we may conclude that the interaction between the tidal motion and the wave motion is such that we have to take this fully into account. This is done in the following way.

The offshore tidal motion is schematized to a number of 12 steps within a representative tidal cycle; The deep water velocities and water levels at a given location are determined by interpolating tidal coefficients in space between measuring stations. The variation in offshore wave conditions is represented by a climate of 80 combinations of wave heights and directions, each combination with its representative wave period and offshore water level set-up. The deep water wave climate at a given location is also obtained by interpolation in space of measured wave climates, based on 10 years of observations at three measuring stations at 20 m water depth. This leads, for a given location, to 960 sets of deep water boundary conditions.

Each of these boundary conditions is then used in a computation of depth-mean wave and current parameters along a line perpendicular to the depth contours, with the help of one-dimensional models.

From these depth-mean parameters, the near-bottom quasi-steady velocity and the relevant velocity moments due to wave asymmetry and long wave - short wave interactions are computed. These are combined

to yield the total velocity moment vectors which are required by the transport model according to equation (1).

In a number of points along the cross-shore line, the thus computed transport vectors are integrated over all combinations; taking into account the frequency of occurrence of each combination. This then leads to the yearly-averaged transport vector in each point along the line.

In the following, the formulations used to achieve this are summarized.

Cross-shore variation of wave parameters

The wave energy decay model formulated by Battjes & Janssen (1978), with the parametrizations from Battjes & Stive (1985) is used:

$$\left[\begin{array}{l} \frac{\partial}{\partial x} (E C_g \cos \theta_w) = -D \\ \frac{\sin \theta_w}{C} = \frac{\sin \theta_{w,0}}{C_0} \\ \rho g h \frac{\partial \bar{\eta}}{\partial x} = - \frac{\partial}{\partial x} S_{xx} \end{array} \right. \quad (5) \quad (6)$$

Here, E is the wave energy, C_g the group velocity, θ_w the angle of the wave propagation direction to the shore normal, D the dissipation due to bottom friction and breaking, C the phase velocity, ρ the density of water, h the total mean water depth, $\bar{\eta}$ the water level set-up and S_{xx} the radiation stress. The subscript 0 denotes deep-water (most offshore location).

Cross-shore variation of current parameters

For the tidal current, the assumption is used that the along-shore pressure gradient is constant along the cross-shore line, and is compensated by bottom friction. Using the Chézy friction-law, we then find:

$$U_t = U_{t,0} \frac{C_h}{C_{h_0}} \left(\frac{h}{h_0} \right)^{0.5} \quad (7)$$

where $C_h = 18 \log \frac{12 h}{k_s}$ is the Chézy friction coefficient, k_s is the bottom roughness, and \bar{U}_t the depth-mean tidal current.

For the wave-driven longshore current, the cross-shore gradient of the alongshore component of the radiation stress S_{yx} is assumed to be compensated by the bottom shear stress due to current and waves. The radiation stress gradient is modelled according to Dinges et al (1987).

$$- \frac{\partial}{\partial x} S_{yx} = \frac{D}{C} \sin \theta_w \quad (8)$$

and for the bottom shear stress τ_y a linearized form is used:

$$\tau_y = \rho C_f \bar{U}_1 \langle |U_{orb}| \rangle \quad (9)$$

where \bar{U}_1 is the longshore current, $\langle |U_{orb}| \rangle$ the mean value of the absolute magnitude of the orbital velocity and C_f a friction coefficient.

From (8) and (9), \bar{U}_1 can be solved.

Near-bottom quasi-steady velocity

Both the tidal current velocity and the wave-driven longshore current at a reference level near the bottom are derived from the depth-mean velocity by assuming a logarithmic profile.

The wave-driven cross-shore current is computed by the method given in Stive & De Vriend (1987); the formulations will not be repeated here.

An empirically found near-bottom long-term net moment as reported in Borst (1987) was added to the near-bottom velocity components.

Velocity moments of wave motions

The relevant velocity moments due to short wave asymmetry and long wave-short wave interaction can be estimated from the rms wave height, the peak period and the water depth by using the method outlined in Roelvink & Stive (1989). For the short wave asymmetry, the method is based on high order non-linear wave theory; for the long wave effects a simple bound long wave model is used.

Total quasi-steady velocity moments

The near-bottom quasi-steady current and the (also quasi-steady) velocity moments of the wave motions are combined to produce the total quasi-steady velocity moments and moment vectors for the given combination of tidal phase and wave condition. This involves lengthy expressions based on Taylor expansion in two directions, which are given in the original report (Roelvink & Stive, 1989a).

5. Results

Computations with this model were carried out for four rays along the Holland coast. The resulting large-scale transport pattern is shown in Figure 1. The arrows indicating the relative strength of the yearly averaged transport are located at 20 m, 15 m, 10 m and 8 m respectively.

Because of the simplicity of the used models, considerable errors are possible. Therefore, an overall calibration of the transports was performed against observed large-scale phenomena. The observations taken into account are:

- The long-term flattening of the middle shoreface, as evident from a steady shoreward migration of the -10 m depth contour line over the last 90 years.
- The order of magnitude of the net longshore transport in the surfzone as a function of the orientation of the coastline. This has been the subject of much studies based on observed morphologic developments, most recently by Dijkman et al (1990).

- The observed northward migration of the navigation channel off IJmuiden Harbour (see Van Alphen et al, 1990).

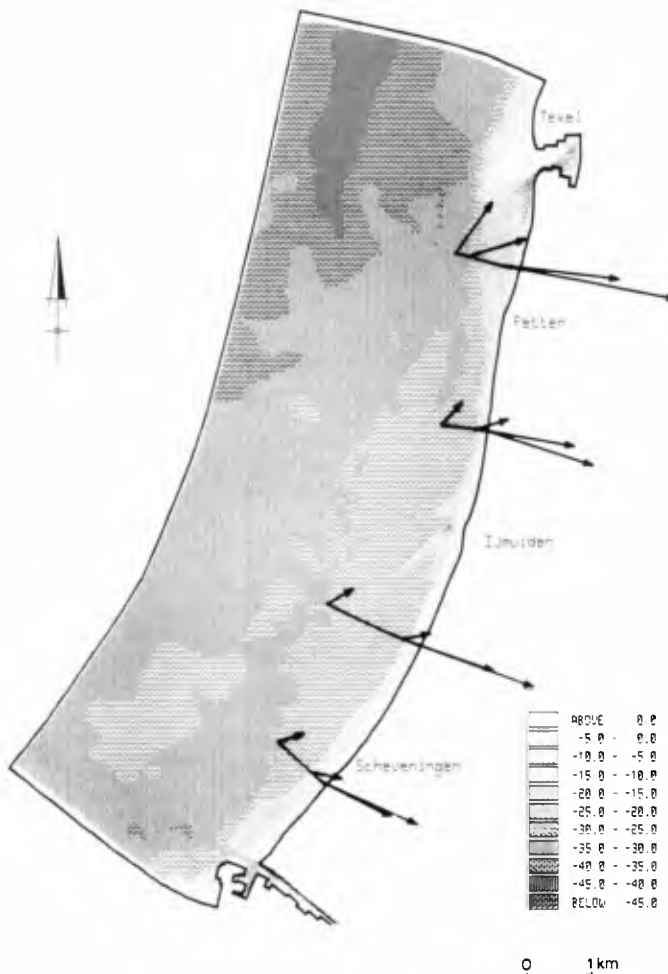

Figure 1 Net transport vectors, uncalibrated

These observations have led to an adjustment of the transport rates; cross-shore transport were reduced by a factor of 2, whereas the longshore transport had to be multiplied by a factor of 2.

Although a factor of 2 in transport formulations is a minor adjustment, the fact that different factors had to be used for long-shore and cross-shore transport is worrying and may be an indication that the transport model, which has proved to perform reasonably for wave-induced transport, does not perform so well in combinations of waves and currents.

The calibrated large-scale transport pattern is shown in Fig. 2. The picture shows a transition from the tide-dominated transport (mainly caused by the coupling of the M2 and M4 components) to wave-dominated transport. Towards the -8 m depth contours, the cross-shore transport increases as a result of increasing wave-induced streaming and short wave asymmetry; the longshore transport also becomes more wave-dominated and shows a clear dependence on the coast orientation.

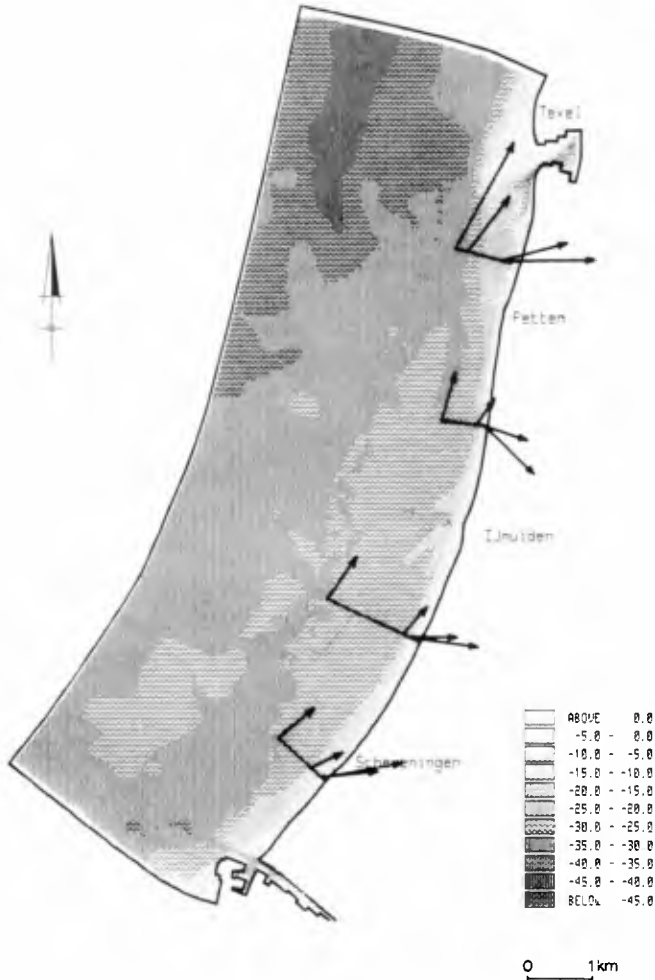

Figure 2 Net transport vectors, calibrated

In Fig. 3a, the variation of the net near-bottom velocity and transport, averaged over all wave conditions, as a function of the tidal phase is given for the most northern ray, at a depth of 18 m;

in Fig. 3b, the same is done at a depth of 10 m. This clearly shows the dominance of the tidal transport in deep water: the transport direction closely follows the tidal velocity; also, the transport increases non-linearly with increasing tidal velocity. At a depth of 10 m, the picture is quite different. The transport has a significant onshore component; also, the dependence of the transport on the tidal velocity is almost linear, which indicates that the waves do most of the stirring of sediment, whereas the tidal velocity merely advects this sediment.

Figure 3 Velocity and transport per tidal phase average over all wave conditions

As an illustration of the variation of the cross-shore transport with water depth, the computed cross-shore transports are plotted against depth in Fig. 4. There is a sharp increase in onshore transport towards the -8 m line. Between approx. 6 m and 10 m water depth, there is a transition from the highly dynamic 'active zone' to the morphologically rather in-active shoreface (see Stive et al, Paper No. 9, these proceedings); therefore, the limit of application of this model also lies somewhere in this transition zone. An important conclusion that can be drawn from Figure 4 is, that for the Holland coast the shoreface acts as a significant source of sand to the 'active zone'.

In Figure 5, the cross-shore transport gradients are shown as a function of depth. These gradients scale directly with the propagation speed of depth contour lines. It follows that the 10 m depth contour moves shoreward at a speed of approx. 2 m per year, which is in accordance with observations.

Figure 4 Net cross-shore transport vs. water depth

Figure 5 Net cross-shore transport gradient vs. water depth

6. Sensitivity analysis

As the value of a number of coefficients in the model and some hydrodynamic input data was rather uncertain, a sensitivity analysis was carried out in order to estimate the total errors in the computed transport rates. This was done in the following way: for a number of input values, the standard deviation was estimated. The effect on the transport rates was assessed by consecutively adding or subtracting this standard deviation from the expected value of the inputs. The errors in the transport rates due to these errors were then squared and added, and the square root was taken to yield an estimate of the total percentage error. This method is known as the 'mean value' approximation. Here we shall not go into all details of the analysis, but simply present the final result in Fig. 6 for the cross-shore transport, and Fig. 7 for the longshore transport.

The errors in the longshore transport increase in seaward direction, up to around 100%. This is mainly due to the fact, that the net transport rate in deep water is very small compared to the gross transport rates, which increases the sensitivity of the output substantially.

The errors in the cross-shore transport also increase in seaward direction, mainly due to uncertainties in the near-bottom net currents.

7. Discussion

The model presented here has been a useful tool in comparing the relative importance of a number of interacting transport mechanisms on the shoreface. After calibration, a plausible transport pattern emerges which in some aspects helps the understanding of the observed large-scale morphologic developments.

Figure 6 Estimated total error; cross-shore transport

Figure 7 Estimated total error; long-shore transport

However, the model has some serious limitations: many of the processes incorporated in it are crudely schematized, and much about the hydraulic conditions, especially in deeper water, is uncertain.

One might therefore agree that, given these uncertainties, it might be better not to build such a model at all. This is not our opinion; as long as the limitations are stated clearly, models like this are useful tools of analysis and at least provide an educated 'best guess' of what is happening.

CROSS-SHORE TRANSPORT DURING STORM SURGES

The Dutch Coast: Paper No. 6

Henk J. Steetzel¹⁾

Abstract

In order to predict the amount of dune erosion due to a storm surge, a model for cross-shore transport during storm surges has been developed. During a storm with intensive wave breaking, suspended sediment transport is predominant. In the model the nett local transport is computed from the time averaged sediment concentration and the time averaged (secondary) flow profiles. Both profiles are related to the local hydraulic conditions. Finally the computed erosion profile development and the amount of dune erosion are well predicted by the model.

1. Introduction and background

On behalf of the Technical Advisory Committee on Water Retaining Structures (TAW) of the Ministry of Transport and Public Works in the Netherlands, a mathematical model for beach and dune profile changes due to storm surges is being developed. The model, which also predicts the beach profile changes in front of dune revetments (Steetzel, 1987), is to be used as a tool to check the safety of the narrow stretch of sandy beaches and dunes which protect the Dutch population against the sea. It should be used in addition to (or perhaps replace) the model as described by Vellinga (1986).

This paper focusses primarily on the computation of the nett cross-shore transport as incorporated in this model. This transport is based on both time averaged sediment concentrations and time averaged secondary currents.

2. Approach

In order to develop a cross-shore transport model series of investigations in wave flumes have been carried out. These model tests were conducted on different scales reaching from small scale ($n_d = 30$) to full scale ($n_d = 1$). Most investigations concern unprotected dunes, whereas there are only a few tests with dune revetments and three tests with partly protected dunes. Most of those tests were carried out in the large Delta Flume of the DELFT HYDRAULICS.

1) Senior research engineer, DELFT HYDRAULICS, P.O. Box 152, 8300 AD Emmeloord, The Netherlands

The amount of information gathered during those tests varies from only initial and final profile to a (complete) profile development, supplemented with data on wave heights, secondary currents and sediment concentrations. The latter were measured using a transverse suction method (Bosman and Steetzel, 1986). Tests with a lot of data are used for (cross-shore transport) model formulation and calibration. In case of only initial and final profiles the test is used for verification.

The different phases of the dynamical model are obvious. On the initial bottom profile the momentary offshore hydraulic conditions determine the local wave heights by using the wave height decay model ENDEC (Battjes and Janssen, 1978). From this the relevant parameters (e.g. cross-shore secondary current and sediment concentrations) are computed resulting in a local cross-shore transport. This step is illustrated in more detail in the next chapter. Finally the bottom changes are computed through application of the mass balance equation of the sediment. The new bottom profile is computed and the procedure is, for a next time step, started all over again.

3. Model formulation

3.1 Introduction

The fomulation of the cross-shore transport is split up into several different aspects, respectively the principle of cross-shore transport computation in both the general and this specific case, the sediment concentrations, the secondary currents and the nett transport computation. Finally some justification of the presented cross-shore transport computation is given.

3.2 Nett cross-shore transport

In general nett cross-shore transport should be computed from the well-known equation:

$$S_x(x) = \frac{1}{nT} \int_{t=0}^{n.T} \int_{z=-d(x)}^{\eta(x,t)} u_x(x,z,t) \cdot C(x,z,t) \cdot dz \cdot dt \quad [\text{kg/m/s}]$$

in which:

S_x	the nett transport (x-component)	[kg/s]
T^x	the wave period	[s]
u_x	the velocity (x-component)	[m/s]
C^x	the sediment concentration	[kg/m ³]
z	the level above the mean water level	[m]
η	the instantaneous water level	[m]

In case of random breaking waves a proper description of time (t) and place (x,z) variation of both velocity and concentration is not available.

In order to evaluate transport contributions, the transport at a certain level above the bottom can be written as a mean (time averaged) product of velocity and concentration. If both parameters are split up into a mean (overbar) and a fluctuating part (accent), the nett transport can be shown to be composed

of a mean contribution of mean velocity times mean concentration and a, more difficult, correlation component:

$$\left. \begin{aligned} u &= \bar{u} + u' \\ c &= \bar{c} + c' \end{aligned} \right\} \bar{S} = \overline{uC} = \bar{u} \cdot \bar{C} + \overline{u'C'}$$

This correlation component $\overline{u'C'}$ is mainly originated from the asymmetry of the waves.

During a storm surge the transports due to intensive breaking of waves and the local beach slope are dominant above other contributions. Relative to non-breaking waves, breaking waves result in a dramatic increase in turbulence level, and therefor lift sediment into suspension over the whole depth. The concentration fluctuations well above the bed are relatively small and hardly correlated with the velocity fluctuations (DELFT HYDRAULICS, 1989). The contribution of the correlation component will therefor be relatively small. This means that the nett transport can be computed from the mean velocities and the mean sediment concentrations.

3.3 Sediment concentration distribution

The time averaged sediment concentration (the overbar is omitted) can be written as a product of a reference concentration (at the bed level) C_0 and a distribution function $f_c(z)$:

$$C(z) = C_0 \cdot f_c(z) \quad [\text{kg/m}^3]$$

Using the one-dimensional stationary convection-diffusion equation to describe the distribution, the vertical profile of the time mean sediment concentration depends on the vertical distribution of the diffusion (mixing) coefficient $\epsilon(z)$, according to:

$$f_c(z) = \exp \left[-w_s \cdot \int_0^z \frac{dz}{\epsilon(z)} \right] \quad [-]$$

in which w_s stands for the (level independent) sediment fall velocity.

In order to describe the diffusion coefficient distribution $\epsilon(z)$, a great number of measured sediment concentrations were analysed. From each of the 68 used data sets (DELFT HYDRAULICS, 1987) the $\epsilon(z)$ -distribution was computed from the concentration profile using:

$$\epsilon(z) = -w_s \cdot [\partial(\ln C(z))/\partial z]^{-1} \quad [\text{m}^2/\text{s}]$$

The amount of mixing increases with increasing level above the bottom, which is in accordance with results of investigations carried out by other researchers (e.g. v.d. Graaff, 1988; Ras and Amesz, 1989). As a final result for the description of the diffusion profile, $\epsilon(z)$ is modelled as a linear function of the level above the bed, according to:

$$\epsilon(z) = \epsilon_0 + \mu \cdot z \quad [\text{m}^2/\text{s}]$$

in which:

ϵ_0 the reference mixing coefficient [m²/s]
 μ the vertical mixing gradient [m/s]

Both ϵ_0 and μ are functions of the local hydraulic conditions. This linear relationship is also suggested by Songvisessomja et al (1988), who compared different $\epsilon(z)$ -relation, by analysing data from Nielsen (Nielsen, 1984).

The vertical distribution of the mean sediment concentration is now simply described by:

$$C(z) = C_0 \cdot \left[1 + \frac{\mu \cdot z}{\epsilon_0} \right]^{(-w_s/\mu)} \quad [\text{kg/m}^3]$$

in which:

C_0 the reference concentration [kg/m³]
 w_s the fall velocity of the bed material [m/s]

An example of the procedure is presented in Figure 1. The relevant steps are:

- (i) From the measured concentration (\square -symbols the $\epsilon(z)$ -values are estimated (x-symbols);
- (ii) Linear fit of $\epsilon(z)$ -values result in ϵ_0 - en μ -values;
- (iii) Fit of $C(z)$ -values in combination with ϵ_0 and μ result in $C(z)$ -equation and C_0 -value.

As a result of each test both concentration and diffusion distributions are available. The latter will be used as an input for the description of the secondary current (undertow).

Figure 1 Example of $C(z)$ -fit-procedure (test T1F1)

3.4 Mean velocity distribution

The suspended sediment load is transported by the mean velocity profile, which is present due to the mass transport of the breaking waves above the level of the wave troughs and results in the (compensating) so-called undertow below this level.

The description of this mean velocity profile below the trough level is started with the assumption of a constant vertical gradient in the (time mean) shear stress (Stive and Wind, 1986):

$$\frac{1}{\rho} \cdot \frac{\partial \bar{\tau}}{\partial z} = \frac{\partial}{\partial z} (\epsilon(z) \cdot \frac{\partial u}{\partial z}) = \alpha$$

After integration follows:

$$\alpha = \frac{\bar{\tau}_t - \bar{\tau}_o}{\rho \cdot d_t} \quad [\text{m}^2/\text{s}]$$

in which:

$\bar{\tau}_t$	the mean shear stress at the wave trough level	[N/m ²]
$\bar{\tau}_o$	the mean shear stress at the reference level	[N/m ²]
ρ	the mass density of the fluid	[kg/m ³]
d_t	the vertical distance between reference and wave trough level	[m]

The velocity gradient can be derived from:

$$\frac{\partial u}{\partial z} = \alpha \cdot \frac{z}{\epsilon(z)} + \beta \cdot \frac{1}{\epsilon(z)}$$

in which the integration constant β equals:

$$\beta = \epsilon_o \cdot \frac{\partial u}{\partial z} (z=0) = \frac{1}{\rho} \cdot \bar{\tau}_o \quad [\text{m}^2/\text{s}^2]$$

The final velocity profile can therefore be derived from:

$$u(z) = u_o + \alpha \cdot \int_o^z \frac{z}{\epsilon(z)} dz + \beta \cdot \int_o^z \frac{1}{\epsilon(z)} dz \quad [\text{m/s}]$$

in which u_o stands for the mean velocity at the reference level. This type of equation is also presented by Okayasa et al (1988).

The vertical diffusion (mixing) coefficient is now taken equal to the sediment diffusion coefficient $\epsilon(z)$.

The use of a non-constant but continuous diffusion coefficient distribution in undertow description differs from the approach of several other authors who use two layers of constant diffusion (e.g. de Vriend and Stive 1987).

After some integrations the mean velocity profile can be shown to be described by:

$$u(z) = u_o + K_{lin} \cdot z + K_{log} \cdot \ln[1 + \frac{\mu \cdot z}{\epsilon_o}] \quad [\text{m/s}]$$

$$\text{where: } K_{lin} = \frac{\alpha}{\mu} \quad [1/\text{s}]$$

$$K_{log} = (\beta - \frac{\alpha}{\mu} \cdot \epsilon_o) / \mu \quad [\text{m/s}]$$

The form and magnitude of the velocity distribution below the wave trough depends on the mass flux m and the shear stress at the trough level $\bar{\tau}_t$.

For continuity reasons the mass flux m equals

$$m = \rho \int_{z=0}^{d_t} u(z) dz \quad [\text{kg/m/s}]$$

Both mass flux and shear stress at trough level are based on relations by de Vriend and Stive (1987).

The mean shear stress at the reference level $\bar{\tau}_0$ is related to the mean velocity u_0 at this level.

3.5 Nett local transport computation

The nett transport has to be split up into two parts: the transport below the (mean) trough level and the transport above this level.

In the lower part the nett seaward transport S_1 follows from the integral of the product of mean velocity $u(z)$ and mean concentration $C(z)$, according to:

$$S_1 = \int_{z=0}^{d_t} u(z) \cdot C(z) \cdot dz \quad [\text{kg/m/s}]$$

From the equations for $u(z)$ and $C(z)$ the result of this integral can be shown to be:

$$S_1 = C_0 [u_0 \cdot I_1 + K_{1in} \cdot I_2 + K_{1log} \cdot I_3] \quad [\text{kg/m/s}]$$

with:

$$I_1 = \frac{\epsilon_0}{\mu} \cdot \frac{1}{K_1} \cdot [K_2^{K_1} - 1] \quad [\text{m}]$$

$$I_2 = \frac{\epsilon_0}{\mu} \cdot \frac{1}{K_1} \cdot [K_2^{K_1} (d_t - \frac{\epsilon_0}{\mu} \cdot \frac{K_2}{K_1+1}) + \frac{\epsilon_0}{\mu} \cdot \frac{1}{K_1+1}] \quad [\text{m}^2]$$

$$I_3 = \frac{\epsilon_0}{\mu} \cdot \frac{1}{(K_1)^2} \cdot [K_2^{K_1} (K_1 \ln K_2 - 1) + 1] \quad [\text{m}]$$

and:

$$K_1 = 1 - w_s/\mu \quad [-]$$

$$K_2 = 1 + (\mu/\epsilon_0) \cdot d_t \quad [-]$$

In the upper zone the nett landward transport S_u follows from:

$$S_u = \int_{z=d_t}^{\infty} u(z) \cdot C(z) dz \quad [\text{kg/m/s}]$$

Since vertical gradients in $C(z)$ near the mean water level are rather small this integral can be simplified to:

$$S_u = C_d \cdot \int_{z=d_t}^{\infty} u(z) dz = C_d \cdot m/\rho \quad [\text{kg/m/s}]$$

in which:

C_d the concentration at the mean waterlevel [kg/m³]
 m the mass flux above the wave trough level [kg/m/s]

Finally the total nett transport S_x can be computed from:

$$S_x = S_l + S_u$$

An example of this nett transport computation is shown in Figure 2. The right side of this figure shows the measured and best-fit concentration distribution, whereas the left part shows the measured and best fit nett velocity profile below the wave trough level. Computing nett transport results in a seaward transport of 0.77 m³/m/hr below the trough level, while the landward transport above the trough level amounts 0.33 m³/m/hr. As a consequence the total nett transport is about 0.44 m³/m/hr seaward.

Figure 2 Transport at $x = 181$ m based on velocity profile and concentration profile (test T3I4); Computed transport: $S(\text{net}) = 0.44 \text{ m}^3/\text{m/hr}$

3.6 Justification

In order to give some justification on this method instantaneous transports, computed by integration of the product of $C(z)$ and $U(z)$ over the water depth, are compared with transports computed from frequently measured bottom profiles.

Figure 3 shows the profile development for a partly protected dune due to both 9.5 and 12.5 hrs of wave attack. In this time interval the amount of erosion above and in front of the revetment slowly increases. From this the transport at every position and time can be computed using mass balance equations.

Figure 3 Example of profile development and transport in a large scale model with revetment (test T3I4); Measured transport at $t = 11.25$ hr: $S(\text{net}) = 0.40 \text{ m}^3/\text{m}/\text{hr}$

In this case position and time correspond with the situation from Figure 2 and result in a nett transport of $0.40 \text{ m}^3/\text{m}/\text{hr}$. This "measured" transport deviates only 10% from the former computed transport.

Figure 4 shows a comparison between 22 measured and computed transports. With the dotted line indicating a deviation of 20%, the agreement was concluded to be rather good. It was therefor assumed that the presented method of nett transport computation in case of breaking waves gives a reliable estimate of the actual nett transport.

Figure 4 Comparison between measured transports (from profile development) and computed transports (using $C(z)$ and $U(z)$)

4. Model calibration

The calibration of the dynamical model is carried out for the "internal" process parameters, whereas the verification is based on "external" process results, such as profile development and the amount of dune erosion above the maximum surge level.

In this case the transport model is calibrated by the use of approximately 150 simultaneously measured concentration and velocity profiles during storm surge conditions in both small and large scale model tests. For calibration the relevant parameters (e.g. mass flux m and reference concentration C_0) are related to the hydraulic conditions which are computed by the use of results of a calibrated wave decay model.

The reference concentration C_o is related to both the intensity of breaking and the way of breaking (spilling or plunging) according to:

$$C_o = \rho_s \cdot K_c \cdot F_D \cdot [\rho/\bar{\tau}_{cr}]^{3/2} \cdot [F_k(\gamma)]^{3/2} \cdot [Diss/\rho] \quad [kg/m^3]$$

in which:

- K_c a constant [-]
- K_D^C a constant related to the sediment diameter [-]
- F_k^D a function which describes the effect of the kind of breaking [-]
- Diss the dissipation of turbulent kinetic energy [W/m²]

In case of the dissipation term there has been made a distinction between the dissipation source term in the wave energy balance equation and the dissipation of the turbulent kinetic energy Diss. The former is actually a production term of turbulent kinetic energy [Roelvink and Stive, 1989].

In order to take in account the effects of the way the waves are breaking, a relation between the near bottom magnitude of the depth and time mean turbulent energy k_o and the total turbulent energy K is suggested:

$$k_o = K \cdot F_k(\gamma) \quad [m^2/s^2]$$

in which γ is the ratio H_{rms}/d .

Considering a exponential downward decrease in turbulence level and a characteristic penetration depth below the mean water level equal to $\alpha_k \cdot H_{rms}$, this function is:

$$F_k(\gamma) = [\alpha_k \cdot \gamma (\exp(1/\alpha_k \cdot \gamma) - 1)]^{-1} \quad [-]$$

In case of $\alpha_k = 1/2$ this equation can be simplified to:

$$F_k = \begin{cases} 0 & \gamma < 0.33 \\ 0.47(\gamma - 0.33) & \gamma \geq 0.33 \end{cases} \quad [-]$$

In case of spilling breakers, wave breaking does not contribute to the reference concentration.

Figure 5 shows a comparison between measured and computed reference concentrations. With respect to the closed symbols the agreement was concluded to be satisfactory.

5. Model verification

The final verification of the model is done by comparing measured dune erosion quantities with computed profile development for 43 model tests and a small number of prototype data. Figure 6 shows a comparison of measured and computed erosion quantities in a small scale model due to different wave heights, wave periods, water levels and dune heights for constant and varying hydraulic conditions.

Figure 5 Comparison between measured and computed reference sediment concentrations (open symbols indicate positions above revetment)

Figure 6 Comparison between measured and computed erosion quantities for constant and varying hydraulic conditions (small scale)

6. Conclusions

During extreme wave attack the suspended transport based on time mean concentrations and velocities is dominant. A predictive model for sediment load and transport due to extreme wave attack is presented which gives a reliable description of the transports and profile development during a storm surge. By the use of this model the amount of erosion for arbitrary coastal profiles, e.g. with bars and tidal gully or with protected dunes (dune revetments) due to arbitrary storm surge conditions can be determined. Finally it should be revealed that in order to increase reliability of the model some further verification and (perhaps) re-calibration for unused data sets will be carried out.

7. Acknowledgement

The present study has been carried out by DELFT HYDRAULICS on behalf of the Technical Advisory Committee on Water Retaining Structures (TAW) of the Ministry of Transport and Public Works in the Netherlands.

CHAPTER 146

PREDICTION OF COASTLINE EVOLUTION FOR THE HOLLAND COAST

The Dutch Coast : Paper No. 7

M.J. Dijkman 1), W.T. Bakker 2), J.H. de Vroeg 3)

Abstract

The Coastal Defence Study, as executed in the Netherlands, involved a 100-year prediction for the coastline evolution of specific parts of the Holland coast. In order to create this prediction a mathematical two-line model was used. In this model the effects of wave driven as well as tidal transports are incorporated, also cross-shore transport is implemented. The model is calibrated using sand balances, derived from measurements of coastal profiles. Qualitatively correspondence is reached, but quantitative differences between model and nature remain.

1. Introduction

The mathematical prediction of the coastline evolution of the Holland coast for the Coastal Defence Study is based on a two-line model, as described by Bakker (1968) and in the Manual on Beach Nourishment (Pilarczyk, ed., 1986). The way of prediction is described by Dijkman et al. (1989); the present paper gives a condensed version of this report.

The Holland coast is the central one of the three parts (Rhine/Scheldt estuary, uninterrupted Holland coast,

Figure 1. The Holland coast

- 1) Veldhorstraat 50, 2161 ER Lisse, The Netherlands
- 2) Rijkswaterstaat, Tidal Waters Division, P.O.Box 20907, 2500 EX The Hague, The Netherlands
- 3) Delft Hydraulics, P.O.Box 152, 8300 AD Emmeloord, The Netherlands

Wadden islands), into which the Dutch coast can be divided (see figure 1). Three harbors (Hook of Holland, Scheveningen, and IJmuiden) partition the Holland coast. The harbor moles of Hook of Holland and IJmuiden have a length of 3 km and therefore have a dominating effect on the coastal behavior.

2. The two-line model

The two-line model is based on a schematization of the coastal profile into two zones (see figure 2) :

- the inshore zone: MSL-5m to MSL-1m (MSL-1m represents the average low water level)
- the beach zone : MSL-1m to the local dune top (varying between MSL+10m and MSL+20m)

Figure 2. Two-line schematization

The model represents the area up to the depth contour of MSL-5m. This value for the lower boundary of the inshore zone is based more on practical (availability of measurements) than on theoretical considerations. In this zone the effect of the wave driven transport will dominate that of the tidal transport. At the seaside, there will be an interaction with the offshore zone: effects of cross-shore transports as well as tides can be important here. Sand losses due to the sea level rise and to wind transport over the dune tops are not taken into account. The sand quantity in either zone of a specific coastal profile is averaged. Doing so for several profiles, and connecting the so found values results (in plan view) in a couple of lines : the 'beach line' and the 'inshore line'. The mathematical basis of the two-line model consists of an equation of motion and an equation of continuity, this for each zone. The equations of motion consist of two components: the longshore and the cross-shore transports. In the following equations the indices 1 and 2 will be used to refer to the beach zone and the inshore zone respectively.

- Longshore transport:

(eq 2.1a/b)
$$S_i(x, t) = S_{tide, i}(x) + S_{0, i}(x) - s_i(x) \frac{\delta y_i(x, t)}{\delta x}$$

 for $i=1,2$ and with :

- $S_i(x, t)$ (m^3/yr) total longshore transport at location x and at time t .
- $S_{tide, i}(x)$ (m^3/yr) tidal transport at location x . This term has been determined for the present situation near the harbors and is assumed to be constant in time.
- $S_{0, i}(x)$ (m^3/yr) constant component of the wave driven transport at location x . This is the wave driven transport for locations x , where the coastal direction is parallel to the x -axis, and varies only with a gradient in the wave climate along the coast.
- $s_i(x)$ ($m^3/yr/rad$) coastal constant at location x , giving the ratio between a change in coastal direction and the wave driven transport. This constant also varies only with a gradient in the wave climate along the coast.
- $y_i(x, t)$ (m) distance between the x -axis and the beach line ($i=1$) or the inshore line ($i=2$), at location x and at time t .

- Cross-shore transport:

The cross-shore transport is modelled following the principle of the equilibrium coastal profile. According to this principle (under given conditions) an equilibrium profile will be formed in the long run. Applying this principle to the two-line schematization of the coastal profile the equilibrium profile converts into an equilibrium distance between the beach and the inshore line. Any occurring difference between the actual and the equilibrium distance results in a cross-shore sediment transport. The cross-shore transport is furthermore assumed to be proportional to this difference.

In formula: $S_y = s_y \cdot [W - (y_2 - y_1)]$ (eq 2.2)

With:

- S_y (m^2/yr) : cross-shore transport (positive when directed seaward)
- s_y (m/yr) : cross-shore transport constant, determining the timescale at which the equilibrium distance (W) is reached.
- W (m) : equilibrium distance between the schematized beach and inshore line.

• Continuity:

Beach :
$$h_1 \frac{\delta y_1(x, t)}{\delta t} = - \frac{\delta S_1(x, t)}{\delta x} - S_y(x) + p_1(x)$$

Inshore:
$$h_2 \frac{\delta y_2(x, t)}{\delta t} = - \frac{\delta S_2(x, t)}{\delta x} + S_y(x) + p_2(x)$$

(eq 2.3 a/b)

- With : $p_i(x)$ ($m^3/m/yr$) : sediment source in the beach zone ($i=1$) resp. the inshore zone ($i=2$).

Model boundaries

For the model the Holland coast was divided into three areas:

- Callantssoog to IJmuiden
- IJmuiden to Scheveningen
- Scheveningen to Hook Holland

These areas all stretch from one harbor mole to the other, except for the most Northern border. Here the model was limited to Callantssoog, because of the influence of the tidal inlet near Den Helder becoming too strong in the more Northern region.

Model parameters

- Wave climate

The wave climate used is derived from measurements in the period 1978-1984. These measurements lack direct information on the direction of wave propagation, only the wind direction is given. To overcome this problem a correction to the directions has been applied based on the correlation as proposed by Hokke and Roskam (1987), who found this correlation between the wind direction and the wave direction from measurements using Wavec-buoys. The so corrected wave climate significantly differs from the original 'uncorrected' one.

Wave data originating from three different sites (Eierland, IJmuiden and LE Goeree) have been used. A comparison between these three sites gives an impression of the variation of the wave climate along the Holland coast, see figure 3.

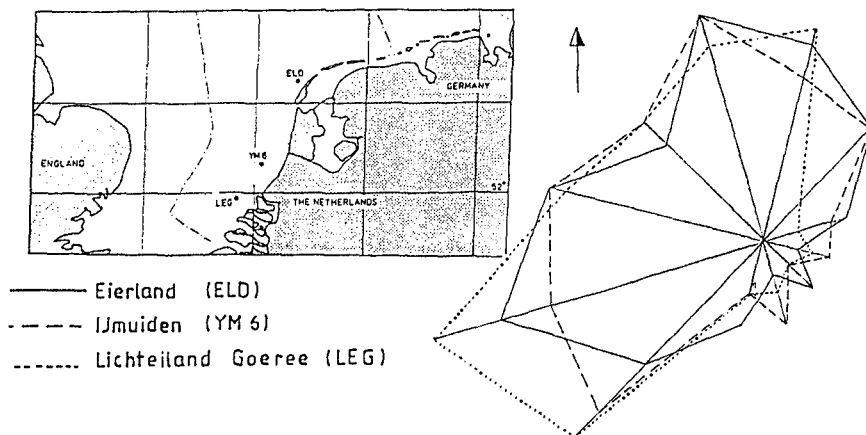

Figure 3. Variation of the wave climate

Furthermore the wave climate as now determined is valid for deep water with a depth of appr. 20-25 m. In order to obtain the required wave climate at shallower water (of appr. 10 m depth) the ENDEC program (ENERgy DECay, Delft Hydraulics, 1988) was

used. This program incorporates the effects of breaking waves, refraction, shoaling, bottom friction and wind.

- Tidal influence

The tidal data have been taken from the HOKU model (Hollandse KUST, which stands for Holland Coast) (Delft Hydraulics, Hartsuiker, 1988). The non-linear relation between tidal velocities and sediment transports has been compensated by using a morphological tide, which is found by multiplying the average tide with a 'tidal factor' (here taken to be 1.1).

In the direct surroundings of the harbors the influence of the tidal effects can be expected to be much more noticeable than at some distance from those harbors. This as a result of the converging/diverging tidal flows, causing sediment transport gradients and accessory erosion/accretion patterns. Qualitatively the formation of an eddy at the leeside of a harbor mole causes a reversal of the longshore transport in this region. For the opposite tide the longshore transport directed to the mole will remain constant until

a much smaller distance from the mole. The resulting effect of a complete tidal sequence will therefore be an accretion at a small distance to the mole, followed by an erosion that at growing distance from the mole becomes less noticeable.

The tidal effects are calculated in the vicinity of the harbors up to the point where the effect of the harbor mole is negligible. In between the harbors a linear interpolation has been used. The tidal velocities at the points in the grid are calculated for an interval of 30 min. (25 in total, covering 12 hours). The probability function for the orbital velocities caused by waves is determined for each grid point. For the fraction of time waves are breaking in this point there is assumed to be no contribution to the tidal transport for that particular combination of waterdepth, wave direction and wave height. Then with the Bijker formula, using both the orbital velocity distributions and the tidal velocities, a resulting tidal sediment transport is calculated. This tidal transport is assumed to be time independent. The results are shown in figure 4.

- Diffraction near the harbors

In the direct vicinity of the harbors the effect of diffracting waves around the harbor moles is an important factor. This effect is implemented in the model, however in a somewhat limited manner: the diffraction and refraction effects have been calculated separately. For the method used see Bakker et al. (1989).

- Coastal constants

These are the constants (constant only in time, but varying along the coast as a result of a variation of the wave conditions along the coast) which determine the longshore wave driven sediment transport ($S_{0,i}$ and s_i in eq 2.1). Calculation of these constants is done using the following assumptions:

- The wave driven longshore transport between two depth contours is proportional to the longshore component of the energy-loss of the driving wave between those depth contours.
- The depth contours are parallel.

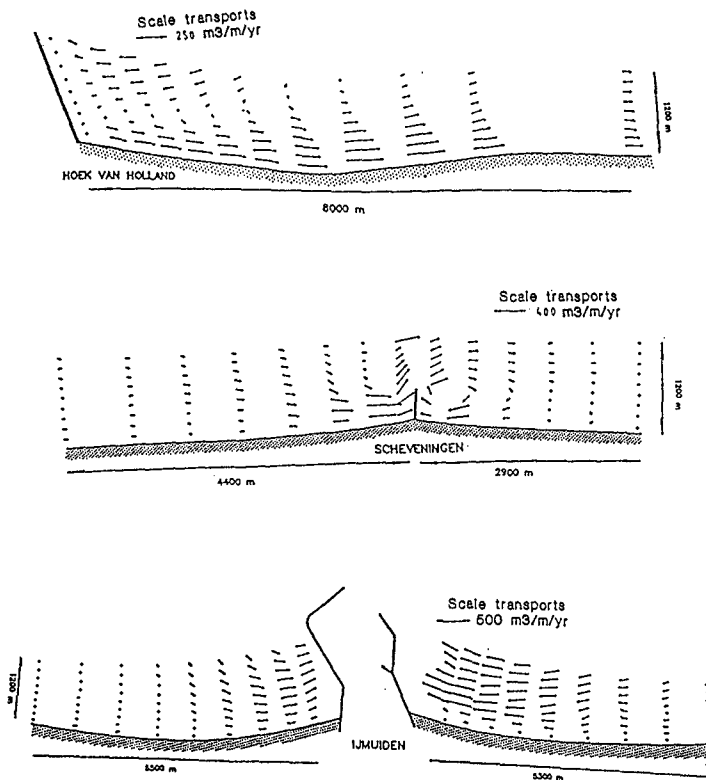

Figure 4. Resulting tidal sediment transports near the harbors. The equation used to calculate the longshore transport is a variation of the CERC formula :

$$s = A * (n_{br} H_{br}^3 c_{br} \sin(\phi_{br}) \cos(\phi_{br})) \quad (eq 3.1)$$

With S : longshore sediment transport (m³/yr)

A : proportionality constant (-)

the wave characteristics at the breaker line:

n (-), H (m), c (m/s), phi (rad)

For a more detailed description of the method used see Svasek (1968), Bakker (1969) and Bakker et al. (1989).

The calculations were performed using the KC program (Kust Constanten, which stands for Coastal Constants, by Casteleyn, 1975) which includes diffraction and refraction effects. In order to compensate for the overestimated diffraction effects, caused by using

monochromatic waves, a reduction factor for the calculated diffraction effect has been applied, this factor is taken to be 0.75. (The difference between the calculated values in the diffraction zone and the value outside this zone is multiplied by the reduction factor). Originally the KC program gives values for the coastal constants for a one-line model, the necessary two line values are derived from the one-line values by assuming a constant ratio between the values for beach and inshore respectively. From calculations a ratio (beach:inshore) of 1:4 was found.

The only remaining unknown in the coastal constants is the proportionality constant A (see eq 3.1). This will be determined in the calibration of the model, just like the cross-shore coastal constants s and W (see eq 2.2).

3. The coastal defence works

There are three different defence methods in use along the Holland coast : groyne, the Hondsbossche Seawall and sand supplies.

The groyne partially block the longshore sediment transport. The effectiveness of the groyne has been roughly estimated by considering the depth to which they reach, in relation to the sediment transport distribution over the depth as found by Bakker (1969). In the model this has been accounted for by using a reduction factor for the coastal constants. Note that this method implies neglecting the impact the groyne may have on the tidal sediment transports : the tidal transports mainly take place at greater depths than the depths to which the groyne reach.

The Hondsbossche Seawall is a rigid seawall, below MSL-1m it is covered by sediment. At both sides of the seawall there are several groyne preventing this area from eroding too severely. In front of the Hondsbossche Seawall the beach zone does not really exist, in the model this has been accounted for by taking the coastal constants in this area equal to zero. In the inshore zone there can be some sediment transport. However, at both sides of the Hondsbossche seawall very strong curves in the coastlines occur, which are not varying too much in time. Therefore the coastal constant s_2 must also be taken equal to zero for this area. This assumption can be backed up by the geological consistency of the bottom material in front of the Hondsbossche Seawall: there are some almost baring clay layers present there (de Mulder, 1983). This implies there can only be a constant transport along the Hondsbossche Seawall: what goes in on one side must go out the other.

The model does not implement the sand supplies, but does take these into account in the calibration of the model, see the next paragraph.

4. Calibration and output

The proportionality constant A, used in the calculation of the coastal constants (see eq 3.1), is used as the instrument to calibrate the model. The calibration is based on the measurements of the coastal profiles of the Dutch Coast on a yearly basis, as stored in the JARKUS database. These measurements are used to create sand balances for the specific parts of the Holland Coast. Some results are shown in figure 5, showing the relative amount of sand (relative to the first year) for three subareas.

Figure 5. Sand balances for the Holland coast.

By making some assumptions these sand balances can be used to give an idea of the average sediment transports in the considered areas. The necessary assumptions:

- No sand leaking around the harbor mole near Hook of Holland.
- No sand from above the MSL-5m passes from one side of the harbor moles of Scheveeningen and IJmuiden to the other.
- Equally distributed sand supply from deeper water over the MSL-5m line for an area between two harbors.

With these assumptions the following conclusions can be derived:

- Accretion of the area Hook of Holland-IJmuiden of 370103 m³/yr, or 6 m³/m/yr. (=p₂ in eq 2.3).

For the area IJmuiden-Callantssoog this accretion is 40103 m³/yr, or 0.9 m³/m/yr. This value has been neglected (p₂=0 in eq 2.3). This relatively low value (relative to the value in the area Hook of Holland-IJmuiden) can be explained by the increase (going Northward from IJmuiden) of the Northward tidal flow in deeper water, 'consuming' the sediment which would otherwise come to benefit the area above the MSL-5m level.

The onshore transports found here compare reasonably well to those found by Stive (1990). The value Stive proposes, is a bit larger : approximately $10 \text{ m}^3/\text{m}/\text{yr}$, almost constant over the entire Holland coast. However this value is derived for an onshore transport over the MSL-8m line, where in this paper the transport over the MSL-5 line is considered.

- The optimum value for the proportionality constant A is 500, determined for the area Hook of Holland - IJmuiden. This value is about a third of the conventional values! With the proportionality constant A now determined, the longshore transports can be calculated, the results are shown in figure 6.

Again, comparing the so found longshore transports to those found by Stive (1990) a reasonable agreement is found, see Dijkman et al.(1989).

Figure 6. Calibration of the longshore transports.

- The coastal constant for the cross-shore transport, s_y (at a depth of MSL-1m) is found to be in the order of $0.05 \text{ m}/\text{yr}$ (for the region Hook of Holland - Scheveningen) to $0.10 \text{ m}/\text{yr}$ (for Scheveningen-IJmuiden). These results were found by using a value of 280 m for the equilibrium distance between beach and inshore line. In the model a constant value of $0.10 \text{ m}/\text{yr}$ is used.

Other scenarios, for instance large offshore transport caused by rip-currents and tidal currents in the immediate vicinity of the harbor moles, have been elaborated with respect to their consequences for the coastal development. (The report by Dijkman et al. (1989) shows results). However, these scenarios had to be rejected because of the coastal behavior according to these scenarios proved to be unrealistic.

5. Results

Figure 7 shows the calibrated coastal development between 1973 and 1984, for the area Callantsoog to IJmuiden. On the left-hand side one observes the effect of the harbor mole of IJmuiden, and between the ranges 20 to 25 the effect of the Hondsbossche Seawall.

Figure 8 shows predictions found in this way for the years 2020 and 2090.

Finally the same results are presented in a different manner, namely with the reference as the initial situation. Figure 9 shows the development of the beach-line, figure 10 that of the inshore line.

Results for the area IJmuiden to Hook of Holland are not presented here, they can be found in the report by Dijkman et al. (1989).

Figure 7.

Figure 8.

Figure 9.

Figure 10.

6. Conclusions

- The results (certainly for an area with harbor moles) strongly depend on the wave climate used (Dijkman et al, 1989). Therefore not only the accuracy, with which the present wave climate is known, but also the accuracy, with which the future wave climate can be predicted highly determines the accuracy of a prediction of the coastline evolution. Accurate wave data (especially concerning wave directions) are vital for accurate coastal prediction.
- The proportionality constant A (giving the ratio between the sediment transport and the longshore component of the wave energy flux, see eq 3.1) found here, is much lower (about a third) than more conventional values.
- The use of the two-line model as an instrument to create a prediction of a coast-line evolution is in creating a qualitative picture giving eroding and accreting areas, but limited in its quantitative accuracy.

CHAPTER 147

MORPHOLOGIC RESPONSE OF TIDAL BASINS TO CHANGES

The Dutch Coast: Paper No. 8

W.D. Eysink¹

Abstract

This paper is part of a series of papers on a study of the Dutch Coast and describes the method used to determine the sand losses of the North Sea coast to the tidal basins of the Dutch Wadden Sea in the North and the estuaries in the South of The Netherlands. The sand losses can be caused by sea level rise, sand mining, closure works, natural land accretion in the basins or bottom subsidence due to gas extraction. The results of this study were relevant boundary conditions for the study on the behaviour of the North Sea coast in the vicinity of the tidal inlets (paper No. 9 of the Dutch Coast of Stive, Roelvink and De Vriend of these proceedings).

