Coastal Engineering

1990 PROCEEDINGS

Twenty-Second Coastal Engineering Conference

Proceedings of the International Conference
VOLUME 1

July 2–6, 1990
Delft, The Netherlands

Conference held under the auspices of the
Coastal Engineering Research Council of the
American Society of Civil Engineers

Organized by the Royal Institution of Engineers in the
Netherlands (KIVI), Division for Civil Engineering and
co-sponsored by the Permanent International Association of
Navigation Congresses and the International Association for
Hydraulic Research.

Edited by Billy L. Edge

Published by the
American Society of Civil Engineers

New York, New York 10017-2398

ABSTRACT

This proceedings contains over 250 papers presented at the 22nd International Conference on Coastal Engineering which was held in Delft, The Netherlands, July 2-6, 1990. The book is divided into eight parts: 1) Characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) the Dutch coast 5) coastal processes and sediment transport; 6) coastal, estuarine and environmental problems; 7) ship motions; and 8) case studies. The individual papers include such topics as the sedimentation and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and related fields with a broad range of information on coastal engineering.

Foreword

The 22nd International Conference on Coastal Engineering was held in Delft, The Netherlands. The 22nd ICCE, like the ones before it, was organized and managed by volunteers from within The Netherlands representing private, industrial and governmental contributors. This Conference represented an opportunity to share scientific and engineering information and provided a forum for interaction with other engineers and scientists working on similar coastal problems. The time and effort contributed to the development and organization of each conference becomes more complex and difficult as they continue to grow in size and content. The Local Organizing Committee worked on the planning for this Conference for nearly four years. All who attended the 22nd ICCE will agree that it was a tremendous success. The **Proceedings** of this Conference will represent a major step forward in the field of coastal engineering.

The chapters in this **Proceedings** have been prepared by the authors who were selected to make presentations at the 22nd International Conference on Coastal Engineering. The authors were asked to make the presentations and submit the final papers based upon review of the abstracts which were submitted well in advance of the Conference. The Technical Review Committee included four professionals who are active in the field of coastal engineering. One of the members is a representative of the Local Organizing Committee, a second member was part of the technical program committee for a previous conference in his country and the other two review members were selected for their broad understanding and recognition in the field. The papers included in this volume are eligible for discussion in the **Journal of the Waterways, Port, Coastal and Ocean Division** of the ASCE. All papers are eligible for ASCE awards.

Venues for the upcoming conferences are listed below:

23rd ICCE - Venice, Italy	1992
24th ICCE - Kobe, Japan	1994
25th ICCE - Orlando, FL, USA	1996
26th ICCE - Copenhagen, Denmark	1998

Coastal engineers who would desire to host a future conference in their country should contact the Secretary of the Coastal Engineering Research Council to receive information about submitting a proposal.

The continuing coordination of the International Conferences on Coastal Engineering is through the Coastal Engineering Research Council of the ASCE. The Research Council began at the instigation of Professor Boris Bakhmeteff who as chairman of the Research Committee of the Engineering Foundation suggested the formation of the Council on Wave Research. The Council was established in June 1950 under the Engineering Foundation.

Subsequently in 1963 the Council was transferred from the Foundation to the ASCE

and was renamed the Coastal Engineering Research Council which better described its expanded function.

Members of the Foundation and subsequently members of the Council recognized that coastal engineering problems required broad based research to better define the coastal and ocean phenomena with which they dealt. The Foundation felt that it was important that all disciplines working in the coastal area should have an opportunity and be encouraged to communicate with one another through the mechanism of interdisciplinary conferences.

The first conference was held in Long Beach, CA in 1950. The papers which were delivered at that conference were published and became the first coastal engineering conference **Proceedings**. Although the conferences began with a national focus they quickly became international in scope. After planning and conducting 22 conferences on coastal engineering the Series has been established as the principal conference on coastal engineering in the world. Contributors to the conference represent nearly all coastal nations and the numbers of abstracts which are submitted for consideration are generally twice as large as the available opportunity for presentations. The **Proceedings** of the conferences are all available from the ASCE.

Billy L. Edge, Secretary
Coastal Engineering Research Council, ASCE

ACKNOWLEDGMENTS

ORGANIZING COMMITTEE

Chairman:
E.W. Bijker - formerly Delft University of Technology

Secretary:
J. van der Weide - Delft Hydraulics
A.P.H. van Baardewijk - International Contracting
J.A. Battjes - Delft University of Technology
P.H.A. Hoogweg - Rijkswaterstaat
J.M. van der Kamp - Congress Office KIVI

SCIENTIFIC COMMITTEE

Chairman:
J.A. Battjes - Delft University of Technology
W.T. Bakker - Rijkswaterstaat
J. van de Graaff - Delft University of Technology
K.W. Pilarczyk - Rijkswaterstaat
P.J. Visser - Delft University of Technology
J.J. de Vriend - Delft Hydraulics

ACCOMPANYING PERSONS' COMMITTEE

Mrs. Fenneke d'Angremond-Pols
Mrs. Lenie Bakker-Walter
Mrs. Gerie Battjes-Hollander
Mrs. Greta Bijker-Jellerna
Mrs. Connie van de Graaff-Goedendorp

COASTAL ENGINEERING RESEARCH COUNCIL (ASCE)

Chairman:
Robert L. Wiegel

Vice-Chairman:
Orville T. Magoon

Secretary:
Billy L. Edge

Members:
Eco W. Bijker
Robert G. Dean
Kyoshi Horikawa
Ronald M. Noble
Thorndike Saville, Jr.
Leonardo Zeevaert

FINANCIAL SUPPORT

Financial Support has been given by:

Ministry of Transport and Public Works, Dept. Rijkswaterstaat
Ministry of Economic Affairs, Netherlands Foreign Trade Agency

C.B. Association of Dutch Dredging Contractors
D.H. Delft Hydraulics
K & O Netherlands Coastal Works Association
NABU Netherlands Association of International Contractors
NEDECO Netherlands Engineering Consultants
VGB Dutch Association of Major Contractors

CONTENTS

OPENING ADDRESS

His Royal Highness Prince Claus of The Netherlands

KEYNOTE ADDRESS

Rethinking Our Role in Coastal Zone Development
by J.E. Prins

Part I: CHARACTERISTICS OF COASTAL WAVES AND CURRENTS

Chapter 1 - Distribution Function Fitting for Storm Wave Data by Y. Goda and K. Kobune	18
Chapter 2 - A Model for Surf Beat by P.J. van Lecuwen and J.A. Battjes	32
Chapter 3 - Evaluation of Empirical Model for Wave Runup Elevations by R. Hallermeier, K.B. Nosek and C.J. Andrassy	41
Chapter 4 - Model Predictions of Nonbreaking Shoaling Waves by S. Elgar, M.H. Freilich and R.T. Guza	55
Chapter 5 - Transition Zone Width and Implications for Modelling Surfzone Hydrodynamics by R.B. Nairn, J.A. Roelvink and H.N. Southgate	68
Chapter 6 - The Group Characteristics of Sea Waves by Y.-X. Yu and S.-X. Liu	82
Chapter 7 - Field Observation on Wave Set-Up Near the Shoreline by S.-i. Yanagishima and K. Katoh	95
Chapter 8 - Modelling Shoaling Directional Wave Spectra in Shallow Water by J.T. Kirby	109
Chapter 9 - Modeling of Energy Transfer and Undertow in the Surf Zone by A. Okayasu, A. Watanabe and M. Isobe	123

Chapter 10 - Numerical Simulation of Nonlinear Wave Transformation Over a Submerged Plate by X. Yu, M. Isobe and A. Watanabe	136
Chapter 11 - Vertically 2-D Nearshore Circulation Model by T. Yamashita, Y. Tsuchiya and D.A. Suriamihardja	150
Chapter 12 - Violent Water Motion at Breaking-Wave Impact by M.J. Cooker and D.H. Peregrine	164
Chapter 13 - Wave Group Properties of Coastal Waves by H. Mase, T. Yamashita and K. Hayashi	177
Chapter 14 - Measurement and Computation of Wave Induced Velocities on a Smooth Slope by J.W. van der Meer and M.K. Breteler	191
Chapter 15 - A Numerical Model for Refraction Computation of Irregular Waves Due to Time-Varying Currents and Water Depth by M. Yamaguchi and Y. Hatada	205
Chapter 16 - Extreme Storms in the Adriatic Sea by L. Cavaleri, L. Bertotti, P. Canestrelli and P. Lionello	218
Chapter 17 - Set-Up Driven Undertows on a Barred Beach by P.D. Osborne and B. Greenwood	227
Chapter 18 - Nearshore Circulation with 3-D Profiles by I.A. Svendsen and U. Putrevu	241
Chapter 19 - Conditional Simulations in Laboratory Flumes by M.H. Gimenez, L.E. Borgman, R.T. Hudspeth, J.R. Medina, C. Sanchez-Carratala and H. Tuah	255
Chapter 20 - The Effect of Wave Directionality on Nearshore Waves by M.J. Briggs and J.M. Smith	267
Chapter 21 - Similarity of Velocity Profiles in Non-Uniform Longshore Currents by H. El A.A. Refaat, Y. Tsuchiya and Y. Kawata	281
Chapter 22 - Time and Frequency Domain Analyses of Shallow Water Waves on a Slope by D.H. Swart and J.G. Crowley	293

Chapter 23 - Extension of Mild Slope Equation for Waves Propagating Over a Permeable Submerged Breakwater by T. Izumiya	306
Chapter 24 - Another Quasi-3D Model for Surf-Zone Flows by A. Sanchez-Arcilla, F. Collado, M. Lemos and F. Rivero	316
Chapter 25 - Wave Attenuation on an Offshore Coral Reef by T.A. Hardy, I.R. Young, R.C. Nelson and M.R. Gourlay	330
Chapter 26 - Application of Lognormal Truncated Distribution to Prediction of Long Term Sea State Using Visual Wave Height Data by A. Gonzalez, J. Martinez and R. Blazquez	345
Chapter 27 - Extreme Waves and Wave Counts in a Hurricane by R.J. Sobey, B.A. Harper and B.D. Chandler	358
Chapter 28 - A Prediction Model of Irregular Wave Run-Up Height on Coastal Structures by C.-R. Ryu and H.-Y. Kang	371
Chapter 29 - Effects of the Gulf Stream on Nearby Coastal Waves by L.H. Holthuijsen and H.L. Tolman	384
Chapter 30 - Improved Calculation of the Shoaling Wave Field by M. Hattori and T. Katsuragawa	396
Chapter 31 - A Model for Long Waves at Grazing Angle to a Rubble-Mound Jetty by E. Melo and R.T. Guza	410
Chapter 32 - Movable Bed Friction Factors for Spectral Waves by O.S. Madsen, P.P. Mathisen and M.M. Rosengaus	420
Chapter 33 - Second Order Wave Generation and Application to Shoaling Investigations by A. Gotschenberg and K.F. Daemrich	430
Chapter 34 - Computation of 3-D Wind-Driven Currents by Response Function Method by S.-K. Liu and J.J. Leendertse	444
Chapter 35 - Velocities and Bed Friction in Combined Flows by J.F.A. Sleath	450
Chapter 36 - On the Fitting of Jonswap Spectra to Measured Sea States by E.P.D. Mansard and E.R. Funke	464

Chapter 37 - An Efficient Method for the Reproduction of Non-Linear Random Waves by G. Klopman and P.J. van Leeuwen	478
Chapter 38 - An Experimental Study of Waves on a Strongly Sheared Current Profile by C. Swan	489
Chapter 39 - Wave Kinematics in the Surface Zone by J.E. Skjelbreia and A. Torum	503
Chapter 40 - Stochastic Modeling of Surfing Climate by W.R. Dally	516
Chapter 41 - Wave Model Application in a Wadden Sea Area by J.D. den Adel, H.D. Niemeyer, A.F. Franken N. Booij, J. Dekker and J.A. Vogel	530
Chapter 42 - The Mass Transport of Waves Propagating on a Sloping Bottom by H.H. Hwung and C. Lin	544
Chapter 43 - Turbulence Scales in the Surf and Swash by R.E. Flick and R.A. George	557
Chapter 44 - Reflection From Swash Zone on Natural Beaches by S. Kubota, M. Mizuguchi and M. Takezawa	570
Chapter 45 - Instabilities in the Longshore Current by N. Dodd, J. Oltman-Shay and E.B. Thornton	584
Chapter 46 - A Comparison of the Performance of Three Mathematical Models of Wave Disturbance in Harbour Approaches by J.V. Smallman and N.P. Tozer	597
Chapter 47 - Observations of Wind Wave Nonlinearity by T.H.C. Herbers and R.T. Guza	611
Chapter 48 - Applicability of a New Hybrid Parametric Wave Prediction Model by Y. Hatada and M. Yamaguchi	623
Chapter 49 - Bottom Shear Stress and Friction Factor Due to the Asymmetric Wave Action by C.-T. Kuo and W.-J. Chen	637
Chapter 50 - Estimation of Directional Spectrum Expressed in Standard Form by M. Isobe	647

Chapter 51 - Characteristics of Oscillatory Flow Over Ripple Models by K. Horikawa and S. Ikeda	661
Chapter 52 - Sensitivity Analysis for Multi-Element Wavemakers by G.S. Harkins, R.A. Dalrymple and M.A. Losada	675
Chapter 53 - A Model to Propagate Nonlinear Water Waves by J.M.C. Leitao and J.L.M. Fernandes	689
Chapter 54 - Wave Direction Measurement Using Marine X Band Radar by H. Hirakuchi and M. Ikeno	703
Chapter 55 - Variation of Surf Zone Turbulence In a Wave Period by Y. Tada, T. Sakai and E. Obana	716
Chapter 56 - Wave Group Forced Nearshore Circulation by R.E. Fowler and R.A. Dalrymple	729
Chapter 57 - Bore-Like Surf Beat on Reef Coasts by E. Nakaza, S. Tsukayama and M. Hino	743
Chapter 58 - Bragg Reflection of Waves by Artificial Bars by J.T. Kirby and J. Anton	757
Chapter 59 - Generation Mechanism of Abnormal Waves Along the Japan Coast by T. Komaguchi, Y. Tsuchiya and N. Shiraishi	769
Chapter 60 - Field Measurements and Analysis of Wave Induced Nearshore Currents by H. Niemeier	783
Chapter 61 - Directional Random Wave Propagation on Beaches by J.M. Grassa	798
Chapter 62 - Spatial Variation of Wave Group Statistics and Representative Wave-Heights of Swell by A. Ukai, T. Yasuda and K. Ito	812
Chapter 63 - Sea-Air Interactions in the Coastal Circulation Around Gran Canaria Island (Spain) by B. Tejedor, M. Alejo and L. Tejedor	826
Chapter 64 - A Numerical Method of Solitary Wave Forces Acting on a Large Vertical Cylinder by T. Ohyama	840

Chapter 65 - A Numerical Model of the Rough Turbulent Boundary Layer in Combined Wave and Current Interaction by H.-T. Son and A. Temperville	853
Chapter 66 - Runup, Setup and the Coastal Watertable by P. Nielsen	867
Chapter 67 - Application of the Second-Order Mode Coupling Equation to Coastal Engineering Problems by M. Tanaka	881
Chapter 68 - Full-Scale Measurements of Wave Run-up at Sea Dykes by U. Sparboom, J. Grune, S. Grosche and M. Haidekker	895
Chapter 69 - Statistical Characteristics of Offshore Currents by M. Ochi	909
Chapter 70 - Breaking and Reflection of a Steep Solitary Wave Caused by a Submerged Obstacle by T. Yasuda and M. Hara	923
Chapter 71 - Report from the NATO ARW on Water Wave Kinematics, May 1989 by A. Torum and O. T. Gudmestad	935
Chapter 72 - Prediction of the Dimensions of a Rip Current System on a Coast With Bars by J. Zyserman, J. Fredsoe and R. Deigaard	959
Chapter 73 - Scale Effects in Breaking Waves by A.D. Toumazis and K. Anastasiou	973
Chapter 74 - Comparison of Wave Hindcast Methods for Lower Gulf of Thailand by S. Weesakul and S. Charulakana	986
Chapter 75 - Developing Wave-Current Boundary Layers by R. Simons and A.G. Kyriacou	993
Chapter 76 - Incorporation of Wave Effects in a 3D Hydrostatic Mean Current Model by H. de Vriend and N. Kitou	1005
Chapter 77 - Nonsteady Computations of Undular and Breaking Bores by A.F.T. da Silva and D.H. Peregrine	1019
Chapter 78 - Experimental and Numerical Study on Solitary Wave Breaking by H. Nishimura and S. Takewaka	1033

Chapter 79 - Wave Reflection by a Number of Thin Porous Plates Fixed in a Semi-Infinitely Long Flume by S. Twu and D.T. Lin	1046
Chapter 80 - Modeling of Wave Transformation on Submerged Breakwater by S. Rojanakamthorn, M. Isobe and A. Watanabe	1060
Chapter 81 - Wind-Induced Cross-Shore Water Flows by J.B. Crowley and D.H. Swart	1074
Chapter 82 - Irregular Waves on a Current by H.-H. Pruser and W. Zielke	1088
Chapter 83 - Wave Spectra Transformations by G. Chiaia, L. Damiani and A. Petrillo	1102

Part II: LONG WAVES AND STORM SURGES

Chapter 84 - Evolution of Infragravity Variance During a Storm by P.A. Howd, J. Oltman-Shay, R. Holman and P.D. Komar	1118
Chapter 85 - Theory Versus Experiments in Two-Dimensional Surf Beats by H.A. Schaffer, I.G. Jonsson	1131
Chapter 86 - Bottom Pressures Due to Long Waves: Laboratory & Field Measurements by F. Raichlen, J.D. Ramsden and J.R. Walker	1144
Chapter 87 - Sea Level Rise: A Probabilistic Design Problem by J.K. Vrijling and I.J.C.A. van Beurden	1160
Chapter 88 - Nearfield Tsunamis Generated by Three Dimensional Bed Motions by J.-J. Lee and J.J. Chang	1172
Chapter 89 - Numerical 3-D Current Modelling of Stratified Seas by E.B. Rasmussen, H.J. Vested and L.C. Ekebjerg	1186
Chapter 90 - Long Wave Interaction with Steeply Sloping Structures by S.T. Grilli and I.A. Svendsen	1200
Chapter 91 - North Sea Winds on Tides and Storm Surges by H.L. Tolman	1214
Chapter 92 - Decomposition and Interception of Long Waves by a Submerged Horizontal Plate by H. Kojima, T. Ijima and A. Yoshida	1228

Chapter 93 - Observations of the Swash Expression of Far Infragravity Wave Motions by R.A. Holman, P.A. Howd, J.M. Oltman-Shay and P.D. Komar	1242
Chapter 94 - Safety Philosophy for Dike Design in The Netherlands by A.W.C.M. Vrouwenvelder and P. Struik	1254

Part III: COASTAL STRUCTURES

Chapter 95 - Dynamic Stability of Armor Units - A BEM Approach by C. Chian and F. Gerritsen	1270
Chapter 96 - Wave Forces on Cylindrical Members at Offshore Structure by Y. Mizuno, K. Tokikawa, M. Hirasawa, Y. Nagai and T. Kadono	1280
Chapter 97 - The Effect of Seawalls on Long-Term Shoreline Change Rates for the Southern Virginia Ocean Coastline by D.R. Basco	1292
Chapter 98 - Rock Slopes Under Irregular Wave Attack by N. Kobayashi, A. Wurjanto and D.T. Cox	1306
Chapter 99 - Dynamic Analysis of Floating Breakwater Mooring Systems by J.R. Headland and Vallianos	1320
Chapter 100 - Wave Induced Pore Pressure In Rubble Mound Breakwaters by H. Oumeraci and H.W. Partenscky	1324
Chapter 101 - Reduction of Wave Forces and Overtopping by Submerged Structures in Front of a Vertical Breakwater by B. Gonzales-Madrugal and J. Olwares Prud'Homme	1348
Chapter 102 - Stability of Breakwaters Constructed on Dredged Sand Mound by K. Yano, Y. Mizuno, N. Umezawa and T. Yanase	1362
Chapter 103 - Stability of Low-Crested and Reef Breakwaters by J.W. van der Meer and K.W. Pilarczyk	1375
Chapter 104 - Forces on and Particle Motions Around Submerged Structures in Steep Waves by J. Skourup and I.G. Jonsson	1389
Chapter 105 - Reliability Analysis of Composite Breakwaters Protected with Armor Blocks by M. Yamamoto, K. Mizumura, T. Endo and N. Shiraishi	1403

Chapter 106 - Stresses in Dolosse by H.F. Burcharth, L. Zhou, G.L. Howell and W.G. McDougal	1417
Chapter 107 - Verification and Practical Use of Block Revetment Design Method by A. Burger, A. Bezuijen, K.W. Pilarczyk and M.K. Breteler	1431
Chapter 108 - Rock Armour Stability Formulae - Influence of Stone Shape and Layer Thickness by A.P. Bradbury, J-P Latham and N.W.H. Allsop	1446
Chapter 109 - Reflection Performance of Rock Armoured Slopes in Random Waves by N.W.H. Allsop	1460
Chapter 110 - A Model for Breaking Wave Impact Pressures by M.J. Cooker and D.H. Peregrine	1473
Chapter 111 - Overtopping of Solitary Waves at Model Sea Dikes by E. Ozhan and A.C. Yalciner	1487
Chapter 112 - Permeability Characteristics of Rubble Material - New Formulae by R.W.K. Shih	1499
Chapter 113 - Morison Equation Coefficients and Data Condition by R.T. Hudspeth	1513
Chapter 114 - New Criteria for Granular Filters and Geotextile Filters Under Revetments by K.J. Bakker, M.K. Breteler and H. den Adel	1524
Chapter 115 - Wave Forces on Breakwater Armour Units by J. Juhl and O.J. Jensen	1538
Chapter 116 - Effects of Wave Groups on the Stability of Rubble Mound Breakwaters by J.R. Medina, C. Fassardi and R.T. Hudspeth	1552
Chapter 117 - Monitoring Hydraulic Loads on the Eastern Scheldt Storm Surge Barrier by L. Klatter, J. Konter and T. Jongeling	1564
Chapter 118 - Stresses in Tetrapods: Results of Large Scale Model Tests by W.W. Burger, H. Oumeraci and H.W. Partenscky	1578

Chapter 119 - Experiments on Coastal Protection Submerged Breakwaters: A Way to Look at the Results by G. Gomez-Pina and J.M. Valdes Fernandez	1592
Chapter 120 - Numerical Simulation of the Motion of a Loose Revetment Block by A. Bezuijen, J. Wouters and H. den Adel	1606
Chapter 121 - Wave Pressure Attenuation in Breakwater Armour Layers by K.R. Hall	1620
Chapter 122 - Concrete Armor Unit Structural Design Criteria by C.D. Anglin, R.D. Scott and D.J. Turcke	1634
Chapter 123 - A Fundamental Study on Construction Scheme for Rubble Foundation of Deep Water Breakwater from Hopper Barges by Y. Matsumi	1648
Chapter 124 - Resistance of Grassmat to Wave Attack by J.W. Seiffert and L. Philipse	1662
Chapter 125 - Practical Study on Larger-Scale Cylindrical Caisson Breakwater in Port of Kaohsiung by S.-D. Kuo	1675
Chapter 126 - Arctic Slope Protection Methods by C.B. Leidersdorf, P.E. Gadd and W.G. McDougal	1687
Chapter 127 - Bragg Reflection Breakwater: A New Shore Protection Method? by J. Bailard, J. DeVries, J.T. Kirby and R.T. Guza	1702
Chapter 128 - Scale Effect of Wave Force on Armor Units by T. Sakakiyama and R. Kajima	1716
Chapter 129 - Trends in Stability of Dynamically Stable Breakwaters by J.S. Kao and K.R. Hall	1730
Chapter 130 - Forces on Vertical Walls Due to Obliquely-Incident Waves by C.-P. Tsai and D.-S. Jeng	1742
Chapter 131 - Static and Dynamic Loading Tests on the Haro Armor Unit by L. Van Damme, J. de Rouck, L. Taerwe R. Dedeyne and J. Degriek	1755

Chapter 132 - Determination of Coefficients in Morison Formula by a Kalman Filter by P. Wilde, E. Sobierajski and W. Romanczyk	1769
Chapter 133 - Wave Forces on Vertical Breakwater on Reef Coasts by E. Nakaza, S. Tsukayama and M. Hino	1781
Chapter 134 - Local Scour Around a Large Circular Cylinder Due to Wave Action by E. Saito, S. Sato and T. Shibayama	1795
Chapter 135 - Stability of Dolosse with Different Waist Thicknesses for Irregular Waves by A.H. Holtzhausen and J.A. Zwamborn	1805
Chapter 136 - Estimation of Peak Wave Stresses in Slender Complex Concrete Armor Units by G.L. Howell, H.F. Burcharth and J.P. Rhee	1819
Chapter 137 - Research of Wave Forces of Breakwater in Deep Water Area by H.-S. Hou	1827
Chapter 138 - Dynamic Revetments by J. Ahrens	1837
Chapter 139 - Statistical Approach of Duration of Extreme Storms: Consequences on Breakwater Damages by C. Teisson	1851

Part IV: THE DUTCH COAST

Chapter 140 - Coastal Defence Alternative in the Netherlands by C.J. Louisse and T.J. Kuik	1862
Chapter 141 - Reconstruction of the Holocene Evolution of the Dutch Coast by T.J. Zitman, M.J.F. Stive and H.J. Wiersma	1876
Chapter 142 - Long Term Changes in Wind and Wave Climate on the North Sea by F.M. Hoozemans	1888
Chapter 143 - Sand Budget of the Dutch Coast by P. van Vessem and A. Stolk	1895
Chapter 144 - Sand Transport on the Shoreface of the Holland Coast by J.A. Roelvink and M.J.F. Stive	1909

Chapter 145 - Cross-Shore Transport During Storm Surges by H.J. Steetzel	1922
Chapter 146 - Prediction of Coastline Evolution for the Holland Coast by M.J. Dijkman, W.T. Bakker and J.H. de Vroeg	1935
Chapter 147 - Morphologic Response of Tidal Basins to Changes by W.D. Eysink	1948
Chapter 148 - Large-Scale Coastal Evolution Concept by M.J.F. Stive, J.A. Roelvink and H.J. de Vriend	1962
Chapter 149 - Research on Large-Scale Coastal Behaviour by J.H.J. Terwindt and J.A. Battjes	1975
Chapter 150 - Beach and Dune Nourishment in the Netherlands by P. Roelse	1984
Chapter 151 - Offshore Sand Extraction and Nearshore Profile Nourishment by J.S.L.J. van Alphen, F.P. Hallie, J.S. Ribberink J.A. Roelvink and C.J. Louisse	1998
Chapter 152 - Seaward Coastal Defence for the Dutch Coast by M.Pluijm	2010

PartV: COASTAL PROCESSES AND SEDIMENT TRANSPORT

Chapter 153 - The Effect of Shore-Parallel Offshore Breakwater on the Beaches at Ocean City, New Jersey by J.R. Weggel and S.C. Farrell	2020
Chapter 154 - Shoreline Response to a Single Transmissive Detached Breakwater by H. Hanson and N.C. Kraus	2034
Chapter 155 - Flow-Fine Sediment Hysteresis in Sediment-Stratified Coastal Waters by R.G. Costa and A.J. Mehta	2047
Chapter 156 - Nearshore Current Patterns on Barred Beaches by D.G. Hazen, B. Greenwood and A.J. Bowen	2061
Chapter 157 - Berm Erosion Due to Long Period Waves by K. Katoh and S.-i. Yanagishima	2073

Chapter 158 - A Field Experiment on Breach Growth in Sand-Dikes by P.J. Visser, J.K. Vrijling and H.J. Verhagen	2087
Chapter 159 - Multi-Scale Nearshore and Beach Changes by R. Ostrowski, Z. Pruszek and R.B. Zeidler	2101
Chapter 160 - Laboratory Study on Beach Processes Due to Random Waves by R. Nishi, M. Sato and K. Nakamura	2117
Chapter 161 - A Quasi-3D Model for Suspended Sediment Transport by Currents and Waves by I. Katopodi and J.S. Ribberink	2131
Chapter 162 - Method of Prediction of Bar Formation & Migration by S.H. Houston and R.G. Dean	2145
Chapter 163 - A Micro-Computer Based QUASI 3-D Sediment Transport Model by M.H.G. Briand and J.W. Kamphuis	2159
Chapter 164 - Decoupled Numerical Model of Three-Dimensional Beach Change by M. Larson, N.C. Kraus and H. Hanson	2173
Chapter 165 - Oscillatory Flow and Sediment Motion Over a Rippled Bed by P. Blondeaux and G. Vittori	2186
Chapter 166 - Wave Entrainment of Sand from a Rippled Bed by M.O. Green and C.E. Vincent	2200
Chapter 167 - Modelling of Multicomponent Sandy Beds Evolution Under Shallow Water Waves by G. Chapalain and B. Boczar-Karakiewicz	2213
Chapter 168 - Nearshore Sediment Flux and Bottom Boundary Dynamics: The Canadian Coastal Sediment Transport Programme (C-Coast) by B. Greenwood, P.D. Osborne, A.J. Bowen, D.G. Hazen and A.E. Hay	2227
Chapter 169 - Nearshore Nourishment Implementation, Monitoring and Model Studies of the 1.5 M m ³ at Kirra Beach by L.A. Jackson and R.B. Tomlinson	2241
Chapter 170 - A New Approach to 3D Flow and Transport-Modeling by J.C.M. Dijkzeul and J.J. Leendertse	2255

Chapter 171 - The Analysis and Role of Bars on the Protection of a Beach System, Gold Coast, Queensland, Australia by B. Boczar-Karakiewicz and L.A. Jackson	2265
Chapter 172 - Sea Bottom Topography with Imaging Radar by J. Vogelzang, G.J. Wensink, D. van Halsema and G. van der Burg	2279
Chapter 173 - Application of Equilibrium Beach Concepts to Sandy Great Lakes Profiles by M. Stockberger and W.L. Wood	2291
Chapter 174 - Advances in Numerical Modeling of Dune Erosion by D.L. Kriebel	2304
Chapter 175 - Bedforms, Sediment Concentrations and Sediment Transport in Simulated Wave Conditions by J.S. Ribberink and A. Al-Salem	2318
Chapter 176 - The In Situ Measurements of Sediment Transport and Bottom Topography Changes by Y. Kawata, H. Yoshioka and Y. Tsuchiya	2332
Chapter 177 - Single-Phase Fluid Modelling of Sheet-Flow Toward the Development of "Numerical Mobile Bed" by K. Nadaoka and H. Yagi	2346
Chapter 178 - Site Investigation on Sand Concentration in the Sheet-Flow Layer by Z. Yu, H.D. Niemeyer and W.T. Bakker	2360
Chapter 179 - Two-Phase Flow Model on Oscillatory Sheet-Flow by T. Asano	2372
Chapter 180 - Abrasion at the Tanah Lot Temple - Bali - Indonesia, and Its Counter Measures by Syamsudin and Kardana	2385
Chapter 181 - Man-Made Beaches: More Than 20 Years On by F. Rouch and B. Bellessort	2394
Chapter 182 - Littoral Transport Rate by J.W. Kamphuis	2402
Chapter 183 - Causes of Damage to Saldanha Sand Breakwater by J.S. Schoonees, J.W.J. Kluger and J.A. Zwamborn	2416

Chapter 184 - Numerical Modelling of the Dredged Spoil Disposal by C. Zude and W. Guifen	2430
Chapter 185 - Modeling of Wave-Current Interaction and Beach Change by S. Ohnaka and A. Watanabe	2443
Chapter 186 - Validation of Movable-Bed Modeling Guidance by S.A. Hughes and J.E. Fowler	2457
Chapter 187 - Large Scale Laboratory Tests of Dune Erosion by M.F. Overton, J.S. Fishcr and A.L. Stone	2471
Chapter 188 - Practical Application of the Three-Dimensional Beach Evolution Model by T. Shimizu, H. Nodani and K. Kondo	2481
Chapter 189 - Sand Transport Rate Under Wave-Current Action by A. Watanabe and M. Isobe	2495
Chapter 190 - Dynamic Numerical Models for Sand Waves and Pipeline Self-Burial by C. Staub and R. Bijker	2508
Chapter 191 - Even/Odd Analysis of Shoreline Changes Adjacent to Florida's Tidal Inlets by P.A. Work and R.G. Dean	2522
Chapter 192 - Behaviour of Mobile Beds at High Shear Stress By K.C. Wilson and F.N. Nnadi	2536
Chapter 193 - To Retreat in Order to Better Fight: Littoral Protection of Shingle Beaches in the North of France by B. Manoha and C. Teisson	2542
Chapter194 - Experimental Results on the Sediment Grain Threshold Under Short-Wave Action by C. Moutzouris	2552
Chapter 195 - Movable Bed Modeling Criteria for Beach Profile Response by H. Wang, T. Toue and H. Dette	2566
Chapter 196 - Storm Erosion on the Sandy Beach by M. Martinez, R. Alvarcz and I. Alonso	2580
Chapter 197 - A Regional Study of Coastal Morphology by I.H. Townend, C.A. Fleming, P. McLaren and A. Hunter-Blair	2589

Chapter 198 - Function of Detached Breakwater to Control Longshore Sediment Transport by T. Sawaragi, I. Deguchi and G.-Y. Kim	2603
Chapter 199 - Oscillatory Flow Investigations in Porous Media by G.M. Smith and K.R. Hall	2616
Chapter 200 - Instantaneous Sediment Concentration Due to Wave Action at Prototype Scale by K. Uliczka	2630
Chapter 201 - Underground Water Table and Beach Face Erosion by M. Sato	2644
Chapter 202 - A Numerical Model for Sand Transport Under Compound Waves by S. Sato and N. Mitsunobu	2658
Chapter 203 - Dike Failure Calculation Model Based on in Situ Tests by C. Laustrup, H.T. Madsen, J. Jensen and L. Poulsen	2671
Chapter 204 - How To Analyse Beach Profile Measurements? by J. van de Graaff	2682
Chapter 205 - Grain-Grain Interaction in Oscillating Sheetflow by W.T. Bakker, W.G.M. van Kesteren and W.H.G. Klomp	2696
Chapter 206 - Evaluation of Radioactive Sand Tracers to Measure Longshore Sediment Transport Rates by G. Drapeau, B. Long and J.W. Kamphuis	2710

Part VI: COASTAL, ESTUARINE AND ENVIRONMENTAL PROBLEMS

Chapter 207 - Beach Erosion Due to Large Coastal Structure and Its Control by Y. Tsuchiya, T. Yamashita and R. Silvester	2726
Chapter 208 - Beach Erosion Control by Submerged Floating Structure by N. Shimoda, N. Murakami and K. Iwata	2740
Chapter 209 - Function of Sand Fence Placed in Front of Embankment by S. Hotta and K. Horikawa	2754
Chapter 210 - Recent Performance of Linked Concrete Mat Armor Under Wave and Ice Impact by P.E. Gadd and C.B. Leidersdorf	2768

Chapter 211 - Three Dimensional Effects of Seawall on the Adjacent Beach by T. Toue and H. Wang	2782
Chapter 212 - Predicting Damage Benefits of Shore Protection Projects by K.R. Bodge	2796
Chapter 213 - The Impacts of Shoreline Protection Structures on Beaches Along Monterey Bay, California by G.B. Griggs, J.F. Tait and K. Scott	2810
Chapter 214 - Fate of Dredged Material Dumped Off the Dutch Shore by R. Spanhoff, Tj. van Heuvel and J.M. de Kok	2824
Chapter 215 - Development of Water Level Changes in the German Bight, An Analysis Based on Single Value Time Series by J. Jensen, H.-E. Mugge and W. Schonfeld	2838
Chapter 216 - Day Visitor Pontoon - Great Barrier Reef, Australia by A.A.C. Grummitt	2852
Chapter 217 - Salt Intrusion in Tideless Estuaries by E. Jasinska	2866
Chapter 218 - Coastal Lagoon Entrance Dynamics by A.D. Gordon	2880
Chapter 219 - Extent of Contaminated Marine Sediments and Cleanup Methodology by J.B. Herbich	2894
Chapter 220 - Designing for Storm and Wave Damage in Coastal Buildings by S.M. Rogers, Jr.	2908
Chapter 221 - Cross-Sectional Stability of Estuary Channels in the Netherlands by F. Gerritsen, H. de Jong and A. Langerak	2922
Chapter 222 - Variations in Rheological Properties of Muds in the Gironde Estuary by P. Galichon, A. Feral, J. Granboulan and J. Viguiet	2936
Chapter 223 - Hydraulic Aspects of the Construction of the Eastern Scheldt Storm Surge Barrier by J. Konter and L. Klatter	2950

Chapter 224 - Investigation on Improvement of Yangtze Estuary by Y. Kai and Y. Yixin	2964
Chapter 225 - Consolidation and Rheological Properties of Mud Deposits by C. Migniot and L. Hamm	2975
Chapter 226 - Integrated Coastal Research in the SW Netherlands by J.P.M. Mulder, T. Louters, F.P. Hallie, R. Postma J.A. Craeymeersch and O. Hamerlynck	2984
Chapter 227 - Numerical Simulations of Mud Transport by a Multi- Layered Nested Grid Model by H. Tsuruya, K. Murakami and I. Irie	2998
Chapter 228 - Modelling of Cohesive Sediment Transport. A Case Study: The Western Scheldt Estuary by H.P.J. Mulder and C. Udink	3012
Chapter 229 - The Great Belt Link - How to Achieve Zero Environmental Impact on the Baltic Sea by J.S. Moller and N.-E.O. Hansen	3024
Chapter 230 - Mud Transport Rate In Mud Layer Due to Wave Action by T. Shibayama, M. Okuno and S. Sato	3037
Chapter 231 - Estuary Geometry as a Function of Tidal Range by B. O'Connor, J. Nicholson and R. Rayner	3050
Chapter 232 - Flow Area Prediction of Tidal Inlets After Sea Level Rise by H. Kondo	3063
Part VII: SHIP MOTIONS	
Chapter 233 Criteria for Ship Movements in Harbours by O.J. Jensen, G. Viggosson, J. Thomsen, S. Bjordal and J. Lundgren	3074
Chapter 234 - Navigability in Channels Subject to Siltation - Physical Scale Model Experiments by C. Brossard, A. Delouis, P. Galichon, J. Granboulan and P. Monadier	3088
Chapter 235 - Integration of Marine Simulation in Harbour Design by S.E. Sand and O.J. Jensen	3102

Chapter 236 - Extension of the Boussinesq Equations to Include Wave Propagation in Deeper Water and Wave-Ship Interaction in Shallow Water by P.A. Madsen and O.R. Sorensen	3112
Chapter 237 - Safe Underkeel Allowances for Vessels in Navigation Channels by J.M.A. Spencer, E.C. Bowers and G.H. Lean	3126
Chapter 238 - Numerical Model of the Nonlinear Interaction of Waves and Floating Bodies by M. Brorsen and H.I. Bundgaard	3140

Part VIII: CASE STUDIES

Chapter 239 - Ria De Foz: Works Behaviour by J. Diez Gonzalez and V. Escobar	3154
Chapter 240 - Emergency Situation in the Shoreline Reach of an Offshore Oilfield Pipeline and Remedial Measures by J.V. Bandeira, L.C. Araujo and A.B. do Valle	3171
Chapter 241 - Sand Bypassing to "Playa de Castilla" (Huelva-Spain) by J. Fernandez, G. Gomez Pina and A. Munoz	3183
Chapter 242 - Berm Breakwater Contamination Study Sergipe Marine Terminal, Brazil by C.P. Fournier, O.J. Sayao and J.F. Caldas	3194
Chapter 243 - Offshore Breakwater for the Sergipe Marine Terminal, Brazil by M. Malcolm and O.J. Sayao	3207
Chapter 244 - St. Paul Breakwater, Phase I (The Project, the Failure and the Subsequent Investigations) by T. Sorensen and O.J. Jensen	3222
Chapter 245 - The Durban Beach Restoration Scheme After 30 Years by W. Laubscher, D.H. Swart, J.S. Schoonees, W.M. Pfaff and A.B. Davis	3227
Chapter 246 - Design and Construction of Pleasure Craft Harbour - Club Mykonos Langebaan by D.E. Bosman, G. de F. Retief, J.F. Kapp, M. Kloos and A. B. Ridge	3239
Chapter 247 - Artificial Beach Nourishment on Norderney, A Case Study by H. Kunz	3254

Chapter 248 - Design and Installation of Scour Protection for the Acosta
Bridge to Protect Against Hurricane Conditions
by B.L. Edge, D.K. Crapps, S. Jones and W. Dean 3268

Chapter 249 - Influence Functions
by H.G. Wind 3281

OPENING ADDRESS

His Royal Highness Prince Claus of the Netherlands

Mr. Chairman, Ladies and Gentlemen,

It is a great pleasure for me, to be able to speak to you this morning on the occasion of your 22nd International Conference on Coastal Engineering.

You have chosen to hold your conference in a place where the important and fascinating field of Coastal Engineering, in which you are all involved, is particularly significant. Not only would the land we are now standing on still be under water were it not for coastal engineering, but the Faculty of Civil Engineering here at Delft University of Technology is an important centre of education and research in this field.

In Roman times, this area was described as an inhospitable land, lying just above sea level, subject to flooding during storms and sparsely inhabited by a few miserable folk. In the centuries that followed, however, these miserable folk succeeded in forcing back the sea and turning the low-lying land into an area suitable for long-term habitation.

This enormous task could not have been achieved without a joint effort. The awareness of this need to work together grew naturally among the people, and they chose leaders from amongst themselves to coordinate and direct their activities. This was possible, because the members of the community were directly involved, were aware that they had a personal interest in good communal water management in the area in which they lived, and were prepared to contribute to it in any way they could.

These principles of a personal *interest*, an individual *contribution* (both financially and in terms of labour), and an *involvement* in the decision-making process, formed the basis of the structures of cooperation which arose. The water authority which, as a result, was established on a formal basis in the Delft area more than 700 years ago, was actually the first democratic institution in the Netherlands. Some people even claim that this foundation of our first administrative institutions on democratic principles, was an absolute precondition for the establishment and survival of our country. Democracy, as it were, flowed into the Netherlands along with the water.

Although solutions developed in the Netherlands, cannot necessarily be applied wholesale in other countries, it is true that similar organisations for good coastal management, are required in other low-lying areas which are threatened by the sea. In the giving of aid to coastal defence programmes, this institutional aspect, which provides a solid base for coastal defence in society, should receive sufficient attention.

Unfortunately, this is not always the case. On the other hand, one example of this approach being used successfully, is the Beach Protection Authority Queensland in Australia, which was set up along the lines of the Schieland Water Authority in the Province of South Holland.

Ladies and Gentlemen,

It may seem strange that people should choose to live in such a low-lying and vulnerable area, but this is by no means a purely Dutch phenomenon. People have settled in low-lying areas all over the world, since these generally have very fertile soil, and the water facilitates transport and communications, which in turn promote trade and industry. And of course, fish are readily available as a welcome supplement to the daily diet. This then is the reason why your field of interest is so important for these coastal areas, and has always received a great deal of well-earned interest.

Of course, the fight against the sea has always been a process of trial and error, but one in which a considerable pool of knowledge has slowly but surely been built up concerning the relationship between those factors which present a threat - such as waves and currents - and the behaviour of the coast itself. Throughout the world, this knowledge acquired from centuries of practice represented the first humble beginnings of the science of coastal engineering.

This process, of course, went hand in hand with all kinds of other technical developments. A good example of this, was the use of windmills here in the Netherlands to control the water level in the polders. Windmills had already been in use for some time, particularly around the Mediterranean Sea, but the most important innovation in the Netherlands was the development of the mill with the revolving cap. The wind blows in all directions in this country, so this innovation increased the productivity of the mills considerably. The oldest surviving record of mills of this type being built dates from 1408, and refers to mills in Gouda and Alkmaar. These mills, many examples of which can still be seen in the Netherlands, also played another important role, namely in the development of our crafts and industry. Windmills were used not only, for example, for the grinding of grain and spices, but also to provide power for the mechanical sawing of the wood used to build ships. This enabled the Netherlands to strengthen its position as a shipbuilding nation and to establish itself as a prosperous seafaring and trading power in the seventeenth century. Clearly, the Netherlands and other similar areas have much reason to be grateful to the sea and the wind. We have an expression here in the Netherlands, "van de wind kun je niet leven", which literally means "you cannot live from the wind". I have no idea where it comes from, but it certainly does not apply to the mill operators.

Ladies and Gentlemen,

The first time science really took a hand in your branch of hydraulic engineering in the Netherlands, was in the enclosure of the Zuider Zee. The decision to undertake this ambitious project was prompted by the great floods of 1916, during which large areas around the Zuider Zee were under water. One of the civil engineers who devoted himself to the project and drew up carefully considered plans for the dam, was Dr. Cornelis Lely. As Minister of Transport and Public Works at the time, he introduced the Bill proposing the project into Parliament and successfully defended it.

In order to investigate the possible effects of the enclosure on the water levels and currents in the Waddenzee and the adjoining part of the North Sea, the Netherlands Department of Public Works called in Dr. Hendrik Antoon Lorentz, theoretical physicist, Nobel Prize winner and professor at the University of Leiden. Professor Lorentz had not previously worked in this field of applied fluid mechanics, but he was a brilliant fundamental scientist with a great interest in technology, making him the perfect man to solve the problem - an excellent example of the symbiosis of science and technology. He also had the young engineer Johannes Thijssse, assisting him, who combined intuition and technical insight with a fine scientific mind. It can be said that Professor Thijssse took over from Professor Lorentz as the torchbearer, promoting this scientific approach to hydraulic engineering. He was in a position to do this as director of the Delft Hydraulics Laboratory and as a Professor at Delft University of Technology, training a whole generation of engineers to pave the way for the second great challenge for the science of coastal engineering in the Netherlands, the development and implementation of the Delta Project.

This project - a reaction to the disastrous floods in Zeeland in 1953 - entailed the building of a series of dams in the delta area in the southwest of the Netherlands, rendering the coastline continuous, and in particular, the construction of the storm surge barrier in the Eastern Scheldt. The Delta Project practically guarantees this previously vulnerable area against flooding. I was pleased to see that your programme for the conference includes a visit to the storm surge barrier. This barrier across the Eastern Scheldt, which can be opened and closed as the situation demands, was the perfect solution to the conflict which arose between the need for a permanent dam to protect this coast, and the desire to preserve the natural environment behind the dam. The movable barrier represents the successful reconciliation of the technological requirements with other interests, for example, those of the biological environment. This remarkable construction could never have been completed, without the contributions of many other scientific disciplines.

The latest product of this line of development in coastal protection in the Netherlands, is the Coastal Genesis Project, which was set up to study the origins and evolution of our sandy coastline, with the aim of making reliable predictions for the future. The results of this study will be presented in detail at this conference.

Coastal management in the Netherlands, like that of many other plans and policy proposals, is set within the now well-known framework of "sustainable development". The findings of the Genesis Project, prompted the Netherlands Government to decide on a coastal policy for the future based on preserving the present coastline, but doing so in a responsible and intelligent way. Not, therefore, a policy of large-scale intervention with grand projects and no expense spared, but more what might be considered a typically Dutch approach, allowing the sea - or nature, if you like - to work for us where it is necessary to defend ourselves against her power. Or, as Andries Vierlingh, the first engineer to build coastal and dyke defences systematically in the Netherlands, put it as long ago as 1560, to entice the water to follow the desired course by using "gentle persuasion".

Nature, the earth on which we live, is our host. If we treat her with care and respect, we shall achieve our aims more often and with better results.

Ladies and Gentlemen,

I remember once, years ago when I was living and working in Ivory Coast, being taken to the Canal du Vridi, the approach channel to the port of Abidjan. A relatively short mole had been built there, together with a specially shaped approach channel. I was told that this design directed the sand, which was driven along the coast by the strong current generated by the waves, in such a way as to deposit it with great precision in a canyon in the seabed, the "trou sans fond". "Ah, ce sont les Hollandais qui ont trouvé la solution" said my African friend. As I discovered later, upon my first visit to Delft, it had been devised by Professor Thijsse and by Chief Engineer Jan Schijf of the Delft Hydraulics Laboratory. This was, of course, an intervention in nature, but one which took as great advantage as possible of the natural forces present, rather than tackling them head on. We have another saying in the Netherlands "Wie tegen de wind spuwt, krijgt een vuile baard", which means "If you spit into the wind, you will get a dirty beard".

With both small and large scale projects, it is often possible to fall back on more traditional or locally developed techniques, if the circumstances call for this. For example, in 1985, when the Feni river in Bangladesh had to be dammed as part of the large Muhuri irrigation project, (a joint Bangladeshi, Canadian, World Bank and Dutch endeavour), the decision was made by the project managers, to use traditional - age old - highly labour intensive techniques of dyke building, using fascine mattresses and bags of clay. One million bags, put into place by fifteen thousand workers, were required to complete the dam. This great mobilisation of people and materials, was excellently organised by local Bangladeshi contractors. With the exception of modern geo-textiles, the fascine mattresses which were used to protect the river bed, were made entirely according to traditional methods.

The Dutch are, of course, not the only ones who are involved in the field of coastal defence. It is no coincidence that these conferences were originally organised by the United States, with their long

tradition of coastal defence projects on both the Atlantic and Pacific coasts. And a number of other countries, whose representatives are present here, have also won their spurs in this field.

All of you here have one thing in common, you devote yourselves to defending the land against the sea. Often our friend and ally, the sea is a formidable enemy when she is seen as a threat to the land or to man. This tends to lead a belief in the maxim "safety first". Yet, as you are all aware, the concepts of safety and protection must be applied in a sensible and responsible way. We should not only protect densely populated areas, but also the environment - for example, the wetlands and the tidal forests which are so important for our animal and plant life. And when we inevitably have to sacrifice a valuable natural area for reasons of safety, or indeed for economic development, we should only do it after very careful consideration and see to it that the lost area is replaced somewhere else. If this is not possible, then let us strive to leave irreplaceable natural areas alone.

Just how much attention can and should be given to the protection of the environment is a difficult question to answer. The Netherlands gives a great deal of attention to the protection of both the population and the environment behind the Eastern Scheldt Barrier. Under normal circumstances, the storm surge barrier is open, allowing the water to flow freely and thereby maintaining the natural tidal environment. It is only closed when there is threat of a storm surge, to protect the hinterland. By taking into account the requirements of the environment, as well as the safety aspects, the costs of the project more or less doubled. The results were, however, that the technology applied enabled a particularly valuable ecosystem to be preserved, and new methods to be developed which can be employed in other parts of the world. As a matter of fact, the costs involved in coastal defence in general in the Netherlands are not high, relatively speaking, and can fortunately be borne by the community without causing undue problems.

However, the message which should be accepted by all coastal engineers at this time, is that they are the guardians of our extremely precious and vulnerable coastal areas. In fulfilling this task, they will often have to let the sea have its way to some extent, as in the case of the dune coast in the Netherlands. Dune erosion due to storms, such as we have experienced in the Netherlands in the past few months, need not be a cause for alarm, as long as it remains within the predicted and tolerable limits.

Ladies and Gentlemen,

The question of rising sea levels as a result of global warming also inevitably comes to mind here. Although it is by no means certain, let alone proven, that sea levels are actually rising, we cannot afford to ignore the possibility. The precautionary principle also applies here. It would be foolish to wait until we know exactly how much of a threat exists, because by then it may already be too late to do anything about it. Uncertainty is no reason for complacency. The costs of doing nothing could prove in the long run to be far higher than the costs of taking adequate action immediately. We should therefore not only be alert, but should also make immediate

plans for the taking of countermeasures. The area around here would of course be directly affected by any rise in sea level. The Public Works Department has already carried out a preliminary study, which indicates that the most probable expected rise, of between sixty and eighty centimetres in the next one hundred years, would present the Netherlands with no insurmountable problems. A rise of these proportions could, however, have disastrous consequences in other areas of the world. Thorough investigation should therefore be carried out in these areas into possible solutions. I am thinking here in particular of the Maldivé Islands and the great river deltas, such as those of the Nile in Egypt and the Ganges and Brahmaputra in Bangladesh. It is quite possible that traditional Dutch methods could be applied in some of these areas. Relatively simple constructions, such as training moles, could be used to try and change current and wave patterns in such a way, that sand and silt would be deposited in the threatened areas. As I mentioned before, the secret is to use the gentle touch to influence nature and encourage her to work together with man.

Simply thinking about countermeasures is not enough, however. The causes of the problem have to be identified and tackled. Growing trees that are resistant to acid rain is not a solution, any more than it is desirable that people should eventually be born with webbed feet as a solution to rising sea levels.

"State of the art" technology and the current possibilities it offers in coastal engineering, are undoubtedly impressive, but a great deal of research and study is still necessary if we are to tackle the challenges we are now faced with. That is why I believe that it is important for the latest developments in your field to be discussed regularly. These biennial International Coastal Engineering Conferences have proved to be an excellent forum for such discussions over the past forty years.

I wish you all a good reference, with searching and fruitful discussions, and it is with pleasure that I hereby declare the twenty-second International Coastal Engineering Conference open.

Thank you.

RETHINKING OUR ROLE IN COASTAL ZONE DEVELOPMENT

J.E. Prins^{*}

Your Royal Highness, Mr. Chairman, Ladies and Gentlemen,

For the twenty-second time the International Conference on Coastal Engineering is ready to start. The first Conference was the one in Long Beach, 40 years ago! I hope you noticed that it is your 8th Lustrum today! Congratulations!

There is something special in consistency. Those things in life that for sure are there and give anchorage. The regular participants share the same past experiences and have the same anticipations of seeing each other back next time. The world events pass by, but there is something to hang on to: ICCE, the International Conference on Coastal Engineering. And, for sure, at the Conferences we do meet many of our friends in the profession and beyond that, between many families personal friendships for life have grown.

40 years of Coastal Engineering Conferences is quite a considerable time, but there are institutions that go back in time much further. Take for instance ICES, the International Council for the Exploration of the Sea, dating from July 22, 1902. Once an older colleague told me how back in the thirties delegates of ICES went to Reykjavik on Iceland by ship to attend their meeting. And even in 1955 I went to the United States sailing by the flagship of the Holland-America line, the New Amsterdam, to enjoy a Fulbright scholarship. But shortly after, in 1957, I crossed the Atlantic by plane to be at the 6th ICCE in Miami, Florida.

Today we fly Amsterdam-Los Angeles and back for a day's meeting with cabin luggage only, in order not to let our break cost too much time.

Why am I telling this to you? Well, *I wanted to illustrate that society changes with time, not only because of technological development, but also because of change of mentality. Those changes can go rather fast and obviously are rather unpredictable in view of the time frame.* Extending the example with reference to shipping: the Queen Elisabeth II was ordered in 1965 to become a liner for regular services between the UK and the USA. After completion in 1969, four years later, it rather immediately was engaged in tourist cruises. The big liners were history.

* Former General Director DELFT HYDRAULICS, The Netherlands
Secretary General International Association for Hydraulic Research

Apart from gradual or obvious changes we may encounter surprises of physical, ecological, social, economic or political nature, such as the cyclone that hit Bangladesh in 1970 and caused the death of 300,000 people; recently the death, due to a virus infection, of 60% of the seals in the North Sea within a year's time; the illness AIDS, for which there is no remedy yet; the oil crisis in 1973 and the political landslides of today. *Such changes call for fundamental adaptations, heavily bearing upon the societal structure.*

It is about the changes with time and how these effect our coastal engineering profession, that I wanted to dwell on with you for a while, **rethinking our role in coastal zone development.** In fact His Royal Highness did so already and gave us a bird's-eye view of the developments from Roman times to the present. I will in addition to that cover more explicitly our individual position as it stands today and has to develop.

As I mentioned before, the ICCE is a constant factor in life. It rather strictly maintains its character as a meeting place for discussing sciences and technologies related to engineering aspects. But it is quite clear, as was pointedly indicated by His Royal Highness, that the context within which coastal engineering performs, shows changes over the years and will change in the future. Thus thrusting continuously upon the coastal engineer different demands of positioning himself in the creative processes in which coastal engineering is incorporated.

Saying this I express that coastal engineering cannot be exercised in isolation and it is necessary that the coastal engineer should be aware of that and plan accordingly. How can we anticipate on this?

In the course of the second half of this century, which means for the last 40 years, the structure of thinking has changed tremendously and with it the range of our responsibility for the deeds we perform; that is to say, today we are held responsible for the overall impact of our deeds even when the deeds in themselves are legal. I would call this moral engagement our "extended responsibility". In coastal engineering we are dealing with projects and processes with very large time scales - from decades to centuries - and we really saddle our descendants with our produce. So it is a must to incorporate the appreciation that future generations will have for our coastal works. For that reason it is of interest to try to analyse how thinking developed over time and to see what that means for the future.

One observation before starting this exercise. Of course, I was much interested which audience I was going to address. From the list of presentations it is evident that you, my audience, predominantly consist of scientists, researchers and engineers dealing with the physical environment, primarily with the aim to understand processes in order to control, to reshape or to maintain a physical condition, either related to nature itself or related to man-made works. I found only a few contributions that link up with conceptual thinking at large. Say, with a very liberal interpretation, some 8%. Moreover, the nature of this type of congresses is such that there is not much of a formal synthesis on the ten subjects you are going to deal with, although there will be in-depth discussions, particularly in the social hours. This makes the congress result in quite an individual experience. And regardless of the huge capital of

brains united here in this auditorium the follow-up action due to a joint effort will be absent. This - to my view - "lost opportunity" much engages me as it is an imperfection of many congresses, but difficult to overcome. I will return to this later.

Coming back to the analysis of developments in thinking, I want to explore with you in what kind of framework our thinking operates. As I noted already, since the middle of this century, the framework has changed considerably and logically will change in the future. Of course, we can do much to that change and guide it towards a desirable direction.

There is the big question on how far we can and should relate our specific task as coastal engineer to the broad context in which we work. And how broad do we go?

Generally speaking, at the beginning of this century technical matters got a very direct approach. Once the decision makers had decided to go for a project, the engineers performed their job straightforwardly in producing a technically sound solution within the boundaries of their available know-how. Today there is a definite interplay between the various actors in a project.

For thinking in a broad context I will distinguish four important components in the structure of thinking. They are:

- the scale of time,
- the scale of space,
- the extended responsibility and
- the knowledge base.

I had better give you an example of what I mean and you can assimilate your own examples with it.

I will use the sealing off of the Zuider Zee from the North Sea (Figure 1 and 2). This project is known to you in the meantime through the reference His Royal Highness made to it, because of the pronounced role science played there. This undertaking has a long history through which I can illustrate the gradual growth of the time and space dimensions in the project induced by technological and scientific development, the knowledge base.

The long coastline of the Zuider Zee encountered many threats from storm surges. When a storm surge occurred in the North Sea the inflowing water was swept up anew in the shallow Zuider Zee. In 1667 already, Hendric Stevin suggested to separate the Zuider Zee from the North Sea and reclaim land. He was inspired by the many polders that were created at that time as investment projects of the rich merchants of the 17th century. It is obvious that the scientific level and the technical means at that time were insufficient to execute such a huge work that even today would need mobilization of advanced design capabilities, equipment and organization.

Only after the stormsurge of 1825 a well thought-out plan was launched in 1849. It proved to be too ambitious and was followed by a more modest approach (Figure 3), which got a legal status in 1877, but was abandoned again. Fortunately, as the plan - by ignorance - did not consider the effects of change in resonance characteristics of the remaining basin - becoming in length about one quarter wavelength! - which would have augmented the stormsurge levels along the new dikes and remaining coastlines by 1 to 2 meters! The 1891 plans of Lely (figure 4) did incorporate increase of the tidal amplitude,

but they could not be calculated and were mere guesses. Only in the nineteen-twenties the physicist and Nobel Prize winner, Lorentz, managed to perform sufficiently accurate calculations. However, we may note that in 1891 the relative upward movement of the mean sea level due to tectonic movement of the earth crust was taken care of. So, we see *the space and time dimensions gradually entering the concept of thinking thanks to a growing knowledge base.*

After the severe storm surge of 1916, the Law of 1918 officially settles the closing off and reclamation of the Zuider Zee. The Law also allows for the execution of technical works in the interest of safety, water management and navigation, in those cases where there would be adverse effects due to the closing. Aggrieved parties can call on the government.

It should be noted that the drastic change of the ecological system of this 4000 km² large sea, that would turn into a freshwater lake and reclaimed land, and a possible impact on the Wadden Sea area due to the changed flow regime and tidal range, was not referred to at all. The disappearance of herring and anchovy was incorporated in the project as a matter of course and only the loss of economic value was compensated financially to the fishermen. I could not trace whether at that time there was something present in the sense of a feeling of extended responsibility in the minds of the scientists and coastal engineers. The historical words spoken by the president of the combined contractors on the very site just after closing to the Minister of Public Works, expressed only pride: "Excellency, we have completed your order. The Zuider Zee is closed off".

Today it is out of the question that the Wadden Sea would be closed off from the North Sea, although it is technically logic and practically possible.....**Why?**

Well, in the second half of this century many factors did change our way of thinking:

- I remember that in the fifties, in the Royal Institution of Engineers, we were formulating a code of ethics - like medical doctors have their Hippocratic oath. This committed the engineer to a broader responsibility than the mere technical features.
- In the seventies we enter global thinking initiated by the Report for the Club of Rome by Dennis L. Meadows (1972), who at that time presented his views on the **Limits to Growth** in this same auditorium.
- Writing scenarios becomes "en vogue".
- At the same time we enter the era of thinking in systems, recognizing interrelations. As a consequence systems approach and policy analysis emerge. The computer makes interrelations manageable and provides easy generation of alternative solutions, optimization, sensitivity analysis, etc.
- Also, technological development brings us informatics and extremely accurate detection methods revealing ruthlessly the presence of toxics in our environment.
- Public opinion becomes an ingredient in decision making.
- In the design of large coastal engineering works a new formula is applied by introducing probabilistics as a philosophy for safety.
- In 1987 the Brundtland Report was issued under the stirring title "Our Common Future".

*In the nineties the keyword will be **sustainable development**, defined as development that meets the needs of the present without compromising the ability of future generations to meet their own needs (Our Common Future, 1987, page 43).*

For us, coastal engineers, this mission was nicely framed by His Royal Highness by calling on us to act as prudent guardians of the precious and vulnerable coastal zone.

Our framework of thinking has been shaken up:

- Our **time dimension** changed from short term to long term
- Our **space dimension** went beyond that of the locality into the global sphere
- The **extended responsibility** forces us to integrate our own expertise in the multidisciplinary system of which our project is part
- The **knowledge base** seems to set the limitations on this "liberation" of mind.

It is interesting how much this - somewhat abstracted - picture fits activities in coastal engineering. It is a fact that the coastal zone, including the deltas, is the most intensively used area of our planet, providing many vital functions for our society. It is expected that in 2000 about 80% of mankind is living in this area. With this in mind sea level rise is more catastrophic than at first sight. It will be a real global threat. And we might add to this that the following hypothesis considerably contributes to the importance of the coastal zone:

When climate change develops, most likely the coastal zones are less affected than the central areas of the continents and act as a basis for continuity. This poses a great value on the coastal zones and the coastal zone resources derived from it - on land and water. This throws a new light on coastal zone development in view of taking note of scale of time, extended responsibility and knowledge base.

Here the keyword **sustainable development** is particularly on its place; seen in the light of both physical and ecological processes.

In the context of thinking given above, we have to try to find ourselves back as the individual, or the alliance of individuals, that is held responsible for his produce.

The reality is that we, as scientists, researchers and engineers in coastal engineering have - because of our specialization - a specific task that demands priority. At the same time we have to acknowledge that our produce is part of a system in which it has to function - in coastal engineering for decades or centuries - and has to match the environment at large.

To indicate an individual position we might use the STEM diagram (Figure 5).

Some 15 years ago MIT applied this kind of approach for the different kind of engineers they wanted to deliver. Also, for continuing education it is helpful. But above all we might check our own place in the diagram and that of the counterparts with whom we communicate. Science, technology, engineering and management are related to their orientations, which are subject, product and control orientation. The shaded areas show the main position of the respective actions. In a career a person might even cross the complete matrix along the diagonal.

orientation action	subject orientated	product orientated	control orientated
science (knowledge)			
technology (tools)			
engineering (workplan)			
management (master plan)			

Figure 5 STEM diagram

Knowledge generation is very essential as the knowledge base is determinative for the quality of decisions. This does not mean that created knowledge automatically is implemented. Communication along the diagonal to adjust to application is required.

This brings me back to congresses where, as I said some minutes ago, a capital of brains is united. Communication is the major agent for effectiveness. A congress with only scientists and researchers asks for presentations directed towards what I call: **horizontal exchange** - one is speaking essentially the same language, but there may be use of different jargon, considering the various disciplines (we stay within the top left boxes).

A congress where scientists want to communicate with managers, c.g. decision makers, asks for a different type of presentations directed towards what I call: **vertical exchange** - application oriented and users friendly language (we go from top left to bottom right). Awareness for this aspect is important for congress organizers and participants, and would facilitate to conclude congresses with pertinent conclusions and recommendations. This is as you know my great wish.

The above might also lead to a review of what is going on in the related congress world. The ICCE, the IAHR (International Association for Hydraulic Research), the PIANC (Permanent International Association of Navigation Congresses), the COPEDEC (Int. Conference on Coastal and Port Engineering in Developing Countries), the ECOR (Engineering Committee on Oceanic Resources) and SCOR (Scientific Committee on Oceanic Research), all have their own identity but they definitely show overlap too.

When I am going to summarize I like to do that with another example, that of integrated coastal zone policy.

You will appreciate that from the "solo"-conception from a century ago we have entered the era of the "long-term thinking in interrelations" - conception. We are looking at the system at large with its physical, ecological, social, economic, and political components.

You could visualize the structure by considering a successive support system (Figure 6). The physical foundation supports the ecological system that provides living conditions for the social system - nature, habitat and food. The social system creates the cultural values. The economic system secures the distribution of resources and the political system provides the forum for decisions.

For an integrated coastal zone policy the coastal engineering fits in at the physical basis of the system at large and its knowledge base is fundamental for the result a coastal zone policy can produce.

Integrated coastal zone resources management has got intensive attention in the Netherlands and progressed into a scientifically based action thanks to the joint effort of the Public Works Department, Delft Hydraulics and the International Federation of Institutes for Advanced Study - IFIAS. Through the channels of IFIAS and Delft Hydraulics the principles could be and are disseminated to various places in the world.

In the Netherlands the politician Ronald Waterman has presented proposals for integrated projects along the Dutch coast, extending into the sea and serving various functions. For instance a considerable extension of the coastal area between Hook of Holland and Scheveningen has been proposed by him (Figure 7). By considering all functions, including "nature", that are performed in society he adapts the extended area to the relevant functions of the area by optimizing them in relation to the existing coastal zone. He eventually ends up with an economically feasible project.

Of interest to the coastal engineers is that the extended coastal area would maintain itself at long term, predominantly by natural morphological processes. Hence Waterman's expressive catchword: Building with nature. For smaller projects intelligent use of the forces and materials of nature has proved profitable. In the large scale projects, however, the long term prediction of the topography due to currents, waves, wind and vegetation is a real challenge for the coastal engineering profession. The Kansai international airport and the Aeropolis coastal development project in Osaka Prefecture is another product of an integrated coastal policy.

Figure 6 Successive support system as base for integrated coastal zone policy

For this type of multi-functional coastal extensions we are discussing here, the advice given by the coastal engineers are determinative for the economics of the project. *The responsibility going together with the advice is extremely large, as such an advice should incorporate long term considerations, such as sustainable development, sensitivity to climate change and sea level rise. Large size projects of this kind tend to "technology venturing" where the risk-taking has to be defined beforehand. They are, in particular, apt for a probabilistic approach.*

Figure 7 Plan for integrated coastal zone development by Ronald Waterman

Research projects such as the **Coastal Genesis Project** are a fundamental need for long-term extrapolations. You will certainly hear about it this week.

And let me also mention here with much joy the **Marine Science & Technology Programme** of the European Commission. This MAST programme shortly starts its first phase with a budget of 50 M\$, whereof about 10 M\$ is allocated for the coastal engineering component.

The importance of the coastal zone for the -rapidly increasing- world population is evident and it is crucial to safeguard its optimum outturn at long-term through sound coastal zone management. *As coastal engineering is absolutely determinative for sound management*

the coastal engineers might internationally intensify the coordination of education, research and transfer in the domain of coastal engineering. There is a need for creating worldwide awareness and giving directives. The ingredients are there! You only have to unite them. The coastal engineers should be the promoters, they are the people having the ability to control the physical system and bring into effect sustainable development, including terrestrial and water quality aspects.

Overlooking the position of the coastal engineer, including his colleagues in science and research, *I conclude that for the coastal engineer thinking in large time and space scales is a necessity. Extending his knowledge base is fundamental in view of the determinative role coastal engineering plays and increasingly has to play. Exercising a fair deal of extended responsibility will be needed to assure that the coastal engineer is a good, and above all, wanted partner in integrated coastal zone management.*

Let me close my lecture with this little story:
Ten years ago I had a serious discussion with the Public Works Department to finance research projects to deepen the understanding of the processes in and along the North Sea. They told me that for their policy decisions the available knowledge base was sufficient. I asked them whether they would be able to do their job with the knowledge of ten years ago. The answer was no. I am convinced that also today the answer is no when we refer to 1980 and ten years from now, in 2000, the answer will be no again referring to 1990. And that gives the meaning to this conference where we check the state-of-the-art and try to find the deficiencies to get them compensated - to ensure progress.

I wish you a fruitful Conference.

PART I

Characteristics of Coastal Waves and Currents

CHAPTER 1

Distribution Function Fitting for Storm Wave Data

Yoshimi Goda¹ and Koji Kobune²

Abstract

New objective criteria are established for rejecting unfitting distribution functions to a sample of extreme wave data. Another criterion is also introduced to select the best fitting function among the eligible ones. Application of these criteria to storm wave data around Japan indicates a possibility of identifying the parent distributions for the regional population of storm wave data.

Introduction

Selection of design wave height is generally made on the basis of storm wave data fitting to some model distribution function. Methodology of distribution fitting has been discussed by many people including Goda [1988], and various techniques are used in design processes. However, selection of the distribution function for a given set of wave data among several candidates is still left to subjective judgment of a wave analyst or design engineer. Although the correlation coefficient between the extremal wave height and its reduced variate provides a measure of the degree of fitting, there is no guarantee that the best fitting distribution represents the true distribution of storm waves. The bootstrap technique as applied for storm wave data by Rossouw [1988] and Andrew and Hemsley [1990] provides an alternative means for distribution function selection, but it is not effective enough for distinguishing the true distribution from other candidate functions.

The first step to find the true distribution is to establish sound criteria by which inappropriate candidate functions can be rejected from distribution fitting to a given set of wave data. Application of such rejection criteria to a number

¹ Prof., Yokohama National Univ., Dept. Civil Engg., Hodogaya-Ku, Yokohama 240, Japan, M. ASCE.

² Dr. Eng., Chief, Marine Obs. Lab., Marine Hydrodyn. Div., Port and Harbour Res. Inst., Nagase, Yokosuka 239, Japan.

of storm wave data sets within a particular region would yield an indication of the parent distribution pertinent to that region. The present paper describes the derivation of such rejection criteria based on the Monte Carlo simulation as well as a best-fitting criterion for the case of the least square method application. Examination of storm wave data around Japan with the newly derived rejection criteria indicates existence of regional parent distributions as discussed in the last part of this paper.

Candidate Distribution Functions and Plotting Position Formulas

The distribution functions examined herein are the Fisher-Tippett type I and II (hereafter denoted as FT-I and FT-II) and the Weibull distribution of the following form:

$$\text{FT-I : } F(x) = \exp\{-\exp[-(x - B)/A]\} \quad (1)$$

$$\begin{aligned} \text{FT-II : } F(x) &= \exp\{-[1 + (x - B)/kA]^{-k}\} \\ &: k = 2.5, 3.33, 5.0, \text{ and } 10.0 \quad (2) \end{aligned}$$

$$\begin{aligned} \text{Weibull : } F(x) &= 1 - \exp\{-[(x - B)/A]^k\} \\ &: k = 0.75, 1.0, 1.4, \text{ and } 2.0 \quad (3) \end{aligned}$$

where $F(x)$ denotes the distribution function of extreme data x , and A , B , and k are the scale, location, and shape parameters, respectively. The fixing of the shape parameter k of the Weibull distribution at the four values above is due to Goda [1988]. The functional form of the FT-II distribution is so selected to make it asymptotically approach to FT-I as $k \rightarrow \infty$. It is essentially same as the generalized extremal distribution by Jenkinson [1955]. The shape parameter k for FT-II is so set that $1/k$ would linearly increase from 0.1 to 0.4. In addition to the above distributions, the two-parameter log-normal distribution is also examined.

The present paper employs the least square method for parameter estimation for a sample of storm wave data, because of its simple algorithms, adaptability to censored data, and well-established information on confidence intervals of return wave heights based on a Monte Carlo simulation study (Goda 1988). The choice of the plotting position then becomes crucial to yield unbiased estimates of return wave heights. The unbiased plotting position formulas for the FT-I, Weibull, and log-normal distributions have been recommended by Goda [1988]. Another Monte Carlo simulation was carried out by Goda and Onozawa [1990] for the FT-II distribution with the sample size ranging from 10 to 200. For each condition, 10,000 samples were simulated and analyzed. Based on this simulation, the following plotting position formula has been derived:

$$\widehat{F}_m = 1 - \frac{m - 0.11 - 0.52/k}{N_T + 0.12 - 0.11/k} \quad (4)$$

where \widehat{F}_m is an estimate of the non-exceedance probability for the m -th largest variate, and N_T denotes the total number of storm wave events occurring during the period of data analysis.

The extremal analysis of storm wave data is usually made for the peak values of individual storms which exceed a certain threshold value. The number of storm wave data thus collected, N , is less than N_T . The ratio of N to N_T is called the censoring parameter (Goda 1988) and denoted by ν .

Equation (4) becomes same as the Gringorten formula for the FT-I distribution as $k \rightarrow \infty$. According to the simulation study with the above plotting position formula, the mean value of return wave height (averaged over 10,000 samples) estimated at the return period 10 times the sample duration showed a difference of $-2.7\% \sim +0.3\%$ from the true value, depending on the sample size and shape parameter. For the shape parameter $k = 5$ and 10, the difference was $-0.6\% \sim +0.3\%$.

Confidence Interval of FT-II Distribution

Another simulation study was carried out to examine the sample variation of the return value of the FT-II distribution. Two sets of 10,000 sample runs were analyzed and their results were averaged. An empirical formula for the standard deviation of the estimated return value \widehat{x}_R at the return period R has been given as (Goda and Onozawa 1990)

$$\sigma(\widehat{x}_R) = [1 + a(y_R - c + \alpha \ln \nu)^2]^{1/2} \sigma_x / N^{1/2} \quad (5)$$

where ν is the censoring parameter defined as N/N_T , σ_x is the unbiased standard deviation of sample data, a , c , and α are empirical coefficients given by Eq.(6) and Table 1, and y_R is the reduced variate for the return period R expressed by Eq.(7) below:

$$a = a_1 \exp\{a_2[\ln(N \nu^{0.5}/N_0)]^2 - \kappa [\ln(\nu/\nu_0)]^2\} \quad (6)$$

$$y_R = k \{-\ln[1 - 1/(\lambda R)]\}^{-1/k} - 1 \quad (7)$$

in which λ denotes the mean rate, or the average number of storm events per year.

The senior author (Goda 1988) proposed empirical formulas for the correction of possible bias in the estimate of return wave height when the true distribution is unknown. He also presented other formulas to estimate standard errors under the

Table 1 Empirical Coefficients for The Standard Deviation of The FT-II Return Value

Shape Par.	a_1	a_2	N_0	κ	ν_0	c	α
$k = 2.5$	1.27	0.12	23	0.24	1.34	0.3	2.3
$k = 3.33$	1.23	0.09	25	0.36	0.66	0.2	1.9
$k = 5.0$	1.34	0.07	35	0.41	0.45	0.1	1.6
$k = 10.0$	1.48	0.06	60	0.47	0.34	0	1.4

same situation. In the present paper no proposal is made however, because it is hoped that the use of new rejection criteria to be discussed below will diminish the possibility of choosing a distribution other than the true one.

Rejection Criterion Based on Outlier (DOL Criterion)

Another series of Monte Carlo simulations were carried out to explore the possibilities of establishing new criteria for distribution fitting. The sample size was from 10 to 400, the censoring parameter was set at 0.25, 0.50, and 1.0, and 10,000 sets of simulated data were produced and analyzed for each combination of the distribution function, sample size, and censoring parameter.

In the extremal analysis of wave data, presence of an outlier or an abnormally large data often causes a trouble for analysts in data interpretation and distribution fitting. However, the outlier can provide a good measure of sample deviation from its population. Let x_1 be the value of largest data among a sample. Then its magnitude is measured with the following dimensionless deviation ξ :

$$\xi = (x_1 - \bar{x})/s \quad (8)$$

where \bar{x} and s are the mean and the standard deviation of sample data.

In the statistical test of the normality of a sample, Thompson's test is sometimes used against its mean value in comparison with the overall means of many samples. By dividing the data set into a sample composed of the largest data only and that of remaining data, Thompson's test can be applied to the dimensionless deviation ξ . Then, the ξ value having the non-exceedance probability P is approximately given by

$$\xi_P = \left[\frac{(N-1)F(1, N-2; \alpha)}{N-2 + F(1, N-2; \alpha)} \right]^{1/2} \quad (9)$$

where $F(1, N-2; \alpha)$ denotes the F distribution with the $(1, N-2)$ degrees of freedom at the exceedance probability α . For the largest data x_1 in a sample with the size N , α is given as $2(1-P^{1/N})$.

Analysis of simulated samples from the Normal distribution has yielded the cumulative distribution of ξ as shown in Fig. 1. Simulated data are in agreement with the theory by Eq.(9) except for the range of low ξ value. Difference is

Fig.1 Cumulative distribution of ξ value.

Fig.2 Examples of $\xi_{5\%}$ value.

Fig.3 Examples of $\xi_{95\%}$ value.

attributed to the fact that use of Thompson's test for a single sample with the constraint of the largest data among the whole sample is beyond its range of applicability. Thus, the simulation data rather than theory were used in the following analysis of cumulative distribution of ξ value.

If the ξ value of a sample occupies a location at either the upper or lower tail of the cumulative ξ -curve of the distribution function being tested for fitting, the chance that the sample belongs to that population is slim and the fitting of that distribution could be rejected. The 5% and 95% cumulative ξ values were tentatively chosen as the threshold values for rejection. These threshold values were obtained from the simulation data for various sample sizes. Figures 2 and 3 shows examples of such ξ values for the case of uncensored samples. These results were formulated into the following expression:

$$\xi_{5\%}, \xi_{95\%} = a + b \ln N + c (\ln N)^2 \quad (10)$$

The coefficients a , b , and c have been expressed as the functions of the censoring parameter ν for each distribution function as listed in Tables 2 and 3. The difference between the estimates of $\xi_{5\%}$ and $\xi_{95\%}$ by Eq. (10) and the simulation data was less than 2%.

Fitting of a distribution function to a given sample could be rejected, if the ξ value of the sample is either greater than the $\xi_{95\%}$ value or less than the $\xi_{5\%}$ value of that distribution. This rejection criterion is hereby called the DOL (Deviation of OutLier) criterion. Note that the DOL criterion is applicable to any sample regardless of data fitting methods.

Table 2 Empirical Coefficients for The Lower DOL Criterion $\xi_{5\%}$

Distribution	Coefficient a	Coefficient b	Coef. c
FT-II ($k = 2.5$)	$1.481 - 0.126 \nu^{1/4}$	$-0.331 - 0.031 \nu^2$	0.192

Weibull ($k=2.0$)	$-0.322 + 0.641\nu^{1/2}$	$1.414 - 0.326\nu$	-0.069
Log-normal	$0.178 + 0.740\nu$	$1.148 - 0.480\nu^{3/2}$	-0.035

Rejection Criterion Based on Correlation Coefficient (REC Criterion)

Rejection of distribution fitting can also be made by using the absolute value of the correlation coefficient r between the extremal wave height x_m and its reduced variate y_m . Figure 4 shows examples of the cumulative distribution of the residue of r from 1, i.e., $\Delta r = 1 - r$ for the case of the uncensored Weibull distribution with $k = 1.0$. If a sample is fitted to this distribution and the residue of correlation coefficient shows a value located at the upper tail of cumulative curve corresponding to the size of the sample, then the fitting of this distribution to that sample should be rejected. For quantitative analysis, the 95% exceedance value was taken as the threshold value and analyzed from the simulation data. Figure 5 shows examples of the variation of $\Delta r_{95\%}$ with respect to the sample size N . An empirical formulation has been made for $\Delta r_{95\%}$ as

$$\Delta r_{95\%} = \exp[a + b \ln N + c (\ln N)^2] \quad (11)$$

The coefficients a , b , and c are expressed as the functions of censoring parameter for each distribution as listed in Table 4. The difference between the estimates of $\Delta r_{95\%}$ by Eq.(11) and the simulation data was mostly within $\pm 3\%$.

The 95% exceedance value of the residue of correlation coefficient can be utilized as a reference for the rejection of distribution fitting. This is hereby called the REC (Residue of Correlation coefficient) criterion. This rejection criterion is introduced primarily for the case of parameter esti-

mation by the least square method, but it can also be applied to the case of other distribution fitting method after the parameters have been estimated.

Best Fitting Criterion Based on Correlation Coefficient (MIR Criterion)

After rejection of unfitting distribution functions, there arises the question of choosing the distribution closest to the true one. However, the parent distribution of the population of storm wave heights is unknown at present. When one

set of extremal wave data at a particular location is analyzed for design purposes, a distribution function which seems best fitting to the sample is chosen as representative of the unknown true distribution. The senior author (Goda 1988) proposed to use the absolute value of the correlation coefficient between the extremal height x_m and its reduced variate y_m as the measure of best fitting: *i. e.*, to choose the distribution exhibiting the largest value of correlation coefficient.

Examination of the nature of the correlation coefficient, however, has indicated the fact that its mean value varies from one distribution to another. Figure 6 shows examples of the mean residual values of correlation coefficient Δr_{mean} of various distribution functions against the sample size N . The distribution with a long tail such as the Weibull with $k = 0.75$ yields a relatively low value or a large residual value of the correlation coefficient. It is therefore not fair to compare the degree of fitting of various distributions to a sample by means of the absolute value of correlation coefficient alone.

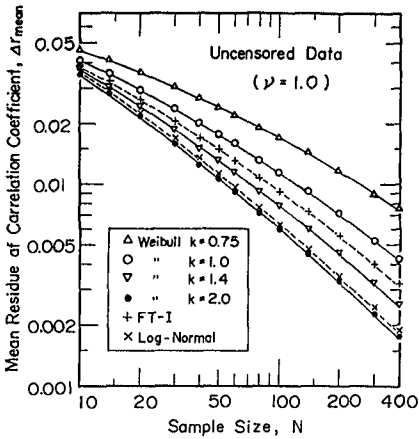

Fig. 6 Examples of Δr_{mean} versus N .

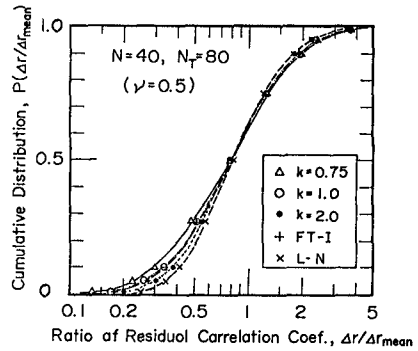

Fig. 7 Cumulative distribution of $\Delta r/\Delta r_{mean}$.

Differences in the absolute magnitudes of Δr among various distributions become insignificant, however, when their ratio to the respective mean values are compared. Figure 7 gives such an example, showing the cumulative distribution of $\Delta r/\Delta r_{mean}$ for the case of censored data with the sample size $N = 40$. Thus it is hereby proposed to employ the ratio $\Delta r/\Delta r_{mean}$ as the measure of best fitting and adopt the distribution which shows the minimum value of this ratio. This is called the MIR (Minimum Ratio of residual correlation coefficient) criterion for best fitting. It will be found in actual data analysis however that the MIR criterion is satisfied by most of distributions which show the largest correlation coefficient among various candidate functions.

The MIR criterion requires the formulation of Δr_{mean} for various distribution functions, sample sizes and the value of censoring parameter. An empirical expression same as Eq.(11) has been applied to the simulation data, *i.e.*,

$$\Delta r_{mean} = \exp[a + b \ln N + c (\ln N)^2] \quad (12)$$

and the coefficients a , b , and c have been formulated as listed in Table 5. The difference between the estimate of Δr_{mean} by Eq.(12) and the simulation data was mostly within $\pm 3\%$.

Table 5 Empirical Coefficients for Δr_{mean} in The MIR Criterion

Application of New Criteria to Wave Data around Japan

Japanese islands have various wave climates along their coasts owing to their topography. As seen in Fig. 8, one side of the long stretched islands faces the Sea of Japan, the other side faces the Pacific, and the southwestern side is in the East China Sea. Waves in the Sea of Japan are fetch-limited wind waves, while waves from the Pacific are typhoon-generated seas and swell. Several dozens of nearshore wave stations at the depth 20 to 50 m have been operating with cable-connected acoustic wave recorders. Every 2 hours these wave sensors register surface wave records for 20 minutes. Most of the wave data which are under control of the Ministry of Transport are collected at the Port and Harbour Research Institute, analyzed and filed in a database. From this archives of wave records, extremal data of storm waves up to 1984 were selected and analyzed. (Further analysis with addition of recent data will be made in near future.)

REMARKS:

- Column (1) : Effective duration of observation in years.
 (2) : Number of storm wave events above a threshold value.
 (3) : Censoring parameter ($=N/N_T$).
 (4) : ξ value of storm wave data.

Distribution Functions :

- I = FT-II ($k = 2.5$), VI = Weibull ($k = 0.75$),
 II = FT-II ($k = 3.3$), VII = Weibull ($k = 1.0$),
 III = FT-II ($k = 5.0$), VIII = Weibull ($k = 1.4$),
 IV = FT-II ($k = 10.0$), IX = Weibull ($k = 2.0$).
 V = FT-I,

Distribution Fitting :

- = Fitting acceptable,
 △ = Rejected by the upper DOL but not by the REC criteria,
 ▲ = Rejected by both the upper DOL and the REC criteria,
 ▼ = Rejected by the lower DOL but not by the REC criteria,
 ▼ = Rejected by both the lower DOL and the REC criteria,
 × = Rejected by the REC but not by DOL criteria.

Table 6 lists the location names of wave stations, the effective durations of wave observations in years excluding the periods of downtime, the number of storm wave data analyzed, and so on. The locations of these stations are shown in Fig. 8 with the alphabet. The average number of storm wave events at these stations was about 50 to 60 per year, and the threshold wave height for censoring varied from station to station; thus the censoring parameter ranged from 0.18 to 0.78. In total, wave data at 29 stations were analyzed, and the duration of wave observation ranged from 3.0 to 13.9 years.

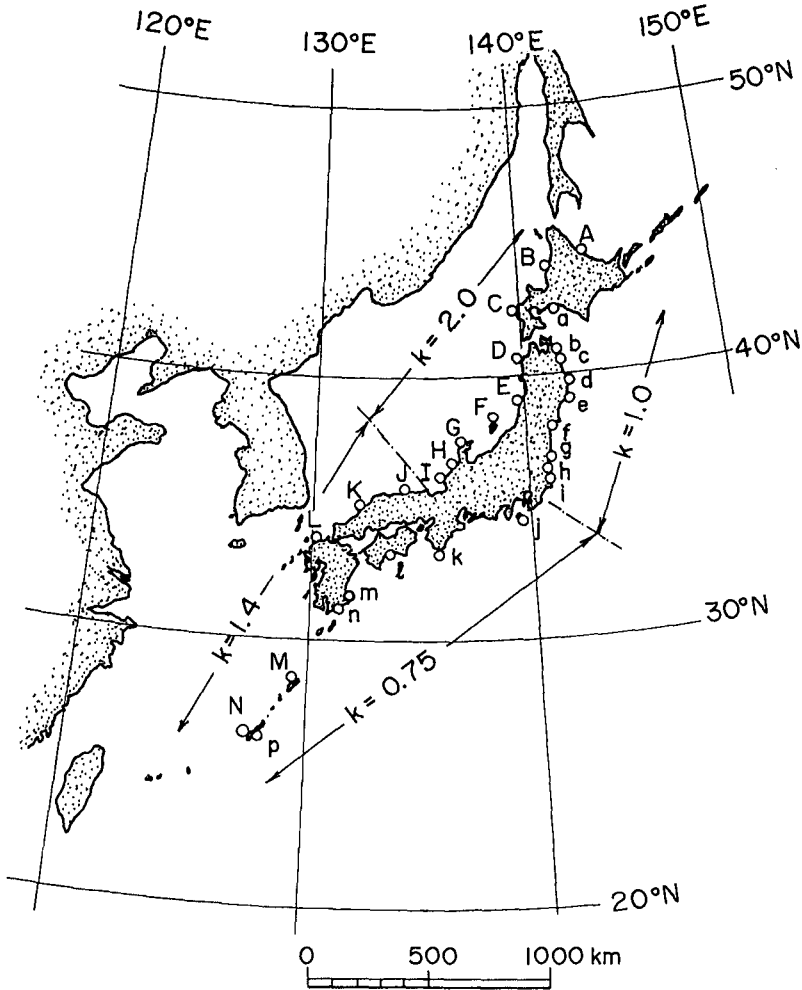

Fig. 8 Location map of wave stations used in the analysis.

The dimensionless deviation ξ of the largest data at each station is listed in the column (4) of Table 6, and the rejection test of the distribution functions of Eqs.(1) to (3) has been made with this ξ value and the residue of correlation coefficient Δr . The result of rejection test is marked with various symbols for each distribution. The upper DOL criterion is applied when the sample ξ value exceeds the $\xi_{95\%}$ value of the distribution being fitted, while the lower DOL criterion is for the case of $\xi < \xi_{5\%}$. The marks except for the open circle indicate that the distribution fitting should be rejected with the probability of misjudgment being less than 5%. In other words, one sample out of 20 samples would be rejected even if all the 20 samples are drawn from the same population.

Although the rejection test for the storm wave data of individual stations yields versatile answers, the results point out the presence of a characteristic distribution which is unrejectable in a group of stations located in the same region. For example, the stations 'A' to 'I' along the Sea of Okhotsk and the upper part of Japan Sea seems to support the Weibull distribution with $k = 2.0$ as the common distribution. For the stations 'J' to 'N', the Weibull with $k = 1.4$ seems more appropriate, probably because of occasional high waves generated by typhoons. In the region covering the stations from 'a' to 'i', the Weibull distribution with $k = 1.0$ has the least frequency of rejection. This area is exposed to swell from typhoons, but direct attack of typhoon waves is infrequent. The region for the station 'j' to 'p' where typhoon-generated waves dominate extreme wave climate seems to accept three distributions of the Weibull with $k = 0.75$ and the FT-II with $k = 5.0$ and 10.0 as the candidates for the population distributions.

The analysis of Table 6 will require further examination with additional data after 1985, especially from the viewpoint of the data homogeneity. Analysis of seasonal or monthly extremal wave data will be the easiest way to separate storm waves generated by different types of meteorological disturbances. Nevertheless, the result of Table 6 indicates the possibility of identifying the parent distribution for the regional population of storm wave data by filtering out various candidate functions with the new rejection criteria.

Concluding Remarks

Choosing a distribution function for a sample of extremal data sample is always a troublesome task, because no steadfast guidelines exist. It will be very difficult and almost impossible to establish such guidelines for affirmative recommendation. The present paper is intended to enable to issue negative recommendations for distribution fitting by establishing

objective rejection criteria for extreme statistics. Two empirical criteria introduced herein well function in identifying possible regional population distributions of storm waves around Japan.

A question often asked is the minimum size of extremal sample at which an analyst can answer with confidence which one of candidate distributions is the true distribution of the population for that sample. An answer can be obtained by examining the sample size at which the lower DOL criterion $\xi_{5\%}$ of a longer-tailed distribution becomes equal to or greater than the upper DOL criterion $\xi_{95\%}$ of a shorter-tailed distribution. Beyond that sample size, the two distributions could be safely discerned. However, this sample size turns out to be quite large. For example, the FT-I and FT-II with $k = 3.3$ are only discernible at the sample size greater than 900 for an uncensored sample and greater than 1900 for a censored sample with $\nu = 0.25$. The FT-I and the Weibull with $k = 1.4$ are very difficult to distinguish each other by means of the DOL criterion alone.

In the extremal analysis of storm wave data, emphasis should be placed on the effort of collecting as many data as possible over a period as long as feasible, so that the danger of choosing a distribution not belonging to the population will be minimized and the range of confidence interval of the return wave height will be lowered.

CHAPTER 2

A MODEL FOR SURF BEAT

P.J. van Leeuwen¹ and J.A. Battjes¹

Abstract

A model is presented for the generation of low-frequency waves propagating normal to the beach. The input parameters are the bottom profile and the variance spectrum of the incoming wind waves. The model predicts the variance spectrum of the low-frequency waves. Also correlations between e.g. wind wave envelope and low-frequency surface elevation can be calculated. Results of the model are compared to field data.

1 Introduction

When wind waves approach mildly sloping beaches, a significant amount of energy can be found at frequencies an order of magnitude lower than those of the incoming wind waves. Part of this low-frequency energy can be ascribed to edge waves, whose phase variation is alongshore. An important part however can be assigned to two-dimensional shorenormal waves, which are here called surf beat.

The first observations of surf beat were made 40 years ago by Munk (1949). He found a linear relation between the amplitudes of the low-frequency waves and those of the wind waves. Looking at the time records of both types of waves he found that the low-frequency waves lagged behind the wind wave envelope with about 140 seconds, which he attributed to the time needed for the wind wave envelope to travel to the surf zone and for the low-frequency waves to travel back to the wave recorder. Tucker (1950) reported the same kind of measurements, but he used correlograms to analyze his data. He also found that the low-frequency waves are lagging behind the wind wave envelope, and that the largest absolute value of the correlation coefficient occurs when this coefficient is negative. This means that the wind wave envelope and the low-frequency waves are 180 degrees out of phase, apart from travel considerations.

Biésel (1952) proved theoretically that groups of short waves are accompanied by nonlinear long waves, bound to these groups. Longuet-Higgins and Stewart (1964) clarified this theoretical result with the concept of radiation stress. Due to this nonlinear effect, water is pushed away from areas with high waves and accumulated

¹ Delft tech. Univ., Dept. of Civil Engineering, Delft, The Netherlands.

under low waves. This results in long waves, bound to the wind wave groups. An important feature is that the bound long waves are 180 degrees out of phase with the wind wave envelope. A way to explain the observations by Munk (1949) and Tucker (1950) qualitatively is to suppose that the bound long waves are reflected in the surf zone, and propagate seaward as free long waves. Since the paper pays no attention to the mechanism of reflection, it is difficult to compare the theoretical results with experiments.

Quantitative models were lacking until 1981. The relatively simple case of bichromatic wind waves is here addressed first. Lo (1981) presented a bichromatic model which calculates in the time domain and in which he could explain the linear relation between the low-frequency wave amplitude and the wind wave envelope height by taking the generation of low-frequency waves due to the breaking of the regular wave groups into account. He found that the surf zone region was very important for low-frequency wave generation, and that the smaller the beach slope, the higher the surf beat wave heights. The reason for this is that more time is available for the energy transfer from the wave groups to the low-frequency waves. Lo (1981) did not mention how the forcing of the low-frequency waves due to wave breaking was modelled.

Symonds et al. (1982) investigated the forcing of low-frequency waves by the time variation of the location of the break point. This variation gives rise to a time-varying set up and hence produces low-frequency waves. The analysis was performed for bichromatic short waves with periodic wave groups. The difference between this model and that of Lo (1981) is that the calculations are done in the frequency domain and that the bound long waves are ignored. Kostense (1984) verified this model in a wave flume and found good qualitative agreement.

Schäffer and Svendsen (1988) presented a spectral bichromatic model in which they allow for wave height modulations after the waves are broken by taking a fixed (in space) break point. The model uses both the bound long waves and the long wave generation due to wave breaking, but because of the wave modulations inside the breakpoint bound long waves are generated in this region too. In a later paper by Schäffer and Jonsson (1990) the model is compared with the Kostense (1984) data. An overestimation of the outgoing low-frequency wave amplitude was attributed to bottom friction, which is not included in the model. This is the only model which allows for wave height modulations inside the surfzone and the consequent generation of low-frequency waves in this region.

The calculation of surf beat using random wind waves was first addressed by Lo (1981). He uses both types of forcing of low-frequency waves and calculates in the time domain. A comparison of his model with field data by Goda (1975), using a full wind wave spectrum as input, showed the right order of magnitudes for the low-frequency spectral components.

List (1990) also proposed a model for random wind waves in which both generating mechanisms are present and in which the calculations are done in the time domain. The model uses as input measured wind wave envelope time series, from which low-frequency wave time series are calculated. A comparison with field data showed results for the low-frequency wave energy levels which are 5 to 50% off, and good qualitative results for the correlation between wind wave envelope and low-frequency surface elevation.

The present paper also deals with low-frequency wave generation by random wind waves. The main difference with the models of Lo (1981) and List (1990) is that the calculations are here performed in the frequency domain. The input of the model is the energy spectrum of the wind waves, the idea being that the low-frequency energy spectrum is not dependent on one specific realisation of the process described by the energy spectrum of the wind waves.

In the present paper the theoretical model is developed first. Then a few remarks are made about the collection and the processing of the field data, used for comparison with model results. The next section deals with the comparison and a discussion of the results. Some concluding remarks close the paper.

2 The model

The basic philosophy behind the model is to combine the ideas of Longuet-Higgins and Stewart (1962) and Symonds e.a. (1982), and to extend them to the case of wind waves with a continuous spectrum. A spectral approach will be followed, because usually input information is in that form, and not in the form of time series. The basic equations are the linearized shallow water equations. After elimination of the velocity a second order partial differential equation results for the low-frequency surface elevation (see e.g. Symonds e.a. 1982):

$$\frac{1}{g} \zeta_{tt} - h_x \zeta_x - h \zeta_{xx} = -\frac{1}{g\rho} S_{xx} \quad (1)$$

in which ζ is the low-frequency surface elevation, h the mean water depth, ρ the water mass density, g the acceleration of gravity and S the radiation stress. The subscripts denote partial differentiation. The driving term for the low-frequency waves is the second space derivative of the radiation stress. Because the wind waves have a continuous spectrum the radiation stress is randomly varying.

The idea is now to expand the variables in a Fourier-Stieltjes (FS) integral according to

$$\alpha = \int_0^{\infty} e^{i\omega t} dA$$

in which dA is a random increment function for an interval $d\omega$. It can be seen as the complex amplitude of the waves in a frequency interval $d\omega$ and is related to the variance spectrum $G_{\alpha\alpha}$ of α by

$$G_{\alpha\alpha} d\omega = \frac{1}{2} \langle dA dA^* \rangle \quad (2)$$

where $\langle \dots \rangle$ indicates ensemble averaging, and the asterisk denotes the complex conjugate.

For the FS transformed long wave equation one now finds

$$\frac{\omega^2}{g} dZ(x, \omega) + h_x dZ_x(x, \omega) + h dZ_{xx}(x, \omega) = -d\phi_{xx}(x, \omega) \quad (3)$$

in which dZ is the FS transform of the low-frequency surface elevation ζ , and $d\phi$ the FS transform of the forcing. First note that equation (3) is a second order ordinary differential equation, which is much easier to solve than its partial counterpart. For instance in the case of a plane sloping bottom, the solution of (3) is found as a combination of integrals over Bessel functions of first and second kind.

The calculation of the forcing term in equation (3) needs extra attention. Because it is a complex quantity its absolute value as well as its phase has to be calculated.

The phase will be space and frequency dependent. The frequency dependence of the phase cannot be determined because only the wind wave variance spectrum is given. However, we want to calculate the variance spectrum of the low-frequency waves so this frequency dependence is of no importance. The space dependence of the phase of the forcing will be important. The forcing will have a phase shift along the spatial coordinate due to the fact that the forcing is related to the wind wave envelope squared via the radiation stress. Because it takes the wind wave envelope some time to pass through the surf zone, a certain distance Δx corresponds to a phase shift $\Delta\psi$ in the forcing. A way to calculate this phase shift is to assume that the wind wave envelope travels with group velocity C_g of the peak frequency. The phase shift due to the finite travel time of the wind wave envelope now becomes

$$\Delta\psi(x - x_0) = \arg\{d\phi(x, \omega)\} = \int_{x_0}^x \frac{\omega}{C_g} dx \quad (4)$$

The absolute value of the forcing term in equation (3) will be calculated from the variance spectrum of the forcing which in turn will be determined from the variance spectrum of the wind waves. As mentioned above, the forcing term is proportional to the second space derivative of the radiation stress, which in turn is proportional to the wave envelope R squared. Consequently, the variance spectrum of the envelope squared has to be determined to obtain the variance spectrum of the forcing. A way to calculate the variance spectrum of the wind wave envelope squared is to start from the covariance of two squared envelopes:

$$C[R^2(t), R^2(t + \tau)] = E[R^2(t)R^2(t + \tau)] - E^2[R^2(t)] \quad (5)$$

in which $C \dots$ is the covariance, and $E \dots$ is the expected value operator. The Fourier transformation of the covariance gives the required variance spectrum.

The expected values in equation (5) can be found from the joint probability density $p(R_1, R_2)$ of two envelopes at a time lag τ . For a narrow-band Gaussian process, this probability density has been derived by Rice (1944, 1945). It has since been called the 2-D Rayleigh distribution. This density has been used successfully by Kimura (1980) in his description of wave groups. In the case of breaking waves

the probability density $p(R_1, R_2)$ has to be modified because the wave height is limited to a critical value, mainly determined by the local depth. A truncated 1-D Rayleigh distribution developed and used successfully by Battjes and Jansen (1978) to determine the mean energy dissipation in breaking waves is adopted here, extended in a straightforward manner to the two-dimensional case.

Now that the variance spectrum of the forcing has been found in which both breaking and nonbreaking waves are incorporated, the variance spectrum of the low-frequency waves can be obtained by solving the ordinary differential equation (3) and using (2).

The method outlined above also gives one the opportunity to calculate correlation coefficients, for instance for the correlation between low-frequency surface elevation and wind wave envelope. At first sight this may seem impossible because the frequency dependence of the phases of the spectral components of e.g. low-frequency surface elevation is not known. To solve this problem it is noted that only the phase difference between the FS transform of the low-frequency surface elevation and the FS transform of the wind wave envelope at each frequency has to be known, not the phase difference between different spectral components. The required phase differences at each frequency follow directly from differential equation (3).

3 Data collection and processing

The data used are from a field experiment conducted at the U.S. Army Corps of Engineers Field Research facility in Duck, North Carolina, U.S.A., on September 9, 1500 EST 1985. The beach was approximately two-dimensional. A cross-shore array of eight pressure sensors and bi-axial horizontal current meters provided time series with a sample rate of 2 Hz. Figure 1 shows the bottom profile with the positions of the sensors. The pressure sensors were of the diaphragm type and the current meters were Marsh McBirney electromagnetic meters.

The data describe swell with highly grouped waves and a narrow spectral peak near 0.08 Hz. The root mean square wave height was 0.4 m. This data set was chosen because of the profound group structures present during the measurements and the nearly shorenormal incidence.

The low-frequency wave band is defined as $0.007\text{Hz} < f < 0.03\text{Hz}$, because outside this region the waves were found to be uncorrelated with the wave groups. Low-frequency standard deviations were calculated from the pressure sensors at each of the sensor locations. The cross-correlation coefficient between wind wave envelope and incoming and outgoing low-frequency waves at a sensor location outside the surfzone ($x=222\text{m}$) was calculated. The wind wave envelope was found by calculating the Hilbert transform of the time series, using an approximate temporal Hilbert filter given by McClellan et al. (1979), with 95 points (Pierce, 1985). The low-frequency waves were obtained by lowpass filtering the time series and separated into incoming and outgoing waves using the method proposed by Guza et al. (1985):

$$\zeta_{\text{in}} = \frac{\xi + \sqrt{\frac{h}{g}}U}{2}, \quad \zeta_{\text{out}} = \frac{\xi - \sqrt{\frac{h}{g}}U}{2} \quad (6)$$

in which ξ is the low-frequency surface elevation and U is the low-frequency orbital velocity defined positive offshore.

As mentioned before, the model needs as input the variance spectrum of the wind waves. This was obtained by a Fourier transform of the time series from the seawardmost sensor.

Figure 1 Bottom profile, arrows indicate sensor locations.

4 Comparison and discussion

To verify the model, both field data and laboratory data will be used. In this paper only field data are used to test the model. The first test uses the standard deviation of the outgoing low-frequency waves $\sigma_{\xi_{out}}$. The second uses the correlation between wind wave envelope and surface elevation of the incoming and outgoing low-frequency waves.

The ratio of breaker height to local depth, γ , is a free parameter in the model. It has been set equal to 0.4. However, a change in γ does not give a strong change in the results presented here.

The reason for the test using the standard deviation of the outgoing low-frequency waves is the following. The outgoing low-frequency waves are a combination of low-frequency waves of three different origins: waves, which were first incoming and bound to the wave groups, and then reflected on the beach to become outgoing; waves which are produced by the time-varying breakpoint mechanism as outgoing waves, and finally waves which are produced by the time-varying breakpoint mechanism as incoming waves, and which then are reflected by the beach to become outgoing. If a model can reproduce the energy level of this complicated mixture within the error margins (5% in this case) without tuning parameters (except maybe γ), the physics in that model can be close to the real physics involved. Of course, more situations have to be used as test cases for the 'can' to be a 'must'.

Figure 2 Standard deviation of surface elevation of outgoing low-frequency waves as function of distance from the water line. (+) data, (-) theory.

In figure 2 the standard deviation of the outgoing low-frequency surface elevation is given as function of the distance from the shore line. The surfzone extends to about 60 m from the water line. The model shows good agreement with the data from six sensors. Unfortunately the two innermost pressure sensors have spurious energy in the low-frequency band, so that the comparison in this region is not conclusive. The reason that some energy must be spurious is that these sensors both show a large peak at a different frequency, with a spectral energy density as high as that of the wind waves, while outside the surfzone these peaks are not observed. In principle it could be possible that some unknown forcing mechanism for low-frequency waves is active inside the surfzone, the waves of which are cancelling each other somehow when they try to leave the surfzone. It is noted however that the beach does not have a certain length scale, like a bar, so this might be unlikely to happen on this beach.

Figure 3a shows the correlation coefficient for the wind wave envelope and the surface elevation of the incoming low-frequency waves. The 95% confidence interval on zero correlation was found to be below 0.09 for the data. A strong negative peak can be observed at zero lag, which must be attributed to the bound low-frequency waves. The fact that the peak from the field data is not that pronounced shows that the bound low-frequency waves are not the only low-frequency waves with a shorenormal particle velocity component. Probably edge waves and shore-oblique leaky mode waves are present.

Figure 3b shows the correlation coefficient for the wind wave envelope and the surface elevation of the outgoing low-frequency waves. Again the 95% confidence interval on zero correlation was found to be below 0.09 for the data. A strong negative peak can be seen in the theoretical curve at a time lag of about 100 s, which is precisely the time needed for the bound long waves to travel to the beach (at the still-water line), reflect from the beach, and travel back as free waves to the pressure sensor again. The data also show a peak at this time lag. The theory additionally shows significant oscillations at smaller and larger time lags. The reason for this is not entirely clear yet. The negative peak at about 62 s time lag may be associated with the outgoing waves produced by the time-varying breakpoint mechanism. This time lag corresponds to the time needed for the wave

envelope to travel to the 'mean' breakpoint and for the generated low-frequency waves to travel back to the sensor. The 'mean' breakpoint is here defined as the point in which the rms wave height is maximum. The data do not show significant correlations at this time lag.

Figure 3 Cross correlations between wind wave envelope and low-frequency surface elevation at $x=222$ m. a) incoming low-frequency waves, b) outgoing low-frequency waves. The thick line represents the data, the thin line represents the theoretical results.

5 Conclusions

A model has been developed for the generation of shorenormal low-frequency waves by random wind waves. The model needs as input the energy spectrum of the wind waves, and calculates in the frequency domain. The results of the model are compared to field data.

The comparison showed that the measured low-frequency standard deviations at a range of distances from the water line are predicted within their error margins. However the innermost pressure sensors are believed to contain spurious low-frequency energy, so the comparison was not conclusive in this region.

The time lag of strongest cross-correlation between wind wave envelope and incoming and outgoing low-frequency waves is predicted correctly, although the magnitude of the correlation coefficient is overestimated. The remaining structure of the theoretical cross-correlation function requires further investigation.

Acknowledgements

The investigations were supported by the Working Group on Meteorology and Physical Oceanography (MFO) with financial aid from the Netherlands Organization for the Advancement of Research (N.W.O.). The U.S. Army Corps of Engineers is thanked for the DUCK85 field data from their Field Research Facility in Duck, North Carolina, U.S.A..

CHAPTER 3

EVALUATION OF EMPIRICAL MODEL FOR WAVE RUNUP ELEVATIONS

Robert J. Hallermeier*, Kevin B. Nosek*,
Christopher J. Andrassy*

Abstract

Predicted runup elevations for given waves and nearshore profile are confirmed as accurate by large tank and field studies with over 400 published measurements, the majority exceeding 1 m above static water level. Predictions are provided by a public-domain computer code incorporating detailed empirical guidance for smooth slopes developed by Stoa (1978). This model examines the geometrical match with specified situations, applies the composite-slope method of Saville (1958) where necessary, treats barrier texture using standard runup-reduction coefficients, and executes suitable interpolation and iteration for a fully consistent runup estimate. With irregular wave action, basic empirical guidance for uniform waves gives the mean runup elevation from the mean wave description. There is definite agreement between predictions and measurements for smooth or rough barriers with uniform waves, for controlled irregular waves, and for field situations.

INTRODUCTION

Runup may define the landward limit to wave effects, defined as a vertical distance above static water level on the shore barrier. Expected runup elevations can be important in forecasts of flooding hazards due to storms and in designs of coastal structures meant to halt wave action. The improved prediction of wave runup has been

Engineers, P.O. Box 2711, Los Angeles, CA 90053-2325

a continuing engineering concern, with progress assisted by data collection programs, analytical approaches, and developments in numerical modeling. This paper describes evaluation of a convenient prediction model implementing long-available guidance with an extremely detailed basis in laboratory runup elevations.

Measurements with breaking waves indicate that runup elevation normalized by wave height is primarily related to the value of the surf similarity parameter (ratio of the barrier slope to the square root of wave steepness). With reflecting waves, peak water elevation at the barrier is more susceptible to theoretical treatment but still has an empirically defined dependence on the type of barrier surface. Within an individual study of certain shore geometries, runup effects for a range of wave action may often be summarized by some relatively simple expression spanning the two regimes of behavior. However, runup exhibits appreciable dependences on detailed wave characteristics such as nonlinearity, and on geometrical particulars such as the seaward extent to the shore barrier and its approach slope. Thus, the most accurate runup guidance consists of empirical curves pertaining to a specific range of situations. Examples include the curve sets provided by Horikawa (1978), the U.S. Navy (1982) *Coastal Protection Design Manual*, and the U.S. Army (1984) *Shore Protection Manual*.

The detailed guidance utilized here is that originally documented by Stoa (1978), where each set of runup curves pertains to a precisely specified two-dimensional geometry at small scale. Ten distinct configurations of smooth shore barrier and approach have been addressed for wide ranges of barrier slope and wave steepness, with mean runup elevation indicated for uniform incident waves described in deep water. A computer code provides automated application of the Stoa guidance to a given situation, for an estimate of runup elevation with a definitive empirical basis.

COMPUTER CODE

In 1979, the Federal Emergency Management Agency contracted Stone & Webster Engineering Corporation to develop a consistent method for determining wave runup elevations associated with extreme storms. Such methodology was required within the National Flood Insurance Program to assess coastal wave hazards additional to stillwater inundation during the 100-year flood. The product was a computer code giving an empirically based estimate of representative runup elevation for a profile of linear segments with specified incident waves (Stone & Webster,

1981). Later tests demonstrated that the original code was liable to provide inaccurate results because of oversimplifications in following the basic guidance given by Stoa (1978). The effort reported here has consisted of an extensive upgrade to the code details, along with verification of computed results using the large data base now available.

Automated implementation of detailed runup guidance meant for manual application informed by engineering judgment has entailed the development of several objective analyses to summarize basic shore geometry. The code is fully documented in a comprehensive report on the present study (Dewberry & Davis, 1990), but Figure 1 shows a flowchart indicating the level of detail in these analyses. Each decision block relates to a separate consideration affecting runup estimation, according to basic guidance given by Stoa (1978). This suite of decision-making has required several quantitative distinctions in characterizing shape, and these choices treated shore geometries in documented runup investigations as typical. Results generally show smooth variations of runup for changed input, but the automatic analyses are not foolproof; runup estimates will be most appropriate if engineering judgment is applied in idealizing the actual profile, by taking into account the code's operations.

Initial analysis within the code effects a separation of the specified profile into a steep shore barrier, an appreciably inclined approach, and a seaward portion; for example, the designated barrier sequentially incorporates additional profile segments which do not lower the overall slope appreciably (cotangent increases less than 20%). A major distinction is whether the approach is effectively horizontal or sloped, since there are separate curve sets for these cases; an overall approach slope steeper than 1 on 15 is regarded as equivalent to the 1 on 10 specified by Stoa (1978). Other factors considered in detail are the length of the approach slope, since Stoa specified a minimum extent, and the expected breaker location, to check congruence with basic laboratory situations where waves do not break seaward of the approach.

The strategy implemented in the code is full reliance on Stoa's runup guidance where it is fully appropriate, i.e., where the situation of interest falls within the range covered by that specific guidance. In such cases, runup elevation is defined by wave dimensions along with the overall slope from barrier toe to runup limit, the water depth at the barrier toe, and the approach geometry. Where the geometrical match to tested situations is found to be inexact, some reliance is placed on the original composite-slope method of Saville (1958) with the entire

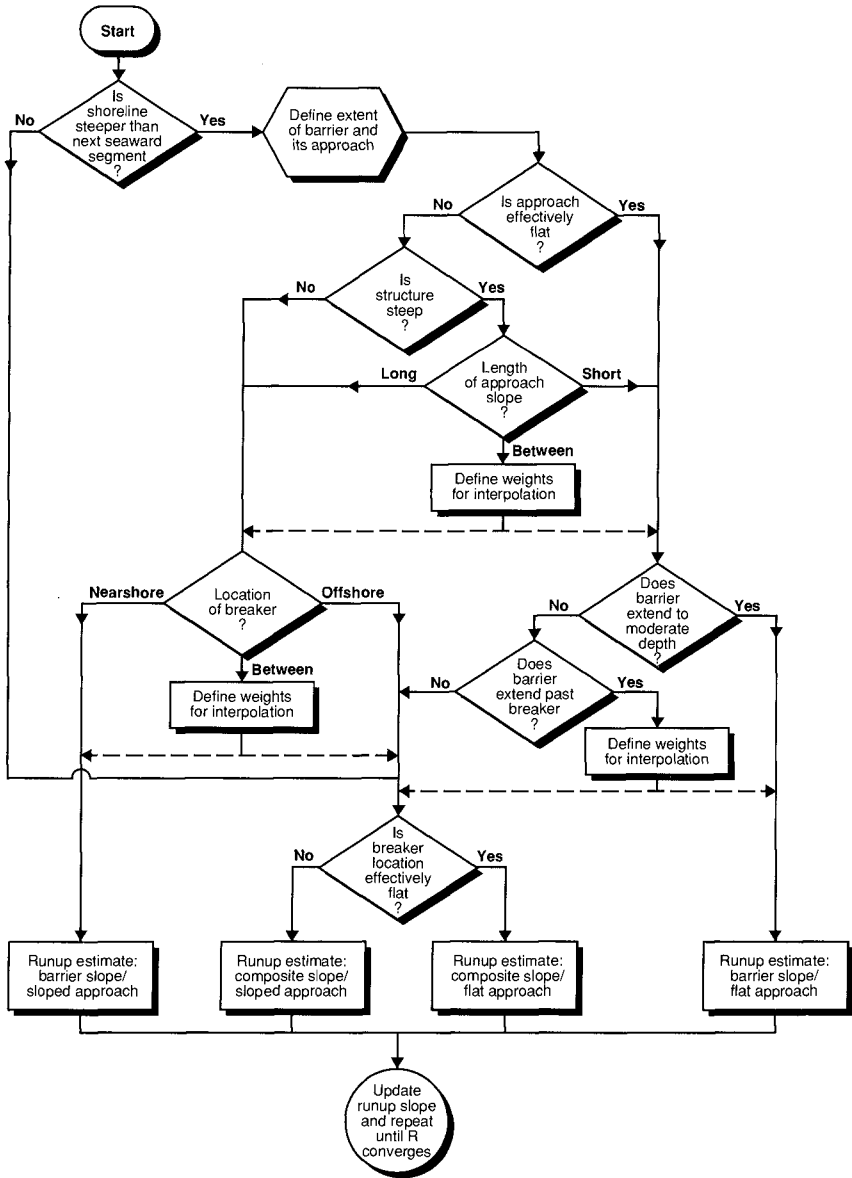

FIGURE 1. FLOWCHART OF ANALYSES WITHIN THE COMPUTER CODE.

breaker zone considered in estimating runup. Then the geometrical parameters are the overall slope from break point to runup limit, along with water depth and approach slope at the break point. The code incorporates Goda's guidance on uniform wave breaking, presented in Horikawa (1978) as normalized water depth versus wave steepness and bottom slope. An allowance for a runup scale effect on smooth slopes is applied using the multipliers proposed by Stoa (1978). Roughness and permeability of the runup surface is treated by means of usual values for a reduction coefficient (r) shown useful in considering barrier texture for wave runup and overtopping computations.

Although all might be utilized, four basic alternatives arise in runup determination: applying a barrier slope or a breaker-zone slope, and treating the approach as horizontal or inclined. The runup curves in Stoa (1978) are used in each case, but with different entry points. Transitions between these distinct computation bases provide finite ranges where runup elevation is determined by more than one viewpoint; Figure 1 indicates the various possibilities in blends of empirical results. Each contribution to the runup estimate is defined where possible by interpolation between separate curve sets bracketing the given situation. In addition, a runup elevation is extracted from an individual curve set by suitable interpolation between results originally provided in logarithmic format. The controlling slope can depend on runup limit, so the computation procedure is repeated until it converges to a self-consistent runup estimate.

For a specified profile and water level, along with wave height and period, the automatic procedure gives a runup prediction firmly based on detailed empirical guidance. Simple geometrical approximations are applied in treating the profile, and results generally reflect a blend of pertinent viewpoints in runup estimation. Computed runups are confirmed to be accurate by the following comparisons with large runup elevations measured in many studies. Data are considered in order of increasing complexity of the situations investigated.

VERIFICATION FOR UNIFORM WAVES

Figure 2 displays measurements versus computations for large tank tests with (a) smooth barriers and (b) rough structures in uniform or monochromatic wave action. These results exhibit extremely strong correlation for runup elevations typically on the order of 1 to 3 m, i.e., of common prototype magnitudes.

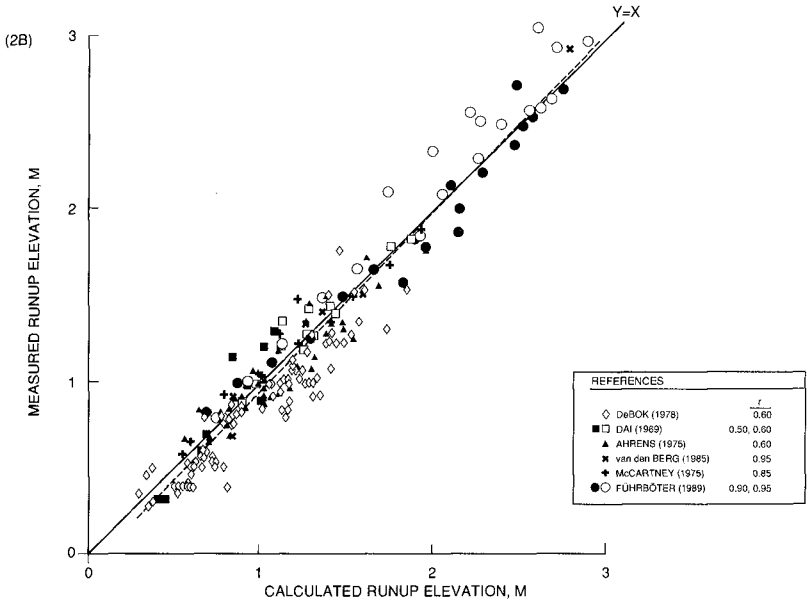

FIGURE 2. RUNUP MEASUREMENTS VERSUS PREDICTIONS FOR LARGE, UNIFORM WAVES.

For the hydraulically smooth surfaces of plywood, sand, or asphalt, almost all these 96 test situations are fully congruent with the shore configurations treated in the Stoa guidance: either a horizontal or a 1 on 10 approach to a plane barrier. Thus, the nearly ideal agreement in Figure 2a isolates the appropriateness of interpolation procedures for runup curves, along with the accuracy of scale-effect allowances up to 12% used for these barrier slopes of 1 on 3, 4, 6, 15, or 40. Differences between measurements and computations may be summarized best as random and about ± 0.1 m, rather than as some percentage error. These results are for fairly simple geometries with no very steep barriers.

The results for rough structures in Figure 2b reflect more comprehensive tests of computations. Barrier cotangents are 1.5, 2, 2.5, 3, 3.5, 5, and 6, with surfaces of loose or fitted stones, quadripods, various concrete blocks, or artificial grass. Approach geometries include a notable range in tests by DeBok and Sollitt (1976). The stated r values of runup reduction relative to a smooth barrier conform to standard guidance for these roughness types. There is marked correlation between the 199 measurements and computations, but differences amount to about ± 0.15 m; this is appreciable in view of the reduced runups.

Along with the greater uncertainty in runup measurements for rough, permeable structures, some of the increased error in Figure 2b is due to the often noted inaccuracy in assuming a constant r value for each given surface. Runup elevations on rough barriers are not linearly related to those on smooth slopes of similar geometry. The large data set of Ahrens (1975) clearly indicates greatest runup reductions relative to smooth slopes for collapsing breakers, with surf similarity parameter near 3 and minimum stone stability. However, other data sets do not show such notable error introduced by taking r as a constant for uniform waves and more stable structures. In addition, constant r may improve as an approximation in irregular waves, where an appreciable variation of surf similarity parameter must arise for a given case.

Addressing the actual variations in r would appear to require detailed empirical investigations, rather than use of a general expression. Since runup elevations are well defined over a broad range of smooth geometries, for some applications the convenience of taking r as constant can outweigh inaccuracies typically introduced. The evidence of Figure 2 manifests notable predictive capability for runup elevation in independent tests similar to those providing the basic guidance.

APPLICATION TO IRREGULAR WAVES

There is modest variability in runup elevations with uniform waves on a given barrier, but a greatly enlarged runup range occurs for irregular waves. The probability distributions of runup elevation must have some common value for comparable uniform and irregular wave action with a similar shore geometry. In fact, the mean runup elevation for irregular waves is predictable if mean wave condition is taken as the appropriate description to use with empirical guidance for uniform waves. This finding contradicts a runup treatment in terms of significant conditions presented in the *Shore Protection Manual*, but a recent publication (Walton et al., 1989) has described that methodology as "untested." Actually, measurements from small tests with smooth slopes of 1 on 1 through 10 (Kamphuis and Mohamed, 1978; Mase, 1989) demonstrate clearly that mean conditions provide the correct link between runup curves for uniform waves and effects in irregular wave action.

To date, only limited data have been openly published on irregular wave runups measured in large tank situations. Figure 3a compares the documented mean or median runup elevations to computed results using the mean wave description. The major data set here is that presented by Führböter et al. (1989) for 1 on 6 slope and moderate wave steepnesses with a Pierson-Moskowitz spectrum; only periods for peak wave energy were reported, and they are converted into mean wave periods using measured results for the same spectrum and steepnesses provided by Mase and Iwagaki (1984).

There is close agreement in trend here, but an apparent tendency for the 41 measurements to exceed computations. Other runup data from proprietary Delft Hydraulics tests have also been examined (Dewberry & Davis, 1990), with similar agreement between measurements and computations for additional wave conditions and barriers. All this evidence might be taken to indicate that the steady-wave setup on steep slopes is not fully represented in runup guidance for uniform waves. However, empirical results on wave runup and setup do not appear to permit a definitive judgment in view of the limited ranges of test geometries and wave conditions, and Figure 3a does not demonstrate a significant deficiency in the present runup computations.

Field data on wave runup provide the final level of complexity in variables and processes. Three sets of field measurements serve as useful examples covering a range of situations: Battjes (1971) for a 1 on 3.6 dike,

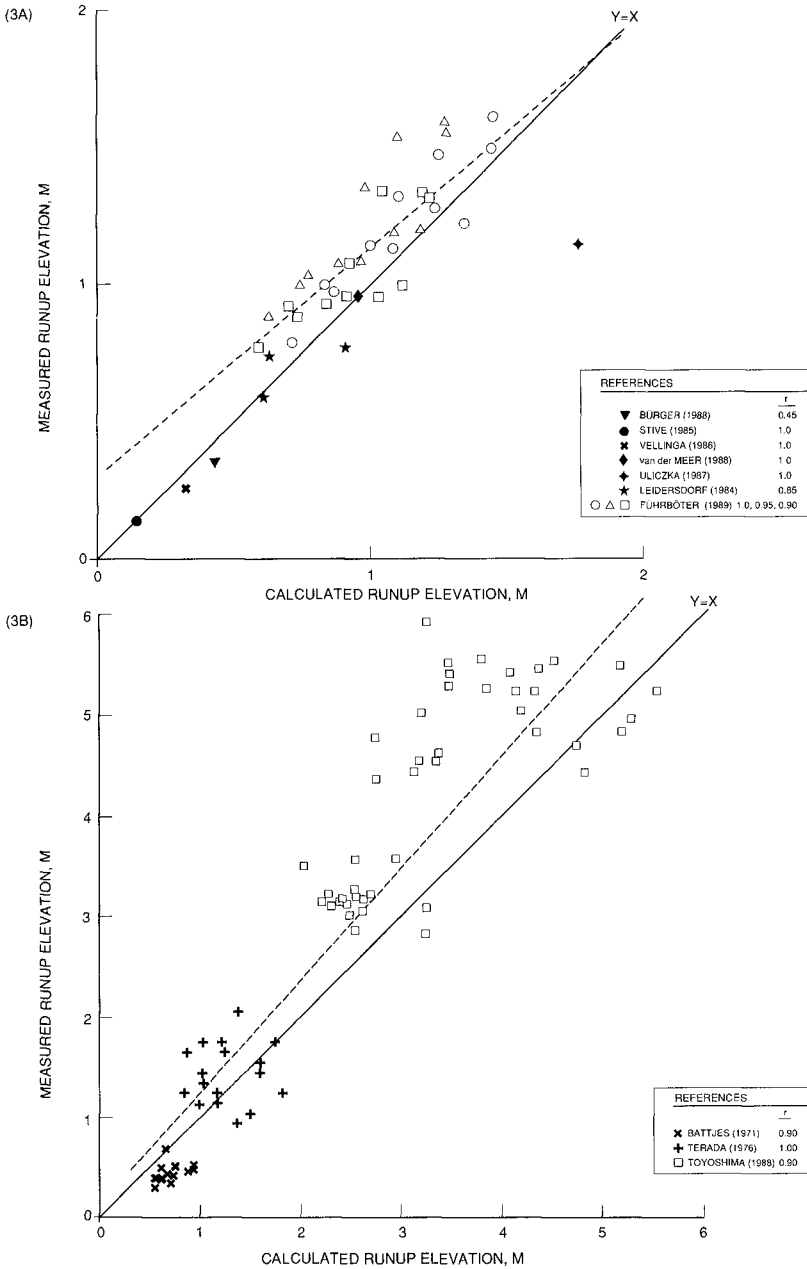

FIGURE 3. RUNUP MEASUREMENTS VERSUS PREDICTIONS FOR LARGE, IRREGULAR WAVES.

Terada (1976) for a 1 on 10 sand foreshore, and Toyoshima (1988) for a 1 on 5 seawall. Runup computations have proceeded using documented conditions in a straightforward way (Dewberry & Davis, 1990), and Figure 3b compares results to the representative elevations as reported for 76 situations. There is notable agreement in magnitudes and trend, but also sizable scatter and a marked tendency to underpredict the large runup elevations of Toyoshima (1988). Those results might be taken to corroborate the finding (Grüne, 1982) that runup elevations are increased as a direct effect of onshore storm winds. However, each of these field data sets has important shortcomings in regard to documentation.

Battjes (1971) reported winds but not waves for 7 days of measurements at two tideless lake sites. Published runup elevations are apparently with respect to mean water level at the shore, thus excluding the wave setup contribution. Presuming a moderate fetch, wave characteristics can be estimated following procedures in the *Shore Protection Manual*, and then converted to a mean wave condition in deep water; this yields a narrow range in wave steepnesses and a typical mean period of 3.5 sec, in agreement with other reported information. Terada (1976) documented deep-water wave conditions, without directions, and runup elevations relative to mean sea level, for 7 days on a Pacific Ocean beach. It is not clear what statistics were used in reported measurements. Toyoshima (1988) provided offshore wave conditions, water levels, and runup heights for 8 days of measurements at a Sea of Japan site. Wave directions are omitted, and statistical measures employed are non-standard, mixed, and somewhat extreme (beyond the significant conditions). Other information pertains to infragravity wave effects, indicated by the numbers of incident waves versus runups; however, basic variations in the numerical ratios with wave steepness are opposite findings from other field data (Holman, 1986). Finally, the total range in reported water level is 0.35 m, much less than the tidal range at the shore, so it appears that runup elevations refer to offshore not local water level.

Given these perplexing aspects in documentation, perhaps only simplified analyses are warranted for these data sets. Note that runup variations in the data of Terada (1976) and Toyoshima (1988) show definite agreement with the dependence on wave steepness given by Hunt's equation for breaking waves, although runup elevations appear magnified by about 20% above that equation in each field situation. Nevertheless, Figure 3b confirms that computed runup elevations over a very wide range are appropriate in some quantitative sense.

ADDITIONAL DISCUSSION ON APPLICATIONS

Usual applications may require a more extreme measure than the mean runup elevation predictable from the mean wave conditions. The Rayleigh distribution seems to provide an appropriate, generally conservative formulation for relating common runup elevations to those occurring only rarely in a given situation. Battjes (1971) documented field runup measurements conforming to the Rayleigh distribution at least for 0.95 to 0.05 exceedance probabilities; he concluded that a submerged berm contributed to this agreement, and expressed the expectation that runup elevations with a plane slope would extend over a narrower range than given by the Rayleigh distribution. Measured runup distributions now documented for a variety of situations all support such an effect of barrier geometry, although other factors may merit consideration in regard to conformance with the Rayleigh distribution. For example, a narrow wave energy spectrum or a sizable contribution from wave setup might act to decrease the runup range relative to the mean elevation.

The Rayleigh distribution must be expected to become inaccurate for truly extreme runup values, perhaps on the order of 0.01 exceedance probability. In addition, extrapolation from the mean elevation can require multiplication by appreciable factors, for example, 2.23 for the exceedance probability of 0.02 commonly considered. This may introduce significant magnification of usual uncertainty associated with a mean elevation prediction. Where possible, direct empirical investigation at large scale must be preferred in defining actual extreme runup elevations for a given situation. Of course, such data need not be organized using the mean wave description.

Some complications clearly require further consideration in predicting wave runup elevations for extreme storms. Several factors ignored in the present treatment seem unlikely to make an appreciable difference, viewed here as a 10% change in runup elevations; oblique incidence of waves is one such factor (Tautenhain et al., 1982), and one more is the runup scale effect on rough barriers (subsumed into chosen r values). Notable difficulties may be involved in the specification of deep-water wave conditions as input to predictions, since runup guidance is fundamentally based on incident wave characteristics at the approach to the shore barrier. Determining those waves and converting to offshore conditions may involve appreciable uncertainties in some situations. However, the most significant questions appear to require further measurements for storm conditions, to clarify effects of winds, wave setup, and infragravity motions.

CONCLUSIONS

The present computer code provides mean runup elevations based on detailed empirical guidance for uniform waves on smooth slopes (Stoa, 1978). The specified situation is analyzed to identify suitable prediction procedures, with interpolation and iteration automatically executed for a consistent runup elevation. Published data sets confirm computations of runup elevations to be usefully accurate for wide ranges of wave action and geometry. Despite the notably larger errors to be expected for increasing complex situations, appropriate magnitudes and trends demonstrate that there is no definite defect in present runup predictions.

This verification of automated computation procedures supports the model's applicability for the full coverage of incorporated runup guidance. Appreciable refinement in empirical runup predictions for steep barriers and storm waves appears to require additional data sets from large tank investigations of realistic situations and from field studies with complete documentation.

Acknowledgments. The present investigation relates to the development of upgraded methodology for predicting wave runup elevations associated with a 100-year flood, a task undertaken by Dewberry & Davis as technical evaluation contractor for the National Flood Insurance Program, Federal Insurance Administration, Federal Emergency Management Agency. However, analyses and determinations reported here represent the views of the authors alone. We wish to thank Chuck Wood of Dewberry & Davis for assistance in the code development. ABSTRACT

The predictions of linear and nonlinear (Boussinesq) shoaling wave models for nonbreaking unidirectional surface gravity waves are compared to field observations, with particular emphasis on quantities that may be important for cross-shore sediment transport. The extensive data sets were obtained on two natural beaches, span water depths between 1-10 m, and include incident wave power spectra with narrow, broad, and bimodal shapes. Significant wave heights varied between approximately 30 and 100 cm and peak periods between approximately 8 and 18 seconds. Only the nonlinear theory predicts the increasingly asymmetric sea-surface elevations and horizontal velocities (pitched-forward wave shape) and the weaker variation of skewness (difference between crest and trough profiles) which are observed to occur during shoaling. The nonlinear theory also models qualitatively well the large skewed accelerations which occur during the passage of asymmetric waves.

INTRODUCTION

Because nonbreaking shoaling waves are both weakly nonlinear and weakly dispersive they are frequently described by models based on the nonlinear Boussinesq equations (Peregrine 1967). In general, the Boussinesq equations

include the effects of shoaling, refraction, reflection, and diffraction for arbitrary wave fields (i.e. directionally spread and broad banded in frequency). Most implementations of Boussinesq shoaling models include a subset of these phenomena, and have been successfully tested against a variety of laboratory data and analytical results. Freilich & Guza (1984, FG) and Liu et al. (1985) have respectively derived one- and two-dimensional nonlinear shoaling models based on perturbation solutions to the Fourier transformed Boussinesq equations. The models clearly identify nonlinear near-resonant triad interactions as the primary cause for evolution of third moments of the wave field. The one-dimensional, many mode (i.e. broad banded in frequency) Boussinesq model has been compared to a limited set of ocean field data (FG, Elgar and Guza 1985 (EG), 1986, Elgar et al. 1990).

The Boussinesq equations require both shallow water depths ($(kh)^2 \ll 1$, where k is the wavenumber and h is the water depth) and small wave amplitudes ($a/h \ll 1$, where a is the wave amplitude) such that the Ursell number, $U = (a/h)/(kh)^2$ is approximately unity. The one-dimensional shoaling model assumes that the waves are normally incident to a beach with plane-parallel contours, and neglects dissipation and reflection.

The one-dimensional model is cast in terms of coupled, nonlinear, ordinary differential equations with the (temporal) Fourier coefficients of the wave field as the dependent variables. Since the model describes the spatial evolution of the Fourier coefficients (i.e. both the amplitudes and phases), it contains information relating to wave shapes and instantaneous oscillatory velocities.

Freilich and Guza (1984) give details of numerically implementing the nonlinear model. Fourier coefficients used as initial conditions for nonlinear model predictions are provided by measurements at the seaward edge of the region of interest. The model equations are then integrated numerically, yielding predicted values of Fourier coefficients of sea-surface elevation in shallower water. The predicted and observed Fourier coefficients can then be manipulated and compared in various ways. Alternatively, after inverse Fourier transforming the predicted coefficients, comparisons can be made between predicted and observed time series.

The present study evaluates the performance of the 1-D shoaling model for nonbreaking waves in 18 data sets obtained from month-long field experiments at two beaches. A variety of incident wave conditions were observed, including swell from a distant storm, locally generated sea, and combinations of swell and sea. The model performance is good. The spatial evolution of sea surface elevation (SSE), velocity, and acceleration statistics are at least qualitatively well predicted for a wide range of ocean conditions.

FIELD EXPERIMENTS AND DATA REDUCTION

Two field experiments conducted in 1980 (Torrey Pines and Santa Barbara, California) provide the data used for model verification. The bottom contours were relatively straight and parallel at both experimental sites, and the mean beach slopes through the shoaling region were 0.022 and 0.050 at Torrey Pines and Santa Barbara, respectively. Data were obtained from wave staffs and bottom-mounted pressure and electromagnetic current meters. The field experiments, including representative beach profiles and descriptions of the sensors and data reduction are presented in FG, EG, and Thornton & Guza (1986). Measurements from cross-shore arrays extending for approximately 267 m (Torrey Pines) and 56 m (Santa Barbara) are used in the model-data comparisons presented below.

Initial conditions for the nonlinear Boussinesq shoaling model were generated with data from a bottom-mounted pressure sensor in 10 m depth at Torrey Pines and in 4 m depth at Santa Barbara. Short sections of data were Fourier transformed and converted to Fourier coefficients of sea-surface elevation using linear finite depth theory. Results of integrations of the Boussinesq shoaling wave model for consecutive short sections were averaged together for statistical comparisons. The maximum frequency considered is 0.234 and 0.4 Hz at Torrey Pines and Santa Barbara, respectively. The different cutoff frequencies reflect the requirement that the waves be relatively long compared to the depth, and the relatively deeper water at Torrey Pines.

All pressure and current meters were positioned within 80 cm of the sea bed, and the pressure data were converted to sea-surface elevation using linear theory. Because linear theory accurately relates local values of near-bottom pressure and elevation in nonbreaking waves (Guza & Thornton 1980 and references therein), hereafter no differentiation will be made between direct measurements of sea-surface elevation and sea-surface elevation inferred from pressure data. Comparisons between model predictions and current meter data are made at the known depth of the current meter sensing element (i.e. no theory is applied to the current meter data).

Energy dissipation was not important in the model-data comparisons discussed here because the evolution distances were relatively short, white-capping was not pronounced, and the comparisons were terminated when measured energy losses owing to wave breaking were significant. The Torrey Pines experiment was designed to study nonbreaking waves, and thus all sensors were seawards of the breaking zone and dissipation was found to be negligible. Many of the Santa Barbara sensors were sometimes within the surf zone, and the estimated dissipation was sometimes significant in depths less than 1.6 m. Model-data comparisons are presented only for sensors where the total shoreward energy flux (integrated over all frequencies) was at least 85% of the value measured at the most seaward instrument.

The effects of directional spread and/or non-normal incidence in the incoming wave field on the nonlinear evolution of shoaling waves are not yet well understood. Boussinesq models appropriate for this case (e.g. Liu et al. 1985) have not been applied to random ocean waves. The data sets discussed here include locally generated wind-driven seas having broad directional spread, as well as wave fields composed of swell and sea arriving from different directional quadrants. Although the incident wave field was neither unidirectional nor normally incident, 1-D Boussinesq model predictions are possible because fundamentally nondirectional statistics are considered here. Moreover, as refracting surface waves propagate into shallower water they are strongly polarized in the cross-shore direction and thus the approximation of normal incidence often is not grossly violated. A longshore array of sensors in 10 m depth at Torrey Pines and a colocated pressure sensor-bidirectional current meter pair in 4 m depth at Santa Barbara showed that the principal wave directions at the offshore, initial conditions for the model predictions are less than 20° relative to normal incidence (FG, EG, Thornton & Guza 1986, Freilich et al. 1990)

MODEL-DATA COMPARISONS

As a primarily swell wave field (S11 and F2 in fig 1) shoals, the power spectrum undergoes significant evolution, with harmonics of the spectral peak increasing in power with decreasing water depth (fig 2). Linear finite depth theory (LFDT) does not predict the growth of harmonics, but the Boussinesq model accurately predicts the observed spectral evolution, except for high frequencies (e.g. $f \geq 0.3$ Hz for the data considered here). Along with cross-spectral transfers of energy (e.g. harmonic growth) owing to nonlinear interactions as the waves shoal, there is also substantial nonlinear phase evolution of the individual Fourier components (equivalent to a nonlinear effect on the phase speed). In shallow water where nonlinear effects are largest, phase differences between the nonlinear model and the data are small, while the phase differences between data and LFDT are large (fig 2). The coherence between the nonlinear model predictions and data is high (fig 2), except for a decreasing coherence with increasing frequency, which can be explained by directional spreading of the wave field (FG). Boussinesq model predictions for wave fields with broad band and bimodal spectra are also more accurate than LFDT predictions (not shown). LFDT predictions that include the effects of the directional distribution of energy (EG) are not substantially better than the unidirectional LFDT predictions shown in fig 2.

As waves shoal, their profiles evolve from nearly sinusoidal shapes in deep water to positively skewed (sharp peaks and broad troughs) shapes to vertically asymmetrical, sawtooth shapes just prior to breaking. The change in wave form during shoaling is statistically described by the skewness, S and

Figure 1. Initial power spectra of sea surface elevation for the model predictions. Top, Torrey Pines, $h \sim 10$ m (solid line, S11, $H_{sig} = 90$ cm; dashed line, S16, $H_{sig} = 56$ cm); bottom, Santa Barbara, $h \sim 4$ m (solid line, F2, $H_{sig} = 63$ cm; dashed line, F12, $H_{sig} = 57$ cm; dotted line, F15, $H_{sig} = 66$ cm), where H_{sig} is the significant wave height at the depth indicated.

Figure 2. Comparison of model predictions (based on initial conditions in 4.5 m depth, F2 in fig 1) to swell data in 1 m depth. Coherence and phase differences between Boussinesq (solid line) and LFDT (dotted line) model predictions and observations are shown in the upper and center panels, respectively. The power spectra predicted by the Boussinesq (solid line) and LFDT (dotted line) models are compared to observed values (dashed line) in the lower panel.

asymmetry, A (third moments of the wave field, which measure deviations from symmetry about the horizontal and vertical axis, respectively (Masuda & Kuo 1981)). A sawtooth shape has $S = 0$ and $A \neq 0$, while a "Stokes wave" shape (broad, low troughs and narrow, tall crests) has $S \neq 0$ and $A = 0$.

The observed and predicted evolution of skewness and asymmetry for swell is displayed in fig 3. Third moments are small in deep water ($A = S = 0$ for linear waves), and increase owing to nonlinear interactions as the waves shoal. In both the observations and the model predictions, skewness of SSE and velocity attains a maximum and starts to decrease before the waves break (wave breaking is significant only for the shallowest sensor shown in fig 3). Asymmetry increases approximately monotonically, consistent with the steepening shape of shoaling waves. The random phase assumption underlying linear theory results in sinusoidal waves, and thus LFDT cannot predict the changes in wave shape as the wave field shoals. On the other hand, the Boussinesq model accurately predicts the observed evolution of third moments of the wave field, as shown in fig 3.

Observed and predicted third moments for a broad band wave field (i.e. locally generated sea, F15 in fig 1) are shown in fig 4. Although the shape of the power spectrum at the seaward edge of the shoaling region differs from the narrow band wave field discussed above, many aspects of the evolution during shoaling are similar. In particular, the wave shapes undergo similar shoaling evolution from sinusoidal to sawtooth profiles.

For broad band wave fields, the total skewness and asymmetry are not dominated by contributions from a few isolated harmonic triads, as is the case with narrow band wave fields. Rather, nonlinear interactions significantly couple many frequencies within the wind wave band, with each triad of coupled waves contributing to the overall third moments. The assumptions underlying the Boussinesq model become invalid at high frequencies where the lowest order Boussinesq dispersion relation deviates significantly from the exact finite-depth solution. Thus, it is not surprising that nonlinear model predictions of third moments for broad banded conditions (fig 4) are not as accurate as those for swell-dominated spectra (fig 3). This is especially true for acceleration statistics (fig 4c), where high frequency motions are even more important (Elgar et al. 1988). Nonetheless, the nonlinear model correctly predicts the depth-dependent trends in the third moments of sea-surface elevation, horizontal velocity, and acceleration.

Observed and predicted third moments for a wave field consisting of both sea and swell, S16 and F12 in fig 1) are shown in fig 5. The sea and swell arrived at the outer edge of the shoaling region from different directions, separated by about 45° at Santa Barbara and about 25° at Torrey Pines. As in the narrow- and broad-band cases discussed above, the steepening of the wave profile during shoaling is fairly well predicted by the Boussinesq model, as shown in fig 5a. The predictions of near-bottom velocity third moments (figs

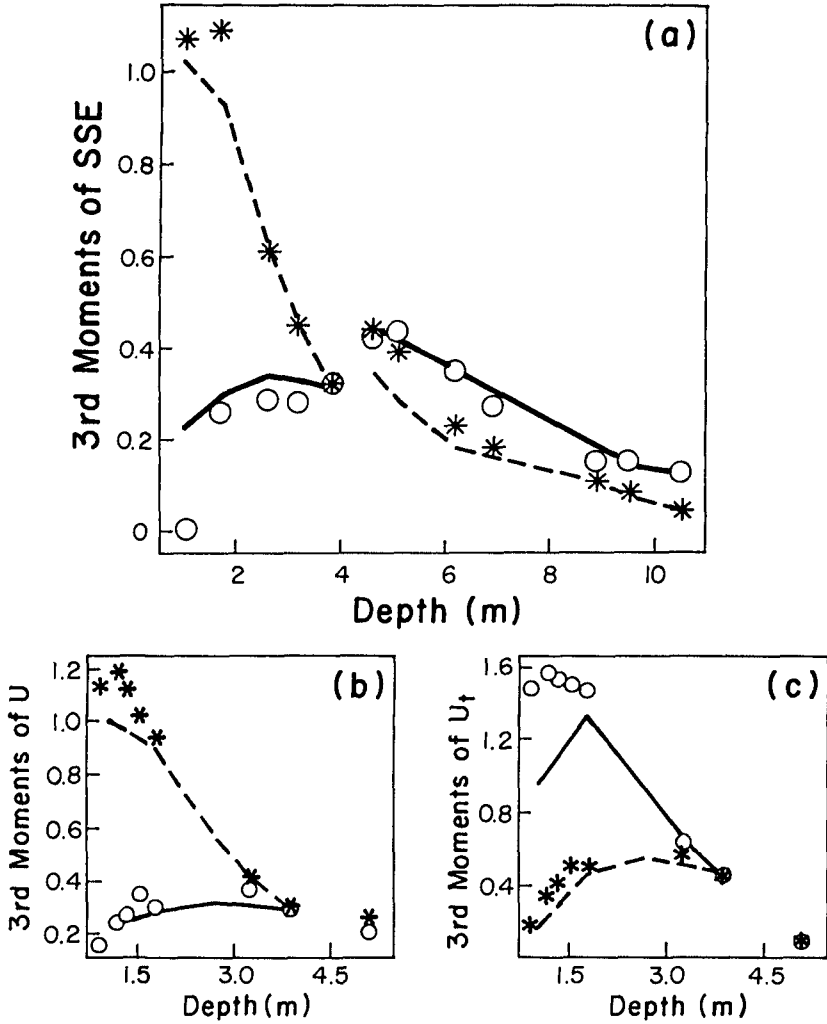

Figure 3. Predicted and observed normalized third moments versus depth for the narrow band swell data ($h > 4$ m, Torrey Pines (S11); $h \leq 4$ m, Santa Barbara (F2)). a) sea-surface elevation; b) near-bottom horizontal (e.g. cross-shore) velocity; c) near-bottom horizontal acceleration. Solid and dashed lines are model predictions of skewness and -asymmetry, respectively. Circles and asterisks are observed values of skewness and -asymmetry, respectively.

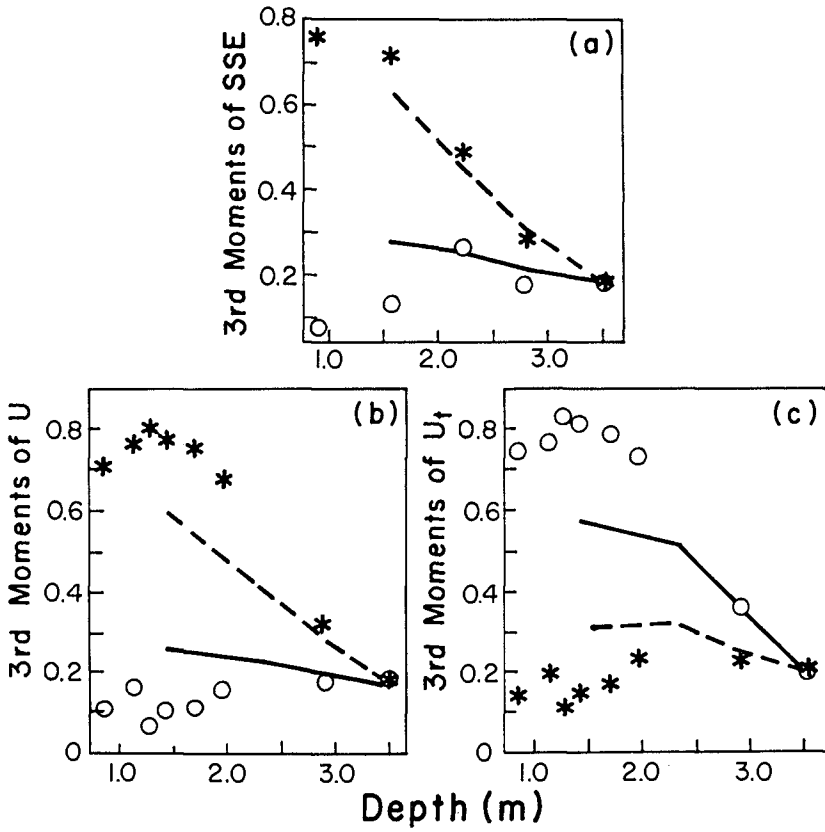

Figure 4. Predicted and observed normalized third moments versus depth for the broad band data, Santa Barbara (F15). a) sea-surface elevation; b) near-bottom horizontal velocity; c) near-bottom horizontal acceleration. Format is the same as Figure 3.

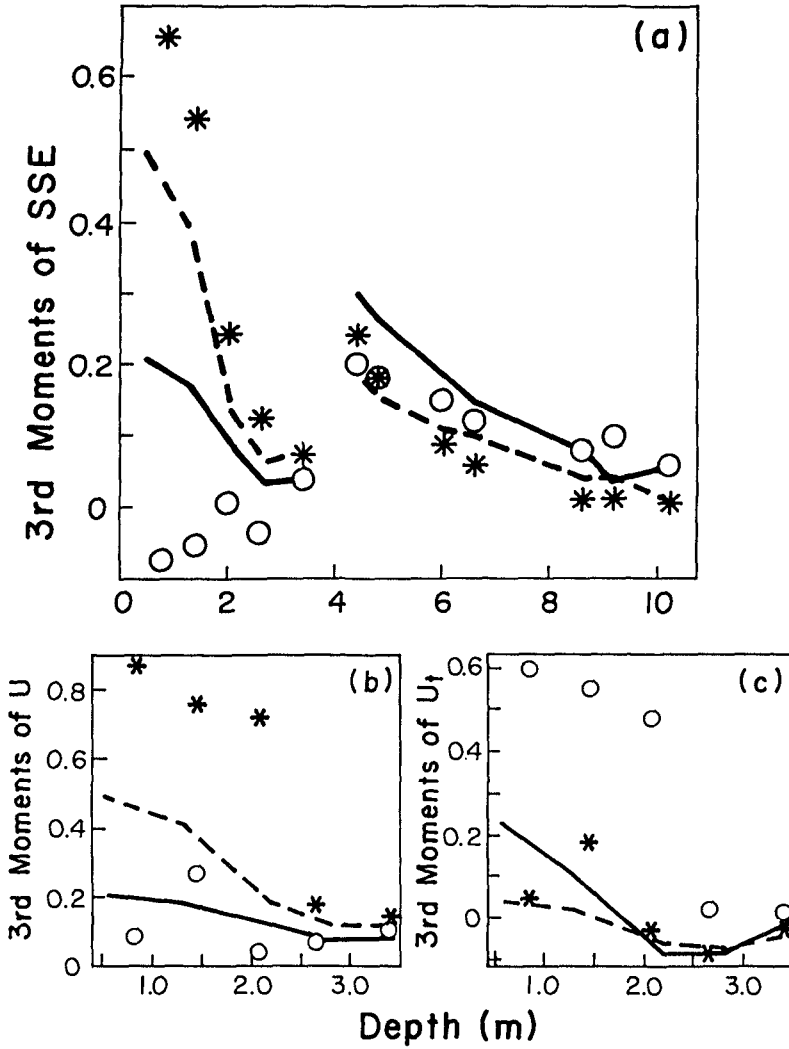

Figure 5. Predicted and observed normalized third moments versus depth for the bimodal data ($h > 4$ m, Torrey Pines (S11); $h \leq 4$ m, Santa Barbara (F2)). a) sea-surface elevation; b) near-bottom horizontal velocity; c) near-bottom horizontal acceleration. Format is the same as Figure 2.

5b,c) are considerably less accurate, perhaps owing to directional effects.

From the model-data comparisons discussed above it is clear that the one-dimensional Boussinesq model predicts the evolution of shoaling waves for the conditions considered at least qualitatively well. In addition, model-data comparisons for many more data sets are displayed in fig 6, where predictions of SSE and near-bottom horizontal velocity third moments are compared to observed values. The Boussinesq model predictions of SSE skewness are accurate for both field sites. The predictions of SSE asymmetry for the Torrey Pines data are qualitatively correct, but somewhat less than observed values, while the predictions of SSE asymmetry for the Santa Barbara data are accurate (fig 6a). Model predictions of third moments of near-bottom velocity in 4.5 m depth, 250 m from the initial conditions ($h \approx 10$ m) at Torrey Pines and for 12 and 56 m from the initial conditions at Santa Barbara are compared to observations in fig 6b. Overall the predictions are good. The Boussinesq model also provides accurate predictions of acceleration skewness and asymmetry (fig 6c).

CONCLUSIONS

Given measurements of the incident wave field, low-order statistics of the shoaling wave field seawards of the surf zone can be accurately predicted by the Boussinesq equations, as demonstrated by the model-data comparisons presented above. The Boussinesq model has no free or adjustable parameters, is not limited to any particular spectral shape, and accurately predicts the evolution of the wave field for swell, locally generated sea, combinations of swell and sea, and other typical field conditions. The nonlinear model also is not dependent on the particular field location, as long as dissipation outside the surf zone and reflection from the beach face are negligible. Although the two beaches discussed here were nearly planar, more complex bathymetry can, in principle, be incorporated into the nonlinear model.

CHAPTER 5

Transition Zone Width and Implications for Modelling Surfzone Hydrodynamics

Robert B. Nalrn¹, J.A. (Dano) Roelvink² and Howard N. Southgate³

INTRODUCTION

The surfzone associated with a wave breaking on a plane slope may be subdivided into three regions: the transition zone, the inner zone and the swash zone. The transition zone is the region just shoreward of the point of wave breaking and is characterised by rapid wave decay and also by constant wave setdown (and thus constant radiation stress). In this paper, an empirical expression for the width of this zone is developed from monochromatic wave data. Two techniques are proposed for the consideration of this phenomenon in the numerical modelling of surfzone hydrodynamics for random waves. The implications of a zone of nearly constant radiation stress inside the breakpoint are examined with respect to wave-induced current generation - both cross-shore and longshore - and sediment transport prediction. Comparisons are made to both field and laboratory data from plane and undulating profiles.

BACKGROUND

The existence of a zone of transition between the unbroken wave shape and the turbulent bore form of the broken wave was first reported by Svendsen et al (1978) based on visual observations of wave breaking. Svendsen (1984) proposed a definition of the transition zone as the region of nearly horizontal or very weakly sloping water level inside the breakpoint before the beginning of a steep gradient in the water level due to wave setup.

Both Svendsen (1984) and subsequently Basco and Yamashita (1986), were concerned with the influence of the transition zone on the description of wave height decay and mean water level variation in the surfzone through the solution of the energy and momentum balance equations. The transition zone features rapid wave decay without an associated increase in energy dissipation. Svendsen (1984) suggested that the large amount of potential energy lost in this region is converted to forward

momentum flux, specifically in the surface roller. Basco and Yamashita (1986) viewed the process in the transition zone as a transformation from oscillatory wave motion to highly rotational (turbulent) motion. Thus, the region is essentially a development zone where the just broken wave is transformed into a turbulent bore. Basco (1985) notes that both plunging and spilling breakers feature this same development process, albeit at much different scales. Two approaches for considering the role of the transition zone processes in the prediction of wave height decay are presented in the above-noted papers.

A zone of nearly constant mean water level, through consideration of the momentum balance equation, implies that the radiation stress is also constant. Consequently, the generation of wave-induced cross-shore and longshore currents by the reduction in radiation stress due to energy dissipation does not commence until the inner limit of the transition zone is reached. In a comparison of numerical model estimates to laboratory measurements of the distribution of longshore currents across a profile for plunging waves, Visser (1984) found that it was critically important to delay the initiation of the influence of energy dissipation on the generation of longshore currents until the plunge point. As noted by Basco and Yamashita (1986), the distance from the breakpoint to the plunge point is a significant fraction of the transition zone width. A similar influence of the transition zone has been observed in the prediction of wave-induced return flow in the surfzone (or undertow) by Roelvink and Stive (1989), Nairn (1990a) and Okayasu et al (1990).

TRANSITION ZONE WIDTH

Basco and Yamashita (1986) proposed that the width of the transition zone would vary with the surf similarity parameter; the zone would be wider for spilling breakers than for plunging breakers. Whilst this may be so in an absolute sense, considering that the plunging breaker must undergo a much greater change in wave shape, it is more likely that the dimensionless width of the transition zone (normalised by the depth at breaking) will be larger for plunging breakers. An empirical expression can be developed for the dimensionless transition zone width using dimensional analysis techniques. The ratio of the depth at the inner limit of the transition zone, d_t , to the depth at breaking, d_b , is found to be a function of two parameters as follows,

$$\frac{d_t}{d_b} = f \left(\frac{m_b}{(H_b/L_o)^{0.5}}, \frac{d_b}{L_b} \right) \tag{1}$$

The first variable is the surf similarity parameter, where m_b is the bottom slope in the vicinity of the breakpoint, H_b is the wave height at breaking and L_o is the deepwater wavelength; the second variable is the ratio of the depth at breaking to the wavelength at breaking and provides an indication of the scale of the wave with respect to the width of the surfzone. A data set on the width of the transition zone was gathered from laboratory experiments with monochromatic waves - the width was defined as the distance from the breakpoint to the abrupt change in slope of the mean water level (an example of one of these laboratory experiments is given in Figure 1). By combining the two variables of Equation 1 into a single parameter and performing a regression analysis on the data set, the following relationship was derived,

$$d_v/d_b = 0.47 \xi_{bb}^{-0.275}, \text{ for } \xi_{bb} \geq 0.05$$

$$d_v/d_b \sim 1, \text{ for } \xi_{bb} \leq 0.05$$

$$\xi_{bb} = m_b / (H_b/L_b)^{0.5} \quad (2)$$

Note that the dimensionless transition zone depth is given as a function of the surf similarity parameter evaluated entirely with breakpoint values. This differs from the conventional surf similarity parameter in that the local wavelength at breaking is used in the definition of wave steepness instead of the deepwater value (thus accounting for the second variable in Equation 1). A comparison of this relationship to the data set is given in Figure 2, the correlation coefficient for the regression analysis was 0.85. As anticipated, the dimensionless width (which varies from 5 to 50 % of a plane sloping surfzone) increases with the surf similarity parameter and consequently is greater for plunging breakers than for spilling breakers. In a random wave climate, the transition zone width will vary according to the surf similarity parameter of each individual wave at breaking.

MODELLING THE INFLUENCE ON WAVE-INDUCED CURRENTS

1) Empirical Approach

A numerical model has been developed for the prediction of cross-shore and alongshore sediment transport on a beach profile. The principal components of the model include: 1) wave transformation based on the technique of Battjes and Janssen (1978) for random waves; 2) a description of the mean cross-shore flows under random waves using an adaptation of the method presented by DeVriend and Stive (1987); 3) prediction of the longshore current variation across the profile employing the technique of Southgate (1989); 4) calculation of the central velocity moments based on the non-linear Vocoldal theory (after Swart, 1978) for time-varying orbital velocities; and 5) prediction of the cross-shore and alongshore sediment transport rates across the profile using a modified version of the Energetics approach which was originally developed for coastal applications by Bailard (1981) and Bowen (1980). The influence of the transition zone primarily affects the calculation of the mean wave-induced cross-shore and longshore currents of steps 2 and 3 above. Of course, this influence will also be transmitted to the calculation of sediment transport rates based on the modified currents.

The Battjes and Janssen (1978) description of random wave transformation at each point across a profile consists of two parameters, the root mean square wave height, H_{rms} , and the fraction of broken waves, Q_b . In this time-averaged approach to modelling random waves, the fraction of broken waves represents the proportion of time that waves are breaking at a given point on the profile over a model time step. Both the techniques of DeVriend and Stive (1987) and Southgate (1989) for wave-induced cross-shore and longshore currents respectively are based on a similar approach to random waves. The principal driving force for currents under breaking waves is represented by the reduction in radiation stress, which in turn may be related to the dissipation of wave energy. Therefore, in a time-averaged sense, a driving force for the currents between any two points on a profile is derived from the local decay in the rms

wave height multiplied by the fraction of broken waves. However, the stipulation of the transition zone influence suggests that the incremental increase in the driving force due to the local initiation of wave breaking - represented by the increase in the fraction of broken waves between the two points - should be delayed by a distance equivalent to the transition zone width. Therefore, at each point across the profile a revised value of the fraction of broken waves is determined by delaying the incremental increase in Q_b for a distance equivalent to the local transition zone width (i.e. using the local wave height, wavelength and beach slope in Equation 2). The revised Q_b is treated as a new variable and is used in the calculation of energy dissipation for the driving force of radiation stress related quantities such as mean currents and wave setup. A comparison of the revised Q_b to the actual Q_b is presented in Figure 3 which shows the details of the prediction of wave transformation across a profile corresponding to Case 5 of the DUCK85 sediment transport field experiments (this experiment is discussed in more detail later). The revised Q_b distribution is shifted onshore approximately 10 m for this example.

2) Analytical Approach

The mean wave energy balance equation:

$$\frac{\partial}{\partial x} EC_g = S \tag{3}$$

where E is the mean wave energy, C_g the group velocity and S a (negative) source term, has been used successfully to describe the decay of organised wave energy by means of a bore model. Battjes and Janssen (1978) extended the formulation to the case of random waves by assuming a parametric shape for the wave height distribution. If it is assumed that the organised wave energy is instantly converted to isotropic turbulence energy, the horizontal cross-shore momentum balance reads:

$$\frac{\partial}{\partial x} \tilde{S}_{xx} + \rho gh \frac{\partial \eta}{\partial x} + \tau_b = 0 \tag{4}$$

where \tilde{S}_{xx} with a tilde is the radiation stress related to the organised wave motion, ρ is the density of water, g the acceleration of gravity, h the water depth, η the mean water level and τ_b the bottom shear stress. Since the term τ_b is generally small, the setup should respond directly to the radiation stress gradients. As has been noted previously, this is not the case; this means that an additional term should exist in the momentum balance equation.

Svendsen (1984) suggested that part of the organised wave energy is first converted into forward momentum flux in the roller, and accounted for this roller influence both in the energy balance, by means of a term:

$$E_r = \rho AC^2/2L = \rho AC/2T \tag{5}$$

where A is the roller area, C is the phase velocity and T the wave period, and in the momentum balance by means of a term:

$$S_{xx, roller} = \rho AC^2/L = \rho AC/T = 2E_r \quad (6)$$

The equations for the energy balance and the momentum balance can then be written respectively as:

$$\frac{\partial}{\partial x} EC_g + \frac{\partial}{\partial x} E_r C = -D \quad (7)$$

where D is the dissipation per unit area, and:

$$\frac{\partial}{\partial x} \tilde{S}_{xx} + \frac{\partial}{\partial x} 2E_r + \rho gh \frac{\partial \eta}{\partial x} + \tau_b = 0 \quad (8)$$

Svendsen (1984) then relates the roller area directly to the local wave height H by using the empirical finding:

$$A = 0.9 H^2 \quad (9)$$

When this formulation is used, the absolute magnitude of the setup changes, but the spatial distribution of the setup remains directly linked to the wave energy decay, and no transition zone lag effect is found.

On the other hand, Roelvink and Stive (1989) suggested that the organised wave energy is first converted to turbulent kinetic energy which is not dissipated immediately. They proposed to use a k -equation in which the production of turbulent kinetic energy is equal to the decay of organised wave energy:

$$\frac{\partial}{\partial x} EC_g + \frac{\partial}{\partial x} \beta_f khC = -\rho \beta_d k^{3/2} \quad (10)$$

where k is the depth- and time-mean turbulence intensity and β_f and β_d are coefficients of order one. The second term in this equation represents a storage term, whereas the term on the right is the actual dissipation. Due to the storage term, which is positive in the area of initial decay of wave energy, the dissipation lags behind the production of turbulence energy. The influence of the turbulence on the momentum balance was estimated as:

$$S_{xx, turbulence} = \int_{-d}^{\eta} (\rho u'^2 - \rho w'^2) dz \sim \beta_s \rho kh \quad (11)$$

so the momentum balance in this case reads:

$$\frac{\partial}{\partial x} \tilde{S}_{xx} + \frac{\partial}{\partial x} \beta_s \rho kh + \rho gh \frac{\partial \eta}{\partial x} + \tau_b = 0 \quad (12)$$

The value of β_s depends on the ratio between the turbulence intensities in the x , y and z -directions; based on the analogy of a wake, a value of 0.22 was suggested. The result

was that hardly any influence on the setup distribution was found, although there was a significant lag between the production and dissipation of turbulence energy. This leads to the conclusion that either the turbulence which is generated is much more anisotropic than assumed, or that the wave motion is converted into a different form of motion.

A synthesis of these two approaches can be developed using Svendsen's concept of a roller as a 'block' of water moving at the phase velocity, dropping the empirical Equation 9, and assuming the sink term S of the organised wave energy to be a known function of the local wave parameters, as for instance in the Battjes and Janssen model. The roller energy, E_r , in this case becomes the unknown parameter; if the dissipation can be related to this parameter, E_r can be solved from Equation 7. In this way the roller will serve as a storage of kinetic energy, leading to a lag effect similar to that modelled by Equation 10.

The dissipation in this case can be modelled according to Delgaard and Fredsoe (1989) as the work performed by the shear stress, τ_r , between the roller and the organised wave motion:

$$D = \overline{\tau_r} C \quad (13)$$

The shear stress can be deduced by considering the vertical force balance equation on the roller, which leads to:

$$\overline{\tau_r} = \beta \rho g A / L \quad (14)$$

where β is the mean slope under the roller. Combining Equations 13 and 14,

$$D = \beta \rho g A / T = 2\beta g E_r / h \quad (15)$$

so Equation 7 can be written as:

$$\frac{\partial}{\partial x} EC_g + \frac{\partial}{\partial x} E_r C = -2\beta g E_r / C \quad (16)$$

This equation is quite similar to Equation 10; if it is assumed that $E_r = \rho kh$, $C = \sqrt{gh}$ and the order of magnitude estimate $k \sim 1/2 \beta_1 C^2$ is taken, the result is:

$$\frac{\partial}{\partial x} EC_g + \frac{\partial}{\partial x} \rho kh C = - (2\sqrt{2} \beta / \sqrt{\beta_1}) \rho k^{3/2} \quad (17)$$

The above expression, with $\beta \sim \beta_1 \sim 0.10$, leads to Equation 10 with $\beta_d \sim 1$.

Comparison of Equations 6 and 11 now shows that the roller contribution to the radiation stress is $0.22 E_r$ in the turbulence model, against $2 E_r$ according to the Svendsen concept. In view of the fact that for the first estimate no significant transition zone lag effect in the setup was found, the second estimate seems more realistic. In order to check this, two tests documented in Battjes and Janssen (1978) were hindcast with respect to wave energy decay and setup, specifically, Test HJ2, with a plane beach, and HJ12, with a schematised bar-trough profile. A Battjes type model was used to predict the sink term S ; the roller energy E_r was solved both from Equation 10 and from

Equation 16 and the setup was computed from Equation 8. A value for the roller slope of 0.10 was applied in Equation 14. In Figures 4 and 5, the results are presented for the wave energy, represented by $H_{rms} = \sqrt{3E/\rho g}$, and for the setup, without the transition zone lag effect and with the lag effect according to both formulations. There is a considerable improvement in the setup prediction in the area of incipient breaking; also, Equations 10 and 16 produce very similar results. With respect to wave-driven currents it is likely that the dissipation rate should be the term D in Equation 7, rather than the sink term S in Equation 1, however formal proof of this has not yet been derived and should be the subject of further study.

The analytical approach described above can be applied to predict the general behaviour of the transition zone width as a function of beach slope and wave steepness. The model was tested for a plane beach with slopes in the range of 0.005 to 0.05 and incident wave steepnesses - defined as H_{rms}/L_o - in the range 0.01 to 0.04. The transition zone width was defined as the distance between the peak of the sink term S and the peak of the dissipation term D , as the peak in S defines the location of maximum gradient in H_{rms} , and the peak in D a location of rapid water level increase. Though this definition differs slightly from that used for the empirical approach, the general behaviour can be expected to be quite similar. The analytical approach may also be applied to either monochromatic or random waves.

The dimensionless transition zone width (i.e. the ratio of the depths at the dissipation peak and the sink term peak) is plotted against the deepwater surf similarity parameter, ξ_o , the similarity parameter at breakpoint values, ξ_{bb} , and against the bottom slope in Figures 6a, b and c respectively. The empirical approach is also plotted in Figure 6b and reasonable agreement with the analytical approach is apparent. Figure 6c demonstrates that the analytical approach is almost entirely dependent on beach slope (there is very little dependence on wave steepness). In contrast, the empirical approach does have a significant dependency on wave steepness based on the monochromatic wave data. The existence of a steepness influence in random waves is indirectly shown in the next section; however, a direct proof of this should be the topic of further study.

COMPARISON TO DATA ON WAVE CURRENT PREDICTION

In this section, examples of the influence of the transition zone width on the prediction of undertow and longshore currents under random waves using the empirical approach are presented. However, the first example relates to the measurement of mean cross-shore flows generated by monochromatic waves. The vertical distributions of mean flow for five locations across a laboratory profile (Case 5 of Nadoaka and Kondoh, 1982) are shown in Figure 7 along with the predicted extent of the transition zone width. Clearly, the measured distribution located between 2 and 3 m on the baseline - which is shoreward of the breakpoint and in the transition zone - bears more similarity to the seawardmost distribution (which relates to the mean flow under an unbroken wave) than to the shoreward breaking wave undertow distributions. This apparent lag between wave breaking and the generation of undertow has been noted on several occasions in the literature (i.e. Nadoaka and Kondoh, 1982 and Longuet-Higgins, 1983 among others). Within the transition zone, the forcing of the undertow due to the reduction in radiation stress is not yet realised; this demonstrates the importance of considering the influence of the transition zone shift on the prediction of mean return flow.

The predictions of undertow under random waves for two laboratory tests with and without the use of a revised Q_o are shown in Figures 8 and 9 (the data for these two

tests were given by Roelvink and Stive, 1989 and Sato et al, 1988 respectively). In both cases, the influence of the transition zone has a considerable effect on the predictions; the results with a revised Q_b provide a much better match to the measured data. Field measurements of the cross-shore distributions of undertow (along with the important recordings of profile shape and inshore wave climate) are generally unavailable, however, as a demonstration of a field case, the predicted undertow for the DUCK85 Case 5 example (corresponding to Figure 3) is compared to the measurements from two electromagnetic current meters in Figure 10. It is difficult to assess the validity of the predictions from this data, however, the exercise does reveal the importance of accounting for the transition zone shift in the predictions.