1. Introduction

In the scope of the study on the consequences of sea level rise on the North sea coast of The Netherlands, a practical method has been developed to assess the morphologic response of tidal basins to natural or man-made changes in such a system in terms of sand volumes. This was necessary to quantify the interaction between the North Sea coast and the tidal basins of the Dutch Wadden Sea in the North and the estuaries in the South (Fig. 1).

The hydraulic conditions in tidal basins are important as dominant energy sources causing sediment transports, erosion and sedimentation, and sorting of sediment to size, mineral density and rollability. Together these phenomena form the basis of a very complex geomorphodynamic system in which also flocculation of silt and clay particles and coagulation of those particles by shell fish and diatoms play an important role.

Today it is not possible yet to simulate the above complex processes sufficiently accurate in a numerical model. However, in spite of the complex and dynamic character of these areas, some systems can be recognized in nature if we look in a broad way neglecting details such as migration of channels and shoals. It appears that we can express certain characteristic quantities in empirical relationships which are useful tools for engineers.

¹ DELFT HYDRAULICS, P.O. Box 152, 8300 AD Emmeloord, The Netherlands

Figure 1a The Dutch Wadden Sea

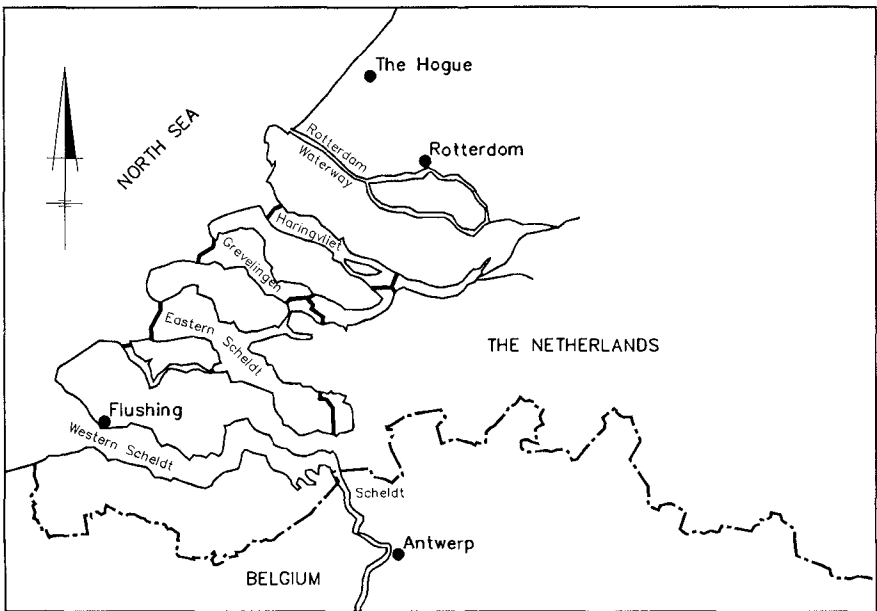

Figure 1b The Dutch Delta Area

2. Morphological relationships

A well known relationship from literature is the relation between the flow area of a tidal inlet and the tidal prism passing that inlet (e.g. O'Brien, 1969 and Bruun and Gerritsen, 1960) or related characteristic quantities such as the mean tidal flow velocity (e.g. Kreeke and Haring, 1979), maximum tidal flow velocity (e.g. De Jong and Gerritsen, 1984) or related shear stress velocities (e.g. Gerritsen and De Jong, 1985).

From data of one tidal channel in the Dutch Wadden Sea presented by De Glopper (1967) it appeared that also along a channel the flow area was related to the tidal volume passing the local cross section. Lateron this was confirmed by extensive investigations of Gerritsen and De Jong (1984, 1985) for various tidal channels in the Dutch Wadden Sea and in the estuaries in the Dutch Delta area in the South.

All results show that a rather good description is presented by the relationship:

$$A_{\text{MSL}} = c_A V^A \quad (1)$$

where:

A_{MSL} = flow area below MSL

c_A = empirical coefficient

V^A = characteristic tidal volume

Also some relation seems to exist between the mean depth of a tidal channel and the tidal volume (Fig. 2). This relationship is less firm and may show deviations due to the occurrence of hard bed layers or man-made bank protections.

Equation (1) does suspect that integration along a channel should result in a relationship for the volume of the entire channel system of a tidal basin. Plotting data of the channel volumes of the different tidal basins of the Dutch Wadden Sea versus their tidal volumes showed such a relation (Fig. 3). A similar relationship was found by plotting channel volumes of the Grevelingen and of various sections of the Eastern Scheldt versus the related tidal volumes (Fig. 4). Data of the Western Scheldt at first glance showed a different picture (Fig. 5). However, the deviation from that of the relationship for the other basins may be explained by the deepening of the River Scheldt and the Western Scheldt in the back of the estuary for a proper access to the Port of Antwerp. In general, the following relationship seems to be valid for the channel volume of a tidal basin or estuary (with minor upland discharge):

$$V_C = c_C V^{3/2} \quad (2)$$

where:

V_C = channel volume below MSL

c_C = empirical coefficient

Figure 2 Mean tidal volume versus channel profile and depth

Figure 3 Channel volume versus mean tidal volume tidal basins of the Wadden Sea

Figure 4 Channel volume - mean tidal volume relation Eastern Scheldt and Grevelingen

Figure 5 Comparison of channel volume relations Wadden Sea, Eastern Scheldt/Grevelingen and Western Scheldt

Another important relationship is the one for the sand volume stored in the outer deltas in front of tidal inlets which is shown in literature (Bruun, 1978). This relationship is derived for outer deltas in the USA and reads (Fig. 6):

$$V_o = c_o V^{1.23} \quad (3)$$

where:

V_o = sand volume stored in outer delta

c_o = empirical coefficient

Figure 6 Sand volume outer deltas in America in relation to the mean tidal volume of the inlet

For the time being this relationship has been assumed also valid for the Dutch coast. Its validity will be verified in the near future.

Further, the relative tidal flat area in the Dutch Wadden Sea seems to show a relationship with the size of the basin (Fig. 7).

Also for the estuaries in the South of The Netherlands such a relationship was found which, however, differs from the one for the Wadden Sea. A possible explanation for the trend of the relationships could be the increasing activity of local wind waves in the larger basins (fetch). The difference between the two relationships might be caused by the difference in shape of the basins and the orientation relative to the dominating wind direction. Further investigations on this item may yield a better understanding.

1. Before closure of the Lauwerszee
2. After closure of the Zuiderzee (IJsselmeer); no equilibrium yet?

Figure 7 Relative area of the intertidal zones in the Wadden Sea

Finally, it is believed that the crest level of the tidal flats in between the tidal channels somehow are related to a characteristic tide level (e.g. MSL or MHW), local wave activity and flow conditions. The level is determined by a dynamic balance between sediment transport from the tidal channel to the flats during flood and vice versa during ebb. Also in this respect more investigations could support this hypothesis.

The above relationships are derived for situations where morphology is in a dynamic equilibrium with the hydrodynamic conditions.

3. Application of relationships in coastal engineering

The relationships are very suitable means to determine in what way Nature will respond to changes in the existing dynamic equilibrium. The equations (1) to (3) allow for a quantification of the ultimate change from the disturbed equilibrium to the new equilibrium. The relations of the relative tidal flat area and the height of the tidal flats may be helpful in the interpretation in what way

the developments will occur in combination with knowledge on general sediment transport theories and hydraulics.

For example with Figure 8 it can be demonstrated what will happen in response to closure works. Such works make part of the original basin inactive resulting in a reduction of both the channel volume ΔV and the tidal volume ΔV . The new situation will deviate from the equilibrium lines:

- the remaining channel volume is a m^3 too big, and
- the sand volume of the outer delta has become a volume of $b \ m^3$ too big.

The sand of the outer delta lays on the doorstep of the tidal basin and is readily available for the adaptation of the channels in the basin. The rest ($a-b \ m^3$) has to be supplied from outside.

Figure 8 Example of application of morphological relationships

In Figure 9 another example is shown, that is the response of the system to natural accretion of new land mainly by deposition of silt (salt marshes) along the borders of the basin. This is a very slow process causing a gradual reduction of the tidal volume of the basin at a rate ranging from 0.3% in the western Wadden Sea, 0.7% in the more sheltered eastern part of the Dutch Wadden Sea to 0.5% in the sheltered basin of the Dollard (Eysink, 1979). In the same way as before this results in a demand for sand from the outside. The Dutch Wadden Sea reached its greatest extension around the year 1500 and decreased in size ever since due to accretion. Therefore, it is realistic to assume that the adaptation of the channel system and the outer delta keep in pace with the accretion process.

Sand borrowing from the outer delta or the tidal channels of a basin does not effect the tidal volume but only locally the flow velocities. It is obvious that in that case the removed sand will be ultimately replaced by sand from the adjacent North Sea coast or its foreshore.

Figure 9 Example of application of morphological relationships

With respect to the effects of increased sea level rise the answers are more difficult to assess. From storage curves of the different basins it follows that, without adaptation of the levels of the tidal flats, the tidal volume will increase and the area of intertidal zones will decrease. The latter effect will be most serious in the Wadden Sea, especially in the western part where the levels of the tidal flats are low (see Table 1). If this scenario is realistic, the channels in the basin will widen and sand will be transported partly to the outer delta, which will extend, and partly will become available for accretion of the North Sea Coast adjacent to the tidal inlet.

Area	losses in km ² /cm SLR
Wadden Sea-East	3.0
Wadden Sea-West	6.0
Eastern Scheldt	0.2
Western Scheldt	0.02

Table 1 Loss of intertidal zone due to increased sea level rise without adaptation of tidal flats

However, an increase of sea level rise also will effect the level of the tidal flats. In a relative sense the disturbance of the characteristic water depth at the flats will be much greater than in the channels. Hence, the sediment transports in the channel will be far less effected than those on the flats. Consequently, it seems realistic to assume that the response of Nature will be the strongest on the tidal flats. If it is assumed that the levels of the tidal flats can follow the extra sea level rise, this implies that the tidal volume of the basin remains unchanged, whereas the volume of the channels increases. Thus, this scenario results in a demand of sand from outside.

There are indications that the response of tidal flat levels to changes in HW is fast and may follow the sea level rise very closely. However, there is no proof that the latter scenario is fully realistic. Anyway, it is a pessimistic scenario for the North Sea Coast.

4. Model for adaptation histories

The above mentioned relationships only give an indication of the new equilibrium between morphology and hydrodynamic conditions in case of changes. They don't give any information how the adaptation will take place and what time this will take.

Adaptation processes generally show a logarithmic character; examples of this are found in:

- accretion history of the Dollard (Fig. 10),
- adaptation of the Zoutkamperlaag after the enclosure of the Lauwerszee (Postma and Reenders, 1986),
- infill of sand borrow pits (Kniess, 1976).

This shows that the adaptation history can be described by an expression like:

ca. 1500 largest extension of the Dollard

Figure 10 Accretion of the Dollard

$$X/X_0 = \exp.(-t/\tau) \tag{4}$$

where:

- t = time since disturbance of existing equilibrium,
- X = quantity (depth, area or volume) representing difference from new equilibrium,
- X₀ = initial difference from new equilibrium,
- τ = characteristic time for adaptation equal to:

$$\tau = X_0 / \Delta X_0 \tag{5}$$

where: ΔX₀ = initial rate of adaptation.

The initial disturbance of the system X₀ can be derived via the change in the hydraulic conditions and the morphologic relations.

The initial adaptation rate can be obtained through monitoring or computations with mathematical models. Then the characteristic time τ can be calculated with equation (5) and the adaptation history can be determined by equation (4). This provides a fair indication of reality.

The above approach can not be applied in case of a (sudden) change in sea level rise as this is a process of gradual and continuous growing disturbance of the existing equilibrium. In this case it is not realistic to assume that this will result in an immediate response of the sea bed in a tidal basin. It is more likely that the sea bed will follow with a certain time lag. Based on geological and historical evidence it can be stated that the tidal basins are sedimentation areas. This only can occur if the sediment transport capacities inside the basin are slightly less than outside. This could be explained if it is assumed that the bed of the basin lags slightly behind (below) the actual equilibrium level. This hypothesis is based on the principles of a sand trap. The bed lag causes a small overdepth resulting in a small reduction of flow velocities and sand transport capacities inside the basin. Thus sand is trapped to follow the present sea level rise.

If the sea level suddenly rises faster, more sand has to be trapped. Due to the extra sea level rise the overdepth in the basin initially increases. Consequently, gradually more sand is trapped until the sea bed again rises at the same rate as the sea level.

This process can be calculated in a schematic way by using a fictive overdepth. This quantity can be determined based on the percentage of the annual sand influx that is trapped in the basin and the relation between sand transport and flow velocity. If x percent of the sand is trapped, the fictive overdepth is $l-(1-x)^{1/n}$ percent of the weighted mean depth of the basin if the sand transport is proportional to the flow velocity to the power n . If the annual sand influx of a tidal basin is known, the percentage x can be determined for different rates of sea level rise (sedimentation is equal to the area of the basin times the rate of sea level rise). Next, the adaptation of the bed lag to the increased sea level rise can be calculated numerically (Fig. 11).

5. Conclusions

The above approach with proper interpretations are suitable for practical application in coastal engineering. It can be further developed as a conceptual model for areas like the Wadden Sea by implementing also other relations such as those for the tidal flat areas and heights of tidal flats in relation to characteristic hydraulic parameters.

CHAPTER 148

LARGE-SCALE COASTAL EVOLUTION CONCEPT

The Dutch Coast: Paper No. 9

Marcel J.F. Stive¹, Dano (J.)A., Roelvink¹ and Huib J. de Vriend¹

Abstract

Using the coastal evolution of the Netherlands in the Holocene up to the present as an example and a test case, a coastal evolution concept is proposed and materialized with which shoreline position changes for different sea level rise scenarios are predicted. The (more generally applicable) model applies to quasi-uniform coastal stretches. It accounts for morphodynamic processes from the shelf to the first dune-row, and integrates over coastal units of approximately 10 km alongshore length. The added value, compared to earlier published concepts or models, lies in the full inclusion of cross-shore and alongshore processes, and in the distinction between a - with respect to sea level rise - instantaneously responding active zone and a noninstantaneously responding central shoreface zone. Relevant differences have been found to exist between coastal cells on the closed and the interrupted coast. An important conclusion is that the cross-shore effective Bruun-effect is only of limited importance. This is especially true in the case of the interrupted coast. Longshore sand transport gradients are very large there. This is mainly related to the sand demand which is placed on coastal stretches adjacent to estuary mouths of those estuaries which tend to follow the sea level rise.

1. Introduction

Since the early 1970's Rijkswaterstaat stimulated Dutch coastal research with the TOW Coastal Research Programme. The Programme was mainly devoted to the study of coastal processes from the coastal engineering perspective. Around 1985 - initiated by coastal erosion management questions in general and by the anticipated increase in relative sea level rise in particular - an interest grew into larger scale, longer term coastal evolution processes. It was realized that the TOW Programme as such (which focussed on coastal evolution processes of typical time- and space-scales of a year and a kilometer) was too limited in scope. In order to gain an understanding of large-scale, long term coastal evolution, a variety of geo-morphological processes with a diversity of time- and length-scales needs to be considered which,

1 DELFT HYDRAULICS, P.O. Box 152, 8300 AD Emmeloord, The Netherlands

in turn, calls for the deployment of many specialisms. This approach has been applied in a new research programme, called Kustgenese (Coastal Genesis). In this Programme the fields of geomorphology, hydro- and morphodynamics, physical and historical geography and geology have been linked in order to study and understand coastal evolution at the scales of interest and, subsequently, to arrive at a (physical-mathematical) tool for coastal evolution. This has led to Coastal Genesis Phase I in 1987, reporting on the available knowledge of the physical processes responsible for the reconstructed evolution of the Dutch coastal system (for a summary see Zitman et al, Paper No. 2, these proceedings).

The Kustgenese Programme was more or less interrupted for a period of two year to prepare a Coastal Defence Policy Study for the Dutch Government. This study looks into the near (5 years) and far (several decades) future (Louisse and Kuik, Paper No. 1, these proceedings). A main technical item of the study is the prediction of the coastline development, in which one of the topical aspects is the effect of an accelerating rate of eustatic sea level rise due to the greenhouse effect. The look into the far future more or less forced the researchers (drafted from the Kustgenese team and) responsible for the coastline prediction to materialize their concepts of coastal evolution into a predictive, quantitative tool. This has stimulated a coastal modelling approach which considers larger coastal development scales than sofar has been done in the Netherlands. The approach is described below. First however, a concise sketch of the Dutch coastal system and its Holocene evolution is given, with an identification of the relevant processes and external conditions.

2. Recent Holocene evolution of the Dutch coast

The present Dutch coastal system exists of three typical coastal subsystems, which basically differ with respect to the dominance of particular physical processes (see Figure 1). The complexity of the system is due to the fact that these systems place boundary constraints on one another. In the South of the Netherlands the relics of the Rhine-Meuse Delta are located. Centrally, the closed dune system of the Holland coast safeguards in the most literal sense the Randstad, which is the commercial center of the Netherlands. In the North the southend of the Wadden region is found, which extends up to Denmark. A sketch of these subsystems and their evolution is as follows.

The central part of the coast of the Netherlands is called the Holland coast. Geologically speaking it is a recent, closed coastal system, since it was only formed during the Holocene some 5000 years ago. It is expected (Beets et al, 1990) that the Pleistocene based lagoon mouth positioned there, closed itself off during periods of a strongly decreasing rate of sea level rise. Its basic contents are a relatively young (1000 to 1600 A.D.) dune system of variable width, covering an older dune system formed approximately 5000 year ago. By and large the coast has retreated over the last 2000 years, near Rotterdam and Den Helder the most and centrally less and less. Now - mostly due to human regulation - it has come to a standstill centrally and it is retreating under control in the North.

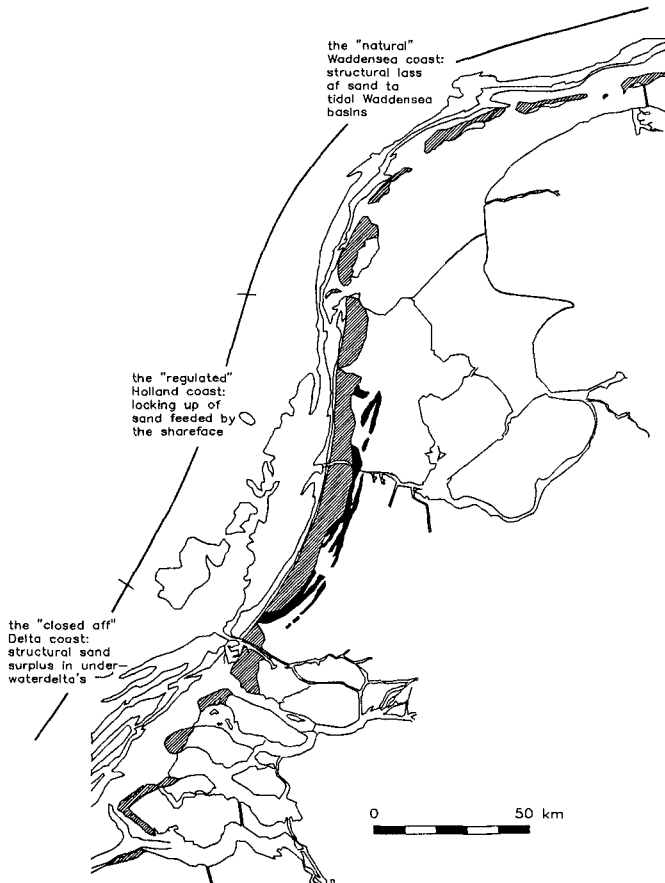

Figure 1 Three subsystems of the coast of the Netherlands

In the South of the Netherlands we find the area which is usually denoted as the Delta-region. It is a region which over the last millennia has experienced considerable variations in opening and closing of the coast, largely related to human agricultural activities. The Delta-works in the region were initiated by the flooding disaster in the region in February 1953. They consist mainly of permanent closure works of the estuary arms, which have the delta now more or less changed into a relic. One of the arms, the Westerscheldt, is still open, being the shipping entrance to Antwerp. The Westerscheldt estuary mouth is a strongly active system of bars and gullies, with important impacts in the form of coastline undulations on the adjacent coastal stretches.

The Dutch Wadden Sea coast consists typically of a system of relatively longstretched barrier islands, with active delta systems. Its present form was more or less reached a thousand years ago, when

important breakthroughs were formed towards the former Almere lagoon in the center of Holland thus creating the Zuiderzee. A characteristic feature of the Wadden Sea region is its continuous sedimentation of the tidal flats in order to keep pace with relative sea level rise, and its siltation along the Wadden shores. These processes are responsible for an important influx of sand, which is basically delivered by the adjacent coastal system. This is the cause of a structural retreat of the Wadden island shores.

By studying the evolution of the Dutch coast over the Holocene up to the present, as was done in Coastal Genesis Phase 1, the following aspects were identified as important for the large scale evolution (see also Zitman et al, Paper No. 2, these proceedings):

- (1) sediment transport in cross-shore direction is at least as important as longshore transport, where the terminology cross-shore refers to the surfzone and the shoreface: in this respect it is emphasized that what counts is the exchange of sediment between shoreface and surfzone (the diabathic exchange) and the exchange of sediment between longshore coastal stretches both in the surfzone and on the shoreface (the parabathic exchange);
- (2) the Subboreal coastal advance (approximately 5000 C14 years BP) and the subsequent formation of the Old Dunes are very likely related to a strong decrease in relative sea level rise (Beets et al, 1990). The physical process responsible for the closing of the coast is similar to that of the behaviour of an underwaterdelta after closure of its tidal basin (Steijn et al, 1989);
- (3) the formation of the Young Dunes along the Holland coast some thousand years ago cannot be explained by longshore motions of sediment alone. The external conditions which may have initiated a diabathic exchange may be those related to relative sea level rise fluctuations;
- (4) tidal basins or estuary mouths bear important effects on adjacent coastal stretches. For instance the Waddensea tidal basins in dynamic equilibrium keeping pace with sea level rise demand high amounts of sediment (Eysink, Paper No. 8, these proceedings), which are eventually delivered by the adjacent North Holland coast and the barrier island coasts.

3. Coastal evolution concept

The need for a longer term prediction has -more so than before- made us aware of the fact that we have to distinguish between coastal evolution concepts or models on a range of scales. Also, there is a relation between the space scale of a coastal feature and the time scale on which its behaviour is manifest. A schematic relation is given in Fig. 2 for the following three spatial and temporal scales of coastal evolution which we have chosen to distinguish:

- (1) Large scale coastal evolution (LSCE) with a morphodynamic length scale of 10 km and a time scale of decades, for which a conceptual model was developed, which is described below. The evolution character in this class can vary between mean trend (e.g. geological processes related), fluctuating (e.g. boundary conditions related) and asymptotic (e.g. morphodynamic constraints related) behaviour. This is typically the sort of model with which longer term predictions can be made, needed for a longterm planning of coastal development both due to large scale natural processes, such as an increasing sea level rise or a changing

- climate, and to large scale human activities, such as an estuary or tidal basin closing;
- (2) Middle scale coastal evolution (MSCE) with a morphodynamic length scale of 1 km and a time scale of years. Important distinctions in this evolution class are cyclic and damping coastline developments. Cyclic developments are for instance due to interactions between geometry and water motions in the low-frequency range, or due to (quasi-)cyclic channel-shoal shift patterns in estuary mouths. Damping developments are mostly due to human interferences like harbour moles, beach nourishments, channel dredging etc. This is typically the sort of model which is used to identify the impact of coastal works on the coastline development;
 - (3) Small scale coastal evolution (SSCE) with a morphodynamic length scale of 100 m and a time scale of storms to seasons. In this class of development it is the local (on the scale of the wave length) variability of topography and hydraulic conditions which interact to result in short-term, often rhythmic, coastline fluctuations. Generally, these fluctuations seem to have little interaction with the longer-term structural coastline evolution. This is typically the sort of model which is used for the more detailed design of coastal defence works.

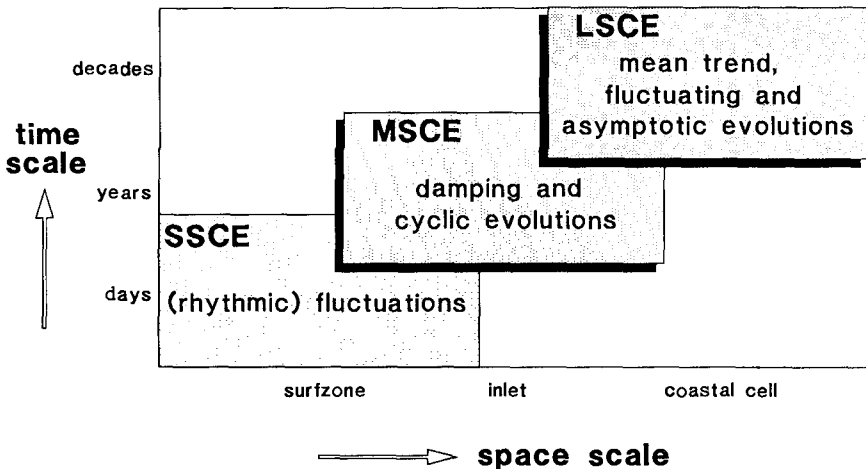

Figure 2 Coastal evolution scales

It is our opinion that the state-of-the-art in deductive modeling (i.e. models deduced from basic physical process knowledge) just about enables us to make predictions of SSCE. While in predictions of MSCE inductive concepts (i.e. model concepts inferred from observed or through analogy expected behaviour) commonly are included, this is certainly the case in predictions of LSCE. We share the viewpoint that the two approaches do not exclude one another, on the contrary: "induction is really the inverse process of deduction" (Jevons, 1958). So, in the following formulation of the large scale coastal evolution concept we try to combine our detailed process knowledge with inductive knowledge.

Our concept is in principle derived for the Dutch coast, but is expected to have some generality for sandy dune coasts and barrier island coasts. The concept further applies to (quasi-)uniform coastal stretches or cells of several km's length, of which it is assumed that the longterm average coastal profile (from the dune to the shelf) and wave, current and sand transport conditions and gradients vary only weakly alongshore. Relatively important interruptions due to river delta's, harbours, shipping channels, headlands, submarine canyons are either point sources or a principal boundary to the cells. Cross-shore three units are distinguished, i.e. the active zone (the upper shoreface, extending from the first dune row to 8 m waterdepth), the middle and lower shoreface (from 8 m to 20 m water depth) and the inner shelf (below 20 m water depth). The waterdepths mentioned are approximate figures for the Holland coast and depend in general largely on the wave climate. We define the important transition of the active zone to the middle shoreface as the level above which profile changes occur as observable from profile measurements over one average year. Alongshore we distinguish two types of coastal cells, i.e. cells on the closed coast and cells on the interrupted coast. The former category is formed by those coastal stretches which develop unaffected by coastal interruptions due to estuary or tidal basin mouths, under offshore hydro-meteo conditions which are relatively slowly varying alongshore. In contrast, the latter category is strongly affected by these interruptions; a tidal basin in dynamic equilibrium keeping pace with the sea level rise, for instance (see Eysink, Paper No. 8, these proceedings), may be the cause of a structurally retreating coastline in adjacent coastal stretches. It is found that alongshore gradients of net sediment transport, wave-induced as well as tidal, may differ by an order of magnitude between these categories. The variety of physical processes which may act on these two categories of coastal cells is summarized in Figures 3 and 4. Also, an indication is given of the relative frequency and intensity of the processes.

The morphodynamic processes are integrated over the three distinguished units, resulting in transport gradients over their control volume, under adoption of the following inductive concepts:

- The active zone has, averaged over the longer term, a steady profile form relative to the position of the mean sea level. This determines the vertical position of the profile. It is noted that this is basically the assumption behind the Bruun-rule. However, here we only adopt this inductive concept to be valid for the active zone, while it is furthermore only one of the factors determining the horizontal position of the active zone and thus of the shoreline. The horizontal position is principally determined by the sediment balance, which takes account of the vertical motion (sea level rise driven), alongshore gradients (wave and current driven) and cross-shore gradients (transport over the "foot" of the active zone and (winddriven) over the first dune row);
- The middle and lower shoreface is a morphodynamically weakly varying zone, where the gross changes over a decade are such that they can be derived from initial sediment transport considerations (Roelvink and Stive, Paper No. 5, these proceedings). This is typically the zone where at the most seaward boundary the transports are tide-dominated and at the shoreward boundary wave-dominated;

Figure 3 Overview of sediment transport processes in a coastal cell along the closed coast

Figure 4 Overview of sediment transport processes in a coastal cell along a coast interrupted by a coastal inlet

- The inner shelf is morphodynamically negligible for the scales under consideration, and is assumed to stay unchanged.

An overview of the general behaviour and possible displacements of the several cross-shore profile zones is given in Table 1.

PROFILE ZONE	BEHAVIOUR AND DISPLACEMENT
Active zone	<ul style="list-style-type: none"> • Yearly averaged, steady profile form • Upward profile displacement with sea level rise • Shoreward horizontal profile displacement due to: <ul style="list-style-type: none"> - upward profile displacement with sea level rise - aeolian transport over first dune row - positive alongshore transport gradient (alongshore loss) - downwelling transport on shoreface • Seaward horizontal profile displacement due to: <ul style="list-style-type: none"> - wave asymmetry and upwelling transport on shoreface - negative alongshore transport gradient (alongshore gain)
Upper shoreface	<ul style="list-style-type: none"> • Inclining or declining depending on: <ul style="list-style-type: none"> - horizontal nearshore zone displacement - declining or inclining shoreface
Central and lower shoreface	<ul style="list-style-type: none"> • Declining (and eroding) in case of: <ul style="list-style-type: none"> - dominance of wave asymmetry and upwelling transport - negative alongshore transport gradient • Inclining (and accreting) in case of: <ul style="list-style-type: none"> - dominance of downwelling transport - positive alongshore transport gradient
Inner shelf	<ul style="list-style-type: none"> • Steady average level with undulations due to: <ul style="list-style-type: none"> - ripples induced by instantaneous currents and waves - megaripples or ridges induced by large scale circulations

Table 1 Large scale evolution of a coastal stretch; general case

Two of the typical evolutions of the cross-shore units that can occur according to the above overview, are actually found on the Holland coast (see Figure 5). On the central part of the Holland coast alongshore net losses in the active zone are small enough that the net shoreface feeding of the active zone (due to wave asymmetry and density flow driven upwelling) can also compensate for the losses due to vertical profile movement with sea level rise and wind induced transport. This causes the active zone to move seaward and the middle shoreface to flatten. As a result, the transition between the active zone and the middle shoreface steepens. On the northern part of the Holland coast alongshore losses in the active zone are

so large that despite compensation due to shoreface feeding appreciable regression occurs. The regression is so strong that the transition between the active zone and the middle shoreface flattens, even though the central shoreface flattens as well. The actual quantitative confirmation of these effects can be found in Knoester (1990), where e.g. long term evolution data (1896-1975) of the -7 m and the -10 m depth contour are presented.

Figure 5 Typical behaviour of the transition between the active zone and the middle shoreface

In accordance with the above concept of LSCE the "present" (i.e. averaged over the last 5 to 10 years) dynamic coastal sediment budget for the whole of the Dutch coastal system has been drawn up (see Figure 6). As explained it is based on a combination of deductive physical process knowledge and inductive concepts, with the latter supported or verified by observations. On the considered time and space scale the dynamics of the model are of a weakly varying character. With hydro-meteo scenarios involving wind, wave, tide, surge level and mean sea level predictions for the next decades as input parameters it was used as a basis for predictions (Louisse and Kuik, Paper No. 1, these proceedings).

Results of the actual coastline predictions are omitted here, since they are not considered to be of interest in this context. One of the most generally interesting results though is the relative importance of the several sources and sinks that contribute to the displacement of the active zone (and therewith of the shoreline). A quantification of the several effects as found for the Holland coast gives the following result:

Effect	Closed coast	interrupted coast
sea level rise direct (Bruun-effect)	15% > 40%	5% > 10%
sea level rise indirect (estuary-pull)	-	55% > 61%
feeding by shoreface	65% > 46%	25% > 20%
dune formation (loss over first dune row)	10% > 7%	5% > 3%
longshore drift (wave-driven)	10% > 7%	10% > 6%

Table 2 Relative importance of absolute contribution to active zone displacement on the Holland coast for a sea level rise of 0.2 m/century > 0.6 m/century (Note: ">" stands for changing to)

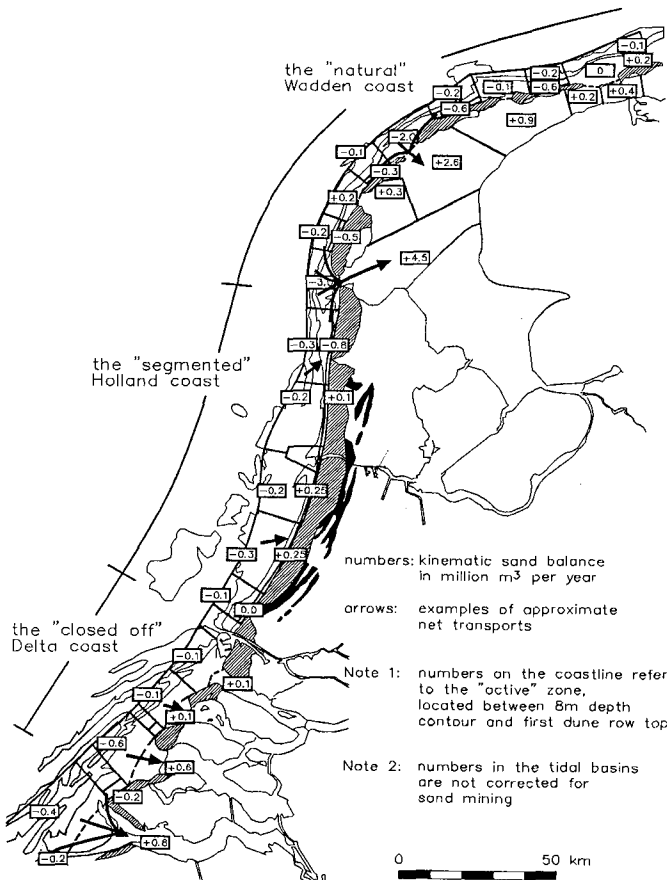

Figure 6 Present sand balance of the Dutch coastal system

From these results, several conclusions may be drawn of which two are mentioned. Firstly, it follows that the Bruun effect is generally of minor importance. Only in the case of a triplication of the present rate of sea level rise on the closed coast sections does it become important. Secondly, wave-driven longshore drift is of minor importance in general. In the following section these conclusions are brought in as contributions to the ongoing discussion of the relevance of sea level rise for coastal erosion.

4. Discussion

The above presented coastal evolution model contains important elements of earlier published work. Without striving for completeness, and certainly not fully aware of all the existing literature in this field, the following categories of references are mentioned. For the "Bruun Rule" aspects reference is made to Bruun (1962), Edelman (1968, 1970) and Dean and Maurmeyer (1983). For the exchange processes between the shoreface and the active zone reference is made to Niedoroda et al (1984) and Wright (1987). For a discussion of coastline recession models and especially the relative importance of cross-shore and longshore effects reference is made to Everts (1985), Pilkey and Davis (1987) and Galvin (1989).

The conceptual model presented here, however, does contain several aspects which make it differ from and more extensive compared to earlier suggested models or concepts in the following sense:

- in cross-shore direction the model includes not only the active zone, which instantaneously follows the relative sea level rise, but also the (central) shoreface which responds non-instantaneously to the relative sea level rise;
- the model takes full account of longshore effects, not only those induced by wave-induced longshore drift variations, but also those induced by coastal inlet systems.

Especially, the quantification of the several effects makes the presented model contribute importantly to the ongoing discussions on the effects of relative sea level rise on coastal recession. From the present application to the Dutch coastal system, it is found that the cross-shore Bruun effect is generally less important than other effects such as shoreface feeding or alongshore effects due to estuary inlets. Since the Dutch coast covers a variety of systems, these conclusions may be of more universal value than the length of the Dutch coast in first instance would seem to justify.

Finally, it needs to be mentioned that the results of these studies enabled the Dutch coastal researchers to identify several research aspects for further study, for instance:

- the morphodynamic behaviour of the shoreface, with specific emphasis on the sediment exchange with the active zone;
- the degree of profile invariance of the active zone relative to mean sea level.

These and other questions are being addressed in the framework of the Coastal Genesis Programme Part II. In this context it is important to point out the following. The resulting coastline development is assumed to be due to a superposition of the abovementioned three scales of evolution. Here, there is a fundamental research

question. This concerns the assumption that smaller scale phenomena are not interacting with or initiators of larger scale phenomena. The degree to which this is indeed true will largely determine the degree of predictability of coastal evolution.

CHAPTER 149

RESEARCH ON LARGE-SCALE COASTAL BEHAVIOUR

The Dutch Coast: Paper No. 10
J.H.J. Terwindt¹, J.A. Battjes²

ABSTRACT

Large scale coastal behaviour (LSCB) regards the development of a certain coastal stretch (order tens of km's) in time (order decades). Knowledge of LSCB is still very limited. Three approaches for analysis of LSCB are distinguished with increasing complexity and necessary level of knowledge, viz. the geostatistical, the phenomenological and the modelling approach. Every approach has serious shortcomings to such an extent that predictions of LSCB are as yet impossible. Nevertheless it is necessary to develop a research strategy which may serve future studies on LSCB.

1. INTRODUCTION

The prediction of the development of sedimentary coasts is still a difficult problem. Coastal changes normally have different spatial and temporal scales and are influenced by developments in adjacent areas in variable degrees.

Policy decisions concerning coastal management, including maintenance of beaches and dunes, require a time span of decades and a space scale of entire coastal units, with lengths up to 10^2 km, say. The changes in underwater topography, shoreline position, beach- and dune profiles on these scales are referred to as "large scale coastal behaviour" (LSCB) in this paper.

¹Dept. of Physical Geography, Utrecht University,
P.O. Box 80.115, 3508 TC Utrecht, The Netherlands

²Dept. of Civil Engineering, Delft University of Technology,
P.O. Box 5048, 2500 GA Delft, The Netherlands

Much of the conventional present-day research related to quantitative modelling of coastal behaviour focusses on relatively small-scale processes such as the wave propagation and decay across the surf zone and the associated velocity field for a single sea state or even a single periodic incident wave. The sediment transport is usually considered locally at the scale of the bottom boundary layer. There is also a tendency of this research to go to even greater resolution both in time (resolving the variations between wave groups or even within individual waves) and in space (horizontally: resolving variations within a wavelength, as in diffraction problems; vertically: resolving variations over the depth, in 2½D or 3D models).

We thus see an increasingly wide gap between the practical needs related to LSCB on the one hand and the focus and trend of ongoing research on the other. This raises serious questions, in particular inasmuch as results of the small-scale approach are not directly transferable to the (much) larger scales.

Research on large scale coastal behaviour (LSCB) is important to determine the long term effects of changing boundary conditions (sealevel rise, wave climate) or of huge interferences by man (closure of tidal inlets, construction of extensive breakwaters, dredging and major beach nourishment operations).

In order to discuss possible LSCB research approaches, a Colloquium was held in Amsterdam on July 10-13, 1989 under auspices of the Royal Dutch Academy of Arts and Sciences. A number of experts was invited to express their views on this subject. This paper deals with some general aspects of LSCB. It also gives an overview of the results of this Colloquium and the plans for Phase II of the Dutch Coastal Genesis Project (see also Zitman et al., 1990), which is an interdisciplinary research project aimed at resolving some LSCB-problems of the Dutch coast.

2. THE PROBLEM OF SCALES

A multitude of processes with a range of time - and space scales has to be considered in coastal morphology problems. Starting at the level of turbulent fluctuations with a time scale of about 1 s, and going up through wind waves, storms or tidal cycles, seasons, years and all the way to durations of several decades (10^{10} s) as required in LSCB, we cover a range of 10^{10} . Likewise, going from the length scale of a sand grain (10^{-1} mm) to that of a stretch of coast of 10^2 km we cover a range of 10^9 .

In general, a hierarchy is present between the (hydrodynamic and morphological) processes at different scales. The larger scale processes only provide (slowly varying) boundary conditions for the smaller-scale ones. Processes of comparable scales interact dynamically. Smaller-scale processes are just noise for the larger scale processes or they may contribute to them in an averaged sense.

One problem arising in this connection is whether LSCB is "just" the net result of small-scale processes or whether autonomous large(r) scale processes are also at work. An example: has the welding of an offshore bar to the coast on a time scale of many years any relationship with the short-term fluctuations of coastal profiles? Or are the latter just noise for the former and may they be omitted in an analysis of large scale behaviour?

The major problem is to specify the process-systems on the meso and large scales. For the small scale the process-systems are much better known because of the wealth of laboratory and field investigations.

3. RESEARCH APPROACHES TO LARGE SCALE COASTAL BEHAVIOUR

The main objective of LSCB research is to identify, analyse and quantify large scale variations in the position of the coastline and the nearshore bottom for purposes of understanding and prediction. Three approaches with increasing complexity and level of knowledge can be distinguished, viz. the statistical, the phenomenological and the modelling approach.

The **geostatistical approach** is purely descriptive. It envisages a paleogeographical reconstruction of the position of the coastline and coastal profiles. Approaching the present time the information density may increase to such an extent (e.g. in the Dutch data set) that statistical analysis becomes possible. Such data sets may be analysed for areas showing similar trends, and for systematic changes in trend over time (fig. 1). This type of descriptive statistical analysis gives insight in the temporal and areal scales of LSCB. It may be used for the extrapolation of the coastal development under the assumption that the past tendencies will proceed in the future (fig. 2). In addition, the data set may provide net sediment budgets over time and area (Van Vessem and Stolk, 1990). The main difficulties in this approach are: inadequate data sets (too short, too small an area), the development of appropriate methods of analysis, and hidden effects of human interferences.

Figure 1 Position of the foot of the dunes along the central part of the Dutch coast as a function of time (1857 as a reference). Note areas showing similar trends in time (e.g. km 65-100; km 8-15 etc.) (after Wiersma 1987).

The **phenomenological approach** tries to find empirical relations for the observed behaviour starting from assumed operating processes. Parameters are selected that are considered relevant to the processes of interest and empirical relations are derived without formulating or using a model for the basic physical processes. For instance, we may try to correlate the Dean and surf-scaling parameters to coastal stages (Wright and Short, 1981). Such parameters include some variables like wave characteristics, slope, sediment size, which are assumed to be of interest for small scale coastal development.

Figure 2 Position of LW-line in time in a line normal to the coast of the island Schouwen. Note the occurrence of a beachwave. The extrapolation of the trend over 150 years is different from that for the last 20 years. If another time interval was chosen, say the last 80 years, another extrapolated trend would have evolved (after Van Vessem, 1988).

Perhaps similar parameters, based on the notion of physical processes, may be developed for large scale coastal behaviour. The main difficulty is the specification of "relevant parameters" for these processes and for the morphological responses. Such parameters are not known for LSCB at the present time.

Another challenging example is the prediction of the dimensions of tidal channel and shoal systems on the basis of equilibrium velocity profile/area considerations (O'Brien, 1931; Bruun, 1978). This approach has recently been extended to non-equilibrium situations, e.g. due to human interference or accelerated sea level rise (Eysink, 1990; Kondo, 1990; Gerritsen et al., 1990; O'Connor et al., 1990).

The **process-modelling approach** starts from the basic driving forces leading to the operative processes assumed to govern LSCB. The process systems may be cast in

a model. The problem is now: can we specify the driving forces, and identify the processes on a level of integration relevant to LSCB? In the most pessimistic view (the "dooms" hypothesis) LSCB is governed by unpredictable inputs fed into a non-linear system, producing a highly unpredictable outcome. In a more optimistic view LSCB is characterized by rather gradual, apparently non-random developments. In this view the underlying process-system may be very complicated and variable but the response viz. the coastal behaviour is rather gradual. Perhaps we may average or simplify the process-system or its response.

The question arises whether existing small scale models can be used for modelling LSCB. During the Colloquium great scepticism was expressed about the possibility to scale up small-scale process models to account for LSCB. The main reasons advanced for this scepticism were: the inadequacy of the present knowledge of small scale processes, especially the sediment transport formulations, and the amplification of errors every time the non-linear mathematical system is integrated to a larger scale.

In this connection it should also be noted that there is a gradual **qualitative** shift in our knowledge as we go from the smaller to the larger scales. The following points are relevant here:

- Residual transports resulting from random advection on the smaller scale can usually be described as diffusion on a larger scale. The Pelnard Considère (1956) approach to the calculation of coastal plan forms is an example where this is utilized. It is deemed likely that the same principle can be extended to other applications.
- Parameterisations of residual effects at each scale require empirical calibration and verification. Small-scale descriptions can be more theoretical, deductive and mechanistic. The larger the scale becomes the more empirical and inductive our knowledge is.
- For empirical investigations relating to small-scale processes, special-purpose, short-term measurements suffice. The empirical input needed in the larger-scale process description calls for more general, continuous monitoring programs.
- The need to go far back into the past to obtain empirical input for LSCB necessitates a multi-disciplinary approach involving not only mechanics but also sedimentology, stratigraphy, geology, climatology and history.

The development of new formulations, appropriate for LSCB, was advocated during the Colloquium. Two ways of arriving at such LSCB-models have been suggested.

The first is to formulate large scale processes, with inclusion of the effects of small scale processes in a parameterized form. The other approach may be the scaling up by filtering the processes at the small scale to arrive at formulations of the larger scale.

As there is so little experience with LSCB-models, several important questions were raised in the Colloquium:

- how to identify processes operating on the larger scales;
- how to cope with catastrophic events like storms which may cause irreversible changes after exceeding threshold values (bifurcation);
- how to introduce the time-sequence of storms. The influence of this parameter is lost in a simple integration over time, although this parameter may be important because of the relatively slow adaption of the coastal morphology;
- how to cope with relaxation times;
- how far is it necessary to solve in detail the small-scale sediment transport problem.

It was generally accepted at the Colloquium that at present long-term prediction of LSCB is impossible. Process-based small-scale simulations remain valuable, not as a predictive tool, but as a research tool, to get a better understanding of the above-mentioned questions.

4. RESEARCH STRATEGIES

The following possible strategy evolved from the discussions during the Colloquium.

1. Make a survey of relevant results of previous studies and reexamine these from the viewpoint of LSCB.
2. Formulate a hypothetical but coherent concept of how the large system works and develop a state-of-the-art model for that. At present such model may be rather rough, but it can serve as a first step (Stive et al., 1990; Roelvink and Stive, 1990). It is expected that different models may evolve for straight coasts and for barrier-island coasts because of the differences in morphology and interaction of the current and wave-system.
3. Make hindcasts of LSCB, on the basis of the aforementioned state-of-the-art model, for field sites for which reliable data are available that can be used for verifications. This may give indications for the potentials and the limitations of the model and it may lead to specific laboratory or field

experiments defined by the applicability of the model.

4. Long-term monitoring programs are indispensable for all LSCB studies. It may be of special interest to select some sites where important coastal engineering works have recently been completed, in order to evaluate the effects of human interference on the coastal system over a long time scale.

The Dutch Coastal Genesis Project Phase I (1985-1989) contains a number of these elements (Zitman et al., 1990). On the basis of the outcomes of Phase I and the discussion at the Colloquium on Large Scale Coastal Behaviour, the following objectives were formulated for the Coastal Genesis Project Phase II (1990-1994).

A distinction is made between the straight central part of the Dutch coast and the intersected barrier island coast in the northern and southern part with their ebb and flood tidal deltas, tidal basins and channel movements affecting coastal developments.

The basic strategies are:

- to continue the paleo-geographic reconstruction of the coastal developments and the statistical analysis of the data on coastline positions and hydro-meteo data in time including geological, sedimentological and historical input;
- to perform theoretical and experimental studies on fundamental gaps in our knowledge (e.g. low-frequency waves, wave-current interactions, bed forms, sand transport with ripples and in sheetflow conditions);
- to conduct some extensive field measurement campaigns in order to increase our understanding of several interacting processes on a natural scale and to provide data for further empirical and modelling studies;
- to explore further the possibilities of morpho-dynamic modelling; this involves:
 - * the development of state-of-the-art models for the straight coast and the barrier islands coast;
 - * the modelling of the behaviour of banks in open sea, shoreface-connected ridges, and breaker bars;
 - * the modelling of the development of channel-shoal system in the ebb tidal deltas and tidal inlets in relation to the morphological developments in the tidal bays;
 - * preliminary efforts to perform reconstruction of past LSCB using existing data on wave and current climate and morphodynamical developments.

It should be noted that the Coastal Genesis Project Phase II incorporates efforts on coastal research of Rijkswaterstaat, Delft Hydraulics, Geological Survey and the Universities of Delft and Utrecht. It is an integrated national research plan.

CHAPTER 150

BEACH AND DUNE NOURISHMENT IN THE NETHERLANDS

The Dutch Coast: Paper No. 11

Piet Roelse

ABSTRACT

In the Netherlands up to the fifties of this century, dike and groyne building were the most important coastal defence measures. Because of the increased awareness of the importance of the sandy coast the demand for a more environmentally friendly coastal protection measure increased. However, artificial beach nourishment was very expensive. In the past two decades the costs of nourishment have decreased as a result of technical developments in the dredging industry, and erosion control by means of sandfills has become in general cheaper than the construction of groynes and dikes. In that period also large volumes of sand have become available from harbour extension and maintenance dredging. These have been the conditions that led to a new coastal defence method. Up till now nearly 50 beach nourishment projects have been carried out, with a total amount of 60 million m³.

This paper provides a review of the projects carried out in the last 4 decades, with a description of the most important aspects.

1. INTRODUCTION

For centuries severe losses of land occurred along the Dutch coast. Besides local effects such as the shifting of tidal channels and periodical movements of the coastline, the main reasons for the coastal erosion were sea level rise and the effects of decreasing tidal volumes of estuaries. In former days the communal problems caused by coastline withdrawal were small, because of the low economic value of the dune area. The fishing-villages behind the outer dune ridges were simply replaced backwards. Only at some locations where flooding of the land was threatening, people tried to stop the erosion.

In the 19th century the interests in the coastal area increased. Because of the rising value of the land behind the dunes, keeping the land dry became increasingly important. Beach recreation arose, as did settlements for industry and housing. Also the awareness of the natural values and the use as drinking water reservoir increased. All these interests led to the construction of extensive groyne fields in the threatened coastal sections during

the second half of the 19th century and the first half of the 20th century.

Since the main reasons for the erosion were not removed, however, the coastline withdrawal could not be fully stopped by groynes. In spite of successful applications of artificial beach nourishment to compensate beach erosion in the USA and in Germany, and the availability of the dredging equipment in the Netherlands, the long tradition of dike and groyne building resisted a new soft method of coastal defence. Only during the last 20 years is beach and dune nourishment being practiced more and more in the Netherlands as well.

After the severe storm surge of February 1953, which flooded large parts of the Delta area, new safety standards were developed and dikes were heightened. After intensive investigations on dune erosion during storm surges, leading to a guide-book for the testing of dune profiles, it appeared that many dune stretches had to be strengthened as well.

During the last 20 years, the experience with beach and dune nourishment has grown considerably and led in 1987 to the publication of the "Manual on Artificial Beach Nourishment". In 1988 and 1989 this experience was used in the Coastal Defence Study for the Netherlands (Louisse and Kuik, 1990).

figure 1. The Dutch coast; erosion areas.

2. PROJECTS IN THE PERIOD 1950 - 1989

2.1. Locations, projects

In the Netherlands, 3 coastal types can be distinguished (fig. 1):

- The Wadden coast with several tidal inlets. The coastal profile is rather flat, except in the neighbourhood of the ebb-deltas where deep tidal gullies occur. Some of the Wadden islands are protected with groynes.
- The Holland coast with some harbour entrances. The coastal profile is flat. In general the dune area is wide. At both ends of this coast where the dunes are narrow, the beach is protected by means of groynes.
- The Delta coast where most of the tidal inlets are closed. Although the shoals in the ebb-deltas protect the coast against severe wave attack, the shifting of the deep tidal channels caused much erosion. Along these channels very steep shore faces occur. Because of the narrow dune ridges most of the coastal sections are protected with groynes to reduce the coastline withdrawal.

In figure 1 the eroding coastal sections are marked. Figure 2 gives the situation with the nourishment locations. It is obvious that most of the sand fills are placed in locations with existing groynes. Table 1 gives a list of the projects up to and including 1989. In 1990 sandfill projects are running, at various locations, mainly to restore beaches and dunefaces after a period of storm surges.

In the period 1950 - 1989, the mean yearly amount of sand is 1.5 million m³. However in the fifties and sixties the nourishment efforts were very small. In the period 1970 - 1989 the mean yearly quantity rose to 3.0 million m³. In table 2 the nourishments are classified by volume. It appears that 67% of the projects had a volume less than 1 million m³, whereas only one of the project quantities was greater than 5 million m³ (the dumping of dredged material near Hoek van Holland). In 65% of the years the volume was less than 1 million m³ or there were no projects at all. Four times the yearly volume succeeded 5 million m³.

quantity (10 ⁶ m ⁶)	year		project	
	number	perc.	number	perc.
0	40	100	-	-
>0	28	70	48	100
>1	14	35	16	33
>2	12	30	8	17
>3	7	18	6	13
>4	4	10	1	2
>5	4	10	1	2

table 2. Classification after volume.

2.2. Aims

In the Netherlands the major aims of sand nourishment are:

- Safeguarding the land against flooding.

In the Netherlands the maximum failure frequencies of dikes and dunes have been established at 1/100,000 to 1/20,000 per year, depending on the expected damages.

- Protection of interests in the dunes.

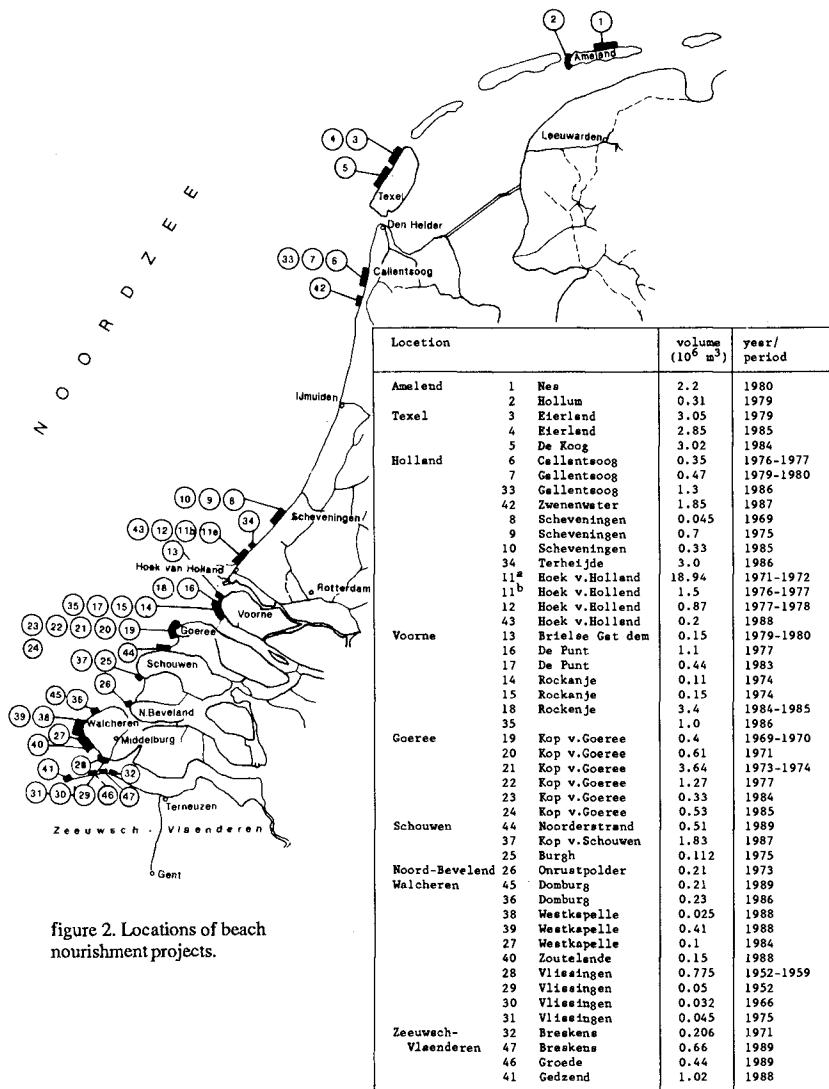

figure 2. Locations of beach nourishment projects.

table 1. Nourishment projects in the Netherlands 1950 - 1989.

Dune areas are valuable from an ecological point of view, but also represent interests for housing, industrial settlements and drinking water reservoirs.

- Prevention of further loss of land.
Each year about 0.3 km² valuable dune area is being lost to the sea. This appears to be small, but most of the erosion takes place in those coastal sections with the narrowest dune ridges.
- Protection of beach recreational interests.
Especially in areas where beaches are bound by dikes or dune foot revetments, beach erosion is detrimental to recreational interests.
- Creation of dump sites for dredged material.

From capital dredging, mainly for harbour extension near Rotterdam, large amounts of sand has become available and much of it has been applied to adjacent coastal sections. From regular maintenance dredging the sand is used for beach replenishment.

Figure 3 shows the yearly amounts of sand with an indication of the aims of the projects. It appears that of many projects the choice for beach replenishment had several reasons. Reviewing the main objective, the total volume can be divided as follows:

figure 3. Aims of nourishment projects.

Main objective	Volume	
safeguarding the land	24.6 million m ³	(40%)
nature conservation:	12.3 „	(20%)
recreational interests:	5.1 „	(9%)
dumping dredged material:	19.1 „	(31%)
	61.1 million m ³	

The first application of beach nourishment took place on the Walcheren coast in the fifties. Small amounts of sand from maintenance dredging were dumped on the foreshore and the shoreface to safeguard dune and dike revetments after beach erosion. In the period 1969 - 1971, sand fills were placed on the coast of Goeree to strengthen the dunes and to alleviate expected extra erosion after the closure of the tidal inlets. In the years after 1970 large amounts of sand became available from harbour extension works near Rotterdam. In 1971/72 a large part was dumped near Hoek van Holland, creating a recreational and natural area. In the seventies and eighties many nourishment projects have been carried out to strengthen dunes or to maintain their safety-level. Protection of natural values was mainly a secondary goal. Beaches were restored mainly for recreational interests in seaside resorts as Vlissingen, Scheveningen and Hoek van Holland. On the Wadden islands and in the northern part of the Holland coast large amounts of sand have been placed to conserve natural areas.

2.3 Design

In order to define the coastal problem, studies of the morphological processes and of the interests involved have to be carried out. If the problem is considered serious, the appropriate measure can be selected. After making a choice the project design can start.

The design of a nourishment programme mainly depends on the objective(s) and the coastal processes. In addition there are the circumstances for the execution, the aspects of landscape and the costs and benefits. Tools and methods for the design are:

Trend extrapolation. Based on the shoreline movements or lost volumes in the past, by means of curve-fitting an estimation is made of the coastal development in the years after the execution of a sandfill.

Equilibrium coastal profiles/ cross shore transport models. Calculations can be made for short term (dune erosion) and long term (equilibrium profile) profile changes. This is applicable to dune strengthenings and recreational beach nourishments. The effects of massive elements such as a dune foot revetment can also be calculated.

Coastal models. The analytical one-line and two-line models calculate the time dependent wave induced evolution in longshore direction. Two-dimensional coastal models can measure the influence of waves and currents. Presently, however, they are only suited for initial calculations. With both types of models, the influence of groynes and harbour moles can be taken into account.

In the Netherlands, measurements of the shoreline position have been carried out since the middle of the 19th century. Therefore trend extrapolation is the basis of the design of all projects in the coastal area. In the case of dune strengthenings, the dune erosion model (Vellinga, 1986) is used. In general this model is very usable. However the application presents problems in situations with a very steep foreshore or more than one dune ridge and at locations where a dune meets a dike.

Up to now the use of analytical and numerical models for coastline development in longshore direction has not become routine. Because of the complicated morphologic processes in the Dutch situation with tidal inlets and various types of groynes, it is not easy to find the dominant processes and to interpret model results. In most of the cases the sandfills are very long with respect to their width, so longshore deformation is rarely the most important process.

In the last decade the design practice in the Netherlands has been to derive the erosion volume from trend extrapolation and to use the dune erosion model in case of lack of safety. To compensate for dispersion, the volume needed at the seaside of the dune face was added with a certain percentage depending on the local situation. In situations with less tidal influence 25 to 50% was added depending on wave influence and the dimensions of the beach fill. At locations with a steep foreshore sometimes a surplus of 75% was applied. In some cases the choice of the percentage also was based on calculations with coastal models.

In general the textural properties of the borrowed sand were rather similar to those of the native sand. Therefore a fill factor or a renourishment factor based on grain size differences is hardly used.

2.4 Execution, borrowing and transport of sand

Whenever possible the sand was borrowed in the direct neighbourhood of the fill site at a location with a mild current and wave climate. The lowest prices were reached if the sand was pumped directly by the dredger to the shore. In some cases the sand was borrowed from other dredging operations such as harbour extension. In the past decade the possibilities of direct pumping decreased. The main reasons were less capital dredging, the fear for instability of the coastal profile and the prohibition of sand extraction in the closed tidal inlets.

In cases where a shipping channel had to be crossed, where the transport distance was very long or where the sand was borrowed from maintenance dredging, the sand was transported in hoppers. In some projects with small amounts stationary hopper dredgers (hopper volume 500 to 2000 m³) were used in combination with a reclamation dredger near the beach. Generally trailing suction hopper dredgers (hopper volume 1500 to 8000 m³) are used at present. Depending on the draught of the vessel, the depth at the mooring point on the foreshore must be MSL -5 to 12 m. Mostly a combination of a flexible floating pipe and a pipe on the bottom is needed for the transport through the surf zone. In case of a flat shoreface the distance can be so long that an extra source of power is needed (fig.4).

Originally the sand for dune strengthenings often was extracted in the dune area itself and transported by truck (fig.5). This process is not considered as nourishment and therefore is not mentioned in table 1. If the sand came by hopper from elsewhere two main execution methods were used:

-At the back or on the top of the dunes.

With the use of bunds a depot on the beach was made. After some months of desalination the sand was transported by dumping-carts to the fill site.

-At the dune face.

With the use of bunds in 2 or 3 layers the sand was pumped up to a height of about 10 m above MSL.

In the future mining of sand only will be allowed seaward of the MSL - 20 m depth contour to avoid effects on coastal profile stability as much as possible. Exceptions are made for mining in shipping channels and locations where by means of the sand extraction a better morphological situation can be created.

figure 4. Mooring point at the Holland coast.

figure 5. Dune heightening and sand extraction at Walcheren.

2.5 Costs

The price per m^3 depends on many factors, for example: the amount of sand, the circumstances for the dredging operations, the transport distance and labour market tensions. Therefore it is impossible to obtain absolutely comparable data. Nevertheless a relation has been made between the m^3 -price and the quantity of sand, in which the reported project costs have been indexed to a standard price level. Because of the strong labour market tensions, projects in the last 5 years are excluded. Also excluded are projects of which the sand was borrowed from other dredging operations. Figure 6 gives the relation between the sand quantities and the m^3 -prices, indexed to a 1985 price level. The following general conclusions can be made:

- The lowest prices per cubic meter were attained when relatively large amounts were handled, and by operations where the sand was directly spouted to the fill site.
- The most expensive method was that by which the sand was transported by hopper-dredgers and spouted either by the hopper itself or with assistance of a (barge unloading) dredger, or transported further by dump truck.

It should be remarked that before 1985 no big beach nourishment projects were carried out by means of hopper dredgers. Furthermore the equipment used by the hopper dredgers to bring the sand ashore was less developed than at present, so nowadays the price difference between hydraulic transport and water carriage probably will be less.

figure 6. Cubic meter price in relation to sand quantity.

a. Ameland (1980)

b. Schouwen (1987)

c. Walcheren (1984)

figure 7. Examples of cross shore profiles.

2.6 Examples

To get an impression of the applied types of sand fills in cross shore direction, in figure 7 profiles at some nourishment locations are shown.

Ameland.

Along the North Sea coast of the Isle of Ameland dune erosion occurred during storm surges. To protect the valuable dune area, in 1980 6 km of the duneface of the outer ridge were restored with 2.2 million m³ of sand. The main objective of this type of fill was to have the optimum protection with the available budget. After nourishing of course the profile was out of balance, so in the following years a natural profile was shaped.

Schouwen.

At the Schouwen coast the shifting of a tidal gully caused severe shoreline withdrawal over many decades. To protect the nature of the area and drinking water reservoir in the dune area, in 1987 in a stretch of 2.3 km the gully was artificially shifted in seaward direction. By a stationary dredger 1.5 million m³ of sand was extracted from the edge of the shoal and pumped through a floating pipe to a pontoon at the shoreface. By means of a booster the shoreface was nourished. The beach was restored by the so-called "rainbow method" (fig.8).

figure 8. Rainbow system at the Schouwen coast.

Walcheren.

Over time the south-western coast of Walcheren was eroded by a shifting tidal channel. Although the erosion of the shoreface nearly stopped, dune erosion went on in spite of a dense groyne field. To maintain a sufficient safety level of the dune ridge, in 1984 a restoration of the back-

shore and the duneface was carried out. Because of the narrow beach and the fear for losses to the very steep shoreface only 0.1 million m³ could be placed. The profile development was as expected and it appears that the required safety level can be maintained by replenishment with intervals of about 5 years.

2.7 Environmental aspects

In general the environmental effects of artificial nourishment in the coastal zone are temporary. In case of sandfills against the duneface, percolation of salt water posed problems to dune vegetation or agriculture at some locations. The effects on the beach fauna were investigated on the Isles of Ameland and Texel (Dankers et al, 1983). It appeared that after 20 months the biomasses returned to a normal level. At the Schouwen coast the influence on the beach was negligible (Adriaanse and Coosen, 1990). In the borrow area there was a temporary influence. Though the benthic community was destroyed, within some months the area was taken over by pioneers and after a year a

community had developed, belonging to the new habitat, that was very similar to the nearby gully. At Schouwen as an effect of the rainbow-system during some months, damage to the dune vegetation could be observed.

3. EFFECTIVENESS OF ARTIFICIAL BEACH NOURISHMENT

3.1 Evaluation.

To inform the Minister of Transport and Public Works about the possibilities of coast line maintenance by means of beach nourishment, 9 representative projects have been selected for an evaluation (Pluym, 1988). Figure 9 shows the locations of these projects. In general the aim of these projects was to compensate erosion, in some cases after a

figure 9. Evaluated nourishment projects.

figure 10. Critical effectiveness of groynes.

dune strengthening. One project was carried out in order to create a better recreational beach. The criterium for the evaluation was: Was (or will be) the duration of life of the beach fill as expected?

The main conclusions are:

- 7 of the 9 evaluated projects were succesful and in one case the expectations are positive. Only one project did not meet the expectations. In the tidal inlet north of the island of Texel over a period of 6 years, a large amount of sand was extracted three times. This has likely influenced the behaviour of the 1985 sandfill at the adjacent coastal section. The nourished volume had disappeared after 4 years instead of the planned 5 years.
- It seems possible to design a beach nourishment with a planned duration of life, even in a dynamic coastal situation with a sometimes capricious morphological behaviour.
- Artificial beach nourishment is very effective as a measure for coast line maintenance.

3.2 Relation with groynes

To maintain the present shoreline, sand fills have to be repeated regularly and therefore can be expensive. However, in comparison to the capitalized costs of building and maintenance of groynes, nourishment for the most appears to be cheaper. Furthermore groynes cannot fully stop erosion, so supplementary nourishment is needed. On behalf of the Coastal Defence Study, a costs comparison has been made for several technical solutions for erosion control (Beafort et al, 1989). As an example figure 10

shows the calculated graphs for the 3 coastal types, with the critical effectiveness of new build groynes due to shoreline withdrawal.

The critical effectiveness is defined as the percentage of the erosion that has to be stopped by the groynes to make shoreline maintenance by means of new build groynes and additional nourishment cheaper than shoreline maintenance by nourishment alone. These calculations also have been made for scenario's with maintaining existing groynes and with removing them. Considering the supposed effectiveness of the groynes, the following situations are concluded:

a. Sandy coastline without groynes:

generally, the construction of just groynes is not advisable for reasons of effectiveness and costs;

in the delta area, where landward shifting of tidal channels presents erosion problems, a combination of groynes and nourishment may be cost effective.

b. Sandy coast with groynes:

existing groynes must be maintained for reasons of erosion control;

the costs of nourishing such a coast are relatively low compared to the costs of nourishment in case of removal of the groynes.

The costs of the construction and maintenance of groynes have been derived from prices reported by coastal managers. For future nourishment projects cost estimations have been made. The variable circumstances for dredging operations along the Dutch coast imply various execution methods with different dredging equipment. Therefore the estimated costs per m^3 (on the beach) differ from Hfl 3.00 in case of large amounts and favourable circumstances, to over Hfl 10.00 in case of small amounts and unfavourable conditions. If the sand has to be transported from the beach into the dune area, the extra costs amount from Hfl 4.00 to Hfl 5.50 per m^3 .

Abstract

Because of the increasing need of sand for use on land and coastal protection, offshore sand extraction has become commonplace. On the other hand, the practice of beach nourishment has become a common method to combat beach erosion. Here, economic and other interests may be served by dumping the sand not directly onto the beaches, but nearshore. Within the framework of the Coastal Defence Study for the Dutch coast and the preparation of a Marine Aggregate Extraction Plan model studies were performed in order to obtain indications and quantitative estimates of the morphological effects of offshore sand extraction and nearshore profile nourishment. The major results of the model computations are:

- offshore sand extraction landward of the 16 m isobath may affect the coastline within a century.
- nearshore nourishments landward of the 7 m isobath have positive effects on the coastline.

The model computations could not be validated in the field. Due to the relatively large margins of inaccuracy the political implication of this study is that sand extraction landward of the 20 m. isobath is not licensed.

Introduction

Within the framework of the Coastal Defence Study for the Dutch coast several methods to combat beach erosion have been investigated (Roelse, this volume). One of these methods, and maybe a very promising one, is nearshore profile nourishment. This method consists of the nearshore dumping of sand, say landward of the 10 m. isobath in the breaker zone, followed by onshore transport by the orbital wave motion.

in the breaker zone, followed by onshore transport by the orbital wave motion. Encouraging field experience with this method has been gained in e.g. Australia (Jackson & Tomlinson, 1990).

For all kinds of nourishments the sand will be extracted offshore. From a coastal zone management point of view offshore sand extraction is an interesting problem. On the one hand sand extraction becomes more expensive with increasing distance offshore (in the Dutch situation several percents of the m³ price per kilometer). On the other hand sand extraction nearshore may induce coastal erosion, because extraction can be considered as withdrawal of sand from the sand budget of the shoreface and adjacent beaches and dunes. In the past the Dutch regulatory authority did not license sand extraction landward of the 20 m. isobath. This policy was based on the idea that wave induced onshore sand transport becomes increasingly important in shallow waters, especially landward of the 20 m. isobath. Results of foreign field studies indicated a similar value (Migniot & Viguier, 1980; C.E.R.C., 1984)

Within the framework of the Coastal Defence Study and the preparation of a Marine Aggregate Extraction Plan for the Dutch part of the North Sea model studies were performed to obtain better and more quantitative estimates of the morphological effects of offshore sand extraction and nearshore nourishments. Various existing modelling techniques for waves, currents, sediment transport and morphology were applied, combined with new knowledge, field data and surveys.

This paper will address the morphological impact of offshore sand extraction and nearshore nourishment, including nourishment with simultaneous extraction. The approach adopted and representative results are presented.

General background

The orientation of the Dutch coastal section considered changes from SW-NE in the southern part to S-N in the northern part (see Table 1). The 20 m. isobath, situated 5 to 15 km. offshore, separates the shelf from the sloping shoreface, on which wave action becomes increasingly important with decreasing waterdepth. Shoreface gradients vary from 1:1000 near the 20 m. isobath to 1:100 near the 10 m. isobath, which is situated about 1 km. offshore. Landward of the 10 m. isobath breaker bars are abundant. Shoreface sediments consist of non-cohesive sands with a median grain size of 0.150-0.300 mm.

Sediment transport on the upper shoreface (breaker or active zone, situated landward of about the 8 m. isobath) is wave dominated due to wave asymmetry, swell action, breaking waves and wave induced currents. On the lower shoreface sediment transport is dominated by tidal currents. They are mainly longshore directed and reach maximum surface velocities of about 1.0 m/s. Tidal action, wind, salinity gradients and waves induce relatively small residual currents. A persistent landward residual bottom current of about 0.03 m/s. exists on the Dutch shoreface (Van der Giessen et al., 1990).

Especially during storm conditions waves act as a stirring mechanism, bringing sand into suspension and ready for transport by currents. Waves approach the coastline predominantly from directions varying from 240 to 360. Year averaged wave height and period are about 1 m. and 5 s. respectively.

Set-up of the study

Although a reasonable qualitative knowledge exists of the dominant physical processes

of sediment transport in the Dutch coastal zone, there is still a considerable lack of:

- quantitative descriptions of these processes
- knowledge of the representative input conditions
- verification and calibration of the existing mathematical models in the field.

Moreover, no general two-dimensional morphodynamic modelling system is available yet in which the sub-models for hydrodynamics and sediment transport are applied in direct interaction with computed changes in sea bed level. Nevertheless, in the present study an attempt was made to estimate and compare morphological effects of different sand extraction and/or near-shore nourishment schemes with relatively simple existing mathematical modelling techniques.

The study focussed on different locations along the Dutch coast (Table 1).

	EXTRACTION			NOURISHMENT			EXTRACTION + NOURISHMENT
LOCATION	S	B		D	N	E	D
ISOBATH (m)	10,	16,	20	3, 5, 7,	10		10+ 5
VOLUME* (10 ⁶ m ³)	0,2	1	10				
(m ³ /m)	100,	500,	2000, 5000	100 , 200			100

Table 1: extraction and nourishment schemes: locations and variants. S = Scheveningen, D = Delfland, N = Noordwijk, E = Egmond, B = Bergen. *: different volumes of extraction are obtained by different combinations of extraction length (2000 and 5000 m.), width (100, 500 and 1000 m.) and depth (1, 2 and 5 m.).

Different sand extraction schemes between the 10 and 20 m. isobath were analyzed, varying in length, width and extraction depth and, accordingly, in volume (Table 1). Nourishment schemes were assumed between the 3 and 10 m. isobath, varying in width and height. One combined extraction (10 m.) and nourishment (5 m.) simulation was performed.

The morphological processes, as distinguished in the present approach, are outlined in Figure 1.

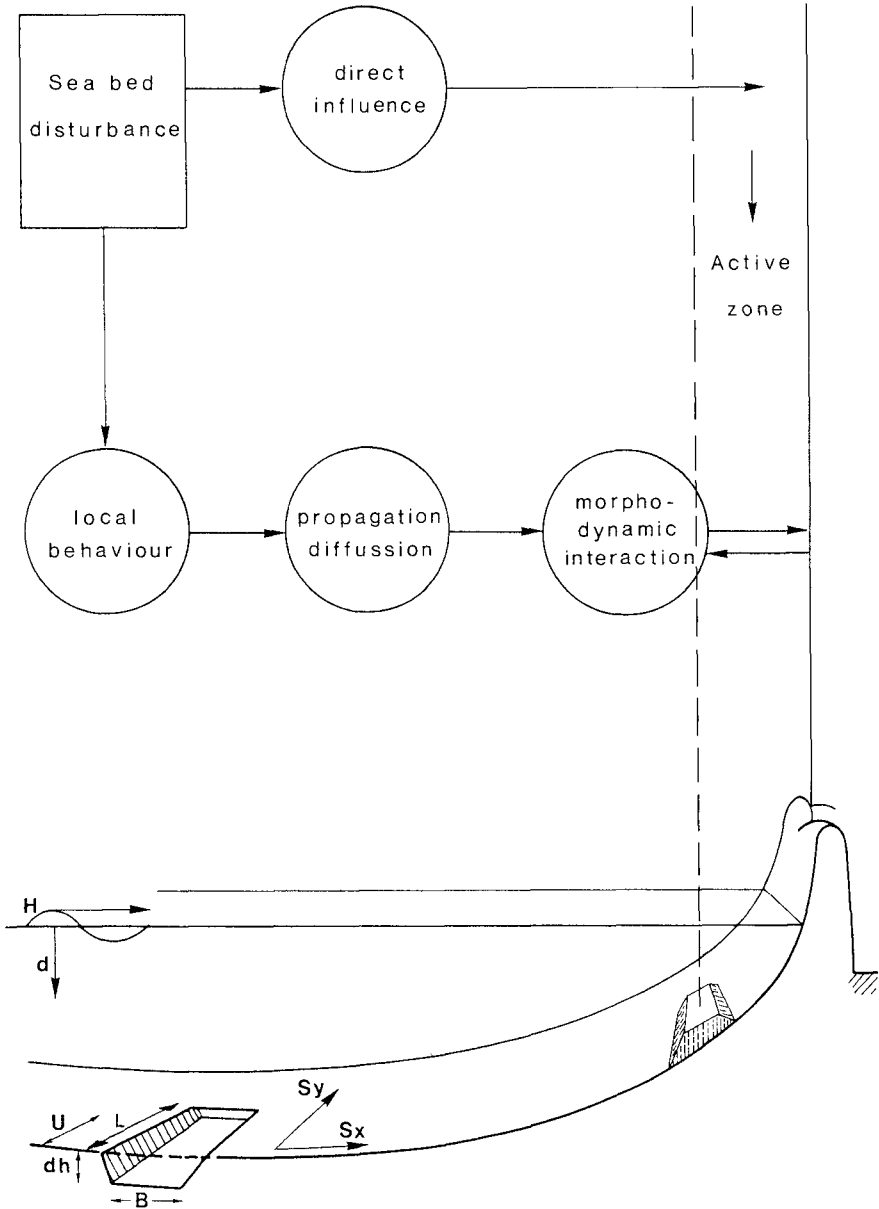

Figure 1: schematization of relevant processes, symbol definition (H = wave height (m), d = water depth (m), dh = depth of extraction (m), B = width of extraction (m), L = length of extraction (m), U = tidal current (m/s), S_x , S_y = cross-shore and along-shore component of sediment transport).

Sand extraction in relatively deep water leads to a local disturbance of the sea bed topography which, under the combined action of waves and currents, can directly affect the hydrodynamics, sediment transport and morphology of the near-shore zone. Moreover, the local sea bed disturbance may lead to erosion of the near-shore zone at a larger time-scale, for example by onshore propagation/diffusion of the extraction pit and/or by acting as a sink for sediment that is eroded from the near-shore zone.

The direct hydrodynamic effects of the different extraction schemes were analyzed by studying:

- the disturbance of the tidal current pattern around the extraction pit (streamline convergence/ divergence), using a two-dimensional (2DH) flow model for depth-averaged currents and water levels.
- the disturbance of the waves (refraction), using a wave field model to obtain the 2DH propagation, refraction and energy dissipation.

The direct and long term morphodynamics of the extraction pits were estimated in longshore and cross-shore direction separately, assuming that this is allowed within certain time limits.

The cross-shore development of the different extraction schemes was computed with a one-dimensional morphodynamic model (CROSTRAN, see Roelvink and Stive, 1988), in which the sediment transport model of Bailard (1981) is adopted. The hydrodynamic input of the transport model is derived from a one-dimensional wave energy decay model in combination with:

- non-linear wave theory for the computation of near-bed velocities (wave asymmetry),
- wave induced net bottom currents (drift currents)
- a persistent onshore directed residual bottom current of 0.03 m/s.

Input conditions were derived from a schematized measured deep water wave climate. The longshore development of the different extraction schemes was estimated with a quasi-2DH morphodynamic model (LOMOR). The sediment transport in longshore direction is dominated by tidal currents. The behaviour of the tidal current along the extraction pit is computed with a simplified steady 2DH flow model. It is assumed that the longshore axis of the pit coincides with the (undisturbed) tidal flow direction and can be considered as symmetry-axis. This model is applied in a quasi-steady way at 10 moments during a characteristic tidal cycle (12h 30 min), using boundary conditions from a calibrated overall 2DH flow model of the area (without seabed disturbance). To be consistent with the cross-shore model the same sediment transport (capacity) formulation, based on the same Bailard model, is used. The sediment stirring effect of waves is incorporated for a selected characteristic wave height-wave period combination ($H_s = 1.5$ m., $T = 6$ s.).

The adjustment of suspended load transport to the changing hydraulic conditions is modelled with a depth-averaged suspended load model, based on Galappatti (1983). Computed local erosion and sedimentation rates are integrated over the tidal cycle. Bed level changes are computed after selecting an appropriate morphological time step. The adjusted sea bed topography is then fed back into the flow model and the computation with the morphological model is repeated. With this technique the long term morphodynamics of the different extraction schemes were estimated for periods up to 40 years.

As a result of the process-schematization and modelling techniques time estimates have

an inaccuracy in the order of a factor 3 to 5.

The nourishment schemes are situated inside the active zone. Here sediment transport is more intense and morphological changes take place on shorter time-scales than on the lower shoreface.

The sediment transport and morphodynamics of the nourishment schemes and nearshore profile were also studied with the above mentioned CROSTRAN model. This model proved to be able to simulate some overall characteristics of the natural nearshore behaviour of e.g. breaker bars (Roelvink and Stive, this volume). Input for this nearshore application were daily averaged values of wave height, wave period and swell characteristics derived from a deep water wave record of 1983. In the computations this time sequence of wave conditions was used as input for 6 consecutive years. The same model was also applied for the combined extraction-nourishment scheme.

Results

The direct effects of extraction on the cross shore distribution of the near bed maximum tidal current velocity is shown in Figure 2a. Only an extreme extraction of 5 m. at a waterdepth of 14 m. ($L = 2000$ m., $W = 1000$ m.) gives a small decrease (about 10 %). On both sides of the extraction pit the width of the affected area is about two times the extraction width. There are no immediate effects landward of the 10 m. isobath.

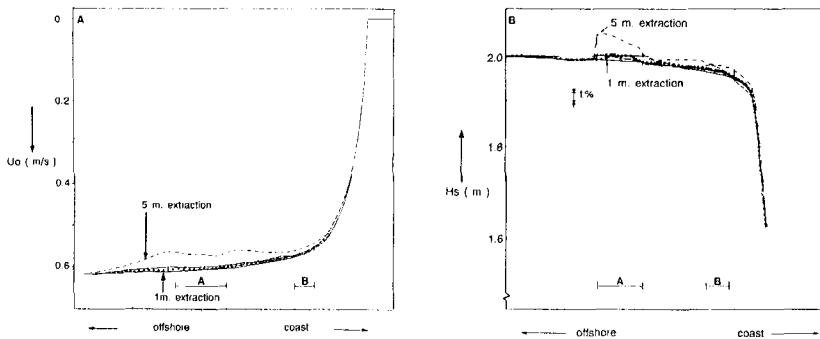

Figure 2a: predicted cross-shore distribution of near bed tidal current velocity and (b) significant wave height. Sand extraction at $d = 14$ m. (A: $W = 1000$ m., $dh = 1$ m. and 5 m.) and at $d = 10$ m. (B: $W = 500$ m., $dh = 1$ m.).

The immediate effect of extraction on the wave climate is local and minor as well. Figure 2b shows that in case of incoming waves ($H = 2$ m., $T = 6$ s.) only an extreme extraction of 5 m. on the 14 m. isobath results in a 1 % increase of the wave height which has disappeared before the 10 m. isobath.

Because of these minor direct changes in hydrodynamics, instantaneous morphological adaptation is negligible as well. Computations on initial transport show that within the affected area vertical sea bed movements are within the order of 0.001 to 0.01 m. per year, which is insignificant compared to the inaccuracy of sounding.

The predicted longterm longshore behaviour of the extraction pit and near bed current

velocity is shown in Figure 3.

In this case the extraction pit is situated on the 16 m. isobath ($L = 2000$ m., $W = 300$ m., $dh = 1$ m., $t = 15$ years). Initially there are gradients in current speed near the head and tail of the pit, but because of the interaction between currents and morphology the steep sea bed slopes become smaller and the gradients in velocity decrease in time. Apart from this diffusive kind of behaviour the pit is relatively stable in time under the given input conditions. Similar results were obtained for other locations and extraction volumes.

Figure 3a: predicted longshore behaviour of extraction pit and (b) near bed tidal current velocity. $d = 16$ m., $L = 2000$ m., $W = 300$ m., $dh = 1$ m., $t = 15$ years.

The predicted longterm effects in cross-shore direction are shown in Figure 4a and 4b. for extractions on the 20 m. and 16 m. isobath respectively. Extraction on the 20 m. isobath shows almost no cross shore effects, the pit remains stable for at least 40 years.

Extraction on the 16 m. isobath results in a minor change in depth of the pit. In addition, as a result of a small net onshore sediment transport, deposition on the offshore margin and erosion of the landward boundary leads to a onshore migration of the pit with a rate of 1 to 2 m. per year. The gradients in the profile smooth in time.

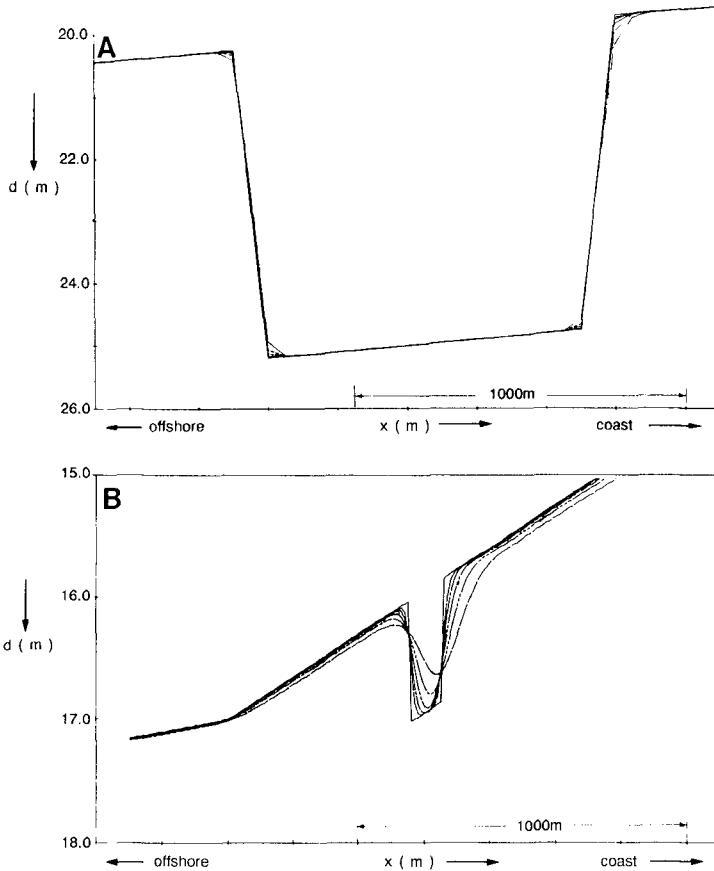

Figure 4a: predicted cross-shore behaviour of extraction pit at $d = 20$ m. ($W = 1000$ m., $dh = 5$ m.) and (b) $d = 16$ m. ($W = 100$ m., $dh = 1$ m.) over a period of 40 years.

According to the CROSTRAN and LOMOR computations the morphological development of the pit mainly occurs at the boundaries of the pit and take place in similar time scales in long and cross-shore direction. This indicates that the separate treatment in long and cross-shore dynamics is justified within the time limits considered (40 years).

By comparing Figure 4a with 4b the increasing importance of wave action with

decreasing waterdepth and distance offshore is illustrated. As a consequence of this phenomenon predicted migration rates of sea bed disturbances speed up rapidly landward of the 16 m. isobath (Figure 5a). Based on these migration rates the necessary time for the head of a given extraction to reach a given isobath was estimated. Figure 5b shows that at Scheveningen the head of an extraction landward of the 14 m. isobath may reach the active zone within a century. It was found that with steeper shoreface slopes the time scale for a sea bed disturbance to reach the active zone decreases. E.g. at Bergen this time scale is twice as small (shoreface slopes between the 10 and 14 m isobath are 0.0016 and 0.0040 for Scheveningen and Bergen respectively).

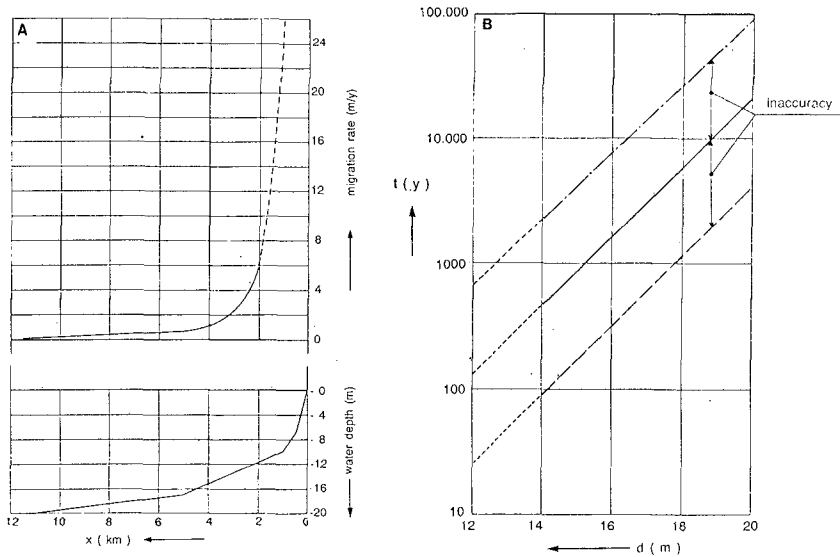

Figure 5a: predicted cross-shore migration rate (m/y) of sea bed disturbance at Scheveningen (S in Table 1) and (b) time necessary to reach the active zone. The dashed lines indicate the margins of inaccuracy.

It should be noted that the time needed for the head of the pit to reach the breaker zone is dependent on the cross shore sand transport rates rather than on the amount of extraction. However when the pit approaches the shore, the amount extracted represents the lack in the sand budget. Then it determines the rate of erosion and the period erosion prevails.

Figure 6 shows the behaviour of a nearshore nourishment of 100 m^3 per m. on the 3, 5 and 7 m. isobath. The thickness of the nourishment is 1 m. As a result of wave induced onshore transport in the landward part and a seaward directed undertow the nourishment volume is divided into an onshore and offshore directed transport in all cases. However when deposited on the 7 m. isobath only a small part of the original volume reaches the beach within 6 years.

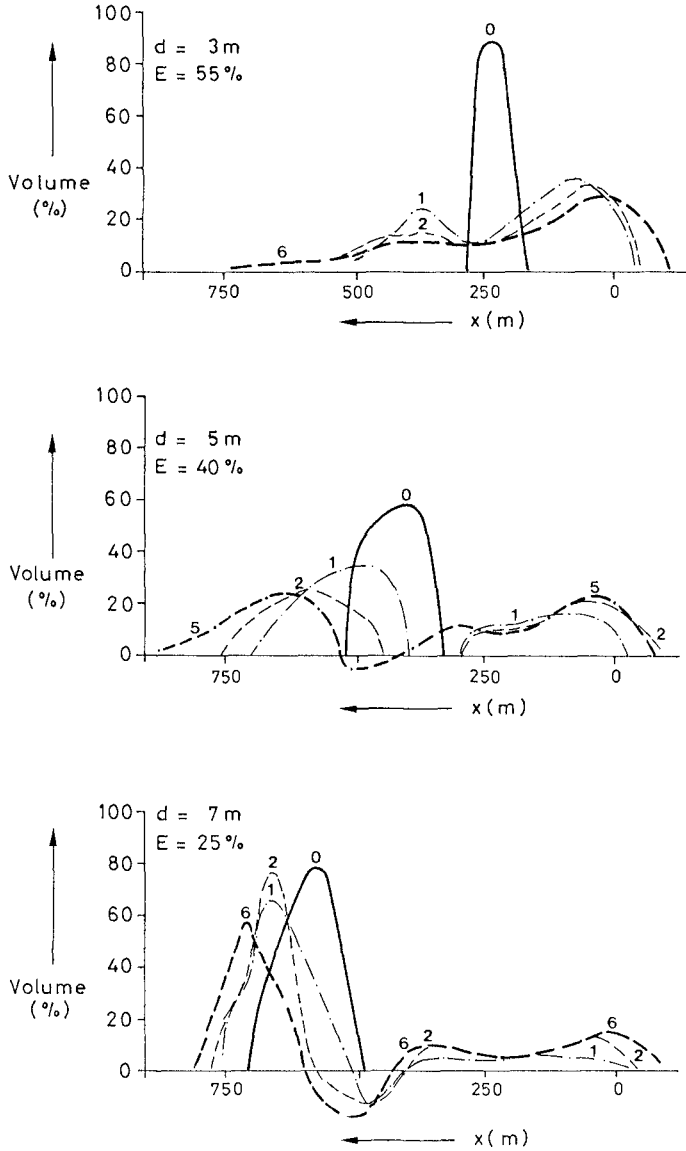

Figure 6: relative volumetric distribution of 100 m³/m profile nourishments at waterdepths of 3, 5 and 7 m. in time. E = Effectivity (see text).

The effectivity of the nearshore nourishment (E) is expressed as the volumetric change of a 300 m. wide zone along a line of reference on the beach, compared to the original volume of the nourishment. It can be seen that the effectivity of nourishments increases in a landward direction: from 25 % of nourishments on the 7 m. isobath towards 55 % of those on the 3 m. isobath. With other words, the seaward loss of the nourishment volume decreases with nourishments in shallower water.

These results hold for the Delfland location but are similar on other locations. It was also found that the relative distribution of the initial volume over the profile is independent on the volume of the nourishment.

Figure 7: relative volumetric distribution of 100 m³/m. profile nourishment at d = 5 m. after 6 years, with (A) and without (B) simultaneous extraction of 100 m³/m. at d = 10 m.

The effect of extraction during nourishment was studied in a model run with a 100 m³/m. nourishment on the 5 m. isobath and simultaneous extraction of the same amount on the 10 m. isobath. The distribution of the nourishment volume after 6 years with (A) and without (B) extraction is very similar (Figure 7). Only in the most seaward part of the profile with extraction the sea bed is a little lower. It looks as if the sand extraction nearby has no negative effects on the nourishment itself within this period of 6 years. However, the long term studies presented in the former section suggest that on a timescale of decades to centuries detrimental effects may show up in this zone due to the approach of the extraction pit. The lowering of the seabed in the seaward part of the profile may be a signal of this already.

Conclusions

The computations performed showed the following results:

- the direct effects of the studied sand extraction schemes on hydrodynamics (current and wave climate) are very local. On both sides of the extraction pit the affected area has a width that is two times the extraction width.
- on the long term sand extraction landward of the 16 m. isobath may affect the coastline within a
- century by landward migration of the extraction pit, leading to a deficit in the nearshore sand budget.

- nourishments landward of the 7 m. isobath have positive effects on the coastline.
- simultaneous extraction has no significant effects on the nourishment within a period of 6 years, but may have on a larger time scale.

It should be emphasized that the results presented could not be verified in the field. A large scale field experiment like the one reported in Jackson & Tomlinson (this volume) is urgently needed to validate the models and assumptions on which the results are based, and to reduce the margins of inaccuracy.

The political implication of this study is that, from a precautionary point of view, the Dutch regulatory authority will refrain from licensing sand extraction landward of the 20 m. isobath, even if this sand extraction is meant for nourishments (an exception is made for extraction in navigation channels). In addition the Environmental Impact Assessment, prepared for the Dutch Marine Aggregate Extraction Plan, showed that this zone landward of the 20 m. isobath coincides with a area that is very valuable from an environmental point of view (i.e. relatively rich in benthic life and nursery area for several species of commercial fish).

CHAPTER 152

SEAWARD COASTAL DEFENCE FOR THE DUTCH COAST

The Dutch coast : Paper No. 13

Marco Pluijm

1. INTRODUCTION.

The Dutch Delta-works are nearing their completion. Decades of construction of dikes and dunes come to an end. It is obvious that after the completion of these Delta-works, this infrastructure of coastal defence works needs its year to year maintenance as well. Therefore the Dutch Government asked for the so called "Coastal Defence study" and mobilized all the available knowledge with respect to this item, in order to draft a report with which the political decisionmakers could come to the selection of the most suitable maintenance-strategy. Four different possibilities were investigated.

It appeared that the so-called full maintenance strategy will be the most cost effective and profitable solution and was therefore chosen. According to this strategy all retreat of the coastline will always be compensated (in general by beach-nourishment).

However, some parts of the Dutch coast are facing extreme erosion as well as very poor reserves and for those locations the application of a somewhat different approach can be profitable or (in time) even necessary (for instance with respect to sealevel rise). This approach was roughly investigated as the "Seaward Coastal Defence" strategy. According to this strategy additional measures will be taken to influence the morphological system in such a way, that the coastline will not erode any longer, but be kept on its place or even grow in seaward direction. The effectiveness of this approach has to be compared with maintenance by beach-nourishment as such as well as the effects it will have elsewhere on the morphological system.

A pilot-study has been defined at the isle of Texel. The north-point of this island suffers severe erosion. Several beach-nourishments have been carried out here. Unfortunately the effectiveness was not always as planned.

This paper contains a brief description of the seaward strategy as such and more specific the preliminary results of the "Texel" pilot-study as obtained so far. In 1991 the finite conclusions will be available.

Rijkswaterstaat, Tidal Waters Division, P.O.Box 20907, 2500 EX The Hague, The Netherlands

2. SEAWARD COASTAL DEFENCE STRATEGY.

In the Coastal Defence study four strategies have been worked out, respectively retreat (only the real hot spots will be maintained for safety reasons), partially maintenance (also some other uses of the coastal zone can be a reason for maintenance), full maintenance (all retreat of the coastline will always be repaired) and "seaward".

The seaward-strategy aims permanent reinforcement of the weakest, heavy eroding spots along the Dutch coast by "changing" the erosion into a more or less stable situation or even sedimentation. In order to start this process, it is necessary to influence the (large scale) sand-transport phenomena along the Dutch coast. The placement of an initial construction will be the driving force behind this "sand-trapping" process. Because of the difference between the several morphological systems along the Dutch coast, it is not possible to suffice with one solution. Therefore for each of the hot spots specific solutions have been created (tabel 1 and figure 1).

name	aim	construction
Texel	creation of sedimentation along eroding coast. sedimentation, (partially)	large dam, perpendicular to the coastline. In case of to large timescale for natural artificially nourishment to an extended beach.
N.Holland	creation of sedimentation along eroding coast	one or two large dams, perpendicular to the coastline. In case of to large a timescale of sedimentation, artificial placement of sand in the shape of a beach or barrier with a lagoon.
Voordelta	reduction of wave attack	artificial initial raise of sandbanks with ridges of stone or "sand-sausages", stimulation of sand accumulation with artificial seaweed, creation of sand-drift.
Walcheren	prevention of progression erosion by currents	two or more dams to shift currents. Stimulation of sedimentation in an enclosed area.
Cadzand	prevention of negative effects "sandwaves"	sub-merged dams between the groynes. Pending beach.

tabel 1 : possible "seaward" solutions for the Dutch coast

figure 1 : view of possible solutions for seaward defence

These sketches are of an preliminary status. They are based on many assumptions and with respect to several items, further research will be necessary. Therefore Rijkswaterstaat has decided to start a pilot study.

The most likely location for such a study has been found on the heavily eroding northern point of the isle of Texel.

3. THE "TEXEL" PILOT-STUDY.

The pilot-study concerns the hydraulical and morphological background of the erosion at the north part of the isle of Texel, the layout and construction of some solution(s) and determination of its effectiveness from morphological and economical point of view. These solutions have to be compared with the present way of coastline maintenance i.e. beach-nourishments.