It has become abundantly clear that the distribution of undertow across the profile is a primary factor in the reshaping of beach profiles during erosion events (see Nairn, 1990a and Roelvink and Stive, 1989). A brief example of the influence of the transition zone shift on profile development is shown in Figure 11. This laboratory test corresponds to the undertow prediction given in Figure 8, the test duration was 12 hours. Again, the importance of considering the transition zone effect is revealed by a comparison of the predictions with and without the shift to the measured profile change. Specifically, the bar position is shifted too far seaward in the numerical model test without the transition zone influence (i.e. using the unrevised value for the fraction of broken waves, Q_b).

A field experiment to measure alongshore sand transport in the surfzone was conducted at the Field Research Facility of the Coastal Engineering Research Centre, U.S. Army Corps of Engineers at Duck, North Carolina (see Kraus et al, 1989). Eight tests were performed in September of 1985 as part of the DUCK85 programme using a series of portable sand traps deployed across the surfzone (the traps consisted of polyester sieve cloth streamers suspended on a rack). Two electromagnetic current meters were also deployed to monitor the cross-shore and longshore flow velocities in the surfzone. For a selected test, the cross-shore flows were presented in Figure 10 and the wave transformation prediction including the revised fraction of broken waves accounting for the transition zone influence were given in Figure 3. A demonstration of the effect of using the revised fraction of broken waves in the prediction of longshore currents for the same DUCK85 test is shown in Figure 12. The peak longshore current is reduced and predicted velocities in the outer part of the surfzone have been considerably diminished. The influence is large due to the low steepness of the incident wave ($H_{rms} = 0.31$ m, $T = 9.7$ s), indicating that a plunging breaker and a correspondingly large transition zone width would have existed. The predicted velocities compare well with the field measurements, however, the two isolated recordings are not sufficient to verify the transition zone phenomenon.

In the numerical model used for these investigations, both the longshore and cross-shore sediment transport rates are calculated using a modified version of the Energetics approach adapted for coastal sediment transport by Bowen (1980) and Ballard (1981) from the original formulation of Bagnold (1963) for sediment transport in rivers. Modifications to the cross-shore and alongshore components of this approach are given in Nairn (1990a) and Nairn (1990b) respectively. Simply stated, the Energetics approach is based on the concept that the wave action acts to support the sediment in bed and suspended load which is then advected by mean currents, orbital velocity asymmetry and gravity. Therefore, the distribution of the longshore current across the profile is a critically important element of the alongshore transport estimate. This is reflected in a comparison of the predicted (with and without the transition zone influence) and measured alongshore transport rates given for the selected test of the DUCK85 field

experiment in Figure 13. Clearly, this figure serves indirectly to confirm the extent of the transition zone influence on the generation of longshore currents.

DISCUSSION

The existence of a transition zone where wave decay and turbulent energy production occur unaccompanied by energy dissipation is clearly evident for monochromatic waves. The processes which are associated with the reduction in radiation stress (caused by the dissipation of wave energy) - including wave setup, undertow and longshore current - are initiated at the inner limit of the transition zone instead of at the breakpoint due to the lag between the production and the dissipation of wave energy from wave decay after breaking. The transparency of the problem in monochromatic wave situations allows for an empirical expression to be developed relating the dimensionless transition zone width (i.e. the depth at the inner limit of the transition zone divided by the depth at breaking) to the surf similarity parameter evaluated entirely with breakpoint parameters (see Equation 2). The dimensionless width is found to be greater for plunging breakers than for spilling breakers.

The clarity of this phenomenon is obscured for random waves since the width of the surfzone and the transition zone varies with each individual wave in the incident climate. However, if wave-wave interaction is ignored in the surfzone, it may be assumed that each individual wave behaves as a wave from a monochromatic wave train and the expression derived for transition zone width should be equally applicable to this situation. Neglecting wave-wave interaction is probably an acceptable assumption since the larger waves will have a celerity proportional to the depth based on the shallow water assumption and thus the possibility of one wave overtaking another is limited. Therefore, whilst the influence of the transition zone shift is less transparent in random wave surfzones, it is nonetheless very important to consider in the numerical prediction of the time-averaged values of wave setup, undertow and longshore current. With the aid of field and laboratory experiments it has been demonstrated that transition zone influence has a significant effect on the generation of time-averaged currents and the associated sediment transport (i.e. both alongshore and cross-shore).

Two techniques are presented for the description of the transition zone influence on random wave processes. The empirical approach has the benefit of responding to different incident wave conditions. However, the development of the analytical technique will ultimately allow for a better understanding of the physical phenomena.

Caution is advised in applying Equation 2 to situations of waves with very low steepness breaking on steep slopes - especially for surging and collapsing breakers (i.e. high values of the surf similarity parameter at breaking) - as there are indications that the transition zone width is over-estimated for these cases. More data on the monochromatic transition zone width is required to improve the reliability of Equation 2 in these instances. There is also a need to verify directly the transition zone influence in random waves through the analysis of a time series of simultaneous measurements of velocity, turbulence and water surface elevation.

CHAPTER 6

THE GROUP CHARACTERISTICS OF SEA WAVES

Yu-xiu Yu¹ and Shu-xue Liu²

Abstract -- A review concerning the methods of studying and describing wave groups is presented in this paper. After analysing 73 field records collected in Shijiu Port, China, the measured parameters of wave groups and some factors describing wave groupiness and their variations are given. Moreover, these results are compared with that of theory.

1. INTRODUCTION

It is found that the higher waves often appear in group in a continuous record. The existence of wave groups has been known to sailors for a long time, but the phenomena had not been studied systematically until the first year of 1970's. Many experiments have shown that the wave groups are not only more disastrous to the rubble mound breakwaters, the moored floating bodies and capsizing of ships, but also important for harbour resonance. Therefore wave groups received more attentions and they are studied by field experiments, simulation (physioal and numerioal) tests and theoretical analyses. In this paper, the existing methods for studying wave groups and some factors describing wave groupiness are summarized. Then, the 73 field records collected in Shijiu Port are analysed. Based on these analyses, the wave group parameters and the factors describing wave groupiness and their variations are investigated, and their results are used to examine the existing theoretical methods. It may be a good reference for theoretical study and engineering practice.

2. METHODS OF STUDYING WAVE GROUPS

2.1 Theory of wave envelope

The concept of wave group has been proposed in classical hydrodynamics. Wave groups can be formed by two trains of waves of the same height propagating in the

1. Prof., Department of Civil Engineering

Dalian University of Technology, Dalian, 116024, CHINA

2. Assistant Researcher, Department of Civil Engineering

Dalian University of Technology, Dalian, 116024, CHINA

same direction with slightly different frequencies. But the sea waves are considerably more complicated. Nolte (1972) and Ewing (1973) used the envelope theory proposed by Rice and Longuet-Higgins to study the sea wave groups and obtained many results. In Fig.1, the crest and trough envelope can be obtained by linking the top and bottom points respectively. Making a horizontal line at the specified level to cross the crest envelope, t_1 , t_2 etc. are obtained which are

Fig.1 Sketch of wave envelope

called the time durations of wave groups at ρ_0 level. One can also use the wave number Ω_1 included in a wave group to describe the time duration. In the case of narrow-band spectrum, the mean wave number of wave group expressed by the spectral moment can be derived using the envelope theory, i.e.,

$$\bar{\Omega}_1 = [\bar{m}_2 / (2\pi \bar{\mu}_2)]^{1/2} m_0^{1/2} / \rho_0 \quad (1)$$

where m_r is the r th moment of wave spectrum and μ_r is the r th central spectral moment.

$$\mu_r = \int_0^{\infty} (\omega - \bar{\omega})^r S(\omega) d\omega \quad (2)$$

where $\bar{\omega} = m_1 / m_0$

The mean wave number between two successive wave groups is defined as

$$\bar{\Omega}_2 = [\bar{m}_2 / (2\pi \bar{\mu}_2)]^{1/2} m_0^{1/2} / \rho_0 \cdot \exp[\rho_0^2 / (2m_0)] \quad (3)$$

2.2 Statistical theory of runs

Goda (1978) determined the wave heights by means of the zero-up-crossing method and defined successive waves whose heights exceed a specified threshold H_0 as a run. As shown in Fig.2, the threshold $H_0 = H_{1/3}$ and the first run contains 3 waves in a group ($j_1 = 3$). He also defined the wave number between two successive wave groups exceeding H_0 as the total run length j_2 . For example, $j_2 = 8$ in Fig.2. Assuming the change of successive wave height is stochastic and independent, and letting the occurrence probability of $H > H_0$ be denoted as p_0

and non-occurrence probability by $q_0 = 1 - p_0$, the mean run length and its standard

Fig. 2 Sketch of run

deviation can be obtained by the probability distribution method as

$$\bar{j}_1 = 1/q_0 \quad \sigma(j_1) = \sqrt{p_0/q_0} \quad (4)$$

$$\bar{j}_2 = 1/p_0 + 1/q_0 \quad \sigma(j_2) = \sqrt{p_0/q_0^2 + q_0/p_0^2} \quad (5)$$

In the case of $H_0 = H_{1/3}$, according to the Rayleigh distribution $p_0 = 0.1348$, $q_0 = 0.8652$, one can obtain that $\bar{j}_1 = 1.16$, $\sigma(j_1) = 0.42$ and $\bar{j}_2 = 8.57$, $\sigma(j_2) = 8.91$.

Goda pointed out that in the case of wide-band spectrum, the run length got by Eq. (1) is probably less than 1, which is irrationable. He tried to modify it and derived the relationship between the average number of wave in a wave group \bar{j}_1 and the mean length of the group \bar{L}_1 as follows

$$\bar{j}_1 = 1 / (1 - \exp(-1/\bar{L}_1)) \quad (6)$$

Goda used the spectral peakedness parameter Q_p to describe the spectral width, i.e.,

$$Q_p = 2/m\sigma^2 \int_0^{\infty} f \cdot s^2(f) \cdot df \quad (7)$$

He obtained that \bar{j}_1 increases with increasing Q_p from field data and numerical simulation. But the values of \bar{j}_1 from field data are very scattered and they are greater than that from Eq. (6) generally. It is because the successive wave heights in field are not independent. The average value of the correlation coefficients between successive waves heights is 0.324 (see Table 2) from our data.

Kimura (1980) gave the probability theory of wave run length by considering the correlation of wave heights. Assuming the distribution of wave height obey Rayleigh distribution, he derived the joint probability function, $p(H_1, H_2)$ of two successive wave heights (H_1 and H_2) as

$$p(H_1, H_2) = \frac{4H_1H_2 / [(1-4\rho^2)H_{rms}^4] \exp\{-(H_1^2+H_2^2)/[(1-4\rho^2)H_{rms}^2]\}}{I_0(4H_1H_2 / [(1-4\rho^2)H_{rms}^2])} \quad (8)$$

where H_{rms} is the root-mean-square value of wave heights, I_0 denotes the

modified Bessel function of zeroth order and ρ is a correlation parameter and can be defined as a function of the correlation coefficient $\gamma_{HH}(1)$ between H_1 and H_2 , i.e.,

$$\gamma_{HH}(1) = [E(2\rho) - (1-4\rho^2)K(2\rho)/2 - \pi/4] / (1-\pi/4) \quad (9)$$

where K and E are the complete elliptic integrals of first and second kinds respectively. $\gamma_{HH}(1)$ will be defined by the following Eq. (21).

Let the probability that neither H_1 nor H_2 exceeds the threshold H^* be denoted as p_{11} and that of H_1 and H_2 simultaneously exceed as p_{22} , i.e.,

$$\left. \begin{aligned} p_{11} &= \int_0^{H^*} \int_0^{H^*} p(H_1, H_2) dH_1 dH_2 / \int_0^{H^*} q(H_1) dH_1 \\ p_{22} &= \int_{H^*}^{\infty} \int_{H^*}^{\infty} p(H_1, H_2) dH_1 dH_2 / \int_{H^*}^{\infty} q(H_1) dH_1 \end{aligned} \right\} \quad (10)$$

where $q(H_1)$ is the wave height distribution which Rayleigh distribution can be used, i.e.,

$$q(H_1) = 2 \times H_1 / H_{rms}^2 \exp(-H_1^2 / H_{rms}^2) \quad (11)$$

Then the probability of the run with the length of j_1 can be given by

$$p(j_1) = p_{22}^{j_1 - 1} (1 - p_{22}) \quad (12)$$

The mean and the standard deviation of run length are

$$\bar{j}_1 = 1 / (1 - p_{22}) \quad \sigma(j_1) = \sqrt{p_{22} / (1 - p_{22})} \quad (13)$$

The probability of the total run length is

$$p(j_2) = \frac{(1 - p_{11})(1 - p_{22})}{(p_{11} - p_{22})} (p_1^{j_2 - 1} - p_{22}^{j_2 - 1}) \quad (14)$$

The mean and the standard deviation of total run length are

$$\left. \begin{aligned} \bar{j}_2 &= 1 / (1 - p_{11}) + 1 / (1 - p_{22}) \\ \sigma(j_2) &= [1 / (1 - p_{11})^2 + 1 / (1 - p_{22})^2 + 1 / (1 - p_{11}) + 1 / (1 - p_{22})]^{1/2} \end{aligned} \right\} \quad (15)$$

The agreement between Kimura's theoretical results and \bar{j}_1, \bar{j}_2 obtained from field swell record ($\gamma_{HH}(1) = 0.881$) is quite good.

2.3 Wave energy history method

Because the wave energy is directly proportional to the variance of the wave record, the energy at the crest of a crest envelope is greater than that at its trough (Fig. 1). The wave groups can be described effectively by the wave energy history. Funke and Mansard (1979) and Nelson (1980) proposed some similar methods. Here, Funke's method is illustrated.

Calculate the mean square of the wave surface elevation within a time duration (time window) T_p and define it as the instantaneous wave energy $E(t)$ at

the middle time t of T_p .

$$E(t) = 1/T_p \int_{\tau = -T_p/2}^{T_p/2} \eta^2(t+\tau) d\tau$$

It can be rewritten as follows after smoothing above $E(t)$.

$$E(t) = 1/T_p \int_{\tau = -T_p}^{T_p} \eta^2(t+\tau) Q_1(\tau) d\tau \quad (16)$$

$T_p \ll t \ll T_n - T_p$

where T_p is the wave period at the spectral peak, T_n the total length of wave record and $Q_1(\tau)$ the smoothing function. A superior smoothing function is the Bartlett window which is given as

$$Q_1(\tau) = 1 - |\tau|/T_p \quad -T_p \leq \tau \leq T_p \quad (17)$$

$= 0 \quad \text{others}$

$E(t)$ defined by Eq.(16) is called smoothed instantaneous wave energy history (SIWEH) and can describe the extent of wave groupiness (Funke and Mansard, 1980, Yu, 1986) effectively (Fig.3). Let $\xi(f)$ denotes the spectral density of SIWEH, i.e.,

$$\xi(f) = 2/T_n \left| \int_0^{T_n} [E(t) - \bar{E}] \exp(i\omega t) dt \right|^2 \quad (18)$$

$$\bar{E} = 1/T_n \int_0^{T_n} E(t) dt = \int_0^{\infty} S_{\eta\eta}(\omega) d\omega = m_0 \quad (19)$$

Funke and Mansard used the groupiness factor GF to describe the extent of wave groupiness, i.e.,

$$GF = \sqrt{1/T_n \int_0^{T_n} [E(t) - \bar{E}]^2 dt} / \bar{E} = \sqrt{m_{E,0}} / m_0 \quad (20)$$

where $m_{E,0}$ and m_0 are the zeroth order moments of SIWEH spectrum and the wave spectrum respectively. The field data of wind waves from the Sea of Japan during a period of six months gave the value of GF in the range of 0.48 and 0.94. From our data, GF changes from 0.38 to 0.93.

Rye (1982) also studied the wave groups by the correlation function.

3. WAVE GROUPINESS FACTORS

The parameters mentioned above such as the number of wave l_1 in a wave group whose heights exceed the specified threshold H_c (or run length j_1) and the number of waves l_2 between two wave groups in succession (or total run length j_2) and so on., are insufficient to represent the wave groupiness. So some factors have been proposed to describe the wave groupiness. In this paper, the following five factors will be studied.

(a) August, 24 1984 11:00 GF=0.914

(b) August, 19 1984 20:00 GF=0.482

Fig.3 Examples of measured SIWEH

(1). Correlation coefficient between succeeding wave heights $\gamma_{HH}(1)$

$$\gamma_{HH}(1) = \frac{1}{\gamma_{HH}(0)(N-1)} \sum_{i=1}^{N-1} (H_i - \bar{H})(H_{i+1} - \bar{H}) \quad (21)$$

$$\gamma_{HH}(0) = \frac{1}{N} \sum_{i=1}^N (H_i - \bar{H})^2$$

where \bar{H} is the average wave height determined by zero-up-crossing method. Larger $\gamma_{HH}(1)$ means that high wave follows high wave. Rye computed $\gamma_{HH}(1)$ for 60 wave records from the North Sea and the average value of $\gamma_{HH}(1)$ was 0.24. Su reported that it was 0.329 for 6 records of wind waves from the Mexico Bay. For swell, $\gamma_{HH}(1)$ is up to 0.68.

(2). Correlation coefficient between succeeding wave periods $\gamma_{TT}(1)$.

$\gamma_{TT}(1)$ is defined in the same way as $\gamma_{HH}(1)$ by replacing H_i and \bar{H} with T_i and \bar{T} respectively. Existing observed results show that $\gamma_{TT}(1)$ varied between 0 and 0.5.

(3). Correlation coefficient γ_{HT} between the wave height and the period.

$$\gamma_{HT} = \frac{1}{N\sigma_H\sigma_T} \sum_{i=1}^N (H_i - \bar{H})(T_i - \bar{T}) \quad (22)$$

where σ_H and σ_T are the standard deviations of wave height and wave periods respectively. γ_{HT} is generally greater than zero.

(4). Wave groupiness factor GF

It has been defined by equatin (20).

(5). Another parameter representing wave groupiness \bar{T}_{SIVEH}

$$\bar{T}_{SIVEH} = \frac{1}{T_p N_g} \sum_{j=1}^{N_g} (T_{SIVEH})_j \quad (23)$$

where \bar{T}_{SIVEH} is the zero-up-crossing period of the time trace of $[E(t) - \bar{E}]$. \bar{T}_{SIVEH} is the average of T_{SIVEH} normalized to peak period of wave spectrum and can represent the wave number in one group approximately.

4. THE CHARACTERISTICS OF THE WAVE GROUPS IN SHIJIU PORT

4.1 General description of field data

During September to November, 1984, a ENDECO 949 recording buoy made in U.S.A. was installed in Shijiu Port, Shandong Province, China, at 14.8m of water depth (d) by the First Design Institute of Navigation Engineering, Ministry of Communications. Wave data were collected for about 17 minutes every three hours. The sampling of record was done at the interval of 0.5 second and the data length was 2048 points in every record. In this paper, only 73 records whose signifoant wave heights are greater than 0.6m are analysed. The average wave heights are in the range of 0.42 and 1.34m, the maximum wave heights of 1.10 and 3.99m, and the average wave periods of 3.444 and 6.04 second. The wave number in one train varies from 167 to 296. \bar{H}/d is equal to 0.03~0.09. So the field situation is basically close to deep water. The wave spectra showed that

some records are of mixed wave with wind wave and swell, but most are wind waves only.

4.2 Parameters of sea wave groups

Letting the threshold height H_c equal to $H_{1/3}$, the statistical analyses are conducted for every record and the average number of waves \bar{N}_1 in a group (i.e., the mean run length \bar{J}_1) and the average number of waves \bar{N}_2 (i.e., the mean total run length \bar{J}_2) between two successive wave groups are listed in Table.1. The results obtained from the theoretical methods are also given in the Table. It is shown by comparing these results that the values from the wave envelope theory, Eq.(1) and Eq.(3), are evidently smaller than measured results, the values calculated by the statistical theory, Eq.(4) and Eq.(5), are also on the small side and \bar{J}_1 obtained from Eq.(6) is smaller yet. The average values of the Kimura's results \bar{J}_1 , \bar{J}_2 are quite close to the observed values, but the calculated distribution are more concentrated.

Table.1 Observed and theoretical parameters of wave group

Theory	Parameter	the ranges	means	deviations
observed	\bar{J}_1	1.15~2.07	1.47	0.18
	\bar{J}_2	7.25~14.90	10.77	1.75
wave envelope theory	\bar{N}_1	0.40~0.52	0.45	0.03
	\bar{N}_2	1.44~3.05	2.33	0.37
theory of runs	\bar{J}_1	-----	1.16	0.42
	\bar{J}_2	-----	8.57	6.91
Eq.(6)	\bar{J}_1	1.09~1.17	1.12	0.02
Kimura's theory	\bar{J}_1	1.26~1.73	1.51	0.12
	\bar{J}_2	8.47~12.69	10.22	0.92

The relationships between \bar{J}_1 , \bar{J}_2 and Q_p are more scattered than that between \bar{J}_1 , \bar{J}_2 and GF (Fig.4), \bar{J}_1 and \bar{J}_2 increase with the increase of GF generally.

4.3 Factors of wave groupiness

The factors of wave groupiness are analysed by above equations for 73 records, and their results are listed in Table.2. The spectral peakednesses Q_p determined by equation (7) are also given in Table.2. The Table shows that some values of $\mathcal{Y}_{TT}(1)$ are negative, but are positive mostly. It means that there are "memory" effect between successive wave heights and periods, which causes the wave grouping phenomena.

Fig.4 Relationships between \bar{J}_1 , \bar{J}_2 and GF

Table.2 Observed wave groupiness factors and the spectral peakedness

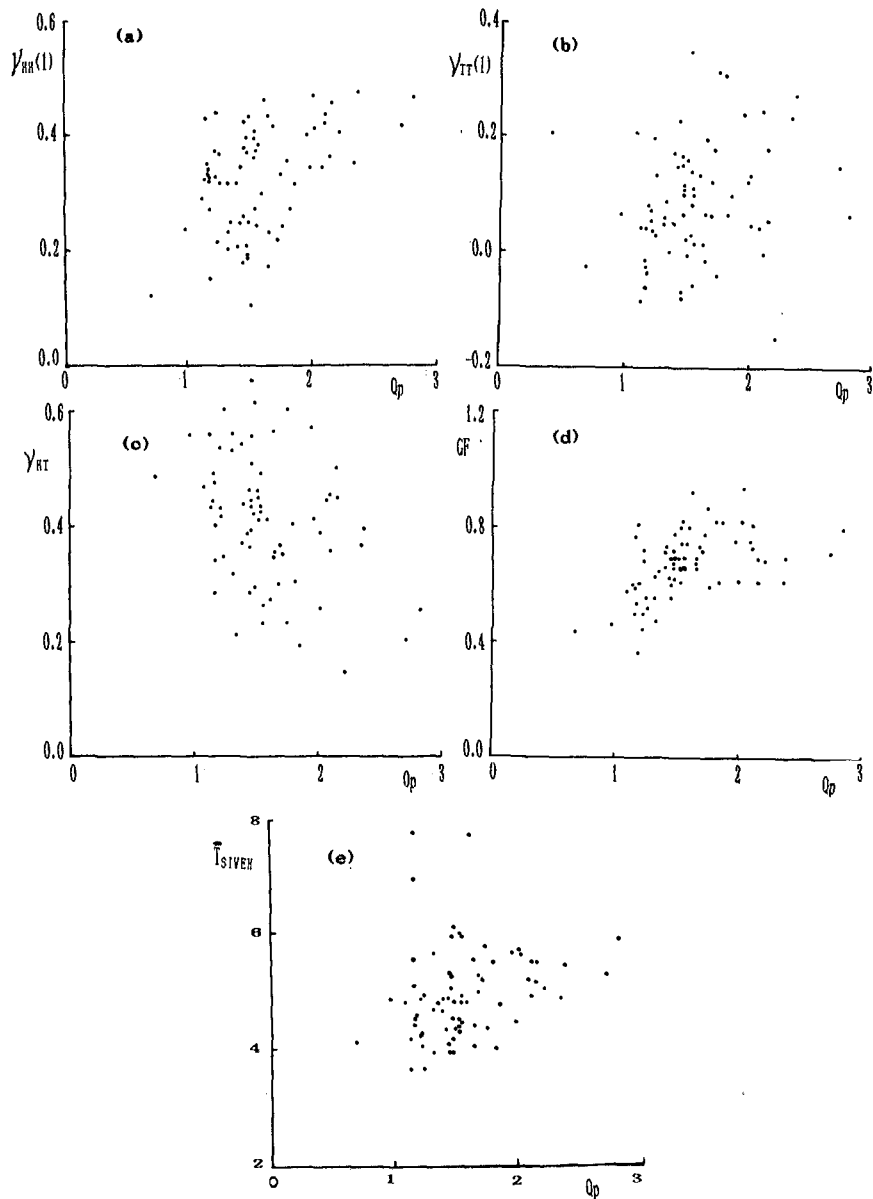

factors	$\gamma_{HH}(1)$	$\gamma_{TT}(1)$	γ_{HT}	GF	\bar{T}_{SIVEH}	Q_p
ranges	0.103~ 0.472	-0.149~ 0.348	0.147~ 0.652	0.360~ 0.932	3.661~ 7.778	0.704~ 2.821
average	0.324	0.085	0.413	0.673	4.953	1.597
deviations	0.093	0.100	0.110	0.113	0.801	0.393

4.4 Relationships between the wave groupiness factors and the spectral width parameter

Many scientists pointed out that the wave groupiness is directly correlated to the width of its spectrum, i.e., the narrower the spectrum is, the more strong of groupiness the wave is. Scientists used to judge the width of the spectrum by the width parameter ϵ . But Rye's work showed that the parameter ϵ is not able to express the spectral width definitely and it also varies significantly with the choice of the high cut-off frequency. However, Q_p defined by Eq.(7) is more stable and reliable than ϵ . So the relationships between the five previously defined wave groupiness factors and the spectral peakedness parameter Q_p are given in Fig.5 according to the field data. In general, $\gamma_{HH}(1)$, GF and \bar{T}_{SIVEH} increase while γ_{HT} decreases as Q_p increases although the points are scattering. But $\gamma_{TT}(1)$ is not evidently correlated to Q_p . It proves that the wave groupiness is strengthened as the spectrum becomes narrower. But the effect of Q_p on the wave groupiness gradually becomes weaker as Q_p increases.

However, Van Vliedder and Battjes (1990) pointed out that Q_p can be affected by the smoothing method and the number of smoothing when estimating the spectrum and suggested a parameter K to express the spectral width, i.e.,

$$K = \int_0^{\infty} s(f) \exp(2\pi ifT_{02}) df / m_0 \tag{24}$$

Fig.5 Relationships between wave groupiness factors and Q_p

where T_{02} is the mean period calculated using the spectral moments. But the correlation function method is used to estimate the spectrum and the spectrum was smoothed by Hamming window once in this paper. The relationships between Q_p , GF and K are given in Fig.6. It is shown that Q_p and K can give similar results in our case and both Q_p and K can be the spectral width parameters for wave group characteristics.

Fig.6 Relationships between Q_p , GF and K

4.5 Relationships between wave groupiness factors and GF

The relationships between $\gamma_{HH}(1)$, $\gamma_{TT}(1)$, γ_{HT} , \bar{T}_{SIVEH} and GF are given in Fig.7. All factors are evidently correlated to GF except $\gamma_{TT}(1)$. It means that GF is the main factor for representing the wave groupiness.

5. CONCLUSIONS

(1). At present, there are several methods for studying the wave group phenomenon. The results of analysis from the field data in this paper indicate once again that the wave envelope theory is not available because its results are far less than the field values. The results obtained from the statistical theory of runs are also smaller. Kimura's probability theory of run length based on the correlated wave heights can give the average values of the wave group parameters which agree with the field values quite well, but the distribution of calculated values are more concentrated than that in field.

(2). There are close relationships between the wave groupiness and the spectral peakedness (or width), i.e., the groupiness is strengthened as the spectrum becomes narrower. Most of the factors representing the wave groupiness are correlated to the spectral peakedness Q_p to some extent, $\gamma_{HH}(1)$, GF , and \bar{T}_{SIVEH} increase and γ_{HT} decreases with the increase of Q_p . K is also a spectral width parameter for wave group characteristics.

(3). Among the factors describing the wave groupiness, the wave groupiness

factor GF defined by Eq.(20) is the principal parameter. The other factors are correlated to GF to some extent except $\gamma_{TT}(1)$ which is not available. The

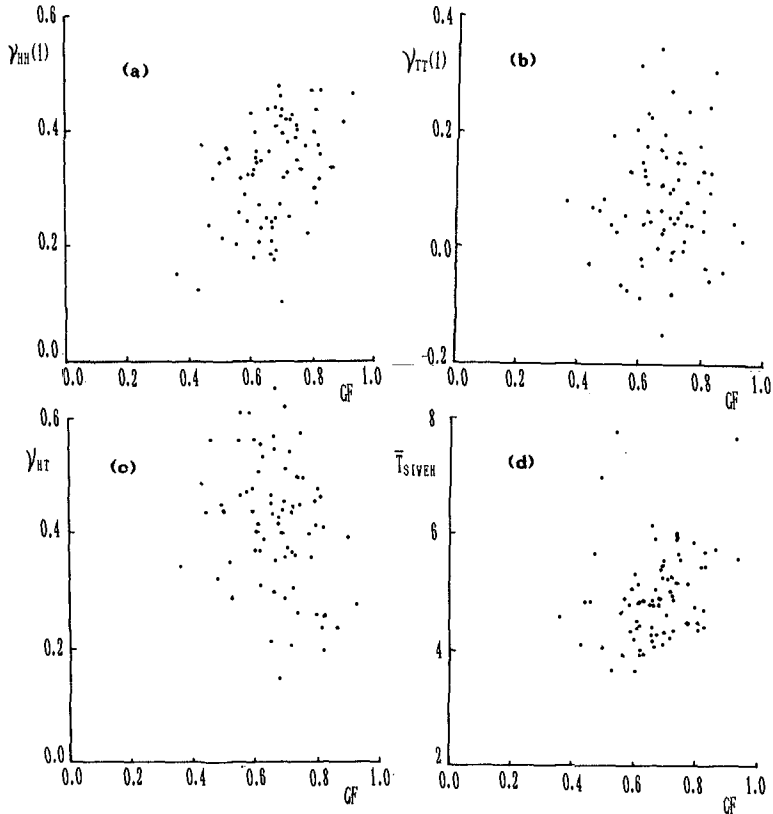

Fig.7 Relationships between wave groupiness factors and GF

mean length of runs (the mean length of wave group) and the mean total length of run (the average number of waves between successive groups) also increases with the increase of GF .

ACKNOWLEDGMENT

The authors wish to express their heartfelt gratitude to the First Design Institute of Navigation Engineering, Ministry of Communications, for offering gratis the field wave records in Shijiu Port and Mr. Minquan Gu, Chief Engineer of the Institute for his valuable suggestions. Also, the gratitude is owed to prof. Dacuo Zhang and Mr. Weitao Tai, both of Qingdao Oceanographic University and Mr. Muguo Li and Mr. Ningchuan Zhang, both of Dalian University of Technology for their great help during data processing.

CHAPTER 7

Field Observation on Wave Set-up near the Shoreline

Shin-ichi YANAGISHIMA¹ and Kazumasa KATOH²

Abstract

To understand the actual condition of the abnormal rise of sea water on the beach in a storm, the field observation has been carried out at Hazaki Oceanographical Research Facility for about one year under the comprehensive conditions. The relation between the sea level rising and the external forces such as waves, deviations of atmospheric pressure and the winds are examined. The contribution of the wave set-up on the sea level rising is large, while those of the atmospheric pressure and the wind are small. The observed wave set-up near the shoreline agrees well with the predicted value by the Goda's theory. There are other factors which slightly affect the sea level changing, that is to say, a time lag behind the storm, the ocean currents, and the wave steepness.

1. Introduction

Since the sea level rising near the shoreline is considered to be strongly related to the beach erosion in a storm, it is important for predicting the changes of beach and for developing more reliable shore protection technique to estimate the precise result of sea level rising in the field.

The incident wave raises the sea level in the surf zone, that is the wave set-up. The mechanism of wave set-up has been already theoretically explained by introducing the concept of radiation stress (Longuet-Higgins and Stewart, 1962). It has been experimentally proved in the laboratory, for example by Bowen, Inman and Simmons(1968). The wave set-up on the complicated beach topography could

¹Littoral Drift Lab., Port and Harbour Research Institute, Nagase 3-1-1, Yokosuka, Kanagawa, Japan

²Chief of Littoral Drift Lab., Port and Harbour Research Institute

be also calculated by using a electric computer. So far, several fields observation on the wave set-up have been done (eg., Hansen, 1978; Holman, 1986). They were, however, not sufficient to verify the predicted wave set-up by these method.

On the actual beach, in addition to the wave set-up, the wind and the depression of atmospheric pressure have also the effects on sea level rising in a storm.

In this study, the field observation has been carried out at Hazaki Oceanographical Research Facility (HORF) for about one year to understand the actual sea level rising near the shoreline and to examine the theory of wave set-up by using the field data.

2. Field Observation

The site of the field observation is a entirely natural sandy beach, being exposed to the full wave energy of the Pacific Ocean, and is classified as micro tidal beach with the tide range of about 1.4 meters (see Figure 1). On this beach, Port and Harbour Research Institute, Ministry of Transport, has constructed the Hazaki Oceanographical Research Facility (HORF) in 1986 for carrying out the field observation in the surf zone even under sever sea conditions. The research pier is a 427 meters long concrete structure. It is supported by 0.8 meter diameter concrete-filled steel piles in a single line, at 15 meters interval. The pier deck is 2.5 meters wide and 7 meters above L.W.L. In this facility, the field observation on the wave set-up had been carried out near the shoreline for about one year from 14 January to 2 December in 1987.

In Figure 2, although many instruments are permanently installed along the research pier, only the locations of

Figure 1 Site of field observation

Figure 2 Locations of instruments

instruments used in this study are shown.

In order to measure the mean sea level at the shoreline with a good precision, it is necessary to measure the wave run-up and down on the beach by the tedious technique such as taking pictures by using 16 mm motion-picture camera (Holman, 1986). It is, however, very difficult to measure the mean sea level by this method for a long time, which will be the main cause of losing the chance to measure the most desirable situation in a storm. Furthermore, this method will take much time to analyze the many films. Then, an ultrasonic wave gauge was installed to the pier deck at the reference point +22m (see Figure 2 and 3). The latitude of installation was 6 meters above the mean water level. The mean grand level at the observation point was 0.3 meter above the datum line. The mean water depth was about 0.4 meter in M.W.L. Since the observation point was fixed, its relative position from the shoreline changed with time due to the change of tide level. The measurement had been done during 20 minutes of every two hours with the sampling interval of 0.3 second.

The wind direction and velocity was measured at the tip of research pier by using the two-component type ultrasonic anemometer. The installed latitude of anemometer was 10 meters above the mean water level. The atmospheric pressure was measured in the laboratory by using a barometer. These measurements had been also carried out every two hours.

The measurements described above were automatically controlled by using a mini-computer in the laboratory at the base of research pier.

The offshore waves have been measured at the mean water depth of 23.4 meters near the Kashima Port (see Figure 1). This measurement

Figure 3 Ultrasonic wave gauge

has been also done during 20 minutes of every two hours.

The beach profile along the research pier was surveyed with a lead from the pier deck. The profile of the backshore and the foreshore was surveyed by using a surveyor's staff and a transit. The cross-shore interval of these measurements was 5 meters. The measurements had been done, once a day except on Sunday and on the national holiday, by the researchers stayed in the HORF. The mean profile during the observation which is calculated with these data is shown in Figure 2.

3. General conditions during Observation

Photo. 1 is the side view of HORF which was taken under a calm condition when we could easily come out from the HORF on foot on the beach. On the other hand, Photo. 2 was taken in a storm wave condition. The facility was isolated since the sea level rose and also the long period wave became larger near the shoreline. In connection with the long period waves in this area, Katoh and Yanagishima(1990) examined the berm erosion in the storm.

Data set of 1305 obtained in these measurements are utilized in analyses. In this chapter, based on these data, the general conditions of sea and whether during the observation are described.

Figure 4 shows the frequency distribution of offshore wave heights which distribute in the range from 0.4 meter to 6.4 meters. The highest frequency is in the rank of 1 to 1.5 meters. There are 91 sets of data containing the storm waves, in which the wave heights are greater than 3.0 meters. Figure 5 is the frequency distribution of the

Photo. 1 HORF (Calm condition)

Figure 4 Frequency of off-shore wave height

Figure 5 Frequency of period

Figure 6 Frequency of steepness

Figure 7 Frequency of wind

Figure 8 Frequency of atmospheric pressure

Figure 9 frequency of water depth

offshore significant wave periods during about one year observation. The periods distribute in the wide range from 3.9 seconds to 13.5 seconds, being about 7.6 seconds in average.

Figure 6 shows the combined distribution of significant wave heights and periods, that is, the wave steepness. The high waves greater than 2 meters have two modes at about 0.015 and 0.032 in the steepness. The former is corresponding to the swells, and the latter is to the wind waves.

Figure 7 shows the wind rose by distinguishing the rank of wind velocities which range from 0.6 to 19.8 m/s. The symbol θ in this figure is a wind direction defined in the later analysis.

Figure 8 is a frequency distribution of atmospheric pressures which range from 987 to 1030 mb, being about 1010 mb in average. On the upper abscissa, the deviation of atmospheric pressures from 1013 mb is also shown.

Figure 9 is the frequency distribution of non-dimensional water depth at the observation point. The mode for all data is at about 0.2 to 0.5, while it is at about 0.1 to 0.2 for the offshore waves greater than 2 meters.

As we have seen so far, the field observation of sea level rising near the shoreline had been carried out under the comprehensive sea and whether conditions.

4. Data Analyses on Wave Set-up

The mean sea water level near the shoreline was estimated by calculating the mean value of the wave profile data measured at the reference point +22m. The mean water depth during the each measurement period of 20 minutes can be estimated with the daily beach profile data. The case that the mean water depth is less than 50 cm has never been included in the total number of available data sets of 1305, since the bottom at the observation point occasionally emerged when the swash run down in this situation.

In order to evaluate the rate of sea level rising, it is

Figure 10 Comparison of astronomical tide level with mean sea level at a tip of pier

Figure 11 Relation between still water level and measured water level

necessary to know the still water level. In the laboratory, it is easy to measure it by stopping the wave generator. It is, however, impossible to control the wave characteristics in the field. One method to estimate the still water level is to measure the offshore sea level where there is no wave set-up due to the waves. There was, however, no facility to measure it in the offshore. The mean water level measured at the tip of research pier is not considered as the still water level, because the research pier is located entirely inside the surf zone when the large waves came to the site. Then, the astronomical tide levels at the site were calculated by composing 40 tidal constituents which is the result of harmonic analysis with the tide data obtained in the Kashima Port, to consider it as the still water level.

Figure 10 is the comparison of the predicted astronomical tide level on an abscissa with the mean sea level measured at the tip of research pier on an ordinate. In this comparison, only the cases which satisfy the following conditions simultaneously are plotted, that is to say; the significant wave height was less than 1 meter, under which the tip of pier was located far offshore from the surf zone; the absolute deviation of atmospheric pressure was less than 5 mb; the wind velocity was less than 3 m/s. There is a good agreement between them in Figure 10 which encourage us to consider the predicted tide level as the still water level.

In Figure 11, the measured mean sea levels near the shoreline are plotted on an ordinate against the predicted still water level on an abscissa for 1305 cases. Almost all of the measured sea levels are higher than the still

levels. In short, there were usually some amount of sea level rising.

Figure 12 shows the changes of offshore wave heights, atmospheric pressures, wind velocities and the sea levels in the storm due to the typhoon in september, 1987. In the lowest figure, the solid line is the predicted still water level and the plotted data are the measured mean sea levels. When the measured sea level was maximum, being about 80 cm higher than the still water level, the offshore wave height was maximum; the atmospheric pressure was minimum; and the wind velocity was maximum. That is to say, the sea level rising depends on not only the incident waves but also the deviation of atmospheric pressure and the wind velocity. Therefore, to examine the wave set-up with the field data, we must take these factors into account at the same time in the analysis as follow;

Figure 12 Sea level rising due to typhoon in 1987

$$\eta = f_1(\text{wave}) + f_2(\text{atmo. pressure}) + f_3(\text{wind}). \quad (1)$$

Concerning to the wave set-up due to the incident waves, the theoretical treatments had been developed since Longuet-Higgins and Stewart (1962) introduced the concept of radiation stress. In the early stage, the rate of wave set-up was expressed by only the wave height. In contrast to this, Goda(1975) theoretically investigated the effects of the beach slope and the offshore wave steepness on the wave set-up, based on his model of the random wave deformation in the surf zone.

Figure 13 shows the Goda's theory on the wave set-up for the sea bottom slopes of 1/50 and 1/100, by taking the non-dimensional wave set-up at the shoreline normalized by the offshore wave height on an ordinate and the offshore wave steepness on an abscissa. To introduce his theory into the

Figure 13 Goda's theory on wave set-up

analyses, let's inspect the natural conditions. The mean sea bottom slope at the observation site is about 1/60 as shown in Figure 2. The value of wave steepness distributes in the range from 0.005 to 0.047 for all wave data, and in the range from 0.01 to 0.047 for the waves greater than 2 meters in height as shown in Figure 6. Therefore, in this scope of conditions, the Goda's theory can be approximated by the straight line in the Figure 13. Taking only the inclination of this line into account, we have

$$f_1(\text{wave})/Ho' = a (Ho'/Lo)^{-0.2}, \quad (2)$$

where a is a coefficient, Ho' and Lo are the offshore wave height and wave length respectively.

As the deviation of atmospheric pressure, ΔP , induces the statistical rising of sea level, let's assume the following proportional relation between them;

$$f_2(\text{atmo. pressure}) = b \Delta P, \quad (3)$$

where b is a coefficient.

Since the shear stress exerted by wind on sea surface is proportional to the square of wind velocity, the relation

$$f_3(\text{wind}) = c U^2 \cos \theta \quad (4)$$

is usually assumed, where c is a coefficient, U is the wind velocity at the altitude of 10 meters above the sea surface, and θ is the wind direction (see Figure 7).

By substituting Eqs.(2), (3), and (4) into Eq.(1) and adding one more coefficient C , we have

$$\eta = a(Ho'^2 Lo^{1/2})^{0.4} + b \Delta P + c U^2 \cos \theta + C. \quad (5)$$

The physical units of the term in Eq.(5) follow the general customs, that is, cm for η , mb for ΔP , m/s for U , and m for Ho' and Lo .

Using the multiple regression analysis with 1305 sets of data, we decided the values of four coefficients as follows;

$$a=5.20(\text{cm/m}), b=0.69(\text{cm/mb}), c=0.04(\text{cm/m}^2/\text{s}^2), C=-4.85(\text{cm}). \quad (6)$$

By using Eq.(5) with the coefficients in Eq.(6), the total sea level risings have been calculated for 1305 cases. Furthermore, to have mean sea level, the predicted still water level (astronomical tide level) has been added to every total sea level rising. Figure 14 is a comparison of the measured sea level with the calculated one, by taking the abscissa for the calculated values. There is a close agreement between measured and calculated values, excepting that the measured sea levels are slightly higher than calculated one when the sea levels are low.

Figure 14 Comparison of measured sea level with calculated one

Figure 15 Comparison of Eq.(8) with Goda's theory

The exception is due to the reason that the observation point was shifted relatively to the onshore-side when the sea level was low, which induced the higher rate of wave set-up.

Now we have the empirical relation between the wave set-up and the wave characteristics, that is,

$$\eta_{\text{wave}} = 0.052(Ho'^2Lo^{1/2})^{0.4}, \tag{7}$$

or

$$\eta_{\text{wave}}/Ho' = 0.052(Ho'/Lo)^{-0.2}, \tag{8}$$

where η_{wave} is the rate of wave set-up near the shoreline. Please pay attention to the physical unit in these expression, that is to say, in meter.

Let's compare Eq.(8) with the Goda's theory in Figure 15. The solid straight line is Eq.(8). The three curved lines are the Goda's theory for the wave set-up rate at the non-dimensional water depth of 0.02, 0.1 and 0.2 respectively on the beach sloping of 1/60. In the storm, the range of non-dimensional water depth at the observation point was from 0.1 to 0.2 as shown in Figure 10, and the wave steepness distributes in the range from 0.01 to 0.047 as shown in Figure 6. Considering these conditions, there is a well agreement between Eq.(8) and the Goda's theory.

The interesting modification can be done by substituting the energy flux of incident wave in the offshore,

$$E_i = (\omega\rho)(g/2\pi)^{1/2}Ho'^2Lo^{1/2}, \tag{9}$$

into Eq.(7), where E_i is the wave energy flux and ω is the density of sea water. In short, the rate of wave set-up near the shoreline can be expressed with the incident

wave energy flux,

$$\eta_{\text{wave}} = 0.14 E_f. \quad (10)$$

Based on the empirical relation obtained, the contribution of each factor on the sea level rising has been estimated for 1305 cases and shown in Figure 16. For example, the level rising of about 80 cm occurred in eleven cases, in which the averaged wave set-up rate is 57 cm, the level rising due to the wind is about 9 cm, and that due to the atmospheric pressure is about 14 cm. According to this figure, the contribution of the wave set-up is predominant, which occupies about 75% portion of the total sea level rising.

5. Contribution of Other Factors on Sea Level Rising

So far, to explain the sea level rising, the waves, the atmospheric pressures, and the winds have been considered as the external forces in the regression analysis. As the result, the real sea level rising have been practically explained by these three factors as shown in Figure 14. There are, however, a little scatter in the plotted data in Figure 14, which may be due to not only the errors in measurements but also the other factors we did not considered. Figure 17 shows the difference between the measured sea levels and the calculated ones in a time series. If the measured and the calculated ones agree precisely, the data should lie in a zero line. The plotted

Figure 16 Contribution of wave on wave set-up

Figure 17 Difference between the mesured sea levels and calculated ones in a time series

data, however, scatter around the line. According to this figure, three items can be pointed out.

First, the data are scattered in a belt of about 15 cm in width. Although the observation point was fixed, the distance from the shoreline to the observation point changed with time since the shoreline position changed with the tide level, yielding the change of wave set-up rate. The tidal range in the site is about 1.4 meters, which introduces the fluctuation of about 13 cm in the wave set-up rate, according to the Goda's theory (see, Katoh et al., 1989). Therefore, it is considered that the data scattering in the belt is mainly due to the change of tide level.

Secondly, there is a large difference between the measured sea levels and the calculated ones, which is denoted by an arrow in Figure 17. In order to investigate the cause of it, it is necessary to inspect more precise data during these days. Figure 18 shows the changes of offshore wave height, wave period, and the measured and the calculated sea level rising during the corresponding days. The measured and the calculated rising change in the similar manner. There is, however, the time lag between them. That is to say, the change of actual sea level rising is 2 to 3 hours behind the calculated one in both the development and decrement of incident waves during the storm, which introduces the large difference on the day denoted by the arrow in Figure 17.

Thirdly, the belt, in which the plotted data are scattered, fluctuates with a period of about one month. To investigate this cause, the ocean currents must be considered since two ocean currents from the north (Oyashio) and from the south (Kuroshio) come across in the offshore area just in front of the observation site. When the Oyashio, the southerly ocean current, is relatively stronger as shown in Figure 19, the Corioli's force due to this current should raise the sea level near the coast. Then, we have inspected the weekly averaged patterns of these currents which are issued by Ibaraki Prefectural Fisheries Experimental Station every week (Figure 19 is an example). The strength of southerly ocean currents have been decided and shown in the lower in Figure

Figure 18 Time lag between measured set-up and calculated one

17. During the period when the southerly ocean current was strong, the measured sea levels were higher than the predicted ones, and vice versa. Then, it can be said that the long period fluctuation of the difference between the measured sea levels and the predicted ones are due to the changes of the Corioli's force which depends on the strength of southerly ocean current.

Next, the dependency of wave set-up on the offshore wave steepness will be examined. According to the Goda's theory, the wave set-up depends also on the offshore wave steepness. In order to confirm this dependency, we had selected the data which satisfy the following three criteria at the same time.

- (a) The offshore significant wave height is greater than 2 meters.
- (b) The non-dimensional water depth, h/H_0' , is less than 0.2, which is a condition to select the data measured close to the shoreline.
- (c) The absolute difference between the measured sea level and the predicted one is less than 5 cm, which is a condition to omit the data containing the unknown effects in it.

Figure 20 shows the comparison of the selected data with

Figure 20 Effect of wave steepness on wave set-up

Figure 19 Pattern of ocean currents

the Goda's theory which is the straight line in the figure. The rate of wave set-up weakly depends on the offshore wave steepness. The non-dimensional wave set-up becomes to be slightly larger with decreasing of the wave steepness.

The dependency of wave set-up on the incident wave angle to the beach have not been examined, since the wave direction had not been measured.

6. Conclusions

The conclusions obtained in this study are as follows:

- (1) The wave set-up measured near the shoreline in the field strongly supports the Goda's theory.
- (2) The rate of wave set-up, which becomes to be larger with decreasing of the wave steepness, can be expressed with the incident wave energy in stead of wave height.
- (3) In total sea level rising, the contribution of the wave set-up is large, which occupies about 75% portion, while those of depression of atmospheric pressure and the winds are small.
- (4) There are other factors which slightly affect the sea level changing as follows:
 - a. The actual sea level rising (or changing) is 2 to 3 hours behind the development and decrement of incident waves during the storm.
 - b. The strength of ocean current velocity in Oyashio in the offshore area induces the sea level changing with the period of about one month.

CHAPTER 8

Modelling Shoaling Directional Wave Spectra in Shallow Water

James T. Kirby¹

Abstract

This paper describes the development of a model for the shoaling and refraction of an incident directional spectrum over beach topography. The present model is limited to topography which varies only in the on- offshore direction, but no restriction is made on allowed angles of incidence with respect to the shore-normal direction. The model is verified in comparison to laboratory data for Mach reflection of cnoidal waves from a vertical plane wall. It is shown that the model provides a more accurate representation of the evolving wave field than does an earlier parabolic approximation, using the same laboratory data.

Introduction

As ocean surface waves propagate towards shore, they pass through a shoaling zone prior to breaking in which nonlinear interactions become strong and can significantly modify the wave train. This zone is characterized by weak frequency dispersion, since waves become relatively long compared to local water depth. In addition, the weak dependence on wavelength in the wave phase speed leads to the occurrence of strong nonlinear interactions at second-order in wave height. The combined effects of weak dispersion and nonlinearity may be modelled by the Boussinesq equations, which serve as a reasonably accurate general purpose model for the domain in question as long as waves do not become too high.

Since the area being studied here can be quite extensive in comparison to the characteristic wavelength of the waves being modelled, the choice of an efficient numerical solution technique is crucial. The Boussinesq equations may be successfully solved by time-stepping techniques, but these methods are too inefficient for the spatial and temporal spans being considered in applications to an open coastal zone. Instead, various prior studies have found that it is efficient to decompose the time-dependent wave train into a stack of frequency components by Fourier decomposition, and then solve for the spatial evolution of each frequency mode. This is exactly the same kind of manipulation that is done in Fourier analysis of data, and is valid as long as the wave train satisfies the requirements for the transform to exist. In field applications, the Fourier decomposition into a finite set of discrete frequencies under the assumption of periodicity is exactly the same as applying an FFT to data. Assumptions about stationarity of the

¹Center for Applied Coastal Research, Department of Civil Engineering, University of Delaware, Newark, Delaware 19716

process are implicit and should be kept in mind when determining if the present approach is useful.

The solution for the spatial behavior of each frequency component is itself involved. A number of studies (Freilich and Guza, 1984; Elgar and Guza, 1985 and 1986 and subsequent contributions) have considered only the shoreward propagation in one space dimension, and have shown that the resulting one-dimensional, first-order coupled mode equations are capable of modelling the evolution of the spectrum and bispectrum of shoaling waves, as verified by comparison with field measurements. Liu, Yoon and Kirby (1985; referred to here as LYK) alternately proposed a parabolic model for the shoreward propagation of each frequency component over two-dimensional topography, and verified the method in comparison to a laboratory experiment on the focussing of periodic long waves by topography. The parabolic model approach has also been used to study a field application (Freilich et al, 1990), with successful results.

In this study, we derive a model for the evolution of each frequency mode in two dimensions, based on the angular spectrum approach. This approach has been applied to the study of intermediate depth waves by Dalrymple and Kirby (1988) and Dalrymple et al (1989). For the case of linear theory, the angular spectrum is usually posed as the continuous Fourier transform of the wave field in the longshore direction. Here, in keeping with the mental framework associated with the discrete transforms being employed in time, we impose longshore periodicity as well and obtain a discrete spectrum in longshore wavenumber. This frequency - longshore wavenumber spectrum is subsequently referred to as the *discrete angular spectrum*.

The model developed here is applicable both to simple periodic waves generated in the laboratory environment and to irregular, "random" waves in the field environment. In this paper, we concentrate on a model verification conducted from the first viewpoint. The model is tested against laboratory data obtained by Hammack, Scheffner and Segur (1990), who investigated the development of a Mach stem arising during the glancing-angle reflection of a cnoidal wave by a vertical wall. Results obtained using the parabolic equation model described in LYK are also compared to data. (The case of Mach reflection of a cnoidal wave has been studied using the parabolic approximation by Yoon and Liu (1989); however, no comparison to data was provided in that study.) The spectral model is shown to give a more accurate representation of the data than the parabolic model over the entire range of angles of incidence considered.

The Boussinesq Equation Model

We first establish the form of a model for waves in a laterally unrestricted domain. A Cartesian coordinate system is adopted which has x pointed in the onshore direction and y pointing alongshore. Depth is assumed to vary as $h(x)$ only. We take as a starting point the variable depth Boussinesq equations as given by Peregrine (1967):

$$\eta_t + \nabla \cdot (h\mathbf{u}) + (\epsilon)\nabla \cdot (\eta\mathbf{u}) = 0 \quad (1)$$

$$\mathbf{u}_t + (\epsilon)\mathbf{u} \cdot \nabla \mathbf{u} + g\nabla\eta = (\mu^2)\left\{\frac{h}{2}\nabla(\nabla \cdot (h\mathbf{u}_t)) - \frac{h^2}{6}\nabla(\nabla \cdot \mathbf{u}_t)\right\} \quad (2)$$

Here, η is the surface displacement and \mathbf{u} is the horizontal wave-induced velocity. The equations are kept in dimensional form; the scaling parameters $\epsilon = \max(\eta)/h$ for nonlinearity and $\mu^2 = \omega^2 h/g$ for weak dispersion are present only schematically and will be subsequently dropped. We will assume that either bottom slope

or the amplitude of bottom features (as scaled by water depth) are also small and hence the model will be developed to leading order in nonlinearity, dispersion, and domain inhomogeneity. This leads to immediate neglect of bottom slope effects in the dispersive terms of (2). Using the linear portion of (1), we may then write (2) in the reduced form

$$\mathbf{u}_t + \mathbf{u} \cdot \nabla \mathbf{u} + g \nabla \eta + \frac{h}{3} \nabla \eta_{tt} = 0. \quad (3)$$

We now make the following assumptions. First, the model will be applied to time-periodic wave trains, where periodicity is in the sense of either a regular wave train, or of a discrete FFT over a finite length of sampled data. Secondly, the wave field will be assumed to be periodic in the transverse y direction. This corresponds again to a fixed longshore wavelength in the regular wave case, or to periodicity over a long spatial interval in the spectral sense.

The governing equations are first split into coupled elliptic models for separate harmonic components. Following LYK, we write the surface displacement and velocity as

$$\eta = \sum_{n=0}^N \frac{\eta_n(x, y)}{2} e^{-in\omega t} + c.c. \quad (4)$$

$$\mathbf{u} = \sum_{n=0}^N \frac{\mathbf{u}_n(x, y)}{2} e^{-in\omega t} + c.c. \quad (5)$$

Substitution of (4) and (5) in (1) and (3) and subsequent elimination of the velocity leads to the following model equation for the η_n in the horizontal plane:

$$n^2 \omega^2 \eta_n + \nabla \cdot (G_n \nabla \eta_n) + [n.l.t.]_n = 0; \quad n = 1, \dots, N \quad (6)$$

Here, $[n.l.t.]_n$ denotes the nonlinear interactions with other discrete frequency components which are sorted by means of the rules for triad interactions applied to the time dependence. (Omitted details may be found in the more complete paper; Kirby (1990).) The mode $n = 0$ corresponding to the steady, wave-induced setdown is neglected since it is at most second order in the largest wave amplitudes present (see LYK). Also,

$$G_n(x) = gh(x) - \frac{1}{3} n^2 \omega^2 h^2(x). \quad (7)$$

We now apply a spectral transform to the y dependence of the wavefield, assuming propagation is to be considered in the on-offshore ($\pm x$) direction. We consider here the case of an unbounded lateral domain and a wavefield which is periodic over the basic interval L . We then represent $\eta_n(x, y)$ as

$$\eta_n(x, y) = \sum_{m=-M}^M \eta_n^m(x) e^{im\lambda_0 y} \quad (8)$$

where

$$\lambda_0 = \frac{2\pi}{L}. \quad (9)$$

Substituting (8) in (6) and neglecting x - derivatives of small terms in G_n then leads to a set of coupled second-order ODE's for the η_n^m , given by

$$\frac{G_n}{gh} \eta_{n,xx}^m + \frac{h_x}{h} \eta_{n,x}^m + (\gamma_n^m)^2 \eta_n^m + \frac{1}{3} m^2 n^2 \lambda_0^2 k^2 h^2 \eta_n^m + \frac{1}{gh} [n.l.t.]_n^m = 0; \quad (10)$$

$$n = 1, \dots, N; \quad m = -M, \dots, M.$$

where $[n.l.t.]_n^m$ now represents triad interactions satisfying resonance conditions in t and y . Here, k is the wavenumber determined by the lowest order dispersion relation

$$\omega^2 = gk^2 h. \quad (11)$$

Also,

$$(\gamma_n^m)^2 = n^2 k^2 - m^2 \lambda_0^2 \quad (12)$$

For fixed n, k, λ_0 , large values of m will make γ_n^m imaginary, which corresponds to modes which are exponential rather than oscillatory in x in the linear approximation. In the linear case, the presence of these modes in the initial conditions would be interpreted in the same light as the presence of evanescent modes in the general wavemaker problem (see Dalrymple and Kirby, 1988). However, the interpretation in the case of possible nonlinear forcing of the offshore portion of trapped modes in the nearshore region is non-trivial and will need to be considered carefully in applications where the inclusion of this effect is desired. In addition, nonlinearity could force the propagation of modes that would not be present in a linearized wave field, and which could affect a detailed representation of an individual wave. At present, the range of M at each value of n may be restricted to $M_n \leq nk/\lambda_0$ in order to eliminate forcing of these modes arbitrarily.

Shoaling Waves

Based on the linear, nondispersive portion of the model (10), we assume that the incident wave may be written in the form

$$\eta_n^m(x) = A_n^m(x) e^{in \int k \tilde{\gamma}_n^m dx} \quad (13)$$

where it is assumed that the x dependence of A , k and $\tilde{\gamma}$ is on a slow scale of $O(\epsilon)$, and where

$$\tilde{\gamma}_n^m = \left(1 - \left(\frac{m}{n}\right)^2 \left(\frac{\lambda_0}{k}\right)^2\right)^{1/2} = \frac{\gamma_n^m}{nk} \quad (14)$$

(where the positive root is taken). The amplitudes A represent the discrete angular spectrum being considered here, and are allowed to vary owing to refraction, shoaling, dispersion and nonlinear interaction. (It would be possible to absorb shoaling and refraction effects by the use of the usual linear refraction formulae; this step is not taken here.) Substitution of (13) in (10) leads to the spectral model for incident waves, given by

$$\tilde{\gamma}_n^m A_{n,x}^m + \frac{(kh\tilde{\gamma}_n^m)_x}{2kh} A_n^m - \frac{1}{6} in^3 k^3 h^2 A_n^m + \frac{ink}{8h} \left\{ \sum_{l=1}^{n-1} \sum_{p=P_1}^{P_2} \Gamma_{n,l}^{m,p} A_l^p A_{n-l}^{m-p} e^i \int \Theta_{n,l}^{m,p} dx \right. \\ \left. + 2 \sum_{l=1}^{N-n} \sum_{p=P_3}^{P_4} \Gamma_{n,l}^{m,p} A_l^{p*} A_{n+l}^{m+p} e^i \int \Upsilon_{n,l}^{m,p} dx \right\} = 0; \quad (15)$$

$$n = 1, \dots, N; \quad m = -M_n, \dots, M_n.$$

Here, $(\cdot)^*$ denotes the complex conjugate. The limits of summation $P_1 - P_4$ are determined by the range of allowed modes taking part in each interaction. The interaction coefficients I and J are given by

$$I_{n,l}^{m,p} = 1 + [\tilde{\gamma}_l^p \tilde{\gamma}_{n-l}^{m-p} + \frac{p}{l} \frac{m-p}{n-l} (\frac{\lambda_0}{k})^2] \cdot [1 + (\frac{m}{n})^2 (\frac{\lambda_0}{k})^2 + \frac{(l\tilde{\gamma}_l^p + (n-l)\tilde{\gamma}_{n-l}^{m-p})^2}{n^2}] \quad (16)$$

$$J_{n,l}^{m,p} = I_{n,-l}^{m,-p}. \quad (17)$$

The phase arguments Θ and Υ represent the basic mismatch in the x direction of the triads chosen based on perfect matching in y and t . Generally, the only components which experience complete resonance in the long wave limit must have parallel propagation directions; all obliquely interacting components are somewhat detuned. The phase arguments are given by

$$\Theta_{n,l}^{m,p} = lk\tilde{\gamma}_l^p + (n-l)k\tilde{\gamma}_{n-l}^{m-p} - nk\tilde{\gamma}_n^m \quad (18)$$

$$\Upsilon_{n,l}^{m,p} = \Theta_{n,-l}^{m,-p} \quad (19)$$

The spectral model (15) is a set of coupled first order ODE's which are solvable by standard techniques. Results presented in sections 4 and 5 were obtained using a standard 4th-order Runge-Kutta scheme with fixed step size and no error checking. Presently, extensions of the model using error control and adaptive step size are being tested and will likely be the vehicle for further field testing of the model beyond the scope of the present study.

Comparison with Data and a Parabolic Model Approximation

In order to verify the basic computational model provided by (15) and to test whether the present angular spectrum provides a more accurate representation of the wave field relative to earlier parabolic models (LYK; Yoon and Liu, 1989), we have compared model predictions to laboratory data obtained by Hammack et al (1990) for the case of glancing, or Mach, reflection of a cnoidal wave by a vertical wall. The experimental tests were conducted using the directional wave maker at the Coastal Engineering Research Center, Vicksburg, MS. A prior use of this facility to study the properties of intersecting cnoidal waves is described in Hammack et al (1989), referred to here as HSS.

Layout of Experimental Facility

For the tests considered here, the wave basin was operated with a water depth of 20cm in a constant depth region extending 12.55m in front of the wavemaker, after which a beach with 1:30 slope provided an efficient wave absorber giving little reflection. The basin floor was leveled to a tolerance of 0.01ft in order to remove some of the spatial irregularity of the waves reported in HSS resulting from local refraction effects. For the Mach stem tests, two parallel false walls were installed perpendicular to the wavemaker axis in order to provide a closed channel. The channel walls were situated 13.26m apart, which fixes the width of the numerical domain to be considered.

Instrumentation and data acquisition are described in HSS, and readers are referred there for greater detail. In the present tests, an array of 18 wave gages

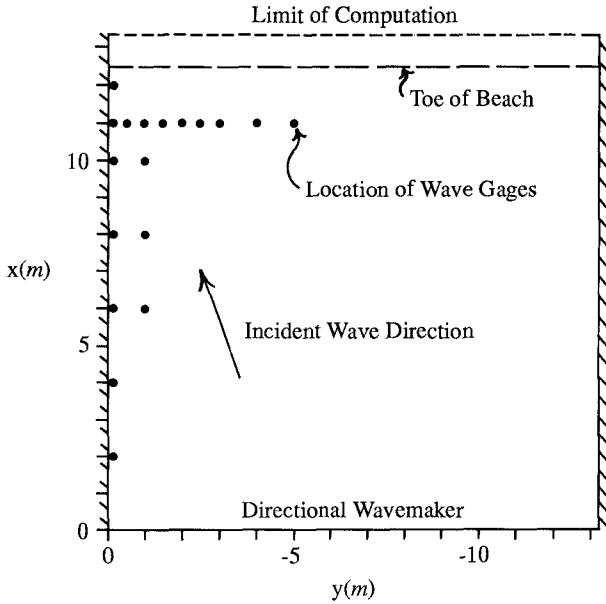

Figure 1: Basin configuration, Mach reflection experiments

were installed in the basin as shown in Figure 1. In this figure, the directional wavemaker occupies the y -axis, and the channel sidewalls lie along the x -axis and the line $y = -13.26m$. The positions of the gages are given in Table 1. The linear gage array 13-9-8-7-6-4-3-2-1 provides a transect perpendicular to the reflecting sidewall which allows a determination of the width and structure of the Mach stem and additional crests in the reflection pattern. This array is used to provide most of the information described below. An additional array 18-17-16-15-14-13-5 provides measurements of the evolution of the reflected stem wave along the wall. For each gage, data consists of a time series of 1250 points with a sampling rate of $25Hz$.

gage	$x(m)$	$y(m)$	gage	$x(m)$	$y(m)$	gage	$x(m)$	$y(m)$

Table 2: Paddle phase angles and directed wave angles; Mach reflection experiments

Specification of the Incident Wave

The generation of oblique cnoidal waves using the directional wavemaker has been described in HSS. In the present laboratory tests, waves were initially specified as having a wavelength of $2m$ and a crest elevation $4cm$ above mean water level. The algorithms given by Goring and Raichlen (1980) were used to generate a time series of paddle displacement corresponding to one-dimensional generation. Oblique waves were then generated by phase lagging adjacent paddles. The relation between paddle phase shift angle β and directed wave angle α is given by

$$\beta = \arcsin(\alpha L/360W) \quad (20)$$

where L is the wave length and $W = 45cm$ is the individual paddle width. Tests were conducted for six paddle phase lags, and are denoted $CRxx0204$, where xx denotes paddle phase lag. Note that (48) corrects a typographic error appearing in HSS. Table 2 gives a list of α and β values for the six tests.

Prior to running the Mach reflection experiments, the nominally $4cm$ high wave was generated in the normally incident direction (traveling parallel to sidewalls) in order to study its characteristics. It was found that the wave actually had a crest elevation close to $3.3cm$ above mean water level. This value was used to specify incident waves in the numerical computation, along with a wave period of $1.478s$ as specified by KdV cnoidal wave theory. We note that it is uncertain whether the value of $3.3cm$ was invariant under changes of angle of incidence in the laboratory experiment. Variation of this quantity would add an untraceable source of error in model-data comparison.

The computed wave angle and the Fourier coefficients for the input cnoidal wave were used to compute the surface displacement for oblique cnoidal waves along the boundary $x = 0m$ corresponding to the wavemaker. For parabolic model calculations, information in the range $-13.26m \leq y \leq 0m$ was used to start the computation. The model was run with reflective sidewalls at $y = 0, -13.26m$. For the spectral model, a periodic interval was constructed by using a mirror image about $y = 0m$; the computational domain thus corresponds to the region $-13.26m \leq y \leq 13.26m$. The computed waveform was then Fourier transformed over this interval and the resulting frequency-wavenumber spectrum was fed into the spectral model. (It is noted that the problem as stated could be handled directly by means of a cosine transform over the true model domain; this was not done because of the reprogramming of the basic model that would have been required.)

For the examples shown here, the parabolic model was run with a grid spacing $\Delta x = \Delta y = 0.0625m$, and $N = 9$ frequency components were used. Tests were performed for two cases for both half the grid spacing and twice the number of harmonics to insure that convergence was adequate for the parameters finally used. In the spectral model, we used $N = 9$ and $M = 64$. The large value of M insures that all freely propagating modes of the solution are retained for the highest harmonic considered. The forward grid space step was also $\Delta x = 0.0625m$. Again, these parameters were found to give sufficient convergence of solutions

when compared to runs with smaller grid steps and more retained frequency components.

Results

Results of model calculations are presented here in two forms: gray level contour plots of instantaneous surface over the model basin, and time series computed from model output and compared to experimental data. The gray level plots are actually of the quantity $-\partial\eta/\partial x$, and the pictures thus mimic the visual image that would be obtained in an overhead photograph resulting from lighting at a low angle from the direction of the wavemaker. (This is similar to the photographic arrangement in HSS). In all cases, the gray level plots from parabolic model computations are similar to those from spectral model computations, and only spectral model results are shown. Figure 2 presents results for the test CR150204, which clearly shows the evolution of a wide Mach stem wave along the reflecting boundary. In contrast, the wave field for test CR580204, where the angle of incidence is about 45° , exhibits almost a regular (i.e., linear) reflection pattern consisting of superposed waves (Figure 3).

Figure 2: Predicted wave field, test CR150204. Spectral model

In order to compare time series from experiment and model calculations, the

Figure 3: Predicted wave field, test CR580204. Spectral model

following procedure is used. First, after allowing some time for nearly periodic motion to be established in the experiment, a reference time t_0 is established at the position of a wave crest at gage 13 ($x = 11m, y = -0.07m$). This start time is used for all other gages as well, in order to maintain synchronization. Then, a start time is also established for the model- predicted time series by identifying a crest at model gage 13. Synchronization between model and data time series is thus based on correlating the series at a gage location, rather than (more correctly) correlating at the wavemaker. This step is necessary since the wavemaker control is not available and since absolute time in the model-constructed time series is arbitrary.

After determining the synchronous start times for model and data at gage 13, time series were plotted for the transect along the wall (gages 18-17-16-15-14-13-5) and perpendicular to the wall (gages 13-9-8-7-6-4-3-2-1). Aside from the presence of experimental errors, a correct model result would be indicated by complete agreement between model and data time series at each gage. As examples, two periods of time series for the perpendicular transect are shown in Figure 4 for the spectral model predictions for CR150204. The plot shows a stem developed near the wall in the area spanned by gages 13-9-8-7, beyond which there is a clear phase lead at each subsequent gage, indicating the approach of

Figure 4: Measured and predicted time series for test CR150204, perpendicular transect. —, model; ---, data. Spectral model

the incident wave at a small angle of incidence. In this plot, model predictions are indicated by solid lines and experimental data by dashed lines. At the opposite extreme, Figure 5 shows spectral model predictions and data for the case CR580204. This figure indicates the structure of a short crested wave field, with one complete diamond over the range of gages 13-9-8-7-6-4-3, whereas the signal in gages 3-2-1 indicating a strong progressive phase lag, corresponding to a wave travelling *away from* the wall at close to 45° . The structure of the plots in Figures 4 and 5 may be further clarified by comparison with the surface plots in Figures 2 and 3, respectively.

In order to quantify the comparison between model predictions and measurements, an rms error measure was constructed. This measure e is given by

$$e_j = \sqrt{\frac{\frac{1}{j} \sum_{i=1}^j (\eta_{2,j}(i) - \eta_{1,j}(i))^2}{\frac{1}{j} \sum_{i=1}^j (\eta_{1,j}(i))^2}} \quad (21)$$

for each gage, where the normalization of the mean square error is with respect to the true (data) standard deviation. A composite value \bar{e} for each angle or test is constructed from the ratio of the rms error for all points divided by the total

Figure 5: Measured and predicted time series for test CR580204, perpendicular transect. —, model; ---, data. Spectral model

standard deviation for all points. Table 3 gives the computed error estimates for all tests, and Figure 6 shows the composite error as a function of incidence angle for the two models. In this case, the trend towards increasing error with increasing angle is clear in the parabolic model results. The spectral model also shows an increasing trend in this case, which would not necessarily be expected.

One possible reason for an increase in error in the spectral model as wave angle becomes large rests in the fact that the reflected wave crests at the wall and in the short-crested wave pattern away from the wall result from the interaction between waves that are colliding head on to the same extent as they are interacting colinearly. Tests and analysis of head on collision and vertical wall reflection of solitary waves have indicated that the leading order theory (as in the Boussinesq model employed here) is not capable of predicting the height of the runup or maximum elevation, or the phase lag associated with the opposite-going interaction. See Su and Mirie (1980) for an example of this type of analysis. Effects of this nature may be present in the experiments being considered here. It is also possible that the increase in error with incidence angle in the spectral model is due to a change in the incident wave height with angle, as mentioned above. This error, if present, would tend to increase the wave height with angle,

Discussion

We have described the development of a solution technique for the Boussinesq model of long waves, based on a discrete representation of the angular spectrum for waves incident towards shore from the ocean. The model is similar in intent to the parabolic model developed earlier by LYK, with the exception that the present model does not impose a restriction on the range of directions that can be accurately modelled. This advantage is counterbalanced (at this stage of development) by the need to impose periodic boundary conditions on the modelled problem. This restriction must be alleviated before the various representations of angular spectrum models (present model; Dalrymple and Kirby, 1988; Dalrymple et al, 1989) become generally applicable as coastal wave models.

Comparison of the present model, a parabolic model and laboratory data indicates that differences do occur between predictions of a small-angle approximation and the fully directional expansion employed here, and that the deviation is apparent even at small angles of incidence. This result indicates that the further development of the angular spectrum model is worth pursuing as a means of providing accurate prediction of coastal wave fields. The first extension of the present model to include weak longshore topographic variation and on-offshore reflection is presently underway and will be described shortly.

CHAPTER 9

MODELING OF ENERGY TRANSFER AND UNDERTOW IN THE SURF ZONE

Akio Okayasu¹, Akira Watanabe² and Masahiko Isobe³

Abstract

A model is presented to describe accurately the energy transfer under breaking waves. In the model, the energy of organized large vortexes as well as those of wave-induced motion and turbulence is taken into account. The model allows to estimate the dissipation rate and distribution of energy, and then the cross-shore two-dimensional distribution of an undertow. The applicability of the model is confirmed by laboratory experiments.

1. Introduction

In order to predict the sediment transport and the material diffusion in the surf zone, it is necessary to estimate the distribution of an undertow. Since the undertow distribution has been evaluated from local properties of waves and turbulence in most of previous models, additional models are needed to evaluate the local properties from incident wave conditions. These undertow models have another disadvantage that they are applicable only to wave breaking in the inner region of the surf zone. Hence, to complete an undertow model which is valid through the whole surf zone, it is necessary to combine it with an accurate description of wave attenuation, energy distributions or generation of turbulence based on the actual breaking mechanism. However, energy of the organized vortexes which were pointed out to be formed around crests of breaking waves was not taken into account in the previous models for wave deformation in the surf zone.

The first objective of the present study is to describe accurately the energy transfer process in the surf zone by taking the energy of the organized

² Professor, Department of Civil Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113, Japan

³ Associate Professor, ditto

large vortexes into account. The second objective is to formulate a model to estimate cross-shore vertically two-dimensional distribution of the undertow on arbitrary beach topographies from the energy distributions obtained by the energy transfer model.

2. Energy Transfer Model

2.1 Energy balance in the surf zone

In order to describe the transfer of energy by wave breaking, a model is presented in which the organized large vortexes are taken into account as a transmitter of energy in the energy transfer process from wave motion to turbulence. The total energy in the surf zone is described as

$$E_t = E_w + E_v \quad (1)$$

where E_t is the total energy of wave per unit area, E_w the energy of wave motion and E_v the energy of organized large vortexes.

The energy of the organized vortexes converted from wave energy is transferred to smaller size eddies, and then dissipates. It is assumed that the converted energy from wave motion to the large vortexes never transferred back to the wave motion and the energy which dissipates directly from the wave motion to heat by wave breaking is negligible. By using the energy flux by wave motion $E_w c_g$ and energy dissipation rate by bottom and wall friction D_{b+w} , the transfer rate T_B from the wave energy to the energy of the vortexes per unit length and unit width is expressed as

$$T_B = -\frac{d(E_w c_g)}{dx} - D_{b+w} \quad (2)$$

where x is the horizontal coordinate in the shoreward direction and c_g is the group velocity of waves. It is considered that D_{b+w} directly dissipates without conversion through the large vortexes and is not negligible for wave propagation in wave flumes.

The organized large vortexes propagate with the wave crests. Since the phase velocity c is nearly equals to the group velocity c_g in the surf zone, the energy flux by the large vortexes can be approximated by $E_v c_g$, which satisfies the following equation:

$$\frac{d(E_v c_g)}{dx} = T_B - D_B \quad (3)$$

where D_B is the dissipation rate per unit area through turbulence by wave breaking. Since the energy once transferred from wave motion to the organized vortexes is kept by the vortexes for a while, difference appears in the spatial distributions between the attenuation of wave energy E_w and the generation of turbulence energy.

2.2 Mass and momentum fluxes by breaking waves

The mass transport by breaking waves consists of those by the wave motion M_w and by the organized vortexes M_v [Okayasu *et al.* (1988)]. By using the linear long wave theory, the mass flux by the wave motion M_w is described as

$$M_w = \rho \frac{c}{h} \overline{(\zeta - \bar{\zeta})^2} = \frac{2c}{gh} E_p \quad (4)$$

where h is the mean water depth, ζ the water surface elevation and E_p the potential energy of waves.

If the length and velocity scales of the organized vortexes can be represented by the wave height H and the wave celerity c , respectively, the mass flux by organized vortexes M_v satisfies

$$M_v \propto \frac{E_v}{c} \quad (5)$$

The total mass flux due to breaking waves can be described in terms of the potential energy and the energy of organized large vortexes as

$$M_t = 1.6 \frac{c}{gh} E_p + \frac{2}{c} E_v \quad (6)$$

in which the coefficients were determined so as to fit the measured values.

As for the radiation stress, the total radiation stress S_t can also be divided into two parts which are the excess momentum flux by wave motion S_w and that by the organized large vortexes S_v . The small amplitude wave theory is adopted for convenience to calculate S_w in this study. The radiation stress by the organized large vortexes S_v is evaluated as

$$S_v = \frac{5}{3} E_v \quad (7)$$

3. Estimation of Energy Distribution

In the present model, the one dimensional time-dependent mild slope equation is adopted to calculate the distribution of the energy of wave motion E_w . The energy of organized large vortexes E_v supplied from E_w at a certain point is assumed to be transferred to the turbulence energy within some distance determined in terms of the local water depth. The energy dissipation rate D_B is obtained by integrating the transferred energy.

3.1 Estimation of energy of wave motion

The time-dependent mild slope equation was originally derived by using the small amplitude wave theory. However, waves in the surf zone can no more be regarded as small amplitude waves. In that sense, the time-dependent mild

slope equation may not be appropriate for waves in the surf zone, but it is also a fact that there is no wave theory which can express the waves in the surf zone adequately. It has been reported that the wave energy calculated by the time-dependent mild slope equation fits well with the measured wave energy [see e.g. Watanabe and Dibajnia (1988)]. Hence, in this study, the time-dependent mild slope equation is adopted as the governing equations to estimate the wave energy variation in the surf zone.

The following time-dependent mild slope equation with the dissipation term is used after Watanabe and Dibajnia (1988):

$$\frac{\partial Q}{\partial t} + c^2 \frac{\partial \zeta}{\partial x} + f_A Q = 0 \quad (8)$$

$$\frac{\partial \zeta}{\partial t} + \frac{1}{n} \frac{\partial(nQ)}{\partial x} = 0 \quad (9)$$

in which t is the time, Q the flow rate, $n = c_g/c$. The attenuation factor f_A by wave breaking is the sum of f_T and f_{b+w} , where f_T is the energy transfer factor from wave motion to large vortexes and f_{b+w} the energy dissipation factor due to energy loss by bottom and wall friction. f_T is expressed as

$$f_T = \alpha_T \tan \beta \sqrt{\frac{g}{h} \left(\frac{\gamma - \gamma_r}{\gamma_s - \gamma_r} \right)} \quad (10)$$

which was given by Watanabe and Dibajnia. In Eq. (10), α_T is a parameter which linearly increases from 0 to 2.5 around the breaking point, then takes a constant value 2.5 in the inner region. The bottom slope $\tan \beta$ is the average value of the bottom slope near the breaking point, g the acceleration of gravity, γ the ratio of water particle velocity to wave celerity. The symbols γ_s and γ_r are γ on constant slope and for wave recovery zone, respectively. The energy dissipation factor f_{b+w} is obtained from the laminar solution by Iwagaki and Tsuchiya (1966) as

$$f_{b+w} = \frac{1}{n} \sqrt{2\nu\sigma} \left(\frac{1}{B} + \frac{k}{\sinh 2kh} \right) \quad (11)$$

where ν is the kinematic viscosity, σ angular frequency of wave, k the wave number, B the width of wave flume. In the surf zone, the bottom and wall boundary layers may not be laminar flow, but the dissipation by wave breaking is so large that the damping due to the bottom and wall friction is negligible.

The breaking point x_b is determined as the point where the wave height takes its maximum value. Isobe (1987) approximated it by the following formula:

$$\begin{aligned} \gamma_b = & 0.53 - 0.3 \exp(-3\sqrt{h_b/L_0}) \\ & + 5(\tan \beta)^{3/2} \exp\{-45(\sqrt{h_b/L_0} - 0.1)^2\} \end{aligned} \quad (12)$$

where L_0 is the deep-water wavelength and subscript b denotes the quantity at the breaking point.

The breaking points slightly differ depending on its definition. Since the energy transfer from the wave motion to the organized large vortexes and also the energy dissipation should occur from the point where the wave crests begin to break, the coefficient α_T in Eq. (10) is set to be 0 at the crest breaking point x'_b and to be the maximum value 2.5 at the transition point x_t . Considering the results by Seyama and Kimura (1988), the crest breaking point is given as

$$x'_b = x_b - 2h_b \quad (13)$$

in this model.

According to the small amplitude wave theory, the value of the potential energy E_p is equal to that of the kinetic energy E_k . However, E_k is larger than E_p for non-linear waves in general. Dibajnia *et al.* (1988) obtained the result that the maximum ratio of E_k to E_p calculated by the finite amplitude wave theory is up to 1.2 as far as the calculation converged. Since the breaking waves in the surf zone can be considered as non-linear, the ratio $R_p \equiv E_p/E_k$ is made to change linearly from 1 at x'_b to its minimum value at the wave plunging point x_p in this model. E_p is reduced to about 90% of $E_w/2$ in the inner region of the surf zone.

The values γ_s and γ_r in Eq. (10) have been determined so that the potential energy agreed well with the measured value. They should be reduced in proportion to the decrease of E_p , because the variation of R_p accelerates the decrease of E_p apparently. Hence, in this study, they are determined as

$$\gamma_s = 0.35(0.57 + 5.3 \tan \beta) \quad (14)$$

$$\gamma_r = 0.45 \left(\frac{a}{h} \right)_b \quad (15)$$

where a is the wave amplitude.

The time-dependent mild slope equation can deal with wave reflection, however, a rapid change of the energy transfer factor f_A generates considerable numerical reflection in the offshore side of the breaking point. Since the energy dissipation by wave breaking occurs with little wave reflection, it is necessary to keep it small for the accurate description of the wave field. It is possible to decrease the energy of the reflected waves by changing the wave number in the onshore region according to the value of f_T . The modified wave number k' is given as

$$k' = \frac{a_k}{2(a_k^2 + b_k^2)} k \quad (16)$$

$$a_k = \frac{\sqrt{1 + \sqrt{1 + \frac{f_T^2}{\sigma^2}}}}{2\sqrt{2}}, \quad b_k = \frac{f_T}{2\sqrt{2}\sigma\sqrt{1 + \sqrt{1 + \frac{f_T^2}{\sigma^2}}}} \quad (17)$$

If $f_T = 0$, k' is equal to k which is calculated by the small amplitude wave theory. In the surf zone, k' is smaller than k in general. The smaller wave number results larger wave celerity. Horikawa and Isobe (1980) found that the wave celerity in the surf zone can be predicted fairly well by the solitary wave theory. It means that the modification agree with the reality. However, k/k' is kept to be less than 1.2 to prevent the wave celerity from increasing too much due to the extremely large value of f_T close to the shoreline.

The offshore and shoreline boundary conditions, the method of numerical computation and the adopted mesh scheme are the same as those employed by Watanabe and Dibajnia (1989). The solution is assumed to be converged when the absolute errors between the values obtained from two successive cycles of the calculation at every point are less than a tolerance error throughout the field. In the present study, the required absolute error is equal to 1% of the incident wave height for both the wave amplitudes and the setup calculation.

3.2 Estimation of energy dissipation rate

In order to evaluate the dissipation rate D_B , the vortex energy supplied from wave energy by wave breaking is assumed to be equally transferred to the turbulence energy in a distance l_d given in terms of the local water depth h . The distance l_d is determined as

$$l_d = \begin{cases} 4 \left(\frac{x_t - x}{x_t - x'_b} + 1 \right) h & (x \leq x_t) \\ 4h & (x > x_t) \end{cases} \quad (18)$$

where x_t is the wave transition point which is the boundary between the outer and inner regions in the surf zone. By using l_d , D_B is calculated as

$$D_B(x) = \int_{-\infty}^x t_d(x; x') dx' \quad (19)$$

where

$$t_d(x, x') = \begin{cases} 0 & (x \leq x') \\ \frac{T_B(x')}{l_d(x')} & (x' \leq x < x' + l_d(x')) \\ 0 & (x' + l_d(x') \leq x) \end{cases} \quad (20)$$

3.3 Determination of transition and plunging points

The determination of the transition and plunging points is necessary for evaluating the energy distribution in the present model. For that sake, the transition and plunging points were measured for various incident waves on different bottom slopes.

Figure 1 shows the relation between the averaged value of l_t/h_{0b} and the bottom slope $\tan \beta$, where l_t is the distance from the breaking point to the transition point and h_{0b} the still water depth at the breaking point. The marks

Fig. 1 Relationships between bottom slope and transition and plunging distance.

in the figure express the averages and the vertical lines express the fluctuations. The solid line expresses

$$l_t = \left(\frac{1}{5 \tan \beta} + 4 \right) h_{ob} \quad (21)$$

by which the transition point can roughly be estimated.

As for the plunging points, the averages are nearly constant and do not depend on the bottom slope. The distance l_p from the breaking point to the plunging point is expressed roughly as

$$l_p = 2.5 h_{ob} \quad (22)$$

4. Undertow Model

4.1 Vertical variation of mean shear stress and eddy viscosity

The Reynolds stress and the eddy viscosity coefficient are quantitatively evaluated from the energy dissipation rate by means of dimensional analysis in the model. By using dimensional analysis, Battjes (1975) obtained the representative velocity of turbulence q as

$$q \approx \left(\frac{D_B}{\rho} \right)^{1/3} \quad (23)$$

The vertically averaged mean shear stress τ_m in the horizontal plane and the vertically averaged mean eddy viscosity ν_m are expressed as

$$\tau_m = C_\tau \rho^{1/3} D_B^{2/3} \quad (24)$$

$$\nu_m = C_\nu \rho^{-1/3} h D_B^{1/3} \quad (25)$$

respectively. C_τ and C_ν are constant and taken to be 0.02 and 0.03, respectively, in this model.

The mean shear stress τ and the eddy viscosity ν_e are assumed to be linear functions of the vertical elevation z' from the bottom [Okayasu *et al.* (1988)] and are expressed as

$$\tau = a_\tau z' + b_\tau = \frac{0.04}{3} \rho^{1/3} D_B^{2/3} \left(\frac{5}{d_t} z' - 1 \right) \quad (26)$$

$$\nu_e = a_\nu z' = 0.06 \rho^{-1/3} D_B^{1/3} \frac{h}{d_t} z' \quad (27)$$

where d_t is water depth at wave troughs.

4.2 Vertical variation of undertow

Though the molecular viscosity ν is far smaller than the eddy viscosity ν_e in the surf zone in general, it cannot be neglected near the bottom or in the offshore region. The total viscosity is therefore defined as follows:

$$\nu_t = \nu_e + \nu \quad (28)$$

By using the eddy viscosity model, the relation between the mean shear stress τ acting on the horizontal plane and the steady current U in x -direction is expressed as

$$\tau = \rho \nu_t \frac{\partial U}{\partial z} \quad (29)$$

Substituting Eqs. (26), (27) and (28) into Eq. (29), the steady current U can be expressed as

$$U = \frac{a_\tau}{a_\nu} z' + \frac{a_\nu b_\tau - a_\tau \nu}{a_\nu^2} \log(a_\nu z' + \nu) + C_1 \quad (30)$$

where C_1 is an integral constant which is obtained in terms of the mass transport by waves M_t as

$$C_1 = -\frac{1}{2} \frac{a_\tau}{a_\nu} d_t - \frac{a_\nu b_\tau - a_\tau \nu}{a_\nu^3 d_t} (a_\nu d_t + \nu) \log(a_\nu d_t + \nu) - \nu \log \nu - a_\nu d_t - \frac{1}{h} M_t \quad (31)$$

In order to obtain the same vertical distribution as what was proposed by Longuet-Higgins (1953) when $D_B = 0$, and to give a continuous solution in and out the surf zone, Eq. (30) is modified as

$$U = \frac{a'_r}{a_\nu} \left(z' - \frac{d_t}{2} \right) + \frac{a_\nu b'_r - a'_r \nu}{a_\nu^2} \left(1 + \log \frac{a_\nu z' + \nu}{a_\nu d_t + \nu} - \frac{\nu}{a_\nu d_t} \log \frac{a_\nu d_t + \nu}{\nu} \right) - \frac{1}{h} M_t \quad (32)$$

$$\left. \begin{aligned} a'_r &= a_r + \frac{\nu a^2 \sigma k}{2h^2 \sinh^2 kh} \left(3kh \sinh 2kh + \frac{3 \sinh 2kh}{2kh} + \frac{9}{2} \right) \\ b'_r &= b_r - \frac{\nu a^2 \sigma k}{4h \sinh^2 kh} \left(2kh \sinh 2kh + \frac{6 \sinh 2kh}{2kh} + 9 \right) \end{aligned} \right\} \quad (33)$$

The values of the second terms in Eq. (33) are far smaller than those of the first terms in the inner region of the surf zone.

Fig. 2 Calculated and measured energy variations (1/20 slope).

5. Results

Figure 2 shows variations of the calculated values of the potential energy of wave motion E_p , the energy of the organized large vortexes E_v and the total energy of wave E_t for wave breaking on 1/20 constant slope. Measured potential energy is also shown in the figure. The period and height of the incident waves are 2.00 s and 8.50 cm, respectively. The calculated and measured value of E_p agree well. E_v takes almost the same value as E_p at the transition point (indicated by T.P.). E_p does not attenuate so much up to the plunging point (P.P.). The calculated values of the energy transfer rate T_B and the energy dissipation rate D_B are shown in Fig. 3. The hatched area corresponds to the rate of change of the vortex energy. The small value of D_B near the plunging point is consistent with the reality.

Fig. 3 Rate of energy transfer and dissipation.

Fig. 4 Calculated and measured undertow distributions (1/20 slope).

Figure 4 shows a comparison of the calculated and the measured distribution of an undertow together with the bottom profile. The variation of the mean water level is also given in the figure. The undertow profiles are well evaluated except near the plunging point. The discrepancy near the plunging point may be caused by the insufficient accuracy of the evaluation of the energy dissipation rate or the energy and mass flux by the organized large vortexes in the outer region. Discrepancy is also found in the variation of setup around the plunging point, but the accuracy is good near the shoreline.

Figure 5 shows a result on a step-type beach. Period and height of the incident waves are 1.20 s and 9.24 cm in this case. The agreement between the calculated and measured values is good, although the calculated energy oscillates in the wave recovery zone. Comparisons of the distributions of undertow and variations of the mean water level are shown in Fig. 6. They agree well in the whole surf zone except around the plunging point, although the calculations were carried out only from the incident wave conditions. It can be concluded that the present model can compute the steady current distributions on various beach topographies with a good accuracy.

5. Concluding Remarks

In order to describe accurately the mechanism of the energy transfer during wave breaking, a model was presented in which the organized large vortexes were taken into account as a transmitter of energy in the energy transfer process from wave motion to turbulence. The mass and momentum fluxes by the organized large vortexes were also discussed.

By using the models of the energy distribution and the mass transport, a model was presented for the two-dimensional distribution of the undertow. The Reynolds stress and the eddy viscosity coefficient were quantitatively evaluated from the energy dissipation rate on the basis of the dimensional analysis. The variation of the mean water level in the surf zone was also predicted with a good accuracy by considering the momentum flux by the organized vortexes. The model can evaluate the distribution of the undertow on an arbitrary beach topography from the incident wave condition.

CHAPTER 10

NUMERICAL SIMULATION OF NONLINEAR WAVE TRANSFORMATION OVER A SUBMERGED PLATE

Xiping Yu * Masahiko Isobe † Akira Watanabe ‡

Abstract

The Euler equation of fluid motion is integrated in the vertical direction by assuming a hyperbolic cosine distribution of pressure. As a result, quasi-linear hyperbolic equations governing the wave motion above a solid bed are obtained. The equations are then applied to describing the wave transformation over a submerged plate.

An algorithm based on the method of characteristics is developed in the numerical computation. The wave reflection and transmission coefficients computed under various conditions are compared with the experimental data, and the overall agreement is found to be fairly satisfactory.

1 INTRODUCTION

Persistent efforts have been devoted to developing efficient and economical breakwaters. The efforts are still needed since new requirements are constantly brought up in the course of further developing coastal zones. As construction sites advanced offshore further and further and the water depth to be dealt with becomes larger and larger, fundamental changes take place even in the design concept of breakwaters. Among many initiatives, it is found that some simple structures are very promising to lower the design wave height for main structures and thus to achieve an overall optimum of the project concerned, or even to stand alone to create a relatively calm area. A submerged horizontal or slightly inclined plate represents one example of such new simple types of breakwaters.

‡Dr. Eng., Prof., ditto.

When incident waves propagate over a submerged plate, part of the wave energy is reflected because of the interaction between the flows above and below the plate. Under certain conditions waves even break above the plate and the energy is thus considerably dissipated. It is by virtue of the reflection and dissipation that a submerged plate functions as a breakwater. However, unlike conventional breakwater, the effectiveness of the submerged plate is very sensitive to the incident wave conditions as well as the dimensions and the placement of the plate. Proper design of the submerged plate breakwaters requires reliable evaluation of the wave reflection and energy dissipation as well as the associated wave transmission under various conditions.

The wave deformation due to a plate has been treated in several previous studies. For example, analytical solution has been obtained for horizontal plate under long wave condition (Hattori and Matsumoto, 1977), and a numerical model based on the time-dependent mild slope equation is also available (Aoyama et al., 1988).

Most of the previous studies are based on the linear wave theory. To ensure the effectiveness, however, the submerged depth of the plate should not be too large, and then the wave nonlinearity becomes significant over the plate. Furthermore, wave breaking, a typical nonlinear phenomenon, is necessary to serve as an energy dissipator to minimize the wave transmission and reflection. Simulation of nonlinear waves is thus needed. In the present study a set of wave equations including nonlinear terms is derived to describe the wave deformation over a submerged plate. The nonlinear equations are solved numerically by the method of finite characteristics. Numerical results are compared with experimental data.

2 GOVERNING EQUATION OF WAVE MOTION

Wave motion is fundamentally governed by the following continuity equation and Euler equations.

$$\frac{\partial u_j}{\partial x_j} + \frac{\partial w}{\partial z} = 0 \quad (1)$$

$$\frac{\partial u_i}{\partial t} + \frac{\partial}{\partial x_j}(u_i u_j) + \frac{\partial}{\partial z}(u_i w) + \frac{\partial}{\partial x_i}\left(\frac{p}{\rho}\right) = 0 \quad (2)$$

$$\frac{\partial w}{\partial t} + \frac{\partial}{\partial x_j}(w u_j) + \frac{\partial}{\partial z}(w w) + \frac{\partial}{\partial z}\left(\frac{p}{\rho}\right) + g = 0 \quad (3)$$

where, u_j ($j = 1, 2$) and w are, respectively, the horizontal and vertical components of the velocity, p the pressure, ρ the fluid density, g the gravitational acceleration, x_j and z the horizontal and vertical coordinates, and t the time. Through denoting the

water surface elevation by η and the still water depth by h , the kinematic boundary conditions on the free surface as well as at the solid bottom are expressed by

$$\frac{\partial \eta}{\partial t} + u_j^f \frac{\partial \eta}{\partial x_j} - w^f = 0 \quad (4)$$

$$u_j^b \frac{\partial h}{\partial x_j} + w^b = 0 \quad (5)$$

in which the superscript f and b represent the values at free surface and bottom, respectively.

It is known that the small amplitude wave theory gives the pressure as

$$\frac{p}{\rho} = -gz + g\eta \frac{\cosh k_M(h+z)}{\cosh k_M(h+\eta)} \quad (6)$$

where a modification has been made to assure that the pressure becomes exactly zero on the free surface, which does not violate the small amplitude assumption. The quantity k_M in Eq. (6) is the modified wave number determined by the following modified dispersion relation:

$$C_M^2 = \frac{g}{k_M} \tanh k_M(h+\eta) \quad (7)$$

in which $C_M = \sigma/k_M$ is the modified wave celerity, and σ the angular frequency.

It has been shown that the small amplitude wave theory is adequate up to the location near the breaking point (e.g., Isobe, 1985). Hence Eq. (6) is regarded as valid in the shoaling zone. In the surf zone, while the small amplitude wave theory is no longer valid, the assumption of hydrostatic pressure distribution may be acceptable. Since Eq. (6) yields the hydrostatic pressure distribution when the water depth becomes small, it may still be a rather good approximation at this situation. Thus Eq. (6) is not erroneous except for a narrow region around the breaking point.

With the assumption of the pressure distribution expressed by Eq. (6), Eqs. (1) and (2) can be integrated with respect to z from the bottom ($z = -h$) to the free surface ($z = \eta$). By recognizing that η is a function of x_j and t , and h a function of x_j only, and introducing the boundary conditions (4) and (5), the continuity equation (1) is integrated as

$$\frac{\partial \eta}{\partial t} + \frac{\partial q_j}{\partial x_j} = 0 \quad (8)$$

where, $q_j = \int_{-h}^{\eta} u_j dz$ is defined as the component of fluid discharge in x_j direction. In a similar way, the integrated momentum equation (9) can be obtained by further considering that the pressure on the free surface vanishes.

$$\frac{\partial q_i}{\partial t} + \frac{\partial}{\partial x_j} \left(\beta \frac{q_i q_j}{h+\eta} \right) + \frac{\partial}{\partial x_i} (C_M^2 \eta) - g\eta \frac{\partial \eta}{\partial x_i} - \frac{g\eta}{\cosh k_M(h+\eta)} \frac{\partial h}{\partial x_i} = 0 \quad (9)$$

where β is the momentum factor. By assuming the vertical distribution of u_i as:

$$u_i = u_i^b(x_j, t) \cosh k_M(h + z) \quad (10)$$

β can be derived as

$$\beta = n_M \alpha \quad (11)$$

with

$$\alpha = \frac{g(h + \eta)}{C_M^2} \quad (12)$$

$$n_M = \frac{1}{2} \left[1 + \frac{2k_M(h + \eta)}{\sinh 2k_M(h + \eta)} \right] \quad (13)$$

Equations (8) and (9) govern the wave motion over a solid bottom. The equations are mathematically termed as quasi-linear hyperbolic differential equations, which have been extensively studied (Courant and Hilbert, 1962). Among many of the properties discovered, it is recognized that discontinuities are included in the solutions under certain conditions even if the initial and boundary conditions are continuous functions. The discontinuity is related to the breaking in wave dynamics (Stoker, 1957).

Since Eq. (9) is derived from the basic equations of ideal fluid flow, the momentum loss is neglected. When waves propagate into the surf zone, the energy loss due to nonlinearity may become remarkable. However, the mechanical energy loss does not always mean a noticeable momentum loss. In some cases, the energy loss is significant but the momentum loss may be negligible, as stated in many textbooks about hydraulic jump (e.g., Rouse, 1946). In the present study we use Eq. (9) and neglect the momentum loss.

Since the pressure distribution given by Eq. (6) is assumed, only progressive waves are considered. Complete or partial standing waves, which are the superposition of two wave trains propagating in the opposite directions, can also be dealt with. However, if there are some rapid changes in boundary conditions, which may cause scattering waves, the validity of Eq. (9) should be reexamined.

3 FORMULATION OF WAVE MOTION OVER SUBMERGED PLATE

3.1 Basic equations

In the following we deal with a vertically two-dimensional wave field in the x - z plane. As shown in Figure 1, the flow field is divided into the four regions: (i) the offshore

Figure 1: Definition sketch of submerged plate

or reflection region, (ii) the region above the plate, (iii) the onshore or transmission region, and (iv) the region under the plate. The flow in the regions (i), (ii) and (iii) can be described by the one-dimensional form of Eqs. (8) and (9).

In order to simplify the equations, we assume that the bottom slope is mild as

$$\left| \frac{\partial h}{\partial x} \right| \ll \left| \frac{\partial \eta}{\partial x} \right| \tag{14}$$

Furthermore, we neglect the terms originating from the nonlinearity but vanishing when the water depth becomes small, because the nonlinearity is considered to become significant only when the water depth is small. Then Eqs. (8) and (9) reduce to

$$\frac{\partial \eta}{\partial t} + \frac{\partial q}{\partial x} = 0 \tag{15}$$

$$\frac{\partial q}{\partial t} + 2\beta v \frac{\partial q}{\partial x} + (C_M^2 - \beta v^2) \frac{\partial \eta}{\partial x} = 0 \tag{16}$$

where $v = q/(h + \eta)$ is the sectional mean velocity.

To derive the equation governing the flow under the plate, the procedure for deriving Eqs. (8) and (9) is followed. If the slope of the plate is small enough, it is expected that the hydrostatic pressure distribution may be assumed in the region (iv) because the flow can reasonably be treated as nearly parallel. Hence,

$$\frac{p}{\rho} = \frac{P_d}{\rho(h - d)} - gz \tag{17}$$

where P_d is the total dynamic pressure force on a vertical cross section below the plate, h and d are the total water depth and the depth above the plate, respectively. Eqs. (1), (2) and (5) are still valid, whereas the boundary condition on the plate becomes

$$w^p \frac{\partial d}{\partial x} + w^p = 0 \tag{18}$$

where the superscript p denotes the values on the surface of the plate. Substituting Eq. (17) into Eq. (2) and then integrating Eqs. (1) and (2) from $z = -h$ to $z = -d$ under the boundary conditions (5) and (18), we have

$$q = \text{const.} \quad (19)$$

$$\frac{\partial q}{\partial t} + \frac{\partial}{\partial x} \left(\frac{q^2}{h-d} \right) + \frac{\partial P_d}{\partial x} = 0 \quad (20)$$

Since q is only a function of t , Eq. (20) can be integrated with respect to x from one end of the plate to the other. Therefore, the differential equation for the fluid discharge under the plate is finally given as:

$$\frac{\partial q}{\partial t} + q^2 \frac{\tan \theta}{(h-d)(h-d_u)} + \frac{P_{dd} - P_{du}}{l \cos \theta} = 0 \quad (21)$$

where l and θ are the length and slope angle of the plate and the subscript u and d represent the values at the upstream and downstream ends of the plate, respectively.

3.2 Boundary Conditions

At the offshore lateral boundary of the reflection region (i), waves are assumed to be described by the superposition of the incident and reflected waves as

$$\eta = \eta_I(x - C_h t) + \eta_R(x + C_h t) \quad (22)$$

where the subscripts I and R represent, respectively, the incident and reflected waves; C_h is the wave celerity in the region of constant water depth h . By differentiating η with respect to t and x , it is found that

$$\frac{\partial \eta}{\partial t} - C_h \frac{\partial \eta}{\partial x} = 2 \frac{\partial \eta_I}{\partial t} \quad (23)$$

Equation (23) gives the offshore lateral boundary condition. In a similar way, at the onshore lateral boundary of the region (iii), it can be assumed that

$$\eta = \eta_T(x - C_h t) \quad (24)$$

where the subscript T represents the transmitted waves. The onshore lateral boundary condition can thus be obtained as:

$$\frac{\partial \eta}{\partial t} + C_h \frac{\partial \eta}{\partial x} = 0 \quad (25)$$

Generally, under the boundary conditions periodic in time, a solution of hyperbolic differential equation consists of two parts: one is the contribution of the boundary

conditions and thus also periodic; the other is the contribution of the initial condition which decays rapidly with time if any damping factor is included. In many practical problems of coastal engineering, only the periodic solution is important. As a result, it allows the initial conditions to be arbitrarily specified so far as they will become trivial after several wave period. In the present case, however, the boundary conditions are given in terms of differential equations. Hence, arbitrary constants involved should be determined so as to make the solution unique. Since the constants may implicitly be specified in the initial conditions of q and η , there should be certain restriction on the specification of q and η at the initial step. However, the state of still water can be utilized as reasonable initial conditions if we do not consider any steady current.

The matching boundary conditions at both ends of the plate are

$$\eta_h = \eta_a \quad (26)$$

$$q_h = q_a + q_b \quad (27)$$

$$\frac{P_{db}}{\rho} = \frac{P_{dh} - P_{da}}{\rho} \quad (28)$$

where the subscripts h , a and b represent, respectively, the values at the region of constant water depth, above and below the plate. It is obvious that Eqs. (26), (27) and (28) physically imply the continuity of the free surface, the conservation of mass and the balance of the pressure force. The substitution of Eq. (6) into Eq. (28) gives

$$\frac{P_{db}}{\rho} = (C_{Mh}^2 - C_{Ma}^2)\eta_h \quad (29)$$

4 METHOD OF FINITE CHARACTERISTICS

The method of characteristics has been developed as an effective technique to solve quasi-linear hyperbolic differential equations. By introducing two families of characteristic curves in the x - t plane, partial differential equations are replaced by the characteristic equations including only ordinary derivatives along the characteristic curves.

Equations (15) and (16) can be rewritten in a matrix form as:

$$\frac{\partial}{\partial t} \begin{pmatrix} \eta \\ q \end{pmatrix} + \begin{bmatrix} 0 & 1 \\ C_M^2 - \beta v^2 & 2\beta v \end{bmatrix} \frac{\partial}{\partial x} \begin{pmatrix} \eta \\ q \end{pmatrix} = 0 \quad (30)$$

It has been shown that the slopes of the characteristic curves are equal to the two eigenvalues of the coefficient matrix (Abbott, 1979). Thus,

$$\begin{aligned} \frac{dx}{dt} &= \beta v \pm \sqrt{\beta(\beta - 1)v^2 + C_M^2} \\ &\equiv \xi_{\pm} \end{aligned} \tag{31}$$

The characteristic equations are, then

$$\frac{dq}{dt} - \xi_{\mp} \frac{d\eta}{dt} = 0 \tag{32}$$

Several numerical techniques for solving the characteristic equations are available (Lin, 1952; Freemman and LeMehaute, 1964; Abbott and Verwey, 1970). Here a scheme, called the method of finite characteristics, is introduced through the improvement of Lin's method. The improvement, which is to include some higher order terms in the computation, has been found necessary because the ratio of the grid size to the wavelength in the computation of sea waves can not be as small as that for flood waves, owing to the restriction of the computational time.

The method of finite characteristics can be explained by Figure 2. Two finite charac-

Figure 2: Definition sketch for FCM

teristic curves are issued backward from the computation point F toward the previous time step. The finite characteristic curves are approximated by straight lines with the slope determined through the algorithmic form of Eq. (31)

$$x_F - x_L = \xi_{+,L} \Delta t \tag{33}$$

$$x_F - x_R = \xi_{-,R} \Delta t \tag{34}$$

where the subscripts F , L and R express the values at the points F, L and R. $\xi_{+,L}$ and $\xi_{-,R}$ are computed through linear interpolation of the values at the grid points A, B and C as follows:

$$\xi_{+,L} = \xi_{+,C} - \frac{x_L - x_C}{\Delta x} (\xi_{+,A} - \xi_{+,C}) \tag{35}$$

$$\xi_{-,R} = \xi_{-,C} + \frac{x_R - x_C}{\Delta x} (\xi_{-,B} - \xi_{-,C}) \quad (36)$$

By substituting Eqs. (35) and (36) into Eqs. (33) and (34), the positions x_L and x_R are explicitly expressed as:

$$x_L = x_F - \frac{\xi_{+,C} \Delta t}{1 + \frac{\Delta t}{\Delta x} (\xi_{+,C} - \xi_{+,A})} \quad (37)$$

$$x_R = x_F - \frac{\xi_{-,C} \Delta t}{1 + \frac{\Delta t}{\Delta x} (\xi_{-,B} - \xi_{-,C})} \quad (38)$$

Provided that the positions of the points L and R are determined, the values of η and q at these points are computed through the following second order interpolation.

$$\begin{aligned} \begin{pmatrix} \eta \\ q \\ \xi_{\pm} \end{pmatrix}_{L,R} &= \begin{pmatrix} \eta \\ q \\ \xi_{\pm} \end{pmatrix}_A \frac{(x_{L,R} - x_C)(x_{L,R} - x_B)}{2\Delta x^2} \\ &- \begin{pmatrix} \eta \\ q \\ \xi_{\pm} \end{pmatrix}_B \frac{(x_{L,R} - x_A)(x_{L,R} - x_B)}{\Delta x^2} \\ &+ \begin{pmatrix} \eta \\ q \\ \xi_{\pm} \end{pmatrix}_C \frac{(x_{L,R} - x_A)(x_{L,R} - x_C)}{2\Delta x^2} \end{aligned} \quad (39)$$

On the other hand, Eq. (32) is discretized along the finite characteristic curves as

$$q_F - q_L = \xi_{-,L} (\eta_F - \eta_L) \quad (40)$$

$$q_F - q_R = \xi_{+,R} (\eta_F - \eta_R) \quad (41)$$

Hence, η_F and q_F can be expressed in terms of η_L , η_R , q_L , q_R , $\xi_{-,L}$ and $\xi_{+,R}$ as:

$$\eta_F = \frac{\xi_{-,L} \eta_L - \xi_{+,R} \eta_R - (q_L - q_R)}{\xi_{-,L} - \xi_{+,R}} \quad (42)$$

$$q_F = \frac{\xi_{-,L} q_R - \xi_{+,R} q_L + \xi_{-,L} \xi_{+,R} (\eta_L - \eta_R)}{\xi_{-,L} - \xi_{+,R}} \quad (43)$$

When the computational point is located at the matching boundaries, the discontinuity of q should be considered. The jump of the value of q is determined through the matching boundary condition (27) as well as the algorithmic form of Eq. (21), that is

$$q^{n+1} = q^n - [q^{n+1} q^n \frac{\tan \theta}{(h - d_d)(h - d_u)} + \frac{P_{dd}^n - P_{du}^n}{l \cos \theta}] \Delta t \quad (44)$$

The offshore and onshore boundary conditions are discretized as:

$$\eta_{\text{off}}^{n+1} = \eta_{\text{off}}^n + \left[C_h \frac{\partial \eta}{\partial x} \Big|_{\text{off}}^n + 2 \frac{\partial \eta}{\partial t} \Big|_{\text{off}}^n \right] \Delta t \quad (45)$$

$$\eta_{\text{on}}^{n+1} = \eta_{\text{on}}^n - C_h \frac{\partial \eta}{\partial x} \Big|_{\text{on}}^n \Delta t \quad (46)$$

in which $\frac{\partial \eta}{\partial x} \Big|_{\text{off}}^n$ and $\frac{\partial \eta}{\partial x} \Big|_{\text{on}}^n$ are calculated through the numerical differentiation method based on Lagrangian interpolation formula (Hildebrand, 1987).

Lin's method was initially developed for the computation of continuous flow, but its further application have shown that it can also simulate discontinuities (Lin et al., 1982).

As long as the water surface elevation near the lateral boundaries is obtained, the reflection coefficient K_R and the transmission coefficient K_T can easily be calculated.

5 SOME COMPUTATIONAL RESULTS

Wave reflection and transmission coefficients are dependent on the incident wave conditions as well as the placement of the plate. The incident wave steepness H_1/L_0 , the relative water depth h/L_0 , the relative submerged depth d/h , the slope of the plate $\tan \theta$ and the relative length of the plate l/L_0 can be chosen as independent dimensionless parameters. To investigate the relationships, the variation of K_R and K_T against l/L_0 is computed for various values of the other parameters. The results are shown in Figs. 3 to 6 along with the experimental data. Table 1 summarizes the conditions.

Figure 3 shows the comparison of reflection and transmission coefficients among linear waves and waves with different incident steepness. It can be found that the influence of the incident wave steepness becomes remarkable when the wave nonlinearity is considered; the transmission coefficient decreases with the increase of the incident wave steepness.

Figure 4 shows the change in the wave reflection and transmission coefficients against the submerged depth of the plate. Since wave motion decays downwards from the free surface, too large a submerged depth of the plate makes little contribution to the wave deformation.

Figure 5 shows the variation of the reflection and transmission coefficients of waves with different relative water depth. It is found that for a given relative length of the plate, the reflection and transmission coefficients does not show very large difference for the wide change of the relative water depth. This indicates, as naturally expected,

Table 1: Conditions for computation and experiment

CASE	$h(\text{cm})$	$T(\text{s})$	$H_I(\text{cm})$	d/h	$\tan \theta$	
STP	1	20.0	0.80	SMALL	0.2	0.0
	2	20.0	0.80	1.5	0.2	0.0
	3	20.0	0.80	3.6	0.2	0.0
SMD	1	20.0	0.80	2.0	0.2	0.0
	2	20.0	0.80	2.0	0.5	0.0
RWD	1	20.0	0.88	1.5	0.2	0.0
	2	20.0	0.62	2.0	0.2	0.0
SLP	1	20.0	0.80	1.8	0.3	0.2
	2	20.0	0.80	1.8	0.3	0.4

that for a given absolute length of the plate, longer waves are easier to transmit over the plate. For very long waves, like tsunami, a plate can not function at all as a breakwater.

Figures 6 indicates that there is no significant change in the reflection and transmission coefficients with the slope of the plate if the mean submerged depth is kept constant. The computation for the inclined plate is available only for l/L_0 less than a certain value, because a longer plate would emerge from the free surface, for which the present model is not valid.

6 CONCLUDING REMARKS

A mathematical model of nonlinear wave motion has been developed and applied to simulating the wave transformation over a submerged plate. Numerical computation based on the method of finite characteristics for general conditions have been proposed. The computed wave reflection and transmission coefficients have been compared with the experimental data under various conditions. The overall agreement is satisfactory.

CHAPTER 11

Vertically 2-D Nearshore Circulation Model

Takao Yamashita¹, Yoshito Tsuchiya²
and
Dadang Ahmad Suriamihardja³

Abstract

A two layer undertow model is developed which consists of surface and inner layer. The surface layer defines breaking wave dynamics and the inner layer defines the mean flow(circulation) and turbulence fields. The interface between two layers is determined by time and depth averaging of the mean water level and wave height in the surf zone (interface model), in which Reynolds stresses are taken into consideration as well as radiation stresses. The system of equations in the inner layer is derived by time averaging the mass and momentum equations over one wave period. Time and space averaging of these equations in the surface layer defines the surface boundary conditions of the mean flow field in the inner layer. Turbulence in the inner layer is described by the standard $k - \epsilon$ model.

The numerical calculation method is also discussed and model calibration is performed by comparing with the experiments by Stive and Wind (1985).

1. Introduction

The vertical circulation occurring in the surf zone consists of both the shoreward mass transport due to breaking wave and the offshore-directed bottom current (undertow). Combining the 2-D vertical and horizontal models, it may be possible to construct a 3-D model of the nearshore circulation system.

Svendsen (1984)[6] developed a theoretical model using the first order approximation technique in describing breaking waves. Hansen and Svendsen (1984) [2] considered the effect of the bottom boundary layer in the undertow. This model was examined by using Stive and Wind's experimental data (1985)[4]. It was shown that the undertow is suppressed by the shear stress at the trough level, the static pressure induced by set-up, and the constraint of zero net flow.

Madsen and Svendsen (1979) [3] developed a theory of vertically integrated conservation equations for breaking waves in the surf zone by introducing the concept of time and depth averaging of mass, momentum and energy between the bottom and mean water level (M.W.L.). From their treatment an idea came

to mind to define the total depth by the surface and inner layers, thus allowing a theoretical treatment of the breaking waves in the surface layer.

In this study, a simplified two layer model is proposed, in which the surface layer is introduced to describe breaking wave dynamics and to obtain the time-averaged boundary conditions for dynamics in the inner layer. The interface between these two layers is set by M.W.L. The breaking waves generate turbulence and the turbulent kinetic energy conservation is considered in the model for the inner layer. Therefore, the boundary conditions for the $k - \epsilon$ equations in the inner layer are defined by modelling the dynamics of surface layer. Mass, momentum, and energy conservation laws are formulated by employing Madsen and Svendsen's model. The motion in the inner layer is decomposed into time-averaged mean flow and turbulence. The governing equations of mean flow motion are expressed in terms of the vorticity and stream function, which are derived from the mass and momentum conservation equations. The standard $k - \epsilon$ model is employed as the governing equation for turbulent motion. The coordinate transformation (conformal mapping) method developed by Wanstrath, Whitaker and Reid (1976)[7], is used to numerically calculate the 2-D vertical circulation pattern in arbitrary depth. Calibration of the numerical model is performed by a comparison with the experimental data of Stive and Wind (1985) [4].

2. Model Outline and Basic Equations

Using the coordinates and variables shown in Fig.1, the governing equations are derived. The inner layer is defined as the region extending from the bottom to the mean water level (wave set-up) $\bar{\zeta}$. While the surface layer extends from the trough of the breaking wave to its crest.

Fig.1 Schematic explanation of the model and coordinate system

The velocities u_i are decomposed into three modes, i.e. the mean flow \bar{u}_i , waves u_{wi} and fluctuations u'_i . Other quantities, σ_{ij} , p , s_{ij} are also decomposed in the

same manner, as:

$$\begin{aligned} u_i &= \bar{u}_i + u_{wi} + u'_i, & \sigma_{ij} &= \bar{\sigma}_{ij} + \sigma_{wij} + \sigma'_{ij}, \\ p_{ij} &= \bar{p}_{ij} + p_{wij} + p'_{ij}, & s_{ij} &= \bar{s}_{ij} + s_{wij} + s'_{ij} \end{aligned} \quad (1)$$

The characteristic time-scales of the three components are assumed to be quite different, therefore no correlation between them is considered. Applying these operations to the mass and momentum equations, the basic equations for the mean flow are obtained. When the Boussinesq's eddy-viscosity assumption is used to describe the Reynolds stresses $\overline{u'_i u'_j}$ by means of velocity gradients, the closure problem becomes a matter of how to determine the eddy viscosity ν_t , which is defined by:

$$\overline{u'_i u'_j} = -\nu_t \left(\frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) + \frac{2}{3} k \delta_{ij}, \quad \nu_t = C_\mu \frac{k^2}{\varepsilon}, \quad k = \frac{1}{2} \overline{u'_i u'_i} \quad (2)$$

(a) Inner layer: mean-flow equations

By differentiating x and z momentum equations and eliminating the pressure term \bar{p} , we get

$$\begin{aligned} \frac{\partial^2}{\partial x \partial z} (\bar{u}\bar{u} + \overline{u_w u_w} + \overline{u' u'}) + \left(\frac{\partial^2}{\partial z^2} - \frac{\partial^2}{\partial x^2} \right) (\bar{u}\bar{w} + \overline{u_w w_w} + \overline{u' w'}) \\ - \frac{\partial^2}{\partial x \partial z} (\bar{w}\bar{w} + \overline{w_w w_w} + \overline{w' w'}) = \nu \nabla^2 \left(\frac{\partial \bar{u}}{\partial z} - \frac{\partial \bar{w}}{\partial x} \right) \end{aligned} \quad (3)$$

When small amplitude wave theory is assumed the momentum fluxes of the total wave component, $\overline{u_w u_w}$, $\overline{u_w w_w}$ and $\overline{w_w w_w}$, become zero in Eq.(3).

The stream function ψ and vorticity Ω are now defined as

$$\frac{\partial \psi}{\partial z} = \bar{u}, \quad \frac{\partial \psi}{\partial x} = -\bar{w} \quad \text{and} \quad \Omega = \frac{\partial \bar{u}}{\partial z} - \frac{\partial \bar{w}}{\partial x} \quad (4)$$

In terms of the stream function and vorticity defined above, the basic equations are rewritten as:

$$\nabla^2 \psi = \Omega \quad (5)$$

and

$$\begin{aligned} \left(\frac{\partial \psi}{\partial z} \right) \left(\frac{\partial \Omega}{\partial x} \right) - \left(\frac{\partial \psi}{\partial x} \right) \left(\frac{\partial \Omega}{\partial z} \right) - \frac{\partial^2}{\partial x \partial z} \left(4\nu_t \frac{\partial^2 \psi}{\partial x \partial z} \right) \\ + \left(\frac{\partial^2}{\partial x^2} - \frac{\partial^2}{\partial z^2} \right) \left\{ \nu_t \left(\frac{\partial^2 \psi}{\partial z^2} - \frac{\partial^2 \psi}{\partial x^2} \right) \right\} = \nu \nabla^2 \Omega \end{aligned} \quad (6)$$

(b) Inner layer: standard $k - \varepsilon$ model

The k -equation is rewritten in the $x - z$ plane as:

$$\bar{u} \frac{\partial k}{\partial x} + \bar{w} \frac{\partial k}{\partial z} = \frac{\partial}{\partial x} \left\{ \left(\frac{\nu_t}{\sigma_k} + \nu \right) \frac{\partial k}{\partial x} \right\} + \frac{\partial}{\partial z} \left\{ \left(\frac{\nu_t}{\sigma_k} + \nu \right) \frac{\partial k}{\partial z} \right\} + \text{Prod} - \varepsilon \quad (7)$$

where

$$\text{Prod} = \nu_t \left\{ 2 \left(\frac{\partial \bar{u}}{\partial x} \right)^2 + 2 \left(\frac{\partial \bar{w}}{\partial z} \right)^2 + \left(\frac{\partial \bar{u}}{\partial z} + \frac{\partial \bar{w}}{\partial x} \right)^2 \right\} \quad (8)$$

The ε -equation is also rewritten as

$$\bar{u} \frac{\partial \varepsilon}{\partial x} + \bar{w} \frac{\partial \varepsilon}{\partial z} = \frac{\partial}{\partial x} \left\{ \left(\frac{\nu_t}{\sigma_\varepsilon} + \nu \right) \frac{\partial \varepsilon}{\partial x} \right\} + \frac{\partial}{\partial z} \left\{ \left(\frac{\nu_t}{\sigma_\varepsilon} + \nu \right) \frac{\partial \varepsilon}{\partial z} \right\} + \frac{\varepsilon}{k} (C_{1\varepsilon} \text{Prod} - C_{2\varepsilon} \varepsilon) \quad (9)$$

(c) Interface model

The boundary conditions for the governing equations in the inner layer are discussed here. The surface boundary is the mean water level $\bar{\zeta}$ which is an unknown value in the two layer system. Previous investigations of surf zone wave height and set-up show fairly good predictability of both quantities. Therefore, Svendsen's (1984)[6] model is employed to determine the wave set-up $\bar{\zeta}$ and breaking wave height variation. Svendsen also presented the mass, momentum, and energy dissipation due to breaking waves in his model by employing the first order approximation of motion, the effect of the surface roller and the wave shape parameter B_o . Consequently, Svendsen's model is needed to determine the wave energy dissipation (production in the k equation), mass flux and shear stress acting on the interface (surface) boundary.

On the other hand, the boundary condition for the stream function ψ , the vorticity Ω , the turbulent kinetic energy k , and its dissipation ε must be determined. For this problem, Madsen and Svendsen's (1979)[3] formulation of the mass and momentum conservation equations are employed.

The momentum equation in the x -direction is integrated over depth and then averaged over the wave period T_w as

$$\frac{\partial}{\partial x} \int_{-h}^{\bar{\zeta}} \rho \bar{u} \bar{u} dz + \frac{\partial}{\partial x} (S' + S_w) = -\rho g (h + \bar{\zeta}) \frac{\partial \bar{\zeta}}{\partial x} \quad (10)$$

where S' is the depth-integrated Reynolds stress and S_w the radiation stress defined by respectively

$$S' = \int_{-h}^{\bar{\zeta}} \rho \left(2\nu_t \frac{\partial \bar{u}}{\partial x} - \frac{2}{3} k \right) dz \quad (11)$$

$$S_w = \int_{-h}^{\bar{\zeta}} \rho \bar{u}_w \bar{u}_w dz + \int_{-h}^{\bar{\zeta}} \bar{p}_o dz - \frac{1}{2} \rho g \bar{\zeta}_w \bar{\zeta}_w \quad (12)$$

where p_o is the dynamic pressure given by

$$p_o = \rho g (z - \bar{\zeta}) + p \quad (13)$$

In Eq.(10), the inertia term, and the depth-integrated Reynolds stress term are added to the usual momentum balance equation. The latter term described by Eq.(11) is the interaction term between a mean flow distribution and k -equation in the inner layer.

The energy equation is given by

$$\frac{\partial B_*}{\partial x} = D_* \quad (14)$$

where B_* is the mean wave energy flux and D_* the wave energy dissipation. The non-dimensional wave energy flux B and energy dissipation D are introduced respectively, as:

$$B = \frac{B_*}{\rho g C H^2} \quad \text{and} \quad D = D_* \frac{4hT_w}{\rho g C H^3} \quad (15)$$

where C is the propagation speed of the breaker. In the surf zone, C is approximated by $C \sim \sqrt{g(h + \bar{\zeta})}$. Using Eqs.(14) and (15), the equation for the wave height variation is finally botained as

$$\frac{H}{H_r} = K_S / \left(1 - \frac{H_r}{8C_r B_r T_w} \int_{x_r}^x \frac{DK_S^3}{h + \bar{\zeta}} dx \right) \quad (16)$$

where the subscript r refers to some chosen reference points, and K_S is the shoaling coefficient.

Solving Eqs.(10) and (16) simultaneously, the wave set-up and breaker wave height variation are obtained. However, in these equations, three parameters must be estimated, B , S_w and D . Svendsen (1984) [5] evaluated these parameters assuming that (i) the mean velocity in the roller is equal to the propagation speed C , (ii) the cross sectional area A of the roller is equal to $0.9H^2$, and (iii) wave energy dissipation is analogous to that of hydraulic jump, these are respectively given as:

$$S_w \simeq \rho g \left(\frac{3}{2} B_o + 0.9 \frac{h + \bar{\zeta}}{L} \right) H^2 \quad (17)$$

$$B = B_o + 0.45 \frac{h + \bar{\zeta}}{L} \quad (18)$$

$$D = - \left[\left(1 + \frac{\zeta_c}{H} \frac{H}{h + \bar{\zeta}} \right) \left\{ 1 + \frac{H}{h + \bar{\zeta}} \left(\frac{\zeta_c}{H} - 1 \right) \right\} \right]^{-1} \quad (19)$$

where L is the wave length, ζ_c :the crest elevation and B_o : wave shape parameter defined by

$$B_o = \frac{1}{T_w} \int_0^{T_w} \left(\frac{\zeta}{H} \right)^2 dt \quad (20)$$

(d) Surface layer model

The boundary conditions for the stream function ψ and the vorticity Ω equations are considered here. To determine the boundary conditions at the surface $\bar{\zeta}$ of the inner layer, the equations of mass and momentum are derived in the

surface layer. The kinematic boundary condition at $z = \bar{\zeta}$ is derived from the conservation of mass in the surface layer as

$$\bar{u}(\bar{\zeta}) \frac{\partial \bar{\zeta}}{\partial x} - \bar{w}(\bar{\zeta}) = -\frac{\partial}{\partial x} \int_{\zeta}^{\bar{\zeta}} u dz \quad (21)$$

The dynamic boundary condition at $z = \bar{\zeta}$ is derived from the conservation of momentum in the surface layer. The pressure at $z = \bar{\zeta}$ is obtained by integrating the vertical momentum equation between ζ and $\bar{\zeta}$ and time-averaging over the wave period T_w , as

$$\frac{\bar{p}(\bar{\zeta})}{\rho} = -\overline{w'(\zeta)w'(\bar{\zeta})} + \overline{u'(\zeta)w'(\bar{\zeta})} \frac{\partial \bar{\zeta}}{\partial x} - \overline{w(\bar{\zeta})} \frac{\partial}{\partial x} \int_{\zeta}^{\bar{\zeta}} u dz \quad (22)$$

where the viscous term is neglected. The time-averaged horizontal momentum conservation in the surface layer is derived from the following definition.

$$\overline{\int_{\zeta}^{\bar{\zeta}} \text{momentum} dz} = \overline{\int_{-h}^{\zeta} \text{momentum} dz} - \overline{\int_{-h}^{\zeta} \text{momentum} dz} \quad (23)$$

The horizontal momentum equation is given by

$$\frac{\partial}{\partial x} \overline{\int_{\zeta}^{\bar{\zeta}} \left(u^2 + \frac{p}{\rho} \right) dz} = -\frac{\bar{p}(\bar{\zeta})}{\rho} \frac{\partial \bar{\zeta}}{\partial x} - \overline{u'(\zeta)u'(\bar{\zeta})} \frac{\partial \bar{\zeta}}{\partial x} + \overline{u'(\zeta)w'(\bar{\zeta})} - \bar{u}(\bar{\zeta}) \frac{\partial}{\partial x} \overline{\int_{\zeta}^{\bar{\zeta}} u dz} \quad (24)$$

Substituting the pressure Eq.(22) into Eq.(24), the right-hand side of the equation becomes:

$$\begin{aligned} \text{RHS} = & \left\{ \overline{w'(\zeta)w'(\bar{\zeta})} - \overline{u'(\zeta)w'(\bar{\zeta})} \right\} \frac{\partial \bar{\zeta}}{\partial x} + \left\{ \bar{u}(\bar{\zeta}) + \bar{w}(\bar{\zeta}) \frac{\partial \bar{\zeta}}{\partial x} \right\} \frac{\partial M_S}{\partial x} \\ & - \overline{u'(\zeta)w'(\bar{\zeta})} \left(\frac{\partial \bar{\zeta}}{\partial x} \right)^2 + \overline{u'(\zeta)w'(\bar{\zeta})} \end{aligned} \quad (26)$$

where

$$M_S = \overline{\int_{\zeta}^{\bar{\zeta}} u dz} \quad (27)$$

When the orders of $\bar{u}(\bar{\zeta})$ and $\partial \bar{\zeta} / \partial x$ are $O(1)$ and $O(\delta)$, the orders of the following terms can be estimated by the kinematic boundary condition, Eq.(21).

$$\bar{w}(\bar{\zeta}) \sim O(\delta), \quad \frac{\partial M_S}{\partial x} \sim O(\delta) \quad (28)$$

In the surface layer, strong shear flow is generated by the mass transport shoreward due to the breaker. Then the following order estimation may be reasonable.

$$\overline{u'(\zeta)w'(\bar{\zeta})} \sim \frac{\partial \bar{u}}{\partial z} \sim O(1) \quad (29)$$

This order estimation leads to the brief expression of Eq.(26), as

$$\text{RHS} = \overline{u'(\zeta)w'(\zeta)} + O(\delta) \quad (30)$$

On the other hand, LHS of Eq.(24) can be estimated as follows. The local pressure is given by integrating the vertical momentum equation between z and ζ as

$$\frac{p(z)}{\rho} = g(\zeta - z) + \frac{\partial}{\partial x} \int_z^\zeta u w dz - \rho w^2(z) \quad (31)$$

Assuming that u^2 is decomposed as

$$u^2(z) = \bar{u}^2(z) + u_w^2(z) + u'^2(z) \quad (32)$$

then, substituting these equations into the left-hand side of Eq.(24) yields

$$\begin{aligned} \text{LHS} = \frac{\partial}{\partial x} \left\{ \frac{g}{2} \overline{(\zeta - \bar{\zeta})^2} + \overline{(\zeta - \bar{\zeta}) \int_z^\zeta u w dz} - \overline{\int_z^\zeta w w dz} \right. \\ \left. + \overline{(\zeta - \bar{\zeta}) (\bar{u}^2(\bar{\zeta}) + u_w^2(\bar{\zeta}) + u'^2(\bar{\zeta}))} \right\} \quad (33) \end{aligned}$$

It is then assumed that in the surface layer, the large scale turbulence exists whose velocity and surface fluctuation have dominant frequency in the spectral domain. If this dominant frequency is a harmonics of the wave, and other spectral components are negligibly small, the turbulence components can be treated in the same manner as wave components. However, this assumption may be too bold to apply at this time since turbulence is usually characterized by multi-phase motion. However, eddies generated by breaking waves seem to have the same dominant frequency which is strongly related to the wave motion. If the above assumption is allowed, the brief expression of Eq.(33) can be obtained, as

$$\text{LHS} = \frac{\partial}{\partial x} \left\{ \frac{g}{2} (\overline{\zeta_w \zeta_w} + \overline{\zeta' \zeta'}) \right\} \quad (34)$$

Finally the dynamic boundary condition at the surface of the inner layer is

$$\overline{u'(\zeta)w'(\zeta)} = \frac{\partial}{\partial x} \left\{ \frac{g}{2} (\overline{\zeta_w \zeta_w} + \overline{\zeta' \zeta'}) \right\} \quad (35)$$

In the equation, the first term on the right-hand side is approximated by Eq.(20) and, for the second term, the following assumption is made.

$$\overline{\zeta' \zeta'} \simeq \left(\frac{A}{L} \right)^2 \quad (36)$$

Furthermore, the shear stress due to turbulence is described by

$$\overline{u'(\zeta)w'(\zeta)} = -\frac{\tau_s}{\rho} \simeq -\nu_t \left. \frac{\partial \bar{u}}{\partial z} \right|_{z=\zeta} \quad (37)$$

Consequently, the dynamic surface boundary condition, which is expressed by breaking wave quantities, is given as

$$\nu_t \left. \frac{\partial \bar{u}}{\partial z} \right|_{z=\bar{\zeta}} = -\frac{\partial}{\partial x} \left\{ \frac{g}{2} \left(H^2 B_0 + \frac{A^2}{L^2} \right) \right\} \quad (38)$$

3. Numerical Model

a. Coordinate transformation

In the numerical model the conformal mapping method (Wanstrath, Whitaker and Reid (1976)[7]) is employed to make the model applicable over a wider range of surf zone topography. The governing equations derived in the Z -plane are transformed to the ζ^* -plane(Fig.2). The arbitrary surface and bottom boundaries in Z -plane are transformed into straightline ($\eta = \pm\beta$) in the ζ^* -plane.

(a) Z -plain

(b) ζ^* -plane

Fig.2 Z and ζ^* -plane in the coordinate transformation

$$x(\xi, \eta) = \xi + \sum_{n=1}^N (b_n \sinh nk_c \eta + c_n \cosh nk_c \eta) \sin nk_c \xi \quad (39)$$

$$z(\xi, \eta) = b_0 + \eta + \sum_{n=1}^N (b_n \cosh nk_c \eta + c_n \sinh nk_c \eta) \cos nk_c \xi. \quad (40)$$

The Fourier coefficients b_n ($n = 0, 1, 2, \dots, N$), and c_n ($n = 1, 2, 3, \dots, N$) are determined by matching the surface and bottom boundaries at $\eta = \pm\beta$, using the least square error. The transformation function J^2 is:

$$\frac{\partial(x, z)}{\partial(\xi, \eta)} = \left(\frac{\partial x}{\partial \xi}\right)^2 + \left(\frac{\partial z}{\partial \xi}\right)^2 \equiv J^2. \quad (41)$$

Using these definitions, the relations of partial differentiations of function ϕ with respect to (x, z) and (ξ, η) are

$$\frac{\partial \phi}{\partial x} = -\frac{1}{J^2} \left(\frac{\partial z}{\partial \xi} \frac{\partial \phi}{\partial \eta} - \frac{\partial x}{\partial \xi} \frac{\partial \phi}{\partial \xi} \right) = a \frac{\partial \phi}{\partial \xi} - b \frac{\partial \phi}{\partial \eta} \quad (42)$$

$$\frac{\partial \phi}{\partial z} = -\frac{1}{J^2} \left(-\frac{\partial z}{\partial \xi} \frac{\partial \phi}{\partial \xi} - \frac{\partial x}{\partial \xi} \frac{\partial \phi}{\partial \eta} \right) = a \frac{\partial \phi}{\partial \eta} + b \frac{\partial \phi}{\partial \xi} \quad (43)$$

where

$$a \equiv \frac{1}{J^2} \left(\frac{\partial x}{\partial \xi} \right), \quad b \equiv \frac{1}{J^2} \left(\frac{\partial z}{\partial \xi} \right). \quad (44)$$

Finally, operators of the first order partial differentiation are given by

$$\frac{\partial}{\partial x} = a \frac{\partial}{\partial \xi} - b \frac{\partial}{\partial \eta} \equiv D_x, \quad \frac{\partial}{\partial z} = a \frac{\partial}{\partial \eta} + b \frac{\partial}{\partial \xi} \equiv D_z. \quad (45)$$

The second order partial differentiations are

$$D_{xx}(\) = aD_{\xi\xi}(a, \) + bD_{\eta\eta}(b, \) - aD_{\xi\eta}(b, \) - bD_{\eta\xi}(a, \) \quad (46)$$

$$D_{zz}(\) = aD_{\eta\eta}(a, \) + bD_{\xi\xi}(b, \) + aD_{\eta\xi}(b, \) + bD_{\xi\eta}(a, \) \quad (47)$$

$$D_{xz}(\) = D_{zx}(\) = aD_{\xi\xi}(b, \) - bD_{\eta\eta}(a, \) + aD_{\xi\eta}(a, \) - bD_{\eta\xi}(b, \) \quad (48)$$

where

$$\begin{aligned} D_{\xi\xi}(a, \) &= \frac{\partial}{\partial \xi} \left(a \frac{\partial}{\partial \xi} \right), & D_{\xi\eta}(a, \) &= \frac{\partial}{\partial \xi} \left(a \frac{\partial}{\partial \eta} \right), \\ D_{\eta\xi}(a, \) &= \frac{\partial}{\partial \eta} \left(a \frac{\partial}{\partial \xi} \right), & D_{\eta\eta}(a, \) &= \frac{\partial}{\partial \eta} \left(a \frac{\partial}{\partial \eta} \right). \end{aligned} \quad (49)$$

The governing equations derived in the Z -plane are transformed to the ζ^* -plane by applying the above mentioned operators. The stream function and vorticity equations are rewritten as:

$$\nabla_{(\xi, \eta)}^2 \psi = J^2 \Omega \quad (50)$$

$$D_z(\psi) \left(a \frac{\partial \Omega}{\partial \xi} - b \frac{\partial \Omega}{\partial \eta} \right) - D_x(\psi) \left(a \frac{\partial \Omega}{\partial \eta} + b \frac{\partial \Omega}{\partial \xi} \right) + F^*(\Omega, \nu_t) = \frac{\nu_t}{J^2} \nabla_{(\xi, \eta)}^2 \Omega \quad (51)$$

where

$$F^*(\Omega, \nu_t) = -4D_{xz}\psi D_{xz}\nu_t + \{D_{zz}(\nu_t) - D_{xx}(\nu_t)\} \{\Omega - 2D_{xx}(\psi)\} \quad (52)$$

Similarly, the k and ε -equations are transformed to the ζ^* -plane as, respectively:

$$\begin{aligned}
 & a \frac{\partial}{\partial \xi} (\bar{u}k) - b \frac{\partial}{\partial \eta} (\bar{u}k) + a \frac{\partial}{\partial \eta} (\bar{w}k) + b \frac{\partial}{\partial \xi} (\bar{w}k) - \left\{ a \frac{\partial}{\partial \xi} \left(\frac{\nu_t}{\sigma_k} \right) - b \frac{\partial}{\partial \eta} \left(\frac{\nu_t}{\sigma_k} \right) \right\} \left(a \frac{\partial k}{\partial \xi} - b \frac{\partial k}{\partial \eta} \right) \\
 & - \left\{ a \frac{\partial}{\partial \eta} \left(\frac{\nu_t}{\sigma_k} \right) + b \frac{\partial}{\partial \xi} \left(\frac{\nu_t}{\sigma_k} \right) \right\} \left(a \frac{\partial k}{\partial \eta} + b \frac{\partial k}{\partial \xi} \right) - \frac{\nu_t}{\sigma_k J^2} \nabla^2_{(\xi, \eta)} k = \text{Prod} - \varepsilon \quad (53) \\
 & a \frac{\partial}{\partial \xi} (\bar{u}\varepsilon) - b \frac{\partial}{\partial \eta} (\bar{u}\varepsilon) + a \frac{\partial}{\partial \eta} (\bar{w}\varepsilon) + b \frac{\partial}{\partial \xi} (\bar{w}\varepsilon) - \left\{ a \frac{\partial}{\partial \xi} \left(\frac{\nu_t}{\sigma_\varepsilon} \right) - b \frac{\partial}{\partial \eta} \left(\frac{\nu_t}{\sigma_\varepsilon} \right) \right\} \left(a \frac{\partial \varepsilon}{\partial \xi} - b \frac{\partial \varepsilon}{\partial \eta} \right) \\
 & - \left\{ a \frac{\partial}{\partial \eta} \left(\frac{\nu_t}{\sigma_\varepsilon} \right) + b \frac{\partial}{\partial \xi} \left(\frac{\nu_t}{\sigma_\varepsilon} \right) \right\} \left(a \frac{\partial \varepsilon}{\partial \eta} - b \frac{\partial \varepsilon}{\partial \xi} \right) - \frac{\nu_t}{\sigma_\varepsilon J^2} \nabla^2_{(\xi, \eta)} \varepsilon = \frac{\varepsilon}{k} (C_{1\varepsilon} \text{Prod} - C_{2\varepsilon} \varepsilon) \quad (54)
 \end{aligned}$$

where

$$\text{Prod} = \nu_t \left[2D_x(\bar{u})^2 + 2D_z(\bar{w})^2 + \{D_z(\bar{u}) + D_x(\bar{w})\}^2 \right] \quad (55)$$

b. Numerical scheme

Numerical solution to an advection and diffusion (A/D) equation such as the vorticity equation, suffers from the numerical (artificial) diffusion as well as wiggles. The Dennis-Chang method is known as one of methods which can reduce these numerical problems in the A/D equation with the second order accuracy. An iteration form is discretized by this scheme and calculated till the solution converges. Using the operator notations, $A(\)$ and $D(\)$, for advection and diffusion terms, finite difference equation are represented as:

$$A_{UD}(\Omega^{n+1}) - D(\Omega) = A_{UD}(\Omega^n) - A_{CD}(\Omega^n) \quad (56)$$

where $A_{UD}(\)$ and $A_{CD}(\)$ are the upwind and centered difference operators, respectively, which given by:

$$\begin{aligned}
 A_{UD}(\Omega) &= \frac{U+|U|}{2\Delta x} (\Omega_{i,j} - \Omega_{i-1,j}) + \frac{U-|U|}{2\Delta x} (\Omega_{i+1,j} - \Omega_{i,j}) \\
 &+ \frac{V+|V|}{2\Delta z} (\Omega_{i,j} - \Omega_{i,j-1}) + \frac{V-|V|}{2\Delta z} (\Omega_{i,j+1} - \Omega_{i,j}) \quad (57)
 \end{aligned}$$

$$A_{CD}(\Omega) = \frac{1}{2\Delta x} \{ (U\Omega)_{i+1,j} - (U\Omega)_{i-1,j} \} + \frac{1}{2\Delta z} \{ (V\Omega)_{i,j+1} - (V\Omega)_{i,j-1} \} \quad (58)$$

and for the diffusion term :

$$\begin{aligned}
 D(\Omega) &= \frac{1}{\Delta x^2} \{ (\nu_t \Omega)_{i+1,j} - 2(\nu_t \Omega)_{i,j} + (\nu_t \Omega)_{i-1,j} \} \\
 &+ \frac{1}{\Delta z^2} \{ (\nu_t \Omega)_{i,j+1} - 2(\nu_t \Omega)_{i,j} + (\nu_t \Omega)_{i,j-1} \} \quad (59)
 \end{aligned}$$

where the advection velocity U and V are written as:

$$U = aD_x(\psi) - bD_z(\psi), \quad V = -\{aD_x(\psi) + bD_z(\psi)\} \quad (60)$$

For stable calculation, the dumping coefficient α_* is used at each iteration as

$$\Omega^{n+1} = \alpha_* \Omega^n \quad (61)$$

In the cases of Dirichlet boundary problem, Woods boundary condition is applicable as

$$\Omega_0 = -\frac{1}{2}\Omega_1 - \frac{3}{\Delta x^2}(\Omega_1 - \Omega_0) + O(\Delta x^3) \quad (62)$$

where the suffix 0 indicates the value at the boundary, and 1 indicates the value just inside the boundary.

c. Interface boundary conditions

At the surface, both the kinematic and dynamic boundary conditions for mean flow variables, ψ and Ω , are determined by the approximate expressions of the momentum and mass conservation equations in the surface layer.

The kinematic boundary condition in the Z -plane determines the stream function in the transformed coordinates. One possible example can be given as follows.

The velocity components \bar{u}^* , \bar{w}^* in the ζ^* -plane can be transformed to

$$\bar{u}^* = -\frac{\partial x}{\partial \eta}(\bar{w}_s - \bar{u}_s \frac{\partial \bar{\zeta}}{\partial x}) = -\frac{\partial M_S}{\partial \eta}, \quad \bar{w}^* = \frac{\partial x}{\partial \xi}(\bar{w}_s - \bar{u}_s \frac{\partial \bar{\zeta}}{\partial x}) = \frac{\partial M_S}{\partial \xi} \quad (63)$$

In these equations $-M_S$ is the stream function in the transformed coordinates system, which gives the surface boundary condition for the ψ -equation.

The boundary condition for the vorticity equation is

$$\Omega_s^* = \frac{\partial \bar{u}^*}{\partial \eta} \Big|_s - \frac{\partial \bar{w}^*}{\partial \xi} \Big|_s = \frac{\tau_s}{\rho \nu_t} \Big|_s - \frac{\partial^2 M}{\partial \xi^2} \Big|_s \quad (64)$$

The boundary condition for the k -equation at the surface can be given by

$$k|_s = \sqrt{\frac{\gamma_s}{C_\mu}} \left| \frac{\tau_s}{\rho} \right| \quad (65)$$

where τ_s is shear stress at the surface. The boundary condition for ε is

$$\varepsilon = \gamma_s \text{Prod}|_s \quad (66)$$

where

$$\text{Prod}|_s = \frac{gH^3D}{4h^2T_w} + \nu_t \left\{ 2 \left(\frac{\partial \bar{u}}{\partial x} \right)^2 + 2 \left(\frac{\partial \bar{w}}{\partial z} \right)^2 + \left(\frac{\partial \bar{u}}{\partial z} + \frac{\partial \bar{w}}{\partial x} \right)^2 \right\} \Big|_s \quad (67)$$

where γ_s is the coefficient to be determined by turbulence properties.

For both side boundary conditions, a third order polynomial stream function may be assumed and for the bottom boundary conditions, usual boundary conditions can be employed.

4. Model tests and conclusions

In order to verify the applicability of the model, test calculations were performed in the inner layer, using the following assumptions; uniform distribution of ν_t , third order polynomial of stream function distribution at both side-boundaries, and the slip condition on the bottom.

Fig.3 shows the changes in the relative values of wave celerity C/C_B , wave heights H/H_B and mean water level ζ/h_B with the relative water depth h/h_B to compare with the experiments by Hansen and Svendsen (1979) [1]. Their experimental conditions are; the beach slope $s = 1/40$, wave period $T = 1.79s$, deep water steepness $H_o/L_o = 0.032$. The figure shows that the calculations of breaking waves and mean water level are in reasonable agreement with the experiments. Furthermore, the test calculation of undertow velocity profile corresponding to Hansen and Svendsen's experimental condition is shown in Fig.4.

Fig.3 Changes in the calculated wave celerity C/C_B , height H/H_B and mean water level ζ/h_B in comparison with Hansen and Svendsen's experiments [1].

The vertical velocity distribution of undertow in the inner layer region is compared with experiments by Stive and Wind (1985) [4] in the relative water depth range of $h/h_B = 0.88, 0.765, 0.647$ and 0.53 . Comparisons between the calculated velocity vectors and the experiments are shown in Fig.5, where solid circles indicate the experimental data of Stive and Wind. The vertical circulation pattern calculated by the 2-D vertical circulation model under their experimental condition is shown in Fig.6.

Because of an insufficient quantity of experimental data verification is not possible, however, the theoretical curves agree reasonably well with experiments. From the comparison between Stive and Wind's laboratory experiment of undertow and our test calculations, where a uniform distribution of eddy viscosity ν_t is assumed,

it could be concluded that the undertow velocity field in the inner surf zone can be calculated by the 2-DV model developed in this study. For the cases of arbitrary bathymetry, this model is more applicable than the previous 1-DV model.

Fig.4 Test calculation of undertow velocity profile

Fig.5 The vertical distributions of undertow velocity vectors and horizontal velocity profiles (solid curves) by Stive and Wind's experiment [4], at the points of $h/h_B = 0.88, 0.765, 0.647, 0.53$.

Difficulties, however, still exist in improving the side boundary conditions which are in consistency with both mean and turbulent flow fields including bottom and surface boundary conditions. In other words, further extension of the proposed 2-DV model is required to clarify the treatment of the bottom boundary conditions which can satisfy the no-slip condition of mean flow and wall boundary condition of the $k - \epsilon$ equations. It is emphasized that development of the 2-DV undertow model, which includes turbulent properties, contributes to the progress of surf zone investigations, such as sand transport mechanism, numerical calculation of the equilibrium beach profile, 3-D nearshore circulation model.

Fig.6 The vertical circulation field calculated by the model under the experimental condition of Stive and Wind [4].

CHAPTER 12

Violent Water Motion at Breaking-Wave Impact

M.J. Cooker* and D.H. Peregrine†

Abstract

A numerical study of water waves breaking against a vertical wall is described. The exact equations for free-surface potential flow are solved. Solutions for a simple overturning wave meeting a vertical wall placed at several positions give unexpectedly violent water motion. The face of the incident wave can converge towards a point on the wall causing very high pressure, acceleration and velocity. It seems likely that this particular type of flow corresponds to the most extreme conditions encountered in laboratories and on coasts despite the lack of any direct water impact. Details of the flow reveal that compressibility of the water is unlikely to be relevant for wave forces, but that scaling from laboratory to prototype should allow for wall roughness and for small waves riding on the incident wave.

1. Introduction

We describe results from a computational study of waves which are breaking or near breaking as they strike a vertical wall. Our aim has been to see how much information can be obtained about violent wave impacts, from a two-dimensional numerical model of irrotational inviscid flow. The model accurately deals with the overturning motion of a breaking wave and provides full information on velocities, pressures etc. up to the instant of impact.

A prototype example of the type of wave impact we envisage is sketched in figure 1. Shoaling water in front of a sea wall or breakwater causes an incident wave to break. Since such waves can cause appreciable damage many model experiments have been performed, e.g. Bagnold (1939), Nagai (1960), Mitsuyasu (1966), Richert (1968), Kirkgöz (1982), Chan & Melville (1988) and Partenscky (1988).

*Research Assistant. †Professor.

The underwater shape of the structure, or bed profile may cause the height/depth ratio of breaking waves to be much greater than that for a typical wave on a gently sloping beach. For example in some of Nagai's experiments the base of the vertical wall was exposed in front of some incident waves. This large height/depth ratio indicates that either the particular topography of an experimental or prototype structure should be modelled or an unconventional incident wave, much higher than the depth, should be used. We make the latter choice.

In addition we wish to study the effect of varying the distance between the wall and the breaking point of the wave. We do this by forming a wave which propagates over a flat horizontal bed. The initial wave has a gradual, monotonic increase in surface elevation. Hence, when it propagates, it steepens as the higher parts tend to catch up the lower portion of the wave. By choosing wave heights larger than 0.3 times the depth, the wave continues to steepen until it breaks. There is zero flow in front of this wave so that a vertical wall can be placed at any chosen spot in the path of the wave. This gives two primary parameters that may be varied:

- (i) the wave height
- (ii) the position of the wall relative to the position at which the wave would break in the absence of a wall.

In this paper, we consider a single wave height and look at variations of the wall position. Comparisons can be made with other types of wave by noting that our initial depth of water, h , corresponds to the depth of water in the *trough* of oscillatory waves, and not to the mean water level.

2. The mathematical and numerical model

The flow is assumed to be inviscid, two-dimensional and incompressible with irrotational flow so that a velocity potential satisfying Laplace's equation can be used. The effect of the air above the water is neglected, so that the free surface is at constant pressure. No further approximations are made in the mathematical formulation.

The numerical modelling is carried out with a program developed from the accurate and efficient, high-order, boundary-integral method of Dold and Peregrine (1986). Recent examples of work with closely related programs are Tanaka, Dold, Lewy and Peregrine (1987) and Cooker, Peregrine, Vidal and Dold (1990).

The initial wave, we have chosen, has a horizontal velocity

$$u(x,0) = -\frac{1}{2}u_0(gh)^{\frac{1}{2}}[1+\tanh \lambda(x-x_0)]$$

and elevation $\zeta(x_0) = (|u_0| + \frac{1}{2}u_0^2)h$.

This corresponds to a "simple-wave" solution of shallow-water theory for a wave propagating in the $-x$ direction if the initial surface slope is gentle enough. Using units in which g and h are both unity, we illustrate results for the wave of height

$$\Delta h = \zeta(\infty, 0) - \zeta(-\infty, 0) = 1.5$$

(i.e. $u_0 = 1.1623$). With $\lambda = 0.5$, there was no significant wave in the $+x$ direction and the wave soon develops into a plunging breaker as shown in figure 2 where $x_0 = 0$. Although shallow-water theory guides our choice of initial conditions, the computations make no such simplifying assumptions.

A vertical wall can be inserted in this flow at any chosen place. In fact, the wall is modelled by using symmetry: two equal and oppositely-directed waves travel towards each other starting a distance x_0 from the line of symmetry ($x=0$). For example $x_0 = 9$ gives a wall positioned at $x = -9$ in figure 2, directly in the path of the overturning jet. On the other hand $x_0 = 7.5$ places a wall close to the point where the wave first has a vertical tangent to its free surface.

For purposes of illustration just the one initial wave, $\Delta h = 1.5$, $\lambda = 0.5$, is used with different values of x_0 . This wave can be compared with other more realistic waves by noting that at the initial time there is no motion at the wall and water is moving towards the wall. Thus, our initial condition resembles an oscillatory or irregular wave at the moment its trough is adjacent to the wall. That means our depth h , corresponds to *minimum* water depth at the wall.

3. Examples of wave motion against a wall

First we consider the case $x_0 = 9$ where an overturning wave meets the wall. This is illustrated in figure 3. As may be seen, the profile of the overturning part of the wave appears to be unaffected by the wall. Examination of the computed velocities and accelerations shows that the velocity of the jet is unchanged at $2.6 (gh)^{\frac{1}{2}}$ and the horizontal acceleration under the jet, which is $3.4g$ in the undisturbed wave, changes little. On the other hand, the part of the wave near the water-line cannot pass through the wall and *rises quickly up the wall*. For the last profile calculated the vertical velocity and acceleration at the wall are $18.5 (gh)^{\frac{1}{2}}$ and $17.5 g$, respectively.

The current program is unable to model the direct impact of the jet on the wall (though see Cooker and Peregrine, 1990). However, experiments from those of Bagnold (1939) onwards, clearly show that maximum pressures occur if the wave has a vertical face when it meets the wall. Hence we could expect from figure 2 a value of $x_0 = 7.5$ to give us a more severe impact.

As may be seen in the illustrations of figure 4(a) and (b) the wave with $x_0 = 7.5$ fails to develop a vertical face, because of the proximity of the wall. The water surface rises smoothly and then forms a thin vertical jet at the wall, so no actual impact occurs. Except for the region near its base the jet is in free fall. Its velocity of $14 (gh)^{\frac{1}{2}}$ indicates it could rise to a height of about $100h$. In practice its motion is likely to be disrupted by the air.

The flow at the base of the jet is interesting, especially at its inception. Here a maximum water acceleration of nearly $2000g$ is computed and the correspondingly high pressure gradients lead to a brief high pressure on the wall, as the jet forms. The distribution of pressure on the wall at the time of maximum pressure is given in figure 5. Note how the pressure is significantly greater than instantaneous hydrostatic pressure all the way down to the bed. In figure 6 contours of pressure field throughout the water are shown. It can be seen that substantial pressures extend some distance from the wall.

From an engineering point of view it is the pressure distribution on the wall which is usually most relevant. This is plotted as a function of time in figure 7. Only a brief interval $(-0.7 \text{ to } +0.045)(h/g)^{\frac{1}{2}}$ each side of the maximum is shown, but as may be seen this covers all the pressure greater than $8\rho gh$. The values that would be read by a fixed pressure gauge on the wall are easily deduced by looking along a horizontal line in the diagram.

As already noted the incident wave does not become vertical for $x_0 = 7.5$; computations with $x_0 = 8$ do give a vertical face. As shown in figure 8 this wave only briefly has a vertical face. The free surface flow is dominated by a convergence toward the wall. Again a jet forms. This example gives the most severe conditions we have computed so far. Compared with the case of $x_0 = 7.5$ the greater convergence of the flow gives a smaller, more violent jet. Its velocity is $20 (gh)^{\frac{1}{2}}$, corresponding to a height of $200h$ in free fall. The small jet size leads to greater computational effort being needed to resolve the motion. At the last reliably resolved time, pressure and acceleration are still increasing at levels in excess of $50\rho gh$ and $6000g$, respectively. Maxima of over $60\rho gh$ and $8000g$ are expected. The maximum value of $\partial p/\partial t$ has been calculated and is $3000\rho g^{\frac{3}{2}}h^{\frac{1}{2}}$, which gives a typical time scale for the pressure rise of about $0.005(h/g)^{\frac{1}{2}}$.

4. Discussion

It has been a surprise that high "impact-type" pressures are found in a smooth potential flow. These pressures are of the same order of magnitude as the maximum pressures found experimentally for laboratory waves. As is well known these do not agree well with large-scale measurements when Froude scaling is used. Nevertheless we show in table 1, how our estimated maximum results scale for different heights of wave from laboratory to full-scale.

Table 1: Scaling of extreme conditions

Initial water depth	h	<u>50mm</u>	<u>100mm</u>	<u>1m</u>	<u>5m</u>
Total initial wave height	1.5h	75mm	150mm	1.5m	7.5m
Maximum velocity	$20(g/h)^{\frac{1}{2}}$	$14m\ s^{-1}$	$20m\ s^{-1}$	$60m\ s^{-1}$	$140m\ s^{-1}$
Maximum acceleration	8000g				
Maximum pressure (as a head of water)	$60\rho gh$	3m	6m	60m	300m
Time scale of pressure rise	$0.005(h/g)^{\frac{1}{2}}$	0.35ms	0.5ms	1.6ms	3.5ms

The maximum pressures occur while a jet forms from a flow which has converged towards a point on the wall. Experimental descriptions mention an impact of the vertical wave face, yet this does not occur, the water surface violently "flips through" from a contracting half-cavity to a high speed vertical jet. In a recent paper Chan and Melville (1988) observe from high-speed photography "that wave impact occurred through the focussing of the incident wavefront onto the wall; that is through a convergence of the wave crest and the surface intersection point at the wall"; a description which fits our results.

Hattori (private communication 1990) measures high impact pressures of $120\rho gh$ in an experiment which looks similar to our computation. There is a trace of a jet in one of his video frames. However we expect the jet to be only 0.3mm thick and to form on a time scale of 0.3ms so it is not surprising that it is difficult to observe, for example Chan and Melville use film at 1100 frames per second, and Hattori's video is at 200 frames per second. Both these recent experiments were made on a scale where the incident wave was only a few centimetres high, and both measured highest peak pressures at the "flip through" condition.

Our results lead us to speculate that if the filling "cavity" contracts to a small enough size then there is no upper limit on pressure and jet velocity within our model. Clearly, neglected physical properties such as viscosity and compressibility might change this picture. Since we have full details of the potential flow it is easy to assess the relevance of these effects.

We have considered incident waves as low as 10mm high and estimate that the effects of surface tension and viscosity are unimportant until after the formation of the jet. Even then it is only in the jet that surface tension can be relevant. The major physical effects in this "flip through" motion are the fluid inertia and the pressures it generates. Once water is in the jet these hydrodynamic pressures become negligible so that we expect surface tension and aerodynamic effects to become important, e.g. thin jets rapidly break up into spray.

The role of compressibility has often been discussed in the context of water wave impact. In the most violent impact we have calculated, where no air is trapped, we have a maximum value of $\partial p / \partial t = 3000 \rho g^{\frac{2}{3}} h^{\frac{1}{3}}$. This can be used to compare terms in the continuity equation for a *compressible* fluid. We find the ratio

$$\frac{\partial p}{\partial t} / \rho \frac{\partial v}{\partial y} \approx 15 \frac{gh}{a^2}$$

where a^2 is the velocity of sound.

A low value of $a = 100 \text{ m sec}^{-1}$, corresponds to water aerated with 1% by volume of small bubbles. Even then for $h = 1 \text{ m}$ this ratio is 0.015. Hence compressibility has little effect on the fluid dynamics. However a loud noise only requires a small amount of energy compared with that in the water motion.

Although it is hard to compare prototype conditions with experiments it is generally considered that the Froude scaling, which is natural for relating our computations to physical reality, generally overestimates prototype pressures. Since compressibility and viscosity appear to be irrelevant for this scaling we consider a different possibility.

From our computations it appears that high pressures are obtained when the wave surface focusses toward a point before a vertical jet is formed. Superficially, there seems to be no limit to this focussing and hence to the maximum pressure. On the other hand finer focussing implies a smaller and more violent jet. The minimum size of coherent jet that can be created depends on the roughness of the wall and liquid surfaces involved, e.g. if a wall has a roughness of about 10mm amplitude then pressures computed for the generation of a jet of width 10mm at a smooth wall are likely to be gross over-estimates. Large waves almost always have smaller waves upon them, and this free surface "roughness" is also likely to influence the maximum pressures at a wall, by either disrupting the surface focussing or inducing premature jet formation.

One further unexpected feature is the large extent of short-lived pressures which are several times higher than the hydrostatic value. The bed experiences this pressure pulse and it is interesting to speculate on the response of sediments to such a loading.

5. Conclusion

Potential flow computations reveal that there is violent water motion and very high pressures when near-breaking waves meet a vertical wall. The highest pressure occurs when a high-speed vertical jet forms at the wall. It seems likely that this "flip-through" type of interaction between wave and wall can give higher pressures than a direct impact by the jet from an overturning wave. The computed results indicate that the compressibility of water is unlikely to be of any importance, but that roughness of the wall or water surface may be significant in limiting extreme pressures for coastal waves.

The solid upper curve is the position of the water-line. The contour interval is 2 pgh, except for the broken-line contour at 5 pgh.

Wave Group Properties of Coastal Waves

Hajime Mase¹, M. ASCE, Takao Yamashita² and Katsuyuki Hayashi³

ABSTRACT

This paper examines the following properties of observed wave groups: (1) the change of wave grouping from offshore to shallow water region including the surf zone; (2) the relation between wave groupiness and wave height distributions; and (3) the distribution of run lengths and time series of wave heights of extreme wave groups which contain the maximum wave height in each wave record. Main results are summarized as follows: (1) wave groups become flattened as they propagate landward; (2) no clear maximum in mean length of runs is seen around the position where the significant wave height is the maximum, in contrast to the laboratory data, while the tendency of the change of GF is the same as the experimental data; (3) when wave grouping becomes pronounced, the distribution of wave heights becomes wider; (4) extreme wave groups accompany more large waves than ordinary wave groups; (5) for the case of narrow spectra, the time series of wave heights of extreme wave groups is represented fairly well by that of the wave group formed by the side-band instability, and the distribution of three high waves is also in qualitative agreement with that of envelope soliton, and (6) for wide spectra, which may occur during the peak of storms, wave heights in front and rear of the maximum wave are half as large as the maximum wave height, implying that a maximum wave tends to appear without accompanying other large waves.

INTRODUCTION

Certain sequences of large waves or wave groups are important not only in engineering problems, such as the stability of rubble mound breakwaters, the fluctuation of wave overtopping, and the slow drift oscillation of moored and floating structures, but also in hydrodynamical problems, such as the surf beat, the modulational instability, and the evolution of finite amplitude waves.

The degree of wave grouping is described by run lengths of large waves, groupiness factors, correlation coefficients of successive wave heights, and parameters related to the wave spectra. Elgar et al. (1984) showed that the observed mean lengths

¹ Research Assoc., Department of Civil Engrg., Kyoto University, Kyoto, 606, Japan.

² Research Assoc., Disaster Prevention Research Institute, Kyoto University, Uji, 611, Japan.

³ Engineer, Aichi Prefectural Government, Nagoya, 460, Japan.

of runs and occurrence probabilities of run lengths in relatively deep water were statistically consistent with the numerical simulations based on linear wave theory using the measured spectra with assumed random phases. However, the observations in shallow water deviated from the linear simulations and the observed mean lengths of runs were larger than the simulated mean lengths. Lake and Yuen (1978) explained amplitude-modulation periods of laboratory wind waves from a hydrodynamical viewpoint such as the side-band instability. Su (1986) examined the time series of wave heights of extreme wave groups which contained the maximum wave height in each wave record and showed that the observed time series of wave heights was described by the wave height sequence of the wave group formed by the side-band instability. The fact that wave group properties can be explained in different ways may show that various phenomena or mechanisms exist in random sea waves. Therefore, further examinations of wave group properties from various aspects or by different methods are necessary so that the wave group properties may eventually become predictable.

This study is a part of large field observations to investigate wave transformations, directional spectra, nearshore currents, and sediment transports. This paper examines the following aspects of wave groups by analyzing the observed wave data: (1) the change of wave grouping from offshore to shallow water region as well as in constant shallow water region; (2) the relation between wave groupiness and wave height distributions; and (3) the distribution of run lengths and time series of wave heights of extreme wave groups. These properties are compared with theoretical and experimental results.

FIELD OBSERVATION

Wave observations were carried out at the Ogata Wave Observatory, Disaster Prevention Research Institute, Kyoto University, located at the Ogata Coast facing the Japan Sea. A T-shaped observation pier, which is 256 m long in the cross-shore direction and 107 m long in the alongshore direction, was constructed with truss girders of five spans of 50 m supported by piers composed of three steel piles to minimize its effects on the nearshore hydrodynamics and sediment transport. The location of the Ogata Wave Observatory and the bottom topography in the vicinity of the T-shaped pier are shown in Fig.1.

The field data were collected from November 27 to December 8, 1987, and from January 11 to 18, 1989. Fig.2 shows the arrangement of sensors used in the observations. Nine capacitance-type and seven ultrasonic-type wave gauges were mounted on the pier, as indicated by the letter 'C' and 'US' in Fig.2 (a). Three ultrasonic current meters, indicated by the letter 'CM', were installed at the elevation of approximately 1 m above the seabed under the ultrasonic wave gauges. On the extension of the line of the pier (along the straight line normal to the shoreline), a waverider buoy ('WR' in short) was installed at the water depth of 30 m (in the first observation) or 20 m (in the second observation), and three sets of an ultrasonic wave

Figure 1 Location of Ogata Wave Observatory and bottom topography around T-shaped pier (from the pamphlet of Ogata Wave Observatory, Kyoto University).

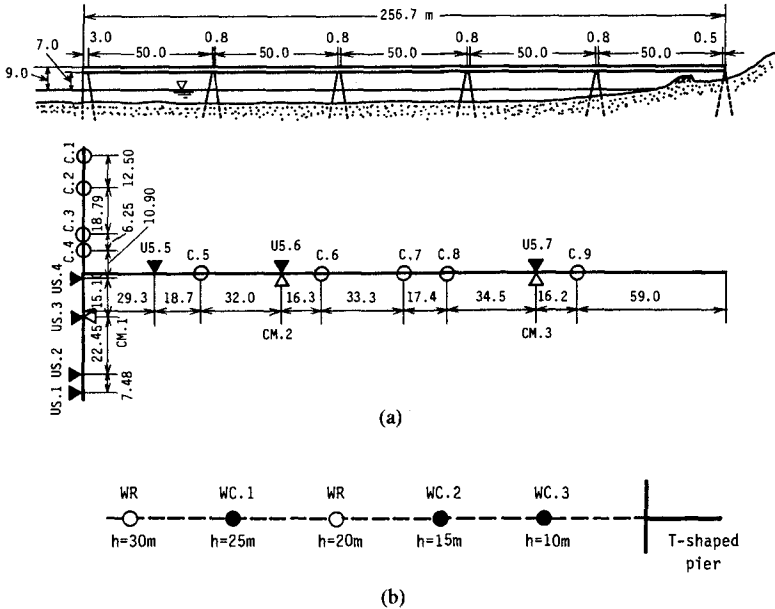

Figure 2 Arrangement of sensors at T-shaped pier in (a) and seaward of T-shaped pier in (b).

gauge and a two-components electromagnetic current meter ('WC' in short) were set on the seabed at the water depths of 25, 15 and 10 m, which are indicated by 'WC.1', 'WC.2' and 'WC.3' in Fig.2 (b). The water depth at the locations of 'C.1'~'C.8' is approximately constant and 5.1 m. The bottom slope seaward of the tip of the pier is about 1/100. For the first field data from November 27 to December 8, 1987, the time series from all sensors were recorded by two analog data recorders for 90 minutes every three hours. The recorded time series were digitized at a sampling interval $\Delta t=0.256$ sec. For the second field data from January 11 to 18, the time series from the sensors 'C', 'US', 'WR' and 'CM' were recorded directly on digital magnetic tapes as follows: for 40 minutes every hour at $\Delta t=0.1$ sec from 11th 19:00 to 15th 7:40; for 20 minutes every hour at $\Delta t=0.2$ sec until 16th 8:20; and hereafter for 20 minutes every two hours at $\Delta t=0.2$ sec. The data of 90 and 40 minutes long were divided into segments of 20 minutes. The time series of 'WC' were stored on an internal digital magnetic tape for 17 minutes every hour at $\Delta t=0.5$ sec.

In order to remove low and high frequency motions from each wave record and limit the following analyses to incident wind waves only, the Fourier components with frequencies smaller than half the peak frequency and larger than six times of the peak frequency were set zero. The modified Fourier components were then transformed into the time domain variations by a inverse FFT technique. The observed data included a wide range of incident wave conditions from narrow-banded to broad-banded spectra. The significant wave heights measured by 'WR' ranged from 0.5 m to 4.5 m, and the significant wave periods ranged from 4.0 sec to 10.0 sec. Dominant wave directions were normal to the shoreline.

RESULTS AND DISCUSSION

Change of Wave Grouping from Offshore to Shallow Water Region

In order to describe the magnitude of wave grouping, at least two parameters are needed (Mase and Iwagaki, 1986): One parameter for representing the length of sequence of high waves in a time series such as the mean length of runs, $\overline{\lambda(H)}$, exceeding the mean wave height, \bar{H} ; and the other for representing the magnitude of the variation of wave energy such as the groupiness factor, GF . The measured changes of the two parameters $\overline{\lambda(H)}$ and GF will indicate whether wave grouping becomes pronounced or not. When wave grouping pronounced, GF increases but $\overline{\lambda(H)}$ may not decrease. When wave grouping becomes weakened, GF decreases but $\overline{\lambda(H)}$ may increase or decrease. Fig.3 shows the changes of $\overline{\lambda(H)}$ and GF against the nondimensional water depth, $k_m h$ with k_m being the wavenumber based on the mean wave period in the water depth h , where the data of 'WR', 'WC.3', 'C.4', and 'US.4' were plotted. It is noted that the classification by wave steepness did not show any clear tendency. The linear regression lines plotted in Fig.3 show that GF decreases and

$\overline{J(H)}$ increases as $k_m h$ is decreased. This implies that wave groups of shoaling random waves tend to become flattened.

Figure 3 Change of wave grouping from offshore to shallow water region: (a) mean length of runs; (b) groupiness factor.

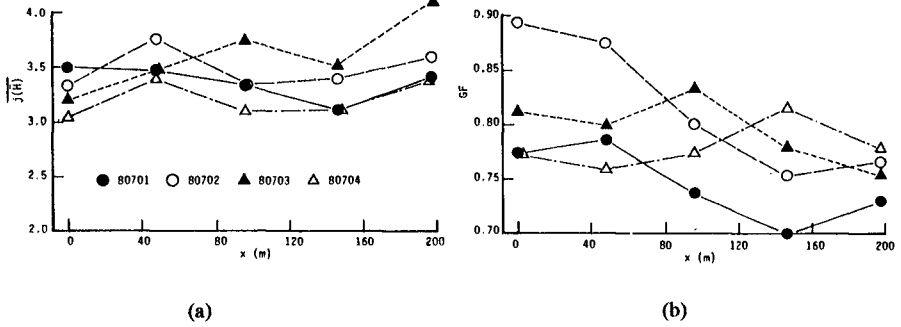

Figure 4 Change of grouping of non-breaking waves in shallow water of constant depth: (a) mean length of runs; (b) groupiness factor.

Change of Grouping of Non-Breaking Coastal Waves in Shallow Water of Constant Depth

Fig.4 shows the values of $\overline{\lambda(H)}$ and GF at the locations of 'C.4', 'C.5', 'C.6', 'C.8' and 'C.9' (the horizontal coordinate x is positive landward with $x=0$ at the location of 'C.4') under the condition of $k_m h < 1.0$, narrow-banded wave spectra, and no wave breaking. For the cases of B0701 (20:30 of November 30, 1987) and B0702 (23:30 of November 30, 1987), $\overline{\lambda(H)}$ is nearly constant and GF decreases in the shoreward direction. For the case of B0703 (2:30 of December 1, 1987), GF decreases and $\overline{\lambda(H)}$ increases. These tendencies mean that wave groups of random waves become flattened with the propagating distance as was the case with the experimental results of Mase and Iwagaki (1987) in which the flattening of a single wave group was verified in laboratory experiment and by numerical simulations using the nonlinear Schrödinger equation.

Change of Wave Grouping in Shallow Water Including Surf Zone

Fig.5 shows the changes of $\overline{\lambda(H)}$ and GF against the normalized water depth h/H_0' (H_0' is the deep water significant wave height estimated from the significant wave at 'WR' using linear wave theory). The curves in Fig.5 (a) and (b) are the fifth and fourth polynomial regression curves, respectively, which are found to give the best fit among the first to fifth polynomial equations. The change of the significant wave height $H_{1/3}/H_0'$ against h/H_0' is shown in Fig.6, where the curves are the results calculated by the random wave model of Mase et al. (1986) for wave steepness of 0.01 and 0.04, approximately corresponding to the observed maximum and minimum wave steepness. The experimental data on $\overline{\lambda(H)}$ by Mase (1989) became the maximum around the point where $H_{1/3}/H_0'$ was the maximum. This point for the present field data is roughly at $h/H_0'=2.5$; however, no clear maximum in $\overline{\lambda(H)}$ is seen around $h/H_0'=2.5$ in Fig.5 (a). It is seen in Fig.5 (a) that the range of $\overline{\lambda(H)}$ in the region of $h/H_0' > 2.5$ is larger than that in the region of $h/H_0' < 2.5$. GF is almost constant in the region of $h/H_0' > 3.0$, and decreases with the decrease of the water depth for $h/H_0' < 3.0$. This is the same tendency as the experimental data by Mase (1989). The mean length of runs seems to be more unstable statistically than the groupiness factor, since the number of runs is small for twenty-minute-long records.

Wave Grouping and Wave Height Distribution

The observed wave height distributions were presented by the Weibull distribution whose the shape factor, m , was estimated by the maximum likelihood method (Cohen, 1965). The Rayleigh distribution is a special case with $m=2$ of the Weibull distribu-

Figure 5 Change of wave grouping in shallow water including surf zone: (a) mean length of runs; (b) groupiness factor.

Figure 6 Transformation of significant wave heights in shallow water.

Figure 7 Relation between groupiness factor GF and shape factor m of wave height distribution.

tion. Fig.7 shows the relationship between GF and m . The tendency of the data points may be represented simply by the broken line proposed by Mase (1989), whereas the solid line is the following fifth polynomial equation fitted to the data points:

$$m = 9.45 - 37.83 GF + 76.33 GF^2 - 75.34 GF^3 + 35.30 GF^4 - 6.17 GF^5 \quad (1)$$

Fig.7 shows that as wave grouping increases (GF becomes larger), the distribution of wave height becomes wider (m becomes smaller). The Rayleigh distribution would underestimate the occurrence probability of extreme wave heights. The scatter in the data suggests that the relationship between the two parameters is not simple because of neglected effects of other wave characteristics.

Distribution of Run Lengths of Extreme Wave Groups

A phenomenon that the maximum wave in a wave record seldom appears alone but usually accompanies with several large waves was reported by Goda (1976). Fig.8 (a) shows that the occurrence probability of $j(\bar{H})=1$ is the largest for the case of ordinary runs of wave heights, as indicated by the symbols of \circ and \square corresponding to the data of 'WR' and 'C.4', respectively, while the occurrence probability of $j(\bar{H})=4$ is the

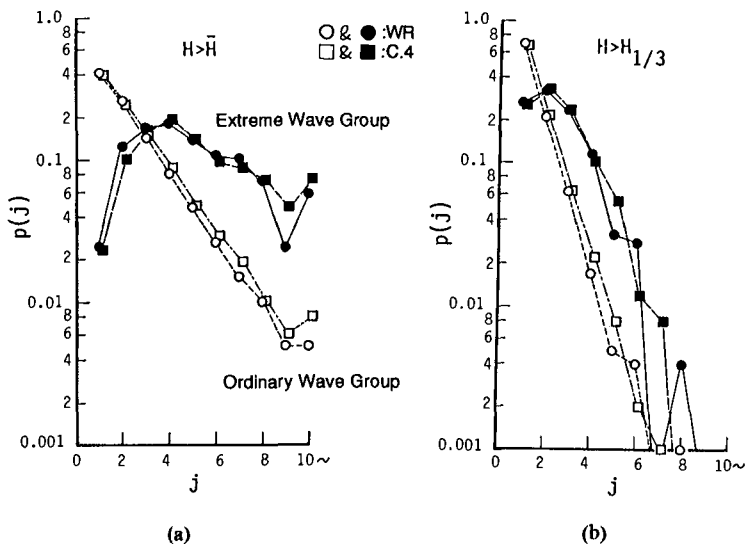

Figure 8 Occurrence probabilities of run lengths of ordinary and extreme wave groups where the threshold is the mean wave height in (a) and the significant wave height in (b).

largest for the conditional runs containing the maximum wave height in each wave record (extreme wave groups), as indicated by the symbols of ● and ■. The occurrence probabilities of run lengths with the threshold of $H_{1/3}$ are shown in Fig.8 (b), which also shows that extreme wave groups contain more large waves than ordinary wave groups. However, this analysis of runs is based on the number of large waves exceeding a threshold and does not account for the relative magnitude of the waves around the maximum wave.

Time Series of Wave Heights in Extreme Wave Groups

Following the analysis of Su (1986), we describe the time series of wave heights in a extreme wave groups as $H_{-3}, H_{-2}, H_{-1}, H_0, H_1, H_2, H_3$, where H_0 is the maximum wave height. Su (1986) found that the extreme wave group consisted of three high waves whose heights were greater than the significant wave height. On the basis of the experimental observations of the nonlinear side-band instability of finite amplitude waves, Su (1986) showed that the extreme wave group could be explained as the manifestation of the maximum modulation of waves. Time series of the surface displacement, $\eta(t)$, under the maximum modulation due to the side-band instability, was expressed as:

$$\eta(t) = a_0 \sin 2\pi f_0 t + \frac{a_0}{\sqrt{2}} \left[\sin\{2\pi(1-a_0k_0)f_0t\} + \sin\{2\pi(1+a_0k_0)f_0t\} \right] \tag{2}$$

which can be simplified as

$$\eta(t) = a_0 \left\{ 1 + \sqrt{2} \cos(2\pi a_0 k_0 f_0 t) \sin(2\pi f_0 t) \right\} \tag{3}$$

where a_0, k_0 and f_0 are the amplitude, wavenumber and frequency of a carrier wave. Under the maximum modulation, the amplitudes of disturbances were equal to $a_0/\sqrt{2}$ and the frequency differences from a carrier wave were $\pm a_0 k_0 f_0$. For $a_0 k_0 = 0.1$ as a typical value, the phase of wave envelope changes 36° during one cycle of the carrier wave. If the maximum wave height is taken as

$$H_0 = 2a_0(1 + \sqrt{2} \cos 0^\circ) = 4.828a_0 \tag{4}$$

the wave heights around the H_0 are expressed by

$$\left. \begin{aligned} H_{-1}, H_1 &= 2a_0(1 + \sqrt{2} \cos 36^\circ) = 0.888H_0 \\ H_{-2}, H_2 &= 2a_0(1 + \sqrt{2} \cos 72^\circ) = 0.595H_0 \\ H_{-3}, H_3 &= 2a_0(1 + \sqrt{2} \cos 108^\circ) = 0.233H_0 \end{aligned} \right\} \tag{5}$$

Zakharov and Shabat (1972) showed that finite disturbances could evolve into a number of envelope solitons. Extreme wave group may be attributed to envelope solitons formed by some mechanism even in usual wind wave fields. As an attempt, time series of wave heights of extreme wave groups are analyzed using the envelope soliton model as well as the instability model by Su (1986), although these models may not be really applicable to the field data.

The temporal variation of amplitude of the envelope soliton in deep water region was described by

$$A = a_0 \operatorname{sech}\{(a_0^2 \beta / 2\alpha)^{1/2} C_g t\} \quad (6)$$

$$\text{with } \left. \begin{aligned} \alpha &= \omega_0 / 8k_0^2 \\ \beta &= \omega_0 k_0^2 / 2 \\ C_g &= \omega_0 / 2k_0 \end{aligned} \right\} \quad (7)$$

Substitution of Eq.(7) into Eq.(6) yields

$$A = a_0 \operatorname{sech}(a_0 k_0 \omega_0 t) \quad (8)$$

For $a_0 k_0 = 0.1$ as a typical value, the maximum wave height may be taken as

$$H_0 = 2a_0 \operatorname{sech}(0) = 2a_0 \quad (9)$$

The wave heights around H_0 may be estimated by

$$\left. \begin{aligned} H_{-1}, H_1 &= 2a_0 \operatorname{sech}(0.2\pi) = 0.831H_0 \\ H_{-2}, H_2 &= 2a_0 \operatorname{sech}(0.4\pi) = 0.527H_0 \\ H_{-3}, H_3 &= 2a_0 \operatorname{sech}(0.6\pi) = 0.297H_0 \end{aligned} \right\} \quad (10)$$

The observed time series of wave heights of extreme wave groups normalized by the square root of the zero moment m_0 of the spectral density $S(f)$ were analyzed statistically according to the classification of spectral width based the following parameter:

$$\kappa(T_p) = \left[\left\{ \int_0^\infty S(f) \cos(2\pi f T_p) df \right\}^2 + \left\{ \int_0^\infty S(f) \sin(2\pi f T_p) df \right\}^2 \right]^{1/2} / \left[\int_0^\infty S(f) df \right] \quad (11)$$

where T_p is the peak period and f is the frequency. The parameter κ represents the correlation between two points of wave envelope separated by the time lag T_p and is more stable than the spectral peakedness parameter Q_p in terms of the degree of

freedom and resolution frequency of wave spectrum. In the calculation of $S(f)$, the number of data points was 4096, the Nyquist frequency 0.014Hz, and the degree of freedom was 30. The range of integration in Eq.(10) was taken to be $0.5f_p$ to $1.8f_p$ with f_p being the peak frequency instead of 0 to ∞ . As a whole, κ was found to be linearly correlated to Q_p , seen in Fig.9.

Figure 9 Relation between correlation coefficient κ and spectral peakedness parameter Q_p .

Fig.10 shows the time series of wave heights, in which the data of 'WR', 'C.4' and of Su (1986) are denoted by \circ , \bullet , and Δ , respectively. The solid line and dotted line bars denote the ranges of wave heights when a_0k_0 is taken as 0.1 and 0.2 in Eqs.(3) and (8), respectively. For the case of narrow spectra shown in Fig.10 (a), the wave height sequence is represented fairly well by that of wave groups formed by the nonlinear side-band instability as well as by the envelope soliton, although the agreement depends on the selected value of a_0k_0 . Even in shallow water (the data of 'C.4') where wave breaking may have occurred and the side-band instability cannot occur theoretically, the distribution of wave heights of extreme wave group is almost the same as that in deep water.

For the case of wide spectra of Fig.10 (b), usually observed during the peak of a storm, the wave heights in front and rear of the maximum wave are half as large as the maximum wave height. This implies that the maximum wave tends to appear without accompanying other large waves comparable to the maximum wave.

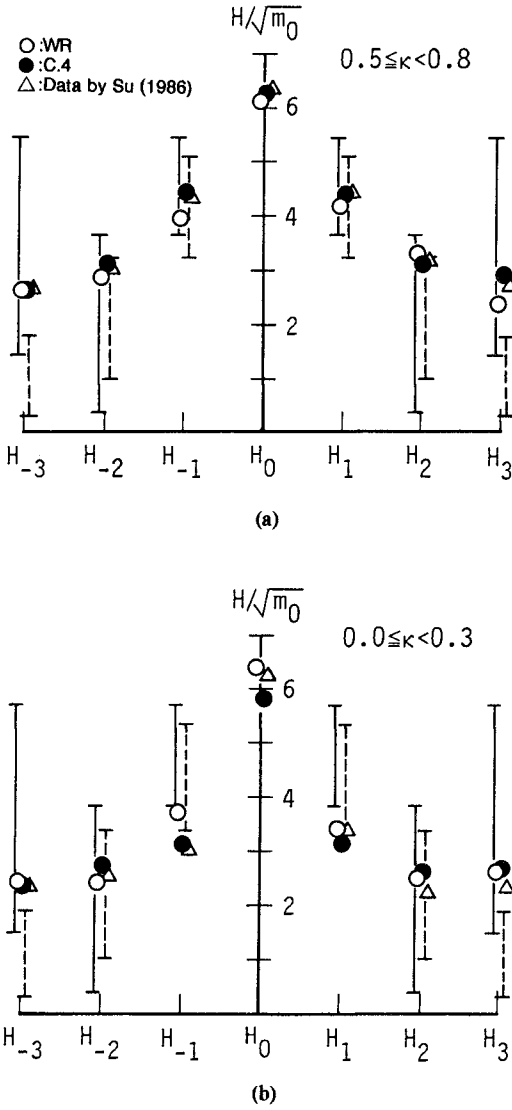

Figure 10 Time series of wave heights of extreme wave groups: (a) narrow band spectra; (b) wide band spectra.

CONCLUSIONS

The wave group properties observed in the field and analyzed in this paper are summarized as follows:

1. The observed tendencies of increase in $\overline{H(H)}$ and decrease in GF with the decrease of $k_m h$ from offshore to shallow water as well as with the increase of propagating distance in shallow water of constant depth imply that wave groups become flattened as they propagate landward.

2. No clear maximum in $\overline{H(H)}$ was seen around the position where the significant wave height was the maximum, in contrast to the laboratory data, while the tendency of the change of GF is the same as the experimental data. The mean length of runs was more unstable statistically than the groupiness factor, since the number of runs was small for the twenty minutes records.

3. When wave grouping became pronounced, the distribution of wave heights became wider. The Rayleigh distribution would underestimate the occurrence probabilities of higher waves.

4. Extreme wave groups accompanied more large waves than ordinary wave groups. However, the analysis of runs yields the number of waves only and does not account for the relative magnitude of the waves around the maximum wave.

5. For the case of narrow spectra, the time series of wave heights of extreme wave groups was represented fairly well by that of the wave group formed by the side-band instability (Su, 1986). The distribution of three high waves was also in qualitative agreement with that of envelope soliton. For wide spectra, which may occur during the peak of storms, wave heights in front and rear of the maximum wave were half as large as the maximum wave height, implying that a maximum wave tends to appear without accompanying other large waves.

ACKNOWLEDGEMENTS

Field observations were performed by the staff of Coastal Disaster Research Section, Disaster Prevention Research Institute, Kyoto University, and the authors would like to acknowledge their efforts. The authors would like to thank N. Kobayashi, University of Delaware, for his review and critical comments on the initial manuscript. This work is a result of research supported by The Ministry of Education, Science and Culture, under Grant-in-Aid for Co-operative Research (No.62302045, Representative Y. Tsuchiya, Disaster Prevention Research Institute, Kyoto University).

CHAPTER 14

MEASUREMENT AND COMPUTATION OF WAVE INDUCED VELOCITIES ON A SMOOTH SLOPE

Jentsje W. van der Meer¹⁾ and Mark Klein Breteler¹⁾

Abstract

Two main items are treated in this paper. The first item is measurement of wave induced velocities in a large scale model and the second one is a verification of the 1-D numerical model, developed by Kobayashi and Wurjanto (1989).

Wave induced velocities on a smooth slope were measured in Delft Hydraulics large Delta flume. The run-up and run-down velocities were compared with theoretically derived upper bounds and formulas for these velocities were derived on the basis of these upper bounds.

Computations were performed with the numerical model of Kobayashi and the results (velocities, pressures and run-up and run-down levels) were compared with measurements, partly from the investigation mentioned above. The results for run-down velocities and run-up levels were acceptable, the results for run-up velocities were a little worse and the results for pressures and run-down levels were bad.

Introduction

Knowledge of wave induced velocities on a slope is an important step towards a better understanding of the behaviour of coastal structures under wave attack. These velocities are important to calculate wave forces on rubble mound structures and on placed block revetments and to calculate run-up or overtopping.

Therefore, large scale physical model tests were performed in the Delta flume of Delft Hydraulics with regular waves on a smooth slope. Velocities were measured at various locations and for various wave conditions. Furthermore, the numerical model of Kobayashi and Wurjanto (1989) was used to calculate wave induced velocities and these results were compared with the measurements.

The numerical model is a 1-D model and is based on solving the non-linear equations for long waves on a slope. The model was a ver-

1) Delft Hydraulics, PO Box 152, 8300 AD Emmeloord, The Netherlands

sion, specially developed for CERC, USA and Prof. N. Kobayashi of the University of Delaware and Mr. J.P. Ahrens of CERC are gratefully acknowledged for the permission of using this model.

Tests in the Delta flume

Large scale model tests have been performed which were aimed on measuring the water velocities just above (about 3-5 cm) the slope surface. The dimensions of the Delta flume are 230 m long, 5 m wide and 7 m deep. All tests were performed with regular waves and on a smooth slope of 1:3. The slope consisted of a placed block revetment with block dimensions 0.5 m x 0.5 m and thick 0.15 m. Some blocks had circular holes in the center of the block, but these were filled with shingle during the tests.

The velocities were measured with four-quadrant electro-magnetic velocity meters (EMS) mounted on a horizontal rod just above the slope. The EMS was developed and constructed by the Instrumentation Section of Delft Hydraulics. The disc of the EMS has a diameter of 0.035 m and the range is +/- 5 m/s. The accuracy is 2% of the recorded value or 0.02 m/s for small velocities. The velocities were measured at seven locations around the still water level. The water depth was 5 m during all tests.

The test program is shown in Table 1. Four wave periods were generated and for each wave period 3-4 wave heights. The Table gives the wave periods, T, wave heights, H, wave steepnesses, s_{op} , defined as $s_{op} = 2\pi H/gT^2$ and the surf similarity parameter, ξ_o , defined as $\xi_o = \frac{op}{\tan\alpha\sqrt{s}}$, where α is the slope angle of the structure.

Table 1 Tests for measurement of velocities on a smooth 1:3 slope

The time signals of the velocity meters were analysed. The maximum run-up and run-down velocity for each wave in a record of 30 s was established. The maximum run-up and run-down velocities in this paper are defined as the average of the highest three recorded values.

Theoretical considerations on velocities

A simple theory was developed to support the analysis of the measurements. The water velocity on a slope due to breaking waves depends largely on the process of wave run-up, run-down and wave impact. With respect to the run-down velocity, v_d , the theory is based on the fall velocity of a particle, falling without friction.

$$E_{kin} = 0.5 m v_d^2 = mg(R_u - z) = E_{pot} \quad (1)$$

where:

E_{kin} = kinetic energy

E_{pot} = potential energy

m = mass of water particle

g = gravity acceleration

R_u = level of maximum run-up relative to swl

z = location on slope, measured vertically relative to swl

Elaboration of Eq. 1 gives:

$$v_d = \sqrt{2g(R_u - z)} \quad (2)$$

This means that the run-down velocity is independent on the wave height and period, but only on the run-up level and the location on the slope. In order to use a dimensionless velocity both parts can be divided by \sqrt{gH} . But again, strictly speaking, this is not required. The final formula for the run-down velocity becomes then:

$$v_d/\sqrt{gH} = \sqrt{2R_u/H} \sqrt{(1-z/R_u)} \quad (3)$$

Eq. 3 shows that the dimensionless run-down velocity is a function of the dimensionless run-up level and the dimensionless location on the slope. This equation is an upper bound for the run-down velocity, since the friction influence is neglected.

With respect to the run-up velocity, v_{up} an upper bound can be derived from the wave celerity, c , defined for deep water by $c = \sqrt{gL/2\pi}$. If this wave celerity is assumed to be the run-up velocity at swl and if again \sqrt{gH} is used to make the velocity dimensionless (again strictly speaking not required), the run-up velocity becomes:

$$v_{up}/\sqrt{gH} = \sqrt{1/2\pi s} \quad (4)$$

where s = wave steepness, H/L . The run-up velocity will become zero at the maximum run-up level R_u . A similar term as used in Eq. 3 gives this effect. The final formula for the run-up velocity becomes then:

$$v_{up}/\sqrt{gH} = \sqrt{1/2\pi s} \sqrt{(1-z/R_u)} \quad (5)$$

The dimensionless run-up velocity is a function of the (dimensionless) wave steepness and the dimensionless location on the slope. As quite a lot of energy is dissipated by the wave breaking process, Eq. 5 can be regarded as a high upper bound.

Analysis of measurements

Run-down velocity

The measured run-down velocities are plotted versus the location on the slope, z/R_u , in Fig. 1. The maximum run-up level, the still water level and the maximum run-down level are shown in the Figure. The maximum upper bounds given by Eq. 3, are shown for $\xi_0 = 1.5$ and 2.5, giving more or less the measured range. As the run-up level R_u/H depends on ξ_0 , the upper bound depends on this parameter too.

The relationship between R_u/H and ξ_0 is shown in Fig. 5 and will be treated there.

Fig. 1 shows that all points are below the upper bound and that for $z/R_u > -0.4$ the same trend is found as for the theoretical upper bound. For smaller values of z/R_u (below the run-down point), the velocities decrease rapidly. In order to analyse the trend for the higher values of z/R_u , Fig. 2 was composed with on the horizontal axis the parameter $\sqrt{R_u/H} \sqrt{1-z/R_u}$, according to Eq. 3.

Figure 1 Run-down velocity as function of the location on the slope

Figure 2 Run-down velocity for $z/R_u > -0.4$

This Fig. 2 gives the maximum upper bound for $\xi_o < 2.5$ and makes also a distinction between the plunging waves ($\xi_o < 2.5$, see Fig. 5) and surging waves ($\xi_o > 2.5$). Although there is some scatter, a linear expression between the parameters on respectively the horizontal and vertical-axis is acceptable, which means that the trend of Eq. 3 can be maintained. An expression for the run-down velocity on a smooth slope for $z/R_u > -0.4$ becomes then:

$$v_d/\sqrt{gH} = 1.1 \sqrt{R_u/H} \sqrt{(1-z/R_u)} \tag{6}$$

This equation is also shown in Fig. 2. As the run-down velocity is in fact not dependent on the wave height, a better expression is:

$$v_d/\sqrt{gR_u} = 1.1 \sqrt{(1-z/R_u)} \tag{7}$$

For the run-down velocity below the point $z/R_u = -0.4$, an expression can be found based on Fig. 1. The velocity decreases rapidly with decreasing z/R_u and the relationship can therefore be given by a power curve:

$$v_d/\sqrt{gH} = 0.18 z/R_u^{-2.3} \quad \text{for} \quad z/R_u < -0.4 \tag{8}$$

Run-up velocity

The measured run-up velocities are shown in Fig. 3 as a function of z/R_u . Fig. 3 is similar to in Fig. 1. Both upper bounds for $\xi_o = 1.5$ and 2.5 are shown. The measured velocities are well below these upper bounds which means that quite some energy is dissipated by the wave breaking process. As the influence of the surf similarity parameter is large, see the difference between the two upper bounds, it can not be concluded on the basis of Fig. 3 that the velocities for $z/R_u > 0$ follow the same trend as the upper bounds. Therefore, another figure was composed based on Eq. 5.

Figure 3 Run-up velocity as function of the location on the slope

Fig. 4 gives the run-up velocity as a function of $1/\sqrt{s} \sqrt{(1-z/R_u)}$, including the upper bound. Again a linear expression fits the data and the following equation for the run-up velocity for $z/R_u > 0$ can be derived:

$$v_{up}/\sqrt{gH} = 0.27 \frac{1}{\sqrt{s}} \sqrt{(1-z/R_u)} \quad (9)$$

Figure 4 Run-up velocity for $z/R_u > 0$

This equation is shown in Fig. 4. Fig. 3 shows furthermore that the run-up velocity in the area $-0.4 < z/R_u < 0$ is not really dependent on the location. Analysis showed that it is only a function of the wave steepness:

$$v_{up}/\sqrt{gH} = 0.2/\sqrt{s} \quad \text{for} \quad -0.4 < z/R_u < 0 \quad (10)$$

Finally the run-up velocity decreases rapidly for decreasing z/R_u and for $z/R_u < -0.4$, see Fig. 3. A relationship similar to Eq. 8 which gives a good fit is:

$$v_{up}/\sqrt{gH} = 0.30 \frac{z/R_u}{z/R_u^2} \quad \text{for} \quad z/R_u < -0.4 \quad (11)$$

Eqs. 6 - 11 give empirical relationships for the run-down and run-up velocities on a smooth slope. The relationships are based on large scale experiments for a slope of 1:3. A limit for application of the formulas is therefore a slope close to 1:3.

The model IBREAK

Kobayashi and Wurjanto (1989) describe the model IBREAK that can simulate the wave motion on an arbitrary rough or smooth slope. The model IBREAK is a second and more user's friendly version than the original model and runs on a main frame computer. Broekens (1988) developed the same model, based on Kobayashi's papers and reports, but now for a personal computer and more user's friendly. This was done at the time that IBREAK was not yet available. As IBREAK is the

original work of Kobayashi it was decided to verify this model and not the version of Broekens (although the results would be similar).

The model is based on the non-linear long wave equations and is a 1-dimensional model, i.e. only a depth averaged water velocity is assumed. This means that breaking (plunging) waves are simulated by a "bore-type" wave. The wave front can become almost vertically as a limit. Furthermore, pressures are assumed to be hydrostatic. A rough slope is simulated as a "smooth" slope with a large friction coefficient.

Applications of the model to stability of rock slopes were described by Kobayashi and Otta (1987) and applications to run-up and reflections on rough slopes by Kobayashi et al. (1987). The model of Broekens (1988) was used to describe the stability of rock slopes (De Graaf (1988)).

Most applications described by Kobayashi are for rough impermeable slopes. Only Kobayashi and Watson (1987) describe the application and verification of the model for a smooth slope. There conclusions were:

- Water velocities were not verified.
- Water pressures were verified with 3 model tests for one location on the slope. Large deviations were found for the maximum and minimum pressures.
- Run-up and run-down were verified with formulas described by Ahrens and Titus (1985). Run-up was a little smaller for the calculations and run-down was not accurate.
- The general conclusion was that the model is applicable for smooth slopes, although the friction coefficient should have a small value, greater than zero. A value of 0.05 was recommended.

The model IBREAK was used by permission of CERC and prof. Kobayashi. Calculations were performed in order to verify the model more in depth for a smooth slope. The large scale measurements in the Delta flume described in the first part of the paper, form the main basis for this verification. The following parameters were taken into account: the maximum run-up and run-down levels, the water velocities and the water pressures.

Verification of run-up and run-down

Fig. 5 shows the results of calculations and measurements on run-up and run-down levels on a 1:3 smooth slope with waves roughly between 0.2 and 1.1 m. On the basis of the measurements the following relationships for run-up and run-down levels were established:

$$R_u/H = \xi_0 \quad \text{for } \xi_0 < 2.6 \quad (\text{plunging waves}) \quad (12)$$

$$R_u/H = -1.5\xi_0 + 6.5 \quad \text{for } 2.6 < \xi_0 < 3.0 \quad (\text{collapsing waves}) \quad (13)$$

$$R_u/H = 2.0 \quad \text{for } \xi_0 > 3.0 \quad (\text{surging waves}) \quad (14)$$

$$R_d/H = -0.1\xi_0^2 + \xi_0 - 0.5 \quad (15)$$

Eqs. 12-15 are shown in Fig. 5. From this figure it can be concluded that:

- IBREAK gives a constantly increasing curve for the run-up and does not give a maximum for the transition from plunging to surging waves ($\xi_0 = 2.6 - 3.0$). This is probably caused by the fact that the model simulates a bore-type wave. The run-up is a little too small for plunging waves and a little too large for surging waves.
- The average deviation between calculated and measured run-up is 12% which is reasonable. The general conclusion is that the run-up is predicted within acceptable limits.
- The calculated run-down is much smaller than the measured one, especially for the smallest ξ_0 values. The deviation is very large there and not acceptable for practical use.

Figure 5 Measured and calculated run-up and run-down on a 1:3 smooth slope

Verification of velocities

A few tests from the series described in the first part of this paper were also calculated with the model IBREAK. Fig. 6 shows a part of the time signal of one of the tests with a surging wave of $H = 0.3$ m and $T = 5$ s. The location was -0.42 m which means about $1.5H$ below the still water level. The qualitative agreement between the measured and calculated signal is good. The quantitative results will be described below.

The maximum value (run-up velocity) and the minimum value (run-down velocity) of the time signal were used for comparison. First the influence of the friction factor f on the run-up and run-down velocities was studied. Friction factors of 0.0, 0.02 and 0.05 were used. Fig. 7 gives the results together with the measured values.

From Fig. 7 it can be concluded that a lower friction factor leads to higher velocities. A decrease of the friction factor from 0.05 to 0.02 leads to an increase in velocities of about 20%. A decrease of f from 0.05 to 0.0 leads to an increase of the velocities of about 40%. This means that even for a smooth slope the friction factor plays an important role with regard to velocities.

During run-down the energy dissipation is only due to friction, where for run-up the wave breaking process is important too. There

Figure 6 Time series for measured and calculated velocities on a 1:3 smooth slope

fore, the "calibration" of the friction factor for the model should be based on the run-down velocities. For the run-down values a friction factor of $f = 0.02$ gives the best results and this factor of 0.02 was used for the further calculations.

Figure 7 Influence of friction factor on run-up and run-down velocities

It should be noted again that the model gives a depth-averaged horizontal velocity and that the model tests give the velocity a few centimeters above and along the slope.

Fig. 8 gives the results on velocities for 3 tests, ranging from plunging to surging waves (ξ_0 values of 1.51, 2.07 and 2.92 respectively). The average deviation of the calculated run-up velocities from the measured ones was 16%. This average deviation amounted to

10% for the run-down velocities. Values smaller than 40% of the maximum velocities on the slope were not taken into account for the calculation of the deviations. Fig. 8 shows furthermore that the calculated velocities were consequently smaller than the measured velocities. A smaller friction factor than 0.02 would therefore increase the agreement.

Fig. 8 shows no influence of the surf similarity parameter on the results. The deviations of the calculated velocities from the measured ones is similar for plunging, collapsing or surging waves.

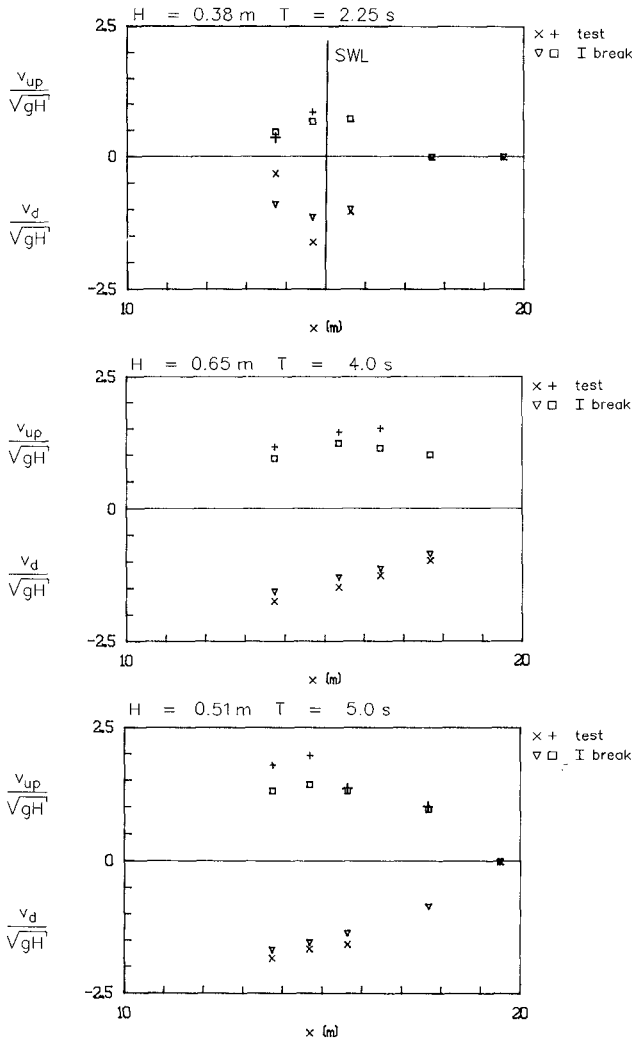

Figure 8 Measured and calculated maximum velocities on a 1:3 smooth slope

The general conclusion is that IBREAK gives a reasonable prediction of the velocities on a smooth slope.

Verification of wave pressures

A part of the time signal for the wave pressure on a location below the still water level is shown in Fig. 9 for one of the large scale tests on a slope of 1:3. The qualitative agreement is good. Fig. 10 shows again a part of a time signal for the wave pressure, but now for a small scale test on a slope of 1:2. Here the agreement is very poor. The only agreement is the irregularity of the signal.

Figure 9 Measured and calculated wave pressures on a 1:3 smooth slope

Figure 10 Measured and calculated wave pressures for a 1:2 smooth slope (small scale tests)

The influence of the friction factor on the calculated wave pressures was investigated for the same test as shown in Fig. 9. Fig. 11 gives the results for $f = 0.02, 0.05$ and 0.10 . A value of 0.0 led to numerical instability. This figure shows that the influence of the friction factor on the wave pressures is small and not consistent. Sometimes the lowest value of the friction factor gives the highest wave pressures, sometimes the highest value, depending on the location of the slope.

Fig. 12 gives the results on wave pressures of three tests. The upper graph gives the results of a large scale test on a slope 1:3 with a wave height of 1.38 m and a wave period of 5.37 s. The other

graphs give small scale tests on a slope 1:4. The middle graph that of a plunging wave and the lowest graph that of a surging wave.

Figure 11 Influence of the friction factor on wave pressures

Calculations were performed for three large scale tests and for five small scale tests (two on a slope 1:2, one on a slope 1:3 and two on a slope 1:4). In all tests the pressures were measured on nine locations as shown in Fig. 12. From the comparison of measured and calculated pressures it could be concluded that the average deviation for the large scale tests was 37% for the minimum pressure and 44% for the maximum pressure. For the small scale tests this was respectively 55% and 113%. Values smaller than 40% of the maximum pressure on the slope were not taken into account for calculation of the deviation of the pressures.

The deviations between measurements and calculations are larger than for the velocities described in the previous section. Furthermore, the deviations for the small scale tests are larger than for the large scale tests. Although the deviations between measurements and calculations are large, the trend along the slope is similar. The location where the maximum pressure occurs on the slope is calculated fairly accurate. In most cases the calculated pressure is (much) higher than the measured one. A smaller friction coefficient than used, however, has almost no influence, see Fig. 11.

The general conclusion on pressures is that IBREAK can not accurately simulate wave pressures on a smooth slope. It can simulate the location where the maximum wave pressure occurs.

Conclusions

Eqs. 6 - 11 give empirical relationships for the run-down and run-up velocities on a smooth slope, based on theoretically derived upper bounds. The relationships are based on large scale experiments for a slope of 1:3. A limit for application of the formulas is therefore a slope close to 1:3.

Eqs. 12 - 15 give empirical relationships for maximum run-up and run-down levels on a smooth slope, based on large scale experiments on a slope of 1:3.

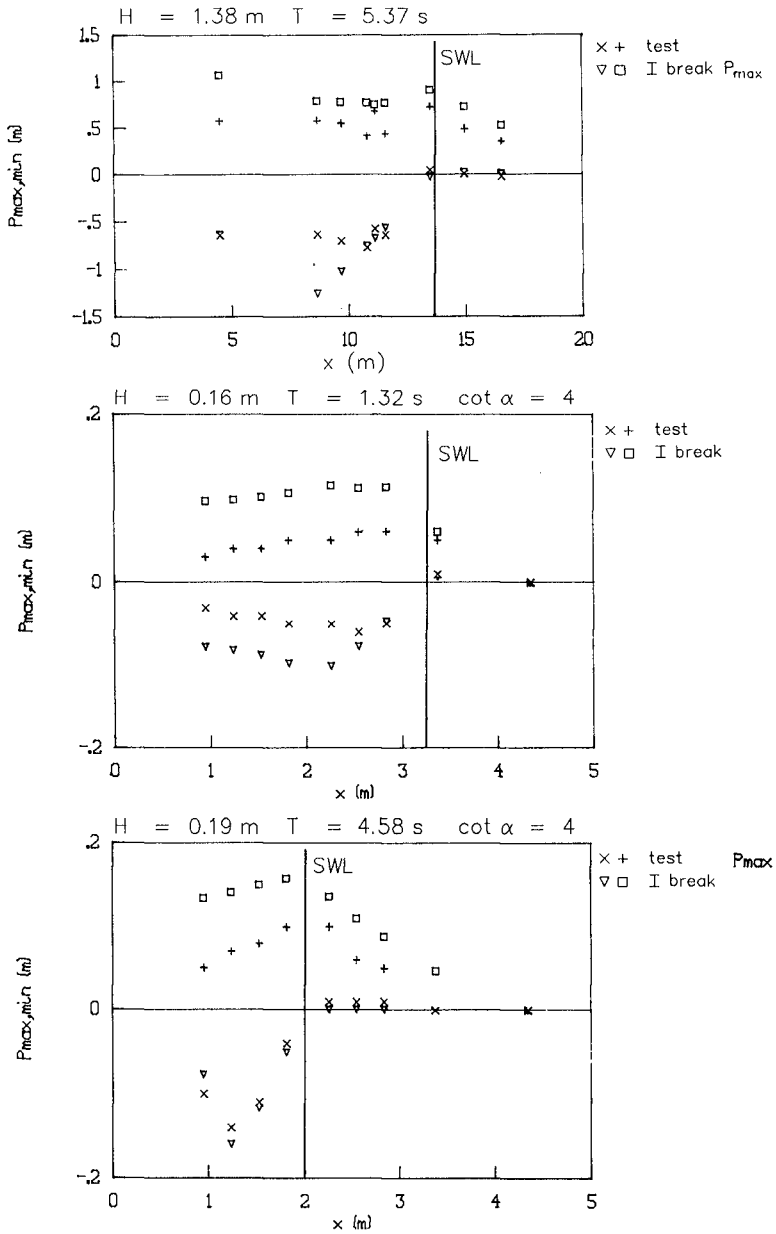

Figure 12 Measured and calculated maximum and minimum pressures

The model IBREAK was verified on maximum run-up and run-down levels, and velocities and water pressures along and on a smooth slope.

The average deviation between calculated and measured run-up is 12% which is reasonable. The general conclusion is that the run-up is predicted within acceptable limits. The calculated run-down is much smaller than the measured one, especially for the smallest ξ_0 values. The deviation is very large there and not acceptable for practical use.

The friction factor plays an important role with regard to velocities, even for a smooth slope. The general conclusion is that IBREAK gives a reasonable prediction of the velocities on a smooth slope.

The friction factor has no influence on wave pressures when this factor is in the range of $f = 0.02 - 0.10$. The general conclusion on pressures is that IBREAK can not accurately simulate wave pressures on a smooth slope. It can simulate the location where the maximum wave pressure occurs.

CHAPTER 15

A NUMERICAL MODEL FOR REFRACTION COMPUTATION OF IRREGULAR WAVES DUE TO TIME-VARYING CURRENTS AND WATER DEPTH

Masataka Yamaguchi¹ and Yoshio Hatada²

ABSTRACT

This paper presents two models for current-depth refraction of directional spectra due to time-varying currents and water depth, in which a piecewise ray method and a full ray method are used for numerical computations respectively. The results computed by the piecewise ray model in the cases of time-varying one-dimensional and two-dimensional currents are in reasonable agreement with those by the full ray model, which gives the almost exact solution in the case of linear current and water depth variations, except for a slight difference during the phase of strong opposing currents. The computations indicate that time-dependency of currents gives rise to a phase difference between wave height and current variations, and reduction in the amplification effect of directional spectrum due to opposing currents in comparison with steady current case.

1. INTRODUCTION

It is empirically known that waves are greatly amplified by the presence of strong opposing currents and that waves affected by tidal currents vary regularly with a pseudo-period of tidal currents (Vincent, 1979). As an example, Fig. 1 describes the time variation of significant waves observed at Naruto Strait which is located between Shikoku Island and Awaji Island. Naruto Strait is very famous for strong tidal currents and tide-induced large scale vortices. The investigation of such a phenomenon which might be caused by wave-current interac-

2 Research Assistant, Dept. of Ocean Eng., Ehime Univ., Bunkyocho 3, Matsuyama 790, Ehime Pref., Japan

tion, and the establishment of the evaluation method are of great importance for mitigation of coastal hazard, design of maritime structures, ship operation and so on.

Fig. 2 is a classification of the existing current-depth refraction models for irregular waves. The previous models assume time-independent fields for currents and water depth. Recently, Yamaguchi et al.(1988) and Tolman(1988) proposed numerical models applicable to the refraction computation of irregular waves with time-varying currents and water depth. The former model is a generalization of the time-independent model by Mathiesen (1984) and

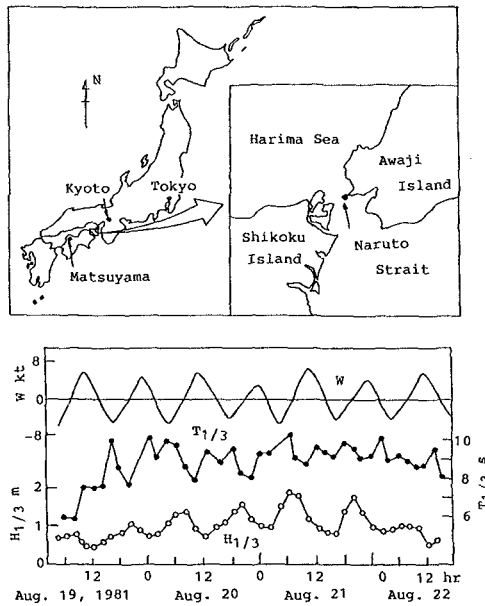

Fig. 1 Naruto Strait, and observed tidal currents and significant waves.

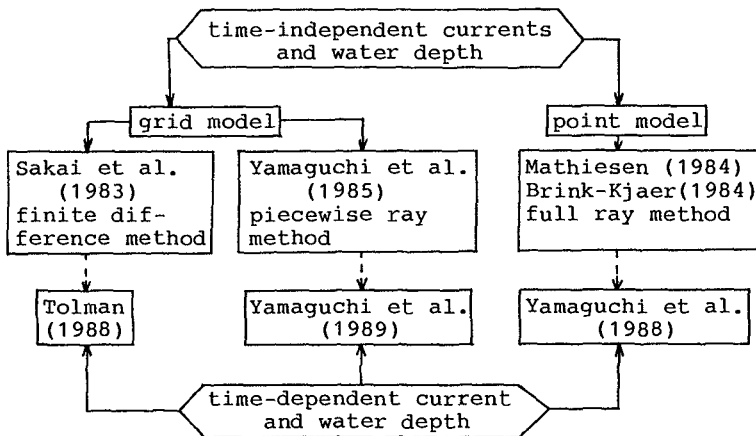

Fig. 2 A classification of current-depth refraction models for irregular waves.

Brink-Kjaer(1984) using a full ray method hereafter referred to as point model or full ray model, and the latter model is an extension of the time-independent model by Sakai et al.(1983) based on a finite difference method to a time-dependent model. Yamaguchi et al.(1989) also developed another numerical model for the refraction computation of directional spectra due to time-varying currents and water depth, which is a generalization of the authors' model(1985) based on a piecewise ray method hereafter referred to as grid model or piecewise ray model.

The aim of this study is to present two models for the time-dependent current-depth refraction of irregular waves developed by the authors and some examples of the numerical computation based on both models. First, the computation methods used in the models are explained in detail. Next, the models are applied to the computation of wave refraction caused by time-varying one-dimensional and two-dimensional model currents on a uniformly sloping beach. The accuracy of the piecewise ray model is investigated in comparison with the results based on the full ray model. The effect of time-dependency of currents and water depth on wave transformation is also examined from the comparison with the results for steady current case.

2. MODEL DESCRIPTIONS

(1) Basic Equations

The basic equations used in the model are the conservation equation for wave action density spectrum $N(\mathbf{k})$ defined by the ratio of wave number spectrum $E(\mathbf{k})$ to intrinsic angular frequency σ_m ,

$$\begin{aligned} \frac{\partial N(\mathbf{k})}{\partial t} + (C_\theta \cos \theta + U) \frac{\partial N(\mathbf{k})}{\partial x} + (C_\theta \sin \theta + V) \frac{\partial N(\mathbf{k})}{\partial y} \\ + \frac{dk_x}{dt} \frac{\partial N(\mathbf{k})}{\partial k_x} + \frac{dk_y}{dt} \frac{\partial N(\mathbf{k})}{\partial k_y} = 0 \end{aligned} \quad (1)$$

a set of equations for wave number vector components k_x and k_y ,

$$\begin{aligned} \frac{\partial k_x}{\partial t} + (C_\theta \cos \theta + U) \frac{\partial k_x}{\partial x} + (C_\theta \sin \theta + V) \frac{\partial k_x}{\partial y} \\ = - \frac{gk^2 \operatorname{sech}^2 kh}{2 \sigma_m} \frac{\partial h}{\partial x} - k_x \frac{\partial U}{\partial x} - k_y \frac{\partial V}{\partial x} \end{aligned} \quad (2)$$

$$\begin{aligned} \frac{\partial k_y}{\partial t} + (C_\theta \cos \theta + U) \frac{\partial k_y}{\partial x} + (C_\theta \sin \theta + V) \frac{\partial k_y}{\partial y} \\ = - \frac{gk^2 \operatorname{sech}^2 kh}{2 \sigma_m} \frac{\partial h}{\partial y} - k_x \frac{\partial U}{\partial y} - k_y \frac{\partial V}{\partial y} \end{aligned} \quad (3)$$

the Doppler relation,

$$\sigma = \sigma_m + k_x U + k_y V, \quad \sigma_m = \sqrt{gk \tanh kh} \quad (4)$$

and the equation of absolute angular frequency σ

$$\begin{aligned} \frac{\partial \sigma}{\partial t} + (C_g \cos \theta + U) \frac{\partial \sigma}{\partial x} + (C_g \sin \theta + V) \frac{\partial \sigma}{\partial y} \\ = \frac{gk^2 \operatorname{sech}^2 kh}{2 \sigma_m} \frac{\partial h}{\partial t} + k_x \frac{\partial U}{\partial t} + k_y \frac{\partial V}{\partial t} \end{aligned} \quad (5)$$

where C_g is the group velocity of a component wave, θ the wave direction, k the wave number, $k_x = k \cos \theta$, $k_y = k \sin \theta$, h the water depth, g the acceleration of gravity and (U, V) are the current components. Eq. (2) to Eq. (5) are not mutually independent, as is clear from their derivation. We choose the three equations, Eq. (2) to Eq. (4) for their relative simplicity of computation.

Eq. (1) means that even in the case of time-varying currents and water depth, the action spectrum for each wave component is conserved along the wave ray defined by

$$\frac{dx}{dt} = C_g \cos \theta + U, \quad \frac{dy}{dt} = C_g \sin \theta + V \quad (6)$$

where the wave number components are computed from

$$\frac{dk_x}{dt} = -\frac{gk^2 \operatorname{sech}^2 kh}{2 \sigma_m} \frac{\partial h}{\partial x} - k_x \frac{\partial U}{\partial x} - k_y \frac{\partial V}{\partial x} \quad (7)$$

$$\frac{dk_y}{dt} = -\frac{gk^2 \operatorname{sech}^2 kh}{2 \sigma_m} \frac{\partial h}{\partial y} - k_x \frac{\partial U}{\partial y} - k_y \frac{\partial V}{\partial y} \quad (8)$$

Thus, the conservation of the action spectrum $\psi(f, \theta)$ in frequency-direction space (f, θ) is written as

$$\begin{aligned} \psi(f, \theta) &= |(C_{g1} + U_1 \cos \theta_1 + V_1 \sin \theta_1) / 2 \pi k_1 \sigma_{m1}| E(f_1, \theta_1) \\ &= |(C_{g2} + U_2 \cos \theta_2 + V_2 \sin \theta_2) / 2 \pi k_2 \sigma_{m2}| E(f_2, \theta_2) \\ &= |(C_g + U \cos \theta + V \sin \theta) / 2 \pi k \sigma_m| E(f, \theta) \\ &= \Phi(f, \theta) E(f, \theta) = \text{const.} \end{aligned} \quad (9)$$

where f is the absolute frequency, $\Phi(f, \theta)$ the amplification factor due to current-depth refraction, $E(f, \theta)$ is the directional spectrum, and subscripts '1' and '2' are used for denoting different time as well as different place. This is the basic relationship used to compute current-depth refraction of directional spectrum.

Wave statistics are obtained by the numerical integration over wave direction and frequency using

$$\begin{aligned} E(f) &= \int_0^\pi E(f, \theta) d\theta, \quad \epsilon = \int_0^\infty E(f) df, \quad H_{1/3} = 4\sqrt{\epsilon}, \\ T_{1/3} &= 1.22 \sqrt{\epsilon / \int_0^\infty f^2 E(f) df}, \quad \bar{\theta} = \tan^{-1} \left\{ \frac{\int_0^\pi \int_0^\infty E(f, \theta) \sin \theta d\theta df}{\int_0^\pi \int_0^\infty E(f, \theta) \cos \theta d\theta df} \right\} \end{aligned} \quad (10)$$

where $E(f)$ is the frequency spectrum, ϵ the total wave energy, $H_{1/3}$ the significant wave height, $T_{1/3}$ the significant wave period and $\bar{\theta}$ the mean wave direction.

The input directional spectrum is given as

$$E_0(f, \theta) = E_0(f) \cdot D_0(f, \theta) \tag{11}$$

where $D(f, \theta)$ is the angular spreading function and subscript '0' indicates the offshore boundary. The frequency spectrum and angular spreading function rely on the Bretschneider-Mitsuyasu type spectrum and the Mitsuyasu type function respectively. They are expressed as

$$E_0(f) = 0.257 H_{1/3}^{(0)2} T_{1/3}^{(0)} (T_{1/3}^{(0)} f)^{-5} \exp \{-1.03 (T_{1/3}^{(0)} f)^{-4}\} \tag{12}$$

$$D_0(f, \theta) = \frac{1}{\pi} 2^{2s-1} \frac{\Gamma^2(s+1)}{\Gamma(2s+1)} \cos^{2s} \frac{(\theta - \theta_w)}{2}, \quad S = \begin{cases} S_{\max}(f/f_{op})^5 & ; f < f_{op} \\ S_{\max}(f/f_{op})^{-2.5} & ; f \geq f_{op} \end{cases} \tag{13}$$

where S and S_{\max} are the energy concentration factor and its maximum value, θ_w the principal wave direction, Γ the gamma function, $f_{op} (= 1/1.05 T_{1/3})$ the peak frequency, and superscript '(0)' denotes the offshore boundary as well as the above-mentioned subscript '0'.

(2) Numerical Methods

a. Piecewise ray model: The basic idea in the numerical computation is to assume that the action spectrum of a component wave of interest at an inner point (x, y) at $t - \Delta t$ -time, $\psi(f_r^{t-\Delta t}, \theta_s^{t-\Delta t}; x, y, t - \Delta t)$ becomes the one at a grid point (i, j) at t -time, $\psi(f_p, \theta_q; i, j, t)$ after propagation along a ray over time increment Δt , where subscripts ('r', 'p') and ('s', 'q') denote the frequency and direction at different positions and times respectively, and the directional spectrum at a grid point (i, j) at t -time, $E(f_p, \theta_q; i, j, t)$ can be evaluated using the action spectrum $\psi(f_p, \theta_q; i, j, t)$ and the characteristics of a component wave, water depth and current components at the same grid point and time, $(C_s^t, k^t, \sigma_m^t, h^t, U^t, V^t)$. Time-variability and inhomogeneity of current and water depth fields induce changes of not only wave direction but also absolute frequency of a component wave with its propagation.

A piecewise ray method is used to obtain the horizontal distribution of wave characteristics. The method consists of two steps. The first step is to trace all wave ray components from the grid points backward by one time step Δt , as shown in Fig. 3. Each wave ray is followed by solving the equations of wave number vector components, Eqs. (2) and (3) with the Runge-Kutta method under initial values of wave number components at a starting grid point. The initial values are estimated from iterative numerical solution of the Doppler relation, Eq. (5) under the given conditions of absolute frequency,

wave direction, water depth and current components. It should be noted that there exist sets of cut-off direction and frequency where propagation of directional spectrum is blocked. In the ray computation, input wave direction and current direction are reversed, and current components and water depth at the ray tip are interpolated not only in space but also in time owing to their time-dependency.

Fig. 3 Backward piecewise ray tracing.

The second step is to interpolate the action spectrum at the ray tip for the wave direction and absolute frequency shifted due to refraction. First, the Lagrange interpolation formula with third order accuracy is applied to the action spectra at the grid points surrounding the ray tip in order to estimate the action spectra for six sets of the prescribed input wave directions and absolute frequencies, namely two input wave directions (θ_n, θ_{n+1}) putting the refracted wave direction at the ray tip $\theta_s^{t-\Delta t}$ between them, and three input frequencies (f_{m-1}, f_m, f_{m+1}) putting the shifted absolute frequency at the ray tip $f_r^{t-\Delta t}$ among them. The formula is given as

$$\psi_{i+r, j+s} = \sum_{i=1}^{i+2} \sum_{j=1}^{j+2} \left(\prod_{k=1}^i \frac{x - x_k}{x_i - x_k} \right) \left(\prod_{l=1}^j \frac{y - y_l}{y_j - y_l} \right) \psi_{ij}$$

$$r = (x - [x]) / \Delta x, \quad s = (y - [y]) / \Delta y \tag{14}$$

Second, the action spectrum at the ray tip for the refracted wave direction and the input frequency is obtained by a linear interpolation over wave direction of the action spectra for the input wave directions estimated every input frequency as

$$\begin{aligned} \psi(f_k, \theta_s^{t-\Delta t}; x, y, t - \Delta t) = & \psi(f_k, \theta_n; x, y, t - \Delta t) + |\psi(f_k, \theta_{n+1}; x, y, t - \Delta t) \\ & - \psi(f_k, \theta_n; x, y, t - \Delta t)| \cdot (\theta_s^{t-\Delta t} - \theta_n) / (\theta_{n+1} - \theta_n) \end{aligned} \tag{15}$$

where k ($=m-1, m, m+1$) means the index of input frequency. Third, the action spectrum at the ray tip for refracted wave direction and frequency is estimated by use of parabolic interpolation of the log-transformed action spectra with respect to frequency as

$$\log \psi(f_r^{t-\Delta t}, \theta_s^{t-\Delta t}; x, y, t - \Delta t) = a(\log f_r^{t-\Delta t})^2 + b(\log f_r^{t-\Delta t}) + c \tag{16}$$

where a, b and c are the coefficients in a parabola curve determined from three sets of $\{ f_k, \psi(f_k, \theta_s^{t-\Delta t}; x, y, t - \Delta t) \}$, $k = m-1, m, m+1$. This procedure is required because the frequency of each wave component changes due to time-variation of currents and water depth.

b. Full ray model: The basic idea used in the model is the same as the one in the piecewise ray model. The computation in the full ray model consists of two steps.

The first step is to trace the wave ray of a component wave backward from a selected computation point to the grid boundary by the numerical integration of Eqs. (2) and (3) with the Runge-Kutta method, as illustrated in Fig. 4. In the ray tracing, currents and water depth at the ray tip are interpolated from those at the grid points, taking into account their space and time dependency.

Fig. 4 Backward full ray tracing.

The second step is to estimate the action spectrum at grid boundary for frequency and direction shifted due to refraction at an arrival time of the ray, using input data for directional spectra. It should be emphasized that the arrival time of each ray is different. By iterating these procedures every direction and frequency, directional spectra at a certain time at the prescribed position can be computed.

The full ray model can give the almost exact solution in a simple case of linear currents and uniformly sloping bottom, because errors associated with interpolation are negligibly small, but it is less advantageous for the evaluation of horizontal distribution of wave characteristics when compared to the piecewise ray model, as the computation is conducted separately and independently at each position.

3. COMPUTATIONAL RESULTS AND CONSIDERATIONS

(1) One-dimensional current case

Fig. 5 shows the computation region with a grid spacing of $\Delta x=4$ km and a spatial distribution of sinusoidally-varying unsteady one-dimensional linear currents with period of $\widehat{T}=12$ hours on a uniformly sloping beach of $i=1/1000$. The currents are given by

$$U=0, \quad V= \begin{cases} -0.2(j-4) \sin [(k-1)\pi/6]; & j \geq 4 \\ 0 & ; j < 4 \end{cases} \quad (17)$$

Fig. 5 Computation region and current distribution.

Fig. 6 Input directional spectra.

where k is the index denoting the time of the input currents given every 1 hour. The input wave conditions at the offshore boundary are also indicated in the figure. The 30 unevenly-spaced frequency data ranging from 0.09 to 0.571 Hz and the 37 evenly-spaced direction data from 0 to 180° are used with a time increment of 5 min. We focus our discussion on the wave characteristics at the grid point where water depth is 8 m deep and maximum current velocity is 1.4 m/s. Fig. 6 is the contour plot of input directional spectra.

Fig. 7 is the comparison between the time variations of wave height computed by both the full ray model and the piecewise ray model. The figure contains time variations of a current component V and wave height at the offshore boundary $\bar{H}_{1/3}^{(0)}$. This wave height is different from the input wave height given in the directional spectral model, Eqs. (11) to (13), defined on the entire circle ($\theta = 0 - 360^\circ$), because the computation is conducted on the half circle ($\theta = 0 - 180^\circ$). Both models are in close agreement except for a slight difference during the phase of opposing currents. The figure also shows that time-dependency of currents brings about a phase shift between the time variations of wave height and currents, and reduction in the amplification effect of wave height due to opposing currents in comparison with the steady current case.

Fig. 7 Time-variation of wave heights with unsteady one-dimensional currents.

Fig. 8 Time variations of directional spectra with unsteady one-dimensional currents.

Fig. 8 describes the variations every 3 hours of the directional spectra at the before-mentioned point computed by both models. Shrinking and expanding of the distribution of directional spectra associated with temporal variation of currents are observed in the figure. Comparison between the results with the piecewise ray model and those with the full ray model suggests that both models give similar distributions of directional spectra at each time, although the piecewise ray model predicts smoother distribution in the vicinity of cut-off direction and frequency by use of interpolation formulas in the computation of action spectrum.

(2) Two-dimensional current case

Current-depth refraction of directional spectra induced by sinusoidally-varying unsteady two-dimensional model currents with period of $\bar{T}=6$ hours shown in Fig. 9 was computed on a uniformly sloping beach of $i=1/250$ divided into 17×10 with a grid spacing of 1 km. This current pattern is a modeling of tidal currents flowing in and out of a river mouth. The 18 unevenly-spaced frequency data from 0.09 to 0.351 Hz and the 37

Fig. 9 An example of two dimensional current patterns given in the computation.

Fig. 10 Spatial distribution of wave heights and directions with unsteady two-dimensional currents.

Fig. 11 Time variation of wave heights with unsteady two-dimensional currents.

evenly-spaced direction data are used with a time increment of 1.5 min. Input wave conditions are given in the figure. The computation making use of the symmetry of the solution was carried out to save computer processing time. We concentrate our concern on the change of wave characteristics at the points A and B except for wave height distribution.

Fig. 10 illustrates the horizontal distribution of wave height and wave direction at the phase of almost maximum opposing currents and the one at the phase of almost maximum following currents respectively, which are obtained by use of the piecewise ray model. At the phase of opposing currents, waves tend to converge toward the river mouth and wave height increases rapidly. But the amplification ratio is not so large as that in the case of steady opposing currents, as seen in the one-dimensional case. On the other hand, at the phase of following currents, waves tend to refract so as to be away from the river mouth and wave height reduces slowly compared to the opposing current case.

Fig. 11 shows the time variations of currents and wave height at the points A and B computed with both models.

The wave height variation follows the current variation behind about 1 hour. Due to energy leakage introduced through the repeated interpolation of action spectra, the piecewise ray model gives slightly smaller variation of wave height, when compared to the full ray model.

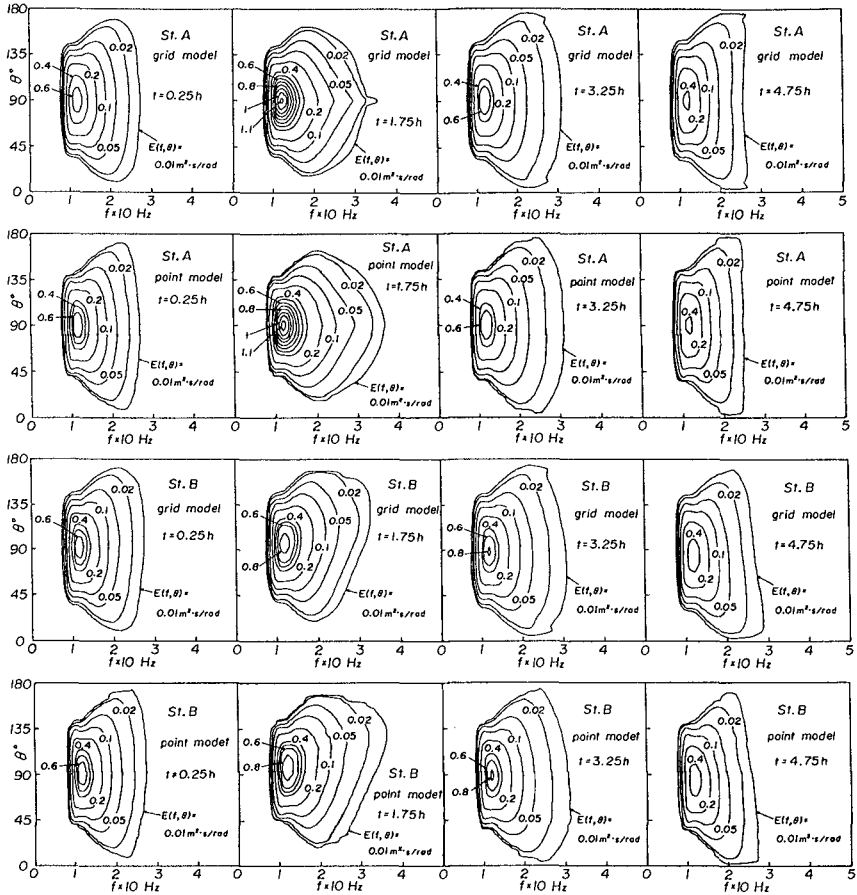

Fig. 12 Time variation of directional spectra with unsteady two-dimensional currents.

The time variations of directional spectra at the points A and B computed with both models are illustrated in Fig. 12. Both models produce close agreement in general patterns of directional spectra, but the distribution with the piecewise ray model are slightly smoother than those with the full ray model as well as the

case of one-dimensional currents. Convergence and divergence of the directional spectral distribution are alternately repeated with time-variation in direction and velocity of currents.

The directional spectra at the point A has a symmetrical distribution with respect to $\theta=90^\circ$ axis. Whereas at the point B of some distance from the center line of the region, component waves with directions of 90 to 180° receive stronger effect of currents than those with directions of 0 to 90° because of the current direction, and the resulting directional spectra at the phase of maximum opposing currents and those at the phase of maximum following currents have asymmetrical distribution relative to input wave direction. But, at the phase of zero currents, directional spectra have quasi-symmetrical distribution and the effect of currents is not clear.

4. CONCLUSIONS

The results obtained in this study are summarized as follows;

- 1) Two models for current-depth refraction of directional spectra due to time-varying currents and water depth are established, in which a piecewise ray method and a full ray method are used in numerical computation for propagation of directional spectra respectively.
- 2) The results computed with the piecewise ray model in the cases of time-varying one-dimensional and two-dimensional currents are in relatively close agreement with those by the full ray model except for a slight difference associated with the repeated interpolation of action spectra.
- 3) Time-dependency of currents gives rise to a time lag between wave height and current variations, and reduction in the amplification effect of directional spectrum due to opposing currents in comparison with steady current case.

5. ACKNOWLEDGEMENTS

Thanks are due to Mr. M. Ohfuku, Technical Officer, Department of Ocean Engineering, Ehime University, for his sincere help during the study. A part of this study was accomplished with the support of the Science Research Fund (No. 01550408) of the Ministry of Education, for which the authors express their appreciation.

Abstract

We discuss the application of the third generation WAM wave model to the Adriatic Sea. We focus in particular on one of the extreme storms that produced also heavy flooding in Venice. We discuss the problem of a correct description of the wind fields as a crucial input information to the wave model. After hindcasting the wave conditions during the storm, we use them as input for an estimate of the wave set-up towards the shore. We show that its consideration is essential for a proper evaluation of the flood level in the town.

Introduction

We discuss the application of the third generation WAM wave model to the Adriatic Sea. The recent tendency in wave modelling (see WAM-DI Group 1988, Tolman 1989) of neglecting, as far as possible, any empirical parametrization, and to numerically describe the field evolution only in terms of the physics of the phenomena involved, has allowed to properly model also storms with a complicated structure. The Adriatic Sea, enclosed between Italy and Yugoslavia, with a pronounced bordering orography, is characterized by strong gradients, both in space and time, of wind and wave fields. Provided the basin is represented with a sufficiently fine grid, a third generation wave model is likely to provide a very good overall description of the storm.

Three of us (see Cavaleri et al. 1989) have done extensive application of WAM to the Adriatic Sea, considering the various kind of storms acting in the basin, particularly in its northern part. We focus here on one of the heaviest storms, occurred in December 1979. The storm produced also a strong flood of the Venice Lagoon. The main task of this paper is to show how the evaluation of the wave set-up at the coast, obtained from the hindcasted wave conditions offshore, is an essential step for a correct estimate of the flood level in the town of Venice.

Wind and Wave Modelling

The WAM wave model is based on the numerical integration of the wave energy balance equation. This describes, point by point, time step by time step, the energy budget connected to advection, production and dissipation, and to the exchange among the various wave components. The model has been extensively described in the literature (e.g. WAM-DI Group 1988, Cavaleri et al. 1989) and we will limit here to the essential information. In the version used for this study the model runs with twenty-five frequencies in geometric progression ($f_1 = 0.0418$ hz, $f_{n+1} = 1.1 f_n$) and twelve directions at 12 degree intervals. The Adriatic Sea (Fig. 1) is represented on a 20 km step grid. The main axis of the basin, whose dimensions are approximately 750 x 200 km, is aligned from north-west to south-east; Venice is located at the upper left end. The last 200 km to the north are shallow, the depth of the continental platform decreasing with a more or less constant 1/1000 slope toward the northern end.

Fig. 1. Grid representation of the Adriatic Sea. The grid step is 20 km. C marks the position of the oceanographic platform off the Venetian coast. The wind model uses the same grid, but with one point out of two in each direction. Depths are in metres.

In general the most crucial aspect in the evaluation of a wave field is the accuracy of the wind field. It is obvious that, if a sophisticated wave model is to be used, the input wind field must have at least a comparable accuracy. This can be a problem when we are dealing with a relatively small basin with a complicated surrounding orography. In this case the large scale atmospheric models fail to correctly reproduce the relatively small details of the field that are nevertheless essential at the scale of the basin. The Adriatic Sea (Cavaleri et al., 1989) is almost completely bordered by high mountain ridges (Apennines to the west, Dinaric Alps to the east), and there is experimental evidence of wind space gradients up to 10 s in modulus and 10 deg m in direction. In these conditions the required grid resolution is of the order of 30-50 km, compared to the 100-150 km resolution of the present models, and to the 70 km one of the high resolution local models. Better examples do exist for specific areas, but they cannot be considered for generalized applications. Note anyhow that these figures should be halved with the next generation models, expected to come into operation in 1990-1991.

To satisfy the accuracy requirements we resorted therefore to a much simpler model (Cavaleri et al., 1990), where the accuracy is obtained by tuning the model to the local conditions. The model makes use of the one-layer balance equation whose solution provides the gradient wind. This is then transferred to the surface on the base of wind speed and air-sea stability conditions. The field modification, in modulus and direction, due to the constraintment of the bordering ridges is evaluated on the base of long-term experimental evidence. The input information is given by the atmospheric pressure recorded at the bordering meteorological stations. These are interpolated in space at the knots of a 40 km grid (Fig. 1) fitted to the wave model grid. A higher resolution would be only apparent because of the distance among the various stations. The above procedure provides one wind field for each synoptic time at the 3-hour interval.

The Storm of 21-23 December 1979

In these days strong wind over 20 ms , aligned all the way along the axis of the basin, produced very high waves in its central and northern part. Fig. 2 shows the wind and wave fields at 06 UI of 22 December. Note how the wave field is aligned along the axis of the basin till the northern coast (the left in the figure). No detailed comparison between model results and recorded data is possible as the oceanographic tower located offshore the Venetian

coast (point C in Fig. 1) suffered heavy damage during the storm. Our estimate of wave height at the tower is anyhow consistent with the damage reported on board.

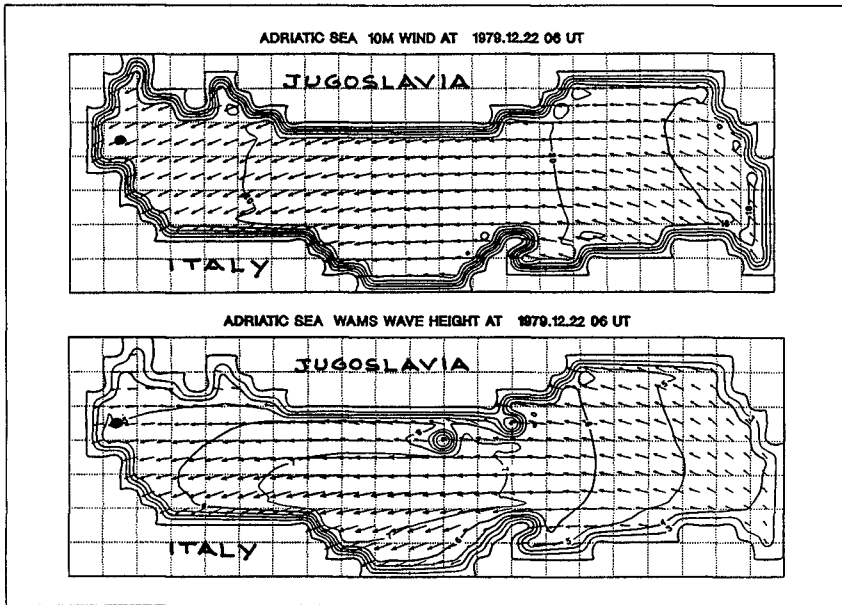

Fig. 2. Wind and wave fields at 06 UT of 22 December 1979. The wind has been interpolated from its 40 km resolution on the original grid. The dot to the left marks the position of the oceanographic platform.

The storm produced also one of the most severe floods ever recorded in Venice. The local geometry is shown in Fig. 3. At the town the peak sea level was measured at +1.66 metres above m.s.l., +1.85 metres at the Lido harbour entrance. Subtracting the expected +30 cm due to astronomical tide (Fig. 4a,b), we are left with +1.36 and +1.55 cm surge respectively. Fig. 4b shows also the predicted storm surge level, obtained by a statistical model fitted to data of the last decade (Canestrelli et al., 1986). There is an evident strong underestimate of the flood, particularly at and after the peak. This was not surprising. On the average the model works

rather well (r.m.s. error at the peak of the order of 10 cm), but it seems to fail, with a permanent underprediction, for the largest storms.

The only oceanographic instrument on the platform to survive the storm was the tide gauge, and we could therefore compare its record with the one at the Lido entrance (point B in Fig. 3). The two records showed up to 40 cm difference (Fig. 4c), the higher values being recorded at the coast. Notwithstanding our immediate doubts, a careful check confirmed the correct functioning of the gauge on board and the correctness of the data.

Fig. 3. Geometry of the Venetian coast. Lido and Malamocco are two of the three inlets connecting the lagoon to the sea. A and B show the position of the tide gauges. Depths are in metres.

Fig. 4. a) Recorded and astronomical tide at Venice; b) recorded storm surge level (difference of the two graphs in a) and model prediction; c) wave height at the tower, evaluated and recorded set-up at the harbour entrance; d) recorded storm surge level (same as b) and corresponding model result (addition of prediction in b) and recorded set-up in c).

The explanation of this large difference is found in the wave fields. The entrance pier extends 3 km offshore till 6-metre depth. Both the reported damage on the platform and the hindcast (Fig. 4c) indicate that the waves were already breaking well before reaching the pier end. We must therefore expect that wave set-up was present at the pier end (and higher at the beach of course) and contributing to the local sea level. Starting from the hindcasted wave conditions at the platform we have evaluated the set-up at B (Fig. 3) making use of a one-dimensional set-up model (Bertotti and Cavaleri, 1985). The model assumes equilibrium conditions and evaluates the surface profile due to set-up from the platform till the shore. The one-dimensionality is justified by the strong concentration in direction of the wave field perpendicular to the shore, the equilibrium conditions by the limited distance (16 km) between the platform and the coast and the consequent fast response to any change in conditions.

The evaluated set-up, as sea level difference between the pier end and the platform, is shown in Fig. 4c. Its fit with the recorded difference is excellent (average difference at the estimate times + 1 cm), and we confidently conclude that the difference between the two gauges is effectively due to set-up.

We now make the hypothesis (discussed in the next section) that the storm surge model does not take set-up into consideration. Consequently we combine the predicted sea level and the set-up (Figs. 4b and 4c respectively) and compare again with the recorded sea level. The result is in Fig. 4d. The error has been drastically reduced (average error -1 cm, r.m.s. 9 cm), and the model evaluation is now good for all practical purposes.

Discussion

In the previous section we have stated that the statistical model of storm surge is actually evaluating the sea level off the coast, and, for the evaluation of the coastal sea level, we have to take into account the set-up due to waves. To be conclusive this statement must be made consistent with the general behaviour of the storm surge model, i.e. good results in most of the cases, with underestimate in the worst storms.

We first point out the structure of the storm surge model. Its estimate for the immediate future is based on the local sea level data during the last 15 hours and on the pressure values at some chosen station. Whatever the physics at the base of the phenomenon under study, it would be natural to assume that a statistical model should reproduce it, the degree of accuracy depending on the

complication of the phenomenon itself and on that of the model.

The second argument points to the structure of the wind fields during the storm surge events. These are basically due to the Sirocco wind, blowing from the southeast along the axis of the Adriatic Sea. Fig. 2 is a good example in this sense. But the Sirocco produces also heavy sea conditions in the northern part of the basin. Hence a surge in the Venice area is usually associated with high waves from the southeast, that produce also a coastal set-up. For our purpose, i.e. for the evaluation of the surge in Venice, we are not interested in the set-up at the shoreline, but at the end of the pier (point B in Fig. 3). A positive set-up at B is present only when breaking begins before B, which is true only for the heaviest sea conditions. Consequently the storm surge model statistically fitted to the data of the last decade, and implicitly to the main body of them, is unavoidably built with no set-up information into it. When this appears also at B, the model produces only the surge part, with a consequent underestimate of the sea level.

Our conclusion is therefore that the set-up plays an important role in determining the flood level in the Venice Lagoon during the worst event. As a correct estimate of the set-up requires the knowledge of the wave conditions off the Venice coast, their estimate becomes mandatory for a correct tidal forecast at the town.

CHAPTER 17

SET-UP DRIVEN UNDERTOWS ON A BARRED BEACH

Philip D. Osborne¹ and Brian Greenwood¹

ABSTRACT

Field measurements of cross-shore velocity and water surface elevation from a natural barred surf zone during two storm events confirm the presence of undertow. The undertow is characterized by:

- i) mean cross-shore velocities reaching 0.20 m s^{-1} and directed offshore;
- ii) mean cross-shore velocity decreasing towards the surface with occasional reversals in the mean flow to a landward direction in the upper water column;
- iii) a strongly oscillatory velocity field with speeds increasing towards the surface and a distinct landward skewness superimposed.

The undertow is strongly correlated with set-up of the mean water surface. The set-up is characterized by:

- i) increasing values shoreward with perturbations closely following topography indicative of a primary forcing by waves;
- ii) maxima (0.35 m in the inner system) occurring over the bar troughs in association with decreasing wave height over the preceding bar crest as predicted by theory and laboratory experiments.

INTRODUCTION

Traditionally, undertow was thought to be a major control on shoreface erosion and the development and maintenance of nearshore bars (e.g. Johnson (1919), Keulegan (1948), Dally (1980), Roelvink and Stive (1988)). Although attention shifted towards horizontal circulation mechanisms rather than vertically stratified flows following work by Shepard and LaFond (1939) and Shepard et al. (1941), the theoretical basis for a two-dimensional

¹ Scarborough College Coastal Research Group, University of Toronto, Scarborough, Ontario, Canada, M1C 1A4.

circulation was firmly established by Longuet-Higgins (1953), Longuet-Higgins and Stewart (1962; 1963; 1964) and Lundgren (1963). A considerable effort has now been directed at modelling cross-shore mean flows which occur under shoaling and breaking waves (e.g. Stive and Wind, 1986, and Svendsen and Hansen, 1988) and the driving mechanism, the pressure gradient due to set-up (and set-down) of the mean water surface (e.g. Battjes and Janssen, 1978, and Dally et al., 1985). However, field observations which document the spatial and temporal structure of undertow and which demonstrate a direct relationship to water level set-up by wave breaking have been lacking.

Recently, Greenwood and Osborne (1990a, 1990b) carried out eulerian measurements of the horizontal velocity field and water surface elevation from a natural barred surf zone in order to:

- i) examine the spatial and temporal variability of cross-shore flow; especially its vertical structure;
- ii) examine cross-shore flow in relation to topography; especially its possible role in bar formation;
- iii) identify the mechanism(s) responsible for cross-shore flow; especially its relationship to wave-induced set-up.

Measurements were taken during two storm events in June 1986 at Wymbolwood Beach, Georgian Bay, Ontario, Canada. Measurements from the first storm event on June 16-18, 1986, clearly identified an undertow which was shown to respond in a coherent manner to measurements of wave-induced set-up of the mean water level. In this paper we illustrate that measurements from a second, smaller storm event on June 24-25, 1986, compare favourably with those from the previous event under similar surf zone conditions and confirm the existence of undertow on barred beaches.

LOCATION OF STUDY

Wymbolwood Beach is a lacustrine, barred shoreface composed of medium-to-fine sands situated on southern Georgian Bay, Ontario, Canada (Figure 1). The site is ideal for measuring set-up and cross-shore flows; periods of wave activity are restricted to discrete storm events associated with the passage of meteorological depressions and are separated by periods of flat calm. The beach is exposed to fetch-limited storm waves, which may reach 1.5 m at breaking. Water level shifts are restricted to seasonal hydrologic and climatic effects, higher frequency seiching and wind and wave set-up.

During the experiment two bars were present on a mean nearshore slope of 0.015 (Figure 2). The inner bar had relatively steep slopes (landward = 0.083; lakeward = 0.047 - 0.031). The outer bar consisted of a laterally extensive,

Figure 1. Location of study; bathymetric contours are in fathoms.

very gently sloping landward slope (0.005) and a lakeward slope approximately equal to that of the mean beach slope. Changes in the beach profile along the instrument transect during the two storm events were restricted essentially to the inner bar and beach face. The outer bar remained essentially two-dimensional and unchanged throughout the experimental period (Greenwood and Osborne, 1990a). No rip channels or other irregularities were present.

EXPERIMENTAL DESIGN

Sensor deployment was designed to satisfy two aims:
 i) to relate waves, mean water-surface elevation and cross-shore flows to varying topographic constraints, horizontal spatial coverage should be as complete as possible;
 ii) to relate cross-shore flows to elevation above the bed, a dense network of sensors in the vertical was necessary. However, deployment was constrained by the number of sensors available (15 continuous resistance wave staffs, 11 electromagnetic current meters). Figure 2 illustrates the final deployment of sensors along a shore-normal

Figure 2. Nearshore profile and instrument deployment.

transect; note the fairly complete coverage of the nearshore by the wave sensors and the dense tri-level array of current meters on the landward slope of the outer bar. The latter might be expected to provide information on the character of any undertow that might occur and in a location where, according to theory, it might be expected to contribute to sediment transport causing bar growth. All sensors were scanned at 0.42 Hz for approximately 20 minutes. Wind speed and direction were measured at the beach face with a Beaufort anemometer and wind vane. Time-averaged statistics (such as the mean, standard deviation, and skewness) used to describe the wave and velocity fields, were computed over twenty minute sample periods (2925 points) as follows:

$$\bar{u} = 1/n \sum u_{(t)} \quad \text{or} \quad \bar{\eta} = 1/n \sum \eta_{(t)}$$

$$u_s = [1/n-1 \sum (u_{(t)} - \bar{u})^2]^{1/2} \quad \text{or} \quad \eta_s = [1/n-1 \sum (\eta_{(t)} - \bar{\eta})^2]^{1/2}$$

$$u_m = 2.8u_s \quad H_s = 4 s$$

$$u_{sk} = [1/n-1 \sum (u_{(t)} - \bar{u})^3] / u_s^3$$

Where n = sample size, $u_{(t)}$, $\eta_{(t)}$ = time-varying velocity, water-surface elevation, \bar{u} , $\bar{\eta}$ = mean, u_m = maximum orbital speed, H_s = significant wave height, u_{sk} = velocity skewness. Water level set-up and set-down were computed using the difference between mean water levels during the storm events and mean water levels under flat-calm conditions on June 19-20 between the storms.

TEMPORAL VARIABILITY OF WAVE AND VELOCITY FIELDS

Both storms studied were of a magnitude frequently encountered in this location (e.g. the recurrence interval of the June 16 storm was 0.2 years). Temporal variation in wind speed and direction, significant wave height and

peak wave period is presented in Figure 3. Incident wave heights reached 1.5 m with a peak period of 4 to 6 s in the June 16-18 storm. A relatively rapid reduction in wave height occurred following the storm peak due to a reduction in wind speed and a shift in wind direction away from maximum fetch. During the storm peak, a surf zone dominated by spilling breakers extended well beyond the outer bar crest for a period of at least 11 hours and breaking was present on the outer bar crest and area landward for a significantly longer period. Although wave activity lasted for 49 hours, the most intense activity was concentrated between 1600 h and 2330 h on June 16. In the June 24-25 storm, incident wave heights reached 1.1 m with a peak period of 4 s. Both wave height and period increased in response to wind from the WSW but decayed more gradually following the storm peak as wind direction shifted to the W and WNW (maximum fetch) and wind speeds were reduced. Spilling breakers dominated the outer bar crest and area landward for a period of approximately 6.5 hours between 1330 h and 2100 h.

Temporal variation in the near-bed velocity parameters: \bar{u} , u_s , and u_{sk} at 10 m, 65 m and 110 m offshore are shown in Figure 4. The first three moments of the cross-shore velocity field exhibit strong positive correlations with wave energy and a high degree of spatial coherence (Greenwood and Osborne, 1990b). Near identical values of wave-induced orbital currents (u_s) were recorded from the closely spaced flowmeters on the outer bar throughout the two storms.

On June 16, a distinct offshore mean flow was superimposed on the oscillatory motion at all measurement stations from 1300 h until 2330 h. The cross-shore mean-flow was not a local anomaly, but was coherent spatially and temporally. During the storm growth mean flows decreased across the landward slope of the outer bar; in contrast, a lakeward increase in mean flow speeds from 0.12 m s^{-1} to 0.18 m s^{-1} was observed during the storm peak.

On June 24, mean flows were again predominantly offshore, but of much smaller magnitude than in the previous event. In general, mean speeds increased lakeward across the landward slope of the outer bar from near zero ($< \pm 0.03 \text{ m s}^{-1}$) at 60 m to 0.09 m s^{-1} at 70 m. The reduction in mean flow on the lakeward slope of the outer bar (110 m) suggests that the cross-shore mean flow was confined to the surf zone and was being driven by local forcing.

Coincident in time with the offshore mean flows was a large onshore directed skewness in the cross-shore velocity field. There does not appear to be a clear spatial pattern in the skewness, but rather a marked uniformity for a third order statistic which is highly susceptible to sampling variability. The positive skewness coincides well with the period in time when spilling breakers were

Figure 3. Wind and wave conditions, Wymbolwood Beach: June 16 to 18, 1986 (a); June 24 to 25, 1986 (b).

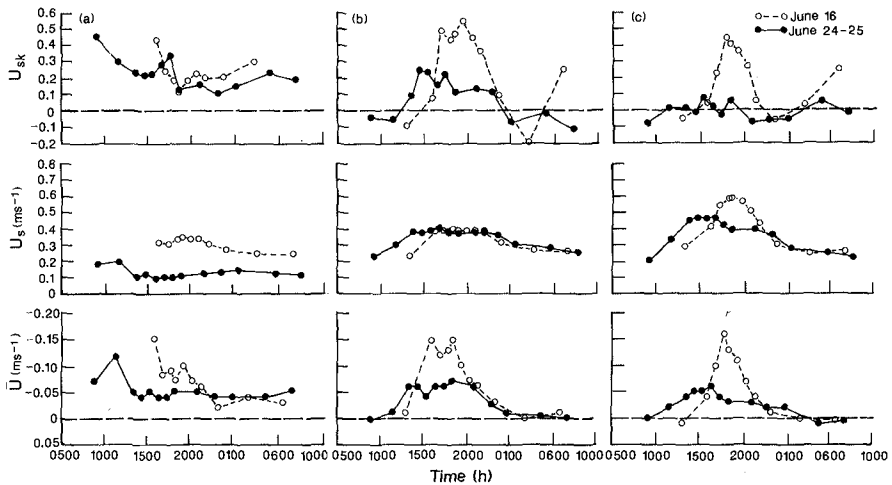

Figure 4. Temporal variation of near-bed (0.10 m) velocity parameters, \bar{u} , u_s , and u_{sk} , during the two storm events: 10 m offshore (a), 65 m offshore (b), and 110 m offshore (c). Note: positive values indicate onshore direction.

propagating through the tri-level sensor array, and this asymmetry was undoubtedly due to the non-linear nature of the surface waves. In the second storm, breaking waves were restricted landward of the outer bar crest, consistent with the near-zero skewness in velocity observed on the lakeward slope (Figure 4c).

CROSS-SHORE FLOW CHARACTERISTICS

Vertical variation in \bar{u} , u_s , and u_{sk} recorded on the landward slope of the outer bar (65 m) during both storms (1700 - 2030 h, June 16; 1500 -1730 h, June 24) is shown in Figure 5. The offshore mean flows exhibit a distinct vertical stratification; they were a maximum at the 0.1 m elevation and decreased in magnitude with elevation above the bed. At times, the mean flow exhibited a reversal, being directed onshore at the 1 m elevation, although these flows were small. In contrast, the wave-induced oscillatory motion was generally uniform in magnitude with elevation above the bed. Orbital speeds were similar during both storm events, indicative of the limiting velocity under wave breaking. Velocity skewness, on the other hand, exhibited more vertical variation, although it was almost always positive (directed onshore) at all elevations.

Figure 6 is an example of time-series of cross-shore velocities and water surface elevations under breaking waves during the storm peaks which illustrates that, even though a significant quasi-steady flow was present, the time-dependent, cross-shore flows were still dominated by oscillatory motion. The strongly non-linear nature of the water surface profile and the resulting velocity asymmetry associated with the spilling breakers is clearly displayed in these time-series; note also the "saw-toothed" water surface profile. Figure 7 illustrates a typical distribution of total velocity vector magnitude as a function of angle relative to the shore-normal during the storm peaks. It is evident that the vectors are distributed across all angles with the majority (greatest density of points) distributed about 200° , indicating that most flow vectors were associated with the offshore and alongshore currents. The distribution is also peaked at $0^\circ/360^\circ$ (the onshore direction); note that the magnitude of the relatively infrequent onshore directed vectors is similar to that of the offshore directed flows. This is in marked contrast with the signature of an active rip current recorded by Bowman et al. (1988).

In summary, the velocity field under spilling breakers was predominantly oscillatory, but with a well-defined offshore mean flow superimposed. The velocities exhibited a landward directed skewness, which was caused by the non-linear breaking waves. The spatial and temporal coherence

of the mean flow, with its maximum near the bed, has the characteristics of an undertow.

SPATIAL AND TEMPORAL VARIATION IN SET-UP AND WAVE HEIGHT

Temporal changes in the set-up of the mean water level in the inner part of the surf zone are shown in Figure 8. The set-up was well correlated with wave energy and also with the offshore mean flow. This is to be expected if the set-up is primarily wave-forced and the undertow is set-up driven.

In general, wave height decreased and set-up increased towards the shoreline during the storm peaks (1800 h, June 16; 1630 h June 24); however spatial variation in the wave height decay and elevation of the water level indicate a strong topographic influence induced by the bars (Figure 9). In both storms there was a rapid decay spatially in wave height across the upper lakeward slope and crest of the outer bar, the minimum height occurring just landward of the bar crest. The overall pattern for June 16 is consistent with the visual observation that breaking occurred by spilling across the whole experimental array and actually began well lakeward of the array. The wave height decay pattern also indicates that more intense breaking was associated with local decreases in water depth on the bar crests and at the shoreline. On June 24, the wave height decay across the lakeward slope of the outer bar (> 85 m) was less rapid than that observed during the June 16 storm owing to the smaller incident wave heights.

Figure 8. Temporal changes in the set-up of the mean water level measured at 10 m offshore.

Figure 9. Shore-normal variations in the significant wave height and mean water surface set-up during the storm peaks: 1800 h June 16 (a); 1630 h June 24 (b).

The maximum local gradient in set-up occurred across the lakeward slope and crest of the inner bar, with maximum set-up in the trough and landward. There was a distinct decrease in the set-up landward of this local maximum. This pattern is consistent with the observed increase in local energy dissipation, often characterized by the presence of plunging breakers, which occurred over the crest and upper lakeward slope of the inner bar and again at the shoreline. No measurements of the water surface across the beach face were possible in this experiment to confirm the expected set-up due to the shoreline breakers, but visual observations confirmed an increase in the elevation of wave run-up during the storm peaks. A similar but less pronounced pattern in set-up is evident over the outer bar in association with the gradients in dissipation occurring in that region.

These observations provide strong evidence that topographic variations introduce spatial variability in both wave height and set-up, the former through enhanced shoaling, breaking and frictional effects as both theory and laboratory experiments suggest (Battjes and Janssen, 1978; Dally et al., 1985). However, the spatial gradients in set-up are significantly smaller than those expected for the measured wave height decay (Greenwood and Osborne, 1990b; Hazen et al., 1991).

DISCUSSION AND CONCLUSIONS

In this paper we illustrate the presence of an undertow on a natural barred beach which responds to both spatial and temporal variations in a wave-induced set-up. This distinctive two-dimensional cross-shore circulation pattern has been identified during two moderate storm events through detailed velocity and water surface elevation measurements.

During periods of breaking waves, the cross-shore velocity field was dominated by wave-induced flows with an average oscillatory speed of 0.40 m s^{-1} . A strong asymmetry in these oscillatory flows was evident in terms of large non-zero mean values (upto 0.20 m s^{-1}) directed offshore, and positive (onshore) directed skewness values. Vertical profiles of the wave-induced oscillatory velocity (u_s), the mean velocity (\bar{u}) and the velocity skewness (u_{sk}) indicate radically different structures. The oscillatory velocities were essentially uniform, perhaps increasing slightly with elevation above the bed, whereas the offshore mean flows generally decreased in speed with elevation, and in some cases flow reversals were present in the upper part of the water column. Velocity skewness was positive with considerable vertical variability, although a less distinct stratification than the mean and oscillatory components. These observations reveal a mean flow, which is separate and distinct, and imply the existence of a quasi-steady

current superimposed on highly non-linear oscillatory motion.

The large positive skewness values together with the vertical structure of the oscillatory and mean flow components suggest a shoreward directed, depth-dependent momentum and mass flux which is greater near the surface as suggested by theory. The mass and momentum balance is achieved by the large offshore mean currents in the lower water column. A large number of vertical profiles with this distinctive vertical structure from across the outer part of a surf zone saturated with spilling waves, suggest a well-developed and spatially coherent undertow.

The undertow responds to changes in the set-up of the mean water level, which in turn is strongly correlated with the growth and decay of the incident wave height. This is consistent with the hypothesis of a two-dimensional circulation driven by the vertical differences in the water column between the depth-dependent radiation stress and a depth-uniform pressure gradient force associated with a sloping water surface.

Local variations in the set-up, wave height and cross-shore mean flow are topographically controlled on a barred beach (see also Hazen et al., 1991). Large set-up gradients on the steepest part of the beach (lakesward slope of the inner bar) are associated with large gradients in wave height decay over the outer bar crest. These observations together with the presence of vertically stratified flows lend support to the notion a two-dimensional circulation system, undertow, driven by wave set-up.

ACKNOWLEDGEMENTS

This research was supported by operating and equipment grants from the Natural Sciences and Engineering Research Council Canada to Brian Greenwood, and an Ontario Graduate Scholarship to Philip Osborne. We would like to thank Drs. D.J. Sherman and B.O. Bauer, together with A. Hincenbergs and R. Blair for their invaluable assistance in the field.

CHAPTER 18

NEARSHORE CIRCULATION WITH 3-D PROFILES

Ib A. Svendsen,¹ Member, ASCE and Uday Putrevu,² Student Member, ASCE.

ABSTRACT

A model that predicts the depth variations of wave generated currents within the framework of a 2-D depth-integrated surf-zone model is described. The equations are formulated and solved for the case of a long, straight coast. The model is used to demonstrate that the effects of current refraction are weak and to determine the variation of the 3-D spiral shaped current profiles across the surf-zone. Finally, we show that the mixing coefficient required to get realistic variations of the longshore current is much larger than what the turbulence measurements can justify.

1. INTRODUCTION

The present paper describes a hydrodynamical model for 3-D wave generated currents in the nearshore region. The model is based on the idea of using a 2D-horizontal, depth integrated description to determine the integration constants in the analytical solutions for the vertical variation of the horizontal velocities. This idea was developed for the 2D cross-shore circulation by Svendsen & Hansen (1988). Independently, Davis (1987) pursued a similar idea for wind generated currents.

Quasi 3-D local solutions for current profiles were derived by deVriend & Stive (1987) based on dividing the flow into a primary and a secondary component. The more general approach used here was developed by Svendsen & Lorenz (1989) (S & L) who used a perturbation expansion to establish the equations. Concentrating on the longshore current profiles, they found that the equation normally used for the depth averaged longshore currents actually applies to the first approximation to the bottom velocity. The longshore velocity above bottom level increases uniformly, yielding somewhat (10-20%) larger depth averaged velocities at all locations than found by the classical depth integrated models.

In the present paper, the method of S & L is combined with the energy and cross-shore momentum equations to form a comprehensive computer model, the solution of which predicts wave heights, set-up, and, longshore and cross-shore currents and their variation over depth. For simplicity, the model equations are only established for a long cylindrical coast. This implies Snell's law is valid and it is possible to incorporate the wave-current refraction in the energy and

Figure 1: The three layer model concept

momentum equations in a simple manner. The basic equations of the model are described in Sections 2 and 3. This includes a description of how the bottom friction is incorporated as a boundary condition in the model.

On a long straight coast, the model equations become ordinary differential equations in x , the cross-shore coordinate. The energy and momentum equations represent initial value problems solved by specifying wave conditions at the seaward boundary. The longshore momentum equation is solved as a boundary value problem.

The system contains a number of features not previously included in such models though for reasons of limited space only a few of them can be analyzed and discussed here. In Section 4, we show that the wave-current interaction is really not modifying the wave motion or the current motion significantly even though the longshore current may be a substantial fraction of the wave speed. This is partly because the refractions due to the longshore and the cross-shore currents counteract each other, partly because the angle of incidence of the waves is usually small.

We also show the full cross-shore array of the 3-D spiral shaped current profiles corresponding to a given wave situation.

Finally, we confirm the logical conflict that still remains between which eddy viscosities are reasonable for the cross-shore circulation ($\nu_t \sim 0.01 h \sqrt{gh}$) and the many times larger coefficient for horizontal mixing required to achieve realistic variations of the longshore currents, particularly outside the surf zone for which we can find no justification in our knowledge about the turbulence characteristics. Though it has been suggested (Thornton & Guza, 1986) that on natural beaches this paradox may be accounted for by including the irregularity of wave breaking, that explanation does not cover experiments with regular waves where the effect seems equally strong (e.g., Visser 1982, 1984). Further examination of this problem would be desirable.

2. BASIC EQUATIONS FOR THE CURRENT VARIATION OVER DEPTH

The three layer model concept

The general approach is to utilize the concept of a 3 layer flow situation first suggested by Hansen & Svendsen (1984) and later used by Stive and Wind (1986) and Svendsen *et al.* (1987) (Fig. 1).

This approach assumes that there is a (mainly oscillatory) boundary layer at the bottom, within which the turbulence characteristics are dominated by the locally generated turbulence. In 2D cross-shore circulation, this assumption is

supported by the variation of current measurements and leads to very accurate results and there is no reason to expect the situation to be different in the general 3D case.

The method concentrates on the central or core layer, between the boundary layer and the wave trough. The third layer, between wave trough and wave crest, is considered separately from the middle layer because in that region there is water only part of the time, so we cannot separate the total particle velocity into an oscillatory and a mean (current) component.

In the central layer it is assumed that the turbulence is primarily produced by the breaking process. This means that it is both more intensive and has a larger length scale than the turbulence in the bottom boundary layer (Svendsen *et al.* 1987). This, in turn, justifies the assumption of a higher eddy viscosity ν_t in the central layer, based on the Prandtl-Kolmogorov assumption that

$$\nu_t \sim \ell \sqrt{q} \quad (1)$$

where q is the turbulent kinetic energy.

The basic equations

The general equations for the wave averaged (current) motion below trough level were derived by S & L. For a steady situation on a long straight coast, where $\partial/\partial y = 0$ (y being the shore parallel coordinate and x the shore normal coordinate pointing shorewards, see Fig. 2) those equations reduce to the following in the x and y directions, respectively:

$$\frac{\partial}{\partial z} \left(\nu_{tz} \frac{\partial U}{\partial z} \right) = \frac{\partial}{\partial x} \left(\overline{u_w^2} - \overline{w_w^2} + gb \right) + \frac{\partial \overline{u_w w_w}}{\partial z} + \frac{\partial U^2}{\partial x} \quad (2)$$

and

$$\frac{\partial}{\partial z} \left(\nu_{tz} \frac{\partial V}{\partial z} \right) = \frac{\partial \overline{u_w v_w}}{\partial x} + \frac{\partial \overline{v_w w_w}}{\partial z} + \frac{\partial UV}{\partial x} - \frac{\partial}{\partial x} \left(\nu_{tx} \frac{\partial V}{\partial x} \right) \quad (3)$$

Here $U(x, z)$, $V(x, z)$ are the cross and longshore current velocity components and u_w , v_w , w_w the oscillatory "wave" velocity components whose mean is zero below trough level. In (2) and (3) we have also modelled the turbulent shear stresses by introducing the eddy viscosity ν_t mentioned earlier. For later discussion we have distinguished between ν_{tx} and ν_{tz} . Reference is made to Fig. 2 for definitions of other variables.

It is inherent in the wave averaged approach that the wave particle velocities u_w , v_w and w_w are assumed known to the extent that the terms on the right hand side containing those parameters can be considered known.

Then (2) and (3) are actually two nonlinear equations for U and V . In classical models for nearshore circulation those terms are usually neglected because they are assumed small. To simplify the presentation, we will also neglect the nonlinear current terms. Furthermore, the findings from the perturbation solution by S & L justify that to the first approximation the horizontal mixing for the longshore current (last term in (3)) can be determined using the value V_b of V at the bottom.

Hence, as far as the depth variation of U, V is concerned, all terms on the right hand side of (2) and (3) are regarded as known forcing terms provided we can determine V_b . We define

$$\alpha_{1x}(x, z) = \frac{\partial}{\partial x} \left(\overline{u_w^2} - \overline{w_w^2} + gb \right) + \frac{\partial \overline{u_w w_w}}{\partial z} \quad (4)$$

Figure 2: Definition sketch

$$\alpha_{1y}(x, z) = \frac{\partial \overline{u_w v_w}}{\partial x} + \frac{\partial \overline{u_w w_w}}{\partial z} - \frac{\partial}{\partial x} \left(\nu_{tx} \frac{\partial V_b}{\partial x} \right) \tag{5}$$

This means that (2) and (3) can be integrated directly, and the solutions written

$$U(x, z) = \int \frac{1}{\nu_{tz}} \int \alpha_{1x} d\xi d\xi + \int \frac{A_1}{\nu_{tz}} d\xi + A_2 \tag{6}$$

and the equivalent for V with α_{1y} instead of α_{1x} .

Thus (2) and (3) can be expressed in closed form for arbitrary α_1 and ν_{tz} . To simplify discussions, however, we will in the following assume $\nu_{tz}(x, z) = \nu_{tz}(x)$ and $\alpha_1(x, z) = \alpha_1(x)$. Hence, (6) simplifies to

$$U(x, z) = \frac{1}{2} \frac{\alpha_{1x}}{\nu_{tz}} \xi^2 + \frac{A_1}{\nu_{tz}} \xi + A_2 \tag{7}$$

$$V(x, z) = \frac{1}{2} \frac{\alpha_{1y}}{\nu_{tz}} \xi^2 + \frac{B_1}{\nu_{tz}} \xi + B_2 \tag{8}$$

where A_1, A_2, B_1 and B_2 are arbitrary functions of x to be determined from the boundary conditions discussed in the following and $\xi = z + h_o$ is the height above the bottom. To determine the four constants A_1, A_2, B_1 and B_2 we need two conditions for each of the two velocity components U and V .

The bottom boundary condition

The first condition used is related to the variation of U, V at the bottom. Strictly speaking, the bottom condition is $U, V = 0$. Due, however, to the assumption of a boundary layer with relatively low eddy viscosity a large value U_b, V_b of U, V exists at a short distance above the bottom (the “top” of the boundary layer). Hence, the mean bottom shear stress in the middle layer is related to U_b, V_b and to the oscillatory motion u_{wb}, v_{wb} at the bottom. We assume here that this relation is given by ($i = 1, 2$ corresponding to the x, y components)

$$\tau_{bi}(t) = \frac{1}{2} \rho f u_{bi}(t) | u_{bi}(t) | \tag{9}$$

where $u_{bi}(t)$ is the ensemble averaged bottom velocity, $| u_{bi} |$ the numerical value of u_{bi} and f is a (constant) friction factor (see, e.g., Jonsson 1966). For u_{bi} we have

$$u_{bi} = U_{bi} + u_{wbi} \tag{10}$$

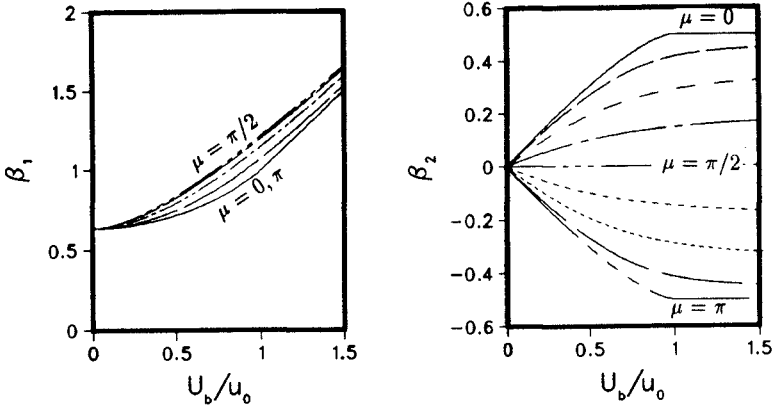

Figure 3: Variation of β_1 and β_2

where $U_{bi} = (U_b, V_b)$ and $u_{wbi} = (u_{wb}, v_{wb})$.

To determine the time mean of $\tau_{bi}(t)$, we also assume that

$$u_{wbi} = u_{oi} \cos \theta \quad (\theta = \omega t - kx) \tag{11}$$

and define, for short

$$u_o = |u_{oi}|, \quad U_b = |U_{bi}| \tag{12}$$

The mean shear stress $\tau_{bi} = \overline{\tau_{bi}(t)}$ is then determined by substituting (10), (11) and (12) into (9) and time averaging.

Liu and Dalrymple (1978) derived expressions for τ_{bi} for the special cases $U_b/u_o \gg 1$ (strong current) and $U_b/u_o \ll 1$ (weak current).

Here we present a more general formulation for arbitrary values of U_b/u_o and also arbitrary angles, μ , between the current direction and the wave direction. Performing the averaging operation we introduce the parameters

$$\beta_1 = \overline{\beta_1(t)} = \left[\left(\frac{U_b}{u_o} \right)^2 + 2 \frac{U_b}{u_o} \cos \theta \cos \mu + \cos^2 \theta \right]^{1/2} \tag{13}$$

$$\beta_2 = \overline{\beta_1(t) \cos \theta} \tag{14}$$

It then turns out that τ_{bi} can be written, without any further approximations, in the simple form

$$\tau_{bi} = \frac{1}{2} \rho f u_o [\beta_1 U_{bi} + \beta_2 u_{oi}] \tag{15}$$

which expresses τ_{bi} as the sum of two contributions, one in the direction of the current vector U_{bi} with weight β_1 , the other in the direction of the wave particle motion with weight β_2 . It is apparent from (13) and (14) that β_1 and β_2 are functions of two variables: U_b/u_o , the current strength relative to wave particle velocity amplitude and μ the angle between wave and current vectors. The variation of β_1 and β_2 with those parameters is shown in Fig. 3.

The expression (15) of course includes the cases of very weak and very strong currents. Though it is not apparent from (15), the case of $U_{bi} \rightarrow 0$ does yield $\tau_{bi} \rightarrow 0$: in purely sinusoidal motion there is no mean shear stress.

In the central layer the shear stress is given by

$$\tau_{zi} = \rho \nu_{tz} \frac{\partial U_i}{\partial z} \quad (16)$$

and for $z \rightarrow -h_o$ this shear stress must equal τ_{bi} determined from (15). Hence, combining (15) and (16) we get the mixed bottom boundary condition:

$$\frac{\partial U_i}{\partial z} - f(u_o, U_i) = 0 \quad z = -h_o \quad (17)$$

or, if we define

$$\begin{aligned} a &= \frac{1}{2} \frac{f}{\nu_{tz}} \beta_1 u_o \\ b_i &= \frac{1}{2} \frac{f}{\nu_{tz}} \beta_2 u_o u_{oi} \end{aligned} \quad (18)$$

and accept the slightly inconsistent nomenclature of $(\partial U_i / \partial z)_{-h_o} = \partial U_{bi} / \partial z$ then we can write (17) as the inhomogeneous mixed pseudo-linear condition for U_{bi}

$$\frac{\partial U_{bi}}{\partial z} - a U_{bi} = b_i \quad z = -h_o \quad (19)$$

This is the first of the boundary conditions used for the depth variation of U_i . Equation 19 is not quite linear because β_1 and β_2 depend on U_{bi} . It may also be noted that this implies that we can specify neither U_b nor τ_b at the bottom. It is the combination of U_b and τ_b imbedded in (19) that is controlled.

Applying (19) to the solutions (7) and (8) for U and V yields

$$U_i = \frac{1}{2} \frac{\alpha_{iz}}{\nu_{tz}} \xi^2 + (1 + a\xi) U_{bi} + b_i \xi \quad (20)$$

which expresses the vertical variation of the current velocity in terms of the unknown bottom velocity U_{bi} .

The second boundary condition

Hence, the function of the second boundary condition to be specified is essentially to determine the bottom velocity U_{bi} . The conditions used here are different in the longshore and in the cross-shore directions. In the longshore (y) direction, the second boundary condition is equivalent to specifying the shear stress τ_{sy} at wave trough level. τ_{sy} can be determined from the momentum balance for the flow above trough level (Stive and Wind 1986).

If the horizontal momentum flux above trough level is M_{ij} then we have

$$\tau_{sy} = \frac{\partial M_{xy}}{\partial x} \quad (21)$$

However, when combining the local depth variation of the flow given by (2) and (3) with a fully depth integrated model to give the horizontal variation it turns out to be more convenient not to impose (21) directly on the depth variation of the current. Instead, we apply the mixed condition (19) also to the fully depth integrated longshore momentum equation. This results, as shown in the next section, in an equation for the x variation of V_b , almost identical with the usual equation for the depth averaged longshore current. Solution of that equation therefore provides V_b and, hence, completely specifies the depth variation of the longshore component.

The question that naturally arises now is the following: Why is using the momentum equation integrated over the total depth to determine V_b completely equivalent to imposing (21) as a boundary condition for (20)? The explanation is the following: Determining the bottom velocity V_b from the total depth integrated momentum equation with (15) included means fixing the bottom shear stress so that depth integrated momentum is satisfied. At the same time, the solution (20) for V automatically accounts for the forcing that occurs below trough. Therefore, (20) with V_b determined as described will show a shear stress at trough level which corresponds exactly to (21) since τ_{sy} represents the difference between the total forcing and the forcing below trough level.

In the cross-shore direction, it is necessary to use a different approach. Because the cross-shore radiation stress is almost equal to the pressure gradient from the set-up, the method described above for V would lead to determining the bottom shear stress τ_{bx} as a (small) difference between these two large contributions (see Svendsen & Hansen, 1988). Instead we utilize that the net cross-shore flux Q_x is zero, so that

$$\int_{-h_o}^{\zeta_t} U dz = -Q_{sx}/(h_o + \zeta_t) \quad (22)$$

where Q_{sx} is the x -component of the mass flux in the wave, ζ_t is the trough elevation below SWL (Fig. 2).

Notice that this approach is only applicable for a straight coast where $\partial/\partial y$ and Q_x are zero. On a general coast we cannot distinguish between "cross-shore" and "longshore" and a different procedure is required.

3. THE DEPTH INTEGRATED EQUATIONS

The depth integrated equations are generalizations of the H-b model for calculation of the wave height H and set-up b in the surf zone first introduced by Svendsen (1984). That approach is based on dimensionless coefficients for radiation stress (P), energy flux (B), and energy dissipation (D). Using Phillips' (1977) equations the method was extended to 2D combination of waves and currents by Svendsen & Hansen (1986).

In most previous applications in the past the model has been applied using the special form of P , B and D found by incorporating experimental data for the real surface profile of the broken waves and including a roller contribution separately (Svendsen, 1984). The method as such, however, is general and by suitable choices of P , B and D can represent all H-b models. That was utilized by Hansen (1990) who specified empirical expressions for many of the surf-zone wave characteristics derived from actual measurements and found, not surprisingly, that they deviate substantially from sine-wave values. Here we use some of Hansen's results. The specific values of P , B and D used will be discussed further in connection with the applications (section 4).

We assume here that the waves are locally plane so that all wave properties can be described by 2-D wave theory. It is then convenient to define the momentum and pressure part of the radiation stress on a section perpendicular to the direction of wave propagation as the scalars

$$S_m = \overline{\int_{-h_o}^{\zeta} \rho u^2 dz} \quad (23)$$

$$S_p = -\overline{\int_{-h_o}^{\zeta} w_w^2 dz} + \frac{1}{2} \overline{\rho g (\zeta - \bar{\zeta})^2} \quad (24)$$

where $u^2 = u_w^2 + v_w^2$ is the horizontal wave particle velocity in the direction of wave propagation, ζ is the surface elevation above the horizontal axes.

We also define

$$e_{ij} = \begin{Bmatrix} \cos^2 \alpha & \sin \alpha \cos \alpha \\ \sin \alpha \cos \alpha & \sin^2 \alpha \end{Bmatrix} \quad (25)$$

where α is the direction of wave propagation relative to the x -axis (Fig. 2).

The radiation stress for a section with arbitrary normal vector then can be written

$$S_{ij} = e_{ij} S_m + \delta_{ij} S_p \quad (26)$$

where δ_{ij} is the Kroenecker δ . The generalized version of the dimensionless radiation stress P then is defined as

$$P_{ij} = \frac{S_{ij}}{\rho g H^2} = e_{ij} \frac{S_m}{\rho g H^2} + \delta_{ij} \frac{S_p}{\rho g H^2} \quad (27)$$

In particular, for our long straight coast we get

$$\begin{aligned} P_{xx} &= \frac{S_m}{\rho g H^2} \cos^2 \alpha + \frac{S_p}{\rho g H^2} \\ P_{xy} &= \frac{S_m}{\rho g H^2} \sin \alpha \cos \alpha \end{aligned} \quad (28)$$

Similarly, we define the dimensionless energy flux B by

$$E_{fi} = \rho g H^2 B c_i \quad (29)$$

where E_{fi} , the energy flux, is given by

$$E_{fi} = \overline{\int_{-h_o}^{\zeta} u_i \left[\rho g z + p + \frac{1}{2} \rho (u_w^2 + v_w^2 + w_w^2) \right] dz} \quad (30)$$

and

$$c_i = c \frac{k_i}{k} \quad (31)$$

k here represents the magnitude of the wavenumber vector, k_i .

Finally, we define the nondimensional energy dissipation D relative to the actual dissipation D by

$$D = D \cdot \frac{4hT}{\rho g H^3} \quad (32)$$

The three depth integrated equations solved are the cross-shore and the long-shore momentum equations, and the energy equation. We introduce the definitions above into the general equations of Phillips (1977) for waves and currents, simplifying to the conditions of a long straight coast including Snell's law. Finally, the dominating terms for H and b are isolated along the same lines as done by Svendsen & Hansen (1986) for the 2D cross-shore case. We then get, neglecting a few small terms, the depth integrated equations in the following form.

Cross-shore momentum equation

$$\frac{db}{dx} = - \left\{ \frac{P_{xx}}{h} [D' + g_1 + H^2 g_2] + \frac{\tau_{bx}}{\rho gh} \right\} \left(1 - \frac{1}{2} P_{xx} \cdot \left(\frac{H}{h} \right)^2 \right)^{-1} \quad (33)$$

where

$$g_1 = \left(\tau_{bi} U_{bi} - S_{xi} \frac{dU_i}{dx} - \frac{dUE}{dx} \right) / (\rho g c B \cos \alpha) \quad (34)$$

$$g_2 = \frac{1}{P_{xx}} \frac{dP_{xx}}{dx} - \frac{1}{2h} \frac{dh_o}{dx} - \frac{1}{B} \frac{dB}{dx} + \tan \alpha \frac{d\alpha}{dx} \quad (35)$$

$$D' = D / (\rho g c B \cos \alpha) \quad (36)$$

Energy equation

$$\frac{dH^2}{dx} = D' + g_1 - H^2 \left[\frac{1}{c} \frac{dc}{dx} + \frac{1}{B} \frac{dB}{dx} - \tan \alpha \frac{d\alpha}{dx} \right] \quad (37)$$

Longshore momentum equation

$$\frac{d}{dx} \int_{-h_o}^{\bar{n}} \nu_{tx} \frac{\partial V}{\partial x} dz - \frac{\tau_{by}}{\rho} = \frac{1}{\rho} \frac{dS_{xy}}{dx} \quad (38)$$

Solution of the equations

The desired equation for the bottom velocity V_b is found by substituting (15) and (20) into (38). Utilizing the findings of the perturbation solution developed by S & L, a first approximation to the resulting equation may be written

$$\frac{d}{dx} \left(\nu_{tx} h \frac{dV_b}{dx} \right) - a V_b = \frac{1}{\rho} \frac{dS_{xy}}{dx} + b_y \quad (39)$$

which is the differential equation we solve for V_b . The approximation made in (39) is that the turbulent mixing can be represented over the entire depth by using the bottom velocity V_b . The boundary conditions used for (39) are

$$V_b = 0 \quad \text{at} \quad x = x_{\text{shore}}, \rightarrow -\infty \quad (40)$$

Further, two matching conditions are used at the transition point x_t which is the point where the radiation stress starts to change. The matching conditions at x_t specify continuity in velocity and shear stress at x_t , that is:

$$V_{b+} = V_{b-}; \quad \nu_{tx+} \left(\frac{dV_b}{dx} \right)_+ = \nu_{tx-} \left(\frac{dV_b}{dx} \right)_- \quad \text{at} \quad x_t$$

where + and – refer to values immediately adjacent to x_i . Outside the surf-zone, dS_{xy}/dx is zero.

4. RESULTS

The 3D model system established above can be used to study a number of effects on a long straight coast which has not been analyzed previously in the literature. For reasons of limited space, the discussion is limited to a few mechanisms.

The numerical results will depend on the wave incidence angle α , the bottom slope h_{ox} (here assumed constant for simplicity, not necessity), and the way the wave properties are modelled, as a function of wave height, including the breaking criteria. Following Svendsen (1987), we have chosen to assume that the breaker height is given by $(H/h)_b = 1.11 \cdot (h_x L/h)_b^{1/4}$. An almost identical expression was suggested independently by Hansen (1990). The vertical eddy viscosity, ν_{tz} , was taken to be $\nu_{tz} = 0.01 h \sqrt{gh}$ (a discussion of the eddy viscosity is given later). The horizontal eddy viscosity, ν_{tx} , was taken to be $\nu_{tx} = 0.01 h \sqrt{gh}/h_x$.

The wave parameters—energy flux (B) and radiation stress (P)—depend on the shape of the surface profile and the area of the roller (Svendsen 1984). The shape of the surface profile is measured in terms of the dimensionless parameter B_o defined as $B_o = (\eta/H)^2$. In the present applications these parameters have been derived using the B_o suggested by Hansen (1990) and modified for waves with a current as in Svendsen & Hansen (1986), and the roller area found by Okayasu (1989). The dimensionless energy dissipation rate is taken to be the same as in a bore. The reason for choosing this set of parameters is that in this way we include the actual characteristics of broken waves. Usually, this model gives the best prediction of the set-up, which means of dS_{xx}/dx . Since S_{xy} through (25) and (26) is related to S_{xx} , it is evident that this also potentially implies a better prediction of the driving force for the longshore current. This point is important though it is usually disregarded in the discussions of surf zone wave theories and longshore currents.

Wave-current refraction

Many of the measurements of longshore currents both in the field and in the laboratory show very high velocities. The steeper the local bottom slope, the higher the velocity. For a coast with a slope of 1:30, velocities typically correspond to a Froude number of 0.2–0.4 or longshore velocities of 20–40% of the wave celerity. Visser in his experiments on 1:20 and 1:10 slope beaches obtained velocities corresponding to Froude numbers as large as 0.7–1.2; i.e., current velocities equal to or higher than the propagation speed of the waves. Wave current refraction is caused by the gradient in current velocity so one would expect a strong change in the wave pattern and hence on the current itself from this mechanism.

Dalrymple (1980) used a perturbation expansion to examine the simplified case of no turbulent mixing. The present model includes both turbulent mixing and the additional effect of the undertow. Based on Kirby & Chen (1989), this cross-shore current is represented by the mean value of the velocity below trough level.

Fig. 4a shows the changes in wave incident angle for a case with slope 1:30, deep water incident angle $\alpha_o = 15^\circ$. Four cases are shown: No current refraction, longshore current only, undertow only, and the full 3D case with both longshore and cross-shore flow. It is seen that the effects of the cross and the longshore

Figure 4: Effect of current refraction

currents counteract and almost cancel each other. Also, the effect of each of the two factors isolated is actually very modest. This is also clear from the resulting longshore current profiles shown in Fig. 4b. The effect of the current refraction is only just discernible at the peak of the velocity distribution even if the undertow is neglected.

Steeper slopes and larger angles of incidence will increase the effect and so will a 3D circulation pattern that locally creates a significant shoreward flow. Even then, however, our computations suggest that wave current refraction is not a very important mechanism for changing the current velocities.

Velocity profiles

Another feature of the present model is its capability of supplying the fully 3-dimensional velocity profiles from the 2-D horizontal, depth integrated solutions to equations (32)–(35).

The generic form of the velocity profiles was shown by S & L. As is apparent from the model, however, to obtain the profiles pertaining to each location it is necessary first to calculate the wave height and setup variation described by (32) and (33). In many previous nearshore models this part is eliminated by simply assuming that the wave height is a constant fraction γ of the waver depth.

Fig. 5 shows a set of consecutive 3D current profiles in the surf zone for a situation with slope $h_{ox} = 1/30$, and angle of incidence at the breakpoint of $\alpha_b = 5^\circ$. To obtain equal detailing, each profile has been scaled relative to the local depth under wave trough and the local wave celerity. We see that in the region where the longshore current is largest the bottom velocity is predominantly longshore, but in other regions the cross-shore motion is more prevailing.

If the angle of incidence increases, the longshore current velocity increases similarly and hence prevails more. Similarly, on a steeper slope, the cross-shore motion becomes stronger.

Figure 5: Variation of the velocity profiles across the surf-zone

Eddy viscosity

The eddy viscosity, ν_{tz} , in the surf-zone has been determined previously by fitting computed undertow profiles to measured data. Values reported range from $0.007h\sqrt{gh}$ through $0.03h\sqrt{gh}$ (Svendsen and Hansen 1988) to a linear variation between zero and $0.3h_x h\sqrt{gh}$ (Okayasu *et al.* 1988), the later yielding $0.01h\sqrt{gh}$ for $h_x = 1/30$.

In contrast, the eddy viscosity, ν_{tx} used by, e.g., Longuet-Higgins (1970) for longshore currents is equivalent to $0.01h\sqrt{gh}/h_x$, which on $1/30$ yields $0.3h\sqrt{gh}$ or about 30 times the value that can be justified for the undertow even inside the surf-zone. The large absolute value of $\nu_{tx} = 0.3h_b\sqrt{gh_b}$ at the breaker point is required to apply everywhere outside that point, and our comparison with Visser's (1982) measurements for regular waves confirm that such a large eddy viscosity is necessary to make the computations match with the measurements. Figure 6 shows that the difference obtained in the longshore current distribution using ν_{tx} equal to the ν_{tz} value found from undertow and ν_{tx} given by the Longuet-Higgins value mentioned above is very substantial.

On the other hand, if we combine the hypothesis described by (1) for the nature of the mechanism behind ν_t with the fact that outside the surf-zone the turbulence is rather weak, it becomes inconceivable that this mixing mechanism can be due to turbulence. In this context, it is interesting that Thornton and Guza (1986) find that the effect of the eddy viscosity in their NSTS data from Santa Barbara is negligible in comparison to the variability of the waves even during periods of narrow banded, almost unidirectional incident waves. In other words, a physically realistic eddy viscosity would still give correct results. However, this does not explain which mechanism causes a similar mixing in the regular wave experiments. It is beyond the space available to discuss possible explanations to

Figure 6: Effect of eddy viscosity

this paradox. What we seem to be able to conclude at this moment is that a very strong mixing process is controlling the longshore current distribution outside the breaker point both in regular and irregular waves.

ACKNOWLEDGEMENTS

INTRODUCTION

A frequent request by sponsors of research projects in maritime laboratories is to analyze the behavior of a structure for a given design sea state. During the years, the testing of physical models in wave flumes has proven to be both cost-effective and reliable. Physical modelling of random waves requires generating random wave trains with a specified variance spectrum.

Funke and Mansard (1987) pointed out that present technology now makes it possible to treat the wave generator and the digital simulation technique as two essentially separate problems in wave generation. During the last decade, digital to analog numerical simulations have become extremely efficient. Several methods are available for generating these numerical simulations. Borgman (1969) identified two fundamental methods: 1) the superposition of sinusoidal waves; and 2) the filtering of white noise. Hudspeth and Borgman (1979) demonstrated the advantages of using FFT algorithms for numerical simulations. Tuah and Hudspeth (1982) introduced deterministic (DSA) and non-deterministic (NSA) spectral amplitude models for random wave simulations based on FFT algorithms. Medina and Sánchez-Carratalá (1988) compared the different methods available for the numerical simulation of random waves.

At the present, the physical simulation of random waves having a specified variance spectrum in a wave flume may be accomplished by using a variety of techniques. However, sometimes research sponsors want to include a deterministic sequence of waves in the random wave simulation used to test structures. For example, sponsors may want to know how a particular wave group that occurs in a random wave simulation that is defined by a specified variance spectrum affects the performance of a structure. This request usually requires a laborious wave by wave analysis of many random wave simulations searching for a sequence of waves that almost resembles the requested one. An alternative method to this searching technique is to use "conditional simulation". This alternative method generates a numerical random wave simulation that has a specified variance spectrum and also includes the deterministic sequence of waves requested by the sponsor. A robust algorithm is derived for this "conditional simulation".

CONDITIONAL SIMULATION

Conditional simulation is a technique for generating a numerical realization that includes a given deterministic sequence of waves and that has a specified variance spectrum. This technique simulates realizations for a stochastic process that is defined by a specified variance spectrum and that contain a deterministic sequence of waves which occur at a prescribed time in the realizations. The method presented here may be used either in the time domain or in the frequency domain. In either case, the method is a two-step procedure.

The first step requires that a random time sequence be simulated that has a specified variance spectrum, $S_u(f)$. This simulation is called an "unconditional time sequence" and is denoted by $\eta_u(t)$. Figure 1-a shows an example of an unconditional time sequence obtained using a DSA algorithm (cf., Tuah and Hudspeth, 1982) and a specified Goda-JONSWAP variance spectrum (cf., Goda, 1985) using: $\gamma=1$, $m_0=1 \text{ m}^2$ and $f_p=0.27 \text{ Hz}$. The total number of points in the time sequence is $N=2048$ and the time interval $\Delta t=0.1$ seconds.

The second step is to embed the deterministic sequence of waves into the unconditional time sequence at a prescribed point in time. These two steps may be done either in the time domain or in the frequency domain. The deterministic sequence of waves is called the "embedded sequence" and is denoted by $\eta_e(t)$. The realization that contains the "embedded sequence" is called the "conditional time sequence" and is denoted by $\eta_c(t)$.

Figure 1-b shows a deterministic wave group or the "embedded sequence" that is to be embedded into the unconditional time sequence shown in Fig. 1-a. The time interval Δt of the "embedded sequence" must be the same as the time interval of the unconditional time sequence (e.g., $\Delta t=0.1$ seconds in Fig. 1). In Fig. 1, the first and last values of the embedded sequence $\eta_e(t)$ are to be embedded at the prescribed times $n_1=961$ and $n_2=1088$, respectively, of the unconditional time sequence $\eta_u(t)$. The total difference between the two prescribed time values is $\nu=n_2-n_1=127$. Therefore, the total number of values of the embedded sequence is $\nu+1=128$.

Finally, Figure 1-c shows the conditional time sequence containing the deterministic wave sequence embedded in a random wave simulation having a specified variance spectrum. The total number of points ($N=2048$) and the time interval ($\Delta t=0.1$ seconds) are the same for both $\eta_u(t)$ and $\eta_c(t)$. Near the two ends of the embedded wave group, the conditional simulation algorithm modifies the unconditional time sequence $\eta_u(t)$ in order to maintain the correlation structure in the conditional time sequence $\eta_c(t)$ in accordance with the specified variance spectrum $S_u(f)$.

TIME DOMAIN ALGORITHM

In the time domain, the conditional simulation algorithm inserts the embedded sequence $\eta_e(t)$ into the unconditional time sequence $\eta_u(t)$ between the two points of time n_1 and n_2 . The remaining values of the unconditional time sequence are modified in order to maintain the correlation structure that is associated with the specified variance spectrum $S_u(f)$.

The conditional time sequence may be obtained from (cf., Hudspeth et al. 1990):

Figure 1. Example of a Conditional Simulation:
a) Unconditional Time Sequence; b) Embedded Sequence;
c) Conditional Time Sequence.

$$\mathbf{n} \in [n_1, n_2] \rightarrow \eta_c(\mathbf{n}\Delta t) = \eta_c(\mathbf{n}\Delta t) \tag{1}$$

$$\mathbf{n} \notin [n_1, n_2] \rightarrow \eta_c(\mathbf{n}\Delta t) = \eta_u(\mathbf{n}\Delta t) + C_{12}\mathbf{X} \tag{2}$$

where:

$$C_{12} = [c_{n-n_1}, c_{n-n_1+1}, \dots, c_{n-n_2}] \tag{3}$$

where c_k is the covariance at lag $|k|\Delta t$ associated with the specified variance spectrum $S_u(f)$; and \mathbf{X} is the solution of the following system of equations:

$$C_{11}\mathbf{X} = \mathbf{v}_e - \mathbf{v}_u \tag{4}$$

where:

$$C_{11} = \begin{bmatrix} c_0 & c_1 & \dots & c_v \\ c_1 & c_0 & \ddots & \vdots \\ \vdots & \ddots & \ddots & c_1 \\ c_v & \dots & c_1 & c_0 \end{bmatrix} \tag{5}$$

$$\mathbf{v}_e = [\eta_e(n_1\Delta t) \dots \eta_e(n_2\Delta t)]^T \tag{6}$$

$$\mathbf{v}_u = [\eta_u(n_1\Delta t) \dots \eta_u(n_2\Delta t)]^T \tag{7}$$

where C_{11} is the covariance matrix; \mathbf{v}_e is the vector of values of the embedded sequence; and \mathbf{v}_u is the vector of values of the unconditional time sequence at the prescribed time values where the embedded sequence is to be inserted.

The conditional simulation algorithm inserts the deterministic sequence of waves into the unconditional time sequence and modifies only those values of the unconditional time sequence that are near the two ends of the embedded sequence (vide Fig. 1). For the values of the unconditional time sequence that are located far from the interval of the embedded sequence, the values of the time lags $|n-n_1|$, $|n-n_1+1|, \dots, |n-n_2|$ are large and the values of the covariances in the matrix C_{12} associated with these large time lags are small. Consequently, at these large values of time from the embedded time interval Eq. 2 becomes, approximately:

$$\eta_c(\mathbf{n}\Delta t) = \eta_u(\mathbf{n}\Delta t) + C_{12}\mathbf{X} \sim \eta_u(\mathbf{n}\Delta t) + [0 \dots 0]\mathbf{X} = \eta_u(\mathbf{n}\Delta t) \tag{8}$$

and the differences are small between the unconditional and the conditional time sequences far from the time interval of the embedded sequence.

FREQUENCY DOMAIN ALGORITHM

In the frequency domain, the conditional simulation algorithm for inserting an embedded sequence $\eta_c(t)$ into an unconditional time sequence $\eta_u(t)$ may be shown to be equivalent to the time domain algorithm (cf., Hudspeth et al. 1990). The advantage the frequency domain algorithm is that FFT algorithms reduce substantially the computer time needed to obtain a long conditional time sequence.

The unconditional and the conditional time sequences may be expressed as a superposition of sinusoidal waves with frequencies which are multiple integers of the discrete frequency interval $\Delta f = 1/(N\Delta t)$ according to

$$\eta_u(n\Delta t) = \sum_{m=0}^{N-1} (a_m - i b_m) \exp(i2\pi mn/N) \quad (9)$$

$$\eta_c(n\Delta t) = \sum_{m=0}^{N-1} (\alpha_m - i \beta_m) \exp(i2\pi mn/N) \quad (10)$$

The FFT coefficients of the conditional time sequence $\{\alpha_m$ and $\beta_m\}$ may be obtained from the FFT coefficients of the unconditional time sequence $\{a_m$ and $b_m\}$. These coefficients are related by

$$\begin{bmatrix} \alpha_m \\ \beta_m \end{bmatrix} = \begin{bmatrix} a_m \\ b_m \end{bmatrix} + C'_{12} X \quad (11)$$

where X is the solution of the same system of equations given by Eq. 4 that were used for the time domain algorithm; and C'_{12} is given by:

$$C'_{12} = S_{\alpha}(m\Delta f) \Delta f \begin{bmatrix} \cos(2\pi mn_1/N) & \dots & \cos(2\pi mn_2/N) \\ \sin(2\pi mn_1/N) & \dots & \sin(2\pi mn_2/N) \end{bmatrix} \quad (12)$$

APPLICATIONS

The solution of Eq. 4 requires two constraints: 1) a goodness-of-fit constraint to the specified variance spectrum and 2) an ill-conditioned constraint for matrix C_{11} .

Firstly, the goodness-of-fit to the specified variance spectrum must be constrained by both the length and characteristics of both the embedded deterministic wave sequence and the unconditional time sequence.

Secondly, the covariance matrix may become ill-conditioned for typical ocean spectra because of the relatively low energy content of the specified variance spectrum at both low and high frequencies for relatively long simulations at relatively small time intervals of Δt . This combination of low energy levels and relatively long simulations at relatively small time intervals may produce numerical instabilities when inverting the ill-conditioned covariance matrix C_{11} in Eq.4. A similar numerical instability was described and solved by Medina and Sánchez-Carratalá (1988) using robust AR models for ocean spectra. Therefore, it is reasonable to use their solution in order to obtain a robust method for the conditional simulation of random ocean waves.

The robust method introduces into the specified variance spectrum a very low level of white noise that is acceptable for any practical application. If m_0 is the specified variance, satisfactory results were obtained by introducing a white noise level of $0.0025m_0$ which reduced the original specified variance spectrum, $S_u(f)$, by a factor of 0.9975. The modified specified variance spectrum which is satisfactory for practical engineering purposes is given by $S_u'(f) = 0.9975 m_0 + \text{white noise}$. Finally, the modified specified variance spectrum $S_u'(f)$ is used in Eqs.3,5 and 12 instead of the original specified variance spectrum $S_u(f)$. The relative advantages of the robust method is illustrated below for typical ocean spectra.

In order to illustrate the stability of the robust method, consider removing a short piece of record from an unconditional time sequence and then inserting the same short piece back into the same unconditional time sequence at the same place. In this case, the vectors v_e and v_u in Eq.4 are equivalent and the resulting conditional time sequence η_c is equal to the unconditional time sequence η_u .

If the values of the embedded sequence shown in Fig. 2-a are modified only by a small amount, then the conditional and the unconditional simulations should differ by only the same small amount. However, that is not always the case if the matrix C_{11} becomes ill-conditioned. For example, if the values of the short piece of record shown in Fig. 2-a between 80-85 seconds are truncated to centimeters (a reduction of about 1%) and then embedded back into the unconditional time sequence at the same position in time, the resulting conditional time sequence shown in Fig. 2-b, is unsatisfactory. However, by using the robust method with a level of white noise of only $0.0025m_0$, the resulting conditional time sequence shown in Fig. 2-c differs only slightly from the unconditional time sequence. We note that any wave record from a laboratory simulation or from the ocean may be contaminated by levels of noise equal to or larger than this amount. Therefore, $S_u(f)$ and $S_u'(f)$ are equally acceptable for representing the variance spectrum of ocean waves. Figure 1 illustrates an application of the robust method for embedding a wave group.

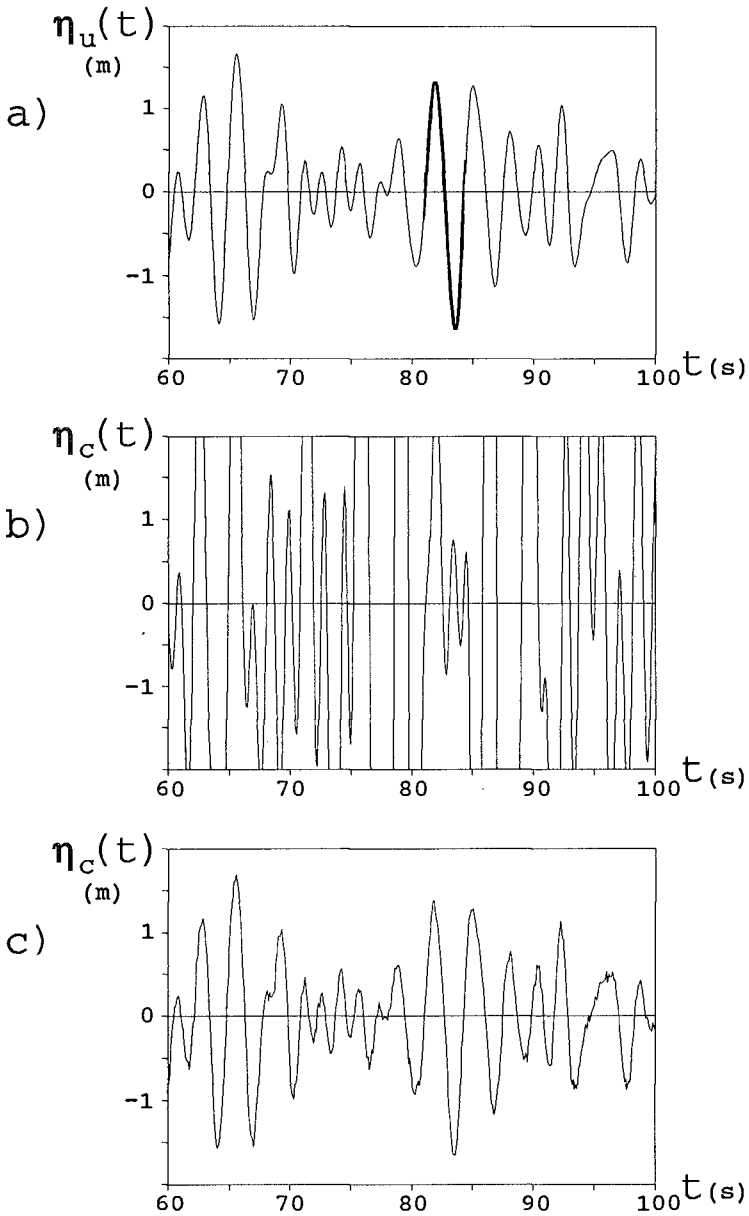

Figure 2. Comparisons of Conditional Simulation Methods: a) Unconditional Time Sequence; b) Example of Unstable Conditional Simulation; c) Example of Stable Robust Simulation.

The goodness-of-fit to the specified variance spectrum is influenced by several variables. First, the lengths of both the embedded sequence and the unconditional simulation must be considered. The wave group ($\nu+1=127$) shown in Fig. 1-b has been embedded into unconditional simulations having total lengths of $N = 512$, 1024 and 2048. These unconditional simulations are realizations from a specified Goda-JONSWAP variance spectrum having spectral parameters: $\gamma=1$, $m_0=1 \text{ m}^2$ and $f_p=0.27 \text{ Hz}$. The variance of the embedded wave group is $2m_0$. Table 1 compares the relative errors of the spectral moments computed from the conditional and from the unconditional time sequences as a function of the total length of the simulation with the length of the embedded sequence held constant ($\nu+1=127$).

TABLE 1. Effect of N on Errors in Spectral Moments Between η_c & η_u

Moments	N=512	N=1024	N=2048
m_0	17.6%	11.6%	4.8%
m_1	16.0%	10.1%	4.3%
m_2	13.9%	8.4%	3.5%

The goodness-of-fit to the specified variance spectrum improves as N increases relative to the length of ν . Figs. 3-a&-b compare the specified variance spectrum for the unconditional simulation with the variance spectrum for the conditional time sequence for $N=512$ and for $N=2048$, respectively.

The goodness-of-fit to the specified variance spectrum must also be constrained by the stochastic properties of the embedded sequence with respect to the specified variance spectrum. One of these stochastic properties is the contribution of the embedded sequence to the specified variance spectrum. Table 2 compares the relative errors of the spectral moments computed from the unconditional and from the conditional time sequences for the conditional simulation in Fig. 1 as a function of the contribution of the embedded sequence to the specified variance spectrum for an unconditional time sequence of length $N=2048$.

Figure 3. Specified Variance Spectrum and Conditional Time Sequence Spectrum for: a) $N=512$; b) $N=2048$.

TABLE 2. Effect of contribution of embedded sequence to specified variance spectrum on errors in spectral moments between η_s & η_e .

Moments	$m_0/2$	m_0	$2m_0$	$4m_0$
m_0	-5.6%	-2.1%	4.8%	18.5%
m_1	-5.1%	-1.9%	4.3%	16.8%
m_2	-4.8%	-2.0%	3.5%	14.5%

The goodness-of-fit improves as the contribution of the embedded sequence becomes more consistent with the specified variance spectrum.

SUMMARY AND CONCLUSIONS

A robust method is presented for the conditional simulation of random ocean waves having a specified variance spectrum and containing a deterministic sequence of waves at prescribed point in time. The addition of a low level of white noise (variance $0.0025m_0$) to the specified variance spectrum for the unconditional simulation avoids the instabilities that are due to inverting an ill-conditioned matrix. The effects of the length of the embedded wave sequence $\nu+1$ compared to the total length of the simulation N and of the contribution of the embedded wave sequence to the specified variance spectrum were illustrated for a Goda-JONSWAP spectrum.

CHAPTER 20

THE EFFECT OF WAVE DIRECTIONALITY ON NEARSHORE WAVES

Michael J. Briggs and Jane M. Smith¹
Member and Associate Member, ASCE

ABSTRACT

A three-dimensional, physical model study of the effects of nonlinearity and wave directionality (i.e. directional distribution of energy or the directional spread of energy about a peak wave direction) on wave transformation in the nearshore region is presented. The model consisted of a 1:30 fixed bed beach with plane-parallel contours. Fifty-four irregular wave conditions, typical of unimodal and bimodal directional spectra, were simulated. Twenty capacitance wave gages formed offshore and nearshore linear arrays to measure directional distributions and a cross-shore array to study transformation of the frequency spectra. Both linear and nonlinear processes were observed in the transformed directional spectra. The primary effect of wave directionality was reduction in the strength of the nonlinear phase coupling between modes. Directional spreading also reduced the formation of subharmonics (i.e. long period energy) in the transformed spectra.

1.0 INTRODUCTION

The transformation of waves in shallow water is dependent on irregularity of the wave field. The wave field is composed of a variety of periods, heights, and directions, but little guidance exists on combined effects of energy and directional distributions on wave shoaling, refraction, and breaking.

Accurate nearshore wave predictions are critical for estimating beach evolution and designing coastal structures. Site-specific wave conditions in the nearshore

¹Research Hydraulic Engineer, USAE Waterways Experiment Station, Coastal Engineering Research Center, 3909 Halls Ferry Rd., Vicksburg, MS 39180.

region are difficult and expensive to acquire, so designers of coastal structures often rely on measurements taken offshore. These measurements are then transformed to the desired shallow-water location using linear, numerical models which include the effects of shoaling, refraction, and bottom friction (Jensen, et. al. 1987). Unfortunately, these numerical models do not include the effects of nonlinear wave-wave interactions and wave directionality.

Although incident nearshore wave energy is usually concentrated in a narrow band of frequencies and directions, measured spectra seaward of the shoaling region are often multi-modal in frequency with broad directional spreading (Long 1989). Waves in the shoaling region are both weakly nonlinear and dispersive.

Elgar and Guza (1985) found that nonlinear coupling between frequencies was a significant mechanism in the transformation of ocean surface gravity waves. Freilich, et. al. (1990) showed that linear theory inaccurately predicts both the shapes and total variances of directional spectra in shallow water. They also found that the "vector resonance conditions" for frequency and wavenumber accurately predicted directions of harmonics due to energy transfers from nonlinear, near-resonant triad interactions in the shoaling wave field. Elgar, et. al. (1990) showed that nonlinear effects observed in nonbreaking waves at Torrey Pines, California, could be successfully reproduced in a laboratory experiment.

Smith and Vincent (1990) conducted a series of flume tests on the shoaling and breaking of bimodal unidirectional wave spectra. They found that during wave decay, wave energy is lost preferentially in the higher frequency mode. The flume results also showed that relative "closeness" and distribution of energy between modes were important. These results support nonlinear wave-wave interactions as a mechanism for wave evolution.

Sand, et. al. (1983) measured diffracted wave energy in the lee of a model entrance breakwater and found larger waves for the directional cases. However, in model tests of wave transformation in the lee of a submerged mound, Vincent and Briggs (1989) found the unidirectional waves higher than equivalent directional waves. Bowers (1987) found that directional spreading significantly reduced the long period energy associated with wave grouping in harbor modelling. Hasselman, et. al. (1963) found that directional spreading and uncoupled waves at harmonic frequencies decreased the measured nonlinearity.

Thus, inclusion of nonlinear transformation processes and wave directionality can have a significant effect on

coastal design by providing more realistic estimates of nearshore conditions. The results of these tests will be used to upgrade numerical wave transformation models for predicting nearshore wave properties from offshore measurements or hindcasts.

In this paper, the experimental setup is described in section 2. In section 3, the wave and test conditions for the 54 unimodal and bimodal, frequency and directional distributions are presented. Data collection and analysis procedures are described in section 4. Section 5 describes preliminary tests conducted to calibrate the model and control signals. Transformation of the directional spectra is discussed in section 6. Finally, conclusions are contained in section 7.

2.0 EXPERIMENTAL SETUP

A three-dimensional, physical model of a gently sloping beach with plane, parallel contours (Fig. 1) was constructed in CERC's 28 m by 40 m directional spectral wave basin. The model scale for the 1:30 slope fixed bed model was approximately 1:25. The toe of the slope was located 4.5 m in front of the directional spectral wave generator (DSWG), in a water depth of 50 cm. The rear of the basin was lined with wave absorber backed by a concrete wall. The basin sides were lined with absorber and open to adjacent basins. Thus, wave energy was able to propagate away from the test area into adjacent larger basins with minimal reflections from distant vertical walls and associated basin cross-seiching.

Fig. 1. Experimental Set-Up

Twenty capacitance wave gages were arranged in patterns and water depths similar to the prototype arrays used in 1978 and 1980 field experiments at Torrey Pines Beach, California (Pawka 1982). The gage pattern consisted of two 8-1-3-2-5 longshore linear arrays to measure changes in directional distributions and a cross-shore array to study frequency spectral evolution. The offshore (OGA) and near-shore (NGA) linear arrays were located in water depths of 40 cm and 16 cm, respectively. Lag spacings between gages for the OGA and NGA were 85 cm and 55 cm, respectively. The design of these arrays allowed measurements of waves with a directional resolution of approximately 8 deg (Pawka 1983). The cross-shore gage array (CSA) was nested within these two linear arrays, transverse to their axes and aligned with the physical model centerline. The spacing between the ten CGA gages was not uniform, varying between 0.5 to 2.0 m.

3.0 WAVE CONDITIONS

A total of 54 directional spectra were simulated as the product of the TMA shallow-water spectral form and a wrapped normal spreading function (Briggs, et. al. 1987). Both unimodal and bimodal frequency spectra with varying energy distributions were tested. The ratios of energy between modes in the bimodal spectra were 1/3:2/3, 1/2:1/2, and 2/3:1/3. Directional distributions were both narrow and broad and varied between modes. Target directional spectral parameters for individual modes were: $T_p = 1.25, 1.75, \text{ and } 2.50 \text{ sec}$ ($f_p = 0.40, 0.57, \text{ and } 0.80 \text{ Hz}$, respectively); $H_{m0} = 6.5, 7.6, 10.8, 12.2, 13.2, \text{ and } 15.2 \text{ cm}$; $\gamma = 3.3 \text{ or } 20.0$; $\theta = 0$ (shore-normal) and 20° ; and $\sigma_m = 0$ (unidirectional), 20 , and 40° . Wave direction is the angle towards which the waves travel, with positive angles measured clockwise from the normal to the DSWG.

These 54 wave conditions were converted into stroke control signals for each of the 61 paddles of the DSWG using a frequency domain, double summation, deterministic amplitude, random phase model. Typically, control signals were digitized at 20 Hz for 750 sec. After Fourier transformation in the frequency domain, this signal duration corresponded to an evenly-spaced frequency increment $\Delta f = 0.00133 \text{ Hz}$, or 1464 frequencies between the lower and upper cutoff frequencies $f_l = 0.05$ and $f_u = 2.00 \text{ Hz}$, respectively.

4.0 DATA COLLECTION & ANALYSIS

The wave gages were calibrated daily with a computer-controlled procedure incorporating a least square fit of measurements at 11-steps. After a waiting time of 20 sec to allow slower traveling high-frequency components to

reach the shallowest gages, surface elevation data were sampled at 10 Hz (i.e. $\Delta t = 0.10$ sec).

Data analyses consisted of single channel frequency spectral analysis for the CGA gages and directional spectral analysis for the OGA and NGA linear arrays. Data records of 500 sec were zero-meanded, tapered by a 10% cosine bell window, Fourier transformed, and band averaged, yielding a frequency resolution $B_e = 0.024$ Hz and $V = 24$ degrees of freedom. For the directional spectral analysis, the measured data again were zero-meanded, windowed, and Fourier transformed to the frequency domain. A Gaussian smoothing function then was used to smooth the cross-spectral matrix of auto- and cross-spectra with approximately $V = 56$. A high-resolution Maximum Likelihood Method (MLM) estimator was used to solve for the Fourier coefficients of the directional spreading function.

5.0 PRELIMINARY TESTS

Prior to wave transformation tests, three preliminary test phases were conducted: basin circulation, signal duration, and signal calibration. Based on current meter measurements and dye and visual observations, wave-induced circulation was not judged significant. In the second phase, measured spectral characteristics from test durations of 200 waves and 400 waves at the peak period were compared to determine proper sampling duration. Wave period, height, and spectral shape variations were within 95% confidence limits, so the shorter duration of 200 waves was selected for further tests. In the signal calibration phase, a frequency domain transfer function (Briggs and Jensen 1988) was used to iteratively correct the measured OGA spectra for variations in target peak period, wave height, and spectral shape.

The agreement between measured and target frequency spectra was very good to excellent. The peak of the measured spectra was often slightly smaller than the target spectra, but within 95% confidence limits. The maximum variation in peak frequency was ± 0.04 Hz (i.e. 2 frequency bands), occurring in only two cases. In most cases there was no significant difference between target values. Wave heights matched target values within 8% for all 54 cases. The agreement between measured and target directional distributions was good to excellent. The agreement for the unidirectional cases was excellent. The directionally spread cases, however, exhibited much more variability, with the measured results somewhat narrower than target distributions. Probable explanations are the resolving power of the arrays and MLM analysis technique and refractive-narrowing between the DSWG and OGA.

6.0 WAVE TRANSFORMATION RESULTS

Since it is impractical to present the results from all 54 cases (Briggs, et. al. 1990), three representative cases will be discussed in detail. The first case is a unimodal, unidirectional spectrum, representative of narrow-banded swell. The second case is a bimodal case, composed of two crossing, narrow-banded (in both frequency and direction) wave trains. The third example is another bimodal case, narrow-banded in frequency and broad-banded in direction. This last case is typical of a sea and swell spectrum with greater energy in the swell peak.

In the paragraphs below, the OGA and NGA directional spectra are presented to illustrate the spectral evolution between linear gage arrays. Next, the frequency spectra from the CGA provide greater detail on the energy transfers closer to shore. Since linear theory does not predict the formation of harmonics, bicoherence spectra from bispectral analysis are used to confirm the presence of nonlinear wave-wave interactions in the shoaling waves. Finally, peak wave period and significant wave height are discussed.

6.1 OGA Directional Spectra

MLM estimates of the directional spectra at the OGA for each of these three cases are shown in Fig. 2. The right vertical panel shows the frequency spectrum obtained by summing energy at each frequency over all directions. The left rear panel is the direction spectrum obtained in a similar manner, except that direction is held fixed and energy is summed over all frequencies. Frequency lines have variable spacing and are denser around the peaks and direction lines are spaced every 2° .

The first case (Fig. 2a) shows a single narrow peak, approaching the beach normally and centered at ($f_p = 0.40$ Hz, $\theta = 0^\circ$). Measured H_{m0} was 7.4 cm. The second example (Fig. 2b) shows a bimodal spectrum with crossing modes centered at ($f_{p,1} = 0.40$ Hz, $\theta_1 = 0^\circ$) and ($f_{p,2} = 0.57$ Hz, $\theta_2 = 20^\circ$), respectively. Measured H_{m0} was 8.4 cm, with a target distribution of 6.5 cm in each mode. A small secondary peak is observed centered at (0.57 Hz, 0°) which may be an artifact of the MLM estimation procedure or due to nonlinear effects on the spectra between the DSWG and the OGA. The third case (Fig. 2c) shows two shore-normal peaks centered at ($f_{p,1} = 0.40$ Hz, $\theta_1 = 0^\circ$) and ($f_{p,2} = 0.57$ Hz, $\theta_2 = 0^\circ$), with different amounts of full-width directional spreading ($\sigma_{m,1} = 20^\circ$, $\sigma_{m,2} = 40^\circ$). Measured H_{m0} was 13.1 cm. Wave refraction produced narrowing of the wider directional distributions by 6 to 10 deg between the DSWG and the OGA. Target wave heights were small enough to prevent wave breaking between the DSWG and the OGA.

Fig 2. OGA Directional Spectra

Fig 3. NGA Directional Spectra

6.2 NGA Directional Spectra

Fig. 3 shows the NGA directional spectra for the three example cases. Fig. 3a for the first case indicates two distinct concentrations of energy: the narrow, unidirectional peak centered at (~ 0.57 Hz, 0°) and a broad, high frequency peak at (~ 1.14 Hz, 0°). Measured H_{m0} was 7.77 cm, indicating that the wave had not yet begun to decay. The transformed directional spectrum for the second case (Fig. 3b) shows five concentrations of energy: the low frequency peak centered at (~ 0.40 Hz, 0°); the high frequency peak at (~ 0.57 Hz, 10°); the "artifact" peak at (~ 0.57 Hz, 0°); a narrow harmonic peak at (~ 0.80 Hz, 0°); and a wider peak at (~ 0.97 Hz, 5°). The spectral energy is more shore-normal and the low-frequency, first mode appears to have gained energy at the expense of the high-frequency, second mode. This wave was still in the shoaling region because its measured H_{m0} was 8.74 cm. Finally, three concentrations of energy are evident (Fig. 3c) for the third case: the first mode centered at (~ 0.40 Hz, 0°); the remnant of the second mode at (~ 0.57 Hz, 0°); and a harmonic at (~ 0.80 Hz, 0°). The low-frequency peak has maintained its energy at the expense of the high-frequency peak, similar to observations in Smith and Vincent (1990). The measured H_{m0} for this last case was 11.68 cm, indicating that it was in the decay region of the surf zone.

The wave fields have transformed significantly between the two gage arrays. In general, the peaks are narrower and closer to shore-normal than the OGA spectra. Linear wave refraction accounts for approximately $10\text{--}14^\circ$ of the observed narrowing of the directional distributions. Wave breaking was observed between the OGA and NGA for all cases. The extent and initial location varied as a function of the target wave energy, being closer to shore for the initially smaller wave heights.

6.3 CSA Frequency Spectra

The NGA directional spectra suggested the formation of harmonics as the waves shoaled between deep and shallow arrays. Greater detail of this spectral evolution can be found by studying the frequency spectra from the CGA gages. Fig. 4 shows semi-log plots of the measured frequency spectra for two gages in the CGA: gage 4 (center of the OGA and incident conditions) and gage 20 (closest to shore). Corresponding water depths were 40.0 and 9.5 cm, respectively.

The first case (Fig. 4a) shows energy transfers from the peak frequency at (0.57 Hz) to second (~ 0.114 Hz) and third (~ 1.71 Hz) harmonics as the wave shoals. The fourth subharmonic (~ 0.14 Hz) experiences a fivefold increase in energy. The second case (Fig. 4b) supports the growth of

harmonics seen in the NGA directional spectrum (Fig. 3b), and suggests even higher harmonic growth at (~ 1.14 Hz, ~ 1.37 Hz, and ~ 1.71 Hz). Subharmonics at the difference frequency between modes (~ 0.17 Hz) and the second mode (~ 0.28 Hz) are indicated. The third case (Fig. 4c) becomes unimodal as it transforms; the "spectral valley" originally between first and second modes disappears. At a depth of 29.3 cm (not shown), energy is initially transferred to the harmonic frequency corresponding to the summation of mode frequencies (~ 0.97 Hz). By the time the wave travels to 9.5 cm depth, energy is transferred out of this harmonic and the second mode ($f_{p,2} = 0.57$ Hz) to the second and third harmonics of the first mode peak at (~ 0.80 Hz and ~ 1.20 Hz). The two subharmonic peaks present in the second case have coalesced into a single peak at the difference frequency at (~ 0.17 Hz).

6.4 Bispectral Analysis

From the previous two sections, it is obvious that both linear and nonlinear processes are responsible for the observed changes in transformed wave spectra. Linear theory does not predict the growth of harmonics during wave shoaling. One method used to detect these nonlinear wave-wave interactions is bispectral analysis. The bispectrum (third-order spectrum) is a useful tool because only phase-coupled components appear. In the absence of this quadratic phase coupling (i.e. mode independence), the bispectrum is zero. Two wave components are harmonically related (i.e. dependent) if their interaction transfers energy at their sum and/or difference frequencies. A special case is harmonics at an integer multiple of a primary mode. The "vector resonance conditions" define this nonlinear, near-resonant triad interaction phenomenon. Both the frequencies f_i and vector wavenumbers k_i must sum to nearly zero and are given by

$$f_3 = f_1 \pm f_2 \quad (1a)$$

$$k_3 = k_1 \pm k_2 \quad (1b)$$

Freilich, et. al. (1990) showed that these conditions accurately predicted phase coupling between wave trains at Torrey Pines, California, approaching the beach at different directions, with energy transferred to a third mode corresponding to the sum frequency and vector sum direction.

Fig. 5 shows the measured bicoherence spectra for our three example cases at gage 20 (9.4 cm). Because of the short durations of collected data, the number of degrees of free-

a)

b)

c)

Fig 4. CGA Frequency Spectra

a)

b)

c)

Fig 5. Bicoherence Spectra

dom for the bispectral analysis is only 58 or 82. Elgar and Guza (1985) recommended $N = 150$ to 300 to improve statistical stability for field data. The minimum contour in the figures is at 0.4, with additional contours at 0.1. The first case (Fig. 5a) has bicoherence maxima (strong nonlinear interactions) between the first mode and its harmonics at $(f_2 = 0.57, f_1 = 0.57)$, $(0.57, 1.14)$, $(0.57, 1.71)$, $(0.57, 2.28)$, $(0.57, 2.85)$, and $(0.57, 3.42)$. Also, the second (1.14 Hz) and third (1.71 Hz) harmonics show similar strong nonlinear phase coupling among themselves and their harmonics. The third frequency f_3 of each triad is the sum of the two in parentheses. The bicoherence peak at $(0.57, 0.57)$ is the self-self-second harmonic triad observed in Figs. 3a and 4a at (1.14 Hz, 0°). It satisfies the "vector resonance condition" since $f_2 = f_1$, $f_3 = 2f_1 = 2(0.57) = 1.14$ Hz, and the wavenumber of the second harmonic is oriented in the same direction (0°) as the first mode.

Fig. 5b shows the bicoherence spectrum for the second example case. The phase coupling is more confused than the previous case due to the addition of the second mode and the non-aligned directions of the wave trains, although the horizontal trends at the two primary modes is similar to Fig. 5a. Bicoherence maxima are observed at $(0.17, 0.28)$, $(0.40, 0.57)$, $(0.40, 0.97)$, $(0.57, 0.57)$, $(0.57, 0.80)$, and $(0.57, 1.14)$. The first set corresponds to an apparent nonlinear interaction of the subharmonics of the difference frequency between primary modes and the second subharmonic of the second mode (Fig. 4b). This is indicative of the low-frequency phenomenon "surf beat" composed of infragravity modes. The second triad corresponds to the peak at $(0.97, 5^\circ)$ in Fig. 4b, at the sum frequency of the primary modes and the direction corresponding to the approximate vector sum of the wavenumbers. Peaks corresponding to the third frequency of the remaining triads can be seen in the high frequency portion of Fig. 4b. Lack of sufficient degrees of freedom in the bispectral analysis and non-alignment of wave directions in the primary modes might explain why the peak at $(0.80$ Hz, $0^\circ)$ does not show a strong nonlinear coupling in the bicoherence spectrum.

The bicoherence spectrum for the third case is shown in Fig. 5c. In this case, energy is narrow-banded in frequency but broad-banded in direction with aligned wave directions normal to the beach. Elgar and Guza (1985) found that directional spreading produced a weaker bicoherence spectrum. Bicoherence maxima are located at $(0.40, 0.40)$, $(0.40, 0.57)$, $(0.40, 0.80)$, and several higher harmonics. The first triad represents the self-self-second harmonic degenerate triad which produces the second harmonic at $(0.80$ Hz, $0^\circ)$ observed in Figs. 4c and 5c. The second triad is the harmonic at $(0.97$ Hz, $0^\circ)$ due to the sum of

the first and second modes. The nonlinear interaction of the primary (0.40 Hz, 0°) with the nonlinearly-generated second harmonic at (0.80 Hz, 0°) produces the third harmonic at (1.20 Hz, 0°). The "vector resonance conditions" are again satisfied since all components are collinear at 0° . Also, the growth of subharmonics seems to be suppressed relative to the first two cases without directional spreading.

6.5 Wave Period and Height Transformation

Peak wave periods in the CGA showed little change. Typically, they remained invariant or shifted slightly to a lower frequency. Since the resolution bandwidth is 0.024 Hz, some of this frequency variation is explained by statistical variability.

As the waves shoaled, wave height initially remained fairly flat or increased slightly. Inside the surf zone (decay region), wave height became locally depth controlled, no longer governed by outside (deep water) conditions, as the waves became saturated. Fig. 6 shows these trends for the CGA gages for 38 cases with target wave heights of 15.2 cm. The first two example cases have been omitted since the shoaling region extended throughout most of the model slope (i.e. closer to shore). A fourth degree polynomial, least square fit to the data is also shown for illustrative purposes. The fitted curve has been smoothed using locally weighted scatterplot smoothing (Cleveland 1979, 1981) which uses a weighted average of the nearby y values.

Fig 6. Wave Height vs. Depth

7.0 CONCLUSIONS

These tests have demonstrated that realistic ocean wave fields can be reproduced in a controlled laboratory experiment to study the mechanisms which effect transformation of nearshore waves. Both linear and nonlinear processes were observed in the shoaled directional spectra. The primary effect of wave directionality was reduction in the strength of the nonlinear phase coupling between modes, more so for directional spreading than wave direction. Directional spreading also reduced the formation of subharmonics (i.e. long period energy) in the transformed spectra.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the Office, Chief of Engineers, U.S. Army Corps of Engineers, for authorizing publication of this paper. It was prepared under the Coastal Flooding and Storm Protection Program of the Civil Works Research and Development Program, managed by Dr. C. Linwood Vincent. We would like to thank Ms. Debra Green, Mr. David Daily, and Mr. Larry Barnes for their assistance. Dr. Charles Long made many helpful suggestions which were greatly appreciated. Dr. Steve Elgar, Washington State University, developed the bispectral analysis software.

CHAPTER 21
SIMILARITY OF VELOCITY PROFILES IN NON-UNIFORM
LONGSHORE CURRENTS

Hossam El-din A.A. Refaat¹, Yoshito Tsuchiya², M. ASCE
and
Yoshiaki Kawata³, M. ASCE

Abstract

In studying beach changes a law for non-uniform longshore sediment transport is generally needed, which concerns the non-uniform longshore currents. Therefore, experimental study on the similarity of velocity profiles in non-uniform longshore currents was carried out on a plane beach. It was concluded that, the velocity profiles are in similitude alongshore by comparing the nominal velocity at the breaker point. The boundary layer approximation can therefore be applied to the nearshore current equations to derive a single integral equation of non-uniform longshore currents. The theoretical solution of the equation is shown to compare with experimental results. The comparison between the theoretical and experimental non-uniform longshore current velocities are in satisfaction.

1. Introduction

In recent years, the coastal region has become an area of intense human activity for industry, transportation, recreation, as well as coastal protection works. The longshore current has a significant influence on beach changes. The prediction of the longshore current is of great importance for studying beach changes. Many investigators have studied uniform longshore currents, but only a few such as Eagleson(1965), Horikawa and Sasaki(1968), and Gourlay(1976) have concentrated on the phenomenon of non-uniform longshore currents. The phenomenon of

¹Research Fellow, Disaster Prevention Research Institute (DPRI), Kyoto University, Gokasho, Uji, Kyoto 611, Japan, on leave from Faculty of Engineering, Cairo University, Giza, Egypt.

²Professor, DPRI, Kyoto University, Gokasho, Uji, Kyoto 611, Japan.

³Associate Professor, DPRI, Kyoto University, Gokasho, Uji, Kyoto 611, Japan.

non-uniform longshore currents can be seen clearly in the vicinity of reefs and headlands, as well as coastal structures. The magnitude of the longshore current velocity increases from the upcoast initial current location and increases rapidly in the downcoast direction until a constant profile shape or uniform longshore current is established. Therefore, we may say that the non-uniform longshore currents are responsible for rapid erosion or accretion around coastal structures, where the non-uniform longshore current exist.

The shoreline is simply defined as the boundary between sea and land. Immediately seaward of the shoreline there exists a narrow band of fluid known as the surf zone. The surf zone is characteristic of extremely complex fluid motion induced by the rapid dissipation of the incoming wave energy. Moreover, in the field of hydraulics, particularly in the open channel flow, there exists a thin layer near the bed. Consequently, it may be possible to describe the longshore current motion in the surf zone using the boundary layer concept. Based on this analogy, the concept of boundary layer theory is introduced to the nearshore region. In order to verify this analogy, an experimental study on the velocity profiles in non-uniform longshore currents was performed. If the similarity in velocity profile can be obtained, the boundary layer approximation may lead to a single integral equation of non-uniform longshore currents from the nearshore current equations.

Applying this similarity of velocity profile in non-uniform longshore currents, we have derived the single integral equation of non-uniform longshore currents which is presented by the nominal longshore current velocity at the breaker point (Tsuchiya and Refaat, 1990). The solution of the equation is very briefly shown in the case of plane beaches, and compared with experimental results in good agreement.

2. Experiments

2.1 Experimental setup

The experiments were performed in the fan-shaped wave basin (semicircular part: $r=17.5$ m and rectangular part: 35×10 m) of Ujigawa Hydraulics Laboratory, Disaster Prevention Research Institute, Kyoto University. A smooth concrete beach was constructed with slope 1:10. Two smooth wave guide walls were installed in the normal direction to the wave board. The upstream guide wall was closed to the beach and the downstream one extended to the toe of the fixed bed, see Figure 1. The purpose for having an upstream guide wall closed to the beach is to keep the wave

height uniform along the beach. While, the opening at downstream guide walls helps to minimize the water circulation between the guide walls and to carry it away behind at the still water area.

Figure 1. Schematic diagram of experimental arrangement of similarity of velocity profiles in non-uniform longshore currents.

2.2 Experimental procedure

The sloping part of the wave basin was marked by a 20 square cm grid. Measurements of current velocity were made at every grid line perpendicular to the shoreline. Two different types of colored tracers were used; 3 cm square shaped paper tracers and 2.5 cm ball tracers. The tracer trajectories within each grid was recorded by using a video camera system. Measurements of wave heights in the constant depth of the basin were made with capacitance type wave gauges. While on the sloping part, measurements of wave heights and mean water level were made over the entire grid area using capacitance type wave gauge and low frequency filter, respectively. The wave gauge and low frequency filter were installed on a vehicle mounted on rails controlled by personal computer. The angles of incoming wave incidence were measured at the constant depth part by measuring the angles of

inclination of the wave generator to the beach. The measurements of angles of incoming waves were done at the breaker line from the video tape record. Snell's law and linear wave theory were used to estimate and compute the measured angles of wave incidence at the breaker line.

2.3 Experimental results

In order to develop a more realistic model for non-uniform longshore currents, it is necessary to employ regular waves under various conditions. To carry out this investigation, eight experiments were performed under the conditions that the still water depth at the constant depth part is 30.6 cm, the wave period is 1.13 sec, the range of angle of incidence is 15° to 55° , and the wave height is varied from 3.8 cm to 8.5 cm, as shown in Table 1 where H is wave height, α is angle of wave incidence, h is still water depth, γ is breaker index, W is mean width of the surf zone, P is Longuet-Higgins parameter and the indices o and b refer to values on constant depth part of the wave basin and the breaker line, respectively.

Table 1. Experimental conditions of wave field

Ex. No.	H_o (cm)	α_o deg.	H_b (cm)	h_b (cm)	γ (H_b/h_b)	α_b deg.	W_b (cm)	P
R1	3.80	17.0	5.68	6.05	0.94	7.32	80	0.20
R2	5.10	17.0	6.73	7.87	0.86	8.36	100	0.09
R3	8.50	17.0	11.61	11.72	0.99	10.22	150	0.10
R4	4.50	35.0	7.98	8.80	0.91	17.56	90	0.05
R5	5.20	45.0	7.21	8.03	0.90	20.81	100	0.10
R6	7.75	45.0	9.63	11.80	0.82	25.51	130	0.10
R7	5.50	55.0	7.74	9.48	0.82	26.56	100	0.10
R8	6.65	55.0	8.60	10.03	0.86	27.38	120	0.08

The experimental results are classified mainly into two categories, they are:

(1) Similarity of velocity profiles

Figures 2 and 3 show the examples of the measured longshore velocities, for two incident wave angles 17° and 45° , compared with the theoretical curves of Longuet-Higgins (1972). The rate of agreement between measured and computed longshore current profiles is influenced by the choice of Longuet-Higgins parameter

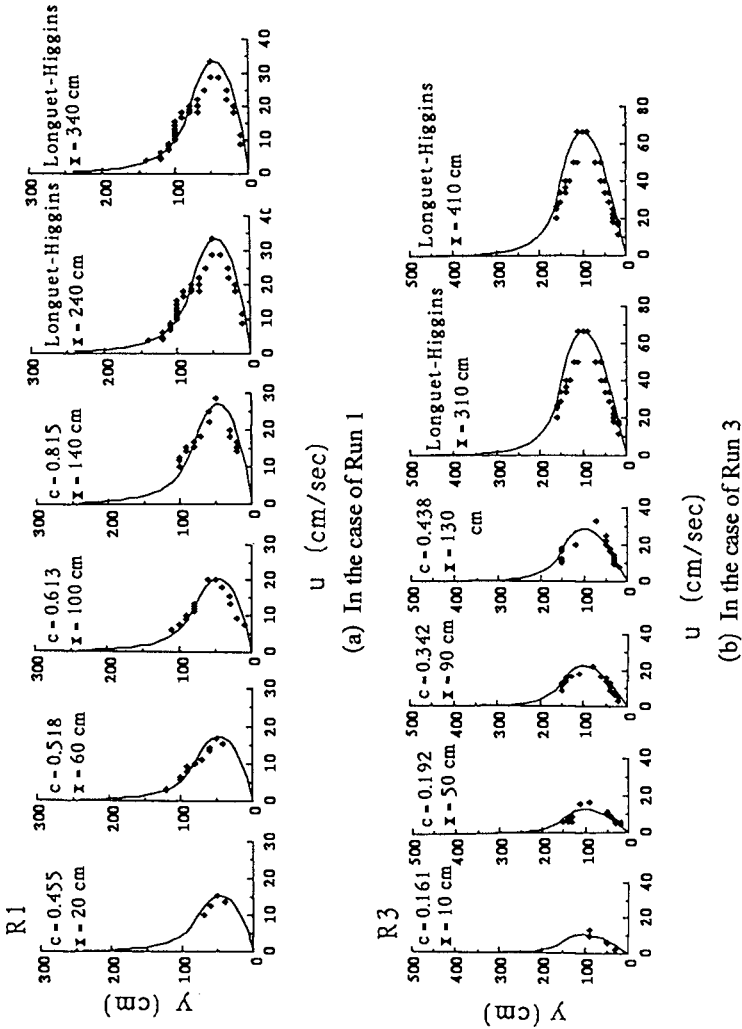

Figure 2. Examples of measured longshore velocity profiles compared with theoretical curves of Longuet-Higgins model in the case of incident wave angle $\alpha_0 = 17^\circ$.