3.1 large scale morphological behaviour.

With respect to the large scale sand transport phenomena, the following remarks can be made. Along the Northsea-coast of the isle of Texel sand is transported in northern and southern direction to the Robbengat and the Molengat (fig. 2) due to the combined effect of longshore and tidal currents. This results in a net loss of sand in the direction of the Wadden-sea.

The Delta between the isle's Texel and Vlieland does show a clear system of eb-tidal channels ("Eierlandse Gat"). The system of flood-tidal channels is far less developed. Both types of channels play its role in the transport of sand in the direction of the isle of Vlieland. Some sand is transported directly along the sea-ward boundaries of this delta due to wave-action.

Some sand is trapped into the so called Slufter, an intertidal area behind the dunes just above the center of the island.

figure 2 : morphological scheme.

From the south the coastline of the island is supplied with sand from the delta between the coast of North-Holland and Texel ("Zeegat van Texel")

Due to cross-shore transport some sand is supplied from deeper water to the coastal zone. This quantity is believed to be of minor importance compared to the mentioned longshore processes.

All this moving sand can not prevent that the entire coastline of the island retreats. In the center of the island this retreat is 1 to 5 meters per year, increasing in northern and southern direction up to 20 meters per year and even more. At some places a retreat of even 30 meters in one year has been occurred.

Predictions have been made, and if nothing would have been done, the coastline north of the Slufter would show an average retreat of 100 to 150 meters for the next ten years (fig. 3).

A retreat like that is absolutely not acceptable for reasons of nature and shipping traffic (a lighthouse is standing close to the edge). Therefore beach nourishments have been carried out.

Upto now in 1979 ($3 \cdot 10^6$ m³) and in 1985 ($2.8 \cdot 10^6$ m³) along this stretch and in 1984 3 billion m³ along the middle of the island. This year the nourishment of 1985 had been disappeared completely. Some parts of the coastline retreated even much further. At present a nourishment is carried out.

The problem with nourishments along this coastline is, that in fact there is not enough

figure 3 : prediction position of dunefront

space to place the sand in such a way that it will not be eroded directly at the toe by tidal currents (fig. 4). From economical point of view, reduction of quantity is therefore needed or the use of coarser material. The latter solution was chosen for the nourishment of this year.

BEACH NOURISHMENT

TEXEL km. 28.4

figure 4 : cross-section beach nourishment 1979

3.2 small scale morphological behaviour.

The coastline of Eierland (north of the Slufter) loses a quantity of sand with an average of 400.000 m³ to 500.000 m³ per year (fig. 5). These figures were valid for the “undisturbed” situation, so before the first nourishment had been carried out. Since then these figures have increased (to 600.000 m³ per year) due to the effect mentioned earlier i.e. the lack of space for placing the right quantity of sand without coming under the direct influence of the tidal currents. As stated before, these quantities are average values and will vary from year to year.

figure 5 : erosion quantities (observed).

These quantities have been established from the yearly soundings of the coastal zone (JarKus = Jaarlijkse Kustmetingen). These soundings have also been used for the analysis of the development of the cross-shore profiles. From this it can be concluded that two different zones can be distinguished. A zone of about 400 meters from the dune-foot with a rapidly changing bottom-topography, followed by a zone of about 600 meters seaward with a rather flat and stable topography.

In the autonomous situation in the first zone the loss of sand amounts approximately 400.000 m^3 per year and in the second zone approx. 125.000 m^3 per year. After the first nourishment the figure for the first zone increased to about 600.000 m^3 per year, whereas in the second seaward zone a sedimentation of about 100.000 m^3 per year was established soon after the works had been completed. However, this was only for a short time. Soon erosion also started here again.

Apart from these figures obtained from measurements, also calculations with relatively simple mathematical models were made on a personal computer. The aim of these calculations was to investigate the different contributions of the transport phenomena with respect to the observed processes.

Calculations were made with respect to wave-height, wave setup, longshore currents and tidal currents, sediment transport (several approaches), dune erosion, etc. It appeared that each of the components could be obtained rather well, compared to the available data. For instance the transport capacities due to the differences in wave setup along this coastline could be checked with tide gauge measurements under storm conditions.

The following contributions to the total erosion due to transport-capacities were calculated (fig. 6) :

- * 60 percent due to waves and currents under normal, "average" conditions;
- * 20 percent due to tidal currents without wave-action;
- * 20 percent due to differences in wave-setup under storm conditions.

This last figure, the 20 percent due to differences in wave-setup under storm conditions, could seem to be of minor importance, but it should be stated that under these circumstances the eroding sand from the dune-front will be transported directly from the coastal zone to elsewhere and does not supply the foreshore. Therefore it will not contribute to the reduction of dune-erosion under these circumstances and will also not be available for the natural restoration processes afterwards.

TRANSPORT PHENOMENA

figure 6 : contributions to erosion (calculated).

3.3 next fase of the study.

The first phase of the study was directed to the establishment of the erosion quantities and the phenomena responsible for this erosion. A first order approach appeared so far to be sufficient. This phase has come to an end now.

In the next phase more detailed research will be carried out with respect to those phenomena that appeared to be of vital importance for the development of this coastline. Therefore, a detailed mathematical model shall be made with respect to the tides (currents and elevations) in the whole area. This area includes the tidal-basin, the entire delta's and large parts of the adjacent coastlines (both islands). After tuning this model, different types of solutions to the problem will be brought in. The effect of each of these possibilities to the hydraulics can then be calculated.

From there it will be decided whether further modelling with respect to waves and sandtransport will be necessary. If so, the necessary models shall be build.

3.4 proposed solutions.

One can think of many solutions to this problem. However, it is of utmost importance that the solution chosen, will not have any negative effect elsewhere. Therefore one should be very carefull.

This could lead to the conclusion that for instance a solution with a long, "sand-trapping" dam will not be the answer. In general these harbour-mole like constructions do stimulate sedimentation on one side, but one should be very carefull with the possible

PROPOSED SOLUTION

figure 7 : proposed solution

effects due to the erosion on the other side. Especially in a sensitive morphological system like this.

It is more likely that a solution with two or three offshore breakwaters will be much better. Wave-attack on the coastline will be strongly reduced and it must also be possible to influence the tidal current in such a way that its transport capacity in the coastal zone will diminish significantly.

Pleasant features of this solution are the possibility of adaption after construction and the possibility of construction in different phases. So, in its way it is a "flexibel" solution and offers several possibilities of tuning to the morphological system. Along the Channel-coast in the northern part of France such a construction appeared to be very successful.

4. CONCLUSIONS.

- * from now on, the Dutch coast will be kept on its place according to the full-maintenance strategy;
- * the most suitable way to do so, is the placement of beach-nourishments;
- * some places facing extreme erosion and/or very poor reserves a different, seaward strategy can be necessary;
- * according to this strategy, initial measures will be taken to influence the morphological system in such a way, that retreat of the coastline will change into a more or less stable situation or even accretion;
- * one of these places is found on the isle of Texel. A pilot study is carried out;
- * each of the components behind the total erosion process has been established by analysis of measurements and first order approach calculations;
- * 60 percent of the erosion takes place due to average wave and tide conditions, 20 percent due to tides alone and 20 percent due to differences in wave setup under storm conditions;
- * more detailed research will be carried out, to start with a mathematical tidal model for the entire area;
- * the construction of two or three offshore breakwaters looks to be the most promising solution to the problem;
- * in 1991 all finite conclusions and designs will be available.

Coastal Processes and Sediment Transport

CHAPTER 153

The Effect of a Shore-Parallel Offshore Breakwater on the Beaches at Ocean City, NJ

J. Richard Weggel, F.ASCE (1)

Stewart C. Farrell (2)

Abstract

The design, construction and performance of a shore-parallel nearshore breakwater at Ocean City, NJ (USA) are described. The breakwater, which is connected to a long, high, impermeable groin at 9th Street, was constructed from armor stone removed from the groin when the groin cross-section was lowered. Constructed over a two month period in late 1987 and early 1988, the breakwater caused accretion immediately behind it and erosion along downdrift beaches. A beach fill of 40,000 cu yd of sand was recommended as a part of the original project; however, the beachfill was not placed until the spring of 1990, more than two years after the breakwater/spur was constructed. The project, in the absence of the recommended beach fill, is performing as would be expected. The sand within the groin compartment has been redistributed with a net gain behind the breakwater just downdrift of the 9th Street groin and a loss updrift of the groin at 11th Street.

Introduction

In 1987 the City of Ocean City, New Jersey, commissioned the design of a shore-parallel nearshore breakwater to provide a "sitting beach" in the vicinity of 9th Street in Ocean City. See Figure 1. The design was to be in conformance with an earlier study (Weggel, Douglass & Sorensen, 1988) which recommended that several of the existing rubble-mound groins in Ocean City be lowered so

Figure 2 Typical Breakwater/Spur Structure Cross-Section

Figure 3 Wave Environment at Ocean City, NJ from WIS Hindcasts (Jensen, 1983)

that sand would be transported over and through them during storms. The resulting breakwater design made use of stone that would become available by lowering the existing groin at 9th Street and by removing a shore-parallel groin stub on the beach face between 9th and 10th Streets. The quantity of stone that would become available by lowering the groin was incorporated into six alternative breakwater designs located in three different water depths with crest elevations of +4 feet (+1.22 m) MLW and +6 feet (1.83 m) MLW. A typical breakwater cross-section is shown in Figure 2. The alternative designs were all connected to the existing 9th Street groin to facilitate construction by land-based equipment. The structure thus formed a shore-parallel groin stub/breakwater rather than a truly detached offshore breakwater. Beach fill was recommended as an integral part of the project. Each alternative was evaluated to estimate its effect on the shoreline.

Design Analyses

The wave environment at Ocean City was determined from the Wave Information Study (WIS) hindcasts of the U.S. Army Corps of Engineers (Jensen, 1983). The 100-year significant wave height at Ocean City is about 17 ft (5.18 m). See Figure 3. Potential net longshore sand transport at the site is generally southward as evidenced by the accumulation of sand along the northerly sides of groins in the area. (About 10 blocks further north the potential net transport is northward because of the proximity of Great Egg Harbor Inlet, the sheltering of the beaches by the inlet's ebb tidal shoal, and a change in shoreline orientation.) Most southward transport takes place during the winter months because of "northeasters" - storms in the North Atlantic that generate winds and waves that approach Ocean City from the northeast. During the summer months, transport is often northward causing some reorientation of the shoreline within groin compartments. Because of the presence of the groins, however, the potential longshore transport is probably never realized. The existing groins are high, long and impermeable and the compartments formed by them are, for the most part, independent cells.

Diffraction analyses for the area behind the breakwater were used to determine if a tombolo would form and the projected shoreline configuration was used to determine how much beach fill was needed. The criterion used to estimate whether a tombolo would form was the location of the $K' = 0.3$ diffraction coefficient line for the range of directions of wave approach at the site. (The breakwater was assumed to be detached with waves propagating around each end and diffraction coefficients were determined

from diffraction diagrams for a semi-infinite breakwater. However, the interaction of the two wave systems coming around each end of the breakwater was not accounted for. Clearly, these assumptions were not met because of the presence of the 9th Street groin at the northerly end of the breakwater.) Incident wave directions at the nearshore site were assumed to range from 15° on either side of a line perpendicular to shore. The breakwater was positioned far enough offshore so that the intersection of the resulting $K' = 0.3$ lines was seaward of the original shoreline location. The post-construction shoreline configuration was estimated from the diffraction analysis. It was judged that the end of the shoreline salient would extend seaward a maximum distance of about 150 ft (45.7 m) from the pre-construction shoreline. The increase in beach area brought about by the breakwater/spur was expected to be about 1,400 sq ft (130 sq m) and, if no sand was to be lost from adjacent beaches, the required volume of fill behind the breakwater was estimated at 40,000 cu yd (30,600 cu m).

The stability of the rubble-mound breakwater/stub was evaluated using the preliminary laboratory test results obtained by Ahrens (1985) for reef-type breakwaters. Ahrens's analysis is for dumped-stone, nearshore breakwaters. He gives the crest height reduction for various levels of wave attack by the equation,

$$\frac{h_c}{h'_c} = \exp(c_0 N_S^* c_1) \quad (1)$$

in which, h_c = the height of the breakwater crest after it has been subjected to wave action, h'_c = the height of the breakwater crest before it has been subjected to wave action, c_0 = a coefficient equal to -0.0000969, and c_1 = a coefficient equal to 3.106. N_S^* = the stability number given by,

$$N_S^* = \frac{\{(H_{mo})^2 L\}^{1/3}}{(W/\tau_r)^{1/3} (\tau_r/\tau_f - 1)} \quad (2)$$

in which, $H_{mo} \approx$ the root-mean-square (rms) wave height at the breakwater, L = the wave length in the water depth at the breakwater, W = the weight of the armor stone, τ_r = the unit weight of the armor stone, and τ_f = the unit weight of the water.

The design significant wave height for the present analysis was 13.6 ft (4.15 m) or an rms height of 9.6 ft (2.9 m). The period was 10 sec. These conditions are

expected to be equalled or exceeded once in 10 years. See Figure 3. The median stone weight available in the existing structure - the material from which the new breakwater was to be built - was about 6 tons (5.45 tonnes). A nearshore breakwater built of 6 ton stone in water 5 feet (1.52 m) deep with a crest elevation of +4 feet (1.22 m) MLW would be reduced in height by no more than 2% by the design wave at the worst stage of the tide (low tide). (Waves at the breakwater were depth limited for many of the design conditions investigated.)

For the above conditions, wave transmission by overtopping can be significant. Ahrens gives the following equation for the wave transmission coefficient.

$$K_T = 1/[1 - (A_T/D_{50}^2)^{0.545} \exp(-6.726 + 3.36 h_c/d_s)] \quad (3)$$

in which, A_T = the area of the breakwater cross-section, d_s = the water depth at the breakwater, and D_{50} = the diameter of the sphere having the same volume as the median stone diameter. For the Ocean City breakwater, $K_T = 0.31$ at low tide. At high tide K_T increases to 0.86. However, some wave transmission by overtopping was deemed necessary to preclude tombolo formation. Based on the design analyses, the alternative selected was a breakwater/spur about 360 feet (109.7 m) long in water about 5 feet (1.52 m) deep, located about 150 feet (45.7 m) seaward of the existing MHW shoreline with a crest elevation 4 feet (1.22 m) above MLW (approximately at MHW). The criteria for selecting this alternative included its ease of construction, the best use of the available stone, the stability of the resulting structure in the selected water depth, and the estimated shoreline location and increased beach area. The estimated volume of beach fill needed for the selected alternative was 40,000 cubic yards (30,600 cubic meters).

Construction

Construction of the breakwater/spur began in October of 1987 and was completed by the end of January 1988. In October and November work was limited to mobilization, site work and lowering the crest elevation of the existing 9th Street groin to obtain stone to construct the breakwater/spur. There was a nine day delay in construction in early December caused by the failure to secure a required permit. Construction of the breakwater/spur itself was completed in December and January. Construction was done using land-based equipment from the tops of the groin and breakwater/spur. The total project cost was \$375,000 of which about \$350,000 was for

breakwater construction including boardwalk removal, lowering the 9th Street groin and breakwater construction. The 9-day construction delay added about \$28,000 to the cost. Beach fill was not placed until spring 1990, more than two years after completion of the breakwater/spur construction. Nourishment sand from the originally proposed source could not be obtained because of pending litigation to determine its ownership. Subsequently, another source was selected. Sand dredged from the navigation channel of Great Egg Harbor Inlet in the fall of 1989 was stockpiled at the north end of Ocean City on the inlet beaches. About 28,000 cu yd (21,400 cu m) of this sand was later trucked to the 9th Street beach and stockpiled north of the groin. In the spring of 1990 some of this sand was moved to the area behind the breakwater/spur. Only about 10,000 cu yd (7,600 cu m) could be placed behind the breakwater because of losses from the stockpile during the preceding winter. Based on a volume of 28,000 cu yd, the cost of obtaining sand for the project was \$7.26/cu yd. About \$2.68 of this cost is associated with trucking the sand from Ocean City's inlet shoreline to the 9th Street area. The rest of the cost (\$4.58/cu yd) is the difference in cost between pumping the sand to Ocean City's inlet beaches and using a hopper dredge with offshore disposal.

Beach Response

The response of beaches in the vicinity of the breakwater/spur was monitored for about 1 1/2 years. Ten profile lines were established; the most northerly profile extends seaward just south of a rubble-mound groin at 7th Street; the most southerly profile extends seaward just north of the groin at 11th Street. See Figure 1. There is also a short timber groin just south of the Music Pier located between 8th and 9th Streets. Thus beaches in the project area are affected by several groins as well as by the breakwater/spur. The lowered portion of the 9th Street groin serves as a control on the amount of sand that enters the compartment between 9th Street and 11th Street. Sand is transported over the groin only during storms and there were only one or two storms during the 1 1/2 year monitoring period during which sand transport over the groin was reported. The compartment between 9th Street and 11th Street is thus practically a closed system, at least for the period of the present analysis. A "pre-construction" survey of the profiles was obtained in November 1987. The first post-construction survey was obtained in January 1988 shortly after construction was completed. Subsequent surveys were obtained monthly during 1988 (except for October) and in January, March and May of 1989. Changes at selected profile lines occurring between November 1987

and January 1988 and February 1988 are shown in Figures 4 through 7. Significant accretion occurred behind the breakwater/spur between November 1987 and February 1988 (Figures 4 & 5). There was little change north of the project while erosion occurred south of the project (Figures 6 & 7). Erosion was greatest adjacent to the 11th Street groin (Profile 10) during this period while intermediate profiles (Profiles 8 and 9) show less erosion. While some erosion at these profiles can be attributed to the normal seasonal profile changes, it appears that the initial accretion behind the breakwater/spur has been at the expense of beaches to the south. A scour hole developed at the southern terminus of the breakwater/spur. The scour hole is shown at Profile 7 in Figure 6. Between March 1988 and August 1988 the profiles north of the site showed some accretion - possibly the normal summer profile recovery after the preceding winter. The profiles through the breakwater showed little change because of sheltering by the breakwater. Following the initial period of accretion, the beach behind the breakwater exhibited little seasonal variation. The scour hole at the terminus of the breakwater filled between March and August 1988 and the profiles south of the project showed accretion - again probably due to the normal summer recovery.

Those beach profiles between the 9th Street and 11th Street groins (Profiles 5 through 10) were subject to detailed analysis to determine how the location of the MSL shoreline and the volume of sand associated with each profile varied with time. (Refer to Figure 1 for the location of the profiles. Also note that the present analysis is for the time period preceding placement of the beach fill in the spring of 1990.) Figures 8 through 11 show the location of the MSL shoreline as a function of time at Profiles 5, 6, 7 and 10, respectively. Profiles 5 and 6 are behind the breakwater; Profile 7 is just south of the southern end of the breakwater and Profile 10 is just north of the 11th Street groin - the most southerly profile within the 9th Street to 11th Street groin compartment. The shoreline at Profile 5 (Figure 8) built out to the breakwater in less than 100 days following the start of breakwater construction. It subsequently receded for a short time but then built out to the breakwater again. The shoreline at Profile 6 (Figure 9) shows similar behavior although it took longer for the shoreline to build. The shoreline at Profile 7 (Figure 10) built out and then receded to about its pre-construction location. Profile 10 (Figure 11) shows significant initial erosion with subsequent recovery and then erosion again. Since this profile is adjacent to the 11th Street groin it shows seasonal accretion and erosion in response to seasonal changes in the direction

Figure 9 MSL Shoreline Movement at Profile 6

Figure 10 MSL Shoreline Movement at Profile 7

Figure 11 MSL Shoreline Movement at Profile 10

Figure 12 Volume Changes Below Given Contour at Profil 5 (Solid line = MSL, Long dashes = +2 ft Short dashes = +4 ft)

of wave approach. Similar behavior, although less pronounced, was observed at Profiles 8 and 9.

Figures 12 through 15 for profiles 5, 6, 7 and 10 show the cumulative change in volume below the given contour line. The solid lines with circles represents changes occurring below the +4 ft NGVD (National Geodetic Vertical Datum, or mean sea level of 1929) contour line. The long dashes with squares give changes occurring below the +2 ft contour line and the short dashes with triangles are the 0 ft contour (MSL). A positive slope represents accretion while a negative slope represents erosion. A horizontal line indicates no change in the volume of sand below the given contour. Figure 12 indicates that after the initial accretion behind the breakwater at Profile 5 little seasonal change in the volume of sand on the beach occurred. Profile 6 (Figure 13) shows a similar, but more dramatic, initial accretion with little subsequent change. Profile 7 (Figure 14) shows a small seasonal fluctuation with the profiles returning to approximately their initial condition. Profile 10 (Figure 15), however, shows rapid initial loss of sand with a subsequent reduction in the rate of loss followed by another rapid loss. Similar, but less dramatic, losses were recorded at Profiles 8 and 9.

The volume changes at Profile 5 through 10 suggest that the sand accumulation behind the breakwater is at the expense of the beaches to the south. Figure 16 is a sediment budget analysis for the beach cell between the 9th Street and 11th Street groins for the period between 7 November 1987 and 18 February 1988. Figure 16 is a mass curve showing the accretion (positive slope) and erosion (negative slope) as one moves southward along the beach from 9th Street to 11th Street. The figure shows the accretion behind the breakwater between about 0 and 300 ft (91.4 m) along the beach and the erosion along beaches farther to the south. Most of the lines on the curve return to a zero cumulative volume change at 11th Street (1,200 ft or 366 m along the beach) indicating that the volume of sand in the cell was conserved for the period of the analysis. Figure 17 summarizes the sediment budget analysis for the 7 November 1987 to 18 February 1988 time period and shows the location of accretion and erosion areas. The numbers on the figure represent the volume of sand accumulated between the given contour intervals and along the various profiles. (The vertical lines on the figure are at the midpoint between two adjacent profile lines, i.e., the first vertical line parallel with the 9th Street groin is midway between Profiles 5 and 6.)

Conclusions

The breakwater/spur at 9th Street in Ocean City has functioned as expected in the absence of the 40,000 cu yd of beach fill recommended in the original project design. Sand which has accumulated behind the breakwater has been at the expense of beaches farther to the south within the same groin cell. During the period of observation, the beach cell formed by the two long, high, impermeable groins at 9th Street and 11th Street functioned as a closed system. Little sand appears to have entered from the north and little appears to have been lost to the south. The net sand gain or loss in the cell was zero; thus, accretion observed behind the breakwater/spur was balanced by erosion along beaches farther south near 11th Street. Seasonal fluctuations in beach width and volume changes are smaller for the beach behind the breakwater than for adjacent unprotected beaches exposed to direct wave action.

CHAPTER 154

SHORELINE RESPONSE TO A SINGLE TRANSMISSIVE DETACHED BREAKWATER

Hans Hanson¹ and Nicholas C. Kraus², M.ASCE

ABSTRACT

Criteria are presented for predicting the long-term shoreline response to a single detached breakwater. The criteria, expressed as two algebraic equations, distinguish tombolo formation, salient formation, and limited shoreline response, and were developed by calculation-intensive application of the shoreline change numerical model GENESIS for a large number of wave conditions and structure configurations. A unique feature of the modeling effort is explicit incorporation of wave transmission at the structure. The two other major non-dimensional parameters in the criteria are the length of the structure divided by the average wavelength at the structure and the average deep-water significant wave height divided by the depth at the structure. Prediction of the generalized criteria agree with available field data.

INTRODUCTION

The response of the shoreline and beach to detached breakwaters is difficult to predict. For example, Seiji, Uda, and Tanaka (1987) in a survey of 1552 breakwaters constructed in Japan found that 60 percent produced accretionary developments and 35 percent did not. A frequency diagram for the data set shows shoreline advance ranging from zero to 140 m. Although some empirical guidance is available to design the basic configuration of detached breakwaters, the criteria are crude and based on a few, typically two to four, out of as many as 14 governing variables. A major variable missing in previous work is wave transmission through the breakwater. The objective of the present study is to perform a generalized calibration of the shoreline change numerical model GENESIS against observed field response to a single shore-

parallel and transmissive detached breakwater for a wide range of structure configurations and wave characteristics.

PROCEDURE

Governing Parameters

By inspection, at least 14 parameters can be identified which control the response of a sandy beach to a single or multiple detached breakwater system (Fig. 1):

$$\text{Beach Resp.} = F[(X, Y, K_T, G), (D, \Delta D, S), (H, T, \theta, \theta_S, \sigma_H, \sigma_\theta, \sigma_T)]$$

or (1)

$$\text{Beach Resp.} = F[(\text{breakwater properties}), (\text{beach properties}), (\text{wave properties})]$$

where X = length of structure segment; Y = distance of segment from original shoreline; K_T = structure segment transmissivity; G = gap distance between segments; D = depth at structure segment; ΔD = variation in depth at the structure, as from the tide; S = sediment availability; H = wave height; T = wave period; θ = predominant wave angle to trend of coast; θ_S = orientation of structure to trend of coast; σ_H = standard deviation (SD) of wave height; σ_θ = SD of wave angle; and σ_T = SD of wave period. In a practical situation, the engineer has control over the first group of parameters only.

In GENESIS, the equilibrium beach profile shape is calculated as $D = A(d_{50}) Y^{2/3}$, where A is an empirical scaling parameter depending on the beach median grain size d_{50} . Once the beach grain size is

Figure 1. Segmented detached breakwater parameters

specified, D is a function of Y and is not an independent variable. The functioning of all 14 parameters governing long-term shoreline change can be represented in GENESIS.

Numerical Model

GENESIS is a numerical modeling system which calculates wave transformation (refraction, shoaling, diffraction from multiple coastal structures, transmission, and breaking), longshore sand transport rate, and associated shoreline change (Hanson 1989, Hanson and Kraus 1989, 1991). The system is generalized in that it allows representation of a wide variety of user-specified offshore wave inputs, initial beach configuration, boundary conditions, coastal structures (groins, jetties, seawalls, and detached breakwaters), and beach fills.

Several numerical and physical model studies have investigated the response of the shoreline to detached breakwaters. However, these studies did not include wave transmission, referring to wave energy passing through and over a structure, which is present in most projects. This capability is included in Version 2.0 of GENESIS (Hanson and Kraus 1989) and has been tested with excellent results for Holly Beach, Louisiana, with six breakwaters of different construction and transmission (Hanson, Kraus, and Nakashima 1989), as well as for Lorain, Ohio, with three detached breakwaters (Hanson and Kraus 1991).

SENSITIVITY TO GOVERNING PARAMETERS

Prior to the generalized calibration of the modeling system, an investigation of the sensitivity of the shoreline response to variations in the main governing parameters was performed. In all the following simulations, the median sand grain size is 0.2 mm. The empirical predictive formula for the longshore sand transport rate used in GENESIS is:

$$Q = (H^2 C_g)_b (a_1 \sin 2\theta_{bs} - a_2 \cos \theta_{bs} \frac{\partial H}{\partial x})_b \quad (2)$$

in which C_g = wave group speed, b = subscript denoting wave breaking condition, θ_{bs} = angle of breaking waves to the local shoreline. The nondimensional parameters a_1 and a_2 are given by

$$a_1 = \frac{K_1}{16(S - 1)(1 - p)W} \quad (3)$$

and

$$a_2 = \frac{K_2}{8(S - 1)(1 - p)W \tan \beta}$$

in which K_1 and K_2 = empirical coefficients, treated as a calibration parameters, $S = \rho_s/\rho$, ρ_s = density of sand ($2.65 \cdot 10^3 \text{ kg/m}^3$), ρ = density of water ($1.03 \cdot 10^3 \text{ kg/m}^3$), p = porosity of sand (0.4), $\tan \beta$ = average

nearshore bottom slope), W = a numerical factor ($1.416^{5/2}$) used to convert from significant wave height to root-mean-square height.

Effect of variation in wave input mean values

An illustration of the effect of changing wave height is given in Fig. 2. The wave climate was held constant during the simulations with a period of 4 sec and a total simulation time of 100 hrs. The breakwater was 300 m long and placed 300 m offshore in 3 m depth. As expected, shoreline advances with increase in wave height. The maximum shoreline progression varies approximately linearly with wave height, whereas accumulated volume for the greater wave height is an order of magnitude bigger than that for the smaller wave height. This is in part explained by the difference in breaking wave height, but also because the bigger waves are less refracted before breaking, they will break under a bigger angle to the shoreline.

An example of the variation in shoreline response behind a detached breakwater due to changing wave period is given in Fig. 3. The wave climate was otherwise held constant during the simulations with a wave height of 1 m, normally incident wave crests, and a total simulation time of 100 hr. The breakwater configuration was the same as in the previous figure.

Increasing wave period results in greater salient growth behind the structure. The explanation for this is illustrated in Fig. 4, displaying the associated wave height distributions behind the detached breakwater for the three simulations in Fig. 3. The wave height distributions associated with waves entering on either side of the breakwater are shown separately. Longer waves results in a higher

Fig. 2. Influence of varying wave height on shoreline change behind a detached breakwater

Fig. 3. Influence of varying wave period on shoreline change behind a detached breakwater

shoaling coefficient, causing these waves to break further offshore, resulting in a greater breaking wave height, the offshore wave height being the same.

This means, for the longer waves, that the first term in Eq. 1 (K_1 - term), with a larger H -value, will transport more sand into the area behind the breakwater. Also, the wave height for longer period waves decreases more steeply alongshore behind the structure. This means that the second term in the transport Eq. 1, (K_2 - term), with a higher $\partial H/\partial x$ -value, will also transport more sand into the area behind the breakwater for the longer waves.

Effect of wave variability

In use of the model in a predictive mode, the factors responsible for beach change are not known in detail. The time series of wave height, period, and direction forecast for use in the shoreline change prediction and can be considered as only one of many possible wave climates that might occur. For shoreline response prediction, it is necessary to incorporate wave variability to calculate a probable range of expected shoreline change. The standard deviation is conveniently used as a realistic measure of wave variability and determines the likelihood and magnitude of extreme events (Kraus, Hanson, and Harikai 1984).

Fig. 5 illustrates an example showing accretion behind a 200-m long detached breakwater located in 2 m depth 200 m from the initial straight shoreline. The mean values in deep water characterizing the wave climate are: $T = 4$ sec, $H_s = 1$ m, and $\theta = 0$ deg. The thin solid

Fig. 4. Influence of varying wave period on wave height distribution behind a detached breakwater

line represents a wave climate with T , H , and θ held constant at their mean values. In the other three simulations, two of the three parameters were held constant while the third was normally distributed with its standard deviation given in the figure as a percentage of the respective mean value.

As seen from the figure, allowing T and H to vary has very little effect on the shoreline response. In contrast, increased variability in the wave direction dramatically increases accumulation behind the structure. The major reason for this is that variation in T and H around their respective mean values merely redistributes the incoming wave energy in time but does not significantly change the total longshore wave energy flux. A deviation in wave direction from normal in any direction, however, increases the longshore component of wave energy flux, which in turn causes more sand to move alongshore. Because of shadowing from the structure, more sand will be transported into than out of the shadow region behind the structure, accounting for the large growth of the salient.

Breakwater Transmissivity

In most cases, detached breakwaters designed for shore protection allow some portion of the incident wave energy to pass through or over the structure because it is economical and often advantageous from the perspective of beach change control to build low or porous structures to allow wave energy to penetrate behind them. Wave transmissivity is difficult to quantify. In order to describe wave transmission in GENESIS, a value of a transmission coefficient K_T must be provided for each detached breakwater (Hanson and Kraus 1989). The transmis-

Fig. 5. Influence of wave variability on shoreline change behind a detached breakwater

sion coefficient, defined as the ratio of the height of the incident waves directly shoreward of the breakwater to the height directly seaward of the breakwater, has the range $0 \leq K_T \leq 1$, for which a value of 0 implies no transmission and 1 implies complete transmission.

To investigate the sensitivity of the calculated shoreline response to variations in wave transmission, a series of simulations was made to investigate predicted sand accumulation in the lee of a shore-parallel breakwater, as illustrated in Fig. 6. The breakwater is 200 m long and located 250 m offshore. Incident waves with $T = 6$ sec and $H_s = 1.5$ m propagate with wave crests parallel to the initially straight shoreline. The simulation time was 180 hr.

As expected, the seaward extent of the induced large salient decreases as wave transmission increases, showing that shoreline response is sensitive to breakwater transmissivity. For example, a 20 percent transmissivity reduces the maximum shoreline advance by 36 percent and the accumulated volume by 25 percent. Because of the difficulty of determining the transmissivity for real structures, the value of the parameter is, at present, determined in the shoreline change calibration procedure.

The capability to simulate wave transmission at detached breakwaters and its impact on shoreline change was first tested with excellent results for Holly Beach, Louisiana, a site containing six breakwaters of different construction and transmission characteristics (Hanson, Kraus, and Nakashima 1989). This application also showed that it would

Fig. 6. Shoreline change as a function of transmission (from Hanson et al. 1989)

not be possible to obtain good agreement between field measurements and model predictions if wave transmission were not taken into account.

RESULTS

With an understanding of model capabilities established in the preceding text, we now turn to the problem of developing design curves to predict shoreline response to single, transmissive detached breakwaters. There are two general problems to be addressed. The first is to determine appropriate parameters for distinguishing tombolo development, salient development, or no effective shoreline change (limited or transitory response). The second problem is to develop design curves relating shoreline response to these governing parameters. Here, we present design curves for shoreline response to a single detached breakwater, based on three nondimensional parameters.

Based on field observations and simulation results, shoreline response was classified into three categories as illustrated in Fig. 7:

- * Limited response - maximum accumulation is less than 4 m.
- * Salient development - maximum accumulation is greater than 4 m, but the salient does not reach the breakwater.
- * Tombolo development - salient reaches (touches) the breakwater.

The wave height distribution behind a structure produced by diffraction to a large extent depends on the wavelength L , where the energy of longer waves penetrates further into the shadow region behind the structure. Also, the length of the structure X controls the amount of wave energy reaching the beach. It is therefore likely that

Fig. 7. Possible shoreline response to detached breakwaters

the shoreline response behind a detached breakwater is a function of the ratio X/L . Waves breaking seaward of a detached breakwater have a greater tendency to develop salients and tombolos than waves breaking on the landward side since there is a greater width of longshore transport. The location of the breakwater relative to the breaker line is conveniently expressed through the ratio H_o/D , where H_o and D are the significant deep-water wave height and the water depth at the location of the breakwater. Thus, these two dimensionless parameters were taken as primary variables for examining prototype data and developing design curves. Other parameters were tested and rejected in favor of X/L and H_o/D , based on their performance in distinguishing shoreline response.

Field Data

Most empirical and modeling analyses of shoreline response to detached breakwaters have relied heavily on physical model results, including combined segmented as well as single detached breakwater cases. There are only a few well-documented field examples in the literature for single detached breakwaters, and Table 1 presents conditions at all such sites known to the authors. The values for the transmission coefficient K_T were subjectively estimated on the basis of descriptive classifications ("poor condition," "high and impermeable," etc.) in the project reports.

In the present study, the numerical shoreline change model GENESIS was used to determine the equilibrium shoreline response behind a single shore-parallel detached breakwater. As mentioned previously, the persistence of shoreline response is closely related to the variability in incident wave height, period, and direction. More realistic

Table 1

Project site	Struct. length X	Wave height H_o	Water depth D	Wave-length L	Estim. trans- mission K_T	Observed beach resp.

simulations of shoreline change are expected by including variability in wave parameters. Seven "standard" yearly wave climates were developed including different means and standard deviations of the wave climate for the simulations, based on review of conditions related to the data in Table 1.

For each of the wave climates a Monte-Carlo simulation technique was applied to input the wave data, with random wave heights generated from a Rayleigh distribution and wave angles and periods specified from normal distributions, resulting in a 1-year wave data set discretized at 12-hr intervals. In these simulations, the mean wave period $T = 2.5, 7,$ and 12 sec with a standard deviation of $T/4$; the significant wave height $H = 0.2, 0.5,$ and 1.0 m; and the mean wave direction was normal to the straight, initial shoreline with a standard deviation of 5 deg. The chosen values encompass conditions along U.S. Atlantic Ocean and Great Lakes beaches. The length of the structure X was varied between 40 and 100 m, with the distance from the initial shoreline Y varying from 16 to 300 m, and with a transmission coefficient of $0.00, 0.20, 0.50,$ and $0.75,$ respectively. The beach median grain size was 0.2 mm in all simulations.

Fig. 8 shows the results of simulations for a single detached breakwater oriented parallel to an initially straight shoreline, for different X/L and H_o/D values. This figure is the main result of this study. Each of the 166 combinations of wave and structure configuration and transmissivity parameter values was run for two years or until a tombolo formed. The different symbols indicate the response type. Situations with short structures in shallow water exposed to high, long-period waves are more likely to produce salients, whereas long structures in deep water exposed to small, short-period waves more often results in a limited shoreline response.

Fig. 8. Calculated shoreline response to a single detached breakwater

Straight lines were drawn to separate the different response types as a function of wave transmissivity. It was found that as breakwater transmissivity increases, shoreline response decreases. Based on these results, the criterion for a salient to form was found to be:

$$\frac{X}{L} \leq 48 (1 - K_T) \frac{H_o}{D} \quad (4)$$

which separates regions of limited shoreline response and clear salient development. Similarly, the criteria for a tombolo to form was found to be:

$$\frac{X}{L} \leq 11 (1 - K_T) \frac{H_o}{D} \quad (5)$$

which separates regions of salient and tombolo formation.

As evidence for the validity of the proposed relationships, the prototype measurements as presented in Table 1 are plotted in Fig. 9. The prototype measurements fit well within the domains of the proposed criteria and provide at least limited validation of the calculated results.

CONCLUSIONS

This paper described a generalized calibration against field measurements of the numerical model GENESIS for simulating shoreline response to detached breakwaters. Three dimensionless parameters, the length of the structure relative to the local wavelength, the deep-water wave

Figure 9. Field measurements and proposed criteria

height relative to the water depth at the structure, and wave transmission through the structure were taken as primary variables in study.

Field measurements and model simulations showed a systematic trend in shoreline response as a function of the three dimensionless variables. In summary, the results indicate that:

- * Holding all other variables constant, as the wavelength (period) increases, shoreline response goes from limited, to salient, to tombolo, because more sand is transported into the shadow zone.
- * Holding all other variables constant, as the length of the structure increases, shoreline response goes from tombolo, to salient, to limited response, because the amount of sand transported into the area behind the structure is distributed over a longer portion of beach.
- * Holding all other variables constant, as the wave height increases, shoreline response goes from limited, to salient, to tombolo, because more sand is transported into the shadow zone.
- * Holding all other variables constant, as the depth at the structure increases, shoreline response goes from tombolo, to salient, to limited response, because a smaller portion of the area behind the structure is located inside the surf zone.
- * Holding all other variables constant, as wave transmissivity increases, shoreline response goes from tombolo, to salient, to limited response because of direct incidence of the transmitted waves, which suppresses protruding features.

* The independent parameters selected (X/L , H_o/D , and K_T) provide effective but preliminary design criteria for distinguishing shoreline response to a single, transmissive detached breakwater.

Although the criteria presented here are based on a most advanced and thorough numerical model study, the results are not intended to replace the judgement of an experienced engineer familiar with a project coast.

CHAPTER 155

Flow-Fine Sediment Hysteresis in Sediment-Stratified Coastal Waters

Rui G. Costa¹ and Ashish J. Mehta²

Abstract

Hysteresis in the relationship between suspended sediment concentration and the flow velocity is shown to be influenced by sediment-induced flow stratification in high energy coastal environment. A 1-D numerical approach combined with field observation from Hangzhou Bay, China is used to highlight the effects of concentration dependent settling velocity, buoyancy stabilized mass diffusion and bottom sediment fluxes on hysteresis. Typical formulations for the bottom fluxes are believed to have limited utility in high concentration environments.

Introduction

Estuaries and coastal bays have traditionally offered multiple advantages for the development of urban and industrial centers. The rapid development of many of those centers has led to competing demands and technical and ecological problems. Some of the important problems are directly related to sediment dynamics and make the study of the physical mechanisms contributing to sediment transport of fundamental importance in predicting any effects of anthropogenic activities.

The nature and significance of estuarine and coastal sediment transport processes has been investigated by several researchers. Although several procedures have been applied to a variety of estuaries having different geometries and stratification conditions, two transport mechanisms, vertical shear and tidal pumping, have been generally found to be dominant (Dyer, 1989 and Uncles et al., 1984). Transport by vertical shear results from residual gravitational circulation due to salt water penetration. Tidal pumping results from phase differences between cross-sectional area variations and variations of average cross-sectional velocities and concentrations of salt or sediment.

Both transport mechanisms depend on the vertical concentration profiles and, consequently, on the magnitudes of the vertical mass transport fluxes. Such fluxes can be significantly modified if stratified conditions exist in the

¹Research Assistant, Laboratório Nacional de Engenharia Civil, Av. do Brasil, 101, 1799 Lisboa Codex, Portugal; formerly Graduate Assistant, University of Florida, Gainesville, FL, USA.

²Professor, Department of Coastal and Oceanographic Engineering, University of Florida, Gainesville, FL, USA.

water column; moreover, the differences between salt and suspended sediment behaviors suggest the importance of studying sediment-stratified flows and differences relative to salt-stratified flows. Observation of such differences, supported by recent field studies, contradicts the assumption implicit in some early studies that the dominant physical mechanisms transporting salt and sediment landward in an estuary or coastal bay are the same. In the particular case of suspended sediment, which is negatively buoyant, vertical fluxes are strongly dependent on the erosion/resuspension and settling/deposition conditions, thus influencing its response to hydrodynamic forcing. Such influence is expressed by the well known flow-sediment hysteresis which reflects the time-lagged response of sediment to flow variations.

The main purpose of the present investigation was to study the effect of sedimentary processes in the evolution of the vertical concentration profile in a sediment-stratified coastal environment. In particular, the influence of the sediment settling properties, stabilized diffusion parameters and bed properties on the general features of the profile and their effects on the lag phenomena contributing to flow-sediment hysteresis were investigated.

A vertical transport numerical model was used to generate concentration profiles. Measurements of water pressure, velocity and suspended sediment concentration were made in a high-concentration coastal environment (Hangzhou Bay, People's Republic of China). Laboratory tests of local sediment allowed the evaluation of the pertinent physical parameters. The field data were used to test the importance of lagged response of sediment to flow changes and to compare with model results.

Flow-Sediment Hysteresis

It is known that, during decreasing estuarine currents, concentrations are usually higher than during increasing currents. This flow-sediment hysteresis can be decomposed into delays caused by global advective phenomena and those associated with the response of sediment to local flow variations. These last can, in the general case of fine sediment transport, be separated into several parts following Dyer and Evans (1989):

- a) A lag associated with settling, corresponding to the time that a sediment particle in suspension at a certain elevation in the water column takes to reach the bed, once the transport velocity (or $\bar{u}|\bar{u}|$, proportional to the bottom shear stress) has decreased below a minimum value. This settling lag is associated with the settling velocity of the sediment particles and, consequently, depends on the aggregation condition of the sediment and on the concentration dependent settling velocity range;
- b) A lag associated with the diffusion process, corresponding to the time taken by a sediment particle once entrained from the bed, to be diffused to upper layers in the water column. This diffusion lag is associated with the buoyancy stabilization characteristics in the water column and depends on the amount of sediment available for resuspension, as well as on the vertical concentration gradients;
- c) A lag associated with the time difference between the occurrence of a transport velocity (or $\bar{u}|\bar{u}|$) in the water column and the occurrence of higher values of the same parameters causing bed erosion. This threshold

lag is associated with the resistance of the top bed layer to erosion and, particularly, to the critical shear stress for erosion;

- d) A lag associated with bed consolidation, corresponding to the fact that in fine consolidated beds, the bed shear strength increases with bed consolidation time. This effect is called consolidation lag.

Such lag mechanisms can then be superimposed to explain the fact that sediment concentrations usually lag hydrodynamic forcing. In a tidal flow following low water slack, a threshold time lag occurs before sediment resuspension occurs. To this lag a lag associated with particle diffusion to upper layers should be added. Furthermore, once the flow begins to decelerate a certain time is needed for the sediment to settle and thus a settling lag should be included. During slack water a residual sediment concentration may remain in the water column, corresponding to the finer fractions of sediment under the effects of residual turbulence and Brownian motion. Further to these local lag effects any delays caused by advection should also be included.

A rough comparison between the magnitudes of the settling lag and diffusion lag following Dyer (1986), by considering the concept of a time dependent mean height of suspension due to Monin and Yaglom (1971) and typical values of the pertinent physical parameters for cohesive sediment, shows the former to be approximately three times the latter (Costa, 1989). This fact must be taken into account when comparing the behavior of salt and sediment in estuarine flows, since salt is not subject to erosion/deposition.

Field Experiments and Laboratory Tests

In order to investigate fine sediment concentration profile response to currents and waves in a high concentration environment two experiments were carried out in Hangzhou Bay, People's Republic of China, a meso-tidal coastal bay dominated by fine grained sediment (figure 1). Some of the bay's important oceanographic features are presented by Su et al (1988) and Su and Yu (1984), and summarized in the following paragraphs.

Hangzhou Bay, a shallow and relatively flat-bottomed water body, is the outer region of the Qiantang estuary. The rivers upstream of the bay discharge an average water flow of 42 km^3 per year and an average suspended sediment load of $7.9 \times 10^9 \text{ kg}$ per year. Due to the different characteristics of the incoming water relative to the coastal waters, a plume is formed at the mouth. North of Hangzhou Bay lies the mouth of the Chiangjiang River, which has an average annual water flow of 925 km^3 and an annual sediment discharge of $486 \times 10^9 \text{ kg}$. This river is believed to be an important sediment source for Hangzhou Bay, since the mineral composition of both sediments is similar. At the mouth of the Chiangjiang River two plumes are formed (a main plume and a secondary plume directed towards the northern end of Hangzhou Bay), which are believed to contribute to the sediment supply into Hangzhou Bay. The secondary Chiangjiang plume forms with the Qiantang plume a single NE/SW oriented front with high near-bottom sediment concentrations at its landward side. Sediment initially carried by the main Chiangjiang plume also accumulates at the seaward side of the front during winter. Tidal resuspension of sediment along the front, although inhibited by stratification, combined with strong cyclonic along-front surface currents, cause southwestward transport of sediment and accretion, at

Figure 1: Location of the measurement site in Hangzhou Bay.

Figure 2: Measurement tower and positions of the equipment used in Hangzhou Bay (deployments C2 and C3).

Figure 3: Settling velocity as a function of concentration for Hangzhou Bay sediment.

a rate of about 20 m per year, of the south bank of Hangzhou Bay where the field experiments took place.

The first test was carried out from the 14th to the 16th of May, 1988. The measurement tower (figure 2) consisted of the following: a turbidity meter (Partech SDM16), an electro-magnetic (EM) current meter (Marsh McBirney, model 512) measuring along two horizontal directions (x and y) and a pressure gage to record water surface variation were installed at the lower level. A turbidity meter (Partech TT10 self cleaning unit) and a second EM meter (of the same model) measuring along a horizontal and the vertical direction (x and z) were located at the upper level. The data were sampled at a rate of 4 Hz and recorded with in a data logger. Two experimental phases took place. In the first (deployment C2), six sampling periods of 10 minutes each, separated by 30 minute intervals, were measured; in the second (deployment C3) fifteen sampling periods of 5 minutes each, separated by 60 minute intervals and encompassing a full tidal cycle, were measured. During the study period wave action was generally weak and turbulence in the water column was mainly generated by the tidal current.

A second measurement program took place at the same location from the 4th to the 5th of August, 1989 (deployment C4). In this case the pressure gage and the EM current meter measuring along the x and y directions were located at the upper level, while the second EM meter, measuring along the x and z directions, was located at the lower level. The positions of the turbidity meters remained the same, as in the first field program. Twenty-four data blocks of 5 minutes duration each separated by 60 minute intervals were sampled at 4 Hz.

The field data were processed in order to separate from the records the time-average values and the tidal trends; the remaining portion, generically denoted by e_1 , included a minor wave-induced part \tilde{e} and a turbulent part e' , which were separated using the pressure data through a filtering procedure (Costa, 1989).

In order to characterize the sediment laboratory tests were performed using samples collected at the measurement site. Grain-size test indicated a median floc diameter of 23 μm , while erosion tests, performed in an annular flume, produced values of $M = 2.1 \times 10^{-3} \text{ g}/(\text{cm}^2 \text{ min})$ and of the critical shear strength $\tau_s = 0.05 \text{ N}/\text{m}^2$ for the expression for the erosion rate, $E = M[(\tau_b - \tau_s)/\tau_s]$, where τ_b is the bottom shear stress. Settling velocity tests produced the parameters for settling in the flocculation and hindered settling ranges, as shown in figure 3.

Model Simulations

A numerical model developed by Ross (1988) was used to simulate concentration profile evolution. The model solves a simplified version of the advection-diffusion equation for suspended sediment in the z direction, in the form

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial z} \left(W_s C + K_z \frac{\partial C}{\partial z} \right) \quad (1)$$

(where C , W_s and K_z are the sediment concentration, the particle settling velocity and the vertical mass diffusivity, respectively), valid for estuarine flows in which the convective vertical velocity is negligibly small and the advective

travel time through the estuary is considerably greater than the characteristic time for sediment settling. In the water column the vertical settling and diffusive fluxes are computed using a finite difference scheme. The settling flux computation includes free settling and the concentration dependent cases of flocculation settling and hindered settling. The neutral mass diffusivities, K_n , are equated to the neutral momentum diffusivities E_n , (using the Prandtl velocity law and assuming a linear shear stress variation) by considering the turbulent Schmidt number (St) to be unity. The mass diffusivity corresponding to the stratified case (K_s) is then obtained through a Munk and Anderson type of damping correction in the form

$$\frac{K_s}{K_n} = (1 + \beta Ri)^{-\alpha} \quad (2)$$

where Ri is the gradient Richardson number and α and β are positive empirical constants.