Figure 3. Examples of measured longshore velocity profiles compared with theoretical curves of Longuet-Higgins model in the case of incident wave angle $\alpha_0 = 45^\circ$.

P . The curves were fitted to the data using the method of least square. It is noted that for all experiments Longuet-Higgins parameter P is less than 0.2. From these figures it is obvious that:

a) The similarity of velocity profiles is quite satisfactory. The shape of the velocity distribution starts to grow from the initial boundary until reaching a constant shape, which represents uniform velocity profile. Therefore, the integration coefficients, which appeared in the equation of non-uniform longshore currents to be described in Eq. (1), are not functions of longshore direction nor time.

b) For a small angle of incidence, the agreement between the measured velocities and Longuet-Higgins curve is good. While in the case of large angle of incidence, the agreement is less.

The development of non-uniform longshore current velocity at the breaker line is shown in Figure 4, where the velocity is normalized by the one at breaker point and the longshore distance is normalized by the factor B to be described in Eq. (4). The longshore current velocity increases rapidly from zero, at the initial condition, to a constant value which corresponds to the uniform longshore current.

Figure 4. Comparison of measured and computed non-uniform longshore current velocity.

(2) Uniformity of wave set-up

Figure 5(a) and 5(b) illustrate the distribution of measured wave height for Run 2 and the mean water level for Run 3 over the entire sloping bed area. In these figures the horizontal axis represents the cross-shore direction, while the longshore direction is represented by the third axis. The uniformity of wave height and wave

(a) Distribution of measured wave height in the case of Run 2.

(b) Distribution of measured mean water level in the case of Run 3.

Figure 5. Distribution of measured wave height and mean water level over the entire sloping bed area.

set-up alongshore are clearly seen in these figures. Figure 6 shows the cross-shore measurements of the wave field for Run 2. The lower part of the figure shows the measured wave height computed with the calculated one by linear wave theory. In the experiments, the breaking wave is a plunging type, this means that the wave height continues to increase up to the breaker point. The effect of nonlinearity is so small that the measured values fit the calculated ones well. The upper part of the figure shows the changes in the mean water level presented by waves. Bowen, Inman and Simmons's (1968) formula for wave set-down was used to fit the measured data. It is clear from this figure that wave set-up increases linearly toward the shoreline. Therefore we can conclude from Figures 5 and 6, that wave set-up is uniform alongshore and increases linearly toward the shoreline.

Figure 6. Cross-shore measurements of wave height and mean water level in the case of Run 2.

Figure 7 illustrates the variation of the measured wave set-up along the shoreline. The measured values used in this figure are 20 cm from the initial shoreline because the limitation of measurements at this region. But, fortunately, the wave set-up increases linearly, thus we can use this value instead of the maximum wave set-up value. In this figure Run 2 shows the maximum variation of wave set-up which is less than 7%, other cases are much smaller. Thus the wave set-up

Figure 7. Longshore variation of measured wave set-up.

will be uniform alongshore. Furthermore, it is well known that wave set-up is a function of breaker index, H_b/h_b . Figure 8 demonstrates the uniformity of breaker index, H_b/h_b , along the shoreline. In this figure, the value of the breaker index, H_b/h_b , is laid between 0.8 and 1.0.

Figure 8. Longshore variation of measured breaker index, H_b/h_b .

3. The Theoretical Solution of Non-Uniform Longshore Current

Based on the similarity of velocity profiles in the non-uniform longshore currents, as previously discussed, a single equation of non-uniform longshore currents can be derived. Tsuchiya and Refaat (1990) have recently applied the so-called boundary layer approximation to the nearshore current equations to obtain the equation of non-uniform longshore currents. This equation can be written as:

$$\alpha_2 \frac{\partial}{\partial x} (U_0^2 h_b^2) + \alpha_3 \frac{\gamma C_f c_b}{\pi} U_0 h_b = f(x) \tag{1}$$

where

$$f(x) = \frac{\gamma^2}{16} g h_b^2 \left\{ \sin 2\alpha_b - 2 \cos^2 \alpha_b \frac{\partial y_b}{\partial x} - (5\beta_1 - 6\beta_2 + 6\beta_3 \sin^2 \alpha_b) \frac{\partial h_b}{\partial x} - 2\beta_3 h_b \sin 2\alpha_b \frac{\partial \alpha_b}{\partial x} \right\} \tag{2}$$

where U_0 is the non-uniform longshore current velocity at the breaker line, $\gamma = H_b/h_b$ is the breaker index where H_b and h_b are the breaker height and depth respectively, y_b is the position of the breaker line from the datum line, α_b is the breaking wave

angle, C_f is the bed shear stress coefficient, $c_b = \sqrt{gh_b}$ is the breaking wave celerity, g is the acceleration of gravity, and α_i, β_i ($i = 1, 2, 3$) are the integration coefficients. These integration coefficients depend only on the velocity profiles of longshore currents. Regarding the similarity of the velocity profiles of longshore currents, these integration coefficients are not functions of the longshore direction nor time.

This equation includes many parameters, but in the case of plane beach it is only one unknown U_0 , because the right hand side becomes constant. With the boundary condition that at $x = 0, U_0 = \bar{U}_0$ the solution of this equation is derived as:

$$\frac{(1 - \bar{U}_0/U_b) \exp(1 - U_0/U_b)}{(1 - U_0/U_b) \exp(1 - \bar{U}_0/U_b)} = \exp(Bx) \quad (3)$$

where

$$U_b = \frac{5\pi\gamma m}{16C_f} g h_b \left(\frac{\sin \alpha_b}{c_b} \right) \cos \alpha_b$$

$$B = \left(\frac{8C_f}{5\pi m} \right)^2 \frac{2}{\alpha_b h_b \sin 2\alpha_b} \quad (4)$$

In Figure 4, a solution to Eq. (3) for boundary condition at $x=0, U_0 = 0$, is shown and compared with the experimental values. Each point in the figure is identified by the plotting symbol corresponding to each run in the experimental measurements. It is shown that most of the points lie around the theoretical curve expressed by Eq. (3). The theoretical curve given by Eagleson (1965) is also shown in the figure for comparison. Based on the similarity of velocity profiles of longshore currents, the theoretical solution given by Eq. (3) describes not only the non-uniform longshore velocity at the breaker line but also at any given relative local depth ratio.

4. Conclusions

In this paper, an experimental study on the velocity profiles in non-uniform longshore currents was performed in order to investigate their similarity. From the comparison of the experimental measurements of longshore currents with the theoretical curves of Longuet-Higgins, it is observed that the degree of agreement between measured and computed longshore current profiles is influenced by the choice of Longuet-Higgins parameter P , and while the shape of the velocity

distribution starts to grow in a similar shape from the initial boundary until reaching a constant shape which represents uniform velocity profile, the similarity of velocity profiles is very satisfactory. The theoretical solution of non-uniform longshore currents on a plane beach was compared with the experimental result. The solution describes not only the non-uniform longshore velocity at the breaker line but also at any given relative local depth ratio.

CHAPTER 22

Time and Frequency Domain Analyses of Shallow Water Waves on a Slope

D H Swart¹ and J B Crowley²

¹ CSIR, P O Box 395, Pretoria 0001, South Africa

² CSIR, P O Box 320, Stellenbosch 7600, South Africa

Abstract

Classical time and frequency domain analyses give results with limited physical meaning when applied to shallow water cases. Lower heights and periods than suggested by the actual data are obtained via these analyses. It appears that slope effects make waves less non-linear for steeper than for flatter slopes. One can obtain useful trends by making use of higher-order analyses, utilising higher-order, asymmetrical waves of the covocoidal type as an example.

Introduction

Most coastal engineering applications are done in water depths shallower than 20 m depth, either inside or outside the breaker zone and nearly invariably on a sloping sea bed.

Scientific and technological advances over the past decade have led to a substantially increased understanding of the physical processes taking place in the nearshore environment. This in turn has led to more sophisticated mathematical descriptions of these physical processes, which form the basis of the extensive numerical treatment of most of these processes.

In sediment transport research, rigorous advances have been made towards understanding the relationship between the driving forces and the resulting sediment movement. Nevertheless, it is still necessary to make, sometimes sweeping, simplifications in order to get workable numerical models of, e.g. cross-shore sediment transport. Baillard (1981) and Nairn (1988) have, amongst others, shown that, in order to correctly predict near-bottom sediment flows, it is essential to take cognisance of the higher, uneven moments of the orbital flow due to non-linear surface waves. The question that

now arises is to what extent the asymmetry of the surface waves in the nearshore region, which are clearly discernable on wave records and with the naked eye, would influence the cross-shore transport models. Similarly, we believe the time has come to critically analyse the saturation spectrum concept for nearshore situations, again with reference to asymmetrical, non-linear, nearshore surface waves.

With this understanding as a platform, we believe that the substantial body of research on nearshore waves and their related phenomena can serve as a bridge to take currently used predictive techniques for sediment transport and other wave-induced processes, such as wave forces, to new levels of sophistication with associated improved predictive skills. At all times, however, one has to be careful not to become more sophisticated just for the sake of it. The additional benefits have to be quantified.

3. Background

Nelson (1981) conducted a series of controlled laboratory experiments to establish the relationship, if any, between wave properties on a sloping bottom and the bed slope itself. His experiments were run on bed slopes ranging from horizontal to 1 in 10. He came to the following conclusions:

- (1) integral wave properties, such as wave length and wave energy, are for all practical intents and purposes *independent* of the bed slope; and
- (2) time-dependent wave properties, such as wave shape, orbital velocities and orbital accelerations, are very definitely dependent on bed slope.

Most traditionally used wave theories suffer from one of two problems, namely, it either predicts a linear wave shape or it is higher order, that is, non-linear, but symmetrical around the wave crest. Typically, as the wave non-linearity increases, the numerical complexity also increases. This led Swart (1978) to develop a wave theory with a fairly simple expansion in terms of a higher power of the cosine function, the so-called vocoidal wave theory, which was subsequently shown (Swart and Loubser, 1979) to be as accurate in predicting nearshore wave parameters as Dean's stream function theory (Dean, 1974).

The wave shape in the variable order cosine theory, or vocoidal theory, is defined by:

$$\eta/H = \text{voc}(P, X) - \eta_{st} \quad (1)$$

$$\begin{aligned} \text{and } \text{voc}(P, X) &= \text{the vocoidal function} \\ &= \{\cos^2(\pi x)\}^P \quad (2) \end{aligned}$$

where η/H = surface elevation, P is the order of the function, with $P \geq 1$, X is the location within the framework from wave crest to wave crest, non-dimensionalised by the wave length, and η_{*t} is the trough depth, relative to the still-water level and non-dimensionalised by the wave height.

On the basis of Nelson's results, referred to above, the thought occurred that it may be possible to, in a similar fashion as was done for vocoidal theory, obtain a function which is on the one hand simple and on the other hand closely resembles the actual behaviour of waves on a sloping sea bed.

As was the case for vocoidal theory, it was again intended to start from first principles, that is, the conformity equation and the equations of motion, with suitable kinetic and dynamic boundary conditions, and to then proceed to derive the wave properties, given the qualitative vocoidal (or in this case covocoidal) wave shape.

After some investigation, the following asymmetrical wave shape was defined (Swart and Crowley, 1989):

$$\eta/H = h_\alpha [\text{voc}(P, X) - \eta_{*t}] + 0.5r_\alpha [\text{cov}(P, X)(1 + \cos\pi X) - (1 - \eta_{*t})] \quad (3)$$

$$\text{and } \text{cov}(P, X) = 1 - \text{voc}(P, X) \quad (4)$$

where the first term in Equation (3) gives a symmetrical shape, basically the vocoidal wave shape, and the second term adds the asymmetry around the wave crest. Furthermore, the order P was assumed to be the same as for the similar case on a horizontal sea bottom, and h_α and r_α are functions of P and the bed slope $\tan \alpha$. These functions had to be determined in the derivation. Figure 1 contains spatial and temporal views of the wave shape.

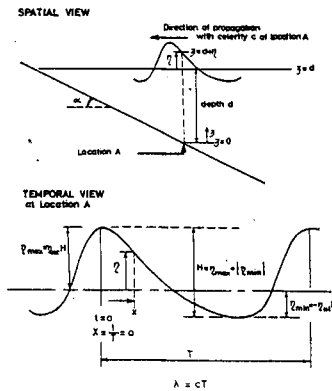

Figure 1. Axis-notation for development of generalised vocoidal theory on a sloping bottom.

A comparison to Nelson's laboratory data showed a very reasonable agreement (Swart and Crowley, 1989) and paved the way for further analyses with the covocoidal theory. It is not intended to submit that the vocoidal and covocoidal theories are the ultimate answers for nearshore, shallow water applications on a horizontal and sloping sea bed respectively, they are definitely not. However, these theories are very useful to investigate trends in data, specifically because of their good adherence to laboratory and field data. Using these theories allows the establishment of numerical techniques which would have been more difficult to construct with more complicated wave theories.

"Uncontrolled" field experiments of surface elevation variations in the nearshore environment in an exposed bay on the southwestern coastline of South Africa, are used in this paper to within the framework of covocoidal theory perform time and frequency domain analyses. These are then used to make some general deductions about the necessity for future research regarding waves on a slope.

4. Experimental set-up

The CSIR has over the past four years repeatedly performed extensive field measurement programmes in the shallow water in a flat bay, ca 20 km long and exposed to the dominant southwesterly swells off the southwestern coast of South Africa.

Figure 2. Location of field measurement site.

Four major field exercises have been performed to date, namely in March and September 1986, November 1987 and March 1990.

The September 1986 data had the best initial conditions to allow a comparison of depth effects and slope effects within the same data set. The three measurement sites that were used are characterised in the table below.

Site	Water depth	Slope	Type of instrument used
1	10-11 m	1 in 220	Pressure transducer
2	1- 2 m	Horizontal	Wave staff
3	1- 2 m	1 in 15	Wave staff

Some typical results obtained at each of these three sites are given below to familiarise the reader with the obvious differences between these sites.

Site 1

Figure 3 contains a few typical time records of wave profile and also a typical energy density spectrum. The wave trace shows a high degree of symmetry around the wave crest and also elements of wave grouping. This is supported by the energy density spectrum which contains two clear peaks, the dominant one at a frequency of 0.087 s^{-1} (11.45) and a secondary peak, more than one order of magnitude lower, but clearly discernable, at 0.014 s^{-1} (70s).

Site 2

Figures 4 and 5 show two sets of results which typify the range of variables found at this very nearshore location, where the bottom is for all practical intents and purposes horizontal in the area around it.

The time record of the wave profile in Figure 4 shows mostly a fair symmetry around the wave crest, as well as some clear indications of surf beat. The frequency domain analysis below shows three distinct peaks, now in descending importance with increasing frequency. The peak frequencies are at 0.011 s^{-1} , 0.045 s^{-1} and 0.07 s^{-1} . It is interesting to note that the tail of the frequency spectrum remains practically constant for frequencies greater than 0.08 s^{-1} at a value around 0.04 s^{-1} .

Figure 5, on the other hand, shows some clear signs of asymmetry around the wave crest, and furthermore a somewhat greater decomposition than in Figure 4, although the same three peaks can still be seen in the energy-density spectrum.

Figure 3. Typical time and frequency domain results for Site 1.

Figure 4. Typical time and frequency domain results for Site 2.

Figure 5. Typical time and frequency domain results for Site 2.

The wave groupiness exhibited in the time domain data is quite substantial.

Most of the data for this site are closer in resemblance to Figure 4 than to Figure 5.

Site 3

The data in Figure 6, for the same general water depth as for Figures 4 and 5, are in quite striking contrast to those for the earlier two figures. Whilst the time domain data also show signs of wave groupiness, the asymmetry of the waves around the wave crest is really very marked. This is general for all data collected at this site.

The energy density spectrum again has three distinct peaks, in order of importance at 0.005 s^{-1} , 0.023 s^{-1} and 0.048 s^{-1} . However, the spectrum now has a clearly saturated tail. Again, this is fairly common for all data collected at this site.

5. Time Domain Analyses

In this section, comparisons will be made of wave height calculated via time domain and frequency domain analysis techniques. The following two time-domain parameters are defined:

H_s ; which equals four times the square root of the variance

$H_{1/3}$; which is the average of the highest one-third waves, using the down-crossing method.

These two time-domain estimates of significant wave height are compared with the spectral estimate H_{m_0} of the significant wave height. All of these apply to the short wave component of the wave trace, defined by $f > 0.033$.

The results are shown in Figures 7 and 8. The results show that there is close correspondence between $H_{1/3}$, H_s and H_{m_0} at Site 1, at 10 m depth. However, at the two shallower sites, both $H_{1/3}$ and H_s are substantially higher than the spectral estimate H_{m_0} of the significant height.

The results are summarised in the table below.

Site	Median value of	
	H_{m_0}/H_s	$H_{m_0}/H_{1/3}$
1	0.99	0.96
2	0.80	0.90
3	0.80	0.65

Figure 6. Typical time and frequency domain results for Site 3.

The reason for H_{m0} being less than H_s and $H_{1/3}$ for shallower water depths, is discussed in Section 6 below. It is noteworthy, however, that H_s is generally slightly higher than $H_{1/3}$.

Logically, because $H_{1/3}$ reflects the average of the highest one-third of the waves in the trace, it should be the reference value. Because of the non-linear nature of the waves in shallow water, the H_s value normally should deviate lower than $H_{1/3}$ progressively more as the non-linearity increases. The data seem to indicate the reverse. The reason for this is not clear.

5. Frequency Domain Analyses

Traditionally, spectral analysis of water waves has implied that a linear analysis was performed, whereby sinusoidally-shaped component waves are extracted. Over the years, various variations have been implemented, basically aimed at using bigger computing power to speed up the analysis. Various verification studies have been performed and it is generally accepted that this is a very sound procedure, yielding reliable, robust results, which can be replicated by any other researcher using standard techniques. However, in shallow water, this is not the case. Swart (1982) and Thompson and Vincent (1985), amongst others, have shown that, due to the fact that shallow water waves are non-linear, spectral estimates of wave height and period are too low in this area. This happens because a monochromatic non-linear wave train would, when analysed with a standard spectral technique, yield a spectrum of "apparent" wave heights rather than a single height at the appropriate frequency.

Thornton (1977) showed, by using both the kinematic and dynamic wave breaking criteria, that waves at higher frequencies in the wave energy spectrum are saturated with energy and that energy falls off in the region with a slope of f^{-2} , where f is the wave frequency. Banner and Phillips (1974) showed that, in

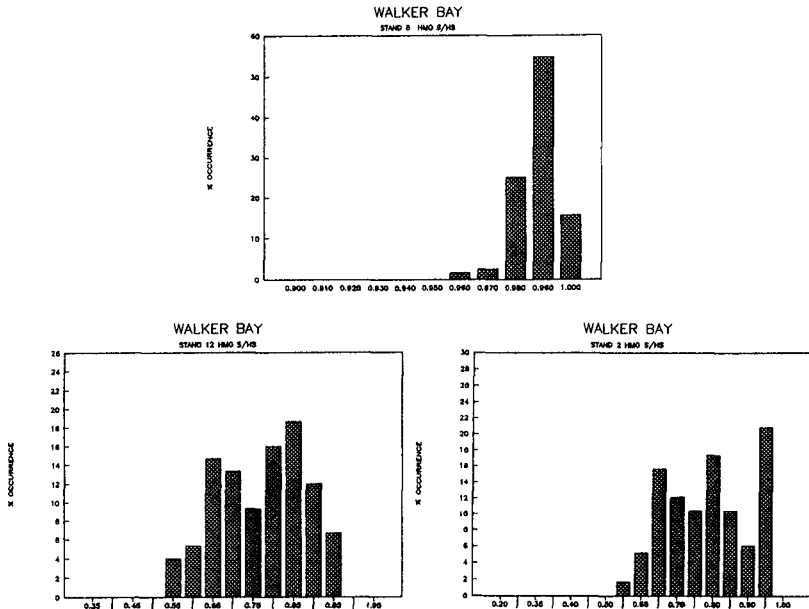

Figure 7. Histograms of H_{mo}/H_s values at Sites 1 to 3.

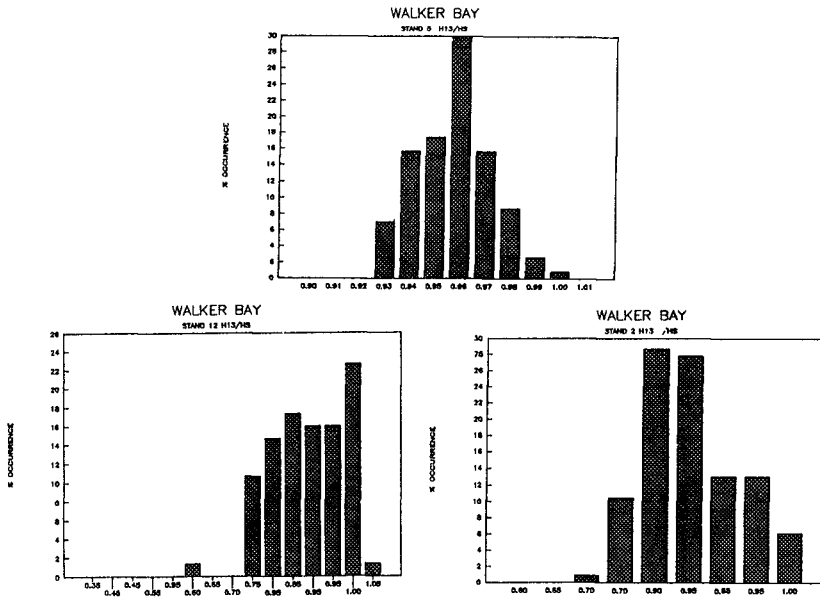

Figure 8. Histograms of $H_{1/3}/H_s$ values at Sites 1 to 3.

deepwater, the critical parameter associated with deepwater wave breaking is the wave celerity which leads to a saturation slope in this area of f^{-5} . Thornton (1977) presented data for 20 m and 1.5 m depth, respectively, and showed that the wave spectrum indeed exhibited saturation at f^{-5} and f^{-3} , respectively. However, vertical orbital velocity spectra at both depths had a saturation slope of f^{-3} . Thornton (1976) contains similar spectra for primarily breaking waves, which have a saturation slope of $f^{-7/3}$, which seems to tie in with theoretical work by Phillips (1966) for cases where surface tension is important. On the other hand, Huntley, Guza and Bowen (1977) present wave run up data which has saturation slopes of f^{-3} .

In all this work, the magnitude of the slope is basically explained in terms of the ease with which energy can be transferred from lower to higher frequencies, thus, by a physical constraint. Thornton (1977) remarks that all the spectra he observed for depths of 20 m and shallower contained some degree of saturation. He remarks that "it is not understood whether the apparent saturation region was the residual of an earlier saturated wave condition, or the transfer of energy by non-linear interaction of wave components".

In the present paper, it is shown that another explanation for the saturated tail in the energy spectrum can be sought in the decomposition of non-linear waves into sinusoidal components, thus, due to a numerical imposition, especially at the shallow water depths.

Swart (1982) came up with the concept of extracting, via a Fourier analysis, non-linear wave shapes instead of sinusoidal wave shapes. Using an iteration procedure, Swart extracted appropriately scaled vocoidal waves (Swart, 1977) from shallow water wave trains. Via numerical simulation, he showed the accuracy with which the original input non-linear wave height spectrum is returned via this method, as well as the corresponding drop in wave height due to spectral decomposition of the non-linear wave shapes when a traditional linear method was used. One could employ any wave shape in this method of analysis, provided that the shape can be described numerically in terms of the initial conditions, typically water depth, wave period (frequency) and wave height. It is due to the last parameter that an iteration is required, because the purpose of the analysis is to determine wave height.

In this paper, the non-linear spectral analysis was performed on sample data sets to establish whether the method yields meaningful results and whether this is an avenue of research worth pursuing for random waves on a slope. The analysis was done for both vocoidal and covocoidal waves.

Examples are given here for the two shallow water stands in Figures 9 and 10. It is immediately apparent that the normal Fourier analysis in the top graph of each figure yields a spectrum which is very flat with an appreciable portion of the energy resident at frequencies greater than 0.2. On the other hand, the lower two graphs,

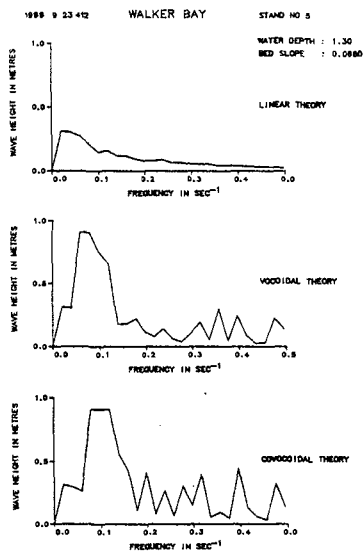

Figure 9. Linear and non-linear Fourier analysis in shallow water for Site 3.

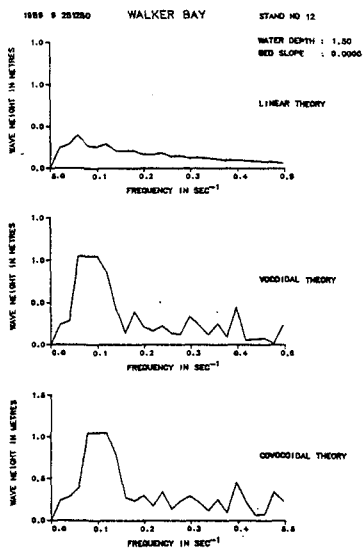

Figure 10. Linear and non-linear Fourier analysis in shallow water for Site 2.

which represent the higher order analysis, show spectra which are much more representative of deepwater spectra. At first sight, it would appear as if the energy associated with the lower two graphs is much higher than that for the upper graph. However, it should be borne in mind (Swart, 1978) that the total energy coefficient for these shallow water waves in a higher order theory is much lower than 0.125.

Furthermore, preliminary calculations show that the tail of a JONSWAP spectrum, of which the wave heights define shallow water wave shapes, falls off at a slope of between $f^{-2.5}$ and $f^{-3.5}$ when the resulting wave trace is subjected to a normal Fourier analysis. This supports the concept of the numerical method leading to the down position of the actual wave.

6. Conclusions

The following is a summary of the main conclusions reached during this study:

- Classical time and frequency domain analyses give results with limited physical meaning when applied to shallow water cases.
- Heights and periods are lower in these analyses than are suggested by actual data.
- Slope effects would appear to make waves less non-linear for the steepest slopes.
- Useful trends can be established by making use of simulations with higher-order, asymmetrical wave shape.
- Higher-order Fourier analysis "pulls" energy from higher frequencies towards lower frequencies, whereby the "saturation" shape disappears and the shallow water spectra then resemble deeper water spectra.
- Heights obtained from higher-order spectral analysis are more in tune with the wave trace than is the case for a linear analysis.

On the basis of these findings, we would suggest a critical review of the physical meaning of shallow water wave spectra and a more indepth analysis of the ramifications of using a non-linear spectral analysis technique.

CHAPTER 23

EXTENSION OF MILD SLOPE EQUATION FOR WAVES PROPAGATING OVER A PERMEABLE SUBMERGED BREAKWATER

Takashi Izumiya

ABSTRACT

A wave equation is presented for predicting reflected and transmitted waves for a permeable submerged breakwater. This equation includes the mild slope equation derived by Berkhoff(1972), which is a vertically integrated refraction-diffraction equation. Therefore, the equation derived can also predict the combined effects of refraction and diffraction. Numerical calculations with a dissipation term due to breaking are performed to obtain reflection and transmission coefficients as well as wave height distributions. Through the comparisons with the experimental results, the validity of the model is confirmed.

1. INTRODUCTION

Detached breakwaters and groins have been constructed on the coasts of Japan to prevent beach erosion. Recently, defense works against beach erosion, which is the combination of submerged breakwaters with wide crown width and large groins, has been planned on the Niigata west coast. It is very important for coastal engineers to estimate an effectiveness of the breakwaters. However, many of us are faced with a problem of how to estimate a distribution of wave height in the region existing such coastal structures.

Several analytical approaches have been done to predict the wave height of reflected and transmitted waves for permeable breakwaters (e.g., Ijima et. al,1971, Sollit and Cross,1972). Analytical solution obtained by them are valid only for rectangular permeable structures on a uniform bottom. These techniques cannot be applied to structures with arbitrary cross-section and require long algebraic operations to estimate the values of reflection and transmission coefficients. More recently, Sulisz(1985) has developed a numerical technique to predict wave reflection and transmission through a rubble mount breakwater of arbitrary cross section. The technique is, however, so complicated that it cannot be applied in the three dimensional problem. Therefore, a simple calculation method for wave transformation is required for coastal engineers.

Berkhoff(1972) has derived the mild slope equation which is a vertically integrated refraction-diffraction equation and is easy to be applied for a three dimensional problem. It should be noted that the mild slope equation can be applicable to waves propagating over bottom slopes as steep as $1/3$ and even to waves propagating across a

Assistant Professor, Department of Civil Engineering, Niigata University, Ikarashi 2-nocho, Niigata 950-21, Japan

step(Booij,1983). In this paper, a theoretical approach utilizes the linearized equation of motion in a permeable structure. A wave equation is derived by vertically integrating the equation of motion. The derivation of the wave equation is based on the assumptions that the slope of the permeable structure is adequately gentle, and that evanescent wave components of larger decay rate are negligible. The wave equation derived under the above assumptions is a two-dimensional elliptic type equation and includes the mild slope equation by Berkhoff.

2. DERIVATION OF EXTENDED MILD SLOPE EQUATION

2.1 Wave transformation within a porous medium

The analytical approach in this study begins with unsteady equations of motion for flow in a porous medium. After Madsen and White (1975), the linearized equations of mass and momentum in a porous medium are expressed as:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \tag{1}$$

$$\frac{\tau}{\lambda} \frac{\partial u}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial x} - f \frac{\sigma}{\lambda} u \tag{2}$$

$$\frac{\tau}{\lambda} \frac{\partial v}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial y} - f \frac{\sigma}{\lambda} v \tag{3}$$

$$\frac{\tau}{\lambda} \frac{\partial w}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial z} - f \frac{\sigma}{\lambda} w - g \tag{4}$$

where (u,v,w) is the average discharge velocity components in the direction of x-, y- and z-axis, respectively. These are conceptual quantities which are averaged over finite and total volumes. The quantity p is the pressure averaged over finite pore volumes, λ is the porosity of the porous medium, f is the linearized friction factor, and τ is a inertia coefficient and expressed in terms of a virtual mass coefficient C_M as:

$$\tau = 1 + \kappa(1 - \lambda) = \lambda + C_M(1 - \lambda) \tag{5}$$

Hence, we assume that the flow in a porous medium is irrotational. Then the velocity potential φ for virtual discharge velocity is defined as:

$$(u, v, w) = \nabla \phi \tag{6}$$

Substituting Eq.(6) into the momentum equations (2)-(4) and integrating yields:

$$\frac{\tau}{\lambda} \phi_t + \frac{p}{\rho} + gz + f \frac{\sigma}{\lambda} \phi = C(t) \tag{7}$$

where C(t) is a integration constant. Equation (7) is the linearized unsteady Bernoulli equation. In order to remove the integration constant C(t), we introduce a new velocity potential defined by

$$\phi' = \phi - e^{-\frac{f\sigma}{\tau}t} \left[\frac{\lambda}{\tau} \int^t C(t) e^{\frac{f\sigma}{\tau}t} dt \right] \tag{8}$$

For simplicity, the prime will be omitted hereafter. The incompressible equations of motion can be expressed in terms of the velocity potential defined in Eq.(8)

$$\nabla^2 \phi + \frac{\partial^2 \phi}{\partial z^2} = 0 \tag{9}$$

$$\frac{\tau}{\lambda} \phi_t + \frac{p}{\rho} + gz + f \frac{\sigma}{\lambda} \phi = 0 \tag{10}$$

where ∇ is the gradient operator in the horizontal plane. The set of equations (9) and (10) govern the flow within a porous medium, should

be solved under appropriate boundary conditions. Boundaries of the domain are the bottom at a depth $z=-h$ and a free surface, $z=\zeta$. The dynamic free surface condition is obtained by setting $P=0$ at $z=\zeta$ in the above linearized Bernoulli equation.

$$\frac{\tau}{\lambda} \varphi_t + g\zeta + f \frac{\sigma}{\lambda} \varphi = 0 \quad : z=0 \quad (11)$$

where φ and its derivative with respect to t are evaluated at the still water level $z=0$. The linearized kinematic boundary condition at a free surface and a bottom are expressed by

$$\varphi_z = \lambda \zeta_t \quad : z=0 \quad (12)$$

$$\varphi_z = -f \varphi / h \quad : z=-h \quad (13)$$

Our task is to seek a solution to the Laplace equation (9) which satisfies the above boundary conditions Eqs.(11) to (13).

It is assumed that a velocity potential φ is expressed by:

$$\varphi = \hat{\phi} e^{-i\omega t} = f(z) \eta(x, y) e^{-i\omega t} \quad (14)$$

In case of constant water depth or very gentle slope, substitution of Eq.(14) into Eq.(9) yields

$$f = A \cosh k(h+z) \quad (15)$$

where k is the complex wave number satisfying a dispersion relation which will be described just later. Elimination of ζ in Eqs.(11) and (12) and substitution of Eq.(14) together with Eq.(15) into the boundary condition gives a dispersion relation as follows:

$$\sigma^2(\tau + if) = gk \tanh kh \quad (16)$$

Equation (16) has a countable infinite number of complex roots. Since evanescent wave components may decrease their magnitudes rapidly, we will neglect them. If $\tau=1$ and $f=0$, then we obtain the dispersion relation for linear free surface waves. In order to obtain a wave equation for the mild bottom slope, we apply the following Green's identity (see, Mei, 1983).

$$\int_{-h}^0 \left\{ \Psi_0 L(\Psi_1) - \Psi_1 L(\Psi_0) \right\} dz = \left[A(z) (\Psi_0 \Psi_1' - \Psi_1 \Psi_0') \right]_{-h}^0 \quad (17)$$

where L is the self-adjoint differential operator which is expressed as

$$L = \frac{d}{dz} \left[A(z) \frac{d}{dz} \right] + B(z) \quad (18)$$

Applying Green's formula for $\hat{\phi}$ and f and integrating from the bottom to the still water level yields

$$\nabla(C^* C^* \nabla \eta) + k^2 C^* C^* \eta = 0 \quad (19)$$

where

$$C^* C^* = \frac{g}{k} \tanh kh - \frac{1}{2} \left\{ 1 + \frac{2kh}{\sinh 2kh} \right\} \quad (20)$$

Equation (19) is the same as the expression as the mild slope equation derived by Berkhoff (1972). However, it is different that the wave number k in Eq.(19) is a complex number. If we put $\tau=1$ and $f=0$, Eq.(19) reduces to the mild slope equation by Berkhoff. In case of constant water depth, Eq.(19) reduces to the Helmholtz equation which has a solution with an exponential decay in the direction of incident wave propagation.

2.2 Wave transformation over a permeable submerged breakwater

Let us consider the wave transformation over a submerged permeable breakwater as shown in Fig.1. In this figure, h is the still

Fig. 1 Definition sketch.

water depth, and h_s is the depth above the interface of a submerged breakwater. The domain is divided into two regions, i.e., regions outside and inside the submerged breakwater, denoted as Region I and Region II, respectively. Irrotationality for the flow in pore of the breakwater permits to define the velocity potential ψ in Region II.

In Region I, governing equation and boundary conditions can be expressed in terms of the velocity potential φ as:

$$\nabla^2 \varphi + \varphi_{zz} = 0 \tag{21}$$

$$\varphi_{tt} + g\varphi_z = 0 \quad : z = 0 \tag{22}$$

$$\varphi_t + \frac{p}{\rho} - gh_s = 0 \quad : z = -h_s \tag{23}$$

$$\varphi_z = -\nabla \varphi \nabla h_s + w_s \quad : z = -h_s \tag{24}$$

where w_s is the average discharge velocity at $z = -h_s$. Equation (22) is the boundary condition arising from the kinematic and dynamic condition at the free surface, and Eq.(23) is the dynamic condition at the interface $z = -h_s$. Equation (24) is the modified kinematic condition including the discharge at the interface of the permeable bed.

In Region II, governing equation and boundary conditions are as follows:

$$\nabla^2 \psi + \psi_{zz} = 0 \tag{25}$$

$$\frac{\tau}{\lambda} \psi_t + \frac{p}{\rho} - gh_s + f \frac{\sigma}{\lambda} \psi = 0 \quad : z = -h_s \tag{26}$$

$$\psi_z = -\nabla \psi \nabla h_s + w_s \quad : z = -h_s \tag{27}$$

$$\psi_z = -\nabla \psi \nabla h \quad : z = -h \tag{28}$$

where Eqs.(26) and (27) are the dynamic and kinematic conditions at the interface $z = -h_s$, respectively, Eq.(28) is the kinematic condition for an impermeable bed. Since the pressure and the vertical discharge velocity at the interface must be continuous, the following continuity

conditions should be required.

$$p_1 = p_{11} \quad : \quad z = -h_s \quad (29)$$

$$\varphi_x = \varphi_x \quad : \quad z = -h_s \quad (30)$$

From Eqs.(23),(26) and (29), we have

$$\varphi_t = (\tau/\lambda)\psi_t + (f\sigma/\lambda)\psi \quad : \quad z = -h_s \quad (31)$$

The velocity potentials φ and ψ may be expressed as follows:

$$\varphi = -\frac{ig}{\sigma} F_1(z) \eta(x, y) e^{-i\sigma t} \quad (32)$$

$$\psi = -\frac{ig}{\sigma} F_2(z) \zeta(x, y) e^{-i\sigma t} \quad (33)$$

Substituting Eqs.(32) and (33) into Eqs.(21) and (25) respectively, and invoking the mild slope assumption, we obtain

$$F_1(z) = A \cosh k(h_s + z) + B \sinh k(h_s + z) \quad (34)$$

$$F_2(z) = D \cosh k(h + z) \quad (35)$$

where A, B and D are integration constants. The free surface boundary condition and the continuity condition for mass flux at the the interface together with Eqs.(32) to (35) give a dispersion relation by

$$\sigma^2 = gk \frac{\tanh kh_s + q \tanh k(h-h_s)}{1 + q \tanh k(h-h_s) \tanh kh_s} \quad (36)$$

where $q = \lambda/(\tau + if)$. When $\lambda=1$, $\tau=1$ and $f=0$, or $\lambda=0$, the dispersion relation Eq.(36) reduces to that for the linear wave over an impermeable bottom.

Applying Green's formula for F_1 and $\hat{\varphi}$, and for F_2 and $\hat{\psi}$,

$$\int_{-h_s}^{-h} \left\{ F_2 \frac{\partial^2 \hat{\psi}}{\partial z^2} - \frac{\partial^2 F_2}{\partial z^2} \hat{\psi} \right\} dz + \int_{-h_s}^0 \left\{ F_1 \frac{\partial^2 \hat{\varphi}}{\partial z^2} - \frac{\partial^2 F_1}{\partial z^2} \hat{\varphi} \right\} dz = \left[F_2 \frac{\partial \hat{\psi}}{\partial z} - \frac{\partial F_2}{\partial z} \hat{\psi} \right]_{-h_s}^{-h} + \left[F_1 \frac{\partial \hat{\varphi}}{\partial z} - \frac{\partial F_1}{\partial z} \hat{\varphi} \right]_{-h_s}^0 \quad (37)$$

and substituting Eqs.(32) to (35) into Eq.(37), we get the extended mild slope equation.

$$\nabla(a\nabla\eta) + k^2 a \eta = 0 \quad (38)$$

$$a = \frac{g}{k} \tanh kh_s \frac{1}{2} \left[1 + \frac{2kh_s}{\sinh 2kh_s} \right] + q \frac{g}{k} \tanh k(h-h_s) \tanh^2 kh_s \quad (39)$$

$$+ q \frac{g}{k} \frac{\tanh k(h-h_s)}{\cosh^2 kh_s} \frac{1}{2} \left[1 + \frac{2k(h-h_s)}{\sinh 2k(h-h_s)} \right] + q^2 \frac{g}{k} \tanh kh_s \cdot \tanh^2 k(h-h_s) \frac{1}{2} \left[1 - \frac{2kh_s}{\sinh 2kh_s} \right]$$

If we put $\lambda=0$, or $h=h_s$ in Eqs.(38) and (39), Eq.(38) reduces to the mild slope equation for an impermeable bed. So the wave equation (38) includes the mild slope equation derived by Berkhoff(1972). Furthermore, when $h_s=0$, we get a wave equation similar to that for wave transformation within a permeable media in previous section, but have a dispersion relation slightly different from Eq.(16).

2.3 Modeling of wave breaking over a submerged breakwater.

Wave breaking over a submerged breakwater is very important mechanism of wave energy dissipation. The wave equation (38) should be modified to include a energy dissipation due to breaking. To do this, we add the energy dissipation term in Eq.(38) to be expressed by

$$\nabla (a\nabla\eta) + k^2 a\eta = -i\sigma f_D \eta \tag{40}$$

where f_D is the energy dissipation factor, σ is the angular frequency and i is the imaginary unit. Since breaking waves over a wide submerged breakwater may recover, the value of f_D for recovered waves must be required to be equal to zero. Referring the studies by Watanabe and Dibajnia(1988) and Isobe et. al(1988), we will adopt the following expression for f_D .

$$f_D = \alpha_D \tanh\left[\beta_D \frac{\bar{h}_s}{L_0}\right] \sqrt{\frac{g}{h_s}} \sqrt{\frac{\gamma - \gamma_r}{\gamma_s - \gamma_r}} s_a \tag{41}$$

where \bar{h}_s and h_s are the water depth above the breakwater crown and the local water depth above the interface of the breakwater, respectively. The quantity γ is the ratio of the wave amplitude to the water depth h_s , γ_s and γ_r show the values of γ for breaking waves over a uniformly sloping beach and for recovered waves over a step type beach, respectively. The quantity s_a is the averaged bottom slope defined by Izumiya and Isobe(1986). The proportionality constants α_D and β_D will be determined from the results of experiment on wave transformation.

3. EXPERIMENTS ON WAVE TRANSFORMATION OVER A PERMEABLE SUBMERGED BREAKWATER

3.1 Experimental equipments and procedure

In order to confirm the validity of the model, the experiments on the wave transformation over a submerged permeable breakwater were conducted. A uniform slope of 1/15 made of wooden board was installed in a wave flume, and a submerged breakwater composed of three kinds of gravels was placed on the slope. The cross section of the model breakwater is shown in Fig.2. The average weight of gravels, W_1, W_2 and W_3 , is 86.3 gf, 10.4 gf and 0.89 gf respectively. The average porosity of the submerged breakwater is 0.433. The experiments with 24 cases were made for various wave heights and periods with the crown water depth of 3 cm.

Fig. 2 Cross section of model submerged breakwater.

3.2 Wave breaking condition over a submerged breakwater

A few investigation on wave breaking over a submerged breakwater has been made. For this, a large number of experiments were carried out to obtain the empirical formula for the breaking condition. In case of wave breaking over a submerged breakwater, the breaking water

depth is defined as a depth from the interface of a submerged breakwater to the still water level. From the experimental data of the breaking water depth h_B , wave period and the local average slope s_a , the following expression for the non-dimensional breaking depth is obtained.

$$\frac{h_B}{H_0} = 0.43 + \frac{0.1}{-0.77 - \log_{10}(H_0/L_0)} + 0.22 \left\{ 1 - \frac{0.184 s_a^2}{s_a^2 - 0.107 s_a + 0.054} \right\} \cdot \left(\frac{H_0}{L_0} \right)^{-0.37} \quad (42)$$

where H_0 is the deepwater wave height and L_0 is the deepwater wavelength. When the local average slope steeper than 0.1, s_a takes a value of 0.1. The relation (42) is obtained to be slightly modified from the expression for steep slopes proposed by Isobe et. al(1988). Using Eq.(42), we can evaluate the breaking water depth as a function of the deepwater steepness and the average bottom slope.

4. METHOD OF NUMERICAL CALCULATION

A two-dimensional problem in the vertical plane is analyzed to examine the validity of the model equation. Equation (38) is discretized into a finite difference form and is solved by using two boundary conditions, i.e., the offshore boundary condition and the non-reflective boundary condition at a shoreward boundary to be expressed by

$$ik_i \varphi + \varphi_x = ik_i H_i e^{ik_i x_0} \quad (43)$$

$$ik_i \varphi - \varphi_x = 0 \quad (44)$$

where k_i is the wave number at the offshore boundary, H_i is the incident wave height and x_0 is the location of the offshore boundary. These boundary conditions are also discretized into finite difference schemes. The procedure of numerical calculation is summarized as follows:

- 1) Solve the dispersion equation, (36), for the first eigen value.
- 2) Assume $f_D = 0$, and solve Eq.(38) with the boundary conditions Eqs.(43) and (44).
- 3) Determine the breaking point using the breaking condition Eq.(42).
- 4) Calculate the wave heights with Eqs.(40), (41), (43) and (44).
- 5) Calculate the difference of wave heights for the successive iterations at each location.
- 6) Repeat 4) and 5) until the solution converges.

Through the above procedure, the converged solutions are obtained within 7 to 8 iterations.

5. COMPARISON OF THE MODEL RESULTS AGAINST THE EXPERIMENTAL DATA

The computed results with Eqs.(38) and (39) are compared with the experimental data to examine the applicability and the validity of the present model. In the calculation, The values of α_D , β_D , τ and f are determined by fitting experimental data for wave height. The results are $\alpha_D = 0.8$, $\beta_D = 90.0$, $\tau = 1.1$ and $f = 10.0$. Figure 3-(a) to (e) show the comparison between measured and calculated values of wave height. The solid lines indicate the wave height distributions calculated with the extended mild slope equation (38) including the dissipation term due to breaking. The closed circles show the experimental data. The agreement of wave heights outside the surf zone is very good. This means that the magnitude and the phase of reflected waves are well predicted by the present model. On the other hand, the

wave heights measured over a submerged breakwater are fairly smaller than the computed results. This is because that since the water depth above the breakwater crown, 3 cm, is shallow, the waves collapse on the breakwater with the strong nonlinearity of motion. So the difference between measured and computed wave heights occurred. Nevertheless, the transmitted wave heights calculated from this model are in good agreement with the experimental results.

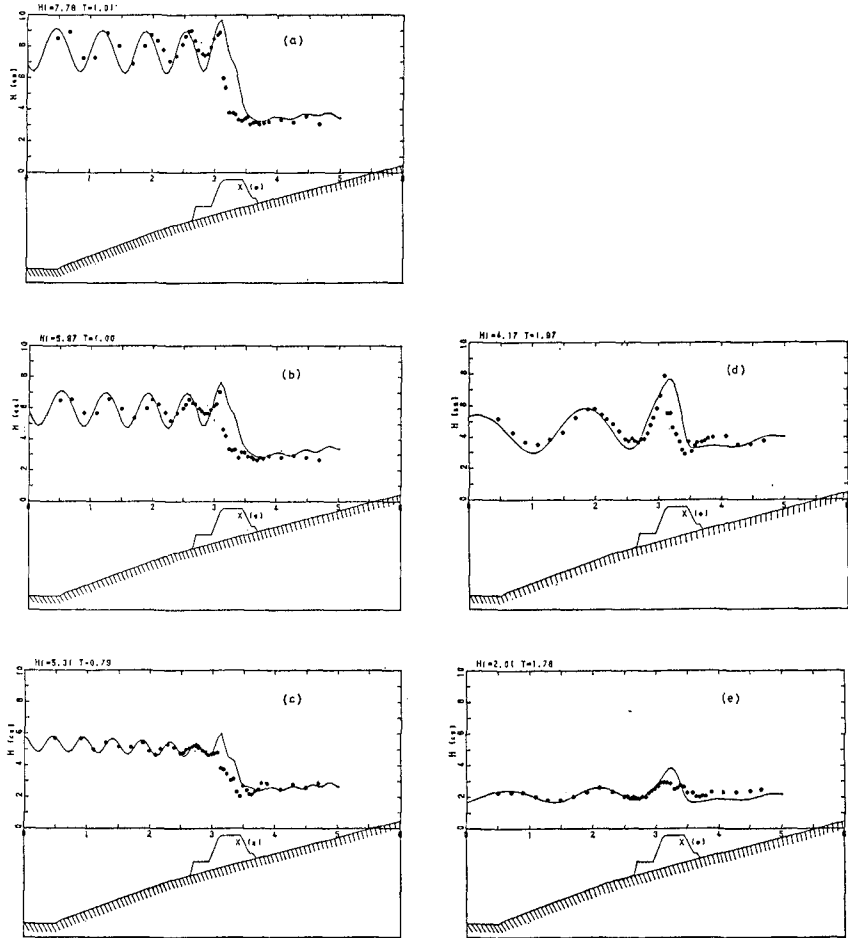

Fig. 3 Wave height transformations.

Figure 4 shows the comparison between measured and calculated values of reflection coefficient as a function of relative crown width B/L_0 . It is found that although the computed results in the range ($0.1 < B/L_0 < 0.2$) indicate values slightly larger than the experimental data, the agreement is fairly good. Figure 5 compares the the transmission coefficients with the measured and calculated results. From this figure, we can find that the estimated values of the transmission coefficient agree well with the experimental data, and also find that the coefficient decreases with decreasing relative crown depth h_s/H_0 . Figure 6 shows the comparison between measured and calculated values of energy loss coefficient as a function of the relative crown depth h_s/H_0 . It is seen from the figure that there is a scatter in the data in the range of $h_s/H_0 > 0.8$, however, the agreement is fairly good in the range of $h_s/H_0 < 0.8$.

Fig. 4 Comparison between measured and calculated values of reflection coefficient.

Fig. 5 Comparison between measured and calculated values of transmission coefficient.

Fig. 6 Comparison between measured and calculated values of energy loss coefficient.

6. CONCLUDING REMARKS

A wave equation has been developed to evaluate the important characteristics of permeable breakwater. The wave equation obtained is applicable in and outside of a permeable structure, and has the advantage that the computation time is fairly shorter than those of existing methods. The validity of the model was confirmed through a comparison with the experimental data for a two-dimensional case. As the result, it was found that the present model can produce accurate results for practical purposes for the reflection, transmission and dissipation characteristics.

CHAPTER 24

ANOTHER QUASI-3D MODEL FOR SURF-ZONE FLOWS

A. Sánchez-Arcilla, F. Collado, M. Lemos, F. Rivero*.

Abstract

In this report, a quasi-3D model for nearshore circulation is presented. The aim of the model is an economic simulation of surf- zone flow features.

This model relies on the efficient integration of three main modules: i) Wave propagation, ii) Depth-uniform currents, and iii) 1DV model for current-profiles calculation.

The basic equations are vertically integrated up to the trough level (z_{tr}), assuming at this level the existence of a rigid-lid, which permits to replace the free surface elevation by an equivalent pressure.

This device allows a continuous description of the flux below z_{tr} , making possible the obtention of the flux components in the same vertical solution domain.

The model is still under development. The results obtained, although insufficient to validate the code, serve to explore its capabilities.

1.-Introduction

A new model for surf-zone flow analysis has been developed at the University of Catalonia U.P.C.. It's a versatile tool, valid for a wide range of coastal engineering problems, that maintains cost/accuracy in the range considered nowadays reasonable (for desk-top computers). This is mainly due to the use of a Quasi-3D scheme (3D codes are still too expensive). In the development of the code, it has been preferred to keep some degree of vertical resolution to make possible, for instance, sediment transport computations.

The code (ALF) is composed of:

- Wave propagation module.
- Rigid-lid 2DH module.
- 1DV module for the vertical profiles.

The last two modules will allow a reasonably accurate 3D resolution, with nearly the cost of a 2DH model.

* Lab. de Ingeniería Marítima, Univ. Politécnica de Cataluña, U.P.C., Barcelona, Spain.

In spite of the general formulation, herein we'll focus on the nearshore circulation, with emphasis on the internal consistency of the equations and associated simplifications.

The solution domain (vertical and horizontal) of the uniform (\bar{u}) and the depth-varying (\vec{u}) current components is the same. The water column is divided into three layers, coupled by mass/momentum transfers. The surface layer (above wave trough level) is not solved, and its effects are considered through boundary conditions identical for \bar{u} and \vec{u} . The middle layer goes from the top of the bottom boundary layer to z_{tr} for both variables. The third layer corresponds to the bottom boundary layer. To begin with and for simplicity, this layer will not be solved explicitly, its effects considered through continuity conditions for \bar{u} and $\frac{\partial \bar{u}}{\partial z}$ at the interphase. Alternatively, and depending on the fit obtained in the selected test cases, the bottom boundary layer could be included in the solution domain. In this case, the boundary conditions become even simpler (for instance, no-slip at the bottom), although some additional complications appear due to the need to make "closure" assumptions for waves and turbulence near the bottom.

The driving terms here considered are basically the incident wind waves, described in terms of frequency (f) and angle of incidence (θ). Although it has been shown that the inclusion of randomness is essential for a rigorous treatment of wind-wave phenomena, for now it has been preferred to run a model lumped in f and θ , assuming that the wave climate is well defined by these two parameters. An additional reason is that most available expressions for D (the rate of wave energy dissipation per unit area, closely related to surf-zone circulation features) have been derived for waves described in this lumped manner. The wave velocity field, \vec{u} , is obtained from linear theory.

With respect to the numerical discretization, suffice it to say that in this initial stage, the simplest possible technique has been selected to concentrate on the physics of the problem.

In what follows, the set of equations and simplifications involved in the model will be exposed, together with some preliminary results.

2.- Current Modelling

2.1- Assumptions

- Incompressible - newtonian fluid.
- z_{tr} , z_b and $\langle \eta \rangle$ are time-independent, ($\langle \rangle$ is the time-averaging operator at the wave-scale), see fig. 1.

Figure 1.

- Horizontal gradients of z_{tr} and z_b are much smaller than the corresponding Reynolds stresses.
- Horizontal gradients of vertical velocities are much smaller than vertical gradients

of horizontal velocities.

- The current flow is quasi-horizontal (i.e. vertical accelerations are negligible). Thus, the pressure is given by:

$$p = p_{\text{hydrostatic}} - \rho \langle \tilde{w}^2 \rangle \quad (1)$$

- There is no mass flow through the z_b and η boundaries, but there certainly is through the z_{tr} level.

Once all these assumptions have been made, the operators $\int_{z_b}^{z_{tr}} () dz$ and $\langle \rangle$ will be applied to the mass and momentum equations. In order to avoid discontinuity problems of the variables describing the surface layer, the following decomposition will be used:

$$\vec{u} = \bar{u} + \tilde{u} \quad (2)$$

where:

\bar{u} : current velocity.

\tilde{u} : depth-invariant component.

\tilde{u} : z -dependent component.

The \tilde{u} component satisfies:

$$\int_{z_b}^{z_{tr}} \tilde{u} dz = 0 \quad (3)$$

From now on, the overbar symbol on a variable will be used to denote its mean value in the middle layer. The symbol " $\tilde{\quad}$ " on a variable has the effect of centering the variable around its mean. So, it will always be:

$$\int_{z_b}^{z_{tr}} \tilde{f} dz = \underline{0}, \text{ for every variable } \tilde{f} \quad (4)$$

2.2- Mass conservation Equation

The continuity equation, obtained after applying the depth-integration and time-averaging operators, is:

$$\frac{\partial(h\bar{u})}{\partial x} + \frac{\partial(h\bar{v})}{\partial y} = -G \quad (5)$$

where G is the net volume flux over z_{tr} , which reads:

$$\begin{aligned} G &= \frac{\partial}{\partial x} \langle \int_{z_{tr}}^{\eta} (u + \tilde{u}) dz \rangle + \frac{\partial}{\partial y} \langle \int_{z_{tr}}^{\eta} (v + \tilde{v}) dz \rangle \\ &= \nabla_h \cdot \langle \vec{Q}_s \rangle \end{aligned} \quad (6)$$

($h = z_{tr} - z_b$ is the thickness of the middle layer)

Invoking the starting assumptions, G is also seen to satisfy:

$$G = [w - u \frac{\partial z_{tr}}{\partial x} - v \frac{\partial z_{tr}}{\partial y}] (z_{tr}) \quad (7)$$

The wave contribution to the volume flux above z_{tr} is calculated with an expression deduced by Svendsen (1984b), which has been later used by other authors (e.g. Stive and De Vriend, 1987):

$$\langle \vec{Q}_s \rangle_w = \left(1 + \frac{7d}{L}\right) \frac{E}{\rho c} \tag{8}$$

d : Water depth.

L : Wavelength.

c : Wave celerity.

E : Wave energy density.

(The second term of the parenthesis is only considered inside the surf zone)

The current contribution to z_{tr} is more difficult to evaluate, due to the loss of physical meaning of this concept in a wave averaged time scale, because in this layer there are then "dry" and "wet" instants. Nevertheless, in the currents time-scale it looks reasonable to expect values of this contribution to be proportional to the values of the current in the middle layer (at $z = z_{tr}$) and the mean width of the surface layer. This term will be thus modelled by:

$$\langle \vec{Q}_s \rangle_c = \alpha \langle \eta \rangle - z_{tr} \vec{u} \tag{9}$$

Where α is a parameter to be evaluated.

2.3- Momentum Conservation equation for \vec{u}

The momentum equation obtained integrating between z_b and z_{tr} and applying the wave time-averaging operator is for the x-component (analogous for y):

$$\begin{aligned} & \frac{\partial(h\bar{u})}{\partial t} + \frac{\partial(h\bar{u}^2)}{\partial x} + \frac{\partial(h\bar{u}\bar{v})}{\partial y} - f(h\bar{v}) + (\bar{u} + \hat{u}(z_{tr}))G \\ &= -\frac{h}{\rho} \frac{\partial p_t}{\partial x} + \frac{\partial}{\partial x}(\bar{R}_{xx} + \hat{R}_{xx}) + \frac{\partial}{\partial y}(\bar{R}_{xy} + \hat{R}_{xy}) + \frac{\langle \hat{\tau}_{tr} - \hat{\tau}_b \rangle_x}{\rho} + \bar{W}_x \end{aligned} \tag{10}$$

Where:

$p_t = \rho g \langle \eta \rangle$, which shows the formal equivalence between pressure and set-up/down.

$\bar{R}_{ij} = h \bar{v}_t \left(\frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right)$, stresses which take account of the horizontal momentum transfer due to \bar{v}_t .

$\hat{R}_{ij} = \int_{z_b}^{z_{tr}} [\hat{v}_t \left(\frac{\partial \hat{u}_i}{\partial x_j} + \frac{\partial \hat{u}_j}{\partial x_i} \right) - \hat{u}_i \hat{u}_j] dz$, term which takes account of the horizontal momentum transfer due \hat{v}_t and the interaction effects of the z-dependent flow in the uniform flow.

$\bar{W}_x = -\frac{h}{\rho} \int_{z_b}^{z_{tr}} \langle \bar{u}^2 - \bar{w}^2 \rangle dz - \frac{h}{\rho} \int_{z_b}^{z_{tr}} \langle \bar{u} \bar{v} \rangle dz$, which represents the horizontal gradient of driving terms due to the correlations of the wave-component velocities. This term doesn't exactly coincide with the usual definition of the radiation stress tensor S_{ij} (in our formulation vertical integration has been made up to z_{tr}).

Comparing (10) with the equation obtained integrating up to the free surface and disregarding time and space derivatives of the current over z_{tr} (and other terms that, according to the assumptions, are negligible), the following expression is obtained:

$$\bar{W}_i + \langle \tau_{tr} \rangle_i = -\frac{\partial \bar{S}_{ij}}{\partial x_j} + (\bar{u}_i + \hat{u}_i(z_{tr}))G \tag{11}$$

Replacing this expression in the momentum equations for \bar{u} and \bar{v} , the usual horizontal gradients of the radiation stress tensor are recovered. This approach requires however variables evaluated at the trough level which is, in the surf-zone, particularly difficult. An interesting alternative, at present under analysis, is the direct calculation of \bar{W} and G , with a suitable wave theory together with a semi-empirical model for $\langle \tau_{tr} \rangle$ as a function of D similar to the formulation used by De Vriend and Stive (1987). This D formulation has been already used for the description of the z-dependent flow.

With all this, the momentum equation can be written (similarly for the y-component):

$$\begin{aligned} & \frac{\partial(h\bar{u})}{\partial t} + \frac{\partial(h\bar{u}^2)}{\partial x} + \frac{\partial(h\bar{u}\bar{v})}{\partial y} - f(h\bar{v}) \\ &= -\frac{h}{\rho} \frac{\partial p_t}{\partial x} + \frac{\partial}{\partial x}(S_{xx} + \bar{R}_{xx} + \hat{R}_{xx}) + \frac{\partial}{\partial y}(S_{xy} + \bar{R}_{xy} + \hat{R}_{xy}) - \frac{\langle \hat{\tau}_b \rangle_x}{\rho} \end{aligned} \quad (12)$$

These equations, together with the continuity equation (5), become the usual ones for the calculation of free surfaces flows upon neglectation of the z-dependent component of the current and horizontal gradients of the volume flux over z_{tr} , and identifying h as the total depth.

2.4- Momentum conservation equation for \bar{u}

Considering that:

- Wave stresses are approximately uniform in the vertical (Stive and Wind, 1986)
- Horizontal gradients of turbulent stresses as well as interaction terms can be neglected (as suggested from an order-of-magnitude analysis)
- \bar{u}/\bar{u} interaction terms associated to convective accelerations do not appear to play an essential role. Thus it has been preferred to retain only the terms which make possible an efficient 1DV model. These terms which preserve the order of magnitude of convective terms, are for the x-component (similarly for y):

$$\hat{u} \frac{\partial \bar{u}}{\partial x} + \hat{v} \frac{\partial \bar{u}}{\partial y} \quad (13)$$

- The coriolis term is also neglected, since its effects (e.g. Ekman's layer) are usually masked by surf-zone turbulence.

Taking all this into account, the resulting equation for \hat{u} is:

$$\frac{\partial \hat{u}}{\partial t} + \hat{u} \frac{\partial \bar{u}}{\partial x} + \hat{v} \frac{\partial \bar{u}}{\partial y} - \hat{u}(z_{tr})G - \frac{\partial}{\partial z}(\nu_t \frac{\partial \hat{u}}{\partial z}) + \frac{\langle \hat{\tau}_{tr} - \hat{\tau}_b \rangle_x}{\rho h} = Res_x \quad (14)$$

The term $\frac{\partial \hat{u}}{\partial t}$ is retained to allow transient computations (in the future) and in order to use t as a marching variable for stationary cases (at present).

The \bar{u} equation, though parabolic in t-z, is of elliptic-type in z. Once it has been discretized in time, the resulting equation is of second-order in z. Thus, only 2 independent boundary conditions are needed to have a "well-posed" problem. Nevertheless, at least formally, there is a larger number of available boundary conditions, as pointed out by Battjes et al (1988). The choice is not obvious, and this remains a still open problem.

The term $\hat{u}(z_{tr})G$ is evaluated lagged backwards one time-step (error $O(\Delta t)$).

The term $Res_x(x, y, z)$ is a residual, which includes:

- All neglected terms (related or not to \hat{u}/\hat{v}).

- Errors (incompatibilities) due to closure submodels.
- Errors due to the discretization.

As for now, to simplify the computations, the term associated to G , will be included inside Res_x . With all this, the \vec{u} equations can be written in a compact manner as:

$$\frac{\partial \vec{u}}{\partial t} + A\vec{u} - \frac{\partial}{\partial x} \left(\nu_t \frac{\partial \vec{u}}{\partial x} \right) + \vec{T} = \vec{Res} \quad z_b \leq z \leq z_{tr} \quad (15)$$

Where:

$$A = \begin{pmatrix} \frac{\partial \bar{u}}{\partial x} & \frac{\partial \bar{u}}{\partial y} \\ \frac{\partial \bar{v}}{\partial x} & \frac{\partial \bar{v}}{\partial y} \end{pmatrix} ; \quad T = \frac{1}{\rho h} \begin{pmatrix} < \hat{\tau}_{tr} - \hat{\tau}_b >_x \\ < \hat{\tau}_{tr} - \hat{\tau}_b >_y \end{pmatrix}$$

These equations (after simplifying some terms) turn out to be similar to the usual ones. For instance, for waves normally incident to the coast, the expression obtained adding the \bar{u} and \bar{v} components is analogous to the one used by Svendsen (1987) in the calculation of undertow.

2.5- Boundary/Initial Conditions

i) Equations for \bar{u}/\bar{v}

- Any initial condition compatible with the continuity equation, as shown in figure 2.

Figure 2.

- Boundary conditions are the same as those required by the 2D Navier-Stokes equations, i.e., Dirichlet or Neumann for \bar{u} and \bar{v} at each boundary point (compatible with the continuity equation).

ii) Equations for \hat{u}/\hat{v}

- Initial conditions: zero velocities.

$$\vec{\hat{u}} = 0, \quad \forall z \in [z_b, z_{tr}].$$

- As for boundary conditions, a summary of possible choices (some of them suggested in publications by authors such as Svendsen, De Vriend and Stive) is:

At $z = z_{tr}$:

$\nu_t \frac{\partial \hat{u}}{\partial x} = < \hat{\tau} >_x ; < \hat{\tau} >_y$, being related to the wave-height decay over z_{tr} , is also strongly related to the shape of $\vec{\hat{u}}(z)$. Furthermore, there is experimental evidence suggesting a non-negligible value of $\frac{\partial \hat{u}}{\partial x}$ at z_{tr} (Hansen et al, 1984; Nadaoka, 1986).

$\vec{\hat{u}}(z_{tr})$; is left free, since it doesn't exist any reliable information on this parameter in the state-of-art.

At $z = z_b$:

If z_b coincides with the upper limit of the bottom boundary layer, then $\bar{u}(z_b)$ and $\frac{\partial \bar{u}}{\partial x}(z_b)$ are obtained from a closure submodel for the bottom boundary layer imposing continuity at z_b .

If z_b coincides with the bottom (zero-intercept level), the no-slip condition $\bar{u}(z_b) = 0$ appears naturally, although its use requires an explicit specification, inside the boundary layer, of poorly-known variables such as the eddy viscosity profile and the correlation (product) of wave velocities.

For now, in order to simplify the numerical development attention will be focussed on the middle layer. The available boundary conditions are (according to what has just been presented) $\bar{u}(z_b)$, $\frac{\partial \bar{u}}{\partial x}(z_b)$ and $\frac{\partial \bar{u}}{\partial x}(z_{tr})$, all of them obtained with closure models. These condition plus an externally obtained $\bar{R}es$, give an over-determined problem. Assuming known values for \bar{u}/\bar{v} and ν_t there are 3 possible options to solve this problem:

- a) Choosing 2 boundary conditions and assuming $\bar{R}es = \bar{0}$
- b) Parameterizing $\bar{u}(z_b)$ and $\frac{\partial \bar{u}}{\partial x}(z_b)$ as a function of \bar{u} . (shear velocity) and using this free parameter to satisfy the third boundary condition (see Stive and De Vriend, 1987).
- c) Inserting in the definition of $\bar{R}es$ an extra degree of freedom in order to accomodate the third boundary condition.

Option c) has been initially selected, since it seems the cheapest way to apply the three boundary conditions. This choice requires $\bar{R}es$ to be kept in the permissible range, which in practical terms, means relatively small values that must verify at the same time the compatibility condition $\int_{z_b}^{z_{tr}} \bar{R}es dz = 0$, which appears integrating vertically the momentum equation for \bar{u} . In fact, defining $\bar{I} = \int_{z_b}^{z_{tr}} \bar{u} dz$, the depth-integrated equation for \bar{u} gives:

$$\frac{\partial \bar{I}}{\partial t} + A \bar{I} - \left(\nu_t \frac{\partial \bar{u}}{\partial x} \right) \Big|_{z_b}^{z_{tr}} + \bar{T} h = \int_{z_b}^{z_{tr}} \bar{R}es dz \tag{16}$$

Assuming that $\bar{u}(t = 0) = 0$ and considering $\nu_t \frac{\partial \bar{u}}{\partial x} = \frac{\langle \tau \rangle}{\rho}$ in z_b and z_{tr} , $\forall t$ (2 Neumann-type boundary conditions), it can be seen that a necessary and sufficient condition for $\bar{I} = \bar{0}$ (the integral condition that must satisfy \bar{u} by definition) is $\int_{z_b}^{z_{tr}} \bar{R}es dz = 0$.

3.-Numerical Solution

3.1.- Equations for \bar{u}

The unknowns are \bar{u}, \bar{v} and p_t (equivalently $\langle \eta \rangle$). The available equations are continuity and the x and y momentum equations (vertically integrated and time-averaged). The equations are solved with an explicit finite-differences method based on a MAC-type grid (see figure 3). The solution algorithm uses an upwind and Euler-type discretization (SOLA-type) allowing for variable h and ν_t .

Figure 3.

The \tilde{u}/\tilde{v} interaction effects are considered via \hat{R}_{ij} and $\langle \hat{\tau} \rangle$. Initially, all terms related to \hat{u}/\hat{v} are assumed zero, when solving the \tilde{u} equations. The possible a posteriori correction effects have not been evaluated yet, leaving this as a still open point.

3.2- Equations for \tilde{u}

Using a forward Euler-type discretization for the time-derivative (error $O(\Delta t)$):

$$\frac{\partial u}{\partial t} = \frac{\tilde{u}^{\bar{n}+1} - \tilde{u}^{\bar{n}}}{\Delta t} \quad (17)$$

We obtain an equation for $\tilde{u}^{\bar{n}+1} = \tilde{u}((n+1)\Delta t)$ which turns out to be a set of linear coupled second order ordinary differential equations for \tilde{u}/\tilde{v} .

$$A_t \tilde{u}^{\bar{n}+1} - \frac{\partial}{\partial z} (\Delta t \nu_t \frac{\partial \tilde{u}^{\bar{n}+1}}{\partial z}) = \tilde{R}^n(z) \quad z_b \leq z \leq z_{tr} \quad (18)$$

Where:

$$\begin{aligned} A_t &= I + \Delta t A \\ \tilde{R}^n &= \tilde{u}^{\bar{n}} + \Delta t (-\tilde{T}^n + \tilde{R}es^n) \end{aligned} \quad (19)$$

The solution technique for this set of equations relies on essentially, three ideas:

i) Uncoupling the \tilde{u}/\tilde{v} , equations with an adequate change of variable $w = Vu$, so that:

$$A_t = V \Lambda V^{-1} \quad \text{with} \quad \Lambda = \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix}; \lambda_1, \lambda_2 \in \mathbb{R}. \quad (20)$$

This change of variables may not always be possible, with cases in which the A_t eigenvalues can be complex or where it cannot be diagonal (in which case it should be replaced by the corresponding Jordan matrix). However, the numerical treatment is essentially identical in all cases, so that without a significant loss of generality, it will be supposed that this kind of situation will never arise in practice. On the other hand if $\frac{\partial \tilde{u}}{\partial y} = 0$ or $\frac{\partial \tilde{v}}{\partial x} = 0$, the equations become automatically uncoupled. The resulting equations can thus be written as:

$$a w_i + \frac{\partial}{\partial z} (K_t(z) \frac{\partial w_i}{\partial z}) = r_i(z) \quad i = 1, 2 \quad (21)$$

ii) The use of a power series decomposition to reproduce the vertical variation of variables such as:

$$u_i(z) = \sum_{j=0}^n a_j z^j \quad (22)$$

$$\nu_t(z) = \sum_{j=0}^p b_j z^j \quad (23)$$

$$\tilde{R}es(x, y, z) = \tilde{R}es(x, y) \left(\frac{z_b + z_{tr}}{2} - z \right) \quad (24)$$

$\bar{Res}(x, y)$ represents the extra degree of freedom inserted to adjust the redundant boundary condition since it is mainly associated to neglected terms. The variation of $\bar{Res}(x, y, z)$ with z has been assumed linear (simplest possible solution satisfying the integral condition).

The power series technique is, among other possible choices, one of the simplest and cheapest, presenting advantages over a finite-differences scheme in z . The reason is that with a power series approach an analytical solution is obtained, whose precision and cost are controlled by the number of terms considered allowing an increase of the vertical resolution where desired in line with the quasi-3D philosophy. An additional advantage is that this approach allows recovering expressions comparable to the polynomial solutions \hat{u}/\hat{v} proposed elsewhere in the literature (see De Vriend and Stive, 1987; Svendsen, '87 '88 '89)

iii) Application of the power series approach to the uncoupled ordinary differential equations associated to the new variables w_i . With this, a recurrent relationship is obtained for the w coefficients:

$$a_{i+2} = f(a_{i+1}, a_i) \quad i = 0, 1, \dots, n - 2 \tag{25}$$

These are $n-1$ equations with $n+1$ unknowns. Additionally there are three extra equations arising from the boundary conditions for $\langle \hat{r}_r \rangle_i, w_i$ and $\langle \hat{r}_b \rangle_i$. The missing unknown, needed to balance the number of equations and unknowns is provided by the degree of freedom associated to $Res_i(x, y)$.

This system of equations is only slightly more expensive than existing 1DV models, since if the equations are adequately ordered, the matrix associated to a_i 's unknowns is approximately lower-triangular.

4.-Closure Submodels

Figure 4.

In this section, some closure submodels will be briefly described, since they are similar to other existing state-of-art models. These submodels, although related, will be separately presented (see figure 4). All closure submodels not mentioned below can be considered identical to those used in De Vriend and Stive (1987).

4.1- Wave Propagation

Wave propagation properties are computed with a pair of equations for the wave number vector \vec{K} , obtained from the Kinematic Conservation Principle, together with a third coupled equation for the amplitude "a", obtained from the energy balance equation (see Yoo, 1986; Yoo and O'Connor, '86a,b). The numerical solution is based on a classical finite differences scheme, with a mesh as schematized in figure 5. This closure submodel reproduces adequately and at reasonable cost wave/current interactions, refraction/diffraction phenomena, and energy dissipation. The current driving terms are considered to be proportional to D (Dingemans et al,1987), which in turn is computed by means of the formula proposed by Battjes and Janssen (1978). The trough level, z_{tr} , is obtained using cnoidal theory.

Figure 5.

4.2- Eddy Viscosity

To model $\nu_t(z)$ the simplest possible approach (based on an algebraic model) has been once again selected. This algebraic model (see for a review De Vriend and Kitou, 1990), includes the contributions of breaking waves and currents (influenced by the presence of the waves). The ν_t value satisfies the relation; $\nu_t^2 = \nu_c^2 + \nu_{br}^2$, equivalent to adding the corresponding values of K (turbulent kinetic energy) for waves and currents (Deigaard et al,1986). Following De Vriend and Stive (1987), the vertical profile of $\nu_c(z)$ is assumed constant in the upper half of the middle layer and quadratic in the lower half, although in both cases the profile is modelled as a function of the shear velocity enhanced by wave-effects. The profile of $\nu_{br}(z)$ is assumed constant in the whole middle layer, as a function of $(\frac{D}{\rho})^{\frac{1}{2}}$ (Svendsen,1987).

The evaluation of turbulent stresses remains nevertheless, an open problem that must be solved in a near future, in view of their strong influence on ν_t . The crucial effect of ν_t on the vertical profile of \bar{u} can be easily illustrated by solving the homogeneous equation for w_i , which looks as:

$$\lambda w + \frac{\partial}{\partial z}(K_t(z) \frac{\partial w}{\partial z}) = 0 \tag{26}$$

Table 1 shows a summary of the wide range of possible expressions for $w(z)$.

Tabla 1: Illustration via of homogeneous eq. for w

$K_t(z)$	$\rightarrow \lambda$	$w(z)$
const > 0	> 0	Exponential
const > 0	< 0	Sinusoidal
Linear	=0	logarithmic
quadratic	Varying	Varying (dep. on BC and λ)

It is important to remark that although the order-of-magnitude analysis carried out in

previous sections assumed equal values of the eddy viscosity for the horizontal and vertical directions (see Svendsen, 1988), several authors have proposed different values. As a matter of fact, some references suggest the horizontal ν_{tH} two orders-of-magnitude larger than the vertical ν_{tV} (see De Vriend and Kitou, 1990).

4.3- Boundary conditions

The expression considered for the shear stress $\langle \hat{\tau}_{tr} \rangle$ is very similar to the formulation proposed by De Vriend and Stive (1987).

The shear stress $\langle \hat{\tau}_b \rangle$ is modelled using the formulation of Nishimura (1983), because of its ability to reproduce adequately the directional features of this stress (Yamaguchi, 1988).

To evaluate $\tilde{u}(z_b)$ there are several available options, though none of them appears, at this stage, to be very convincing. Conceptually, it seems that the clearest solution would be to solve the middle and bottom boundary layers in a coupled way, imposing a non-slip condition at the real bottom. This approach, however, as previously indicated presents some additional difficulties. As a starting point, $\tilde{u}(z_b)$ will be derived from the identity $\tilde{u}(z_b) = \bar{u} + \tilde{u}(z_b)$, with \bar{u} obtained from the depth-averaged equations, and $\tilde{u}(z_b)$ given by a wall-law profile:

$$u_i(z) = \frac{u_{*i}}{\kappa} \log\left(\frac{u_{*i} E}{\nu_{mol}} z\right) \quad (27)$$

where:

$$\begin{aligned} u_{*i} &= \left(\frac{\tau_{bi}}{\rho}\right)^{\frac{1}{2}} \\ E &= 9.0 \\ \kappa &= 0.41 \text{ (Von Karman's constant)} \end{aligned} \quad (28)$$

5.-Validation

To begin with, it must be stressed that the calibration/validation processes is far from finished. The present status can be summarized as follows:

- The code for the 1DV model is already developed, but has not been validated yet.
- The two modules (2DH + 1DV) have not been run yet in a coupled way.
- For the time being, results can only be interpreted in a qualitative manner.

In any case, the list of test cases as follows:

2DH CODE (\tilde{u}):

- Normal and oblique incidence on a plane beach (setup, v_i) (Stive and Wind, 1982; De Vriend and Stive, 1987).
- Circulation behind a detached breakwater (Nishimura et al, 1985; Horikawa, 1987).
- Circulation on a variable bottom topography (Noda, 1974; Yamaguchi, 1986).

1DV CODE (\tilde{u}):

- Undertow (Hansen and Svendsen, 1984; Stive and Wind, 1986; Nadaoka, 1986).
- Long-shore Current (Visser, 1984).

The only case here presented is the 2DH nearshore circulation over a symmetric concave topography with normal wave incidence (Noda, 1974; Yamaguchi, 1986). It has been selected because it is a particularly interesting 2DH problem whose bathymetry can be numerically generated. The obtained results (see figure 6 and 7), are qualitatively similar to those reported

Figure 6
 - Bottom topography and associated wave number vector field for the Noda, 1974 test case.

Figure 7.
 - Current velocities field for the same case of figure 6.

by other authors, showing the presence of two circulation cells near the breaker line, together with another pair of flatter cells near the shoreline.

6.-Conclusions

A newly developed quasi-3D model for nearshore circulation has been presented. The most outstanding features are:

- Same solution domain and boundary conditions for both current-flow components, \vec{u} and \vec{v} (so as to give a consistent physical and mathematical meaning to the algebraic sum of both components).

- Some degree of interaction between \vec{u} and \vec{v} is retained.

- A new treatment for solving the depth-varying component is proposed (allowing local increases in resolution where desired).

- The same grid is used for waves and currents, avoiding thus, spurious effects due to interpolations.

Finally, it's important to point out that a certain number of points remain still open. Among them, the following are worthwhile mentioning:

- **Specific of the model:**

- a) Effects of \vec{u} / \vec{v} interaction.

- b) Effects of G term (Volume flux over z_{tr}).

- c) Effects of introducing the residual \vec{Res} (to accommodate the third boundary condition and other uncertainties).

- d) Effects of \vec{W} evaluated up to z_{tr}

- **General for nearshore circulation code:**

- a) Empirical modelling of wave characteristics inside the surf-zone.

- b) Use and validation of an eddy viscosity model inside the surf-zone.

- c) Effects of solving in a coupled way the middle and bottom boundary layer.

Acknowledgments

The authors wish to express their acknowledgments to the MOPU-PCM for partially supporting this study. They also want to thank CIMNE-UPC for contributing to the financial support of the study.

CHAPTER 25

Wave Attenuation on an Offshore Coral Reef

T.A. Hardy¹, I.R. Young², R.C. Nelson², & M.R. Gourlay³

ABSTRACT

The wave climate along the northeastern tropical coastline of Australia is controlled by The Great Barrier Reef (GBR). However, the processes by which the GBR attenuates and transforms waves are little understood. As the first part of an on-going study of the interaction between waves and coral reefs, a field experiment was conducted to study the processes that occur as waves break on an offshore reef and proceed across the reef flat into the lagoon. Eighteen wave, water level, and current measuring instruments were deployed and data for a wide range of tide and wave conditions were collected. Preliminary results for wave attenuation are presented. Results for wave attenuation across the reef show that wave heights on the reef flat and in its lagoon are controlled by the depth of water over the windward reef flat. As the waves travel across the reef flat, the ratio of significant wave height to water depth reduces to a value of 0.40, and the ratio of maximum wave height to water depth reduces to a value of 0.6 to 0.8. In the deeper water in the middle of the reef lagoon both the ratios of significant wave height to the depth over the reef flat and maximum wave height to the depth over the reef flat remain in the above ranges. However, at the mid-lagoon position these results are less general as wave heights inside a lagoon are also dependant on wind speed, direction, and fetch length inside the lagoon.

INTRODUCTION

The Great Barrier Reef (GBR) stretches for approximately 2000 km along the eastern tropical coast of the state of Queensland in northeastern Australia. Much of the GBR is relatively inaccessible as the reefs are usually more than 50 km, and often much farther, offshore. This is particularly the case in the lower two-thirds of GBR which is

3 Senior Lecturer, Department of Civil Engineering, University of Queensland, Brisbane, Queensland, Australia

nearer to populated areas. Because of its remoteness and the relatively small population on the tropical coast, visits to the GBR were relatively few until the last few years. However a recent boom in overseas tourists who are eager to enjoy the pleasures of snorkelling and SCUBA diving has initiated improvements in transportation including large wave piercing catamarans that have greatly reduced travel times to the reef.

Even with the fast catamarans, the trip out to the reef can be long (over two hours at some locations) and uncomfortable. Few of the reefs have any land permanently above the water; therefore, tourist operators are eager to provide stable platforms at their reef destinations. Numerous pontoons have been anchored inside the lagoons of individual reefs. Furthermore, a "floating hotel" was located for one year inside the lagoon of one reef. The design and operation of such facilities requires information about waves after they have proceeded from relatively deep water across the reef front and into the reef lagoon. Such information is needed for both normal operational conditions, as well as during tropical cyclones.

Coral reefs have a marked effect on waves as the waves reflect, refract, and break on the almost vertical seaward reef front, and also as the waves travel over the shallow and rough coral surfaces on the shallow reef flats. Despite this obviously important role, very little is known about the physics of wave energy reflection, dissipation, and transmission on coral reefs. There have been few studies in the GBR. A preliminary experiment was conducted by Young (1989) at Yonge Reef, one of the outer barrier ribbon reefs near Lizard Island in the Far Northern Section of the Great Barrier Reef Marine Park. Measurements between the GBR and the mainland coast north of Cairns and outside the GBR near Myrmidon Reef, offshore of Townsville, have been published by Murray and Ford (1983) and Wolanski (1985), respectively. In addition, laboratory experiments by Nelson and Leslighter (1985) have been used as a basis for engineering design. These sources confirm that the GBR is a significant barrier to wave penetration but none of the studies is extensive enough to provide understanding of the processes involved.

Published studies of waves on coral reefs from outside Australia have concentrated on landbacked or fringing coral reefs. Gerritsen (1981) and Lee and Black (1979) report on the wave-induced processes occurring on a fringing reef in Hawaii. However, this work has limited application for the GBR, not only because a fringing reef was studied, but also because the Hawaiian wave climate is dominated by longer period swell unlike the shorter period sea which dominates much of the GBR. Other studies include those by Roberts (1981) in the Caribbean and by Kono and Tsukayama (1980) for Okinawa.

In order to gather data on the interaction of waves and coral reefs, a field study was conducted in 1988 on an offshore coral reef in the Great Barrier Reef region. An extensive set of wave, water level, and current data was collected on the windward edge of the reef. The purpose of this paper is to present preliminary results on wave attenuation from this investigation.

DESCRIPTION OF THE STUDY REEF

John Brewer Reef, located approximately 70 km northeast of Townsville, Queensland in the Central Section of the Great Barrier Reef Marine Park (Figure 1), was selected as the experimental reef primarily because of the logistical support that was available. John Brewer was the site of the floating hotel which was located in the lagoon for just over a year encompassing the duration of the experiment. In addition, there was a daily catamaran service to John Brewer from Townsville. It would have

been difficult if not impossible to conduct the experiment without the availability of transport and a safe and stable haven from rough conditions for both computer equipment and researchers.

The Central Section of the Great Barrier Reef Marine Park is one of the least densely reefed segments of the GBR. John Brewer Reef is on the inner (landward) edge of the reef matrix and is elliptical in shape (6 km by 3 km) (Figure 2), with the major axis approximately normal to the southeast which is the predominate wind direction. The elevation of the seabed surrounding the reef drops rapidly to a depth of approximately 50 m below Lowest Astronomical Tide (LAT). The windward edge of the reef is a continuous reef flat which is 200 to 300 m wide and uniform in elevation at approximately 0.1 m above LAT. This reef flat extends along not only the southeastern edge but wraps around both the southwestern and northeastern ends of the reef extending approximately three-fifths of the perimeter of the reef. The leeward edge of John Brewer is much less continuous, being composed of coral heads or "bommies", which reach just higher than LAT and are separated by sandy patches with depths of 10 to 20 m. Whereas the windward reef edge could be considered to be 100% solid reef, from aerial photographs, the leeward edge is estimated as being approximately 50% solid.

Figure 1. Location of experiment.

The lagoon of John Brewer is mostly sandy bottom and is interspersed with hundreds of medium to large sized bommies most of which remain under water at LAT. The lagoon can be separated into two categories based on depth. The deep lagoon occupies approximately 50% of the area of John Brewer and averages about 10 m in depth. A shallower lagoon provides a transition band of several hundred metres between the windward reef flat and the deep lagoon.

In comparison to reefs in most of the other sections of the GBR, John Brewer is relatively isolated from other reefs. However, being on the inner edge of the reef matrix means that John Brewer seldom receives direct wave energy from seaward of the GBR. The nearest reef in the windward directions (east to southeast) is Lodestone which is approximately 7 km southeast of John Brewer.

Figure 2. Instrument positions on John Brewer Reef.

A primary criterion in the design of the experiment involved selecting an experimental site that offered a simple geometry so that the physics of the problem could be more easily understood and also so that results from this site could be more easily transferred to other sites. With this in mind, a linear array was envisioned normal to the reef front and parallel to the predominate direction of the wind, which is from the southeasterly direction. It was anticipated that most of the wave attenuation would be caused by wave breaking and bottom friction over the several hundred metres of the relatively shallow reef flat. Therefore, it was decided to concentrate the wave measuring instruments in this zone.

DESCRIPTION OF THE INSTRUMENTS

A combined total of 18 wave, current, tide, and wind measuring instruments were deployed during the experiment. These were made up of two Waverider buoys, four surface piercing wave measuring staffs, six S4 current meters, four tide gauges, one pressure sensing wave gauge, and one anemometer. Since the purpose of this paper is to present wave attenuation data, only the wave measuring instruments will be discussed.

The two Waverider buoys were specially purchased for the experiment. They were imported from Datawell, The Netherlands and were calibrated in Sydney, before being flown to Townsville. Both the buoys were equipped with telemetry and the data signals were captured by a receiver located in the radio room of the Floating Hotel.

The wave measuring staffs used in the field experiment were first proposed by Zwarts (1974). Each staff was six metres long and consisted of two pipes, one inside the other, forming a coaxial cable. Three of the staffs were made of copper pipe, with diameters of 50 mm and 25 mm for the outer and inner pipes, respectively. Slots in the outer pipe allow the movement of water into the space between the outer and inner pipes. The fourth staff was made of aluminium and was of similar design to the copper staffs.

These wave staffs employ a principle commonly used in the telephone industry to detect the location of faults in coaxial cables. The set up of the pipes in a coaxial cable configuration acts as the tuning element of an electronic oscillator. The battery powered electronics located at the head of the pole direct an electromagnetic wave down the pole. This wave reflects off the discontinuity in the dielectric constant at the air-water interface. The length of the unimmersed section of the staff is directly proportional to the period of the oscillation of the electronic signal. The output of the system is a time series of the number of reflections of the electronic signal during a very small time interval.

A battery powered programmable data logger, developed at the Australian Defence Force Academy for the project, controlled the discrete time interval, the length of the time series, and the start of each time series, as well as stored the data. One logger serviced two wave staffs. Approximately 200 time series (100 from each of two staffs) could be stored.

Each of the staffs had to be calibrated so that the counts resulting from the data collection could be translated into water level. Static calibration tests were conducted several times during the design and testing of the loggers in addition to pre- and post-experiment tests. The results were always extraordinarily linear. That is, the recorded points fell on a straight line of water level vs reflection count with a high degree of accuracy. Also, for a given material (i.e. copper or aluminium) the slope of the plotted line was a constant. The slope did not change from one copper staff to another or from one test to another of the same staff. Therefore, the raw counts recorded by the logger could be reduced to water level through a highly accurate linear relationship.

Although the static calibration results are used to convert the instrument counts to water level, it is important to consider the errors that might affect the measurement of the more rapid movement of the water up and down the pole that will occur with waves. At the conclusion of the field work at John Brewer Reef, dynamic tests were conducted on one of the copper staffs. The testing set up was similar to the static tests. The staff was placed in a PVC tube and supported vertically, the tube was half filled with water, and the electronics connected to the logger and computer. But instead of lowering and raising the water level, the staff was moved vertically by the use of a cable and pulley system driven by a variable speed electric motor. An eccentric cam fitted to the flywheel of the motor caused the position of the water surface on the pole to follow a sinusoidal pattern when plotted against time. The response of the system was excellent, the difference between the sinusoidal input signal and the wave staff output was much less than 1%, even with conditions equivalent to wave periods of 1 s and with wave steepnesses near breaking.

Although the primary purpose of the wave staffs was to obtain wave data, tide data is available from the wave records by averaging over a time period much longer than the 3 to 7 seconds of the predominate wave periods. The water level information would give insight into the wave induced water level changes as well as the tide levels at which the wave records were taken.

EXPERIMENTAL SETUP

Figure 2 shows the experimental layout. The primary instruments of the experiment were the two Waverider buoys and the four wave staffs. The "outside" Waverider, WR1, was located approximately 500 m seaward of the reef front in a depth of 50 m. The four wave poles were aligned in a linear array normal to the reef front. The seaward most staff, ZP1, was 27 m from the reef front and staffs ZP2, ZP3, and ZP4 were located at intervals of 42 m, 49 m, and 50 m, respectively. The "inside" Waverider, WR2, was located in the middle of John Brewer lagoon, approximately 1.5 km from the reef edge and in a depth of 12 m.

The deployment of the wave staffs was a formidable task. Not only was the experimental site on the windward edge of the reef, but the site was 70 km from the mainland. Each wave staff was supported by an aluminium tower which was held in place by rope stays attached to metal fence posts that were driven into the reef flat by hand. The towers had to support the wave staffs and logger, but also had to allow access to the top for researcher and portable computer for downloading of data. Each tower was deployed separately during a two day trip. This one-at-a-time deployment allowed for alterations to the design, as the towers were designed especially for the project and the original design was untested. The position of ZP1 was in the breaker zone and this made it difficult to erect the tower, as well as keep it standing. This front tower was toppled during the first strong winds after its initial establishment. However, after re-deployment with extra stays and continual maintenance (the constant pounding of the waves tended to bend the anchor posts) the tower remained functional during the duration of the experiment. All four towers were erected and were well tested in operational conditions several weeks before the deployment of the wave staffs.

The outside Waverider was deployed in early March 1988. The rest of the instruments were deployed during the period of 12-15 August 1988. There were some initial difficulties with the wave poles and it was necessary to reprogramme the loggers and re-deploy the poles during 1-2 September 1988. The wave poles were removed on 15 October 1988. The Waverider buoys were left in position at the end of the main experiment and were removed on 11 July 1989.

DATA ANALYSIS AND RESULTS

A time series containing 2048 samples of water level at a discrete time interval of $\Delta t = 0.3906s$ was collected once an hour from both Waverider buoys. For the wave poles, a time series of water level with 4800 samples or 20 minutes at $\Delta t = 0.25s$ was collected each hour during the first five days of the experiment and every two hours for the rest of the experiment.

The data collection from the six primary instruments was a great success. More than 3000 individual time series were gathered from these main instruments. There were 286 times when all 6 instruments were operating and of these, 254 were when waves were approaching from the East to South directions for which the experiment was designed. Data were collected for a wide range of tide and wind conditions. We believe that this data set is the largest and most comprehensive ever collected in this environment.

Preliminary analysis for wave height attenuation has been completed on the large data set from the six primary wave measuring instruments. A frequency domain analysis was conducted by transforming the time series into frequency space using an FFT. Significant wave height was calculated as $H_{m_0} = 4.0\sqrt{m_0}$, where m_0 is the zeroth moment of the variance spectral density. A time domain analysis has also been conducted using a zero downcrossing technique, and the maximum wave height, H_{max} , was calculated for each wave record. Each of the time series and spectra were plotted. A twenty second time period surrounding the time of the maximum wave in each time series has also been plotted to aid in the discovery of bad data points.

Figures 3-5 contain plots of the time series of wind speed (Myrmidon Reef, see Figure 1), water level, and significant wave height, at three of the wave measuring stations (WR1, ZP4, and WR2) for 5-6 September 1988. During this period wind speed reached 10.8 m/s (21 knots) during a 2 m tidal range. The influence of the tide is apparent in the plots of H_{m_0} , except for the outside Waverider (WR1). At higher water levels, there is a noticeable reduction in H_{m_0} from the outside Waverider, WR1, through the inner most pole, ZP4, and into the inner Waverider, WR2. At lower water levels the reduction is more dramatic. This is certainly the expected result since all the mechanisms that will reduce wave height (reflection, refraction, wave breaking, and bottom friction) have a greater effect at lower water levels.

Figures 6-11 contain the plots of H_{m_0} vs water depth over the reef flat for WR1, ZP1, ZP2, ZP3, ZP4, and WR2, respectively. The plot (Figure 6) for the outside Waverider (WR1) shows no indication of a dependence of wave height on water level. It is not expected that tidal variations in the inter-reefal areas would significantly effect the wave results because these depths average 50 m and the maximum tidal range at John Brewer is less than 4 m. Therefore, any tidal effect on wave height at WR1 would have to result from the effect of other reefs upwind of John Brewer. There would be a lag between tide level and the effect at WR1 caused by the time the wave train took to travel the distance between reefs. However, studying the time series of tide, wind speed and wave height reveals no obvious trends. The lack of stationarity (the wind does not remain constant) complicates a rigorous statistical correlation analysis.

In contrast to Figure 6, Figures 7-11 all show a marked dependence of H_{m_0} on tide level. The envelope is well defined and reasonably linear, especially at lower water levels. Using the relationship, $H_{m_0} = \gamma d$, where d is the water depth over the reef flat and γ is the slope of the upper envelope of the H_{m_0} vs water level relationship, γ reduces from 0.7 at the outermost pole (ZP1) to 0.4 at the innermost pole (ZP4). These results are similar to results from laboratory experiments conducted by Horikawa and Kuo (1967) in which waves broke on the seaward edge of a horizontal shelf fronted by a sloping offshore bottom, a topography similar to that of a coral reef. Values of γ from their experiment decreased from 0.80 at the shelf edge (recall that ZP1 was 27 m in from the reef edge) to 0.35 to 0.40 landward along the shelf.

Figures 7 to 9 for ZP1, ZP2, and ZP3 show, that for water depths greater than 1.5 m, the larger waves do not reach the limiting value corresponding to the envelope determined for water depths less than 1.0 to 1.5 m. However at ZP4 (Figure 10) the larger waves at depths greater than 1.5 m do approach the same limiting envelope as determined for smaller depths. This behaviour suggests that width of the surf zone may be extending past the location of ZP4 during more extreme conditions at higher tide

Figure 3. Wind Data, September 5-6 1988.

levels. Visual observations indicated that ZP4 was almost always free of wave breaking activity (especially at lower tide levels), but these observations did not include severe conditions at higher tide levels.

The analysis of the wave height data at WR2 is more complicated than at the wave staffs. Wave heights at WR2 were not limited by the depth at that instrument. Recall that WR2 was located in the middle of the reef lagoon in an average depth of 12 m. Wave heights at WR2 generally are smaller than at ZP4. This may be partially explained by the negative shoaling effect as the waves propagated from the shallow water over the reef flat into the deeper water in the lagoon. Also, although outside energy that reached WR2 was limited by the depth of water over the reef front, this outside energy will not necessarily be that which came past the wave staffs. Furthermore, observations while travelling by boat across the lagoon indicated that there could be significant wave growth during periods of high wind speed. Since the distance that locally generated waves travelled across the lagoon to WR2 varied with wind direction, the results shown in Figure 11 should be a function of local wind speed and direction, as well as water depth over the reef front. Although the upper envelope in Figure 11 is not as well defined as those shown in Figures 7-10, the depth of water over the reef flat is clearly an important control on the amount of wave energy reaching WR2. This conclusion is also strongly suggested in Figure 5, where, as previously mentioned, the wave height and water depth over the reef are strongly correlated.

For higher water levels at WR1, there is a trend for the larger waves to fall short of the linear extension of the envelope defined by the lower water levels. This is similar to the trend noted above for ZP1, ZP2, and ZP3. There is a temptation to suggest that using a linear trend, based on the lower water levels, to predict the larger significant wave heights might result in over-prediction. However, it is expected that the envelope would be more poorly defined at higher water levels, since there are fewer wave heights greater than the depth limiting condition as compared with the lower water levels, and (in the case of WR2) the wind speeds and directions for maximizing the wave height may not have been encountered during the experiment. Fortunately, data were collected outside the main experiment which help define the envelope for WR2 at higher water levels. Cyclone Aivu passed approximately 100 km to the south of John Brewer Reef on the morning of 4 April 1989. At 07:32 the high astronomical tide in Townsville was predicted to be 3.6 m, just 0.1 m short of highest astronomical tide. At 07:00 the largest significant wave heights, $H_{m0} = 2.89\text{m}$ and $H_{m0} = 1.65\text{m}$ were measured at WR1 and WR2, respectively. (The wave staffs were not deployed.) There were no water level measurements at John Brewer Reef, but using an estimate of 4.0 m (adding cyclone induced water levels to the astronomical tide) for the depth of water over the reef front, $\gamma \approx 1.65/4.0 = 0.41$, which agrees well with the estimate of $\gamma = 0.4$ taken from the lower portion of Figure 11.

Plots of H_{\max} vs d for all six wave measuring instruments are shown in Figures 12 to 17. Since the maximum wave height is a single wave as opposed to the significant wave height which characterises the whole of the wave field, the upper envelope of the plots of H_{\max} vs d are not as well defined as those of H_{m0} vs d (all records with values of the ratio of H_{\max} to H_{m0} greater than 2.0 were checked for bad data points). Still, as expected, the dependence on depth is clear for the four wave poles (Figures 13-16) and WR2 (Figure 17). Again there is no apparent dependence of H_{\max} on depth over the reef flat for WR1 (Figure 12).

The ratio of maximum wave height to water depth, (γ_{\max} , reduced from approximately 1.1 at ZP1 to between 0.6 and 0.8 at ZP4. As with significant wave height, the results for WR2 are less linear and not as well defined as for the wave staffs. The maximum wave height recorded at WR2 during cyclone Aivu was $H_{\max} = 2.33$ m at an estimated $d \approx 4.0$ m, which gives $\gamma_{\max} = 0.58$. This indicates that at higher water levels the results for γ_{\max} lie more closely on a linear extension of an estimate of $\gamma_{\max} = 0.6$ taken from the lower portion of Figure 17 than the plotted data would indicate. It should be noted that laboratory data for the maximum height of regular waves on horizontal or very flat bottoms, i.e. conditions similar to reef tops give a maximum value of $\gamma = 0.55$ (Nelson, 1985).

The results from WR2 must be used with caution for application to other locations. Although depth over the windward reef flat is clearly an important and perhaps the most important variable for wave heights inside the lagoon, other site specific variables will also play a role. The width of the reef flat will be important, as will the local wind speed, direction, and the length and depth of the fetch inside the lagoon.

FUTURE WORK

The analysis of the wave data has not been completed. For example, the effect of wave breaking on wave frequency is still to be investigated. As a final product, it is hoped to incorporate knowledge gained on the attenuation and transformation of waves on coral reefs into an improved spectral wave model for both inter- and intra-reefal regions. As the first step in this process the partitioning of the energy losses into the components of refraction, breaking, bottom friction, and reflection will be attempted.

Wave induced water levels and currents are important for both engineering and biological requirements. Observations at John Brewer reef indicate that wave induced currents could significantly affect the circulation in the reef lagoon. The current and water level data have not yet been analysed. However, as part of the overall study of wave and reef interaction, laboratory measurements of wave setup and wave generated currents across an idealised two dimensional reef have been completed and are being prepared for publication.

Another component of the overall research is the study of wave induced processes affecting coral cay formation and stability. The construction of a physical model of a planar coral reef with a cay has been completed in the University of Queensland wave basin. Experiments using this physical model to study the wave-induced water levels and currents on a three dimensional planar reef are on-going.

ACKNOWLEDGEMENTS

This research was sponsored by the Marine Science and Technologies Grant Scheme. The considerable help and support of the Australian Institute of Marine Science is gratefully acknowledged. Many people had a hand in the success of this field experiment. Volunteers at James Cook University, including Ian Dight, Lance Bode, and Lou Mason, have been essential especially in the deployment of the instruments. Two people who must be singled out as providing excellent and essential assistance throughout the experiment are Ray McAllister from the Australian Institute of Marine Science who designed, built, and was foreman for the erection of the towers, and Daryl Winterbottom from the Australian Defence Force Academy who designed and built the data loggers.

CHAPTER 26

APPLICATION OF LOGNORMAL TRUNCATED DISTRIBUTION TO PREDICTION OF LONG TERM SEA STATE USING VISUAL WAVE HEIGHT DATA.

Angel González¹ Javier Martínez² Rafael Blázquez³

ABSTRACT

The purpose of this paper is to analyze the behaviour of the lognormal distribution function in wave studies, when visual observations are used to predict the long term wave height distribution.

We are focused our attention on the problem of visual biased samples. For this kind of data the lognormal model does not fit accurately the sample leading to wrong extrapolations.

One possible solution to avoid this problem is to consider the sample as truncated. According to this procedure the distribution function is estimated based only on data higher than the point of truncation.

1.-INTRODUCTION

It is well known that the knowledge of wave parameters, mainly the wave height, is indispensable to carry out projects in maritime engineering, that is the reason why at the present most of the developed countries are trying to improve their measuring networks.

The very best state would be to have a great deal of recorded wave data concerning the area of each particular study, but unfortunately the fact of the matter is that in many cases instrumental data either are not available or do not exist at all, and it is necessary to use other sources of wave data.

2-CENTRO DE E. DE PUERTOS Y COSTAS, CEDEX, Madrid, Spain.
3-INSTITUTO EDUARDO TORROJA, CSIC, Madrid, Spain.

Sources of wave data may be considered under the three groups: instrumental, hindcast and visual data.

Instrumental data usually come from wave buoys records and they are preferred because of their reliability and quality, but among their shortcomings are the reduced area of coverage and the limited availability which is often due to commercial restrictions.

The hindcast wave data can be obtained from wind field analysis. Wave heights are estimated from knowledge of the wind speed and fetch, covering large areas. On the other hand hindcasting methods are not very accurate.

The third source is visual data. Visual observations provide additional information about wave parameters, for instance wave direction, and also cover large sea areas. The reliability of visual data has been fully criticized for different reasons. In this paper we are focused our attention on the problem of visual biased samples.

2.-STATEMENT OF PROBLEM

Visual data usually come from ship reports, that is why an important part of them are concentrating on the main shipping routs.

These data bring up some shortcomings due to the observation itself:

- Wave heights reported in adverse climatic conditions tend to be overestimated by the observer (Jardine,1979).

- More ships sail in good weather conditions consequently samples are biased towards lower wave height values.

The result is that these samples lead to wrong extrapolations of the long term wave height distribution when the observations reported as calms are included in the sample.

3.-METHODOLOGY

3.1.-Fundamentals

Since the lognormal distribution function is by

and large considered appropriate for wave studies, Jasper (1956), Darbyshire (1956), Khanna and Andru (1974), the cumulative distribution function (CDF) corresponding to the sample we are dealing with (figure 1) has been plotted in the lognormal probability paper (figure 2).

Figure 1

Figure 2

It can be seen that, when the calms are included in the sample, a simple straight line does not fit the points accurately enough.

One possible solution to overcome this problem is to consider the sample as truncated in order to get rid of those data causing a biased sample.

A variable may be such it appears to be lognormal except in that part of the distribution for which the values of the variable either can not occur or are not observed. The distribution of such a variable is said to be incomplete or, more commonly, truncated.

The resulting distribution might then have a shape like figure 3 shows, if the distribution of the original population was lognormal.

Figure 3

In this case the members of the population below γ have been eliminated. Below γ point there are no values of random variable, and their probabilities are removed.

Censored distributions differ slightly in application in that the total population is present but the exact frequencies are known only up to (or beyond) a certain value.

In these cases the distribution is assumed to

have the probability below (or above) γ lumped at that γ point. (See figure 4).

Figure 4

The distribution between truncation and censorship arises from the fact that in the first, the available information is confined to the range (γ, ∞) , whereas in the second a limited knowledge of the variable in the range $(0, \gamma)$ permits consideration of the complete range $(0, \infty)$, (Benjamin, 1981).

In practice truncated samples arise with several types of experimental data in which recorded measurements are available over only a partial range of the variable.

In our case the random variable is the visual wave height and the point of truncation does not physically exist. Obviously there are wave heights below the point of truncation and the low wave heights, even calms, occur in Nature.

Strictly speaking we are dealing with a lower bound censored distribution in which probabilities below a certain value are unreliable. However, if the distribution is considered as truncated and we assume that the point of truncation is known, the problem becomes mathematically tractable.

So, a correct value for the point of truncation has to be chosen and the distribution function will be estimated based only on data higher than the point of truncation.

3.2.-Procedural steps

Figure 5 shows the shape of both untruncated and truncated lognormal density functions.

Figure 5

The truncated probability density function only exists above γ point, and obviously its area must equal one, so the PDF is zero up to γ and K times the untruncated probability density function above that point.

Thus, if the original population has a lognormal PDF :

$$f(x) = \frac{1}{x B \sqrt{2\pi}} e^{-1/2 \left(\frac{\ln x - A}{B} \right)^2}$$

then, the truncated PDF may be written as

$$f_t(x) = 0 \quad , \quad x < \gamma$$

$$f_t(x) = K f(x) \quad , \quad x \geq \gamma$$

The probability axiom

$$\int_{\gamma}^{\infty} f(x) dx = 1$$

leads to

$$K = \frac{1}{1 - F(\gamma)}$$

where $F(\gamma)$ is de CDF value at γ point.

Although in principle it would be possible to apply the method of moments to estimate A and B parameters there seems to be no easy way of solving the resulting equations for the first and second sample moments.

Therefore the method of maximun likelihood is a good choice to obtain the estimators of those parameters.

A technique frequently appropriate in maximun likelihood estimation problems is to find the maximun of the loglikelihood function. If the sample is $x_1, x_2, x_3, \dots, x_n$ then the likelihood function of the sample is

$$V = f(x_1) f(x_2) \dots f(x_n) = \prod_{i=1}^n \frac{1}{x_i B \sqrt{2\pi}} e^{-1/2 \left(\frac{\ln x_i - A}{B} \right)^2} \frac{1}{1 - F(\gamma)}$$

and so the loglikelihood function may be written

$$L = \ln V =$$

$$= \sum \ln \left[\frac{1}{x_i B \sqrt{2\pi}} e^{-1/2 \left(\frac{\ln x_i - A}{B} \right)^2} \frac{1}{1 - F(\gamma)} \right]$$

The derivatives with respect to the parameters when set equal to zero, permit to obtain A and B by means of a function which was tabulated by Hald, (Aitchison and Brown, 1957).

4.-APPLICATION OF PROPOSED METHODOLOGY

The application of the truncation method has been carried out using a sample of visual data from the National Climatic Center (Asheville, North Carolina, USA).

The sample concerns the Spanish northern coast, in the Bay of Biscay near Bilbao, exactly from 43.3° to 44.0° North and from 2.5° to 3.5° West.

Figure 6 shows the exact location where the sample was obtained.

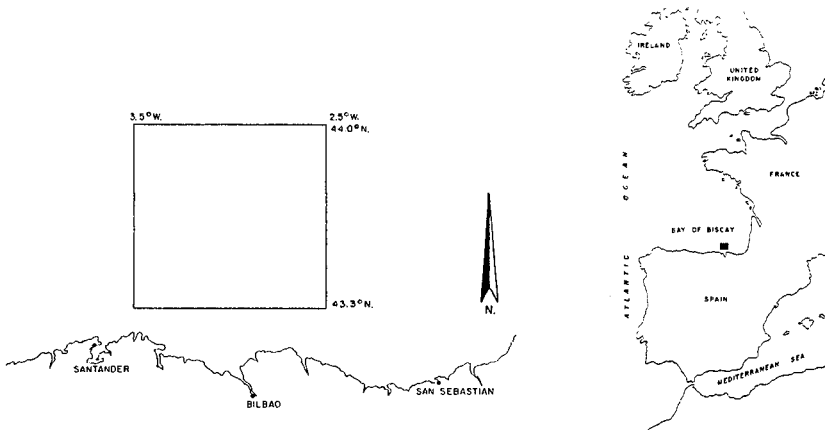

Figure 6

This sample has 572 valid observations and 277 calms. In the histogram (figure 7) the calms are not included and it can be seen how it takes a lognormal distribution shape.

The lowest range of the variable has 53 observations, when the calms are not included, and its probability is almost 0.1, exactly 0.09.

Subsequently the calms have been included in the sample and the cumulative frequencies have been plotted in the lognormal probability paper (Figure 8).

Figure 8

This drawing shows that the probability of the lowest range of the variable is almost 0.4 whereas it hardly was 0.1 when the calms were not included.

At this moment we should consider if the sample is either biased or unbiased. In the second case, there is no problem to include the calms in the lowest range of the variable, but if the sample is biased, as it happens in our present case, a standard fitting of cumulative distribution shows that the straight line does not fit the data points very accurately (see figure 8).

The methodology has been carried out by choosing two different points of truncation, $\gamma = 0.1$ m and $\gamma = 0.5$ m.

In the figure 9 we can see how both truncated distributions are very close whereas the untruncated is quite different.

Figure 9

The prediction given by then show how the truncated distributions are in good agreement. Table I represents wave heights versus cumulative probabilities.

TABLE I

Hv(m)	Probability		
	I	II	III
1.5	0.33	0.41	0.67
2.0	0.52	0.59	0.79
2.5	0.67	0.72	0.86
3.0	0.90	0.91	0.92

\ /
good agreement

5. -GOODNESS OF THE METHOD

In spite of the fact that instrumental data are unbiased, a sample collected by a wave buoy has been truncated at the point $\delta = 0.5$ m in order to test the goodness of the truncated distribution.

So, all the data up to 0.5 m have been removed and the truncation method has been applied.

Thus, we have two populations, the original untruncated sample and the truncated sample in which data below 0.5 m have been removed.

The result is that both, truncated and untruncated CDF's are very close. (See figure 10).

Figure 10

Consequently both of them lead to similar predictions (see Table II).

TABLE II

Hv(m)	Probability	
	Truncated	Untruncated
1.5	0.57	0.64
2.0	0.75	0.80
2.5	0.85	0.88
3.0	0.92	0.93

6.-CONCLUSIONS

1.-In many cases visual wave samples are biased towards lower height values.

2.-The lognormal model, which is usually appropriate for wave studies, does not fit accurately the sample when the calms are included.

3.-For visual wave data the truncation method improves current procedures and avoids wrong extrapolations from observations below the point of truncation.

4.-For instrumental wave data predictions of CDF's of wave heights of both, truncated and untruncated samples, are in good agreement.

5.-The method reported herein is consistent and permits a more effective and accurate use of available visual wave data for coastal and harbour engineering projects.

CHAPTER 27

EXTREME WAVES AND WAVE COUNTS IN A HURRICANE

Rodney J. Sobey¹, Bruce D. Chandler² and Bruce A. Harper³

Abstract

Estimates of wave conditions within a storm event must recognize the variability of wave conditions during the storm and not just the peak conditions. A methodology is presented for the estimation of the probability distribution of the maximum wave in a storm event and the wave count in the same storm event. The predictions are compared with field observations of wave conditions in tropical cyclones from Australia's North West Shelf.

1. INTRODUCTION

The spatial and temporal complexity of wave conditions within a hurricane must be succinctly summarized for the benefit of designers of offshore structures. Conventional limit design is commonly based on a characterization of the wave climate in terms of the maximum wave height and the associated period, whereas fatigue analysis utilizes a wave count distribution.

The classical analysis of wave record statistics involves an explicit assumption that the typical 20 minute wave record is one realization of a stationary stochastic process. Analysis leads to a prediction of the probability density function for the maximum wave in the record, whose mean value is highly sensitive to both the intensity of the sea state and the duration adopted for comparative purposes (e.g. 20 minutes or 3 hours or whatever).

In a storm event however, the sea state is not a stationary stochastic process. Reasonable estimates of maximum wave conditions and wave counts must recognize the slowly-varying evolution of the sea state. Attention must also be given to the restrictions imposed by gravitational instability, especially in

¹Professor of Civil Engineering, University of California, Berkeley, CA 94720, USA

²Riedel & Byrne Consulting Engineers P/L, Mount Lawley, W.A. 6050, Australia

³Senior Ocean Engineer, Woodside Offshore Petroleum P/L, Perth, W.A. 6000, Australia

regard to estimates of maximum wave conditions which likely approach limiting conditions.

A methodology is presented for the estimation of the probability distribution of the maximum wave in a storm event and the wave count in the same storm event. The predictions are compared with field observations of wave conditions in tropical cyclones from Australia's North West Shelf.

2. WAVE OBSERVATIONS DURING TROPICAL CYCLONES

Tropical cyclone (or hurricane or typhoon) conditions are extreme and mercifully infrequent. The intensity is often maintained over a relatively large time and spatial scale and large wave conditions are experienced even at sites relatively distant from the storm track. The available data base of wave observations during hurricane conditions is not extensive. This is a consequence of the rarity of the meteorological event and the erratic nature of storm paths, together with the instrument survival threat posed by such extreme conditions when they do materialize.

In many cases, the measured record includes only a handful of standard 20 minute records during the life of the storm, which generally extends over several days. Where the record is relatively comprehensive, it is often a distant or minor storm. Among the most comprehensive records available are those collected by Woodside Offshore Petroleum on Australia's North West Shelf. The better records are not especially extreme when measured against the brief segment recorded during the infamous Hurricane Camille. They nonetheless loom large in the local wave climate on the North West Shelf and are sufficiently large to characterize expected response patterns.

Wave data from Tropical Cyclone Victor is representative of North West Shelf conditions. TC Victor in early March 1986 reached a minimum central pressure of 930 mb and the storm track was 200 km from the North Rankin data site at closest approach. The standard measuring program of 20-minute records every 6 hours was increased to continuous recording for over two days during the closest approach of the storm. Despite some small data loss, the overall record is comprehensive and provides an excellent illustration of the wave conditions at the North Rankin site during the storm. The water depth at the data site is 125 m, essentially deep water for the measured wave conditions.

The mean rms wave height H_{rms} evolution of the separate 20-minute records is shown in Figure 1. The evolution in the wave height follows the hydrograph pattern of river elevations or flows during flood (i.e. storm) conditions. There is a rapidly rising limb towards a peak, followed by a rather more slowly falling limb to ambient conditions.

There is no such clear trend in the mean zero-up-crossing period τ_z evolution of the separate 20-minute records, which is shown in Figure 2. Also included on Figure 2 are the one standard deviation error bands, which are relatively wide. The change in period during the storm is apparently quite small, which conflicts with the expectation of wind-generated waves in more uniform wind conditions. This somewhat unexpected feature of wave conditions in

hurricanes had previously been noted (Sobey and Young 1986) in the context of peak period. It is also predicted by the Sobey and Young discrete spectral model of wind wave generation in hurricanes.

3. PREDICTIVE CAPABILITY OF RAYLEIGH THEORY FOR STATIONARY RECORDS

Before attempting to accommodate time-varying wave conditions in an analysis of extreme waves and wave counts, it is useful to review the predictive capability of existing approaches to the prediction of extreme waves and wave counts in stationary sea states.

The familiar approach follows Longuet-Higgins (1952) in representing the probability distribution of wave heights within a stationary sea state by the Rayleigh distribution, with probability density function (PDF) and cumulative distribution function (CDF) respectively as

$$\begin{aligned} f(R) &= 2Re^{-R^2} \\ F(R) &= 1 - e^{-R^2} \end{aligned} \quad (3.1)$$

where $R = H/2(2m_0)^{1/2}$ is the normalized wave height. Comparisons of field data provide reasonable visual support for this distribution for near-average wave conditions, with the data being sparse and scattered for the more extreme waves.

The wave count, the number of waves n in a stationary record of N waves whose height equals or exceeds a given height, is related to the exceedence probability as

FIGURE 1
Rms wave height evolution in TC Victor during March 1986.

FIGURE 2
Zero-up-crossing period evolution in TC Victor during March 1986.

$$n(R) = N[1 - F(R)] \quad (3.2)$$

The present writers are not aware of any published comparisons of this wave count distribution with field data. Its reliance however on the Rayleigh distribution leads to the expectation that there would be reasonable visual support for near-average waves with a wider scatter for more extreme waves.

Assuming that consecutive waves are independent, the CDF for the maximum wave in a stationary record of N waves is (Longuet-Higgins 1952)

$$F_{\max}(R) = F^N(R) \quad (3.3a)$$

The PDF for the maximum wave in a stationary record of N waves is then

$$f_{\max}(R) = \frac{d}{dR} F_{\max}(R) = Nf(R)F^{N-1}(R) \quad (3.3b)$$

where $f(R)$ and $F(R)$ are the PDF and CDF for individual wave heights in the record. This distribution for the maximum wave in a stationary record of N waves is strongly dependent on N , as shown in Figure 3 for N values from 10 to 1000, a value of 100 being typical of a 20-minute record. The distribution remains relatively wide for all wave counts in the expected range. The Rayleigh distribution has been included in Figure 3 for perspective.

Evaluation of this prediction with field data is complicated by the sparse data set that is available, each 20-minute data set for example yielding only a single observation for wave counts of order 100. Estimates of the distribution are not available and observations of the maximum wave can only be compared with the mean of the distribution, estimated as (Longuet-Higgins 1952)

FIGURE 3
Rayleigh-theory predictions of maximum wave in N waves.

$$\bar{R}_{\max} = \int_0^{\infty} r f_{\max}(r) dr \approx \ln^{1/2} N + \frac{\gamma}{2} \ln^{-1/2} N \quad (3.4)$$

where γ is Euler's constant.

The predictive capacity of Equations 3.3 and 3.4 was evaluated from the TC Victor data set introduced as Figures 1 and 2. Each of the separate 20-minute records was considered as representative of a stationary sea state. The theoretical estimate of the expected value of H_{\max} for each segment was computed from Equation 3.4 and the Rayleigh distribution, using the measured H_{rms} and N . This was compared with the measured H_{\max} in Figure 4. Although the distribution of H_{\max} is relatively wide, the TC Victor data base nonetheless identifies a systematic overprediction of order 10% by the "Rayleigh" theory.

As this systematic overprediction would likely feed through to predictions of extreme waves in a complete storm, alternatives to the Rayleigh distribution were reviewed. Field observations of amplitude distributions in intense seas have been represented as the empirical Weibull distribution

$$F(\rho; \alpha, \beta) = 1 - \exp\left(-\frac{8}{\beta} \rho^{\alpha}\right) \quad (3.5)$$

where $\rho = H/H_{\text{rms}}$ and H_{rms} , α and β are the parameters defining the distribution. α and β parameter values of 2 and 8 respectively retrieve the Rayleigh distribution. Forristall (1978) estimates 2.13 and 8.42 from Gulf of Mexico data and Krogstad (1985) typically estimates 2.38 and 12.9 from North

FIGURE 4

Comparison of Rayleigh-theory predictions of maximum wave in N waves and measurements for stationary 20-minute record segments from TC Victor.

Atlantic data. Interestingly, these empirical distributions bracket the Rayleigh distribution in the high amplitude tail, the Forristall distribution predicting a lower probability for the higher waves in the sea state and the Krogstad distribution a higher probability. These distributions are based on theoretical arguments or data that are biased towards average conditions in an albeit intense sea state. Confidence levels in the tail are not especially high, although it is the region of potentially major concern in consideration of maximum wave conditions in a storm. Estimates of the PDF for the maximum wave in N waves follow directly from Equation 3.3b and are compared with the "Rayleigh" estimate in Figure 5. As expected, they bracket the Rayleigh estimate. An estimate based on the Krogstad distribution would increase the overprediction to approximately 20%. An estimate based on the Forristall distribution would marginally decrease the overprediction but not significantly.

Also included on Figure 5 is an estimate based on a tabulated $f(R)$ established by Sobey (1990). This estimate is based on a mean Jonswap spectrum and was established by simulation of one hundred separate realizations of wave sequences, each containing in excess of one thousand waves. This methodology gives reasonable recognition to the more extreme waves in the stationary sea state. The tabulated $f(R)$ used together with Equation 3.3 still appears to predict high, though it does come rather closer to the TC Victor than any of the other predictors.

4. A SLOWLY-VARYING SEA STATE

Wave conditions in a stationary sea state may be characterized by the probability distribution of wave amplitudes, represented by either the probability density function $f(a)$ or the cumulative distribution function $F(a)$, where $a = H/2$ is the wave amplitude and H is the wave height. In a slowly-varying seas state, this distribution can be expected to vary slowly with time, the cumulative distribution function, for example, becoming $F(a;t)$.

Within a short interval of time Δt , the wave count is $\Delta t/\tau_z(t)$ where $\tau_z(t)$ is the mean zero-crossing period in the short interval. Under the assumption (Longuet-Higgins 1952) that consecutive wave in the interval are independent, the cumulative distribution function for the maximum wave amplitude in the interval is

$$F_{\max}(a;t) = [F(a;t)]^{\Delta t/\tau_z(t)} \tag{4.1}$$

A storm event from time A to time B may be characterized as J consecutive intervals of duration Δt_j centered at time t_j such that

$$B - A = \sum_{j=1}^J \Delta t_j = \int_A^B dt \tag{4.2}$$

FIGURE 5
Alternative predictions of PDF for maximum wave in 100 waves.

If wave conditions between consecutive intervals remain independent, then the cumulative distribution function for the maximum wave in the storm event is (Borgman 1970)

$$\begin{aligned} F_{\max}(a) &= [F(a; t_1)]^{\Delta t_1/\tau_z(t_1)} [F(a; t_2)]^{\Delta t_2/\tau_z(t_2)} \dots [F(a; t_j)]^{\Delta t_j/\tau_z(t_j)} \\ &= \exp \int_A^B \frac{1}{\tau_z(t)} \ln F(a; t) dt \end{aligned} \quad (4.3)$$

The wave count distribution with amplitude within a storm event will be termed $n(a)$ to distinguish it from the total mean wave count N within the storm event. The number of waves in the short interval Δt that exceed a is

$$\Delta n(a) = [1 - F(a; t)] \frac{\Delta t}{\tau_z(t)} \quad (4.4)$$

For a storm of duration $B - A$, again characterized as J consecutive intervals of duration Δt_j centered at time t_j , the number of waves in the complete storm that exceed a is

$$\begin{aligned} n(a) &= \Delta n_1(a) + \Delta n_2(a) + \dots \Delta n_j(a) \\ &= \int_A^B \frac{1}{\tau_z(t)} [1 - F(a; t)] dt \end{aligned} \quad (4.5)$$

where it has again been assumed that wave conditions between consecutive intervals remain independent.

The time history of the local zero-crossing period and the local cumulative distribution function remains to be specified.

5. PARAMETERIZATION OF SEA STATE IN A STORM EVENT

Statistical summaries (such as significant wave height and zero-crossing period) of measured wave conditions at a fixed site during a storm event typically display the familiar "hydrograph" shape from surface water hydrology. This is especially true of significant wave height and the equivalent rms amplitude. There is a base wave amplitude (analogous to the base flow in surface water hydrology) that is sustained at a reasonably constant level well before and after the storm event. The storm hydrograph itself has the familiar asymmetric rising and falling limbs. In some cases, the time scale of the falling limb is significantly longer than the rising limb but in other cases it is more nearly equal. Storm duration above the base level may range from several hours to several days. The zero-crossing period might be expected to follow a similar trend, although the variation would be much less dramatic. Figures 1 and 2 provide examples of measured hydrographs during TC Victor.

A suitable schematic form for these hydrographs would be

$$q(t) = q_b + \frac{1}{2}(q_p - q_b) \left[1 + \cos\left(2\pi \frac{t - t_p}{4\tau_*}\right) \right] \tag{5.1}$$

where q represent either the local rms wave amplitude $a_{rms}(t)$ or the local zero-crossing period $\tau_z(t)$. The subscripts b and p identify the base and peak hydrograph levels respectively, t_p is the time of the hydrograph peak and τ_* is the half life of the hydrograph, as sketched in Figure 6. Separate half lives of the rising and falling limbs (τ_1 and τ_2) are defined such that the storm event extend from time $t_p - 2\tau_1$ to time $t_p + 2\tau_2$. The finite duration of the storm event is a significant feature in defining the expected maximum wave conditions. A truncated Gaussian form would be equally appropriate.

The adopted form for the local cumulative distribution function has been based on the review of predictive capabilities for extreme waves in stationary conditions, summarized in Figure 4 and 5. It is apparent from these figures that all of the viable alternatives resulted in overprediction of the maximum wave in a typical 20-minute record. The tabulated distribution of Sobey (1990) gave the best agreement with measured data and has been used in the present analysis. It must be anticipated that the overprediction apparent in the stationary sea state analysis will be at least equally apparent in the slowly-varying sea state analysis.

Finally, in recognition of the upper bound imposed by gravitational instability, an empirical modification to the probability distribution was introduced to restrict the maximum wave conditions to the limit wave. The adopted local cumulative distribution function is

$$F(\rho) = \begin{cases} F'(\rho) & \text{for } \rho < \rho_m \\ 1 & \text{for } \rho \geq \rho_m \end{cases} \tag{5.3}$$

FIGURE 6
Schematic storm hydrograph.

where $F'(\rho)$ is the tabulated CDF for a stationary sea state and $\rho_m = H_m/(2a_{rms})$, H_m being the limit wave height appropriate for the local wave period, water depth and current. This expedient has the additional benefit of limiting the significance of the tail to the local population distribution.

The limit wave height has been defined by interpolation from the Williams (1985) tables. This limit wave cutoff should have only marginal influence on the wave count and will likely influence the maximum wave distribution only near the hydrograph peak of the more intense storms.

6. WAVE CONDITIONS IN A HURRICANE

In application to tropical cyclones or hurricanes on Australia's North West Shelf, it was noted in Figure 2 that measured time histories of zero-crossing periods did not change significantly during the storm. Accordingly, the zero-crossing period was assumed to be constant for the duration of the storm. With the rms wave amplitude following the cosine hydrograph, the standard deviate of the local probability distribution becomes

$$\rho(t) = \frac{A}{B + \frac{1}{2}(1-B)(1 - \cos s)} \quad (6.1)$$

where $A = a/a_p$, $B = a_b/a_p$ and $s = 2\pi(t - t_p)/4\tau_*$.

The cumulative distribution function for the maximum wave in the storm then becomes

$$F_{\max}(A) = \exp\left[\frac{N}{\pi}\Phi(A, B, \alpha, \beta, A_m)\right] \quad (6.2)$$

where N is the mean wave count in the complete storm, $A_m = (H_m/2)/a_p$ and Φ is the dimensionless definite integral

$$\Phi = \int_0^\pi \ln F(s; A, B, \alpha, \beta, A_m) ds \quad (6.3)$$

In like manner, the wave count becomes

$$n(A) = \frac{N}{\pi}\Psi(A, B, \alpha, \beta, A_m) \quad (6.4)$$

where Ψ is the dimensionless definite integral

$$\Psi = \int_0^\pi [1 - F(s; A, B, \alpha, \beta, A_m)] ds \quad (6.5)$$

Both integrals were evaluated numerically.

7. COMPARISONS WITH FIELD DATA

Tropical cyclone Victor in February-March 1986 was a reasonably intense storm, having a minimum central pressure of 930 mb. The peak and base rms wave heights were 3.16 m and 0.70 m respectively and the mean wave count in the hydrograph was 62000. The predicted probability density function for the maximum wave in the storm is shown in Figure 7. The distribution is moderately wide. The maximum wave measured during the storm was 8.04 m, which corresponds to a H_{max}/H_p of 2.53. There is order of magnitude agreement between this prediction and the single measurement during TC Victor. It would appear however that the maximum wave in the storm is over-predicted by the theory, as was anticipated with the adoption of the tabulated CDF. The adoption of the Forristall, Rayleigh and Krogstad distributions for the CDF further widens the gap between theory and measurement. A similar trend resulted from the only other storm in the North Rankin data base (TC Ilona) with near-continuous records during the storm.

Figure 7 compares the measured and predicted wave count distributions. Agreement is good for the more frequent waves of average height but the trend at the more extreme wave heights is again over-predicted by the theory.

8. CONCLUSIONS

A methodology has been established for the prediction of the PDF for the maximum wave in a storm event. The maximum wave in the storm appears to

FIGURE 7
Predicted PDF for maximum wave in TC Victor.

FIGURE 8
Predicted and measured wave count in TC Victor.

be marginally over-predicted for hurricane waves on Australia's North West Shelf. Almost exactly the same systematic trend is identified in the prediction of the maximum wave in the (stationary) 20-minute record segments making up the complete data base.

A parallel methodology for the wave count in the same storm event provided good agreement with field data for average wave heights but again over-predicts at the more extreme waves.

CHAPTER 28

A PREDICTION MODEL OF IRREGULAR WAVE RUN-UP HEIGHT ON COASTAL STRUCTURES

Cheong-Ro Ryu¹ and Hong-Yoon Kang²

ABSTRACT

The characteristics of irregular wave run-up on coastal structures are discussed related with spectrum shape and grouping parameters of incident waves using the results of 200 cases of hydraulic model experiments. It is clarified that wave run-up is affected by the effects of the irregularity of incident waves and the slope configurations of structures.

A statistical model to estimate the run-up height from the incident wave properties is proposed considering 90 % confidence intervals. Also, the simple probability distribution model of irregular wave run-up height is developed and proved to be useful to the design of coastal structures.

1. INTRODUCTION

Irregular wave run-up is an important factor for the design of coastal structures. However, the published data on the irregular wave run-up are fairly limited and hardly applicable to the design (e.g., Bruun, 1985 ; Ahrens , 1988). It has been emphasized that the characteristics of run-up waves according to the wave grouping or spectrum shapes of the incident waves should be clarified, and there is necessity for developing a prediction model to estimate the irregular wave run-up height (e.g., Kobayashi and Cox, 1990).

In this study, the characteristics of irregular wave run-up on rough permeable coastal structures have been investigated through a series of model experiments to develop a statistical prediction model of irregular wave run-up height on the structures. Among the many governing factors on wave run-up, the effects of the irregularity of incident wave and the slope configurations of structures are studied and discussed in priority in order to improve the predictive capability of the model. To verify the applicability of the model,

¹ Visiting Prof., Dept. of Civil Engineering, University of Delaware, Newark, DE 19716, USA

Professor, Dept. of Ocean Engineering, National Fisheries University of Pusan, Pusan 608-737, KOREA

² Research Associate, Dept. of Ocean Engineering, National Fisheries University of Pusan, Pusan 608-737, KOREA

some comparative discussions are made using some reported experimental data and / or some conventional formulas for run-up height estimation.

MODEL EXPERIMENTS AND DATA ANALYSIS

Important governing parameters on wave run-up related with irregularity of ocean waves can be summarized as follows with conventionally considered parameters in equation(2).

$$\frac{R_{u1/n}}{H_{1/n}} = f \{ \overline{j(\cdot)}, Q_p(\varepsilon), \xi_{1/n}, \dots \} \quad (1)$$

$$\frac{R_u}{H} = f \{ h_c/h_o, h_o/L_o, d/l_a, H/h_o, \theta(\text{slope type}), k, i, \dots \} \quad (2)$$

where, R_u is the run-up height, H the incident wave height, $\overline{j(\cdot)}$ the mean run-length of a wave group, Q_p the spectrum peakedness parameter, ε the spectrum width parameter, ξ the surf similarity parameter, subscript $1/n$ means the $1/n$ significant value, h_c/h_o relative crest height, h_o/L_o relative water depth, d/l_a relative roughness, θ the slope angle, k the permeability, i the sea bottom slope.

Assuming the conditions of permeable deep-water breakwater, infinite crest height, constant roughness, and bottom slope $i = 1/40$, a series of model experiments are carried out to discuss only the effects of eq.(1) and slope type. In the experiments, A 2-dimensional wave flume with 30m length, 0.7m width and 0.95m height is used. A separator in the middle of the wave flume is set up in order to measure both the incident and run-up waves simultaneously as shown in Fig. 1. The incident wave height is measured by a capacitance type wave gauge, and the run-up height is measured by the run-up measuring gauge which is set along the surface of structure slope. Model structures which are made up of core and revetment layer have the uniform slopes of $1/3$, $1/2$, and $1/1.5$ and composite slope. Irregular waves are simulated by the impulse response function method. Using 3 kinds of Pierson-Moskowitz spectrum and 3 kinds of Neuman spectrum with different peak frequencies f_p , 200 cases of experiments with variation of the power level of wave generator are carried out. More details on experimental conditions are described in Ryu and Sawaragi(1986).

The flow for analyzing the statistical characteristics of both incident and run-up waves is shown in Fig.2. Individual incident and run-up waves are defined by zero-upcrossing method. The data of incident waves and run-up waves recorded in an analog data recorder were digitized at 0.05 sec interval for 20 minutes by the A-D transducer and are analyzed by the wave by wave and the spectral analysis method. The real time comparative analysis between the incident and the run-up waves was also applied for the analysis of grouping characteristics of irregular wave run-up.

STATISTICAL CHARACTERISTICS OF THE INCIDENT WAVES

The characteristics of the spectral shape, the statistical wave height/ period distributions and wave grouping properties used

Fig.1. Layout of test flume and model structure.

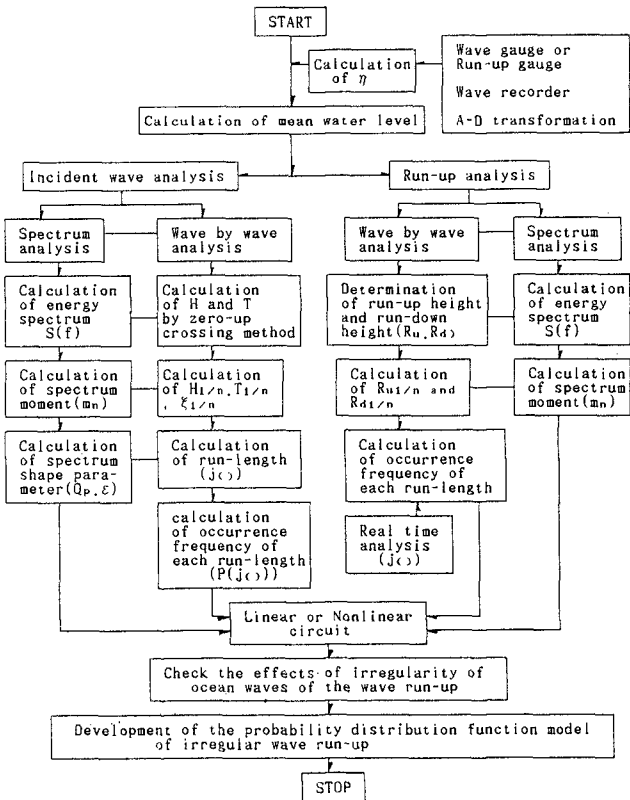

Fig.2. Flow for the analysis of incident and run-up waves.

in the experiments were compared with those of random ocean waves for the reliability of the study.

Wave height and period are very important factors in wave-structure interaction such as wave run-up. An example of the joint distribution of relative wave height (H/\bar{H}) and period (T/\bar{T}) of experimental waves is shown in Fig. 3. In the figure it can be seen that wave period (T/\bar{T}) increases with the increase of wave height in the smaller waves ($H < \bar{H}$), but wave periods are distributed around $T/\bar{T} = 1.1$ in the wave field higher than arbitrary critical value ($H > \bar{H}$). Therefore, the relations among the representative wave periods can be expressed as follows:

$$T_{1/3} \cong T_{1/10} \cong T_{\max}$$

It is identified from the above results that joint distribution of wave height and period has a good agreement with the analyzed results of field data by Goda(1985). In other words, it can be stated that the simulated irregular waves used in model tests represent random ocean waves fairly well.

Fig. 4 shows the distribution of spectral peakedness parameter Q_p by means of the irregular wave data used in model tests compared with field data at Utsira. It can be understood from the figure that most of ocean waves exist mainly in the range of spectral peakedness parameter $1.0 \leq Q_p \leq 3.0$ and that the distribution of Q_p from model tests is also satisfactorily simulated compared with irregular waves in the ocean. Where Q_p have been defined as following equation by Goda (1985).

$$Q_p = \frac{2}{m_0^2} \int_0^{\infty} f S^2(f) df$$

where the spectral moments is

$$m_n = \int_0^{\infty} f^n S(f) df$$

f the frequency, $S(f)$ the energy density of the frequency f .

RUN-UP CHARACTERISTICS OF IRREGULAR WAVES

Grouping Characteristics of Run-up Waves

The grouping characteristics of run-up waves related with the incident wave grouping is important for the stability analysis of rubble mound structures and overtopping control measures on the design of coastal structures (Ryu and Sawaragi, 1986).

One typical example of time histories of incident waves and their corresponding run-up waves is phenomenally shown to examine the cross-correlation in Fig. 5. In the experiment, both incident wave data and run-up wave data are obtained at the same time. In the figure, it can be known that the higher run-up wave groups appear under the the higher incident wave groups attack on steep slopes.

Fig.3. Joint distribution of wave height(H/\bar{H}) and wave period(T/\bar{T}).

Fig.4. Occurrence probability $P(Q_p)$ of spectral peakedness parameter Q_p .

Fig.5. Time histories of incident and run-up waves.

Fig.6. Relations between the run-lengths of higher incident waves ($j_{\bar{H}}$) and those of run-up waves ($j_{\bar{R}u}$).

Where the number inside the circle indicates the run-length.

Fig. 6 shows some examples of the analyzed results for 3 different cases of Q_p by the real time analysis technique. In the figure, it is shown that the run-lengths of run-up waves ($\overline{j_{R_u}}$) exceeding mean run-up height $\overline{R_u}$ are nearly the same or a little larger than those of incident waves ($\overline{j_H}$) exceeding mean wave height \overline{H} . This means that foregoing broken waves or back washes do not affect so much on the motion of following waves on steep, permeable and rough slopes contrary to the results on gentle slopes (Sawaragi and Iwata, 1984).

The Effects of the Irregularity of Ocean Waves on the Wave Run-up

Fig.7 shows the relative run-up heights of irregular waves according to spectrum shape parameters Q_p and ϵ , respectively. It can be understood from the figure that the statistical run-up height becomes larger with the decrease of spectral peakedness parameter Q_p and with the increase of spectral width parameter ϵ as the corresponding tendency with the above illustrated Q_p . This tendency is more remarkable in higher run-up heights ($R_{u1/10} / H_{1/3}$, $R_{u1/3} / H_{1/3}$) than in mean run-up height ($\overline{R_u} / H_{1/3}$).

The results of this study are similar to those of Van Oorschot and D'Angremond(1968) on steep slopes but opposite to those of Mase et al.(1983) on gentle slopes. Therefore, it can be stated that the characteristics of wave run-up heights due to spectrum shapes reverse at the boundary of structure slope 1/4 or 1/5.

In order to analyze the wave grouping effects on the wave run-up, various definitions which can represent the grouping effects are used such as the mean run-length of higher waves ($\overline{j_{H_c}}$), that of ξ^* ($\overline{j_{\xi^*}}$) and that of conditional ξ^* of higher waves ($\overline{j_{(H_c) \xi^*}}$) satisfying the resonance condition on the slope (Ryu and Sawaragi, 1986).

As the same tendency with Fig.7, the extreme run-up heights decrease with increasing the mean run-length of $\overline{j_{H_c}}$, $\overline{j_{\xi^*}}$ and $\overline{j_{(H_c) \xi^*}}$ as shown in Fig.8, Fig.9 and Fig.10. This is remarkably apparent with increasing of slope angle.

A Prediction Model of Irregular Wave Run-Up Heights

Fig. 11 shows the statistical distribution of irregular wave run-up heights on various slopes. In the figure, the distribution of irregular wave run-up heights provides a good approximation to the Rayleigh distribution on the slope steeper than 1 on 2, but it is overestimated in higher run-up on the slope milder than 1 on 3. It seems mainly due to the permeability effects but more detail experiments are required to discuss the above mentioned mechanism.

It is not possible that the irregular wave run-up height can be directly estimated from the incident wave characteristics in the above mentioned distribution. Therefore, it is necessary to derive the relations between surf similarity parameter $\xi_{1/n}$ and normalized irregular wave run-up height $R_{u1/n}/H_{1/n}$.

Non-dimensional run-up heights of irregular waves with respect to surf similarity parameter $\xi_{1/n}$ are shown in Fig. 12. Where solid

Fig.7. Spectral shape effects on wave run-up heights.

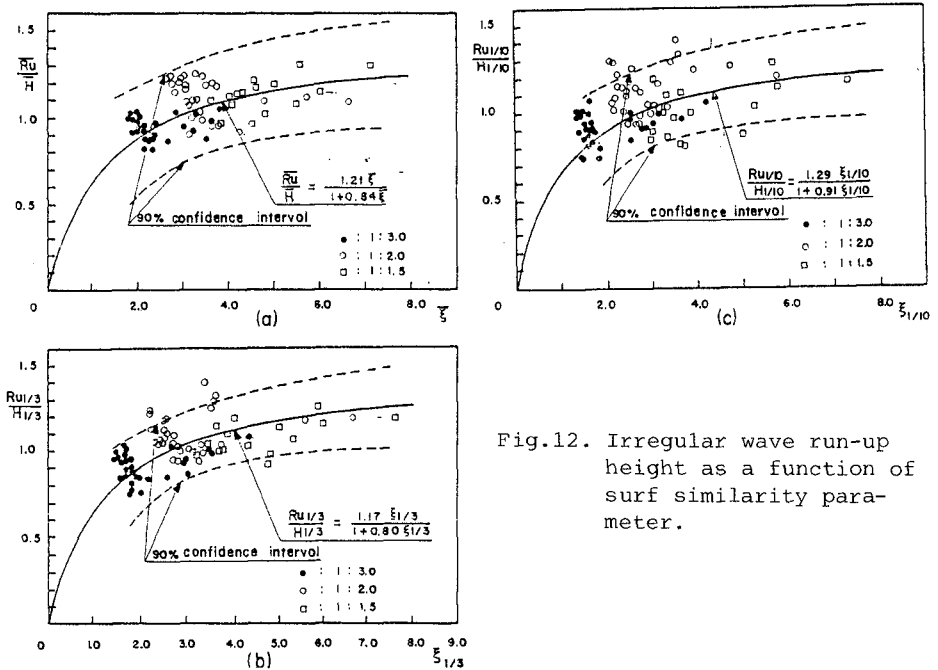

Fig.12. Irregular wave run-up height as a function of surf similarity parameter.

lines denote the regression curves and dashed lines denote 90% confidence interval by eqs. (7), (8) and (9).

The basic formula for estimating the wave run-up height is given as follows

$$R_u = \frac{a \xi}{1 + b \xi} H \tag{3}$$

The regressive curve fitting formulas of the relative run-up heights are as follows

$$\frac{\bar{R}_u}{\bar{H}} = \frac{1.21 \bar{\xi}}{1 + 0.84 \bar{\xi}} \tag{4}$$

$$\frac{R_{u1/3}}{H_{1/3}} = \frac{1.17 \xi_{1/3}}{1 + 0.80 \xi_{1/3}} \tag{5}$$

$$\frac{R_{u1/10}}{H_{1/10}} = \frac{1.29 \xi_{1/10}}{1 + 0.91 \xi_{1/10}} \tag{6}$$

The formulas of 90% confidence interval for regression curves are as follows:

$$\begin{aligned} \frac{\bar{R}_u}{\bar{H}} - (1.66)(0.17) \sqrt{1 + \frac{1}{83} + \frac{(\bar{\xi} - 3.34)^2}{107.90}} < \mu \frac{\bar{R}_u}{\bar{H}} \mid \bar{\xi} \\ < \frac{\bar{R}_u}{\bar{H}} + (1.66)(0.17) \sqrt{1 + \frac{1}{83} + \frac{(\bar{\xi} - 3.34)^2}{107.90}} \end{aligned} \tag{7}$$

$$\begin{aligned} \frac{R_{u1/3}}{H_{1/3}} - (1.66)(0.12) \sqrt{1 + \frac{1}{83} + \frac{(\xi_{1/3} - 3.11)^2}{137.27}} < \mu \frac{R_{u1/3}}{H_{1/3}} \mid \xi_{1/3} \\ < \frac{R_{u1/3}}{H_{1/3}} + (1.66)(0.11) \sqrt{1 + \frac{1}{83} + \frac{(\xi_{1/3} - 3.11)^2}{137.27}} \end{aligned} \tag{8}$$

$$\begin{aligned} \frac{R_{u1/10}}{H_{1/10}} - (1.66)(0.15) \sqrt{1 + \frac{1}{81} + \frac{(\xi_{1/10} - 2.86)^2}{110.77}} < \mu \frac{R_{u1/10}}{H_{1/10}} \mid \xi_{1/10} \\ < \frac{R_{u1/10}}{H_{1/10}} + (1.66)(0.15) \sqrt{1 + \frac{1}{81} + \frac{(\xi_{1/10} - 2.86)^2}{110.77}} \end{aligned} \tag{9}$$

where μ is a function of confidence interval.

The probability distribution function of ξ proposed by Bruun and Günbak(1978) is as follows:

$$P(\xi) = \frac{8 \cdot \xi_d^4}{\xi^5} \exp(-2 \xi_d^4 \cdot \xi^{-4}) \quad (10)$$

$$\text{where } \xi_d = \frac{\tan \theta}{[(2\pi/g)(H_{1/3}/\bar{T}^2)]^{1/2}} \quad (11)$$

where θ is slope angle, $H_{1/3}$ significant wave height and \bar{T} mean wave period.

Using eq.(5) among eq.(4), eq.(5) and eq.(6), one may solve for $\xi_{1/3}$ as follows

$$\xi_{1/3} = \frac{Ru_{1/3} / H_{1/3}}{1.17 - 0.8(Ru_{1/3} / H_{1/3})} \quad (12)$$

Changing random variable from $\xi_{1/3}$ to $Ru_{1/3} / H_{1/3}$ in eq.(12) through Jacobian transformation, the following formulas are obtained:

$$d\xi_{1/3} = \frac{1.17}{[1.17 - 0.80(Ru_{1/3} / H_{1/3})]^2} d \frac{Ru_{1/3}}{H_{1/3}} \quad (13)$$

$$\frac{d\xi_{1/3}}{d \frac{Ru_{1/3}}{H_{1/3}}} = \frac{1.17}{[1.17 - 0.80(Ru_{1/3} / H_{1/3})]^2} \quad (14)$$

combining eq.(10), eq.(11) and eq.(14), eq.(15) is obtained as:

$$p\left(\frac{Ru_{1/3}}{H_{1/3}}\right) = \frac{8 \xi_d^4}{\left[\frac{(Ru_{1/3} / H_{1/3})}{1.17 - 0.80(Ru_{1/3} / H_{1/3})}\right]^5} \cdot \exp[-2\xi_d^4 \left(\frac{Ru_{1/3} / H_{1/3}}{1.17 - 0.80(Ru_{1/3} / H_{1/3})}\right)^{-4}] \frac{d\xi_{1/3}}{d \frac{Ru_{1/3}}{H_{1/3}}} \quad (15)$$

Consequently, substituting eq.(14) into eq.(15), the probability distribution function of irregular wave run-up height can be expressed as eq.(16):

$$p\left(\frac{Ru_{1/3}}{H_{1/3}}\right) = \frac{9.36\xi_d^4(1.17 - 0.80 \frac{Ru_{1/3}}{H_{1/3}})^3}{\left(\frac{Ru_{1/3}}{H_{1/3}}\right)^5} \cdot \frac{\frac{Ru_{1/3}}{H_{1/3}}}{\exp[-2\xi_d^4 \left(\frac{Ru_{1/3}}{H_{1/3}}\right)^{-4}]}{1.17 - 0.80 \frac{Ru_{1/3}}{H_{1/3}}} \quad (16)$$

In order to identify the applicability of the model, the probability distribution of wave run-up height is shown with the experimental data

Fig.13. Probability distribution of irregular wave run-up heights on uniform slope.

Fig.14. Probability distribution of irregular wave run-up heights on the berm type composite slope.

in Fig. 13. It can be stated from the figure that the proposed model is very useful to predict the run-up height on the permeable rough mound type structures.

In addition, applying the technique used for the uniform slopes, the probability distribution of irregular wave run-up heights on the berm type composite slope is investigated compared with that on the uniform slope and Rayleigh distribution as shown in Fig.14. It is seen that the irregular wave run-up heights are more widely distributed than those on uniform slope and also that the probability density of the run-up height on composite slope is higher in the lower values of $Ru_{1/3} / H_{1/3}$ than that on uniform slope. This means that the attenuation effect of wave run-up height on composite slope is stronger than that on uniform slope due to wave-structure interaction. Furthermore, it can be identified that the distribution of the irregular wave run-up height normalized by wave height has different trend with the Rayleigh distribution.

CONCLUSIONS

Statistical and real time characteristics of irregular wave run-up were studied including the effects of spectral shape and grouping characteristics of incident waves. And the simple probability distribution function of irregular wave run-up heights was developed as a prediction model of the run-up height, and proved to be useful to the deterministic design and applicable to the optimal design concept of coastal structures. However, the experimental conditions could not cover all of the sea state and structural characteristics. Furthermore, the proposed model does not include the effect of grouping of incident waves. These problems will be required to be investigated to develop the more accurately and extensively applicable model.

CHAPTER 29

Effects of the Gulf Stream on nearby coastal waves

L.H. Holthuijsen¹ and H.L. Tolman²

Abstract

In the present study a third-generation numerical wave model is used to study effects of a straight Gulf Stream and a Gulf Stream ring, on ocean waves along the coast in swell and storm conditions. The model accounts for all relevant processes of propagation, generation and dissipation of the waves (including current effects) without imposing a priori restraints on the spectral development of the waves. The dominating mechanism affecting the waves appears to be current induced refraction even though the short-crestedness of the incoming waves tends to mask its effects. Depending on wind and wave conditions, refraction may trap locally generated waves in the straight Gulf Stream or it may reflect wave energy back to the open ocean. In the Gulf Stream ring, refraction induces a considerable variation in significant wave height and short-crestedness but it hardly affects the mean wave direction. In storm conditions the processes of generation and dissipation are considerably enhanced in counter-current situations and reduced in following-current situations.

1. Introduction

Observations from ships, aircraft and spacecraft show that ocean waves approaching the east coast of the United States are affected by the presence of the Gulf Stream (e.g. Meadows et al., 1983; McLeish and Ross, 1985; Mapp et al., 1985). The currents tend to create a confused sea state, often with waves that are higher than the incoming waves. In this study a distinction is made between a straight Gulf Stream and a Gulf Stream ring. In the straight Gulf Stream, the wave-current interactions will obviously modify the waves uniformly along the coast whereas down-wave from the ring, the along-shore variations may be appreciable. Several studies have

¹ Delft University of Technology, Department of Civil Engineering, P.O. Box 5048, 2600 GA Delft, the Netherlands

² Delft University of Technology, presently at NASA, Goddard Space Flight Center, Laboratory for Atmospheres, Code 911, Greenbelt, MD 20771, U.S.A.

been carried out to model such modifications of waves across a shear-current or a ring (e.g. Kenyon, 1971; Gutshabash and Lavrenov, 1986; Mathiesen, 1987) but no attempt seems to have been made to include the effects of wind. We therefore use in the present study a numerical wave propagation model extended with source terms representing wave generation and dissipation to propagate waves across a straight Gulf Stream and across a Gulf Stream ring in swell and storm conditions.

2. The wave model

The wave model which we use is a numerical wave prediction model for random, short-crested waves in arbitrary conditions of wind, currents and bathymetry (Tolman, 1989, 1990a, 1990b). It is a discrete spectral wave model accounting for such wave-current interactions as Doppler shifts, radiation stresses and current-induced refraction. It also explicitly models all relevant processes of wave generation by wind and dissipation by white-capping, including an explicit treatment of the nonlinear resonant wave-wave interactions (the WAMDI group, 1988). The model is based on the discrete spectral action balance (e.g. Hasselmann et al., 1973):

$$\frac{\partial N(\omega, \theta)}{\partial t} + \frac{\partial C_x N(\omega, \theta)}{\partial x} + \frac{\partial C_y N(\omega, \theta)}{\partial y} + \frac{\partial C_\omega N(\omega, \theta)}{\partial \omega} + \frac{\partial C_\theta N(\omega, \theta)}{\partial \theta} = \frac{S(\omega, \theta)}{\sigma} \tag{1}$$

where $N(\omega, \theta)$ is the action density of the waves as a function of absolute frequency ω and direction of wave propagation θ (normal to the wave crest) and σ is the relative frequency (as observed in a frame of reference moving with the current).

The left hand side of Eq. 1 represents the local rate of change of the action density (first term), rectilinear propagation in geographic space (second and third term with C_x and C_y), shifting of the absolute frequency due to time variations in depth and currents (fourth term with C_ω) and refraction (fifth term with C_θ). The propagation speeds in geographic space (C_x and C_y) are the group velocity components in x- and y-direction respectively (current speed included). The propagation speeds C_ω and C_θ are given by (Christoffersen, 1982; Mei, 1983):

$$C_\omega = \frac{\partial \sigma}{\partial d} \frac{\partial d}{\partial t} + \mathbf{k} \cdot \frac{\partial \mathbf{U}}{\partial t} \tag{2}$$

$$C_\theta = -\frac{1}{k} \left[\frac{\partial \sigma}{\partial d} \frac{\partial d}{\partial m} + \mathbf{k} \cdot \frac{\partial \mathbf{U}}{\partial m} \right] \tag{3}$$

in which d is depth, \mathbf{k} is the wave number vector, \mathbf{U} is the current velocity vector and m is a coordinate orthogonal to the wave direction. These propagation speeds fully account for the depth and current effects on propagation within the linear theory of slowly-varying surface gravity waves. The depth induced variations of C_x and C_y are normally referred to as "shoaling". To include the current induced variations we use the term "straining" instead. We consider stationary situations in deep water so that all terms involving finite depth and time derivatives of the current are zero (i.e. no shoaling, no depth refraction and no shift of absolute frequencies).

The right hand side of Eq. 1 (the net production of wave action) represents all effects of generation and dissipation of the waves. The processes which are included in the model are:

wave generation by wind (Snyder et al., 1981), nonlinear resonant wave-wave interactions (Hasselmann, 1960; Phillips, 1960), white-capping (Komen et al., 1984) and bottom induced dissipation (Madsen et al., 1988). The actual formulations which are used are those of the WAM model (the WAMDI group, 1988) except for the formulation of the bottom dissipation (but as it has no relevance for the present study, it will be ignored in the following). The model is therefore, like the WAM model, a third-generation wave model in which the wave spectrum develops free of any a priori restraints. All of these processes of generation and dissipation are formulated in a frame of reference moving with the current (implying the use of the relative wind speed). The effects of currents are accounted for by a Jacobian transformation of the computed source term $S(\omega, \theta)/\sigma$ to a stationary reference frame in each time step in the model. The numerical schemes that are used to propagate the waves are predominantly second-order accurate (also refraction). Occasionally the schemes reduce to first-order accuracy when the gradients in the wave field are too sharp. The geographic resolution of the model is $\Delta x = \Delta y = 13.9$ km for the straight Gulf Stream and 15 km for the ring respectively. The spectral resolution is $\Delta f = 0.1f$ in frequency and $\Delta \theta = 15^\circ$ (storm cases) and $\Delta \theta = 7.5^\circ$ (swell cases) in direction. The time step is $\Delta t = 7.5$ min.

3. The Gulf Stream

The current field for this study has been provided by Scott Glenn of Harvard University who used the Harvard Gulf Stream Forecasting Program (Glenn et al., 1987; Robinson et al., 1988) with the Gulf Stream at its climatological location and a warm core ring in a typical location. The currents thus obtained vary sufficiently slowly in time to treat the current field as stationary. For reasons of computational capacity the wave hindcast experiments have been carried out for an infinitely long and straight Gulf Stream and for a ring separately. To obtain the infinitely long, straight Gulf Stream we synthesize a 150 km-wide transverse surface-current profile by averaging the surface-current profile of the forecasted Gulf Stream over a 250 km-long section (Fig. 1). For convenience of discussion, we take the current in this synthesized Gulf Stream to run from south to north (the actual direction is immaterial as only the relative directions of waves and currents are relevant). The surface-current field of the ring (radius to maximum current about 45 km) has been obtained by isolating a 250×250 km² area from the forecasted field (Fig. 2).

4. The waves

We take uniform wave boundary conditions at the open-ocean side of the current fields (some distance up-wave from the current-boundary). The wave condition there are characterized in the storm (wind speed at 10 m elevation $U_{10} = 20$ ms⁻¹) with a two-dimensional JONSWAP spectrum (Hasselmann et al., 1973) of nearly fully developed waves with a $\cos^{2s}((\theta - \theta_0)/2)$ -directional energy distribution. The value of the directional width parameter s is taken from Hasselmann et al. (1980). The swell is characterized with a Gaussian-shaped frequency energy spectrum (standard deviation σ_f) and a $\cos^{20}(\theta - \theta_0)$ -directional energy distribution. Details of the spectral characteristics are given in Table 1. We consider two incoming wave directions relative to the Gulf Stream (swell and storm): 45° from a counter-direction (i.e. waves from north-east) and 45° from a following direction (i.e. waves from south-east). In the case of the

ring the direction of approach is not relevant as the current field is practically rotationally symmetrical. We therefore consider for the ring only one mean wave direction (from east to west for convenience of the discussion).

spectral characteristics		storm	swell
peak frequency	f_{peak}	0.073 Hz	0.071 Hz
peak width	σ_a	0.07	--
	σ_b	0.09	--
	σ_f	--	0.007 Hz
peak enhancement	γ	1.49	--
sign. wave height	H_s	8.10 m	1.99 m
directional width	σ_θ	34.5°	12.4°

Table 1. The spectral characteristics of the wave boundary conditions in the storm and swell cases. For the definition of σ_a , σ_b and γ see Hasselmann et al. (1973).

5. Results for the straight Gulf Stream

5.1 Waves from NE

In the NE swell case the significant wave height shows rather small variations (Fig. 1). An analytical inspection for a monochromatic wave with the same frequency as the peak frequency of the incoming waves shows that this mild variation is mostly due to the opposing effects of refraction on the one hand (which would decrease the significant wave height in the centre of the Gulf Stream) and straining and radiation stresses on the other (which would increase the significant wave height there). The mean wave direction turns only 6° at the centre of the Gulf Stream (more orthogonal to the current) where they are slightly more long-crested than at the open ocean side (quantified with the rms directional width σ_θ of the energy distribution of 12.2° versus 9.5°). The wave field has returned to its undisturbed state after crossing the Gulf Stream.

In the NE storm case the significant wave height increases across the Gulf Stream with an overshoot at the center of the Gulf Stream (Fig. 1) and the relative variations are much larger than in the above swell case. The variations in the other wave parameters such as the mean

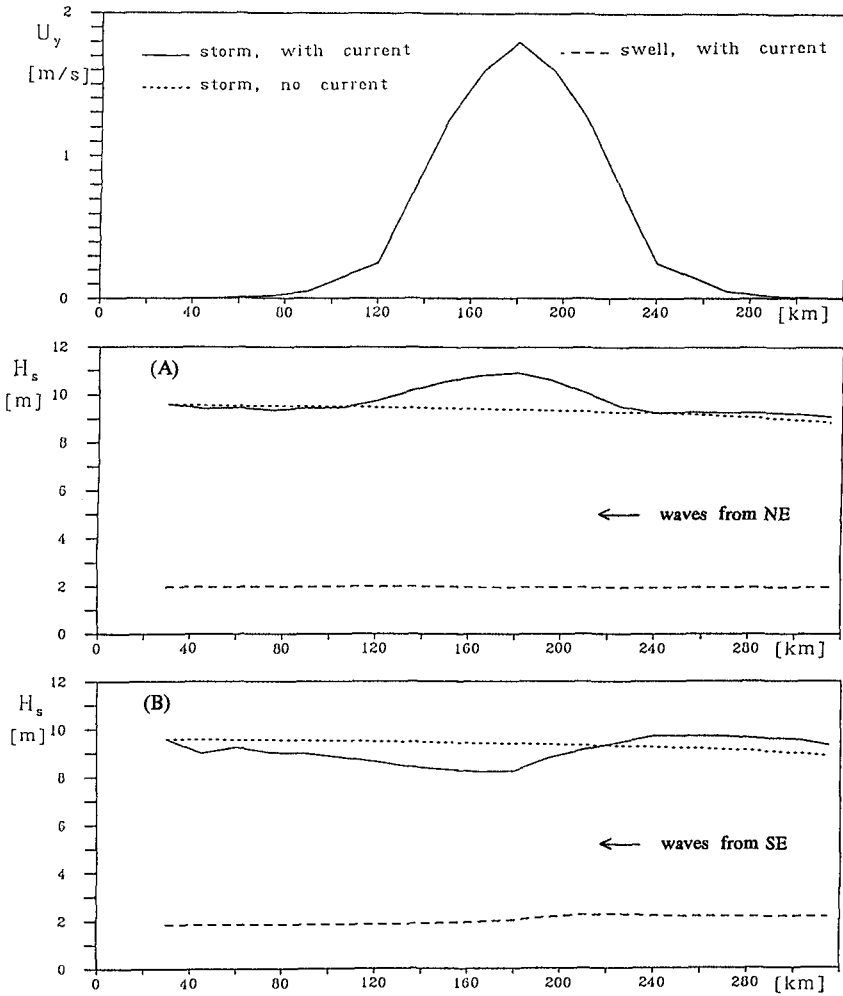

Fig. 1 Profiles in the straight Gulf Stream: current speed (U_y) and significant wave height (H_s). Panel A: waves from counter-current direction (NE). Panel B: waves from following direction (SE).

wave direction are also rather different from those in the swell case. In fact the tendencies are opposite to those in the swell case (e.g. waves turn counter-clockwise towards the centre of the Gulf Stream instead of clock-wise). An inspection of the two-dimensional spectra in this case shows that this is due to wave energy from northerly directions which is added to the incoming spectrum. An analytical inspection shows that this energy propagates along undulating wave rays near the center of the Gulf Stream. It is locally generated by the wind and cannot escape (it is trapped). Our computations therefore confirm the possibility of trapping locally generated waves as suggested earlier by Johnson (1947) and Kenyon (1971). In this storm case the generation and dissipation are much more active in the Gulf Stream than outside the Gulf Stream (in the centre the wind input is enhanced by 48%, dissipation by 80% and nonlinear interactions by 96%, compared with the undisturbed situation). These considerable effects are probably due to a large extent to the trapping of the locally generated waves. They increase the wave steepness, thereby increasing the nonlinear wave-wave interactions and the white-capping. The increase in apparent wind speed (due to the counter-current) may also have some effect.

5.2 Waves from SE

If swell enters the Gulf Stream from the SE direction, the variations in the wave field are somewhat larger than in the NE case (Fig. 1). The behaviour of the significant wave height to increase up-wave from the Gulf Stream and to decrease down-wave from its centre is related to the reflection of some wave energy back to the open ocean. This is clearly visible in the two-dimensional spectra at various locations (not shown here). It is also noticeable in the short-crestedness: the reflected waves travel across the incoming waves at the open ocean side and consequently increase the short-crestedness there (σ_0 increases from the undisturbed value of 12.4° to 24.9°). Beyond the center of the Gulf Stream the absence of the reflected energy turns the mean wave direction slightly counter-clockwise. The spectrum there has a correspondingly narrower directional distribution. Such reflection in a straight (or meandering) shear current is a well-known phenomenon (e.g. Kenyon, 1971; Jonsson and Skovgaard, 1979; Hayes, 1980; Irvine and Tilley, 1988).

In the case of the SE storm, the variations in the wave field are fairly similar to those in the above swell case and reflection is even more important than in the swell case (Fig. 1). This is evident in a sharp decrease of the computed significant wave height near the center of the Gulf Stream and some increase at the up-wave side of the Gulf Stream. However, at some distance beyond the Gulf Stream the wind has generated sufficient wave energy to compensate the reflected energy. In contrast to the NE storm, the intensity of all processes of generation and dissipation are somewhat reduced in the center of the Gulf Stream compared with the undisturbed situation and somewhat enhanced at the boundaries. This is probably due to the current-induced decrease in wave steepness in the following current (lower and longer waves) and a reduction of the apparent wind speed.

The above effects of the Gulf Stream are uniform along the coast so that no variations occur in the wave field along the coast (only across the Gulf Stream). In a more realistic, meandering Gulf Stream, along-shore variations will occur. The wave field in the most extreme meander, a ring, is considered next.

6. Results for the Gulf Stream ring

In the swell case for the ring, the significant wave height increases from 2.0 m up-wave from the ring to 2.7 m just down-wave from the counter-current region and it decreases to 1.4 m just beyond the following-current region (Fig. 2). A ship may therefore encounter nearly a doubling of the significant wave height when travelling from south to north along the lee side of the ring in this situation. In the storm case the pattern of the significant wave height is fairly similar to that in the swell case but with some obvious differences (Fig. 3). The location and extent of the perturbation of the wave field is more confined to the ring and the relative variations are smaller (but still considerable). The variations are largest within the ring (storm case) or just down-wave from the ring (swell case). From there they dampen in the down-wave direction to a situation almost equal to the undisturbed situation (in all respects except that some bimodality in the directional energy distribution is maintained; not shown here). The extent of the disturbance is about one ring diameter in the storm case down-wave from the ring (90 km, affecting coastal waves only if the coast is within this range) whereas in the swell case the effects are still noticeable after two ring diameters (180 km, affecting coastal waves only if the coast is within this range). These wave height variations are well understood from refraction and straining effects. Refraction induces convergence of wave propagation in and beyond the counter-current region and divergence in and beyond the following-current region. Fig. 4 shows the ray pattern for a monochromatic wave with the same frequency as the peak frequency of the swell propagating across the ring. The regions of ray convergence and divergence just beyond the regions of counter-current and following current respectively correspond well with the areas of maximum and minimum significant wave height in the swell case. Such convergence and divergence of wave rays has also been shown by others (e.g. Mathiessen, 1987). The differences in extent and location of the wave field disturbance between the swell case and the storm case seems to be mostly due to the difference in short-crestedness of the incoming waves (see below).

The mean wave direction varies only mildly across the ring (12° maximum in the swell case) and it returns to nearly its undisturbed value at a few diameters distance beyond the ring (swell case) or earlier (storm case). This mild variation of the mean wave direction seems to contrast with the strong refraction effects in the wave ray pattern of Fig. 4. Not only is this variation milder than the variation of individual ray directions, it is also not as lasting as the ray pattern suggests. The reason is that beyond the areas of divergence and convergence, the refracted rays diverge so that the energy represented by these rays decreases and the undisturbed rays dominate. In other words, the divergence of the refracted rays dilutes any effect that they may have on the mean wave direction. In addition, beyond the ring the short-crestedness of the incoming waves mixes disturbed and undisturbed wave components rapidly. It also determines the extent and location of the ring-induced disturbance of the wave field. These effects are stronger in the storm case (with a relatively wide directional energy distribution of the incoming waves, $\sigma_\theta = 34.5^\circ$) than in the swell case (with a relatively narrow directional energy distribution of the incoming waves, $\sigma_\theta = 12.4^\circ$). Across the ring the short-crestedness varies

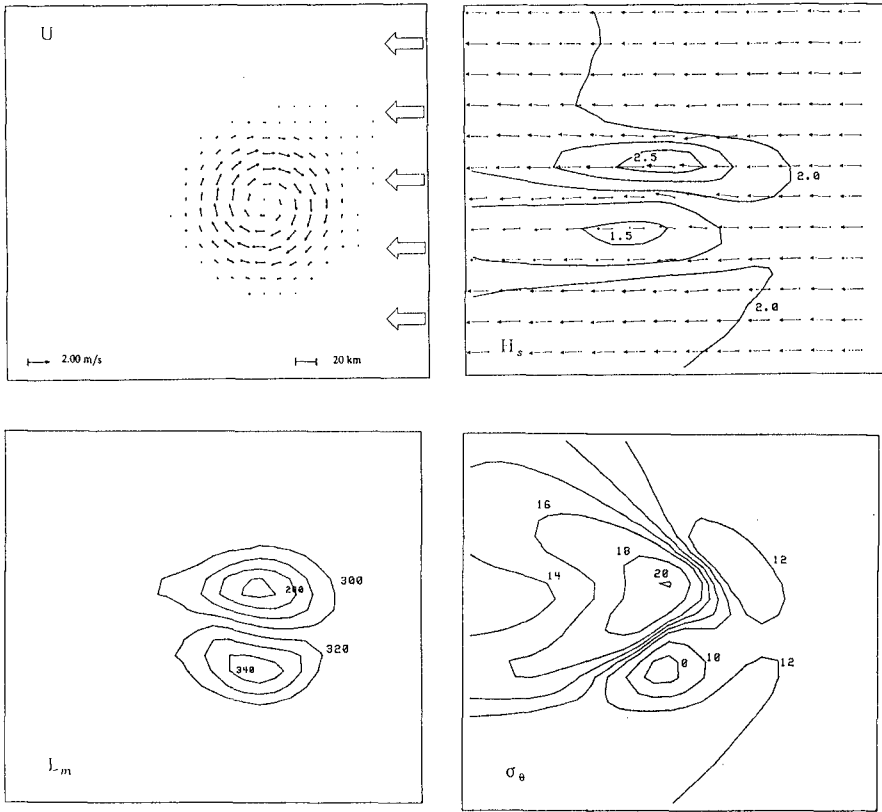

Fig. 2 Contour line plots in the ring area for swell: significant wave height (H_s in m), mean wave length (L_m in m) and directional spread (σ_θ in $^\circ$). Vectors indicate current and mean wave direction.

considerably in the swell case. In the storm case it varies only slightly. Well defined cross-seas (i.e. bimodal spectral directional energy distributions) occur only beyond the counter-current region in the swell case.

Again, as in the Gulf Stream storm cases, the physical processes of wind generation, dissipation and nonlinear wave-wave interactions are considerably affected by the currents. Compared with the undisturbed situation, the wind input is enhanced by 46% (maximum, near the maximum counter-current) and reduced with 26% (minimum, near the maximum following-current). The dissipation is similarly enhanced or reduced with 89% and 46% and the nonlinear wave-wave interactions by 80% and 45% respectively. The computations show that the work done by the radiation stresses when the waves enter the ring is returned when the waves leave the ring.