Appropriate boundary conditions are a no net flux condition at the water surface (the diffusion flux balancing the settling flux) and a bed flux boundary condition. This boundary condition defines a source or sink for the suspended sediment in conditions, respectively, by erosion or deposition. The deposition flux is defined as:

$$F_p = \left(\frac{\tau_b}{\tau_{cd}} - 1 \right) W_s C \quad (3)$$

where τ_b and τ_{cd} are the bottom shear stress and the critical shear stress for deposition, while the erosion flux is defined as

$$F_e = a \exp(-2.33\tau_s) [(\tau_b - \tau_s)/\tau_s] \quad (4)$$

where τ_s and a are the bed shear strength and an empirical erosion parameter, respectively.

Model simulations of the variation of the turbulence-mean value of the sediment concentration (C) with the square of the turbulence-mean horizontal velocity ($\bar{u}|\bar{u}|$) at the elevations corresponding to the measurement positions are shown in figure 4, for the flow conditions during deployment C2. In the figure negative values of \bar{u} denote ebb flow. Agreement between the trends and orders of magnitude of the values of the variables in the simulated loops and the ones measured during the field deployments (figures 5 and 6) is generally observed. For the simulation, the settling parameters determined in the laboratory tests were used, while stabilized diffusivity parameters α and β had the values 2.0 and 1.0, respectively. The bed shear strength and the critical shear stress for deposition, however, had to be assigned values $\tau_s = 15.0 \text{ N/m}^2$, and $\tau_{cd} = 5.0 \text{ N/m}^2$, one order of magnitude higher than those measured in the laboratory.

Sensitivity analysis was performed using the model with adequate variations in the parameters describing the different physical processes. These allowed an evaluation of their effects through the lags involved in sediment response to flow variations. A reference case was computed in which, as occurs in figure 4, C lagged the shear stress in the ebb, while the opposite occurred in the flood. For this simulation the flow conditions, α , β , τ_s and τ_{cd} used for the computation of figure 4 were used while the settling velocities were computed as

$$W_s = 0.406 C^{1.082} \quad (5a)$$

Figure 4: Hysteresis loops simulated using Hangzhou Bay sediment settling properties.

Figure 5: Measured hysteresis loops (deployment C3).

Figure 6: Measured hysteresis loop at the upper position (deployment C4). Numbers next to data points indicate time in hours.

$$W_s = 6.47(1 - 0.00451 C)^{12.067} \quad (5b)$$

in the flocculation settling and hindered settling ranges, respectively.

In figure 7 and 8 plots of C vs. $\bar{u}|\bar{u}|$ and time for the reference simulation are shown, respectively; in figure 7 the elapsed times (in minutes) since the beginning of the simulation (peak flood current) are indicated against the computed points, encompassing a full tidal cycle. The vertical gradient of the net flux (positive values denoting resuspension/diffusion) vs. time is shown in figure 9. From the figure the residual concentration during slack water periods is seen to be almost constant in the water column, suggesting uniform concentration profiles. Comparison of figures 8 and 9 allows the definition of the main periods during which settling and deposition took place. Deposition/settling are clearly dominant around slack water while resuspension/diffusion dominate the subsequent re-entrainment periods. The magnitude of these fluxes, if compared with those occurring during the remaining of the computation period, emphasizes the importance of near-bottom conditions since, clearly, the much higher values of the net flux gradients during deposition and re-entrainment periods are due to these phenomena.

An increase in the stabilization conditions of the water column (parameter β increasing from 1.0 to 2.0) resulting in inhibition of upward mixing showed peak concentrations to increase close to the bed; the ebb maximum concentrations were found to lag the bottom shear stress by an additional 20 min relative to the reference case, which reflects an increase in the diffusion lag. The residual slack water concentrations did not change significantly.

In order to evaluate settling lag effects the settling velocities were decreased by a factor of four, all other parameters remaining the same. An increase in the lag of the concentration relative to the shear stress was observed during ebb, while a similar increase of the lag of the shear stress relative to the concentration during flood was also observed. A decrease in the ebb and flood peak concentrations occurred but, more significantly, a sharp increase occurred in the residual concentration around slack water.

The influence of near bed conditions was investigated by reducing the values of τ_{cd} and τ_s by 4.0 N/m^2 , $\Delta\tau = \tau_s - \tau_{cd}$ remaining constant. Only the lag of the shear stress relative to the concentration in the flood was increased relative to the reference case. Decreasing the critical shear stress for deposition, however, by allowing a shorter period for deposition around slack water, caused higher values of the residual concentration relative to the reference case.

Experimental Results

The time lags in sediment response to flow changes represent a basic manifestation of sediment dynamics in estuaries and coastal bays of which measured flow-sediment hysteresis is an indicator. The net effect of such lags is typically reflected in landward transport of sediment. Figure 5, corresponding to deployment C3, confirms the occurrence of hysteresis. Figure 6, obtained during deployment C4, is of higher clarity. Moreover its similarity with the simulated loop of figure 4 is apparent, despite some differences in the input flow conditions. It should be noted however in figure 6 that, contrary to what happens in the simulated loops, the shear stress lags the concentration in the ebb, while the op-

Figure 7: C vs. $\bar{u}|\bar{u}|$ for the simulated reference case.

Figure 8: C vs. time for the simulated reference case.

posite occurs in the flood. Comparison of figures 6 and 7 also shows agreement between the simulations and the data, and seems to confirm the importance of deposition/settling around slack water and of resuspension/diffusion in periods that follow. Similar conclusions can be drawn by comparing figures 8 and 10.

In order to better assess the role of diffusion in governing hysteresis, the “turbulent” (including wave effects and turbulence) properties of the flow were investigated. Figure 11 shows a plot of the Reynolds stresses at the upper measurement level vs. the mean horizontal velocity \bar{u} , while figure 12 shows the “turbulent” variances which contribute to the turbulent kinetic energy of u (at both levels) vs. \bar{u} . Despite the small number of data points, qualitative hysteresis loops could be drawn, showing higher values of the variables during decelerating flow periods. Since the Reynolds stress at a given elevation can be considered to be an indicator of the bottom shear stress and, consequently related to sediment concentration through erosion/deposition, figure 11 is consistent with the meaning of lagged sediment response to flow variations as an important factor for sediment transport in Hangzhou Bay. Figure 12 provides additional evidence of the same nature since higher turbulent kinetic energy will cause, through increased upward diffusion, higher sediment concentrations during the decelerating periods in the upper layers of the flow.

The mass and momentum diffusivities resulting from the actual field conditions (wave effects and turbulence) were calculated using the difference relations

$$K_s = -\frac{\overline{w'c'}}{\frac{\Delta c}{\Delta z}} \quad (6a)$$

$$E_s = -\frac{\overline{w'u'}}{\frac{\Delta u}{\Delta z}} \quad (6b)$$

which give only rough approximations of the values of the parameters since $\Delta z = 1.5$ m is a rather large value. The mass and momentum diffusivities and the Schmidt numbers using this approach are shown in tables 1 and 2 together with the depth averaged longitudinal velocities computed assuming a logarithmic profile (negative values denoting ebb velocities).

Table 2 — \bar{u}_D and measured momentum diffusivities, Schmidt and flux Richardson numbers

The mass diffusivities calculated by the model for values of \bar{u}_D similar to those of table 1 are presented for comparison in table 3. The values of K_s obtained from the data were of order of magnitude of 10^{-3} m²/sec or lower, while the mass diffusivities computed by the model showed, for comparable depth averaged velocities, values of the order 10^{-2} m²/sec, much higher than the former. This fact points to the need for a more accurate description of turbulent diffusion when modeling sediment-stratified flows. The measured values of K_s compare favorably with those used by van Leussen and Winterwerp (1988) (4×10^{-3} and 4×10^{-4} m²/sec for estuaries showing slight and strong stratification conditions, respectively).

If time scales for vertical mixing and settling are defined as $T_d = H^2/K_s$ (where H is the water depth) and $T_s = H/W_s$, respectively, their ratio T_s/T_d is the Peclet number for the suspension (Teeter, 1986) and reflects the ratio between the settling lag and the diffusion lag. For typical values of the parameters measured in Hangzhou Bay this ratio is, approximately, equal to seven

and, again, underlines the differences between salt-stratified and sediment-stratified environments. For turbulence under conditions of local equilibrium a flux Richardson number, $Ri_f = Ri/S_i$, represents the efficiency of conversion from turbulent kinetic energy to potential energy (Abraham, 1989); Ri_f also reflects, relative to the gradient Richardson number the difference between mass and momentum diffusivities under stratified conditions. The computed values of Ri_f are presented in table 2.

The difference between the values of the erosion shear strengths τ , used in the simulation and that determined for local sediment (5.0 and 0.05 N/m², respectively) also confirms the need to improve the algorithms currently employed to describe bed fluxes. It is obvious that a simplified erosion/deposition description of the bed phenomena is insufficient to simulate the complex manner in which bottom fine sediment is fluidized and entrained.

Summary

Sediment response to flow variation is time-lagged and is represented by the well-known velocity-concentration hysteresis loop. A numerical model was used to investigate the influence of settling, diffusion and erosion/deposition defining parameters in the hysteresis loops. These parameters were found to affect mainly the time lags between the occurrence of the maximum concentrations and shear stresses, and the slack water residual concentrations.

Field data obtained in a high-concentration coastal environment (Hangzhou Bay, People's Republic of China) showed expected hysteresis and, thereby, highlighted the importance of time-lagged response of sediment to flow variations. Comparison between field data and numerical results showed good qualitative agreement. Comparison between the model computed mass diffusivities and those computed from field data showed the former to be higher than the latter. Moreover the simple erosion/deposition description used in the model required the use of physical parameters which were significantly different from those determined in laboratory experiments performed with local sediment. These facts suggest the need to improve both turbulence modeling and the description of the complex near-bed phenomena which include fluidization, entrainment, settling, bed formation, consolidation and gelling.

CHAPTER 156

Nearshore Current Patterns on Barred Beaches

David G. Hazen*, Brian Greenwood†, and Anthony J. Bowen*

INTRODUCTION

The last few years have been marked by a renewed interest in the old concept of undertow, the seaward flow which balances the surface flux of water associated with waves, particularly with breaking waves (Svendsen, 1984; Stive and Wind, 1986; etc.). This is clearly an important current in terms of the sedimentary processes which determine the beach profile. Roelvink and Stive have provided laboratory data that suggests the profile results from a net balance between three main factors; the wave skewness, the undertow, and the beach slope. However, in the field the third dimension, the longshore direction, may play a significant role. Even if the system is assumed uniform alongshore, strong longshore currents certainly influence the mobility of the sediment and may play more complex roles, in generating shear waves for example.

It seems appropriate to represent the system, both on/offshore and alongshore, in one self-consistent model. Recent work has been clearly progressing in this direction (Stive and DeVriend, 1987; Svendsen and Lorenz, 1989). It is therefore also appropriate at this stage to look at existing field data to see how well one can define trends that the modelling results should reproduce.

There are some very clear limitations. In the field it is difficult to describe, in any detail, the longshore variability. Small hydraulic gradients in the alongshore direction may drive longshore currents, rip currents, or some general nearshore circulation associated with larger scale topography. Even in a relatively 2-D situation, it is known that the longshore currents are strongly dependent on the directional distribution of the wave spectrum, a factor which is hard to estimate well, unless the angle of wave approach is large.

The measurements here were taken on a beach at the end of a large bay of restricted width. Large waves can only be generated along the long axis of

* Department of Oceanography, Dalhousie University, Halifax, Nova Scotia B3H 4J1, Canada

† Department of Geography, Scarborough College, University of Toronto, Scarborough, Ontario M1C 1A4, Canada

the system, so that the angles of wave approach relative to the beach tend to be small ($0 - 15^\circ$). Attention is therefore focussed primarily on the on-offshore structure of the flow.

FIELD MEASUREMENTS

The Canadian Coastal Sediment Transport (C-COAST) experiments have taken place over the past three years. These experiments involved the deployment of arrays of up to twenty electromagnetic current meters, ten pressure sensors and an assortment of wave-wires and suspended sediment sensors from the shoreline seawards to a depth of $5 - 7m$. Each of the experiments acquired data during periods of higher wave activity over a period of approximately one month under varying wave conditions. The sites included a two dimensional beach (Queensland, Nova Scotia in 1988), a barred beach with normally incident waves (Bluewater, Ontario in 1987 and 1988) and a multibarred beach with

Figure 1. Bluewater 1988 Instrument Schematic showing locations of pressure sensors (p), two component flowmeters (u, v) and optical backscatter suspended sediment concentration sensors (c).

normal or obliquely incident waves (Stanhope Lane, PEI in 1989). The data discussed in this paper will be primarily from the 1988 Bluewater experiment, which took place in May and June of that year.

The data are gathered from a cross-shore array of pressure gauges ('p'), two component flowmeters ('u' and 'v') and optical backscatter suspended sediment concentration sensors ('c'). These instruments were located as shown in Figure 1 with co-ordinate systems as indicated. The sensors were orientated and connected to the hard-wired UDATS data acquisition system (Hazen *et al.*, 1987). Additional sensors were deployed to record wind speed and direction, concentration profiles by acoustic backscatter, depth of sedimentary activity and to collect physical samples of suspended sediment for concentration and grain size measurement.

Detailed analysis of the current data is limited by the number of working flowmeters and the long periods of calm or offshore winds during the study. For these reasons, discussion will concentrate on data collected from flowmeters at 150m on the crest of bar 3 and flowmeters at 55m, just inshore of bar 2 (both at heights of 10 and 25cm above the bed) together with winds from a 10m tower erected adjacent to the beach.

The data base selected for the paper includes the most severe conditions encountered during the experiment (on June 9, 1988) and a period of wave conditions which were more typical of the wave conditions on the lake (June 16). In both cases the incident waves propagate slightly in the y -positive direction, the angle of incidence being $5-10^\circ$ on 9 June, $3-7^\circ$ on the 16th June. In both cases, the longshore current flows in the direction expected.

The conditions on June the 9th are shown in Figure 2 with the wind rising quickly at noon, reaching a steady velocity of about 12 kts. Visual observations included an estimated significant wave height of 0.8m and white capping to the horizon. Observations report short crested waves during the period of active generation. As the wind drops, the waves become longer crested but tend to disappear due to the size of the bay. The mean water level at the shore responds directly to the wind force changing by 20cm in a few hours. The incident wave frequency drops during the maximum of the wind event and then quickly reverts to its previous level. The mean currents track the wind and significant wave heights peaking at 0.3m/s longshore and 0.2m/s cross shore, based on 10 minute averages taken every 30 minutes. The vertical dashed line indicates the start of the data run used in Figures 5 and 7.

Conditions on June 16, however, are more typical of the lower energy events during the study. As shown in Figure 3, the winds averaged around 9 kts. The system responds quite quickly once a threshold wind velocity of 6-7 kts is exceeded with dips in the incident wave frequency, and a rise in the mean water level and mean currents. Again, the vertical dashed line refers to the start of the data run used in Figure 6.

Figure 4 shows the conditions across the surf zone at the peak of the event of 9 June, indicated by the dashed line on Fig. 2. The continuous lines in Figures

(a) predicted setup, (b) predicted and measured r.m.s. cross shore velocity, (c) predicted and measured significant wave height (dashed line indicates wave heights "uncorrected" to predict pressure gauge response, (d) measured depths.

4b and 4c show the theoretical distributions of on/offshore velocity, wave height and bottom pressure in the incident wave band, derived from a shoaling model based on Thornton and Guza (1983). The empirical parameters, used in such models are γ a ratio of wave height to water depth, and B a general dissipation constant. The results in Figure 4 are for $\gamma = 0.45$, $B = 1$ typical of values used in modelling wave evolution on open ocean beaches. The superimposed data points are from the flowmeter array (Fig. 4b) and the near-bed pressure gauges (Fig. 4c). The pressure has been expressed in terms of meters of water. Note that the pressure is not hydrostatic, the high wave frequencies found in the lake environment mean that the waves are in intermediate, not shallow, water until

very close to the shore.

The model, and the visual observations made during the field program, show that at the height of the storm there is some breaking on the third bar. Dissipation is generally low in the troughs and high on the inshore bars. Comparison with other model runs shows that the incident waves become saturated in the seaward face of the second bar if the incident waves are larger than about $0.4m$. As can be seen clearly in Figure 4b, the shoaling model predicts significant amplification of the wave orbital velocity over the bars, due to the depth dependent term in the linear theory. Whether this happens in reality is questionable, the model assumes that the rate of change of depth is slow, not a very good assumption even here where the incident frequency is high and the incident waves very short. However, the predicted amplification over bar three is clearly seen in the data. Inshore, the instrumental spacing does not allow a critical test of the model. The crests of the inshore bars were not used as instrument positions due to the very limited water depth above them.

Wave set-up was calculated in the dispersion model, the results shown in Fig. 4a. The predicted set-up is very small, a few centimeters. The general lake set-up (Fig. 2), of the order of $0.2m$ was much more noticeable. Measurements of set-up specifically were obtained by taking the difference between measurements for the inshore pressure gauges (and wave staffs) and the pressure gauge at $230m$. The results were somewhat scattered, the lake level changes being clearly seen at all stations, but the differences did not resolve the wave set-up with any accuracy, they confirmed that the set-up was small.

The model and data comparison for 1240 on the 16th of June, show a very similar picture (Fig. 5). The smaller wave height leads to less energy loss on the third bar, but breaking on the second bar results in a saturation condition and wave conditions inshore are essentially the same.

DISCUSSION

As shown in Figs. 2 and 3, the mean flows, averaged over 29 minutes, increase with increasing wave energy. In Figure 6, the seaward mean flow over the second bar ($55m$) and third bar ($150m$) are shown as a function of the incident wave height. For a significant wave height less than $0.25m$ the waves break only at the shoreline and the mean flows are very weak; if there is any tendency, it appears to be for onshore flow. As wave height increases, the mean flow at both positions increases more or less linearly with increasing waveheight.

Figure 6a shows the theoretical values for the set-up as a function of incident wave height and frequency. The field measurements scatter generally around these lines. The Thornton and Guza dissipation model includes a frequency dependence which results in a functional relationship for set-up which is weakly dependent on f . The set-up value shown is the predicted difference between the level at the third bar and that over the nearshore trough (cf. Figs. 4 and 5). The values reach a maximum, shown by the circles, when the surf zone becomes saturated, inshore from the third bar. Again, this wave height at

Figure 5. Cross Shore Profiles during June 16, 1988 'M4' data run, beginning at 1240. (a) predicted setup, (b) predicted and measured r.m.s. cross-shore velocity, (c) predicted and measured significant wave height (dashed line is wave height "uncorrected" to predict pressure gauge response), (d) measured depths.

which this occurs is weakly frequency dependent, but is of the order of 1.0m. Any further increase in wave height should merely raise the water level over the whole system, keeping the difference between these specific points constant.

In this particular situation, the set-up is so small that any further increase in set-up does not seriously change the hydrodynamic conditions inshore. The general change in water level due to the large scale wind effects is much more significant. The overall result is that the set-up reaches a definite maximum as should the undertow. Unfortunately, the wave conditions during the six week experiment did not exceed those shown in Fig. 2.

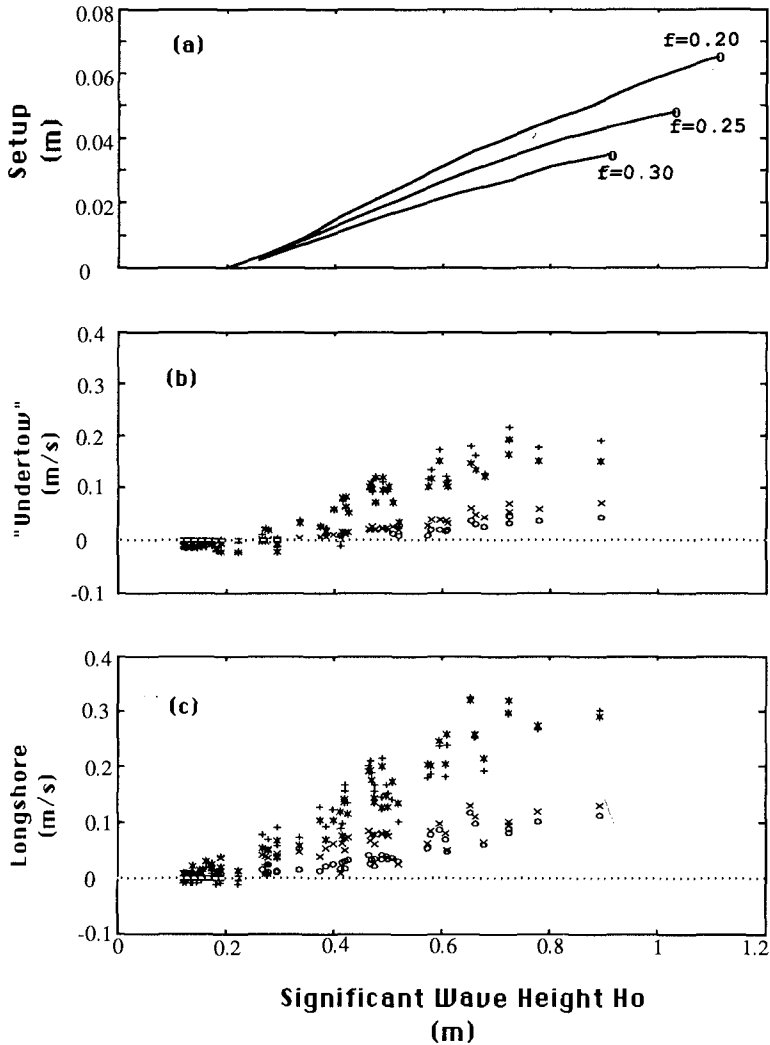

Figure 6. System Response to Various Incident Wave Heights (a) predicted setup at various frequencies (setup defined as (MWL @ 15m) - (MWL @ 150m)) (b) measured mean cross shore flow on June 9 and June 16 (+ = 55m, 10cm; * = 55m, 25cm; o = 150m, 10cm; x = 150m, 25cm), (c) measured mean longshore flow (symbols as in (b)).

The results do however show that the undertow continues to increase even though the wave conditions are *locally* saturated at the point of measurement. This occurs for $H_S \sim 0.5m$ at the 55m station. This is in contrast to the simple

Figure 7. Time Series of Cross Shore Flow at 55m, 10cm height on June 9, 1988 beginning at 1540. (a) Time Series (b) Time series, high-pass filtered at 8 s (0.125 Hz) (c) Time Series, low pass filtered at 8 s (0.125 Hz).

models for plane beaches where the undertow depends primarily on the local conditions.

The discussion has thus far concentrated on the averages taken over a mean length of 29 minutes. This is a compromise between the need to take a reasonable number of points and the need to recognise that conditions at this beach change significantly on timescales of a few hours. However in using values for an analysis of beach equilibrium as in Roelvink and Stive (1989), care has to

be taken to include the motion at all time scales. The time variability seen at the on/offshore flow at the lower flowmeter at 55m is shown in Figure 7a. When this is filtered to separate out the incident waves, using a cut-off frequency of 0.125 Hz, the residual flow is seen (Fig. 7c) as being quite variable on a variety of time scales. While the mean is of over 0.2m/s, pulses in the residual reach 0.4m/s.

CONCLUSIONS

In this rather complex environment, a relatively simple dissipation model based on Thornton and Guza (1983) works reasonably well. Parameter values $\gamma = 0.45$, $B = 1$ suggest that the lake environment is behaving as an ocean environment, although the waves are short and steep there is a full (and rather broad) wave spectrum, tending to be rather short crested during periods of active generation when there are whitecaps to the horizon.

Measurements of the mean flow show a tendency for the flows to be very small during periods of low wave height, increasing approximately linearly with wave height once the waves begin to break on the outer bar. Saturation is predicted, if the motion is primary two-dimensional, for wave conditions slightly more severe than those observed.

The measurements of offshore flow, the undertow, show noticeable variability at all time scales. A factor to be taken into account in any modelling exercise where sediment transport is assumed to be some function of current raised to some power. In general, the wave dissipation over the bars offshore tends to reduce wave activity inshore so that the undertow, the longshore current, and the low frequency oscillations are of the same order of magnitude as the wave orbital velocities.

ACKNOWLEDGEMENTS

The primary funding for the C-COAST experiments came from NSERC (C) Strategic Grants to Greenwood and Bowen and A.E. Hay and Bowen. Additional infrastructure support was obtained from Petro-Canada Ltd. and various branches of the Government of Canada, including the Atmospheric Environment Service, the Atlantic Geoscience Centre, the Marine Environment Data Service, Parks Canada, and the Canadian Coast Guard.

CHAPTER 157

Berm Erosion due to Long Period Waves

Kazumasa KATOH¹ and Shin-ichi YANAGISHIMA²

Abstract

Breakers in the surf zone are saturated, that is, the wave height at any point is limited by the local water depth. The larger waves in a storm break further offshore making the surf zone wider but leaving the wave height in the inner surf zone the same. Why the beach will erode during the storm? To answer this question, there has recently been considerable interest in the long period waves of one to several minutes in period. The field observation has been carried out for more than one year to acquire the field evidences of berm erosion due to the long period waves. Based on the data obtained, two typical evidences of berm erosion will be shown. A critical level of berm erosion will be discussed, which can be predicted with the mean sea level and the height of long period waves at the shoreline.

1. Introduction

Figure 1 shows the approximate distribution of ocean surface wave energy. The energy in the band of period from 1s to 30s is the largest, which is due to the wind waves. Formerly, the wind waves had been considered to be a main external forces of beach erosion in a storm. The second largest energy is in the band of period from 30s to 5 min. The waves in this frequency band are often called infragravity waves. In this paper, however, they will be referred to as " Long period waves ".

It must be said again that Figure 1 is the approximate

¹Chief of Littoral Drift Lab., Port and Harbour Research Institute, Nagase 3-1-1, Yokosuka Kanagawa, JAPAN

²Littoral Drift Lab., Port and Harbour Research Institute

Figure 1 Distribution of ocean surface wave energy

distribution of ocean surface waves, that is to say, in the offshore area. In contrast to the offshore area, for the wave energy in the nearshore, especially in the surf zone, the energy distribution shown in Figure 1 must be modified, since the incident wind waves break and lose their energy in the surf zone. The wave height at any point is limited by the local water depth. The larger waves in a storm break further offshore making the surf zone wider but leaving the wave height in the inner surf zone the same.

On the other hand, the energy in the frequency band of long period waves becomes to be the largest near the shoreline. It has been already known that the amplitude of long period waves at the shoreline becomes larger without breaking in a storm (eg., Bowen and Huntley, 1984).

Therefore, the long period waves of about 1 to several minutes in period have attracted the attentions of researchers as a possible origin of nearshore large scale topographies such as bars. For example, Bowen and Inman (1971) showed theoretically that standing edge waves, which is a kind of the long period waves, can be the origin the formation of crescentic bars. Holman and Bowen (1982) theoretically examined the interaction of two edge waves to predict the three dimensional beach topography such as welded sand bars, and suggested that other three dimensional, complex, rhythmic topographies could also be explained by the same analyses. Katoh (1984) showed with the field data that the two-dimensional multiple longshore bars are formed by the long period standing waves.

Also in the consideration of the mechanism of berm erosion in a storm, it should be very important to take into account not the incident wind waves, but the long period waves, as the external force for the berm erosion. However, we don't have enough field evidences of beach erosion due to the long period waves.

The main purpose of the study is to acquire the field evidences of berm erosion due to the long period waves, and to have a conception for developing a predictive model of abrupt beach erosion in a storm (Katoh et al., 1988).

2. Field observation

The site of field observation is a entirely natural sandy beach, being exposed to the full wave energy of the Pacific Ocean, and is classified as micro-tidal beach with the tide range of about 1.4 meters (see Figure 2). On this beach, Port and Harbour Research Institute has constructed the Hazaki Oceanographical Research Facility (HORF) in 1986 for carrying out the field observation in the surf zone even under sever sea conditions. The research pier is a 427 meters long concrete structures. It is supported by 0.8 meter diameter piles in a single line, at 15 meters interval. The pier deck is 2.5 meters wide and 7 meters above L.W.L. In this facility, the field observation on the relation between the berm erosion and the long period waves had been carried out for more than one year from the 1st of September, 1987 to the 22nd of November, 1988.

Photo. 1 is the side view of the facility, which was taken in a calm wave condition. There is a laboratory at the base of research pier, where two researchers are permanently stationed to measure and observe the many phenomena in the surf zone.

Photo. 2 was taken in a storm condition. Although the facility was isolated in the sea, the two researchers had not any troubles. As a matter of fact, one of them came out from the laboratory to take this picture and went back not by swimming, not by a boat, but on foot with keeping his shoes dry.

Photo. 2 was taken when the crest of the long period waves run up on the beach. After one minute, however, the trough of the long period waves came to the beach and the sandy beach emerged, on which he could go back on foot. Of course, after another one minute the beach was covered with crest again. Then, he had to go bach with quick steps.

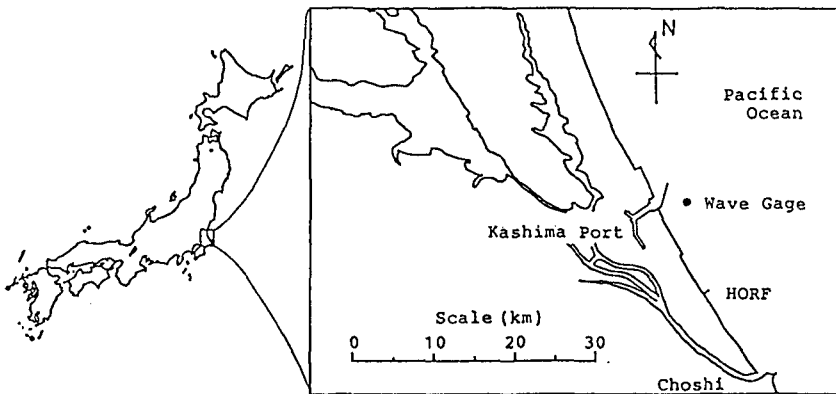

Figure 2 Site of field observation

Photo. 1 Side view of HOLF (in a calm condition)

Under this situation, there was a large wave set-up near the shoreline, which has been discussed by Yanagishima and Katoh (1990).

The field observations conducted in conjunction with this study are as follows;

Survey of beach profile

Beach profile along the research pier was surveyed with

Photo. 2 Isolated HOLF (in a storm)

Figure 3 Mean profile and location of observation

a lead from the pier deck. The profile of the backshore and the foreshore was surveyed by using a surveyor's staff and a transit. The cross-shore interval of these measurements was 5 meters. The measurements have been being done, once a day except on Sunday and the national holiday, by the researchers in the HORF. The mean profile during about one year is calculated with these data, and is shown in Figure 3. The foreshore slope is mild, about 1/50 in average, while the mean bottom slope in the surf zone is a little milder, 1/60.

Wave observation near the shoreline

In order to measure the waves near the shoreline, an ultrasonic wave gauge was installed to the pier deck at the reference point of +22m as shown in Figure 3 and 4. The mean grand level at the observation point was 0.3 meter above the datum line. The mean water depth was about 0.4 meter in M.W.L.

The wave measurements were carried out during 20 minutes of every two hours with the sampling time of 0.3 second, which was automatically controlled by using a mini-

Figure 4 Location of ultrasonic wave gauge

computer in the laboratory at the base of research pier.

By utilizing the wave profile data of 0.3 second interval, the wave heights of incident wind waves and those of long period waves were calculated by the following equations based on the result of spectra analysis;

$$H_s = a \cdot \left[\int_{f_c}^{\infty} S(f) df \right]^{1/2}, \quad (1)$$

$$H_L = a \cdot \left[\int_0^{f_c} S(f) df \right]^{1/2}, \quad (2)$$

where H_s and H_L are the wave heights of the incident wind waves and the long period waves respectively, f is the frequency, $S(f)$ is the spectral energy density, f_c is the threshold frequency of 0.33Hz, and a is the constant coefficient of 4.0.

For trial, to measure the velocity at the same point as that of wave observation, the two-component type electromagnetic current meter was set on the sea bottom. It was, however, impossible to obtain the continuous data for a long time because the current meter was buried under the sea bottom due to the sand accumulation in some time or it caught floatage in another time.

Wave observation in the offshore

The offshore waves have been being measured at the mean water depth of 23.4 meters near the Kashima Port (see Figure 1) during also 20 minutes of every two hours.

3. Evidences of berm erosion

Based on the daily beach profile data for more than one year, the evidences of berm erosion have been abstracted. Those are 28 cases in total. To present the concrete participation of the long period waves in the berm erosion, two typical examples, in which there are large time lags between the occurrence of the maximum peak of wind waves and that of long period waves, will be shown.

Berm erosion due to the typhoon No.8713

The upper in Figure 5 shows the changes of the offshore significant waves during the days when the typhoon No.8713 came to near the observation site in September 1987. The significant wave height in the offshore began to be larger on the 11st of September and was larger than 3 meters on the 14th. It decreased a little in the following two days. During these days, the swell had been arriving with the significant period of 12 to 13 seconds. After that, the waves abruptly increased, being the maximum peak of 5.98 meters in the significant wave height at 16 o'clock on the 17th of September, and gradually decreased from this day on. During the latter period, the wind waves with the

Figure 5 Waves in typhoon No.8713

period of 10 seconds were predominant.

Figure 6 shows the foreshore profiles during the corresponding days. The berm had been formed on the 12th of September, which level was higher than High Water Level. The foreshore profile was not surveyed on 13rd September because it was Sunday unfortunately. We cannot see the berm on the beach profile measured on the 14th of September. This change means that the berm had eroded within two day from the 12th to the 14th of September,

Figure 6 Berm erosion in typhoon No.8713

which is denoted with a blank arrow in Figure 5. It is noticed that the abrupt berm erosion occurred when the swell was coming, being about 4 days before the maximum peak of the offshore waves. When the offshore wave height was maximum, the foreshore also eroded. Its degree, however, was very small as shown in Figure 5. Then, it is rather difficult to obtain the offshore incident waves as the cause of this berm erosion.

The heights of incident waves and the long period waves near the shoreline are shown in the lower in Figure 5. The height of incident waves, H_s , changed periodically, independent on the offshore waves, because the wave height was limited by the shallow water depth which changed with the tide. The detail inspection of Figure 5 reveals that the incident wave height gradually increased with periodical fluctuations during days from the 11st to the 17th of September and also gradually decreased to the end of typhoon. It was due to the sea level rising, including the wave set-up, near the shoreline (Yanagishima and Katoh, 1990). Anyhow, the incident wave heights during the berm erosion were less than 0.5 meter near the shoreline, which was nearly the same values as the incident wave height before the berm erosion, on the 11st of September. Therefore, we cannot decide the incident waves near the shoreline as the cause of berm erosion.

On the other hand, the heights of long period waves, H_L , were nearly 1.0 meter on the 13rd or more on the 14th of September, and were about 0.6 to 0.7 meter when the offshore wave height was maximum on the 17th of September. That is to say, the berm erosion occurred during the days when the heights of long period wave were the largest.

One more notice must be given in Figure 6. There was a interesting paradox that the sand deposited on the greater elevation when the berm eroded, as Bascom (1954) had already pointed out.

Berm erosion due to the typhoon No.8818

The upper in Figure 7 shows the changes of the offshore significant waves during the days when the typhoon No.8818 came to the site in September, 1988. The offshore wave became to be higher since the 14th of September, and had a maximum height on the 16th of September. After that, it decreased with time. The wave period abruptly became to be longer from 6 seconds on the 13rd to 11.9 seconds on the 14th of September. From the 15th on, it fluctuated around 10 seconds.

Figure 8 shows the foreshore profiles during the corresponding days. The berm had been formed on the 13th of September in 1988. Until next day, the 14th of September, this berm had eroded. Since the measurements of beach profile had been carried out just before noon, it can be decided that the initiation of berm erosion occurred before noon on the 14th of September. Also in this case,

Figure 7 Waves in typhoon No.8818

there was the sand deposition on the greater elevation than the berm crest level. Unfortunately, because it is the national holiday on the 15th of September in Japan, we did not measure the beach profile on that day.

The berm erosion occurred about 3 days ahead of the

Figure 8 Berm erosion in typhoon No.8818

occurrence of the maximum incident wave height as shown in Figure 7. During the berm erosion, the offshore wave height was less than 2.0 meters. In short, also in this example, it is very hard to explain the berm erosion by taking the offshore incident wave energy into account.

In the lower in Figure 8, the height of incident waves and long period waves near the shoreline are shown. The height of incident waves was less than 0.5 meter during the berm erosion. The height of long period wave became to be larger up to 1 meter in the early morning on the 14th, and was maximum on the 15th of September. Therefore, it can be said that the height of long period waves near the shoreline was large when the berm eroded.

Based on these two examples of berm erosion, we have following tentative conclusions.

- (a) When the berm eroded, the height of offshore wave was small. It was 2 to 4 days before the occurrence of the maximum height of offshore waves. This conclusion can be obtained owing to the time lag between the changes of the incident wave height and the long period waves. In the remaining 26 cases, both the offshore wave height and the height of long period waves near the shoreline were maxima on the same day when the berm eroded.
- (b) When the berm eroded, the height of incident waves near the shoreline were usually less than those of the long period waves. This consideration is supported by all 28 evidences of berm erosion.
- (c) When the berm eroded, the sand accumulated on the greater elevation at the same time. This kind of sand accumulation existed in 23 cases out of 28 evidences of berm erosion.

4. Critical level of berm erosion

It is shown that the waves which have the direct effects on the berm erosion is the long period waves near the shoreline. Then, let's examine the critical level of erosion in the storm, which is shown in Figure 6, in conjunction with the long period waves.

The total wave run-up level on beach will be assumed as

$$R = (\bar{\eta})_0 + R_L + R_s, \quad (3)$$

where R is the total run-up level, $(\bar{\eta})_0$ is the mean sea level, R_L and R_s is the wave run-up due to the long period waves and the incident waves, respectively. These physical values are defined at the shoreline. Since the total wave run-up level is considered to be closely related to the critical level of accumulation, which is also shown in Figure 6, it can be decided in the following manner.

Estimation of mean sea level, $(\bar{\eta})_0$

The mean sea level at the observation point can be calculated by averaging the wave profile data. However, as the observation point was located a little bit offshore side from the shoreline, the calculated mean sea level must be modified to the value at the shoreline. According to the Goda's theory, the rate of wave set-up on this beach increases at the rate of 9% of the decrement in the water depth (Katoh et al., 1989). Then, the mean sea level at the shoreline can be estimated by the following equation:

$$(\bar{\eta})_0 = \bar{\eta}_0 + 0.09h, \tag{4}$$

where $\bar{\eta}_0$ and h are the mean sea level and the actual water depth at the observation point, respectively.

Estimation of run-up due to the long period waves, R_L

The run-up due to the long period wave is considered to be proportional to its wave height at the shoreline as a first approximation, since it is a standing mode. That is to say,

$$R_L = a (H_L)_0, \tag{5}$$

where a is a coefficient and $(H_L)_0$ is the height of long period waves at the shoreline.

In order to have the height of long period waves at the shoreline, we must modify the value of H_L at the observation point. For this purpose, the Goda's (1975) empirical relation between the offshore significant waves and the height of long period waves at any water depth will be introduced.

Based on the wave data measured both in the surf zone and offshore, Goda (1975) obtained the following relation:

$$\frac{\zeta_{rms}}{(\zeta_{rms})_0} = \frac{A}{\left[\frac{H_0}{L_0} \cdot \left(1 + \frac{h}{H_0} \right) \right]^{1/2}}, \tag{6}$$

where ζ_{rms} and $(\zeta_{rms})_0$ are the root-mean-square values of the wave profiles of long period waves and offshore waves, respectively, h is the water depth, L_0 is the significant wave length in deep water, and A is a coefficient which takes a value of 0.04 in the Goda's relation.

By replacing the left term of Eq.(6) with the following relation

$$\frac{\zeta_{rms}}{(\zeta_{rms})_0} = \frac{H_L}{H_0}, \tag{7}$$

the values of Goda's parameter have been calculated and plotted in Figure 9. As seen in Figure 9, almost all data are plotted below the straight line given by Goda. If the Goda's line will be moved parallel downward by employing

the value of 0.023 for A, the relatively good approximation to the data will be obtained.

By taking the Goda's parameter into account, we have the transformation equation as

$$(H_L)_0 = H_L * (1+h/H_0)^{1/2}, \quad (8)$$

being independent of the value of A, where H₀ is the offshore significant wave height.

Estimation of run-up due to the incident waves, R_s

According to the result of field observation conducted by Guza and Thornton (1982), the swash excursions of the long period components increase with the offshore incident wave height, while those of the incident waves is constant, being independent of the offshore wave conditions. Therefore, we can assume the constant value for R_s,

$$R_s = \text{const.} \quad (9)$$

By substituting Eq.(5) and (9) into Eq.(3), we have

$$R = (\bar{\eta})_0 + a(H_L)_0 + \text{const.} \quad (10)$$

In order to assume that the total run-up level is corresponding to the critical level of accumulation, we must give full consideration to the choice of data. The beach profile had been surveyed once a day, while the mean sea level and the height of long period waves had been observed every two hours. Then, after some consideration, it is decided to choose the data set of the mean sea level and the height of long period waves which summation is maximum among 12 sets of data in 24 hours between the successive surveys of profile. Then, in stead of Eq.(10), we can have

$$A_1 - (\bar{\eta})_0 = a(H_L)_0 + \text{const.}, \quad (11)$$

where A₁ is the critical level of accumulation, which value can be obtained by utilizing the beach profile data.

Twenty three sets of data which are estimated with the measured values in the manner described above are plotted in Figure 10. Of course, they are the cases that the sand accumulation have been recognized during the berm erosion. Since the data are plotted close to a solid line which is decided by applying the least squares method to the data,

Figure 9 Value of Goda's parameter

we have

$$R = (\bar{\eta})_0 + 0.96(H_L)_0 + 0.31.(m), \quad (12)$$

Please pay attention to the replacement that R has been used in place of A_1 in Eq.(12). Equation (12) means that the total run-up level is the sum of mean sea level which contains the tide level and the sea level rising such as the wave set-up, the height of long period waves near the shoreline, and the constant which is the effect of incident wave run-up.

Figure 11 shows a comparison of the total run-up level with the critical levels of accumulation and erosion. On the abscissa in Figure 11, a symbol R_{max} is used since the largest total run-up level in a day during

Figure 10 Comparison of wave run-up with the height of long period waves

Figure 11 Comparison of critical run-up level of accumulation and erosion with maximum run-up level

the berm erosion has been chosen. The critical levels of accumulation agree well with R_{max} , while those of erosion are about 40 cm lower than R_{max} .

5. Conclusions

The conclusions obtained in this study are as follows:

- (1) When the berm eroded, the height of long period waves near the shoreline was large.
- (2) The paradox that the sand accumulates in the greater level when the berm erodes, which have been already pointed out by Bascom (1954), is confirmed with many evidences of field data.
- (3) The critical levels of accumulation and the erosion depend not on the incident waves, but on the height of long period wave and the mean sea level at the shoreline.

CHAPTER 158

A FIELD EXPERIMENT ON BREACH GROWTH IN SAND-DIKES

by

P.J. Visser ^{*}, J.K. Vrijling ^{*} and H.J. Verhagen ^{**}

ABSTRACT

The set-up and results of a field experiment on sand-dike breach erosion are described. It is found that the breaching process for the 2.2 m high sand-dike is similar to that in Visser's (1988) laboratory experiments with a 0.6 m high sand-dike.

Confrontation of Visser's (1988) breach erosion model with the field data shows reasonable agreement for the first stages of the breaching process. As yet the model is not applicable to the final phase of the sand-dike breach erosion. If applied then it would fairly overestimate the breach growth in this final stage.

1. INTRODUCTION

Since dikes have been constructed, in The Netherlands for more than 800 years now, the failure of these high-water defences has been the immediate cause of many inundations. The polder "Alblasserwaard", for instance, has been flooded 33 times since the year 1200. The consequences of a number of these inundations were disastrous, with great losses of human lives, livestock and properties. Curiously the knowledge of the breaching process in dikes is still very limited.

The Technical Advisory Committee on Sea Defences (TAW) in The Netherlands is completing a probabilistic design method for dikes.

Fig. 1 Map of The Netherlands showing the locations of the IJsselmeer Dam, the lake IJsselmeer and Cadzand (site of the field experiment). The dark area is land below Mean Sea Level.

This method determines the optimal dike-design as function of the construction costs and the expected damage costs (deaths, loss of property and revenues, repair costs, etc.) due to a failure of the dike.

In order to be able to determine the damage costs, it is necessary to predict the rate of inundation of the polder. This inundation rate is especially governed by the discharge rate through the breach in the dike, which largely depends on the process of breach erosion.

An example illustrating the benefit of a good breach erosion model is the IJsselmeer Dam in The Netherlands (see Fig. 1). This dam, which was completed in 1932, prevents the penetration of storm surges from the North Sea into the lake IJsselmeer and in this way flooding and collapsing of the dikes of the polders around the lake IJsselmeer. The IJsselmeer Dam is a primary dike, the dikes of the polders around the lake IJsselmeer are secondary dikes.

The height and stability of the IJsselmeer Dam do not meet the modern Dutch standards for sea defences. Expensive dike construction works are necessary to meet these requirements.

However, in case of failure of the IJsselmeer Dam it is possible that the dimensions of the breach(es) in the dike remain confined, consequently also the flow rate through the breach(es), such that the water level increase in the lake IJsselmeer remains relatively small and the dikes of the surrounding polders can withstand the higher water level. So it is possibly not necessary to reinforce the IJsselmeer Dam.

The present investigation is part of a project aimed at the development and verification of a mathematical model for breach erosion that describes the breach growth and the discharge rate through the breach in case of a dike-burst.

A first version of the breach erosion model, see Visser (1988), was especially developed for the huge (i.e. about 75 m high) sand-dike of a proposed pumped-storage plant along the Dutch coast.

The heart of the model is a modified Bagnold (1963, 1966) energetics-based sand transport conception combined with a simplified Galappatti and Vreugdenhil (1985) pick up mechanism for the suspended sediment. The model has been tested to three scale experiments in the laboratory giving a good agreement between model predictions and experimental results, see Visser (1988).

Additional experimental data of Dieteren and Pottinga (1988) have also shown good agreement with the model predictions. Dieteren and Pottinga (1988) have also found that the combination of Bagnold's sand transport theory and Galappatti and Vreugdenhil's sand pick up mechanism gives much better results than the erosion functions of Chee (1978) and Mastbergen and Winterwerp (1987) and the sand transport formulas of Engelund and Hansen (1967), Ackers and White (1973) and van Rijn (1984a, 1984b) combined with the Galappatti and Vreugdenhil (1985) sand entrainment formulation.

A field experiment was performed to test the applicability of the model to (sand-)dikes with a height of order of magnitude of 10 m. This paper describes the set-up and results of this experiment, some further work on the model aimed at the present application and the confrontation of the model with the field data.

2. FIELD EXPERIMENT

2.1 Introduction

The field experiment took place on December 13, 1989 in the Zwin Gully near the village of Cadzand, in the south-western part of The Netherlands (see Fig. 1). The experiment was initiated and directed by study group TAW-C and financed by Rijkswaterstaat. De Looff (1990) has reported on the experiment.

2.2 The sand-dike

The Zwin Gully is a tidal inlet connecting the nature reserve "the Zwin" with the North Sea (see Fig. 2). The width of the inlet varies between 50 and 100 m. The bottom of the Zwin Gully is at about 0.3 m above Mean Sea Level.

The sand-dike was constructed, exclusively for the field experiment, with local sand ($D_{50} \approx 0.20$ mm) at low tide. The sand-dam temporarily closed the Zwin Gully, see Fig. 3.

The length of the dike was about 50 m, its cross-section is shown in Fig. 4: outer (seaward) slope is 1:1.25, inner (landward) slope is 1:3, height H_d above the Zwin Gully bottom is 2.2 m and width at the top is about 8 m. A small initial breach, about 0.2 m deep, about 0.5 m wide and about 8 m long was made in the crown of the dike to ensure breaching of the dike near the middle of the Zwin Gully (see Fig. 5).

2.3 Growth of breach width

The sand-dike was constructed at low tide, as described above,

Fig. 2 View of Zwin Gully and distantly natural reserve "the Zwin".

Fig. 3 Photo of sand-dike in Zwin Gully (seaside is to the right, landside is to the left).

Fig. 4 Cross-section of sand-dike.

Fig. 5 Plan view of sand-dike and positions of measuring equipment (B = breach width at the top of the dike).

and was breached during (the final phase of) the next rising tide. The flow of water through the small initial breach at high water (at sea) started the breach erosion process. Let us define this point of time as $t = 0$.

The breaching process was both video-taped and photographed. Levelling-staffs in the top of the dike (see one in Fig. 7) provided the proper length-scale for the readings from the video-images and photographs. The main result of these readings, i.e. the increase in time of the breach width at the downstream end of the crown of the dike (point P in Fig. 4) is shown in Fig. 13. Fig. 6 shows the breach at $t \approx 2$ min (minutes), Fig. 7 at $t \approx 10$ min.

2.4 Water level and current velocity measurements

Fig. 5 shows the positions of the points A, B and C where current velocity measurements were made (with Ott propeller current

Fig. 6 Photo of breach at $t \approx 2$ min.

Fig. 7 Photo of breach at $t \approx 10$ min.

Fig. 8 Measured current velocities in points A, B and C.

meters, in A and C at a level of 0.60 m above the bottom of the Zwin Gully and in B 0.30 m above the bottom). Fig. 5 also gives the positions of the points D and E where water levels were measured (with tide-gauges). Fig. 2 shows the Ott propeller current meter in point C and the tide-gauge in point E. Fig. 3 shows the current velocity meters in the points A and B and the staff-gauge in point D.

The measured current velocities are given in Fig. 8, the observed water levels above MSL + 0.30 m are shown in Fig. 9.

3. BREACH EROSION PROCESS

Both the laboratory experiments, see Visser (1988) and Dieteren and Pottinga (1988), and the present field experiment have indicated that in case of sand-dike breaching, after a small initial gap in the dike top at $t=0$, the following four stages can be distinguished in the breach erosion process (see Fig. 10):

- I. Steepening of the inner slope angle β upto a critical value β_0 for $0 < t < t_0$.
- II. Continuing erosion of the inner slope for $t_0 \leq t \leq t_1$: the width of the top of the dike in the breach gets smaller while

Fig. 9 Measured water levels h above MSL + 0.30 m in points D and E.

β remains equal to β_0 .

III. Lowering of the dike top in the breach and a subsequent increase of the breach width.

IV. Continuation of the breach growth horizontally and in vertical direction (scour hole) after the complete wash-out of the dike in the breach.

Essential for this process of breach erosion is that suspended sediment transport dominates bottom transport, see Visser (1988).

Fig. 10 Four stages in process of breach erosion.

4. MATHEMATICAL MODEL

4.1 Entrainment and transport of sand

The entrainment and subsequent transport of sand in suspension along the inner slope is described by (see Visser, 1988):

$$s(x') = \frac{x'}{L_a} s_s \quad \text{for } 0 \leq x' \leq L_a \quad (1)$$

in which

$$L_a = \frac{q}{w \cos \beta} \quad (2)$$

$$s_s = \frac{0.01 C_f u^4}{(1-p) \Delta g w \cos^2 \beta} \quad (3)$$

where $s(x')$ is the suspended sand transport per unit width along the inner slope (bulk volume transport), s_s is the transport capacity for the suspended sand, x' is the coordinate along the inner slope ($x'=0$ at the top of the dike, see Fig. 11), L_a is the adaptation length, w is the fall velocity of sand in water, C_f is the friction coefficient for the bed (about 0.01), u is the depth-averaged current velocity of the flow on the inner slope with discharge rate q per unit width, p is the bed porosity, $\Delta = (\rho_s - \rho)/\rho$, ρ_s is the sand mass density, ρ is the water mass density, g is the acceleration of gravity and β is the angle of inclination of the inner slope.

Equations (1) and (2) describe the pick up of sediment in suspension for large values of u_*/w (u_* is the bed shear velocity) according to Galappatti and Vreugdenhil (1985). Equation (3) rests on a modified Bagnold (1963, 1966) energetics-based sand transport conception for the suspended sediment load (which dominates bottom load here), see Visser (1988). The factor 0.01 in (3) is also according to Bagnold (1963, 1966). It is assumed that the transport of sand over the top of the dike in the breach is negligible.

4.2 Discharge rate through the breach

The discharge rate q per unit breach width is described by

$$q = m_0 \frac{2}{3} \left(\frac{2}{3} g \right)^{1/2} (H_w - \hat{z})^{3/2} \quad (4)$$

where m_0 is the discharge coefficient (≈ 1.0), H_w is the water level at sea in front of the dike, \hat{z} is the height of the dike top in the breach, both H_w and \hat{z} are measured above $z=0$ (i.e. above the Zwin Gully bottom), see Fig. 11.

It can be concluded from Fig. 9 that for $0 < t < 20$ min: $H_w \approx h_D$ at $t = 10$ min, so $H_w \approx 2.2$ m. For $t > 20$ min: $h_E > (2/3)H_w \approx 1.5$ m, see Fig. 9, so for $t > 20$ min the downstream water dammed up the flow of

Fig. 11 Erosion of inner slope.

water through the breach. Consequently, equation (4) can be applied for the present field experiment only for $0 < t < 20$ min.

4.3 Breach growth

Fig. 11 shows the process of erosion as discussed by Visser (1988) using theoretical arguments; this process is in agreement with that of Fig. 10 as observed in both the laboratory experiments and the field experiment.

Visser (1988) argues that for $t_0 \leq t < t_2$ the erosion of the inner slope is determined by the erosion at $x' = L_{eq}$ (where the depth-averaged current velocity reaches the equilibrium value for uniform flows), which comes down to the same as the erosion at the toe of the slope (at $x' = L$, L is the length of the inner slope):

$$-L \frac{dz'_b}{dt} = s_L \quad \text{for } t_0 \leq t < t_2 \quad (5)$$

where $z'_b = z'_b(x', t)$ is the position of the sloping bottom in z' -direction and s_L is the sand transport at the toe of the slope.

The current velocity for $x' = L$ can be written as

$$u_L = \left(\frac{g q \sin \beta_0}{C_f} \right)^{1/3} \quad (6)$$

The relation between the decrease dx_c of the width of the crown of the dike and dz'_b , and that between the fall $d\hat{z}$ of the top of the dike and dz'_b , follow both from simple geometrical considerations, see Fig. 12:

$$\frac{dx_c}{dt} = \frac{1}{\sin \beta_0} \frac{dz'_b}{dt} \quad (7)$$

$$\frac{d\hat{z}}{dt} = \frac{\sin \alpha}{\sin(\alpha + \beta_0)} \frac{dz'_b}{dt} \quad (8)$$

Fig. 12 Decline dx_c of the crown width x_c of the dike and fall $d\hat{z}$ of the top height \hat{z} of the dike, both as function of an erosion dz'_b of the inner slope.

where α is the angle of inclination of the outer slope.

Figures 11 and 12 show the erosion of the inner slope and the breach growth in vertical direction in a 2D-situation. For the 3D-situation Visser (1988) argues that the breach width B at the crown of the dike can be coupled with the breach depth $H_d - \hat{z}$:

$$B = r (H_d - \hat{z}) \quad \text{for } t_0 \leq t < t_2 \tag{9}$$

where H_d is the height of the dike and r is a coefficient with a value of about 3.8 (for sand-dikes).

The effect of the breaching process in horizontal direction on the breach growth in vertical direction is that the latter slows down with a factor f compared with the 2D-situation:

$$f = \frac{b + 2q/u}{2b} \tag{10}$$

where b is the depth-averaged breach width, see Visser (1988).

Substitution of (5), (1) with (2) and (3), (6) and (4) successively into (7) and (8) and taking into account the factor f gives:

$$\frac{dx_c}{dt} = - f k_1 (H_w - \hat{z}_0)^{1/2} \quad \text{for } t_0 \leq t \leq t_1 \tag{11}$$

$$\frac{d\hat{z}}{dt} = - f k_2 (H_w - \hat{z})^{1/2} \quad \text{for } t_1 \leq t < t_2 \tag{12}$$

in which \hat{z}_0 is \hat{z} at $t = t_0$ and where

$$k_1 = \frac{0.0082}{(1-p)\Delta} \left(\frac{m_0}{C_f}\right)^{1/3} (g)^{1/2} \frac{(\sin\beta_0)^{1/3}}{\cos\beta_0} \quad (13)$$

$$k_2 = k_1 \frac{\sin\alpha \sin\beta_0}{\sin(\alpha + \beta_0)} \quad (14)$$

Equations (9), (11) and (12) with (10), (13) and (14) describe the breach erosion for $t_0 \leq t < t_2$. The model is not (yet) valid for $t \geq t_2$, after the complete wash-out of the dike in the breach, since it rests on the erosion process of a (relatively) steep slope.

In principle it is also possible to describe the steepening of the inner slope for $t < t_0$ with the present approach. However, in practise the time period t_0 is very sensitive for the dimensions of the small initial breach.

5. CONFRONTATION OF MODEL WITH FIELD DATA

If $H_w = \text{constant}$, as can be assumed in the present field experiment for $0 < t < 20 \text{ min}$ (see section 4.2), simple analytical solutions for (11) and (9) with (12) result.

Integration of (11) gives with $x_c = 0$ for $t = t_1$:

$$x_c = f k_1 (H_w - \hat{z}_0)(t_1 - t) \quad \text{for } t_0 \leq t \leq t_1 \quad (15)$$

Hence, with $x_c = W_d$ for $t = t_0$, where W_d is the width of the crown of the dike (see Fig. 12):

$$t_1 = t_0 + \frac{W_d}{f k_1 (H_w - \hat{z}_0)} \quad (16)$$

Substitution of the result of the integration of (12), with $\hat{z} = 0$ for $t = t_2$ and $H_d = H_w$, into (9) gives

$$B = r \left[\frac{1}{4} f^2 k_2^2 (t - t_2)^2 + f k_2 (t - t_2) H_w^{1/2} + H_w \right] \quad \text{for } t_1 \leq t < t_2 \quad (17)$$

where

$$t_2 = t_1 + \frac{2}{f k_2} [H_w^{1/2} - (H_w - \hat{z}_0)^{1/2}] \quad (17)$$

The photos and video-images of the breach growth in the field experiment show that: $t_0 \approx 3 \text{ min}$. The results of the computations of t_1 , t_2 and B with $t_0 = 3 \text{ min}$, $H_w - \hat{z}_0 = 0.2 \text{ m}$, $p = 0.4$, $\Delta = 1.65$, $m_0 = 1.0$, $C_f = 0.015$ (see Visser, 1988), $\beta_0 = 32^\circ$ and $\alpha = 39^\circ$ are shown in Fig. 13. Fig. 13 also gives the measured values for B (field experiment). The agreement for $t < t_2$ is good.

The extrapolation in Fig. 13 for $t > t_2$ was done with a constant value for dB/dt , i.e. the value at $t = t_2$.

Fig. 13 Comparison of measured and computed development of breach width B at the crown of the dike.

6. DISCUSSION

The agreement between the process of breach erosion in the 0.6 m high laboratory sand-dikes, see Visser (1988), and that in the present 2.2 m high prototype sand-dike gives satisfaction. It means that much of the experimental work on sand-dike breach erosion can be done in the laboratory. This also applies to the comparable process of breach erosion in dunes.

As yet the model is only valid for the breach growth for $t < t_2$, since the model rests on the erosion process of a (relatively) steep slope. The agreement between the model predictions and both the laboratory experiments of Visser (1988) and the present field experiment is quite satisfactory.

The present investigation indicates that extrapolation of the model for $t > t_2$ (in stage IV) gives a significant overestimation of the breach growth. Hence it is meaningless to apply the model in its present state for $t > t_2$. Therefore it can be concluded that further study is necessary to include the process of breach erosion in stage IV in the model.

CHAPTER 159

MULTI-SCALE NEARSHORE & BEACH CHANGES

by

R.Ostrowski, Z.Pruszek & R.B.Zeidler¹

ABSTRACT

Empirical orthogonal functions in one- and two-dimensional formulation are employed to identify the variability of longshore and cross-shore features in different scales, ranging from days to years. The prototype topographic data was measured in coastal zones of the Baltic and Black Seas. Conspicuous features such as berms, bars, salients and cusps can be identified through e_{2x} . Temporal variation of cross-shore transport is reflected in e_{2t} and e_{3x} while linkage of e_{3t} to coastal factors remains unspecified.

1 Introduction

Beach transformation processes are usually dealt with in categories of longshore and cross-shore sediment transport. Both modes are discussed in this paper. At the same time one distinguishes different spatial and time scales. For the purposes of this paper, we identify short-term, meso-scale and long-term beach changes. The former include changes ranging from days to weeks, the meso-scale transformation encompassing changes from days to seasons, the seasonal yearly and multi-yearly variation being placed in the category of long-term changes.

We are in possession of a bulk of data for shore transformation along the Polish coast of the south Baltic, the Bulgarian coast of the Black Sea, and some other sites. For illustration, Fig. 1 shows excerpts from bathymetric charts compiled for the years 1967, 1975 and 1987 in the central part of the Polish coastline. It is seen that some parts of the coastal profile undergo very intensive changes while some other display a node-type behaviour with very minor variations. Together with the obvious need for more exploration of coastal processes, that finding has inspired us to undertake the investigation of nearshore and beach changes reflected in this paper.

2 Field Measurements

Field measurements provide the most obvious tool for analysis of nearshore transformation. We have collected data basically at two coastal research stations, one at Lubiatowo on the south Baltic Sea, some 75 km to the west of Gdańsk and the other at Shkorpilovtsi, some 50 km south of Varna, on the Bulgarian Black Sea. The two sites differ in many

¹all Polish Academy of Sciences' Institute of Hydro-Engineering IBW PAN, 80-953 Gdańsk, Kościuska 7, PL

Fig. 1. Examples of shore profiles measured on Polish coast

Fig. 2. Shore profile and measuring posts at IBW PAN Station at Lubiatowo (PL)

respects. The coastal zone at Lubiatowo is of dissipation type, with multiple bars, the inclination of bed being about 1%, and the sediment consisting of medium sand having $D_{50} \approx 0.22$ mm. The Bulgarian site is rather reflection type, with average bed slope about 1.5-2%, with one or no bar, its bed consisting of sand with $D_{50} \approx 0.4$ mm.

Fig. 2 depicts typical summer and winter profiles at Lubiatowo while Fig. 4 provides a rough idea of the Shkorpilovtsi environment. Data for short-term and meso-scale changes provided in this paper originate primarily from the Shkorpilovtsi station while the long-term variation is mostly based on measurements at Lubiatowo.

3 Empirical Orthogonal Functions (EOF)

Most of our analysis for bed changes is based on the method of empirical orthogonal functions, see Winant et al. (1975) for reference.

An one-dimensional approach, the variation of depth in time t and across shore, in the

direction x can be given as the following linear series:

$$h_{xt} = \sum_n c_{nt} \cdot e_{nx} \quad (1)$$

in which the index x varies from 1 to n_x , the total number of points along the profile where data is taken, while t is contained between 1 and n_t , the total number of times at which profiles were recorded.

If we require that the orthonormality condition is satisfied as:

$$\sum e_{nx} \cdot e_{mx} = \delta_{nm} = \begin{cases} 1 & m = n \\ 0 & m \neq n \end{cases} \quad (2)$$

then the quantities e_{nx} form a set of normal modes, or eigenfunctions. It is recollected that usual Fourier series also conform to the above condition. The value of EOF consists in the fact that a set of empirical eigenfunctions is selected to fit the data in the least squares sense.

The eigenfunctions e_{nx} are found from the empirical symmetric correlation matrix B having the following elements:

$$b_{ij} = \frac{1}{n_x n_t} \sum_{t=1}^{n_t} h_{it} h_{jt} \quad (3)$$

Any square matrix possesses a set of eigenvalues λ_n being found from the following determinant:

$$\det [B(\lambda)] = 0 \quad (4)$$

and a set of corresponding eigenfunctions, which are found from the following matrix equation:

$$B \cdot e_n = \lambda_n \cdot e_n \quad (5)$$

The coefficients c_{nt} , which may be referred to as a temporal eigenfunctions, are all also orthonormal:

$$\sum_{t=1}^{n_t} c_{nt}^* c_{mt} = \delta_{mn} = \begin{cases} 1 & m = n \\ 0 & m \neq n \end{cases} \quad (6)$$

in which $c_{nt}^* = c_{nt} / \sqrt{\lambda_n n_x n_t}$.

The coefficients c_{nt} are found by analogy from:

$$c_{nt} = \sum_n h_{xt} \cdot e_{nx} \quad (7)$$

For the mean shore profile represented by the first mode ($n = 1$ in Eq. 4) one has

$$h_{xt} = c_{1t} \cdot e_{1x} \approx e_{1x} \cdot (\lambda_1 \cdot n_x)^{\frac{1}{2}} \quad (8)$$

The above one-dimensional description can be expanded to the two dimensions (long-shore and cross-shore), cf. Hsu et al. (1986):

$$h(x, y, t) = \sum_k e_k(x, t) e_k(y, t) \quad (9)$$

The functions $e_k(x, t)$ and $e_k(y, t)$ are given by the following equations:

$$e_k(x, t) = \sum_n (\lambda_n n_x n_t)^{\frac{1}{2}} e_k^n(x) C_{kx}^n(t) \quad (10)$$

$$e_k(y, t) = \sum_m (\lambda_m n_y n_t)^{\frac{1}{2}} e_k^m(y) C_{ky}^m(t) \quad (11)$$

Fig. 3. Short-term bed changes measured at Shkorpilovtsi (Bulgarian Academy of Sciences)

in which:

k = two-dimensional mode of eigenfunction

λ_n, λ_m = eigenvalues for cross-shore and longshore direction, respectively

n_x, n_y, n_t = number of points measured across shore (x axis) and along shore (y axis) and profiles measured in time t , respectively

$e_k^n(x), C_{kx}^n(t)$ = cross-shore (space and time) eigenfunctions

$e_k^m(y), C_{ky}^m(t)$ = longshore (space and time) eigenfunctions.

4 Short-Term Bed Changes

The data for short-term bed changes have been collected at Shkorpilovtsi, where ultrasonic probes of 40-W power and 5° emission angle were deployed across shore in the years 1987 and 1988.

Fig. 3 illustrates the findings, from which it is clear that the most intensive changes occur again in the surf zone stretching between the underwater bar and shoreline. Since the longshore sediment transport did not exist for the particular configuration of shore, the cross-shore transport rates were computed from the continuity equation, as depicted at the bottom of Fig. 3.

The variability of bed prior to during, and after storm can be assessed from Fig. 4. Slow onshore transport is observed before storm. The dramatic changes towards offshore transport at a speed of 0.9 m/h are comparable with the estimates given by Birkenmeier (1984) (1.2 m/h) for waves $H \leq 2$ m and $T \leq 4$ s. During the recovery after storm the onshore transport occurs at a speed of 4 m/day, again somehow comparable with Sunamura (1989) who sites $v \approx 0.5$ m/day for a 1-m underwater bar and $H_b = 0.75 - 1$ m; a quantity which is fifty times smaller than that during the storm!

5 Meso-Scale Changes

5.1 Single-Bar Profile

Multi-yearly measurements of meso-scale variation of shore profiles have been conducted in two regions of single bars and multiple bars. The range of bed changes observed was

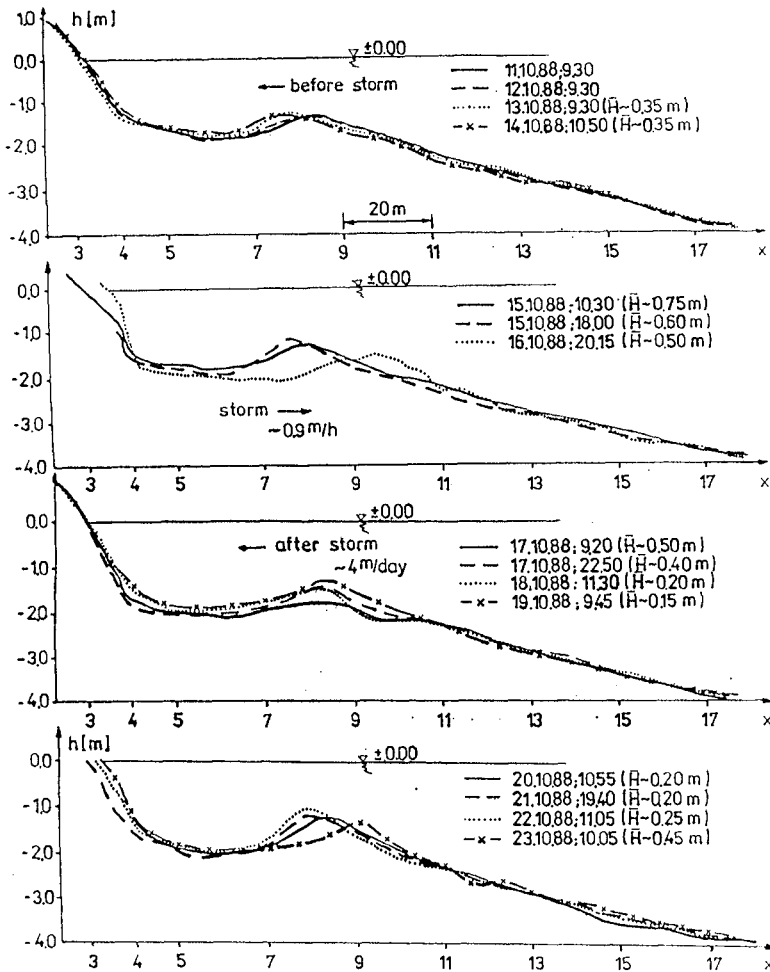

Fig. 4. Single-bar profile transformation in a storm at Shkorpilovtsi

Fig. 5. Mesoscale single-bar profile transformation at Shkorpilovtsi in 1976

about 1 m, which is somewhat visible in Fig. 5 for the Black Sea site of Shkorpilovtsi.

The meso-scale variation on single-bar profile was measured every month from 1973 to 1977.

One-dimensional EOF analysis for the profiles measured every month over the period of one year in the years 1974 and 1976 for the first three eigenfunctions e_{1x} , e_{2x} , e_{3x} has exposed certain relationships between them and pertinent coastal processes. An illustration is provided in Fig. 6. The following findings can be outlined:

- The first eigenfunction e_{1x} describes the average shore profile in which all underwater forms are smoothed out
- The second eigenfunction e_{2x} identifies the location of the underwater bar and berm in the summer (through its maxima). The minimum of the second eigenfunction identifies the location of bar in the winter season
- The third eigenfunction e_{3x} denotes the locations where accretion (maximum) or erosion (minimum) prevails.

The following can be said for the temporal eigenfunctions (the coefficients c_{it} (Fig. 7):

- The first coefficient c_{1t} can be regarded as constant about $c_{1t} \approx \sqrt{n_x \cdot \lambda_1}$, in the range from 9 to 13
- The second temporal eigenfunction c_{2t} depicts the seasonal (yearly) predominance of cross-shore transport direction (offshore or onshore). It is confirmed that the onshore mode prevails in the summer versus the offshore direction in the winter (negative value in the drawing)
- The coefficient c_{3t} is most difficult to identify as it oscillates and varies quite strongly. It can be attributed to the instantaneous predominance of erosion or accretion processes, much as the third eigenfunction e_{3x} . The places where onshore and offshore transport prevails are shown by arrows.

Fig. 6. Mesoscale changes at Shkorpilovtsi in 1974: bed profiles (top) and eigenfunctions (bottom)

Fig. 7. Coefficients c_{it} at Shkorpilovtsi, 1973 - 1977

5.2 Multiple-Bar Profiles

5.2.1 General Observations

Analysis of the variability of topographical features measured on the multiple-bar profile of the Polish coastline (Lubiatowo) illustrated in Fig. 8 has provided the following findings:

- Seasonal variability of the multiple-bar profile largely depends on the direction of cross-shore transport, the regions of the second and third bars (counted from shoreline) displaying the most intensive bed changes;
- In the summer, the onshore sediment transport prevails, primarily as bedload. This holds particularly for the surf zone, so that the second and third bars and beach are subject to clear transformation;
- If more violent storms appear in the summer, a strong accretion in the central part of underwater profile is noted, particularly about the third bar, which is supplied under these conditions from both land and sea;
- During calm periods most transformations are confined to the zone about shoreline and the shallowest bars.

The variation of shoreline and dune toe, coupled with the above changes in the underwater profile are depicted respectively in Fig. 8 b, c. It is seen that the migration of shoreline exceeds 10 m, the widest beach being exposed in the summer, as anticipated. The variation of the dune toe is generally less pronounced as it is due to extreme storm events, which have not appeared in the period of measurements.

5.2.2 EOF Analysis

The analysis has been based on the measurements performed at Lubiatowo a few times in the period from mid-May to mid-October 1987, in about twenty cross-shore profiles stretching over 700 – 1000 m and spaced from 100 to 200 m. In the one-dimensional representation depicted in Fig. 9 one can see that the first eigenfunction e_{1x} again depicts the average shore profile with characteristic macroforms. The second eigenfunction e_{2x} is attributed to underwater bars, its maximum being associated with clear accretion and its minimum being associated with erosion. The peak of the function e_{2x} is proportional to the intensity of local bed changes. Sharp peaks are localized about crests or troughs while smeared shallow extrema denote local accretion or erosion. The third eigenfunction e_{3x} is correlated with the predominance of offshore or onshore sediment transport. The maximum of e_{3x} can be linked to periodic predominance of onshore transport, while the minimum denotes the offshore mode.

The characteristic features repeat in the cross-shore profiles deployed along shore.

Two-dimensional EOF analysis provides a deeper insight into the coastal phenomena, although very few findings are clear-cut and conclusive.

The prototype results for meso-scale variability measured at Lubiatowo are depicted for the cross-shore eigenfunctions and longshore ones in Figs. 10 and 11, respectively. The following features for the first mode deserve attention:

- The first eigenfunction $e_1^1(x)$ represents the cross-shore profile averaged over the entire area (x, y) ;
- The second eigenfunction $e_2^1(x)$ displays the location of underwater bars representative for the entire area as implied from analysis of the cross-shore profiles measured;

Fig. 8. Mesoscale changes in coastal topography at Lubiato in 1987: (a) bed profile; (b) shoreline; (c) dune toe

Fig. 9. Bed profiles and eigenfunctions at Lubiatowo in 1987

Fig. 10. Cross-shore spatial eigenfunctions (2-D) for modes $k=1$ (a) and $k=2$ (b); Lubiatowo 1987

Fig. 11. Longshore spatial eigenfunctions (2-D) for modes $k=1$ (a) and $k=2$ (b); Lubiatowo 1987

- The third eigenfunction $e_1^3(x)$ is linked to locations of predominant erosion or accretion, again averaged over the entire area (x, y) .

It should be noted that the extremum values of the eigenfunctions e_{2x} and e_{3y} appear where the profile changes are maximum.

The findings for the second mode $k=2$, i.e. $e_2^1(x)$, $e_2^2(x)$ and $e_2^3(x)$ have not displayed any clear correlation with profile parameters, as shown in Fig. 10b. It should be stressed that the maximum changes in the function $e_2^3(x)$ are similar to those for $e_1^3(x)$ and appear in the zone of the most intensive profile transformation.

The respective longshore eigenfunctions $e_1^1(y)$, $e_1^2(y)$, $e_1^3(y)$ are illustrated in Fig. 11, for the first mode $k=1$ and second mode $k=2$ respectively, in parts a and b. The first eigenfunction $e_1^1(y)$ again characterizes the average feature, this time the allocation of shoreline. The second longshore eigenfunction $e_1^2(y)$ is difficult to identify. It is not excluded that its existence is associated with longshore forms, but more data is required to confirm this hypothesis. The third longshore eigenfunction $e_1^3(y)$ is associated with longshore changes in cross-shore profiles. The maxima of $e_1^3(y)$ point to the places of prevailing accretion while the minima are linked to erosion.

The longshore EOF for the second mode $k=2$, i.e. $e_2^1(y)$, $e_2^2(y)$, $e_2^3(y)$ do not show any clear correlation whatsoever with the coastal features except for the first function $e_2^1(y)$ which represents the average shape of shoreline (but not its location!).

The temporal eigenfunctions measured at Lubiatowo are depicted in Fig. 12 for cross-shore modes. The following observations can be made:

- The first function $C_{1x}^1(t)$ is constant, which implies that the average profile can be treated as time independent;
- The second function C_{1x}^2 is associated with the net cross-shore sediment transport, or processes of erosion and accretion, in good agreement with Winant et al. (1975) and Hsu et al. (1986);
- The third eigenfunction C_{1x}^3 seems to be uncorrelated with coastal features;

Fig. 12. Cross-shore coefficients c_{it} for modes $k=1$ and $k=2$; Lubiatowo 1987

- The cross-shore characteristics for the second mode $k=2$ do not display any clear-cut regularity or relationship to geometrical and dynamic characteristics.

The geometric and dynamical features of shoreline can be analyzed in terms of one-dimensional EOF. Some findings are illustrated in Fig. 13. For instance, the second eigenfunction e_{2y} indicates the places where the net accretion is the highest (maximum of e_{2y}) or erosion prevails (minimum of e_{2y}) along shore during the entire period of analysis. Oscillations about zero exhibit places of small net variation of shoreline.

The following remarks can be put forth for the temporal eigenfunctions c_{1t} , c_{2t} and c_{3t} (not illustrated):

- c_{1t} is approximately constant
- c_{2t} averaged over all shoreline locations shows a tendency towards accretion or erosion in consecutive time intervals. Positive values of this function point to the seaward advancement of shoreline while negative values indicate the landward retreat.

6 Long-Term Changes

6.1 Single-Bar or Smooth Shore Profiles

Our analysis of long-term single-bar profile changes has been based on multiyearly measurements carried out on the Black Sea coastline in the years 1974 - 1977. Fig. 14 illustrates the results obtained by one-dimensional EOF method. The findings are similar to those obtained for meso-scale changes, but it is because of the addition of multiyearly effects that individual functions are pronounced to a lesser extent. For instance, the average profile $h = c_{1x} \cdot \sqrt{\lambda_1 n_x}$ does not exhibit clear underwater bars and other forms, as they are smoothed out by individual profiles.

6.2 Multiple-Bar Profiles

These changes have been analyzed for the shoreline measured on the Baltic Sea in the years 1983 - 1989. Fig. 15a shows that the shoreline changes in the years 1983 - 1986 were

Fig. 13. Longshore empirical eigenfunctions (1-D); Lubiatowo 1987

Fig. 14. Long-term variation of single-bar profile at Shkorpilovtsi, 1973 - 1977

Fig. 15. Long-term variation of shore topography at Lubiatowo: shoreline from 1983 to 1989 (a); longshore EOF (1-D) 1983 - 84 (b); longshore EOF (1-D) 1987 - 89 (c); coefficients c_{it} (d)

Fig. 16. Longshore empirical eigenfunctions (1-D) at Lubiatowo, for the entire period 1983 - 1989

by far less intensive than those in the years 1987 - 1989. This is also reflected in the second eigenfunction e_{2y} , cf. Fig. 15b vs. Fig. 15c. The coefficients c_{it} are depicted in Fig. 15d.

The interpretation of the eigenfunctions and the temporal coefficients is similar to that provided earlier for the shorter time scales. For comparison, Fig. 16 shows the EOF for the entire period 1983 - 1989.

In order to provide an expanded background for the shoreline changes we analysed the variability of shoreline back to 1890 for the central coastline mentioned in the introduction. Reliable precise bathymetric charts were retrieved for the period from 1967 to date. One interesting feature observed was that in long scales the seabed varied in the vertical range of 1.0 - 2.5 m about both inner and outer bar, although the changes at the outer bar occur in a wider strip. As already mentioned, quasimodes with insignificant changes were observed in between the bars, some 150 - 175 m from shoreline. Beyond the zone of bar migration another node appears 300 - 350 m from shoreline.

7 Conclusions

1. The use of EOF, in 1-D and 2-D formulation, for analysis of bed & shoreline changes in multiple scales, and in different barred environments has confirmed the adequacy of the tool.
2. Some earlier linkage of eigenfunctions to factors of coastal dynamics has been given an extensive experimental support, and some other relationships have been exposed.
3. The following association of eigenfunctions and coastal features have been confirmed:
 - 1st mode e_{1x} → mean profile and/or shoreline
 - 2nd mode e_{2x} → berm/bars and/or salients/cusps, etc.
 - 2nd time f. c_{2t} → temporal predominance of off/onshore transport
 - 3d mode e_{3x} $_{1-bar}$ → intensive bed changes
 - e_{3x} $_{>1bar}$ → predominance of off/onshore transport
 - 3d time f. c_{3t} → difficult to attribute...
4. 2-D EOF sometimes obscures data analysis due to excessive smoothing out, although permits identification of longshore features.
5. Further application of EOF in analysis of scale-model and prototype data is intended.

A b s t r a c t

The beach processes due to regular waves, grouping waves and random waves are studied. The beach models which consist of coarse or fine sand are set to consider bed load and suspended load sediment, respectively. To obtain the equivalent beach topographics between regular wave and random wave conditions, the concept of same energy flux and same representative wave height are applied.

1. P r e f a c e

Natural beach conditions are dominated by random waves and three dimensional sediment transport (Goldsmith, 1982, Nishi, 1989), etc. Much data concerning coastal processes has been collected through experimental and theoretical studies. Regular waves and wave flume have been used mainly in these studies. Recently some reports on beach processes due to random waves have also been published (Dette, 1986, Hsiang, 1976, Irie, 1986, Mimura, 1986, Nishi, 1988, Tsuchiya, 1974).

It is necessary to study beach processes due to random waves in order to correlate knowledge gained from studies under regular wave conditions. It is also important to define regular wave characteristics for coastal and beach process experiments based on the natural random wave record. It seems that the hydraulic model experiment is the first step to correlate the physical phenomena between the numerical and full scale models. The wave irregularity, wave groupiness, the effects of infragravity waves and grain size distribution, as well as the three dimensional sediment transport on beach processes and sea level fluctuation have to be taken into account in the model experiments.

The following points are the results of this laboratory study.

- 1) Development of a measuring system which can simultaneously process numerous topography and wave data.
- 2) The effect of wave irregularity on beach deformation by the

action of random waves, grouping waves and regular waves on the movable bed beaches which consist of coarse(0.6mm) or fine(0.29mm) sand.

3) The effect of three dimensional sediment transport on beach deformation.

2. Experiments

A wave basin 26.7m long, 14m wide and 1.2m deep, as shown in Fig.1, was used. Two separate 1/20 slope movable bed beaches, which consist of 0.29mm and 0.6mm medium grain size sand, were set to find the effect of suspended sediment and bed load, respectively.

This study was conducted with three experimental series A, B and C. In the first experimental series A, the beach topographies were measured by the bamboo stick system. The beach topographies were measured at 672 evenly spaced points (50cm intervals) by visual measurement at 0.0, 0.5, 1.0, 2.0, 4.0, 8.0, 12.0, 24.0 hours. The incident wave field were measured at the same time. The wave characteristics of random waves, grouping waves and regular waves were chosen to satisfy the same energy wave flux conditions. The schematic graphs of these waves are shown in Fig.2. The BretschneiderMitsuyasu spectrum defined by eq.(1) (Mitsuyasu,1971) was used for generation of random waves in this study.

$$S(f_n) = 0.257 \left(\frac{H_1}{T_1} \right)^2 f_n \exp(-1.03(T_1 f_n)^{-4}) \tag{1}$$

Fig.2 Schematic diagram of waves.

In the second experimental series B, automatic topography measurement system(Fig.3) was used as same as series C. The topographies were measured at 2800 evenly spaced points(30cm intervals) at 0.0 , 0.5, 1.0, 2.0, 4.0, 8.0, 12.0, 24.0hrs. The wave fields were also

measured by 30 wave gauges at the same time. The wave gauges were set in 1.0m spacing parallel to the shore and moved by 0.5m offshore.

The wave characteristics of random waves and regular waves were chosen to satisfy the same characteristic wave heights, viz.

- (i) regular wave height equals maximum wave height
- (ii) regular wave height equals significant wave height
- (iii) regular wave height equals mean wave height

In the third experimental series C, the beach consist of fine (0.29mm) sand were used to investigate the suspended sediment transport. The wave heights were also chosen as those in experimental series B.

The wave conditions are shown in Table 1. The installation of instruments are shown in Fig.5. The nearshore current systems were observed by dye(MnO₄ solution) and tracer(fluorescent light).

Fig.3 Automatic measurement system for wave and topography.

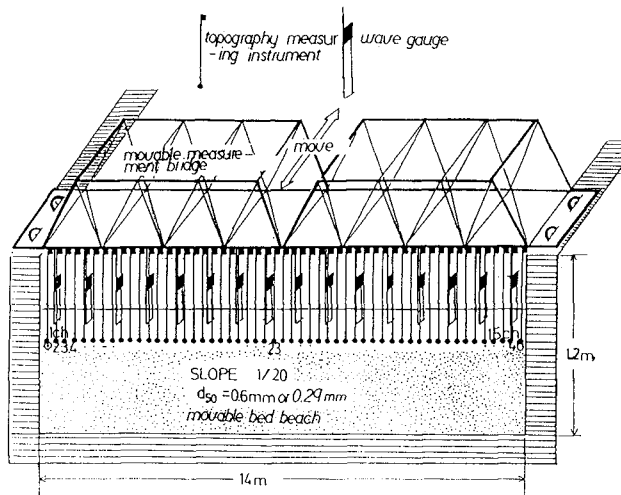

Fig.4 Installation of wave gauges and topography measuring instrument.

3. Results

The purpose of this study is to discover how to correlate knowledge gained under regular wave conditions to that gained under random wave conditions to find a characteristic wave for beach deformation from natural random wave records obtained on the natural beaches.

In regards to the above points, the knowledge which obtained from this study is still limited. This study consists of three experimental series, therefore results are discussed separately. The general results through series A to C are discussed in the final section.

3.1) Experimental Series A.

The purpose of series A is to find "how to obtain the equivalent beach topographies among the action of regular waves, grouping waves and random waves". To obtain the equivalent beach profiles due to each waves, the same energy flux concept was applied. The wave conditions of the three waves were chosen to satisfy the same energy wave flux. This concept is as follows,

$$W_{reg} = \frac{1}{8} \rho g H^2 C_g \tag{2}$$

$$W_{group} = \frac{1}{8T_z} \sum_1^{\infty} \rho g H_n^2 C_{g_n} \tag{3}$$

$$W_{ran} = \frac{1}{8} \sum_1^{\infty} \rho g H_n^3 C_{g_n} \tag{4}$$

$$\begin{aligned}
 &= \sum_1^{\infty} \rho g S(f_n) C_{g_n} \\
 &\quad \text{(deep water wave approximation)} \\
 &= \sum_1^{\infty} 0.78 \rho g S(f_n)/f_n \\
 &= 0.0854 \rho g H_{1.3}^3 \tag{5}
 \end{aligned}$$

where, W_{reg} , W_{group} , W_{ran} ; the energy flux of regular waves, grouping waves and random waves. The Bretschneider-Mitsuyasu spectrum was applied for $S(f_n)$.

$$S(f_n) = 0.257 \left(\frac{H_{1.3}}{T_{1.3}^2} \right)^2 f_n^{-5} \exp(-1.03(T_{1.3} f_n)^4)$$

$$C_g = nC = \frac{1}{2} \left(1 + \frac{2kh}{\sinh 2kh} \right) \left(\frac{gT}{2\pi} \tanh \frac{2\pi h}{L} \right)$$

Therefore, this concept can be written as follows.

$$W_{reg} = W_{group} = W_{rand} \tag{6}$$

(a) Regular waves

(d) Group waves

(c) Random waves

Fig.5 Beach topographies.

Fig.6 Beach profiles (series A).

Twenty eight on-offshore profiles were measured at 50cm intervals for single measurement of topography. The beach topography caused by random waves is somewhat smooth compared to the other topographies.

The mean profiles are calculated based on these lines and are shown by a solid line in Fig.5. Beach profiles caused by regular waves, grouping waves and random waves do not result in equivalent beach profiles. There are also representative beach profiles under the rip current and mass transport areas, which are shown by a broken line and a dot line respectively. Nearshore circulations are more easily generated by regular waves in the wave basin experiments compared to the wave action of random waves. Related beach profile differences exist between the rip current areas and the mass transport areas.

With regards to the three dimensional sediment transport, the schematic diagrams of sediment drift and hydraulic phenomena in the nearshore zone under regular wave conditions are shown in Fig.7.

Sediment transport is closely related to concave points in the crescentic longshore bar. The floats with fluorescence paint showed zig-zag motion on the crescentic bar due to wave breaking and rip-currents. This movement is related to sediment transport, and suggest that there are cases where the sediment drift direction is not the same as that of corresponding currents. This phenomena could not be generated thoroughly in this case , due to random waves. Some researchers have discussed the relationship between the edge waves and the rhythmic topographies. However, those relationships are not discussed here in detail.

Fig.7 Schematic diagram of
 (a)coastal process and sand drift
 (b)hydraulic phenomena in the nearshore zone.

3.2) Experimental Series B.

The application of the concept of same energy wave flux have been discussed in the previous section. It does not result in equivalent topographies. Therefore, the method of the same representative wave heights was examined here. This concept is based on the statistical analysis of random waves. The three methods for comparison of the topographies due to regular and random waves are employed. The concepts are as follows,

- (i) one-tenth maximum wave height equals regular wave height
- (ii) significant wave height equals regular wave height
- (iii) mean wave height equals regular wave height.

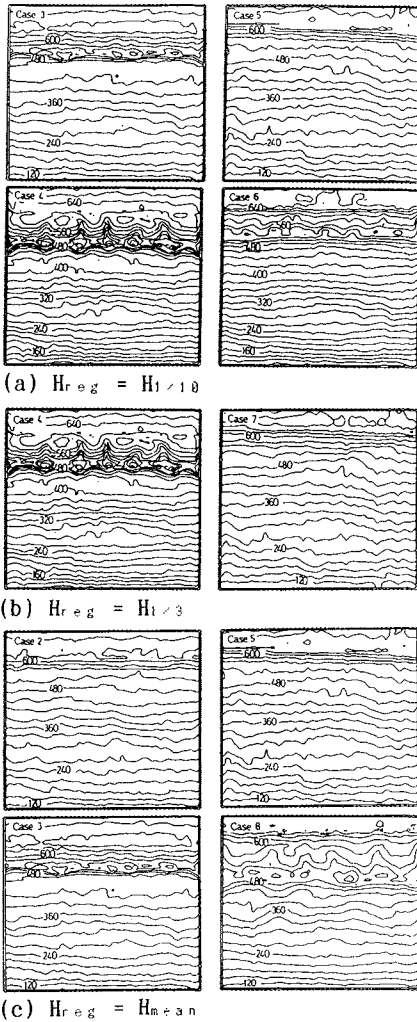

Fig.8 Beach topographies due to regular waves and random waves

The comparison of beach topographies related to the above concept are shown in Fig.12(a), (b), (c). It does not result in the equivalent topographies between the regular wave and random wave cases.

The mean on-offshore sediment transport rate of both cases and the mean beach profiles are shown in Fig.9 and Fig.10, respectively. The onshore beach profile changes due to random wave action are quite large compared to those due to regular waves, since random waves include

Fig.9 On-offshore sediment transport and distribution of depth change.

many large swash waves. The position of the longshore bar is also farther offshore than in the case of regular waves. Sediment transport due to regular waves is concentrated around the breaking point. The wave breakings of regular wave conditions are generated in a narrow area compared to it of random wave conditions.

3.2.2) Comparison of mean beach profile characteristics

As mentioned in section 3.2, any certain characteristic wave which result equivalent beach topographies as those due to regular waves could not achieved, yet. However, in correlating the knowledge obtained from researches on random waves to that obtained under regular waves, the mean beach profiles are used. The relationships concerning critical water depth for sand movement, shoreline position, berm height, and mean depth change etc. are examined here.

Fig.10 Mean beach profiles (series B).

3.2.2.1) Critical water depth for sand movement.

The critical water depth for sand movement in this study is defined, and shown schematically, in Fig.13. The critical water depth proposed by Tanaka and Sato (eq.(8)) is shown by a solid line in this figure. The critical water depth for sand movement under regular wave conditions is deeper by 2cm than the calculated value, but the tendency is similar to equation (8). The data of the random wave experiment vary widely compared to it due to the regular waves. The data with respect to mean wave are much deeper than equation (8).

$$\left(\frac{H}{H_0}\right)^{-1} \left(\frac{\sinh 2\pi h_i}{L}\right) \left(\frac{H_0}{L_0}\right)^{-1} = 1.770 \left(\frac{L_0}{d}\right)^{1/3} \tag{8}$$

The results using significant waves also have some variance, but they distribute around the calculation and are somewhat shallower than the results of regular waves. Therefore, the significant wave characteristics should be applied for the calculation of critical water depth under random wave action rather than mean wave. This corresponds to the results from a natural beach by Sato et al.

3.2.2.2) Shoreline changes

A time series of shoreline changes from initial position are shown

Fig.11 The critical water depth for sediment movement and definition sketch.

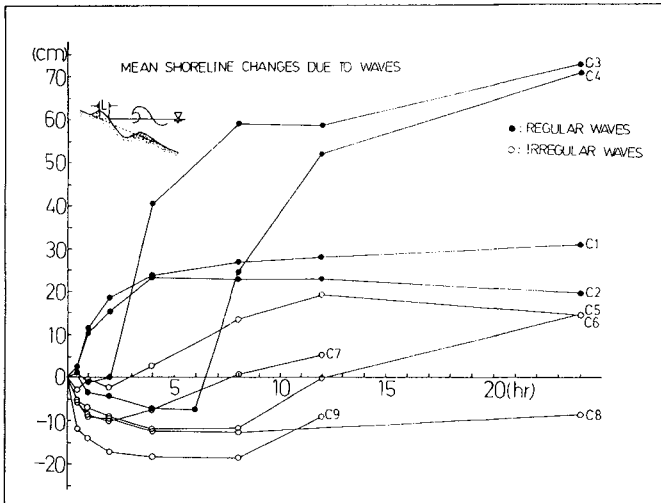

Fig.12 Time series of shoreline changes.

in Fig.14. The shoreline changes due to random waves are smaller than those due to regular waves. The abrupt changes of shoreline position are caused by the welded bar as shown in Fig.8. The shoreline changes at 12 hours are shown in Fig.15. There are some cases where the same representative waves give the contrast topographies between regular waves and random waves .

3.2.2.3) Berm height

Wave run-up contribute to built the berm , this berm height after 12 hours is shown with respect to the wave height in Fig.16. In contrast to shoreline changes, berm heights due to random waves are higher than those due to regular waves. The probability of a large wave run-up in the random waves is higher than that in regular waves, so that random waves result in higher berms.

Fig.13 Berm height.

3.2.2.4) Mean depth change

Some researchers have indicated that the topography changes due to random waves are somewhat smaller and smoothed compared to those due to regular waves.

To examine this, two graphs are prepared. One shows the distance from onshore limit of beach deformation to offshore one with respect to wave height. The other shows the sum of depth change, also with respect to wave height. These two graphs are shown in Fig.17 and Fig.18. The distance from onshore limit of beach deformation to offshore one

Fig.14 The length of on-offshore depth change limits.

Fig.15 The sum of depth change at 12hours.

caused by regular waves exists between those based on mean and significant waves. The sum of depth changes due to regular waves is nearly equal to those of mean waves and greater than those due to significant waves.

The mean depth change is defined as (sum of depth change) / (length of beach deformation). As a result, mean depth changes due to random waves are smaller than those of regular waves.

3.3) Experimental Series C.

Beach processes were examined by a model consisting of coarse sand (0.6mm) in series A and B. In these experiments, a type III beach (proposed by Horikawa and Sunamura) was not generated. Therefore, a beach model consisting of fine (0.29mm) sand was used to consider the suspended sediment transport and erosion of beach.

3.3.1) comparison based on the same representative wave heights.

Beach topographies based on the same representative wave heights are shown in Fig.19. This seems that the beach topography due to regular waves is characterized by the rhythmic longshore bar, and topography due to random waves is characterized by rhythmic step. These topographies are not similar. Rhythmic topographies are generated in the offshore region on the fine sand beach, but not on the coarse sand beach in this experiments.

3.4) Effect of grain size

The mean beach profiles of fine sand and coarse sand due to same wave conditions are compared and shown in Fig.21. The two upper

Fig.16 Beach topographies due to regular waves and random waves.
 $H_{reg} = H_{mean}$ (series c)

Fig.17 Comparison of profiles of fine sand and coarse sand beaches.

Fig Depth change and sediment transport

profiles resulted from regular waves and the six lower profiles from random waves. The two upper profiles correspond to the lowest two profiles on the basis of same representative wave height (mean wave height). The beach profiles which consist of fine sand, show a larger topographical change.

4. Conclusion

This paper is a basic laboratory study for beach processes due to random waves. However, the main purpose, "obtaining the equivalent topographies for both regular waves and random waves", have not been achieved yet.

The conclusions are;

- (1) The topography measuring instrument system with A/D converter, developed here, can simultaneously collect numerous accurate data.
- (2) Beach topographies due to similar energy flux waves result in different topographies.
- (3) Beach topographies due to the same representative wave height as regular wave height result in different topographies.
- (4) Critical water depth for sediment movement due to random waves can be calculated by using significant wave characteristics.
- (5) There are cases where the direction of sediment drift differ from the corresponding longshore and rip-current directions.
- (6) Rhythmic topographies were observed in the inshore region of coarse and fine sand beaches, and also in the offshore region of fine sand beaches.

CHAPTER 161

A QUASI-3D MODEL FOR SUSPENDED SEDIMENT TRANSPORT BY CURRENTS AND WAVES.

Irene Katopodi¹ and Jan S. Ribberink²

ABSTRACT

A QUASI-3D model for suspended sediment transport based on an asymptotic solution of the convection-diffusion equation is developed for currents and waves. The influence of waves on the sediment concentration is included through the diffusion analogy and the bed boundary condition. Validity analysis provides conditions that permit the check of the model applicability. The presence of waves enhances the validity area of the model considerably. The model compares favourably with a 3D model and experimental data.

1. INTRODUCTION

In compound mathematical models for coastal morphological problems the suspended sediment transport module forms an essential submodel. For the suspended sediment transport description a wide range of models has been presented in the past (e.g. transport formulas, 3D or 2D horizontal convection-diffusion models).

In this study a quasi-3D formulation is developed based on the analysis of Galappatti and Vreugdenhil (1985) for 2D vertical problems. This quasi-3D modelling technique combines the reduced computational effort of 2DH models with the generality of the 3D models (ie variations in vertical structure of sediment concentration are reproduced and the bed boundary condition is applied as in 3D models). The QUASI-3D model has been recently used for morphological problems of tidal rivers and estuaries (Wang, 1989). The present study is aimed at coastal morphology where wave influence is of importance.

2 Researcher, Delft Hydraulics, P.O. Box 152, 8300 AD Emmeloord the Netherlands.

2. BASIC EQUATIONS

The mass balance equation for the suspended sediment when integrated over the wave period (after concentration and velocity components have been split into a wave averaged and an oscillating part) gives rise to wave averaged plus correlation terms. It is assumed that for the correlation terms the Boussinesq assumption holds so they can be connected to the concentration gradients by means of a proper mixing coefficient (diffusion analogy). Then the suspended sediment transport due to current and waves is governed by the wave-averaged convection-diffusion equation:

$$\frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} + v \frac{\partial c}{\partial y} + (w-w_s) \frac{\partial c}{\partial z} = \frac{\partial}{\partial x}(\epsilon_x \frac{\partial c}{\partial x}) + \frac{\partial}{\partial y}(\epsilon_y \frac{\partial c}{\partial y}) + \frac{\partial}{\partial z}(\epsilon_z \frac{\partial c}{\partial z}) \quad (1)$$

where c, u, v, w are concentration, longitudinal, lateral and vertical velocity components respectively, all averaged over the wave period, sediment fall velocity is w_s and ϵ_x, ϵ_y and ϵ_z are mixing coefficients for the combined action of current and waves.