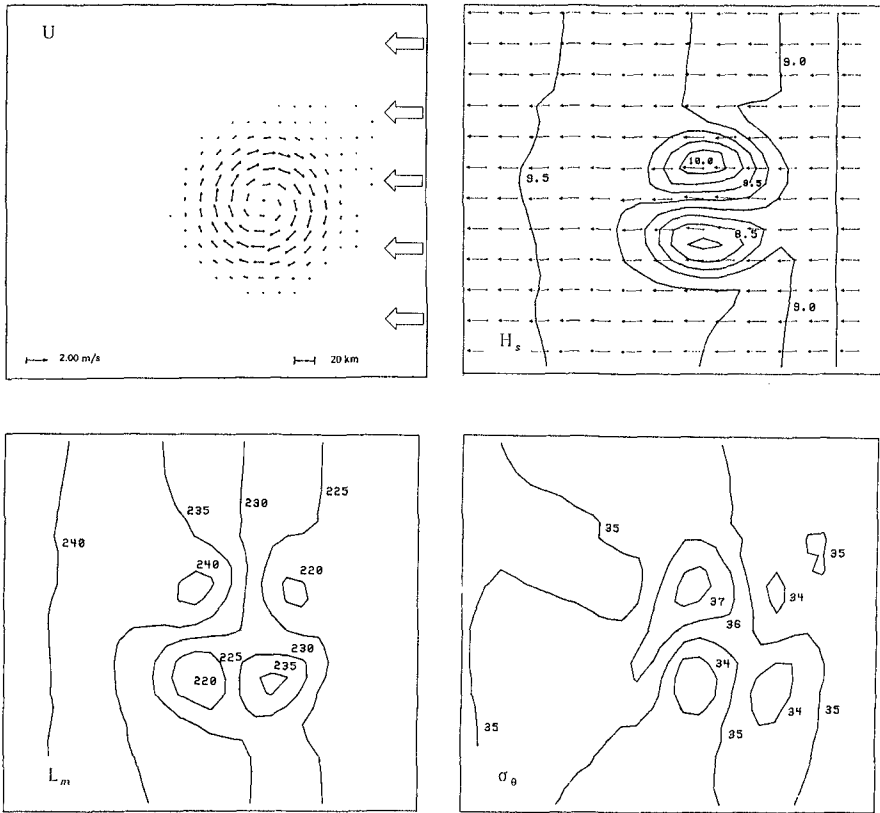

Fig. 3 Contour line plots in the ring area for storm condition: significant wave height (H_s in m), mean wave length (L_m in m) and directional spread (σ_θ in $^\circ$). Vectors indicate current and mean wave direction.

7. Conclusions

If waves from the open ocean travel across the straight Gulf Stream, refraction is the dominating mechanism affecting the waves. Its most notable effect is the trapping of locally generated waves in an adverse-wind situation (wind against the current) and reflection of incoming waves if waves approach from a following direction (waves travelling with the current). In a Gulf Stream ring, refraction affects considerably the significant wave height and the short-crestedness but it affects the mean wave direction only slightly. Well-defined cross-seas occur beyond the ring in swell conditions but not in storm conditions. These effects are not as persistent as refraction computations for monochromatic, unidirectional waves suggest.

In fact, they disappear after a few ring diameters due to the diluting effect of frequency and direction dispersion of the waves. Along the United States east coast the presence of the Gulf Stream will therefore be noticeable in the wave field only from an occasional reduction of incoming swell and from along-shore swell variations at the lee-side of nearby rings (or meanders). In storms practically no effects on the wave field along the coast will be noticeable.

CHAPTER 30

IMPROVED CALCULATION OF THE SHOALING WAVE FIELD

Masataro Hattori¹ and Tetsuyuki Katsuragawa²

Abstract

Nonlinear wave theories was improved to describe the asymmetry in time histories of the wave elevation and associated particle velocities under relatively steep nonbreaking waves. The improvement was based on the idea that the asymmetry causes both the amplitude changes of the primary and harmonic Fourier components, and the relative phase shifts between the primary and harmonic components.

Relationships between the asymmetry and local wave parameters were prerequisite to the improved calculation, and were derived by using experimental data. The improved calculation proposed was made for a specified local wave condition, without aids of direct numerical simulation techniques. Good agreements of the improved calculation with measurements confirmed applicability of the calculation to the practical use.

1. INTRODUCTION

Coastal engineers have been fully aware of the fact that nonlinearity as well as irregularity in wave motions plays an essential part in various coastal processes, such as the cross-shore sediment transport and the wave-structure interaction. In examining such problems, especially under relatively steep waves, time-dependent characteristics of the kinematic field of wave motions at a certain location are usually predicted from flat bottom solutions of nonlinear theories of permanent waves.

When a surface wave advances over a gently rising slope, it is subjected various nonlinear effects due to convective inertia and bottom friction. The inertia effects bring about asymmetric wave forms both about the horizontal and vertical planes, as shown in Fig. 1. Nonlinear theories of constant wave forms describe reasonably well the vertical asymmetry in wave form about mean water level, but they do not allow the horizontal asymmetry about the wave crest, the front slopes of the waves become steeper than the back slopes. In this sense, no appropriate nonlinear wave theory exists for practical use.

The present paper discusses the asymmetry in shoaling wave profiles, with taking into account the bottom slope effect as well as the incident wave property. Based on wave elevation records, empirical

equations for the asymmetry in the wave form are derived. Improvement of nonlinear wave theories is made by using the empirical equations. This study is concerned with modified versions of the Stokes 5th order wave theory, ST 5, (Isobe, Nishimura, and Horikawa, 1978; Fenton, 1985) and Dean's 10th order stream function representation of theoretical waves, SFMB 10 (1965), because they are computationally simpler.

Fig. 1 Asymmetry in the wave profile.

2. OBJECTIVE

Objective of this study is to develop an improved calculation of the wave elevation and particle velocities, with respect to time, under relatively steep nonbreaking waves. From a practical viewpoint, the improved calculation is made for a specified local wave condition: wave height H , wave period T , water depth D , and bottom slope m . In so doing, four sub-objectives are defined: (1) To examine the transformation of shoaling waves by experiments, (2) to obtain empirical relationships of the wave profile asymmetry in terms of the local wave properties and the bottom slope, (3) to modify the theoretical solutions so as to describe the horizontal asymmetry, and (4) to evaluate applicability of the improved calculation by comparisons with measurements.

3. EXPERIMENTAL SETUP AND MEASUREMENTS

Experiments were made in a glass-walled wave flume, 0.30m wide, 0.55m high, and 20m long. Regular waves were generated by a reflection-absorbing type wave maker. Model beaches with slopes of 1:10 and 1:20 were used for all the surface and velocity measurements. The water depth in the flat portion of the flume was between 0.33m and 0.43m.

Simultaneous measurements of the wave elevation and particle velocities were made at various locations over sloping bottom. Wave elevations were measured with a resistance-type wave gage having excellent linearity and high frequency response. Horizontal and vertical particle velocities at the wave measurement section were measured with a two-component LDA velocimeter. These outputs were recorded on a digital recorder with a sampling frequency of 200Hz for extensive processing by computer.

Individual waves in a time series of wave elevation at a certain location were defined by means of the zero-up-crossing method. Based on the individual wave data, the time series of wave elevation and particle velocities were averaged 50 waves with respect to the phase. The harmonic amplitudes were computed from the time series by fast Fourier transform (FFT).

4. EVALUATION OF THE IMPROVED CALCULATION

Applicability of the improved calculation was examined by the overall root-mean-square E of difference between the measurement and calculation of wave elevation and particle velocities for one wave cycle, given by Eq. (1).

$$E = \left(\sum_{i=1}^N (X_i - Y_i)^2 / \sum_{i=1}^N X_i^2 \right)^{1/2} \quad (1)$$

, in which X_i and Y_i are the measured and calculated values at evenly spaced phases ($\Delta\theta = N/T$) for one wave period of the time history, determined by ensemble averaging technique. Taking account of the experimental validity range of water wave theories (Hattori, 1986), the applicability limit of the improved calculation was set as $E < 1.0$.

5 EXPRESSION OF THE SKEWED WAVE FORM

5.1 Brief review of previous studies.

A number of experimental and theoretical studies have been made to examine physical processes in the skewed kinematic field under steep waves propagating on the sloping bottom. However, physical processes of the horizontal asymmetry, wave front faces are steeper than back faces, are still poorly understood.

As to the asymmetric characteristics, Adeyemo (1968 and 70) conducted extensive experiments focused on the asymmetry in wave forms and particle velocity changes with respect to time. He tried to parametrize the asymmetry with respect to various incident wave characteristics. However, he did not succeed to derive any synthetic relationship between the asymmetry and wave parameters.

Hedges and Kirkoz (1981), based on wave elevation data, proposed the transformation zone, which is the region between the point where waves start to lose horizontal symmetry and the breaking point. They found that the rate of horizontal asymmetry transformation increases as the bottom slopes get steeper (Galvin, 1967). In addition, the transformation zone tends to broaden with decreasing in the incident wave steepness.

Flick, Guza, and Inman (1981) presented a very interesting approach for examining the horizontal asymmetry in shoaling wave profiles. Fourier analysis of measured wave elevation records revealed the two following facts, on which the improvement is based:

(1) Harmonic amplitude data provide the principal control over the vertical asymmetry, and are predicted well by the nonlinear theories of permanent waves.

(2) The skewed wave profile causes relative phase shifts ζ_n between the primary and nth harmonic components, given by Eq. (2).

$$\zeta_n = \arctan(S_n/C_n) - n \cdot \arctan(S_1/C_1), \quad (2)$$

where S_n and C_n are the sine and cosine Fourier coefficients. Thus, the measured wave elevation $\eta(t)$ as a function of time can be written as

$$\eta(t) = a_1 \cos \omega t + \sum_{n=2}^M a_n \cos(n \omega t + \zeta_n), \quad (3)$$

in which a_1 and a_n : the amplitudes at primary and nth harmonic frequencies, and ω : the frequency of the primary wave. According to Flick et al. (1981), the harmonic phase shifts ζ_n start to increase from zero as the waves advance over a rising slope, and increase toward the asymptotic values $\zeta_n = (\pi/2)(n-1)$.

5.2 Formulation of the harmonic phase shift ζ_n

The previous studies disclosed the horizontally asymmetric or skewed wave profile is closely related to the local wave parameters and the bottom slope. After careful examination of the experiments by the authors ($m = 1/10$ & $1/20$) and Flick et al. ($m = 1/25$), we found that Goda's nonlinearity parameter Π (1983), given by Eq. (4), is of the most

acceptable, for representing synthetically effects of the incident wave properties on the harmonic phase change inside the transformation zone (Hedges and Kirko³ 1981).

$$\Pi = (H/L) \cot^3 kD, \tag{4}$$

where H is the wave height, L is the wavelength, computed from Airy wave theory, $k(=2\pi/L)$ is the wave number, and D is the water depth. As a consequence, the harmonic phase shifts ζ_n are given by Eq. (5), in terms of the Π parameter and the bottom slope m .

$$\left. \begin{aligned} &\text{For } \Pi < 10^{-2} (B_n/A_n) \\ &\zeta_n / (n-1) = 0, \\ &\text{and for } \Pi > 10^{-2} (B_n/A_n), \\ &\zeta_n / (n-1) = A_n \log \Pi + B_n, \end{aligned} \right\} \tag{5}$$

in which $A_n = (n-1)/30 + 0.60$ and $B_n = 1.33 \cdot m^{1/4}$.

Figures 2 and 3 are comparisons of Eq. (5) with the harmonic phases ζ_n computed from the wave elevation records for the bottom slopes of 1/10, and 1/25. Figure 3 is depicted by utilizing the experimental data of Flick et al. (1981; Fig. 5). The fairly good agreements persuade that the asymmetric wave profile is expressible by substituting Eq. (5) into the analytical solutions of nonlinear wave theories.

6. IMPROVED CALCULATIONS

The improved calculation is based on the idea that the horizontal asymmetry in wave elevations and particle velocities, as a function of time, is expressible by the nonlinear wave theory, when the relative harmonic phase shifts are taken into account (Flick et al., 1981). Therefore, this study is concerned with the improvement in the Stokes 5th order wave theory, ST 5, and Dean's 10th order stream function representation of theoretical waves, SFMB 10 (1965). The cnoidal wave theory is excluded from the present study, because the cnoidal solutions are analyzed into the Fourier components in order to generate the horizontal asymmetry by means of the harmonic phase shift. This is very tremendous and barely suitable for practical use.

6.1 Improved Stokes 5th order theory, ST' 5

Figure 4 shows the details of improved calculation of the Stokes 5th order theory. After inputting a specified local wave condition and bottom slope, ST 5 starts to calculate the wave elevation and to determine the primary and harmonic amplitudes. In parallel with this step, the harmonic phase shifts ζ_n are computed from Eq. (5).

Substitution of ζ_n into the phase functions of ST 5 solutions, yields the first approximation of skewed free surface elevation. However, it usually brings about a slight deviation of wave height from the inputted one. Thus, the wave height is iteratively corrected by changing only the primary wave amplitude, because the harmonic amplitudes and their contribution to the wave height deviation are relatively smaller than these of the primary. After determining the skewed wave elevation, the horizontal and vertical velocities are calculated.

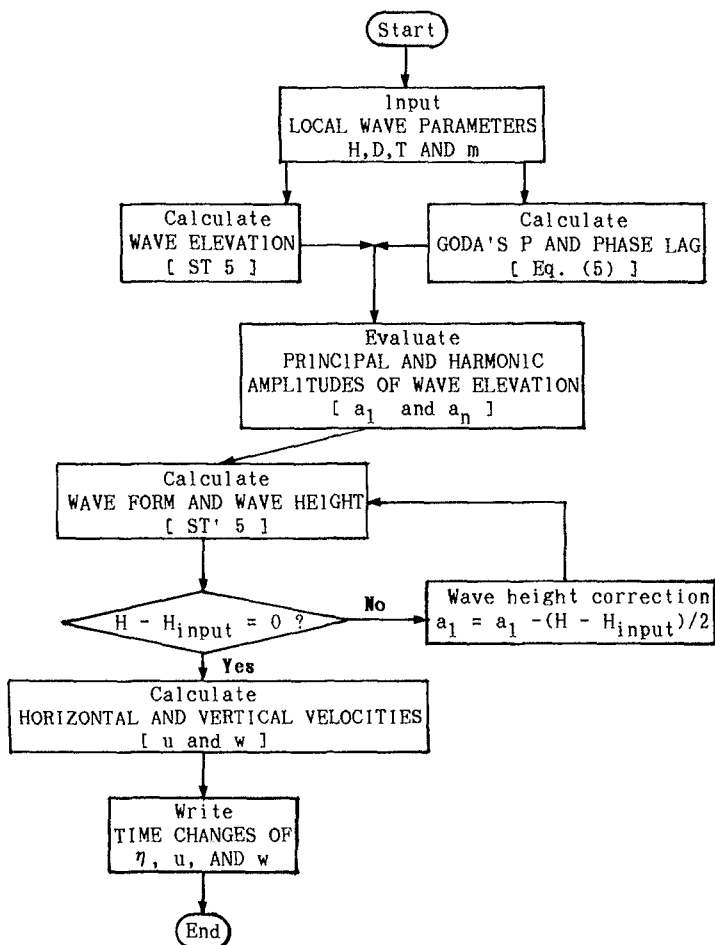

Fig. 4 Flow chart showing the details of ST' 5

Figures 5 and 6 are examples of the comparisons of ST 5 and ST' 5 with measurements of the wave elevation, η , and particle velocities, u and w . The solid and broken lines represent the measured and calculated. Since the local wave conditions are very close to the convergence limit of the Stokes wave theory (Dean and Dalrymple, 1984), instability is clearly observed in the calculated wave elevation after the crest phase. Nevertheless, the ST' 5 yields better agreements with the measurements than the ST 5.

Equation (5) for the harmonic phase shift was derived only from the wave elevation data. It is, therefore, necessary to survey its applicability to the particle velocities. Figure 7 illustrates comparisons between the calculated and measured velocities at the middle and near bottom levels of the water column, for the same case shown in Fig. 6. As in Figs. 6 and 7, ST' 5 predicts fairly well the measured velocity changes in the wave crest, where their profiles are steeper and significantly asymmetric. The agreement, in visual, appears to be reasonably

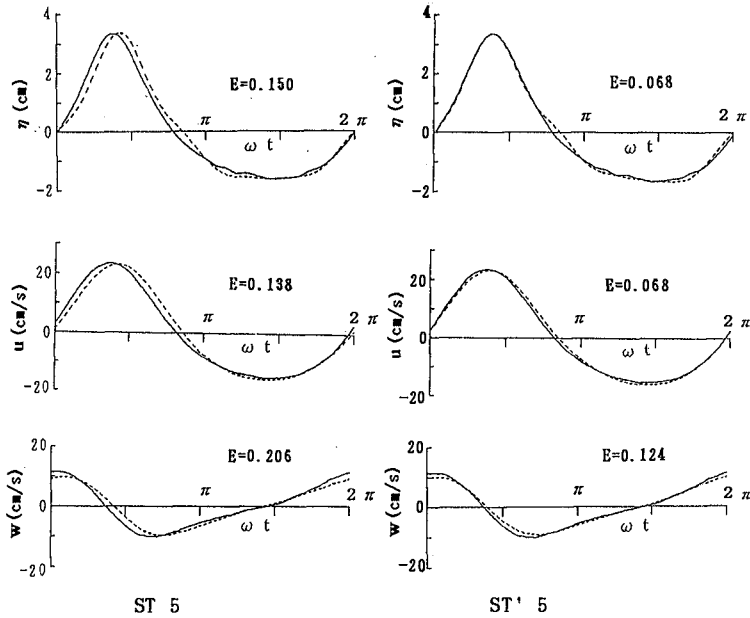

Fig. 5 Comparison of ST 5 and ST' 5 with the measurements.

 particle velocities by ST 5 and ST' 5.
 (the same case for Fig. 6)

good. However, the overall-rms value E increases gradually toward the bottom. This implies that (1) since the velocity profile get the symmetry with the depth, ζ_n for particle velocities changes at different rates, and (2) decreasing the vertical velocity magnitude toward the bottom gives rise to the increase in E value, even for very small difference between the measured and calculated velocities.

6.2 Improved Stream Function: SFMB' 10 and SFMC' 10

As the wave shoals and wave form becomes more asymmetric, the SFMB tends to overestimate the wave elevation and horizontal particle velocity around wave crest phase (Dean, 1965). To reduce such stream function errors, Saito and Isebe (1987) proposed a modified version of SFMB, using the wave crest height η_c above the mean water level, instead of the wave height (SFMC). Better representation of the wave surface profile is prerequisite to the improvement of the SFMB. Thus, an improved version of SFMC is proposed as an alternative to the SFMB.

In calculations by the SFMC, the wave crest height needs to evaluate from the given wave condition. Steepening of the wave crest as well as skewing the wave form relates both to the wave property and the

bottom slope. Empirical equation for the relative wave crest height, η_c/D , with respect to the relative wave height H/D and the bottom slope m , is determined by using the measuring data of the present authors ($m=1/10$ & $1/20$), Eagleson ($m=1/15$, 1956), Hansen and Svendsen ($m=1/34$, 1979), and Goda ($m=1/100$, 1964).

$$\eta_c/D = m f_1(H/D) \cdot \text{Exp}[f_2(H/D)], \tag{6}$$

in which

$$\left. \begin{aligned} f_1(H/D) &= (H/D) \{2.44(H/D)^2 - 9.24(H/D) + 3.18\} \times 10^{-2}, \\ f_2(H/D) &= (H/D) \{-1.93(H/D)^2 + 1.05(H/D) + 5.58\} \times 10^{-1}. \end{aligned} \right\} \tag{7}$$

Figure 8 is comparisons of Eq. (6) with the measurements for the bottom slopes of $1/20$ and $1/100$, and shows fairly good agreements. The solid lines labeled $\eta_c=H$ and $\eta_c=H/2$ correspond to the solitary and Airy waves.

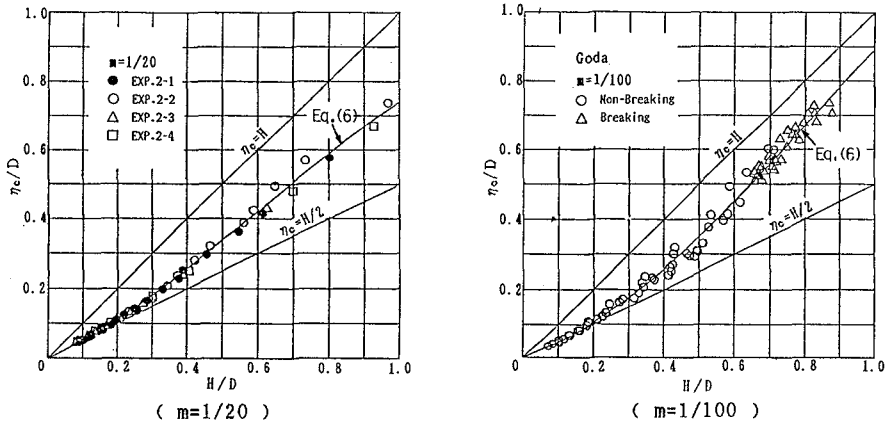

Fig. 8 Relative crest height η_c/D and H/D .

The 10th order stream function method, SFMB 10, can be improved by the almost similar procedure adopted to the ST 5 theory. Figure 9 shows the details of the improved stream function methods, SFMB'10 and SFMC' 10. After determining the asymmetric wave profile with aids of the relative phase shifts ζ_n , the velocities associated are calculated with the aid of SFMA 10 for irregular waves (Dean, 1965).

Comparisons between the measured and calculated wave elevations near wave breaking, as shown in Figs. 10 and 11, indicate superiority of the SFMC' 10 over SFMB' 10. SFMC' 10, and represent reasonably well the asymmetry as well as the maximum elevation of the wave profile in wave crest phase.

Fig. 10 Comparison of SFMB' 10 and SFMC' 10 with the measured wave elevation. ($H=4.3$ cm, $T=0.99$ s, $D=7.0$ cm, $Ur=84.3$, $m=1/20$)

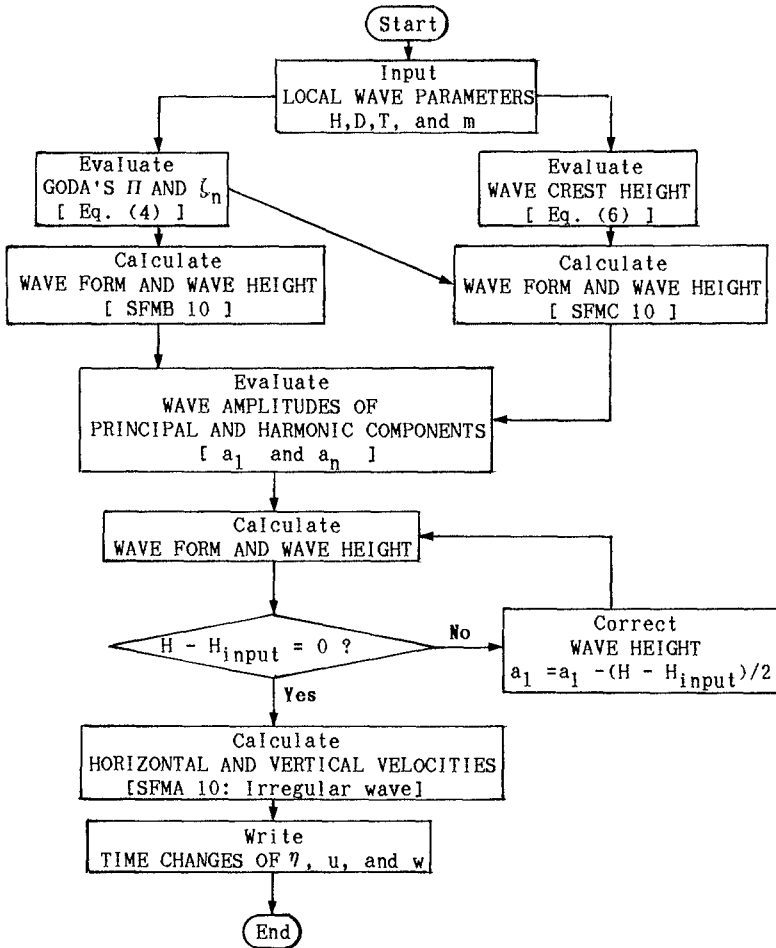

Fig. 9 Flow chart showing the details of SFMB' 10 and SFMC' 10.

Fig. 11 Comparison of SFMB' 10 and SFMC' 10 with the measured wave form near wave breaking. (Buhr Hansen & Svendsen, 1979) (H=4.7 cm, T=1.0 s, D=6.0 cm, Ur=127.9, m=1/34) [---- : calculated, — : measured]

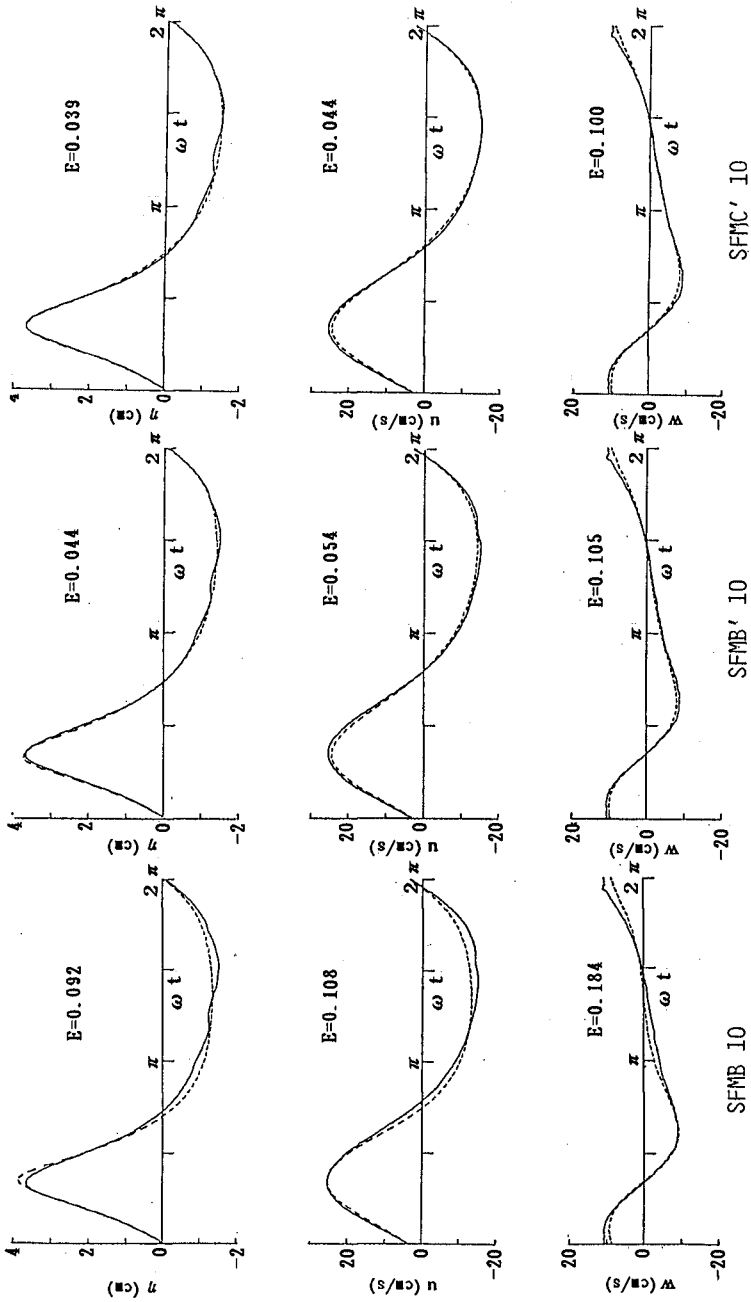

Fig. 12 Comparisons of SFMB 10, SFMB' 10, and SFMC' 10 with the measured wave profile and particle velocities. ($H=5.2$ cm, $T=0.84$ s, $D=9.0$ cm, $z/D=-0.444$, $Ur=44.4$) (—: measured, - - -: calculated)

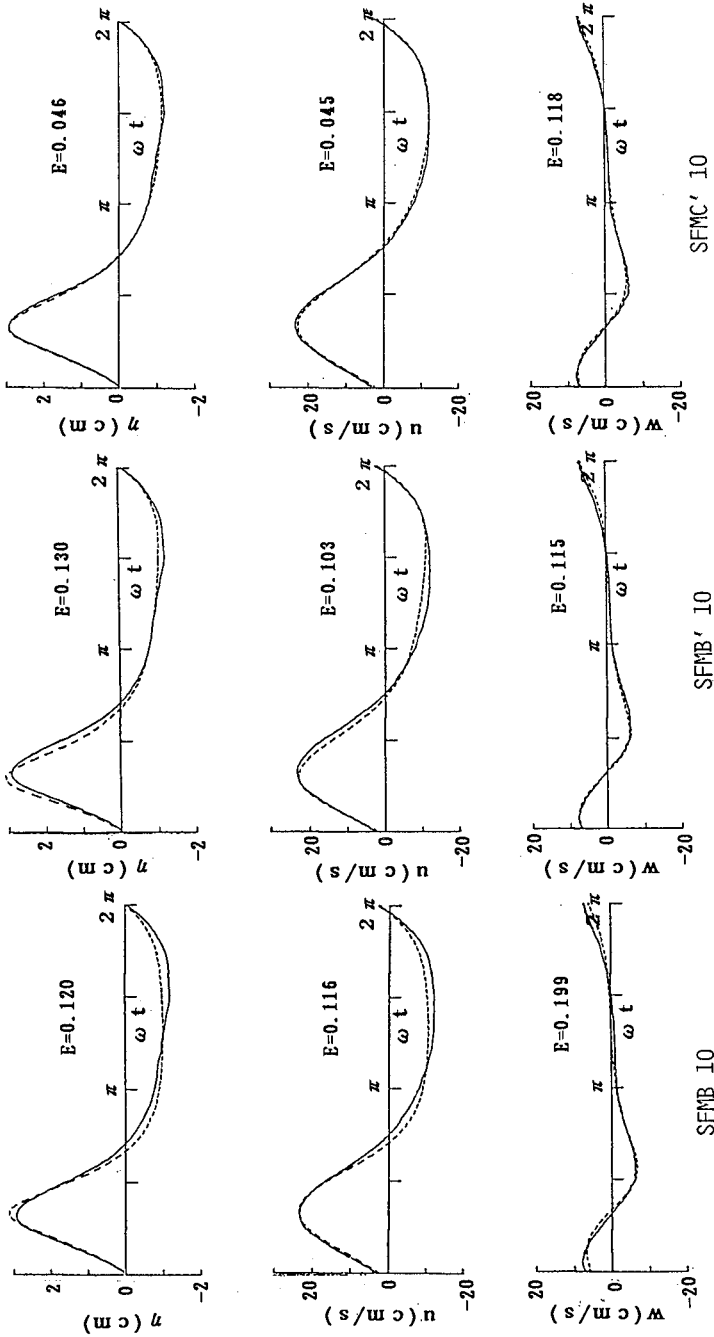

Fig. 13 Comparisons of SFMB 10, SFMB' 10, and SFMC' 10 with the measured wave profile and particle velocities. ($H=4.3$ cm, $T=0.99$ s, $D=7.0$ cm, $z/D=-0.786$, $Ur=84.3$) (—: measured, - - -: calculated)

Figures 12 and 13 illustrate comparisons of the measured wave elevation and particle velocities with the computed ones by SFMB 10, SFMB' 10, and SFMC' 10. Measured velocities under breaking waves tend to lag the surface elevation (Adeyemo, 1972; Flick et al., 1981), while these of the nonbreaking wave occur in phase with the wave profile, as seen in Figs. 11 and 12. This supports that the particle velocities are predicted with aid of the SFMA 10, using the calculated wave elevation. The good agreement of SFMC' 10 with the measurements around the crest phase brings about the better agreement in the trough phase.

It is concluded that the improvement in SFMC' 10 successfully achieves demonstration of the highly asymmetric variation of the wave kinematics even near the wave breaking. Moreover, the improved calculation yields the reasonable prediction both of the magnitude and phase of the peak velocities, which are of fundamental importance to the cross-shore sediment transport.

7. CONCLUSIONS

(1) The improved calculation of the kinematic field under relatively steep and nonbreaking waves was developed to describe asymmetric characteristics of wave kinematics. The improvement is made for the Stokes 5th order theory and Dean's 10th order stream function theory.

(2) The improvement is based on the idea that the vertical asymmetry in the wave elevation can be described by the harmonic amplitude of the nonlinear solution, and the horizontal asymmetry is caused by the relative phase shifts between the primary and harmonic wave component.

(3) Based on the experiments, the harmonic phase shifts are determined as a function of Goda's nonlinearity parameter H and the bottom slope.

(4) Agreements of the calculations with the measured wave elevation and particle velocities confirm that the improved calculations, ST' 5, SFMB' 10, and SFMC' 10, predict reasonably the temporal changes in one wave period.

In concluding, the improved calculation can predict the strongly nonlinear wave field for specified local wave conditions, without aids of direct numerical simulation techniques.

CHAPTER 31

A Model for Long Waves at Grazing Angle to a Rubble-Mound Jetty

Eloi Melo *
R.T.Guza †

Abstract

The main features of a model proposed recently by the authors for the propagation of long waves at grazing angle to a rubble-mound jetty are reviewed. Model results for a single jetty and for a jettied channel are shown.

1 Introduction

The behavior of ocean waves normally incident upon a rubble-mound breakwater has received considerable attention. Models describing wave reflection and transmission, the stability of the breakwater, energy dissipation, wave run-up and so on, are available for normal incidence. The case of oblique wave approach is less studied. Recently Melo & Guza (1990 a,b) proposed a linearized model for the propagation of long waves at grazing angle to a rubble-mound jetty. The model combines earlier work on waves normally incident on permeable breakwaters [Sollitt & Cross (1976), Madsen & White (1976)] with the localized dissipation diffraction model of Dalrymple, Kirby & Hwang (1984). Model results for a channel bounded by jetties compared favorably to an extensive data set obtained at the Mission Bay entrance channel in San Diego, California. This paper reviews the main features of the grazing angle model and briefly illustrates its applications.

2 Model Description

Following the idea of Madsen & White's (1976) model for normally incident waves, the grazing angle model also divides the dissipation of wave energy in the rubble-mound jetty into "external" and "internal" components. The "external" dissipation is associated with fluid motion over the sloped face, and the "internal" dissipation with fluid motion within the pores of the structure. Internal dissipation is modeled with a permeable, surface piercing, homogeneous core of rectangular cross-section. External dissipation caused by run-up over the rough, sloped face is simulated with a surrounding region of comparable *bottom* roughness (Figure 1). The dimensions of the core and external dissipation regions and the representative stone size are estimated from the actual (usually trapezoidal and multi-layered) structure. Incident waves are assumed to be long, linear (nonbreaking), monochromatic and to approach the jetty at grazing angle with respect to the jetty axis (Figure 1).

The key model equation is the Helmholtz equation

$$\nabla^2 \phi + \bar{k}^2 \phi = 0 \quad (1)$$

where ∇ is the horizontal (x, y) gradient, and $\phi(x, y)$ the wave potential, proportional to the free surface displacement. Energy dissipation is accounted for in the model by allowing \bar{k} to be complex.

$$\bar{k} = \sigma(gh)^{-\frac{1}{2}} (1 - if)^{\frac{1}{2}} \quad (2)$$

where σ is the wave frequency, g the acceleration of gravity, h the water depth and f a linearized dissipation coefficient discussed in section 3.

As opposed to the normal incidence situation, the grazing angle case has a wave crest propagating *simultaneously* over three distinct regions: "open" water, the external dissipation region and the permeable core. The portion of the wave within the dissipative zones will be locally damped; gradients in wave height will be generated and a diffraction pattern will appear. Plane wave solutions (with a fixed amplitude and propagation direction) are not possible. Dalrymple, Kirby & Hwang (1984) were the first to study wave diffraction caused by areas of energy dissipation and their solution method is also utilized here (section 4).

3 Linearized Dissipation Coefficients

The linearized dissipation coefficient quantifies the amount of dissipation taking place in each region. In "open" water, dissipation is usually negligible compared to that associated with the jetty, so $f = 0$ away from the jetty.

Figure 1: Plan view (upper) and cross-section (lower) of model breakwater.

The evaluation of f in the external region (f_{ext}) requires an estimate of the energy dissipated over a rough, steep slope by a wave at an arbitrary incidence angle. Until more is learned about this very complex problem, a representative value of f_{ext} is obtained from Madsen & White's (1976) reflection measurements of long waves *normally incident* on an impermeable, rough slope

$$f_{ext} \approx \frac{1 - R^2}{kD_e} \quad (3)$$

where R is a reflection coefficient, D_e is the width of the external dissipation region and k is the wavenumber. Madsen & White (1976) found that R was nearly independent of the incident wave height when $kl_s < 2$, where l_s is the length of the sloped face. The above condition is usually satisfied for swell waves in relatively shallow water and steep jetty faces, and makes f_{ext} indeed linear.

Nonlinear turbulent dissipation in the permeable core is included in the linearized model by means of the Lorentz principle of equivalent work [Sollitt & Cross (1976), Madsen & White (1976), Madsen (1983) and others]. In the general case, the internal dissipation coefficient, f_{int} , takes different values at different positions within the core (i.e. $f_{int}(x, y)$). The present model uses the fact that the core width is small compared to the wavelength (for relatively long waves) and assumes f_{int} to be constant in the transverse direction (y -dir). However, (slow) variations in the wave height within the core in the direction of wave propagation (x -dir.) make f_{int} a function of x . The iteration procedure used to calculate f_{int} and the parameterization of the porous medium are exactly the same ones utilized for normally incident waves (see, for example, Madsen (1983)).

4 Solution Method

The solution method suitable here is the parabolic approximation [Radder (1979), Booij (1981), Dalrymple, Kirby & Hwang (1984), Liu, Yoon & Dalrymple (1986), Kirby (1986)]. The governing Helmholtz equation (1) is split into parabolic equations for the transmitted and back-reflected fields. The back-reflected field is neglected and the resulting parabolic equation for the transmitted part is solved numerically. The equation to be solved, if the lower-order parabolic approximation is used, is

$$2i\bar{k} \frac{\partial A}{\partial x} + \left[2\bar{k}(\bar{k} - k) + i \frac{\partial \bar{k}}{\partial x} \right] A + \frac{\partial^2 A}{\partial y^2} = 0 \quad (4)$$

where A is the complex amplitude of the forward scattered wave field (ϕ^+)

$$\phi^+(x, y) = A(x, y) e^{ikx} \quad (5)$$

The applicability of the parabolic method relies on two assumptions:

- (i) That the wave propagates nearly along the axial direction of the jetty.
- (ii) That the back reflected (i.e. in the $-x$ -dir) wave field is negligible.

Assumption (i) is in accordance with the grazing angle requirement. For assumption (ii), the jetty head is the only place capable of producing strong back scattering. Elsewhere, x -variations in the medium of propagation are slow and no significant back reflection should occur. However, the effect of head scattering is expected to be small in the area of interest (i.e. for $x > 0$, Figure 1). Of course, assumption (ii) also implies the existence of a nonreflective boundary at the down-wave side (like a dissipative beach for example).

Numerical solutions are obtained by the Crank-Nicolson finite-difference scheme for a given initial condition. Solutions in the different regions must satisfy continuity of pressure and mass flux at the separating interfaces. This is straight forward at the interface between “open” water and the external dissipation region. However, at the permeable core interface there is a change in the porosity of the medium; a discontinuity in the normal velocity is required to assure mass conservation, and special matching conditions are necessary. Note also that the marching forward nature of the parabolic method is very convenient for the calculation of f_{int} by the Lorentz principle. The correct value of f_{int} is obtained after about 5 iterations.

5 Application Examples

In this section we illustrate the model results with two examples: a single jetty and a jettied channel.

Figure 2 shows the solution for a wave incident at 0° on a crib-style (rectangular cross-section) permeable jetty. In this particular application, all dissipation takes place in the permeable core and there is no external dissipation region. The opposite case of a virtually impermeable, sloped face structure can be treated by considering only external dissipation in the model. It is clear that the presence of the jetty alters significantly the wave field around it, even for a 0° incident wave. Even though the net effect of the jetty is to dissipate wave energy, the diffraction-reflection pattern can result in normalized wave heights greater than 1 (Figure 2). The solution for f_{int} is shown in Figure 3. The current example is for water of constant depth. However, this is *not* a constraint of the model, depth variations of mild slope can also be included. Preliminary tests show satisfactory results for incidence angles as large as 30° . More detailed studies of the single jetty case are under

Figure 2: Normalized, instantaneous surface elevation field. Incoming wave: incidence angle = 0° , period = 14 sec, height = 0.8 m, length = 120 m. Model jetty: core width = 32 m, stone diam. = 1.25 m, porosity = 0.45. The origin of the semi-infinite jetty is at (0,0).

Figure 3: Corresponding f_{int} for Figure 2.

way and will be presented in a forthcoming paper.

Figure 4 shows the solution for a wave propagating in a constant depth channel bounded by nontransmitting (sealed) rubble-mound jetties. The wave is initially at 0° to the channel axis and the model jetties have both external and internal dissipation. As we anticipated, energy dissipation occurring along the jetties generate cross-channel gradients in wave height and the initially plane wave is deformed by diffraction. A damped plane wave is not possible in a wide channel with strong energy dissipation localized at the edges. The solution is a modulated wave with bent crests in spite of the constant water depth. The down-channel variation in f_{int} , shown in Figure 5, corresponds to regions of higher and lower wave heights within the permeable cores.

Model results for a jettied channel compared favorably to an extensive data set obtained at the straight, 1-km long, 250-m wide, 8-m deep Mission Bay entrance channel. The model predicted both the observed rapid wave height decay on the channel centerline and the observed insensitivity of the normalized rate of decay to variations in wave conditions (Figure 6). In the Mission Bay study, the linearized dissipation coefficients were evaluated with the methodology summarized in this paper, *not* by fitting to the data. A complete account of the jettied channel application can be found in Melo & Guza (1990 a,b).

6 Concluding Remarks

The linearized model proposed by Melo & Guza (1990 a,b) for the propagation of long waves at grazing angle to a rubble-mound jetty has been reviewed. Although a crude approximation to the full problem of a directional spectrum of waves propagating about a permeable, multi-layered, sloped structure, we believe it realistically captures the main physical mechanisms of dissipation in the jetty and diffraction in the wave. The model may be a useful engineering tool and, with further refinements, may serve as a basis for dealing with obliquely incident waves on many types of dissipative structures.

CHAPTER 32

Movable Bed Friction Factors for Spectral Waves

Ole S. Madsen¹, Paul P. Mathisen², M. Michel Rosengaus³

Abstract

This paper presents a summary of carefully conducted laboratory experiments on the attenuation of simulated spectral waves propagating over an 18-m-long bottom section covered by 10-cm-thick layers of 0.12- and 0.2-mm-diameter uniform quartz sands. The measured attenuation is used in conjunction with the theory for spectral wave attenuation developed by Madsen et al. (1988) to determine values of the movable bed friction factor for spectral waves. When the values of movable bed friction factors, f_{wr} , are plotted against a fluid-sediment interaction parameter, the ratio of skin friction Shields parameter for an equivalent monochromatic wave, ψ_{mr}' , and the critical value of Shields parameter for initiation of sediment motion, ψ_c , a well-defined relationship between f_{wr} and ψ_{mr}'/ψ_c emerges. This relationship is independent of spectral shape (both finite-depth Jonswap and Neumann spectra were simulated) and is the same for the two sediment types tested. Although limited by the range of experimental conditions achieved in the laboratory study the results suggest a simple methodology for the evaluation of spectral wave attenuation from knowledge of sediment and wave characteristics.

Introduction

In order to predict the attenuation by bottom friction for waves propagating in finite water depth over a movable bottom, it is necessary to estimate the value of the bottom roughness or alternatively the wave friction factor. For wave conditions exceeding the threshold of sediment movement, bottom roughness or wave friction factor is governed by wave-sediment interaction and is related to the characteristics of the wave-generated bedforms. Based on rather limited experimental evidence obtained for wave-sediment interaction, corresponding exclusively to simple periodic waves, predictive relationships for the roughness of movable beds subjected to wave agitation have been proposed, e.g., Grant and Madsen (1982). Neither theoretical nor experimental justification appeared to exist for the transfer of this "knowledge" to the more realistic description of waves in terms of their spectrum until Madsen et al. (1988) presented a theoretical model for the attenuation of spectral waves propagating over a rough bottom, described by its equivalent roughness, k_b . Based on this model Madsen and Rosengaus (1988) developed a methodology for the prediction of spectral wave attenuation by bottom friction. This methodology consisted of:

- 1) representing the spectral wave condition by a representative monochromatic wave having the same root-mean-square near-bottom orbital velocity, u_{br} , and excursion amplitude, A_{br} , as the spectral wave;
- 2) using the representative wave in conjunction with empirical relationships established for monochromatic waves to predict the geometry, relative height, η/A_{br} , and steepness, η/λ , of the wave-generated bottom bedforms;
- 3) obtaining the relative equivalent bottom roughness from an empirical relationship giving k_b/A_{br} as a function of bedform geometry.

The empirical relationships necessary for the implementation of the procedure outlined above were established through extensive and carefully conducted experiments with monochromatic waves (Madsen and Rosengaus, 1988) and the proposed methodology for the prediction of spectral wave attenuation by bottom friction was tested against experimental data. However, the experimental data on which the methodology was based were *limited* by having been obtained for a single sediment, a 0.2-mm quartz sand, and the test of the spectral wave attenuation methodology was *limited* to wave conditions exceeding only slightly the critical condition for initiation of sediment motion. For these reasons Madsen and Rosengaus (1988) emphasized that

their proposed spectral wave attenuation methodology "should be regarded as preliminary until further experiments, covering a wider range of experimental parameters, can support its general validity."

The objective of the present study was to remove the limitations of the previous experimental investigation by: i) performing experiments with a different sediment (a 0.12-mm quartz sand); and ii) extending the range of spectral wave conditions tested to values well above those corresponding to initiation of sediment motion.

The philosophy behind the experimental methodology and procedures used in the present study is unchanged from that of Madsen and Rosengaus (1988). Simply stated, it is to measure the attenuation of water waves (periodic as well as simulated spectral waves) propagating over a long section of movable bed and from the measured attenuation of each incident wave component backfigure the appropriate value of the wave friction factor for each incident wave component using the theoretical model for spectral wave attenuation developed by Madsen et al. (1988). Attempts to relate the experimentally obtained values of friction factors through the corresponding equivalent bottom roughness to geometry of the bottom bedforms, i.e., using the Madsen and Rosengaus (1988) procedure in reverse, were unsuccessful. Therefore, in contrast to Madsen and Rosengaus (1988), the friction factor values obtained here are used directly in an attempt to establish a *friction factor relationship* without the intermediate steps of relating friction factors to equivalent roughness and then relate equivalent roughness to geometry of the wave-generated bottom bedforms.

Methodology and Procedures

The experimental set-up, methodology, and procedures used in this study are identical to those described by Madsen and Rosengaus (1988).

Experimental Set-up. Laboratory experiments were performed in a 0.75-m-wide, 0.90-m-deep, and 30-m-long wave flume in the R. M. Parsons Laboratory. This wave flume is equipped with a programmable piston-type wave maker and has a 1-on-10 sloping absorber beach, which in the present experiments was covered by 7.5-cm-thick horsehair mats to further decrease reflections. At the wavemaker a trapezoidal wooden ramp provided a smooth transition to a level 10 cm above the flume bottom. The region between the ramp--approximately 3 m from the

wavemaker--to the start of the absorber beach--approximately 19 m from the wavemaker--was covered by a 10-cm-thick layer of very uniform 0.12- or 0.2-mm-diameter quartz sand. The water depth above the movable bed test section was 0.6 m for the majority of the experiments with a few experiments conducted at a depth of 0.5 m.

Waves. In order to mobilize the bed material it was necessary to generate waves of large amplitudes and wave length. The standard wave condition of Madsen and Rosengaus (1988) corresponded to a 6-cm-amplitude, 2.65-sec-period wave for which the depth-to-wavelength ratio $h/L = 0.1$ in the 0.6-m-deep section. In the present investigation the wavemaker motion was programmed to simulate the generation of an incident wave spectrum with a peak period corresponding to a depth to peak period wave length ratio of 0.1 in the test section and a root-mean-square wave height ranging from 8.4 cm to 13.4 cm. Both broad-banded Pierson-Neumann spectra and narrow-banded finite-depth Jonswap ($\gamma = 3.3$) spectra were simulated by five frequency components of equal energy.

Measurements. The incident and reflected wave spectra were determined from measurements of surface profiles obtained by two three-gauge arrays located 3 m and 18 m from the wavemaker, respectively. Although not used directly in the analysis of the experimental data obtained in the present study bottom bedform geometry was determined photographically by taking pictures of 1-m sections of the bed profile at four stations along the test section. These pictures, including horizontal and vertical scales, were then projected onto a digitizing tablet and analyzed. Using a vertically mounted laser to trace the bottom profile at different distances from the flume sidewalls it was shown that the trace along the sidewalls accurately represented the bedform geometry.

Procedures. Given the philosophy behind the experiment as outlined in the Introduction the procedure to be followed is quite simple. From the analysis of Madsen et al. (1988) we may write the energy conservation principle for each wave component when only bottom dissipation is considered

$$c_{gn} \rho g a_n \left[\frac{\partial a_n}{\partial x} \right]_{bf} = -E_{d,n} = -\frac{1}{4} \rho f_{wn} u_{br} u_{bn}^2 \quad (1)$$

where ρ is the fluid density, g is gravity, a_n and c_{gn} are the amplitude and group velocity of the wave

component of frequency ω_n , respectively, and for a finite number of wave frequency components

$$u_{br} = \sqrt{\sum_n u_{bn}^2} \quad (2)$$

$$A_{br} = \sqrt{\sum_n (u_{bn}/\omega_n)^2} = u_{br}/\omega_r \quad (3)$$

Thus, for a single wave component--whether it is alone or one of two or more--we have from Eqs. (1) through (3) and linear wave theory

$$\left[\frac{\partial a_n}{\partial x} \right]_{bf} = -f_{wn} \frac{u_{br}}{4gc_{gn}} \left[\frac{\omega_n}{\sinh k_n h} \right]^2 a_n \quad (4)$$

In principle the experimental determination of a_n at two stations, Δx apart, suffices to determine a value of f_{wn} from Eq. (4). In practice, however, life is unfortunately not that simple.

All the experimental determinations of Δa_n involve the "small" difference between two "large" quantities. As an example we may take the standard periodic wave ($a_n = 6$ cm, $T_n = 2\pi/\omega_n = 2.65$ sec, $h = 0.60$ m) and a friction factor of $f_{wn} = 0.2$ to obtain a change in amplitude of $\Delta a_n \approx 7$ mm over the 15-m-long test section. While this value of Δa_n is well above the accuracy with which the individual amplitude is determined experimentally--estimated to be of the order 0.5 mm--it should be recalled that component amplitudes of the order 2 to 3 cm are used in spectral simulations. In fact, the decision to simulate the wave spectra by five frequency components was arrived at precisely from consideration of desired accuracy. Nevertheless, we are in some cases attempting to measure differences of the order a mm or less, i.e., approaching the magnitude of uncertainty of each measurement used to determine the difference. For this reason alone it is essential that the experiments be conducted with great thoroughness and repeated several times in order to minimize the effect of experimental errors. In the present investigation all experimental determinations of wave attenuation for a given wave condition were repeated five to ten times.

As a result of the inherent experimental difficulties associated with an accurate determination of Δa_n the variability in friction factors for the individual frequency components, f_{wn} , obtained from Eq. (4) is quite large. However, the theory developed by Madsen et al. (1988) assumed the friction factors for

the individual frequency components, f_{wn} , to be the same for all frequency components. For these reasons the wave attenuation data were used to obtain values of f_{wn} from Eq. (4) and these values were then used to obtain a single "representative" wave friction factor, f_{wr} , from

$$f_{wr} = \frac{\sum_n f_{wn} u_{bn}^2}{\left[\sum_n u_{bn}^2 \right]} \quad (5)$$

In passing, it should be noted that the representative wave friction factor, defined by Eq. (5), will conserve total spectral dissipation when applied to each individual frequency component.

However, other effects in addition to those directly related to measurement accuracy play a role in these experiments. Owing to the requirement of long waves of substantial amplitude--to set the bottom sediment in motion--it can be expected that nonlinear effects come into play. To illustrate this, assume the change of amplitude, Δa_n , to have been determined experimentally over a distance Δx . Formally, we may then write

$$\frac{\partial a_n}{\partial x} \simeq \frac{\Delta a_n}{\Delta x} = m = m_{nl} + m_{sw} + \left[\frac{\partial a_n}{\partial x} \right]_{bf} \quad (6)$$

in which m_{nl} denotes amplitude changes associated with non-linearity, m_{sw} the changes associated with dissipation along the side walls, and $(\partial a_n / \partial x)_{bf}$ is the quantity expressing the contribution of bottom friction, i.e., the quantity we are looking for. A priori we cannot neglect the unwanted contributions, m_{nl} and m_{sw} , in particular when the overall requirement of accuracy is kept in mind.

To evaluate the magnitude of the terms m_{nl} and m_{sw} in Eq. (6) a series of experiments was first conducted in which the incident wave characteristics at the two measurement stations were determined corresponding to flat-bed conditions, i.e., sufficient time following the start of the wavemaker was allowed for transients to die out and the bed was covered by thin steel plates to prevent bedform development. Experiments of this type were performed 5 to 10 times and the measured amplitude change in these experiments (denoted by subscript p)

$$\left[\frac{\Delta a_n}{\Delta x} \right]_p = m_p \simeq m_{nl} + m_{sw} + m_{fb} \quad (7)$$

was taken to represent nonlinear and sidewall effects also in the movable bed runs. The bottom friction

effect, m_{fb} in Eq. (7), was calculated theoretically--the bottom boundary layer remained laminar for flat bed conditions.

Following the preliminary runs the wave condition was maintained in the flume for sufficiently long time to ensure the bedforms on the bottom to be fully developed (in some cases this took several hours). Several wave measurements were then performed corresponding to fully developed bed conditions with bottom bedform geometry determined between individual wave measurements (to ensure that the bed indeed was fully developed). Combining the preliminary and the fully developed wave measurements produced experimental results for the isolated effect of wave attenuation

$$\left[\frac{\partial a_n}{\partial x} \right]_{bf} \approx \left[\frac{\Delta a_n}{\Delta x} \right]_{bf} = m - m_p + m_{fb} \quad (8)$$

caused by the movable bed, which in turn were used in Eqs. (4) and (5) to obtain friction factors.

Results

The experimental values obtained for the representative spectral wave friction factor, f_{wr} , are presented as full symbols (with one standard deviation error bars indicated) in Figure 1 versus the representative value of a fluid-sediment interaction parameter

$$S_r = \frac{\psi_{mr}'}{\psi_c} \quad (9)$$

in which

$$\psi_{mr}' = \frac{\tau_{bm}'}{(s-1)\rho g d} \quad (10)$$

is the Shields parameter obtained from the maximum bottom shear stress predicted for the representative monochromatic wave defined by Eqs. (2) and (3) based on grain-size bottom roughness, i.e., for $k_b = d$, and ψ_c is the critical shear stress for initiation of sediment movement obtained from Shields criterion (Madsen and Grant, 1976). Thus the parameter S_r represents the extent to which threshold conditions are exceeded. For comparison the wave friction factors obtained from monochromatic wave experiments are included as open symbols in Figure 1.

Figure 1. Movable bed friction factors for spectral waves (solid symbols) and periodic waves (open symbols). Triangles: 0.2-mm, Pierson-Neumann spectrum; circles: 0.12-mm, Pierson-Neumann spectrum; squares: 0.12-mm, finite-depth Jonswap spectrum

A striking feature of the spectral wave friction factors presented in Figure 1 is that they appear to form a unique relationship $f_{wr} = f_{wr}(S_r)$, despite the fact that the values were obtained for different sediments (0.2-mm- and 0.12-mm-diameter quartz sands) and for different spectral shapes (broad-banded Pierson-Neumann and narrow-banded finite-depth Jonswap spectra with $\gamma = 3.3$). While this finding is extremely fortunate from the point of view of practical application of the results it is of some concern that the spectral wave friction factors consistently fall considerably below the values of their monochromatic counterparts for $S_r > 1.5$.

The methodology for the determination of spectral wave friction factors proposed by Madsen and Rosengaus (1988) should result in a negligible difference between spectral and monochromatic wave friction factors so long as their associated bottom bedforms are similar. Examination of the height and length of bedforms generated by spectral and monochromatic waves reveals that the spectral bedforms have a slightly smaller

height and a somewhat smaller steepness than their monochromatic counterparts. However, accounting for this difference in bedform geometry would at most account for a 20-percent decrease in the spectral wave friction factors relative to the monochromatic values when the bedform geometry is used in conjunction with the empirical relationship for bottom roughness proposed by Madsen and Rosengaus (1988). Referring to the results presented in Figure 1 it is evident that a larger-than-20-percent reduction of the monochromatic wave friction factors is called for to bring them in line with the spectral results. It is therefore concluded that the methodology for the evaluation of spectral wave friction factors proposed by Madsen and Rosengaus (1988) indeed is limited by the limited range of their experiments. In fact, it worked for them only because their spectral experiments were limited to values of $S_r < 1.5$, i.e., those represented in Figure 1 by the three points with $S_r \approx 1.3$, which just happened to overlap with the monochromatic results.

In an attempt to explain the reduction of spectral wave friction factors the digitized records of the bottom profiles, obtained from photographs of the fluid-sediment interface along the glass side-walls of the flume, were carefully examined with particular emphasis on the characteristics of the ripple crests. In this manner it was found that ripple crests generated by spectral waves were somewhat more rounded than those generated by monochromatic waves. Clearly, the rounding of a sharp ripple crest only reduces the ripple height slightly (as observed) but results in a significant reduction of the strength of flow separation over the crest. It is hypothesized that the larger waves in a spectral simulation shave off the sharp ripple crests thereby causing the observed reduction in dissipation and friction factors for spectral waves. Since maximum near-bottom orbital velocities associated with spectral waves are approximately Rayleigh-distributed regardless of spectral shape, this hypothesis supports our finding that spectral dissipation is independent of spectral shape.

Summary and Conclusions

The spectral wave friction factors obtained from our experiments and presented in Figure 1 may be represented with a 20-percent error by the following movable bed friction factor relationship

$$f_{wr} = 0.29 S_r^{-1.5} \quad \text{for} \quad S_r > 1.2 \quad (11)$$

This expression may in turn be used with the spectral wave boundary layer theory of Madsen et al. (1988) to obtain a relationship, accurate to within 30 percent, for the movable bed roughness associated with spectral waves

$$k_b/A_{br} = 1.5S_r^{-2.5} \quad \text{for} \quad S_r > 1.2 \quad (12)$$

It is tentatively proposed that these relationships are generally valid for cohesionless sediments regardless of spectral shape. Having been burned once, it should be *emphasized* that experimental support of these expressions is limited to values of $S_r < 2.5$. However, some comfort in extrapolating the expressions beyond this limit may be found in the dependency of the relative roughness on S_r to the negative 2.5 power being identical to the S_r -dependency of the bottom bedform roughness of Grant and Madsen (1982) for large values of S_r .

CHAPTER 33
2ND ORDER WAVE GENERATION
AND APPLICATION TO SHOALING INVESTIGATIONS

by

A. Götschenberg and K.F. Daemrich¹

ABSTRACT

Model tests have been carried out in a wave channel with and without consideration of 2nd order wave components in the control signal for the wave paddle. The wave channel was equipped with a 1:30 sloped bottom starting 57.00 m in front of the paddle. The water depth was 1.00 m during all tests.

The Self-Correcting System was proved to be able to suppress unwanted free higher and lower harmonics during the generation process.

On the slope measured amplitudes of the 2nd order waves were lower than predicted by 2nd order theory. Commonly used wave height parameters are not influenced significantly by the type of control signal.

1. Introduction

A large number of shoaling investigations have been carried out in the last two decades. Starting with pure regular wave investigations, later on tests were performed with irregular seastate and finally with directional spectra in the increasing number of 3D wave basins in the world. On the other hand with the increasing amount of computer hardware power available, software tools were developed to calculate shoaling phenomena in 2D or 3D models. But still there is a lack of information concerning the behaviour of non-linear waves generated in a wave channel either in a horizontal section and especially over a sloping bottom.

This paper deals with the generation of 1st and pertinent 2nd order waves in a wave channel. A technique is presented leading to proper 2nd order wave components without unwanted free waves in the horizontal section of the channel. Measured values of 2nd order wave amplitudes and commonly used wave height parameters are plotted for the shoaling area.

2. 2nd Order Wave Theory for Wave Groups and Spectra

The theoretical solution of 2nd order wave phenomena is referred to SAND (1982, "Long Wave Problems ...") and SAND/MANSARD (1986, "Reprod. of Higher Harmonics..."). They present transfer function formulas which allow the computation of the amount of 2nd order wave components in irregular wave trains. Fig. 1 shows a time series of a simple wave group, composed of two frequencies f_1 and f_2 . The extension of 1st order theory to 2nd order shows that additional wave components appear at frequencies $f_2 - f_1$ (bounded long wave) and $f_1 + f_2$ (higher harmonic). Furthermore the higher harmonics $f_1 + f_1$ and $f_2 + f_2$, known from the regular wave theory, are 2nd order effects related to each basic frequency component. The superposition of 1st and 2nd order waves shows the typical flatter troughs and sharper crests compared to the linear wave train. Lower and higher harmonics are bound to the group of the basic linear waves, i.e. they do not propagate as linear waves with similar frequencies but with the group velocity.

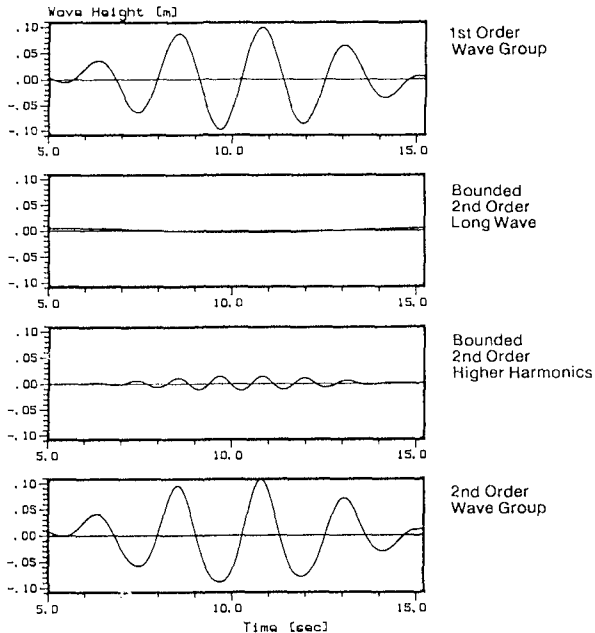

Fig. 1: Example of a Wave Group and Pertinent 2nd Order Components

2nd order waves of an irregular wave train are calculated by superposition of lower and higher harmonics of all possible combinations of frequencies in the 1st order spectrum.

The amplitudes of lower and higher harmonics are calculated from transfer functions given in the above mentioned papers.

When a 1st order wave train is generated in a hydraulic model, a transformation process occurs near the wave paddle generating the group bounded long wave (f_2-f_1) and also the bounded higher harmonics f_1+f_1 , f_1+f_2 , and f_2+f_2 . During this process also free long waves and free higher harmonics are created which are about 180° out of phase at the paddle compared to the bounded wave components and move independent from the basic linear wave combinations. At a certain frequency (i.e. f_2+f_1) two waves are existent in the channel: the bounded one which belongs to the 1st order waves and should not be suppressed and the unwanted free one which should be suppressed because it is only due to the technique of wave generation in the model and may cause problems in model test interpretation.

Fig. 2: Experimental Setup

3. Model Test Layout

Fig. 2 shows the experimental setup during the tests in the wave channel at FRANZIUS-INSTITUT. The channel has a horizontal bottom of 57.00 m length and a 1:30 sloped plywood beach at the end. The width of the channel is 2.20 m and the water depth is 1.00 m. The wave paddle was driven in "pusher mode" during all tests. Some wave gauges are installed in the area with the horizontal bottom. The greater part is concentrated on the slope, mainly in the region with low water depth. Test series contained regular waves, bichromatic waves (groups composed of two frequencies) and spectra with different incident wave steepness and peak enhancement factors.

The sequence length of the wave groups was 20.48 sec and the sequence length of the spectra was 102.4 sec. All signal creation and measurement analysis work was done on a HP1000/A600+ computer equipped with DA/AD converter. The sampling rate of signal input and output was 80 msec in the case of wave groups and 100 msec in the case of spectra. The measurement of the gauge signals starts when the wave paddle starts to move and lasts 4 minutes if wave groups are generated and 6 minutes for wave spectra respectively.

4. Generation of Wave Groups

4.1. Analysis over Test Duration

In order to value the existence of bounded and free waves an FFT-analysis of the measured time series was performed for several time windows. Fig. 3 shows results from tests with 1st order wave generation. The variation of the measured amplitudes of the frequency component f_2-f_1 with increasing test duration is plotted in different water depths ($f_1=0.25$ Hz, $f_2=0.30$ Hz). In comparison the theoretical amplitudes according to the formula of SAND applied to the measured components f_1 and f_2 is shown. The control signal in this test contains no 2nd order amplitude, especially no (f_2-f_1) -component. It clearly can be stated, that the amplitude of this component is different in space and time dimension. The top frame contains the component at gauge 1 (water depth $h=1.00$ m) near the paddle. The amplitude is about 2 mm, increasing to 15 mm after 70 sec test duration due to reflection. At gauge 4 ($h=1.00$ m) the amplitude increases from 4 to 13 mm and at gauge 9 ($h=0.27$ m), where still no breaking occurs, the amplitude reaches 25 mm and decreases to 18 mm after 100 sec. From

the results in the time windows without reflection it can be seen that in the channel a system of two waves, both with the frequency f_2-f_1 , a bounded and a free one, exists. The superposition leads to different resultant amplitudes in space because of different propagation velocities in the channel.

Fig. 3: Amplitude of 2nd Order Frequency Component f_2-f_1 versus Test Duration without Compensation ($f_1 = 0.24$ Hz, $f_2 = 0.29$ Hz, dotted line: Theory)

A proper generation method should create the bounded lower and higher components without parasitic free waves. Measured amplitudes would then be constant in space and, as long as there is no influence from reflection, in time. Ignoring the theoretical solution of 2nd order theory for computation of the control signal we have used the "Self-Correcting System" (DAEMRICH, EGGERT, 1981) for the generation of the control signal with the higher and lower harmonic components.

The target wave train was computed first with lower and higher harmonics according to the theory. Then a control signal for the wave paddle was calculated using linear

hydromechanic transfer functions as a first input. 3 or 4 test runs with the Self-Correcting System were made to find the best fitting of desired and target wave train at the reference gauge. For an easy and definite detection of deviations from the target wave train the reference wave gauge has to be chosen close to the wave paddle. In our test it was chosen to be the gauge 1 m in front of the wavemaker.

Fig. 4 shows the component f2-f1 now with compensation of 2nd order waves in the above mentioned way. Top and middle curve are gauges in the horizontal section of the channel. The third graph is again gauge 9 on the slope. The wave group reaches this point after 30 sec, at that time the amplitude of the component f2-f1 starts to increase.

Amplitudes fit the theoretical values very well in the horizontal section up to the time step 40 sec. The amplitudes of the basic linear components f1 and f2 are stable during the whole test run. The increasing amplitude after 40 sec indicates a reflected wave at the frequency component f2-f1. From our analysis it cannot

Fig. 4: Amplitude of 2nd Order Frequency Component f2-f1 versus Test Duration with Compensation (f1 = 0.24 Hz, f2 = 0.29 Hz, dotted line: Theory)

Fig. 5: Amplitude of 2nd Order Frequency Components f_1+f_1 , f_1+f_2 , and f_2+f_2 versus Test Duration with Compensation ($f_1 = 0.24$ Hz, $f_2 = 0.29$ Hz, dotted line: Theory)

be clearly stated whether it is a reflected bounded long wave or a reflected free wave, created during the propagation of the basic linear waves over the sloping bottom at the end of the channel.

At gauge 9 in a water depth of 0.27 m (bottom curve, Fig. 4) the measured amplitude was always lower than the theoretical one, but both curves are nearly stable over time when the group reaches this point.

The time variation of the amplitudes of the higher harmonics are similar to the variation of the lower component in Fig. 4. In Fig. 5 the higher harmonics are plotted over test duration for the case with 2nd order compensation in the control signal. The measurements fit very well with calculations and are stable over time. In the higher harmonic components almost no free parts are detectable. On the slope the measured amplitudes are always lower than predicted by theory.

4.2. Analysis over Channel Length

In Fig. 6 the measured amplitude of the lower harmonic ($f_2 - f_1$) is plotted over the channel length with (Fig. 6, top) and without (Fig. 6, bottom) compensation of 2nd order waves. The FFT-analysis starts 40 sec after start of the wave paddle movement. Test conditions are the same as in the previous plots. If no free wave component exists in the channel, the curves labeled "theory" and "model test" should be parallel to x-axes and have similar course in the horizontal section of the channel. Without compensation of 2nd order waves the amplitudes differ in space, indicating the existence of both bounded and free components. With compensation nearly no free component is detectable.

In Fig. 7 the 2nd order higher harmonic wave amplitudes are plotted from tests with and without compensation. The tendency is the same as for the lower harmonic: Without compensation of 2nd order waves, the amplitude differs over the channel length, a free wave exists. With compensation almost no free wave is detectable in the horizontal section.

Fig 8 and 9 are similar plots like Fig. 6 and 7 but for a shallow water wave group.

The results reported were obtained from tests with groups that only contain two frequencies. The tests with spectra were performed in a similar way with the Self-Correcting System. However, the principle of generating free and bounded harmonics can be studied easier in

compensation ($f_1 = 0.20$ Hz, $f_2 = 0.24$ Hz)

simple wave groups because every higher and lower harmonic has only one pair of basic linear waves as source. In a spectrum a lot of combinations of frequency components will contribute to a lower and higher harmonic frequency, each with a bounded and free part. A separation to each source couple f_1 and f_2 and verification and analysis in the hydraulic model seems to be a Sisyphean task.

4.3. Analysis in the Shoaling Area

The difference of 2nd order wave amplitudes between measurement and theory is obvious in the area of the slope and detectable in all cases (Fig. 6 - 9).

In Fig. 8 and 9 the incident linear waves are shallow water waves. There is good agreement in the horizontal bottom section but no agreement of theory and measurement in the area with low water depth. Although the measured amplitudes increase, they never reach the theoretical ones.

The analysis of 2nd order waves on the slope is dominated by the fact that measured amplitudes are lower than the predicted ones. Theoretical values are obtained by using only the two basic linear components as a source, although spectral deformation on the slope occurs (s.Ch. 5). Incorporating the complete spectrum to calculate the higher harmonics on the slope as well as considering wave setup only leads to insignificant reduction of theoretical values.

This leads to the question whether 2nd order waves can be generated stable in time and space dimension for significant lower water depth.

5. Spectral Deformation

It was the aim of the test to prove whether in the shoaling area a difference occurs in measured wave parameters with and without compensation of 2nd order waves in the control signal.

In a first step the ratio of $H_{1/3}$ over H_{m0} is plotted against relative water depth (Fig. 10). The two graphs in one frame are tests without and with compensation. Starting with the common value of 0.95 for deep water the ratio increases up to 1.2 in the first case and 1.10 in the second. A general tendency in the behaviour of 2nd order and 1st order spectra is not detectable.

Fig. 10: Ratio of Waveheight Parameters

Fig. 11 shows a plot of H_{13} over H_{130} against the ratio of water depth over incident wave height. Again no difference can be detected whether compensation of 2nd order was used or not. The curve without dots shows the result of GODA's theory for the irregular wave deformation process. Regarding the results of all tests it can be stated that theory and measurements are in good agreement in shallow water but for values of h/H_0 between 1.6 and 4.0 the theory overestimates the measurement.

Fig. 11: Variation of Significant Waveheight H_{13}

6. Conclusion

The Self-Correcting System was found to produce irregular waves with strongly reduced unwanted free 2nd order waves when theoretical 2nd order time series served as target wave trains.

It has been shown, that in the case of wave groups the amplitudes of the 2nd order waves in the shoaling area differ dependent on the consideration of 2nd order waves in the control signal. In both cases they are lower than predicted by theory.

In a wave spectrum, wave height parameters seem to be not significantly changed whether a compensation of 2nd order waves was used or not.

CHAPTER 34

COMPUTATION OF 3-D WIND-DRIVEN CURRENTS BY RESPONSE FUNCTION METHOD

Shiao-Kung Liu and Jan J. Leendertse

1. INTRODUCTION

The paper describes the principle and the computational procedure for the calculation of coastal wind-driven circulation by means of the response function technique. Response functions for a specific coastal seas are derived by use of a three-dimensional model of the area. This method computes the dynamic features associated with the coastal circulation via numerical convolution. Consequently, it is several orders of magnitude more efficient than using the direct integration of the three-dimensional coastal model itself.

2. TECHNIQUES USED

For computing coastal wind-driven currents, the traditional, simple fixed drift-ratio method has many difficulties when applied in shallow coastal area with complicated boundaries. Strictly speaking, the fixed ratio method is applicable only for cases of steady wind with constant speed blows over water with infinite depth and with no boundaries. However the concept is rather good and simple. The proposed response function method is the extension of this basic idea except it includes the nonlinear dynamics associated with a specific coastal area.

The RAND Corp. Santa Monica, CA. 90406

When used in conjunction with a verified model, the wind driven currents of different vertical levels can be calculated using numerical convolutional technique. When deriving the response function, local parameters such as the inertial period, tidal regime and tidal dissipation effect associated with the particular coastal area are all included. To generate a complete set of response functions, five computer simulation runs are needed. One computer run is without wind but with tide. The other four computer runs are with tides and with winds from each of four directions. The four response function sets are derived from the difference between them and the one with tide as the only forcing function. The magnitude of tidal currents at different coastal areas produces variable wind responses under the same wind, so the tide has to be included when deriving wind response functions, otherwise they will be overestimated. This is why in a coastal area with strong tidal currents the drift ratio would be lower than in the open ocean because of the quadratic nature of the bottom friction.

Wind driven currents over stratified waters vary with the degree of vertical stability associated with the stratification. Shore effect further complicates the three-dimensionality of the hydrodynamics of the coastal wind driven currents. To illustrate this point we use a simple case where the E-W and N-S components of the response function of water movement at two nearby locations in Norton Sound is plotted (Figs. 1 and 2). These response functions for the easterly wind are derived by applying east wind for a duration of 12 hours (close to the inertial period) over the water. The response of surface water at two nearby locations is not the same to satisfy the continuity principle of water within the bay. Response functions over the water column of the entire modeled area are calculated by the three-dimensional model.

When response functions are saved in discrete time intervals (usually 15 to 30 minutes) the drift velocity under a future wind scenario at a certain time is computed by numerical convolution.

$$U_{ijk}(n\Delta t) = \Delta t \sum_{m=0}^n (W^2) h_{ijk}(n\Delta t - m\Delta t)$$

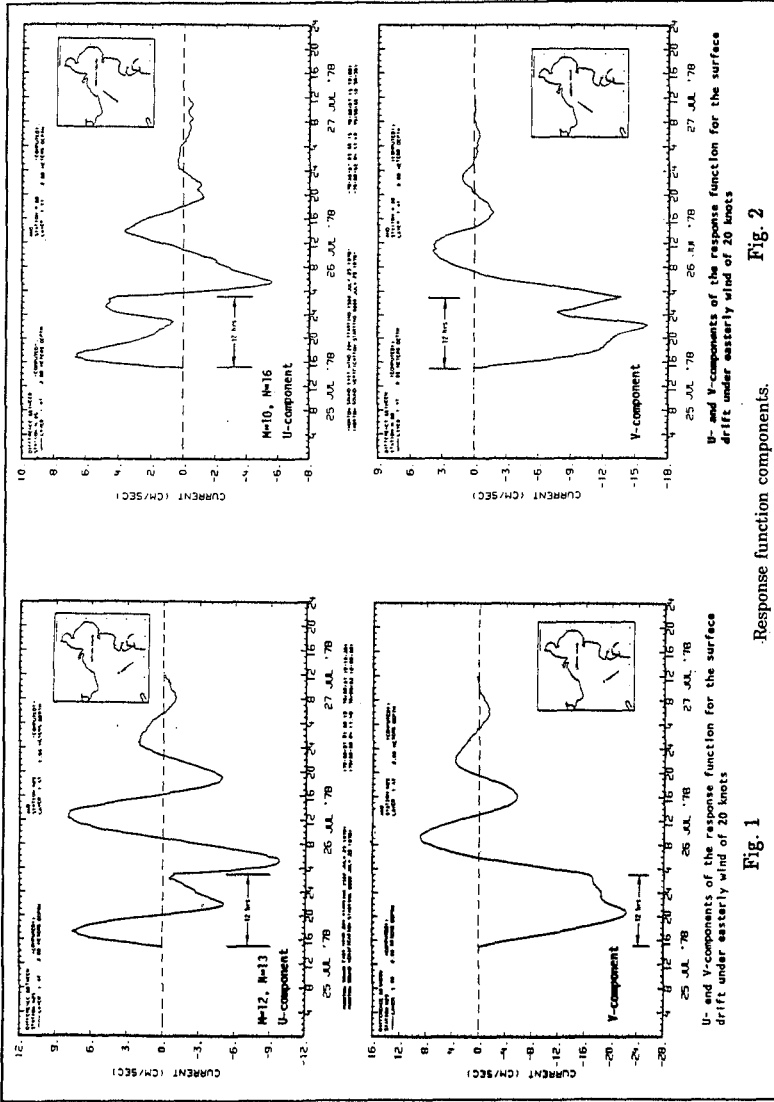

Fig. 1

Response function components.

Fig. 2

U- and V-components of the response function for the surface drift under easterly wind of 20 knots

Two sets of wind response functions for the surface layer of two neighboring coastal locations showing the difference due to the effects of shore distance, depth, bottom friction, and vertical stratification.

where W = wind speed from a certain direction,

U_{ijk} = velocity at a particular point

in space (i,j,k)

h_{ijk} = time domain response function between

squared wind speed and velocity at
point (i,j,k)

With this formula the velocity at point i,j,k can be determined if the wind speed from a specific direction is known, as well as the response function. The same principle applies for complex wind scenarios, then the vectorial decomposition is involved. Similarly, the principle has been extended to simulating movements and dispersion of pollutant, oil movements under ice, multivariant system analysis involving environmental impact due to multiple sources, etc. (Liu and Leendertse, 1987, 1989, 1978). Figure 3 shows a typical results of coastal drift as computed with numerical convolution. Computer time required by this method is approximately two orders of magnitude lower than the direct 3-D simulation method.

3. ACKNOWLEDGEMENTS

The study was supported by the Mineral Management Service, Department of the Interior, through an interagency agreement with the National Oceanic and Admospheric Administration, under which a multiyear program responding to the needs of petroleum development of the Alaskan continental shelf is managed by the Outer Continental Shelf Environmental Assessment Program office.

CHAPTER 35

Velocities and Bed Friction in Combined Flows

J.F.A. Sleath*

Abstract

Velocity measurements have been made with a laser doppler anemometer in a steady flow flume with an oscillating bed. The velocity profiles in these tests, for which the oscillation was at right angles to the steady current, were found to be qualitatively similar to those observed in previous measurements with currents collinear with the direction of oscillation. Measured time-mean velocity profiles show moderate agreement with the predictions of the models of Grant & Madsen (1979) and Christoffersen & Jonsson (1985) in the outer layer (the 'current boundary layer') but poor agreement close to the bed (the 'wave boundary layer').

1. Introduction

The problem of wave/current interactions is of importance in many areas of coastal engineering. The present paper is concerned with the velocity profiles, and hence the shear stresses, in the boundary layer near the bed. There have been a great many theoretical studies of this problem (see, for example, Sleath, 1990) and also several experimental studies for current collinear with the wave direction (Kemp & Simons, 1982, 1983, Van Doorn, 1981). But, as far as the writer is aware, there have been no systematic boundary layer measurements for waves at right angles to the current. The aim of the present study was to provide such measurements although, as will be seen from the next Section, the experimental situation investigated was not quite the same as that of waves at right angles to a current.

*Lecturer, Cambridge University Engineering Department,
Trumpington Street, Cambridge CB2 1PZ England.

2. Experimental equipment

One of the reasons for the absence of systematic laboratory measurements of boundary layer profiles for waves at right angles to a current is that a very large apparatus is required. It is difficult to obtain in a wave tank Reynolds numbers high enough to ensure fully-developed turbulence in the wave-induced boundary layers. In order to get round this problem it was decided to replace the wave motion by an oscillatory flow produced by oscillating the bed. It may be shown that, relative to axes fixed in the oscillating bed, the velocity profiles obtained in this way are identical with those which would be obtained in an oscillatory flow water tunnel with a steady current at right angles to the direction of oscillation. In other words, the oscillatory flow is that which would be produced in the vicinity of the bed by waves of infinite length. Second-order effects, such as the wave-induced mass transport current, are not reproduced.

Figure 1 shows a plan view of the experimental apparatus. It consists, essentially, of a steady flow re-circulating flume with a section of bed replaced by an oscillating plate. The direction of oscillation of the plate is at right angles to that of the steady current. Its length is 0.81 m in the direction of the steady flow and it extends across the full width of the flume, through slits in the walls, into outer chambers fitted with compensating cylinders. The oscillation of the plate is produced by a Scotch Yoke mechanism driven by a variable speed motor. The amplitude of oscillation can be varied from 0 to 0.19 m and the period from 0.5 to 6 sec. The steady flow flume is of length 5 m and width 1.2 m. Meshes are fitted at the upstream end to produce a uniform entry flow. In these tests the depth of water was usually held at about 0.26 m. Under these circumstances the pumps can produce mean velocities in the test section of up to 0.2 m/s.

Three different bed roughnesses were investigated: smooth stainless steel plate, sand of median diameter D equal to 1.64 mm, and gravel of median diameter 8.1 mm. The sand and gravel were glued to the oscillating section of bed. A thin layer of contact adhesive, diluted with petrol, was spread uniformly over the bed and then the sediment was sprinkled on top. The same roughness was spread for a distance of 1.7 m upstream of the oscillating section of bed and for a distance of 1.0 m downstream. The Nikuradse roughness length k_s was determined from the steady flow velocity profiles on the assumption that for rough beds the zero intercept of the

Figure 1. Plan view of the flume

Figure 2. Steady current velocity profiles on the centre line of the flume. Distances downstream of the upstream edge of the oscillating bed are: (0) - 0.05 m, (1) - 0.05 m, (2) 0.09 m, (3) 0.22 m, (4) 0.47 m, (5) 0.72 m. For all profiles except (0) the cross-channel oscillation of the bed was of amplitude ± 0.14 m and period 2.9 sec.

logarithmic velocity profile is equal to $k_s/30.2$. The values of k_s obtained in this way were 20.3 mm for the 8.1 mm^s gravel and 1.49 mm for the 1.64 mm sand. The explanation for the surprisingly low values of k_s for the 1.64 mm sand is probably that the grains were very rounded and that the glue tended to fill the voids between grains.

The velocities were measured with a single component fibre optic laser doppler anemometer manufactured by DANTEC. The probe was operated in back-scatter mode with a 30 mW He-Ne laser. Further details of this instrument and of the flume are given by Lee Young (1989).

3. Boundary layer growth with downstream distance

Most of the velocity profiles in the main test series were measured, on the centre line of the flume, at a distance of 0.65 m from the upstream edge of the oscillating plate. Since a new boundary layer will grow from the edge of the oscillating plate it is reasonable to ask whether this distance is large enough for the velocity profile to have reached an equilibrium value. Figure 2 shows examples of the steady current velocity profiles at various distances from the upstream edge of the oscillating plate. Profile (0) was measured without oscillation of the plate whereas all of the other profiles were measured with a plate oscillation of amplitude 0.14 m and period 2.9 sec. The mean flow rate was the same for all profiles. Profiles (0) and (1) were each measured at a distance of 0.05 m upstream of the oscillating plate. The fact that these two profiles are almost identical suggests that the upstream influence of the plate oscillation is very slight. On the other hand, the effect of plate oscillation on the steady current profiles downstream of the upstream edge is significant. As might be expected, the change in velocity profile with downstream distance is most rapid just downstream of the leading edge of the oscillating plate. At 0.47 m from the upstream edge the velocity profile appears to have reached an equilibrium up to a height of about 40 mm from the bed.

4. Time-mean currents and shear stresses

The time-mean velocities and shear stresses discussed in this Section are in the direction of the mean current. With the present experimental apparatus time-mean quantities perpendicular to this direction are zero.

4.1 Smooth beds

The velocity profiles in Figure 2 were measured with the 8.1 mm gravel. Very similar results are obtained with the 1.64 mm sand but the smooth bed profiles are

different. Figure 3 shows two smooth bed time-mean velocity profiles measured on the centre line of the flume 0.65 m from the leading edge of the oscillating plate. The pump setting was the same for both profiles but in one case there was a plate oscillation of amplitude 0.125 m and period 2.41 sec and in the other there was no oscillation. It is clear that oscillation of the smooth plate has a negligible effect on the time-mean velocity profile. The reason is probably that the oscillatory flow is not at a sufficiently high Reynolds number to generate additional turbulence with this smooth plate. On the other hand, oscillation of the rough beds generates significant additional turbulence and it is this which changes the time-mean velocity profile, as shown in Figure 2.

4.2 Rough beds

One of the aims of the present study was to provide new data with which to test the predictions of theoretical models. Figure 4 shows a typical comparison of two measured time-mean velocity profiles with the curve obtained from the model of Grant & Madsen (1979). We see that there is quite good agreement between the measurements and the predictions of the model in the outer layer (the 'current boundary layer') but that the agreement is much less good close to the bed (the 'wave boundary layer'). Similar discrepancies are found with other models. This suggests that the assumptions of existing models for the wave boundary layer are not adequate.

Figure 5 shows how the measured values of the apparent roughness k_a compare with the values predicted by the models of Grant & Madsen (1979) and Christoffersen & Jonsson (1985). The predicted value has been obtained by assuming that the measured and predicted velocities are the same at a height of 25.4 mm above the bed. This allows k_a and the time-mean shear velocity to be calculated independently.

We see that the theoretical models predict the value of k_a/k_s quite well at low values of this parameter but that the agreement is less good at high values. It should be emphasized, however, that there is considerable uncertainty in the estimation of k_a even when, as in the present case, a least-squares technique is adopted. This is because the velocity profile is only logarithmic over a restricted range of heights so that experimental error in a velocity measurement can cause an appreciable change in the apparent value of k_a .

On the whole, Christoffersen & Jonsson's model appears to give closer agreement with experiment when $n = 2.0$ and $r = 0.925$ than when $n = 0.367$ and $r = 0.450$.

Figure 6. k_a/k_s versus $\hat{u}_{*c} / \bar{u}_{*c}$. GM and CJ represent the predicted curves of Grant & Madsen (1979) and Christoffersen & Jonsson (1985) for (a) $a/k = 94.8$ and (b) $a/k = 6.9$. Symbols are: \square - present tests $D = 1.64$ mm, O - present tests $D = 8.1$ mm, \bullet - Van Doorn (1981), x - Kemp & Simons (1982), $+$ - Kemp & Simons (1983)

A different way of predicting the apparent roughness k_a was suggested by Coffey & Nielsen (1986). They observed that existing laboratory measurements could be represented by a single curve if k_a/k_s was plotted against \hat{u}_*/\bar{u}_{*c} , where \hat{u}_* is the amplitude of the fluctuation in shear velocity at the bed and \bar{u}_{*c} is the time-mean value. Figure 6 suggests that the same curve would not be valid for the present measurements. This may be because the present measurements are for currents at right angles to the oscillation whereas the previous measurements were for currents collinear with the oscillation or it may be that another parameter is important. The models of Grant & Madsen and Christoffersen & Jonsson both suggest that the ratio of orbital amplitude a to Nikuradse roughness k_s is important. Figure 6 shows the curves predicted by these models for the two bed roughnesses. In the present tests $a/k_s = 6.9$ for the 8.1 mm gravel and 94.8 for the 1.64 mm sand. We see that the predicted change in k_a/k_s with a/k_s is quite large.

Another quantity of interest which may be obtained from the slope of the time-mean velocity profiles in the outer region is the time-mean shear velocity \bar{u}_{*c} . This may be used to calculate the time-mean friction coefficient:

$$\bar{f}_c = \frac{2 \bar{u}_{*c}^2}{U_o^2}, \quad (1)$$

where U_o is the amplitude of the velocity of the oscillating plate. Figure 7 shows how the measured values of \bar{f}_c for the present tests compare with the values predicted by the models of Grant & Madsen (1979) and Christoffersen & Jonsson (1985). It is difficult to draw definite conclusions because the experimental scatter is considerable. On the whole, the agreement between theory and experiment is closer than for the apparent roughness k_a . However, there does seem to be a consistent tendency for the theory to underestimate the friction factor at large values of this parameter. In this case the choice of the values of n and r in Christoffersen & Jonsson's model appears to make little difference to the overall comparison.

Figure 7. Comparison of predicted and measured values of time-mean friction factor \bar{f}_c . (a) Grant & Madsen (1979) (b) Christoffersen & Jonsson (1985) with $n = 0.367$, $r = 0.450$ (c) Christoffersen & Jonsson (1985) with $n = 2.0$, $r = 0.925$. Symbols as for Figure 5.

Figure 8. Oscillatory velocity profiles at phase intervals of 45° . Oscillation amplitude = $+ 0.14$ m, period = 2.75 sec in each case. $D = 1.64$ mm. \bullet - no steady current, \circ - steady current with $\bar{u}_{*c} = 0.0094$ m/s.

5. Oscillatory velocities and shear stresses

5.1 Velocities and shear stresses parallel to the direction of oscillation

In the present tests the influence of the steady current on the oscillatory velocity profile was much less marked than the influence of the oscillation on the steady current. This is illustrated in Figure 8 which shows typical velocity profiles at various phases of oscillation with, and without, a steady current.

The same situation is shown in Figure 9 which represents the ratio of the oscillatory friction factors with and without a steady current. In this figure

$$f_w = \frac{\hat{\tau}_{\omega t}}{\frac{1}{2}\rho U_o^2} \quad (2)$$

where $\hat{\tau}_{\omega t}$ is the amplitude of the shear stress at the bed in the absence of a steady current. The definition of f_{wC} is the same except that the shear stress amplitude is that in the presence of a steady current. The values of f_w and f_{wC} used in this Figure are those determined from the experimental measurements, with the aid of the momentum integral. Figure 9 shows that for this range of \bar{u}_{*c}/U_o the experimental results are in good agreement with the predictions of Grant & Madsen and Christoffersen & Jonsson.

5.2 Oscillatory velocities and shear stresses parallel to the mean current

The oscillation of the rough plates also generates an oscillatory velocity, and hence a shear stress, in the direction of the mean current. This is because the additional turbulence generated by the oscillatory flow fluctuates in intensity during the course of the cycle (Sleath, 1987). If the angular frequency of the oscillation is ω the frequency of the fluctuation in turbulence intensity is 2ω . Consequently the fundamental frequency of the oscillatory velocity and shear stress in the direction of the mean current is also 2ω . Interaction between the various oscillatory components also produces higher-order harmonics both parallel and perpendicular to the mean current direction but the magnitude of these harmonics is much less than that of the fundamental components.

The fluctuating component of velocity in the mean current direction is relatively weak but the shear stress it generates at the bed is not negligible, as indicated in Figure 10. We see that the amplitude $\hat{\tau}_{2\omega t}$ of the

Figure 9. Ratio of oscillatory friction factors measured with and without a superimposed steady current.
 O - 8.1 mm gravel, ● - 1.64 mm sand

Figure 10. Amplitude of oscillatory shear stress $\hat{\tau}_{2wt}$ in the mean current direction.
 O, ● - 8.1 mm gravel; ⊗, □ - 1.64 mm sand

fluctuating shear stress ranges from about 20 % to 80 % of the time-mean shear stress $\bar{\tau}_c$. However, this fluctuating stress in the mean current direction is still small compared with the amplitude $\hat{\tau}_{\omega t}$ of the fluctuating shear stress in the direction of oscillation. As shown in Figure 10, the ratio of these two shear stresses was usually significantly less than 10 % in these tests.

In Figure 10, the shear stress $\hat{\tau}_{\omega t}$ in the direction of oscillation was calculated from Jonsson's (1963) expression for friction factor whereas the component $\hat{\tau}_{2\omega t}$ in the mean current direction was determined from the momentum integral

$$\tau = \int_0^{\infty} \frac{\partial}{\partial t} (u_{\infty} - u) dy$$

where u is the fluid velocity at height y and u_{∞} is the fluctuating velocity outside the wave boundary layer. In these tests u_{∞} was either zero or very nearly so. It is well known that calculations of shear stress based on the momentum integral tend to be inaccurate and this is particularly true in the present case because the boundary layer for the 2ω component of velocity is very thin. The values of $\hat{\tau}_{2\omega t}$ in Figure 10 should consequently be treated with caution.

6. Conclusions

(1) Velocity measurements show that equilibrium profiles are established relatively quickly above the oscillating section of bed. For example, 0.47 m downstream of the leading edge of the oscillating bed the velocity profile was in equilibrium to a height of about 0.04 m above the bed.

(2) The measurements with smooth beds showed no significant effect of the oscillation on the velocity profile of the steady current. This lack of interaction is probably because the oscillatory Reynolds numbers were not high enough for additional turbulence generation with smooth beds.

(3) In contrast, the measurements with the rough beds showed significant modification of the time-mean velocity profile when an oscillation was superimposed on the flow. The modification was qualitatively similar to that observed, by previous investigators, for steady currents parallel to the direction of oscillation.

(4) The effect of the steady current on the oscillatory flow was small, even for the rough beds, for the present test conditions.

(5) Measured time-mean velocity profiles are in quite

good agreement with the profile predicted by Grant & Madsen's (1979) model in the outer layer (the 'current boundary layer') but in poor agreement close to the bed (the 'wave boundary layer'). Measured outer layer quantities such as apparent roughness and mean shear velocity also show moderate agreement with Grant & Madsen's model and with that of Christoffersen & Jonsson (1985) with $n = 2.0$ and $r = 0.925$.

(6) With the rough beds it was possible to observe a fluctuating shear stress at right angles to the direction of oscillation. The amplitude of this shear stress was small compared with the shear stress in the direction of oscillation but quite significant compared with the time-mean shear stress.

CHAPTER 36

ON THE FITTING OF JONSWAP SPECTRA TO MEASURED SEA STATES

E.P.D. Mansard¹ and E.R. Funke²

ABSTRACT

A new technique has been described for the optimal fitting of JONSWAP model spectra to measured sea states. This technique, validated by numerical simulations, can provide enhanced estimations of the peak frequency, the peak enhancement factor and the significant wave height of natural seas.

1.0 INTRODUCTION

The variability of spectral estimates resulting from conventional variance spectral density analysis of relatively short wave records, is appreciable. It is, therefore, difficult to obtain from them a reliable appraisal of spectral parameters that reflect the properties of the sea state prevailing over a large area and over a long duration. Furthermore, wave data recorded in nature are frequently corrupted with background noise, such as transmission interference or data loss due to buoy submergence. As a result, the variance spectral densities of such wave data must usually be band-limited at arbitrarily chosen upper and lower cut-off frequencies. This truncation can have a significant effect on the values of estimated wave parameters, particularly those which depend on the calculation of spectral moments.

Various algorithms for the estimation of spectral wave parameters exist. Some of these are published in the IAHR/PIANC List of Sea State Parameters (1986). Other authors have also described methods for the determination of spectral sea state parameters (Houmb and Øyan, 1981). So far these techniques have been evaluated only by application to field recorded wave data, for which the expected values are not known accurately. It was therefore not possible to determine how well these methods succeeded in recovering the underlying process parameters from the analysis of relatively short samples of the sea state.

Mansard and Funke (1988b) investigated a several of the known computational methods for spectral parameter estimation and evaluated their ability to recover the known process parameters by a numerical simulation of waves. This study used 200 numerically simulated wave records, each containing approximately 110 waves. These were derived from JONSWAP spectra with γ -values of 1 and 3.3, using the "random complex spectrum" method (Funke and Mansard, 1987). The JONSWAP parametric spectrum was chosen for this study because it is the most commonly used model, and it covers also the Pierson-Moskowitz as well as the Bretschneider (i.e. the ITTC or ISSC) spectra as special cases.

The "random complex spectrum" method of numerical wave synthesis is based on the Fourier transform, but is akin to a simulation of waves from long term "white noise" and is, therefore, a spectrally non-deterministic method. Miles and Funke (1988) demonstrated that the spectral domain characteristics of wave records produced by this method, mimic the natural variability of stationary, linear stochastic processes. This is to say, that individual realizations of synthesized waves exhibit the same variability of spectral estimates as would be encountered from filtered white noise. Whereas the properties of the underlying generating process are not known for natural sea states, they are known completely for numerically synthesized wave data. A numerical simulation of waves and subsequent spectrum analysis permits, therefore, the evaluation of conventional methods of parameter estimation by comparing the mean, the standard deviation, the maximum and the minimum values of the spectral parameters to the known simulation inputs.

Estimations of some spectral characteristics are linked to a basic assumption of the spectral shape characteristics. For deep water waves, one usually assumes a JONSWAP type of spectrum of which the Pierson-Moskowitz and the Bretschneider are special cases. For these parametric model spectra, one must know three fundamental parameters, i.e. the peak frequency, the significant wave height and a spectral width measure. (The peak width parameters σ_a and σ_b will be assumed in this study to have the same values as those suggested by JONSWAP, i.e. 0.07 and 0.09 respectively).

Various spectral width measures have been proposed, such as the peakedness factor, Q_p , or the spectral width parameters ϵ_2 or ϵ_4 (IAHR/PIANC, 1986). Mansard and Funke (1988a) have shown that the peakedness factor is highly sensitive to the choice of cut-off frequencies. Because the spectral width parameters ϵ_n are derived from higher spectral moments, the same problem applies to these as well (see also Rye, 1977). In any case, for a JONSWAP spectrum, the most suitable spectral width measure would be the peak enhancement factor, γ . Knowledge of this parameter would permit matching of the parametric model spectrum to the measured sea state spectrum. LeBlond (1982) published a technique for this purpose, which will be described below.

The work presented both here and in Mansard and Funke (1988b), was undertaken to enhance computational methods for the discovery of the underlying spectral parameters of a sea state, and to provide the means of assigning confidence limits to such estimates. The authors consider it important that relatively short samples

of ocean waves, taken at a single point in an area of interest, should reveal the generally prevailing sea state over the storm area with as much confidence as possible. This would then allow the use of such wave data for the verification of hindcasting or forecasting techniques. It would also permit a more credible use of this data for design or simulation applications, where wave recording stations had been deployed at some distance from the site of interest.

A particular case in point is the situation which the authors encountered with the Ocean Ranger capsizing investigations during 1982. At the time of the accident, only one wave recording buoy was operational and was located some 37 km from the accident site. However, prior to the accident, 3 buoys were operational, with the second 17 km from the Ocean Ranger and the third quite near the platform. Comparative analysis between the three buoys indicated considerable differences in peak frequency (Mogridge, 1985). A preliminary reanalysis of the data from two of these stations was carried out recently, using the enhanced method of analysis presented here. It was then found, that the differences were relatively small and that data from the two sites could be used interchangeably.

2.0 PRELIMINARY RESEARCH

By applying the technique of numerical wave simulation, Mansard and Funke (1988b) evaluated traditional algorithms for the estimation of three principal spectral parameters, i.e. the peak frequency, the peak enhancement factor and the significant wave height. The investigation was carried out for a range of JONSWAP γ -values varying from $1 \leq \gamma < 12$. From this it became apparent that the results of the analysis are:

- in most cases, highly dependent on the arbitrary higher and lower cut-off frequencies, which are used for the analysis;
- a function of the resolution of the spectral density analysis;
- a function of the γ -value of the JONSWAP spectrum;
- biased due to the skewed profile of wave spectra.

Because it was the ultimate objective of the study to devise a technique of optimally fitting a parametric model spectrum to the simulated sample spectra, and because it was known that any multi-parameter optimal fit relies heavily on the initial guesses of the parameters to be optimized, it was considered essential to improve on existing algorithms for the estimation of the three above mentioned spectral wave parameters before attempting the use of optimization procedures.

2.1 Estimation of the Peak Frequency

2.1.1 Initial guess of the peak frequency

Mansard and Funke (1988b) considered 5 algorithms for the estimation of the peak frequency. The simplest of these is the detection of that frequency that corresponds to the largest value of the sample spectrum, S_{\max} (i.e. $f_p = f(S_{\max})$). Because of the large variability of spectral estimators, this method also leads to a large variability

in the estimation of the peak frequency.

For this reason, some researchers prefer to use the "Delft" method (IAHR/PIANC List of Sea State Parameters, 1986). This is defined as the frequency computed as the centroid of the spectral band between the lower and the upper intercepts of the spectral density and the threshold which is 80% of $S_{\eta}(f_p)$, i.e.

$$f_{pD} = \frac{\int_{f_1}^{f_2} f \cdot S_{\eta}(f) \cdot df}{\int_{f_1}^{f_2} S_{\eta}(f) \cdot df} \quad (1)$$

where f_1 and f_2 are the upper and lower frequencies corresponding to the intercepts. This parameter is also referred to here as f_{pD8} .

A third option is similar to the second, except that the threshold is chosen to be 60% rather than 80% of the spectral peak value. It offers an advantage over the second method by including a larger portion of the spectrum, and thereby reducing variability. To distinguish it from the f_{pD8} parameter, it is referred to here as f_{pD6} .

The fourth and the fifth methods were used by Read (1986). The peak frequency estimator, referred as f_{p5} , is given by:

$$f_{p5} = \frac{\int_0^{f_2} f \cdot S^5(f) \cdot df}{\int_0^{f_2} S^5(f) \cdot df} \quad (2)$$

The fifth method yields f_{p8} , which is similar in definition to f_{p5} , except that the power coefficients are 8 instead of 5.

These five estimators of peak frequency (f_p , f_{pD8} , f_{pD6} , f_{p5} and f_{p8}) were evaluated by Mansard and Funke (1988b) through numerical simulation using a Pierson-Moskowitz model spectrum with a peak frequency of 0.55 Hz as a generating function. Using the random complex spectrum method, 200 wave trains, each 200 seconds long, were synthesized and then subjected to spectral analysis. The various estimates of peak frequency derived from these spectra were then subjected to statistical analysis. In order to evaluate the effect of spectral resolution on these statistics, three different resolutions, corresponding to 10, 20 and 30 degrees of freedom were also used. The main conclusions of this study are given below.

The traditional estimate of peak frequency (i.e. f_p) has by far the largest variability, which improves however, as the degrees of freedom of spectral analysis increase. The mean values of peak frequency from all five methods demonstrate a bias toward higher values. In terms of variability, the f_{p5} algorithm is superior to others and can be computed with relative simplicity, i.e. without bidirectional threshold detection, as required for f_{pDx} calculations. Because of this, f_{p5} was selected as the basis for the development of an enhanced wave parameter estimator, for which it will serve as the "initial guess".

2.1.2 The bias corrected estimate for the peak frequency

The JONSWAP parametric model spectrum is not symmetrical about its peak frequency f_0 . The leading edge of the spectrum is steeper than its trailing edge. As

a result, any peak frequency definition based on centroid calculation is expected to provide a bias in the estimation of peak frequency. However, this bias does not constitute a serious concern since it can be corrected, and furthermore, it becomes insignificant as the peakedness of the spectrum increases.

The bias correction function for f_{p5} as a function of γ can be determined by applying the f_{p5} -calculation to smooth theoretical JONSWAP spectra, for which the peak frequency is predefined and therefore known. Such a calculation is free of variability. This was carried out and the result was subjected to a multivariate regression analysis, which in turn yielded to the following function:

$$C_f = 1.005 + 1 / [50.746 \cdot (\gamma - 0.2397)^2] \quad (3)$$

This function can only be evaluated once the γ -value is known. As this information is available only at a later stage of the analysis, C_f is initially estimated as $C_f \approx 1.02$ for the purpose of computing γ . This bias correction is applied as follows:

$$f'_{p5} = \frac{1}{C_f} \cdot \int_0^{\infty} f \cdot S^5(f) \cdot df \bigg/ \int_0^{\infty} S^5(f) \cdot df \quad (4)$$

As will be described later, this bias corrected estimate will be used as the initial condition in an optimization procedure for the determination of an enhanced peak frequency estimator.

2.2 Estimation of the Peak Enhancement Factor.

2.2.1 The initial guess of the peak enhancement factor

It was shown in Mansard and Funke (1988b), that the peak enhancement factor γ may be estimated through the use of the parameter of a bivariate Rayleigh probability density, κ_f , given by Battjes and van Vledder, (1984). This is approximated by:

$$\kappa_f^2 \hat{m}_0^2 \approx \left[\int_{f_1}^{f_2} S(f) \cdot \cos(2\pi f\tau) \cdot df \right]^2 + \left[\int_{f_1}^{f_2} S(f) \cdot \sin(2\pi f\tau) \cdot df \right]^2 \quad (5)$$

where $S(f)$ is the spectral value, $\tau = \sqrt{\hat{m}_0/\hat{m}_2}$, and \hat{m}_0 and \hat{m}_2 are the estimators of the zeroth and the second spectral moment functions respectively. These were computed over the spectral range from $0.5f_{p5}^l$ to $2.5f_{p5}^l$. In this computation, f_{p5}^l is evaluated using $C_f = 1.02$ in Equation (4).

By applying linear regression analysis to the κ_f -values, as derived from smooth JONSWAP parametric model spectra for various values of γ ranging from 1 to 12, a conversion formula was derived that established the relationship between κ_f and γ . This formula was given in Mansard and Funke (1988b) as:

$$\begin{aligned} \gamma_0 &= 50.69 - 404.97\kappa_f + 1211.2\kappa_f^2 - 1599.6\kappa_f^3 + 817.26\kappa_f^4 \quad \text{for } \kappa_f \geq 0.4 \\ &= 1 \quad \text{for } \kappa_f < 0.4 \end{aligned} \quad (6)$$

The results of applying this formula to simulated wave data were reported in Mansard and Funke (1988b).

2.2.2 Enhanced estimator of the peak enhancement factor

When applying Equation (6) to sample spectra derived from a 10-degrees of freedom spectral density analysis of 200 numerical simulation of wave trains, synthesized from JONSWAP class of spectra and using the "random complex spectrum" method of wave synthesis, it was found that an additional bias of the recovered γ -values for the range of $\gamma < 2.5$ occurred. Whereas the relation in Equation (6) was established from smoothed parametric model spectra, during the application of Equation (6) to numerically synthesized data, estimates of γ with values less than 1 were found to occur. By rounding these values up to 1, the mean value of the γ -estimator tends to be increased slightly. For this reason, an improvement to the relationship between κ_γ and γ was derived here. This new peak enhancement factor is now given by:

$$\begin{aligned} \gamma' &= -0.835 + 1.797\gamma_0 - 0.2011\gamma_0^2 && \text{for } \gamma_0 < 2.5 \\ &= \gamma_0 - 0.10 && \text{for } \gamma_0 \geq 2.5 \end{aligned} \tag{7}$$

Applying this estimation formula to a numerical simulation leads to the statistics given in Table 1

2.3 Estimation of the Significant Wave Height

2.3.1 Initial guess of the significant wave height

The significant wave height (H_{m0}) is computed from:

$$H_{m0} = 4\sqrt{m_0} \tag{8}$$

where m_0 is the zeroth moment, i.e. the area under the population variance spectral density function. Because of the presence of both high and low frequency noise, the zeroth moment is traditionally derived by spectral integration between some arbitrarily chosen upper and lower cut-off frequencies. As a result, the total variance is consistently underestimated by an amount corresponding to the spectral areas that have been eliminated by truncation. This energy loss can easily be

recovered as a cut-off frequency dependent bias correction. Because the authors have usually carried out wave data analysis for the band of $0.5f_p \leq f \leq 2.5f_p$, this was adopted for this investigation as well, using f_p^1 for the peak frequency.

2.3.2 Enhanced estimate of the significant wave height

Mansard and Funke (1988b) determined the truncation induced bias by integrating smooth parametric JONSWAP class spectra over the range of $0.5f_p \leq f \leq 2.5f_p$. The resultant values of the zeroth moment were then subjected to regression analysis, which yielded a bias correction function. This was incorporated into an equation for the enhanced estimation of the significant wave height, namely:

$$m'_0 = C_m^2(\gamma) \cdot \int_{f_1}^{f_2} S_\eta(f) \cdot df \quad (9)$$

where:
$$C_m(\gamma) = 1.0015 + \frac{1}{[19.9178(\gamma' + 2.6937)]} \quad (10)$$

The variability of the enhanced estimate of the significant wave height, H_{m0}^1 , obtained by Equations (8) and (9) is given in the following table for the numerical simulations described in Section 2.2.2.

TABLE 2. Variability of Enhanced Estimates of the Significant Wave Height, H_{m0}^1

3.0 FITTING OF PARAMETRIC MODEL SPECTRA

The concept of optimally fitting a parametric model spectrum to spectral density estimates, as derived from the analysis of relatively short samples of a stochastic process, is founded on the hypothesis that knowledge of the spectral profile (i.e. a parametric model spectrum such as the JONSWAP class of spectrum), will improve the recovery of spectral parameters, because all spectral estimates are expected to contribute equally to the recovery process. Spectral fitting could be achieved as a multi-parameter or a single parameter optimization. In the former, several parameters are optimized concurrently, whereas only one is optimized at each pass in the latter case.

Optimization procedures must always start with some initial guess of the unknown parameters. The enhanced estimates of the spectral parameters described above,

such as the peak frequency f_{p5}^I , the peak enhancement factor γ^I and the spectrally derived significant wave height H_{m0}^I , were considered to be the best possible initial guesses for this purpose. (Any spectral fit which uses just these initial guesses will be called as initial guess fit).

Optimization is achieved through the application of a criterion, which is generally computed from some error function between the measured spectral density and the theoretical spectral density evaluated with the optimally fitted parameters. The evaluation of the criterion at the end of the optimization process is also a measure of the goodness of fit obtained through the use of the particular criterion.

For this study, a 3-parameter optimization was attempted first and the fitting method used was the Simplex Algorithm (Caceci and Cacheris, 1984). This method has the advantage of permitting multiple parameter optimization with arbitrary optimization criteria. Four different criteria were investigated for this purpose.

After carrying out extensive experiments, it was found that in most cases, the optimal values achieved through a 3-parameter fit were different from those known to be correct. The only exception to this was the fitting of Pierson-Moskowitz spectra (i.e. for γ values of 1). At this stage of the development, it appears that multi-parameter optimization cannot be used. Since an extensive discussion of the optimizing criteria and the results of the multi-parameter fitting are beyond the scope of this paper, they will be reported separately in Mansard and Funke (1991).

As indicated earlier, optimization can also be employed by fixing one or two of the parameters, and then optimizing the remainder. This approach led to a very satisfactory result in the improvement of the estimation of the peak frequency.

The technique, which is now used, computes the initial guesses for all three spectral wave parameters, as described above. The best guess for H_{m0} and γ is then fixed, (i.e. H_{m0}^I and γ^I) and optimal fitting is applied to find the best peak frequency f_0^I . The optimizing criterion used for this purpose can be defined as follows:

$$\sum_{j=1}^N [(\sqrt{S_m(f_j)} - \sqrt{S_s(f_j)}) \cdot \sqrt{W_j}]^2 \text{ is to be a minimum} \tag{11}$$

where $S_m(f_j)$ is the fitted model spectrum, $S_s(f_j)$ is the sample spectrum and W_j is the weighting function. The weighting function can be defined as follows:

$$W_j = \begin{cases} \frac{S_m(f_0)}{S_m(f_j)} & \text{if } S_m(f_0) < 100 \cdot S_m(f_j) \\ 0 & \text{otherwise} \end{cases} \tag{12}$$

where f_0 is the peak frequency.

A brief discussion of this criterion can be found in Mansard and Funke (1988b).

The results of this one parameter fitting are shown in Figure 1 for γ -values from 1 to 7, together with the results obtained from traditional and bias-corrected estimations. From this it is evident, that the spectral fitting, in combination with a carefully selected criterion function, can significantly enhance the estimation of a process parameter.

Generally, the spectral resolutions used in this fitting procedure correspond to 10 degrees of freedom (DOF). By using a small resolution such as this, a large number of statistically independent spectral estimates are included in the optimization procedure.

Figure 1 shows that for broad spectra (i.e. $\gamma = 1$), the standard deviation of peak frequency obtained by the traditional estimate can be improved by a factor of about 7 through spectral fitting. Preliminary results indicate that, even if a coarser resolution such as DOF = 30 is used in the traditional estimate of f_p , the improvements that can be achieved by the spectral fitting would be in the order of 6. Effects of the resolution will be discussed separately in Mansard and Funke (1991).

Figure 2 illustrates an example of one sample spectrum, derived by synthesis of a random wave train, and subsequently submitted to spectral analysis with 10 degrees of freedom. The figure also shows the population spectral density (JONSWAP with $\gamma = 1$), the "initial guess" spectral fit, and the optimally fitted spectrum using criterion given in Equation (11). This example illustrates the improvements which may be achieved over the more traditional methods of analysis.

4.0 THE LEBLOND METHOD FOR THE ESTIMATION OF THE PEAK ENHANCEMENT FACTOR

LeBlond (1982) developed and used a technique for the estimation of the JONSWAP peak enhancement factor. This technique is based on an assumption that a certain relationship exists between the spectra's Phillip's constant α and the significant wave height H_{m0} (Mitsuyasu et al, 1980). The method is also limited to γ -values that are less than 4.

LeBlond analyzed his wave data with very low resolution, corresponding to 30 DOF, and determined the spectral peak frequency by the traditional method; that is, by taking the frequency of the largest spectral value. After this, LeBlond integrated the spectrum from 0.05 to 0.5 Hz (full scale units) to get the significant wave height, and used the formula:

$$\gamma = \left[\frac{S(f_p)}{\frac{5}{16f_p} H_{m0}^2 e^{-5/4}} \right]^{3/2} \quad (13)$$

to compute the JONSWAP peak enhancement factor.

TABLE 3. Results of LeBlond Analysis

The important result from Table 3 is the fact that the standard deviation of the LeBlond estimator for γ -values is only 65% of that obtained with the authors' method. The mean value of γ and peak frequency values are, however, not as satisfactory, and the significant wave height estimators look good only because the numerical simulation used here was free of noise, and the integration limits could be extended from 0 to the Nyquist frequency.

However, the positive result from the LeBlond example suggests that further improvements in the estimation of the peak enhancement factor may be possible.

5.0 EXAMPLE ANALYSIS OF OCEAN WAVE DATA

Figure 3 compares the peak frequency, estimated by the spectral fitting, for two wave recording stations at the Ocean Ranger and the Sedco 706, nearly 17 km apart. Although there were 3 sites near the Ocean Ranger platform, only these two stations were chosen for this preliminary investigation since continuous wave records were available from them. The third station, Zapata Uglund, which was 30 km away from the Ocean Ranger, had records only at 3 hour intervals during that period.

For purpose of comparison, the traditional estimates of peak frequency and the bias-corrected values of f_{p5} are also shown in Figure 3. This figure clearly illustrates the improvements that can be achieved in the interpretation of prototype data through optimal fitting. It can be seen from this figure that, while the traditional and bias-corrected estimates show considerable differences in the peak frequencies at these stations, the optimally fitted values indicate the similarity of the two sites during the time of the storm. For these two stations, the variability of peak frequency between consecutive records of 20 minutes is reduced considerably when spectral fitting is applied.

6.0 CONCLUSIONS

An enhanced method for estimation of the spectral peak frequency for ocean wave data has been presented. The method was tested by numerical simulation of short wave records. For JONSWAP spectra with $\gamma = 1$, the variability of the peak frequency estimate can be improved by a factor of 7. Two methods for the estimation of JONSWAP peak enhancement factors are presented, but neither is considered satisfactory.

Further work will seek improvements in the estimation of the JONSWAP peak enhancement factor, establish suitable bias correction functions for the significant wave height as a function of spectral cut-off frequencies, and establish convenient confidence bands for the estimation of the three principal spectral wave parameters. Improvements in computational efficiency and the effects of spectral resolution will also be investigated.

The new method is believed to improve the validation of hindcasting and forecasting numerical models. At this time, the method applies only to the deep water situation, where spectral estimates of contributing frequencies are statistically independent. Future development may be able to address the intermediate and shallow water depth situation as well, where the spectral estimates are interdependent because of nonlinear interactions.

CHAPTER 37

AN EFFICIENT METHOD FOR THE REPRODUCTION OF NON-LINEAR RANDOM WAVES

Gert Klopman ¹ and Peter Jan Van Leeuwen ²

Abstract

For the laboratory study of many random-wave induced phenomena, wave-board control signals according to linear wave theory are not sufficient: apart from bound sub- and superharmonic waves, spurious free waves are generated. Wave generation according to a higher-order wave theory is necessary in order to suppress these spurious waves. The perturbation method of multiple scales is used to derive formulas for the second-order wave-board control signal, assuming the carrier-wave spectrum is narrow banded. The resulting algorithm is much faster than the one based on the full second-order theory. Furthermore, the applicability of the narrow-band approximation is indicated for carrier-wave spectra frequently used in coastal and ocean engineering.

1 Introduction

For the extrapolation of laboratory data to full scale sea conditions it is essential to have a realistic reproduction of the sea in laboratory experiments. In a natural wave train, with the spectral energy density concentrated around the peak frequency, the non-linearity of the free-surface boundary conditions introduces sub- and superharmonics which are phase locked to the primary wave components. When the system under investigation is perceptible to these sub- and superharmonics, it is important to reproduce them correctly in the laboratory.

The subharmonics (or bound long waves) can generate the forcing for long-period harbour oscillations, slow-drift motions of moored vessels and tension-leg platforms, and offshore sand-bar formation due to sediment transport. The superharmonics introduce sharper-peaked wave crests and flatter troughs, they are important for sediment transport due to wave asymmetry and can be of importance for forces on offshore structures.

²Delft University of Technology, Dept. of Civil Engineering, P.O. Box 5048, 2600 GA Delft, The Netherlands.

An incorrect (linear) reproduction in the laboratory generates free waves at the same frequencies as the bound sub- and superharmonics, but travelling at a different speed. This difference in speed between the free and bound wave components results in spatial variations in the root-mean-square (rms) free-surface fluctuations, for instance obscuring the interpretation of the results from models with a movable bed.

The problem of reproducing the subharmonics correctly up to second order, for long-crested random waves in the laboratory, has been solved for translating wave boards by Sand (1982), and for translating and rotating wave boards by Barthel et al (1983). The reproduction of superharmonics is dealt with by Sand & Mansard (1986), both for translating and rotating wave boards.

Both the sub- and the superharmonic second-order corrections to the wave-board control signal are determined at every frequency by computing an integral over an appropriate frequency range (involving the Fourier transform of the first-order free-surface elevation and a second-order transfer function). The work needed for generating a control signal correct up to second order is thus proportional to the square of the work needed for generating the first-order signal.

Since most engineering applications deal with sea conditions characterized by quite narrow-banded spectra, the perturbation method of multiple scales is an alternative to generate second-order long-crested random waves in the laboratory. All operations to compute the second-order control signal from the first-order free-surface elevation can be performed in the time domain, and involve only a few simple algebraic operations on the first-order free-surface signal. Therefore, the work needed for generating the second-order control signal is proportional to and only slightly more than the work for generating the first-order signal.

The application of the perturbation method of multiple scales for the present random-wave generation problem, is very similar to the use of the same method by Agnon & Mei (1985) and Agnon, Choi & Mei (1988) for determining the slow-drift motion of two-dimensional bodies in beam seas.

In this paper we first consider some aspects of the usefulness of the narrow-band approximation, for coastal and ocean engineering applications. Next, the perturbation method of multiple scales is applied to the present problem of generating second-order wave-board control signals. Here, we only present results for the subharmonic bound-wave corrections, and not for the superharmonics.

2 Applicability of narrow-band approximation

The accuracy of the multiple-scales method increases as the spectral width decreases. The errors, introduced by the use of the narrow-band approximation in the multiple-scales approach, should be small for the wave spectra normally used in coastal and ocean engineering. In order to get some indication of the usefulness of the multiple-scales perturbation-series method, some comparisons

were made between second-order free-surface elevation spectral densities obtained with the multiple-scales perturbation-series method, as described by Mei (1989, Chapter 12), and those obtained by a full second-order theory, as described by Laing (1986). This comparison only gives an indication of the accuracy, since a non-linear random process is not fully characterized by its autospectrum.

Here, we consider gravity waves on the free surface of a fluid domain of initially constant depth h . The fluid is assumed to be homogeneous, inviscid and incompressible, and the flow is assumed to be irrotational. Surface tension effects and effects of the air above the free surface are neglected. The flow can be described by a velocity potential Φ , with the fluid velocity vector equal to the gradient of the velocity potential.

The perturbation method of multiple scales was used to simulate a finite duration realization of the second-order free-surface elevation in the time domain. The free-surface elevation $\zeta(x, t)$ and the velocity potential $\Phi(x, z, t)$ are expanded into perturbation series:

$$\begin{aligned}\zeta &= \sum_{n=1}^{\infty} \varepsilon^n \zeta_n(x, t), \\ \Phi &= \sum_{n=1}^{\infty} \varepsilon^n \phi_n(x, z, t),\end{aligned}\tag{1}$$

with x the horizontal space coordinate, positive in the wave propagation direction, z the vertical space coordinate, with $z > 0$ above the still water elevation. The time coordinate is denoted by t and ε is a small non-linearity parameter proportional to the wave slope.

Because we are considering propagating wave phenomena, the terms from the perturbation series are expanded into harmonic functions. The amplitudes of the harmonic functions are assumed to vary only slowly in space and time, i.e. the carrier waves are assumed to have narrow-banded spectra. This slow modulation is formalized by the introduction of fast coordinates (x_0, t_0) and a cascade of slow coordinates $(x_1, t_1), (x_2, t_2), \dots$ in the horizontal space and the time direction:

$$\begin{aligned}x_0 &= x, & x_1 &= \varepsilon x, & x_2 &= \varepsilon^2 x_2, \dots, \\ t_0 &= t, & t_1 &= \varepsilon t, & t_2 &= \varepsilon^2 t_2, \dots,\end{aligned}\tag{2}$$

where it has been assumed that the modulation effects are of the same order as the non-linearity effects.

The (quadratic) non-linearity of the problem, due to the non-linear free-surface boundary conditions, introduces higher harmonics into the higher-order solutions:

$$\begin{aligned}\zeta &= \sum_{n=1}^{\infty} \varepsilon^n \sum_{m=-n}^{+n} \zeta^{(n,m)} E_0^m, \\ \Phi &= \sum_{n=1}^{\infty} \varepsilon^n \sum_{m=-n}^{+n} \phi^{(n,m)} E_0^m,\end{aligned}\tag{3}$$

with:

$$E_0 = e^{ix_0}, \quad \chi_0 = k_0 x_0 - \omega_0 t_0, \tag{4}$$

and

$$\begin{aligned} \zeta^{(n,m)} &= \zeta^{(n,m)}(x_1, x_2, \dots; t_1, t_2, \dots), \\ \phi^{(n,m)} &= \phi^{(n,m)}(x_1, x_2, \dots; z; t_1, t_2, \dots), \end{aligned} \tag{5}$$

expressing the slow variation of these complex-valued amplitude functions $\zeta^{(n,m)}$ and $\phi^{(n,m)}$. In (4), k_0 is the carrier wave number and ω_0 is the carrier-wave angular frequency. Because ζ and Φ are real-valued functions, $\zeta^{(n,-m)}$ and $\phi^{(n,-m)}$ have to be the complex conjugates of respectively $\zeta^{(n,m)}$ and $\phi^{(n,m)}$.

The solution of both the first-order and the second-order problem can for instance be found in Mei (1989, Chapter 12):

$$\begin{aligned} \zeta_1 &= \frac{1}{2} (Ae^{ix_0} + *), \\ \phi_1 &= \phi^{(1,0)}(x_1, t_1) - \frac{1}{2} \frac{g \operatorname{ch} Q}{\omega_0 \operatorname{ch} q} (iAe^{ix_0} + *), \end{aligned} \tag{6}$$

and

$$\begin{aligned} \zeta_2 &= \left\{ -\frac{1}{g} \frac{\partial \phi^{(1,0)}}{\partial t_1} - \frac{\omega_0^2}{4g \operatorname{sh}^2 q} |A|^2 \right\} + \\ &\quad + \frac{k_0 \operatorname{ch} q}{8 \operatorname{sh}^3 q} (2 \operatorname{ch}^2 q + 1) (A^2 e^{2ix_0} + *), \\ \phi_2 &= \phi^{(2,0)} - \frac{1}{2} \frac{g \operatorname{ch} Q}{\omega_0 \operatorname{ch} q} \left(\frac{1}{\omega_0} + \frac{q \operatorname{th} q - Q \operatorname{th} Q}{k_0 C_g} \right) \left(\frac{\partial A}{\partial t_1} e^{ix_0} + * \right) + \\ &\quad - \frac{3}{16} \frac{\omega_0 \operatorname{ch} 2Q}{\operatorname{sh}^4 q} (C A^2 e^{2ix_0} + *), \end{aligned} \tag{7}$$

with $q = k_0 h$, $Q = k_0(z+h)$, $C_g = d\omega_0/dk_0$ the group velocity, g the gravitational acceleration, $A(x_1, t_1)$ the complex-valued amplitude of the carrier waves and an asterisk (*) denoting the complex conjugate of the preceding term. We have chosen $\zeta^{(2,1)}$ equal to zero, i.e. the first-order solution ζ_1 completely describes the free-surface elevation spectral density near the peak frequency. The wave number k_0 is related to the angular frequency ω_0 by the linear theory dispersion relation:

$$\omega_0^2 = g k_0 \operatorname{th} q, \tag{8}$$

and further use has been made of

$$\frac{\partial A}{\partial t_1} + C_g \frac{\partial A}{\partial x_1} = 0, \tag{9}$$

which is correct up to second order.

The second-order correction (7) to the free surface elevation ζ still contains $\phi^{(1,0)}$. This is determined from the solvability condition for the third-order zeroth-harmonic $(n, m) = (3, 0)$ problem, see e.g. Mei (1989, Chapter 12), and assuming

that the waves propagate according to Stokes's second definition of wave celerity (i.e. the mean mass flux through a vertical plane perpendicular to the wave propagation direction is equal to zero), resulting in $\langle \zeta \rangle = 0$, with $\langle \cdot \rangle$ denoting a time average. The second-order correction ζ_2 becomes:

$$\zeta_2 = \frac{1}{2} \frac{g}{C_g^2 - gh} \left\{ \frac{C_g}{C_0} + \frac{q}{\text{sh } 2q} \right\} (|A|^2 - \langle |A|^2 \rangle) + \frac{k_0 \text{ch } q}{8 \text{sh}^3 q} (2 \text{ch}^2 q + 1) (A^2 e^{2i\chi_0} + *), \quad (10)$$

with $C_0 = \omega_0/k_0$ the phase velocity.

Equations (6) & (10) are used to simulate part of a realization of the second-order random free-surface elevation. The first-order complex-valued random wave signal $A \exp(i\chi_0)$ is generated from a given first-order free-surface elevation spectrum with the random-amplitude/random-phase method (Tucker et al.; 1984).

The second-order free-surface spectrum can be computed without making the narrow-band approximation with the formulations of Laing (1984). The (one-sided) non-linear free-surface elevation spectrum $S_{\zeta\zeta}(\omega)$ is expanded into a perturbation series:

$$S_{\zeta\zeta}(\omega) = \sum_{n=1}^{\infty} \varepsilon^n S_{\zeta\zeta}^{(n)}(\omega), \quad (11)$$

of which we consider only the first two terms. For a given first-order spectrum $S_{\zeta\zeta}^{(1)}(\omega)$, the second-order correction $S_{\zeta\zeta}^{(2)}(\omega)$ becomes:

$$S_{\zeta\zeta}^{(2)}(\omega) = \int_{\frac{1}{2}\omega}^{\infty} D_{20}(\omega, \omega') S_{\zeta\zeta}^{(1)}(\omega') S_{\zeta\zeta}^{(1)}(\omega' - \omega) d\omega', \quad (12)$$

with $D_{20}(\omega, \omega')$ the second-order transfer function, given by:

$$D_{20} = \frac{2 (D_2(\omega, \omega'))^2}{g^2 (1 - \omega^2/g\kappa \text{th } \kappa h)^2}, \quad (13)$$

$$D_2 = \frac{1}{2} \left\{ (\omega')^2 + (\omega - \omega')^2 + \omega'(\omega - \omega') - \omega'(\omega - \omega') \coth k'h \coth(\kappa - k')h + \omega\omega' \coth \kappa h \coth k'h + \omega(\omega - \omega') \coth \kappa h \coth(\kappa - k')h \right\}, \quad (14)$$

with κ the wave number of the bound waves, and:

$$\begin{aligned} (\omega')^2 &= gk' \text{th } k'h, \\ (\omega - \omega')^2 &= g(\kappa - k') \text{th } (\kappa - k')h, \end{aligned} \quad (15)$$

the dispersion relationships for the free waves. Equation (12) shows that an integral over all frequency pairs has to be computed, in order to obtain the second-order spectrum.

Both descriptions of the second-order free surface elevation, i.e. the multiple-scales perturbation method as well as the full second-order theory in the frequency domain, include the subharmonic as well as superharmonic bound waves. Both methods were used to obtain second order spectra, assuming the first-order spectrum to be of JONSWAP shape:

$$S_{\zeta\zeta}^{(1)}(f) = \frac{\beta H_{rms}^2}{f_p} \left(\frac{f}{f_p}\right)^{-5} \exp\left[-\frac{5}{4}\left(\frac{f}{f_p}\right)^{-4}\right] \gamma^{-\frac{1}{2}} \left(\frac{f-f_p}{\sigma f_p}\right)^2, \quad (16)$$

with $f = \omega/(2\pi)$ the frequency, H_{rms} the rms wave height, f_p the spectral peak frequency, γ the peak enhancement factor, σ the peak width parameter and β a form factor chosen in such a way that $H_{rms}^2 = 8 \int_0^\infty S_{\zeta\zeta}^{(1)}(f) df$.

The results of three simulations will be shown, all with a rms wave height $H_{rms} = 0.7062[m]$, a peak frequency $f_p = 0.25[Hz]$, a still water depth $h = 3[m]$, and with the mean JONSWAP values for σ , i.e. $\sigma = 0.07$ for $f < f_p$ and $\sigma = 0.09$ for $f \geq f_p$. The simulation with the multiple-scales perturbation method in the time domain had a duration of 6400[s] and a sample rate of 5.12[Hz]. The following three values for the peak enhancement factor γ were used:

$\gamma = 20$, a very narrow-banded first-order spectrum,

$\gamma = 3.3$, the mean JONSWAP value, and

$\gamma = 1$, the Pierson-Moskowitz spectrum.

Figures 1-3 show a comparison between the autospectra of the free-surface elevation, obtained from the multiple-scales perturbation method and from the full second-order theory. The relative differences between both approaches become larger when the spectral width increases, and are of the order of 10% of the square root of the spectral density (a measure for corresponding wave amplitude) near $f = 0.02[Hz]$, where the subharmonic spectral density is high. It should also be noted that the relative importance of the bound long waves decreases as the spectral width increases. The difference between the spectrum obtained from the multiple-scales perturbation-series simulation and the theoretical first-order spectrum is due to the random-amplitude approach during the generation of the first-order signal and the finite duration of the numerical simulation (therefore also H_{rms} , obtained from finite-duration realizations, is a random variable). Since the mean free-surface elevation is equal to zero, the spectral density falls off near $f = 0[Hz]$ for the spectra obtained from the numerical simulation, but is not exactly equal to zero due to the computational method used for obtaining the spectra (Fast Fourier Transform on half-overlapping segments, with Van Hann data window).

The deviations, due to the narrow-band approximations implied by the use of the multiple-scales perturbation-series method, were considered to be very acceptable for the spectra commonly used in coastal and ocean engineering.

3 Second-order random-wave generation method

The generation of subharmonic waves, both bound and free waves, is described by Agnon & Mei (1985) in their study of the small-amplitude slow-drift motion due to beam seas of a two-dimensional rectangular block, sliding over the sea bed. Agnon, Choi & Mei (1988) extended this analysis to the case of floating two-dimensional cylinders undergoing both small- and large-amplitude slow-drift motions ('large' meaning motions comparable to or even greater than the motions at the carrier-wave frequency). Here, we use the results of Agnon & Mei (1985) for the determination of the low-frequency wave-board control signal, in such a way that only bound long waves are generated, and no spurious free long waves.

The horizontal wave-board position is denoted by $X(t)$, and the still position is at $x = X = 0$. As in (1), the free-surface elevation $\zeta(x, t)$, the velocity potential $\phi(x, z, t)$, and now also the wave-board position $X(t)$ are expanded into perturbation series:

$$\begin{aligned}\zeta &= \sum_{n=1}^{\infty} \varepsilon^n \zeta_n(x, t), \\ \Phi &= \sum_{n=1}^{\infty} \varepsilon^n \phi_n(x, z, t), \\ X &= \sum_{n=1}^{\infty} \varepsilon^n X_n(t).\end{aligned}\tag{17}$$

The terms in the perturbation series are again expanded into harmonic functions, as in (3). We introduce a cascade of slow variables, cfm. (2). However, now the amplitudes of the harmonic functions vary fast in space near the wave board due to the presence of evanescent modes. Therefore, the solution is assumed to be of the following form:

$$\begin{aligned}\zeta &= \sum_{n=1}^{\infty} \varepsilon^n \sum_{m=-n}^{+n} \zeta^{(n,m)} e^{-im\omega_0 t}, \\ \Phi &= \sum_{n=1}^{\infty} \varepsilon^n \sum_{m=-n}^{+n} \phi^{(n,m)} e^{-im\omega_0 t}, \\ X &= \sum_{n=1}^{\infty} \varepsilon^n \sum_{m=-n}^{+n} X^{(n,m)} e^{-im\omega_0 t},\end{aligned}\tag{18}$$

with:

$$\begin{aligned}\zeta^{(n,m)} &= \zeta^{(n,m)}(x_0, x_1, x_2, \dots; t_1, t_2, \dots), \\ \phi^{(n,m)} &= \phi^{(n,m)}(x_0, x_1, x_2, \dots; z; t_1, t_2, \dots), \\ X^{(n,m)} &= X^{(n,m)}(t_1, t_2, \dots),\end{aligned}\tag{19}$$

i.e. the harmonic functions $\zeta^{(n,m)}$ and $\phi^{(n,m)}$ are also functions of x_0 , and it is not assumed that the first-order solution only contains propagating waves $A \exp [i(k_0 x_0 - \omega_0 t_0)]$, but also evanescent modes fixed to the wave board.

The derivation of the first-order solution and the second-order subharmonic solution can be found in Agnon & Mei (1985), including how to remove the evanescent mode contributions from the subharmonic solution. These derivations will not be repeated here, but we only present the results for our problem of second-order wave-board control. The first-order first-harmonic solution is:

$$\begin{aligned}
 \zeta^{(1,1)} &= \frac{1}{2} A(x_1 - C_g t_1) e^{ik_0 x_0} + \\
 &\quad - i \frac{\omega_0 C_g}{C_0} \frac{1}{2} A(-C_g t_1) \sum_{l=1}^{\infty} \frac{1}{k_l} \frac{1}{C_g - \frac{1}{2}(q_0^2 + q_l^2)/(k_D h)} e^{-k_l x_0}, \\
 \phi^{(1,1)} &= -i \frac{g \operatorname{ch} Q_0}{\omega_0 \operatorname{ch} q_0} \frac{1}{2} A(x_1 - C_g t_1) e^{ik_0 x_0} + \\
 &\quad - \frac{g C_g}{C_0} \frac{1}{2} A(-C_g t_1) \sum_{l=1}^{\infty} \frac{1}{k_l} \frac{\cos Q_l}{\cos q_l} \frac{1}{C_g - \frac{1}{2}(q_0^2 + q_l^2)/(k_D h)} e^{-k_l x_0}, \\
 X^{(1,1)} &= i \frac{C_g}{C_0 \operatorname{th} q_0} \frac{1}{2} A(-C_g t_1),
 \end{aligned} \tag{20}$$

with $k_D = \omega_0^2/g$, $q_l = k_l h$, $l = 0, 1, 2, \dots$ and $Q_l = k_l(z + h)$, $l = 0, 1, 2, \dots$. The propagating wave number k_0 and the evanescent-mode wave numbers k_l , for $l = 1, 2, \dots$ satisfy the linear-theory dispersion relationships:

$$\omega_0^2 = \begin{cases} g k_0 \operatorname{th} q_0 & , l = 0, \\ g k_l \tan q_l & , l = 1, 2, \dots \end{cases} \tag{21}$$

The first-order zeroth-harmonic solution is:

$$\begin{aligned}
 \zeta^{(1,0)} &= 0, \\
 \phi^{(1,0)} &= \frac{g^2 [2\omega_0 k_0 + C_g(k_0^2 - k_D^2)]}{4\omega_0^2 (C_g^2 - gh)} \left(\int_{-\infty}^{x_1 - C_g t_1} |A(\psi)|^2 d\psi \right), \\
 X^{(1,0)} &= -\frac{g^2}{4\omega_0^2 C_g} \left(\frac{2\omega_0 k_0 + C_g(k_0^2 - k_D^2)}{C_g^2 - gh} + \frac{2\omega_0 k_0}{gh} \right) \times \\
 &\quad \times \int_{-\infty}^{-C_g t_1} (|A(\psi)|^2 - \langle |A|^2 \rangle) d\psi,
 \end{aligned} \tag{22}$$

where $X^{(1,0)}$ is the desired subharmonic bound-wave contribution to the wave-board control signal X . Note that $\phi^{(1,0)}$ and $X^{(1,0)}$ are proportional to $|A|^2$, and thus in fact higher-order quantities. This is due to the fact that their derivatives $\partial\phi^{(1,0)}/\partial x_1$ and $\partial X^{(1,0)}/\partial t_1$ are the relevant physical quantities which are second-order quantities within the multiple-scales perturbation-series approach.

From the second-order zeroth-harmonic contribution to the solution, only the $\zeta^{(2,0)}$ -term is needed:

$$\zeta^{(2,0)} = -\frac{1}{g} \left\{ \frac{\partial \phi^{(1,0)}}{\partial t_1} + \left[\left| \frac{\partial \phi^{(1,1)}}{\partial x_0} \right|^2 - k_D^2 |\phi^{(1,1)}|^2 \right]_{z=0} \right\}. \quad (23)$$

In summary, $\zeta^{(1,1)}$, $\phi^{(1,1)}$ and $X^{(1,1)}$ in (20) are the terms proportional to the wave amplitude A , and $\zeta^{(2,0)}$, $\phi^{(1,0)}$ and $X^{(1,0)}$ in (22) & (23) are the subharmonic terms proportional to $|A|^2$.

The first-order random free-surface signal $A \exp(-iC_g t_1)$ is generated with the random-amplitude/random-phase method (Tucker et al.; 1984), for a given first-order free-surface elevation spectrum, as in Section 2. Next the wave-board control signal, correct up to second order, is computed. Required time integrations are performed with the modified midpoint rule, and time differentiation with central finite differences, both of second-order accuracy, i.e. $O(\Delta t^2)$. Also deterministic waves, such as monochromatic and bichromatic waves, can be generated correctly up to second order with these equations.

At the moment, flume tests are performed at Delft University of Technology, for the experimental verification of the second-order wave-board control system.

4 Concluding remarks

The perturbation-series method of multiple scales has been used to derive an efficient method for the generation of second-order random waves in wave flumes with a translating wave board. The method is presented in detail for the subharmonic corrections to the wave-board control signal, but can easily be extended to include the superharmonic corrections.

The amount of work to generate the second-order corrections with the proposed method is proportional to the amount of work to generate the first-order signal. In previously used second-order frequency-domain methods, this amount of work was proportional to the square of the effort for generating the first-order signal.

Furthermore, the narrow-band approximation, implied by the use of the multiple-scales perturbation-series approach, seems to be very acceptable for the first-order spectral shapes most frequently used in coastal and ocean engineering problems.

CHAPTER 38

An Experimental Study of Waves on a Strongly Sheared Current Profile.

Christopher Swan.*

Abstract.

This paper describes a series of observations within a combined wave-current flume. A two dimensional progressive wave train was superimposed upon a co-flowing current profile. The direction of this current was reversible, thereby allowing the formation of both a "favourable" current velocity (one in which the current is in the same direction as the wave celerity), and an "adverse" current velocity. The combined flow field was measured using laser Doppler anemometry. The nature of the current profile was modified so as to allow an investigation of the interaction resulting from both a uniform current and a sheared current profile.

In the case of a uniform current, there was no observable phase change between the surface elevation and the velocity profile. In this respect the present measurements are very different from the observations presented by Brevik (1980a). Indeed, they confirm that a description of the oscillatory motion merely requires the introduction of a Doppler shift as was suggested by Fenton (1985). In the case of a sheared current profile the oscillatory component of the wave motion is found to be strongly dependant upon the vorticity within the current profile. The analytical solution proposed by Kishida and Sobey (1988) appears to underestimate the extent of the interaction, while the numerical solution proposed by Chaplin (1990) provides a better description of the combined flow field. The departure from irrotational theory is significant. In the case of waves superimposed on a strongly sheared "adverse" current the horizontal velocity component may be as much as 80% larger than the predicted irrotational motion.

1.0 Introduction.

The interactions resulting from the combination of waves and currents has been the subject of numerous publications. Thompson (1949) presented the first solution for waves on a linear shear current (ie. the current varies linearly in the vertical direction, but does not vary in the horizontal direction). Tsao (1959) also considered this problem, and established that the wave motion will remain irrotational provided the vorticity profile is uniform with depth. He conducted a classical Stokes' expansion, and obtained the third order expressions for the surface displacement and the velocity field in conditions of arbitrary depth. Dalrymple (1973) obtained the dispersion equation for finite amplitude waves on a bi-linear current profile. Using a stream function expansion he obtained a higher order numerical solution for waves on a linear, bi-linear, and arbitrary current profile. Further investigations of finite amplitude waves on a sheared current profile are given in Brink-Kjær and Jonsson (1975), Brink-Kjær (1976), Dalrymple (1977), and Kishida and Sobey (1988). These articles, together with the many other aspects of wave-current interaction, have been discussed in a number of review articles, of which Peregrine (1976) and Jonsson (1990) are two very good examples.

Despite the large number of theoretical solutions, the quantity of experimental data is extremely limited, and that which is available has tended to concentrate on the flow features within the near bed region (eg. Van Doorn, 1981). Brevik (1980a) investigated a number of different wave forms on an essentially uniform current profile (some shear did exist within the near bed region). Much of this work was directed towards the determination of the combined wave-current friction factor, and the reduction in wave height along the length of the experimental flume. However, he did take some measurements of the horizontal velocity component using a MIC-PAC micro-propeller. Unfortunately, the velocity measurements are limited to the case of a co-flowing "favourable" current (in the same direction as the wave motion), and because of the measuring system the velocity could only be determined within the lower half of the flow field. Nevertheless, the results are important in that there appeared to be a phase change between the velocity field and the surface profile. In two separate cases the horizontal water particle velocity was observed to lag behind the surface elevation by approximately 30° . The magnitude of this phase change was found to be uniform with depth. In a second series of observations Brevik and Aas (1980b) considered the interaction of waves and currents over a rough bed.

Kemp and Simons (1982 & 1983) provide the only other measurements of wave-current interactions. In the first

paper they considered the case of a "favourable" co-flowing current, and in the second an "adverse" co-flowing current. In both cases the experimental measurements are concentrated within the near bed region, and have been used to determine the variation in the turbulence intensity, the bed stress, and the nature of the bottom boundary layer. A limited number of measurements were taken at greater heights above the bed. However, because the current was introduced through the bed of the wave flume (similar to Brevik, 1980a) the current profile at these positions is essentially uniform with depth.

In many practical cases it may, of course, be assumed that the current velocity is approximately uniform with depth. Examples of this type of behaviour would include the large scale ocean currents, and the majority of tidal flows. However, in many other instances the current velocity will vary significantly with depth leading to the creation of a vorticity profile. Perhaps the most important example of this type of behaviour is the wind driven current where the magnitude of the current velocity varies exponentially with depth, leading to a very strong shearing action within the upper layers of the flow field.

The purpose of the present investigation was to obtain experimental data describing the interaction between waves and currents throughout the depth of the flow field for a number of different current profiles. In particular, to observe the modification of the oscillatory motion in the presence of a strongly sheared current velocity, and to compare this data with the existing theoretical solutions.

2.0 Apparatus.

The experimental observations were made in the Cambridge University Engineering Department's wave flume. This facility is 0.6m wide, 18m long, and allows a maximum water depth of 0.45m. The waves were generated via a hinged paddle, located within a deepened section at one end of the wave flume. The bed conditions were smooth (covered with plate glass), and the beach slope was maintained at 1:20. At this angle the effects of beach reflection were eliminated in all but the very longest waves considered. In these cases, an additional wave absorber was placed approximately half way up the beach slope. With this in place the reflection coefficient was never larger than 2.7%.

The re-circulating current was introduced via two loops of 50mm diameter pipework each connected to a self priming centrifugal pump. The total volume flow could be adjusted up to a maximum of 0.05m³/s. In the first half of the experiment the current was in the same direction as the wave celerity, and therefore constituted a co-flowing

"favourable" current. In the second half, the pipework was reversed, and the case of waves on a co-flowing "adverse" current was considered. In each of these cases the nature of the current profile, $U(z)$, was found to be dependant upon the height of the inlet and outlet pipes above the bed. To reinforce this pattern the outflow pipes, (the high pressure ends), were fitted with an appropriately shaped diffuser; while the inflow pipes (the low pressure ends), were located beneath a horizontal plate to prevent the formation of a vertical vortex and the resulting air entrainment. To further stabilise the flow field a small thickness of honeycomb, or flow straightener, was placed directly in front of both the in-flow and out-flow pipes. Figure 1 indicates the general arrangement of the experimental apparatus. This corresponds to the first case of a co-flowing current.

Figure 1. Experimental apparatus.

The velocity field was measured using laser Doppler anemometry. A 15mw. Helium-Neon laser was mounted above the wave flume. This was used to create a two beam system from which the horizontal component of the velocity field could be determined within a measuring volume which was estimated to be approximately 1.0mm^3 . Using this system the velocity could be determined to $\pm 3\%$.

3.0 Measuring technique.

Unfortunately, the introduction of a current within a wave flume is not as straight forward as indicated on figure 1. There are a number of practical problems which limit the superposition of a current profile and a progressive wave train. When the pumps were initially switched on, a long wave was generated leading to a seiching motion within the wave flume. Although the wave absorber reduced the effective life span of this motion, it was still found to take approximately 45 minutes until the variation in the surface elevation could be considered negligible ($< 1\text{mm}$). Furthermore, the action of the current itself leads to the formation of surface ripples. If these features are allowed to develop along the length of the flume, they can reach an appreciable height, often having

an amplitude in excess of 12mm. However, the addition of teepol in approximately 15 ppm. reduces the surface tension and thereby limits the formation of these features. This disturbance was never larger than 1.5mm in amplitude, and was for the most part considerably less.

The generation of a two dimensional current was rather more difficult to achieve. After a large number of experimental tests it was concluded that the honeycomb placed directly in front of the inflow and outflow pipes was critical in the development of an appropriate current profile. If the flow straightener was removed, or was of insufficient thickness, then the flow field would develop a three dimensional component, and in many cases become unstable within the central portion of the wave flume. Figure 2 shows the variation in the current profile across the tank width with the honeycomb in place. Although the magnitude of the current velocity does appear to be slightly larger along the centre line, the general form of the current profile is surprisingly consistent. In figure 3 the time variation in the current profile is shown throughout the duration of a test run. The current profile appears to be relatively unchanged even after a period of 8 hours. These measurements were obtained with a 75mm thickness of honeycomb as indicated on figure 1.

While the addition of honeycomb allows the development of a suitable current profile, its presence within the wave flume produces an important source of wave reflections. A problem which is further complicated by the horizontal plate located above the inflow pipes. As a result of these difficulties it became apparent that the creation of a reasonable current profile, and a continuous progressive wave train was not possible using the present arrangement. However, it was possible to achieve the required current profile and superimpose the effects of 5 or 6 gravity waves before the flow field is disrupted by the presence of the reflected waves. The measuring technique thus developed along the following lines. The required current profile was established within the wave flume. The long wave seiching was allowed to dissipate before the commencement of the experimental run. The wave maker was switched on, but the sampling procedure was delayed until the first two or three waves had passed the measuring section. At this point the wave profile will have achieved a regular form. The combined velocity field is then sampled for the duration of three or four wave cycles, but ceases before the reflected components start to disrupt the established order. The resulting pattern is shown on figure 4.

For this technique to provide information about the vertical variation in the horizontal velocity, it must be repeatedly applied at a number of different locations in the same vertical section. If the resulting data is to be

representative of the combined wave-current motion, then it is essential that the wave maker is capable of generating the same wave form throughout the duration of a test run (approximately 8 hours). To ensure that this requirement did not cause any difficulties, the wave amplitude was continuously monitored. The variation was generally found to be small ($<3\%$). However, this variation did become more significant as the wave length was reduced. In an attempt to average out these fluctuations extreme waves, or those waves in which the surface amplitude differed from the mean value by more than $\pm 5\%$, were neglected. Furthermore, the measured kinematics at any one depth were based on an average of five bursts, each containing three complete wave lengths.

In addition to the repeatability requirement, the wave motion should reduce to the irrotational solution proposed by Stokes (1880) in the absence of a current. Figure 5 shows the variation in the horizontal velocity at a number of different depths for the case $U(z)=0$. Although the current velocity was zero, the experimental arrangement is as indicated on figure 1. Both the flow straightener and the pipework were still located within the wave flume. The agreement with the third order irrotational solution is remarkably good.

Figure 5. Horizontal velocity component (Waves only).

4.0 Experimental results.

A total of six different types of interaction were considered, the experimental details of which are given in table 1.

Case	Wave form.	Current profile.
(1)	a=35.1mm, h=0.35m, T=1.412s.	Uniform, favourable.
(2)	a=35.7mm, h=0.45m, T=0.877s.	Uniform, adverse.
(3)	a=22.5mm, h=0.45m, T=0.869s.	Linear, favourable.
(4)	a=31.5mm, h=0.35m, T=1.418s.	Linear, favourable.
(5)	a=45.5mm, h=0.45m, T=0.998s.	Linear, adverse.
(6)	a=61.5mm, h=0.35m, T=1.420s.	Linear, adverse.

Table 1. Experimental parameters.

The first two cases correspond to a preliminary set of measurements in which the current profile was essentially uniform with depth. Case (1) considers the effects of a "favourable" current velocity ($U_{mean}=0.108m/s$,

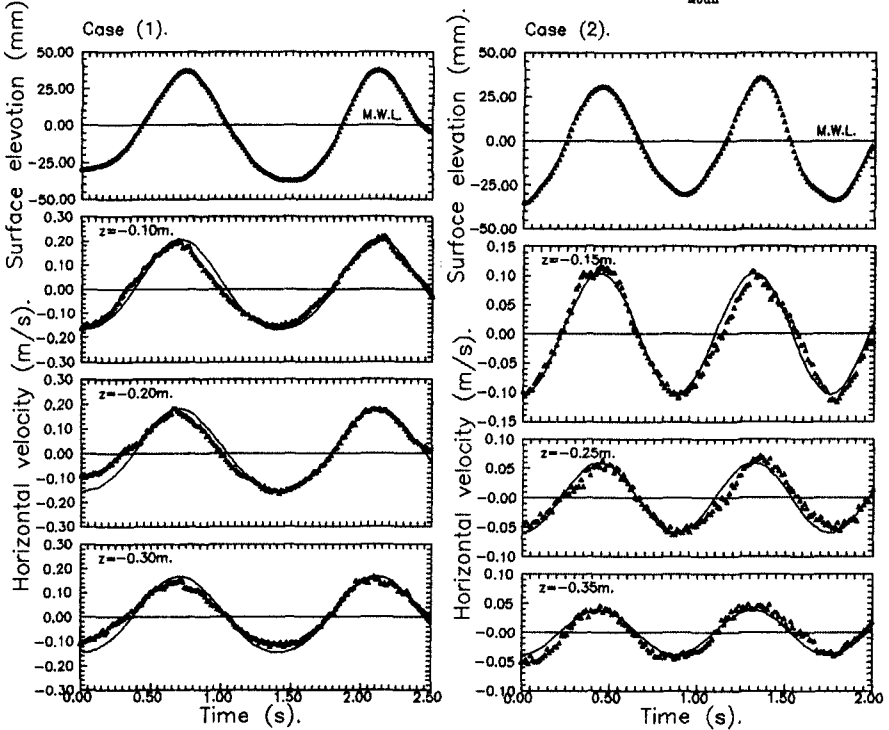

Figure 6. Waves on a uniform current.
 _____ Fenton (1985).

and case (2) the effects of an "adverse" current velocity ($U_{\text{mean}} = -0.120 \text{ m/s}$). In each case the only significant shearing motion occurred within a relatively thin layer directly above the bed. The oscillatory motion resulting from this type of wave-current interaction is shown on figures 6a and 6b respectfully. In both cases, the observed kinematics are shown to be in phase with the surface elevation. Furthermore, the magnitude of the oscillation appears to be in agreement with Fenton's (1985) Doppler shifted solution.

The remaining experimental results all concern the interaction with a sheared current profile. In cases (3) and (4) a "favourable" current profile with positive shear is considered (ie the velocity increases with height above the bed), while in cases (5) and (6) an "adverse" current with negative shear is considered. In each case the variation in the current velocity with depth is approximately linear. The importance of this assumption will be considered in section 5. One interesting feature of each current profile is the reversal in the current

Figure 7. Waves on a linear shear current.
 Fenton (1985).

velocity within the near bed region. This would appear to correspond to a large scale longitudinal circulation along the length of the wave flume. It was consistently observed throughout the working section (figure 2.), and was small in comparison with the magnitude of the surface current ($U_{z=0}$).

In each of the above cases the oscillatory motions were again found to be in phase with the surface elevation. Figure 7 concerns the flow conditions in case (6) and shows the characteristics of the surface elevation together with the time variation in the horizontal velocity at a number of different depths ($z=-0.1m$, $-0.2m$, and $-0.3m$). The amplitude of the oscillatory motion for cases (3)-(6) are shown on figures 8a-8d.

5.0 Comparisons with other work.

The experimental data appertaining to waves on a uniform current (Cases 1 and 2) differs from previous measurements (Brevik, 1980a) in that there is no observable phase change between the velocity profile and the surface elevation. In this respect, the present measurements appear to be in agreement with the existing analytical solutions (Fenton, 1985) and the recent numerical simulations (Chaplin, 1990). The accumulated evidence therefore suggests that the phase change observed by Brevik (1980a) does not represent a true wave-current interaction. A possible explanation of these results may well be found in the nature of the velocity measurements. Indeed, Brevik comments on the suitability of a horizontal micro propeller in the presence of a substantial vertical velocity component, ie. at significant heights above the bed. Wave reflection may also have contributed to the creation of the observed phase change. This latter point is at least partially substantiated by the asymmetrical nature of the measured surface profile.

The amplitude of the oscillatory motion produced by waves on a uniform current (figures 6a and 6b) shows good agreement with the Doppler shifted solution proposed by Fenton (1985). This clearly indicates that provided the magnitude of the surface drift velocity is taken into account within a modified dispersion equation, the measured characteristics of the velocity field for waves on a uniform current may be described on the basis of a modified Stokes' (1880) expansion.

In contrast, the measurements shown in figures 7 and 8 cannot be explained by the introduction of a simple Doppler shift. The shearing motion within the current profile produces an associated vorticity profile which must be taken into account when describing the combined flow field. However, in the case of a linear shear current the vorticity profile is constant with depth.

Figure 8a-8d. Waves on a linear shear current.
 — Doppler shifted solution (Fenton, 1985).
 - - - Linear shear solution (Kishida et al,1988).
 - · - · - Numerical solution (Chaplin, 1990).

Tsao (1959) considered this situation and concluded that the waves would remain irrotational, though different from Stokes' (1880) classical expansion. Kishida and Sobey (1988) extended this argument and obtained a 3rd. order solution for waves on a linear shear current. The results of this theory are shown on figures 8a-8d. The numerical solution proposed by Chaplin (1990) is also shown on figures 8a-8d. This solution allows a "best fit" cubic approximation of the current profile to interact with the required wave motion. There are no prior assumptions regarding the nature of the vorticity profile, and convergence is achieved after the summation of a large number of terms within a stream function expansion.

It is clear from figure 8 that the solutions proposed by Kishida and Sobey (1988) and Chaplin (1990) both predict the nature of the observed departure from the Doppler shifted solution (Fenton, 1985). The interaction with a co-flowing "favourable" current having positive shear is shown to produce a reduction in the amplitude of the horizontal velocity component; while the interaction with a co-flowing "adverse" current having negative shear is shown to increase the amplitude of the horizontal velocity component.

The analytical solution proposed by Kishida and Sobey (1988) appears to underestimate the extent of these interactions. This is particularly noticeable in the case of an "adverse" current having negative shear. In case (6) the observed velocity amplitude was as much as 81% larger than the Doppler shifted solution (Fenton, 1985), and 42% larger than the 3rd. order solution for waves on a linear shear current (Kishida and Sobey, 1988). Although this case corresponds to the steepest wave form investigated, it is, according to the classification code proposed by Dean (1970), a third order wave. As a result, the apparent discrepancies between the solution proposed by Kishida and Sobey (1988) and the experimental observations is rather surprising. One possible explanation for this observation is that the wave-current interaction increases the non-linearity of the wave form by enhancing the relative contribution of the higher harmonics. As a result, the wave energy is transferred to the higher harmonics, and consequently the traditional classification codes used for progressive gravity waves may be less appropriate in the presence of a significant wave-current interaction. The numerical solution shown on Figures 8a-8d (Chaplin, 1990) appears to support this view. By incorporating the full effects of the higher harmonics within a stream function expansion it provides a very good description of the experimental data in all cases.

6.0 Concluding remarks.

The present observations have shown the importance of the interaction resulting from a combination of waves and currents. In many practical cases it may, of course, be assumed that the current velocity is approximately uniform with depth. Under these conditions the horizontal velocity component remains in phase with the surface elevation, and the Doppler shifted solution proposed by Fenton (1985) is shown to provide a good description of the velocity field.

In many other instances the current velocity will vary significantly with depth. This leads to the creation of a vorticity distribution which must be taken into account when defining the characteristics of the oscillatory motion. Under these conditions the introduction of a simple Doppler shift within the dispersion equation is no longer sufficient to define the flow field. The third order analytical solution proposed by Kishida and Sobey (1988) is shown to predict the general effects of the vorticity profile. However, in the case of a strongly sheared "adverse" current profile it appears to underestimate the extent of the resulting interaction, thereby hinting at the increasing importance of the higher harmonics. In contrast, the numerical solution proposed by Chaplin (1990) is shown to provide a good description of the flow field in all cases.

The modification of the wave induced flow field in the presence of a strongly sheared "adverse" current profile is of particular importance, and undoubtedly warrants further study. The effect of this type of interaction is to significantly increase the amplitude of the oscillatory motion. Indeed, the effect is so pronounced that an interaction of this type may, under some circumstances, represent a possible "loading criteria" for the design of coastal and near-shore structures.

7.0 Acknowledgements.

The author would like to express his appreciation to Professor J. Chaplin for providing the results of his numerical model.

CHAPTER 39

WAVE KINEMATICS IN THE SURFACE ZONE

James E. Skjelbreia¹, Member ASCE
Alf Tørum²

Abstract

An extensive series of laboratory experiments have been carried out with regular and irregular waves travelling over a horizontal bottom. Velocity measurements of the flow were obtained at numerous vertical positions with major emphasis given to the surface zone. The flow measurements were made possible by use of a custom designed LDV having the special characteristic of being operative very near the free surface. Presented is an overview of the study and some of its majors results.

1 Introduction

The study of the flow within water waves has a long history, yet, it seems, some of the fundamental aspects of the phenomenon are poorly or not satisfactorily understood. Specifically, how reliable is current knowledge on details of wave surface shape, velocity field, induced current, or effects of ambient current over the spectrum of wave heights, periods, and water depths? Even for regular waves, let alone irregular waves, the answers to this question are far from complete. For more complex situations, say, for instance, three-dimensional ocean waves, the present methods for predicting the flow field are, at best, dubious. Clearly the problem is difficult and is one that deserves continued yet careful study—even at the most fundamental level.

¹ Senior Research Scientist, MARINTEK, Box 4125, 7002 Trondheim, Norway

² Head of Research, SINTEF NHL, 7034 NTH, Norway

Presently, designers for the offshore environment are often faced with the problem of using flow descriptions, and hence loading information, that might be of uncertain reliability. For fixed structures, one can take steps to alleviate the uncertainties by use of a safety factor and/or a wave theory that has proven to be conservative. Although this approach may solve the problem it can add substantially to overall development costs. For structures affected dynamically by waves, the problem is more acute; an overly conservative approach may render a design impractical due to excessive motion, for instance, when, in fact, if more realistic knowledge of the flow were known, the design might be completely acceptable.

The number of studies concerning measurement of wave kinematics is few and their scope often limited. These facts are a reflection of the difficulties, partially described above, that one encounters in such endeavors. Recent reports on field measurements and comparison to theory have been made, e.g., Lambroskos (1981), Forristall (1986), and one on the WADIC experiment presented at this forum. Among others, laboratory measurements of wave kinematics have been reported by Vis (1980), Bosma and Vugts (1981), Anastasiou *et al.* (1982), Bullock and Short (1985), and Gudmestad *et al.* (1988). Though each of these reports contain interesting and useful information, they still lack unification and presentation of sufficient evidence in a way that, say, designers can utilize the information with confidence. This is a problem, and in fact it is quite unlikely that generalized procedures to tackle the wave kinematics issue will be available soon.

The primary intent of this paper is to present examples of and discuss an extensive series of laboratory experiments that have been carried out with regular and irregular waves travelling over a horizontal bottom. Velocity measurements of the flow were obtained at numerous vertical positions with major emphasis given to the surface zone. The flow measurements were made possible by use of a custom designed LDV having the special characteristic of being operative very near the free surface.

2 Theoretical and Experimental Considerations

Linear Random Wave Theory. As a first approach to the problem of irregular waves, one can assume the flow to be composed with the sum of many individual *linear* waves each with its own frequency, direction, phase and celerity as predicted by the linear dispersion relation. This technique is often referred to as *linear random wave theory* (see Forristall, 1981 for a description). Bosma and Vugts (1981) performed experiments using one-dimensional irregular waves and reported on comparisons of velocity measurements obtained by laser Doppler velocimetry to linear random wave theory. They show that the agreement far

Figure 1 Example of linear random wave theory, — measurement, ··· linear random wave theory (Case 6, $z = -0.10\text{ m}$).

below the mean water level is reasonable, but tends to deviate increasingly with increasing elevation. This tendency of deviation can be explained, at least partially, by the significance of the higher wavenumber components *riding atop* the lower wavenumber components and hence may be displaced many of their own wavelengths from the mean water line. For large wavenumber, k , the amplitude of the velocity contribution is proportional to e^{kz} , where z is the coordinate measured vertically upward from the mean water line. The higher wavenumber contributions can become excessively large when $z > k^{-1}$ and similarly, significantly diminished when $z < -k^{-1}$. The net effect is that contributions from the higher wavenumber components will be over-represented in crests and under-represented in troughs. A good example of this can be seen in Figure 1. Shown are measurements of ζ , u , and w , the surface elevation, and the horizontal and vertical velocities respectively. The dotted line is the velocity obtained using linear random wave theory. The velocity shown in Figure 1 was measured at 0.1 m below the mean water line using the facility described in the next section; the wave conditions correspond to Case 6 of Table 1. We see significant departure of measurement from theory in the crests and troughs, on the other hand when ζ is near zero the comparison is better. This latter feature should be

expected if one believes in the linear superposition of waves since all wave components are, at least momentarily, at the elevation that linear theory presumes they are, namely $z = 0$, the mean water line.

Stretching Approximations. The notion of predicting kinematics beneath irregular waves from a spectral decomposition of the surface elevation, such as that done with linear random wave theory, is very attractive for its simplicity and speed of computation. Suggestions to cope with the problems inherent with linear wave theory have been made by Chakrabarti (1971) and Wheeler (1979), though both approaches fail to satisfy the Laplace equation Forristall (1981) mentions that use of Wheeler's method results in a lower error in the kinematics boundary condition when compared to linear random wave theory. With Wheeler's approach the variable z in the linear solutions for flow velocity is substituted as follows:

$$z \leftarrow \frac{z - \zeta}{1 + \zeta/d} \quad (1)$$

where d is the undisturbed water depth. The new expression for z is never greater than zero and for each wavenumber will effectively *stretch* or *compress* the velocity profile from the mean water line to the instantaneous free surface. For the case of irregular waves the higher wavenumber components, which tend to be of lesser amplitude than the low wavenumber components they ride atop, will be more reasonably represented. Taking the same example as shown in Figure 1 and using Wheeler's approach, we see in Figure 2 that a better

Figure 2 Example of a stretching approximation, — measurement, ... Wheeler's method (Case 6, $z = -0.10$ m).

approximation to the measured velocity over linear random wave theory is obtained. Still there are differences and this is but one comparison. The velocity in this case was computed using similar steps as for linear random wave theory; the procedure is complicated somewhat by the fact that ζ now appears in the equations for flow velocity such that it is not possible to form a simple transfer function relating surface elevation information to the flow velocity beneath.

3 Experimental Equipment and Procedures

The experiments for this investigation were carried out using the wave tank illustrated in Figure 3, which is located at the Norwegian Hydrotechnical Lab-

Figure 3 Wave Tank.

oratory in Trondheim. The tank is 33 m long, 1.02 wide and 1.8 m deep. It is constructed of concrete with a glass section 4.22 m wide, located approximately 10 m from the end of the tank, that allows viewing over the full depth. The wave generator is hydraulically driven and can be discretely varied from a pure hinge mode to a pure piston mode. At the end of the tank, opposite the wave generator, is located a passive wave absorber developed by the National Research Council of Canada. This device consists of a series of vertical perforated steel plates and has a reflection coefficient of approximately 5% over a broad frequency range that encompassed the range of frequencies with significant wave energy typical in this study. (For more details on this device see Jamieson and Mansard, 1987). Just ahead of the absorber, in the direction of the wave generator, is a positively buoyant mat 2.5 m in length that floats on the water surface. Usage of the mat significantly reduces high frequency reflections from the absorber and helps to reduce cross waves.

Flow velocity was measured on the centerline at a single longitudinal position along the tank, coinciding with gage 1, but at several different elevations (see next section) by a two-component laser Doppler velocimeter (LDV). The two velocity components measured were in a plane parallel to the side walls of the tank with a measurement volume cross-section of approximately $100\ \mu\text{m}$ in diameter. Frequency shifting was utilized enabling the resolution of directional ambiguities in the flow. The LDV was specifically designed for this study and has the special feature of using only a *single* laser beam in the flow. This feature allows measurements very near arbitrarily oriented surfaces, including the free surface. This device is similar to and based on one described by Skjelbreia (1987).

The surface elevation was measured with standard resistive-type gages having streamlined supports to minimize disturbances. One wave gage was positioned at the LDV station, it was displaced from the wave tank's centerline $0.34\ \text{m}$ to avoid disturbance to the flow in the vicinity of the LDV measurement point. The wave generator control signal was constructed from a JONSWAP target wave spectrum using $\gamma = 3.0$. The spectrum was divided into 1000 frequency components and each component assigned a random phase. Great care was given to maintaining reproducible wave conditions in the tank. This was necessary to construct a *snap-shot* of the flow throughout the depth since the LDV is capable of only a single point measurement. Careful control of the water depth was found to be very important for reproducibility and it was maintained to within $\pm 1\ \text{mm}$ by an overflow connected by tubing to the tank and by having a water inflow of $0.11/\text{min}$ into the tank to offset small leaks in the overall system.

4 Test Program

The complete test program consisted of nine wave conditions, six irregular wave cases, two regular wave cases, and one case that the control signal to the wave generator was constructed from two sinusoids, these are listed in Table 1. In total there were 269 runs recorded.

Listed in Table 1, the peak period, T_p , is the value used to create the control signal for driving the wave generator and the significant wave height, H_s , was determined from the measured energy spectrum at the LDV station. For the two period case, the values for H_s/gT_p^2 and d/gT_p^2 are based on the average of the two periods and for the regular wave cases, T_p and H_s are simply T and H , the period and waveheight.

Velocity measurements of the flow were obtained at as many as fifteen separate elevations for each of the nine cases considered. The majority of the elevations were clustered in the surface zone with a few covering the flow on down to the bottom.

Table 1 Test Program.

Case	Type	T_p (s)	H_s (m)	d (m)	H_s/gT_p^2	d/gT_p^2
1	Irregular	1.2	0.11	1.3	0.0078	0.092

5 Presentation and Discussion of Results

The results to be presented have been selected from Case 6 listed in Table 1. There have not been any adjustments to the velocity measurements to account for a current that may be present or to remove the effects of reflected or resonant waves. Instead, all measurements presented are the raw, unfiltered information that was obtained by the wave gages and the LDV. A note on the flow velocity time traces to be presented: measurements near the surface have varying degrees of intermittent behavior depending on what level they were obtained. This occurs when the water surface drops below the probe volume of the LDV and the measurement ceases. Until the water surface moves back up to the level of the LDV the signal holds at the last measured value, these *drop-out* periods will be noted as the flat portions in the time traces. Occasionally when the water surface just crosses the LDV level, a spike in the measurement occurs, these should not be interpreted as valid measurements.

Irregular Waves. We will present a few comparisons to contrast the differences between linear random wave theory and Wheeler's method. In Figure 4 are shown measurements taken from Case 6 of the horizontal velocity at elevations throughout the depth together with predictions using linear random wave theory. The upper measurements illustrate the well know fact of the unsuitability of linear random wave theory in the surface region (the ordinates for $z = 0.20, 0.10,$ and 0.05 m have multiplying factors of $10^{21}, 10^9,$ and 10^3 respectively). Beginning at $z = 0.00$ (mean water level) we note the near 250% over-prediction of velocity beneath the crest located at 136.7 s. The surface is relatively steep about this crest and hence has energy at the higher wavenumbers as compared to other portions of the signal where there is not the same

Figure 4 Measurements (—) of surface elevation and horizontal velocity compared with linear random wave theory (···), Case 6.

degree of error. The measurement level at $z = -0.10$ m is beneath nearly all the troughs in this segment, note that the velocity is consistently under-predicted in magnitude. Moving further down the comparison improves, still the velocity at $z = -1.11$ m under the crest at 136.7 s is over-predicted by 25%.

In Figure 5 we move on with the same case and time segment as the previous figure but now the horizontal velocity is compared with Wheeler's method. There is general improvement in the comparison. In the surface region reasonable values are now predicted and the actual measurement have become visible. In particular, the velocity measurements beneath the crest at 136.7 s are all within 8% of the predicted values with the exception of the two measurements nearest the bottom. The trough values at $z = -0.10$ m are under-predicted as was the case with linear random wave theory. There are a number of interesting features we can observe in this figure, for instance note the rapid increase in horizontal velocity as the surface is approached in the crest located at 136.7 s, pointing out the importance of wave steepness and the need for measurements near the surface. A good example of the frequency dependence of the velocity can be seen by comparing the wave with its crest at 134.5 s to the one with its crest 136.7 s. For example the measurement made at $z = 1.11$ m shows the horizontal velocity in each wave to be similar while the surface profile indicates that one wave has nearly twice the waveheight as the other. One can see this type of feature elsewhere in the signal as well.

To complete our comparison, shown in Figure 6 are measurements of vertical velocity and predictions according to Wheeler's method corresponding to the same time segment as in the two previous figures. In general, the comparison is good. The maximum vertical velocity is consistently over-predicted just ahead of the crest at 136.7 s in the surface region, $z = 0.05$ to -0.10 m. At $z = -1.11$ m the magnitude of the flow is low and near the resolving level of the LDV, the jaggedness in the signal is not necessarily turbulence. In contrast to the horizontal velocity, the vertical velocity is better predicted at this level.

Figure 5 Measurements (—) of surface elevation and horizontal velocity at various levels compared with Wheeler's method (···), Case 6.

Figure 6 Measurements (—) of surface elevation and vertical velocity at various levels compared with Wheeler's method (···), Case 6.

6 Conclusions

Presented has been an overview of, what we consider, a systematic and well planned series of experiments to investigate the wave kinematics problem. Preliminary analysis has shown Wheeler's method to compare well with the presented measurements, including a regular wave case during the early stages of a run.

7 Acknowledgements

We greatly appreciate the financial support from NTNF, Amoco, Conoc, Exxon, Mobil and Statoil. An additional special thanks to Amoco Norway who provided the funds needed to design and construct the LDV, an essential component in this study.

CHAPTER 40

STOCHASTIC MODELING OF SURFING CLIMATE

William R. Dally¹, M. ASCE

Abstract

A continued increase in the popularity of surfing, coupled with the potential for adverse impacts by coastal construction projects on favored surfbreaks, has recently confronted engineers with the problem of defining and quantifying a 'good' surfbreak. A rudimentary analysis of surfing mechanics demonstrates that conditions can be examined in terms of the joint statistical climate of 1) breaker peel rate, and 2) attainable board speed as characterized by the Irribarren Number. Assuming a planar beach and using linear wave theory, two theoretical models for the joint probability density of peel rate and Irribarren Number can be used to appraise short-term surfing conditions. Results indicate that the short-crested character of real waves plays a primary role in enhancing surfbreak. For practical calculations of long-term surfing climate at specific sites, offshore wave gage data can be transformed across a measured beach profile to predict breaker conditions in the outer surf zone. Application of such a numerical algorithm to the beach at Duck, North Carolina indicates that the waves are suitable for surfing roughly 25% of the time.

Introduction

Often the major impetus for beach nourishment and structural projects is not only erosion control and the protection of upland real estate, but also the preservation of the recreational opportunities afforded by a fronting beach. Surfing is one such activity, and although Morahan

¹ Assistant Professor, Oceanography and Ocean Engineering, Florida Institute of Technology, 150 W. University Boulevard, Melbourne, Florida 32901, U.S.A.

(1971) and others have assigned substantial monetary value to surfing recreation, the economic and cultural benefits of surfing have usually been overlooked during the development of beach projects. Consequently the physical impact of a particular project on the local surfbreak, and the subsequent impact on surfing recreation, have rarely been considered.

In recent years, surfers have begun to increase public awareness as to the importance of preserving good surfbreaks (see Pratte, 1987), and some engineers and planners have begun to at least take surfing into consideration during project design. This immediately gives rise to the problem of how to define and quantify a 'good' surfbreak and the suitability of a particular beach for surfing. Viable engineering models for beach 'surfability' are required in order to prevent negative impacts on surfing, to guide mitigation if such impacts are unavoidable, and to perhaps even enhance the surfbreak at a project site.

Background

Criterion for a Ridable Wave

According to Walker (1974) and Dally (1989), the qualitative definition of 'surfable' is a wave on which a surfer can maintain a mean speed (termed 'board speed') that is as fast or faster than the rate at which the point of incipient breaking translates along the wave crest (termed 'peel rate'). If the breaking segment of the wave overtakes the surfer, the wave 'closes out' and becomes unsurfable. In the most basic sense, it is the joint statistical climate of attainable board speed and peel rate that determine the surfing climate of a particular beach.

Board Speed

To date there appears to have been no comprehensive studies which specifically address the speeds attainable on surfboards. Using aerial photographs, Walker (1974) was able to infer mean board speed from estimates of the peel rate of waves that were surfed, and found maximum speeds on the order of 12 m/s (27 mph). Although direct measurements of board speed have yet to be obtained, parameters currently found in engineering practice can be utilized to provide insight.

Attainable board speed is a function of the size and shape of the face of the breaker, the weight of the surfer, and board characteristics. For a given board shape and surfer weight, the board speed can be inferred by using the

wave height at incipient breaking (H_b) to quantify the size and the Irribarren Number (I) to represent shape of the wave face. Irribarren Number is defined as

$$I_b = m/[H_b/(gT^2/2\pi)]^{1/2} \quad (1)$$

$$I_o = m/[H_o/(gT^2/2\pi)]^{1/2} \quad (2)$$

in which m is bottom slope, T is wave period, g is gravitational acceleration, and the subscripts "b" and "o" denote conditions at incipient breaking and in deep water, respectively. The Irribarren Number has been shown to characterize breaker type (Galvin, 1968 and Battjes, 1974). Spilling breakers are surfable, but not as desirable as plunging breakers. Collapsing breakers are unsurfable and in fact are quite dangerous to surfers. Table 1 presents surf climate classifications in terms of Irribarren Number and breaker type.

TABLE 1 - Surf Climate Classifications

Irribarren Number	Breaker Type	Surfing Terminology
$I_b < 0.4$ $I_o < 0.5$	Spilling	'mushy'
$0.4 < I_b < 2.0$ $0.5 < I_o < 3.3$	Plunging	'tube' or 'hollow'
$2.0 < I_b$ $3.3 < I_o$	Surging or Collapsing	'cruncher'

Peel Rate

The peel rate, V_{bp} , as defined by Walker (1974) is given by

$$V_{bp} = c_b/\sin(\alpha_b) \quad (3)$$

where α_b is (in planform) the angle between the wave crest and the path scribed by the moving break point. This angle is determined by the gradient in wave height along the wave crest, which has contributions from both oblique incidence and longshore variation in wave height. Referring to Figure 1 for definitions, and assuming the bottom contours are locally straight and parallel, α_b is given by

$$\tan \alpha_b = ds/dn = \tan \theta_b + ds_*/dn \quad (4)$$

where ds is the incremental path length scribed by the breakpoint projected in the direction of wave propagation. As mentioned, a portion of this distance, ds_* , is associated with the local longshore gradient in wave height, i.e. the short-crestedness of the breakers. This quantity is given by

$$ds_* = (H_b - H_*) / (dH/ds) \quad (5)$$

where H_* is the height of the wave as it passes the bottom contour. If there is no longshore gradient, the breakpoint simply moves along the bottom contour. Assuming that the ratio of wave height to water depth at incipient breaking (K) is spatially uniform, it can be shown that

$$ds_*/dn = \frac{-(dH/dy)}{[(dH/ds) \cos \theta_b] + (K m \cos^2 \theta_b)} \quad (6)$$

Figure 1 - Schematic diagram of breakpoint mechanics showing movement of breakpoint during an increment of time.

The rate of shoaling, dH/ds , required in Eq.6 can be derived from conservation of energy flux. For a planar beach and adopting shallow water linear wave theory, this is given by

$$dH/ds = (H/4h) m \cos \theta_b + (H/2) \tan \theta_b (d\theta_b/ds) \quad (7)$$

If it is assumed that $d\theta_b/ds$ is small, at the breakpoint Eq.7 becomes

$$dH/ds = (K/4) m \cos \theta_b \quad (8)$$

and Eq.4 becomes

$$\tan \alpha_b = \tan \theta_b + \frac{-(dH/dy)}{(5/4) K m \cos^2 \theta_b} \quad (9)$$

Based on this background, stochastic models for the joint statistical behavior of board speed (Irribarren Number) and peel rate can be developed to assess the surfing climate at a beach. In order to study the relative importance of wave obliqueness versus short-crestedness in determining peel rate and surfing climate, two stochastic models are derived below. The first one neglects short-crestedness whereas the second neglects obliqueness. As will be seen, they are based on the assumption of stationarity in the incident wave climate, and so may be used to assess surfing climate in only a short-term sense.

Stochastic Model for Short-Term Surfing Climate #1

If it is assumed that the bottom contours are straight and parallel and that there is no longshore variation in wave height, $\alpha_b = \theta_b$ (see Eq.9). From Eq.4, Snell's Law then dictates that V_{bp} is predetermined in deep water, i.e.

$$V_{bp} = c_o / \sin(\theta_o) \quad (10)$$

where $c_o = gT/2\pi$. By utilizing Eqs.2 and 10, surfing conditions can be characterized entirely in terms of deepwater conditions. With a given constant bottom slope, a joint probability distribution function (pdf) of the three random variables H_o , T , and θ_o is required. It is further assumed that wave direction is independent of height and period, i.e.

$$\text{pdf}(H_o, T, \theta_o) = \text{pdf}(H_o, T) \cdot \text{pdf}(\theta_o) \quad (11)$$

From Longuet-Higgins (1983), the pdf(H_o, T) is given by

$$\text{pdf}(R_o, \tau) = C_1 (R_o/\tau)^2 \exp\{-R_o^2[1+\epsilon^{-2}(1-\tau^{-1})^2]\} \quad (12a)$$

where

$$R_o = H_o/H_{\text{rmso}} \quad (12b)$$

$$\tau = T/\bar{T} \quad (12c)$$

$$C_1 = [4/(\pi\epsilon)^{1/2}][1+(1+\epsilon^2)^{-1/2}]^{-1} \quad (12d)$$

H_{rmso} is the root mean square wave height in deep water, \bar{T} is the mean period, and ϵ is a band width parameter. Adopting a cosine-squared type distribution for pdf(θ_o), i.e.

$$\text{pdf}(\theta_o) = (2/\pi) \cos^2(\theta_o - \bar{\theta}_o) ; \quad -90^\circ \leq (\theta_o - \bar{\theta}_o) \leq 90^\circ \quad (13)$$

straightforward transformation of random variables leads to

$$\text{pdf}(I_o, \tau) = 2 C_1 \frac{m^6 \tau^4}{I_o^7 \bar{S}_o^3} \exp\{-\frac{m^4 \tau^4}{I_o^4 \bar{S}_o^2} [1+\epsilon^{-2}(1-\tau^{-1})^2]\} \quad (14)$$

$$\text{pdf}(\hat{V}_{\text{bp}}) = (2/\pi) \frac{\tau}{[1-(\tau\hat{V}_{\text{bp}})^2]^{1/2}} \cos^2[\sin^{-1}(\tau\hat{V}_{\text{bp}}) - \bar{\theta}_o] \quad (15)$$

where \hat{V}_{bp} is dimensionless peel rate defined by

$$\hat{V}_{\text{bp}} = (g\bar{T}/2\pi)/V_{\text{bp}} \quad (16)$$

and \bar{S}_o is a deepwater wave steepness defined as

$$\bar{S}_o = H_{\text{rmso}}/(g \bar{T}^2/2\pi) \quad (17)$$

The marginal pdf of I_o and \hat{V}_{bp} is found by integrating numerically with respect to wave period.

Sample results are shown in Figures 2a, b, and c. The lines separating surfable from unsurfable conditions are shown only conceptually, with the exception that the upper limit on Irribarren Number is dictated by the exclusion of collapsing breakers. Integrating the volume of probability density contained in the surfable region

Figure 2 - Sample results of theoretical model for surfing climate given by numerical integration of Eqs.14 and 15. Volume contained in surfable region represents the proportion of incoming waves that are surfable.

Figure 2 - concluded

yields the proportion of the incoming waves that can be regarded as surfable, and provides a number that can be used to quantify the surfing climate for a particular beach and incident wave conditions.

Figures 2a and b are for a mean angle of incidence of zero, but for different bottom slopes. Note that more probability density is shifted into the unsurfable region if the bottom slope is decreased from 1/20 to 1/30. If the mean angle of incidence is oblique to the shoreline as in Figure 2c, the pdf changes shape significantly and more density falls within the surfable region.

Stochastic Model for Short-Term Surfing Climate #2

In this model it is assumed that all waves break parallel to the bottom contours of a planar beach, and that a single uniform value can be used to represent the longshore gradient in wave height. Starting again from Eq.12, and employing Eq.2 and linear wave theory to shoal waves from deep water to the break point, transformation of random variables leads to

$$\text{pdf}(I_o, \hat{C}_b) = C_1 \frac{m^2 \hat{C}_b^4 K^2}{I_o^3 \bar{S}_o^3 \pi^2} \exp -\left\{ \frac{m^4 \hat{C}_o^4}{I_o^4 \bar{S}_o^2} [1+\epsilon^{-2}(1-\hat{C}_o^{-1})^2] \right\} \quad (18a)$$

in which

$$\hat{C}_o = \hat{C}_b [(K^2/2\pi^2)(I_o/m)^4]^{1/5} \quad (18b)$$

Using Eqs.3 and 9 yields the relation

$$\hat{C}_b = \hat{V}_{bp}^{-1} [\Omega(1+\Omega^2)^{-1/2}] \quad (19a)$$

in which

$$\Omega = [(-dH/dy)/(1.25 K m)] \quad (19b)$$

and a final transformation leads to

$$\text{pdf}(I_o, \hat{V}_{bp}) = C_1 \frac{m^2 K^2}{I_o^3 \bar{S}_o^3 \pi^2} \frac{[\Omega(1+\Omega^2)^{-1/2}]^5}{\hat{V}_{bp}^6} \exp -\left\{ \frac{m^4 \hat{C}_o^4}{I_o^4 \bar{S}_o^2} [1+\epsilon^{-2}(1-\hat{C}_o^{-1})^2] \right\} \quad (20)$$

Sample results for a value of dH/dy of -0.005 are displayed in Figure 3. In comparison to Figures 2b and 2c, it is clear that for the same bottom slope and mean deepwater steepness a much greater proportion of waves fall within the bounds of the surfable region. Although the two models are quite simple and heuristic, these results do indicate that the contribution to the peel rate from the short-crestedness of waves is more important than that from wave obliqueness. Future investigations and modeling of surfing climate should be focused accordingly.

Computational Model for Long-Term Surfing Climate

Because the formulations above inherently assume that the incident waves are a stationary random process, they can only be valid on a time scale on the order of several hours to perhaps several days. To quantify the surfing climate of a site on a seasonal or yearly time scale, a long-term model or methodology is required. In addition, surfers usually line up at the outer edge of the surf zone and choose to ride only the higher waves in the incoming groups. Therefore it appears that a reasonable description of the long-term surfing climate would be the joint distribution of board speed and peel rate associated with

Figure 3 - Sample results of second theoretical model for short-term surfing climate given by Eq.20.

only the larger breaking waves (e.g. $H_{1/10}$), analyzed at intervals of several hours.

Wave height and period provided by long-term wave gage records, hindcast predictions, or even manual observations might be used to calculate Irribarren Numbers. However, wave direction information needed to partially determine peel rate is more difficult to obtain, plus observations of the longshore gradient in breaker height are almost nonexistent. At present, development of usable methodologies to assess long-term surfing climate must therefore be guided by available data.

As an example, detailed, long-term wave information is available in the Monthly Data Summaries published by the Field Research Facility in Duck, North Carolina. The data utilized herein is derived from pressure gage time series collected for 34 min, once every six hours, and is reported in the form of energy based significant wave height, H_{m0} , and associated peak spectral period, T_p . The gage is located at a nominal water depth of 8 m.^p Concurrent tide measurements are also provided, plus high quality nearshore bathymetry is available from CRAB surveys.

Numerical Algorithm

H and T can be used as the input required by the joint probability density function of wave height and period derived by Longuet-Higgins (1983) by assuming that $H_{rms} = H_{po}/\sqrt{2}$ and $\bar{T} = 0.8 T$. With the pdf discretized into a joint histogram, the routine steps landward along a measured beach profile, shoaling each representative wave according to the theory of Shuto (1974):

$$H^2 C_g = \text{const. (linear theory)} \quad \text{for } gHT^2/h^2 < 30 \quad (21a)$$

$$Hh^{2/7} = \text{const.} \quad \text{for } 30 < gHT^2/h^2 < 50 \quad (21b)$$

$$Hh^{5/2} [(gHT^2/h^2)^{1/2} - 2\sqrt{3}] = \text{const. for } 50 < gHT^2/h^2 \quad (21c)$$

where C_g is the group velocity. Each representative wave shoals until the condition for incipient breaking developed by Weggel (1972) is satisfied:

$$(H_b/h) = b(m) - a(m) H_b/gT^2 \quad (22a)$$

where

$$a(m) = 43.8(1.0 - e^{-19m}) \quad (22b)$$

$$b(m) = 1.56/(1.0 + e^{-19.5m}) \quad (22c)$$

Because the bottom profile at the FRF is irregularly shaped and often contains a bar formation, an estimate of the effective bottom slope is needed in Eq.22. This estimate is determined from the section of profile immediately seaward of the point of interest, by averaging the slope over a distance of one wave length. The routine continues to step across the profile until 10% of the waves have broken. At this point the average incipient breaker height and average of the associated Irribarren Numbers at breaking ($H_{b.1}$ and $I_{b.1}$) are calculated for this 10% of the waves that broke first.

Sample results from this algorithm are presented in Figure 4 for the month of January, 1989, and in Figure 5 for the month of July, 1989. It is interesting to note that the predicted Irribarren Numbers fall predominantly in the range of spilling breakers, and that $H_{b.1}$ and $I_{b.1}$ are inversely correlated - unfortunate from the surfer's point of view.

Figure 4 - Results from the numerical algorithm for the long-term surf climate at Duck, North Carolina during the month of January, 1989. The correlation between Hb.1 and Ib.1 is -0.71 .

If a criterion for surfable conditions is imposed such that $Hb.1 > 1.25m$ and $Ib.1 > 0.3$, the waves were surfable roughly 35% of the time in January and 33% of the time in July. Raising the requirement on Hb.1 to 1.5m reduces January to 20% surfable, and July to 15%.

Figure 5 - Results from the numerical algorithm for the long-term surf climate at Duck, North Carolina during the month of July, 1989. The correlation between Hb.1 and Ib.1 is -0.23.

Summary and Conclusions

Viable engineering models and methodologies that can be used to evaluate the surfing climate at a beach are needed to preserve the recreational benefits of the coast. A rudimentary analysis of surfing mechanics demonstrates that the basic parameters in need of study are 1) the peel

rate of a breaking wave, and 2) the attainable board speed. Assuming a planar beach and using linear wave theory, two heuristic models have been presented that can be used to appraise short-term surfing conditions, given beach and incident wave characteristics. Results indicate that it is essential to include the short-crested character of real surf in model formulations. Also presented is a numerical algorithm which utilizes arbitrary beach profiles and measured offshore wave data to evaluate surfing conditions on a seasonal or yearly time scale.

Future investigations of surfing should include a better parameterization of attainable board speed in terms of wave and wind characteristics, with verification to direct measurements. Another important aspect to consider is the paddling effort required in order to catch a wave, i.e. the interplay of the mechanics of catching a wave and the transformation of the individual wave as it approaches breaking. This can play a major role in assessing the surfbreak on a particular day.

CHAPTER 41

WAVE MODEL APPLICATION IN A WADDEN SEA AREA

J.D. den Adel (1), H.D. Niemeyer (1), A.F. Franken (1),
N. Booij (2), J. Dekker (3), J.A. Vogel (4)

ABSTRACT

A verification study of the numerical 2D wave propagation model HISWA is presented for a complex coastal area. Model predictions are confronted with field measurements. Also the effects of specific model possibilities and limitations are examined. Results have been fair: mean errors in wave height of 12% and in wave period of 4%, at a distance of 4 km from the incoming boundary over which measured wave heights reduced 40% and periods 21%.

1 INTRODUCTION

The aim of using wave propagation models, is to estimate nearshore wave conditions from offshore available wave data, by considering the onshore wave processes. In this paper the performance of the wave propagation model HISWA in a German part of the Frisian Wadden Sea (fig. 1) is discussed. As the study is still continuing, only intermediate results will be presented, unsolved questions might be answered in the near future.

2 THE MODEL HISWA

To get an idea of the sort of model, the basic formulation of HISWA and the physical processes involved will be discussed briefly. Detailed information can be found in papers by BOOIJ et al. (1985) and HOLTHUIJSEN et al. (1988).

HISWA is a numerical, 2D wave propagation model, based on the action balance equation for stationary conditions. Action is an energy derived quantity, by dividing energy by the relative frequency. Unlike energy, action is also conserved in the presence of a current. The action balance equation has the following shape:

$$\frac{\partial(c_x A)}{\partial x} + \frac{\partial(c_y A)}{\partial y} + \frac{\partial(c_\theta A)}{\partial \theta} = S \quad (1)$$

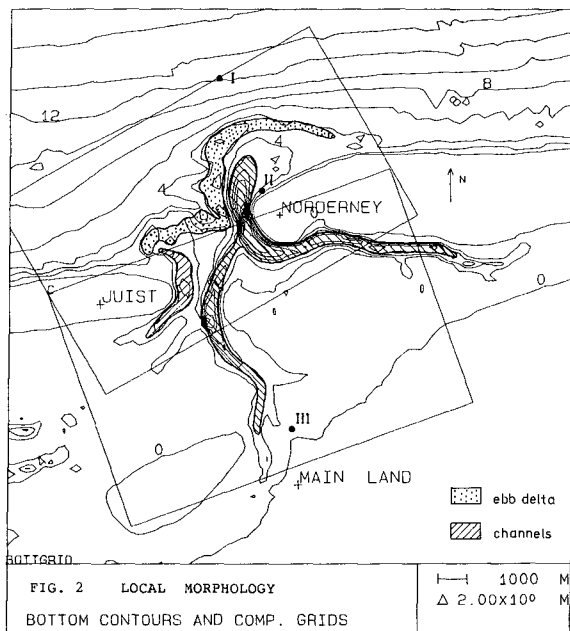

On the left hand side the transport terms (gradients) of the action density integrated over the frequency (A) are written. c_x and c_y denote the translation speeds of A , c_θ the speed with which A changes its direction. The transport terms cause a redistribution of existing energy in

space and over the directions, which implies propagation and shoaling and refraction but not diffraction.

On the right hand side the S , denoting sinks and sources, stands for the sum of all external processes removing wave energy from or introducing wave energy into the system. These are wave breaking, bottom friction, current dissipation and wind growth. They are represented by suitable semi-empirical functions.

The frequency is not constant; there is an equation similar to (1) from which the action averaged frequency can be found. By employing the θ -dimension, the concept of a directional wave spectrum is retained. The action balance is projected on a regular grid (x, y, θ) for numerical operation.

HISWA can produce several types of output, for a number of wave parameters. In this study the wave height and period serve as test parameters. HISWA operates with a significant wave height $H = 4(M_0)^{0.5}$ and a mean period $T = M_{-1}/M_0$ in which M_0 and M_{-1} are the 0th and the -1st frequency moments of the wave spectrum. Anywhere in this paper H and T are those given by the above definitions.

3 MORPHOLOGY

Because of its relevance for wave propagation, a short outline of the local morphology is given (fig. 2). The area of interest lies in the surroundings of the barrier islands Norderney and Juist. North of the islands initially there is a mildly sloping bottom. This smooth topography is interrupted by an ebb delta, lying at a distance of at most 2 km out of the northwest coast of Norderney. It partly shelters the tidal inlet between Norderney and Juist. In the tidal inlet two main channels have formed. The larger eb channel in the east splits up into two tributaries, one bending around the west end of Norderney and another directed to the main land coast in the middle. The flood channel in the west, bends around the eastern shore of Juist.

South of the islands physiographically quite a different situation occurs. Here the area consists of a system of tidal flats and narrow channels, a typical part of the Wadden Sea stretching along the Dutch, German and Danish coasts. But currently the investigations are focussed on the northern part.

Two dominating features with respect to wave propagation are the ebb delta and the tidal channels. The ebb delta causes a lot of wave breaking during storm occasions. The channels are corridors through which wave energy penetrates. Also the course of wave directions along the channels remains rather constant for a wide range of incoming wave directions (NIEMEYER, 1986).

The frames in fig. 2 indicate the computational areas, measuring about 7.5 x 12 km and 9 x 12 km north and south. Points I, II and III are observation points.

4 FREQUENCY SHIFT

HISWA simulates the frequency change associated with each of the dissipative or generative processes. For wave breaking and bottom friction the frequency change can optionally be switched on or off. The change of frequency is based on certain assumptions of the frequency spectrum in relation to energy dissipation. As indicated by DINGEMANS (1987) these assumptions do not fully match physical reality. Compared with a laboratory experiment (DINGEMANS, 1987) the frequency would get too high (or the period too low). A constant frequency on the other hand, is physically also unrealistic in relation to wave breaking and bottom friction.

A change in frequency will affect the processes on both sides of the action balance equation and thus the wave height. Refraction, getting weaker with increasing frequency, has especially much influence on the steep slopes of the main channel along Norderney. So it is of importance to have a good estimation of the frequency. To examine the effect of the frequency change, ratios between the wave height computed at a constant frequency and at a changing frequency were calculated for regularly spaced points over the area. It was found that these ratios lie between 0.60 in the eastern main channel and 1.25 at the western part of the ebb delta. Just as an example fig. 3 shows a block print of such ratios for a part of the area. (A block print is a table of values for a grid of regularly spaced points, like a value map with different x,y-scales).

VOGEL et al. (1988) applied HISWA in a comparable sort of area with the frequency change switched on. Instead of the expected underestimation of the wave period by letting the frequency change, their computations showed a small overestimation of the period of 7% on average.

fig. 3 ratios of the wave height obtained with the frequency switches turned off and turned on

In order to decide for this area whether to run HISWA with a changing or a constant frequency, tests were done both with the frequency change switched on and off. For both situations the calculated wave periods and wave heights were compared with field measurements. For the wave period an overall better performance was found by having the frequency change switched on, as can be seen in figure 4 and table 1: a mean percent error $e(T)$ of -4% with the frequency change switched on against 29% with the frequency change switched off. The percent error of the period is defined as $e(T) = 100\% * (T_{his} - T_{obs}) / T_{obs}$, with the subscripts his and obs referring to HISWA and observed values. For the wave height there is hardly any difference between cases with a changing or a constant frequency: mean errors $e(H)$ of 12% for both cases (fig. 5, table 1). This could be due to the position of the observation point (II) in front of the deep channel along Norderney, where the wave height is still relatively unaffected by refraction. The scatter (standard deviation sd) gets a little lower when the frequency change is switched on. On account of the improvement of the wave period, it was decided to run HISWA with the frequency change switched on.

fig. 5 WAVE HEIGHT TESTS WITH THE FREQUENCY SWITCHES TURNED ON AND TURNED OFF

5 ENERGY LEAK

For reasons of numerical stability HISWA can only operate within a directional sector of limited range. The sector width should be predefined and usually is taken near 120 degrees. Energy transported beyond the directional limits

is removed out of the system. This unintended energy loss, called (energy) leak, is thus caused by numerical restrictions and should not physically occur. So leak arises when the wave energy is distributed over a wider directional range than the predefined directional sector.

In the area of investigation leak occurs on the steep slopes of the deep channel along Norderney due to strong refraction (fig. 6). To get an idea of the error in the wave height caused by leak, the directional sector was enlarged to 162 degrees (which is about the maximum attainable and not suited for operational purpose). By this, leak will be reduced and the wave height increased and so a link can be made between leak and wave height. In the region where leak was largest, it was reduced strongest by expanding the directional sector as can be seen in figs. 6 and 7 (within the small rectangle). By means of block prints it was found that leak reduced here about three times whereas the wave height only increased 4%. This is about the largest effect leak can have upon the wave height, because here leak reduces from the highest value to a rather low value. So leak has only little effect upon the wave height.

Besides expanding the directional sector there are some other ways to influence the leak. The computational grid can for instance be rotated in such a way that as much energy as possible falls within the directional limits (fig. 8). In this way an orientation with lowest leak was found, the x-axis directing 150 to 160 degrees clockwise from the north. Because wave directions in the tidal channels are rather consistent, this orientation will be suited for incoming waves of all relevant (on-shore) directions.

Leak will also be influenced by the use of the frequency switches. Switching on the frequency change will reduce refraction because of an onshore frequency increase. Thus the energy will be spread over a smaller directional range and the leak will be reduced. In case of a changing frequency leak is about 3 times less than in case of a constant frequency.

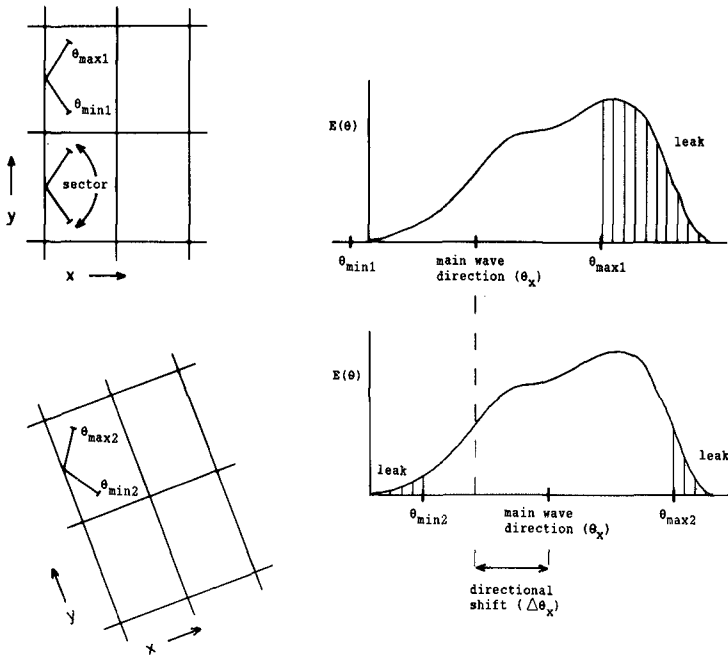

fig. 8 turning the computational grid and energy leak

6 MODEL RESULTS

Before looking at the results it should be noted that the sink and source functions of HISWA contain some empirical coefficients for which default values are assumed, which can however be adjusted. A calibration took place, based on two storm occasions, after which both wave breaking coefficients of Miche were lowered. They were given values of 0.75 and 0.90 for shallow and deep water respectively. Their standard model values were 0.8 and 1.2.

As test conditions, wind speeds ranged from 10.3 to 18.6 m/s at 10 m height, wind directions from 280 to 340 degrees and wave directions from 270 to 320 degrees (going clockwise from the north to the incoming direction). Currents were not included, but computations were generally done at low stream conditions.

Results have already been shown at the tests with the frequency switches (table 1, figs. 4 and 5). It might

fig. 9 COMPARISON OF PREDICTED AND MEASURED
ONSHORE WAVE HEIGHT CHANGES

however be more convenient to use the change in wave height between offshore boundary and nearshore observation point as test parameter, rather than the wave height. By this it will be more apparent whether the predictions concern situations of substantial onshore change or not, indicating the quality of the tests. In fig. 9 the percent onshore wave height change of the HISWA computations is plotted against the measurements. The percent onshore wave height change is defined as $c(H) = 100\% * (H_{off} - H_{near}) / H_{off}$, with the subscripts off and near referring to offshore and nearshore observation points. As is seen HISWA predicts too small changes which means wave heights are still too high despite the downward adjustment of the wave breaking coefficients. The mean percent error $\overline{e(c)}$ of the percent onshore wave height change is -21% at a standard deviation $sd(e(c))$ of the percent error of 24% .

Fig. 10 shows a typical wave height plot for onshore directed waves. A rapid wave height decrease occurs along the ebb delta. In the inlet channels wave heights are more persistent.

7 SINKS AND SOURCES

The sensitivity of the model to the processes of wave breaking, bottom friction and wind growth was tested by putting alternately one of these processes out of order and comparing the results with the normal case (all processes functioning). In fig. 11 wave height profiles between incoming boundary and observation point show the evolution of the wave height for each case. It is seen that wave breaking is a most dominating process, reducing the wave height up to 45% (beach margins excluded, as waves totally diminish there). The influence of bottom friction and wind growth is much less, at most 4% and 3% respectively. The calculated value comes closest to the measurement when all processes are considered or when the wind growth is not functioning. The wave height reduction between the incoming boundary and the observation point calculated by HISWA is 43%. This lies close to the 42% which NIEMEYER (1987) found as a mean value over a large range of field measurements.

fig. 11 onshore wave height evolution in dependence of energy sinks and sources

The distribution of the percent changes over the total area was examined by means of block prints. Wave breaking can reduce wave heights up to 60% in the centre of the tidal inlet. In the same way the maximum reduction by bottom friction was found to be 7% and the maximum increase by wind growth 9% (at the end of the fetch). Of course these figures depend upon each situation individually and only serve to get an idea of the relative importance of the various sinks and sources in this area. In the study by VOGEL et al. (1988) it was for instance shown that under their conditions, wind growth can be a much more dominating process.

CONCLUSIONS

- Running HISWA with the frequency changes switched on has a positive effect on the wave period and the energy leak. The computed wave height in the observation point hardly improved by use of the frequency switches.
- The presence of leak does not harm the model results significantly.

- Of the various energy sinks and sources, wave breaking has the largest influence upon the wave height.
- HISWA does give fair results in the area of investigation where wave breaking is a dominating process.

ACKNOWLEDGEMENTS

This study is sponsored by the GERMAN FEDERAL MINISTRY FOR SCIENCE AND TECHNOLOGY (BMFT) in the framework of the research programme managed by the GERMAN COMMITTEE FOR COASTAL ENGINEERING RESEARCH (KFKE). The authors also wish to thank all colleagues who gave support to this study, especially those of the section of coastal hydrodynamics of the COASTAL RESEARCH STATION.

CHAPTER 42

THE MASS TRANSPORT OF WAVES PROPAGATING ON A SLOPING BOTTOM

H.H. Hwung¹ and C. Lin²

ABSTRACT

This paper presents the experimental results on Eulerian mass transport which is induced by waves propagating on a sloping bottom. The measurements are carried out by laser Doppler velocimeter(LDV) in wave flume. A particular installation of measuring system is required to detect the boundary layer flow extremely close to the point of 0.15mm above the sloping bottom. From the experimental results, it is clear to see that the off-shore mass transport takes place inside the region from the proximity of bottom up to wave trough. Around the elevation of wave trough, the mass transport velocity changes its direction to on-shore rapidly, and it reaches the maximum value at still water level, then it decreases to zero at crest. Further, the vertical distribution and similarity profile of Eulerian mass transport inside boundary layer are also obtained and discussed in this paper.

1. INTRODUCTION

Eulerian mass transport of wave shoaling process is a

1. Professor of Hydraulic and Ocean Engineering Department and Director of Tainan Hydraulics Lab. National Cheng Kung University. Tainan, Taiwan, R.O.C.
2. Dr. Engineering, National Cheng Kung University. Tainan, Taiwan, R.O.C.

very important hydrodynamics, which is closely related to the on-shore and off-shore sediment transport, the vertical distribution of suspended materials and the dispersion of pollutants in coastal waters. Within the last decade, Watanabe et al. (1980), Isobe and Horikawa (1981) and Nadaoka et al. (1982) employed hot-film anemometer and LVD (Laser Doppler Velocimeter) to measure the Eulerian mass transport in wave tank, respectively. Moreover, Sleath (1984) detected the mass transport inside boundary layer as wave propagating on a rough bed. Although the previous studies paid more attention on Eulerian mass transport of wave motion, however, the characteristics of mass transport of waves propagating on a sloping bottom has not been fully understood. Accordingly, in this paper the mass transport of wave shoaling from crest through the bottom, including the bottom boundary layer are detected by LDV and the results are discussed.

2. EXPERIMENTS

The experiments were carried out in a $9.5\text{m} \times 0.7\text{m} \times 0.3\text{m}$ wave tank in which the bottom was adjusted on one-fifteenth slope. The testing sections of internal field and boundary layer of waves shoaling on the sloping bottom are sketched in Fig.1. Four kinds of wave steepness were made in wave flume and the experimental conditions are listed in Table 1. In

Table 1. The experimental conditions

case	T (sec)	H (cm)	d_o (cm)	H_o/L_o	Breaker
1	1.41	5.3	33.0	0.0186	plunging
2	1.23	6.6	33.0	0.0313	plunging
3	0.96	5.3	33.0	0.0405	plunging
4	0.96	8.2	33.0	0.0617	spilling

order to understand the distribution of mass transport , it had more fifty points measured by LDV in every testing section. Especially in the boundary layer within about 0.5cm height, it even had twenty-five measuring points detected by LDV in the experiment.

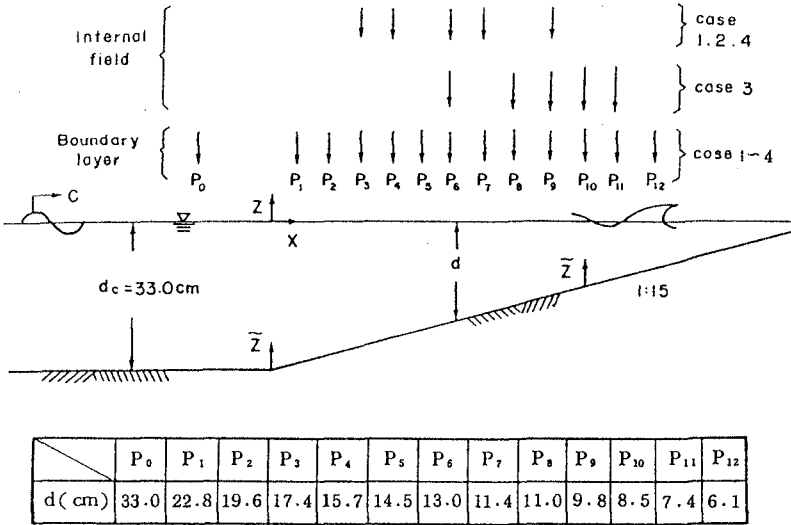

Fig.1 The sketch diagram of testing sections.

Because the light beam of LDV system would be obstructed by the edge of sloping steel plate in the proximity of the bottom, that a particular installation of LDV system was required in order to detect the flow fields extremely close to the point of 0.15mm above the sloping bottom . The sketch diagram of the measuring installation is shown in Fig.2 . According to the experience , water quality control is very important for the fluid dynamic experiments employed by LDV. In this paper two sets of 5 μ m filter screen are used to remove the larger natural particles suspended in water before the fresh water discharges into wave flume. After that , the signals drop-out would be reduced and the experimental quality would keep in good condition.

Fig.2 The sketch diagram of measuring installation.

The water surface elevation and the corresponding water particle velocity from crest through bottom were detected by wave gages and LDV simultaneously. All the sampling interval and rate were set with 18~36 seconds and 100Hz respectively . The wave reflection was also examined in this experiments . Since all the reflection coefficient were less than 4.5% , that the effects of reflection was ignored in this paper.

3. RESULTS AND DISCUSSIONS

One case of the experimental results listed in Table 1 are shown on following figures. Fig.3(a) \ (b) are the measuring records of the time series of water surface elevation and horizontal particle velocity on a testing section which the water depth is $d=17.4\text{cm}$, and the measuring point is $\bar{z}=6.8\text{cm}$ above the bottom. Fig.4 (a) \ (b) are the same results at $\bar{z} = 15.7\text{cm}$. It is obviously to see from Fig.4(b) that the part of negative velocity records become straight line . This is because the measuring volume of LDV exposes into air , that the signals drop-out take place as wave trough passing by . In this situation the signals of the above mentioned straight line should be replaced by zero, as we calculate the horizontal velocity and mass transport from LDV measuring records.

Fig.3 Time series of water surface elevation and horizontal particle velocity at $d=17.4$ cm and $\bar{z}=6.8$ cm for case 1.

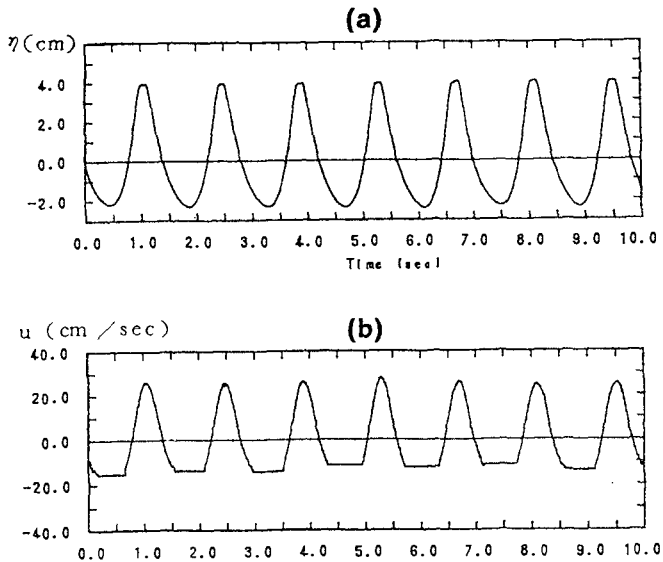

Fig.4 Time series of water surface elevation and horizontal particle velocity at $d=17.4$ cm and $\bar{z}=15.7$ cm for case 1.

After employing the phase average method and then taking average for wave period, the vertical profiles of Eulerian mass transport can be obtained and the results are shown in Fig.5(a) \ (b) \ (c) respectively. Furthermore, the comparison between our experiments and some of the theoretical calculations proposed by Longuet-Higgins(1953), Dalrymple(1976) and Nadaoka et al. (1982) are also made in those figures. From the above results, it is clear to see that the off-shore mass transport takes place inside the region from the proximity of bottom up to wave trough. Around the elevation of wave trough, the mass transport changes its direction to on-shore rapidly, and it reaches the maximum value at still water level, then the mass transport decreases to zero at crest. Further, we can see the magnitudes of on-shore and off-shore mass transport velocity increases in the process of wave shoaling on a sloping bottom. Additionally, it is obvious that the theoretical calculations of mass transport from Longuet-Higgins (1953) have more difference with our experiments. As for the results obtained from stream function by Dalrymple(1976), the calculations are coincident with experiments in the region from wave trough to crest. And the results from Nadaoka et al. (1982) are in agreement with our experiments in deep water, but it has more difference in shallow water area.

Fig.6 and Fig.7 show the experimental results of surface profiles and the corresponding horizontal flow fields inside boundary layer at the testing section of $d=15.7\text{cm}$ and 9.8cm , respectively. In above figures, the parameter δ is defined as $\delta = \sqrt{2\nu/\sigma}$ which is the characteristic length scale of boundary layer, ν is kinematic viscosity and σ is angular frequency of wave. From the experimental results inside boundary layer of waves propagating on a sloping bottom, it shows apparently that the flow fields change its direction periodically as wave passed from crest to trough. The on-shore and off-shore flow patterns become asymmetrical gradually, due to the effects of wave shoaling process, and the magnitudes of horizontal particle velocity increases as water depth decreases. Further, the overshooting induced by wave motion taking place near the bottom is also displayed from our experiments.

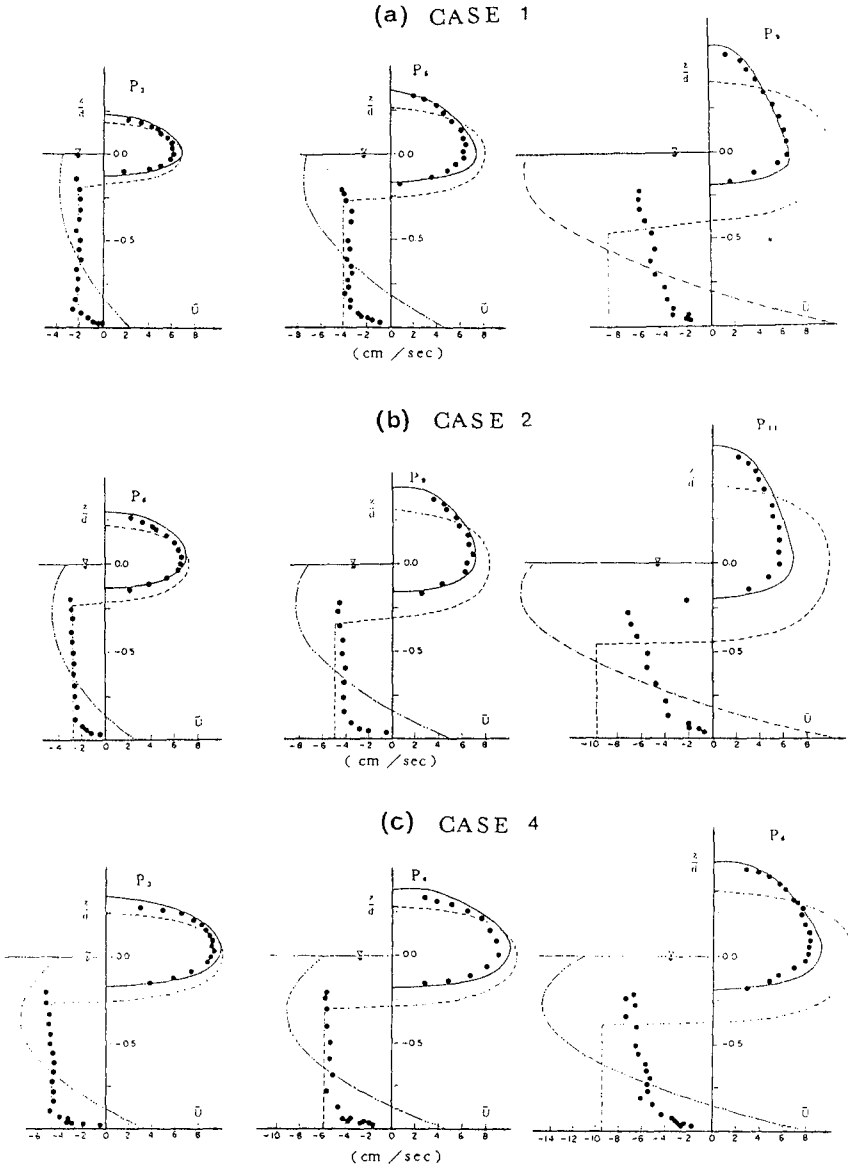

Fig.5 Comparison between experiments and theoretical calculations [● experiments, --- Longuet-Higgins(1953), — Dalrymple(1976), - - - Nadaoka(1982)].

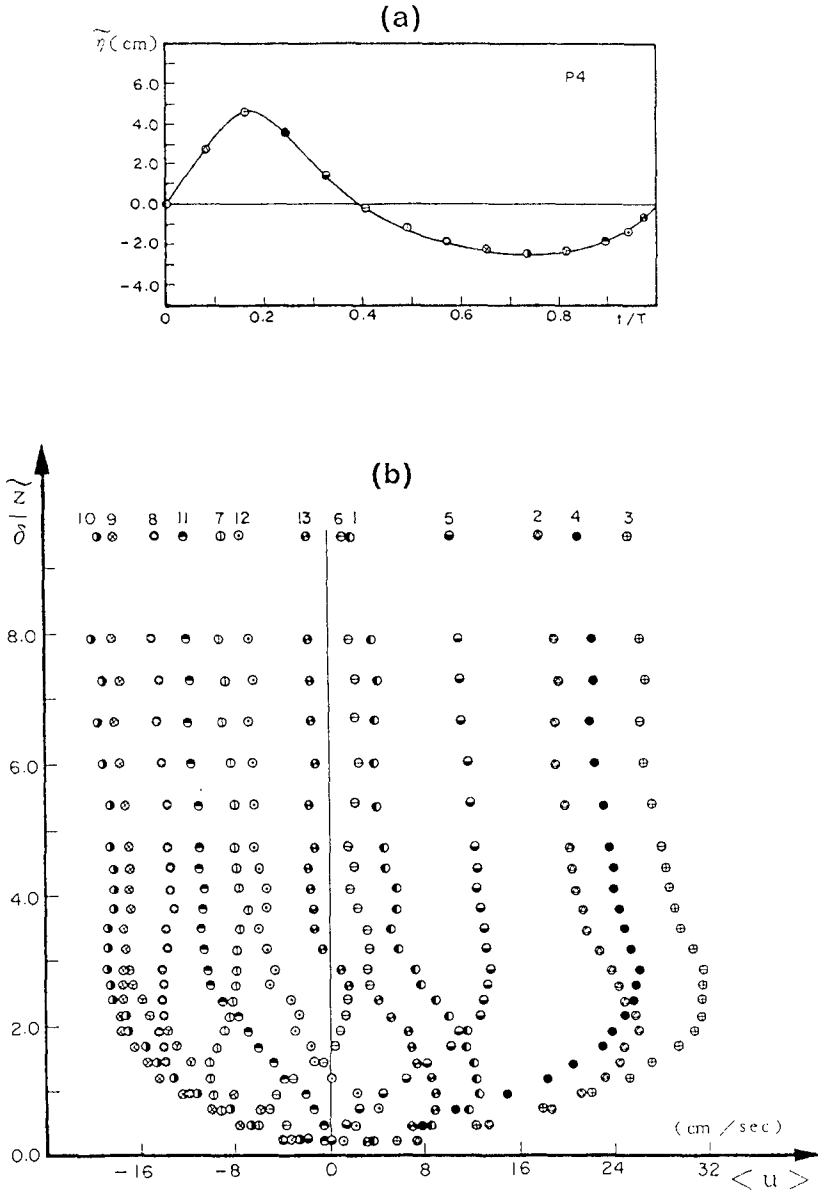

Fig.6 Water surface elevation and horizontal particle velocity inside boundary layer at $d=15.7\text{cm}$ for case 2.

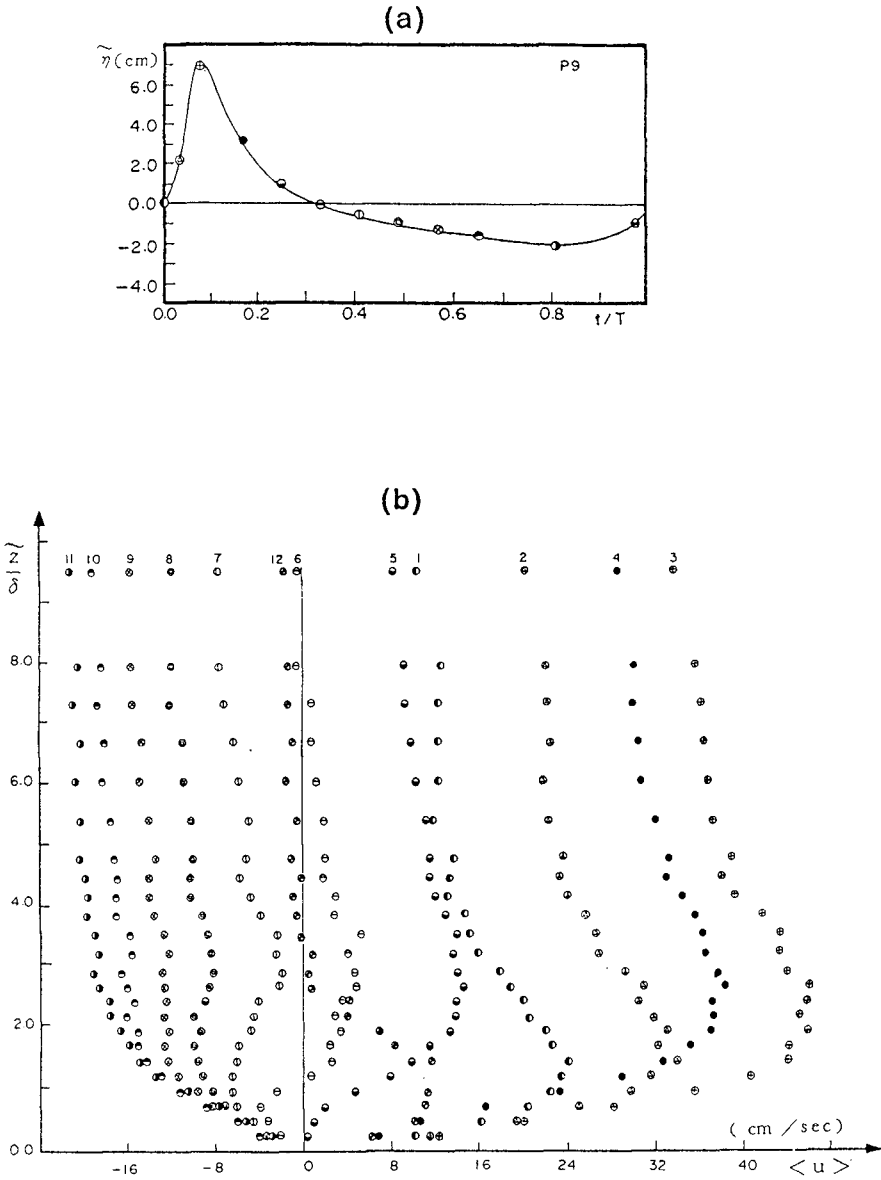

Fig.7 Water surface elevation and horizontal particle velocity inside boundary layer at $d=9.8\text{cm}$ for case 2.

Fig.8 Vertical profiles of Eulerian mass transport inside boundary layer for case 1.

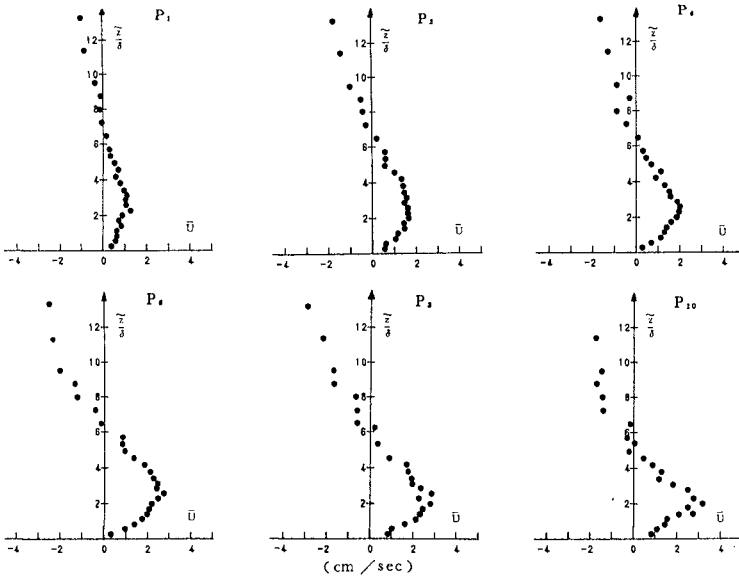

Fig.9 Vertical profiles of Eulerian mass transport inside boundary layer for case 2.

Fig.10 Vertical profiles of Eulerian mass transport inside boundary layer for case 3.

Fig.11 Vertical profiles of Eulerian mass transport inside boundary layer for case 4.

According to all of measuring results , the Eulerian mass transport velocity inside boundary layer are plotted from Fig.8 through Fig.11 , respctively. We can see that the vertical profiles of mass transport increase from bottom and reaches the maximun at the dimensionless distance $\bar{z}/\delta = 2\sim 3$, then decreases gradually to zero at $\bar{z}/\delta = 6.5$. Beyond the above region , Eulerian mass transport becomes negative (off- shore) as the dimensionless distance increasing. Moreover, the similarity profile of Eulerian mass transport velocity inside boundary layer has found from the definition of characteristic velocity proposed by Lin & Hwung(1989),and the result is shown in Fig.12 .Finally, the distribution of the above similarity profile is obtained from regressive analysis and it can be expressed by the combinations of hyperbolic functions as follows:

$$\frac{\bar{u}}{\bar{u}_\infty} = \begin{cases} 0.21 \tanh\left(0.3 \frac{\bar{z}}{\delta}\right) - 0.17 \tanh^2\left(0.3 \frac{\bar{z}}{\delta}\right) & \text{for } 0 \leq \frac{\bar{z}}{\delta} \leq 2.5 \\ -0.087 + 0.39 \operatorname{sech}\left(0.3 \frac{\bar{z}}{\delta}\right) - 0.25 \operatorname{sech}^2\left(0.3 \frac{\bar{z}}{\delta}\right) & \text{for } 2.5 \leq \frac{\bar{z}}{\delta} < 6.5 \end{cases}$$

Fig.12 The similarity profile of Eulerian mass transport inside boundary layer.

4. CONCLUSIONS

The characteristics of Eulerian mass transport of waves propagating on a sloping bottom are described in the paper . From the bottom , the magnitude of on-shore mass transport increases gradually and reaches the maximun at the point of $\bar{z}/\delta = 2\sim 3$, then it decreases to zero at $\bar{z}/\delta = 6.5$.Beyond the

above region, the mass transport becomes off-shore up to the elevation of wave trough, then the mass transport velocity changes its direction to on-shore rapidly, and it reaches the maximum value at still water level. After that the mass transport decreases to zero at crest. From the experiments, the similarity profile of mass transport inside boundary layer is also found in this paper.

Abstract

Ocean surface gravity waves breaking on gently sloping beaches generate substantial turbulent velocity fluctuations, both from overturning at the surface bore and from shear stresses at the bottom. We have used measurements made with laboratory-style hotfilm anemometers in the surf and swash on a *natural beach* to determine the relevant length and velocity scales. Battjes (1975) has pointed out the importance of determining the turbulence scales in the surf zone. Modelers, such as Svendsen and Madsen (1984), for example, rely on length and velocity scale estimates to parameterize and solve the complicated equations that govern surf zone flows. We find that turbulence length scales depend essentially on the bore height, and therefore on the local depth, but may decrease sharply under the bore. We also determine that at least the horizontal velocities approach isotropy at frequencies of 2 to 3 Hz, which turn out to also correspond to length scales on the order of the local depth.

Introduction

The determination of "scales" plays an important role in turbulence research, since turbulent flows must be described by their characteristic times, lengths, velocities, kinetic energies, Reynolds stresses, eddy viscosities and dissipation rates. Much of the theory of turbulence is concerned with establishing connections and relationships between these parameters and much experimental effort has gone into guiding these concerns. The basic reason why this approach is necessary, is that turbulent flows typically contain velocity fluctuations at a broad range of length scales, particularly small ones, so that direct analytical or numerical solution of the governing equations is unmanageable. The parameterizations that arise more or less

naturally from the flow conditions then become the description of that flow. The two key scales are turbulence length and velocity, and we concentrate on characterizing these from measurements.

In a shear flow, any sharp vertical gradients in horizontal velocity, $U(z)$, makes the flow unstable and causes turbulent velocities (u, v, w) to grow in all three directions. The turbulence serves to smooth the mean velocity profile by exchanging momenta, and \overline{uv} , \overline{uw} and \overline{vw} , which are respectively proportional to the Reynolds stresses, τ_{xy} , τ_{xz} and τ_{yz} determine how efficient this is. The Reynolds stresses cannot be calculated in closed form using the original equations of motion (this is the closure problem of turbulence) and they are difficult to measure, even in laboratory flows.

Some of the earliest efforts to understand turbulence were aimed at parameterizing the Reynolds stresses in terms of mean flow quantities (Boussinesq, 1877; Prandtl, 1925; von Karman, 1930), so that:

$$\frac{\tau_{xz}}{\rho} = -\overline{uw} = \nu_t \frac{dU}{dz}, \quad (1)$$

where ν_t represents the turbulent eddy-viscosity, ρ is the fluid density, and dU/dz is the mean shear. This formulation introduced the parameter ν_t which is analogous to the kinematic viscosity and has the dimensions L^2/T , or λq , where λ and $q = \sqrt{k}$ represent respectively turbulence length and velocity scales, and k is the turbulent kinetic energy scale. The turbulent kinetic energy dissipation rate turns out to be $\epsilon = q^3/\lambda$ (Tennekes and Lumley, 1972). Svendsen and Madsen (1984) use (1) and the form $\nu_t = k^2/\epsilon$, as the basis for a model of flow in a surf zone bore.

In considering the role of horizontal turbulent eddies in smoothing the profile of longshore currents in the surf zone, Battjes (1975) arrived at a relationship very similar to (1). He argued that the mean shear (cross-shore gradient in longshore current, in this case) must give rise to anisotropy that is measured by $-\overline{uv}/q^2$ and decays at a rate λ/q , balanced only by the mean shear rate itself, or

$$-\overline{uv} \approx q\lambda \frac{\partial V}{\partial x}. \quad (2)$$

Many different formulations of ν_t are possible, involving different combinations of λ , q , k and ϵ , and each implies a different solution procedure which determines exactly how the closure is made. A spectral method (due to Kolmogorov) can also be used to make estimates of ϵ based on assumptions of local isotropy in an equilibrium range of length scales (see, for example Grant, et al, 1961) but we do not pursue this in the present paper. In principle, such determinations could serve as consistency checks on estimates made in other ways.

We describe our instrumentation and calibration and deployment procedures in the next section. This is followed by a discussion of several experiments we have conducted in the surf zone over the last few years, and the results that are relevant to the determination of turbulence scales.

Instrumentation and Calibration

Experiments have been performed over a number of years at the moderate-energy, gently sloping beach adjacent to Scripps Institution of Oceanography at La Jolla, California. Wave conditions on this beach are highly variable, but we are confined to carrying out measurements when breaking wave heights are under about 2 m. Instruments are generally mounted on pipe supports cantilevered from other pipes which are jettied into the sand and braced to avoid vibration, as illustrated in Figure 1. We deploy instrumentation in the surf zone during times of low tide and then take data when the tide has brought the waves to the sensors. Tide changes of 1 to 2 m are common during spring tide times of the month, particularly in winter and summer, when local tide ranges are highest. This approach also serves to allow measurements at different mean water depths, or relative position in the surf zone, without the need to move the instruments.

Figure 1. Instrument mounting frame hardware showing typical set-up for measurements in the inner surf zone.

We have deployed current meters, pressure sensors, wave staffs, thermistors and two styles of hotfilm sensors. The current meters were standard, 2-axis, spherical, electromagnetic instruments 4 cm in diameter manufactured by Marsh-McBirney, Inc. The calibration of these meters is linear and relatively stable, the only disadvantages being that the frequency response is limited to about 3 Hz, and there is a severe response distortion when the probes are within a few diameters of the free surface (Guza, et al, 1988).

We have made bottom pressure measurements using standard, strain-gauge type sensors with a resolution of several parts per thousand in equivalent water

elevation. The pressure signal is a relatively smooth version of the actual sea surface profile, since the high frequency portions of the velocity potential decay with depth. Pressure signals have been mainly used to have a continuous depth record and a qualitative indication of the wave elevation and phase available for comparison with the higher frequency, turbulence signals. Surface piercing, resistance wire wave staffs have been used extensively in the laboratory, and when carefully prepared and cleaned, can achieve resolutions of better than 1 part per thousand (Flick, et al, 1981). We have found resistance wire wavestaffs to be generally unsatisfactory for routine, unattended data acquisition in the surf zone since debris floating on and in the water, particularly kelp, often stretches or even breaks the wires.

We have used thermistor probes to continuously record water temperature for use in calibrating the hotfilm anemometers. Our probes were "Fastip" model FP-07 microbead thermistors, manufactured by Thermometrics, Inc. The calibrations were done in a water bath and are linear and reproducible to about $\pm 0.1^\circ \text{C}$, absolute. Relative temperature changes are accurate to about $\pm 0.02^\circ \text{C}$, with a half-power frequency response cutoff of about 22 Hz.

Hotfilm Probes

We have successfully adapted laboratory-style hotfilm probes for use in the natural surf zone. We have used Thermo Systems, Inc. (TSI) model 1230-NaCl, quartz-coated platinum, cone shaped sensors, as well as the less rugged model 1210-NaCl cylinder-shaped probes. Despite many difficulties, particularly with breakage and calibration drift reminiscent of the critical and pessimistic review of Frey and McNally (1973), we believe that hotfilm technology is the only one currently capable of providing high-frequency, small scale measurements of velocity fluctuations in the surf. The presence of bubbles and debris in the surf zone greatly inhibits the use of either laser-doppler or acoustic measurement systems, assuming these could be made small enough to avoid serious flow interference, as with fiber optic techniques.

One of the serious drawbacks of single hotfilm sensors is that they do not discriminate direction. In fact, their response is closer to omnidirectional than it is to a much more convenient cosine of the angle of attack. The rectification of the velocity signal is an advantage, however, in one sense, since it selects out the longitudinal component of the turbulence fluctuations u , in the presence of a strong, although oscillating "mean" flow, U . We have had some success in de-rectifying calibrated hotfilm time series in selected instances, by either using current meter records or high shutter-speed video camera images to identify the time of flow reversal. The cone probes were generally deployed pointing offshore, into the oncoming wave flow. The cylinder probes were oriented with their axes aligned in the longshore direction, thus minimizing interference from longshore directed currents.

Hotfilm anemometry rests on the principal that the heat conducted away from the probe by the moving fluid is proportional to some function of the flow speed, S past the probe and the difference in temperature (overheat) of the sensor, T_p and the water, T_w (King, 1914). The sensor is kept at a constant temperature (in our case) by

a bridge feedback circuit (TSI model 1755) that provides an overall frequency response of several hundred Hz. The output (bridge voltage) E is related to the flow speed by King's law

$$E^2 = (A + B S^n) (T_p - T_a), \quad (3)$$

where A , B and n are calibration constants.

Probe calibrations do not stay stable sufficiently long to simply calibrate the sensors in the laboratory and then shift them to the surf. We have consequently constructed a scheme where we calibrate the hotfilm sensors continuously by comparison with a co-located current meter. Results have been very satisfactory for deployment off the end of Scripps Pier, in 5 m water depth well outside the surf zone. With minor adjustments to this method, we have achieved calibration accuracies of about ± 5 cm/sec in peak flows of up to 200 cm/sec, even in the surf zone.

Operating temperatures of the hotfilm probes were generally set to about 25° C above ambient water temperature, which at La Jolla varies from about 14 to 21° C. This resulted in a relatively low overheat ratio of between 5 and 8% to prevent the formation of bubbles on the probes. The equivalent velocity sensitivity, ΔS , of the probes to fluctuations in ambient water temperature can be determined from relation (3) to be

$$\frac{\Delta S}{S} = - \frac{\delta}{\Delta T} \frac{1}{n} \left(1 + \frac{A}{B S^n} \right),$$

where $\delta/\Delta T$ is the fractional change in temperature relative to the overheat, and is assumed small. Assuming E is measured in volts, S in cm/sec and the temperatures are in ° C, typical values for the calibration coefficients are $A = 0.2$, $B = 0.1$ and $n = 0.5$. For an overheat of $\Delta T = 30^\circ$ C and water temperature fluctuations of $\delta = 0.1^\circ$ C, the fractional speed error, $\Delta S/S$ is less than about 2%, so long as flow speeds are larger than about 10 cm/sec.

Surf Zone Turbulence Scales

Figure 2 shows time series data from two hotfilm cone probes and a (rare) wavestaff signal measured in the surf zone at a depth of about 35 cm, with a bore about 25 cm passing the sensors. These data were taken on 21 April 1988, at a sampling rate of 2560 Hz. No current meter data are available, so we were forced to rely on laboratory calibrations of the hotfilm probes, which we believe to be accurate to $\pm 25\%$. The hotfilm data are labelled "upper" and "lower" and represent, respectively, the probe at elevation 38 cm off the bottom and the probe at 20 cm off the bottom. The lower probe was essentially submerged over the entire data run, while the upper probe was out of the water until arrival of the bore at time 12:58:19.

Four seconds of data from this run have been analyzed and Figure 3 shows the autocorrelation functions for the upper and lower probe signals. Note that these functions do not, to first order, depend on the probe calibrations. The temporal lag correlations, $\theta(\tau)$ have been adjusted to equivalent spacial lag correlations, $\theta(r)$, by

Figure 2. Time series from upper (38 cm) and lower (20 cm) hotfilm probes (upper two traces) and wavestaff signal (lowest trace).

Figure 3. Autocorrelation function from upper and lower hotfilm data (Figure 2) Length scale derived from time scale with $U=150$ cm/sec.

choosing a mean advective speed, $U = 150$ cm/sec and invoking Taylor's hypotheses, $r = U\tau$. The upper and lower rms turbulence levels are about 30 and 20 cm/sec, respectively, so that $q_{rms} \ll U$ is satisfied. We can use the correlation function $\theta(r)$ to estimate the integral scale of the turbulence, defined as

$$\lambda_i = \int_0^{\infty} \theta(r) dr.$$

Results show a decrease in both decorrelation scale and integral scale with depth in the water column. Decorrelation length at the upper probe is on the order of 150 cm, while the integral scale is about 50 cm. The respective lengths at the lower probe turn out to be about 60 and 25 cm, about half the upper values. This supports the intuitive idea that the turbulent eddy length scales are on the order of the bore height in the bore, and that they are therefore of the same order of magnitude as the local depth. It also suggests that length scales and turbulence levels are both smaller below trough level than in the actively overturning bore. With respect to the turbulence intensity, this conclusion is not new or surprising, but there may be some new information in the suggestion that turbulence length scales decrease from the surface downward.

Note that the actual values of these estimates *do* depend on the hotfilm calibrations (through U in Taylor's hypotheses). However, the *relative difference* in length scales would be exaggerated for any plausible calibration corrections, since the mean advective velocity at the upper probe could not be smaller than that at the lower probe. This would *increase* the length scale estimate at the upper level, relative to the lower one. The same argument holds for the turbulent velocity scale.

Corresponding estimates of dissipation rates, $\epsilon = q^3/\lambda$ range from about 100 to 300 cm^2/sec^3 at the lower sensor, and from about 200 to 400 cm^2/sec^3 at the upper sensor, depending on the choice of length scale. It is noteworthy that any of these values far exceed corresponding estimates of dissipation rates in tidal channels, which range from 10^{-3} to 1 cm^2/sec^3 (Grant, et al, 1961). By comparison, it has been estimated that the dissipation rate of oceanic tide motions is on the order of 10^{-5} cm^2/sec^3 (Grant, et al, 1961).

Figure 4 shows the first 32 sec of a 256 sec time series of hotfilm data (dark line) and the cross-shore component of a current meter signal (dashed line). These data were taken on 14 March 1990, at a sampling rate of 4096 Hz. The current meter was mounted 64 cm above the bottom, and total water depth during the data run varied between 75 and 100 cm, with breaking wave heights of about 1.2 m. The current meter record has been offset downward by 20 cm/sec for clarity. The hotfilm measurement has been calibrated and de-rectified using the current meter data as a standard. The agreement is quite good.

Figure 5 shows the ratio of longshore to cross-shore velocity measured by the current meter as a function of frequency. The velocity ratios were calculated from spectral levels of each component. It is clear that V/U increases from values around 0.2 at frequencies corresponding to the incoming wave period of about 10 sec, to

Figure 4. Time series from hotfilm probe (solid trace) and current meter (dashed) in mid surf zone, showing good de-rectification and calibration agreement. Current meter trace is offset -20 cm/sec for clarity.

Figure 5. Ratio V/U from current meter data in mid surf zone as a function of frequency and depth, showing approach to isotropy at about 2 or 3 Hz.

values approaching 1 at the current meter cut-off frequency around 2 or 3 Hz. The indicated levels, 0.76, labelled "Shear Layer," and 1.0, labelled "Isotropic Turbulence" correspond to the expected value of V/U for these flows.

Even though fluctuations were only measured in two directions, these data strongly suggest that passing bores generate local turbulent velocities in all three directions. This result should not be surprising, and supports the idea that turbulence under surf zone bores may resemble shear layer turbulence in the transition regime between frequencies associated with wave orbital motions and about 2 or 3 Hz. We would expect the turbulent fluctuations to become increasingly isotropic at higher frequencies, but cannot confirm this with the present measurements. The scatter in the ratio estimates is too large to distinguish a dependence on total depth, which only changes about 20% in the experiment.

Rigorous estimates of the length scales associated with these time scale estimates cannot be made by a straightforward application of Taylor's hypothesis, since the mean flow is unsteady (Figure 4). However, a rough estimate is possible by noting that the peak advective velocities are on the order of $0.25c$, where $c = \sqrt{gh}$ is the shallow water phase velocity, and $g = 980 \text{ cm/sec}^2$, is the acceleration of gravity. Invoking Taylor's hypotheses with $h = 80 \text{ cm}$, results in an upper bound estimate of the length associated with the maximum frequency (2 or 3 Hz) shown in Figure 5, which turns out to be about 35 cm. This reveals that the length scales of the eddies at the lowest frequencies that are "fully" turbulent, here assumed to be those approaching isotropy levels consistent with values expected in a shear layer, are on the order of the waveheight. The wave (or bore) height, H in the surf zone is approximately proportional to the local depth, $H = \gamma h$, where $\gamma \approx 0.7$ is an empirical constant. Therefore, we expect that the turbulent length scale is likewise proportional to the local depth.

Considering all the assumptions, not to mention the limited data, this is remarkably consistent with the above derived result from the auto correlation analysis of the "lower" hotfilm probe. There is again nothing particularly surprising about this, indeed, it would be surprising if it were otherwise. The results are noteworthy, however, since these seem to be the first published field measurements that tend to confirm our intuitive expectations. Furthermore, these suggestions also support the idea stated explicitly by Battjes (1975), that turbulent eddies in the surf zone scale according to the depth, or vertical dimension, and *not* a horizontal dimension, such as distance to the shore, or length between bore crests. The horizontal scales are larger than the depth by a factor on the order of β^{-1} , where β is the beach slope. On a gently sloping shore such as La Jolla, this factor typically ranges from 50 to 100.

It is interesting to consider the expected ratio of longshore to cross-shore orbital velocity in a plane wave that has been subject to refraction into water depths equivalent to those in our experiments. Assuming that Snell's law is valid for waves with period 10 sec, in a water depth of only 1 m, it can be shown that a deep water approach angle of 10° is reduced by linear refraction to a shallow water angle of only 2° . This results in $V/U \approx 0.03$, a ratio much smaller than observed.

Swash Turbulence Scales

Measurements were made in the swash region using a cylinder type hotfilm probe on 8 March 1990. The swash region is defined as that part of the beach which is alternately dry and then covered by water as a result of the wave runup. Due to the prevalence of significant low frequency surf beat, and a mild beach slope of about 1:75, the swash region can be tens of meters wide and each bore may or may not reach the sensor location (Guza and Thornton, 1982; 1985). Equivalently, each individual backwash event may or may not drain the beach at the sensor location. The probe was mounted 1 cm off the bed. Figures 6a and 6b show time series from the hotfilm that have been de-rectified using video tape images. We used the 1/4000 sec shutter speed available on our video camera to ensure clear images at the (fixed) 30 frame/sec sampling rate. We were thus able to resolve the flow reversals to approximately 1/30 sec.

Figure 6a shows 64 sec of data which include 4 prominent up-rush and backwash cycles, but the probe does not get dry until the very last cycle, shortly after $t = 64$ sec. The maximum water depth, h_0 , during each bore was about 30 cm. Unfortunately, we had no direct measure of the depth except what could be estimated from the (oblique) video images. Each swash cycle is characterized by a sharp reversal from offshore (negative) to onshore (positive) flow, followed by a gradual, nearly linear slowing and finally a turning to offshore flow as the wedge of water drains off the beach face. This sequence forms the characteristic sawtooth shape of the velocity time series.

There is turbulent motion with amplitude scales on the order of 5 cm/sec apparent in each of the deceleration phases, but the most prominent occurs starting at about $t = 50$ sec (Figure 6a). Apparently due to the build-up of water on the beach face over a number of preceding uprushes, enough offshore momentum was built up to change the character of this particular backwash. It lasted longer than was typical, and as shown in Figure 6a, reached a larger offshore velocity than normal. Viewing of several hours of video tape shows that this type of event occurs at surf beat intervals, which means in perhaps 5 to 10% of the bores.

This portion of record is plotted in Figure 6b on an expanded scale. Inspection of the video tape corresponding to this time reveals that the strong turbulence was accompanied by a thick cloud of suspended sediment in the layer of water which was approximately 15 cm deep at $t = 50$ sec. The sediment essentially erupted from the bottom at about this time, and remained in suspension at the sensor location until it ran dry. The water surface also noticeably changed character at about $t \approx 52$ sec, from a smooth layer to an extremely rough one. This transition is readily apparent on the video images since reflections of the straight mounting pipes, which are very clear at one instant, suddenly become jagged and then disappear. We interpret this transition in roughness as the surface manifestation of the bottom boundary layer turbulence reaching the water surface.

A low-pass trend shown as a dashed line in Figure 6b was subtracted from the signal to leave an estimate of the turbulence residual. This residual was examined using a scheme that measured the time interval between zero-crossings and averaged

Figure 7. Turbulent time scale (A, upper panel) and length scale (B, lower panel) calculated from zero down-crossings of time series shown in Figure 6b, after removal of low-pass mean. Mean velocity also used to adjust time scale to length scale using Taylor's hypotheses.

Figure 6. Time series of swash cross-shore velocity measured with hotfilm anemometer. Upper panel (A) shows entire 64 sec record, lower panel (B) shows time 48 to 64 sec. Dashed line is low-passed, mean velocity.

the results over 0.5 sec periods. The method was insensitive to the precise shape chosen for the trend filter. The results are shown in Figure 7a, and suggest that the average zero-crossing time decreases as the flow continues its offshore acceleration.

Application of Taylor's hypothesis to this data, using the low-pass velocity signal mentioned above, yields the results shown in Figure 7b. Here it is revealed that the mean eddy scale is just slightly over 1 cm after $t \approx 52$ sec and remains constant until the end of the record. This result is consistent with the expectation that the eddy scales of flow near a boundary must be on the order of the distance from the boundary. Turbulent eddies cannot transfer momentum in the direction perpendicular to a wall at scales larger than the distance from the wall (Tennekes and Lumley, 1972). This is one characteristic, actually an assumption, that leads to the so-called law-of-the-wall.

Conclusions

Our primary conclusion is that the length scale of turbulence in the surf zone is on the order of the local wave (or bore) height, or equivalently, on the order of the local depth. We also find that turbulent velocity scales are indeed a modest fraction of the local shallow water wave phase speed, $c = \sqrt{gh}$, consistent with laboratory results, but we do not have measurements over a sufficient range of depth to establish the functional dependence, or to quantify the proportionality.

Turbulence length and velocity scales seem to decrease with distance from the surface under a bore. This suggests that the turbulent eddy viscosity, $\nu_t = \lambda q$, and the dissipation rate $\epsilon = q^3/\lambda$, may be strong functions of vertical position in the water column, as well as functions of depth. These findings may have some bearing on detailed models of both longshore currents and undertow (shore normal currents), since the turbulence quantities enter into the current structure through relations like (1) and (2).

At least the horizontal components of velocity in the surf zone approach isotropy at frequencies on the order of 2 or 3 Hz. This is found to be a gross violation of Snell's law, which predicts that ratios of V/U should be only a few percent. This is a clear manifestation of the generation of turbulence by wave breaking in the surf zone.

Limited data in the swash suggest that the length scales in the boundary layer flow near the bottom during backwash events are proportional to the distance from the bottom. Video tape images of swash flow suggest that fully developed backwash events, where the turbulent bottom boundary layer thickness reaches the full flow depth, occur at beat periods and *not* at individual wave periods.

CHAPTER 44

REFLECTION FROM SWASH ZONE ON NATURAL BEACHES

Susumu Kubota¹, Masaru Mizuguchi² and Mitsuo Takezawa³

ABSTRACT

For separating incident and reflected waves, three methods based on linear long-wave theory, small-amplitude wave theory, and quasi-nonlinear long-wave theory were applied to field data recorded on a steeply sloping beach and on a gently sloping beach. The method based on the quasi-nonlinear long-wave theory gave the best results and described well the observed, incident, and reflected wave field.

I INTRODUCTION

The understanding of wave dynamics in the swash zone on natural beaches is important for determining beach erosion, designing coastal structures, and estimating beach deformation after the construction of such structures. However, the properties of the waves are not yet well understood because measurement of waves on natural beaches is difficult to perform. The authors measured the swash oscillation and waves and wave particle velocities in the surf zone by using 16 mm memo-motion cameras, capacitance-type wave gages, and electromagnetic current meters. A part of the results was presented at the 21st Coastal Engineering Conference (Takezawa et al., 1988), where separation of the incident and reflected waves was carried out with good results using the linear long-wave theory. However, application of the linear long-wave theory to field data collected later at a gentle beach gave poor results. Therefore, the small-amplitude wave and the quasi-nonlinear long wave theories were employed for the wave separation. The small-amplitude wave theory

3 Dr. Eng., Professor, Dept. of Civil Eng., College of Science and Technology, Nihon University

did not improve the previously obtained results. However, using the quasi-nonlinear long-wave theory produced better results. The present paper describes the analytical procedures and the results from analysis of the field observations.

11 THEORETICAL BACKGROUND FOR SEPARATING INCIDENT AND REFLECTED WAVES

2.1 Method Based on Linear Long-wave Theory

The separation method which employs linear long-wave theory was given by Guza, Thornton and Holman (1984),

$$\eta_I = \frac{1}{2} \left\{ \eta + \alpha \left[\frac{h}{g} \right]^{1/2} u \right\} \text{----- (1)}$$

$$\eta_R = \frac{1}{2} \left\{ \eta - \alpha \left[\frac{h}{g} \right]^{1/2} u \right\} \text{----- (2)}$$

where η , η_I and η_R are the water surface elevation of the observed, incident and reflected waves, u is the on-offshore component of water particle velocity, g is the acceleration due to gravity, h is the water depth, and α is a constant. The constant α theoretically takes the value of unity.

2.2 Method Based on Small-amplitude Wave Theory

If it is assumed that the observed wave is a result of linear superposition of the incident and reflected waves, then,

$$\eta = \eta_I + \eta_R \text{----- (3)}$$

$$u = u_I - u_R \text{----- (4)}$$

where u_I and u_R are the on-offshore component of water particle velocity of the incident and reflected waves respectively. It is also assumed that the incident wave is a sum of sinusoidal waves with different frequencies. Then, the following expressions are obtained,

$$\eta_I = \sum_{i=1}^{\infty} A_i \cos(\sigma_i t + \epsilon_i) \text{----- (5)}$$

$$\left. \begin{aligned} u_I &= \sum_{i=1}^{\infty} H_i A_i \cos(\sigma_i t + \epsilon_i) \\ H_i &= \frac{\sigma_i \cosh k_i (h+z)}{\sinh k_i h} \\ \sigma_i^2 &= g k_i \tanh k_i h \end{aligned} \right\} \text{----- (6)}$$

where t is the time, z is the vertical distance taking the origin of the coordinate system at the still sea water level, $\sigma_i = 2\pi / T_i$, $k_i = 2\pi / L_i$, and A_i , ε_i , L_i , and T_i are the wave amplitude, the phase difference, wavelength and wave period of an elementary wave. Expression for u_R is similarly,

$$u_R = \sum_{i=1}^{\infty} H_i B_i \cos(\sigma_i t + \varepsilon_i') \text{ ----- (7)}$$

where B_i and ε_i' are the amplitude and the phase difference. A finite Fourier series is used for expressing u as,

$$u = \sum_{i=1}^N (C_i \cos \sigma_i t + D_i \sin \sigma_i t) \text{ ----- (8)}$$

where C_i and D_i are the Fourier coefficients. A sum of independent elementary waves is considered, therefore, or each elementary wave, the following relation can be stated:

$$\begin{aligned} C_i \cos \sigma_i t + D_i \sin \sigma_i t \\ = H_i A_i \cos(\sigma_i t + \varepsilon_i) - H_i B_i \sin(\sigma_i t + \varepsilon_i') \text{ ----- (9)} \end{aligned}$$

Dividing both sides of Eq. 9 by H_i and adding terms i from 1 to N , we have:

$$\begin{aligned} \sum_{i=1}^N \frac{1}{H_i} (C_i \cos \sigma_i t + D_i \sin \sigma_i t) \\ = \sum_{i=1}^N A_i \cos(\sigma_i t + \varepsilon_i) - \sum_{i=1}^N B_i \sin(\sigma_i t + \varepsilon_i') = \eta_I - \eta_R \text{ ----- (10)} \end{aligned}$$

From Eq. (10) and Eq. (3), the final equations for the wave separation is obtained as:

$$\eta_I = \frac{1}{2} \left\{ \eta + \sum_{i=1}^N \frac{1}{H_i} (C_i \cos \sigma_i t + D_i \sin \sigma_i t) \right\} \text{ ----- (11)}$$

$$\eta_R = \frac{1}{2} \left\{ \eta - \sum_{i=1}^N \frac{1}{H_i} (C_i \cos \sigma_i t + D_i \sin \sigma_i t) \right\} \text{ ----- (12)}$$

A problem is the proper choice of N . Measurement noise is usually inherent in the high-frequency region. The power of the noise becomes predominant if a large number is taken on N . Thus, a suitable value on N must be chosen.

2.3 Method Based on Quasi-nonlinear Long-wave Theory

Ignoring any interaction between the incident and reflected wave, it may be assume that Eqs. (3) and (4) are valid. The basic equations in nonlinear long-wave theory of constant depth becomes:

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} \{ (h + \eta) u \} = 0 \quad \text{-----} \quad (13)$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial \eta}{\partial x} = 0 \quad \text{-----} \quad (14)$$

Expanding u in a series and considering up to second order, the following relation between u and η is assumed:

$$u = \left[\frac{g}{h} \right]^{1/2} \eta + \beta \eta^2 \quad \text{-----} \quad (15)$$

Substituting Eq. (15) into the equation of continuity, Eq. (13), β is determined:

$$\beta = -\frac{1}{h} \left[\frac{g}{h} \right]^{1/2} \quad \text{-----} \quad (16)$$

Equation (16) does not satisfy the equation of motion, Eq. (14). In order to satisfy Eq. (14), β should be:

$$\beta = -\frac{1}{2h} \left[\frac{g}{h} \right]^{1/2} \quad \text{-----} \quad (17)$$

Equation (14) itself is originally only approximately correct for the real waves, and the second order terms of Eq. (14) partially vanish. Therefore, it was assumed that Eqs. (13) and (14) would be better satisfied if Eq. (16) was used instead of Eq. (17). Substituting Eq. (16) into Eq. (15):

$$u = \left[\frac{g}{h} \right]^{1/2} \eta \left(1 - \frac{\eta}{h} \right) \quad \text{-----} \quad (18)$$

From Eqs. (3), (4) and (18), Eqs. (19) and (20) result in

$$\eta_I = \frac{1}{2} \left\{ \eta + \alpha u \left[\frac{h}{g} \right]^{1/2} \frac{h}{h - \eta} \right\} \quad \text{-----} \quad (19)$$

$$\eta_R = \frac{1}{2} \left\{ \eta - \alpha u \left[\frac{h}{g} \right]^{1/2} \frac{h}{h - \eta} \right\} \quad \text{-----} \quad (20)$$

III FIELD OBSERVATIONS

3.1 Field Observation Sites

Data analyzed here were measured at Oarai Beach on July 29 (Takezawa et al., 1988) and at Hasaki Beach on July 30, 1987. Oarai Beach is located about 100 km north of Tokyo facing the Pacific Ocean. The Beach is bounded by a commercial harbor at its northern end, and groins were constructed for protecting the harbor against intruding sand from the south. Sand accumulates immediately south of groins and erosion is occurring in an area approximately 2 km south of the largest groin. The observation site was located approximately 1.8 km south of the largest groin. The sand in the swash zone was well sorted with a median diameter of 0.45 mm and a sorting coeffi-

cient, defined as $S=d_{75}/d_{25}$, where d_p is the grain diameter at which p percent of the sand weight is finer, of around 1.25.

Hasaki Beach is located at the southern part of Tokai Coast facing the Pacific Ocean about a distance of 100 km from Tokyo. A research pier belonging to the Hasaki Oceanographical Research Facility, the Port and Harbor Research Institute, Ministry of Transportation, is located here for facilitating field studies in the nearshore zone. The average tidal range at the beach is about 1.2 m and beach slope was considered to be gentle. The beach is composed of sand with a grain size in the range of 0.1 to 0.5 mm. The median grain diameter on the swash zone was around 0.18 mm. Figure 1 shows a location map of the field observation sites.

Fig. 1 Location map of field sites.

3.2 Measurement Procedure

Figure 2 shows the beach profile and the arrangement of the instrumentation at both beaches ((a) at Oarai Beach and (b) at Hasaki Beach).

In the swash zone, a target stick array of iron bars painted yellow was installed normal to the shoreline for photographic recording by 16 mm memo-motion cameras. The stick array consisted of 41 bars with an interval of 50 cm covering 20 m of the swash zone at Oarai and of 31 bars with an interval of 1 m covering 30 m of the swash zone at Hasaki. For photographing the waves from the side, a scaffold was elevated at the midpoint of the swash zone approximately 50 m south of the stick array at Oarai. Two sets of cameras recorded the waves from the scaffold. At Hasaki, waves in the swash zone were photographed by two sets of cameras on the pier.

The run-up meter, a capacitance-type wave gage with a modified measuring range, was also stretched parallel to the stick array and 50 cm beside it. The capacitance wire was held at a constant height of 2 cm above the sand surface by supporting rods installed at an interval of 2 m. A plastic scale was pasted to each supporting rods. In order to keep the wire at a constant height, two men were engaged in adjusting the movable supporting device of the wire to follow the sand surface fluctuations.

To record the sea surface variation, target poles for the 16 mm cameras were installed in the sea. A capaci-

Fig. 2 Beach profiles and arrangement of measuring instruments.

tance-type wave gage and a two-component electromagnetic current meter (EMCM) were attached to the target poles of St. 4 and St. 5 at both beaches. Waves were photographed by two sets of 16 mm cameras on a scaffold elevated at the berm crest at Oarai and on the pier at Hasaki. Figure 3 shows the arrangement of the sticks on the swash slope.

At Oarai, data collection was started on 16:10 and ended 17:50, giving a 100 min experimental duration. During the experiment the tide rose about 20 cm. Average breaking wave height and period estimated by visual observation were about 1m and 12 sec. The average breaker line was located between Sts. 2 and 3. The type of breaker was plunging and the wave direction was almost normal to the shoreline. Additional information may be found in Takezawa et al. (1988). At Hasaki the measurements started on 17:15 and ended on 18:31, with seventy six minutes of data collection. During the measurements the tide rose about 20 cm. The average breaker line was located near St. 2 and an

Fig. 3 (a)

Fig. 3(b) arrangement of the sticks on the swash slope.

average breaking wave height of 0.95 m and a wave period of 12.1 sec were recorded. The waves broke as the plunging type.

Analyzing data obtained by EMCM, no significant power was found in the longshore velocity at both sites except in the very low frequency range.

IV WAVE SEPARATION

In the following, results analyzed at St.4 on Oarai Beach (Hereafter this case will be abbreviated as OA87.St.4) and St.4 on Hasaki Beach (Hereafter abbreviated as HA87.St.4) are described and discussed. Wave data obtained by 16 mm cameras were analyzed in the present study and the wave data obtained with the capacitance-type wave gages were not employed.

Before the results of the analysis are shown, some supplementary information is given. The data collection with the electrical instruments and the photographing with the 16 mm cameras were simultaneously started by hand. No electrical synchronization between the measuring systems were done. The target poles and the electromagnetic current meters were placed close to each other but they were not placed exactly at the same location. It is expected that there was some time lag between the sea surface variation and the water particle velocity. In order to find the time lag, cross-spectral analysis was carried out and the time lag of 0.6 sec (OA87.St.4) and 0.4 sec (HA87.St.4) were obtained between the data records. The time lag was removed in the later analysis.

In the wave separation using Eqs. (11) and (12), a suitable value of N had to be chosen. There are no guide lines for selecting a value of N . Therefore, considering the power spectral functions, three critical frequencies, 0.35 Hz, 0.6 Hz, and 1.0 Hz for OA87.St.4 and 0.4 Hz, 0.9 Hz and 1.2 Hz for HA87.St.4, were evaluated. The three chosen frequencies did not give any noticeable difference

when analyzing the data records. The results obtained for the frequency 1.0 Hz at OA87.St.4 and for 1.2 Hz at HA87.St.4 are discussed later.

In the wave separation using Eqs. (1) and (2) and Eqs. (19) and (20) a value of α has to be determined. The value of α was chosen as the ratio of $(\overline{\eta^2}/\overline{u^2})^{1/2}$ between the observed and the calculated from small-amplitude wave theory, in the primary frequency range of progressive wave domain.

The most suitable value α of was 1.54 for OA87.St.4 and 1.26 for HA87.St.4.

4.1 Wave Separation

Figure 4 shows a portion of the resolved waves by the three methods at OA87.St.4, and Fig. 5 displays results from HA87.St.4. The incident and corresponding reflected waves are easily identified for primary individual

Fig. 4 Observed wave profiles, and separated incident and reflected wave profile by the three methods.

waves (Mizuguchi, 1982) at Oarai Beach, which had a steep swash zone slope. In contrast, reflected waves do not appear at Hasaki Beach, which had a gentle swash zone slope. It is difficult to recognize the correlation between the incident waves and the reflected waves, instead long-period waves appears predominantly in the reflected waves. This implies that primary individual waves ranging from about 5-20 sec in period, having the main power of the incoming waves, lost their energy in the swash zone, resulting in negligible reflection, and only the remaining long-period waves were reflected.

There is no standard method for determining the best separation technique. However, there is a tendency that an excess rise in sea water level appears for a portion of the reflected wave profile separated with linear long-wave theory (Eqs. (1) and (2)), and small-amplitude wave theory (Eqs. (11) and (12)), where this portion corresponds to the crest of the incident wave, when the reflected wave profiles are examined in detail.

Fig. 5 Observed wave profiles, and separated incident and reflected wave profile by the three methods.

The excess rise does not appear in the reflected wave profile separated with the method based on quasi-nonlinear long-wave theory, (Eqs. (19) and (20)). An example is found at an elapsed time of 23 sec for OA87.St.4, indicated by arrows. This is because the water particle velocity is smaller to apply Eqs. (1) and (2), and Eqs. (11) and (12). However, in the reflected wave profiles separated using Eqs. (19) and (20) for HA87.St.4, an abrupt sharp depression is found at an elapsed time of 45 sec. This was due to an exceptionally large observed water particle velocity, although it is not clear why this occurred.

As a measure to evaluate the different methods, the cross-correlation functions between incident and reflected waves were calculated and are shown in Fig. 6. Close to the time lag zero, the cross-correlation function derived from small-amplitude wave theory and linear long-wave theory fluctuate in comparison with quasi-nonlinear long-wave theory for both OA87.St.4 and HA87.St.4. This means that wave separation using Eqs. (1) and (2) and Eqs. (11) and (12) involves some uncertainty. In addition, the value of the maximum cross-correlation coefficient obtained by the method based on Eqs. (19) and (20) was the highest among the three methods compared at OA87.St.4, where waves were highly reflected because of the steep swash slope. According to the preceding discussion, it is concluded that the separation method based on the quasi-nonlinear long-wave theory is the best among the three investigated methods.

Fig. 6 Cross-correlation function between the incident and the reflected waves.

4.2 Spectral Considerations

Figure 7 shows the power spectral density function for the observed waves, and for incident and reflected waves at OA87. St.4 and HA87. St.4. Figure 8 shows the cross-spectral function between the incident and reflected waves.

At OA87. St.4, in the range below 0.15 Hz, which include the peak frequency, the power spectral shape of the incident and reflected waves are similar and the coherence function is nearly 1.0. This suggests that signifi-

Fig. 7 The power spectral density function of the observed, incident and reflected waves.

Fig. 8 Cross-spectral function between the incident and reflected waves.

cant wave reflection occurred. In the range higher than 0.15 Hz, the power of the reflected waves is considerably smaller than that of the incident waves. The energy in this range, were lost during the swash process, resulting in a small amount of reflection.

At HA87.St.4, in the range higher than 0.05 Hz, which includes the main power of the incident waves, the power of the reflected waves is very small compared with the power of incident waves, and coherence function is also small. In the range below 0.02 Hz, the power of the incident and reflected waves are of almost the same magnitude and coherence function is almost unity. This indicates that the significant reflection occurred only for long period components.

4.3 Joint Distribution of Wave Height and Period

Figure 9 shows the joint distribution of wave height and period for observed, incident, and reflected waves. The distribution of the observed waves is similar to that of the separated incident waves at both observation sites, OA87.St.4 and HA87.St.4, apart from that the distribution of the incident waves has two maxima. This implies two wave groups, with primary individual waves coming from the off-shore and secondary waves with small heights and periods mainly produced by disturbances in the surf zone. It was noted in the analysis of the

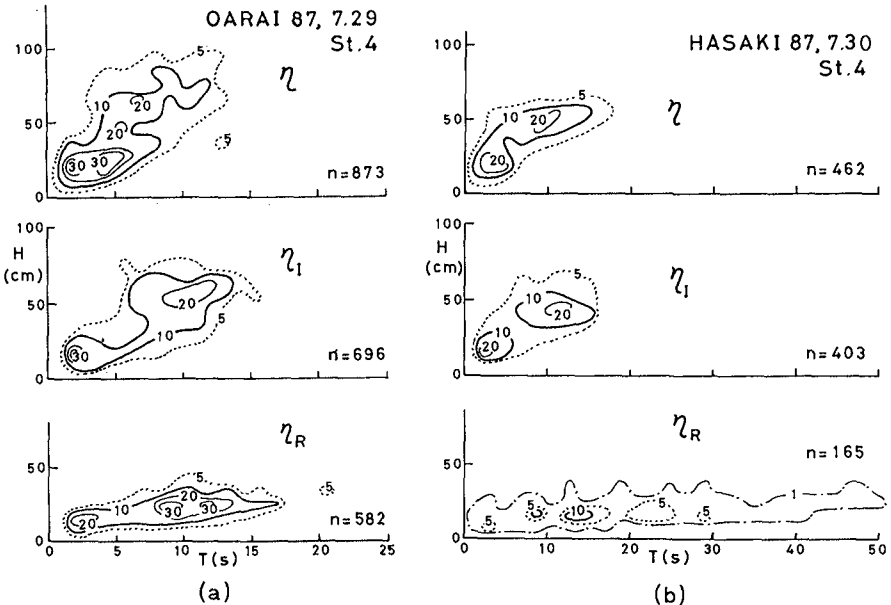

Fig. 9 The joint distribution of wave height and period for the observed, incident and reflected waves.

distributions of incident and reflected waves at OA87.St.4, that the number of defined waves somewhat decreased in the reflected wave field compared to the incident wave field, and the distribution of the reflected waves spread a little towards longer periods. However, the decrease in the number of waves mainly occurred for waves with small height and period, and the decrease did not occur for the primary individual waves ranging from 5 to 20 sec in period although they were reduced in height. This means that primary individual waves in the incident wave field return to the offshore with a decreased height.

The corresponding development does not appear for the waves at HA87.St.4. The number of defined waves considerably decreases and long-period waves not identified in the incident wave field appear in the reflected wave field. These long-period waves are found in the reflected wave profile in Fig. 4(b) and in the range below 0.06 Hz in the power spectral density function shown in Fig. 7(b). Thus, the waves that had the main energy in the period range 8 to 20 sec in the incident wave field lost their energy due to wave breaking on the slope and disappeared in the reflected wave field, implying no reflection. Instead, the long-period waves, which are difficult to distinguish in the incident wave field, are more easily identified in the reflected wave field. Following the above discussion, it is noted that the distribution of the observed waves at OA87.St4 is a result of superimposed incident and reflected waves, which does not show the proper characteristics of an incident wave distribution. The distribution of the observed waves at HA87.St.4 gives almost the same distribution as that of the incident waves. In summary, we need to consider wave reflection when the characteristics of incident waves on steep beaches are estimated.

V CONCLUDING REMARKS

The wave separation method based on quasi-nonlinear long-wave theory gave reasonable results using field data observed at a steeply sloping beach and also from a gently sloping beach. The separated incident and reflected wave field well described the wave characteristics in the surf zone, that is, high frequency waves lost their energy due to breaking and disappeared in the reflected wave field. The waves ranging in period from 5 to 20 sec, which have the main power of the incident waves and are ordinary wind waves, partially lost their energy due to wave breaking and returned to the offshore as reflected waves on the steep foreshore beach. Individual reflected waves were well related to the corresponding incident waves. However, on the gently sloping beach the waves lost their energy on the foreshore slope

and no reflection occurred. Low-frequency waves not easily identified in the incident wave field emerged in the reflected wave field and formed on-offshore standing waves without any breaking on the slope.

The critical frequencies to distinguish between perfect and partial reflection, and partial and no reflection depended on the gradient of the foreshore beach slope. Further field studies at beaches with different slopes should be carried out in order to qualify the wave characteristic in the nearshore zone. Also, further improvement of measurement instruments and development of the theoretical considerations are needed.

ACKNOWLEDGEMENTS

The authors would like to thank the Port and Harbor Research Institute, Ministry of Transportation, for permission to use the observation pier. We also gratefully acknowledge the assistance of Dr. S. Hotta, Professor, Dept. of Civil Eng., College of Science and Technology, Nihon University, during the field observation and in the preparation of this paper. We would also like to express our appreciation to our universities students who provided considerable supports during the field work. Without their help we could not have carried out this field experiment.

A portion of this study was supported by the Research Grant for Assistants and Young Researchers, Nihon University Research Grants for 1989 (Kubota) and Joint Research Grant, College of Science and Technology Research Grants for 1989, Nihon University (Takezawa and Kubota).

CHAPTER 45

Instabilities in the Longshore Current

N. Dodd¹, J. Oltman-Shay² and E.B. Thornton³

Abstract

Measurements made during one day of the 1986 SUPERDUCK experiment at Duck, North Carolina are used in order to investigate the model of Bowen & Holman (1989). This model explains low-frequency oscillations in the longshore current, which were observed during that experiment, in terms of a shear instability in that flow. The model is extended to include dissipation (in the form of bottom friction), and it is found that there is good agreement between it and observation.

1. Introduction.

During the 1986 Superduck experiment, at Duck, North Carolina, Oltman-Shay et al. (1989) noticed considerable along-shore progressive wave-like motions. These motions possessed periods of up to the order of 1000 seconds, and can therefore be described as low frequency. However, their associated wavelengths were of the order of 100 metres; this distinguishes them from infragravity waves which possess much longer wavelengths. Furthermore, they were only observed in the presence of a strong longshore current, which was a feature of most days of this experiment: when this current subsided, the oscillations were no longer apparent.

The measurements were made in about 1 to 2 metres of water, in the trough of the offshore bar which developed during the experiment. The incident swell had a period of about 5 seconds and approached the north-south tending beach at large angles. The longshore current was generated when these waves broke on the offshore bar. The waves then reformed and finally broke at the shore. Outside the surf zone, a corresponding long-time modulation of the incoming wave train was not noticed.

³Professor, Oceanography Dept., Naval Postgraduate School, Monterey, CA 93943, U.S.A.

Bowen & Holman (1989) have since presented a model, based on the inviscid, linear 2-dimensional shallow water equations, (under the rigid-lid assumption), to describe these motions. Their hypothesis is that these oscillations are manifestations of a shear instability in the along-shore shear flow (longshore current). This approach is in contrast with those of Symonds et al. (1982), Tang and Dalrymple (1989), and Shemer et al. (1990), all of whom assume low frequency nearshore motions to be forced phenomena.

In the analysis of Bowen & Holman, the mean longshore current is considered time independent and known a priori. The assumption of along-shore (y) uniformity is introduced, which allows the governing equations to be reduced to a single equation, analogous to the Rayleigh stability equation; the difference being due to the dependence of the water depth, h , on the cross-shore coordinate, x . Normal mode analysis then predicts a spectrum of eigenvalues/functions, each of which corresponds to a temporally stable or unstable perturbation, (or mode), of the shear flow. The authors assume the observed perturbations to be the fastest growing unstable modes, for a particular wavelength, λ ; i.e. the unstable modes with the largest growth rates. The spectrum of eigenvalues/functions is defined by the cross-shore depth, ($h(x)$), and longshore current, ($V(x)$), profiles. The situation is depicted in figure 1. They supported their hypothesis by applying this model to a highly simplified set of profiles. Dodd & Thornton (1990) have since shown more rigorously that the model agrees with observation on the non-dispersive nature of the oscillations in frequency-wavenumber (f,k) space.

Figure 1. Nearshore bathymetry, $h(x)$, and longshore current, $V(x)$, and their relation to the coordinate system used.

In the following work we examine results from one day of the SUPERDUCK experiment, and we apply the model of Bowen & Holman to the measured V and h profiles for that day. Being a linear analysis, no information concerning the absolute amplitudes of these perturbations can be obtained. Therefore, we concentrate our efforts on comparing observed and predicted (f,k) spectra. In doing this it must be assumed that V and h are dependent only on the cross-shore coordinate, x . Though the bathymetry was mildly three-dimensional, this is a reasonable assumption.

2. Theoretical and Numerical Background.

We consider the domain $0 < x < \infty$, $-\infty < y < \infty$, with the shoreline situated at $x=0$. The total velocity vector, \underline{u}^* , is defined as

$$\underline{u}^* = (u(x,y,t), v(x,y,t) + V(x)). \quad (1)$$

Thus u and v represent the perturbed velocity field and V represents the longshore current. When (1) is introduced into the shallow water equations, which are linearized under the assumption $V_0 \gg u_0$, (where V_0 is a representative amplitude of the longshore current and u_0 is a similar quantity for the perturbed velocity field), we get:

$$\begin{aligned} u_t + Vu_y &= -g\zeta_x \\ v_t + uV_x + Vv_y &= -g\zeta_y \end{aligned} \quad (2)$$

where t is the time coordinate, ζ is the free-surface elevation, and g is the gravitational acceleration constant. Under the rigid-lid assumption, a stream function, $\Psi(x,y,t)$, is introduced into (2), where $u = -\Psi_y/h$ and $v = \Psi_x/h$; this allows the equations (2) to be combined into a single equation. Making the further assumption that the along-shore behavior is simple harmonic, then

$$\Psi(x,y,t) = \Re\{\psi(x)e^{i(ky-\omega t)}\} \quad (3)$$

Thus, the cross-shore structure is described by $\psi(x)$. The resulting linearized equation is

$$(V-c)\{\psi_{xx} - (h_x/h)\psi_x - k^2\psi\} = h(V_x/h)_x\psi. \quad (4)$$

The wavenumber, $k=2\pi/\lambda$, is assumed to be real. The phase velocity, c , (and therefore the frequency, $\omega=c k$), will in general be complex. Thus if c possesses a positive imaginary part, Ψ will be a temporally unstable mode, with wavelength $2\pi/k$, real radian frequency $\Re(\omega)$, and growth rate $\Im(\omega)$. One condition for there to be an instability is that the potential

vorticity associated with the shear flow, V_s/h , should possess a local extremum. This condition is satisfied for all the profiles examined here.

In general, (4) must be solved numerically. Here we use a finite difference solution. In this scheme, (4) is discretized at N nodes on the domain $0 < i\Delta x < (N-1)\Delta x = L$, ($i=1, \dots, N-2$), where Δx is the distance between nodes, and L is some suitably large value. The scheme is accurate to $O(\Delta x^4)$, and the relevant finite-difference approximations for the derivatives in (4) can be found in Collatz (1960). At the boundaries, non-symmetric approximations are derived to the same order of accuracy, although it should be noted that the comparatively large coefficient of the truncation error term, due to the non-symmetric nature of the boundary conditions, degrades accuracy somewhat. The problem may then be posed as a generalized algebraic eigenvalue problem,

$$A\underline{\psi} = cB\underline{\psi}, \quad (5)$$

(where $\underline{\psi} = (\psi_0, \dots, \psi_N)$, and $\psi_i = \psi(i\Delta x)$), and solved subject to the no-normal-flow boundary conditions: $\psi_0 = \psi_N = 0$. In fact, (5) may be solved more rapidly as a classical eigenvalue problem by operating on it with B^{-1} , which is easily calculated since B is well-conditioned. Such a solution yields $N-1$ eigenvalues, c_i , each with an associated eigenfunction, $\underline{\psi}_i$. This method of solution has the disadvantage of being computationally expensive, in both storage and cpu time, and of being generally less accurate than initial-value methods. It is usually used in order to generate initial estimates to eigenvalues, which can then be more accurately estimated using a shooting method. Here this method is used by itself, because the profiles we will be looking at are not smooth, analytic functions, but discrete and numerically generated. This severely restricts the usefulness of shooting methods for this problem. A value of $N = 201$ was the largest that the available storage and cpu time would allow on an IBM 3033. This was adequate for the investigation.

3. Bottom Friction.

The model presented in the preceding section neglects dissipative effects. However, such effects can be important in damping unstable modes. Bowen & Holman included a damping factor, $e^{-\nu t}$, in (3), and estimated that ν would be $O(10^{-2}-10^{-3} \text{ s}^{-1})$, implying that $\Im(\omega)$ must be larger than this for an instability to develop. In fact, dissipative effects can be included in the momentum equations on a rational basis. The equations (2) represent a decoupling of higher order effects, (i.e. perturbations in the longshore current), from the lowest order balance. This balance is between the radiation stress gradients, which are generated by waves breaking at a beach and which lead to the formation of a longshore current, and the bottom friction, and is discussed by Longuet-Higgins (1972). In the higher-order balance wave breaking is absent, and so the most significant dissipative effect is bottom friction. This effect may be included by adding an appropriate term to the momentum equations:

$$\begin{aligned} u_t + V u_y &= -g \zeta_x - \mu u \\ v_t + V v_y + V_x u &= -g \zeta_y - \mu v \end{aligned} \quad (6)$$

Thus the term μ represents the dissipation in the problem. It may be derived on the assumption that the amplitude of the orbital velocity of the incoming gravity wave, U_0 , is much greater than the representative longshore velocity, V_0 ; i.e. $U_0 \gg V_0$. Thus,

$$\mu = \frac{2}{\pi} c_D U_0 \quad (7)$$

where c_D is a dimensionless drag coefficient. (In fact, this assumption is invalid for Duck. However, it is the size of μ which is of importance here and not its form). These equations can then be combined as before to give

$$\left(V - \frac{i\mu}{kh} - c \right) \{ \psi_{xx} - (h_x/h) \psi_x - k^2 \psi \} = h(V_x/h)_x \psi - \frac{i\mu}{kh} (h_x/h) \psi_x \quad (8)$$

It can be seen that μ is always accompanied by i ($= +(-1)^{1/2}$).

The equation (8) can be solved by the method already outlined in the previous section. It is this equation which will be applied to measured V and h profiles from the SUPERDUCK experiment.

4. Observations.

We examine observations from one day of the SUPERDUCK experiment, October 16th, which exhibited the most energetic low frequency motions. For a full description of the field site and the methods of data collection the reader is referred to Oltman-Shay et al. (1989).

Some of the strongest evidence presented by Oltman-Shay et al. for the existence of low frequency perturbations in the longshore current is in the form of iterative maximum likelihood estimated (IMLE) frequency-cyclic wavenumber (f, K) spectra, (where $K = k/2\pi$). Figure 2 shows one such diagram for Oct. 16th, which was constructed from the along-shore component of velocity as measured on that day. Note that the frequency is cut off at 0.05 Hz (20 seconds), thus excluding the incoming swell. The diagram therefore shows only low frequency motions, (compared to the incoming wave train). The figure shows theoretical edge wave dispersion lines for 0 mode and two higher mode edge waves (for a plane beach). Note that frequency bins are now of width about $\Delta f = 0.001$ Hz, and are thus better resolved than the original figures of Oltman-Shay et al.; otherwise, the diagram is similar to those presented, (for other days), by Oltman-Shay et al.

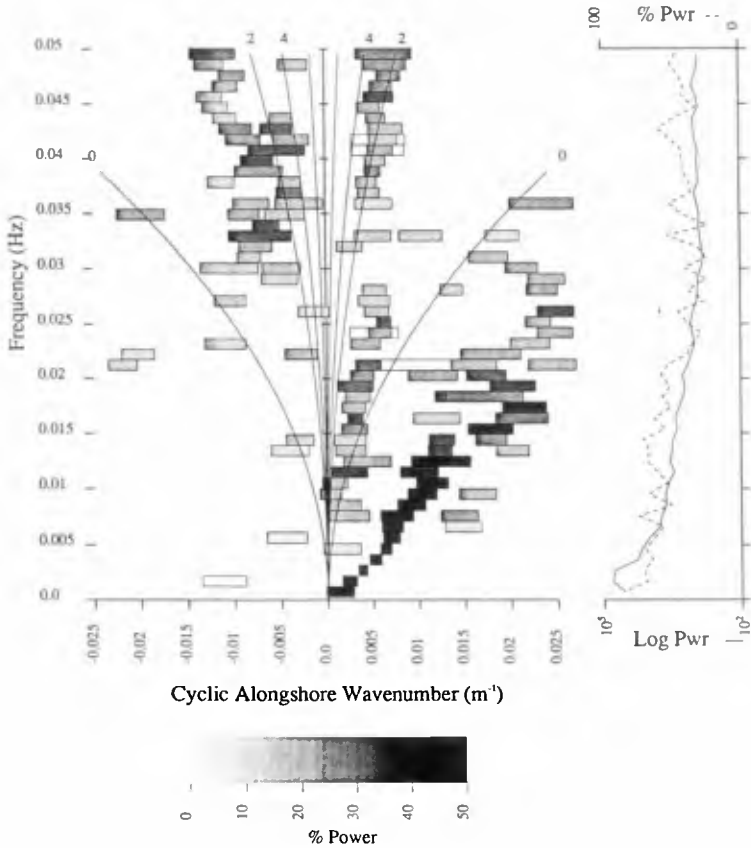

Figure 2. IMLE frequency-cyclic wavenumber spectrum of along-shore velocity on October 16th. Positive wavenumbers indicate southward propagation. Rectangular boxes indicate position of variance peaks defined as those wavenumber maxima having an adjacent valley below their half-power. The wavenumber width of each box is the half-power bandwidth of the peak. Shading density indicates the percent variance in the frequency bin that lies within the half power bandwidth of the peak. Theoretical edge wave dispersion curves (0, 2 and 4), and leaky-trapped boundary are shown. Log power density (cm²/s, solid) and total percent variance displayed in the frequency-wavenumber spectrum (dashed) as a function of the frequency are shown alongside. $\Delta f = 0.00098$ Hz.

There is evidence of edge wave activity in the diagram, which is mostly restricted to frequencies above 0.01 Hz, though it is hard to tell which modes are present. This is partly due the array being too short to successfully resolve them. However, the shorter, low frequency motions do not suffer from this problem; in fact, the most well defined variance

peaks lie well outside the edge wave dispersion curves, and below 0.015 Hz. They appear to describe a roughly linear relation between frequency and wavenumber. As Oltman-Shay et al. noted, these lines are not attributable to advected edge waves, (due to the longshore current), or to deviations of the edge wave dispersion curves from the theoretical form indicated on the figure, (due to deviations of the beach profile from its theoretically plane form). These oscillations can be seen to be progressive, with a phase speed of about 0.9 m/s. They are in the same direction as the longshore current on that day, the maximum value of which was about 1.2 m/s. On this and other days examined, the measured phase speeds were about one half to three quarters the corresponding maximum longshore current value. This is in agreement with theory.

5. Computations.

In order to use the model (8) the cross-shore bathymetry, $h(x)$, and longshore current profile, $V(x)$, must be constructed for October 16th. In the case of h this presents no problems, but for V things are not so simple. This is because there were very few measurements of longshore current made; in fact there are only five such measurements for the 16th. It is therefore difficult to know what the true profile is. However, small differences in this profile can substantially affect the predicted stability characteristics for that day. It is therefore important that we have reasonable confidence in the profile used. Another problem, which is linked to the first, is that the profile was measured sequentially, over a period of about four hours, as a sled was moved in a transect across the foreshore. Although this process was centered about low tide, the depth changed by about 0.2 m during the time the measurements were made. This, combined with other changes which may have occurred in the incoming wave field, may be enough to considerably affect the mean longshore current profile and thus render any profile interpolated from the measured profile dubious at best.

Unfortunately, there is little or no analytical work available for longshore current generation on a barred beach. Therefore, we use the model of Thornton & Whitford (1990) to generate a set of V profiles for the period during which the measurements were taken, to allow for the affects of tidal variations. There are five such profiles in all, (denoted cases A to E), each with an associated depth profile, which covered the tidal range. They are shown in figures 3(a) and 3(b). The actual measured values of V are also shown in figure 3(a). It can be seen that there is a fairly large difference between the first and the last profiles, (A and E), and that the measured values agree closely with profiles C and D. Case E is markedly different from the rest. Moving beach-ward from offshore, each profile is, however, qualitatively similar: there is a maximum in V , followed by a sharp decrease, then a slowing of the decrease, and finally a rapid decay to zero at the shoreline. The large peak in each profile is due to the waves breaking on the bar, and the slowing of the rate of decrease, (which results in a "kink" in the onshore shear), is a result of waves finally breaking at the shore. These features are typical of longshore current profiles on barred beaches. It is easy to see that merely interpolating from the measured values will lead to a qualitatively different profile. There will be no such secondary breaking modeled. The drag coefficient, c_D , was measured at about 0.003, and this value is used throughout the following analysis.

The profiles shown in figures 3(a) and 3(b) are now inserted into (8) and the resulting eigenvalue problem solved. Recall that it is the fastest growing unstable modes which will be of importance; other unstable modes may be present but the modes with the

(a).

(b).

Figure 3. Longshore current (a). and depth (b). profiles used in the stability analysis. Case A is shown by the solid line and cases B to E by dashed lines with progressively shorter dash lengths. Measured longshore current values are indicated in 3(b) by an asterisk.

largest growth rates are expected to be apparent first. We denote the growth rates: $G = \Im(\omega)$. Each of these unstable modes possesses an associated real frequency, $F = \Re(\omega)/2\pi$. In figure 4 we compare the predicted frequencies with the measured frequency-cyclic wavenumber spectra. In this diagram the shading present in figure 2 is omitted so that the

comparison can be seen more clearly.

Figure 4. Reproduction of IMLE spectrum shown in figure 2, without shading. Also shown are the predicted dispersion curves, corresponding to the fastest growing unstable modes, for each of the cases A to E. Case A is shown as a solid line, and thereafter cases B to E are shown as dashed lines with progressively shorter dash lengths.

It can be seen that cases A to D give similar dispersion curves. They agree well with measurement. Case E differs substantially from these. Considering the aforementioned difference between this V profile and the rest, this is not surprising. The dispersion curve predicted in this case agrees comparatively poorly with the measured spectra, and for these reasons we now discard case E. Note also that a number of the cases give discontinuous dispersion curves. In these cases, each segment of the curve corresponds to a different unstable mode (eigenvalue) from adjacent segments. They result from G increasing as K increases, for one mode, while for another G decreases. Hence there is a "jump" from one mode to another as the growth rate of the latter exceeds that of the first.

It should be remembered that no information concerning the absolute amplitudes of these oscillations may be obtained from this linear analysis. Thus only relative intensities

can be compared. The model of Bowen & Holman explains perturbations of a shear flow as instabilities in that flow. On this assumption it is natural to extend this interpretation to explain more vigorous perturbations as more unstable modes; i.e. modes with larger growth rates. To make this comparison the IMLE diagram shown in figure 2 is rescaled. In the original figure degrees of shading represent wave energy at a particular wavenumber as a percentage of total energy in that frequency bin. In figure 5, although the original IMLE "boxes" are retained, the shading now represents absolute variance, (or energy), thus allowing comparisons between different frequencies to be made.

Figure 5. IMLE frequency-cyclic wavenumber spectrum for along-shore velocity, on October 16th. Shading indicates absolute log variance density. Log variance density in the frequency-cyclic wavenumber spectrum as a function of frequency is shown alongside. $\Delta f = 0.00098$ Hz. Also shown are the predicted growth rates, G , (units, rad/s) for the cases A to D. A is shown by the solid line, and B to D by dashed lines with a progressively decreased dash length.

In this figure, measured variance is virtually all concentrated below 0.01 Hz, showing that these motions are far more energetic than any other low frequency motions. In the accompanying log variance plot, the variance can be seen to increase, from very low frequencies, up to a peak in the second frequency bin, (about 0.001 to 0.002 Hz), and decrease thereafter.

The predicted growth rates, G , are shown in the same diagram, (excluding case E). Each of these shows an increase in G , from low wavenumbers, and frequencies, (see the corresponding frequencies in figure 4), to a peak growth rate, and then a decrease as K increases further. This is in rough agreement with the observed spectra. The main area of disagreement is at very small wavenumbers, (very low frequencies), where theory predicts no instability, but quite energetic motions were measured. As we proceed from case A through to case D, the maximum growth rates of the predicted instabilities becomes larger. That this is not solely due to differences in the V profiles can be discovered by re-solving the eigenvalue problem (8) using the longshore current profile for case A and the depth profile for case E. Larger growth rates are found for this case than for case A alone.

6. Discussion and Conclusions.

The further analysis of the observations made on one day of the SUPERDUCK experiment provides some further support for the hypothesis of Bowen & Holman: these motions are manifestations of a shear instability in the longshore shear flow. The improvement in resolution of the IMLE spectrum shown here, ($\Delta f=0.00098$ Hz as opposed to 0.002 Hz), clearly indicates the presence of these motions, lying in a straight line. They also clearly dominate other wave activity. They also reveal the existence of a peak in the energy of these motions, (lying between 0.001 and 0.002 Hz). Theory concurs. The predicted dispersion lines agree well with observation. The results for the 16th are typical for those on other days.

There are some notable discrepancies however. The range of the predicted instability, though in general agreement with measurement, is not the same, and in particular, energetic motions at very low frequencies and wavenumbers are shown by the measurements, and these are not predicted by the theory. These discrepancies may be explained by the fact that there is, in each case, more than one unstable mode. The existence of the motions at larger frequencies may be a result of interactions between such modes. Dodd et al. (1990) have also shown strong evidence of an offset (non-zero intercept) of the linear dispersion lines in IMLE spectra constructed from the cross-shore component of velocity. They thought that this could be caused by the existence of a rip current, and this could explain the existence of intense motions at very low frequencies. Dissipation, as modeled here, appears to be play the important role of damping unstable modes with very small growth rates. This is in agreement with Bowen & Holman.

Finally, we consider the stream function, ψ . For case A, the unstable mode with the maximum growth rate exists at about $K=0.006$ m^{-1} ; see figure 5. At this wavenumber another unstable mode exists. It is not shown in figure 5 because its growth rate, for this value of K , is smaller than that of the first mode by a factor of about 5. The growth rates shown in figure 5 are, of course, the eigenvalues in the problem (8), and with each of these is associated an eigenfunction. We denote these ψ_1 for the fastest growing mode (at $K=0.006$ m^{-1}), and ψ_2 for the second. In figure 6, we show $|\psi_1|^2$ and $|\psi_2|^2$ as functions of x . Also shown in this figure is the cross-shore potential vorticity profile (V_x/h) defined by case A. Note that the peaks in $|\psi_1|^2$ and $|\psi_2|^2$ occur in different places: the first at the local

maximum in V_x/h , and the second at the second local minimum. Looking at figures 3(a) and 3(b), it can be seen that the minimum is associated with the offshore facing shear in V , and that the maximum is associated with the onshore facing shear. Specifically it is due to the "kink" in the V profile due to waves breaking at the shore. If this kink is removed, then the most unstable mode, ψ_1 , disappears, leaving ψ_2 as the most unstable mode. This can be tested by either redefining the V profile between about $x = 40$ m and 100m, or by cubic interpolation between the measured V values shown in figure 3(a). A little further smoothing results in stability; i.e. the problem defined by (4) may be unstable, but the dissipative effects included in (8) damp such instabilities, since the growth rates associated with them are very small. All of this is also true of cases B, C and D. What it seems to indicate is that the instabilities associated with the longshore current profile at a barred beach are due specifically to the form of the onshore shear, and not the offshore (or back) shear, as first suggested by Bowen & Holman (1989).

Figure 6. Potential vorticity of shear flow case A (solid line, left scale) and $|\psi_1|^2$ and $|\psi_2|^2$, (moduli squared of the stream functions of the first and second fastest growing modes in case A for $K = 0.006 \text{ m}^{-1}$) (long and short dashed lines respectively, right scale) as functions of x .

CHAPTER 46

A comparison of the performance of three mathematical models of wave disturbance in harbour approaches

Jane V Smallman¹ and Nigel P Tozer²

Abstract

In many design studies for coastal harbours mathematical models are used to define wave conditions in the vicinity of their entrance. There is a wide variety of models available for this purpose, each with their own characteristics. This paper compares the performance of three models which are in use for this type of study. The advantages and drawbacks of each of the models is considered by comparison with results from a physical model of a typical harbour approach bathymetry.

Introduction

Mathematical models of wave disturbance are in frequent use for predicting wave conditions both within and in the approaches to a harbour. Information on wave activity in the approaches to a harbour will be required to make a full assessment of ship manoeuvrability, and the movement of sediments. In the case of a harbour entered by a dredged channel, estimating wave disturbance will often be of importance in studies directed towards optimising channel depth and alignment.

There are presently available a wide variety of models which can be used to estimate wave disturbance. In this work attention is directed towards situations in which wave conditions are to be calculated at many locations, rather than at a few isolated points, in the harbour approaches. The performance of the models within a harbour is not considered here, either because their behaviour in such circumstances has already been examined, or they are unsuited to that type of application.

In developing wave disturbance models comparisons are often made between their results, and those from analytical solutions to

¹ Manager, Ports and Harbours Section, Maritime Engineering Department, Hydraulics Research, Wallingford, Oxon, OX10 8BA, UK

idealised problems. In this case the technique which is used is to compare the results from the three mathematical models, with those from a physical model for a typical harbour approach bathymetry. Four sets of results from the physical model were available covering different incident wave conditions. In addition to the accuracy of the representation achieved by the mathematical models, consideration was also given to the speed of the calculation procedure.

The three mathematical models used in the comparison were a wave ray model and two finite difference models. The three models, and the physical assumptions inherent in their mathematical derivation, are described in detail in the following section. In subsequent sections the physical model test case is described and the performance of the models examined. In the final section the overall conclusions resulting from this work are given.

Description of the mathematical models

The three models used in this comparison were PORTRAY (see Smallman, 1987) and two finite difference wave models based on alternative formulations of the mild slope equation. PORTRAY, which is based on a ray tracking technique, was developed at Hydraulics Research, and is in frequent use in site specific studies. Both of the finite difference models were developed at UK Universities and were transferred to Hydraulics Research during 1987. The finite difference models are based on hyperbolic, see Copeland (1985), and parabolic, see Dodd (1988), approximations to the mild slope equation. The mild slope equation is given by

$$\nabla \cdot (c c_g \nabla \phi) + \omega^2 \phi c_g / c = 0 \quad (1)$$

where $\phi(x,y)$ is the velocity potential, c is the phase velocity, c_g the group velocity and ω the radian frequency. The equation, first derived by Berkoff (1972), describes the propagation of periodic, small amplitude surface gravity waves over a seabed of mild slope and will represent the combined effects of refraction, shoaling and diffraction. A more detailed description of each of the models follows.

PORTRAY is based on a ray tracing technique developed from the theory of light. Under the assumptions that the waves are linear, and that a wave in water of local depth, d , will behave similarly to a wave in water of constant depth d , wave refraction and shoaling can be shown to be governed by Snells law. Rays are tracked in the direction of wave propagation, and wave heights are calculated using the principle of conservation of energy between neighbouring rays. This approach has a limitation in that diffraction, ie a lateral transfer of wave energy, which can be caused by rapid gradient changes in the bed, is not included explicitly in the governing assumptions of the model. This can lead to some difficulties in applying the model, particularly in

areas where relatively long period waves are incident along the line of a dredged channel. The model has, however, been extensively validated against physical models and in most situations, particularly in harbour wave disturbance studies, found to provide accurate results, see Smallman (1987).

A set of linear hyperbolic equations to model refraction and diffraction processes in coastal zones was put forward by Ito and Tanimoto (1972) at about the same time as the elliptic mild slope equation was derived. Later Copeland (1985) derived similar equations from the transient form of the mild slope equation. This hyperbolic form can be written as

$$\begin{aligned} \frac{\partial Q}{\partial t} + \frac{c^2}{n} \nabla(n \eta) &= 0 \\ \frac{\partial n}{\partial t} + \nabla \cdot Q &= 0 \end{aligned} \quad (2)$$

Here the water surface elevation η is

$$\eta = A(x,y)e^{-i(\chi - \omega t)}$$

where A is the amplitude of the water surface fluctuation and χ is the phase angle.

Also, $n = \frac{c}{g}$ and Q is a dummy variable representing the flow rate, defined as a vertically integrated function of particle velocity. The equations can represent diffraction, refraction and reflections under the assumptions made in their derivation.

By creating a hyperbolic form from the original equation the mild slope problem has been embedded in a larger space (x,y,t) . This appears to be an unnecessary complication as the time dependence, $e^{-i\omega t}$, is known in advance. Therefore time stepping will produce only a phase change. If it does not then there is a basic inconsistency in the derivation.

This point has been explored by Madsen and Larsen (1987). They make the observation that the time stepping is actually only an iteration towards the steady state, and that only the steady state solution is a solution to the mild slope equation. This accounts in part in the difficulties which are known to occur in getting the hyperbolic form to converge to the steady state. A difficulty which needs to be resolved more satisfactorily before the method can be used reliably in practice.

The time taken to solve the elliptic mild slope equation computationally, and the mathematical uncertainties of the hyperbolic form, means that attention has been given to the parabolic approximation. This will be computationally efficient to solve and mathematically more rigorous in its derivation. However, this is achieved at the expense of accuracy in the representation of physical problems. That is, whilst refraction

and diffraction are represented in the parabolic approximation, reflections are not. A consequence of this is that it is therefore not suitable for representing wave disturbance in harbours where reflected waves will be important.

The first comprehensive account of a parabolic approximation to the mild slope equation was given by Radder (1979). The equation modelled here is based on an improvement to this work given by Booij (1981). The derivation assumes that the reflected wave field is negligibly small so that only forward travelling waves are considered. This leads to the equation

$$\frac{\partial \phi}{\partial x} = \frac{i}{2k} \frac{\partial^2 \phi}{\partial y^2} + \left\{ ik - \frac{1}{2k} \frac{\partial k}{\partial x} \right\} \phi \quad (3)$$

where x is the main direction of wave propagation, y is the transverse direction. Deviations from the x direction are considered in the equation as oblique amplitude modifications. The parabolic approximation will allow refraction, shoaling and seabed diffraction to be modelled. The approximation works best where the important effects occur in the direction of wave propagation, as transverse effects are only included in a weak sense. A detailed account of the deviation of the governing equation for the parabolic model used in this work, and its application to a number of test problems, is given in Dodd (1988).

The equation (3) can be solved numerically using an evolutionary finite difference technique; this type of method only requires storage of one or two adjacent rows of solution points and, as a consequence, is considerably less expensive in terms of cost and storage than the equivalent numerical solution to an elliptic equation. Thus, the main advantage of the parabolic equation is that it permits a more rapid and straightforward method of solution than would be possible for the elliptic equation.

Finally, all three of the models were modified to include the effects of wave breaking. This was done using an empirical formulation put forward by Weggel (1972).

Physical model

The physical model layout is shown in Figure 1. In the tests carried out random waves tests for two spectra from each of two directions were carried out. The characteristics of the incident conditions are given in Table 1.

Test No	Significant wave height H_s (m)	Peak wave period T_p (s)	Direction ($^\circ$)	
1	4.3	8.6	0	Storm
2	1.9	6.0	0	Typical
3	6.0	10.0	25	Storm
4	3.2	7.5	25	Typical

Table 1. Incident wave conditions for physical model tests.

Figure 1 Physical model layout

All of the physical model tests were run at a fixed still water level of +1.9m CD. Measurements of wave height (H_s) were made in the physical model at the ten locations shown on Figure 1. These positions were selected to be representative of conditions within and at the sides of the channel. This particular bathymetry is typical of a dredged harbour approach channel and, as such, will provide a good test of the capabilities of the models for a range of incident wave conditions.

Mathematical model set up

All of the mathematical models require the bathymetry to be described as a set of depth values over a regular grid. Firstly, the bed contours were digitised and then output on a 7m (prototype) mesh. This mesh size gave at least ten points per wave length to the incident wave conditions given in Table 1. This choice of mesh size satisfied the accuracy of representation constraints of the two finite difference models. PORTRAY is not reliant on such grid constraints, so a second set of grid data, each node 35m (prototype) apart, was generated without significant loss of resolution in the description of the bathymetry. PORTRAY was run both for the 35m and 7m mesh layouts.

The mathematical model grid systems were deliberately aligned to one of the wave propagation directions. This was done because, in the derivation of the parabolic model, the coordinates are assumed to be in the main wave propagation direction. It is possible for the model to include wave effects in directions up to 45° different from the main direction, but with its accuracy reducing as the angle increases. This point will need to be borne in mind when considering the parabolic model results for the 25° direction cases.

All of the mathematical models are monofrequency, unidirectional models. It is possible to run each of them repeatedly for different frequency components, and then use linear superposition to achieve a spectral description of wave propagation. This would give a true comparison with results from a random wave physical model. However, for this study monofrequency runs were made using the peak period of the incident wave spectrum to represent the random wave train. This is not ideal, but has been found in many applications to give a reasonable approximation to an incident wave spectrum. It is intended that this research will be extended subsequently to include mathematical models with random wave incident conditions.

For the hyperbolic finite difference model it remained to select a time step. To satisfy the stability criterion of this model, time steps were selected such that 25 elapse in each wave period. To achieve convergence for this model it was typically necessary to run it for 10 wave periods. Neither the parabolic model nor PORTRAY are time dependent models, so no time step was required for either.

Comparison of results

For the purposes of discussion of the results each of the conditions in Table 1 will be referred to as 'typical' or 'storm' waves with an associated direction. For example, the condition storm (25°) will refer to results from test 3.

For each of the four test cases wave height coefficients at analysis points corresponding to the probe positions of the physical model were calculated. These are presented in Tables 2 to 5 for the physical model, each of the mathematical models on the 7m grid and PORTRAY over the 35m grid (referred to as PORTRAY CG). Each of the tabulated values is averaged over nine grid points centred at the analysis point, thus providing values which can be confidently accepted as representative of wave conditions at the given locations.

Discussion of results

Before examining the numerical results in more detail it is worth observing some of the more quantitative aspects of the results which are shown in Figure 2.

Figure 2 represents the calculated significant wave heights for each of the model tests for the storm (0°) condition. Figures 2a and 2b represent the results of PORTRAY for the fine and coarse grid solutions respectively. Figures 2c and 2d represent the calculated wave field for the hyperbolic and parabolic models.

Considering Figures 2a and 2b, it can be seen that PORTRAY models the wave effects on a fine and coarse mesh in a similar manner. The ray approximation means that diffraction by the channel is not represented, and the rays are reflected at the channel sides. This leads to the formation of caustics, and consequently excessively large wave heights at the channel sides. Physically, there will be an area of higher wave activity in this location, but the lack of representation of seabed diffraction in ray models will exaggerate this effect. This behaviour is more clearly seen in the finer grid case, where distinctive regions of large wave heights can be seen. Figure 2b shows how PORTRAY over a coarser grid has led to a more even distribution of the wavefield. This is because the averaging procedure (Southgate, 1984), used to calculate wave heights in the ray models, has effectively introduced a type of numerical diffraction. Also of note are the regions of very low wave heights. Since the PORTRAY model is based on tracing out wave orthogonals there will be some regions where no rays have been able to penetrate. Wave heights in these regions will be physically low, but PORTRAY predicts zero or negligibly small wave heights. It should be observed that, as far as the ray models are concerned, the storm (0°) was the most stringent of the four cases tested. This is because it represents long period waves incident along the line of a dredged channel, ie the case where physical diffraction will be an important mechanism. It will be seen from the numerical results that its performance improves for shorter period waves (typical (0°)), and more markedly for waves from 25° .

Considering the two finite difference models, Figures 2c and 2d, both hyperbolic and the parabolic models produce a similar

Figure 2a. Waveheight contours. PORTRAY. Storm(0°).

Figure 2b. Waveheight contours. PORTRAY_CG(Coarse Grid),Storm(0°).

wave pattern to that of PORTRAY, and compare more favourably with the coarse grid solution. Diffraction of waves in the vicinity of the channel results in a more even distribution of wave heights. At the channel sides waveheights are generally larger than in the channel region itself. It can be seen that the patterns of wave activity produced by these two models differ away from the channel. The hyperbolic model appears to concentrate energy close to the channel whereas the parabolic model spreads this diffractive energy out more evenly over a larger region.

Examination of the tabulated results allows a quantitative comparison with the measured data. The following discussion will consider positions along the centre, to the left and to the right of the channel, for each test case, in turn. The results shown in Table 2 correspond to measured and predicted waveheight coefficients at the prediction points, see Figure 1, for the illustrated storm (0°) condition, see Figure 2. At positions 3 and 6, along the centre of the channel, all of the models underpredict the waveheights compared with the measured values. The finite difference models are more reliable, within 30% of the measured data, than the PORTRAY solutions. This will be due to an insufficient number of rays penetrating into this region. Further along the channel, shorewards, at position 10, each model predicts significantly higher waveheights than was measured, although the predictions lie within 20% of their combined average. Considering positions to the left of the channel, at points 1, 2, 5, 8 and 9, the finite difference models' results are more consistent with the measured data, notably at position 1 and 5 where the results lie within 10% of the recorded values. Elsewhere, for all the models there are some discrepancies for which there is no apparent trend. To the right of the channel at point 4 each model overpredicts slightly compared with the measured value. However, at position 7 the numerical models underpredict conditions compared with those measured.

The tabulated results in Table 3 corresponding to the typical (0°) condition indicate that each model's performance will change for different incident wave periods. Only some of the trends discussed above are repeated. At position 3 improvement in the predictions is limited to PORTRAY-CG, although the finite difference models' prediction is only slightly worsened. The underprediction shown at position 6 for the storm (0°) condition is reversed for the typical (0°), and at position 10 the finite difference models' prediction is much improved at just over 20% difference. Only at position 1 to the left of the channel do one of the PORTRAY solutions differ from the measured values by more than the finite difference models do. However, the largest variations from the measured value oscillates between the models. The trend for the storm (0°) condition at position 4 and 7 is repeated for the typical (0°); the trends worsened at 4 but improved at 7.

It is clear from Table 3 that the performance of the finite

difference models for the storm (25°) conditions is considerably worse than that of the PORTRAY solutions with the parabolic model performing slightly better, but results which vary considerably from the measured values are commonplace. The results also indicate that the PORTRAY-CG solution offers the best comparison with the physical model result. Along the centre of the channel the finite difference models show the largest discrepancies with the measured values. To the left of the channel PORTRAY-CG and PORTRAY compare well with the measured data with PORTRAY-CG marginally better at 5, 8 and 9. Predictions by the finite difference models offer slightly better solutions to the left of the channel than along the centre, but still differ markedly from the measured values. Along the positions to the right of the channel, these discrepancies are reduced at position 4, but are again large at 7. Again the performance of PORTRAY-CG is best overall.

The tendency for the finite difference models to overpredict the waveheights for the storm (25°) is not apparent for the typical (25°) condition. Along the centre of the channel the PORTRAY-CG offers the best solution. To the left of the channel all the models perform well with results rarely more than 20% different, and in general closer to 10% different. To the right of the channel at positions 4 and 7 the largest deviation from the measured data are predicted by PORTAY-CG and PORTRAY respectively, with the results within 20% from the measured data at position 4, and 10% at position 7. The results from the finite difference models in this region are in good agreement with the physical model values.

Summary of results

The numerical models in general tend to exaggerate the physical features. In particular they display large spatial variations in wave height, which are not seen in the physical model. However, the mathematical models all give a reasonable representation of the overall physical behaviour.

For waves incident along the line of the channel, the finite difference models perform better in general than PORTRAY, although for incident waves in the off normal direction, notably the storm (25°) condition, the accuracy of the difference models is reduced. This confirms the expectation implied in the assumption made in the derivation of the parabolic approximation, but is less easy to explain in the case of the hyperbolic model.

Running the PORTRAY model over a carefully selected coarser grid has the effect of introducing numerical diffraction into the solution. This leads to a better representation, compared with the physical model, than the fine grid case.

In general the hyperbolic model took considerably longer, of the order of 8 to 10 times, to run than the parabolic and PORTRAY

models. The formulation of the hyperbolic model, which introduces the time variable, also gives rise to difficulties in determining the converged solution. For the test cases described here the parabolic and PORTRAY models took approximately 30 minutes elapsed time on a SUN 3/50 workstation.

Conclusions

All of the mathematical models tested give a reasonable description of the overall physical effects of waves propagating in the vicinity of a dredged channel. This was certainly good enough to justify their use in comparison of harbour approach schemes. Further calibration of the models, against a physical model or site specific measurements, is recommended if they are to be used for calculation of absolute values.

The PORTRAY model performed better for shorter period waves, and incident directions not along the line of the channel: For longer period waves, and where the waves were directly incident along the channel, the parabolic model gave a good representation, but does require that the grid is aligned in the main wave propagation direction. The combination of these two models appears to encompass most of the important physical features. The hyperbolic model did not appear to offer any significant advantages in terms of accuracy over the parabolic model and PORTRAY in these situations, and its run-times were significantly longer.

These conclusions are based on the comparisons made with the physical model tests described here, but are consistent with the anticipated behaviour inherent with the governing assumptions made for each of the mathematical models. Further work is in progress to examine improvements in the mathematical models' performance when random incident conditions are represented.

Abstract

Observations of pressure fluctuations at the sea floor in 13 m depth are compared to an existing theory for weakly nonlinear surface gravity waves (Hasselmann, 1962). In this depth, free surface waves (obeying the dispersion relation) at sea and swell frequencies (0.05 - 0.3 Hz) are weakly attenuated, but free waves at frequencies higher than about 0.4 Hz do not reach the sea floor. However, nonlinear interactions between (primary) free waves of about the same frequency, propagating in nearly opposing directions, theoretically excite long wavelength, double frequency (secondary) forced waves that are only weakly attenuated at the sea floor. Bottom pressure spectra observed in 13 m depth show an ($O(10^2)$) increase in high frequency (0.35 - 0.6 Hz) forced wave energy levels in only a few hours after a sudden large veering in wind direction. Estimates of the free wave frequency-directional spectrum show a correspondingly rapid change with unidirectional seas when forced wave energy levels are low before the wind veering, and two nearly directionally opposing seas (0.15-0.3 Hz) when forced wave energy levels are high, consistent with the theoretical generation mechanism. The observed forced wave energy levels are in good agreement with theoretical predictions based on the directional spectrum estimates. Estimates of average wave numbers verify that sea and swell obey the dispersion relation, and show that double sea frequency forced waves have longer wavelengths than the interacting free waves, consistent with theory. Observed third order statistics confirm that the double frequency forced waves are coupled to the directionally opposing seas with a phase relationship predicted by theory.

Introduction

Wind generated surface gravity waves can be represented approximately by a linear superposition of statistically independent wavelets obeying the linearized equations (e.g., Kinsman, 1965). Observations presented here concern some of the weak, but interesting, nonlinear properties of natural wind waves. Theories for weakly nonlinear surface gravity waves, based on a perturbation expansion for small wave steepness, have been developed by various authors (Phillips, 1960; Hasselmann, 1962; and others). The lowest order wave

field is a frequency-directional spectrum $E(f, \theta)$ of free linear waves obeying the dispersion relation

$$f = \frac{1}{2\pi} [g |\mathbf{k}| \tanh(|\mathbf{k}| h)]^{1/2} \quad (1)$$

where \mathbf{k} is the vector wave number, h the water depth and g the acceleration of gravity. At the next order, forced (i.e., not obeying Eq. 1) secondary waves are generated in non-resonant triad interactions with two free wave components. Each pair of primary (free) waves, with frequencies and wave numbers (f_1, \mathbf{k}_1) and (f_2, \mathbf{k}_2) , is accompanied by a pair of secondary waves with the sum and difference frequency and wave number $(f_1 \pm f_2, \mathbf{k}_1 \pm \mathbf{k}_2)$. These lowest order nonlinearities theoretically result in weakly nonGaussian statistics and possibly large deviations from the dispersion relation (e.g., Phillips, 1960; Hasselmann et al., 1963). For example, if $E(f, \theta)$ is narrow and unimodal, then the dominant secondary wave contribution to sea surface elevation is due to the interactions of free wave components with nearly equal frequency ($f_1 \approx f_2$) and wave number ($\mathbf{k}_1 \approx \mathbf{k}_2$). The sum interaction yields the familiar $(2f, 2\mathbf{k})$ Stokes forced wave, in phase with the free wave components, that theoretically distorts the sinusoidal linear wave surface to a profile with sharper crests and flatter troughs. The Stokes correction, which in deep water has double the wavelength of a free wave with the same frequency, contributes a positive skewness to sea surface statistics.

At great depth the theoretically expected local nonlinear effects are markedly different than at the sea surface. Surface gravity waves (both free and forced components) are very strongly attenuated at depths below the sea surface that exceed about half their wavelength. Free waves obeying the dispersion relation (Eq. 1) with typical sea and swell frequencies (0.05-0.3 Hz) are therefore confined to the upper 10-300 m of the ocean, as are the Stokes-type $(2f, 2k)$ secondary waves. Forced waves, however, can have very long wavelengths if $\mathbf{k}_1 \approx \pm \mathbf{k}_2$ and penetrate virtually unattenuated to the ocean floor. A long wavelength, double frequency forced wave $(2f, \mathbf{k} \approx 0)$ can be generated by the sum interaction of two free waves of nearly equal frequency travelling in opposing directions ($f_1 \approx f_2, \mathbf{k}_1 \approx -\mathbf{k}_2$, Miche, 1944). This nonlinear effect is believed to cause high frequency sea floor pressure oscillations and microseisms in the deep ocean (e.g., Longuet-Higgins, 1950).

The present study examines the properties of high frequency secondary forced waves in natural wind waves. Array measurements of wave pressure were collected offshore of Chesapeake Bay in a water depth of 13 m. In this depth locally generated seas (0.15-0.3 Hz) are only weakly attenuated at the sea floor while free waves at double sea frequencies (> 0.35 Hz) are very strongly attenuated, so that relatively weak (at the sea surface) double sea frequency forced waves with longer wavelengths are theoretically dominant at the sea floor. The present observations show, in agreement with theory, that long wavelength high frequency forced waves are generated by the sum interactions of seas travelling in nearly opposing directions. The experiment is described in section 2. In section 3, frequency spectra of pressure on the sea floor are presented that show a rapid increase in forced wave energy levels at double sea frequencies after a large veering in local wind direction, as a result of the nonlinear interactions of nearly directionally opposing seas. The observed energy levels of forced waves are consistent with weakly nonlinear theory. In section 4, deviations from the dispersion relation and nonGaussian statistics associated with weakly nonlinear waves are examined with estimates of average wave numbers and third order

statistics of the bottom pressure field. The results are summarized in section 5. A full account of the observations is given in Herbers and Guza (1990 b, c).

Experiment

Arrays of pressure transducers were deployed at the Chesapeake Light Tower, as part of the SAXON (SAR and X-band Ocean Nonlinearities) experiment. The tower is situated on an exposed shoal approximately 30 km offshore of Cape Henry, Virginia, U.S.A.. The water depth at the tower is 13 m with approximately 0.5 m tidal fluctuations. Two arrays were deployed, each consisting of seven capacitance sensing pressure transducers. One of the arrays (dimensions 20 m x 20 m) was mounted on the tower structure at mid-depth and the other array (dimensions 12 m x 12 m) on the seabed (Fig. 1). The primary purpose of the mid-depth array was to provide estimates of the frequency-directional spectrum $E(f, \theta)$ of (free) sea and swell. The bottom array was deployed to measure the secondary pressure

Figure 1. Plan view of mid-depth (6 m below Mean Sea Level) and bottom (13 m below Mean Sea Level) array geometries and analysis coordinate frame. k is the wave number vector and θ is the wave propagation direction. $\theta = 65^\circ$ corresponds to waves arriving from the South.

field. It is better suited for detecting weak high frequency forced waves than the mid-depth array because high frequency free waves are more strongly attenuated at the sea floor than at mid-depth. The bottom array was displaced approximately 24 m East from the center of

the tower (Fig. 1) to reduce tower interference, all bottom sensor locations were accurate to within 5 cm, and the sensors were buried about 10 cm in the sand to reduce flow noise. Data was collected with a 2 Hz sample frequency on a nearly continuous basis from 17 September through 14 October, 1988, spanning a wide range of conditions. Surface elevation data (sampled at 30 Hz) from a surface piercing wire gage, located on the East side of the tower (Fig. 1), was collected intermittently by A. T. Jessup (1989, personal communication). Throughout the experiment the predominantly tidal mean flows, observed at mid-depth and on the bottom, were smaller than about 25 cm/sec and their effect is negligible.

3. Forced Wave Energy and Directionally Opposing Seas

Fig. 2 shows the evolution of the average (over all bottom sensors) bottom pressure frequency spectrum $E_b(f)$ during a 85 hour period, 9 through 13 October 1988. The local wind during this period was highly variable with moderate speeds less than 15 m/sec (Fig.

Figure 2. A 3-dimensional surface of $\log E_b(f)$ from 9 October 20:30 h through 13 October 09:30 h, 1988 (local time) at hourly intervals.

3) and significant wave heights ranged from 0.5 to 1.5 m. The high variability in the bottom pressure spectra in the frequency range of 0.35 - 0.7 Hz is striking. In particular, between $t \approx 49$ and 53 h the energy in this range suddenly increases by more than 2 orders of magnitude and a broad feature develops with its peak at approximately 0.47 Hz (Fig. 4). The present study is focused on this event; Herbers and Guza (1990 b, c) discuss the entire period. These high frequency pressure fluctuations cannot be explained with linear wave theory because of the strong attenuation of high frequency free waves. For example, for a surface gravity wave component with frequency $f = 0.5$ Hz, that obeys the linearized equations, the attenuation of pressure at the sea floor relative to the surface is approximately 10^6 . Sea surface excursions of $O(1$ km) would be needed to generate free 0.5 Hz bottom pressure oscillations with $O(1$ mm) amplitude (approximately the root mean square value of the high frequency pressure fluctuations at $t = 53$ h). Wave staff data and visual observations show significantly smaller seas.

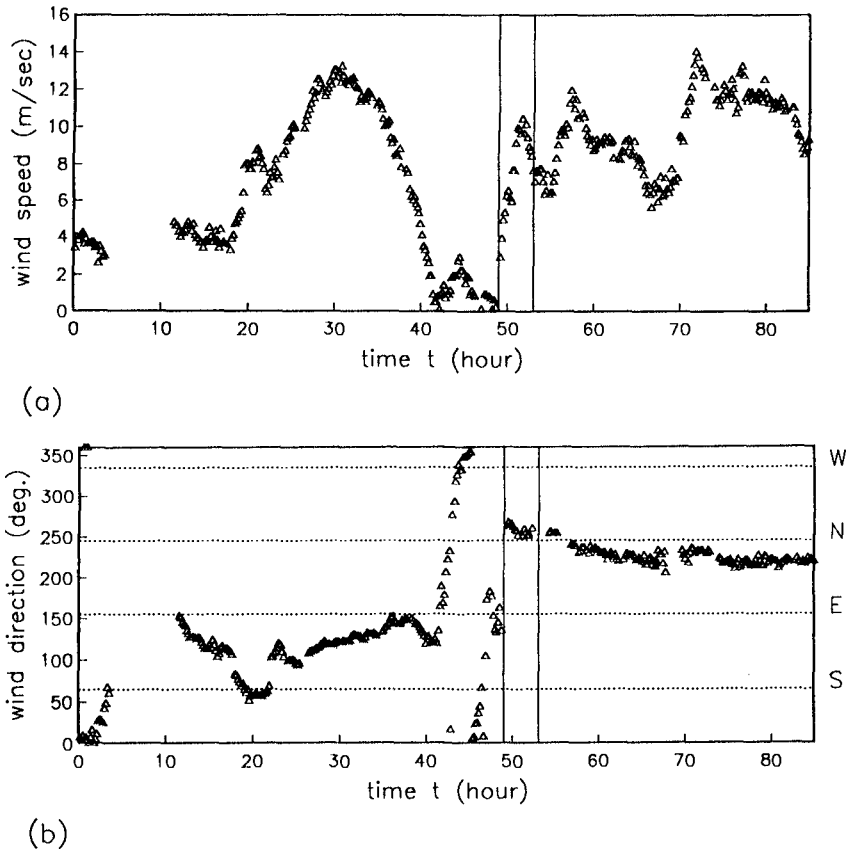

Figure 3. Ten minute averages of wind speed (a) and direction (b) measured 42 m above the sea surface on top of the light tower (edited data provided by A.T. Jessup, personal communication). The vertical lines indicate times selected for detailed analysis.

Between $t = 20$ h and 40 h, the wind was relatively steady in direction from the South-East ($\approx 110^\circ$) with speeds increasing from 4 m/sec to a maximum of 13 m/sec at $t = 30$ h and decreasing to near calm at $t = 40$ h (Fig. 3). During the period $t = 40 - 50$ h, the wind remained calm, followed by a rapid increase to about 10 m/sec at $t = 50$ h, with a direction from the North ($\approx 260^\circ$) nearly opposing the wind direction 20 hours previous (Fig. 3). The dramatic increase in high frequency energy levels between $t = 49$ h and $t = 53$ h (Fig. 4) is related to this change in local winds, but the nonlinear interactions are more complicated than the familiar Stokes second harmonic corrections. In a narrow band surface elevation frequency-directional spectrum $E_s(f, \theta)$ with peak frequency f_p and peak direction θ_p , generation of high frequency secondary waves on the sea surface is dominated by the ("self-self") interactions of energetic components near the spectral peak ($f_1 \approx f_2 \approx f_p$, $\theta_1 \approx \theta_2 \approx \theta_p$). However, these $(2f_p, \theta_p)$ second harmonics have double the wave number k_p of the free wave components and are very strongly attenuated at the sea floor if $k_p h \gg 1$. For the present observations of local seas with periods of 4 to 5 sec in 13 m depth, $k_p h \approx 3$. Stokes self-self interactions in this relatively deep water are both weak at the sea surface (i.e., not amplified by near-resonance) and very strongly attenuated at the sea floor. Longer wavelength forced waves that are generated by the interactions of seas and swell propagating in (nearly) opposing directions are expected to dominate the secondary bottom pressure spectrum.

Figure 4. Observed (solid, an average of all bottom sensors) and predicted (dotted, at double sea frequencies 0.3 - 0.5 Hz) bottom pressure frequency spectra, before and after a large increase in forced wave energy levels.

To verify that the observed forced waves are generated by directionally opposing seas, frequency-directional spectra $E_s(f, \theta)$ of free waves (i.e., obeying the dispersion relation, Eq. 1) were estimated from the mid-depth pressure array data. $E_s(f, \theta)$ is expressed as

$$E_s(f, \theta) = E_s(f) S(\theta; f) \tag{2}$$

where $E_s(f)$ is the surface elevation frequency spectrum and $S(\theta; f)$ is the directional distribution at frequency f . On a frequency band by frequency band basis the "smoothest" $S(\theta)$ "consistent" with the array data is obtained by minimizing a roughness measure of the form

$$\int d\theta \left[\frac{d^2 S(\theta)}{d\theta^2} \right]^2$$

subject to the constraint that $S(\theta)$ is a nonnegative function with unit integral that fits the array cross-spectra within a 75 % confidence level (Herbers and Guza, 1990a). Fig. 5 shows estimates of $E_s(f, \theta)$, obtained from the mid-depth array cross-spectra (200 degrees of freedom), at $t = 49$ and 53 h in the frequency range 0.05 - 0.3 Hz, where the energy spectra are energetic and assumed to be dominated by free waves obeying the dispersion relation. This assumption is verified in section 4. At $t = 49$ h, when forced wave energy levels are low, the $E_s(f, \theta)$ estimate shows nearly unidirectional seas from the South with peak frequency 0.18 Hz (Fig. 5a). Four hours later (Fig. 5b), more energetic, slightly higher frequency ($f_p \approx 0.26$ Hz) locally generated seas arriving from the North are also present in a bimodal $E_s(f, \theta)$. The sudden, nearly 180° veering in wind direction from South to North between approximately $t = 40$ h and $t = 50$ h is consistent with the observed change in $E_s(f, \theta)$. Predictions of the forced wave bottom pressure spectrum in the frequency range 0.3 - 0.5 Hz, based on the two $E_s(f, \theta)$ estimates (Fig. 5) and weakly nonlinear theory (Hasselmann, 1962; see Herbers and Guza, 1990b, for the details of the calculations), are compared to the

Figure 5. Estimates of the surface elevation frequency-directional spectrum (units $\text{cm}^2/\text{Hz}^\circ$) at $t = 49$ h (a) and 53 h (b). Solid lines (b) indicate bispectral peak frequencies (Fig. 8).

observed bottom pressure spectra (an average of all bottom sensors) in Fig. 4. At frequencies below 0.35 Hz the observed pressure spectrum shows increasingly more power than the forced wave prediction because free waves reach the sea floor. In the frequency range 0.35 - 0.5 Hz, predicted forced wave spectra show the dramatic increase in forced wave energy after the wind veered, due to the interactions of opposing seas, and are in good agreement with the observed forced wave energy levels. However, a change in local wind conditions is not the only mechanism for generation of directionally opposing seas and associated long wavelength forced waves. The double sea frequency forced wave peaks at $t \approx 32$ h and $t \approx 80$ h (Fig. 2) are generated by a similar change in the directional wave spectrum, but the bi-directional seas are the result of the arrival of nonlocally generated wind waves rather than a veering wind (Herbers and Guza, 1990b).

Fig. 6 shows the frequency spectra of all pressure sensors in the mid-depth and bottom array, and a surface elevation spectrum computed from surface piercing wire gage data (provided by A.T. Jessup, personal communication) at $t = 53$ h. The observed vertical decay of sea and swell (0.05 - 0.3 Hz) is consistent with the dispersion relation for free waves (Herbers and Guza, 1990b). The relative decay between mid-depth and bottom pressure at the double sea frequency forced wave peak is not only much weaker than the theoretical value for linear waves but also weaker than the decay of the interacting seas, consistent with the long wavelengths of forced waves generated by opposing seas. As expected from theory, free wind generated waves dominate surface elevation at high frequencies but are very strongly attenuated below about mid-depth (at 0.5 Hz the predicted power decay of free waves at the mid-depth array, relative to the surface, is 10^{-5}). Forced

waves smaller in amplitude, but with longer wavelengths, are only weakly attenuated and dominate the high frequency pressure field in the lower part of the water column.

4. Average Wave Numbers and Third Order Statistics

Secondary forced wave components cause nonGaussian statistics and deviations from the dispersion relation. Third order statistics of weakly nonlinear waves are nonzero owing to a statistically consistent phase relationship between free and forced wave components. The resulting nonzero skewness of the bottom orbital velocity field may be important to sediment transport on the shelf. The deviations of forced waves from the dispersion relation can be very large and cause errors in the interpretation of bottom pressure measurements which is often based on the linear dispersion relationship. This is true in particular at frequencies high enough that free waves are strongly attenuated and forced waves contribute significantly to the spectral density. In this section deviations from the dispersion relation and statistical coupling of free and forced waves are examined in the bottom pressure data at $t = 53$ h with high forced wave energy levels (Fig. 4).

A bulk averaged wave number $k_{rms}(f)$ defined as

$$k_{rms}(f)^2 \equiv \int dk |k|^2 E_b(f,k) / \int dk E_b(f,k) \quad (3)$$

Figure 7. A $k_{rms}(f)$ estimate at $t = 53$ h. The dashed curve is the surface gravity wave dispersion relation.

with $E_b(f, k)$ the bottom pressure wave number-frequency spectrum, can be estimated from a compact array of bottom pressure sensors with spacings L_{ij} small compared to the surface wavelength. The details of the technique, which utilizes a linear combination of the cross-spectral elements, are described in Herbers and Guza (1990c). Fig. 7 shows a $k_{rms}(f)$ estimate at $t = 53$ h. In the frequency range 0.05 - 0.3 Hz, the wave number estimate agrees with the linear dispersion relation within a few percent, consistent with the assumption (used when estimating $E_s(f, \theta)$, Eq. 2) that this part of the spectrum is dominated by free sea and swell. In the spectral valley between the wind wave and double frequency peaks $k_{rms}(f)$ drops sharply and reaches a minimum near the double sea frequency peak ($f \approx 0.5$ Hz). In fact the observed forced waves (that do not obey the dispersion relation) have longer wave lengths than the free waves forcing them, qualitatively consistent with the theory for forced waves excited by the observed directionally opposing seas (Fig. 5).

To examine statistical coupling between the directionally opposing sea peaks and the double frequency forced wave peak, bispectra (Hasselmann et al., 1963; Elgar and Guza, 1985; and others) were computed from the bottom pressure data. Fig. 8 shows an estimate of the normalized bispectrum $b(f_1, f_2)$

$$b(f_1, f_2) \equiv \frac{B(f_1, f_2)}{[E_b(f_1) E_b(f_2) E_b(f_1 + f_2)]^{1/2}} \quad (4)$$

Figure 8. A $b(f_1, f_2)$ estimate (spectra averaged over all bottom sensors) at $t = 53$ h. Contours at levels -6, -5, -4, -3, -2, 2, 3, 4, 5, and 6 $\text{Hz}^{-1/2}$ are shown.

with the bispectrum $B(f_1, f_2)$ defined as the expected value of the third order moment of the bottom pressure Fourier-Stieltjes transform $dZ(f)$:

$$B(f_1, f_2) df_1 df_2 \equiv 2 E\{dZ(f_1) dZ(f_2) dZ(-f_1-f_2)\} \quad (5)$$

The bispectrum vanishes for the wind generated Gaussian free waves and statistically significant deviations of $b(f_1, f_2)$ from zero can be interpreted as nonlinearity of the bottom pressure field associated with the presence of forced waves. Theoretically, the contributions of triad interactions between f_1 (free), f_2 (free) and $f_1 + f_2$ (forced) wave components to $b(f_1, f_2)$ are real (Hasselmann et al., 1963), which means that the bottom pressure field is skewed (i.e., different crest and trough profiles) but statistically symmetric about a vertical plane (i.e., wave crests are not pitched forward or backward). In 13 m depth, the bispectrum at double sea frequencies is theoretically negative and these long forced waves may contribute to a negative skewness of sea floor pressure and orbital velocity fields, rather than the positive skewness of Stokes waves (Herbers and Guza, 1990b). Fig. 8 shows that the observed $b(f_1, f_2)$ is real (deviations of the imaginary part from zero are statistically insignificant), negative, and has a large peak centered at $f_1 \approx 0.26$ Hz, $f_2 \approx 0.18$ Hz. These frequencies are very close to the peak frequencies of the two directionally opposing wind wave systems (Fig. 5b). The observed bispectrum is thus consistent with the theoretical phase relationship between directionally opposing primary waves and secondary long waves (Herbers and Guza, 1990b). Integrals of $B(f_1, f_2)$ along constant sum frequency $f_1 + f_2$ (not shown here, discussed in Herbers and Guza, 1990c) show that nearly all of the wave energy in the range 0.4 - 0.5 Hz is statistically coupled to the two directionally opposing seas. The bispectral estimate thus provides an independent verification of the hypothesis that the observed forced waves are generated by directionally opposing seas.

5. Summary and Conclusions

To examine local nonlinear effects on natural wind generated surface gravity waves, arrays of pressure transducers were deployed at mid-depth and on the sea floor in 13 m deep water, approximately 30 km offshore of Cape Henry, Virginia. Bottom pressure data show enhanced energy at double sea frequencies that appears to be nonlinearly driven by local seas. These nonlinear bottom pressure observations are explained using an existing theory for weakly nonlinear waves (e.g., Hasselmann, 1962). The perturbation solution to second order in wave steepness consists of (primary) free waves obeying the dispersion relation and (secondary) forced waves that do not obey the dispersion relation, generated by interactions between pairs of free waves. Free and forced wave components are both strongly attenuated at depths exceeding about half a wavelength, but forced waves excited by the interactions of directionally opposing free waves of nearly equal frequency have much longer wavelengths than free waves of the same frequency, and thus penetrate to greater depths. In narrow band directional spectra the dominant nonlinear interactions at the sea surface are between waves near the spectral peak having nearly equal frequency and propagation direction. However, in 13 m depth the bottom pressure energy levels of "Stokes harmonics" at double sea frequencies are strongly attenuated, approximately 10^4 - 10^6 weaker than the energy levels of relatively unattenuated forced waves generated by two narrow seas of equal frequency and energy, travelling in nearly opposing directions. Forced wave energy levels on the sea floor in 13 m depth at double sea frequencies are thus theoretically expected to be weak in unidirectional seas and increase dramatically when directionally opposing seas are present.

After the local wind veered, the observed bottom pressure spectra show a large ($O(10^2)$) increase in forced wave energy levels over only a few hours. Estimates of the frequency-directional spectrum of free sea and swell were extracted from the mid-depth array data, before and after this large increase in forced wave energy levels. The estimates show nearly unidirectional free waves when forced wave energy levels were low, and seas travelling in opposing directions when forced wave energy levels were high. Theoretical predictions of forced wave energy spectra, obtained using the estimated free wave directional spectra, confirm that the observed forced waves are generated by the interactions of 0.15 - 0.3 Hz seas travelling in much different directions. The observed large fluctuations in forced wave energy levels are in good agreement with the theoretical predictions. Estimates of average wave numbers confirm that sea and swell obey the dispersion relation and double sea frequency forced waves have longer wavelengths than the interacting seas. Observed third order statistics show nonlinear coupling between directionally opposing seas and forced waves with a phase relationship predicted by theory.

Acknowledgments

This work is a result of research sponsored by the Office of Naval Research, under grants N00014-89-J-3097 and N00014-86-K-0789. The staff of the Center for Coastal Studies (Scripps Institution of Oceanography), led by R. L. Lowe, W. A. Boyd, and M. C. Clifton, installed and maintained the arrays and data acquisition systems. We thank A. T. Jessup for generously providing wind and sea surface elevation data, and S. Elgar for helpful discussions and sharing his bispectra code with us.

CHAPTER 48

APPLICABILITY OF A NEW HYBRID PARAMETRIC WAVE PREDICTION MODEL

Yoshio Hatada¹ and Masataka Yamaguchi²

ABSTRACT

DOLPHIN-I is a new hybrid parametric deep water wave prediction model developed by the authors. This paper examines the applicability of DOLPHIN-I, on the basis of the comparison of the computation with the data of significant waves obtained in five sea areas with different horizontal scales around Japan during monsoons and typhoons. In particular, the wave data in Osaka Bay includes frequency and directional spectra. It is verified that the model practicality is excellent, because it reproduces well the wave data observed in any concerned sea area.

1. INTRODUCTION

In the past 10 years, a number of hybrid parametric wave prediction models such as HYP A, TOHOKU, GONO (SWAMP, 1985), HYPAS (Günther et al., 1984) and Graber & Madsen's model (1988) have been proposed. The advantages of these models which imply the effects of wind input, wave-wave interaction and wave breaking in a parametric representation, are the capability to save computer processing time, as compared with the discrete spectral model, and to give reasonable estimation of wave growth under a gradually-varying simple wind field.

However, the degree of freedom in the models is not enough to properly resolve the directional characteristics of a confused wave field in the rapidly-varying wind field of a typhoon and in the sea area enclosed by complicated shorelines, because wave direction is approxi-

1 Research Assistant, Dept. of Ocean Eng., Ehime Univ., Bunkyocho 3, Matsuyama 790, Ehime Pref., Japan

2 Prof., Dept. of Ocean Eng., Ehime Univ., Bunkyocho 3, Matsuyama 790, Ehime Pref., Japan

mated by only one parameter such as a mean wave direction averaged with respect to frequency and direction.

Yamaguchi et al.(1988) developed a new directionally-decoupled hybrid parametric wave prediction model in deep water, hereafter referred to as DOLPHIN-I, in order to improve this situation. DOLPHIN-I assumes that the directional energy of wind-sea defined separately for each direction grows according to a parametric equation derived from an analysis of observed wave growth data under the assumption of ideal generation conditions and that each swell component propagates independently, undergoing energy dissipation. It is formulated so as to make it possible to estimate the time variation of directional spectra at a prescribed location through the computation along the straight wave rays focusing at the location. The computed results for test cases given in SWAMP(1985) showed physically sound behavior in each case (Yamaguchi et al., 1988).

The aim of this paper is to examine the applicability of DOLPHIN-I, based on the comparison between computation and observation. First, a brief explanation of the model is provided from the view points of model formulation and computation method. Wave hindcast is conducted in five sea areas with different horizontal scales during monsoons and typhoons, and wave observation data used in the comparison include not only significant waves but also frequency and directional spectra.

2. OUTLINE OF DOLPHIN-I

(1) Model Formulation

The radiative transfer equation is given as

$$\frac{\partial E(f, \theta)}{\partial t} + C_g(f) \cos \theta \frac{\partial E(f, \theta)}{\partial x} + C_g(f) \sin \theta \frac{\partial E(f, \theta)}{\partial y} = G(f, \theta) \quad (1)$$

where $E(f, \theta)$ is the directional spectrum, f the frequency, θ the direction, $C_g(f) (= g/4\pi f)$ the group velocity of a wave component, g the acceleration of gravity and $G(f, \theta)$ the source function modeling inflow and outflow of wave energy. When a straight propagation path of a wave component is selected such that $dx/ds = \cos \theta$ and $dy/ds = \sin \theta$, Eq.(1) is rewritten as

$$\frac{\partial E(f, \theta)}{\partial t} + \frac{\partial C_g(f) E(f, \theta)}{\partial s} = G(f, \theta) \quad (2)$$

The integration of Eq. (2) over frequency yields the following equation which describes the evolution of directional energy density of wind waves $E(\theta)$

$$\left. \begin{aligned} \frac{\partial E(\theta)}{\partial t} + \frac{\partial \bar{C}_g E(\theta)}{\partial s} &= \int_0^\infty G(f, \theta) df \\ E(\theta) &= \int_0^\infty E(f, \theta) df, \quad \bar{C}_g = \int_0^\infty C_g(f) E(f, \theta) df / E(\theta) \end{aligned} \right\} \quad (3)$$

where \bar{C}_g is the frequency-averaged group velocity.

We assume that wind waves grow under the ideal generation condition, in which case directional spectrum is expressed as a product of the JONSWAP spectrum (Hasselmann et al., 1973) and $\cos^4\theta$ -type angular spreading function and that evolutions of spectral parameters such as saturation range constant α , dimensionless peak frequency ν , and peak enhancement factor γ are governed by the energy-dependent relations which are derived from the empirical expressions of Mitsuyasu et al. (1980). Then, the frequency-averaged group velocity and source function in Eq. (3) can be determined, and evolution of the directional energy of wind-sea $E^*(\theta)$ is described as

$$\left. \begin{aligned} \frac{\partial E^*(\theta)}{\partial t} + \frac{\partial}{\partial s} [C_g(f_m) f(\gamma) E^*(\theta)] &= 2.851 \times 10^{-4} \left\{ \frac{E^*(\theta)}{D^*(\theta)} \right\}^{0.3273} \cdot \exp \left[-0.0875 \right. \\ &\cdot \left. \left\{ \frac{E^*(\theta) |D^*(\theta)|}{1.43 \times 10^3 - E^*(\theta) |D^*(\theta)|} \right\}^{0.8542} \right] \cdot \frac{u_*^3}{g} \cos(\theta - \theta_w) D^*(\theta) \\ D^*(\theta) &= \begin{cases} (8/3 \pi) \cos^4(\theta - \theta_w); & |\theta - \theta_w| < \pi/2 \\ 0 & ; |\theta - \theta_w| \geq \pi/2 \end{cases} \\ f(\gamma) &= 0.8572 \gamma^{0.0426} \end{aligned} \right\} \quad (4)$$

where f_m is the peak frequency, u_* the friction velocity, θ_w the wind direction and $D(\theta)$ the angular spreading function. The asterisk means the ideal generation condition.

Propagation of a swell component is formulated by the above-mentioned one-dimensional radiative transfer equation with an energy dissipation term. It is given as

$$\frac{\partial E_s(f, \theta)}{\partial t} + \frac{\partial C_g(f) E_s(f, \theta)}{\partial s} = \begin{cases} -0.25(u_*|C|)^2 f E_s(f, \theta); & |\theta - \theta_w| < \pi/2 \\ -\beta_M(f, \theta) E_s(f, \theta) & ; |\theta - \theta_w| \geq \pi/2 \end{cases} \quad (5)$$

where $E_s(f, \theta)$ is the directional spectrum of a swell component, $C (=g/2\pi f)$ the wave celerity, and β_M the damping rate due to opposing wind.

In the general sea state, directional spectra of sea waves $E(f, \theta)$ are divided into frequency-integrated directional energy of wind-sea $E_s(\theta)$ and directional spectra of swell components $E_s(f, \theta)$. The directional energy of wind-sea is defined by

$$E_s(\theta) = \int_{\partial f_{m0}}^\infty E(f, \theta) df \quad (6)$$

where $f_{m\theta}$ is the peak frequency of directional spectra for each direction and $\delta(=0.6)$ the correction factor used for the separation of wind-sea and swell. Setting $E_\delta(\theta)$ equal to $E^*(\theta)$ at the growth stage of wind-sea, evolution of wind-sea energy for each direction is computed from Eq. (4) and then total wave energy parameter of wind-sea $\tilde{\epsilon}^*$ is evaluated by $\tilde{\epsilon}^* = E^*(\theta)/D^*(\theta)$. Directional spectra of wind-sea $E_w(f, \theta)$ are established using both the JONSWAP spectrum with the spectral parameters related to dimensionless wave energy and the angular spreading function $D^*(\theta)$. On the other hand, change of directional spectrum for each swell component $E_s(f, \theta)$ is obtained from Eq. (5).