The convection-diffusion equation has been used to describe the current-waves induced suspended sediment transport before (e.g. van Rijn 1986, van Rijn and Meijer 1988).

Van Rijn (1986), based on measurements of equilibrium concentration profiles, proposed an empirical vertical mixing coefficient for current and waves. According to this empirical approach the influence of waves on the mixing coefficient comes through the following wave quantities: Wave period T , particle size diameter $D_* = D_{50} \{(\rho_s - \rho)/g(\rho\nu^2)\}^{1/3}$, significant wave height H_s , peak value of orbital velocity near the bed \hat{u}_{orb} , a_{br} a breaking coefficient, water depth h and thickness of the near bed mixing layer δ (≈ 3 ripple heights). The influence of the current comes through the current bed shear velocity u_* , the von Karman constant κ , the water depth h and the relative strength of the wave orbital velocity and mean current velocity (van Rijn 1986, van Rijn and Meijer 1988).

The horizontal mixing coefficients are taken constant over the depth. Their magnitude is of the order of $1 \text{ m}^2/\text{s}$ (van Rijn and Meijer, 1988).

To solve equation (1) boundary conditions are needed not only at the vertical boundaries but also at the water surface and at the bottom.

At the water surface the vertical flux is taken to be zero.

The bed boundary is taken at a specified height z_a above the mean bed level (reference level) that here is specified as a small fraction of the depth. At the reference level the concentration is assumed to adapt immediately to equilibrium conditions and is given as function of the local hydraulic and sediment parameters ("concentration" bed boundary condition). Alternatively the concentration gradient at the reference level can be assumed to adapt immediately to equilibrium conditions ("gradient" bed boundary condition). Here the equilibrium concentration (and equilibrium gradient) at the reference level proposed by van Rijn (1986) is used.

3. THE QUASI-3D MODEL

3.1 Derivation

Galappatti and Vreugdenhil (1985) constructed an asymptotic solution of the convection-diffusion equation in 2DV space for current alone under certain assumptions concerning the scales of domain dimensions, time, flow velocities, and horizontal and vertical diffusion.

The same steps are followed here for the solution of the 3D equation (1). The first order solution can be written (see Katopodi and Ribberink, 1988):

$$c(\zeta) = a_{11}(\zeta)\bar{c} + a_{21}(\zeta)\frac{h}{w_s}\frac{\partial\bar{c}}{\partial t} + a_{22}(\zeta)\frac{h\bar{u}}{w_s}\frac{\partial\bar{c}}{\partial x} + a_{22}(\zeta)\frac{h\bar{v}}{w_s}\frac{\partial\bar{c}}{\partial y} - a_{21}(\zeta)\frac{h}{w_s}\frac{\partial}{\partial x}\left(\epsilon_x\frac{\partial\bar{c}}{\partial x}\right) - a_{21}(\zeta)\frac{h}{w_s}\frac{\partial}{\partial y}\left(\epsilon_y\frac{\partial\bar{c}}{\partial y}\right) \quad (2)$$

where \bar{c} is the depth averaged concentration, \bar{u} and \bar{v} depth averaged velocity components, $\zeta = z/h$, h the water depth and $a_{ij}(\zeta)$ profile functions. The profile functions depend only on the explicit knowledge of the vertical mixing coefficient, fall velocity and normalized velocity profile and can be computed in advance.

In the applications that follow the velocity profile is assumed to have the logarithmic shape -an assumption that can hold for boundary layer flows in combination with small wind waves (van Rijn and Meijer, 1988). Nevertheless the method can handle 3D velocity profiles as soon as they are given as similarity series.

The solution (2) and the equations that give the profile functions have been derived with the use of the surface boundary condition and the assumptions that only the zero order concentration terms contribute to the depth averaged concentration and that shape variations of the equilibrium concentration profile can be neglected.

If further the bed boundary condition is used, then from (2) follows ("concentration" condition):

$$\begin{aligned} \bar{c}_e = & \bar{c} + \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s} \frac{\partial \bar{c}}{\partial t} + \frac{\gamma_{22}}{\gamma_{11}} \frac{h\bar{u}}{w_s} \frac{\partial \bar{c}}{\partial x} + \frac{\gamma_{22}}{\gamma_{11}} \frac{h\bar{v}}{w_s} \frac{\partial \bar{c}}{\partial y} - \\ & - \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s} \frac{\partial}{\partial x} \left(\epsilon_x \frac{\partial \bar{c}}{\partial x} \right) - \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s} \frac{\partial}{\partial y} \left(\epsilon_y \frac{\partial \bar{c}}{\partial y} \right) \end{aligned} \quad (3)$$

where $\gamma_{ij} = a_{ij}(0)$ and \bar{c}_e the depth averaged equilibrium concentration.

Equation (3) is a partial differential equation with constant coefficients and \bar{c} as the unknown. The coefficients γ_{11} , γ_{21} , γ_{22} are known in advance. After solving (3) for \bar{c} (with proper initial and boundary conditions), the vertical concentration profile $c(\zeta)$ can be computed from (2). The sediment transport is calculated afterwards.

An equation analogous to (3) can be derived if "gradient" bed boundary condition is used.

The QUASI-3D model (equation 3) was implemented in the SUSTRA 3D/2DV system following the same numerical (finite volume) method (van Rijn and Meijer, 1988).

3.2 Adjustment effects

If horizontal diffusion terms are omitted equation (3) can be written as:

$$\bar{c}_e = \bar{c} + T_A \frac{\partial \bar{c}}{\partial t} + L_x \frac{\partial \bar{c}}{\partial x} + L_y \frac{\partial \bar{c}}{\partial y} \quad (4)$$

with

$$T_A = \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s}, \quad L_x = \frac{\gamma_{22}}{\gamma_{11}} \frac{\bar{u}h}{w_s}, \quad L_y = \frac{\gamma_{22}}{\gamma_{11}} \frac{\bar{v}h}{w_s} \quad (5)$$

Equation (4) describes the adjustment of the depth-averaged concentration to its equilibrium value. The parameters T_A , L_x and L_y represent the characteristic scales in time and space of this adjustment process (adaptation time, adaptation length). The ratios γ_{21}/γ_{11} and γ_{22}/γ_{11} in (5) can be considered as dimensionless adaptation times and lengths.

If the "gradient" bed boundary condition is used only the expressions for dimensionless adaptation time and length change (see Katopodi and Ribberik, 1988).

The adaptation time and lengths as well as the depth averaged equilibrium concentration are determined by the local, instantaneous hydrodynamic conditions and sediment characteristics and can thus be computed in advance before the calculation of \bar{c} .

If adaptation length (time) is smaller than the maximum allowable grid size (time step) of the numerical calculation, the sediment redistribution is not resolved by the grid. Then the concentration can be assumed close to its (local, instantaneous) equilibrium value and a suspended sediment transport formula can be used for the calculation of the bed level changes. If this is not the case, the adaptation phenomena should be taken into account and the concentration can be computed from (3).

The influence of the wave and current parameters that determine the coefficients of equation (4) and consequently the dimensionless adaptation time and length was studied by computing the coefficients for a wide range of these parameters.

The dimensionless adaptation time and adaptation length appeared to be affected most strongly by the parameters w_s/u_* (current mixing) and H_s/h or $H_s/w_s T$ (wave mixing). The combined influence of the two parameters is shown in figure (1). It is shown that the dimensionless adaptation time (and length) show a considerable increase when waves are superimposed to a current. (Compare the curves of $\gamma_{21}/\gamma_{11} = f(w_s/u_*)$ for $H_s/h = 0$ and for $H_s/h = .2$ etc). This increase is more significant when current alone causes negligible suspension adjustment effects ($w_s/u_* > .5$).

The influence of the other parameters \hat{u}_{orb}/w_s , D_* , δ/h , \bar{u}/u_* and z_a/h was found to be considerably smaller.

3.3 Validity conditions

The validity of the model was studied for the case of waves superimposed to a current through comparison with an analytical solution of the convection-diffusion equation, based on an earlier analysis of Wang and Ribberink (1986) for current alone. The results of this analysis are:

The presence of waves leads to a considerable extension of the validity area of the quasi-3D approach. Generally the validity area increases as the suspended load increases (i.e large current velocities, large waves and fine sediment) or for small values of a suspension parameter "modified for the waves", indicated by the analysis:

$$Z_{c,w} = \frac{w_s}{xu_* + .14 \alpha_{br} H_s/T} < .75 \quad (6)$$

Fig.1 Dimensionless adaptation time as function of (w_s/u_*) and (H_s/h) .

For current only an upper limit holds for the suspension (Rouse) parameter Z_c :

$$Z_c = w_s / (\chi u_*) < 0.75 \quad (7)$$

It is obvious from (6) and (7) that the presence of the waves enhances the model validity area considerably. Of course, the smaller the suspension parameter the better the asymptotic solution.

The assumptions made in order to get the asymptotic solution impose restrictions on the length scale L and time scale T of the particular problem. L and T can be considered as the length scale of changes in hydraulic conditions (e.g bottom shear stress) and time scale of changes in hydraulic conditions (e.g tidal period).

The analysis shows that these changes should be so gradual that the following conditions are fulfilled:

$$L \gg \frac{1}{Z} \frac{u\bar{h}}{w_s} \quad \text{and} \quad T \gg \frac{1}{Z} \frac{h}{w_s} \quad (8)$$

In (8) the suspension parameter Z refers to current or to current and waves (ie Z_c or $Z_{c,w}$)

Comparison of length (and time) scales allowable by (8) for the case of current and current and waves shows that superposition of waves on a current allows the application of the model for less gradual changes in hydraulic conditions than in case of current only and thus enlarges the validity area.

4. RESULTS

4.1 Comparison with a 2DV model

In 2DV plane the problem of suspended sediment transport adjustment in steady uniform flow conditions and zero sediment input at the upstream boundary (similar to fig. 5A) is solved with the asymptotic model and a 2DV numerical model (SUTRENCH, van Rijn, 1986). Several cases with varying current and wave parameters are compared. It should be noted that the chosen problem with a sudden change in bed boundary condition at the upstream boundary (reference concentration goes from zero to equilibrium) is a hard test for the asymptotic model that requires gradually varying conditions.

In figure (2) the transport computed with the asymptotic model and SUTRENCH is shown. The x coordinate is divided by the adaptation length so that the QUASI-3D model is represented in all cases by the same line.

For current only (2A) it is evident that the smaller w_s/u_* (or Z_c), the closer the asymptotic model and SUTRENCH are. The agreement is rather good for the last two cases. This confirms the validity analysis (eqn. 7).

In figure (2B), the worse case of fig 2A ($w_s/u_* = .5$) improves more and more as the wave contribution increases.

4.2 Comparison with a 3D numerical model

The QUASI-3D model is tested by comparison with a numerical 3D solution (SUSTRA 3D). In figure (3) the non-equilibrium suspended sediment transport computed with the two models is presented for the case of flow around a local construction. The agreement is satisfactory except in the zone behind the dam where the two models use different bed boundary conditions.

—— asymptotic model (transport zero order) B: CURRENT AND WAVES

Fig.2 Adaptation of suspended sediment transport.
A: Current only, B: Current and waves

The agreement in the main flow area is depicted more detailed in figure (4 left) where the equilibrium and the non-equilibrium transport along grid line $j=5$ are plotted for the two models. The equilibrium transport, as expected, is exactly the same for both SUSTRA 3D and the QUASI-3D model. The non-equilibrium transport (substantially different than the equilibrium one) as computed with the two models show a very good agreement.

In figure (4 right) the computed non-equilibrium transport along line $j=18$ (much stronger variations) is shown for the two models. In the recirculation zone the difference between the two models becomes considerable.

The necessary computation times of the two models are compared. The QUASI 3D model proved to be 8-10 times faster than SUSTRA 3D.

4.3 EXPERIMENTAL VERIFICATION (CURRENT AND WAVES)

The first order asymptotic model was compared with a laboratory experiment carried out in a mobile bed flume with current and wave conditions and zero sediment transport at the upstream boundary. The experiment was carried out by Galappatti and van Rijn (1984).

Fine sediment particles were entrained by a sediment free flow over a sand bed in the presence of monochromatic waves. The flow and wave conditions were uniform. The velocity profile was logarithmic. The concentration profiles (eight depth points) were measured at six stations along the flume. Upstream the mobile bed, the bed was fixed (experimental set-up in figure 5A).

In figure (5.B) the zero order suspended sediment transport computed with the asymptotic model is plotted against the dimensionless distance along the flume. The results of SUTRENCH (van Rijn, 1986) are also presented. The computed sediment transport is always somewhat smaller than the measured one. The largest deviation is about 20% which can be considered as rather good result.

In figure (6) the concentration profiles computed and measured at the six stations indicated in (5.A) are shown. The agreement again is reasonably good.

In total, the above comparison shows that the QUASI-3D model is able to predict the suspended sediment concentration due to current and waves with a reasonable degree of accuracy against reasonable costs.

Moreover the choice to treat wave mixing in a similar manner to turbulence mixing (diffusion analogy) seems to be justified.

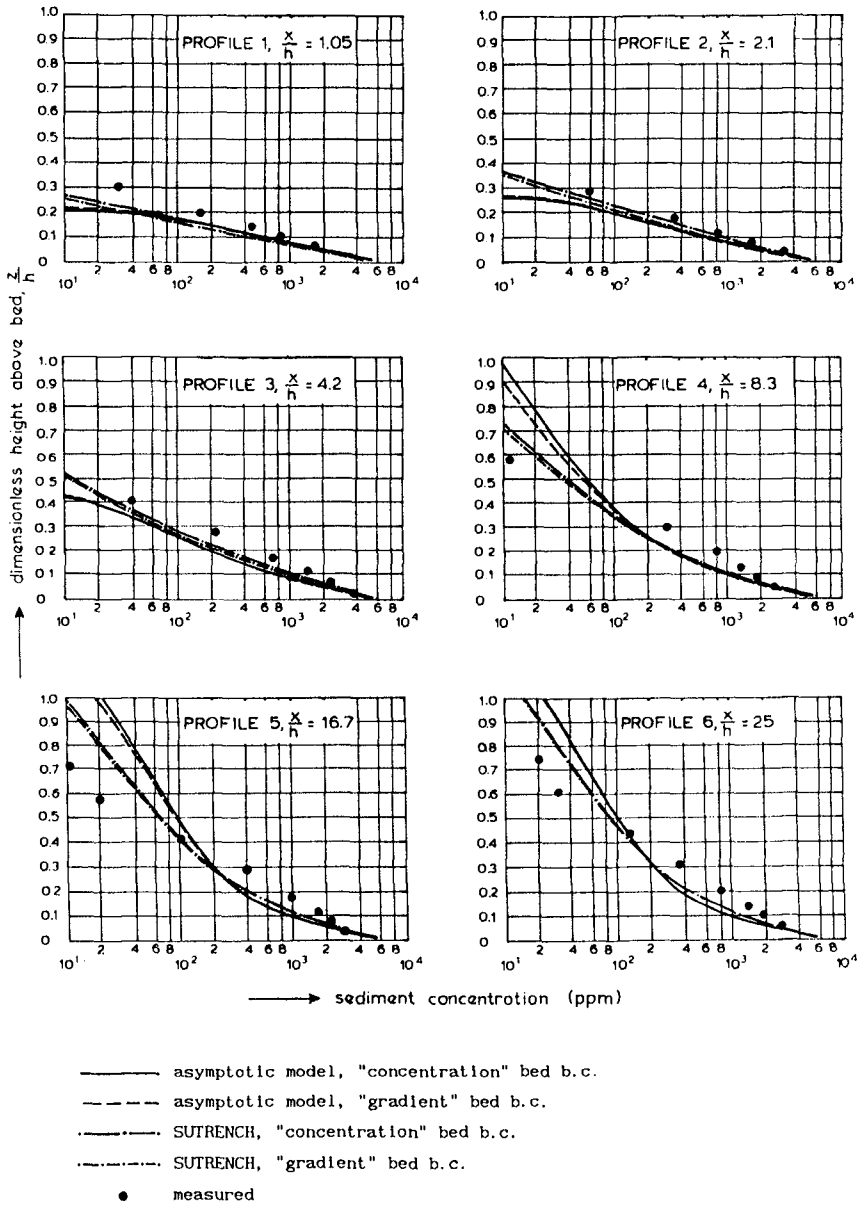

Fig.6 Adaptation of sand concentration profiles in a flume (current and waves).

5. CONCLUSIONS

The QUASI-3D model combines the reduced computational effort of 2DH models with the ability to describe vertical redistribution of suspended sediment concentration while the bed boundary condition is maintained.

The presence of waves leads to a considerable extension of the area of validity of the quasi-3D approach.

The applicability of the model can always be checked beforehand using the validity conditions and this is a big advantage of the model. The validity area indicated by the analysis is in the usual range of many practical (coastal) problems.

As concluded by the the sensitivity analysis superposition of waves on a current appeared to lead to a considerable increase of the importance of the delayed adjustment phenomena.

The numerical as well as the experimental comparison showed that the model behaviour is rather satisfactory.

Introduction of quasi-3D velocities is the next step for the model improvement.

CHAPTER 162

Method for Prediction of Bar Formation and Migration

Samuel H. Houston¹ and Robert G. Dean²

Abstract

A computational model based on sediment conservation and transport equations is presented. The bottom shear stress associated with breaking waves is the primary forcing function for the model. A breaking wave model is used to calculate distributions of wave height and mean water level setup across the surf zone and the profile elevations are updated at the end of every time step for each grid across the profile. Examples of the model prediction using large wave tank data are presented. The results of the tests are encouraging for the prediction of bar formation and migration.

Introduction

A significant feature normally found in beach profiles immediately following a storm is the offshore bar, a shore parallel deposition with a scour trough on the landward side. This feature forms as a result of large wave heights, and short wave periods. Once a bar forms, it can dissipate substantial quantities of wave energy thereby reducing the energy reaching the shore and limiting erosion of the berm and dune. After storm water levels and wave conditions have returned to their normal state, the bar usually acts as a significant element in the recovery process of the beach profile. The sediment stored in the bar is available not only to be returned to the beach face during recovery, the bar also can dissipate wave energy during any subsequent storm event. An example of a bar which formed after a storm along the Florida coast in March 1989 and the recovery which occurred during the subsequent months is shown in Fig. 1.

Cross-shore erosion models, such as that developed by Kriebel and Dean (1985), do not typically allow the formation of bars in the profile. They are therefore only capable of predicting berm and dune erosion over time scales on the order of hours to at most days. More recently Larson and Kraus (1989) developed a numerical cross-shore sediment transport model, which is based on extensive correlations of wave, sediment, and profile characteristics. The model was calibrated using large wave tank data and it was compared with profiles predicted by the Kriebel and Dean model for various wave and water level conditions. Larson and Kraus found their model more realistically described the profile at the dune toe when no bar was present in the profile, and because it allowed the formation of bars, there was less erosion of the dune in a case in which

Figure 1: Example of observed barred (March, 1989) and unbarred (August, 1989) beach profiles at Beverly Beach in Flagler County, Florida USA.

offshore bars were present. The size of the model predicted bars and troughs were underestimated and the problem of beach recovery was not included. This paper presents an explicit computational sediment transport model using bottom shear stress parameters to predict the formation and evolution of offshore bars in two-dimensional cross-shore sediment transport processes.

Approach

The development of the berm and offshore bar has been found to be associated with the dimensionless parameter suggested by Dean (1973) and later tested by Wright and Short (1984)

$$H_b/wT \quad (1)$$

where H_b is the breaking wave height, w is the fall velocity of the sediment, and T is the wave period. Wright and Short (1984) found the value of Eq. (1) to be 4.0 ± 1.5 at Eastern Beach in Australia, where offshore bars were present. This dimensionless parameter is important for bar formation because the breaking wave acts to displace sediment shoreward of the breakpoint in the beach profile. Stive and Wind (1986) investigated the mean cross-shore flow in a two-dimensional surf zone and developed an undertow model based on experimental and theoretical considerations. They found the result of the strong spatial decay after breaking was equivalent to a shear stress at the wave trough level, which caused a mean offshore flow in the water near the bottom. Svendsen and Hansen (1988) considered the problem of incorporation of cross-shore circulations into numerical models, which predict wave height and setup. One of the important forcing functions they investigated was the average bottom shear stress, τ_b . They concluded that computed values of τ_b could be included in comprehensive nearshore numerical models.

The approach used in the computational model presented herein to determine the location, volume, and mobility of offshore bars is based on the assumption that transport of sediment across beach profiles is related to the momentum fluxes due to waves. Breaking waves transfer momentum by exert-

Figure 2: Schematic of the moment due to the wave-related momentum applied to the center of gravity of the water column.

ing a force on the water column directed toward the shore. The momentum force is defined by

$$F = -\frac{\partial S_{yy}}{\partial y} \tag{2}$$

where y is the distance offshore from the shoreline and S_{yy} is the flux in the y -direction of the y -component of momentum due to waves. This momentum is not applied at the centroid of the water column. Instead, the moment of the applied momentum about the center of gravity of the water column, following Boreckci (1982), is

$$M = \frac{Eh}{4} \left(1 + \frac{H^2}{2h^2}\right) \tag{3}$$

where H is the wave height, h is the water depth and $E = (1/8)\rho gH^2$ is the total energy per unit surface area in the wave as determined by linear wave theory. Figure 2 shows a sketch of the water column with the moment due to the applied momentum force. Balancing the moment with the average bottom shear stress leads to

$$\bar{\tau}_b = \frac{2}{h} \frac{\partial M}{\partial y} \tag{4}$$

which is the time-averaged seaward directed bottom shear stress due to the transfer of the wave related moment of momentum. If the applied shear stress is strong enough and the value of Eq. (1) is greater than approximately 4, then a bar would be expected to form in the profile where there was sediment convergence under the breaking wave. A trough would form in the scour region on the shoreward side of the bar, as a result of the turbulence generated by the breaking wave. Once the bar forms, if the wave conditions and water level remain the same, then the breakpoint can move offshore from the bar. This can result in growth and migration of the bar some distance offshore, until there is a balance of transport components, thereby resulting in equilibrium.

Dean (1987) observed that in addition to the tendency for sediment motion due to waves to be offshore, there must be a net “constructive” shoreward force

on the bottom sediment. If not, there would not be an upward slope in the beach profiles in the landward direction. Therefore, the equilibrium profile is the result of a balance between landward forces and seaward forces, including gravity. The average bottom shear stress, which retards the motion of a fluid in unidirectional open channel flow is expressed in terms of a quadratic friction law

$$\bar{\tau}_o = \frac{\rho f}{8} |U|U \quad (5)$$

where f is the Darcy-Weisbach friction factor and U is the velocity of the fluid, and the absolute value ensures the proper direction of the shear stress. It can be shown that whereas simple harmonic bottom velocities result in a zero average bottom shear stress, nonlinear waves cause a shoreward directed average stress. Based on stream function wave theory (Dean, 1974), $\bar{\tau}_o$ can be approximated as

$$\bar{\tau}_o = \frac{\rho f}{8} \frac{0.09 L_o}{d} \frac{H^2}{T^2} \quad (6)$$

where $L_o = gT^2/2\pi$ is the deep water wavelength.

Description of the Computational Model

The computational model used to predict the creation and migration of an offshore bar is based on a sediment continuity and a transport equation. The expression for the conservation of sediment over the profile is

$$\frac{\partial h}{\partial t} = \frac{\partial Q}{\partial y} \quad (7)$$

where h is the water depth, t is time, and Q is the offshore transport. The sediment transport equation used to calculate changes in depth contours is

$$Q = K_1 \bar{\tau}_b + K_2 \bar{\tau}_o + K_3 \frac{\partial h}{\partial y} \quad (8)$$

The forcing functions on the right hand side of this equation include contributions from $\bar{\tau}_b$, the mean bottom shear stress due to nonlinear waves, $\bar{\tau}_o$, and the effect of gravity which is related to the bottom stress, $\partial h/\partial y$. The quantities K_1 , K_2 , and K_3 are transport rate coefficients.

The computational model is an "open-loop" explicit model, which uses finite difference forms of Eqs. (7) and (8) to predict cross-shore sediment transport across a profile. The portion of the profile over which these equations are applied is represented as uniformly spaced offshore grids, although, if desired, smaller grids could be employed in areas of specific interest. Unlike many previous models, this representation allows the model to produce offshore bars, because it does not require monotonic depth increases offshore. The two-dimensional profile for the explicit model begins at the berm or dune and continues offshore to well beyond the maximum breaking depth. The distance offshore can be represented by the contour location, y_i , which is referenced to an arbitrary baseline located landward of the shoreline. To determine the depth at any contour, each elevation contour, h_i , must be considered along with the water level, η_i , which includes tide, storm surge, and wave setup and setdown effects. The total depth at each grid can be represented as $d_i = h_i + \eta_i$.

The continuity equation (Eq. 7) in finite difference form using a space-centered finite difference method, is expressed as

$$\Delta h_i = \frac{\Delta t}{\Delta y} (\overline{Q_{i+1}} - \overline{Q_i}) \quad (9)$$

where $\overline{Q_i}$ represents the time-averaged sediment flux. The terms in the transport equation (Eq. 8) can be considered individually. The most important term for the determination of the location, volume, and mobility of offshore bars is based on the momentum fluxes due to waves. Breaking waves transfer momentum by exerting a force directed toward the shore. By substituting Eq. (3) into Eq. (4), the average moment can be balanced with the average applied shear stress, yielding the following equation:

$$\tau_b = \left(\frac{E}{H} \frac{\partial H}{\partial y} + \frac{E}{2} \frac{\partial h}{\partial y} \right) \left(1 + \frac{H^2}{2h^2} \right) + \frac{E}{2h} \left(\frac{H}{h} \frac{\partial H}{\partial y} - \frac{H^2}{h^2} \frac{\partial h}{\partial y} \right) \quad (10)$$

which can be used to calculate time-averaged moment of momentum induced mean bottom stress acting on the sediment in the bed. expanding this equation and collecting terms leads to the following simplified form of the average bottom shear stress in finite difference form using the total depth, d_i :

$$(\overline{\tau_b})_i = \frac{\rho g}{8} \left[\frac{1}{2} \frac{(H_i)^2}{(d_i)^2} d_i \left(\frac{\partial h}{\partial y} \right)_i + H_i \left(\frac{\partial H}{\partial y} \right)_i \left(1 + \frac{(H_i)^2}{(d_i)^2} \right) \right] \quad (11)$$

Implementation of the Model

The explicit model requires input of a two-dimensional profile with constant offshore grid size, Δy . This input profile (see Fig. 3) must encompass the entire active region from onshore in the dune or berm region to offshore beyond the closure depth. Before transport computations can be made in any time step, the wave height and wave setup model developed by Dally (1980) is implemented. Using this breaking wave model, a realistic calculation of the average bottom shear stress parameters can be made in the explicit model. The instantaneous value of depth, $d_i = h_i + \eta_i$, is found by using the value of wave setup, η_i , determined from the model.

To demonstrate the effects of the average bottom shear stresses, $\overline{\tau_b}$ and $\overline{\tau_o}$, in bar formation and migration, examples of the variations in their values across the profile and in time are presented. The examples used here are from the large wave tank tests documented by Kraus and Larson (1988). It is stressed that in the following, the results are presented for the measured (NOT predicted) profiles. In Case 400 of these tests, the conditions included a breaking wave height of 2.3 m, a wave period of 5.6 s, a constant water level, and a sediment size of 0.22 mm ($w = 0.031 \text{ ms}^{-1}$). Figure 4 shows the values of H/wT across the initial profile (planar with slope 1:15), as well as the values of $\overline{\tau_b}$ and $\overline{\tau_o}$. The maximum value of H/wT (approximately 13, which is much greater than the threshold of 4), located at a distance 30 m offshore, corresponds to the location of the initial break point. The calculated value of $\overline{\tau_b}$ is very small offshore from the breaking wave, but at that point it increases sharply to 700 Nm^{-2} . The average shear stress due to nonlinear waves, which is always negative, has the greatest magnitude at the breakpoint of -3 Nm^{-2} . Toward the shore both values of average bottom shear stress gradually approach zero as the wave

Figure 3: Model representation of beach profile showing depth and transport related to grid definitions; the cross-shore grid elements are of constant length, Δy .

height decreases across the swash zone. One hour later, a bar has formed and the break point has moved offshore to about 37 m, as shown in Fig. 5. The greatest magnitudes of both $\bar{\tau}_b$ and $\bar{\tau}_o$ have also moved offshore with the breaking wave location. After 10 hours Fig. 6 shows the Case 400 bar crest is located at 42 m and the break point is at 48 m, while the largest magnitudes of $\bar{\tau}_b$ and $\bar{\tau}_o$ are both at approximately 45 m.

In the implementation of the predictive model for bar formation and migration, the values of $\bar{\tau}_b$, $\bar{\tau}_o$, and $\partial h / \partial y$ are calculated at each grid point. Because the momentum induced shear stress is based on a local balance, it does not accurately reflect the spreading due to the breaking wave over some distance toward the shore from the breakpoint. In addition, the transport of suspended sediment offshore from the breakpoint must be considered in the computation. The model includes a weighting function which distributes the values of $\bar{\tau}_b$ over adjacent grid cells, with the weights for the onshore values being slightly greater than the offshore portion. The bottom shear stress is lagged using the following expression:

$$\bar{\tau}_{bi} = \sum_{j=-5}^5 W_j \bar{\tau}_{bi+j}$$

Table 1: Lag Weights Used for Prediction of Bar Formation and Migration

i+j	Weight, W_j
i+5	0.01
i+4	0.03
i+3	0.04
i+2	0.05
i+1	0.06
i	0.07
i-1	0.09
i-2	0.10
i-3	0.16
i-4	0.32
i-5	0.07

Figure 4: Initial profile and the ratio H/wT for Case 400 shown in lower panel. The upper panel shows the calculated values of $\bar{\tau}_b$ (units = $100 \cdot Nm^{-2}$) and $\bar{\tau}_o$ (units = Nm^{-2}).

Figure 5: Case 400 at 1 hour.

Figure 6: Case 400 at 10 hours.

The volumetric transport over one time step is

$$V_i = \Delta t [K_1(\overline{\tau_b})_i + (0.3(Q_{2p})_i + 0.7(Q_{2n})_i) + K_3(\partial h/\partial y)_i] \quad (12)$$

where Q_{2p} and Q_{2n} are described in the Appendix. When Eq. (12) is input into Eq. (9), the equation for the change of depth at any grid in the profile is

$$\Delta h_i = \frac{V_i - V_{i-1}}{\Delta y} \quad (13)$$

The portion of the profile over which calculations are made is from onshore at the upper limit of the setup to offshore at the index, $imax - 1$, where $imax$ is the total number of grid points in the profile. The two boundary conditions on the model are 1) $V_{is} = 0.0$ where is is the instantaneous upper limit along the profile of the water level setup and 2) $V_{imax-1} = 0.0$. The elevation contours are updated each time step the explicit model is run, and in the next time step the new profile is used as input into the Dally (1980) model to calculate the new wave heights and setup.

Sensitivity Tests

Sensitivity tests were performed on the explicit model to determine which parameters caused significant changes in the prediction of the size and location of offshore bars. In addition, the stability of the model was investigated for various coefficients and different lags of the bottom shear stress parameter. A few examples of these sensitivity tests will be presented here. The first example was a test in which only the average bottom shear stress, $\overline{\tau_b}$, term was used in the transport equation, with the value $K_1 = 2.9 \times 10^{-6} \text{ m}^4(\text{Ns})^{-1}$ and the time step $\Delta t = 360 \text{ s}$. Figure 7 shows that the predicted profile is unstable after 10 times steps when only the parameter $\overline{\tau_b}$ is used in Eq. (13). By simply adding the slope term, $\partial h/\partial y$, to the transport equation with a value for $K_3 = 5.8 \times 10^{-4}$

Figure 7: The original, one hour observed, and the model predicted beach profiles after 10 time steps; the upper graph is for the model prediction with $\bar{\tau}_o$ only and in the lower graph both the $\bar{\tau}_o$ and $\partial h/\partial y$ terms are included.

m^2s^{-1} , the model prediction after one hour shown in Fig. 7 now has a stable profile with the bar located accurately, even though its height is smaller than was observed in reality. Figure 8 shows the result of combining only the bottom shear stress due to nonlinear effects, $\bar{\tau}_o$, using $K_2 = 5.8 \times 10^{-5} m^4(Ns)^{-1}$, and the slope term in the transport equation. After 100 time steps, the model produces a stable profile, with sand deposited between 0 m and 15 m offshore.

Results

The predictive offshore bar model was first calibrated using the large wave tank data in Case 400. The simulation of the changes in the bars over time periods longer than the sensitivity tests reported above required that different transport rate parameters be used. The coefficients were established at the values: $K_1 = 2.4 \times 10^{-6} m^4(Ns)^{-1}$, $K_2 = 8.4 \times 10^{-5} m^4(Ns)^{-1}$, and $K_3 = 4.2 \times 10^{-4} m^2s^{-1}$. Using the larger K_i values in these computations was found to be necessary to allow the forcing function, $\bar{\tau}_o$, which produces shoreward sediment motion in the model, to compensate for the increasing magnitude of the slope term, $\partial h/\partial y$, as the bar forms. The time steps were also reduced to $\Delta t = 180$ s, which is half the interval used in the sensitivity tests. This had the result of increasing the stability of the model, which requires very little

Figure 8: Same as Fig. 7, except here the model is run for 100 time steps and includes only the $\bar{\tau}_o$ and the $\partial h/\partial y$ terms.

Figure 9: Case 400 profiles initially and one hour observed and predicted.

computational time for the large wave tank beach profiles. The prediction for the first hour shown in Fig. 9 shows the location of the bar agrees very closely with the observed profile, but the size of the predicted bar and trough is nearly half of the actual one hour result. This is an indication of the reduction of the size of the transport rate coefficients. Figure 10 shows the model is simulating the 5 hour profile reasonably well if the size of the bar and its migration offshore are compared with the observed profile. After 300 time steps or 15 hours of simulation, the observed and predicted profiles in Fig. 11 continue to be in good agreement. By the end of 30 hours (Fig. 12), the agreement between the predicted and actual profiles remains quite good. Some of the small differences are likely due to wave reflections in the measured profile.

The model was also run for Case 401, which had nearly the same wave characteristics as Case 400 ($H = 2.0$ m, $T = 5.6$ s), but the sediment size in the large wave tank beach profile was 0.4 mm. The larger sediment size would be expected to result in steeper slopes in the offshore bar, especially on the seaward side of the bar, due to the greater fall velocities associated with sediment having a larger diameter. The profile shown in Fig. 13 after the first 20 time steps of the explicit model run shows very good agreement between the location of the predicted offshore bar when compared with the actual system. Even after five hours (see Fig. 14), the model has predicted correctly the rate of

Figure 10: Case 400 profiles initially and 5 hours observed and predicted.

Figure 11: Case 400 profiles initially and 15 hours observed and predicted.

Figure 12: Case 400 profiles initially and 30 hours observed and predicted.

Figure 13: Case 401 profiles initially and one hour observed and predicted.

Figure 14: Case 401 profiles initially and 5 hours observed and predicted.

migration of the bar offshore, but the predicted trough is slightly less deep than that of the observed profile. The model is obviously overestimating the amount of movement which occurs in the simulations for longer periods of run times (see Figs. 15 and 16). The effects of the coarser sediment need to be included in a realistic manner to slow the bar migration offshore in the computational model.

Conclusions

An "open-loop" explicit model can be used to determine the location of the formation and subsequent migration of bars. The calculation of average bottom shear stress values based on the use of the moment due to the wave-related momentum applied about the center of gravity of the water appears realistic. The model is based on sediment continuity and transport equations, and the latter equation is used by combining the mean bottom shear stress due to breaking waves, $\bar{\tau}_b$, the mean shear stress due to nonlinear waves, $\bar{\tau}_o$, as well as a slope term, $\partial h / \partial y$. The $\bar{\tau}_b$ term acts to direct sediment offshore from the breakpoint, while the $\bar{\tau}_o$ term produces mostly shoreward sediment motion. The slope term maintains stability in the transport of sediment by acting as a gravity control. The explicit sediment transport model can be applied to beach profiles which have waves breaking over them in such a manner that scouring occurs shoreward of the breakpoint. The prediction of the trough created by the scouring process is accomplished by applying weighting lags to the $\bar{\tau}_b$ values. The coupling of the sediment continuity/transport model with the Daly (1980)

Figure 15: Case 401 profiles initially and 15 hours observed and predicted.

Figure 16: Case 401 profiles initially and 30 hours observed and predicted.

breaking wave model allows the formation and migration of the bar.

Appendix

The value of τ_o is decreased across the profile by including the seaward directed component of bottom shear stress due to nonlinear waves using the expression

$$(Q_{2p})_i = K_2 \left\{ -(\bar{\tau}_o)_i + \frac{2}{3} \omega \delta \sin \phi_i \right\} - \tau_{cr} \tag{14}$$

if $\{ \} \geq \tau_{cr}$; $(Q_{2p})_i = 0.0$ otherwise. The critical bottom shear stress is $\tau_{cr} = \frac{2}{3} \rho g (s-1) \delta \sin \phi_{cr}$, where ϕ_{cr} is the critical slope angle (a function of the sediment diameter) and s is the ratio of mass density of sediment to the mass density

of water. The immersed specific weight of the sediment is ω , δ is the sediment diameter, and ϕ_i is the profile slope. The component of the shear stress directed toward the shore is

$$(Q_{2n})_i = K_2 \left\{ 3(\bar{\tau}_o)_i + \frac{2}{3} \omega \delta \sin \phi_i \right\} + \tau_{cr} \quad (15)$$

if $|\{\} | \geq \tau_{cr}$; $(Q_{2n})_i = 0.0$ otherwise.

CHAPTER 163

A MICRO-COMPUTER BASED QUASI 3-D SEDIMENT TRANSPORT MODEL

Marie-Hélène G. Briand¹ and J. William Kamphuis²

ABSTRACT

A quasi three-dimensional numerical model for detailed sediment transport calculations on a beach is developed for a micro-computer. It includes a complete description of the wave climate and wave induced currents over the study area. Vertical concentration profiles of suspended sediments, calculated locally to include the effects of shear stress on the bottom and the intensity of turbulence due to breaking waves, are superposed on local velocity profiles to yield sediment transport rates. Sediment transport is calibrated with laboratory experiments performed on a straight sand beach.

INTRODUCTION

In coastal engineering, where hydrodynamics play a major role, the latest numerical models calculating wave-induced currents and sediment transport are usually developed on large, powerful computers because of the problem's complexity. So far, detailed numerical coastal modeling has thus been largely limited to research projects. But recent innovations and rapid developments in the micro-computer industry have transformed the Personal Computer into an essential tool for scientific applications.

The present paper shows an overview of the theory used in the proposed numerical model. Briand (1990)

- ¹ Hydraulics engineer; Lalonde, Girouard, Letendre et Associés, 485 McGill street, 8th floor, Montreal, Canada, H2Y 2H4
- ² Professor, Civil Engineering, Queen's University, Kingston, Ontario, Canada, K7L 3N6

provides a detailed description of the pertinent theory and numerical methods of solution. The numerical model was developed to work efficiently on a micro-computer.

Several aspects of modeling relatively detailed coastal processes are presented with an emphasis on a simple approach to a wide range of applications. The proposed numerical model includes calculations of wave transformation, wave-induced currents and resulting sediment transport in the surf zone. Numerical results of sediment transport are calibrated with laboratory experiments. A practical "quasi" three-dimensional description of nearshore hydrodynamics and its effect on sediment transport is produced.

NUMERICAL MODEL

Wave Transformation

The model requires a discretized representation of the study area bathymetry in the form of a rectangular grid, and offshore wave conditions must be specified for either regular or random wave fields. Calculations start with a complete evaluation of the wave climate over the gridded area: shoaling, refraction, breaking and energy dissipation inside the surf zone are considered.

A Miche type of breaking criterion is used, as suggested by Goda (1970):

$$H_b = 0.17 L_o \left\{ 1 - \exp \left[-1.5 \frac{\pi d}{L_o} \left(1 + 15 m^{4/3} \right) \right] \right\} \quad (1)$$

where:

- H_b is the breaking wave height;
- L_o the deepwater wavelength;
- d the local water depth;
- m the local beach slope.

This breaking criterion was preferred to others because of its relative simplicity and because it fits better the laboratory results presented in this paper.

The principle of conservation of wave energy flux is applied to calculate wave height transformations:

$$\frac{d(Ec)}{ds} = -D \quad (2)$$

- where:
- c_g is the wave group velocity;
 - E is the total wave energy density;
 - s is the distance along the wave path;
 - D is the wave's energy dissipation rate per unit area.

It is possible to include several terms responsible for energy dissipation in Eq. 2, like friction on the bottom or percolation, but the present application considers wave breaking as the main source of dissipation. Outside the surf zone, D is equal to zero.

Energy dissipation in a breaking wave is calculated from the empirical formulation of Dally, Dean and Dalrymple (1984):

$$D = \frac{K}{d} \left[\left(E - E_{st} \right) c_g \right] \quad (3)$$

- where:
- K is an empirical coefficient;
 - E_{st} represents the "stable" energy that a breaking wave strives to attain on a constant depth bottom.

The stable energy is calculated from the stable wave height H_{st} as, suggested by Horikawa and Kuo (1966):

$$H_{st} = \Gamma d \quad (4)$$

Dally *et al* (1984) show that values of $K = 0.15$ and $\Gamma = 0.4$ give good agreement with their laboratory results.

In the wave transformation calculations, a combination of linear and cnoidal wave theories was used for a better description of wave characteristics, especially in shallow water.

In the case of a random wave field, the offshore wave spectrum is divided into several sinusoidal wave components (approximately 40 for the laboratory tests described in the second part of the present paper) with individual periods, heights, angles of approach and probabilities of occurrence. An empirical method is used to relate the components' wave heights and periods, and the probability is determined from the Rayleigh distribution of wave heights. Each regular wave component is shoaled, refracted individually and then dissipated in

the surf zone. Root-mean-square characteristics of the wave climate are calculated for comparison with measurements.

Hydrodynamics Model

For practical reasons, the complete three-dimensional (3-D) equations for hydrodynamics in the nearshore zone are not solved directly on the micro-computer. Instead, a three-step procedure is used. First, a two-dimensional representation of horizontal, time- and depth-averaged velocities and water levels (2-DH model) is developed. The horizontal velocities and local wave characteristics are then used to calculate the local vertical profiles of velocities (2-DV) at each node of the gridded area. Finally, those vertical profiles, calculated from the 2-DH current pattern, are superposed on the horizontal grid to yield what is called a "Quasi 3-D" representation of nearshore hydrodynamics.

Calculation of Velocities and Water Levels

The first step consists of calculating the time- and depth-averaged wave-induced currents \vec{u} and set-up η over the considered area. A steady state solution is obtained using an Alternate Direction Implicit formulation of the two-dimensional, horizontal (2-DH) equations of motion (Eq. 5) and continuity (Eq. 6):

$$\frac{\partial \vec{u}}{\partial t} + \left(\vec{u} \cdot \nabla \right) \vec{u} + g \nabla \eta = \frac{1}{\rho d} \left[\vec{\tau}_\ell - \vec{\tau}_b - \nabla \cdot \vec{S} \right] \quad (5)$$

$$\frac{\partial \eta}{\partial t} = - \nabla \cdot \left(\vec{u} d \right) \quad (6)$$

where the terms in Eq. 5 are respectively: the local acceleration, the non-linear convective acceleration, the hydrostatic pressure force (per unit mass), the lateral mixing shear stress, the bottom friction shear stress, and the gradient of radiation stress tensor.

To reduce instabilities and accelerate numerical computations, 2-DH calculations are performed starting with an approximation of the velocity and set-up solution based on the infinite beach simplification, i.e. variations in the longshore direction are neglected at first. Mean water depths are adjusted by the calculated wave set-up, and the coastline is allowed to shift inland to account for coastal flooding. This preliminary solution

is then introduced as the initial condition for the ADI scheme until a steady state solution is obtained. The result is a two-dimensional, horizontal current description of the study area.

Calculation of Vertical Distributions of Velocities

In the second step of the model, local vertical distributions of horizontal velocities are evaluated using an extension of Svendsen and Hansen's (1988) theoretical development for undertow, where the depth-averaged velocities calculated in step 1 are taken into account. The vertical profile of velocities is developed from a second-order differential equation for vertical momentum balance, Eq. 7, and from the principle of continuity of flow.

$$\frac{\partial}{\partial z} \left[\nu_t \frac{\partial \vec{u}}{\partial z} \right] = \frac{\partial}{\partial x_i} \left[g\eta \right] + \frac{\partial}{\partial z} \left[\vec{\nabla} \cdot \vec{S} \right] \quad (7)$$

- where:
- ν_t is the turbulent eddy viscosity;
 - x_i represents horizontal axes x and y;
 - \vec{S} is the total radiation stress tensor.

The above undertow model considers that the flow occurs in three layers. In the surface layer, between the wave crest and trough, a detailed description of the highly turbulent flow within the breaking wave roller is not necessary. The only information required is the amount of fluid carried by the roller, which is expressed in an empirical formula suggested by Svendsen (1984). A thin bottom boundary layer in which fluid viscosity is considered, includes the effect of bottom friction on the flow and accounts for steady streaming due to the wave oscillatory flow. Lastly, the middle layer flow is governed by the imbalance between the excess momentum flux induced by the breaking wave in the surface layer and the hydrostatic excess pressure created by the local mean water level gradient, or wave set-up.

Calculation of Sediment Transport

Vertical profiles of wave-induced sediment concentrations in the water column are calculated locally to be combined with vertical profiles of velocities from the hydrodynamics model to yield a quasi 3-D sediment transport pattern over the study area.

The vertical profile of sediment concentration is assumed to follow an exponential shape:

$$C(z) = C_A \exp \left(K_e \frac{(z-z_A)}{z_A} \right) \quad (8)$$

with
$$K_e = -\ln \left(C_B/C_A \right) \quad (9)$$

where: - z_A is taken as the bottom boundary layer thickness;
- C_B is the concentration at which the sediment starts moving.

The reference concentration C_A at the upper limit of the bottom boundary layer is estimated from a mobility number made up of two terms representing the individual influences of the local wave-current bottom shear stress and the turbulence created by the breaking wave:

$$C_A = \frac{K_{A1} (\nu_t/d) + K_{A2} (\tau_{wc}/\rho)^{1/2}}{w_f} \quad (10)$$

where: - K_{A1} and K_{A2} are calibration constants;
- τ_{wc} is the waves and currents shear stress;
- w_f is the sediment fall velocity.

The above sediment concentration profiles are multiplied by the local velocity profiles and integrated over the depth to yield the local sediment transport rates, in bed-load and suspended load modes. A "Quasi 3-D" description of sediment transport is obtained which is both practical and easy to solve on a micro-computer.

The above approach has a strong physical basis, and calibration of sediment transport calculations is relatively simple. Once concentration calibration parameters K_{A1} and K_{A2} , in Eq. 10, are determined, all components of sediment transport are also determined since bed-load, suspended load, longshore and cross-shore transport are coupled.

Swash Transport

The wave motion in the swash zone is a time-dependent process that is not described by the above

numerical model. However, the sediment transport contribution from the swash zone is important and must be included in some way for comparison with laboratory results. A global formulation based on the assumption that sediment concentration in the swash zone is caused only by wave energy dissipation, is proposed:

$$Q_{sw} = K_Q \left(S_{sw} \right)^{1/6} \left(L_{sh} \right)^{1/2} \frac{H_{sh}^{7/3}}{w_f} \quad (11)$$

where:

- K_Q is a calibration constant;
- S_{sw} is the swash zone width;
- L_{sh} is the wavelength at the shoreline;
- H_{sh} is the wave height at the shoreline.

Beach Morphology

Finally, each local vertical profile of sediment transport is integrated over the local water depth and included in the equation of conservation of sediment to calculate the beach morphology with time.

LABORATORY EXPERIMENTS

The numerical model was calibrated with results from experiments carried out in the wave basin of the Queen's University Coastal Engineering Laboratory. Only half of the 28 tests performed with various regular and random wave fields and two different sediment sizes were used for the present calibration (Table 1).

Wave heights, longshore currents, alongshore sediment transport rates and their cross-shore distribution were measured on a deformable sand beach. Beach profile evolution in time was monitored in detail. Wave heights and longshore currents were measured at regular intervals at many locations across the surf zone as a barred profile evolved from the initially plane beach. Sediment transport was measured using a series of 7 or 14 sand traps located at the downdrift end of the beach. Kamphuis and Kooistra (1990) provide a complete description of the laboratory set-up and test results.

To calibrate and compare the numerical model results with laboratory measurements performed on a simulated infinitely long beach, the quasi 3-D numerical model was simplified by neglecting all gradients in the alongshore direction.

Table 1. Description of laboratory tests.

Regular Test	T (sec)	H _d (cm)	D ₅₀ (mm)	Random Test	Tp (sec)	Hs _d [*] (cm)
RE	0.92	4.5	.105	IE	0.92	6.3

			.180	ID*	1.15	11.7
			.180	IK*	1.38	8.4

* Subscript "d" indicates depth at the wave generator. In all tests $d = 0.5$ m, except tests marked with a * for which $d = 0.55$ m.

RESULTS AND DISCUSSION

Numerical results for wave heights show very good agreement with measurements both inside and outside the surf zone (Fig.1), even though some regular wave experiments contained important reflection patterns.

Numerical results for longshore velocities agree well in magnitude with experiments but their cross-shore distribution does not always coincide with observations (Fig.2). This is due to the simplistic wave energy dissipation module used in the calculations. A more realistic computation should simulate the exchanges between potential, kinematic and turbulent energies, and account for the formation of a roller.

To compare longshore sediment transport rates, the swash zone contribution was separated from surf zone transport by identifying sediment traps located above mean water level. Surf zone sediment transport rates agree well with the observed results in a calibration that gives 20 times more importance to the turbulent energy dissipation term than to the bottom shear stress term in the sediment concentration calculations (Fig.3). On the other hand, swash transport predictions, based on a simple global formula that accounts only for the total wave energy dissipation on the beach face, do not agree well (Fig.4). It is of interest that the observed swash transport rates for similar wave conditions are higher for the larger sediment size (0.18 mm) than for the

Fig. 1. Calculated and measured wave heights.