Directional spectrum in general sea state at the same place is evaluated by simply summing up the directional spectral component for the same frequency and direction of both wind sea and swell as

$$E(f, \theta) = E_w(f, \theta) + E_s(f, \theta) \tag{7}$$

The wave statistics are obtained by the numerical integration of directional spectra over wave direction and frequency using the relations such as

$$\left. \begin{aligned} E(f) &= \int_0^\pi E(f, \theta) d\theta, \quad \epsilon = \int_0^\infty E(f) df, \quad H_{1/3} = 4\sqrt{\epsilon} \\ T_{1/3} &= 1.20\sqrt{\epsilon / \int_0^\infty f^2 E(f) df}, \quad \bar{\theta} = \tan^{-1} \left\{ \frac{\int_0^\infty \int_0^\pi E(f, \theta) \sin \theta d\theta df}{\int_0^\infty \int_0^\pi E(f, \theta) \cos \theta d\theta df} \right\} \end{aligned} \right\} \tag{8}$$

where $E(f)$ is the frequency spectrum, ϵ the total wave energy, $H_{1/3}$ the significant wave height, $T_{1/3}$ the significant wave period, and $\bar{\theta}$ the mean wave direction.

(2) Method of Numerical Computation

DOLPHIN-I estimates the time variation of directional spectra of sea waves at a prescribed point by following growth, decay, and propagation of sea waves along a wave ray radiating separately from the point for each direction, as shown in Fig. 1.

The evolution equation of directional energy, Eq. (4) is solved by a finite difference method of the two-step Lax-Wendroff scheme. It is given as

$$\left. \begin{aligned} e_{i+1/2}^{n+1/2} &= \frac{e_i^n + e_{i+1}^n}{2} - \frac{\Delta t}{2 \Delta s} (K_{i+1}^n - K_i^n) + Q_{i+1/2}^n \frac{\Delta t}{2} \\ e_i^{n+1} &= e_i^n - \frac{\Delta t}{\Delta s} (K_{i+1/2}^{n+1/2} - K_{i-1/2}^{n+1/2}) + Q_i^{n+1/2} \Delta t \end{aligned} \right\} \tag{9}$$

Fig. 1 Wave ray and computation of propagation.

where $e = E^*(\theta)$, $K = \overline{C_g} E^*(\theta)$, Q is the source term in Eq.(4), n the index of the time step, i the grid number on a wave ray, and Δs the grid spacing on a wave ray. The value of e is specified in a parametric manner at the upwave open boundary and it is set at zero in the case of the land boundary. At the downwave boundary, directional energy is freely transmitted, and the upwind difference scheme indicated by

$$e_N^{n+1} = e_N^n - \frac{\Delta t}{\Delta s} (K_N^n - K_{N-1}^n) + Q_N^n \Delta t \tag{10}$$

is used, because Eq. (9) is not applicable, where N is the grid number at the boundary. It should be noted that one grid point is added to the grid system for each direction in order to keep the accuracy of computation at the hindcast point.

The computation of the radiative transfer equation, Eq. (5), makes use of a fractional time step method in which the propagation equation and the forcing equation are solved alternatively. The propagation step uses a piecewise ray method with the Lagrange third order spatial interpolation formula expressed as

$$\left. \begin{aligned} E_s(f, \theta) &= a_1 E_{s_{i-2}}^n(f, \theta) + a_2 E_{s_{i-1}}^n(f, \theta) + a_3 E_{s_i}^n(f, \theta) + a_4 E_{s_{i+1}}^n(f, \theta) \\ a_1 &= -(r-2)(r-1)r/6, \quad a_2 = (r-2)(r-1)(r+1)/2, \\ a_3 &= -(r-2)r(r+1)/2, \quad a_4 = (r-1)r(r+1)/6, \quad r = 1 - C_d(f)\Delta t/\Delta s \end{aligned} \right\} \tag{11}$$

At the grid point next to the upwave boundary and at the downwave boundary, the interpolation formulas with the first and second order accuracy

$$\left. \begin{aligned} E_s(f, \theta) &= (1-r)E_{s_i}^n(f, \theta) + rE_{s_{i+1}}^n(f, \theta) \\ E_s(f, \theta) &= a'_1 E_{s_{i-2}}^n(f, \theta) + a'_2 E_{s_{i-1}}^n(f, \theta) + a'_3 E_{s_i}^n(f, \theta) \\ a'_1 &= (r-1)r/2, \quad a'_2 = (1-r)(1+r), \quad a'_3 = r(r+1)/2 \end{aligned} \right\} \tag{12}$$

are applied respectively as well as in the above-mentioned case. The computation of the forcing step is conducted with the analytical solution given by

$$\left. \begin{aligned} E_s^{n+1}(f, \theta) &= E_s(f, \theta) \exp\{-0.25(u_*^2/C)^2 f \Delta t\} \quad ; \quad |\theta - \theta_w| < \pi/2 \\ E_s^{n+1}(f, \theta) &= E_s(f, \theta) \exp(-\beta_w \Delta t) \quad ; \quad |\theta - \theta_w| \geq \pi/2 \end{aligned} \right\} \tag{13}$$

3. APPLICABILITY OF DOLPHIN-I

(1) Conditions in Wave Hindcast

As shown in Fig. 2, wave hindcast is conducted in the five sea areas with different horizontal scales: Lake Biwa with an extension of 15 to 30 km, Osaka Bay and the Kii Channel with an extension of 30 to 100 km, the western part of the Seto Inland Sea with an extension of 150 km, the Japan Sea with an extension of 800 to 1300 km, and the Northwest Pacific Ocean with an extension of more than 2000 km. In the Pacific Ocean, typhoon-generated waves are hindcast, in which case wind distribution is

estimated by a simple parametric typhoon model. In the other sea areas, waves associated with monsoons are computed, in which case evaluation of wind distribution over the sea is based on a spatial interpolation method of the measured wind data or a weather map analysis.

Table 1 is the computational conditions used in wave hindcast on each sea area. The directional range of -180° to 180° , number of directional data N_θ of 37 and directional increment $\Delta\theta$ of 10° are the same in all cases.

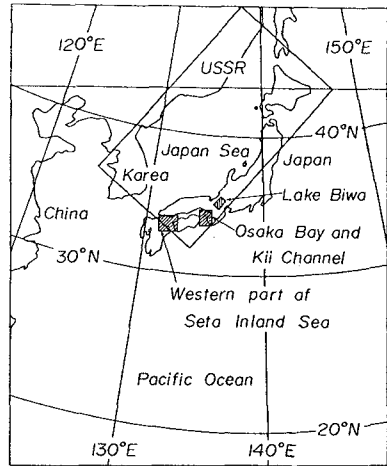

Fig. 2 Five sea areas with different horizontal scales used in wave hindcast.

Wind velocity at the height of 10 m over sea level U_{10} in each sea area is estimated with the method given in Table 1. Friction velocity u_* in DOLPHIN-I is computed from U_{10} by use of a modified form of Mitsuyasus's empirical formula (1984). It is written as

$$C_d = (u_* / U_{10})^2 = \begin{cases} (0.581 + 0.063 U_{10}) \times 10^{-3} & ; U_{10} \geq 10 \text{ m/s} \\ 1.211 \times 10^{-3} & ; U_{10} < 10 \text{ m/s} \end{cases} \quad (14)$$

where C_d is the drag coefficient of the sea surface. Wind characteristics at grid points on each wave ray are evaluated every 30 minutes through linear interpolations with respect to time and space of wind data given every 1 hour at the rectangular grid points.

Table 1 Numerical conditions used in wave hindcast.

	Lake Biwa	Osaka Bay & Kii Chan.	Seto Inland Sea	Japan Sea	Pacific Ocean
MxN	20x15	36x28	30x35	25x44	43x43
$\Delta x = \Delta y$ km	2.5	3	5	40	80
Δs km	2.5	3	5	40	80
Δt min	7.5	6	10	30	60
f_{\min} Hz	0.176	0.1	0.1	0.05	0.04
f_{\max} Hz	2	1.5	1.5	1	1
N_f	22	23	23	24	30
method of wind estimation	interpolation of measured winds	ditto	ditto	weather map analysis	typhoon model

M, N: number of grids in x and y direction, Δx , Δy : grid spacing
 Δs : grid spacing on a ray, Δt : time increment, N_f : number of frequency
 f_{\min} : minimum frequency, f_{\max} : maximum frequency

In the hindcast on the sea areas, except for the Pacific Ocean, land boundary condition in which case the directional spectrum is zero is imposed. On the other hand, directional spectra computed by a product of JON-SWAP-type frequency spectrum referred to as the Ross hurricane model(1976) and $\cos^4\theta$ -type angular spreading function are given at the grid points corresponding to the open boundary of the Pacific Ocean area, in which case input data are local wind characteristics and distance between the concerned grid point and the position of the typhoon center.

In order to initiate DOLPHIN-I, which does not have any term for initial generation of wind waves, directional spectra computed from the before-mentioned model under the conditions of $H_{1/3} = 0.1$ m and $u_* = 0.12$ m/s are provided as an initial condition.

(2) Wave Hindcast in Lake Biwa

Fig. 3 shows the grid system with spacing of 2.5 km placed over Lake Biwa. During winter monsoons, strong winds of more than 10 m/s continue to blow over the lake for two or three days with repetitions of gradual increase and decrease of wind velocity, and the resulting wind fields are quasi-homogeneous and quasi-steady. The wind distribution is obtained by linear interpolation of the wind data measured at three points(B, C and D) with respect to the y direction, in which case uniformity of the wind field in the x direction is assumed.

Fig. 3 Grid system used in Lake Biwa.

Fig. 4 indicates the comparison between time variations of significant wave heights and

Fig. 4 Comparison between the computed and observed significant waves in Lake Biwa.

mean wave periods observed and hindcast at Hikone-Aisei point, where T_z is the mean period defined by the zero and second moments of frequency spectra, as is indicated in Eq. (10). This is typical of wave variations occurring during seasonal winds in Lake Biwa. The figure shows excellent agreement between the computation and the measurement of significant wave height variation, but hindcast mean periods are slightly greater than the observed results. The reason is that the formulation of DOLPHIN-I is based on Mitsuyasus's empirical relation between spectral parameters and dimensionless fetch, which gives smaller estimation than spectral parameters obtained from the analysis of wave data in Lake Biwa. So, improvement of the model applicability to wave evaluation in Lake Biwa is possible by changing the expressions of spectral parameters.

(3) Wave Hindcast in Osaka Bay and the Kii Channel

Fig. 5 is the grid system with a spacing of 5 km used in wave hindcast, in which small circles are the wind observation stations deployed around the concerned sea area. Wind distribution over the area every 1 hour is estimated from the application of a linear interpolation formula to measured wind data on each of the triangular meshes made by connecting the wind observation stations together (Yamaguchi et al., 1981).

Fig. 6 is the comparison between the computation and the observation for time variation of significant waves at the MT station in Osaka Bay during a strong storm brought about with a typical pressure pattern in the winter of Japan. Wave heights show rapid growth to over 2 m high because of the duration of strong winds of maximum 20 m/s with the direction of SW to W and then they reduce to about 1 m high with a change into moderate winds of 10 m/s or so with the direction of WNW, while wave periods of about 4 s do not vary so much as wave heights. DOLPHIN-I reproduces well the observed time variation of wave heights, but gives a slight overestimation of that

Fig. 5 Grid system used in Osaka Bay and the Kii Channel.

of wave periods.

Another comparison of the time variation of significant waves at the MT station is indicated in Fig. 7. Strong stormy winds during the period of wave hindcast were brought about by a developing low system which proceeded easterly over the Japan Sea. DOLPHIN-I again results in good resolution for the observed time variation of significant waves associated with strong winds whose velocity increases rapidly and then decreases with change of the wind direction from SW to NW. But in detail, DOLPHIN-I tends to give a slight underestimation before the peak period of the storm.

Fig. 8 is the comparison between the computation and the observation for frequency spectra and directional spectra at the MT station. DOLPHIN-I behaves well even for reproduction of the observed wave spectra, but the directional spectra in measurement have a smoother distribution than those in computation, because the directional spectra are evaluated with the Fourier series method of poor directional resolution from current records of the three components. A slight difference in the dominant wave direction in directional spectrum is also found because of possible errors in orientation of the instrument and variability of the measured wind direction.

Fig. 6 Comparison between the computed and observed significant waves at the MT station in Osaka Bay (1).

Fig. 7 Comparison between the computed and observed significant waves at the MT station in Osaka Bay (2).

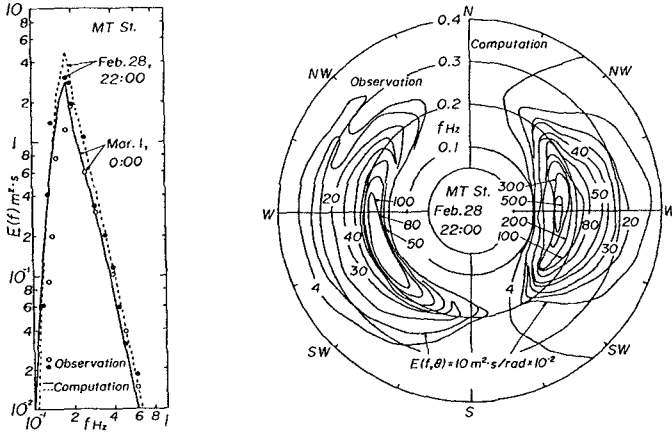

Fig. 8 Comparison of the computed and observed frequency spectra and directional spectra at the MT station in Osaka Bay.

(4) Wave Hindcast in the Western Part of the Seto Inland Sea

Wave hindcast in this sea area is conducted for the period of seasonal winds on the grid system given in Fig. 9, in which case estimation of wind distribution is based on a linear interpolation of measured wind data on triangular elements as well as the case for Osaka Bay. The seasonal winds occurred with the passage of twin low pressure systems over the Japan Sea and the resulting moderately strong winds of over 10 m/s with the direction of WNW to NW continued to blow over the sea area.

Fig. 10 is a simultaneous plot of the time variations of the significant waves at Kanda and Iyo obtained from the computation and the observation. At Kanda with longer fetch for predominant wind direction,

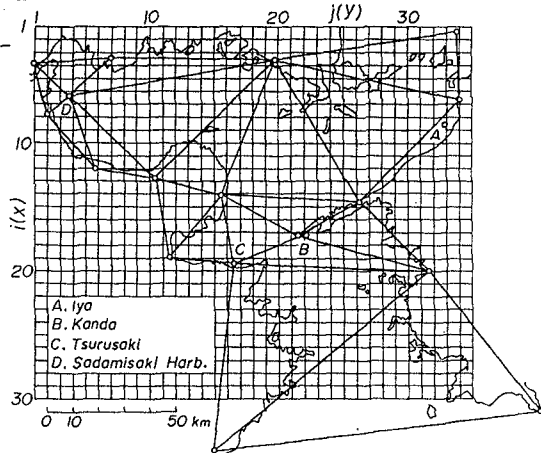

Fig. 9 Grid system used in the western part of the Seto Inland Sea.

correspondence of the computation with the observation is excellent through all periods of the storm, and reasonable agreement between them is also achieved at Iyo with longer fetch, though the observed results are limited in a short period under high wave conditions. The reason why the observed wave periods are slightly greater than the computed ones may be due to the fact that the observation was made with a pressure-type wave gauge.

Fig. 10 Comparison between the computed and observed significant waves at Iyo and Kanda.

(5) Wave Hindcast in the Japan Sea

Fig. 10 is the grid system with spacing of 40 km used in wave hindcast on the Japan Sea. The winter storm of interest was generated by a low system whose time history was that two lows, one proceeding northeasterly along the Japan Sea and the other similarly along the Pacific Ocean side of the Japanese coast, came together over the eastern sea area of north Japan and the central pressure lowered to 970 mb at the severest period. Wind distribution over the area is given by the method (Yamaguchi et al., 1984) which estimates gradient winds by approximating curvature of the isobar line and pressure gradient with a spline function and then converts them to winds over the sea, multiplying a constant coefficient (=0.67) by gradient wind velocity and rotating gradient wind direction by 17° counter-clockwise.

The computed and observed time variations of significant waves at

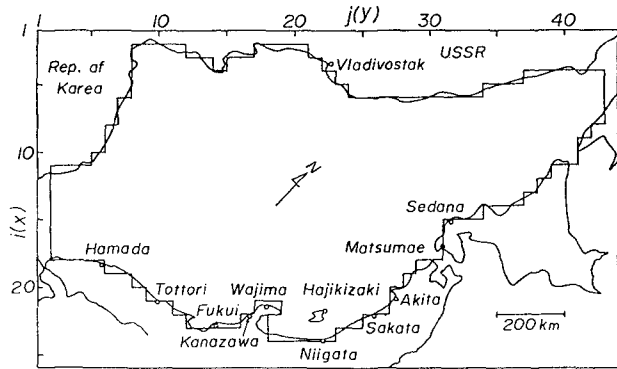

Fig. 11 Grid system used in the Japan Sea.

Wajima with a water depth of 50 m and Tottori with a water depth of 30 m are compared in Fig. 12. The model takes into account the effect of water depth on waves in an expedient way by multiplying the frequency spectrum computed at the hindcast point by a correction factor of $\Phi(kh)=\tanh^2 kh$, where k is the wave number and h the water depth. DOLPHIN-I with a correction for water depth effect predicts the variation of waves with the change of winds in a general sense better than the original DOLPHIN-I, but the degree of agreement between the computation and the observation is not as accurate as in the above-mentioned cases in which wind distribution is estimated with interpolation of measured wind data, because of less accuracy of hindcast winds. In particular, the computed time variation of waves at Wajima is about 4 hours behind the observed one, reflecting the time lag between the computed winds and the measured winds.

Fig. 12 Comparison between the computed and observed significant waves at Wajima and Tottori.

(6) Wave Hindcast in the Northwest Pacific Ocean

Waves caused by a typhoon with rapidly-varying wind fields is hindcast in the Pacific Ocean. Fig. 13 is the grid system with a spacing of 80 km placed on the Pacific Ocean, in which the tracks of two typhoons to be hindcast for wave conditions - Typhoon 8115 and Typhoon 8210 - are also drawn. The estimation of wind distribution in a typhoon relies on the use of a parametric typhoon model. The model in which the exponential function is assumed for the pressure distribution, computes the wind fields in a typhoon

Fig. 13 Grid system used in the Pacific Ocean.

by using parameters such as central pressure, position of the typhoon center, radius to maximum winds and wind inflow angle to the typhoon center. These data are given every 6 hours and through a linear interpolation, wind field is estimated at intervals of 1 hour.

Fig. 14 is the time variation of significant waves at Irouzaki situated on the Pacific Ocean side of the Japanese coast, as is indicated in Fig. 13. The computation is in close agreement with the observation showing propagation of swell with a distant typhoon and rapid growth and decay of wind waves with approach and passage of a typhoon. Accordingly, the model predicts general characteristics of typhoon-generated waves in the northern hemisphere such that waves during Typhoon 8210 when Irouzaki was situated on the right hand side of the typhoon track give more rapid growth and decay associated with approach and passage of a typhoon than those during Typhoon 8115 when Irouzaki was situated on the left hand side of the typhoon track. When the effect of water depth on wave characteristics at Irouzaki where water depth is 50 m deep is introduced in the same way as in the Japan Sea case, the computed results might be slightly smaller than the observed ones.

Fig. 14 Comparison between the computed and observed significant waves at Irouzaki.

4. CONCLUSIONS

Practical applicability of the wave prediction model developed by the authors, DOLPHIN-1, was confirmed by reasonable agreement between the hindcast results and the wave data, including directional spectrum, which were acquired in five sea areas with different horizontal scales around Japan.

5. ACKNOWLEDGEMENTS

The authors thank the Bureaus of Harbor Construction, Ministry of Transportation and the Prefectural Offices for kindly offering the valuable wind and wave data.

CHAPTER 49

Bottom Shear Stress and Friction Factor Due to the Asymmetric Wave Action

C. T. Kuo ¹

W. J. Chen ²

Abstract

A micro shear gauge was used to measure the bottom shear stress under the shallow water wave on the smooth bed, the data show that bottom shear stress have an asymmetric form similar to the surface water elevation due to the non-linearity of wave. The bottom friction factor under wave crest and wave trough were very different with that defined by Jonsson's and the results were contrary when the bottom particle velocity were defined by linear and non-linear wave theory respectively. Empirical formula were obtained for practical use.

Introduction

Because of the development of economic and increase of population, in recent years, utilization of coastal areas has steadily been increasing for human activities such as transportation and industry. All of the development were taken in the nearshore area and the wave phenomena occurred in this area almost influenced by the bottom shear stress, directly or indirectly.

Therefore wave induced bottom shear stress and friction has an impacted relativity with energy decay, sediment transport rate and wave induced current, etc. About two decades, there were many researchers paid their attention to the bottom boundary layer problems, such as Riedel(1972), Jonsson(1976), Kamphuis(1976)

1 Professor, Graduate school of Hydraulics and Ocean Eng., National Cheng Kung University, Tainan 70101 Taiwan, Republic of China.

2 Lecturer, Dept. of Civil Engineering., National Chiayi Institute of Agriculture, Chiayi 60083 Taiwan, Republic of China.

, Iwagaki (1974), John (1982), Kuo & Chuan (1981) etc. Though they have obtained some basic results, those researchs haven't discussed the variation of bottom shear stress and friction affected with the asymmetry of wave profile in shallow water; therefore, the phenomena described by the above may have an important parameter to determine the sediment moving direction and the on-offshore sediment transport rate.

Sawaragi(1974), Tanaka(1987), Iwagaki(1987), etc. have presented that the non-linear effect of shallow water wave could be made a obviously difference on bottom shear stress and friction factor under the wave crest and wave trough passed respectively. Tanaka (1987) used the stream function theory to calculate the shear stress under non-linear wave and took their results to derive the on-offshore sediment transport rate. In spite of there have a few paper mentioned about the bottom shear stress influenced by the non-linear wave, those research haven't analyzed the shear stress under crest and trough detailly, also they haven't measured the bottom shear stress to verify their results.

In this paper, we use a micro shear gauge to measure the bottom shear stress under shallow water wave acting, the data collected from this experiment were taken to analyze the stress under wave crest and trough respectively, the results were compared with the stress that calculate from linear wave theory. Also we use the non-linear wave theory to calculate the bottom friction factor, and the analyzed results show a visible difference which compared to the results that obtained from linear wave theory by Jonsson etc.

Experimental Facilities and Conditions

The experiment of this paper is taken in a 40 m long, 1.0 m wide, and 1.0 m deep wave flume. The bottom shear stress is measured by a micro shear gauge which was set up in a steely box and installed into the bottom of flume. The sketch of the experimental equipments were show in Fig. 1. The maximum capacity of this shear gauge is 0.2 g and the diameter of the sensible plate is only 1 cm, therefore the sensitive area is too small when compared to the shear plate, so the measured error which occurred at the shear plate; such as sensitive accuracy of the gauge and the

pressure gradient difference at the each side of plate , etc. could be reduce to minimum; therefore the data measured by this micro shear gauge may be more reasonable.

Fig. 1 Sketch of experimental wave flume.

Fig. 2 shows the sketch of the micro shear gauge used by this paper.

Fig. 2 Sketch of shear gauge.

The test conditions of this experiment are :

- (1) bottom type : smooth bed.
- (2) water depth : 20 cm, 25 cm, 30 cm, 35 cm
- (3) wave period : 1.0, 1.2, 1.4, 1.6, 1.8, 2.0 sec
- (4) wave height : enlarged gradually from 2 cm to before breaking

Fig. 3 shows a example of time series of surface wave height and bottom shear force that just measuring from experiment. In this figure, we could find the asymmetry of bottom shear stress were related to the surface wave profile.

Fig. 3 Time history of measured wave and shear.

Experimental Results and Discussion

(1) Shear stress

In general case, the maximum bottom shear stress τ_{omax} is defined as

$$\tau_{omax} = \mu (\partial u / \partial z)_{z=-h} \dots\dots\dots (1)$$

If the horizontal particle velocity is calculated by linear wave theory and we transformed Eq. 1 to a non-dimensional form, then a dimensionless equation can be represented as Eq. 2

$$\tau_{omax} / \rho g H = \sqrt{2} / [g \sinh(kh)] (\pi / T)^{3/2} \dots\dots\dots (2)$$

where h is water depth, H wave height, k wave number, T wave period, ρ water density, ν is kinematic viscosity and τ_{omax} is the maximum bottom shear stress calculated from Eq. 2.

Fig. 4 represents the non-dimensional measured maximum shear stress under the wave crest (postive direction) and wave trough (negative direction) passed related to the parameter h/L_0 , and the curves on the diagram represent the value that obtained from Eq. 2 which was derived by linear wave theory. From this diagram, we could find that the postive maximum shear stress are large than the negative maximum shear stress obviously, and the measured positive value are large than the value were got from linear wave theory and the measured negative value are small than τ_{omax} , the reason is that in shallow water, wave profile

are no longer be maintained a sine form, it just has a sharp crest and a flat trough, this non-linear effect influence on bottom directly, so the shear stress on bottom also has a profile similar to the surface water elevation. The fluctuation of the measured data were due to the constant value of ν in Eq. 2 and the different bottom friction in each test condition.

The symbol of τ_c , τ_t in the figure represents the measured bottom shear stress under wave crest and wave trough respectively.

Fig. 4 Relation between $\tau_c / \rho g H$, $\tau_t / \rho g H$ and h / L_o .

Fig. 5 shows the relation between τ_c / τ_a , τ_t / τ_a and Ursell number Ur , the data in the figure indicate that the ratio of τ_c / τ_a are great than 1, τ_t / τ_a are less 1, the reason were due to the asymmetric wave action, that just described above. There also exist a obvious tendency of that τ_c / τ_a , τ_t / τ_a were enlarged and reduced gradually related to the increase of Ur respectively, this phenomenon could emphasized that when wave non-linearity increased, the postive shear stress also increased, but the negative shear stress were decreased. The increment of postive direction are more obvious than negative direction. This may has an important effect on the initial motion of sand and the on-offshore sediment transport rate, so this topic will be studied more detail. The regressive equation from data is expressed as Eq. 3 for practical use.

$$\tau_c/\tau_a = 0.903Ur^{0.081} , \quad \tau_t/\tau_a = 1.211Ur^{-0.149} \quad \dots(3)$$

Here $\tau_a = f_w u_a^2 / 2$ and f_w is the friction factor, u_a the maximum bottom horizontal particle velocity by linear theory. Ursell number Ur was defined as

$$Ur = HL^2/h^3 \quad \dots\dots\dots(4)$$

where L is the wave length at water depth h .

Fig. 5 Relation between τ_c/τ_a , τ_t/τ_a and Ur .

(2) Bottom Friction Factor

Fig. 6 shows the relation between Reynold number (RE) and bottom friction factor f_w , f_{ac} , f_{at} Where f_w is defined by Jonsson etc., f_{ac} \ f_{at} respresent the bottom friction factor under wave crest and wave trough action. Where

$$f_w = 2. / \sqrt{RE} , \quad f_{ac} = 2. \tau_c / \rho u a^2 , \quad f_{at} = 2. \tau_t / \rho u a^2 \quad \dots(5)$$

From this diagram, we can find that when linear wave theory was defined to compute the horizontal bottom velocity, the friction f_{ac} is larger than f_w , and f_{at} is smaller than f_w , furthermore, this tendency is more visible when RE increased. The experimental data can be regressed by two empirical formula like Jonsson's ,

$$f_{ac} = 1.386RE^{-0.448} \quad , \quad f_{at} = 4.093RE^{-0.505} \quad \dots(6)$$

Also, we could express f_{ac} , f_{at} in another form, just like Eq. 7

$$f_{ac} = 0.724f_{\omega}^{0.875} \quad , \quad f_{at} = 1.611f_{\omega}^{1.183} \quad \dots(7)$$

Fig. 6 Relation between friction factor and RE

In nearshore area, linear wave theory is unsuitable to describe the wave phenomena. For more realistic conditions, we use the non-linear wave method to define the bottom particle velocity, and use those to calculate the bottom friction factor under wave crest and trough, which were defined as Eq. 8

$$f_{sc} = 2\tau_c / \rho u_{sc}^2 \quad , \quad f_{st} = 2\tau_t / \rho u_{st}^2 \quad \dots\dots\dots(8)$$

where

$$u_s = c \{ F_1 \cosh[k(h+z) \cos(kx - \sigma t)] + F_2 \cosh[2k(h+z) \cos^2(kx - \sigma t)] + F_3 \cosh[3k(h+z) \cos^3(kx - \sigma t)] \} \quad | \quad z = -h$$

$$F_1 = ak / [\sinh(kh)]$$

$$F_2 = 3a^2 k^2 / [4 \sinh^4(kh)]$$

$$F_3 = 3a^3 k^3 [13 - 4 \cosh^2(kh)] / [64 \sinh^7(kh)]$$

When the friction factor were defined by Eq. 8, the relationship between f_{sc} , f_{st} and RE were show in Fig. 7. It shows that f_{sc} is smaller than f_{st} and f_w , but f_{st} is larger than f_{sc} and f_w . These results are just contrary to those obtained from linear wave theory which were defined in Eq. 5, the reason is that when velocity is calculated by finite amplitude wave theory ,there were a sharply velocity under wave crest and a flatly velocity under wave trough due to the wave non-linearity in shallow water. So how are the real bottom friction factor change with wave condition must be studied detailly. For avoid the complex calculation , the data shows in Fig. 7 can be expressed by a empirical formula as Eq. 9 or Eq. 10

$$f_{sc}=2.596RE^{-0.540} \quad , \quad f_{st}=0.613RE^{-0.341} \quad \dots(9)$$

or

$$f_{sc}=0.724f_w^{0.875} \quad , \quad f_{st}=1.611f_w^{1.183} \quad \dots(10)$$

Fig. 7 Relation between friction factor and RE.

Fig. 8 shows the comparisons of f_w , f_{ac} , f_{at} , f_{sc} , f_{st} from this diagram the differences between these factors can be viewed more clearly. When RE

were near transitional flow condition , the data begin scattered away from f_w and f_{st} scattered more obviously, the reason were due to the slowly increased of bottom velocity under wave trough action. There exist a 10% ~ 40% difference between f_{sc} 、 f_{st} and f_w , the variation were depended on the Reynolds number. If we have measured the velocity near bottom simultaneously , then how the friction factor varied may be verified more accurately.

Fig. 8 Comprisions of friction factor and RE.

Conclusion and Suggestion

It shows that the bottom shear stress has a asymmetric form similar to the surface wave profile in shallow water. The positive maximum shear stress (under wave crest) are much larger than the negative maximum shear stress (under wave trough) and those computed from linear wave theory. In addition, the friction factor were varied with what the wave theory was adopted, thers show a constray results when the bottom velocity were defined by the linear and non-linear wave respectively. Phenomena which induced by wave just mentioned above are an important parameter on wave energy decay, nearshore current and may have a determination on the on-offshore sediment transport rate and the particle moving mechanics etc., so how they are changed by the asymmetric wave profile must be study more detailly. If the wave profile, bottom

velocity and shear stress are measured simultaneously, the advanced discussion may get a more reasonable explanation. The next work for us are to improve the experiment and extend to the rough bed condition.

Moreover, we attempt to research a function to express the shear stress and friction factor under a asymmetric wave action and to correlate the results with the on-offshore sediment transport rate.

CHAPTER 50

Estimation of Directional Spectrum Expressed in Standard Form

Masahiko Isobe ¹

Abstract

A standard directional spectrum is determined by a finite number of parameters included in its mathematical expression. In this paper, a theory is developed to estimate the parameters from a given data set on the basis of the maximum likelihood method. The theory is applied to estimating the parameters in the Mitsuyasu-type standard directional spectrum from data obtained by a three-component array. Main results of analysis of field data are 1) the peak wave direction agrees well with the mean direction defined at each wave frequency, 2) the peakedness parameter can be approximated by that estimated from the long-crestedness parameter at each wave frequency, and 3) the peakedness parameter takes its maximum at the frequency slightly lower than the peak frequency.

1. Introduction

A random sea state is described by a directional spectrum. In recent years, field observations of directional spectra have often been carried out using varieties of measuring instruments developed. At the same time, many theories have been developed for the accurate estimation of directional spectrum (Isobe *et al.*, 1984; Kobune and Hashimoto, 1986; Hashimoto and Kobune, 1988). Cross and power spectra, from which the directional spectrum is estimated, are statistically random quantities. However, the statistical variability is not appropriately taken into account in the theories developed so far.

A standard form of the directional spectrum such as the Mitsuyasu-type directional spectrum is determined by a finite number of parameters. This way of describing directional spectra is convenient for practical uses such as establishing a data base of random sea waves or specifying a design wave condition. Hence, it is necessary to develop a theory to estimate the values of these parameters on a reasonable basis.

¹Associate Professor, Dept. of Civil Eng., Univ. of Tokyo, Bunkyo-ku, Tokyo, 113 Japan

In this paper, a general theory is presented to estimate the parameters included in a standard directional spectrum on the basis of the maximum likelihood method, in which the statistical variability of the Fourier coefficients is taken into consideration. Then, an explicit expression is given for the Mitsuyasu-type directional distribution function. The theory is applied to data obtained from field experiments and the characteristics of directional sea state are discussed.

2. Theory

2.1 Probability density of Fourier coefficients

Suppose M kinds of time series data, $\xi^{(m)}(\mathbf{x}_m, t)$ ($m=1$ to M , \mathbf{x}_m : coordinates at measuring points, t : time), of various wave properties at various points are given. The time series $\xi^{(m)}$ are expanded into Fourier series as

$$\xi^{(m)}(\mathbf{x}_m, t) = \sum_{i=1}^{\infty} (A_{ci}^{(m)} \cos 2\pi f_i t + A_{si}^{(m)} \sin 2\pi f_i t) \quad (1)$$

From the central limit theorem, the coefficients $A_{ci}^{(m)}$ and $A_{si}^{(m)}$ have normal distributions with zero means. Hereinafter we deal only with the i th component, f_i , of the frequency and drop the subscript i . Then the coefficients $A_{ci}^{(m)}$ and $A_{si}^{(m)}$ are expressed in a vector form as

$$\mathbf{A} = \begin{pmatrix} \mathbf{A}_c \\ \mathbf{A}_s \end{pmatrix} \quad (2)$$

and the cross covariance matrix, $\Xi \Delta f$, of \mathbf{A} is expressed in terms of co-spectrum matrix, C , and quadrature-spectrum matrix, Q , as

$$\Xi \Delta f = [\langle \mathbf{A} \mathbf{A}^t \rangle] = \begin{bmatrix} C & Q \\ -Q & C \end{bmatrix} \Delta f \quad (3)$$

Where Δf is the frequency range that the coefficient \mathbf{A} represents and $\langle \rangle$ denotes an expected value. The cross-power spectrum matrix, Φ , are defined as $\Phi_{mn} = C_{mn} - iQ_{mn}$ and related with the directional spectrum, $S(f, \theta)$, as

$$\Phi_{mn}(f) = \int_0^{2\pi} H_m(f, \theta) \bar{H}_n(f, \theta) \exp[-i\mathbf{k}(\mathbf{x}_n - \mathbf{x}_m)] S(f, \theta) d\theta \quad (4)$$

(Isobe *et al.*, 1984). Where f is the frequency, θ the wave direction, \mathbf{k} is the wave number vector, H_m the transfer function from the water surface elevation to the m th measured quantity, and $\bar{}$ denotes the complex conjugate.

From the cross-covariance matrix expressed by Eq. (3), the joint normal distribution, $p(\mathbf{A})$, of the Fourier coefficients \mathbf{A} is given as

$$p(\mathbf{A}) = \frac{1}{(\sqrt{2\pi\Delta f})^{2M} \sqrt{|\Xi|}} \exp\left[-\frac{1}{2\Delta f} \mathbf{A}^t \Xi^{-1} \mathbf{A}\right] \quad (5)$$

(Rice, 1944). Where $|\Xi|$ and Ξ^{-1} are the determinant and inverse matrix of Ξ .

Now a complex variable, ζ , is defined as

$$\zeta = \mathbf{A}_c - i\mathbf{A}, \tag{6}$$

then the right hand side of Eq. (5) is expressed in terms of ζ as

$$p(\mathbf{A}) = \frac{1}{(2\pi\Delta f)^M |\Phi|} \exp\left[-\frac{1}{2\Delta f} \zeta^t \Phi^{-1} \zeta\right] \tag{7}$$

in which the dimension of the matrix reduces to M . In deriving the above equation,

$$\Phi \Delta f = [\langle \bar{\zeta} \zeta^t \rangle / 2] = (C - iQ) \Delta f \tag{8}$$

and the relationship, $|\Xi| = |\Phi|^2$, is used.

2.2 Definition of likelihood function

If the directional spectrum is given, Φ can be calculated by Eq. (4) and the joint distribution function of \mathbf{A} is determined by Eq. (7). Since \mathbf{A} is obtained by the Fourier analysis of given time series data, Eq. (7) gives the probability density with which the given \mathbf{A} occurs.

A set, $\mathbf{A}^{[j]}$ ($j=1$ to J), of the Fourier coefficients \mathbf{A} is obtained by dividing the time series into segments or from a small but finite range of frequency. The joint probability with which the set $\mathbf{A}^{[j]}$ ($j=1$ to J) occurs at the same time is obtained by multiplying each probability density. Its J th root, L , is expressed as

$$\begin{aligned} L(\mathbf{A}^{[j]}; \Phi) &= \{p(\mathbf{A}^{[1]}) \times p(\mathbf{A}^{[2]}) \times \dots \times p(\mathbf{A}^{[J]})\}^{1/J} \\ &= \frac{1}{(2\pi\Delta f)^M |\Phi|} \exp\left[-\sum_{m=1}^M \sum_{n=1}^M \Phi_{mn}^{-1} \hat{\Phi}_{nm}\right] \end{aligned} \tag{9}$$

where

$$\hat{\Phi}_{nm} = \frac{1}{2J\Delta f} \sum_{j=1}^J \hat{\zeta}_n^{(j)} \zeta_m^{(j)} \tag{10}$$

From the above definition, $\hat{\Phi}_{nm}$ is regarded as the quantity which can be obtained by operating a rectangular filter to the periodogram $\hat{\zeta}_n^{(j)} \zeta_m^{(j)} / 2\Delta f$ and this means that $\hat{\Phi}_{nm}$ is the cross or power spectrum obtained by the Fourier analysis.

The quantity L expressed by Eq. (9) means the possibility or likelihood that the set $\mathbf{A}^{[j]}$ occur at the same time and called the likelihood function. From field measurements, $\mathbf{A}^{[j]}$ ($j=1$ to J) is given but Φ is unknown. In the maximum likelihood method, Φ is determined so that the possibility becomes maximum.

As seen from Eq. (4), the cross-power spectrum matrix Φ is a function of the parameters included in the standard directional spectrum. However, we

first assume that every component in the cross-power spectrum matrix changes independently and find the maximum value of the likelihood function in a global sense. To obtain the value of Φ which maximizes L , we take the derivative of Eq. (9) with respect to every component, Φ_{kl} (k and $l=1$ to M), of the matrix Φ and make every derivative vanish.

Let the cofactor of the matrix Φ be denoted by ϕ , the following relationships are obtained from mathematical theorems concerning a matrix.

$$|\Phi| = \sum_{k'=1}^M \phi_{lk'} \Phi_{k'l} \quad (11)$$

$$\Phi_{mn}^{-1} = \frac{\phi_{mn}}{|\Phi|} \quad (12)$$

And hence

$$\frac{\partial |\Phi|}{\partial \Phi_{kl}} = \phi_{lk} = |\Phi| \Phi_{lk}^{-1} \quad (13)$$

$$\frac{\partial \Phi_{mn}^{-1}}{\partial \Phi_{kl}} = -\Phi_{ln}^{-1} \Phi_{km}^{-1} \quad (14)$$

Now the derivative of Eq. (9) is expressed as

$$\frac{\partial L}{\partial \Phi_{kl}} = L \times \left\{ -\Phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1} \right\} \quad (15)$$

To make the derivative vanish, we obtain

$$\Phi_{nm} = \hat{\Phi}_{nm} \quad (16)$$

and then the maximum value of L is obtained as

$$L_{\max} = \frac{e^{-M}}{(2\pi\Delta f)^M |\Phi|} \quad (17)$$

Equation (16) means that the cross-power spectra Φ_{nm} should agree with the quantity which is obtained by operating a rectangular filter to the periodogram.

2.3 Estimation of parameters in standard directional spectrum

Once we choose a standard directional spectrum, the components of the cross-power spectrum matrix are not independent of each other. The cross-power spectrum matrix, Φ_{nm} , is now a function of the parameters, λ_i ($i=1$ to I), in the standard directional spectrum through Eq. (4) and is written as $\Phi_{nm}(\lambda_i)$. Hence, to determine the value of λ_i by the maximum likelihood method, we take the derivative of Eq. (9) with respect to λ_i ($i=1$ to I) and make every derivative vanish.

The derivative of the likelihood function with respect to λ_i can be obtained by the chain rule as

$$\frac{\partial L}{\partial \lambda_i} = \sum_{k=1}^M \sum_{l=1}^M \frac{\partial L}{\partial \Phi_{kl}} \frac{\partial \Phi_{kl}}{\partial \lambda_i} \tag{18}$$

On substituting Eq. (15) into the above equation and setting the derivative equal to zero, the following equation results:

$$\sum_{k=1}^M \sum_{l=1}^M \{-\Phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1}\} \frac{\partial \Phi_{kl}}{\partial \lambda_i} = 0 \tag{19}$$

From the above equation with $i=1$ to I , we can determine the values of λ_i ($i=1$ to I) and then the directional spectrum.

Once λ_i are determined, the value, \hat{L}_{max} , of the likelihood function corresponding to λ_i is calculated. Since the global maximum L_{max} is given by Eq. (17), the adaptability of the standard directional spectrum can be defined as \hat{L}_{max}/L_{max} . This is an advantage of the present method.

The concept of the maximum likelihood used in the present study is similar to that used in Hashimoto and Kobune (1988). However, in the present study, the joint normal distribution of the Fourier coefficients is taken into consideration, whereas in Hashimoto and Kobune (1988) the cross-power spectra are assumed to be independent of each other. For example, when two time series data are obtained at very close locations, it is more rational to take into consideration the correlation between the Fourier coefficients as in the present study.

In the numerical calculation of Eq. (19), the Newton-Raphson procedure can be employed. Let the left hand side of Eq. (19) be denoted as

$$f_i(\lambda_{i'}) = \sum_{k=1}^M \sum_{l=1}^M \{-\Phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1}\} \frac{\partial \Phi_{kl}}{\partial \lambda_i} \tag{20}$$

then the second derivatives are expressed as follows:

$$\begin{aligned} \frac{\partial f_i}{\partial \lambda_{i'}} &= \sum_{k=1}^M \sum_{l=1}^M \{-\Phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1}\} \frac{\partial^2 \Phi_{kl}}{\partial \lambda_{i'} \partial \lambda_i} \\ &+ \sum_{k'=1}^M \sum_{l'=1}^M \sum_{k=1}^M \sum_{l=1}^M [-\Phi_{l'k}^{-1} \Phi_{lk}^{-1} + \{\Phi_{lk}^{-1} \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1} \\ &+ \Phi_{l'k}^{-1} \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk'}^{-1}\}] \frac{\partial \Phi_{k'l'}}{\partial \lambda_{i'}} \frac{\partial \Phi_{kl}}{\partial \lambda_i} \end{aligned} \tag{21}$$

By the linear approximation of $f_i(\lambda_{i'})$ the following iteration formula can be obtained:

$$\lambda_i^{(j+1)} = \lambda_i^{(j)} - \sum_{i'=1}^I \left[\frac{\partial f_i}{\partial \lambda_{i'}} \right]^{-1} f_{i'}|_{\lambda_i = \lambda_i^{(j)}} \tag{22}$$

where $\lambda_i^{(i)}$ and $\lambda_i^{(i+1)}$ are the values of λ_i at i th and $(i+1)$ th iteration steps. The above formula is repeatedly used until a converged solution is obtained.

2.4 Expression for Mitsuyasu-type directional spectrum

The Mitsuyasu-type directional distribution function is expressed as

$$S(f, \theta) = P(f) \frac{2^{2s+1} \Gamma^2(s+1)}{\pi \Gamma(2s+1)} \left[\cos \frac{\theta - \theta_o}{2} \right]^{2s} \quad (23)$$

where $P(f)$ is the frequency spectrum, and Γ represents the gamma function. To estimate the directional spectrum for a certain frequency f , the unknown parameters are P , θ_o and s which are denoted by λ_1 , λ_2 and λ_3 , respectively.

In the following, we derive the equations for data obtained by a three-component array in which the water surface elevation, η , and two components, u and v , of the horizontal water particle velocity are measured. By denoting $\xi^{(1)} = \eta$, $\xi^{(2)} = u$ and $\xi^{(3)} = v$, the cross-power spectra for Eq. (23) are

$$\Phi_{11} = P(1 + \epsilon) \quad (24)$$

$$\Phi_{12} = PH_u m_1 \cos \theta_o \quad (25)$$

$$\Phi_{13} = PH_u m_1 \sin \theta_o \quad (26)$$

$$\Phi_{22} = PH_u^2 \left(\frac{1}{2} + m_2 \cos 2\theta_o \right) (1 + \epsilon) \quad (27)$$

$$\Phi_{33} = PH_u^2 \left(\frac{1}{2} - m_2 \cos 2\theta_o \right) (1 + \epsilon) \quad (28)$$

$$\Phi_{23} = PH_u^2 m_2 \sin 2\theta_o \quad (29)$$

where

$$m_1 = \frac{s}{(s+1)} \quad (30)$$

$$m_2 = \frac{s(s-1)}{2(s+1)(s+2)} \quad (31)$$

and H_u is the transfer function from the water surface elevation to the magnitude of the horizontal water particle velocity. Though the quantity H_u can be evaluated by the small amplitude wave theory, the following formula obtained from the relationship among the power spectra is used to eliminate the error included in the data.

$$H_u = \sqrt{\frac{P_u(f) + P_v(f)}{P_\eta(f)}} \quad (32)$$

Equations (24), (27) and (28) are expressions for power spectra and are multiplied by $(1 + \epsilon)$ on assuming that a noise component with a relative power of ϵ is included in the data. Hence, ϵ becomes the fourth unknown parameter, λ_4 , to

be determined by the maximum likelihood method. If another assumption that the noise component is due to a component of the directional spectrum with a uniform directional distribution is adopted, ϵP , $\epsilon PH_u^2/2$ and $\epsilon PH_v^2/2$ should be added to the power spectra Φ_{11} , Φ_{22} and Φ_{33} , respectively. Which assumption should be adopted can be discussed in terms of the adaptability \hat{L}_{\max}/L_{\max} .

It is easy to differentiate Eqs. (24) to (29) with respect to λ_i ($\lambda_1 = P$, $\lambda_2 = \theta_0$, $\lambda_3 = s$, $\lambda_4 = \epsilon$) up to the second order and by substituting the derivatives into Eqs. (20) and (21) the right hand side of Eq. (22) can be determined and then modified values $\lambda_i^{(i+1)}$ are calculated. The initial values of λ_i ($i=1$ to I) are taken to be the power spectrum of η , the mean direction, the value of s obtained from the long-crestedness parameter, and zero, respectively.

Numerical instability sometimes occurred in the algorithm of the original Newton-Raphson method. Hence additional procedures are employed. When modified λ_i gives a smaller value of the likelihood function, the magnitude of the modification by Eq. (22) is made half. When a convergent solution is not obtained within 10 iterations, the procedure is continued by neglecting the second derivatives in Eq. (21). This modification made the numerical calculation convergent for all the cases tried.

3. Application

3.1 Field experiment

The data used in application of the present theory were obtained from three series of field experiments. Sets of an ultra-sonic wave gage and an electromagnetic current meter were installed at the sea bottom. The first and second field experiments were performed from 1 to 2 of October, 1987, and from 29 to 30 of August, 1988, respectively, at Oarai beach, Ibaraki prefecture, Japan, facing the Pacific Ocean. One segment of data record contains 2046 data with the sampling frequency of 0.5s, and 95 and 75 segments were recorded in Oarai 1987 and 1988 experiments, respectively. The bottom topography and the arrangement of the instruments are shown in Fig. 1 for the Oarai 1988 experiment, as an example. The third experiment was performed from 11 to 18 of January, 1989, at Ogata beach, Niigata prefecture, Japan. This experiment was performed as a part of a comprehensive, inter-institutional field experiment, SWAN 89 (Sediment, Wave and Nearshore Circulation Observation, 1989), managed by Professor Tsuchiya, Kyoto University. Data segments with a 17 min. duration were recorded every one hour and total number of segments is 134. The average wave statistics during the observation are shown in Table 1.

3.2 Result of data analysis

Assumptions of noise components are examined first. Figure 2 shows the

Fig. 1 Arrangement of measuring points (Oarai, 1987.10.01-02).

Table 1: Wave statistics during field experiments.

$\bar{\gamma}$: long-crestedness parameter.

result of data analysis for three assumptions of noise component. From the top to bottom figures, average values during the observation are shown for the frequency spectrum, $P(f)$, the peak direction, θ_o , the peakedness parameter, s , and the adaptability, \hat{L}_{\max}/L_{\max} , are plotted. In each figure, the solid line corresponds to the assumption of the noise component proportional to the frequency spectrum, and the dotted line to the assumption of the noise component with uniform directional distribution. The broken line represents the result when the noise component is neglected. Without noise component, the adaptability \hat{L}_{\max}/L_{\max} decreases significantly. The adaptabilities are almost the same for the two assumptions of noise component, but the difference of the estimated s between the two assumptions is large. Since the assumption of noise component proportional to the frequency spectrum gives a slightly higher adaptability and gradual increase of s with decreasing water depth, this assumption is adopted in the following analysis.

In the top of each figure through Figs. 3 to 6, P is the frequency spectrum, ϵP the noise component, and P_η the frequency spectrum of the water surface elevation. In the second figure, θ_o denotes the estimated peak direction. The symbols θ_m and θ_p represent the mean and principal directions, respectively, which are calculated from the power and cross spectra (Horikawa, *ed.*, 1985). In the third figure, s is the estimated peakedness parameter, and s_γ represents s

Fig. 2 Effect of formulation of noise component on directional spectrum estimation.

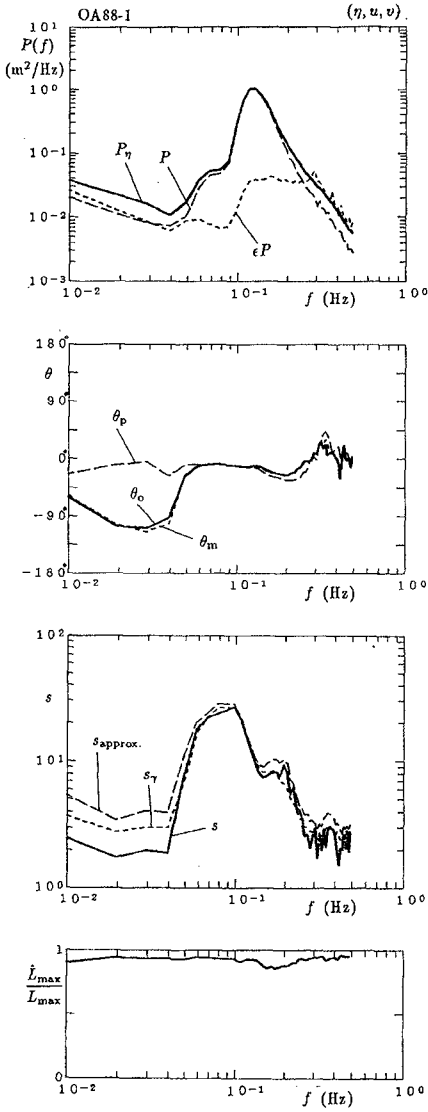

Fig. 3 Result of directional spectrum estimation (1).

Fig. 4 Result of directional spectrum estimation (2).

Fig. 5 Result of directional spectrum estimation (1).

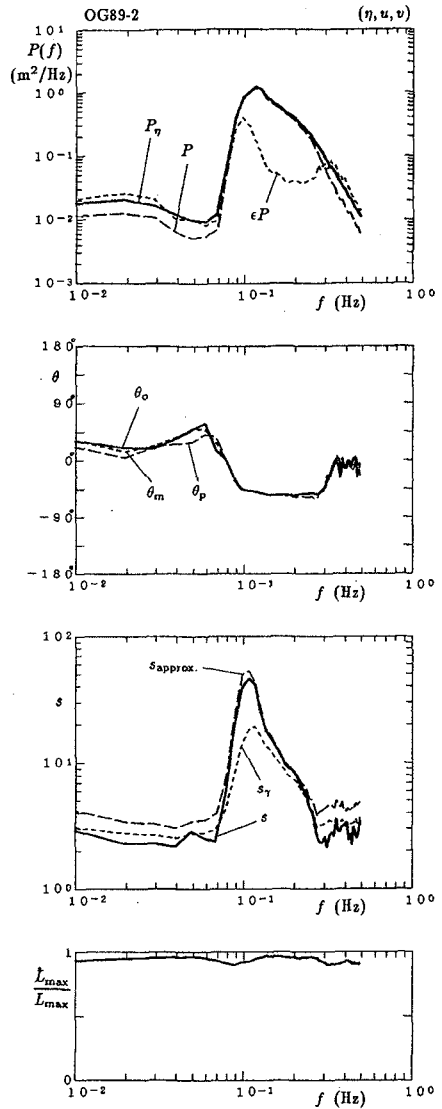

Fig. 6 Result of directional spectrum estimation (2).

calculated by the following equations:

$$\gamma^2 = \frac{\hat{\Phi}_{20} + \hat{\Phi}_{02} - \sqrt{(\hat{\Phi}_{20} - \hat{\Phi}_{02})^2 + 4\hat{\Phi}_{11}^2}}{\hat{\Phi}_{20} + \hat{\Phi}_{02} + \sqrt{(\hat{\Phi}_{20} - \hat{\Phi}_{02})^2 + 4\hat{\Phi}_{11}^2}} \quad (33)$$

$$\gamma^2 = \frac{2s + 1}{s^2 + s + 1} \quad (34)$$

Equation (33) is the definition of the frequency-dependent long-crestedness parameter and Eq. (34) gives the relationship between the long-crestedness parameter and the peakedness parameter. The quantity s_{approx} is an approximation of s which is obtained by substituting γ_α for γ in Eq. (34). The quantity γ_α is calculated by the following equations:

$$\left(1 - \frac{\gamma_\alpha^2}{\gamma^2}\right) = \alpha \frac{\sin^2 2\theta_m}{4 - 2\sin^2 2\theta_m} \left(1 - \frac{\gamma'^2}{\gamma^2}\right) \quad (35)$$

$$\alpha = 0.859 - 0.174\gamma^2 - 0.104\sin^2 2\theta_m \quad (36)$$

where γ is calculated by Eq. (33) and γ' denotes the value of γ which is calculated from Eqs. (34) and (37).

$$\frac{s}{s + 1} = \sqrt{\frac{\hat{\Phi}_{10}^2 + \hat{\Phi}_{01}^2}{\hat{\Phi}_{00}(\hat{\Phi}_{20} + \hat{\Phi}_{02})}} \quad (37)$$

For Fig. 4, the pressure variation is used instead of the water surface elevation. The small amplitude wave theory is used to determine the transfer function from the water surface elevation to the pressure variation. The results are almost the same as those shown in Fig. 3 in which the water surface elevation is used.

Figures 5 and 6 shows the results for Oarai 1987 and Ogata 1989 experiments, respectively. From these figures, it can be concluded that the estimated value P of the frequency spectrum, the peak direction θ_o , and the peakedness parameter s agree well with the power spectrum P_η of the water surface elevation, the mean direction θ_m , and the approximated value s_{approx} , respectively. Since the latter parameters are very easy to calculate, the computational time can greatly be reduced.

In the frequency spectrum, the high frequency range seems to follow the -4 power law. The maximum s occurs at the frequency slightly lower than the peak frequency and the dependence of s on the frequency is different from the formula proposed by Mitsuyasu *et al.* (1975). Accumulation of much more data is necessary for a further and more reliable discussion.

4. Conclusion

A general procedure is given on the basis of the maximum likelihood method for estimating the parameters included in a standard directional spectrum. As

an example, formulas are given for estimating the parameters in the Mitsuyasu-type directional spectrum from the data of the water surface elevation and two components of the horizontal water particle velocity. The present method is applied to the data obtained by three series of field experiments. It is found that the parameters in the Mitsuyasu-type directional spectrum can be approximated by the parameters which can be calculated with much less computational time. Accumulation of much more data is necessary to discuss the characteristics of directional sea states such as the functional dependence of the peakedness parameter s on the frequency. The appropriate assumption on the noise component remains to be studied in the future work.

CHAPTER 51

CHARACTERISTICS OF OSCILLATORY FLOW OVER RIPPLE MODELS

Kiyoshi Horikawa¹ F.ASCE
Syunsuke Ikeda² M.ASCE

ABSTRACT

The results of extensive laboratory investigations on the oscillatory flow over ripple models were presented. The ripple models were installed in an oscillatory flow flume. A two-dimensional laser doppler velocimeter was utilized to measure the fine structure of flows in the vicinity of the whole length of a ripple model which was induced by various types of oscillatory flow. The results of measurements were displayed in the form of distributions of mean fluid velocity, stationary velocity, fluid turbulence intensity and Reynolds stress. By using these data the characteristics of oscillatory flow, such as the formation and decay of vortices, the generation of stationary velocity and the variation of kinematic eddy viscosity were discussed.

INTRODUCTION

More than 40 years ago Bagnold (1946) made his laboratory investigations on the oscillatory flow over sand ripples by oscillating the arced bottom harmonically through still water. Since then considerable amount of laboratory investigations have been attempted to clarify the stated phenomena in connection with various subjects, such as the mechanism of ripple formation, the ripple geometry, the sediment transport in the vicinity of sand ripples, and the wave energy dissipation due to the existence of sand ripples.

1. Professor, Department of Foundation Engineering, Saitama University, 255 Shimo-Okubo, Urawa, Saitama 338, Japan. Professor Emeritus, The University of Tokyo.
2. Professor, Department of Civil Engineering, Tokyo Institute of Technology, 2-12-1 O-okayama, Meguro-Ku, Tokyo 152, Japan.

During the last decade the laser doppler velocimeters (LDV) have been adopted together with the data acquisition system to display precisely the fields of mean velocity and turbulence intensity within the domain which was set for the measurement (Du Toit et al., 1980 ; Sawamoto et al., 1981 ; Sato, 1987 ; Sleath, 1987).

Therefor our knowledge on the fine structure of oscillatory boundary layer flow has been deepend during the last decade. The most remarkable phenomenon observed around sand ripples is the generation of vortices separated from a certain location near the ripple crest. It has been realized that the life of vortices from generation to decay is an important element for determining the structure of flow field which has strong influence on the suspension of sediment near the sand ripple and on the decay of wave energy (Ikeda, et al., 1989). In order to clarify more the detailed structures of the oscillatory boundary layer flow, we have continued to carry out a series of laboratory investigations in an oscillatory flume in which sand ripple model was installed. The model of sand ripples has a characterized shape with a sharpened crest as shown in Figure 1. The reason why we adopted such a peculia sharp-crested ripple, which is quite different from the actual sand ripples with a rounded crest, is, for the sake of simplicity, to fix the separation point of flow at a definite point; that is at its crest (Longuet-Higgins, 1981).

Fig.1 Profile of the ripple model. (unit:mm)

EXPERIMENTAL FACILITIES AND PROCEDURES

An oscillatory flow flume with 13 m in length and 0.3 m x 0.3 m in cross-section was used for the laboratory experiment, the observation section of which was 2 m long and was made of glass except the flume bottom (Figure 2). The oscillatory fluid motion was produced by a piston driven by a DC-motor, and the maximum amplitude of the fluid motion was 70 cm. The period of fluid oscillation was variable between 1 s and 20 s.

The height and length of the ripple model were selected to be 5 cm and 30 cm, respectively (Figure 1).

The surface of the ripple was finished smoothly. Seven of model ripples were placed at the test section, among which the region between the 3rd and the 4th crests was selected for the precise velocity measurement. We took four cases as experimental runs as shown in Table 1. The periods of test runs varied from 3 s to 9 s. The measuring points were decided to be 316 points in total as indicated in Figure 3. That is to say, one wave length of ripple was divided into 12 sections, and the vertical spacing were taken to be 5 mm, 10 mm and 20 mm from the bottom to a certain elevation as shown in Figure 3.

Fig.3 Data sampling points.

At each measuring point the velocity measurement was made for 30 cycles of waves by using a 2-D LDV. The lens of the velocimeter was moved by a 3-D traverse facility controlled by a mini-computer with a minimum displacement of 0.5 mm. Thus horizontal and vertical velocity components were measured. The commencement of data sampling was controlled by an electric signal generated at the piston. The phase 0 was selected at the instant when the movement of the piston became stationary, i.e. the cross-sectionally averaged fluid velocity became zero. The sampling time was selected to be 0.0195 s, during which 5 data were obtained. Therefore, 150 data were acquired for one phase at a measuring point. The interval of the sampling phases was $\pi/8$. The local mean fluid velocity, the intensity of fluid turbulence, the Reynolds stress, the kinematic eddy viscosity and the stationary velocity components were calculated by using 150 data at one phase and at one point and displayed in a graphical form.

RESULTS OF LABORATORY INVESTIGATION AND DISCUSSION

Mean Fluid Velocity

The boundary layer developed along a ripple surface can be divided into two parts. The first one is the inner boundary layer or the Stokes layer existing very close to the bottom boundary, where the fluid flow is strongly controlled by fluid viscosity. The second one is the outer boundary layer where the flow structure is characterized by the behavior of organized vortices

separated from the crest of the ripples. The thickness of the inner boundary layer is very thin with the order of $\sqrt{\nu T}$, where ν is the kinematic viscosity of fluid and T is the oscillation period.

Variation of the mean velocity fields during the phases 0 to $7\pi/8$ for Run 3 was illustrated in Figure 4 with a time interval of $\pi/8$. Through the careful observation of time variation of velocity field illustrated in Figure 4, the behavior of an organized vortex covering its growing and then decaying processes can be realized. This phenomenon is a remarkable feature of the outer boundary layer of the oscillatory flow.

In order to clarify the characteristic behavior of the flow in the inner boundary layer, the velocity distribution at the section just above a ripple crest was measured. The reason is that the thickness of the boundary layer at the crest must be specified in predicting the circulation of the vortices. Based on the result of velocity measurement, the temporal variation of the boundary layer thickness for two selected cases were plotted as shown in Figure 5. It is clearly noticed that the thickness reduces considerably at flow accelerating phases, while the thickness tends to increase at decelerating phases. Even though the boundary layer thickness shows such a temporal variation as stated above, the temporally averaged value of the thickness is reasonably well described by $\sqrt{\nu T}$ as seen in this figure.

It has been predicted theoretically that stationary cells are generated in the outer boundary layer of the oscillatory flows over a wavy boundary. In our study the stationary velocity component was derived by averaging the fluid velocity for one period of oscillatory flow at each measuring point. The result for Runs 2 and 3 were drawn in Figure 6, from which it can be clearly observed that two stationary cells were generated. The maximum steady flow velocity seems to occur near the bottom close to the ripple crests. The ratio of the maximum steady velocity to the velocity amplitude of the undisturbed flow, U , was calculated and shown in Table 2. From this table it is found that the stated ratio was affected by the period of fluid oscillation. For $T = 3$ s, the ratio was about 0.76, while it was about 0.58 for $T = 9$ s. These results indicate that the magnitude of stationary velocity is very large near the bottom. This fact suggests that the stationary cell has an important role in amplifying the height of ripples. It can also be observed that the

Fig.4 Distributions of temporally averaged fluid velocity for Run 3.

Fig.5 Temporal variation of the inner boundary layer thickness above the ripple crest.

Fig.6 Stationary velocity distributions for (a) Run 2 and (b) Run 3.

Table 2 Maximum speed of stationary current, V_{\max} .

T (s)	3	6	9
\hat{U} (cm/s)	20.9	20.9	13.9
V_{\max} (cm/s)	15.8	13.3	8.02
$\frac{V_{\max}}{\hat{U}}$	0.76	0.64	0.58

stationary cells are significantly correlated with the vortices which seem to strengthen the stationary velocity component compared with that predicted for rolling grain ripples. The laboratory data at the University of Tokyo (Hamamoto, et al., 1982) obtained by using a sinusoidal shape bottom boundary indicated that the questioned ratio was about 0.3, considerably smaller than the present results. Therefore the circulation of the vortices generated over the round-crested ripples is expected to be smaller than that over sharp-crossed ripples. The second series of our experiment using a round-crested ripple model, which is now going on, is expected to give more definite conclusions on this subject.

Fluid Turbulence Intensity

The intensity of fluid turbulence was calculated by using 150 data for each velocity component obtained for each phase at each measuring point. Figure 7 shows the variation of the vertical distribution of turbulence intensity expressed in the form of RMS value during a half-cycle of fluid oscillation. The intensity of fluid turbulence was slightly large in the area where the vortex separated from the right hand side crest in the preceding period was still existing at the phase of $(0/8)\pi$ and gradually attenuated in due course. On the contrary to this, the turbulence intensity in the right hand side area of the left crest increased and the area with large turbulence intensity increased its size. The turbulence intensity reached the maximum at the phase $4\pi/8$ near the center of the vortex, the value of which became as large as 80 % of the velocity amplitude of the undisturbed oscillatory flow, \hat{U} . The fluid turbulence was convectively transported toward the down stream, and prevailed in almost all over the boundary layer between the two neighbouring crests at the phase $6\pi/8$. The turbulence intensity became to decrease its magnitude at

(e)

(b)

(f)

(c)

(g)

(d)

(h)

Fig.7 Distributions of the fluid turbulence intensity for Run 3.

the phase $7\pi/8$, but the intensity still kept the level of 60 % of the velocity amplitude.

The Reynolds Stress

The kinematic Reynolds stress, $-\overline{u'v'}$, was also obtained as depicted in Figure 8. The distributions of the Reynolds stress show more clearly the effect of the vortices on the turbulent fluid. At the phase $(0/8)\pi$, the Reynolds stress was almost zero everywhere except the limited region on the right hand side where a weak negative Reynolds stress was observed corresponding to the vortex shed from the right hand side ripple crest. At the phase $\pi/8$ a weak positive Reynolds stress began to appear in the downstream of the left crest corresponding to the release of vorticity from the crest. The Reynolds stress increased very rapidly at the phase $2\pi/8$, where the value was positive below the prescribed streamline with the maximum fluid velocity and negative above the streamline. The region of large Reynolds stress moved downstream, and the absolute value of the Reynolds stress reduced considerably at the phase $3\pi/8$. This reduction corresponds to the fact that the vertical distribution of mean fluid velocity became more uniform near the crest. The Reynolds stress took positive value almost everywhere, and reached its maximum at the phase $4\pi/8$ in the vortex region.

The Reynolds stress began to appear in the region above the ripple trough, and was probably induced by a large fluid velocity transported convectively from the left hand side ripple crest. The maximum fluid velocity at the trough located at about $y = 70$ mm, below and above which the Reynolds stress was positive and negative respectively. The overall Reynolds stress gradually decreased toward the phase $7\pi/8$.

These observations reveal that the Reynolds stress is significantly correlated with the release of the vorticity from the ripple crest and is essentially zero in the area where the vorticity is not supplied from the ripple crest even if the turbulence intensity has non-zero value there.

Kinematic Eddy Viscosity

The kinematic eddy viscosity, \mathcal{E}_v , was calculated at a few fixed points as well as at the center of the organized vortex. Because the generation of the Reynolds stress is significantly correlated with the vortex formation as revealed previously, the temporal variation of the kinematic eddy viscosity at the vortex

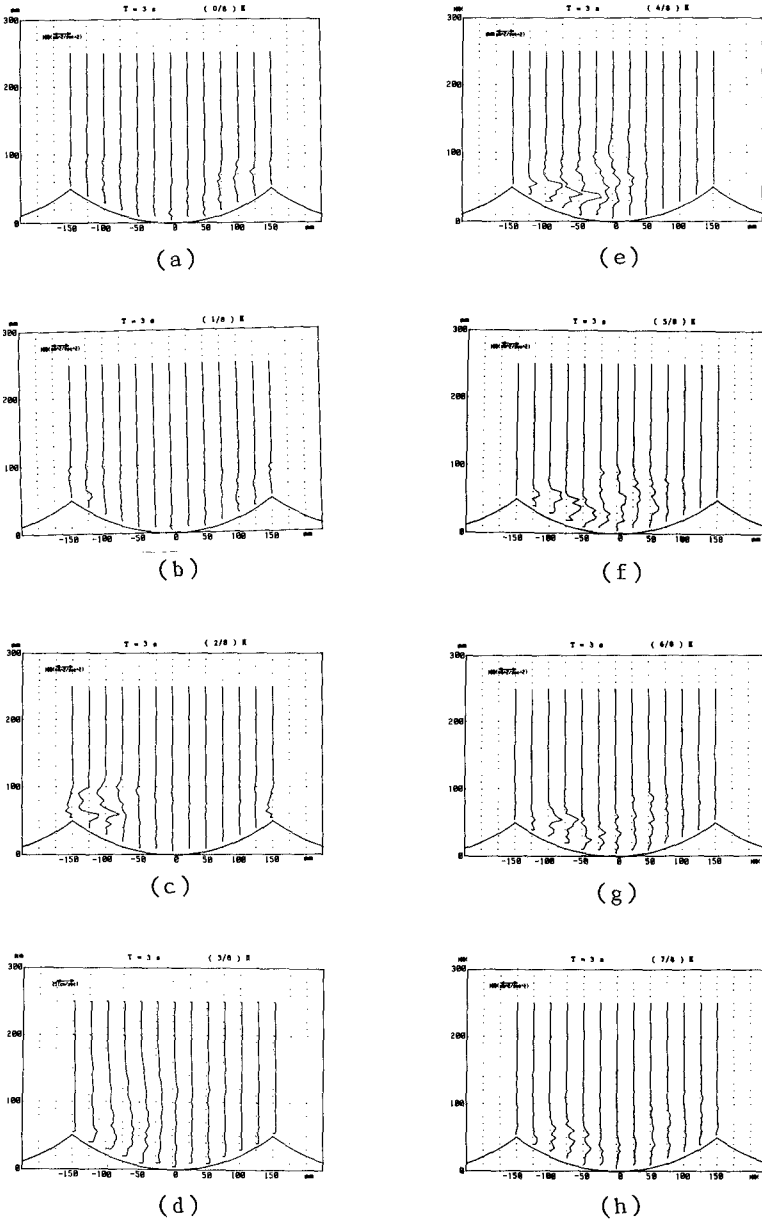

Fig.8 Distribution of kinematic Reynolds stress for Run 3.

center will be described here. The results were given in Figure 9, in which the kinematic eddy viscosity was calculated from the raw data, without smoothing, of the distribution of the fluid velocity and the Reynolds stress. A large variety of the kinematic eddy viscosity with time is almost in accordance with the undisturbed oscillatory flow for each case. It is clearly seen that the kinematic eddy viscosity increased linearly with phase until the phases $4\pi/8$ and $12\pi/8$, at which the fluid velocity reached its maximum. The kinematic eddy viscosity, then, decreased rather gradually, and therefore it indicated a slightly unsymmetrical distribution with respect to the phase. The above feature was common for each run. The distribution of the kinematic eddy viscosity non-dimensionalized by the velocity amplitude of the undisturbed oscillatory flow and the ripple height, becomes nearly identical as shown in Figure 10. The results obtained here suggests that the assumption of constant kinematic eddy viscosity does not hold in the present type of flow, and a turbulent model such as two equation model must be employed to predict the flow field.

Fig.9 Temporal variations of kinematic eddy viscosity at the vortex center.

Fig.10 Temporal variation of the non-dimensionalized kinematic eddy viscosity.

CONCLUSIONS

A detailed measurement was performed for the oscillatory boundary layer flow over a sharp-crested ripple model by using a 2-D LDV controlled by a computer. The conclusions are summarized as follows:

- (1) The oscillatory boundary layer over a ripple model is separated into two parts ; the inner and the outer boundary layers. The thickness of the inner boundary layer is well expressed by $\sqrt{\nu T}$. The feature of the outer boundary layer is characterised by the organized vortices, and the growth of the vortices has a phase-lag against the undisturbed main flow.
- (2) The stationary velocity component constitutes two cells between two ripple crests, the distribution of which is similar regardless of the test conditions. The flow is moving toward the crests, and the velocity is very large near the bottom boundary close to the ripple crests.
- (3) The fluid turbulence is found to be closely correlated with the vortices. The generation of the Reynolds stress is limited essentially within the vortex region. Some minor part of the vortices is convectively transported downstream, and yields weak Reynolds stress there.

- (4) The kinematic eddy viscosity obtained at the near-center of the organized vortices reveals that it varies sinusoidally in accordance with the oscillatory flow. The variation of the kinematic eddy viscosity with respect to the phase is similar to the other regardless of the test conditions reported herein.
- (5) The three-dimensional structure of the oscillatory boundary layer is still left as a future subject.

CHAPTER 52

SENSITIVITY ANALYSIS FOR MULTI-ELEMENT WAVEMAKERS

Gordon S. Harkins,¹ Robert A. Dalrymple² and Miguel A.
Losada³

1 Abstract

Lateral variations in wave height have been observed in directional wave basins when generating monochromatic plane waves. Two numerical schemes are presented to examine wave height sensitivity to perturbations in stroke length between paddles and gaps between either adjacent paddles or the sidewall of the basin. A non-uniform wavemaker front generates both the desired wave and can generate waves at an angle and at the same frequency as the main wave.

2 Introduction

Simulation of realistic sea states requires the use of directional wave basins which can produce directional spectra. These basins generally consist of numerous wavemakers along one side of the tank and either reflecting or absorbing walls for the other sides. Before realizing the full potential of these tanks one must first understand the production of uniform monochromatic waves by a multi-element wavemaker system and the errors inherent in any possible nonuniform wavemaker front.

A numerical procedure is developed to examine wave height sensitivity to gaps which may exist between paddles and variations in paddle stroke length in a wave basin with reflecting

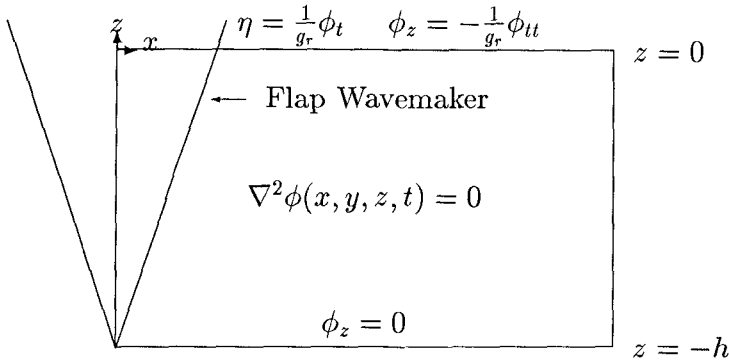

Figure 1: Boundary value problem specifications for both numerical models

sidewalls. To study variations in paddle motion for a multi-element wavemaker system a technique was developed to numerically model individual paddles. A sinusoidally varying “top hat function” consisting of the difference of two Heaviside functions is used to represent the paddle motion. This allows each paddle to have its own stroke length. For small amplitude waves the total wave height at a particular location in the tank can be found from the summation of waves produced by each individual paddle. No-flow gaps between paddles are created by positioning the “top hat functions” a small distance apart.

A second technique was used to specify the flow through gaps for uniform motion of a multi-element wavemaker system. A dual series relation is developed by matching the water particle velocity across the gaps and wavemakers and matching the velocity potential in the gaps. The perturbations in the wave field produced by the gaps is examined for two cases. The first involves an infinitely long tank with infinitely wide wavemakers placed in the middle of the tank. The second cases involves wavemakers placed a finite distance away from a fully reflecting backwall.

3 Formulation of the Boundary Value Problem

For an incompressible fluid with irrotational motion Laplace’s equation

$$\nabla^2\phi(x, y, z, t) = 0$$

holds throughout the domain of the problem. Laplace’s equation is elliptic and can only be solved uniquely if boundary conditions are given around the domain of the problem. For small amplitude waves the boundary conditions can be seen in Figure

1. Along the free surface the dynamic free surface and the combined free surface boundary conditions are applied. A no flow condition is specified for the bottom at $z = -h$. Applying the bottom boundary condition and the linear combined free surface boundary condition the velocity potential can be written as

$$\Phi = \phi(x, y) \cosh k(h + z)e^{-i\sigma t} \quad (1)$$

where a temporally periodic solution has been assumed. The angular frequency is given by the usual dispersion relationship

$$\sigma^2 = g_r k \tanh k(h + z)$$

where g_r is gravity, k is the wave number defined as $\frac{2\pi}{L}$ where L is the wavelength. Since we are interested in the cause of the lateral variation along the whole length of the tank, the vertically evanescent modes have been neglected because of their rapid decay away from the paddles.

We will also specify a no flow condition through the side walls given as

$$\phi_y = 0 \text{ at } y = \pm b$$

Two families of solutions exist that satisfy the side wall condition. The first family of solutions is symmetric about the x -axis and is referred to as the even modes and is given by the y portion of the velocity potential below

$$\phi_e(y) = \cos \lambda_j y$$

where

$$\lambda_j \equiv \frac{j\pi}{b} \text{ for } j = 0, 1, 2, \dots$$

One should note that the usual plane progressive mode is the $j = 0$ mode which has no variation in wave height across the tank. The second family of solutions is anti-symmetric about the x -axis and is referred to as the odd modes and the y component of the velocity potential is

$$\phi_o(y) = \sin \gamma_l y$$

where

$$\gamma_l \equiv \frac{l + \frac{1}{2}\pi}{b} \text{ for } l = 0, 1, 2, \dots$$

In general the y component of the velocity potential is just the sum of the even and odd modes.

Figure 2: Top hat function generated by the difference of two Heaviside function

The x component of the velocity potential which satisfies Laplace's can be written as

$$\phi(x) = e^{i\sqrt{k^2 - \alpha^2}x}$$

where α represents either the even or odd mode wave number.

The velocity potential can be separated into its even and odd contributions and be written as the sum of

$$\phi_e = \sum_{j=0}^{\infty} A_j e^{i(\sqrt{k^2 - \lambda_j^2}x - \sigma t)} \cosh k(h + z) \cos \lambda_j y$$

$$\phi_o = \sum_{l=0}^{\infty} B_l e^{i(\sqrt{k^2 - \gamma_l^2}x - \sigma t)} \cosh k(h + z) \sin \gamma_l y$$

This is the same solution Dalrymple (1989) found for a constant depth wave basin. To solve for the unknowns A_j and B_l we will use the wavemaker boundary conditions.

3.1 Wavemaker Boundary Conditions for Perturbations in Stroke Length

For a wave tank whose paddle spans the width of the tank the usual linearized kinematic wavemaker boundary condition can be shown to yield

$$u(0, z, t) = -iU_0 e^{-i\sigma t} \text{ for } |y| < b \quad (2)$$

where U_0 is the magnitude of the paddle velocity at $x = 0$ along the z^{th} plane and i is the $\sqrt{-1}$.

A more attractive technique exists for specifying (2) which can be expanded to account for a multi-element wavemaker. We will denote the Heaviside function as H and define $H(y - b)$ as

$$H(y - b) = \begin{cases} 0, & \text{for } y < b \\ 1, & \text{for } y \geq b \end{cases}$$

We can also combine two Heaviside functions to generate a "top hat function". Figure 2 was generated using the difference of two

Heaviside function as given below

$$\mathbf{H} = H(y + b) - H(y - b). \tag{3}$$

Multiplying the “top hat function” by $U_0(z)$ and a complex exponential of time yields the wavemaker boundary condition in terms of Heaviside functions and can be written as

$$u(0, y, z, t) = -iU_0\mathbf{H}e^{-i\sigma t}$$

The “top hat function” approach can be expanded to account for a multi-element wavemaker. The width of the Heaviside functions and placement controls the paddle width and the no flow gap width between paddles. In general the wavemaker boundary condition for the n^{th} paddle can be written as

$$u_n(x = 0, y, z, t) = -iU_{0,n}\mathbf{H}_n\mathbf{e}^{-i\sigma t}$$

and the full wavemaker boundary condition is the sum of the contribution from each wavemaker

$$u(0, y, z, t) = \sum_{n=1}^N u_n \tag{4}$$

where N is the number of wavemakers and the constant $U_{0,n}$ allows for non-uniform paddle motion. For stroke length perturbations $U_{0,1} \neq U_{0,2} \neq \dots U_{0,N}$. This is different from waves that are generated at an angle to the wavemaker in which there is a sinusoidal variation in the phase between paddles but the stroke length for each paddle is the same.

For an N wavemaker system a summation over the N paddles must also be added and the even and odd velocity potentials reduce to

$$\phi_e = \sum_{n=1}^N \sum_{j=0}^{\infty} A_{n,j} e^{i(\sqrt{k^2 - \lambda_j^2}x - \sigma t)} \cosh k(h + z) \cos \lambda_j y \tag{5}$$

and

$$\phi_o = \sum_{n=1}^N \sum_{l=0}^{\infty} B_{n,l} e^{i(\sqrt{k^2 - \gamma_l^2}x - \sigma t)} \cosh k(h + z) \sin \gamma_l y. \tag{6}$$

The constants $A_{n,j}$ and $B_{n,l}$ can be solved uniquely by applying the wavemaker boundary condition given in (4) for the n^{th} paddle and the orthogonal relationship between trigonometric series and the hyperbolic cosine function. For the even coefficients we first multiply by the $\cos \lambda_j y$ term and integrate over the

width of the tank and then multiply by $\cosh k(h+z)$ term and integrate over the depth. Similarly for the odd coefficients except we multiply by the $\sin \gamma_l y$ series instead of the cosine series. The coefficients are given as

$$A_{n,j} = -\frac{\int_{-b}^b U_{0n}(y) \mathbf{H}_n \cos \lambda_j y dy \int_{-h}^0 U(z) \cosh k(h+z) dz}{\sqrt{k^2 - \lambda_j^2} \int_{-b}^b \cos^2 \lambda_j y dy \int_{-h}^0 \cosh^2 k(h+z) dz} \quad (7)$$

$$B_{n,l} = -\frac{\int_{-b}^b U_{0n}(y) \mathbf{H}_n \sin \gamma_l y dy \int_{-h}^0 U(z) \cosh k(h+z) dz}{\sqrt{k^2 - \gamma_l^2} \int_{-b}^b \sin^2 \gamma_l y dy \int_{-h}^0 \cosh^2 k(h+z) dz} \quad (8)$$

The free surface elevation can be found from the linear dynamic free surface boundary condition.

3.2 Wavemaker Boundary Condition for Flow between Paddles

In the previous formulation Heaviside functions were used to model wavemakers where a perturbation between paddle stroke length could be analyzed. In this section a numerical procedure is introduced to study the wave field created by gaps between paddles for uniform paddle motion. These gaps allow flow between the paddles unlike the previous section where no flow gaps were assumed. Since there is a transmission of fluid through the gaps, an eigenfunction expansion method describes the wave field on each side of the wavemakers.

Two cases will be analyzed for the gap problem. The first case involves an infinitely long tank with an infinitely wide wavemaker located in the center of the tank. In the second case, the gap problem is solved in a semi-infinite long tank with infinitely wide wavemakers placed next to a reflecting backwall.

3.2.1 Infinitely Long Tank

The solution technique Dalrymple and Martin (1990) applied to the problem of waves impinging on an infinite row of offshore breakwaters can be applied to the problem of wavemakers with gaps. Following the coordinate convention Dalrymple and Martin introduced, the wavemakers are modelled as infinitely thin barriers, centered at $y = \pm nb$ where $n = 1, 2, 3, \dots, \infty$ and are separated by gaps of width $2g$. The lines $y = \pm nb$ are lines of symmetry assuming the wavemaker motion is uniform. Instead of solving the problem for an infinitely long row of wavemakers an analogous problem in which a sidewall or barrier is placed

Figure 3: Boundary conditions for an infinitely long tank

along the lines of symmetry will be solved. Waves that initially travelled across these lines are now reflected back and the wave pattern seen is unchanged.

For uniform paddle motion the wave field is symmetric about the center of the wavemakers and thus only the even family of solutions should be retained in the y component of the velocity potential. The velocity potential for $x < 0$ can be written as

$$\phi_1(x, y) = \sum_{j=0}^{\infty} A_j \cos \lambda_j y e^{-i\sqrt{k^2 - \lambda_j^2} x}$$

where the negative complex exponential allows waves traveling to the left and for $x > 0$

$$\phi_2(x, y) = - \sum_{j=0}^{\infty} B_j \cos \lambda_j y e^{i\sqrt{k^2 - \lambda_j^2} x}$$

where the minus sign has been kept for convenience. The full velocity potential can be found using equation (1).

The wavemaker boundary conditions shown in Figure 3 will be used to solve for the constants A_j and B_j . Three conditions are specified. The first is the kinematic wavemaker boundary condition matching the wavemaker velocity with the water velocity. In the gaps we match the velocities and the velocity potentials to ensure a matching of the free surface. Setting the velocities and the velocity potentials in the gaps equal we find that

$$\sum_{j=0}^{\infty} A_j \cos \lambda_j y = 0 \quad \text{for } |y| \leq g \tag{9}$$

Matching the velocity at the wavemaker

$$\sum_{j=0}^{\infty} (A_j \sqrt{k^2 - \lambda_j^2} \cos \lambda_j y - U_0) = 0 \text{ for } g < |y| \leq b \quad (10)$$

Sneddon (1966) termed the two conditions (9) and (10) a dual series relation which can be combined to make one mixed boundary condition given as $G(y) = 0$ where

$$G(y) = \begin{cases} \sum_{j=0}^{\infty} A_j \cos \lambda_j y, & \text{for } |y| \leq g \\ \sum_{j=0}^{\infty} A_j \sqrt{k^2 - \lambda_j^2} \cos \lambda_j y - U_0, & \text{for } g < |y| \leq b \end{cases} \quad (11)$$

The above expression can not be solved analytically and we will resort to using a least squares techniques to solve for the unknown coefficients A_j . This requires that the following equation be a minimum

$$\int_{-b}^b |G(y)|^2 dy. \quad (12)$$

by definition $|G(y)|^2 = GG^*$ where the $*$ denotes the complex conjugate. If we minimize the above integral with respect to A_j we find

$$\frac{\partial}{\partial A_m} \int_b^b |G| dy = 0$$

or

$$\int_b^b G^* \frac{\partial G}{\partial A_m} dy = 0 \text{ for } m = 0, 1, \dots$$

where

$$\frac{\partial G}{\partial A_m} = \begin{cases} \cos \lambda_m y & \text{for } |y| \leq g \\ \sqrt{k^2 - \lambda_m^2} \cos \lambda_m y & \text{for } g < |y| \leq b \end{cases}$$

3.2.2 Semi-Infinite Tank

The above problem of an infinitely long tank only needs to be slightly modified to account for a reflecting backwall located behind the wavemakers. This problem can be seen in Figure 4 where the backwall is located a distance ℓ behind the wavemakers. To account for the backwall an additional term must be added to ϕ_1 and is shown below

$$\phi_1(x, y) = \sum_{j=0}^{\infty} (B_j e^{-i\sqrt{k^2 - \lambda_j^2} x} \cos \lambda_j y + C_j e^{i\sqrt{k^2 - \lambda_j^2} (x + \ell)} \cos \lambda_j y)$$

Figure 4: Boundary conditions for a semi-infinite tank

Applying the no-flow condition at $x = -\ell$ we can first find an expression for B_j in terms of C_j and re-write ϕ_1 as

$$\phi_1(x, y) = \sum_{j=0}^{\infty} B_j \cos \lambda_j y [e^{-i\sqrt{k^2 - \lambda_j^2} x} + e^{i\sqrt{k^2 - \lambda_j^2} (x+2l)}].$$

By matching the velocities in the gap we find

$$B_j = -\frac{A_j}{1 - e^{2i\sqrt{k^2 - \lambda_j^2} l}}$$

thus ϕ_1 can be written as

$$\phi_1 = \sum_{j=0}^{\infty} -A_j \frac{\cos \lambda_j y}{1 - e^{2i\sqrt{k^2 - \lambda_j^2} l}} (e^{-i\sqrt{k^2 - \lambda_j^2} x} + e^{i\sqrt{k^2 - \lambda_j^2} (x+2l)})$$

We will use the remaining two boundary conditions to find a new dual series relationship given as

$$G(y) = \begin{cases} \sum_{j=0}^{\infty} A_j \cos \lambda_j y (1 + \beta) = 0, & \text{for } |y| \leq g \\ \sum_{j=0}^{\infty} A_j \sqrt{k^2 - \lambda_j^2} \cos \lambda_j y - U_0, & \text{for } g < |y| \leq b \end{cases}$$

where β is

$$\beta = \frac{1 + e^{2i\sqrt{k^2 - \lambda_j^2} l}}{1 - e^{2i\sqrt{k^2 - \lambda_j^2} l}}$$

4 Numerical Results

4.1 Perturbed Paddle Motion

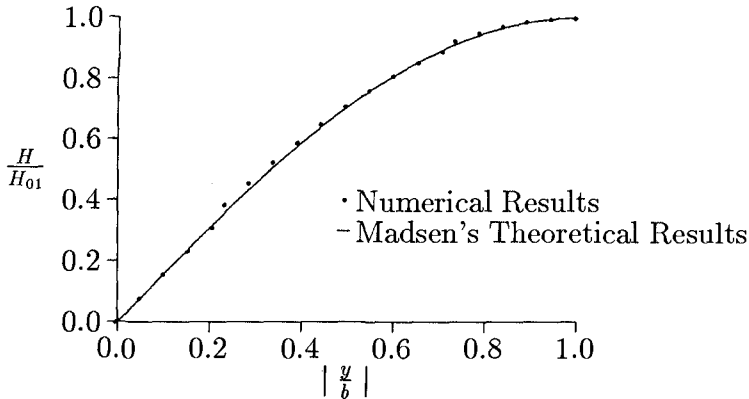

Figure 5: Relative wave height variation where H is the calculated wave height divided by the theoretical wave height H_{01} versus the dimensionless position across the tank $\frac{y}{b}$.

Madsen (1974) analyzed the results of a two wave paddle system in which the paddles were 180° out of phase located between reflecting sidewalls and a flat impermeable bottom. Madsen's numerical results which correspond very closely with his experimental results are plotted versus the authors numerical results in Figure 5. The horizontal axis shows the nondimensional position across the tank, and the vertical axis is the nondimensional wave height given by the calculated wave height H divided by the theoretical wave height along the sidewalls. The figure shows very good agreement between the two models.

We will again use the two wavemaker system utilized by Madsen but instead of 180° phase difference between paddles we allow a 10% variation in the stroke length between paddles. The importance of the lateral variation can be calculated by the ratio of a_{max}/a_0 where a_{max} is the combined amplitude of the non-plane modes and a_0 is the amplitude of the plane progressive mode (the $j = 0$ mode). Figure 6 shows the importance of the non-plane modes for varying kb values. This problem is purely anti-symmetric and cross tank resonance occurs at $kb = \pi/2$ and $3\pi/2$.

The usefulness of the first model is not limited to a two wave-maker system. Figure 7 was produced by a 10 paddle system with a 10% variation in the paddle stroke where the no flow gaps between paddles are 10% of the paddle width and $kb = 5.6$. The figure is a computer generated instantaneous picture of only the perturbed wave field where the wave crests are the darker regions and the wave troughs are the lighter regions. The paddles are located at the bottom of the figure and the reflecting sidewalls are

Figure 6: The lateral variation produced by a 10% stroke length difference for a two paddle system.

Figure 7: Instantaneous picture of the perturbed wave field. The paddles are located at the bottom of the figure and the sidewalls are located on the left and right margins.

Figure 8: Resonance curves for an infinitely long tank. A gap width of 5% of the paddle width is marked with \square and a 10% gap width is marked with $+$.

located on the left and right margins. A 15% variation in the waveheight was found for this case.

4.2 The Gap Problem

A lateral variation in the wave field can also be produced by flow through the gaps between paddles for an infinitely long tank. For the gap problem we assumed symmetric motion about the center of the tank and resonance should occur at $kb = n\pi$. Graphing kb versus a_{max}/a_0 defined previously, Figure 8 clearly shows the first three resonance peaks. Decreasing the gap width by 5% greatly reduces the lateral variation generated.

The wave field produced by placing a reflecting backwall just over a half wavelength behind the wavemaker can be seen in Figure 9. In this case the location of the backwall is near resonance and with $kb = 3.6$ the tank is near resonance across the tank. Graphs showing lateral variation as a function of kb for different gap sizes and backwall distances can be found in Harkins (1990).

Figure 9: Instantaneous picture of the wave field produced by gaps between paddles. The backwall is located at the bottom of the figure.

5 Conclusions

Both the generated wave length and the basin geometry are important in creating a clean monochromatic plane wave. Even small perturbations in the paddle stroke length as well as flow between paddles can generate large lateral variations in the wave field especially near resonance conditions.

Heaviside functions can accurately represent discrete paddles of a multi-element wavemaker. This technique is useful in analyzing perturbations in the stroke length between paddles since the stroke length of each paddle is easily defined. Lateral variations will be present whenever the tank width is wider than the half wavelength of the generated wave and can be significant when the kb is a multiple of $\frac{\pi}{2}$. For small amplitude waves, the wave field is produced by the contribution of each paddle and thus the complexity of the wave field increase with the number of paddles.

If water is allowed to flow through the gaps between paddles, then an eigenfunction expansion can be used to describe the wave field produced. Since the wavemaker motion was assumed to be uniform, lateral variation will be present when the paddle plus gap width is greater than the wavelength of the generated wave. The lateral variation can be significant when the kb ratio is a multiple of π and when the flow through the gaps is stronger.

CHAPTER 53

A MODEL TO PROPAGATE NONLINEAR WATER WAVES

J. M. Chambel Leitão*

J. L. M. Fernandes**

Abstract

The aim of the work presented here is to propagate random waves from deep or intermediate water depth to the nearshore region with a Boundary Integral Equation Method (BIEM) which is able to handle the nonlinear effects that occur in the process. A two-dimensional (x,z) mild nonlinear model to propagate waves over an uneven bottom is presented here. It takes into account 2nd order nonlinear effects of the wave transformation entering into shallow water. If energy dissipation is neglected, the flow field generated by the wave propagation can be described by a velocity potential formulation which is governed by the Laplace's equation in the domain. The results obtained from the model are time-dependent. The model is tested with solitary and irregular waves and compared with analytical and experimental results.

Introduction

The previous work done by the authors, (Fernandes, 1988) and (Leitão and Fernandes, 1989), led to the evidence that the computer CPU time required by a linear BIEM model (which cannot handle nonlinear effects) was relatively small whereas the nonlinear one was prohibitively expensive for real problems. This high cost is primarily due to the moving free surface boundary because the operation count includes forming a new coefficient matrix and solving the system every time step.

A mild nonlinear model, was developed to meet the needs of affordable computer time and significant nonlinear effects. A Stokes-like expansion provided second order terms of the kinematic and the dynamic free surface boundary conditions that were introduced into a BIEM model. The important advantage of this is that these free-surface conditions are now applied at the mean water level which precludes moving elements. A constant coefficient matrix is used in this case. The boundary is discretized into linear elements and the time stepping is based on multistep integrators.

Basic Equations

Considering the flow to be irrotational and inviscid and the fluid to be incompressible, the Laplace's equation for the velocity potential (ϕ) is valid.

$$\nabla^2 \phi = 0 \quad (1)$$

This equation is subjected to a number of boundary conditions, namely: a) prescribed velocity (at the bottom or vertical boundaries),

$$\frac{\partial \phi}{\partial n} = \gamma(x, z, t), \quad (2)$$

where n is the unit outward normal; b) radiation (at vertical boundaries),

$$\frac{\partial \phi}{\partial t} + c \frac{\partial \phi}{\partial n} = 0, \quad (3)$$

where c is the outgoing wave celerity; c) two nonlinear conditions (dynamic and kinematic) for the free-surface:

$$\frac{\partial \phi}{\partial t} + \frac{1}{2} |\nabla \phi|^2 + g\eta = 0; \quad z = \eta \quad (4)$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial \phi}{\partial x} \frac{\partial \eta}{\partial x} - \frac{\partial \phi}{\partial z} = 0; \quad z = \eta \quad (5)$$

where η is the surface elevation.

2nd order free surface equations

In order to avoid problems and costs caused by a moving boundary on the numerical model, a Taylor series expansion of both dynamic and kinematic conditions is made about the level $z=0$.

$$\phi(x, \eta, t) = \phi(x, 0, t) + \eta \frac{\partial \phi(x, 0, t)}{\partial z} + \eta^2 \frac{\partial^2 \phi(x, 0, t)}{\partial z^2} + O(\eta^3) \quad (6)$$

The following expressions result for the free-surface conditions, considering only the two first terms of the Taylor series:

$$\frac{\partial \phi}{\partial t} + \eta \frac{\partial^2 \phi}{\partial z \partial t} + g\eta + \frac{1}{2} \left(\frac{\partial \phi}{\partial x} \right)^2 + \eta \frac{\partial \phi}{\partial x} \frac{\partial^2 \phi}{\partial x \partial z} + \frac{1}{2} \left(\frac{\partial \phi}{\partial z} \right)^2 + \eta \frac{\partial \phi}{\partial z} \frac{\partial^2 \phi}{\partial z^2} = 0; \quad z = 0 \quad (7)$$

$$\frac{\partial \eta}{\partial t} + \frac{\partial \phi}{\partial x} \frac{\partial \eta}{\partial x} + \eta \frac{\partial^2 \phi}{\partial x \partial z} \frac{\partial \eta}{\partial x} - \frac{\partial \phi}{\partial z} - \eta \frac{\partial^2 \phi}{\partial z^2} = 0; \quad z = 0 \quad (8)$$

In order to assess the importance of each term, dimensionless variables are introduced as follows:

$$\phi = \frac{AL}{T} \phi'; \quad x = Lx'; \quad z = h z'; \quad t = Tt'; \quad \eta = A\eta'$$

The typical scales used are: A - wave amplitude; L - wave length; T - wave period; h - depth. Using also parameters $\epsilon = A/h$ and $\delta = h/L$ (dropping primes) expressions (7) and (8) result in:

$$\begin{aligned} \frac{\partial \phi}{\partial t} + \epsilon \eta \frac{\partial^2 \phi}{\partial z \partial t} + \frac{T^2}{L} g\eta + \epsilon \delta \frac{1}{2} \left(\frac{\partial \phi}{\partial x} \right)^2 + \epsilon^2 \delta \eta \frac{\partial \phi}{\partial x} \frac{\partial^2 \phi}{\partial x \partial z} + \frac{\epsilon}{\delta} \frac{1}{2} \left(\frac{\partial \phi}{\partial z} \right)^2 + \\ + \frac{\epsilon^2}{\delta} \eta \frac{\partial \phi}{\partial z} \frac{\partial^2 \phi}{\partial z^2} = 0 \end{aligned} \quad (9)$$

$$\frac{\partial \eta}{\partial t} + \epsilon \delta \frac{\partial \phi}{\partial x} \frac{\partial \eta}{\partial x} + \epsilon^2 \delta \eta \frac{\partial^2 \phi}{\partial x \partial z} \frac{\partial \eta}{\partial x} - \frac{1}{\delta} \frac{\partial \phi}{\partial z} - \frac{\epsilon}{\delta} \eta \frac{\partial^2 \phi}{\partial z^2} = 0 \quad (10)$$

Neglecting terms of $O(\epsilon^2)$, $O(\epsilon^2/\delta)$ or larger and getting back to dimensional form, the free-surface conditions read:

$$\text{- Dynamic} \quad \frac{\partial \phi}{\partial t} = -g\eta - \frac{1}{2} |\nabla \phi|^2 - \eta \frac{\partial^2 \phi}{\partial z \partial t} \quad (11)$$

$$\text{- Kinematic} \quad \frac{\partial \eta}{\partial t} = \frac{\partial \phi}{\partial z} - \frac{\partial \phi}{\partial x} \frac{\partial \eta}{\partial x} + \eta \frac{\partial^2 \phi}{\partial z^2} \quad (12)$$

These equations are both valid at level $z = 0$ which allows the upper boundary in the numerical model to be constant in time. The last two terms of (11) and (12) account for the most important nonlinear effects while the others represent the linear ones.

Boundary Integral Element Method

The Laplace's equation with prescribed Dirichlet, Neumann, Robin and mixed boundary conditions is an elliptic problem which can be suitably solved by the BIEM. Our problem for the velocity potential is an hyperbolic one which includes variable time. Thus, we can use that method for the spatial discretization and let the time dependency be handled by a finite difference stepping scheme. A direct boundary element formulation, based upon Green's second identity, relates potential and normal velocity at the boundary. This way, the discretization involves only the boundary. For each element, x , z , ϕ , $\partial\phi/\partial n$ and η are piecewise linearly interpolated using their nodal values. Boundary conditions and unknowns can then be manipulated to form a system of equations. Having done this, one obtains an approximate solution that is equally accurate on both potential and normal velocity. The computation, upon request, of the potential and the velocity vector at interior points is explicit.

Time Marching Procedure

The free-surface equations for the second order model include linear terms, which are integrated by a trapezoidal rule (implicit), plus second order terms for which Adams predictor-corrector formulas are adequate. The blended predictor formulae are as follows:

$$\text{Dynamic} \quad \frac{1}{\Delta t} (\phi^{i+1} - \phi^i) = -\frac{g}{2} (\eta^{i+1} + \eta^i) + D_P^{(i,i-1)} \quad (13)$$

$$\text{Kinematic} \quad \frac{1}{\Delta t} (\eta^{i+1} - \eta^i) = \frac{1}{2} (\phi_z^{i+1} + \phi_z^i) + K_P^{(i,i-1)} \quad (14)$$

Here D_P and K_P represent differences from linear equations and can be predicted as:

$$D_P^{(i,i-1)} = \frac{1}{4} (\phi_x^2 + \phi_z^2)^{i-1} - \frac{3}{4} (\phi_x^2 + \phi_z^2)^i + \frac{1}{2} (\eta^{i-1} \phi_{zt}^{i-1} - 3 \eta^i \phi_{zt}^i)$$

$$K_P^{(i,i-1)} = \frac{1}{2} (-3 \phi_x^i \eta_x^i + \phi_x^{i-1} \eta_x^{i-1} - 3 \phi_{xx}^i \eta^i + \phi_{xx}^{i-1} \eta^{i-1}).$$

The corrector step makes use of the formulas:

$$\text{Dynamic} \quad \frac{1}{\Delta t} (\phi^{i+1} - \phi^i) = -\frac{g}{2} (\eta^{i+1} + \eta^i) + D_C^{(i+1,i)} \quad (15)$$

$$\text{Kinematic} \quad \frac{1}{\Delta t} (\eta^{i+1} - \eta^i) = \frac{1}{2} (\phi_z^{i+1} + \phi_z^i) + K_C^{(i+1,i)} \quad (16)$$

where D_C and K_C are given by:

$$D_C^{(i+1,i)} = -\frac{1}{4} (\phi_x^2 + \phi_z^2)^{i+1} - \frac{1}{4} (\phi_x^2 + \phi_z^2)^i - \frac{1}{2} (\eta^{i+1} \phi_{zt}^{i+1} + \eta^i \phi_{zt}^i)$$

$$K_C^{(i+1,i)} = -\frac{1}{2} (\phi_x^{i+1} \eta_x^{i+1} + \phi_x^i \eta_x^i + \phi_{xx}^{i+1} \eta^{i+1} + \phi_{xx}^i \eta^i).$$

The numerical computation of the derivatives is omitted for brevity, being the vertical acceleration (ϕ_{zt}) the most unstable. A linear relation between ϕ and $\partial\phi/\partial n$ is sought with these formulae and it is accomplished by substitution of η^{i+1} in (13) with the corresponding expression taken from (14). The same is done for the correction procedure. Due to their linearity, other boundary conditions are of straightforward discretization in time.

Test Case 1

This first example aims to test the model with solitary waves propagating over a constant depth channel. Amplitudes were made to vary from 0.1 to 0.4 times the depth. From figure 1 an amplitude decay can be observed near the generation region and becoming less apparent as the wave moves rightwards. For

Figure 1. water surface profiles, for several time instants, and maximum amplitude curve along the channel; BIEM numerical results

Figure 2. Comparison between numerical and Boussinesq's solitary wave profiles: a) $A/h \approx 0.1$; b) $A/h \approx 0.4$

Figure 3. Comparison between numerical and analytical results for: a) volume under solitary waves; b) celerity

higher amplitudes this decay is more pronounced. Also a dispersive tail can be seen as the wave propagates. In figures 2a and 2b comparisons are made between the numerical profiles and the analytical solution of Boussinesq. These numerical profiles were taken when the wave reached the right end of the channel and had already an almost constant amplitude. The agreement seems good. Computations of celerity and of the volume under the solitary waves are also compared with their corresponding analytical values available from Boussinesq's theory (figure 3). Again both numerical and analytical values agree well and even the different trend that can be identified in the numerical results of celerity is also present on some experimental results (Goring, 1978). The CPU time needed for each run (1000 time steps and 620 nodes) was about 6m30s on a CONVEX C220.

Test Case 2

A solitary wave propagating over a step is tested and results are compared with experiments by (Goring, 1978). In figure 4 time series of surface elevation at several points are displayed along with some experimental values. The effects of viscosity and bottom and wall shear, present when a real wave propagates on a channel, tend to decrease the amplitude of the wave. Since those effects are not accounted for on the numerical model, differences found both in amplitude and phase should be expected. The second wave on gauge 1 is the one reflected from the step which, after reflecting again on the generation plate, appears once more on that same gauge. This second reflection on the generator is not present on the experimental results maybe because that wavemaker had a nonreflecting surface. After passing over the step, the solitary wave evolves into three solitary waves. On gauge 5 those three waves, going to and coming from the right wall, can be very distinctly observed. Figure 5 shows the free-surface numerical profile when the first and second waves are almost completely formed. They are compared with two analytical Boussinesq's profiles of equal amplitudes. The CPU time needed for this example (3500 time steps and 683 nodes) was 22 min on a CONVEX C 220.

Figure 4. Water surface elevation time histories at five gauges along the channel; comparison between BIEM and experimental results

Figure 5. BIEM water surface profile; comparison with Boussinesq's theoretical solitary wave profiles

Test Case 3

The shoaling of random waves is a problem of current interest and it is addressed here in the perspective of comparing experimental and field results with numerical BIEM results. A limitation of this numerical model is that it cannot include breaking effects on shoaling studies. As this is a second order model, propagating waves of two individual frequencies, say f_i and f_j , would produce waves of frequency f_i+f_j and f_i-f_j . For a continuous spectrum, energy is transferred to lower and higher harmonics of the peak frequency; see for example (Mansard et al.,1988).

Three random wave cases were simulated with three different significant wave heights (5.0, 8.0 and 8.5 cm) each corresponding to a Bretschneider spectrum with 0.6 Hz peak frequency. The effects of shoaling, on a 1/20 slope, upon spectral shape, groupiness factor, shape factor of Weibull Distribution and skewness of water surface variation are investigated and compared, when it was possible, with experiments from (Mase, 1989). Although Mase's experiments were made by taking several samples from a spectrum (Pierson-Moskowitz with peak frequency of 0.6 Hz) but with different groupiness factors, the 3 numerically generated samples of random waves used in this study had 3 different spectra for each one and no imposed groupiness factor.

Figure 6. Numerical flume (dimensions in meters)

The "numerical flume" in figure 6, had the generation region at 45cm depth, and a slope of 1/20 until 19 cm depth. At the right end of the channel a radiation boundary is used. The referred experiments of (Mase, 1989) also include the breaking region. Records of surface elevation were stored for 50 nodes of

the free-surface during 250 sec., containing about 170 waves, and for each one a time and frequency analysis was done. The spectra in fig. 7 are: the one imposed, with a significant wave height of 8.5 cm and source of the random wave sample, and the other three result from the frequency analysis at 45cm (toe of the slope), 23.5cm and 19 cm depth. Sub and superharmonics appear very clearly for decreasing depths in fig. 7. This energy transfer inside the spectrum, a nonlinear effect, is present when waves reach shallow water.

Figure 7. Spectra resulting from numerical BIEM data frequency analysis at several depths and source spectrum of the random waves introduced at the left end of the channel

The most important parameters computed were:

- The groupiness factor (GF) calculated from SIWEH (Funke and Mansard, 1979);
- The shape factor of the one parameter Weibull Distribution (m) (Cohen, 1965);
- The skewness of water surface variation ($\sqrt{\beta_1}$);
- The spectral width parameter Q_p defined by (Goda, 1970).

In fig. 8 the variation of Q_p along the slope can be seen and, though no comparison is made with other results, the trend seems to be correct according to data from (Thompson and Vincent, 1985). In fig. 9 the variation of the groupiness factor and the skewness along the slope is shown. When compared with results from (Mase, 1989) it can be seen that for similar tests similar values and trends are encountered. A correlation between the groupiness factor and the shape factor of Weibull Distribution proposed by (Mase, 1989) is presented in fig. 10 with some of the numerical results. These seem to fit quite well in the 95% confidence interval.

Figure 8. Spectral Width Parameter along the 1/20 slope

Conclusions

A 2nd order BIEM model to propagate waves in intermediate and shallow water was presented. The tests made with solitary and irregular waves showed that it can handle quite well nonlinear waves up to, at least, 0.4 of relative wave height. Although it cannot include breaking effects, studies of irregular wave propagation are possible within a moderate range of relative wave heights (this limit would be about $0.5Hm_0/h$)

Figure 9. Variation along the 1/20 slope of: a) the Groupiness Factor; b) the Skewness of Water Surface Variation

Figure 10. Relationship between Groupiness Factor and Shape Factor of Weibull Distribution

although it was not thoroughly studied). In that range of relative wave heights it is possible to compute pressure inside the 2D domain which allows also to evaluate forces acting on submerged bodies. Depending on the size of the discretization, this model is about 10 times faster than a fully nonlinear BIEM model. The ideas presented here can be extended to three-dimensional problems as more computer power becomes available.

CHAPTER 54

WAVE DIRECTION MEASUREMENT USING MARINE X BAND RADAR

Hiromaru Hirakuchi, Masaaki Ikeno

ABSTRACT

Spatial radar signals received by a conventional marine radar are digitized as a 8-bit word by means of an A/D converter. The numerical procedure is discussed to estimate the two-dimensional radar spectrum from a digitized radar image. Directional spectra of sea waves are also observed by a 3-component wave array. A comparison of the mean wave direction and period estimated from the radar spectrum with the results from the array spectrum shows that the developed data acquisition system and numerical procedure represent a reliable and very cost-effective means to observe the properties of sea waves.

1. INTRODUCTION

In addition to wave height and period, wave direction has great influence upon the coastal problems. The measuring techniques for wave direction can be classified into two major groups, the direct measurement method and the remote sensing method. In recent years, considerable interest has been showed in the application of the remote sensing techniques; a synthetic aperture radar (SAR) mounted on a satellite or an airplane, a shore-based high frequency (HF) radar. One of such studies has dealt with the use of a marine X band radar.

Ijima et.al.(1964) and Wright(1965) were the first to report the use of the marine radar for imaging ocean waves. Willis and Beaumont(1971), Evmenov et.al.(1973), and Mattie and Harris(1978) have also presented photographic radar images. In order to estimate the mean wave direction and period, these early researchers visually inspected the radar images as displayed on the plane position indicator (PPI).

Making use of the digitized radar images, Hoogeboom and Rosenthal(1982) and Young et.al.(1985) have calculated the 2- and 3-dimensional spectra of the spatial radar images. It appears that the numerical procedure is very useful to determine the properties of ocean waves. In these studies, however, the radar images displayed on the PPI were once recorded on photographic films, and the

Senior Research Engineer, Central Research Institute of Electric Power Industry, Abiko, Abiko-Shi, Chiba, Japan.

photographic images were digitized by means of an image processor. Therefore, it is difficult to apply a marine radar to routine data collection.

The purpose of this study is to overcome some of the technical difficulties associated with the routine data collection and to verify the numerical procedure employed for analysis of digitized radar images through comparison with the directional wave spectra obtained by the direct measurement method.

2. MARINE RADAR SYSTEM

The marine X band radar used in this study is of the conventional rotating type. Parameters of the radar system are as follows: frequency of 9.4GHz, antenna type of 2.81m slotted wave guide, nominal peak power of 25kW, pulse length of 20ns at 5.6km range, pulse repetition frequency of 2000Hz, antenna rotation speed of 24rpm, HH polarization, and horizontal/vertical beam width of $0.8^{\circ}/25^{\circ}$.

The data acquisition system is shown schematically in Fig.1. The intensity of the reflected signals from nearby sea surface is stronger than that from distant sea surface. In order to extend the measurable range of distance, the received signals were fed into a log-amplifier, and the resultant signals were digitized as a 8-bit word (0-255) by means of an A/D converter controlled by a personal computer. The digitized images were stored on floppy disks.

Two successive radar images, having time delay of the antenna rotation period, can be observed by the system. Each radar image in a quadrant area with the angle of 90° consists of 256 pixels along a radar beam and 512 pixels along an arc. The sampling frequency along a radar beam is 10MHz; the distance resolution and range are 15m and 3.84km, respectively. The azimuthal signals of the rotating antenna are used to collect the proper azimuthal data; The azimuthal resolution is about 0.176° .

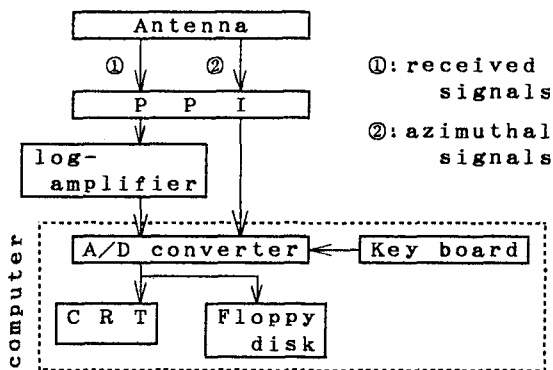

Fig.1 Flow diagram of data acquisition system.

3. FIELD OBSERVATION

A field observation was carried out near the coast of Kashiwazaki, Japan, in Feb., 1988. The marine radar was mounted on a rooftop at the distance of 50m from the shoreline: the height of the antenna is about 20m above the sea level. Fig.2 shows the observation area. Four radar images each with a different direction were observed every 2 hours during two periods; from 18:00 on 15 to 12:00 on 17, and from 16:00 on 27 to 12:00 on 29. As shown in Fig.2, the direction of the first radar image is from 200° to 290°, second 220°-310°, third 245°-335°, and fourth 290°-20°. Where the direction is defined clockwise from the north.

In addition to the radar system, five wave arrays were also deployed to observe the directional spectra of sea waves, as shown in Fig.2, where ST.1-ST.5 represent the wave observation points. ST.1 and ST.4 are 10m deep, ST.3 and ST.5 are 20m deep, and ST.2 is 15m deep. A 3-component wave array was used for the direct wave measurement; a supersonic wave gauge and a two-component electro-magnetic current meter. The wind speed and direction during this observation were measured by Tokyo Electric Power Company at the point A and B in Fig.2. The heights of A and B are 10m and 78m from the ground level, respectively; 20m and 160m from the sea surface, respectively.

An example of the digitized radar images of the 3rd quadrant (245°-335°) are shown in Fig.3(a)-(c), which were observed at 6:00 on Feb. 16 (CASE-1), at 0:00 on Feb. 17 (CASE-2), and at 20:00 on Feb. 27 (CASE-3). Incident wave directions in Fig.3(a) and Fig.3(c) are about 290° and 0°, respectively. The striking feature in Fig.3(b) is the pronounced bi-directional sea state.

Fig.2 Field observation area.

In this study, radar images for CASE-1, 2 and 3 are examined. Wind data at point A and wave data are shown in Table 1, together with the data observed before and after 2 hours of each radar observation.

(a) CASE-1 (at 6:00 on Feb. 16)

(b) CASE-2 (at 0:00 on Feb. 17)

(c) CASE-3 (at 20:00 on Feb. 27)

Fig.3 Observed radar images.

4. DATA PROCESSING

4.1 DISTANCE CORRECTION

The intensity of the radiated energy decreases with the square of the distance from the antenna, and the intensity of the backscattered energy also decreases with the square of the distance from the target.

However, the clutter cross-section is proportional to the distance from the antenna, because the depression angle of the antenna is very small. Therefore, the intensity of the received signals varies inversely as a cube of the distance, rather than inversely as the fourth power as is the case for point targets. In the radar system, the received signals were fed into a log-amplifier, so that the digitized radar signals are expressed as follows:

$$\zeta = \log C = \log \lambda + \log \sigma_0 - 3 \log R \quad \text{----(1)}$$

where ζ is the signal through the log-amplifier, C is the received signal, σ_0 is the cross section per unit area, R is the distance from the antenna, and λ is defined as

$$\lambda = P_t G A_e \theta_B (c \tau / 2) / (4 \pi)^2 \quad \text{---(2)}$$

Where P_t is the transmitter power, G is the antenna gain, A_e is the antenna effective aperture, θ_B is the azimuthal beam width, c is the velocity of radar propagation, and τ is the radar pulse width.

$\log \lambda$ in Eq.(1) is a constant value, because λ is associated with the only specifications of the radar antenna as shown in Eq.(2). Since the distance range considered in this study is from 1 to 4km offshore, $\log R$ in Eq.(1) is approximated to a linear line over this range. $\log \sigma_0$ in Eq.(1) represents the intensity of sea clutter, so that its spatial variation is very important to estimate the wave direction and period.

If the characteristics of the sea surface are spatially homogeneous, a spatially averaged value of $\log \sigma_0$ is in close proximity to a constant value. On these assumptions, the signals after correcting the distance effect along a radar beam were expressed as follows:

$$\xi = \zeta - \delta(R), \quad \delta(R) = a + b R \quad \text{---(3)}$$

where ξ is the distance corrected signal, $\delta(R)$ is the fitting line, a and b are coefficients of a least square approximation.

Examples of the digitized radar signals along a radar beam are shown in Fig.4. Fig.4(a) represents the typical signals reflected from the wind wave surface. The signals in the range of 1km are saturated owing to the strong echo. However, the signals over that range show the images of the irregular sea waves. The fluctuated curve around 0 level indicates the signals after distance correction which was carried out over the range of 1km. This figure shows the property of the distance correction method described above.

Fig.4(b) represents the signals observed under the snowy weather condition. Characteristics of this case are that intensity level is high, but the fluctuation of the signals is very small. It is difficult to recognize the wave image in Fig.4(b) owing to the radar scattering from snow.

Fig.4(c) was observed under the calm condition. Wind speed was less than 2m/s, and the significant wave height and period were about 1.2m and 8s, respectively. Swell can not be detected outside the breaker zone. This figure indicates that short ripples generated by the wind are essential to the detection of long waves.

Fig.4 Example of digitized radar signals along a radar beam.

4.2 RADAR SPECTRAL ESTIMATION

The data analysis procedure is shown in Fig.5(a). After correcting the distance effect, the digitized radar image defined in the polar coordinate system is converted to the Cartesian coordinate system. A square region with a length of 960m as shown in Fig.5(b) is extracted from the converted data.

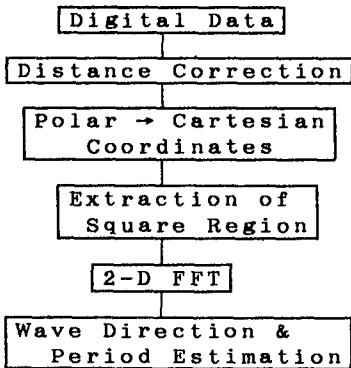

Fig.5(a) Data analysis procedure.

Fig.5(b) Analyzed area.

Fig.6 shows an example of the extracted spatial radar image and the wave number spectrum calculated from the 2D-FFT procedure. It is difficult to estimate the wave direction from Fig.6(b), because a 180° directional ambiguity exists in Fig.6(b) which has point symmetry. It is possible to remove this ambiguity by use of two successive images (Atanassov et.al.(1985)). However, this ambiguity can be removed by assuming that the reflected waves from the beach are very weak and most of the waves are coming from the offshore. Using this assumption, mean wave direction and period can be estimated from the wave number at the radar spectral peak, making use of the dispersion relationship.

(a) Spatial radar image

(b) Wave number spectrum

Fig.6 Example of spatial radar image and wave number spectrum.

5. RESULTS

Fig.7(a) for CASE-1 represents the wave numbers at the radar spectral peaks observed every five minutes from 5:50 to 6:10 on 16, together with the results of the averaged radar spectrum. ① and ② denote a first and second spectral peak, respectively. The wave numbers observed every five minutes represent slightly different values owing to the statistical variation of the random sea surface; the directional estimate from a radar image has a statistical error of about 10° . The averaged radar spectrum should be used to estimate the mean wave direction and frequency.

The wave direction and period estimated from the averaged radar spectrum were compared with those observed by the 3-component wave array. The contours in Fig.7(b) represent the directional wave spectrum observed at ST.3, making use of the extended maximum likelihood method (EMLM) proposed by Isobe et.al.(1984). As shown in Fig.7(b), the peak of the directional spectrum and integrated directional function represent the directions of 304° and 314° , respectively. The first peak of the radar spectrum is the direction of 313° , which is in good agreement with the array estimate.

Fig.8(a) for case-2 shows the results observed every five minutes from 23:50 on 16 to 0:10 on 17. Since the wave number ① and ② in Fig.8(a) are rather stable results in five radar spectra, the radar spectrum exhibits a bimodal directional distribution with the major peak at 341° and 313° , the frequency of 0.11Hz and 0.125Hz. However, the direction and period at the radar spectral peaks are much different from the results of the array spectrum, as shown in Fig.8(b).

The array spectrum observed 4 hours later than CASE-2 measurement are shown in Fig.9, together with the results of wave number ① and ② obtained in CASE-2. In Fig.9, the directions of the array spectrum which represents the bimodal structure show good agreement with ① and ②, although the frequencies of the array spectrum are slightly low. Fig.9 shows that the bimodal structure observed by the radar spectrum in Fig.8(b) is probably a true indication of the wave field.

Fig.10 for case-3 represents the results observed at 20:00 on 27. In this case, only one radar image is used for wave number estimation. The array spectrum in Fig.10 observed at ST.3 represents the two distinct spectral peaks; the long and short waves with the frequency of 0.12Hz and 0.22Hz, respectively. The direction of the long waves is about 345° , which is in good agreement with the results of radar spectral peaks (346°). The wave direction of the long waves in CASE-3 is approximately 45° further to the north than that of CASE-1.

6. CONCLUSIONS

The data acquisition system has been developed to record the spatial radar signals, and the numerical procedure employed for analysis of the digitized radar images has been proposed. Using this radar system and numerical procedure, the mean wave direction and period in the uni- and bi-modal wave field can be estimated more easily than the conventional method. Moreover, it will be possible to record the consecutive radar images by means of this system and to calculate the three-dimensional radar spectrum.

CHAPTER 55

Variation of Surf Zone Turbulence in A Wave Period

Y. Tada¹, T. Sakai², M. ASCE and E. Obana³

Abstract

The phase variation of turbulent intensity in the surf zone during one wave period is discussed. The existing data show a peak near the wave crest phase and a following gentle decrease. The peak delays downwards. The model by Deigaard et al. (1986) which uses the one equation model for the turbulent kinematic energy transportation explains the above mentioned trend roughly. The vertical convection term has no significant effect on the phase variation. The production term given by Deigaard et al. overestimates the energy production at the water surface by wave breaking.

Introduction

It is well known that the turbulence generated by wave breaking is responsible to the suspension of sediment in the surf zone. Also it determines the vertical profile of the undertow. At present, its time average over the wave period is important for practical purpose. To discuss these phenomena more in detail, however, we have to know its phase variation during one wave period.

In this study, the phase variation of the surf zone turbulence is discussed by using existing data. Then, the calculated results by using the existing analytical prediction techniques are compared with the data. Especially the application of the one equation model of

3 Osaka Prefectural Government, Tanimachi 2-3-4, Chuoh-Ku, 540 Osaka, Japan.

the turbulent kinematic energy transportation is discussed.

Experimental Data on Phase Variation

Stive(1980) published his data on the turbulent intensity in a surf zone on a uniform slope beach in a wave tank. The experimental conditions are shown in Table 1. The breaking water depth h_b was about 26cm. He presented the results in several figures. Fig.1 is an enlarged copy of one of his figures. The mean water depth d at the measuring point was 18.6cm. The abscissa shows the wave phase. The ordinate shows a non-dimensional height above the mean water level. The curves are the contour lines of turbulent intensity. It is clear that the turbulent intensity is large under the wave crest.

Table 1 : Experimental Conditions

	Stive(1980) test 2	Sakai et al.(1982) case H2
i	1/40	1/28
T(sec)	3.0	1.16
H_o (cm)	14.2	
h_b	26.0	17.7
H_b	22.6	12.8
H_o/L_o	0.010	0.066

Fig.1 Experimental result by Stive(1980) ($d = 18.6\text{cm}$)

To make clear the phase variation of the turbulent intensity, its values were read from his figure at several levels, and plotted in a usual phase-intensity figure. Fig.2 shows the result at $d = 14.3\text{cm}$. z is a vertical coordinate and positive upwards. The origin is at the still water.

As seen in the curve at $z = -2.4\text{cm}$, the profile of phase variation of turbulent intensity is similar to that of the water level. It has a peak near the wave crest phase. At $z = -4.7\text{cm}$, this trend still exists. At $z = -7.4\text{cm}$, the trend is not so clear. At least at the upper two levels there is a peak and then a gradual decrease follows. One interesting fact is that the phase of the peak delays downwards. In the case of 18.6cm water depth (Fig.1) the same trend is seen. The peak under the

Fig.2 Phase variation of turbulent intensity (Stive, 1980, test 2, $d = 14.3\text{cm}$)

wave crest and the following gradual decrease are seen. The peak phase delays downwards.

To examine whether or not other data show the similar trend, other data are checked. One of the authors measured the turbulent intensity in a surf zone in a wave tank (Sakai, Inada and Sandanbata, 1982). The experimental conditions are shown in Table 1, and compared with Stive's conditions. Fig.3 is one example of the results. The still water depth h was 12.3cm. The similar trend is found. The data of Nadaoka (1986) shows a long tail of the contour lines. This also means the downward delay of the peak phase.

Fig.3 Phase variation of turbulent intensity (Sakai, et al., 1982, case H2, $h = 12.3\text{cm}$)

Models on Phase Variation

Deigaard et al. (1986) applied the one equation model for the turbulent kinematic energy transportation to simulate the phase variation of turbulent intensity during one wave period in a surf zone. The equation which they used is given as follows :

$$\frac{\partial k}{\partial t} = \frac{\partial}{\partial y} \left(\frac{\varepsilon}{\sigma_k} \frac{\partial k}{\partial y} \right) + \frac{\text{PROD}}{\rho} - c_d \frac{k^{3/2}}{l} \quad , \quad (1)$$

where k is the turbulent kinematic energy, y is the vertical coordinate directed upwards from bottom, ε is the turbulent eddy viscosity given by $l\sqrt{k}$, l is the length scale of turbulence, $\sigma_k = 1.0$, ρ is the density of water and $c_d = 0.08$.

Eq.(1) is a simplified equation of one equation model for the turbulent kinematic energy transportation. The three terms in the right hand side represent the diffusion of turbulent kinematic energy by the turbulence itself, the production of it and the dissipation. They thought that the turbulence energy is generated at the water surface, diffused downwards by itself and dissipated.

The production of turbulent energy at the water surface is given by

$$\text{PROD} = E_{loss} \frac{36}{(H\beta T)^2} z \left(1 - \frac{z}{H}\right) t \left(1 - \frac{t}{\beta T}\right) \quad (2)$$

$$: 0 \leq z \leq H, \quad 0 \leq t \leq \beta T$$

$$E_{loss} = \frac{H^3}{(4D^2 - H^2)} \gamma D \quad , \quad \beta = 2 \frac{D + H/2}{L} \quad ,$$

where H is the wave height, D is the mean water depth, γ is the unit weight of water, L is the wave length, T is the wave period and z is the vertical coordinate directed downwards with its origin at the surface. This expression is based on experimental data of a hydraulic jump.

They calculated the phase variation of turbulent intensity for the conditions of the experiment by Stive. They presented the calculated result in the similar manner as Stive did(Fig.1).

The values are read from their figures, and compared with the experimental result by Stive. Fig.4 is the case of 18.6cm water depth. The experimental result is shown with thick full line. The calculated result by Deigaard et al. is shown with chain line. It explains the experimental result roughly.

The dotted line is the calculated result by using a model of one of the authors(Sakai et al., 1982). The broken line is the calculated result by using a model of

Svendsen(1987). The model of Sakai et al. also explains the experimental result roughly. In the model of Svendsen, the production and diffusion terms were neglected. So this model explains only the gradual decrease. Although the model of Sakai et al. explains the experimental result as roughly as the model of Deigaard et al., the model of Deigaard et al. is most suitable physically.

Fig.4 Comparison of predicted results with experimental result(Stive, test 2, $d = 18.6\text{cm}$)

Convection Terms

Svendsen(1987) compared the vertical distribution of mean turbulent intensity of Stive's experiment with that of Deigaard et al.(Fig.5). The calculated vertical distribution by Deigaard et al.is steeper than that of the experimental result by Stive. Svendsen thought that this was due to the neglecton of the convection term in the turbulent kinematic enery transportation equation.

Fig.5 Comparison of predicted mean turbulent intensity (Deigaard et al., 1986) with experimental data (Stive, 1980) (Svendsen, 1987, Fig.9)

$$\frac{\partial k}{\partial t} + u \frac{\partial k}{\partial x} + v \frac{\partial k}{\partial y} = \frac{\partial}{\partial x} \left(\frac{\epsilon}{\sigma_k} \frac{\partial k}{\partial x} \right) + \frac{\partial}{\partial y} \left(\frac{\epsilon}{\sigma_k} \frac{\partial k}{\partial y} \right) + \frac{\text{PROD}}{\rho} - c_d \frac{k^{3/2}}{l} \quad (3)$$

Eq.(3) is the full equation of the one equation model for the turbulent kinematic enery transportation. This equation was originally developed for the two-dimensional boundary layer flow. The second and third terms in the left hand side are the convection terms. The first and second terms in the right hand side are the horizontal and vertical diffusion terms respectively. Deigaard et al. neglected the convection terms and the horizontal diffusion term. From the data by Stive, the magnitude of the vertical diffusion term was estimated. It was found that the magnitude of the vertical convection term might be same order as that of diffusion term.

To check the effect of the convection terms, a similar calculation to that by Deigaard et al. is done. Fig.6 shows the discretization of the wave phase and the height above the bed for the case of $d = 18.6\text{cm}$ of Stive's experiment. The i' and j' values indicate the discretization of the phase and the height above the bed. Only the vertical convection term is included. In Stive's paper, there was no data on the vertical water particle velocity. It was assumed, therefore, that the velocity field is similar in the surf zone. The vertical water particle velocity was calculated from other data (Nadaoka, 1986).

Fig.6 Discretization of wave phase and height above bed for case of $d = 18.6\text{cm}$ of Stive's experiment

The dotted line in Fig.7 is the calculated result in which the vertical convection term is included for the case of $d = 18.6\text{cm}$ of Stive's experiment. The production and dissipation terms are multiplied by 0.3 and 0.5 respectively (explained later). The full line is the calculated result without the convection terms. The cross points are the measured result by Stive. There is no significant improvement on the calculated result.

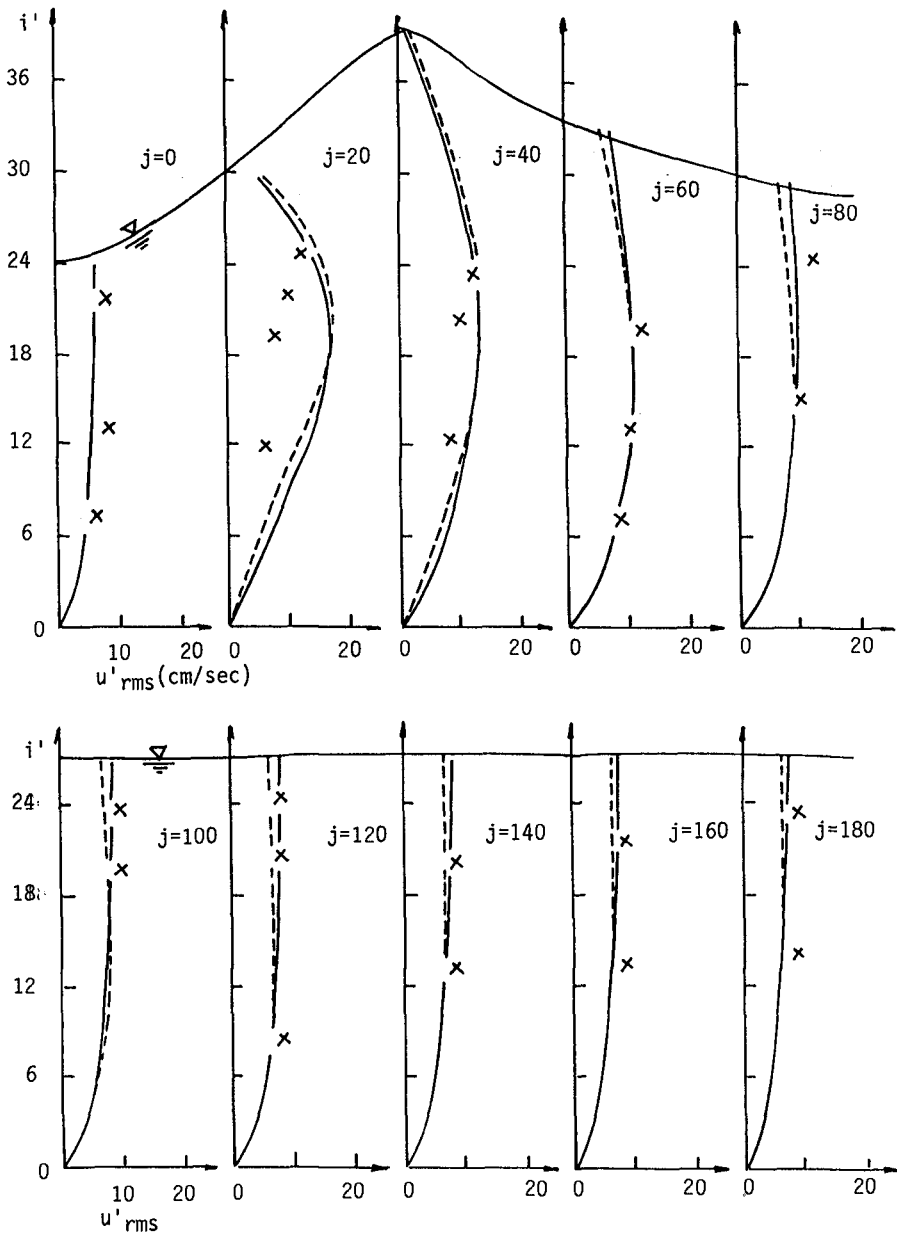

Fig.7 Effect of vertical convection term on phase variation of turbulent intensity

Production Term

Then the production term was also estimated from the data by Stive. It was found that the production term was predominant at least under the wave crest. The production of turbulent energy is expressed by Eq.(4). It is a product of the Reynolds stress and the vorticity.

$$\overline{-u'_\alpha u'_\beta} \left(\frac{\partial U_\alpha}{\partial x_\beta} \right) \approx \overline{-u'v'} \frac{\partial U}{\partial y} \approx \overline{u'v'} \left(\frac{\partial V}{\partial x} - \frac{\partial U}{\partial y} \right) \quad (4)$$

In the 20th Conference on Coastal Engineering, one of the authors presented a numerical simulation of the motion after wave breaking on a beach (Sakai et al., 1986) (Fig.8).

Fig.8 Numerical simulation of motion after wave breaking on beach (Sakai et al., 1986)

Fig.9 Time variation of vorticity (Sakai et al., 1986)

The vorticity was estimated from the simulation result at two points indicated by the circled cross point. Fig.9 is the time variation of vorticity.

The vorticity increases and decreases very rapidly. The time interval is about 0.1sec. In the model of Deigaard et al., the time interval of the production term is given by δT in Eq.(2). The calculated value of δT for the simulated case is about 0.3sec. The Deigaard et al.s' model may overestimate the time interval of the production term.

To check the effect of the production term, a similar calculation to that by Deigaard et al. is done. In this case, the discretization of the phase and the height above the bed is rather rough as indicated by the i and j values in Fig.6. The full curves in Fig.10 show the result when the Deigaard et al.s' equation is used for the case of $d = 18.6\text{cm}$ of Stive's experiment..

Fig.10 Effect of production term on phase variation of turbulent intensity

The calculated result overestimates the turbulent intensity under the wave crest. Then, the production term was multiplied by 0.3. And the dissipation term was multiplied by 0.5. The calculated value decreases as indicated by the dotted curves. This means that the production given by Deigaard et al. is too large, and its 30% is enough to reproduce the measured result.

In fact, from a personal communication with Deigaard, it was found that he himself did a similar

correction in his calculation. The production term is strongly related to the slope of the vertical distribution of turbulent intensity(Fig.5). The correct estimation of the production is, therefore, necessary to improve the prediction.

The reason for the reduction of the dissipation remains unclear.

Conclusions

(1) The existing data on the phase variation of turbulent intensity in surf zone during one wave period show a peak near the wave crest and a following gentle decrease. The phase of the peak delays downwards.

(2) The model of Deigaard et al.(1986) which utilized the one equation model for the turbulent kinematic energy transportation, explains the experimental results roughly.

(3) The vertical convection term in the turbulent kinematic energy transportation equation has no significant effect on the variation.

(4) The production term of Deigaard et al. gives a longer time interval than the vorticity in a numerical simulation of motion after wave breaking by Sakai et al.(1986).

The production term of Deigaard et al. gives a steeper slope of the vertical mean turbulent intensity distribution than the existing experimental results.

The production multiplied by 0.3 and the dissipation multiplied by 0.5 gives a reasonable result.

It is necessary to refine the production term to predict more accurately the phase variation of turbulent intensity during one wave period in the surf zone.

CHAPTER 56

WAVE GROUP FORCED NEARSHORE CIRCULATION

Rachel E. Fowler¹ and Robert A. Dalrymple,² F.ASCE

Abstract

Forcing of the nearshore circulation system by incident wave groups is examined. Attention is focused on the generation of migrating rip currents and development of low frequency motion. Analysis of experimental results categorises the migrating rip currents as very low frequency motion in the FIG energy band. It is suggested that migrating rip currents, in addition to shear waves, are a valid generation mechanism for very low frequency motion in the nearshore region.

Introduction

The primary currents in the nearshore area are longshore currents, cross-shore currents (or undertow), and rip currents. Longshore currents, generated by incident waves with an oblique approach to the shoreline, flow parallel to the beach carrying sediments downwave. Cross-shore currents develop to maintain the mass flux balance in the surf zone. They can transport sediments offshore, although they can not carry sediments far beyond the breaker line. Rip currents are more powerful surface currents and are a major mechanism for water exchange across the breaker line. They can transport large amounts of sediment a considerable distance beyond the surf zone. Numerous theories exist for the presence of rip currents as discussed by Dalrymple (1978). All these features of the nearshore circulation system are generally considered stationary processes.

Underlying the nearshore currents is a low frequency motion which is typically unsteady and periodic in nature. This motion includes surf beat, edge waves, and far-infragravity motions. Much attention has been given to the characterization of these wave motions, but as yet, their generation mechanisms are not totally understood.

The fundamental aim of the research work described in this paper was to study the nearshore circulation system and evaluate its response to forcing by offshore wave groups. In particular, we examined the generation of slowly migrating rip currents by the offshore wave groups, and the corresponding development of low frequency motions in the surf zone.

²Professor, Center for Applied Coastal Research, University of Delaware, Newark, Delaware 19716 USA

Wave Groups and Low Frequency Motion in the Nearshore Region

Initial discoveries of low frequency motion (frequencies $<$ incident wave frequency, periods 30–300s) in the nearshore region are attributed to Munk (1949) and Tucker (1950). They observed oscillations in the water surface elevation which had periods of several minutes. Munk named these long, low frequency waves 'surf beat'. Tucker found the best evidence of surf beat during periods of long, regular groups of incident waves, and noted that the long waves were out of phase with the wave groups.

Longuet-Higgins and Stewart (1962, 1964) demonstrated theoretically, using radiation stresses, that a small second-order undulation accompanies a first-order wave group, leading to the development of a set-down wave, a long, forced wave in the nearshore region. It was shown that the forced wave has the same wave length and period as the incident wave group and is 180° out of phase with the group, as observed by Tucker. They suggested that the surf beats seen by Munk and Tucker were seaward propagating free waves formed by the release of the forced, set-down waves as they are reflected near the coastline.

Following these initial surf beat studies, the majority of research on the interaction of wave groups and the nearshore circulation system has focused on edge waves. Gallagher (1971) showed that non-linear interactions between wind waves, leading to an inter-frequency energy transfer, can initiate forced edge waves in the surf zone which can grow resonantly. In a laboratory study, Bowen and Guza (1978) considered both resonant and non-resonant interactions between incoming wave trains and confirmed that, when the frequency and longshore wave number of incident wave groups satisfy the edge wave dispersion relationship, theoretically predicted edge wave motions can be generated and maintained.

Huntley, Guza and Thornton (1981) summarised that there are three different generation mechanisms for nearshore low frequency motion: progressive edge waves, standing edge waves (caused by an obstruction or topographic form), and forced second-order waves under incident wave groups. From their analyses of data from the National Sediment Transport Study field experiment at Torrey Pines Beach, California, they found the most important of these generation mechanisms to be progressive edge waves. They observed long-wave motion in the surf zone with frequencies and wave lengths that corresponded to those predicted by the edge wave dispersion relationship. However, they also found that other generation mechanisms were important, primarily forced motion due to standing edge waves.

Tang and Dalrymple (1989) also worked with the NSTS data set, but concentrated on nearshore motions at much lower frequencies than those in the edge wave band. Figure 1 shows the edge wave energy identified by Huntley, Guza and Thornton, but there is also a significant pocket of energy in the lowest frequency band. Tang and Dalrymple demonstrated, through various statistical analysis methods, that offshore wave groups were significantly correlated with the measured, very low frequency motion ($<$ 0.0015 Hz, periods $>$ 660 sec.). During the field experiment, observations were made of slowly migrating rip current cells in the surf zone which had the same wave length as the very low frequency motion. Tang and Dalrymple hypothesised that the incident wave groups forced a response in the surf zone in the form of migrating rip currents, which, in turn, had a very low frequency motion signature in wave number-frequency space.

Figure 1: Wave number-frequency spectrum derived from cross-shore current measurements at an offshore location. Torrey Pines Beach, California, USA. (Fig. 10B-5 of Tang and Dalrymple, 1989)

Data from the SUPERDUCK field experiment (see Crowson *et al.* (1988)) conducted at Duck, North Carolina, were analysed by Oltman-Shay, Howd and Birkemeier (1989) and produced solid evidence of high energy motion at very low frequencies. These low frequency oscillations can be clearly seen in the velocity records (fig. 2), particularly in the longshore velocity records. Oltman-Shay *et al.* also analysed their data in wave number-frequency space and clearly demonstrated that the high energy, low frequency motion is distinct from edge wave motion (fig. 3). An approximately linear relationship between wave number and frequency was also revealed, implying that the low frequency motion is non-dispersive. This very low frequency motion was observed only in the presence of a mean longshore current, and changed speed and direction with that mean current. Oltman-Shay *et al.* named this kinematically distinct, low frequency band of energy the 'far infra-gravity (FIG) band' and, in a companion paper by Bowen and Holman (1989), it was suggested that the observed motions were generated by instabilities in the mean longshore current. These instabilities lead to the formation of a longshore-progressive shear wave, which has the restoring force of vorticity rather than gravity.

Theoretical Considerations

Since incident wave groups appear to be important to the dynamics of the nearshore circulation system, we examine their simplest form. Consider the summation of two sinusoidal incident wave trains, as described by linear theory. The

Figure 2: Time series measurements of (a) longshore (v), (b) cross-shore (u) velocity, and (c) surface displacement (η) collocated in the surf zone. Duck, North Carolina, USA. (Fig. 2 of Oltman-Shay *et al.*, 1989)

Figure 3: Wave number-frequency spectrum derived from cross-shore velocity measurements in the surf zone. Duck, North Carolina, USA. (Fig. 6b of Oltman-Shay *et al.*, 1989)

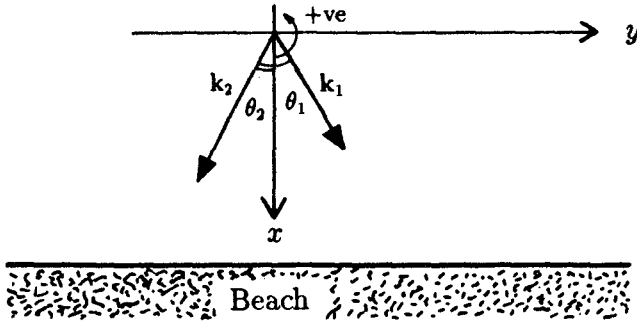

Figure 4: Coordinate system.

velocity potential and water surface elevation are given by:

$$\phi(\mathbf{x}, z, t) = \frac{ga_1 \cosh k_1(h+z)}{\omega_1 \cosh k_1 h} \cos \psi_1 + \frac{ga_2 \cosh k_2(h+z)}{\omega_2 \cosh k_2 h} \cos \psi_2 \quad (1)$$

$$\eta_t(\mathbf{x}, t) = \left. \frac{1}{g} \frac{\partial \phi}{\partial t} \right|_{z=0} = a_1 \sin \psi_1 + a_2 \sin \psi_2 \quad (2)$$

where $\psi_i = (\mathbf{k}_i \cdot \mathbf{x} - \omega_i t)$, phase function of wave train, $i = 1, 2$
 $\mathbf{k}_i = |\mathbf{k}_i| \cos \theta_i = k_i \cos \theta_i$, wave number of wave train, $i = 1, 2$
 $\omega_i =$ frequency of wave train, $i = 1, 2$
 $a_i =$ amplitude of wave train, $i = 1, 2$
 $g =$ acceleration due to gravity
 $h =$ water depth
 $\mathbf{x} = (x, y)$

The wave numbers, \mathbf{k}_i , are related to the angular frequencies of the waves by the linear dispersion relationship. Note from figure 4 that the x axis is positive onshore.

Through the use of various trigonometric identities, the total water surface elevation can be rewritten and expressed as the sum of a modulated sine wave and a plane wave train:

$$\eta_t(\mathbf{x}, t) = 2a_1 \sin \left(\frac{\psi_1 + \psi_2}{2} \right) \cos \left(\frac{\psi_1 - \psi_2}{2} \right) + (a_2 - a_1) \sin \psi_2 \quad (3)$$

By introducing the definitions:

$$\left. \begin{aligned} \omega_1 &= \omega - \frac{\Delta\omega}{2} \\ \omega_2 &= \omega + \frac{\Delta\omega}{2} \end{aligned} \right\} \begin{aligned} \omega &= \frac{\omega_1 + \omega_2}{2} \\ \Delta\omega &= \omega_2 - \omega_1 \end{aligned} \quad \left. \begin{aligned} \mathbf{k}_1 &= \mathbf{k} - \frac{\Delta\mathbf{k}}{2} \\ \mathbf{k}_2 &= \mathbf{k} + \frac{\Delta\mathbf{k}}{2} \end{aligned} \right\} \begin{aligned} \mathbf{k} &= \frac{\mathbf{k}_1 + \mathbf{k}_2}{2} \\ \Delta\mathbf{k} &= \mathbf{k}_2 - \mathbf{k}_1 \end{aligned}$$

we develop η_t in terms of the average frequency, ω , the average wave number

vector, \mathbf{k} , and their difference terms, $\Delta\omega$ and $\Delta\mathbf{k}$:

$$\eta_t(\mathbf{x}, t) = 2a \underbrace{\sin(\mathbf{k} \cdot \mathbf{x} - \omega t)}_{\text{carrier wave}} \underbrace{\cos\left(\frac{1}{2}(\Delta\mathbf{k} \cdot \mathbf{x} - \Delta\omega t)\right)}_{\text{wave envelope}} + (a_2 - a_1) \sin\left(\underbrace{\mathbf{k} \cdot \mathbf{x} - \omega t - \left(\frac{1}{2}(\Delta\mathbf{k} \cdot \mathbf{x} - \Delta\omega t)\right)}_{\psi_2}\right) \quad (4)$$

For $a_1 = a_2$, the second term is eliminated. The total water surface elevation now consists of a carrier wave, propagating in the $(\mathbf{k}_1 + \mathbf{k}_2)/2$ direction, at speed $(\omega_1 + \omega_2)/|\mathbf{k}_1 + \mathbf{k}_2|$, modulated by a wave envelope, which propagates at speed

$$Cg = \frac{\omega_1 - \omega_2}{|\mathbf{k}_1 - \mathbf{k}_2|} \quad (5)$$

in the $\mathbf{k}_1 - \mathbf{k}_2/2$ direction. The longshore component of the speed of propagation of the wave envelope, Cg_y , is easily obtained from equation 5.

From the velocity potential (eq 2), expressions can also be developed for the longshore and cross-shore velocities:

$$u = -\frac{\partial\phi_t}{\partial x} = g\mathbf{k}f(\mathbf{k})(a_1 \cos\theta_1 \sin\psi_1 + a_2 \cos\theta_2 \sin\psi_2) + O(\Delta\mathbf{k}, \Delta\omega) \quad (6)$$

$$v = -\frac{\partial\phi_t}{\partial y} = g\mathbf{k}f(\mathbf{k})(a_1 \sin\theta_1 \sin\psi_1 + a_2 \sin\theta_2 \sin\psi_2) + O(\Delta\mathbf{k}, \Delta\omega) \quad (7)$$

where

$$f(\mathbf{k}) = \frac{\cosh k(h+z)}{\cosh kh}$$

From these expressions it can be noted that the cross-shore velocity and the water surface elevation (eq 2), are in phase at both the incident wave frequency and the group frequency. However, the longshore velocity moves in and out of phase at the incident wave frequency and is 180° out of phase at the wave group frequency. Similar phase differences at the group frequency were observed in the field by Kim and Huntley (1986).

As the incident wave trains propagate towards the shore they alternatively reinforce and cancel each other out, creating periodic, longshore variations in wave height. Lines of cancellation, or nodal lines, can be seen in the wave field. For the special case where the intersecting wave trains are of the same frequency $Cg = 0$, and the wave groups do not propagate. At the intersection of the nodal lines with the beach, rip currents develop, as demonstrated by Dalrymple (1975). The longshore spacing of the nodal lines, and hence the rip currents, can be predicted by:

$$Lg_y = \frac{2\pi}{k_2 \sin\theta_2 - k_1 \sin\theta_1} \quad (8)$$

In general, for two incident wave trains with slightly different frequencies, $\omega_1 \neq$

Figure 5: Graphical representation of the incident wave conditions suitable for the development of migrating rip currents.

ω_2 , the speed of propagation of the wave envelope is no longer zero. Therefore, the nodal lines in the wave field are no longer stationary. Since we know that rip currents can develop in the surf zone for $Cg_y = 0$, we now suggest that for $Cg_y \approx 0$ rip currents can be generated and will migrate slowly along the beach with the nodal lines. To facilitate prediction of suitable conditions for migrating rip currents, a dimensionless expression is developed from equation 5:

$$\frac{Cg_y}{C_2} = \frac{(k_r - 1)(k_r \sin \theta_1 - \sin \theta_2)}{k_r^2 + 1 - 2k_r \cos(\theta_1 - \theta_2)} \quad (9)$$

using the shallow water assumption, $\omega_1/\omega_2 = k_1/k_2$, and where $k_r = k_1/k_2$, the ratio of the wave numbers of the two wave trains, and C_2 is the celerity of the second wave train. This expression must be $\ll 1.0$ to enable rip currents to develop. Equation 9 is represented graphically in figure 5 which is for the case where θ_1 is fixed at $+10^\circ$.

The lines represent contours of Cg_y/C_2 . The dashed line represents the conditions for stationary rip currents. The graph shows two families of solutions. The horizontally oriented lines represent conditions when the nodal lines are propagating in the on/offshore direction, at large angles to the beach normal. These conditions do not lead to the development of rip currents on the beach, but instead create a surf beat effect. The vertically oriented family of solutions represent conditions which do lead to the development of rip currents. Values of $Cg_y/C_2 = \pm 0.1$ were arbitrarily selected as limits for the development of migrating rip currents, and several test cases were selected within these limits for the experimental work. Care was taken to avoid incident wave conditions that would initiate edge waves.

Experimental Facilities and Procedures

The migrating rip currents were simulated in the directional wave basin at the University of Delaware. The basin measures 20m x 20m x 1.1m. Along

Figure 6: Plan and elevation of the directional wave basin at the University of Delaware, showing the experimental set-up.

one wall there is a segmented wavemaker composed of thirty individually actuated paddles (fig. 6). A wooden beach, 14.65m in length, was installed in the basin providing an idealised, planar slope of 1:10. A closed basin condition was maintained as required for wave generation using the 'designer waves' technique, Dalrymple (1989). The water depth was maintained at 81cm for the duration of the experiments.

Cross-shore and longshore currents were measured at ten locations along the beach using Marsh-McBirney electromagnetic current meters. The instrument locations were in the form of a ten-point, linear array, 1.52m seaward from the still water line, outside the surf zone. The data sampling frequency was set at 10Hz and record lengths containing 4096 data points were obtained.

Four experimental cases were run and are summarised in figure 7. The first two cases, RTEST and PTEST, are identical except for their wave heights. The fourth experimental case, STEST, is of note since the rip currents propagate along the beach in a direction opposite to that of the incident waves. Further details of the laboratory experiments are presented in Fowler (1990).

Results

Cross-shore and longshore velocity records were obtained for each experimental case at all ten locations in the linear array. Typical velocity records from one location are presented in figure 8. The cross-shore record clearly shows the wave groups arriving in the nearshore region. The two records are seen to be out of phase as suggested by the theory, although quantitative evaluation of this has not been performed. The longshore velocities have about half the magnitude of

Figure 7: Summary of the four experimental cases.

the cross-shore velocities, but the low frequency modulation is very prominent. This low frequency modulation can be very clearly seen in the frequency spectrum (fig. 9). The incident waves are easily identifiable, but the spectrum is dominated by a low frequency peak due to the rip currents migrating along the beach. This conclusion is confirmed by visual observations of the period of the rip cells in the laboratory.

With the exception of the RTEST data, for each experimental case the cross-shore velocity records from all ten instrument locations were combined and analysed using either a direct Fourier transform method (DFT), or a maximum likelihood method (MLM), to create a wave number-frequency spectrum. Frequency is represented on the vertical axis, and alongshore wave number, here defined as $2\pi/L$, where L = wave length, is along the horizontal axis. Within this framework, contour lines of energy are plotted. The curved lines represent the theoretical edge wave dispersion relationship for modes 0, 1 and 2. For the RTEST experimental case, data from three locations were considered unreliable and discarded. A wave number-frequency spectrum was produced from the remaining seven velocity records.

The low frequency portion of the wave number-frequency spectra for each of the four experimental cases are presented in figures 10 through 13. In each graph the occurrence of low frequency motion is clearly represented and cannot be due to edge wave motion as it is not coincident with any of the edge wave dispersion relationship curves. The frequency of the energy in each case corresponds to visual observations in the laboratory of the period of the migrating rip cells passing a fixed point.

Compared to QTEST and STEST, the PTEST and RTEST experimental cases produced stronger rip currents, which flowed further offshore before dissipating. Consequently, the current meters were further from the head of each passing rip current and the offshore velocities due to the rip were more pronounced. The rip current signature in the cross-shore velocity records is sharper for these cases. When their experimental results were analysed in wave number-frequency space, a second pocket of energy appeared at twice the frequency and half the wave length of the primary feature, a harmonic of the fundamental mo-

Figure 8: Typical cross-shore (top) and longshore (bottom) velocity records from one location in the instrument array.

Figure 13: Wave number-frequency spectrum derived from cross-shore velocity records for the STEST experimental case.

tion. This is seen in figures 10 and 11.

The first three experimental cases, RTEST, PTEST, and QTEST, were analysed using the DFT method. Peak splitting due to large directional spread ruled out the use of an MLM for these cases. The DFT method tended to spread the energy over several wave number bins, but the central wave number is still in fairly good agreement with the observed wave lengths. The theoretically calculated wave numbers are over-predicted compared to the wave number-frequency spectra results. However, it must be remembered that equation 8 is based on linear wave theory and includes a shallow water assumption.

MLM analysis was successful on the STEST results producing a better definition of the low frequency motion in the wave number-frequency spectrum. The pocket of low frequency energy is located in the positive wave number region, unlike the previous cases, simply because the rip currents were migrating in the opposite direction.

Conclusions

Incident wave groups have been shown to be important to the dynamics of the nearshore circulation system. Simple linear theory, based on two incident wave trains with $\omega_1 \approx \omega_2$, provided a generation mechanism for slowly migrating rip currents. This suggested mechanism was verified in a laboratory wave basin. Rip currents developed in the surf zone where nodal lines in the offshore wave field intersected the beach. The rip currents propagated along the beach at the same speed as the nodal lines propagated through the wave field.

The longshore spacing of the rip currents can be predicted with some limitations. All the rip spacings were somewhat over predicted and this is thought to be due to the use of linear theory and the shallow water assumption.

The theory predicted the cross-shore and longshore velocities to be out of phase by 180° , a phenomenon previously observed in the field and qualitatively seen in the laboratory results.

Offshore, incident wave groups have been shown to force a response of the nearshore circulation system in the form of migrating rip currents. In turn, these migrating rip currents have a signature in wave number-frequency space that classifies them as very low frequency motion in the nearshore region, in the previously named 'FIG' energy band. It is therefore proposed that migrating rip currents are an alternative to shear waves as a generation mechanism for very low frequency motion in the nearshore region. Future research should include consideration of how to uniquely identify these two mechanisms in the field.

CHAPTER 57

BORE-LIKE SURF BEAT ON REEF COASTS

Eizo NAKAZA,¹⁾ Seiko TSUKAYAMA²⁾ and Mikio HINO³⁾

Abstract

Reef coasts, because the wave height of incoming stormy high waves are extremely dampened by coral reef, have been believed as calm sea areas. However, many coastal structures have actually been damaged by stormy waves dampened by the reef. Surf beat with large wave height was discovered through field observations. The surf beat has been named as "Bore-like Surf Beat". The wave height and the wave velocity of the Bore-like surf beat is larger than that of individual waves. Numerical simulation taking into account of non-linear effect of surf beat phenomenon on the reef shows good agreement with laboratory data.

The main reason of the disasters of coastal structures on the reef coasts is existence of the Bore-like surf beat resonantly excited incoming wave groups.

Introduction

The coasts around the Southwest Islands of Japan are what is called the reef coast, which is surrounded by natural coral reef. On the reef coasts, the sea area is made comparatively calm due to the energy dissipating effect of the reef to the incoming waves, as the natural submerged breakwater. Therefore, it has been believed that the existence of the reef is contributed for the safety of the coastal structures. But actually, disasters caused by Typhoon waves have frequently occurred on reef coasts and is contradictory to the general concept that "the reef coast is a calm sea area".

1) Research Associate, 2) Associate Professor, Dep. of Civil Engineering, Faculty of Engineering, Ryukyu University, Japan.

3) Professor, Dep. of Civil Eng., Faculty of Eng., Dep. of Tokyo Institute Technology.

Since 1973, the waves on reef coasts have been investigated by Kohno and Tsukayama. They mainly clarified the wave deformation on the reef by laboratory experiments and/or field observations. Takayama et al. (1977) experimentally investigated the waves on the reef with irregular waves, and proposed an empirical estimating formula for the wave height and wave set-up on the reef. After Takayama et al., the estimating formula of the wave height on the reef has usually been used in design for coastal structures in reef coasts of the Southwest Islands of Japan. The wave height expected by Takayama's empirical equation gives about 1m for incoming waves with the wave height above 10m. As for the wave set-up, it is about 1.5m. In the traditional design concept, as generally speaking, the reef area is one of the calm sea.

Surf beat phenomena on the reef were discussed by Seelig (1983). He firstly showed that the surf beat contributes the wave run-up. But no characteristic of surf beat is clarified.

Recently, Tsukayama and Nakaza clarified the wave deformation due to the large roughness of the coral reef as well as the wave breaking deformation.

There are many studies on the individual waves in sea areas with the reef, as shown above. But the surf beat on the reef coasts has not been studied enough. In this paper, first of all, the actual condition of wave disasters on the reef coasts is shown, and then it is disclosed that the main reason of the severe coastal disasters is the existence of surf beat with the wave height larger than one of individual waves. Secondly, the surf beat phenomena resonantly excited by incoming wave groups on the reef are shown by field observation data as well as experimental and numerical ones.

2. What happened on reef coasts ?

- (i) A typical topography of the reef coasts in the Okinawa Islands of Japan, and waves on there

Figure-1 shows a topography of typical reef coast of the Okinawa Islands in Japan. It may be the same type as the reef in Australia, which is well known as the Great Barrier Reef. The width of the reef is about 300m to 1000m, and the water depth at high tide is about 2m to 3m. The heel of the beach is called as beach front, and the offshore edge of the reef flat is called as reef front. As shown in Fig.-1, many coral reefs of the Okinawa Islands have a steep slope, which is about 1/10 in front of the reef flat. In some cases, the offshore side of the reef flat edge becomes more sharply sloped.

Photograph-1 shows the wave condition on the reef when the deep water wave height is about 4m. As shown in this photograph, the incoming waves are rapidly dampened. Therefore, the wave height on the reef is extremely small, except near the reef front. For example, as seen in photo.-1(b), near the shore line, a child can play with the waves, for its height is very small.

Fig. 1 Cross-sectional topography of a typical reef coast of Okinawa Islands in Japan

(a) Wave braking near the reef front

(b) waves near the shore line

Photo.-1 waves on a reef coast under a Typhoon condition

In Okinawa Islands, the coastal structures have usually been constructed in the reef zone. Existence of a coral reef has been believed that it acts as safety guard for coastal structures against incoming high waves. Because the water depth on the reef is about 2m, and it has a wide breaking zone which perfectly reduces the height of incoming waves.

(ii) Damages of coastal structures by stormy high waves due to Typhoon

The results of recent surveys of coastal disasters on the reef have shown that many coastal structures severely been destroyed. These disasters are due to extremely high storm surges (flood-like waves) which are higher than 5.0m above Datum Level.

Photograph-2 shows a seawall, roads, and houses damaged by a typhoon. The elevation of foundations of the houses and roads is between 5.5m and 7m above the high water level. And the elevation of seawall crown near the shore line is 5.5m above the high water level.

Figure-2 shows a sketch drawn by three civil engineers who happened to have been there during that typhoon disaster. They explained the disaster as follows.

Photo. -2 Destroyed seawall and road due to storm surges (Sosu coast, Typhoon T8613)

Fig. -2 Sketch of an overtopping wave

The damage was caused by big floods, meaning stormy surges. The big floods surged on the seawall and overtopped it at about 10-minutes intervals (as will be shown, which corresponds to the natural period of the reef coast).

From the traditional estimating method, the wave set-up for a 10m wave in deep water is estimated as about 1.5m. Such a extremely high surge on coral reef zones can not be supposed from the traditional design concept.

(iii) Bore-like surf beat

Photograph-3 shows a reef coast when the tide is high and at a calm sea condition. In this Photograph, The solid line shows the shore line at high water level condition. And the crown level of the coastal cliff is between 6m and 7m above datum level. The pole held by the man is 2m in height.

Photograph-4 was successively taken with time interval of about 15sec. when a typhoon approached the Okinawan main Island on 9:22 at Aug. 29th in 1987. In photo. (a), the waves superimposed on the surge induced by incoming high wave groups can be seen. When this photo. was taken, the significant wave height at the offshore was about 6m. Photograph-(b) was taken after 15sec from the state in Photo. (a). The white line can seen as the breaking wave near the middle of this Photo. is the front of a surge advancing to the shore. And the short period wave, so-called individual waves, can be seen too. After 15sec from that, the surge attacked the near shore cliff. Photograph(c) shows the attack of the surge.

Photo. -3 Shore line under a calm sea condition (high water level)

(a) 9:22:00

(b) 9:22:15

(c) 9:22:30

**Photo. -4 Bore-like surf beat Occurred on Aug. 29, 1987
(Minatogawa coast, T8712)**

As seen in photo.-3, the storm surge or surf beat phenomenon on the reef is one of violent wave phenomena. The surf beat very resembles to the Tsunami, so the authors (1988(a) (c), 1990) named it "Bore-like surf beat" or "Tsunami-like surf beat."

Usually, the surf beat has been believed to be a kind of mild and static wave phenomenon compared to the wave with short period. However, as mentioned before, the surf beat phenomenon in the coral reef zone is a violent wave phenomenon. So, we can conclude that they can cause the severe damage on the coastal structures in the reef coasts, where are usually thought that merely the small individual waves exist. And it is clarified that the above mentioned disaster, explained by three engineers, is due to the Bore-like surf beat. Because the interval of the surge attacking the seawall coincided with the natural period of the reef basin.

3. Theory

For the long period fluctuations of mean sea level, the long wave equations has been normally used. Because the violent surf beat phenomenon on the reef is considered, the nonlinear term in the governing equations can not be ignored. Therefore, the Bore-like surf beat, one of the fluctuations of mean sea level, is governed by the long wave equations,

$$\frac{\partial \eta}{\partial t} + \frac{\partial u(h+\eta)}{\partial x} = 0 \quad (1)$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + g \frac{\partial \eta}{\partial x} + \frac{1}{\rho(h+\eta)} \frac{\partial S_{xx}}{\partial x} + \frac{f}{h+\eta} u|u| = 0 \quad (2)$$

where t : time, x : onshore distance from the reef front, η : mean sea-level elevation, u : cross-sectional mean velocity in the vertical section, h : water depth measured from the still water surface, S_{xx} : x -component of radiation stress, ρ : water density, f : bottom friction coefficient, and g : acceleration of gravity. In the momentum equation, a predominant forcing factor of the nonstationary periodic response of water is the term of radiation stress, which is proportional to the square of incident short period wave heights, and varying with time.

The radiation stress at a x from the reef front is given by

$$S_{xx} = \frac{1}{8} \rho H(x, t)^2 \left(\frac{2kh}{\sin h 2kh} + \frac{1}{2} \right) \quad (3)$$

where $H(x, t)$ is the wave height on x at time t . the time variation of the wave height on the reef can be calculated by

$$\frac{H(x, t)}{H_o(t)} = B \exp\{-Ax/L\} + ah/H_o(t) \quad (4)$$

$$H_o(t) = \overline{H_o}(1+0.5 \sin \sigma_o t) \quad (5)$$

where $H_o(t)$: incident wave height at the time t , h : still water depth on the reef, σ_o : angular frequency of incident wave groups. And mean wave set-up on the reef is given by the equation,

$$\overline{\eta} = \overline{H_o} \left[C - \frac{3}{8} \beta \left(\frac{H(x)}{\overline{H_o}} \right)^2 \right]^{1/2} - h \quad (6)$$

The coefficients A , B , C , α and β are proportionality constants to be determined by experiments.

Figure-3 shows the numerical simulation of surf beat taking into account of the non-linear effect of long period fluctuation of mean sea-level, for the wave group period is 27.2sec, and the mean incident wave height $\overline{H_o}=6.5\text{cm}$. On the other hand, fig.-6 shows the result of simulation by Symonds' Method (1982, 1984) which ignored the non-linear effect. As seen in Fig.-5, compare to the result from liner simulation, the surf

Fig. -3 Numerical simulation of Bore-like surf beat

beat profile at shore line very inclines onward. And it shows one of the future of the Bore-like surf beat.

4. Experiment

4.1 Experimental equipments and method

Two-dimensional experiment has been performed using laboratory equipments in Fig.-4. The wave tank is 27m long, 0.7m wide and 1.0m deep. The prototype of reef coast has the reef flat of 400m in width and the steel water depth of 2m. The experiments were conducted with two types of regular and irregular incident wave groups. In this paper, only the results from the case with regular incident wave groups will be explained.

Fig.-4 Experimental equipment

4.2 Results

Figure-5 shows an example of the bore-like surf beat. The upper trace is the profile of deep water waves, and the lower one is the profile of sea surface oscillation on the near shore line. As shown in this figure, the Bore-like surf beat phenomenon is excited by incoming wave groups.

Fig.-5 Example of the experimental waves in deep area and near shore line

Figure-6 shows the comparison of the numerical simulation with the experiments for long period sea oscillation at near shore line. In the figure, circles indicate the experiments, and the solid line represents the results of the numerical simulation. The numerical simulation shows good agreement with the experiments.

Fig. -6 Comparison of numerical simulation with experiments for long period sea oscillation

Reef coast has the natural period of the seich in a reef basin. Figure-7 shows the oscillation mode of the sea surface in the reef basin. The natural period of the reef coast can be approximately estimated by equation (7).

$$T_0 = \frac{4l}{(2n+1)\sqrt{gh}} \quad (n=0,1,2 \dots) \tag{7}$$

where l : width of the reef flat, and h : still water level.

Fig. -7 Long period oscillation mode of sea surface on the reef basin

Figure-8 shows the resonance diagram of sea surface oscillation plotted against the non-dimensional period of wave groupiness. The solid line in the figure corresponds to the numerical solution. As seen in this figure, clear resonant responses are induced when the periods of groupiness of the incoming waves coincide with the natural periods of the reef basin. And the results of numerical solution show good agreement with the experimental results.

Fig.-8 Resonance diagram
(η_0 , T_{wg} :root mean square amplitude
and period of incident wave groups)

5. Field observation of surf beat on the reef

Figure-9 shows records by pressure-type wave gages simultaneously obtained under the Typhoon at three different locations as shown in Fig.1. The station point 1 is located at 250m offshore from the reef front, the point 2 is located near the reef front and point 3 is located near shore line. As seen in these wave records, wave profile observed at St.1 shows only the feature of wave groupiness, while the other wave profiles observed at St.2 and St.3 show the low frequency oscillation of the mean sea level with period of from 1 to 5 minutes. At St.3 the high mean sea elevations occurred between 10 and 17 minutes corresponding to the clear incoming wave grouping.

Figure-10 shows the power spectrum of the low frequency oscillation of mean sea level at St.3. In this Figure, the arrows n_1 , n_2 , and n_3 indicate the natural frequency of the reef coast for the fundamental mode, second mode, and third mode respectively. The power spectrum has the two peaks corresponding to the natural

frequency of the reef coast. Estimating the power spectrum for the lower frequency than the peak frequency nearly corresponding to the significant wave period of the incident waves, we can obtain the frequency response of mean sea level. But straightly calculating from the sea surface oscillation obtained by wave recorder, the low frequency power spectrum of incident waves can not be obtained. In this study, for the slowly varying wave height time history, the smoothed instantaneous wave energy history proposed by Funke-Mansard(1980) is used.

Fig. -9 Wave gage records simultaneously obtained for Typhoon T8520 at three different locations

Fig. -10 Power spectrum of the low frequency oscillation of mean sea level at point 3

Figure-11 shows the low frequency power spectrum of incident wave energy. Seeing this figure attentively, it can be noticed that there are two peaks of the low frequency spectrum. The second peak from the lowest frequency is corresponds to the frequency for the repetition length of high waves (Goda's j_2). But what does the first peak mean ?. the period for the first peak is about twice of the second peak. The authors has been thought that the surf beat on the reef coasts has resonantly excited by the wave energy on the second peak, because the period corresponds to the natural period of the reef coasts around the Okinawan Islands.