Fig. 2. Calculated and measured longshore velocities.

Fig. 3. Global longshore sediment transport results, without swash contribution.

Fig. 4. Global swash transport.

smaller (0.105 mm) sand. From a comparison of calculated and measured swash transport, it is postulated that a bottom shear stress model that accounts for the critical shear stress, based on the Shields curve, would simulate the observed results better.

The calculated cross-shore distributions of long-shore sediment transport agree well with observations (Fig.5); but again, the predicted peak does not always coincide with observations. A better wave energy dissipation model should improve these results.

The numerical model is successful in predicting the proper bar location in all cases, but the observed bars are flatter than in the numerical results, indicating a lack of cross-shore convection in the undertow calculations (Fig.6). This is an effect of the quasi 3-D velocity calculations which could be improved by adding cross-shore convection artificially in the numerical scheme. The fact that swash zone processes are not taken into account in the numerical calculations can also explain the underprediction in offshore sediment transport.

Finally, Figure 7 shows a simulation of a beach profile submitted to the same wave conditions over a long period of time. After 9 hours of constant wave attack, the profile evolution slows down and the only bar transformation that still occurs is a slight accumulation of sediment on the offshore slope. The bar thus slowly moves offshore, as was observed in the laboratory.

CONCLUSIONS

The proposed quasi 3-D numerical model for sediment transport works efficiently on a micro-computer. It is also flexible, as it can account for various natural phenomena (e.g. tides, wind) by simply including additional terms in the momentum equations.

One interesting finding of the present study is that sediment transport in the surf zone is dominated by the influence of the turbulent wave energy dissipation on the sediment suspension process, whereas swash zone transport is clearly driven by the bottom shear stress effect on sediment.

There is one important limitation to the model in its present form: it should not be applied to complex bathymetries since diffraction and wave-current interactions are neglected in calculations, and because of the first approximation approach used in current calculations.

Further research to improve this model will consider swash zone processes, the energy transition in breaking waves, and calibration with field measurements.

CHAPTER 164

DECOUPLED NUMERICAL MODEL OF THREE-DIMENSIONAL BEACH CHANGE

Magnus Larson¹, Nicholas C. Kraus², M. ASCE, and Hans Hanson³

ABSTRACT

This paper describes a numerical model of three-dimensional beach change as produced by breaking waves and wave-induced currents. Cross-shore lines spaced at intervals alongshore form the basic calculation element, and cross-shore and longshore transport rates are calculated independently on the lines. Transport rates are coupled indirectly through the mass conservation equation and a contouring routine that determines local depth contour orientation for calculating wave transformation. The model has reduced calculation time compared to fully gridded hydrodynamic and beach change models, yet allows representation of complex boundary conditions, coastal structures, and movement of longshore bars and berms. Results of two test series are presented, one for the movement and protective functioning of a linear mound constructed of dredged material, and the other for impoundment at a jetty.

INTRODUCTION

The goal of beach change numerical modeling is to describe the three-dimensional (3D) evolution of nearshore bottom topography resulting from spatial and temporal differences in sand transport. For practical use, five model capabilities were considered to be essential: (1) accurate and reliable beach change simulation compatible with input data routinely available at engineering projects; (2) representation of sand transport and beach change on temporal and spatial scales of engineering interest; (3) representation of general boundary conditions and coastal structure configurations; (4) calculation robustness, meaning that uncertainties typically present at projects do not produce

(1) Assist. Prof., (3) Assoc. Prof., Dept. of Water Resources Engrg., Institute of Technol., Univ. of Lund, Box 118, Lund, Sweden S-221 00.
(2) Sr. Res. Sci., Coastal Engrg, Res. Center, U.S. Army Engr. Waterways Experiment Station, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199.

aberrant model predictions; and (5) economical execution time. The second capability implies that both short-term processes (e.g., storm-induced beach erosion/recovery, and cyclical daily and seasonal change in the beach profile shape and position) and long-term processes (e.g., accretion and erosion at shore-normal structures) are simulated, including approach to an equilibrium bottom configuration under constant forcing and boundary conditions. A model having these capabilities is now under development, and this paper introduces the model and representative initial test results.

Model Architecture

To develop a 3D bathymetric change numerical model with the aforementioned five capabilities for wide-application use, the model architecture was founded on two design concepts. The first concept was to combine essential features of two previous successful beach change models, SBEACH for calculating storm-induced beach erosion and recovery (Larson et al. 1988, Larson and Kraus 1989, Larson et al. 1990) and GENESIS for calculating long-term change in shoreline position (Hanson 1989, Hanson and Kraus 1989). The 3D modeling system also allows extension of capabilities of the two models that is not possible within the limits of the individual models. The second design concept was to treat lines running across the shore as the basic calculation element. Waves, longshore current, and longshore and cross-shore transport rates are calculated independently on the cross-shore lines, thereby decoupling the transport rate calculation along the beach. Neighboring areas of the beach interact through a local contouring routine that calculates the beach orientation at each grid point on the cross-shore lines and through the sand mass conservation equation, from which the change in bathymetry is obtained from the transport rates.

The resultant model, called 3DBEACH for 3-dimensional Decoupled model of BEAch CHange, is significantly more efficient than "point models" that require computation-intensive and sophisticated 2D gridded hydrodynamic wave and current models, yet it gives stable, equilibrium beach profile shapes that are difficult to attain in point models. Despite the simplification introduced by the decoupling approach, the model has substantial generality in representation of profile shape, such as multiple bars and troughs, than allowed in "line models" that require monotonically increasing depth with distance offshore.

By decoupling cross-shore and longshore transport processes, execution time is minimized, allowing the model to be applied either on the local or regional level and for long simulation times. The local validity of the cross-shore line as the basic calculation element restricts model applications to situations with mild bottom slopes alongshore; also, partially enclosed embayments where the shoreline intersects a cross-shore line more than once cannot be represented. Thus, 3DBEACH is targeted toward the open coast, and local bathymetric disturbances such as rip currents and rip channels are not represented directly.

Model Structure

3DBEACH consists of six calculation modules that function semi-independently, allowing modification of any module without affecting or requiring detailed knowledge of the other modules. Principal quantities calculated by the respective modules are: (1) wave height, wave angle, mean water level, and runup; (2) longshore current; (3) cross-shore sand transport rate; (4) longshore sand transport rate; (5) bottom contour orientation; and (6) bottom topography change.

Fig. 1 is a schematic of a 3DBEACH calculation grid. A Cartesian coordinate system is placed on the project coast with the x-axis pointing offshore and the y-axis following the trend of the shoreline. Cross-shore lines are placed along the coast with an interval Δy , and grid points on the line are spaced Δx apart. Typically, Δy is much larger than Δx under the assumption that the beach slope changes much more gently alongshore than across-shore. Fine grid spacing across-shore (typically 1 to 5 m) is needed to describe dominant morphological profile features such as bars, troughs, berms, and rapid change occurring during storms, whereas a coarse spacing alongshore (typically 25 to 100 m) is compatible with more gradual beach change produced by gradients in longshore sand transport. A time step in the range of 5 to 40 min is used in the model, with a typical value of 20 min. Short descriptions of the six calculation modules follow.

Fig. 1. Schematic of a 3DBEACH calculation grid

(1) Wave module. The wave module calculates the wave height H and other wave-related quantities, such as wave angle θ and wave- and wind-induced setup, at grid points on each profile line (Kraus and Larson 1990). Cell opening (wetting) and closing (drying) occurs according to the wave and wind conditions, and tide level. Assuming locally plane and parallel depth contours the wave height is determined by linear

wave theory in regions of nonbreaking and by the Dally et al. (1985) model where waves break. Either regular or random wave height can be specified. The module reproduced wave breaking and reformation over bar and trough profiles measured in a large wave tank (Kajima et al. 1982), as well as wave height and setup in laboratory experiments with a plane beach and oblique wave incidence (Visser 1982). The wave module only requires input time series of wave height, period, and direction (and wind speed and direction if wind is important).

(2) Longshore current module. The longshore current V is calculated at grid points on each cross-shore line as in the model NMLONG (Kraus and Larson 1990, Larson and Kraus 1991b). NMLONG was developed to calculate the longshore current over a multiple bar and trough profile produced by oblique wave incidence and wind, and it contains linear or nonlinear bottom friction as options, and lateral mixing. The model was verified using two field data sets (Kraus and Sasaki 1979, Thornton and Guza 1986) and one laboratory data set (Visser 1982), and default values of empirical parameters are provided. The longshore current is used to calculate the longshore sand transport rate.

(3) Cross-shore transport module. The net cross-shore sand transport rate on each cross-shore line is calculated as in SBEACH (Larson and Kraus 1989). The profile is divided into four zones of different wave and transport properties, with the magnitude of the transport mainly governed by energy dissipation in the surf zone. SBEACH has been verified with data both from large wave tank experiments and the field (Larson and Kraus 1989, 1991a, Larson et al. 1990). The calculation procedure can generate bars and berms, but at present it is restricted to cross-shore transport related to breaking waves. The wave module supplies the main input to this module, which also requires an initial profile shape and sediment grain size.

(4) Longshore transport module. A local transport rate formula proposed by Kraus et al. (1988) based on field measurements is used, in which the needed longshore current velocity and wave height are obtained from modules (1) and (2). Inputs are supplied by the wave and longshore current modules. This module contains an empirical transport rate parameter that must be determined in calibration.

(5) Contour module. The orientation of depth contours is required to define a local wave angle to determine the magnitude and direction of the longshore transport. The contour orientation at each grid point is obtained by approximating the local bathymetry with a plane. The calculation requires depths from neighboring cross-shore lines and provides indirect interaction among the lines.

(6) Bottom change module. Changes in the bottom topography are obtained from the mass conservation equation after the cross-shore and longshore transport rates have been calculated at each grid point for the particular time step.

MODEL TESTS

Results of two of many model test series are described. The objective of these initial "proof of concept" tests was demonstration of correct qualitative behavior for simulating realistic project conditions. One series focused on the response of a subaqueous mound of dredged material and the feedback to the waves, current, and beach from the mound. The other series focused on impoundment at a jetty or groin. In the simulations, if a random wave input time series was used, the wave height and/or angle were uniformly distributed over a given interval. The longshore grid spacing varied between 20 and 50 m, and the cross-shore spacing varied between 2 and 5 m, depending on the test. The time step was fixed at 20 min.

Placed Mound (Silver Strand, Calif.)

Simulation conditions pertain to a Corps of Engineers project at Silver Strand Beach, California, located south of San Diego Harbor (see Junke et al. 1989). In December 1988, approximately 80,000 cu m of sand with median diameter 0.18 mm were dredged from the harbor entrance channel and placed offshore of Silver Strand in the form of a short linear mound on the existing bottom of 0.25-mm sand. The mound was intended to break higher, potentially erosive waves, as well as nourish the beach by onshore migration. The mound was initially 381 m long and 76 m wide, extending from about 225 m to 450 m from the shoreline (between bottom contours of 4.5 and 9 m), and with an average relief of 2.1 m at its crest. The bathymetry was surveyed periodically for two years on seven profile lines spaced at 76-m intervals, five lines on the feature and two to the south (historic direction of littoral movement alongshore). The bathymetry shortly after construction of the feature was completed is shown in Fig. 2. This configuration served as the initial condition for this model test series.

Fig. 2. Initial bathymetry for offshore mound test series

Four tests distinguished by input wave conditions are presented: (1) moderately erosional waves; (2) storm with shore-normal approach; (3) storm with oblique approach; and (4) accretionary waves. A semi-diurnal tide with amplitude of 0.56 m (mean amplitude for Silver Strand) was applied in all tests, and calculations were carried out for simulated times of 3 to 10 days. A pinned-beach boundary condition (Hanson and Kraus 1989) was specified at both sides of the grid, whereby sand could freely enter and leave the calculation domain from the lateral boundaries. The cross-shore lines ended in a depth of 11.4 m, necessary to ensure that negligible transport occurred at the seaward boundary, even under storm waves. The net direction of transport as erosive (offshore directed) or accretionary (onshore directed) is determined in the model according to the criterion used in SBEACH (Larson et al. 1988, Larson and Kraus 1990) that has subsequently been further verified with a large field data set (Kraus et al. 1991).

Test 1: Moderately erosive waves. Fig. 3 displays simulation results after exposure of the coast to moderately erosional waves for 10 days. The deepwater wave height H_0 randomly varied between 1 and 2 m, the wave period T was 12 sec, and the incident deepwater wave angle θ_0 randomly varied between -10 and $+10$ deg. Because of their relatively small height, the waves passed over the mound with little change and broke further inshore. The waves gradually removed material from the foreshore and deposited it shoreward of the mound to produce an almost uniform longshore bar. This storm bar has distinct depressions resulting from refraction at the ends of the mound. Mound end effects also produce depressions on the foreshore.

Fig. 3. Bar formation and beach erosion by moderately erosive waves

Test 2: Strong storm, normal wave incidence. It is of considerable interest to quantitatively evaluate the protection afforded by a mound to the beach in its lee. Thus, simulations were conducted for a 3-day

storm with H_0 randomly varying between 4 and 6 m and $T = 12$ sec, with the waves incident normal to the mound. Fig. 4 shows the bathymetry at the end of the storm, in which a pronounced and curved longshore bar is seen. The shape of the mound significantly changed because the waves breaking on its seaward side moved material from the mound offshore to form part of the bar. At the sides of the mound the bar lies closer to shore because material forming it had to be taken from the inner surf zone, whereas the mound supplied sand to the erosive waves breaking directly seaward of it. The mound therefore protected the beach and surf zone directly shoreward of it, both satisfying the demand for sand by the breaking waves in development of the storm bar and by causing additional wave breaking. The sand supplied by the mound replaced that taken from the surf zone in the regions on the sides of the mound, as seen by the more seaward movement of contour lines on the unprotected sides. The beach face does not show significant change alongshore, because erosion on the foreshore is strongly controlled by water level, and not depth-limited breaking waves. The complete symmetry of the calculation with respect to a shore-normal line at the center of the mound is an indication of the stability of the calculation.

Fig. 4. Bathymetric change for a storm, normally incident waves

Test 3: Strong storm, oblique wave incidence. The previous test, a strong storm, was repeated, but with θ_0 varying between 0 and 20 deg to introduce net longshore transport. Fig. 5 shows that the bathymetric response is no longer symmetric as in Test 2. Because of wave refraction, the longshore sand transport rate was reduced at the downdrift end of the mound; a local depth maximum appeared downdrift of the mound, further modifying the wave transformation. The present test produced satisfactory results; however, in related tests examining sensitivity to incident wave angle, if a large oblique angle was maintained for a long time interval, the greatly changing bathymetry induced numerically-generated rhythmic features. In such extreme cases,

decoupling of the cross-shore lines was not satisfactory because the longshore depth gradients were not small.

Fig. 5. Bathymetric change for a storm, obliquely incident waves

Test 4: Accretionary waves. Simulations with low waves were conducted to calculate the response of the beach and mound to accretionary forcing conditions. Such conditions occur in the summer (in the northern hemisphere) and after storms, when low waves of long period typically arrive. Fig. 6 shows the results of one such test performed with H_0 varying between 0.6 and 0.8 m, $T = 14$ sec, and the θ_0 varying between 0 and 20 deg. The waves were run for 10 days. The mound shape was only slightly altered by the low waves which passed over it and travelled shoreward to break in shallower water. A distinct berm formed on the foreshore that is not uniform alongshore due to refraction of the incident waves at the mound.

Impoundment at Jetty

This test series examined model predictions for impoundment at a jetty or groin. Two tests are described which exercised the "groin boundary condition," one without bypassing and the other including bypassing. Mildly erosional monochromatic waves were applied ($H_0 = 2$ m, $T = 8$ sec, $\theta_0 = 20$ deg). Similar calculations performed with random waves did not change the essential features of the bathymetric response, randomness only acting to produce a smoother topography. Fig. 7 shows the initial bathymetry for the groin test series, consisting of a groin situated on a plane-sloping profile joining an equilibrium ($x^{2/3}$) profile at the still-water shoreline. The tide was semidiurnal with an amplitude of 0.5 m, and the area was exposed to 3 days of wave action.

Fig. 6. Bathymetric change for accretionary waves

Fig. 7. Initial bathymetry for jetty test series

Infinitely long jetty. Fig. 8 shows impoundment by a long jetty (long with respect to the width of the surf zone) located on the right side of the grid. The jetty acts to completely block sand moving toward it. A longshore bar formed with its crest curving offshore with approach toward the jetty from the updrift coast. A plateau more gently sloping than the initial beach formed in the vicinity of the jetty; its buildup continued to the high-tide water level if the simulation was run for a very long time. The time scale of the beach response here and in other tests is controlled by empirical coefficients that enter as factors in the cross-shore and longshore transport rate predictive

relations. These two coefficients must be determined by model calibration at the project site.

Bypassing at jetty. For this test the jetty was terminated at the initial 2-m depth contour. The incident waves broke at approximately this depth, but the changing tide moved the break point seaward and shoreward of this contour. The longshore sand transport rate tailed off seaward of the break point in accordance with the tail in the longshore current. Sand that was transported alongshore seaward of the tip of the jetty was allowed to pass the jetty as an implementation of a simple boundary condition representing bypassing. As shown in Fig. 9, for these conditions, the bar was almost straight alongshore because the jetty did not extend to where the bar developed. The jetty still impounded sand and a gently sloping plateau developed near it, but the plateau extended only to the end of the structure.

Fig. 8. Impoundment at a long jetty (no bypassing)

Additional simulations were carried out for a long jetty, encompassing 10 days of wave action ($H_0 = 1$ m, $T = 8$ sec, $\theta_0 = 20$ deg), which illustrates the equilibrium properties of 3DBEACH. Fig. 10 shows the time evolution of the profile line located closest to the groin and how the sand build-up occurs along the groin. The accumulation of sand on the updrift side of the groin will continue as long as the waves have a predominant direction. However, as the beach contours adjust towards a position where they are parallel to the incident wave crests, the sand transport decreases and the rate of accumulation becomes smaller. Thus, the model correctly describes the equilibrium characteristics of a beach with groins observed in the laboratory and field.

Fig. 10. Profile evolution immediately updrift an infinitely long jetty

CONCLUDING DISCUSSION

This paper described initial tests of a new class of numerical model of three-dimensional beach change. The distinguishing characteristic of the model is decoupling of wave, current, and sediment transport processes on cross-shore lines spanning the nearshore. The decoupling

approximation reduces calculation time significantly over beach change models using full two-dimensional wave and current calculation schemes, yet still describes morphologic nearshore profile features of engineering interest. The model is expected to be valid if longshore bathymetry gradients are small and significantly less than cross-shore gradients.

The model presently describes sediment transport and beach change in and around the surf zone as produced by breaking waves. Because the model calculates process-driven sediment transport rates and uses the mass conservation equation to determine beach change, inclusion of non-breaking wave sediment transport generating mechanisms is possible and will be incorporated in the next phase of the study.

The tests series demonstrated that the model can describe changes in large-scale morphologic features such as breakpoint bars, berms, and plateaus formed near structures. Important features of the model are a stable approach to an equilibrium bottom configuration under steady waves and ease of implementing boundary conditions. Without possessing a regular approach to equilibrium, both the time scale and reliability of model predictions would be ambiguous. Such properties were well studied in the beach change modeling technology underlying 3DBEACH (Kraus and Larson 1988, Hanson and Kraus 1989, Larson and Kraus 1989).

CHAPTER 165

OSCILLATORY FLOW AND SEDIMENT MOTION OVER A RIPPLED BED

Paolo Blondeaux¹ & Giovanna Vittori²

Abstract

Experimental visualizations have been performed of the oscillatory flow and of the sediment motion produced by a sea wave propagating over a rippled bed. In particular the dynamics of the vortex structures generated by flow separation at the ripple crest is investigated along with the mechanism through which sediments are lifted up from the bed and carried in suspension. A numerical model is formulated and the results obtained are successfully compared with the experimental data.

Introduction

Field observations seem to indicate that the main contribution to the total load in the nearshore region is due to the suspended load (Sleath, 1984). It is thus clear that an important aspect controlling sediment transport in the coastal area is the mechanism through which sediment grains are lifted and maintained in suspension. The latter mechanism is largely affected by the bottom profile which may exhibit a regular pattern of sandy waves (ripples). Indeed it was recognized as early as Ayrton (1910) that the formation of sand ripples on the sea bottom is connected with the existence of vortices shed at the crests of the ripples in alternate directions every half wave cycle and that these vortex structures play a crucial role in sediment transport. Experimental evidence (Nielsen, 1979; Sunamura, 1980) suggests that in a wave cycle two distinct mechanisms operate. The first mechanism is the trapping of sediments in the vortex structures which are generated by flow separation at the ripple crests. When flow reverses and the vortex structures are no longer reinforced but simply convected by the local velocity, the second mechanism operates: sediments are carried into suspension far from the point where they were picked up. Finally sediments are slowly released along the ripple profile when vortices decay because of viscous effects.

A model able to transform these qualitative observations into quantitative results has not been formulated yet.

¹ Associate Professor, Hydraulic Institute, University of Genoa, Via Montallegro, 1, 16145 Genova, Italy.

² Researcher, National Research Council, Via Opera Pia 11, 16145 Genoa, Italy, also Hydraulic Institute, University of Genoa.

Some attempts have been made to determine the oscillatory flow over a rippled bed as a first step towards the prediction of the sediment motion (Sleath, 1973; Sato et al., 1984; Longuet-Higgins, 1981). Numerical approaches have been used to solve momentum and continuity equations. Sleath (1973) and Sato et al. (1984) made use of finite difference schemes. Longuet-Higgins (1981) used a discrete vortex method. Even though some information on vorticity dynamics has been gained, the above methods present some drawbacks. The finite difference approaches fail when applied to conditions characterized by the relatively large values of the Reynolds number characteristic of the flow at the bottom of gravity waves. In fact a large number of grid points would be necessary in order to describe both the irrotational part of the flow and the boundary layer adjacent to the bottom; consequently an extremely large amount of CPU time would be required. The main drawback of a discrete vortex method is that it is essentially inviscid. In other words it is assumed that viscous boundary layers remain thin and passive at all times except at singular geometrical points where they separate and generate a vortex sheet. Whence if applied to the oscillatory flow over a rippled bed, a discrete vortex method fails to provide quantitative results when the boundary layer thickness is of the same order of magnitude as the ripple height and when flow separation is induced along the flat portion of the ripple profile by pressure gradients. Moreover, to the authors' knowledge no attempt has been made in the past to formulate a model able to predict sediment motion.

In the present contribution we study the oscillatory flow over a rippled bed solving the vorticity equation and Poisson equation (which relates vorticity and stream function) by means of a new numerical approach based on spectral methods and finite difference approximations. The proposed numerical approach makes it possible to obtain detailed quantitative results for values of the parameters of physical relevance using a limited amount of CPU time. Using the computed flow field we then formulate a numerical model which provides a description of the dynamics of sediment grains in suspension. The numerical results are also compared with experimental visualizations described in the first part of the present contribution.

Experimental Visualizations

In order to obtain new information on the sediment motion produced by an oscillatory flow over a rippled bed, experimental visualizations have been performed.

The experimental apparatus consists of a duct 290 cm long with a rectangular section, the width and the height of which are equal to 46 cm and 63 cm respectively. The duct is filled with water and the lower part of it is covered with sand. The fluid motion is produced by two pistons located at the ends of the duct and driven by a pneumatic motor. The amplitude and the period of the piston oscillations can be continuously varied by means of an electronic device.

Sediments in suspension are visualized using a sheet of light produced by a 2 kw lamp and an appropriate system of lenses. Sediment motion is then filmed by a standard video camera and recorded using a video tape recorder. Then a sequence of images of sediment trajectories during the flow cycle is digitalized and transferred onto the computer HP 9000. Each image is computer-analysed and different shades of grey are assigned to different light intensities. This type of procedure allows

qualitative information on sediment concentration to be gained. Moreover, looking at a sequence of images, it is also possible to obtain the trajectories of the clouds of sediments picked up and carried in suspension by the vortex structures characteristic of the flow field in the presence of ripples.

An example of the results obtained is shown in plate 1. Fluid oscillations are characterized by an amplitude S equal to 8 cm and a period T equal to 2 s. Quartz sand is used with a relative density ρ_s/ρ equal to 2.65 and a mean diameter d equal to 0.28 mm.

In photo a the flow is directed from the right to the left and the fluid velocity is maximum. The combined action of the attached boundary layer along the stoss side of the ripple and of the vortex structure generated by flow separation at the ripple crest creates a cloud of sediment just above the lee side of the ripple where a recirculating cell of fluid is located. After $T/10$ (photo b) the flow decelerates, the vortex structure strengthens and the size of recirculating cell increases. Sediments tend to be piled up at the ripple crest by the action of the vortex.

$T/10$ later (photo c) the flow goes into reverse and the vortex has almost reached its maximum strength. A lot of sediments are carried in suspension far from the bottom leaving the ripple profile at the crest. Now (photo d) the flow has reversed its direction and the main vortex structure is no longer reinforced but simply convected from the left to the right by the action of the local velocity. Sediments are carried in the same direction. Most of them tend to move close to the bottom but still a relevant part remains in suspension.

After $T/10$ (photo e) the strength of the main vortex structure decays because of viscous effects. Gravity effects tend to prevail over drag forces and sediments are slowly released along the bed profile, only few of them being in suspension. In the meantime a new vortex structure is generated by flow separation at the ripple crest and a new cloud of sediment is formed along the lee side of the ripple. Photo f, which was taken $T/2$ after photo a, shows a flow field and a sediment concentration distribution which are the mirror image of those shown in photo a. Then the sediment time development repeats similarly during the second half of the cycle.

Similar results have been obtained for different values of the parameters even though quantitative differences have been detected. In plates 2 and 3 sediment distribution is shown for T equal to 2 s, d equal to 0.28 mm and S equal to 7 cm and 10 cm respectively. It can easily be observed that in the former case less sediment is moved by the oscillatory flow and that the larger part moves close to the bottom, few sediments being picked up from the bed and carried in suspension far from the ripple profile.

The Numerical Model

Let us consider the oscillatory flow over a rippled bed and introduce a cartesian coordinate system (x^*, y^*) with the x^* -axis lying on the bottom and the y^* -axis directed upwards. Let us assume the bed profile to be described by the following equations

$$y^* = \frac{h^*}{2} \cos(k^* \xi^*) \quad x^* = \xi^* - \frac{h^*}{2} \sin(k^* \xi^*) \quad (1)$$

Plate 1 Experimental visualization of sediment motion over ripples in an oscillatory flow.

($S = 8$ cm, $T = 2$ s, $\rho_s/\rho = 2.65$, $d = 0.28$ mm.)

(a) $t^*/T^* = 3/4$; (b) $t^*/T^* = 17/20$; (c) $t^*/T^* = 19/20$; (d) $t^*/T^* = 21/20$;
 (e) $t^*/T^* = 23/20$; (f) $t^*/T^* = 5/4$.

Plate 2 Experimental visualization of sediment motion over ripples in an oscillatory flow.

($S = 7$ cm, $T = 2$ s, $\rho_s/\rho = 2.65$, $d = 0.28$ mm.)

(a) $t^*/T^* = 3/4$; (b) $t^*/T^* = 17/20$; (c) $t^*/T^* = 19/20$; (d) $t^*/T^* = 21/20$;
 (e) $t^*/T^* = 23/20$; (f) $t^*/T^* = 5/4$.

Plate 3 Experimental visualization of sediment motion over ripples in an oscillatory flow.

($S = 10$ cm, $T = 2$ s, $\rho_s/\rho = 2.65$, $d = 0.28$ mm.)

(a) $t^*/T^* = 3/4$; (b) $t^*/T^* = 17/20$; (c) $t^*/T^* = 19/20$; (d) $t^*/T^* = 21/20$;

(e) $t^*/T^* = 23/20$; (f) $t^*/T^* = 5/4$.

where $k^* = 2\pi/l^*$ is the wavenumber characteristic of the ripple, h^* , l^* its height and wavelength and ξ^* a dummy variable. As observed in real ripples the bed profile (1) exhibits crests sharper than the troughs. Moreover a comparison between experimental profiles and relationships (1) performed by Sleath (1984) shows good agreement. Assuming the flow to be two-dimensional, the differential problem governing the flow field is posed by the vorticity equation along with the Poisson equation which relates the vorticity ω^* with the stream function ψ^* and boundary conditions which force no-slip at the bottom and the matching of the flow in the bottom boundary layer with the outer irrotational flow. The latter can be assumed to be:

$$(u^*, v^*) = (U_o^* \sin 2\pi t^*/T^*, 0) \quad (2)$$

where u^* , v^* are the velocity components in the x^* and y^* directions, U_o^* and T^* the amplitude and the period of the velocity oscillations far from the bottom and t^* is time.

In order to solve the problem it is useful to introduce a new orthogonal coordinate system (ξ^*, η^*) defined by the following relationships (Sleath, 1973)

$$\xi^* = x^* + \frac{h^*}{2} e^{-k^* \eta^*} \sin(k^* \xi^*) \quad \eta^* = y^* + \frac{h^*}{2} e^{-k^* \eta^*} \cos(k^* \xi^*) \quad (3)$$

which maps the bottom profile into the line $\eta^* = 0$. Introducing the following dimensionless variables

$$t = t^* 2\pi/T^* \quad (\xi, \eta) = (\xi^*, \eta^*)/\delta^* \quad \omega = \omega^* \delta^*/U_o^* \quad \psi = \psi^*/U_o^* \delta^* \quad (4)$$

where $\delta^* = \sqrt{vT^*/\pi}$, the governing differential problem reads

$$\frac{\partial \omega}{\partial t} + \frac{R_\delta}{2J} \left[\frac{\partial \psi}{\partial \eta} \frac{\partial \omega}{\partial \xi} - \frac{\partial \psi}{\partial \xi} \frac{\partial \omega}{\partial \eta} \right] = \frac{1}{2J} \left[\frac{\partial^2 \omega}{\partial \xi^2} + \frac{\partial^2 \omega}{\partial \eta^2} \right] \quad (5)$$

$$\frac{\partial^2 \psi}{\partial \xi^2} + \frac{\partial^2 \psi}{\partial \eta^2} = -J \omega \quad (6)$$

$$\frac{\partial \psi}{\partial \xi} = \frac{\partial \psi}{\partial \eta} = 0 \quad \text{at } \eta = 0 \quad (7)$$

$$\frac{\partial \psi}{\partial \xi} \rightarrow 0 \quad \frac{\partial \psi}{\partial \eta} \rightarrow \sin t \quad \text{for } \eta \rightarrow \infty \quad (8)$$

In the equations above R_δ is the flow Reynolds number defined as $U_o^* \delta^*/\nu$ and J is the Jacobian of transformation (3). The problem is solved numerically by following a procedure which makes use of spectral methods and finite difference approximations. First of all we consider the values assumed within a ripple wavelength l by the stream function $\psi(\xi, \eta, t)$ and the vorticity $\omega(\xi, \eta, t)$ on a regular grid along the ξ -direction. Then the discrete Fourier coefficients are introduced (Orzag, 1971)

$$\psi\left(\frac{j l}{N}, \eta, t\right) = \sum_{n=0}^{N-1} \Psi_n(\eta, t) e^{i 2\pi n \frac{j}{N}}$$

$$j = 1, 2, \dots, N \quad (9)$$

$$\omega\left(\frac{j l}{N}, \eta, t\right) = \sum_{n=0}^{N-1} \Omega_n(\eta, t) e^{i 2 \pi n \frac{j}{N}}$$

Making use of (9), the problem posed by (5)-(8) is transformed into a time dependent boundary value problem in the variable η which is amenable to a classic computational approach. The solution starts with the establishment of initial conditions for the complex fields Ψ_n, Ω_n which are assumed to vanish. Then the computational cycle begins by the implementation of finite difference equations analogous to the partial differential equations for the discrete Fourier coefficients. A balance between computational costs and the attainment of accurate results made it advisable to use a first order forward scheme to approximate time derivatives and a second order central scheme to approximate spatial derivatives (Roache, 1972). It is worthwhile pointing out that a further variable $\tilde{\eta}$ was defined [$\tilde{\eta} = \ln((\eta + b)/b)$] in order to stretch the region near the bottom where the gradients of the dependent variables are larger. The value of 'b' was suitably chosen on the basis of numerical experiments. With these approximations, Ω_n inside the computational domain at a new time level is determined explicitly starting from the knowledge of Ω_n and Ψ_n at the previous time level. These updated values of Ω_n make the solution of the Poisson equation for Ψ_n possible. Indeed the implementation of a finite difference equation analogous to the Poisson equation leads to a tridiagonal system for the values assumed by Ψ_n on a regular grid along the $\tilde{\eta}$ direction. The latter system can be solved by standard methods. The last step in the computational cycle consists in calculating Ω_n on the boundary of the domain. This step is accomplished by forcing vanishing values of Ω_n far from the ripple and computing Ω_n at $\eta = 0$ according to the first order scheme suggested by Thom (1928). The above numerical procedure makes it possible to use up to 256 Fourier components and 256 grid points in the $\tilde{\eta}$ direction with a limited amount of CPU time.

Once the flow field is known, a picture of the motion of sediment grains in suspension is obtained releasing sand particles near the bottom and computing their trajectories taking into account the action of their weight, drag and lift forces. Flow acceleration effects have been ignored since the values of the Keulegan-Carpenter number characteristic of sediments are usually very large for sand at the bottom of sea waves.

It is easy to see that the equations governing the motion of a single sediment particle are

$$\begin{aligned} \frac{d \xi_p}{d t} &= \frac{v_{p \xi} R_b}{\sqrt{J} 2} & \frac{d \eta_p}{d t} &= \frac{v_{p \eta} R_b}{b e^{\eta p} \sqrt{J} 2} \\ \frac{d v_{p \xi}}{d t} &= \frac{R_b^2}{2 s R_d} \left[\frac{0.5 h k e^{-h \eta} \sin k \xi}{\sqrt{J} F_d^2} + \frac{3}{4} \left| \underline{v}_f + \underline{v}_p \right| \left(C_D (v_{f \xi} - v_{p \xi}) - C_L (v_{f \eta} - v_{p \eta}) \right) \right] \\ \frac{d v_{p \eta}}{d t} &= \frac{R_b^2}{2 s R_d} \left[\frac{1 - 0.5 h k e^{-k \eta} \cos k \xi}{\sqrt{J} F_d^2} + \frac{3}{4} \left| \underline{v}_f - \underline{v}_p \right| \left(C_D (v_{f \eta} - v_{p \eta}) + C_L (v_{f \xi} - v_{p \xi}) \right) \right] \end{aligned}$$

where the subscripts f and p refer to fluid and particles respectively and an underline denotes a vector.

R_d , F_d and s are the Reynolds number, the Froude number of the sediments and the ratio between sediment and fluid density respectively

$$R_d = \frac{U_o * d^*}{\nu} \quad F_d = \frac{U_o^*}{\sqrt{(s-1)gd^*}} \quad s = \frac{\rho_s}{\rho}$$

Finally it should be pointed out that the drag coefficient C_D has been computed by means of the relationship holding for the steady flow in terms of the instantaneous Reynolds number of the relative motion fluid-particle and that the ratio C_L/C_D has been assumed constant along the bottom and exponentially decaying with the distance of the particle from the ripple profile.

These approximations are likely to be very poor for large concentrations of suspended sediments; however we feel that the gross features of particle dynamics are likely to be well reproduced for low concentrations.

In figure 1 regions of clockwise and counter-clockwise vorticity are shown for $R_\delta = 100$, $k = 0.19$, $h/l = 0.15$.

The flow far from the bottom starts from rest and behaves like $\sin(t)$. It appears that clockwise vorticity is generated along the bed profile and particularly near the crest of the ripple during the first part of the cycle. By increasing t , the boundary layer thickens in the downstream side of the ripple till flow separates and vorticity of the opposite sign is generated at the bottom. Then the roll up of clockwise vorticity generates vortex structures (see figure 1_a). When the flow goes into reverse (see figure 1_b), the main vortex structure induces flow separation along the lee side of the ripple and the generation of a free shear layer characterized by vorticity of the opposite sign. In the second half of the cycle the main vortex structure is no longer reinforced but simply convected away by the local velocity.

The free shear layer originates a new vortex which couples with the previous one forming a vortex pair which travels along the bed profile moving with its self-induced velocity (see figures 1_c, 1_d). Then further counter-clockwise vorticity is shed from the ripple crest and when the flow is about to reverse its direction again, a new vortex structure is present near the crest (see figure 1_d) and the phenomenon is repeated similarly. Similar results are obtained for values of the parameters of physical relevance.

As regards the trajectories of sediment grains released near the bottom, the experimental observations are found again. Indeed looking at figure 2 where sediments in suspension are drawn for $R_\delta = 50$, $R_d = 27.5$, $F_d = 2.5$, $s = 2.65$ at different times during the cycle, it can be seen that for $t = 5.25$, when the flow is almost maximum and its direction is from right to left, a cloud of sediment is present just above the lee side of the ripple. The numerical results, in accordance with experimental findings, show that the vortex structure generated by flow separation tends to pile up sediments near the ripple crest and to carry some of them in suspension far from the ripple profile. When flow reverses, sediments are carried from left to right. Both numerical results and experimental visualizations indicate that most sediments move close to the bottom even though a relevant part is in suspension. Thus the results depicted in figure 2 show that many of the sediments rolling and sliding along the ripple profile are trapped by the new vortex forming along the lee side of the ripple. On the other hand, the sediments in suspension are

Figure 1 - Vorticity contours: $\Delta\omega = 0.15$ (— clockwise vorticity, --- counter clockwise vorticity) $R_\delta = 100$, $k = 0.19$, $h/l = 0.15$, (a) $t = 3\pi/4$; (b) $t = \pi$; (c) $t = 5\pi/4$; (d) $t = 3\pi/2$.

Figure 2 - Sediment particles: $R_b = 50$, $R_d = 27.5$, $F_d = 2.5$, $s = 2.65$, (a) $t = 5.25$; (b) $t = 7.0$; (c) $t = 8.05$; (d) $t = 8.95$.

Figure 3 - Particle density (c, 2c, 4c, 8c,...); $R_b = 50$, $R_d = 27.5$, $F_d = 2.5$, $s = 2.65$,
 (a) $t = 5.25$; (b) $t = 5.95$; (c) $t = 7.0$; (d) $t = 8.05$.

slowly released along the ripple profile since the strength of the old vortex decays because viscous effects and gravity effects prevail over drag forces. When the irrotational flow reaches its maximum in the opposite direction a new group of sediment particles is piled up at the crest of the ripple and in the next cycle the phenomenon is repeated similarly.

A rough idea of the time development of concentration over a rippled bed during a wave cycle can be gained from the numerical results by looking at the regions characterized by the same particle density. Because the number of particles moved in the numerical model is arbitrary, only relative information is obtained (see figure 3).

Clouds of sediments can be identified, which have the same dynamics as those visualized in the experiments, for the sake of brevity we will not describe the results obtained for different values of R_s , R_d , F_d , but we only state that the present model can be used to investigate the influence of the parameters on flow time development and sediment dynamics. Moreover asymmetric ripples can be obtained by slightly modifying relationships (3) and asymmetric flow forcing can also be considered.

The qualitative agreement between experimental visualization and the numerical model is encouraging for the development of the work. Information on the tendency of sediments to move onshore or offshore depending on wave and sediment characteristics can be gained.

CHAPTER 166

Wave Entrainment of Sand from a Rippled Bed

Malcolm O. Green¹ and Christopher E. Vincent²

Abstract

Wave-orbital velocities at 20 cm above the bed and continuous vertical profiles of near-bed suspended-sediment concentration were measured seaward of the surfzone over a rippled bed. Sand was intermittently entrained from the bed and ejected upwards in discrete clouds. The typical sequence of events in the entrainment cycle, with sand being rolled up in a thin near-bed layer and ejected into the flow on alternating wave strokes, is attributed to the action of vortices shed from the bed ripples by the reversing flow. The orderly cycle of events causes a time-domain correlation between the wave fluctuations of velocity and concentration, and the resulting sediment flux is comparable in size, and at some elevations directed opposite to, the mean sediment flux.

Introduction

Time-averaged horizontal suspended-sediment flux in a combined wave and current flow may comprise two terms: a "mean" term, which is readily understood, and a "correlation" term, which arises from correlation in time of the wave fluctuations in suspended-sediment concentration and horizontal velocity (e.g., Jaffe et al., 1984; Vincent and Green, 1990). The latter component of the total flux is analogous to the vertical turbulent flux of horizontal momentum that occurs in the benthic boundary layer. In the case of the boundary layer, sublayer bursting drives the momentum flux; in the

case of the sediment transport, the correlation flux is driven by the orderly process of flow separation and vortex-shedding associated with reversing flows over ripples.

The process of vortex shedding from rippled beds by reversing flows has been studied using flow visualization techniques in the laboratory (e.g., Bijker et al., 1976; Honji et al., 1980); Eulerian measurements of the resulting suspended-sediment concentrations and fluid velocities have been made in the laboratory by several workers (e.g., Homma et al., 1965; Nakato et al., 1977; Sleath, 1982); and theoretical models of the velocity and suspended-sediment fields have been developed (e.g., Tunstall and Inman, 1975; Nielsen, 1984). Although rippled beds are virtually ubiquitous in nature, and vortex shedding has been invoked to explain the cause of measured correlation fluxes that were a significant fraction of the total flux (e.g., Vincent and Green, 1990), there have been few descriptions of the process in the field from either a Lagrangian or Eulerian point of view.

Our objective is to describe field observations of the cycle of vortex-entrainment and ejection into the flow of sand by waves from a rippled bed. Vincent and Green (1990) used part of the same data set in an analysis of the time-averaged suspension profile and of the distribution of the two components of the total sediment flux close to the bed. In that analysis, we hypothesized that vortex-shedding was the underlying cause of the measured correlation fluxes. Our objective here is to describe in more detail, using wave-by-wave and statistical analyses, the temporal variability of the entrainment process and the vertical and temporal structure of the individual clouds of suspended sediment.

Data

The data are from an experiment conducted over a rippled sand bed in 1.7 ± 0.2 m water depth seaward of the surfzone on the North Norfolk coast of England. The modal grain size of the bed sediment was 0.023 cm, which is a fine to medium noncohesive sand, and bed ripples were a few centimeters high by several tens of centimeters long. The ripple dimensions were not measured, however Vincent and Green (1990) estimated, using Grant and Madsen's (1982) model, that the ripple height was ~ 3 cm.

Continuous profiles of suspended-sediment concentration from 48 cm above the bed down to the bed level were obtained every 0.58 s using an acoustic

backscatter sensor (ABS). The ABS emitted 2.8-MHz acoustic pulses and the backscattered acoustic pressure was sampled at 13 μ s intervals, which provided a vertical resolution of 1 cm. A calibration equation was applied to convert the measurements of backscattered pressure into estimates of suspended-sediment concentration. The particular calibration equation used was based on the grainsize distribution of the bed sediment, thus we make an implicit assumption that the suspended-sand population is the same as the bed-sediment population.

Simultaneous measurements of horizontal current velocity at 20 cm above the bed were obtained with an electromagnetic current meter. In this analysis, we use one record, termed run 2046, of 12-min duration, which consists of 1250 measurements of velocity and concentration at 1-cm intervals above the bed. The wave period during the deployment was \sim 6 s, and the significant on-offshore velocity was 60 cm/s, which was superimposed on an alongshore current of 15 cm/s.

The ABS was positioned 2 m seaward of the current meter, thus a correction had to be made to align the velocity and concentration time series. This is required in order to compute cross-correlation functions and ultimately to estimate correlation sediment fluxes. In order to align the two series, the phase spectrum, $\phi_{U_w C_z}(\omega)$, was examined, where U_w is on-offshore zero-mean velocity (which is taken to be the wave-orbital velocity) and C_z is concentration at an elevation z above the bed. If the estimated phase function approximates a straight line through the origin (i.e., 0 or 360 degrees):

$$\phi_{U_w C_z}(\omega) = -d\omega$$

then this indicates a delay or constant offset of $d \cdot \Delta t$ seconds between U_w and C_z where $-d$ is the slope of the phase function and Δt is the sampling interval (Chatfield, 1980). Shown in Figure 1a are the phase spectra for U_w crossed with concentration at 5 levels.

Each phase spectrum falls off at a rate that indicates a constant offset of $2\Delta t$ between the velocity and concentration series. The velocity series was thus shifted forward by $2\Delta t$ relative to the concentration series, and the phase spectra were recomputed. The rolloff is thus removed from the phase function (Figure 1b). This shift is applied throughout this analysis; note that an identical offset was indicated by consideration of the average phase speed of the waves and the measured separation of the sensors.

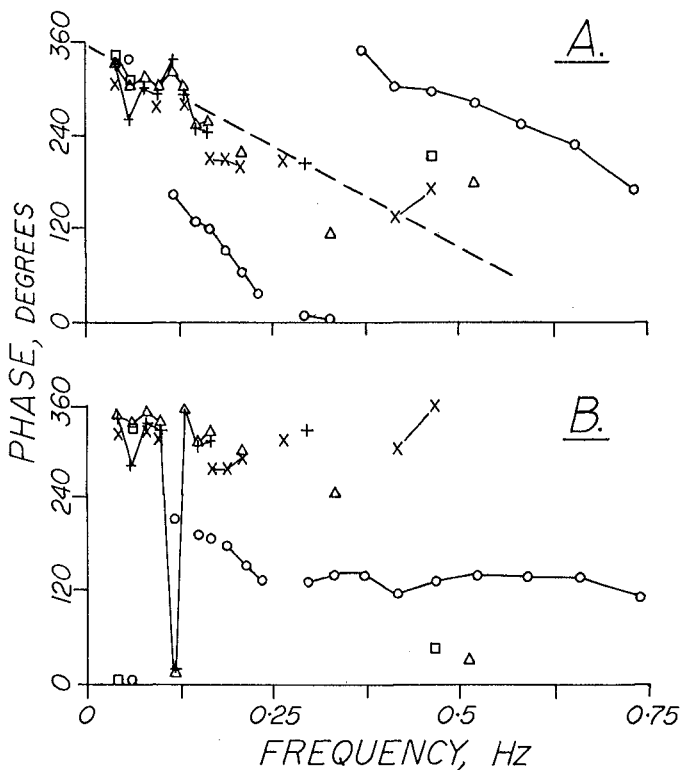

Figure 1. (a) Phase spectra $\phi_{U_w C_z}(\omega)$. All spectra appear to roll off at a constant rate indicated by the dashed line, the slope of which is consistent with a constant offset of $2\Delta t$ between the velocity and concentration series. (Note that only the statistically significant estimates of phase are shown. $o = U_w$ vs. C_2 , $\square = U_w$ vs. C_3 , $\Delta = U_w$ vs. C_5 , $+$ = U_w vs. C_{10} , $x = U_w$ vs. C_{20} .) (b) The same spectra as in (a) but with the velocity series shifted forward in time by $2\Delta t$.

Description of Time Series

Shown in Figure 2 are time series of U_w measured at $z = 20$ cm and concentration measured at 5 elevations above the bed. The elevations are shown normalized by the ripple height of 3 cm, i.e. $z^* = z/\eta$, where η is the wave-ripple height.

Sand was intermittently entrained from the bed and ejected upwards into the water column. Although the intermittency appeared to be related to the waves, not every wave initiated a suspension event. The intermittency leads to unacceptably large amounts of leakage when computing energy spectra, thus we avoid frequency-domain analyses of the data and instead use wave-by-wave and other statistical methods.

Figure 2. Time series of wave-orbital velocity (U_w) and concentration at 5 elevations above the bed. Elevation is nondimensionalized by the ripple height (3 cm).

Wave-By-Wave Analyses

The shapes of individual sediment clouds are shown in Figure 3 for two elevations above the bed. For these plots, zero-downcrossings of on-offshore velocity were used to identify 123 individual waves in the 12-min record, but waves were selected for analysis only if the concentration at $z = 1$ cm, which was the lowest usable bin, exceeded a certain threshold value. In this way, 26 well-developed sediment pulses were chosen for display. Also shown are the corresponding cycles of zero-mean velocity (U_w) measured at $z = 20$ cm. Note that a lot of the "noise" in the plots is due to the fact that wave periods varied from wave to wave and so the effective resolution also varies from wave to wave.

Figure 3. Wave cycles of zero-mean velocity and concentration at $z^+ = 0.7$ and $z^+ = 3.3$. The horizontal axes are wave phase in degrees, with zero phase defined as the instant of velocity zero-downcrossing. Each cycle of velocity has been nondimensionalized by the maximum onshore velocity that occurred in the cycle. Each cycle of concentration has been nondimensionalized by the maximum concentration that occurred in the cycle.

The wave-orbital velocities were skewed onshore: note that in any one cycle the onshore stroke was usually the stronger of the two, and the offshore velocities typically persist for longer than half of the wave period (Figure 3). At $z^+ = 0.7$, there are often two peaks in the concentration cycle. The first, which occurs while the orbital velocity is directed onshore, is stronger, and corresponds to the initiation of a sediment pulse at the bed. The second, which occurs while the orbital velocity is directed offshore, is weaker and corresponds to the advection back through the beam of the sediment pulse generated on the previous shoreward stroke. This second pulse is weaker since sand has settled back to the bed since the pulse was generated half a wave period previously.

At $z^+ = 3.3$ the picture is quite different: the water column is clear whilst the orbital velocity is directed onshore, and the sediment cloud only arrives at this elevation after the orbital velocity has reversed. Thus, ejection from the bed of the sediment cloud that is initiated during the onshore wave stroke only occurs after the flow has reversed.

Cross-Correlation Analyses

Cross-correlation functions were computed to investigate the phasing of the peak concentration in the sediment cloud with the peak orbital velocity.

At $z^+ = 0.7$, the peak suspension is exactly coincident with the peak onshore orbital velocity (Figure 4). In a fully rough turbulent flow, the peak bed shear stress leads the orbital velocity by approximately 10° , however the sampling rate was insufficient to resolve any such lead of the concentration over the velocity. We conclude then that, within the resolution of the data, the peak concentration very close to the bed was exactly in phase with the peak bed shear stress and that there was therefore a causal relationship between the two.