Fig. -11 Low frequency power spectrum of a incident wave groups

Fig. -12 Frequency response of mean sea level in a reef basin

Considering the linear wave phenomenon, the frequency response of mean sea level with long period is estimated by

$$S_{00}(f) = |H(f)|^2 S_{11}(f)$$

Figure-12 shows the frequency response $|H(f)|$. The frequency response has two clear resonant frequency corresponding to estimated ones by equation (2). As seen in this figure, the surf beat (that is to say, Bore-like surf beat) should be considered that it is resonantly excited by incoming wave groups.

6. conclusion

In a coral reef zone, resonant long period oscillations with the predominant natural frequency have been induced by incoming wave groups. The wave groups may resonantly excite Bore-like surf beat on the reef, and the severe disasters of coastal structures on the reef have always been induced by Bore-like surf beat. The simulation taking into account of the non-linear effect of the surf beat is good agreement with experimental one. A method for estimating the low frequency spectrum of incident waves is proposed. The frequency response of mean sea level with long period can be estimated by the method proposed in this study. And it indicates one of the resonant diagram for the long period fluctuation of mean sea level. The frequency response for a reef coast is identified. The periods for the first and/or second peak of the low frequency spectrum can be used in the estimation of occurrence of resonant response of mean sea-level in bays, harbor, and coasts with clear natural frequency.

CHAPTER 58

BRAGG REFLECTION OF WAVES BY ARTIFICIAL BARS

James T. Kirby¹, Jeffrey P. Anton²

Abstract

We consider the extension of previous theories for Bragg reflection of surface waves by parallel bars to the case of artificial bars placed discretely on the seabed. The case of non-resonant, weak reflection is considered first, followed by a consideration of the application of resonant interaction theory to the dominant Fourier mode of the bar field. Both theories are compared to numerical results, and discrepancies are seen in both cases. Finally, experimental results are compared to theory.

Introduction

The discovery that the Bragg reflection mechanism leads to strong reflection of incident surface waves by periodic bottom undulations has led to speculation that artificial bars could be constructed which would partially shelter shores or localized structures from wave attack. Possible bar configurations of this sort have been discussed previously by Mei et al. (1988) and Naciri and Mei (1988). The paper by Bailard et al. (1990) in this conference describes an effort which was made to install and test an artificial bar field offshore of a natural beach.

The purpose of the present study was to extend the scope of available theory and techniques which were available for predicting wave reflection from bars, in support of the proposed field study. Here, we discuss the application of analytic perturbation methods for both non-resonant and resonant cases. We also discuss numerical results, which point out limitations present in both analytic approaches. Finally, experimental results largely provide a qualitative verification but in turn show some limitation of the small amplitude bar theory.

Theory for Small Amplitude Bars

The theory which provides the framework for analysis here is given by an extended mild-slope equation derived by Kirby (1986).

We treat the water depth $h'(x, y)$ as the superposition of a mildly-sloping bottom $h(x, y)$ and a rapidly-varying but small-amplitude undulation $\delta(x, y)$:

$$h'(x, y) = h(x, y) - \delta(x, y) \quad (1)$$

¹Assoc. Prof., Center for Applied Coastal Research, Dept. of Civil Engrg., Univ. of Delaware, Newark, DE 19716

²Formerly, Grad. Stud., Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611

Figure 1: Bar field with four discrete bars.

Using $h(x, y)$ as the reference depth in the mild-slope sense, the model equation

$$\nabla_h \cdot (CC_g \nabla_h \phi) + k^2 CC_g \phi = \frac{g}{\cosh^2 kh} \nabla_h \cdot (\delta \nabla_h \phi) = 0 \tag{2}$$

is obtained, where ϕ is the value of the linear wave potential at the still water surface. The model coefficients are obtained from

$$\omega^2 = gk \tanh kh ; C = \frac{\omega}{k} ; C_g = \frac{\partial \omega}{\partial k} \tag{3}$$

and are determined by the value of $h(x, y)$ in all cases.

The Artificial Bar Field

In the absence of appropriate field data, we have restricted our attention here to the study of periodically spaced bars ($\delta = \delta(x)$) and an otherwise uniform depth $h = \text{constant}$. In principal, δ is arbitrary aside from the small amplitude restriction. In the present study, we have chosen a bottom consisting of rectified sine waves, given by

$$\delta(x) = \begin{cases} D \cos \frac{\pi}{b_L}(x - NL) ; & NL - \frac{b_L}{2} \leq x \leq NL + \frac{b_L}{2} \\ 0 & \text{otherwise} \end{cases} \tag{4}$$

$N = 0, \dots, N_b - 1$

where N_b is the number of bars, L is the periodic bar spacing, b_L is the footprint of the bar on the bottom, and D is the bar height. The rectified cosine form is chosen mainly for its convenience in later analysis. An example bar field is shown in Figure 1. The bar field is periodic over intervals of width L , and can be conveniently represented by the cosine series,

$$\delta(x) = \sum_{n=0}^{\infty} D_n \cos(n\lambda x) ; \lambda = \frac{2\pi}{L} \tag{5}$$

where

$$D_0 = \frac{D}{\pi} ; D_1 = -\frac{D}{2} ; D_n = D \frac{\cos\left(\frac{n\pi}{2}\right)}{\pi(1 - n^2)} (1 + \cos n\pi) \tag{6}$$

Non-resonant Reflection

For the case of h constant, the model equation (2) may be written as

$$\nabla_h^2 \phi + k^2 \phi = \alpha \nabla_h \cdot (\delta \nabla_h \phi) \quad (7)$$

where

$$\alpha = \frac{4k}{2kh + \sinh 2kh} \quad (8)$$

With $\delta(x)$ representing bars varying in the x -direction, we represent oblique waves according to

$$\phi(x, y) = \tilde{\phi}(x) e^{imy}; \quad m = k \sin \theta \quad (9)$$

and obtain

$$\begin{aligned} \tilde{\phi}_{xx} + \ell^2 \tilde{\phi} &= \alpha (\delta \tilde{\phi}_x)_x - m^2 \alpha \delta \tilde{\phi}, \\ \ell^2 &= k^2 - m^2 = k^2 \cos^2 \theta \end{aligned} \quad (10)$$

This equation has been obtained by Miles (1981) who used it to study reflection from a single isolated obstacle.

For $\delta(x)$ confined in a finite region of space, we may write

$$\begin{aligned} \tilde{\phi}(x \rightarrow \infty) &= T e^{i\ell x} \\ \tilde{\phi}(x \rightarrow -\infty) &= e^{i\ell x} + R e^{-i\ell x} \end{aligned} \quad (11)$$

where T and R are complex transmission and reflection coefficients. With δ small, we expand $\tilde{\phi}$, T and R as series in the small parameter $\epsilon = D/h$, and obtain

$$\phi_0 = e^{i\ell x} \quad R_0 = 0 \quad T_0 = 1 \quad (12)$$

at leading order. At second order, the reflection coefficient R_1 for an arbitrary topography $\delta(x)$ is

$$R_1 = -\frac{i\alpha}{2\ell} (\ell^2 - m^2) \int_{-\infty}^{\infty} \delta(x) e^{2i\ell x} dx \quad (13)$$

as found by Miles (1981). Note that R_1 is singular in the limit as $\theta \rightarrow \pi/2$. This effect has not been previously noted and its practical implications are unclear.

For the case of a simple sinusoidal bottom

$$\delta(x) = D \sin(\lambda x); \quad 0 \leq x \leq N_b L \quad (14)$$

we obtain the expression

$$|R| = \begin{cases} \frac{\alpha D}{2} \left(\frac{\ell^2 - m^2}{\ell^2} \right) \frac{2\ell/\lambda}{\frac{2\ell^2}{\lambda} - 1} \left| \sin \left(\frac{2\ell}{\lambda} \pi N_b \right) \right|; & \frac{2\ell}{\lambda} \neq 1 \\ \frac{\alpha D}{2} \left(\frac{\ell^2 - m^2}{\ell^2} \right) \frac{\pi N_b}{2}; & \frac{2\ell}{\lambda} = 1 \end{cases} \quad (15)$$

This result extends the non-resonant theory of Davies and Heathershaw (1984) to include obliquely incident waves.

For the periodic bar field described by (5) and (6), we substitute (5) in (13) and obtain the expression

$$R_1 = \frac{-i\alpha}{2} \left(\frac{\ell^2 - m^2}{\ell} \right) \sum_{n=0}^{\infty} D_n I_n, \quad (16)$$

where the integrals I_n are given by

$$I_n = \int_{-\frac{\ell}{2}}^{(N_b-1)L+\frac{\ell}{2}} \cos(n\lambda x) e^{2itx} dx. \quad (17)$$

As in the case of a single sinusoidal bar, the integral I_n takes on special values when $2\ell/n\lambda = 1$ for the corresponding value of n . We further simplify the notation by setting

$$\gamma = \frac{2\ell}{\lambda} \quad (18)$$

Then, for $\gamma \neq n$, we obtain the expression

$$I_n(\gamma) = \frac{\gamma^2}{\ell(\gamma^2 - n^2)} e^{i\ell N_b L} \sin \ell N_b L; \quad \gamma \neq n \quad (19)$$

For $n = \gamma$, we obtain the expression

$$I_n(\gamma = n) = \frac{N_b L}{2} \quad (20)$$

We thus obtain the general solution for obliquely incident waves

$$R_1 = -\frac{i\alpha}{2} \left(\frac{\ell^2 - m^2}{\ell^2} \right) \left\{ \sum_{n=0, \gamma \neq n}^{\infty} \frac{\gamma^2 D_n}{(\gamma^2 - n^2)} e^{i\ell N_b L} \sin \ell N_b L + D_n \delta(n - \gamma) \frac{\ell N_b L}{2} \right\} \quad (21)$$

where $\delta(n - \gamma)$ is the delta function, and there $n = \gamma$ can only occur for one wavenumber component for a fixed value of ℓ . For the case of normally incident waves (studied further below), we let $\ell \rightarrow k$, $m \rightarrow 0$ and obtain

$$R_1 = -\frac{i\alpha}{2} \left\{ \sum_{n=0}^{\infty} \frac{\gamma^2 D_n}{(\gamma^2 - n^2)} e^{ik N_b L} \sin k N_b L + D_n \delta(n - \gamma) \frac{k N_b L}{2} \right\} \quad (22)$$

From the form of the solution, it is apparent that each harmonic of the bar field contributes to the reflection process, with the dominant contribution of the n^{th} harmonic coming from the neighborhood $\lambda \approx n$. An example plot of reflection coefficient $|R_1|$ is shown in Figure 2 for a case of 4 bars with crest-to-crest spacing equal to the unrectified wavelength ($b_L = L/2$). Waves are normally incident on the bar field. The peak in $|R_1|$ at $2k/\lambda = 1$ corresponds to the usual Bragg interaction between the surface wave and the fundamental harmonic of the bar field, when the surface wave length is twice the bar spacing. A second prominent peak is located at $2k/\lambda = 2$, corresponding to a surface wavelength equal to twice the length of the second harmonic of the bar field (and thus equal in length to the bar spacing). This strong second peak is absent when the bar

Figure 2: Reflection for four discretely placed bars. Non-resonant theory, equation (22).

field being considered is a simple sinusoid, as in Davies and Heathershaw (1984) and Mei (1985).

In general, the relative amplitude of the peaks in the reflection coefficient may be adjusted by changing the spacing of artificial bars, assuming the cross-section of each bar to stay the same. Pushing bars closer together makes the bar field more sinusoidal and reduces the importance of higher harmonics. Placing the bars further apart makes them into relatively more “solitary” features, and thus emphasizes the relative importance of higher harmonics. Two cases illustrating these extremes were investigated in the experiments described below.

Resonant Reflection

The reflection coefficient described in (21) is defective for the cases $2\ell \approx n\lambda$, where the coefficient can become arbitrarily large as $N_b \rightarrow \infty$. While this limit would never be reached in practice, the result shows that the theory is not strictly valid in the neighborhood of the resonances. The problem lies with assuming that R_1 is $O(1)$ in the perturbation series used above. Mei (1985) has developed a resonance theory which allows for $O(1)$ reflection in the neighborhood of each resonance. Mei et al. (1988) further suggested that, for the case of a bar field with multiple Fourier components, the reflection could be estimated using the resonance theory applied to the Fourier mode corresponding to the bar wavelength. This approach would not account for the occurrence of multiple strong peaks. In the present study, we define a neighborhood of each resonance $2\ell/\lambda = n$ to be the range $n - 1/2 \leq 2\ell/\lambda \leq n + 1/2$. Then, in each range, Mei's theory is used with $2\ell/\lambda^*$ replacing $2\ell/\lambda$, with $\lambda^* = n\lambda$. We refer the reader to Mei (1985) for the expressions defining the reflection coefficients. The only necessary modification to the theory account for oblique incidence and the presence of multiple resonant peaks. The frequency ω_n of the n^{th} resonant peak is given by

$$\omega_n^2 = \frac{gn\lambda}{2 \cos \theta} \tanh \left(\frac{n\lambda h}{2 \cos \theta} \right) \quad (23)$$

The cutoff condition Ω_0 defined by Mei is replaced by

$$\Omega_{0n} = \frac{\ell^2 - m^2}{\ell^2} \frac{\omega_n k D_n}{2 \sinh 2kh} ; \quad k = \frac{\ell}{\cos \theta} \quad (24)$$

where the D_n are the amplitudes of the bar Fourier coefficients, and there Ω_{0n} refers to the n^{th} resonant peak.

An example of the reflection calculated for the case of normal incidence is given in the following section, in comparison with numerical results and results of the non-resonant theory.

Numerical Solutions

In order to study the validity of each of the perturbation solutions, direct numerical solutions of equation (10) were also performed. For a bar field in the region $0 \leq x \leq N_b L$, an incident wave boundary is established at $x = A < 0$, and a downwave, transmitting boundary is established at $x = B > N_b L$. For an incident wave $\tilde{\phi}_I = e^{i\ell x}$, the appropriate boundary conditions are

$$\tilde{\phi}_x = \begin{cases} i\ell(2\tilde{\phi}_I - \tilde{\phi}) ; & x = A \\ i\ell\tilde{\phi} ; & x = B \end{cases} \quad (25)$$

Equations (10) and (25) are finite-differenced using central differences, leading to a tridiagonal system which is solved using the Thomas algorithm.

Figure 3 shows a sample of calculated reflection coefficients obtained with the numerical solution and the two analytic solutions, for the bar field described in Figure 2. As expected, the non-resonant solution over-predicts reflection at $2k/\lambda = 1$, in comparison with the resonant theory of Mei (1985). The discrepancy is relatively minor at the second peak $2k/\lambda = 2$, where the resonance is relatively weaker. In contrast to both analytic theories, the numerical results

Figure 3: Comparison of non-resonant, resonant and numerical solutions for a bar field with $N_b = 4$. ———, non-resonant theory; - - -, resonant theory; - · -, numerical results.

show a strong downshift of the reflection peaks to lower values of $2k/\lambda$. This downshift is related to the simultaneous interaction between the wave field and several bottom modes; a similar effect occurs for the case of a sinusoidal bar field, but it is much more subtle. The numerical scheme also predicts a higher reflection coefficient at each peak. The large downshifts and higher peaks are largely validated by data described below. These results indicate that either of the two analytic solutions are at best qualitatively accurate when used to describe reflection from the type of bars that could be built in an actual construction project.

Experimental Results

Experiments were conducted in the 60 cm wide wave flume in the Coastal and Oceanographic Engineering Laboratory, University of Florida, in order to verify the basic aspects of the theory for normally incident waves. For the experiments, a water depth $h = 15$ cm was used. Bar height D was 5 cm, giving $D/h = 0.33$, which is relatively large and could contribute to some of the discrepancies between theory and data noted below. The bar footprint $b_L = 50$ cm. Two bar spacings, $L = 80$ cm and 120 cm, were tested, corresponding to cases with bar field higher harmonics of low importance and great importance,

Figure 4: Bar field and wave gage placement

respectively. The bar fields tested contained four discrete bars.

In order to maintain a close correspondence between the assumed linearity of the wave theory and the experiments, incident waves on the order of 1 cm in height were generated. (Actual height varied with wave frequency, as would be expected from wavemaker theory.) Wave heights were measured using capacitance wave gages mounted with 6 cm-long wires, which were calibrated over their full length. Data was sampled using 12-bit digitization, giving a resolution of 0.012 mm/division. The wavefield was sampled at a $10Hz$ frequency, with experimental waves being generated in the range $0.4Hz \leq f \leq 1.6Hz$.

Due to the small wave heights being used, there was an additional source of noise in the data associated with mechanical vibration in the wavemaker and other high-frequency effects. In retrospect, it would be better to use slightly higher waves in future experiments unless great care were taken to isolate mechanical vibration. (For a particularly spectacular example of clean data in a related low-amplitude wave experiment, see Benjamin et al. (1989)).

The three-gage, least squares method developed by Funke and Mansard (1980) was used to separate incident and reflected waves. The gage layout relative to the bar field is shown in Figure 4. The incident-reflected separation was performed both upwave and downwave of the experimental bar field. The downwave separation indicated a reflection from the absorbing beach on the order of 5–6%. This reflected energy was neglected in subsequent processing and the downwave region was assumed to be perfectly transmitting.

Figure 5 shows the measured reflection coefficient for the case of $L = 80cm$, when bar field harmonics are relatively unimportant. Also included in the figure is the prediction of the numerical model described in the previous section. The data largely validates the theory, although there is a great deal of scatter. (It also appears that shifting the data to higher values of $2k/\lambda$ would bring the data into fairly close agreement with theory. No systematic error was ever detected in the experimental procedure which could account for such a shift, unfortunately.)

Figure 6 shows corresponding data for the case of $L = 120cm$, where the

Figure 5: Experimentally measured reflection coefficient, $L = 80\text{cm}$.

Figure 6: Experimentally measured reflection coefficient, $L = 120\text{cm}$.

second harmonic component of the bar field is comparable in height to the fundamental harmonic. Due to time constraints, the data here is relatively sparse, and tests were grouped in order to show the relative heights of the two reflection peaks. Both the presence and the relative importance of the two numerically-predicted peaks are substantiated by the data.

Response of a Closed-end Channel

One question that arises in response to the realization that bars can reflect significant amounts of incident energy is whether or not a region downwave of a bar field experiences a less severe wave condition than the region on the incident site. The answer to this question can be positive or negative, depending on the geometry of the downwave region and the reflectivity of the end boundary. For cases where reflection from the end wall is nearly complete, waves travelling back towards the bar field are partially re-reflected into the sheltered region. The possibility of resonating the sheltered region exists, as does the possibility of reducing the wave activity, and depends primarily on whether the sheltered region contains an integer multiple of one-half the surface wavelength.

Figure 7 shows the numerically predicted amplitude at a vertical wall situated four barfield wavelengths downwave of a bar field with four bars, as in the previous examples. The incident wave has an amplitude of unity, and so an amplitude of 2 represents simple reflection. The figure shows that the amplitude at the wall can reach as high as 3.6 and as low as 1, representing a range of

Figure 7: Wave Amplitude at End Wall of a Channel Sheltered by an Artificial Bar Field

resonance and sheltering conditions.

For the case where the channel end is primarily absorbing (due to wave breaking or frictional effects), the possibility of resonating the sheltered region is greatly reduced. This virtually guarantees that a bar field designed to shelter a beach from wind-wave band waves would not resonate the shoreline. However, as the wave frequency becomes low, even a mildly-sloped shoreline can become essentially reflective. It is thus possible that broad, low bars contribute significantly to amplifying long wave energy on the beach face. The long waves that could be amplified or resonated by this mechanism may be locally generated by nonlinear processes in the surfzone, or they may be arriving as part of the forced or free long wave climate incident from offshore. Problems of this sort need further investigation to determine the relative importance of bottom interaction in influencing the nearshore wave climate.

Acknowledgements

The work described in this paper was supported by the Office of Naval Research and the Naval Civil Engineering Laboratory through contracts N00014-86-K-0790 and N00014-89-J-1717. Both authors were affiliated with the Coastal and Oceanographic Engineering Department, University of Florida at the start of this study; use of the facilities there is greatly appreciated. Conversations with Jim Bailard, Bob Guza, and Dan Hanes were instrumental in the early stages of problem formulation.

CHAPTER 59

GENERATION MECHANISM OF ABNORMAL WAVES ALONG THE JAPAN COAST

by
Tomoaki Komaguchi¹
Yoshito Tsuchiya² M.ASCE.
and
Naofumi Shiraishi³

Abstract

The conditions under which abnormal waves occur in the western part of the Japan Sea and the northwestern part of the Pacific Ocean are examined. A numerical study of the abnormal waves was performed for a selected monsoon condition in winter. The mechanism of abnormal wave development is clarified using a wave spectrum model. It was found from the directional spectra that the effect of wind duration plays a key role in abnormal wave generation. For typhoon conditions, the relation between a standard project typhoon and the abnormal waves induced, is considered and the simulation method of the typhoon model is improved by introducing the typhoon stagnation effect. Finally, it was shown that abnormal waves generated by typhoons are due to long typhoon stagnation.

1. Introduction

Recently, as urbanization develops around the coastal zone, more regard to safety against coastal disaster is required. It is essential to take the enormous disaster potential of the low probability of occurrence of storm surge, high waves, etc. into account when planning and designing coastal structures. Abnormal waves which are the primary cause of coastal disasters

¹ Civil Engineer, Hydraulic Laboratory, Nippon Tetrapod Co., Ltd., 2-7, Higashi-Nakanuki, Tsuchiura, Ibaraki Pref., 300 Japan

² Professor, Disaster Prevention Research Institute, Kyoto University, Goka-sho, Uji, Kyoto 611, Japan

³ Chairman, Nippon Tetrapod Co., Ltd., 2-7-1, Nishishinjuku, shinjuku-ku, Tokyo 163, Japan

along the Japan coast, are generated by monsoons in winter and typhoons in summer. They often cause severe damage to the coast, so prevention of coastal disaster by predicting the possibility of occurrence for waves of long return period, location of appearance, etc. is important. Unfortunately, even in this day and age, the mechanism of abnormal wave development is still not satisfactorily clear.

The major causes of abnormal wave generation are geographical features, such as sea bottom topography, and wind properties, such as wind duration. The effect of wind duration is of particular importance in developing waves. Figure 1 shows the location map of Japan and the representative typhoon courses. The Japan Sea, located between Japan and the Asiatic continent is almost enclosed by Sakhalin, Hokkaido, Korea and Kyushu. During winter, convection currents, the so-called monsoon, occur between the Asiatic continent and the Pacific Ocean and low pressures often take place. If low pressure stagnation occurs on the northern side of

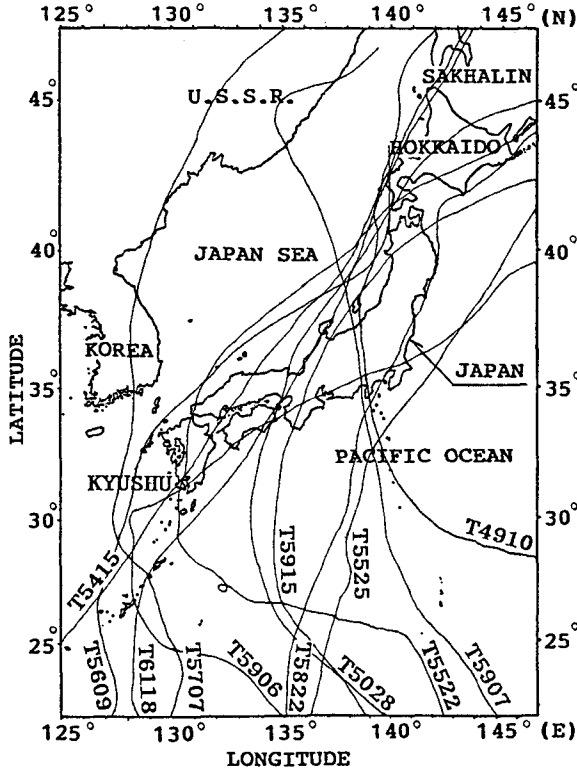

Figure 1. Location map of Japan and representative typhoon courses

Hokkaido, the typical meteorological condition of winter exists and waves develop to a great extent due to duration of the monsoon.

In a typhoon situation, on the other hand, high waves are also generated. These also cause damage. A typhoon is a very large air vortex and wind field, so it is considered that waves induced by typhoons yield duration-limited wave growth curves. In general, a typhoon first moves in low latitude from south to north or northwest, but a change of course to Japan mainland occurs. Stagnation of the typhoon occurs at this turning point. If a typhoon stagnates at low latitude, swell develops rapidly due to the long duration propagating from the wind fields to the coast. This can occur from distances even as great as 2000 km.

One of the ways to investigate the occurrence and conditions of abnormal waves is statistic approach using observed and hindcasted wave data (Yamaguchi et al., 1978) and wave prediction model studies for the greatest typhoon to date (Yamaguchi et al., 1986). In Japan, the typhoon model simulation is usually employed. This is an effective method for the investigation of abnormal waves induced by a typhoon. Nevertheless, it does not satisfactorily take the effect of typhoon stagnation into account, so the mechanism of abnormal waves of very long return periods is not made clear. As mentioned above, waves can develop great energy due to the long duration and it is considered that the wind field of a typhoon is a duration-limited condition. Therefore, abnormal waves induced by a typhoon can be predicted using an extension of typhoon model by introducing the typhoon stagnation effect.

In this paper, using the wave data observed at harbors on the western Japan Sea coast, extremal wave statistics are examined to consider the actual wave conditions induced by monsoons and typhoons in the Japan Sea. The mechanism of abnormal wave development was then clarified using a wave spectrum model. For typhoon conditions, a method for direct investigation of abnormal waves is considered and the typhoon model was improved by introducing the typhoon stagnation effect. Consequently, the statistic properties of duration of typhoons were examined. Furthermore, using the improved typhoon model, it is shown that if a typhoon stagnated at a low latitude and the duration is extremely long, waves would develop to a remarkable extent along the Japan coast.

2. Methodology

2.1 Wave conditions in the Japan Sea

First, we discuss the actual wave conditions for the occurrence of abnormal waves in the western part of the Japan Sea. Extremal statistics of wave heights observed at Misumi and Tottori harbors on the Japan Sea coast were obtained. These are shown in Figure 2. It is confirmed that the waves induced by monsoons are indeed larger than those from typhoons, at both locations.

(1) Typhoon (induced waves) (2) Monsoon (induced waves)

Figure 2. Applicability of Gumbel distribution to extremal wave statistics. Locations of each harbor are indicated in Figure 3.

As already mentioned, the Japan Sea is almost closed, so that it is considered that waves induced by monsoons follow the fetch-limited wave growth curves. Monsoon wind speeds are generally lower than those of typhoons. Even so, in the winter monsoon condition, the wind direction is nearly constant and the duration is very long, so waves receive great energy from them. If a monsoon wind changes its direction, waves turn into large swell and wind waves rapidly develop in the new direction. These waves interfere with each other. It can be assumed herein that abnormal waves induced by monsoon may be generated as a result of a combination of energy from swell that develop due to long duration and wind waves. Using a wave model, the mechanism of this process is confirmed for a selected monsoon condition.

2.2 Wave model

The model used for the numerical experiments is the wave spectral model proposed by Yamaguchi and Tsuchiya (1979). It is a so-called Second Generation (SWAMP, 1985) spectral wave model based on the two-dimensional properties of ocean waves. The total energy is evaluated by integrating the energy balance equation (Hasselmann, 1968)

$$\frac{\partial E(f, \theta, \mathbf{X}, t)}{\partial t} + \nabla \cdot (E(f, \theta, \mathbf{X}, t) \cdot \mathbf{C}_g) = S(f, \theta, \mathbf{X}, t) \quad (1)$$

where E is the two-dimensional energy density spectrum for frequency f and direction θ at x , y , and t , and \mathbf{C}_g is the group velocity derived from linear theory. The source function S is represented for the three stages of the sea state, i.e. the growing, decaying and opposing wind states.

In the growing stage, the generation term is composed of a linear (Phillips, 1957) and exponential growth (Miles, 1957), such as $A + B \cdot E$. In the model, the term A represents Phillips' external turbulent pressure forcing and the term $B \cdot E$ corresponds to the Miles' linear feedback mechanism. The numerical values of A and B are calculated using two formulae proposed by Inoue (1967). The fully developed JONSWAP spectrum is assumed and the energy-subtracting term is introduced according to the hypothesis that a fully developed sea state exists in equilibrium. Using the modified parameter as written down by Barnett (1968), the resonant nonlinear wave-wave interaction effects are also incorporated. In the second decaying stage, dissipation due to the nonlinear effect is assumed to play a part. For opposing winds conditions, adding the second stage, it is assumed that the winds produce the reverse effect to Miles' exponential growth.

2.3 Hindcast results

Numerical studies on the mechanism of wave development and propagation for a selected monsoon condition experienced in 1989 were conducted. High waves were observed along the Western Japan Sea coast on that occasion. Figure 3 shows the computational domain of the study. The domain covers the total Japan Sea area. Points A, B, C and D indicate the locations of Misumi, Tottori, Kyogamisaki and Kashiwazaki. Estimated significant wave heights and periods are compared with those measured at these points. Figure 4 shows comparisons of measured and estimated values at point C. As shown in this figure, it is concluded that the wave characteristics can be predicted satisfactorily by this wave model.

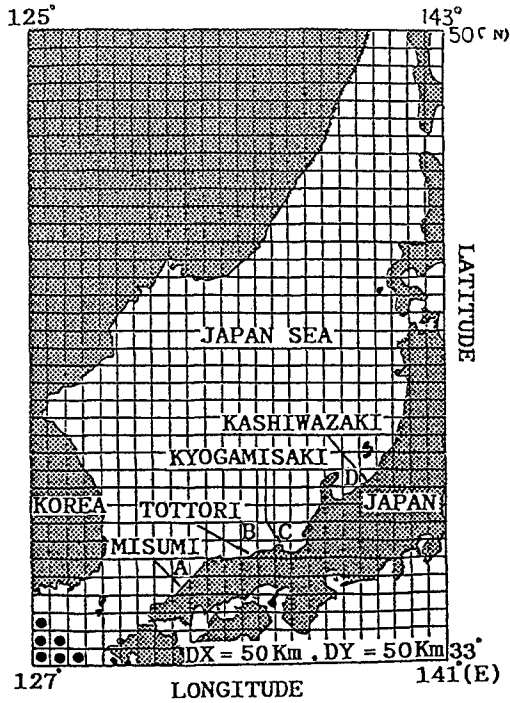

Figure 3. Computational domain for monsoon condition

Figure 4. Comparisons between estimated significant wave heights and periods and those measured at point C(KYOGAMISAKI)

The Custer diagrams shown in Figures 5(a) and (b) show wave fields using the calculated wind fields. The unit arrows in each figure indicate the wind direction and mean wave direction. As can be seen in the figures, the wind first blew from SW in the same direction. When the wind field changed its direction from SW to NE because of the low pressure movement, waves develop sufficiently from the NE direction due to the long duration and long fetch. Furthermore, after the low pressure passed through the Japan Sea, it became the typical monsoon condition of winter and the wind blew strongly from the NW or N direction. The influence of this wind caused waves to change into large swell and wind waves developed from the NW direction. The net results of this process is that the waves change their directions from NE to NW and came to the Western Japan Sea coast.

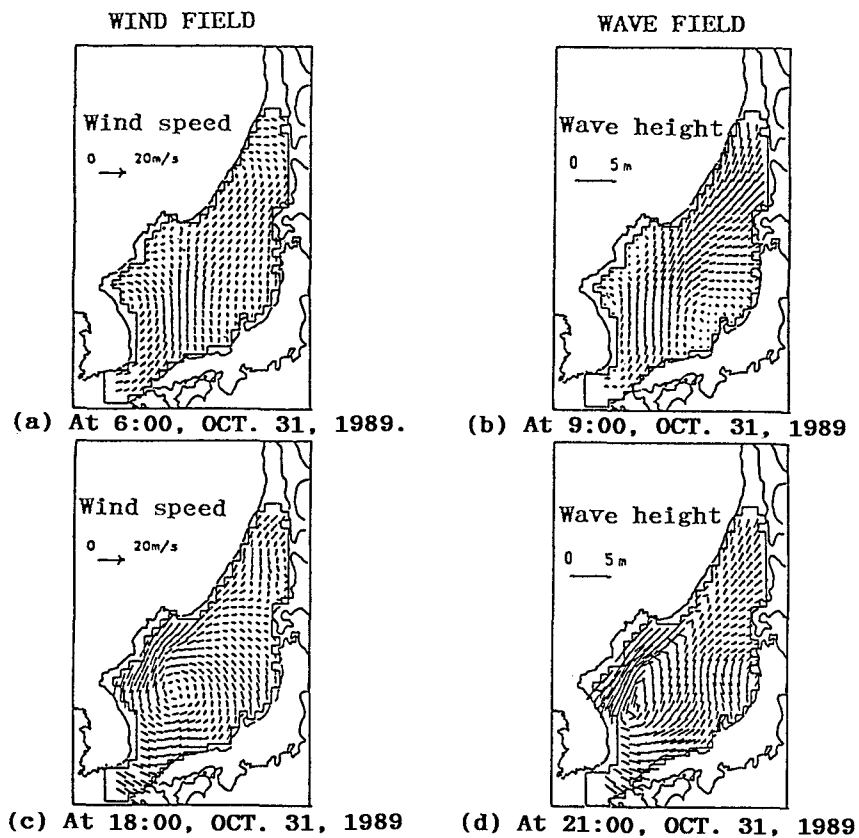

Figure 5(a). Changes in wind and wave field calculated
 (see also Figure 5(b))

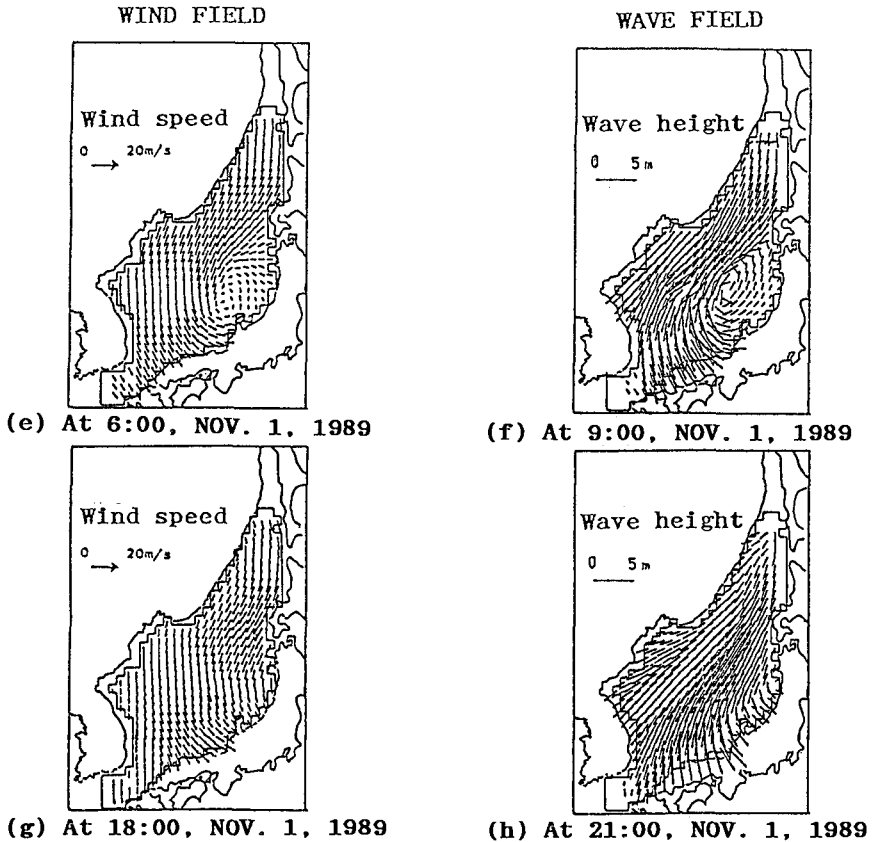

Figure 5(b). Changes in wind and wave fields calculated

2.4 Discussion

Figure 6 shows the changes of distributions of directional spectra at Point C. The top and bottom of the circle indicate the North and South direction and right and left side correspond to East and West. The energy densities of all wave components are distributed inside the circle. The center area of each circle indicates the components of swell and the area of near circumference also indicates wind waves. As can be seen, at first the energies of wind waves developed from the SW direction, but their energies are of low level. However, after the waves accumulated a lot of energies from the NW direction, swell developed rapidly and their energies increased dramatically due to the monsoon duration. It can be concluded for the Western Japan Sea that abnormal waves are generated as a result

of a combination of energy from swell that develop due to the long duration of monsoons and wind waves. Thus, we emphasize here that wind duration is an important factor in abnormal wave development.

Figure 6. Directional spectra calculated by selected monsoon condition.

From the monsoon results, it is clear that wind duration plays a key role in abnormal wave generation, so a method to investigate abnormal waves directly using typhoon model simulation was considered. Usually, as a wind field of a typhoon is quite large, waves induced by typhoons yield the duration-limited wave growth curves. If a typhoon stagnates at low latitude for a very long time and the wind duration increases to an extreme, waves can develop their energies rapidly. Therefore, the generation of abnormal waves from a typhoon can be predicted by a numerical model if the typhoon duration is very long and the intensity and magnitude of the typhoon just before and after landing is taken into consideration.

Figure 7 shows correlation between T_d and P_c , where T_d is the wind duration when the eye of the typhoon passes from $25^\circ N$ to $29^\circ N$ in latitude and P_c is the central atmospheric pressure depth. The figure indicates that T_d and P_c are independent of each other.

Figure 7. Correlation between central pressure depth P_c and duration of typhoon T_d .

The extremal statistics of annual maximum T_d are shown in Figure 8. The solid line is a regression analysis line obtained from the Gumbel distribution. The correlation coefficient between the solid line and T_d is 0.969, so that applicability of the Gumbel distribution to extremal statistics of annual maximum T_d is very good. It is concluded from these results that we must treat the duration of typhoon as a statistic parameter.

Figure 8. Extremal statistics of annual maximum duration of typhoons.

3. Simulation and Results

3.1 Improved typhoon model

In this paper, it is considered that the way to investigate abnormal waves directly is to use a typhoon which has a low probability of occurrence. As a first step, the relation between a Standard Project Typhoon (Mitsuta, 1965, Fujii and Mitsuta, 1986) and the abnormal waves induced is considered and it is concluded that the abnormal waves induced by the typhoon are predicted by a typhoon model. The statistic properties of duration of typhoon are investigated. From these results, the simulation metho of the typhoon model was improved upon by introducing the typhoon stagnation effect (Tsuchiya and Komaguchi, 1987).

Table 1 shows the return period of typhoon duration in the region of low latitude. According to the table, the extended duration of a 50 year return period is around 120 hours.

Table 1. Return period of typhoon duration in the region of low latitude.

Return period T_m (year)	Extended duration T_d (hours)
10	82.84
20	99.30
30	108.76
50	120.58
100	136.52
150	145.81
200	152.40
300	161.67
500	173.34

As already mentioned, in Japan, wave hindcast model studies are usually conducted for the greatest typhoon, such as in the case of the Isewan typhoon. The duration time of the typhoon is only 15 hours. Using the improved typhoon model, it is shown that the situation for abnormal waves can be predicted under the condition of an extremely long duration.

3.2 Results

The domain of computation for the typhoon model is shown in Figure 9. The duration time of typhoon 8218 is actually 36 hours. The conditions for calculation are $DX = DY = 50$ km and $DT = 30$ minutes. As initial and boundary wave conditions, the parametric model of Ross(1976) is used and the directional spectrum assumed to be a JONSWAP spectrum with a cosine square angular spreading.

Figure 9. Domain of computation for typhoon model

Figure 10 shows a comparison of the distribution of the wave fields made in a case (a) where an extreme duration of a 500 year return period of T_d was taken and compared with a case (b) where typhoon stagnation was not considered. The figures indicate that when a typhoon stagnates at low latitude and the wind duration is extremely long, waves will develop to a remarkable extent along the Northwestern Pacific Ocean coast.

(a) Typhoon stagnation occurred. (b) Typhoon stagnation did not occur.

Figure 10. Comparison of the distribution of the wave field along the Northwestern Pacific Ocean coast.

4. Conclusions

The major conclusions of the study are as follows:

- (1) It was considered in the Western Japan Sea that waves induced by monsoons have a possibility of obtaining energies larger than those from typhoons. From the directional spectra, it was clarified that abnormal waves are generated as a result of a combination of energy from swell that develop due to the long duration of the monsoon and wind waves.
- (2) By consideration of the relation between the standard project typhoon and abnormal waves induced by the typhoon, the typhoon model was improved by introducing typhoon stagnation.
- (3) The statistic properties of typhoon duration were examined. It was concluded from the results that the duration of a typhoon must be introduced as a statistic parameter.
- (4) The results of numerical simulation using an improved typhoon model showed that if typhoon stagnation occurred and the duration was extremely long, waves would develop to a remarkable extent along the Japan coast.

FIELD MEASUREMENTS AND ANALYSIS OF WAVE INDUCED NEARSHORE CURRENTS

H. D. NIEMEYER

Coastal Research Station/NLWA-Forschungsstelle Küste
Norderney/East Frisia, Federal Republic of Germany

ABSTRACT

Two data sets of field measurements of wave-induced nearshore currents are analyzed and discussed with respect to cross-shore transport phenomena and the effectiveness of beach groynes. The results are discussed in order to improve future artificial beach nourishments.

1. BACKGROUND AND SETUP OF INVESTIGATIONS

Subject of this contribution are the results of field measurements carried out on beaches of the East Frisian island of Norderney at the southern North Sea coast (FIG. 1). These investigations are part of a research programme for the optimization of future beach nourishments in the framework of interactions between hydrodynamics and existing solid structures.

In the past the East Frisian barrier islands were enforced to migrate their shape due to migra-

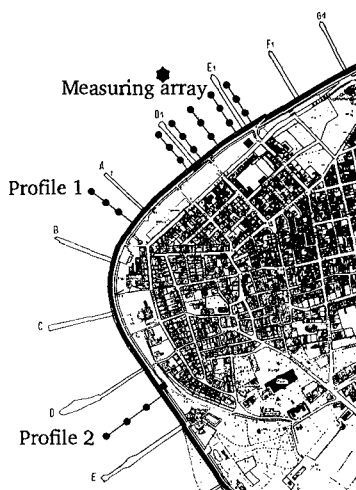

Fig. 1: Island of Norderney in the southern North Sea with measuring array and profiles

tion of tidal inlets creating a new ebb delta geometry with a furthermore updrift overlap of the ebb delta along the downdrift inlet shoreline. The sediment transport due to the eastward directed littoral drift bypasses the inlet in the form of large, migrating swash bars via the ebb delta and leads finally to a welding process of swash bars and island shore. Downdrift of their landfall the beaches suffer therefore from insufficient sediment supply causing erosion. For almost the last two centuries the morphological development of the western part of the island of Norderney was particularly governed by these processes (LUCK 1977). In order to stop further shoreline retreat solid structures have been erected since the middle of the last century. In spite of the construction of groynes, revetments and seawalls the problems remained unsolved till the introduction of repeatedly executed artificial beach nourishments as a successful tool of coastal protection which each remedied the grievance for a certain period of time (KRAMER 1960).

Though artificial beach nourishments have appeared as a rather successful tool to counterbalance the effects of continuous beach erosion, the demand for further improvements has been steadily present and has recently been more and more growing with respect to the effects of an expected acceleration of sea-level rise. Therefore in 1988 an intensive monitoring programme was started including hydrodynamical field measurements, beach and foreshore survey and sediment sampling.

Waves and currents are measured in one array with 16 and in 2 profiles with 3 measuring stations. Each station is equipped with both a pressure gage and an electromagnetic current meter, whose sensor heads are fixed closely to the bottom in order to measure velocities and directions of the currents there. First results gained from data in the measuring array (FIG. 2) are presented here. Special emphasis is laid on cross-shore transport phenomena and effectiveness of groynes. Due to limited space the discussion is focused on two data sets being representative of storm surge conditions and of swell occurring at ordinary tide water levels. In order to get a better in-

Fig. 2: Marks of measuring points in the measuring array and velocity ranges of the current roses

sight into the complex structure of the near-bottom currents on the beach the following analysis procedures were applied for this study:

- Any with a sampling rate of 11,78 Hz measured vector for a time series of twenty minutes are distinguished for sectors of $22,5^\circ$ and five classes of velocity ranges and plotted as current roses (FIG. 5, 6, 14). Additionally resulting current roses are gained by the addition of any counterdirectional components of the original rose (FIG. 7).
- The total amount of spectral energy is summarized for sectors of 5° and plotted as directional spectra (FIG. 8, 10-12).

2. HYDRODYNAMICAL BOUNDARY CONDITIONS

The mean tidal range in the area of Norderney is about 2.4 m with variations of ± 0.7 m due to spring and neap. The tide is lunar semidiurnal with a mean period of 12 h 25'. Until now the highest measured storm surge set-up was some 3 m above MHWL. The averaged yearly exceedence frequencies of storm surge peaks above MHWL due to German standard classification are 10 for 0,93 m; 0,5 for 1,95 m and 0,05 for 2,86 m (NIEMEYER 1987a). Tidal currents are rather weak on the beaches with mean velocities of about 10 cm/s and a range of maximum velocities of 2,5 to 29,8 cm/s for flood and 5,1 to 39,5 cm/s for ebb tide with respect to 21 continuously measured tides (NIEMEYER 1987b).

High energy wave conditions occur for winds from west to northeast generating landward traveling waves in the southern North Sea. On the island's shoreface on the average the sector of wave directions is reduced from 135° to 85° for mean conditions due to refraction. The predominantly western and northwestern directions of wind and swell create a system of longshore currents with north-eastern direction on the northwestern beach and south-eastward in the vicinity of the main channel of the tidal inlet (NIEMEYER 1986). The ebb delta overlaps in longshore direction the island's shoreface seaward of the beaches which have to be nourished from time to time and are now subject of this investigation. Waves propagating onshore from sea into this area have to pass the ebb delta with its shoals forcing higher waves to break. The energy dissipation due to that process effects not only a reduction of wave heights and a transformation of periods, lengths and steepness but also as well an energy shifting to higher frequencies as a decay of energy concentration leading to multi-peak spectra (NIEMEYER 1987c).

Fig. 3: Beach erosion due to storm surges and aftermath recovery

3. WAVE-INDUCED CURRENTS AND CROSS SHORE TRANSPORT PHENOMENA

3.1 Recovery of erosion profiles

The typical seasonal shift of beach profiles due to changing wave conditions is a well known as the phenonema of summer and winter profiles (BASCOM 1954). After the occurrence of numbers of severe storm surges HOMEIER (1976) investigated the behaviour of beaches on the East Frisian islands including those in the suppletion area of Norderney. The most important result was that even a recovery of those beaches takes place which suffer from continuous erosion. The beach erosion due to storm surges was balanced by an accumulation of material on the shoreface which moves slightly back shoreward within a few weeks. After that period the rate of erosion has decreased to mid-term tendency. A typical example of storm surge erosion and following recovery for a beach profile in the investigation area is shown in FIGURE 3. One major subject of this study is to get to know the governing hydrodynamical processes of this phenonema in order to make eventually use with respect to the design of future beach nourishments.

3.2 Analysis of Storm Surge Current Measurements

Storm surges are usually accompanied by high energy waves. For these conditions there is a broad surf zone on the

Fig. 4: Broad surf zone with white rollers during a storm surge

beaches of the investigation area characterized by subsequently following white rollers (FIG. 4). The energy dissipation of the waves establishes a complicated secondary system superimposing the incident waves. In this study data of a storm surge at high tide with a set-up of approximately 1,5 m above MHWL are taken. Wind direction was 290° with speeds between 15 and 16 m/s within the last three hours before. Significant wave heights ranged from 1,96 m (station m3; waterdepth $h = 2,6$ m) close to the revetment to 2,21 m (m1; $h = 3,3$ m) in the most seaward row of the measuring array (FIG. 5 + 6).

The current roses for the most seaward (FIG. 5) and for the most shoreward measuring row (FIG. 6) show a shoreward increasing overbalance of seaward directed components. This effect becomes more apparent, if resulting current roses are used. The example of the inner line of the array (FIG. 7) shows evidently that at least there are only resulting components in updrift longshore and especially in offshore direction with a reasonable part of high velocities. The same results are gained if data analysis is carried out with directional spectra (FIG. 8).

This data seem to be a reasonable hydrodynamical explanation for the high erosion rates and especially the shoreward increase of seaward directed currents explains sufficiently the scouring in front of revetments due to storm surges. The deposition of eroded material on the shoreface is possible as the overbalance and intensity of offshore directed currents decreases with distance from the shore.

Abb. 7: Resulting current rose of the measuring stations w3, m3, o3 (storm surge)

Abb. 8: Directional current spectra of the measuring stations o1, o2, o3 (storm surge)

The overbalance of seaward directed currents is expected to be an undertow effect (SVENDSEN 1984; STIVE & WIND 1986) due to breaking waves which occur -as explained before- across the whole breadth of the beach as white rollers. Their onshore directed mass flux must be compensated by a "relatively strong seaward flow below trough level" (BATTJES 1988). The high turbulence in the surf zone creates high suspension rates so that the transport capacity of the undertow does not only base on bed load. This might be a further explanation for the short term erosion created by storm surges.

3.3 Wave Induced Currents for Swell Conditions

Contradictory to storm surges with its broad surf zone for usual conditions wave breaking takes place in a narrow area in front of the revetment with a swash zone (FIG. 9). The waves on the shoreface and especially on the beach steepen due to shoaling before they break finally. Here a data set is taken from a normal tide with a peak height of 0,3 m below MHWL. There were offshore directed winds with speeds of about 5 m/s. The significant waves in the center line of the array range from 0,93 m (m_1 ; $h = 1,8$ m) to 0,66 m (m_3 ; $h = 0,6$ m).

The directional current spectra for the data from the array (FIG. 10-12) indicate a well established circulation in the groyne field. The primarily driving force is the overbalance of onshore directed energy along the updrift groyne E1 which is intensified by an also resulting

Abb. 9: Waves on the beach with narrow breaker line and swash zone

Abb. 11: Directional current spectra of the measuring stations m1, m2, m3 (normal tide)

shore-ward directed energy in the center point m2 of the array. This onshore drift creates especially close to the revetment a downdrift longshore current and due to the guiding effect of the downdrift groyne D1 concentrated seaward directed currents, which are superimposed by the return flow from the swash zone. This circulation pattern does doubtlessly depend on the geometry of the existing groyne-revetment system, especially if considered that the return flow does not occur in the place of the minimum breaker height. But its driving force must be the measured onshore near bottom drift which might be explained as an effect of very steep nonlinear waves (VAN RHIJN 1990).

As these waves are still non-breaking suspension is much lesser than in the high turbulent surf zone. Sediment transport takes place therefore mainly or even only as bed load. This explains the lower capacity in comparison with the undertow created by storm waves on the beach. If it is expected that onshore drift effects like those observed here cause the recovery of eroded beaches the longer duration of this process compared to the short period necessary for the erosion is reasonable.

In this case fortunately data of a beach profiling are available for the same period (FIG. 13). A comparison of the levelling in the three measuring lines w, m and o is in good agreement with the expected transport processes:

Date : 17-feb-89
Record : 21:18 - 21:38

50 m² s⁻²

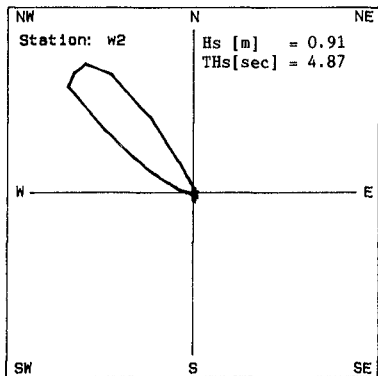

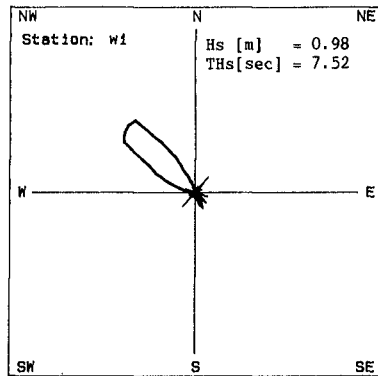

Abb. 12: Directional current spectra of the measuring stations w1, w2, w3 (normal tide)

Abb. 13: Beach profiles of the measuring array

the beach is relatively high where onshore directed drift has been measured whereas it is remarkable lower in its other parts.

4. EFFECTIVENESS OF GROYNES

The purpose of beach groynes is to reduce or even to prevent longshore currents and the caused sediment transport. The effectiveness of the groyne system has already been shown by the example of forced circulation. Furthermore the two data sets will be used to get a better insight in the interactions between waves and wave-induced currents with groynes.

Exemplary the effectiveness of the updrift beach groyne E1 is investigated here. The data of the storm surge event show a remarkable longshore current both the points m1 and m3. The longshore components in the position o1 close to the updrift groyne are at least of the same order of magnitude as those measured in m1 which may be explained by the fact that the groyne has no effect on the longshore currents (FIG. 5). In contrast to position o3 the longshore components of the currents are remarkably reduced in comparison with those in m3 (FIG. 6). Obviously the greater height of the groyne in this place causes this effect.

The same effect becomes apparent for the data of the normal tide (FIG. 14) by comparison with the current roses in the measuring points o1, o2 and o3. Whereas the longshore components in the positions o2 and especially o3 are remarkably reduced, in the most seaward situated measuring point the incident waves induce significant up-drift longshore components which are independent of the provoked circulation in the groyne field (FIG. 10-12).

A comparison of the geometrical boundary conditions of both data sets shows that the water depth above the groyne crest at position o3 for the storm surge is greater than in position o1 at the normal tide (FIG. 15). Apparently this parameter is not a reasonable measure for the effectiveness of groynes. Considering additionally the groyne elevation above the beach it is likely that the relative reduction of the total water column above the beach by the groyne is a more reasonable geometrical parameter for the effectiveness of groynes than the water depth above the groyne crest. In order to get a deeper insight in the physical background of the interactions between beach, groynes, waves and wave-induced currents systematical data analysis additionally considering hydrodynamical parameters has to be carried out in the next future.

5. CONCLUSIONS

The results give a good indication of the driving hydrodynamical forces which govern storm surge erosion and afterward recovery of beaches with revetments and groynes. It is evident that a shoreward increasing tendency of resulting seaward directed currents effects the enormous scour which become especially visible in front of revetments after storm surges. It is also apparent that their seawardly decreasing overbalance allows the sedimentation of the eroded beach material on the shoreface. It seems to be reasonable that the overbalance of seaward directed currents could be explained as undertow effects created by breaking waves. Due to the high turbulence in the surf zone sediment transport does not only occur as bed load but also as suspension which intensifies its efficiency leading to high erosion rates on the beach and correspondently high deposition rates on the shoreface.

The high nonlinearity of steep shoaling but still non-breaking waves creates drift effects which might effect onshore directed bed load transport. But its capacity is much lesser than that of combined suspension and bed load due to undertow currents in the surf zone. This might be a sufficient explanation for the much longer duration of the recovery process compared with the short time event of storm surge erosion.

Furthermore the data discussed here give the impression that the effectiveness of groynes depends primarily on the relative reduction of the total water column due to the groyne elevation above the beach and not on the water depth above the groyne crest.

The application of these results on future beach nourishments implies that the deposition of material on the shoreface is more effective than on the beach itself. A replenishment on the beach reduces the groyne elevation above its bottom and consequently the the relative reduction of the water column. This would again lead to a diminished effectiveness of the groynes with respect to longshore transport which would effect an increase of material losses in the first period after the execution of the nourishment decreasing with the progress of erosion.

Furthermore a nourishment on the shoreface might be better adjusted to natural transport phenonema. The provoked sediment transport due to the disturbance of the existing dynamical equilibrium by artificial deposition of additional material is mainly directed onshore in the first phase after the execution of the nourishment. As this event usually takes places in late spring or early summer, there will be shift of material from the shoreface to the beach which is expected to build up a slowly growing deposit for the erosion due to harvest and winter events with strong sea conditions including storm surges. The main advantage will be that it takes a certain period of time to build up the deposit and within this period the nourished material will be mainly in a position where it is less sensitive to erosion by longshore currents. In contrast to a nourishment on the beach itself will expose the material from the beginning totally to their eroding capacity. Additionally the reduction of water depth would provoke the breaking of even relative small waves and intensify suspension and erosion. Therefore a nourishment on the shoreface might be a successful solution in order to reduce the high losses in the first phase after the execution and to extend the period of effectiveness of nourishments.

CHAPTER 61

Directional Random Waves Propagation on Beaches José María GRASSA¹

Abstract

The paper deals with a method for the simulation of irregular, directional waves over large coastal areas using a linear model based on a energetically equalized discretization of wave spectrum and a parabolic approximation to the Berkhoff equation for wave evolution. A sensitivity analysis based on a comparison with physical model tests gives some ideas about the applicability of the method.

Introduction

Waves on the coast often shows little directional spreading due to the effect of refraction and diffraction. However, there is now sufficient evidence about the critical importance that directionality can have in the transformation of wave characteristics from deep to shallow waters, as shown through numerical experiences by Goda (1985) and Isobe (1987) and in physical model tests by Vincent and Briggs (1989).

Evolution models for spectral parameters including wave refraction and diffraction and assuming no wave generation or dissipation can be made applying the linear superposition of component waves transformed according to Berkhoff's (1974) equation if wave non-linearities can be disregarded for the specific problem to be studied or not important due to particular wave characteristics. However, over the very large areas often appearing in coastal studies, even the application to a single component of the mild-slope equation can be a formidable task. A solution for that can be the use of a parabolic approximation to the Berkhoff equation. In fact, parabolic equation method (PEM) extension for use with irregular directional waves has been done by Isobe (1987) applying the Radder's (1979) wave equation in the ray - front coordinates system. Very recently, Panchang et al. (1990) have also presented irregular directional results for the Vincent and Briggs tests (1989) using Radder's equation over an orthogonal grid, with a good agreement between computed and physical model results.

The present paper deals with the application of higher order, large angle PEM (Booij, 1981), (Kirby, 1986a, 1986b) to directional wave propagation on large coastal areas. At first, a brief review of the methodology employed is given. Some basic

¹Director, Centro de Estudios de Puertos y Costas, CEDEX - MOPU. c/ Antonio Lopez, 81, 28026 Madrid, SPAIN

questions arise about the method for wave spectrum discretization and they are studied suing a comparison with physical model tests by Vincent and Briggs(1989). Then, the method is applied to an idealized coastal area showing some of the implications that directionality can have on coastal environments.

Methodology

Under the assumption of validity for linear superposition as a method for the description of irregular waves, simulation of directional waves can be made trough the application to a number of monochromatic waves representing the whole wave spectrum of a wave equation for the evolution of monochromatic waves over an irregular bed.

Given a wave spectrum $S(f, \theta) = S(f) G(f, \theta)$ where $G(f, \theta)$ is a normalized shape function for directional distribution, a representation between given cut-off values, (f_{min}, f_{max}) , $(\theta_{min}, \theta_{max})$ in N_f, N_θ components each of which defined by a corresponding frequency, a direction and a wave amplitude $(f_i, \theta_{ij}, a_{ij}, i = 1, N_f, j = 1, N_\theta)$ can be made by a constant step method:

$$\Delta f = \frac{f_{max} - f_{min}}{N_f} \quad \Delta \theta = \frac{\theta_{max} - \theta_{min}}{N_\theta} \tag{1}$$

$$f_i = f_{min} + (i - 0.5) \Delta f$$

$$\theta_{ij} = \theta_{min} + (j - 0.5) \Delta \theta \tag{2}$$

$$a_{ij} = \sqrt{2S(f_i, \theta_{ij}) \Delta f \Delta \theta}$$

The method employed in the present work for an energetically equalized discretization of the spectrum consists of:

$$f_i \text{ given by: } \int_{f_{min}}^{f_i} S(f) df = \left(\frac{m_0}{N_f} \right) (i - 0.5)$$

$$\theta_{ij} \text{ given by: } \int_{\theta_{min}}^{\theta_{ij}} G(f, \theta) d\theta = \left(\frac{1}{N_\theta} \right) (j - 0.5) \tag{3}$$

$$a_{ij} = \sqrt{\frac{2m_0}{N_f N_\theta}}$$

being m_0 the zero order moment of the frequency spectrum. In the context of wave propagation, a similar approach has been presented by Goda (1985); at least for the frequential part of the spectrum.

Having obtained a representation of the irregular waves as a number of simple monochromatic waves, a PEM is employed for solving the wave potential field over the area of interest. It is possible then to recover some wave characteristics as significant wave height, instantaneous free surface, etc, through linear superposition of results for the components. Given the limitation of PEM that assumes a main wave propagation

direction one alternative is to obtain a specific calculation grid over the area modelled as a function of the direction of the incident wave, thus overcoming this limitation. That approach has been taken by Panchang et al.(1990). However, the use of large angle parabolic models such as (Kirby, 1986b), allows for the use of only one calculation grid in some cases even with some quite broad directional spectrum, avoiding the need for an interpolation of results of components in order to recover the irregular wave characteristics of interest.

For his application on wave propagation studies, equalized discretization shows some basic advantages:

1. Grouping of wave components around the spectrum peak, both in the frequency and direction domains (as seen in fig. 1). This is important in connection with PEM, given its intrinsic angular limitations. This makes easier the design and orientation of a calculation grid for a given area and can avoid the need of an arbitrary truncation of the spectrum.

Figure 1.- Equalized discretization for a directional shape.

2. Each one of the equalized components has a same amount of energy and can, in a first approximation, contribute equally to the disturbance in a given point. Then, computational effort is optimized for a given number of wave components.

The main disadvantage is that equalization is more complex and time consuming (when the spectral shape is not directly integrable) than constant step procedures; in the present context, however, equalization is a trivial task in comparison with the effort involved in the propagation of the wave components.

In the present application, solution of equations (3) for the equalized discretization of an arbitrary spectrum shape has been made using standard library routines (Morris, 1987) for evaluation of integrals over finite intervals and equation solving.

From a practical point of view, two main questions should be assessed:

1. Order of magnitude in the number of wave components needed to obtain accurate results, within the intrinsic limitations of the method (linear superposition, approximate PEM).
- 2.- Optimal distribution of the computational effort between the frequency and directional domain.

That points are going to be examined by comparison between the results applying the proposed methodology and some physical model test.

Comparison with Physical Model Tests

A numerical model built within the methodology exposed has been compared with the results of some tests on irregular directional wave propagation performed by Vincent and Briggs (1989) in a wave basin with a directional irregular wave generator. For the irregular waves target spectrum has been a TMA shape (Bouws et al., 1985) in the frequency domain and a wrapped around the circle normal distribution shape for directions. The bathymetry modelled has been a elliptic shoal similar to the one studied by Berkhoff et al. (1982), but over an horizontal bed instead of a sloping one. Figure 2 shows the layout of the model.

Figure 2.- Layout of the model

Cases selected are shown in table 1, and covers both wide and narrow shapes both in the frequency and direction domains for low steepness waves in intermediate water depth, making at first reasonable the use of linear theory. A monochromatic test and two unidirectional tests have also been computed.

<u>Test Id.</u>	<u>Waves</u>	<u>Peak Factor</u>	<u>Standard Deviation</u>
M2	Regular	-	-
U3	Irregular	2	0
U4	Irregular	20	0
N3	Irregular	2	10
N4	Irregular	20	10
B3	Irregular	2	30
B4	Irregular	20	30

Table 1.- Tests selected for comparison

In the numerical calculation, for the irregular cases the equalized discretization of the spectrum has been made taking only 10 frequency components by 10 directional (when required) components with the same frequency cutoff as in the physical model. Then for the narrow directional spreading tests, initial wave direction over the grid has an obliquity of up to around 16 degrees with the assumed main wave direction, avoiding the need for an arbitrary wrapping of the directional distribution in order to satisfy the PEM assumptions. Otherwise, for tests B3 and B4, maximum initial obliquity is around 49 degrees, and is going to be higher given the expected wave pattern after the shoal, thus some truncation should be applied.

The area modelled has been discretized in a calculation grid of 101 x 121 nodes with node distance of 0.25 ms. Wave propagation for each component over the same grid has been calculated using a Crank - Nicholson finite difference scheme based on higher order, large angle Kirby's minimax parabolic equation (Kirby, 1986b) in a linear version and without friction terms. Initial condition for complex wave amplitude ϕ for each oblique component ij in the first row of the grid are:

$$\phi_{ij} = a_{ij} \exp(i(k_i \sin\theta_{ij} y + (S_0)_{ij})) \quad (4)$$

being k_i the wave number corresponding to wave component i,j , and y the coordinate values corresponding to the grid nodes along the first row (x being the main propagation direction). A pseudo random value S_0 , equally distributed between 0 and 2π is added to the initial phase function for each component in order to obtain realistic instantaneous free surfaces.

Minimax parameters for the computations have been taken for 70 degrees of aperture, and a dissipative filter (Kirby, 1986a) has been applied to the computed results.

Figures 3 - 4 shows results of significant wave height along measurement section 4, with the reference of physical model results. The continuous line presents numerical results and the broken line physical results from the graphs of Vincent and Briggs (1989).

Figure 3.- Results for non directional tests

As signaled by Vincent and Briggs (1989), the non-directional cases show very similar features to the ones in the regular test. However, the qualitative agreement is better in tests U3, U4 than in M2, featuring both numerical and physical results the lateral linear caustics that develops behind the shoal, not present in the physical model results for the monochromatic case.

For the directional tests, the magnitude of the caustic shows an intense decrease, practically disappearing for wide spreading tests. Similarly, numerical and physical results fits well, except in the test B4, with a narrow frequency spectrum and

Figure 4.- Test results for directional cases

wide directional spreading, where physical model results shows a systematic trend towards lower values than the numerically computed, perhaps due to some amount of dissipation over the shoal.

A quantitative measure of the quality of results has also been made, using a relative root mean square difference between physical and numerical model for that section:

$$dif_{rms} = \sqrt{\frac{\sum \left(\frac{H_{pm} - H_{nm}}{H_{pm}} \right)^2}{N}} \quad (5)$$

where:

H_{pm} : Wave height in physical model (from graphs in Vincent and Briggs, 1989)

H_{nm} : Wave height in numerical model

N : number of measurement points along section 4

Table 2 summarizes the results.

Test id.	Relative root mean square difference
M2	0.153
U3	0.111
U4	0.069
N3	0.044
N4	0.128
B3	0.046
B4	0.167

Table 2.- Comparison between numerical & physical results

Then it appears that in the cases modelled an irregular linear wave propagation model based on an equalized discretization of the spectrum and the application of a higher order PEM provides a similar quality of results as with PEM applied to monochromatic test.

Sensitivity Analysis

A sensitivity analysis of the results as a function of number of wave components has been made for test case N3, trying to obtain information about which number of wave components is needed for a correct reproduction of irregular propagation in that test and also studying the stability of the numerical model. Results have been evaluated with eq. 5 for an increasing number of discrete components (equal number in frequency and directions) from 4 (2 x 2) to 900 (30 x 30), obtaining the relative difference with physical model tests.

Results are plotted in figure 5 (solid line), together with similar data for results obtained through a constant increment discretization of the spectrum (dashed line).

Figure 5.- Sensitivity to number of components (test N3)

As can be seen, results obtained with equalized discrete components converge in a stable way towards the asymptotic solution for the numerical model and a very little improvement is obtained with more than 100 components. Otherwise, results with constant step shows larger errors with a small number of components and an anomalous behavior when the number of intervals in the directional domain is odd, due to the fact that then a component is placed on the spectral peak, with a predominant amount of wave energy which implies results more similar to the monochromatic situation. Of course, with an increasing number of wave components, differences between both approaches vanishes, but it is still noticeable at the number of wave components used in the present work.

Then it can be concluded that equalized discretization gives, from the point of view of wave propagation, a more reliable representation of irregular waves than constant step methods, in particular if the number of wave components used is not high. The need of a low number of components for the obtention of good quality results is a hopefully conclusion, making possible the application of the methodology over large areas with reasonable computing resources, and implies also the possibility of application of more complex models such as the elliptic mild-slope equation using a similar approach.

Another question is the optimum relationship between number of directional and frequency components involved in the computations. That question is to be solved in a case basis, but given the greater importance of directionality over frequency shape at least in cases involving diffraction, it appears likely to use a larger number of directional components. From a computational point of view, it should be noted that the coefficients in the discretized parabolic equation do not have any dependence on the wave direction (except for the independent term that depends also on initial conditions), being a function of wave frequency, wave number and related quantities (phase and group velocity). Then, when a component has been computed for a given

frequency, only a minor modification on the independent term of the parabolic equation system is needed in order to setup the equation for a new wave direction with the same frequency. Figure 6 shows results for test B3 computed using double number of directional components (dashed line) that of frequency ones and an equal number (solid line).

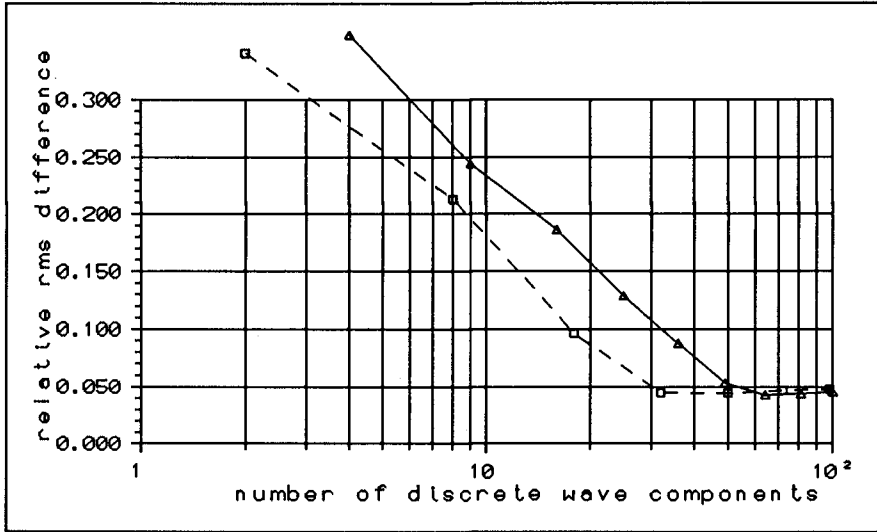

Figure 6.- Comparison of results with $N_0 = 2 N_f$ (Test B3)

A similar quality of results is obtained with $(N_f = 4, N_0 = 8)$ and $(N_f = 7, N_0 = 7)$ with the added advantage of the low computational cost of computing an additional directional component for a given frequency as compared with the cost of the setup of the coefficients of the system of equations that arises from PEM, needed if more frequencies are involved.

Application over an idealized bathymetry

An application has been made over an idealized bathymetry given by:

$$z(x,y) = -10 + 0.001 * x \tag{6}$$

$(0 \leq y \leq 1500.)$
 $(0 \leq x \leq 1000.)$

with x, y and z in meters and representing a plane sloping beach. A shore-parallel breakwater is located at a depth of 7. mt and extends from y = 750 to y = 1500 mt.

Three different wave conditions have been tested:

- a) Monochromatic waves with period 10 sec. and normal incidence.
- b) Swell-like waves, defined by a Jonswap spectrum with $\gamma = 7.$ and directional spread modelled according to the Mitsuyasu - Goda - Suzuki(Goda, 1985) shape

function with $S_{\max} = 100$.

c) Sea-like waves, with $\gamma = 2$, and a broader directional distribution given by $S_{\max} = 25$, at the offshore boundary of the modelled area.

The discretization has been made taking 101×151 equally spaced nodes (distance between nodes 10 mt) and the irregular runs have been made with 5×15 components. Simulation of wave breaking has been artificially introduced in the model in a way similar to Ebersole (1985), trying to obtain qualitative information about breaking along the beach.

Computed results for significant wave height field are given in figures 7 - 9.

Figure 7.- Wave height field for monochromatic test

As can be seen, there are significant differences between for monochromatic and irregular wave results. At first, wave height field seems to be smoother on the coast in the irregular waves tests (the "wavy" variation in wave height associated to wave diffraction vanishes). It is to be noted that for all the tests, a dissipative interface (Kirby, 1986b) has been applied and is needed due to the numerical noise that arises in higher order parabolic schemes. Also, as signaled by Goda (1985) wave penetration along the line between the toe of the breakwater and the coast is higher for the irregular, broad directional test than for the monochromatic and the swell-like test.

Then, it appears than for narrow-directional distributions, wave irregularity can have a main effect of smoothing some of the special characteristics of monochromatic wave response, having a more fundamental effect for sea wave states.

Figure 8.- Wave height field for swell conditions test

Figure 9.- Wave height field for sea wave conditions

Figure 10 shows breaking wave height along the beach for the three tests, being a main characteristic the more slowly decrease in wave height along the diffraction area for sea waves.

Figure 10.- Breaking wave height along the shore

Conclusions

A methodology for the study of irregular directional waves that can be applied to large areas has been presented, based on linear superposition of energetically equalized components of the target spectrum and the application of higher order parabolic approximations to the Berkhoff equation. Comparison with low steepness physical model tests by Vincent and Briggs (1989) and a sensitivity numerical experiment shows that it is possible to obtain quite accurate results even with a very low number of components, and that it could be more interesting to take a higher number of directional components than frequential ones. That should apply also for models builded from the elliptic mild slope equation.

A more extensive comparison including the high steepness tests of Vincent and Briggs (1989) is to be made for studying the expected degradation of predictive capability of the method for situations in which nonlinearities play an important role. As an alternative, another approach, perhaps based on more general equations for free surface flow simulation should be considered. Unfortunately, however, most of those models cannot be applied over the total range of depths to be considered for wave transformation from deep to shallow waters.

An application for an idealized coastal area shows some interesting features in the wave height field along the shore for the test with sea waves condition, giving

results in qualitative agreement with those obtained by Goda (1985) for directional wave diffraction applying semi-analytical models. Additional work is to be done for incorporating a more realistic description of wave breaking into the model.

One of the actual weaknesses for application of directional wave propagation to studies on coastal areas is the absence of information about directional wave conditions and propagation characteristics on nature. Then an effort should be made in order to obtain field data and validate numerical models against that information.

CHAPTER 62

Spatial variation of wave group statistics and representative wave-heights of swell

Akiyuki UKAI^{*}, Takashi YASUDA^{**}, Kazunori ITO^{***}

Abstract

This study derives a practical equation that can describe the weakly nonlinear waves having an arbitrary spectral form and propagating unidirectionally from deep to shallow water, and carries out the numerical simulation using the equation. Based on the simulated results, some investigations are made on the characteristics of spatial variation of wave group and representative wave-heights in the propagation process.

1. Introduction

Characteristics of grouped waves propagating from deep to shallow water are clearly important for engineering purpose, but are little made clear because of the difficulty of the observation in field. Regretably, most of usual investigations are concerned with the statistics of wave grouping derived from temporal wave registrations obtained at fixed locations and lack a view point that the statistics may change spatially during the propagation of the grouped waves.

Hence, in order to investigate on the spatial variations of the characteristics during the propagation from deep to shallow water, it is essentially required to develop a tractable equation that can be easily solved for the nonlinear waves having an arbitrary spectral bandwidth and propagating from deep to shallow water and employ a theoretical approach using the equation, instead of the approach based on the field observation.

** Prof., Dept. of Civil Eng., Gifu Univ., Gifu 501-11, JAPAN

***Graduate student, ditto

In this study, we suggest a single tractable equation of spatial evolution type for describing the unidirectional propagation of swell and carry out numerical simulations using the equation. Further, based on the simulated results, we investigate intensively on the characteristics of spatial variations of wave group statistics and representative wave-heights in the propagation process.

2. A model equation for swell

2.1 Derivation

we derive a tractable equation that can easily describe weakly nonlinear waves having an arbitrary spectrum and propagating unidirectionally from moderately deep to shallow water, by modifying the dispersion term of the following perturbed KdV equation so as to give the correct linear dispersion relation of surface gravity waves.

$$\eta_x + \frac{1}{\sqrt{gh}}\eta_t + \frac{3}{2} \frac{1}{h\sqrt{gh}}\eta\eta_t + \frac{1}{6} \frac{h^2}{(gh)^{3/2}}\eta_{ttt} + \frac{1}{4} \frac{h_x}{h}\eta = 0 \tag{1}$$

where the subscripts x and t denote partial differentiations with regard to them, x the horizontal coordinate, t the time, η the temporal water surface elevation, h the mean water depth in the propagation process and g the acceleration of gravity.

To our best knowledge, there is no equation of spatial evolution type such that can describe actually the propagation process of weakly nonlinear waves having arbitrary spectrum. The necessary conditions for the equation are as follows:

- i) Only if the temporal water surface elevation at any fixed location is given as a boundary condition, the equation can describe its spatial evolution over a sloping bottom from deep to shallow water.
- ii) The equation can be applied to the swell having an arbitrary spectrum.
- iii) The equation should be tractable so as to be for numerical simulation of the long distance propagation.

An equation of wave motion of spatial evolution type can be written for linear waves having correct dispersion relation and propagating on the moving coordinate with the speed of \sqrt{gh} as

$$\partial_x \eta + \int_{-\infty}^{\infty} F(\tau - \sigma) \partial_\sigma \eta d\sigma = 0 \tag{2}$$

where

$$\left. \begin{aligned} F(\tau - \sigma) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{c(\omega) - \sqrt{gh}}{c(\omega)} e^{-i\omega(\tau - \sigma)} d\omega \\ \tau &= \int dx / \sqrt{gh} - t, \quad \omega = 2\pi f \end{aligned} \right\} \tag{3}$$

and $c(\omega)$ is the wave speed of linear dispersive waves.

Here, assuming its solution as

$$\eta = \sum_{-\infty}^{\infty} A_m(x) \exp(i\omega_m \tau), \quad (4)$$

and treating this equation on the frequency domain, we obtain the following mode rate equation.

$$\frac{dA_m}{dx} + ik(\omega_m)[C(\omega)/\sqrt{gh} - 1]A_m = 0, \quad m: -\infty \sim \infty \quad (5)$$

Further, introducing the nonlinear term $3/2\eta\eta_x$ and the shoaling term $h_x\eta/4$ included in the perturbed KdV equation shown in eq(1), we obtain a single tractable equation of spatial evolution type and call it as a model equation for swell unidirectionally propagating from moderately deep to shallow water.

$$\begin{aligned} d\tilde{A}_m/dx^* + ik_m^*(c^* - h^{*1/2})\tilde{A}_m \\ + \sum_{j=-\infty}^{\infty} i \frac{3}{2} k_m^* h^{*-1/4} \tilde{A}_{m-j} \tilde{A}_j = 0, \end{aligned} \quad (6)$$

$m: -\infty \sim \infty$

$$\left. \begin{aligned} x^* &= x/h_0, \quad k_m^* = k(\omega_m)h_0, \quad h^* = h/h_0, \\ c^* &= c(\omega_m)/\sqrt{gh_0}, \quad A_m/h_0 = \tilde{A}_m h^{*-1/4}, \end{aligned} \right\} \quad (7)$$

This equation has two conserved quantities of 1st and 2nd order are derived from the model equation as

$$\frac{d}{dx} I_1 = -\frac{3}{4} \frac{\eta^2}{\sqrt{gh^3}} \Big|_0^{T_0} - \int_0^{T_0} L[\eta] dt, \quad I_1 = \int_0^{T_0} \eta dt, \quad (8)$$

$$\frac{d}{dx} I_2 = -\frac{\eta^3}{2\sqrt{gh^3}} \Big|_0^{T_0} - \int_0^{T_0} \eta L[\eta] dt, \quad I_2 = \int_0^{T_0} \frac{\eta^2}{2} dt, \quad (9)$$

where

$$L[\eta] = \sum_{m=-\infty}^{\infty} i [\sqrt{(k_m/h)\tanh k_m h} - k_m] A_m e^{i\omega_m t}, \quad (10)$$

Assuming the periodicity of η with an observation period T_0 on time domain, we can put the right hand sides of eqs(8) and (9) zero, because of the relation $A_m = A_{-m}$ and the fact that $\omega(k_m)$ is the odd function of k_m . Thus, we can evaluate the accuracy of the numerical solution by examining the conservativeness of I_1 and I_2 . Here, the equation was solved under the accuracy that the errors for both the conservation laws are kept within 0.1 %.

Furthermore, it should be emphasized that the modulational instability occurs in the wave train governed by the model equation, although the nonlinear term of the equation is identical with that of the KdV

Fig. 1
Wave train of a quasi-monochromatic wave train.

Fig. 2 Modulation of peak and its side band modes.

equation which cannot express the instability. Figure 1 shows the spatial evolution of a quasi-monochromatic wave train governed by the model equation. Figure 2 shows the modulation of the peak mode and its side-band modes and explains clearly that the modulation and demodulation successively occur.

2.2 Accuracy

Since the model equation is not derived consistently from the fundamental equation of hydrodynamics, we are required to examine the applicability before carrying out the numerical simulations of long distance propagation of swell through the model equation.

At first, we examined the accuracy of the model equation by comparing with the exact Stokes waves. Figure 3 [Yasuda et al., 1989] shows the applicable region of the model equation and the KdV equation. The boundaries in this figure indicate the critical values of ka and kh under which the maximum value of the error E_1 , defined by

$$E_1(t) = \int_{-\pi/k}^{\pi/k} [\eta(x, t) - Y(x - ct)]^2 dx \bigg/ \int_{-\pi/k}^{\pi/k} Y^2 dx, \tag{11}$$

is kept within 0.06. Here, η denotes the numerical solution of the model equation, Y the exact Stokes wave solution and c is phase speed. Hence, E_1 can be used as an error criterion indicating the accuracy of the numerical solution to the exact solution of steady wave. It could be said that the model equation is applicable within the boundaries shown in figure 3 and that the model equation is superior to the KdV equation in the range of $kh > 0.8$. However, the model equation does not unexpectedly work so well for the waves in

Fig. 3

Applicable region derived from the comparisons with the exact Stokes wave.

Fig. 4

Temporal water surface elevations measured at P.1, and P.2

Fig. 5

Power spectra measured at P.1 and P.2

Fig. 6

Comparison of power spectra at P.2 between the experimental result and the calculated one.

deeper water than $kh > 3.3$, because its nonlinear term is valid only for long waves with $kh \ll 1$.

Secondly, we examined experimentally the applicability of the model equation to the quasi-monochromatic waves suffering from the modulational instability. Figure 4 shows the temporal water surface elevations at P.1 and P.2 of a modulational wave train generated in a wave flume [1m x 1m x 54m] having a servo-controlled wave maker. The distance between the measuring location P.1 and P.2 is $kx = 42\pi$ in this case. It is conjectured from Fig. 5 that the modulation observed at P.2 is primarily due to the growth of the side-band modes of the spectral peak.

Figure 6 shows the comparison of power spectra at P.2 between the measured result and the simulated one.

Comparison of water surface profile at P.2 between the experimental result and the simulated one.

Figure 7 indicates the comparison of temporal wave profile at P.2 between both the results. The simulation carried out by making the waves measured at P.1 propagate to P.2 through the model equation. Both the results corresponds to each other in rough trend. However, it should be noticed that the modulation of the simulated waves is considerably weak and the side-band modes of the simulated waves are not so strengthened in comparison with those of the measured waves. Hence, it should be noted that the growth of the modulation is evaluated a little weakly as far as the model equation is used.

Finally, we examined the applicability of the model equation to irregular waves having various spectral bandwidth, by generating the desired waves of which initial spectra are the Wallops type in the aforementioned wave flume and comparing the measured wave profiles at P.2 with the results simulated as well as the case of the quasi-monochromatic waves mentioned above. The error criterion E_2 for evaluating the applicability of the model equation to the irregular waves is defined as

$$E_2(x) = \int_0^{T_0} (\eta_{ob} - \eta_{ca})^2 dt / \int_0^{T_0} \eta_{ob}^2 dt \quad , \quad (12)$$

This denotes the difference with the water surface elevation including the propagation speed between the simulated result η_{ca} and the measured one η_{ob} at P.2. The relation between the error criterion E_2 and the Ursell number(Ur) is shown in Fig. 8. Qp in the figure denotes the spectral peakedness parameter.

Figure 9 shows the comparison of temporal wave profile at P.2 between the measured result and the simulated one in the case that the aforementioned error E_2 is 0.23.

3 Propagation of swell

Numerical simulations using the model equation are made in order to investigate on the characteristics of spatial variations of wave grouping, by giving the following temporal water surface elevation with the desired statistics to the model equation as the

(a) $Q_p \approx 2$ (b) $Q_p \geq 4$
 Fig. 8 The relation between error criterion E_2 and U_r .

Fig. 9 Comparison with experimental wave profile in the case of the value of $E_2 = 0.23$.

boundary condition at origin.

$$\eta(0, \tau) = \sum_{n=0}^{\infty} 2|A_n| \sin(2\pi f_n \tau + \varepsilon_n) \quad , \quad (13)$$

where, ε_n is the random phase angle distributed uniformly between 0 and 2π , M the number of the Fourier modes and 2^{11} in this study, A_n denotes the amplitude of the n th Fourier mode and is related to the spectral density $S(f)$ as

$$A_j = \sqrt{2 \int_0^{\infty} S(f) \delta(f - f_j) df / T_0} \quad , \quad (14)$$

The initial spectrum $S(f)$ is given so as to have the Wallops type and the values of parameters governing the spectral form are determined for the initial waves so as to have the desired statistics with the dispersion parameter kh , the nonlinear parameter ka and the spectral bandwidth parameter m . Here, k is the wave number which is correspondent to the frequency at the spectral peak and is calculated through the

Q_p	2.00	4.04	5.90	8.07

Wave profile of numerically simulated waves during the propagation ($kh=2.0$, $ka=0.15$ and $m=15$).

linear dispersion relation, and the amplitude equals to the half of the significant wave-height $H_{1/3}$. The value of m is about 5 in the case of wind waves and is over 15 for swell. Table 1 indicates the present relation between m and Q_p .

Figure 10 shows the temporal water surface elevations at $x/L=0$, 33 and 146 of the waves simulated with using the model equation under the initial statistics of $kh=2.5$, $ka=0.15$ and $m=15$.

4 Spatial variation of wave grouping

Groupiness Factor(GF) defined by Funke and Mansard[1979] is employed here as statistics of describing wave grouping and its spatial variation dependent on the initial values is investigated for the simulated waves. Figure 11 indicates the spectral forms

Fig. 11

Variation of the spectral form of the wave shown in Fig.10.

of nonlinear waves shown in Fig. 10. The remarkable growth of the modulation at $x/L=33$ is supposed to be due to the pronounciation of side-band modal components.

Fig. 12

Influences of bandwidth parameter m on the spatial variation of GF of nonlinear and linear waves. ($kh=2.5$, $ka=0.15$)

Figure 12(a) shows the spatial variation of GF of the waves simulated with the model equation under the initial statistics of $kh=2.5$, $ka=0.15$ and some spectral bands of $m=5, 15, 30$ and 55 . The spatial variations of GF of linear waves under the same initial statistics are in Fig. 12(b), in order to show the influence of nonlinearity on wave grouping. It is found from the figures that not only the value of GF of nonlinear waves but also that of linear waves varies spatially during the propagation. The former variation is conjectured to be caused by the modulational instability, while the latter one is clearly due to linear combination of the Fourier modes. However, the former variation gets to exceed greatly the latter one and the influence of the nonlinearity becomes dominant as the value of m increases, that is, the spectral bandwidth becomes narrower.

The influence of kh on the spatial variations of GF is examined. Figure 13 shows the influence under the initial statistics of $ka=0.12$, $m=5$ and 30 and $kh=1.04$, 1.72 and 3.11 . In the broad band case of $m=5$, the spatial variation of GF is not so dependent on the value of kh and the influence of kh is not so conspicuous. However, under the narrow band spectrum of $m=30$, the difference between the case of $kh=1.04$ and those of $kh=1.72$ and 3.11 is very large. This remarks that wave grouping catastrophically changes at the vicinity of $kh=1.40$, which is the critical point of the modulational instability in the model equation, under the spectrum of finite bandwidth.

(a) $m=5$ (b) $m=30$
 Fig. 13 Influences of kh on the spatial variation of GF.

(a) $m=5$ (b) $m=30$
 Fig. 14 Influences of ka on GF under $kh=3.11$.

(a) $m=5$ (b) $m=30$
 Fig. 15 Influences of ka on GF under $kh=1.04$.

In order to investigate the nonlinear effect on the variation of GF, we carried out some numerical simulations. Figures 14 and 15 show the influence of the value of ka on the variation of GF. The statistics of initial waves are $kh=3.11$, $ka=0.06$ and 0.12 , $m=5$ and 30 in the Fig. 14. And, those of initial waves in Fig.

15 are $kh=1.04$, $ka=0.03$ and 0.06 , $m=5$ and 30 . In these cases, the growth of wave grouping becomes strengthened as the spectral bandwidth get to be narrower from $m=5$ to $m=30$. These results show that the effect of nonlinearity on the growth of wave grouping could be almost ignored so long as the value of ka is less than 0.12 .

Fig. 16

Influences of bottom slope on the spatial evolution of GF

In order to investigate the effect of bottom slope on the variation of GF, we carried out the numerical simulation for three different values of bottom slope. The statistics of the initial waves are $kh=3.11$, $ka=0.06$ and $m=15$, and the simulation results are shown in Fig.16. It is found that the bottom slope has little influence on the behavior of GF so long as the value of kh is larger than 1.3 . From this result, we can conclude that the spatial variation of wave grouping should be considered as a result of the modulational instability rather than that of shoaling wave.

6. Spatial variations of representative wave-heights

If wave grouping is a consequence of finely tuned focussing of linear wave trains or modulational instability of nonlinear wave trains, it is natural that the influence of wave grouping comes not only to a time sequence of zero-cross waves but also to representative wave-heights. Figure 17 shows spatial variations of representative wave-heights of the swell of which initial statistics are $kh=2.5$, $ka=0.15$, $m=5$ and 30 . Since the swell propagate on a flat bottom, the values of η_{rms} , \bar{H} and $H_{1/3}$ are almost invariant as the matter of course. On the other hand, the value of H_{max} varies greatly in the propagation process and the

Fig. 17 Spatial evolution of representative wave-heights.

Fig. 18 Spatial evolution of representative wave-heights in linear wave field

ratio of $H_{max}/H_{1/3}$ often exceeds 2.0 that is the value employed in the design of offshore structures. Figure 18 shows spatial variations of representative wave-heights of the linear wave under the initial statistics of $kh=2.5, ka=0.15$ and $m=30$. The value of \bar{H} , $H_{1/3}$ and $H_{1/10}$ are similar to those shown in Fig.17(b). The value of H_{max} varies in the propagation process, but the ratio of $H_{max}/H_{1/3}$ never exceed 2 in this linear calculation. Therefore the appearance of a region with $H_{max}/H_{1/3} > 2$ which was observed in Fig. 18 can be ascribed to the nonlinear interaction. Figure 19 shows the relation between GF and H_{max} under the initial statistics of $kh=2.5, ka=0.15$ and $m=30$. The variation of GF agrees well with that of H_{max} . This indicates that the variation of H_{max} is dependent on GF in the propagation process. Figure 20 shows the relative frequency of the ratio H_{max}/\bar{H} derived from the surface elevation at each location in the propagation process. A solid line denotes the relative frequency of the waves of which zero-cross wave-heights obey the Rayleigh distribution. Although there is no significant

Fig. 19
the present relation between GF and H_{max}

Fig. 20
Relative frequencies of the ratio H_{max}/\bar{H} at each location in the propagation process.

difference in the case of $m=5$ between the result simulated by the model equation and that based on the Rayleighan, the difference between both the results becomes significant in the case of $m=30$. This

demonstrates that the consideration of the influence of wave grouping becomes necessary in the reliable prediction of design waves as the spectral band-width gets to narrower.

7. Conclusions

The accuracy and applicable region of the model equation was made clear with respect to the wave statistics of kh and ka or U , through experimental examinations. Wave groups seen in the swell having $kh \geq 0.14$, $ka \geq 0.12$ and $m \geq 30$ are originated primarily by the modulational instability, although the other wave groups are generally consequences of linear combination of different, independent Fourier modes. Wave packets exhibited generally in the swell varies spatially during the propagation differently from the envelope solitons and should be treated as unsteady phenomena. The characteristics of their spatial variations were made clear through GF and representative wave-heights and were found to be dependent on the statistics of kh , ka and m . The maximum wave-height H_{max} is closely related with the wave grouping and the relative frequency of the ratio H_{max}/\bar{H} considerably deviates from that based on the Rayleigh distribution under the narrow band spectrum of $m \geq 30$.

The authors wish to express their thanks to Dr.M.Tanaka for his valuable advices.

CHAPTER 63

SEA-AIR INTERACTIONS IN THE COSTAL CIRCULATION AROUND GRAN CANARIA ISLAND (SPAIN)

Begoña Tejedor¹, Miguel Alejo², Luis Tejedor³

Abstract

This paper presents the results of analyzing six months of simultaneous records of water levels, currents, wind and atmospheric pressure that have been collected outside the surf zone at three locations in the eastern coast of Gran Canaria (Canary Islands, Spain). The results shown in this paper concern mainly one of the coastal stations, placed at the port of Las Palmas city. Although tides and currents use to be astronomically dominated, a non-permanent term appears in certain time intervals, identified as a long wave -rotary type- with a frequency very close to the inertial one. Another interesting result is the appearance of harmonic tidal periodicities in the atmospheric variables, which suggest a higher importance of the meteorological tides or/and a strong interaction sea-air.

Introduction

As it is well known, nearshore currents outside the surf zone use to be mainly dominated by tide and wind. Wind affects the upper layer of water and does not use to produce permanent periodic terms in the currents. But meteorological variations may give rise to important effects in the current patterns, either by enhancing or weakening some existing periodic terms or by generating new ones, that appear in the spectrum as new peaks which can only be explained via sea-air interaction.

The Canary Islands are a privileged place for observing oceanographic phenomena, as they are oceanic islands that are in the path of a general oceanic circulation and they are wide enough to perturbate it and to super-impose a very interesting local pattern. Moreover, the archipelago is placed between the northern parallels $27^{\circ}30'$ and $29^{\circ}30'$, in the zone where the intense solar radiation and the local earth parameters enhance sea-air interaction and resonance phenomena, and trade winds are dominant.

In the present work, the attention has been focussed in the eastern coast of Gran Canaria Island (fig. 1), where 3 coastal stations were established and at least six months of simultaneous and continuous records of tide, currents and meteorological variables were collected. The results now shown are mainly obtained from the station No. 3 (port of Las Palmas).

Figure 1.- Location of measurement stations

Data collection and analyzing methods

The measurements of currents are performed by 2 current meters placed at 15 and 30 m depth, in areas of about 45 m total depth. The meteorological data recorded are pressure, temperature and wind velocity at 10 m above the sea surface. The instruments are made by Aanderaa, and the sampling interval is set to 30 minutes.

Current and wind velocities were split into North-South and East-West components, approximately corresponding to longshore and transverse directions. For data from station No. 1, another pair of axes was also considered, resulting from linear regression in the polar diagram.

As only long period constituents were to be studied, a low pass filter was applied to the series, after which a final lag of 1 hour resulted.

The main analyses were achieved by both harmonic and spectral methods. The harmonic analysis uses 69 astronomical constituents, being possible to add 77 more ones for including shallow water terms. The least-square technique is applied with nodal corrections for the longest constituents that can be resolved over the length of the record. If the record length does not allow to determine a certain constituent, an estimate may be obtained by inference.

The term "component" has been used for longshore or transverse series, while the term "constituent" was used for harmonics.

The results are amplitude and Greenwich phase of every constituent, as well as the axis length and orientation of the ellipses with respect to the reference system and the phase angle.

By means of spectral analysis, the same results are obtained, as well as the cross-spectra between pairs of variables and the clockwise and anticlockwise rotary spectra.

The study was performed for months, quarters and half-years, what allows to estimate the stability of the constituents as a function of time.

Constituent	Current Component			
	East - West		North - South	
	Mean	σ	Mean	σ
Shallow Water	11.52 %	4.40	4.12 %	1.94
Long Period	4.11 %	2.28	16.83 %	5.13
Diurnal	20.56 %	6.58	20.05 %	4.11
Semidiurnal	30.20 %	12.51	36.85 %	5.75
Third-diurnal	4.36 %	2.21	2.64 %	2.43
Residual	29.25 %	8.48	19.51 %	2.74

Table 1.- Distribution of variance in the current measurements at the Port of Las Palmas. Depth: 15 m

Results of harmonic analysis

Table 1 shows the spectral distribution of the mean variance of the current -a measure of the energy-, with the standard deviation, obtained from the half-year records of station No. 3, at a depth of 15 m.

The maximum flood (south-going) reaches 40 cm/s, and the maximum ebb (north-going) attains a value of 30 cm/s. The currents flow predominantly along the North-South direction (longshore). The transverse current records exhibit a higher variability and a strong level of noise.

The frequency band with the greatest amount of energy is the semidiurnal one in both components, what means a 30.2% for the longshore one and a 12.5% for the transverse one. The diurnal band amounts to 20.6% and 6.5% respectively for the longshore and transverse components.

Figure 2.- Polar diagram of currents at the Port of Las Palmas. Depth: 15 m

In the polar representation (fig. 2) it may be seen that the main direction of the current is almost North-South, with a certain asymmetry: data toward the south and with high speed are deflected to the east, probably due to the gradient currents generated after the strong and persistent trade winds blowing to the south and given rise to an over-elevation at the coast.

The amplitudes and phases of the main tidal constituents in the 3 stations are shown in table 2. It can be seen the relative importance of the semidiurnal and diurnal terms. The stability of the tidal constituents was obtained after analyzing monthly records. The greatest deviations correspond to the S_2 constituent, what suggests that this band may be affected by non-tidal phenomena. Some characteristics of the tide at Las Palmas can be deduced from table 3. The ratio $(K_1+O_1)/(M_2+S_2)=0.11$ means a semidiurnal tide.

With respect to the currents, table 4 offers the characteristic parameters of the ellipses of the main constituents (after Godin, 1972): major and minor half-axis, angle with respect to the East-West axis and rotation sense. The axes of the main constituents are orientated parallelly to the coast.

The stability of the characteristic parameters is shown in table 5, where their amplitudes and phases can be seen. As usual, the stability of the surface displacements is higher than the stability of the currents. Nevertheless, S₂ makes an exception.

The ratio between tidal amplitudes and current amplitudes for the diurnal and semidiurnal bands is not a constant. It gives a significantly higher value for the constituents NO₁ and 2Q₁ (more important for the first one),

what is coherent with the presence of non-tidal terms. Some characteristics of the currents can be appreciated in table 6. Although the ratio $(K_1+O_1)/(M_2+S_2) = 0.39$ suggests a mixed tidal current with semidiurnal predominance, the high value of the NO_1 constituent or other waves with close frequencies causes a certain modulation with diurnal effect, which in certain occasions results in more energy in the diurnal band than in the semidiurnal one.

Results of spectral analysis

The spectral analysis of the records confirms the information given by the harmonic analysis. Figure 3 shows a typical spectrum of the longshore component of the current, at 15 m depth and corresponding to station No. 3 (Port of Las Palmas). Maxima corresponding to diurnal, semidiurnal, third-diurnal, quarter-diurnal periods, etc. can be observed, as well as low frequency maxima for 38 hrs., 50 hrs. and 4.7 days. Analogous results are obtained for depth 30 m.

Figure 3.-Power spectrum of the longshore component (N-S) of the current at the Port of Las Palmas. Depth 15 m

In the transverse components of the current (fig. 4) there is less energy and the ratio signal/noise is lower, for what only for the diurnal, semidiurnal, third-diurnal and quarter-diurnal bands maxima are well defined:

Figure 4.-Power spectrum of the transverse component (E-W) of the current at the Port of Las Palmas. Depth 15 m

Cross-spectra between the series at 15 m and at 30 m below the surface allow to deduce a high coherence (fig. 5), and the phase shift is negligible in the most significant frequencies. Rotary spectra for both depths confirm the clockwise rotation in the astronomical frequencies. So a barotropic movement may be inferred.

In order to correlate the meteorological variables with the currents, the power spectra of the atmospheric pressure and temperature were computed. Figure 6 shows the power spectrum of the pressure. Perhaps surprisingly, the similitude in the energetic distribution is quite high, and what is more, there are maxima at the diurnal, semidiurnal, third diurnal, quarter-diurnal bands, etc. This is not common at all, and a similar trend may be observed in the temperature.

Figure 5.-Cross spectrum of the longshore components (N-S) of the current at the Port of Las Palmas at 15 and 30 m. Square of the coherence function.

Nevertheless, wind analysis does not provide significant results with respect to this phenomenon, but it may be explained taking into account the strong energy and persistence of the trade winds, which mask weaker terms such as breeze.

Other results

When comparing monthly analyses with the analysis of the whole record, two other significant results appear:

- The constituents with frequencies close to 0.0263 cph use to appear in all records.
- While in the complete half-year record of currents the semidiurnal band has more energy (almost 40% of the total energy) than the diurnal one (25%), in some monthly analyses both bands seem to have similar amounts of energy and, in some cases, the diurnal band even overtake the semidiurnal one. The only logical ex-

Figure 6.—Power spectrum of the atmospheric pressure at the Port of Las Palmas

planation for this phenomenon is the presence of non-tidal terms in the diurnal band, what is not strange as the inertial frequency is here 0.0391 cph.

In order to catch this wave, analyses were focussed on sections of the records that fulfil the conditions of having more energy in the diurnal band than in the semi-diurnal one and corresponding to neap tide, with the aim of getting the highest signal/noise ratio.

An example of this occurred between the 15th of February and the 4th of March of 1990 (fig. 7). The energy in the diurnal band is 36.9% and in the diurnal one is only 26.3%. Tides were in the neap cycle. In this period, harmonic and spectral analysis provide different importance for the astronomical constituents. The term NO_1 is the paramount one by spectral analysis, but it is of second order by harmonic analysis. So, one may deduce that a wave with frequency close to that of the NO_1 term is present. Its former energy need not be strong, as non-linear interaction and resonance with the astronomical term may give rise to the significant peak reached in the spectrum.

Figure 7.-Power spectrum of the longshore component (N-S) of the current at the Port of Las Palmas. Depth 15 m

An iterative approach was used in order to define the parameters of this wave. A scanning of the frequencies between the O_1 and the K_1 on the residual series resulting after subtracting the predicted series due to astronomical terms only from the recorded series (Pugh and Vassie, 1976), and fitting by least squares, gives an amplitude of 2.16 cm/s (for the major half-axis) and a frequency of 0.0398 cph, very close to the inertial frequency 0.0391 cph. The generation and propagation of this wave are presently being studied, but a rotary, Kelvin wave is assumed, as water over-elevations are negligible. After subtracting this term to the observed series, the results of the spectral analysis are normal and they are coherent with those obtained by harmonic analysis.

Finally, it is interesting to compare the power spectra of currents and meteorological variables (fig. 8).

Figure 8.-Power spectra of the longshore components (N-S) of the current at 15 m and the wind, the atmospheric temperature and the atmospheric pressure at the Port of Las Palmas

Conclusions

As main conclusions of this work, we can underline:

- The characteristics of the tides and currents use to be astronomically dominated, with a clear influence of the wind in the layer close to the surface.
- A non-permanent term appears in certain intervals of the current records. This term is identified as a long wave with a frequency very close to the inertial one. As there is small correspondence with the elevation of the surface, a rotary wave is assumed.
- Rather surprisingly, the periodicities involved in the meteorological variables go beyond the traditionally assumed ones, showing a pattern very similar to that of the oceanic tide and currents. This important observation agrees with other recent observations (Cartwright *et al.*, 1985), and suggests a higher importance of the meteorological tides or/and a strong interaction sea-air.

CHAPTER 64

A NUMERICAL METHOD OF SOLITARY WAVE FORCES ACTING ON A LARGE VERTICAL CYLINDER

Takumi Ohyama ¹

ABSTRACT

Solitary wave forces acting on a large vertical cylinder are calculated using a time-stepping method which improves upon the conventional boundary element approaches. The effect of this improvement on the numerical solution is a more realistic solitary wave profile. Nonlinear effects on the solitary wave forces are investigated by comparing the numerical results with the first approximations given by Isaacson. The first approximation for overturning moment is underestimated remarkably when the incident wave height is relatively high.

1. INTRODUCTION

In order to design coastal or offshore structures, accurate prediction of wave forces is necessary. In general, the incoming wave height considered during design is substantial, so that the nonlinear wave effects cannot be ignored and the linear potential theory may not predict realistic values of wave forces. Among various numerical studies applied to this problem, the methods of approach may be classified into two groups. One approach is based on a perturbation method. Using Stokes' wave theory, second approximations for wave forces acting on a large vertical cylinder have been recently introduced by many researchers. For example, Hunt and Buddour (1981) gave the solution for deep water, and Eatock Taylor and Hung (1987) attempted to derive the definite solution for arbitrary water depth. However, this type of approach cannot be directly extended to higher-order expansions because of difficulties in the treatment of the free surface condition and the nonlinear radiation condition.

¹Institute of Technology, SHIMIZU CORPORATION, Etchujima 3-4-17, Koto-ku, Tokyo 135, JAPAN

The other approach is a time-stepping method in which the boundary integral equations based on Green's theorem are solved at successive time steps. In this approach, the complete boundary value problem of velocity potential is considered without using the assumption of weak nonlinearity. For example, Isaacson (1982) applied this boundary integral equation method to the problem of nonlinear wave scattering around three-dimensional bodies. A similar method was proposed by Nakayama and Washizu (1981) for two-dimensional sloshing problems. However, the potential values on free surfaces were not estimated accurately in the time-stepping procedure of these conventional methods.

This paper studies interactions between a solitary wave and a large vertical cylinder using a newly developed numerical method. The proposed technique treats the interaction as a three-dimensional transient problem, and it improves the time-stepping procedure of the conventional boundary element methods. The effect of the improvement on the numerical solution is investigated by fundamental examinations. Nonlinear effects on wave forces exerted by a solitary wave on a circular cylinder are discussed by comparing the numerical results with first approximations given by Isaacson (1983). The results obtained from this study may be applicable to the design of coastal structures in shallow water.

2. THEORETICAL FORMULATION

2.1 Boundary Integral Equations

Consider a three-dimensional fluid region Ω as shown in Fig. 1. The region is enclosed by the free surface S_F , the body wetted surface S_V , the wave generating boundary S_C , the wall boundaries S_{W1} , S_{W2} , S_{W3} , and the seabed S_B . The boundaries, S_C , S_{W1} , S_{W2} , and S_{W3} , are located sufficiently far from the body so that the diffracted waves will not reach these boundaries during the duration of computation. The fluid is assumed to be incompressible, inviscid and irrotational, so that the fluid motion can be described by a velocity potential ϕ . The velocity potential can be given as the solution satisfying the following governing equation and the associated boundary conditions:

$$\nabla^2 \phi = 0 \quad (\text{in } \Omega), \quad (1)$$

$$\partial \phi / \partial n = 0 \quad (\text{on } S_B, S_{W1}, S_{W2}, S_{W3}), \quad (2)$$

$$\partial \phi / \partial n = 0 \quad (\text{on } S_V), \quad (3)$$

$$\partial \phi / \partial n = -\partial \phi / \partial x = -U(z, t) \quad (\text{on } S_C), \quad (4)$$

$$\partial \phi / \partial n = n_z (\partial \eta / \partial t) \quad (\text{on } S_F), \quad (5)$$

$$\partial \phi / \partial t + (1/2)(\nabla \phi)^2 + g\eta = 0 \quad (\text{on } S_F), \quad (6)$$

in which n and n_z are the direction and the z -component of outward unit normal vector n defined on the boundary surfaces, respectively, and η is the free surface elevation above the still water level. U in Eq. (4) denotes the water particle velocity in the x -direction of the solitary wave given by the analytical solutions. Equation (1) corresponds to the continuity equation of the fluid motion. Equations (2) and (3) relate to the impermeable conditions on the seabed and the walls and the body surface, respectively. In generating waves, the still-water condition is applied as an initial condition, and the kinematic condition as indicated in Eq. (4) is imposed on S_C . Equations (5) and (6) represent the kinematic and the dynamic conditions on S_F , which are considered to be nonlinear.

Fig. 1 Coordinate system.

Applying the second form of Green's theorem over the closed surface S containing the fluid region Ω , a boundary integral equation is introduced in which the boundary values of the potential ϕ are related to those of the normal derivative $\partial\phi/\partial n$. The potential $\phi(P)$ at the point $P(x_P, y_P, z_P)$ which lies on S is expressed as

$$\phi(P) = -\frac{1}{\alpha(P)} \int_S \left\{ \phi(Q) \frac{\partial G}{\partial n}(P, Q) - \frac{\partial \phi}{\partial n}(Q) G(P, Q) \right\} ds, \tag{7}$$

where $Q(x_Q, y_Q, z_Q)$ is a point lying on S where the integration is performed and G represents a Green function. $\alpha(P)$ denotes a coefficient calculated by

$$\alpha(P) = - \int_{S_F \cup S_C \cup S_{W3} \cup S_V} \frac{\partial G}{\partial n} ds. \tag{8}$$

The Green function involved in Eq. (7) is chosen to account for the symmetry about the boundaries, S_B, S_{W1} , and S_{W2} , such that

$$G(P, Q) = \frac{1}{r_0} + \sum_{n=1}^7 \frac{1}{r_n}, \tag{9}$$

$$\left. \begin{aligned}
 r_0 &= \sqrt{(C_x)^2 + (C_y)^2 + (C_z)^2}, & r_1 &= \sqrt{(C_x)^2 + (C_y)^2 + (D_z)^2}, \\
 r_2 &= \sqrt{(C_x)^2 + (D_y)^2 + (C_z)^2}, & r_3 &= \sqrt{(C_x)^2 + (D_y)^2 + (D_z)^2}, \\
 r_4 &= \sqrt{(D_x)^2 + (C_y)^2 + (C_z)^2}, & r_5 &= \sqrt{(D_x)^2 + (C_y)^2 + (D_z)^2}, \\
 r_6 &= \sqrt{(D_x)^2 + (D_y)^2 + (C_z)^2}, & r_7 &= \sqrt{(D_x)^2 + (D_y)^2 + (D_z)^2}, \\
 C_x &= x_P - x_Q, & D_x &= x_P + x_Q - 2X_L, \\
 C_y &= y_P - y_Q, & D_y &= y_P + y_Q - 2Y_L, \\
 C_z &= z_P - z_Q, & D_z &= z_P + z_Q + 2h,
 \end{aligned} \right\} \quad (10)$$

in which X_L and Y_L are the length and the width of the fluid region, respectively, as shown in Fig. 1. This Green function satisfies $\partial G/\partial n = 0$ on S_{W1} , S_{W2} and S_B , so that the integrals over these boundaries can be excluded from Eq. (7). Substituting Eqs. (2), (3), (4) and (5) into Eq. (7), the following integral equation is introduced:

$$\phi(P) = -\frac{1}{\alpha(P)} \left\{ \int_{S_F \cup S_C \cup S_{W3} \cup S_V} \phi \frac{\partial G}{\partial n} ds - \int_{S_F} G n_z \frac{\partial \eta}{\partial t} ds + \int_{S_C} G U ds \right\}, \quad (11)$$

The dynamic condition on S_F can be transformed into another integral equation by applying the method of weighted residuals. Substituting Eq. (5) into Eq. (6) and integrating it over S_F after multiplying both sides by a weighting function ω , the following integral equation can be obtained:

$$\int_{S_F} \omega \left[\frac{\partial \phi}{\partial t} + \frac{1}{2} \left\{ n_z^2 \left(\frac{\partial \eta}{\partial t} \right)^2 + \left(\frac{\partial \phi}{\partial X} \right)^2 + \left(\frac{\partial \phi}{\partial Y} \right)^2 \right\} + g \eta \right] ds = 0, \quad (12)$$

where (X, Y) is a local coordinate system on the surface plain normal to the vector n as shown in Fig. 2.

Fig. 2 Local coordinates on the free surface.

2.2 Spatial Discretization of Integral Equations

The boundary surfaces, S_F , S_C , S_{W3} , and S_V , are discretized into finite numbers of triangle elements. The local coordinate system (X, Y) is defined as indicated in Fig.3 over each element. In this figure, $j1, j2, j3$ are nodal point numbers comprising the J -th element, and R denotes a point on the element. Representing the variables of ϕ, η, U and ω as Γ , the values of Γ and $\partial\Gamma/\partial t$ on R can be written as

$$\Gamma = N_J^T \Gamma_J, \quad \Gamma_J^T = \{\Gamma_{j1}, \Gamma_{j2}, \Gamma_{j3}\}, \quad (13)$$

$$\frac{\partial \Gamma}{\partial t} = N_J^T (\Gamma_t)_J, \quad (\Gamma_t)_J^T = \left\{ \left(\frac{\partial \Gamma}{\partial t} \right)_{j1}, \left(\frac{\partial \Gamma}{\partial t} \right)_{j2}, \left(\frac{\partial \Gamma}{\partial t} \right)_{j3} \right\}, \quad (14)$$

in which N_J represents interpolation function vector. If linear distributions of Γ and $\partial \Gamma / \partial t$ over the element are assumed, N_J can be expressed as

$$N_J^T = (1/S_J) \{ S_{j1}, S_{j2}, S_{j3} \}, \quad (15)$$

where S_{j1} , S_{j2} and S_{j3} are defined in Fig. 3 and S_J is the area of the J -th element ($= S_{j1} + S_{j2} + S_{j3}$).

Fig. 3 Definition sketch in the J -th element.

Using the expressions of Eqs. (13) and (14), the integral equation (11) is transformed into

$$\alpha_i \phi_i + \sum_{J=1}^M A_{iJ}^T \phi_J - \sum_{J=1}^{M_F} (n_z)_J B_{iJ}^T (\eta_t)_J + \sum_{J=M_F+1}^{M_F+M_C} B_{iJ}^T U_J = 0 \quad (i = 1, 2, \dots, N), \quad (16)$$

$$A_{iJ} = \int_{S_J} N_J \frac{\partial G}{\partial n} ds, \quad B_{iJ} = \int_{S_J} N_J G ds, \quad (17)$$

in which M and N are the total numbers of triangle elements and the nodal points, respectively. M is made up of M_F elements over S_F , M_C elements over S_C , M_V elements over S_V , and M_W elements over S_{W3} . The surfaces are treated in order S_F , S_C , S_V and S_{W3} as J increases from 1 to M . The vectors, A_{iJ} and B_{iJ} can be calculated numerically, even when i coincides with $j1$ or $j2$ or $j3$. Numerical integrals over all the elements, however, may require time-consuming computational efforts. Therefore, the calculations of A_{iJ} and B_{iJ} are simplified by assuming those values to be constant over the J -th element, when $i \neq j1$ nor $j2$ nor $j3$. Thus

$$A_{iJ} \simeq \frac{S_J}{3} \left(\frac{\partial G}{\partial n} \right)_{iJ} \mathbf{E}, \quad B_{iJ} \simeq \frac{S_J}{3} G_{iJ} \mathbf{E} \quad (i \neq j1, j2, j3), \quad (18)$$

$$\mathbf{E}^T = (1, 1, 1), \quad (19)$$

where $(\partial G/\partial n)_{iJ}$ and G_{iJ} are the corresponding values at the center of gravity in the J -th element.

Substituting Eqs. (13) and (14) into Eq. (12), we obtain

$$\sum_{J=1}^{M_F} \left[\int_{S_J} N_J N_J^T ds (\phi_t)_{iJ} + \frac{(n_z)_J^2}{2} \int_{S_J} N_J N_J^T (\eta_t)_{iJ} N_J^T ds (\eta_t)_{iJ} + \frac{1}{2} \{ (\phi_X)^2 + (\phi_Y)^2 \}_{iJ} \int_{S_J} N_J ds + g \int_{S_J} N_J N_J^T ds \eta_{iJ} \right] = 0. \quad (20)$$

The velocity squared on the surface plain, $\{(\phi_X)^2 + (\phi_Y)^2\}_{iJ}$, is assumed to be constant over the J -th element. That is,

$$\begin{aligned} \{(\phi_X)^2 + (\phi_Y)^2\}_{iJ} &= \frac{1}{4S_J^2} \{ (l_{j1}\phi_{j1})^2 + (l_{j2}\phi_{j2})^2 + (l_{j3}\phi_{j3})^2 \} \\ &\quad - \frac{1}{S_J} \left\{ \frac{\phi_{j1}\phi_{j2}}{\tan \theta_{j3}} + \frac{\phi_{j2}\phi_{j3}}{\tan \theta_{j1}} + \frac{\phi_{j3}\phi_{j1}}{\tan \theta_{j2}} \right\}. \end{aligned} \quad (21)$$

The integrals involved in Eq. (20) can be calculated analytically and may be transformed into the form

$$\sum_{j=1}^{N_F} \gamma_j \omega_j = 0, \quad (22)$$

where N_F is the number of the nodal points on the free surface. γ_j involves ϕ_j , $(\partial\phi/\partial t)_j$, η_j , $(\partial\eta/\partial t)_j$ ($j = 1, 2, \dots, N_F$) as unknown variables (see Ohyama, 1989 b). The arbitrariness of the weighting function ω leads to the equation

$$\gamma_j = 0 \quad (j = 1, 2, \dots, N_F). \quad (23)$$

2.3 Time-Stepping Procedure

The discretized equations (16) and (23) are solved simultaneously for successive time steps to estimate the wave motion transition. The surface elevation and the velocity potential at the n -th time step, $\eta^{(n)}$ and $\phi^{(n)}$, are given as

$$\eta^{(n)} = \eta^{(n-1)} + \Delta\eta^{(n)}, \quad \phi^{(n)} = \phi^{(n-1)} + \Delta\phi^{(n)}, \quad (24)$$

in which $\Delta\eta^{(n)}$ and $\Delta\phi^{(n)}$ represent the increments of η and ϕ during the time increment Δt , respectively. Using Taylor expansions around the corresponding values at the $(n-1)$ -th time step and neglecting the higher order terms with respect to Δt , $(\partial\eta/\partial t)^{(n)}$ and $(\partial\phi/\partial t)^{(n)}$ can be expressed as

$$\left(\frac{\partial\eta}{\partial t}\right)^{(n)} = \frac{2\Delta\eta^{(n)}}{\Delta t} - \left(\frac{\partial\eta}{\partial t}\right)^{(n-1)}, \quad (25)$$

$$\begin{aligned} \left(\frac{\partial\phi}{\partial t}\right)^{(n)} &= \frac{2\Delta\phi^{(n)}}{\Delta t} - \left(\frac{\partial\phi}{\partial t}\right)^{(n-1)} - \frac{2\Delta\eta^{(n)}}{\Delta t} \left(\frac{\partial\phi}{\partial z}\right)^{(n-1)} \\ &\quad - \Delta t \left(\frac{\partial\eta}{\partial t}\right)^{(n-1)} \left(\frac{\partial^2\phi}{\partial z\partial t}\right)^{(n-1)} + \left(\frac{\partial\eta}{\partial t}\right)^{(n-1)} \left(\frac{\partial^2\phi}{\partial z^2}\right)^{(n-1)} \quad (\text{on } S_F). \end{aligned} \quad (26)$$

It should be noted that Taylor expansions, with respect not only to time but also to spatial displacement, must be applied to the estimation of the potential values on S_F . The last three nonlinear terms on the right-hand side of Eq. (26) correspond to the change in location of the nodal point on S_F . In the method proposed by Nakayama and Washizu (1981) for two-dimensional sloshing problems, only the expansions with respect to time were considered, so that these nonlinear terms were entirely neglected. Isaacson (1982) also omitted the effect of spatial displacement from the time-stepping procedure. However, the partial effects were taken into account in a recent paper (Isaacson and Zuo, 1989).

Substituting Eqs. (24), (25) and (26) into Eqs. (16) and (23), the linear algebraic equations for $\Delta\phi_j^{(n)}$ ($j = 1, 2, \dots, N$) and $\Delta\eta_j^{(n)}$ ($j = 1, 2, \dots, N_F$) can be obtained. The quantities associated with the boundary surface profile, S_J , $(n_x)_J$, A_{iJ} , B_{iJ} , and so on, are unknown when solving the equations at each time step, since $\Delta\eta_j^{(n)}$ are involved in the equations as unknown variables. Thus, in order to obtain the successful solutions associated with the corresponding free surface profile, the iteration procedure is applied using the surface profile at the previous time step as the initial profile (see Ohyama, 1985). It usually takes two or three iterations to obtain the convergence.

3. ACCURACY AND FUNDAMENTAL EXAMINATIONS

Fundamental examinations were carried out to confirm the validity of the proposed method. Solitary waves with various wave heights, H_0 , were generated numerically in a three-dimensional wave channel with a constant depth h and a constant width Y_L . In the computations, the still water condition ($\phi = \eta = 0$) inside the region was considered as an initial condition, and the third approximation given by Fenton (1972) was applied to the velocity U imposed on S_C . The numerical results were compared with the third approximation in terms of the generated wave profile and the hydrodynamic pressure. Once the velocity potential ϕ is given at successive time steps, the pressure p can be obtained from the Bernoulli equation

$$p = -\rho \left\{ (\partial\phi/\partial t) + (1/2)(\nabla\phi)^2 + gz \right\}, \quad (27)$$

where ρ is the fluid density. The results for the case of $H_0/h = 0.4$ are shown in Figs. 4 (a) and 4 (b) together with the corresponding approximations. In this calculation, X_L/h and Y_L/h were fixed at 14.0 and 2.1, respectively. According to the results of the previous study for a two-dimensional numerical model (Ohyama, 1989 a), the maximum horizontal distance between the neighboring nodal points on S_F , Δl , and the time increment Δt were varied with H_0/h . In the case of $H_0/h = 0.4$, $\Delta l/h$ and $\Delta t\sqrt{g/h}$ were set at 0.7 and 0.4, respectively. As shown in Figs. 4 (a) and 4 (b), the agreements between the numerical result and the third approximation

are fairly good, whereas the first approximation predicts a remarkably larger value for hydrodynamic pressure under the still water level. It may indicate that the proposed method can well predict the wave motion and the induced force even in the case of a relatively high wave height.

(a) Generated solitary wave profile ($y/h = 0$)

(b) Distribution of hydrodynamic pressure under the wave crest

Fig. 4 Comparisons with the corresponding approximation for $H_0/h = 0.4$;
 ○, numerical result; —, third approximation; ---, first approximation.

Additional examinations were performed to ascertain the effect on the numerical solutions of taking into account the nonlinear terms in Eq. (26). Figure 5 shows the numerical result of the generated wave profile with $H_0/h = 0.4$, together with the third approximation. The results calculated by the proposed method and those by the conventional method, in which the nonlinear terms in Eq. (26) are neglected, are denoted by circles and triangles, respectively. It should be noted that the proposed method can eliminate the numerical error accumulation which occurs in the conventional analysis.

4. NONLINEAR EFFECTS ON SOLITARY WAVE FORCES

First approximation for the solitary wave diffraction around a circular cylinder was already given in closed form by Isaacson (1982). According to this approximation, a maximum force coefficient, C_F , and a maximum overturning moment coefficient, C_M , are conveniently described by the single number $(a/h)\sqrt{H_0/h}$, in which C_F and C_M are defined as

$$C_F \equiv \frac{F_{max}}{\rho g H_0 a h}, \quad C_M \equiv \frac{M_{max}}{\rho g H_0 a h^2}, \quad (28)$$

where F_{max} and M_{max} denote the maximum horizontal force and the maximum overturning moment, respectively, and a is the cylinder radius. However, the first approximations were introduced on the assumption of a small wave height. Thus, nonlinear effects on solitary wave forces acting on the cylinder may be discussed by comparing the numerical result with the first approximation.

Figure 6 shows the free surface elevation computed by the proposed method in the case of $(a/h)\sqrt{H_0/h} = 2.0$ and $H_0/h = 0.4$, when the horizontal force acting on the cylinder is at the maximum. Only the half side of the fluid region was considered in the calculation because of the symmetry of the circular cylinder. In the case indicated in Fig. 6, the surfaces S_F , S_C , S_V and S_{W3} were discretized into 846, 120, 112, and 176 elements, respectively, and the total number of the nodal points was 680.

The corresponding numerical results of the temporal variations of the horizontal force F_x and the overturning moment M_y are indicated in Figs. 7 (a) and 7 (b), together with the first approximation. The abscissa in these figures represents nondimensional time, where t' denotes time measured from the instant when the crest of the incident wave passes the center of the cylinder. The calculation was carried out for H_0/h being 0.1 and 0.4. In the case of $H_0/h = 0.1$, the agreements between the numerical result and the first approximation are fairly good for both the horizon-

Fig. 6 Free surface elevation with $(a/h)\sqrt{H_0/h} = 2.0$ and $H_0/h = 0.4$.

tal force and the overturning moment. For $H_0/h = 0.4$, however, the prediction of the maximum overturning moment is remarkably larger than the first approximation, whereas the difference in the maximum horizontal force may not be notable. The reason why the prediction of the overturning moment for $H_0/h = 0.4$ is larger than the first approximation may be explained by the following facts. First, **Figure 8** shows the distribution of hydrodynamic pressure in a horizontal cross section when the horizontal force is at the maximum. For $H_0/h = 0.4$, the pressure over the cylinder surface is found to be smaller than the value predicted by the approximation. This characteristic is the same as the progressive solitary wave, as indicated in **Fig. 4 (b)**. Second, the proposed method takes into account the pressure distribution above the still water level, whereas it is neglected in the first approximation. These two facts have contrary effects on the prediction of the horizontal force, so that the numerical results of the horizontal force may differ slightly from the approximation, even for the case of $H_0/h = 0.4$. Furthermore, the second fact explains that the point of the resultant force shifts upward as the incident wave height increases. Thus, compared to the approximation, the proposed method predicts a larger value for the overturning moment.

Figures 9 (a) and **9 (b)** show the variations of C_F and C_M with $(a/h)\sqrt{H_0/h}$, respectively. When the value of $(a/h)\sqrt{H_0/h}$ is small, the differences between the numerical result and the first approximation are not significant, even for the overturning moment. As this parameter $(a/h)\sqrt{H_0/h}$ becomes larger, however, the approximation predicts a much smaller magnitude of overturning moment. The prediction obtained from the numerical calculation shows a 40% larger value than the approximation for $(a/h)\sqrt{H_0/h} = 3.0$ and $H_0/h = 0.4$.

5. CONCLUSION

A numerical method has been developed for simulating solitary wave diffraction around large structures. The proposed method is based on the nonlinear potential theory, and it improves the time-stepping procedure of the conventional boundary element methods to provide greater accuracy. The effect of the improvement on the numerical solution has been shown by the simulation of a more realistic solitary wave profile.

Comparisons have been carried out with the first approximation for the horizontal

force and the overturning moment, acting on a circular cylinder. The first approximation gives reasonable results when H_0/h is about 0.1. When $H_0/h = 0.4$, however, the same approximation remarkably underestimates the overturning moment.

CHAPTER 65

A NUMERICAL MODEL OF THE ROUGH TURBULENT BOUNDARY LAYER IN COMBINED WAVE AND CURRENT INTERACTION

HUYNH-THANH Son and TEMPERVILLE André
Institut de Mécanique de Grenoble
B.P. 53X, 38041 Grenoble Cedex, France

ABSTRACT

The turbulent boundary-layer flow over flat rough beds due to a wave or a combined wave-current interaction is studied by using a simplified numerical second-order turbulence model. The model results are compared with many sets of experimental data. Excellent predictions for ensemble-averaged velocities and favourable predictions for turbulence quantities are obtained. Variations of kinematic and dynamic characteristics of boundary-layer flow with wave, current and bed roughness parameters are determined. The model is also modified to simulate the oscillatory turbulent flow over rippled beds. The mean velocity field and the distribution of time-averaged turbulence quantities are calculated. The validity of the model is verified through comparison with experimental results. The performance and the limitation of the model are discussed.

I. INTRODUCTION

A knowledge of the boundary layer flow in the vicinity of the sea bed is important for problems of coastal engineering, in particular for investigations of coastal erosion, sediment transport and the transport of pollutants.

Bodies of water that are subjected to currents and waves, according to their characteristics, produce a flat, generally rough bed, or a rippled bed. In order to quantify sediment transport, the amplitude and direction of the velocities and shear stresses in the boundary layer close to these different shapes of bed must be known.

Enquiries into the turbulent boundary layer generated by a sinusoidal wave are not recent. The experiments of Jonsson (1963), Horikawa and Watanabe (1968), Kamphuis (1975), Jonsson and Carlsen (1976) are noteworthy. Recently, experiments have been performed using laser velocimetry, e.g. the experiments of

Sumer et al. (1986), Sleath (1987) and Jensen et al. (1989). Theoretically, numerous investigations exist : from the analytical models of Kajiura (1968), Brevik (1981), Myrhaug (1982), Trowbridge and Madsen (1984) to the numerical models of Bakker (1974), Johns (1975), Sheng (1984), Fredsoe (1984), Asano and Iwagaki (1986), Blondeaux (1986), Justesen (1988), Sheng and Villaret (1989). Also to be mentioned is the semi-empirical model of Jonsson (1980), which proposed a universal distribution law for the velocity in the boundary layer.

As far as the boundary layer due to the interaction between a current and a wave is concerned, few experiments are available, among which only those of Van Doorn (1979), Simon et al. (1988) pertain to the turbulent and hydraulically rough case that is of interest to us. After the analytical model of mixing length due to Bijker (1967), other analytical models are based on the time-invariant turbulent viscosity, as in the case of a wave : Lundgren (1973), Smith (1977), Grant and Madsen (1979), Tanaka and Shuto (1984), Myrhaug (1984), Asano and Iwagaki (1984). For numerical models, that of the mixing length due to Bakker and Van Doorn (1978), Van Kerstern and Bakker (1984) as well as that of Fredsoe (1984), which assumes a logarithmic velocity distribution. Models with more or less complicated turbulent closure are also applied to this problem : Sheng (1984), and Davies et al. (1988).

To investigate the effect of wave and current on the boundary layer, we have selected the second order turbulence model that was originally suggested by Lewellen (1977) and simplified by Sheng (1984), Sheng and Villaret (1989) for the one dimensional flows. A simplified three dimensional version of the model is actually developed for the case of a wave without and with current. The numerical results are compared with experimental results in order to verify the validity of the model. In the last section, the model is written in orthogonal curvilinear coordinates in order to investigate oscillatory turbulent flow over a rippled bed. The results obtained are also compared with the experimental results for the case of symmetric and asymmetric ripples.

II. BOUNDARY LAYER ABOVE A FLAT BED

II-1. Equations of the model

The problem is treated in cartesian coordinates (x,y,z) with the z axis directed upwards (Fig. 1). The flat horizontal bottom is fixed at $z = z_0 = k_N/30$, where k_N represents the equivalent Nikuradse roughness.

The system of equations is established with the following assumptions: (a) the thickness of the boundary layer is much smaller than the wavelength of the wave; (b) the amplitude of the wave velocity \hat{U}_h is much smaller than the wave celerity C .

In these conditions, the momentum equations for the two horizontal components of velocity (u,v) along x and y can be written:

$$(1) \quad \frac{\partial u}{\partial t} = -\frac{1}{\rho} \frac{\partial P}{\partial x} + \frac{\partial}{\partial z} (-\overline{u'w'}) ; \quad (2) \quad \frac{\partial v}{\partial t} = -\frac{1}{\rho} \frac{\partial P}{\partial y} + \frac{\partial}{\partial z} (-\overline{v'w'})$$

where the Reynolds stresses $-\overline{u'w'}$ and $-\overline{v'w'}$ can be modelled in the form :

$$(3) \quad -\overline{u'w'} = \nu_t \frac{\partial u}{\partial z}, \quad -\overline{v'w'} = \nu_t \frac{\partial v}{\partial z}$$

where ν_t represents the turbulent viscosity.

The pressure gradients are expressed as follows :

$$(4) \quad -\frac{1}{\rho} \frac{\partial P}{\partial x} = \frac{\partial U_{hx}}{\partial t} - \frac{1}{\rho} \frac{\partial P_c}{\partial x}, \quad -\frac{1}{\rho} \frac{\partial P}{\partial y} = \frac{\partial U_{hy}}{\partial t} - \frac{1}{\rho} \frac{\partial P_c}{\partial y}$$

where (U_{hx}, U_{hy}) are the two horizontal components of the wave velocity and P_c represents the pressure due to the current.

Turbulent closure is performed by means of two equations for the turbulent kinetic energy K and for the length scale L of the turbulence (Lewellen, 1977) :

$$(5) \quad \frac{\partial K}{\partial t} = \nu_t \left[\left(\frac{\partial u}{\partial z} \right)^2 + \left(\frac{\partial v}{\partial z} \right)^2 \right] - \frac{\nu_t}{L^2} K + 1.2 \frac{\partial}{\partial z} \left(\nu_t \frac{\partial K}{\partial z} \right)$$

$$(6) \quad \frac{\partial L}{\partial t} = 0.175 \frac{\nu_t}{K} \left[\left(\frac{\partial u}{\partial z} \right)^2 + \left(\frac{\partial v}{\partial z} \right)^2 \right] L + 0.075 \sqrt{2} K + 1.2 \frac{\partial}{\partial z} \left(\nu_t \frac{\partial L}{\partial z} \right) - \frac{0.375 \sqrt{2}}{\sqrt{K}} \left[\frac{\partial (\sqrt{K} L)}{\partial z} \right]^2$$

The assumption of local equilibrium of the turbulence made by Sheng (1984) allows ν_t to be put in the form :

$$(7) \quad \nu_t = \sqrt{2} \frac{\sqrt{K} L}{4}$$

Fig. 1 Outline of physical system and reference system of axes (flat bed)

At the bottom ($z = z_0$) the boundary conditions in all cases are the following :

$$(8) \quad u = v = 0 \quad ; \quad \partial K / \partial z = 0 \quad ; \quad L = \alpha z_0 \quad \text{with } \alpha = 0.67,$$

where the von Karman constant is taken as $k = 0.4$.

The conditions at the upper limit of the boundary layer depend on the particular case studied, and will be described later.

The set of equations (1) to (8) is discretised using the implicit finite control volume method (Patankar, 1980) on a grid whose step size increases exponentially from bottom to top, thus giving good resolution near the bed where gradients are important. The time step is constant over the whole period of the wave. Each discretised equation corresponds to a tridiagonal matrix which can be solved by means of Thomas's algorithm (Roache, 1976).

II-2. Case of the wave

In the case of a unidirectional wave, the above set of equations is solved by taking $v = 0$. The pressure gradient is given by :

$$(9) \quad -\frac{1}{\rho} \frac{\partial P}{\partial x} = \frac{\partial U_h}{\partial t}$$

where $U_h = \hat{U}_h \sin \omega t$ is the wave velocity at the upper limit of the boundary layer defined by $z_h = \delta_K$, δ_K corresponds to the thickness beyond which K is zero. The following approximation was obtained :

$$(10) \quad \frac{\delta_K}{k_N} = 0.246 \left[\frac{\hat{a}_h}{k_N} \right]^{0.81} \quad \text{with } \hat{a}_h = \frac{\hat{U}_h}{\omega}$$

For $z = z_h$ the boundary conditions are :

$$(11) \quad K = L = 0 \quad \text{and} \quad U = U_h$$

* *Comparison with experimental results* : The model results were compared with the experiment of Sumer et al. (1986). The lower boundary is at $z_0 = k_N/30 = 0.0133$ cm, and the upper boundary is taken to be at $z_h = 20$ cm. The magnitude of the wave velocity is $\hat{U}_h = 210$ cm/s and the period $T = 2\pi/\omega = 8.1$ s. Good agreement can be seen in Figure 2 for the velocities, except at $z = 0.1$ cm. The values of the friction velocity $u_* = \text{sign}(-\overline{u'w'}) \sqrt{|\overline{u'w'}|}$ are slightly lower than found experimentally (Fig. 3). In Figure 4 the profiles of the fluctuating velocities $\sqrt{u'^2}$ and $\sqrt{w'^2}$ are compared. It can be seen that there is agreement for $\sqrt{u'^2}$ for phases between 30° and 120° , and for $\sqrt{w'^2}$ for the other phases.

* *Wave friction coefficient* : In investigations of the wave boundary layer, the friction coefficient f_h introduced by Jonsson (1963) is often used : $\hat{\tau} = \frac{1}{2} f_h \hat{U}_h^2$ where $\hat{\tau}$ is the amplitude of the shear stress at the bed. The formula for f_h that arises

from the present model as follows :

$$(12) \quad f_h = 0.00278 \exp \left[4.65 \left(\frac{\hat{a}_h}{k_N} \right)^{-0.22} \right]$$

For comparison, Figure 5 shows the curves obtained from the formulae of Kajiura (1968), Kamphuis (1975), Jonsson and Carsen (1976). The curve given by (12) is close to the results of Kamphuis.

Fig. 2 Comparison between the calculated velocity profiles (—) and those measured by Sumer et al (1986) (symbols) for the different phases.

Fig. 3 Comparison between the shear velocity calculated by the present model (—) and that obtained experimentally by Sumer et al (1986) (●)

Fig. 4 Comparison between the fluctuating velocity profiles calculated by the present model and those obtained experimentally by Sumer et al. (1986) for the different phases.

Fig. 5 Variation of the friction coefficient f_h as a function of \hat{a}_h/k_N

II-3. Case of wave and current interaction

The investigation of the wave-current interaction is performed using equations (1)+(8). The wave propagates in a direction at an angle ϕ_h to the current, which is parallel to the direction x (Fig. 1). The upper boundary conditions apply at $z = z_{c0}$ located in the inertial layer of the current and which is taken to be at $(0.10+0.15) z_c$, where z_c is the total height. The two components of the velocity at z_{c0} are assumed to be known :

$$(13) \quad U = U_c + U_{hx} = U_c + U_h \cos \phi_h \quad ; \quad V = U_{hy} = U_h \sin \phi_h$$

where U_c is the current velocity.

In addition, the following boundary conditions are applied:

$$(14) \quad u = U ; v = V ; \partial K / \partial z = 0 ; L = \alpha z ; \partial P_c / \partial x = \partial P_c / \partial y = 0$$

* *Comparison with experimental results* : The results of the model are compared with the experiments of Van Doorn (1981) for the case of colinear wave-current interaction ($\phi_h = 0^\circ$). We selected the test V20RA, for which the upper limit z_{c0} is equal to 4.5 cm. In Figure 6 is shown the mean velocity profile. Good agreement is found with the experiment. The upper limit can be also treated at the surface libre $z_c = 30$ cm (Huynh Thanh and Temperville, 1989).

Fig. 6 Comparison between the mean velocity profiles calculated with the present model (—) and those measured by Van Doorn (1981). Test V20RA.

* *Friction coefficients* : The friction coefficients f_{ch} and f_c are defined as follows :

$$(15) \quad \frac{\hat{\tau}_{ch}}{\rho} = \frac{1}{2} f_{ch} \hat{U}_h^2 \quad ; \quad \frac{\bar{\tau}_c}{\rho} = \frac{1}{2} f_c \hat{U}_h^2$$

where $\hat{\tau}_{ch}/\rho$ and $\bar{\tau}_c/\rho$ are the maximum and mean shear stresses respectively.

Figures 7 and 8 show the variation of f_{ch} and f_c as a function of \hat{a}_h/k_N for different values of z_{c0}/k_N , U_0/\hat{U}_h , and ϕ_h . From these curves, it can be noted that for fixed z_{c0}/k_N and ϕ_h , f_{ch} and f_c increase for increasing U_0/\hat{U}_h . The change in f_c with ϕ_h is substantial only for $U_0/\hat{U}_h < 1$. When the current is stronger than the wave ($U_0/\hat{U}_h \geq 1.5+2$), the influence of ϕ_h on f_c is not marked, which means that in this case the mean characteristics of the current practically do not change under the action of the wave.

Fig. 7. Variation of the friction coefficient f_{ch} as a function of \hat{a}_h/k_N , z_{c0}/k_N , U_0/\hat{U}_h and ϕ_h . $z_{c0}/k_N = 100$ $\phi_h = 0^\circ$

- (1) $U_0/\hat{U}_h = 0.5$ (2) $U_0/\hat{U}_h = 1$ (3) $U_0/\hat{U}_h = 1.5$ (4) $U_0/\hat{U}_h = 2$

Fig. 8 Variation of the friction coefficient f_c as a function of \hat{a}_h/k_N , z_{c0}/k_N , U_0/\hat{U}_h and ϕ_h . Parameters and notations as in Fig. 7.

- $\phi_h = 0^\circ$; - - - $\phi_h = 45^\circ$; - . - . $\phi_h = 90^\circ$

III. BOUNDARY LAYER ON A RIPPLED BED

III-1. Formulation of the model

The physical problem is outlined in Figure 9 : under the action of a wave of wavelength L_h , maximum velocity \hat{U}_h and period T, two-dimensional vortex ripples are assumed to be present on the bed. Laboratory and *in situ* measurements have shown that $L_h \gg L_r$. This allows us to restrict the zone of the calculation : rather than investigating the problem over the whole of the wavelength L_h , we shall only consider the wavelength L_r as shown in Figure 9. Moreover, to simplify the description of the boundary conditions at the surface of the ripple and also to eliminate the unknown pressure gradient due to the bed form, it is convenient in this case to transform the cartesian coordinates (x,z) into orthogonal curvilinear coordinates (X,Z) , and to use the variables ψ (stream function) and ξ (vorticity) instead of the velocities u and w .

Fig. 9 Scheme of the physical system (rippled bed).

In general, the coordinate transformation is given by :

$$(16) \quad \begin{aligned} X &= x + \sum_{n=1}^N a_n \cdot \exp(-n k_r Z) \cdot \sin(n k_r X - \theta_n) \\ Z &= z - \sum_{n=1}^N a_n \cdot \exp(-n k_r Z) \cdot \cos(n k_r X - \theta_n) \end{aligned}$$

where a_n and θ_n are the amplitude and phase difference of the n th harmonic describing the ripple, and $k_r = 2\pi/L_r$ is the wave number associated with L_r .

The stream function ψ and the vorticity ξ are defined by :

$$(17) \quad u = \frac{\partial \psi}{\partial z} \quad ; \quad w = -\frac{\partial \psi}{\partial x} \quad ; \quad \xi = \frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}$$

In coordinates (X,Z) , the set of equations to be solved is :

$$(18) \quad J \nabla^2 \psi = \xi$$

$$(19) \quad \frac{1}{J} \frac{\partial \xi}{\partial t} - \frac{\partial (\psi, \xi)}{\partial (X, Z)} = \nabla^2 (v_t \xi) - J \zeta$$

$$(20) \quad \frac{1}{J} \frac{\partial K}{\partial t} - \frac{\partial (\psi, K)}{\partial (X, Z)} = 1,2 \frac{\partial}{\partial X} \left(v_t \frac{\partial K}{\partial X} \right) + 1,2 \frac{\partial}{\partial Z} \left(v_t \frac{\partial K}{\partial Z} \right) \\ + v_t J \left[\left(\frac{\partial^2 \psi}{\partial X^2} \right)^2 + \left(\frac{\partial^2 \psi}{\partial Z^2} \right)^2 \right] - \frac{1}{J} \cdot v_t K - \frac{1}{J} \frac{v_t}{L^2} K$$

The length scale L is assumed to vary as follows :

$$(21) \quad L = \alpha Z \sqrt{1 - \frac{Z}{Z_h}}$$

and the turbulent viscosity v_t is determined by (7).

In the previous set of equations, ζ and K are terms pertaining to the partial derivatives of ψ and v_t ; J is the jacobian of the coordinate transformation ; ∇^2 is the laplacian operator. The following boundary conditions are applied :

- At the lower limit of the boundary layer ($Z = Z_0 = k_N/30$)

$$(22) \quad \frac{\partial \psi}{\partial Z} = \frac{\partial \psi}{\partial X} = \psi = \frac{\partial K}{\partial Z} = 0 \quad ; \quad \xi_0 = \frac{2 J \psi_1}{(Z_1 - Z_0)^2}$$

where ψ_1 is the stream function at height Z_1 on the second node of the grid (Roache, 1976).

- At the upper limit of the boundary layer ($Z = Z_h$)

$$(23) \quad \psi = Z_h U_h(t) \quad ; \quad K = \xi = 0$$

- At the lateral boundaries ($X = 0$ and $X = L_r$), we assume spatially periodic conditions for ψ , ξ and K .

The above set of equations is discretized using implicit finite difference schemes (centred in space and forward in time). The alternating direction implicit (A. D. I.) method is used to solve the equations for ξ and K . The Poisson equation for ψ is solved by the bloc-cyclic reduction method (Roache, 1976) which allows a huge saving in calculation time compared with the Gauss-Seidel iteration method. The spatial grid contains $M \times N$ nodes with step $\Delta X = \text{const}$, and ΔZ varying exponentially from the bottom upwards. The time step is $\Delta t = T/360$ s. In all the test cases, convergence is obtained after 20 calculation periods.

III-2. Comparison with the experimental results of Du Toit and Sleath (1981)

The dimensional parameters in the test for comparison are the following :

- Symmetric ripple with $L_r = 17.2$ cm, $h_r = 2.9$ cm, $d = 0.04$ cm

- Cosinusoidal wave : $U_h = \hat{U}_h \cos \omega t$, where $\hat{U}_h = 14.3$ cm/s, $T = 2\pi/\omega = 5.37$ s

For the numerical calculation, a 17x25 node grid was chosen with $\Delta X = 1.0625$ cm and ΔZ varying from 0.056 cm to 0.5 cm. The equivalent Nikuradse roughness is $k_N = 2.5 d = 0.1$ cm. The upper limit is chosen to be equal to $Z_h = 5$ cm.

Fig. 10 Comparison between the results of present model (—) and those of the measurements of Du Toit and Sleath (1981) for the time variation of the horizontal velocity u and of the horizontal fluctuating velocity $\sqrt{u'^2}$. Measurements at height $z = 1.65$ cm above the crest

Fig. 11 Vertical variation of the amplitude of the velocity u calculated (+ -) and measured (o -) by Du Toit and Sleath (1981) above the crest.

At height $z = 1.65$ cm above the crest (Fig. 10), good agreement can be seen between the amplitude of the calculated and measured horizontal velocities u , as well as for the fluctuating horizontal velocity $\sqrt{u'^2}$. There is, however, a discrepancy of 25° between the measured local peak ($\omega t = 140^\circ$) and that calculated ($\omega t = 165^\circ$).

The vertical variation of the amplitude of the velocity u , designated by \hat{u} , obtained from the model coincides with that measured above the crest (Fig. 11). Note that the z axis is normalized by the parameter $\beta = \sqrt{\omega/2\nu} = 7.2 \text{ cm}^{-1}$ and z_1 is measured from the ripple crest.

III-3. Comparison with the experimental results of Sato et al. (1987)

The test parameters are the following:

- The ripple is asymmetric with $L_r = 12 \text{ cm}$, $h_r = 2 \text{ cm}$, $d = 0.02 \text{ cm}$.

- The potential flow is a third-order Stokes wave ($T = 2\pi/\omega = 4 \text{ s}$):

$$U_h = -29,5 (\cos \omega t + 0,258 \cos 2\omega t + 0,048 \cos 3\omega t) \text{ (cm/s)}$$

For the modelling, after determining the amplitudes a_n and the phase shifts θ_n of the simulated ripple, we choosed a grid of 13×25 nodes with $\Delta X = 1 \text{ cm}$, and ΔZ varying from 0.06 cm to 0.6 cm . The time step is $\Delta t = 0.011 \text{ s}$. The upper limit is choosen at $Z_h = 6.5 \text{ cm}$.

Figure 12 shows the comparison between the results of the model and those of the measurement for the velocity field and the turbulent kinetic energy K for phase $\omega t = 54^\circ$. It can be seen that the vortex obtained with the model on the right hand leeside of the ripple is weaker than that measured, and the calculated intensity K is smaller in the model than found experimentally.

IV. DISCUSSION AND CONCLUSION

We have examined the problem of the oscillatory turbulent boundary layer on a rough sea bed using different versions of a turbulent closure model with two equations, one for the turbulent kinetic energy K and the other for the length scale L .

* *Performance of the model* : For a flat bed, a simplified three dimensional model was used to investigate the hydrodynamic characteristics of the flow in the boundary layer as a function of the different wave, current, angle of interaction and bed parameters. For the oblique wave-current interaction, the model requires further experimental verifications.

For a rippled bed, we have used a two-dimensional model that can reproduce the velocity and the vorticity fields as well as other turbulent quantities. Comparison with the experimental results shows that this model is able to predict quite well the complex flow properties over a rippled bed. Before applying the model to general cases, it would be necessary to confirm the numerical results by conducting further tests, particularly for the Reynolds stresses and the turbulent quantities.

* *Limitation of the model* : As for all models of turbulent closure (Rodi, 1980), the present model was originally designed for permanent flows in the fully developed turbulent regime at high Reynolds numbers. When the flow is oscillatory, the condition of local equilibrium of the turbulence, which is valid for a permanent flow,

Fig. 12 Comparison between the results of the present model and the measurements of Sato et al. (1987) at phase $\omega t = 54^\circ$.

(a) velocity field; (b) turbulent kinetic energy field

is no longer completely satisfied, particularly at the times when the velocity of the potential flow is small. Consequently there is a time variation of the friction in the oscillatory boundary layer, which induces the change of flow regime in the course of a period. No such change was included in the model. Thus, to obtain more precise results, it is necessary to improve the model not only for high Reynolds numbers but also for moderate Reynolds numbers.

In parallel with investigations into improvements, we shall apply the model to the prediction of certain important parameters of the natural boundary layer, together with analysis of sea measurements in the framework of the GDR Manche project.

CHAPTER 66

RUNUP, SETUP AND THE COASTAL WATERTABLE

Peter Nielsen *

Abstract

The three related phenomena of wave runup, wave setup and the dynamics of the coastal watertable are considered and their inter-relations are investigated via a comprehensive field study. The measured runup distributions confirm the expectation that the Rayleigh distribution is a reasonable model and that the vertical scale of the distributions is proportional to $\sqrt{(H_{orms} L_o)}$ as in Hunt's (1959) formula but that the proportionality to the beach slope, also prescribed by this formula, only applies for fairly steep beaches. The measured setup profiles are quite different from the ones predicted on the basis of $H=\gamma h$ and linear wave theory in the surf zone. The measured profiles are flatter in the outer surf zone and steeper close to the beach. The shoreline setup is generally about $0.4 H_{orms}$, which is somewhat higher than the previously suggested values. This is because the previous values of the shoreline setup were rarely measured but generally extrapolated with insufficient recognition of the steepening of the profile near the shoreline. The watertable data show that the inclined beach face acts as a strongly non-linear filter which makes the watertable variation at a point inside the beach far from sinusoidal (when the tide is approximately sinusoidal) and elevates the average position of the watertable considerably compared to the mean sea level.

1. Introduction

The concepts of wave runup, setup and the coastal watertable have been described previously in the literature but articles dealing with the three together are virtually absent. One notable exception to this rule is Longuet-Higgins (1983).

Articles about wave setup tend to be "geographically" restricted to the area seaward of the swash zone, i.e. where the sand surface is always under water, while papers about the watertable have been restricted to the area landward of the runup limit. Thus the setup profiles and the watertables of the literature rarely meet, see Figure 1. Consequently, since the runup literature, which rules the swash zone, has

Supervising Engineer, Coast and Rivers Branch, Public Works Department, 1 Chifley Square, Sydney 2000, AUSTRALIA.

Figure 1: The literature on setup, runup and the coastal watertable is geographically separated into three non-overlapping areas: the setup literature considers the surf zone seaward of the point of lowest downrush, the runup literature considers the swash zone and the watertable literature considers only the area landward of the runup limit.

has been generally uninterested in the MWS, the latter can only be drawn as a broken line through the swash zone. This is particularly unfortunate because a most important part of the MWS namely the shoreline always falls within the swash zone where the MWS is but vaguely described.

The present study presents an attempt to give an integrated description of the three phenomena with the aid of new field data sets which include runup-, setup- and watertable measurements taken simultaneously.

2. Field equipment

The system of manometer tubes which was applied to get the setup measurements has been described and discussed in detail by Nielsen (1988) and Nielsen et al (1988), it consists of hard though flexible nylon tubes extending up to 500 metres into the surf zone and a separate line has been laid out through the Brunswick River entrance extending from well upstream of the point where the waves normally die out to about 150 metres outside the entrance breakwaters. Additional mean water levels in the inner surf zone and the swash zone and

watertable heights inside the beach were taken with simple stilling wells.

Quantitative information about the runup distributions were obtained simply by counting the number n_i of waves which went past each of the stilling wells or other fixed points on the beach face with known elevation z_i .

3. Wave runup

The following includes quantitative data on runup distributions measured on a wide variety of beaches in New South Wales, Australia.

The runup distributions were, in the present study, measured in terms of the number of waves transgressing certain points on the beach face. It was found (in agreement with Battjes 1971) that the Rayleigh distribution is a good model i e

$$P\{z_{wm} > z\} = \exp[-(\frac{z-z_{100}}{L_R})^2] \quad \text{for } z > z_{100} \quad (1)$$

where z_{wm} is the maximum level reached by a given wave, z_{100} is the highest level which was transgressed by all the waves and L_R is the vertical scale of the runup distribution.

Based on the classical work by Hunt (1959) on the runup of regular waves and the subsequent work by Saville (1961) and Battjes (1971) for irregular waves, it seemed reasonable to expect the vertical scale L_R to be close to the offshore rms-wave-height times the surf similarity parameter i e

$$L_R \approx (H_{orms} L_o)^{0.5} \tan\beta \quad (2)$$

However, the fact that most beach profiles are curved means that the definition of "the beach slope" $\tan\beta$ for use in this formula is not trivial, see Figure 2.

Figure 2: "The beach slope", applicable to the whole surf zone, is not well defined for most beaches, but the beach face slope, $\tan\beta_F$ generally is.

Because of this lack of a good definition, it was decided to leave out the slope in the initial analysis. That is, in order to analyse the measured runup distributions, we plotted the transgression probability in the form $\sqrt{(-\ln n_i/N)}$, where N is the total number of waves, against $(z_i - SWL)/\sqrt{(H_{orms} L_o)}$ and performed linear regression analysis in accordance with

$$\sqrt{(-\ln n_i/N)} = \frac{z_i - SWL}{C_1 \sqrt{(H_{orms} L_o)}} - C_2 \tag{3}$$

where the constant C_1 then has taken the place of "the beach slope" in Equation (2) and the second constant C_2 [= $(z_{100} - SWL)/L_R$] is the dimensionless elevation of z_{100} above the still water level, see Figure 3. A summary of the runup distributions collected so far is presented in Table 1. For a detailed description of the field sites see Nielsen & Hanslow (1991).

Figure 3: Runup data from Palm Beach north of Sydney, 3/8-1990, 13:40-13:55. The Rayleigh distribution is seen to provide a reasonable model.

The Rayleigh distribution (1) combined with Hunt's formula in the form (2) provides a good model for runup by irregular waves onto steep structures, but for the wide range of beach topographies covered in the present study that is not the case. For very flat beaches, the dependence upon the "beach slope" disappears and a relation of the form

$$L_R = 0.05 \sqrt{(H_{orms} L_o)} \quad \text{for } \tan \beta_F \leq 0.10 \tag{4}$$

where $\tan\beta_F$ is the slope of the beach face, seems to hold. See Figure 4.

For the steeper beaches the vertical scale is roughly proportional the slope of the beach face, but because $\tan\beta_F$ is generally larger than "the beach slope" which is probably more like the average slope β_H between the point where $h=H_{orms}$, see Figure 2, a factor of roughly 0.6 applies:

$$L_R \approx 0.6 \tan\beta_F \sqrt{(H_{orms} L_o)} \quad \text{for } \tan\beta_F \geq 0.10 \quad (5)$$

Figure 4: For very flat beaches the vertical scale of the runup distribution is independant of the slope of the beach face.

The second parameter in the Rayleigh distribution (1), namely the highest level z_{100} transgressed by all waves is plotted against the beach face slope in Figure 5. From this figure it can be seen that for very flat beaches ($\tan\beta_F \leq 0.08$), z_{100} is significantly below the still water level, while it is uniformly scattered around the SWL for the steeper beaches. The fact that z_{100} moves seaward of the still water line on very flat beaches is mainly due to the fact that strong surf beats are common on such beaches and; when the surf beat is down, most waves are transformed into bores seaward of the still water line and several pairs of bores will coalesce by overtaking through the surf zone. This deminishes the number of waves which are counted at the still water line.

Table 1. Summary of runup data

4. Wave setup on beaches.

While the wave setup data of the present study are geographically restricted to a few beaches on the coast of New South Wales they do form the most comprehensive set of field data available to day.

The first major conclusion to be drawn from the data is that the measured setup profiles are quite different from the ones that result from assuming periodic waves, constant height to depth ration [$H=\gamma(D+B)$] in the surf zone, and radiation stress given by linear wave theory. These are the simplifying assumptions suggested by Bowen et al (1968).

Figure 5: For very flat beaches z_{100} is significantly below the still water level, but for the steeper beaches the deviation is insignificant.

The difference emerges most clearly when the setup B is plotted against total depth, h as in Figures 6. In such a diagram the setup profile according to the above assumptions is a straight line with slope $S = 3\gamma^2/8$ while the typical field data set shows a very different trend. A contributing factor to the difference of shape is wave irregularity as discussed by Battjes and Janssen (1978) and by Nielsen et al (1988). However, wave height variability can only explain the upward concavity of the profile, not the higher values of the shoreline setup, B_s . The measured values of the B_s ($= z_s - SWL$) are generally about $0.4 H_{orms}$ which is significantly above the Bowen-et-al-model's prediction of $\frac{3}{8} \gamma H_b$ with reasonable values of γ and H_b/H_o .

The difference between observed and expected setup profiles must result from a combination of the following effects:

1. Real waves near breaking carry much less momentum flux than sine waves of the same height (Nielsen et al 1988 and Dean 1974).
2. The momentum flux does not decay as rapidly as H^2 in the outer surf zone (Svendsen 1984).
3. The bores in the swash zone carry considerably more momentum flux than sine waves of the same height.

A theoretical description of the setup profile which accounts for the observed features is not yet available so the best design guidance is probably gained from the data.

Figure 6: Wave setup at Dee Why Beach, Sydney on August 4 1987, $(H_{orms}, T_p) = (1.6m, 8.2s)$.

A close-up look at the setup profile near the shoreline is provided by Figure 7 for a range of beach shapes and wave heights. This plot differs from Figure 6 in

Figure 7: Relative Setup from the swash zones at Brunswick Heads 22/6-89 (*), Palm Beach 6/6-90 (o), and Seven Mile Beach 21/8-90 (Δ). Data details in Table I.

that the abscissa is the dimensionless still water depth rather than the total depth.

One step towards achieving an integrated picture of wave setup, wave runup and coastal watertable dynamics is to determine the position of the shoreline in the runup distribution i.e. what fraction of the waves are expected to transgress the shoreline on a given beach. One example involving a steep beach of coarse sand (Palm Beach) is shown in Figure 8. Such beaches drain rather efficiently and hence the Mean Water Surface will establish itself at a fairly low position relative to the runup/infiltration distribution, with most of the waves transgressing the shoreline. For the shown example, the shoreline was transgressed by about 78 percent of the waves, i.e. $P\{z_g\} = 0.78$.

Figure 8: The relation between wave transgression statistics and the position of the shoreline at the Northern end of Palm Beach. The preceding low tide was at 13:51, the following high at 20:08 with a range of 1.0m. The offshore wave data were $(H_{orms}, T_p) = (0.62m, 8.3s)$.

The position of the shoreline and hence $P\{z_s\}$ is a function of the relative tidal range $A_{\text{tide}}/H_{\text{rms}}$ and the tidal phase as well as of the beach slope and permeability. Still, the data in Table 1, which correspond to mixed tidal phases show a clear relationship between the relative shoreline elevation and the beach slope, see Figure 9.

Figure 9: The relative shoreline elevation $(z_s - \text{SWL})/L_R$ is a decreasing function of the beach face slope because steeper beaches generally drain more efficiently than flat beaches.

Although the combination of Figures 4 and 9 points towards a predictive formula of the form

$$B_s = F[\sqrt{(H_{\text{orms}} L_o)}, \tan \beta_F] \tag{6}$$

the data can also give a rough indication of B_s as function of the offshore wave height irrespective of beach morphology, namely

$$B_s = 0.4 H_{\text{orms}} \tag{7}$$

see Figure 10

Figure 10: Shoreline setup, B_s , as function of offshore wave height. The straight line is given by Equation (7). Legend: * Seven Mile Beach, o Palm Beach, [] Brunswick Heads, Δ Dee Why Beach.

5. Watertable data

Two methods were applied for collecting watertable data. For short records (25 hours or less) an array of simple stilling wells were used. These were monitored with a dip-meter which is a measuring tape with a conductivity sensor on the end. For long term records a self recording pressure sensor in a single well was used.

Figure 11 shows a series of MWS/watertable measurements from Dee Why Beach on the rising tide (high tide at 20:00). Estimated shoreline elevations based on (7) are given on the right. Note that the watertable continues to rise landward of the shoreline due to the infiltration from runup.

One long term record is shown in Figure 12 together with the corresponding wave-, tide- and rainfall data. Rainfall had little impact because the well was located on the narrow sand barrier in front of Dee Why Lagoon but the influence

from waves and tides is very clear. We see that the watertable was at all times more than one metre above MSL, and the tidal variation is highly asymmetrical. That is, the watertable rises very sharply and falls of very slowly in response to an essentially sinusoidal tide. A considerable fraction of the overheight as well as the skewness is due to asymmetry in the boundary condition at the beach face. In qualitative terms we may say that the infiltration at high tide is much more efficient than the draining at low tide.

Figure 11: Successive watertable measurements taken at Dee Why Beach 7/9-87, ($H_{orms}, T_g \approx (1.1m, 8s)$)

6. Watertable modelling

The dynamics of the watertable as forced by waves and tides has been modelled using the following theoretical framework. The flow inside the sand is governed by Darcy's law and the conservation of volume which leads to

$$\frac{\partial \eta}{\partial t} = -\frac{KD_a}{n} \frac{\partial^2 \eta}{\partial x^2} + u_I \tag{8}$$

where K is the permeability, D_a is the depth of the sand body below the average watertable, n is the relative pore volume and u_I is the infiltration velocity due to wave runup.

Figure 12: Watertable record from Dee Why Beach. The measurements were taken in a well situated about 30 metres from the average shoreline position where the sand level was approximately 2.6m AHD.

Analytical solutions to (8) can be found for the two special cases of pure wave forcing and pure tidal forcing, under the additional assumption that the shoreline position can be prescribed, see Nielsen et al (1988). For the pure wave case it can then be shown that the asymptotic inland watertable height above the shoreline is proportional to the horizontal length scale of the runup distribution squared divided by the aquifer depth i e

$$\bar{\eta}(\infty) - \text{SWL} = \text{const } H_{\text{orms}} L_o / D_a \quad (9)$$

It is independent of the beach permeability because greater permeability equally enhances infiltration and drainage.

For pure tidal forcing a perturbation solution has been used to describe the average overheight above MSL as well as the skewness shown by the data in Figure 12. It turns out that the magnitude of the overheight is $0.5kA^2 \cot \beta$ where k is the wavenumber of the tidal watertable wave and A is the tidal amplitude. With typical k -values of 0.08m^{-1} this tidal overheight ranges typically from 0.2 to 0.5 metres on the coast of New South Wales.

CHAPTER 67

Application of The Second-order Mode Coupling Equation to Coastal Engineering Problems

Mitsuhiro Tanaka†

Abstract

The Second-order Mode Coupling Equation (SMCE) is applied to the 3-dimensional evolution of a solitary wave the crest-line of which is not straight but bent initially. It is found that the bent solitary wave recovers a straight crest-line spontaneously by producing a nonuniform distribution of waveheight and hence that of propagation speed along the crest-line.

1. The Second-Order Mode Coupling Equation

1.1 The Mode Coupling Equation

As pointed out by Zakharov(1968), the motion of water waves can be expressed as a Hamiltonian system by using the total energy as the Hamiltonian and the complex amplitude spectrum $b(\vec{k}, t)$ defined by

$$b(\vec{k}, t) = \sqrt{g/2\omega(k)} \bar{\eta}(\vec{k}, t) + i\sqrt{\omega(k)/2g} \tilde{\phi}^s(\vec{k}, t) \quad (1)$$

as the canonical variable. Here $\bar{\eta}(\vec{k}, t)$ and $\tilde{\phi}^s(\vec{k}, t)$ are the Fourier transform of the free surface displacement $\eta(\vec{x}, t)$ and the velocity potential $\phi(\vec{x}, z, t)$ evaluated at the free surface respectively, and $\omega(k) = \sqrt{gk \tanh kh}$, with $k = |\vec{k}|$.

† Assistant, Department of Applied Mathematics, Faculty of Engineering, Gifu University 1-1 Yanagido, Gifu 501-11 JAPAN

When the Hamiltonian is approximated by a power series of $b(\vec{k}, t)$ truncated at the $(n+1)$ th-order, the resulting Hamilton's equation which governs the evolution of $b(\vec{k}, t)$ contains n -th power of $b(\vec{k}, t)$ and is called here the n -th-order mode coupling equation.

In the derivation of the mode coupling equation, it is usually assumed that the nonlinearity of the underlying wave field is small (i.e., $ak \ll 1$) and that the bottom is flat (i.e., $h = \text{const.}$) and impermeable. With regard to the value of kh , however, no assumption is made and the equation can be applied to waves of any wavelength so long as the above-mentioned assumptions hold.

The third-order mode coupling equation reduces to the well-known Zakharov's equation if only the near resonant interactions are taken into account among all the possible four-wave interactions. Zakharov's equation is further simplified to give the nonlinear Schrödinger equation when the assumption of narrow-bandedness of the wave field is added.

Here in this work, we focus our attention to the Second-order Mode Coupling Equation which we'll call the SMCE for short. Following the notation of Stiassnie and Shemer(1984), the SMCE can be expressed as follows,

$$\begin{aligned} \frac{db(\vec{k})}{dt} + i\omega(k)b(\vec{k}) \\ + i \iint V^{(1)}b(\vec{k}_1)b(\vec{k}_2)\delta(\vec{k} - \vec{k}_1 - \vec{k}_2)d\vec{k}_1d\vec{k}_2 \\ + i \iint V^{(2)}b^*(\vec{k}_1)b(\vec{k}_2)\delta(\vec{k} + \vec{k}_1 - \vec{k}_2)d\vec{k}_1d\vec{k}_2 \\ + i \iint V^{(3)}b^*(\vec{k}_1)b^*(\vec{k}_2)\delta(\vec{k} + \vec{k}_1 + \vec{k}_2)d\vec{k}_1d\vec{k}_2 = 0. \quad (2) \end{aligned}$$

This equation reduces to the well-known K-dV equation under the assumptions that the water is shallow (i.e., $kh \ll 1$) and all the wave components propagate only in the positive x -direction.

There are two major reasons why we choose the SMCE here and discard all the higher order nonlinear interaction terms. The

first reason is; It can be shown that the magnitude of the third-order terms of the mode coupling equation relative to the second-order ones is given by the wave steepness ak of the underlying wave. This implies that the third-order terms as well as all the higher order terms would give only negligibly small contributions to the motion of a solitary wave which we focus our attention to in this work, because it is generally true for a long wave like a solitary wave that a/h may be $O(1)$ while kh is very small, resulting in a very small value of ak .

The second reason to choose SMCE is much more pragmatic. The n -th order mode-coupling equation generally contains n -tuple convolution sums, and the number of operations required per each time step would increase as N^n with N being the number of Fourier modes involved in the calculation. However, the operation count necessary for the evaluation of the second-order convolution terms increase only as $N \ln N$ instead of N^2 . This is because these terms can be rewritten to a form to which the pseudospectral method is applicable and so can be evaluated fast by a series of FFT's and inverse FFT's. This reduction of the number of numerical operations becomes crucial when one is to pursue a 3-dimensional problem like the one shown in Sec. 2 of this work, because for such a 3-D problem the number of Fourier modes required for a reasonably accurate expression of the wave field inevitably becomes large. For such a problem with large number of Fourier modes, the higher order mode coupling equations like Zakharov's equation, however valuable they may be from the theoretical point of view, would require unrealistically vast amount of CPU time on the computing facilities now available and would have only a very limited practical value.

1.2 Accuracy of The SMCE

Before proceeding to an application of the SMCE to a practically interesting problem, it may be sensible to know how better the SMCE approximates the behaviour of long waves than the K-dV equation which is one of the most standard equations for long wave problems.

What we've done is to input the steady periodic solution of

fully nonlinear water wave equations to the SMCE and the K-dV as the initial condition and observe how strongly this steady profile is deformed at later times. In the calculation shown below, we tentatively fix the water depth so that $kh = 0.5$. For this value of kh , the linear dispersion relation of the K-dV equation $\omega(k) = \sqrt{gh}k \{1 - (kh)^2/6\}$ is a very good approximation of the exact one $\omega(k) = \sqrt{gk} \tanh kh$ with the error being only less than 0.3%. In this sense the water is sufficiently shallow and we expect that the K-dV equation approximates the steady translation very well.

The deformation of the wave form is measured by a quantity $D(t)$ defined by

$$D(t) = \int_0^L \{\eta(x, t) - H(x - ct)\}^2 dx / \int_0^L H^2 dx, \quad (3)$$

where H is the profile of the steady periodic wave solution employed as the initial condition and c its propagation speed. As the initial condition is an exact steady solution of the fully nonlinear problem, the deformation $D(t)$ should remain zero if the approximation is 'ideal'. Therefore, we can discuss the accuracy of various different approximations by comparing the magnitude of $D(t)$ given by those approximations.

Fig. 1 Growth of Deformation $D(t)$ for a steady periodic solution with $ak = 0.1$ and $kh = 0.5$

Figure 1 shows the growth of $D(t)$ for the steady wave with $ak = 0.1$. It can be seen that $D(t)$ given by the SMCE remains about 500 times smaller than that of the K-dV equation during the period of time considered, implying that the SMCE gives 500 times more accurate result than the K-dV equation does, at least for the steady translation of the particular wave considered here. It may be noted that the length of time shown in Fig.1 is fairly long for the particular steady wave, and during which the wave has propagated more than 250 times the water depth.

If the nonlinear terms of both the SMCE and the K-dV are calculated by the pseudospectral method, and the time-stepping of both equations are carried out by Runge-Kutta-Gill method, the SMCE requires about three times longer CPU time than the K-dV equation does.

2. Three-Dimensional Evolution of A Bent Solitary Wave

2.1 Initial Condition

As an application of the SMCE to a 3-dimensional problem, we investigate the time evolution of a wave which is basically a Boussinesq solitary wave propagating in the positive x -direction but the crest-line of which is slightly bent initially. More specifically, we've prescribed the initial condition as follows:

$$\eta(x, y, 0) = a_0 \operatorname{sech}^2 \{(x - x_c(y))/D\} \quad (4a)$$

$$\phi^s(x, y, 0) = \sqrt{4a_0/3} \tanh \{(x - x_c(y))/D\} \quad (4b)$$

where D is the width of the solitary wave which is related to the waveheight a_0 by $D = \sqrt{4(1 + a_0)/3a_0}$. In the calculation reported here, the initial shape of the crest-line $x_c(y)$ is chosen tentatively as $x_c(y) = x_0 - \epsilon \cos(2\pi y/L_y)$ with x_0 being some appropriate constant. The parameter ϵ determines the magnitude of the y -variation of the crest position, while L_y determines its length-scale. For the sake of numerical computation, the wave field is assumed to be periodic both in the x - and y -direction with the period L_x and L_y , respectively. The period in the x -direction L_x is taken sufficiently long so that the existence of the

periodic boundary would not affect the evolution of the wave field seriously. The water depth is normalized as 1.

Figure 2 shows the bird's-eye view of the wave form at $t = 0$ (Fig. 2a) and $t = 30$ (Fig. 2b) when the crest is not bent initially. The values of parameters chosen for this calculation are $a_0 = 0.2$, $L_x = 61.3$, $L_y = 5$, $N_x = 128$, $N_y = 12$ and $\Delta t = 0.5$. Here N_x and N_y are the number of mesh points in the x - and y -direction, respectively, and Δt is the step-size of the time-integration which is carried out by Runge-Kutta-Gill scheme. The total CPU time is about 57 sec. on FACOM M780 of the Computation Center of Nagoya University. Although the initial condition is not a steady solution of the SMCE but of the Boussinesq equation, the solitary wave seems to be propagating almost steadily on the SMCE as well. This is quite reasonable because the Boussinesq soliton should be a good approximation of the steady solution of the SMCE when the waveheight is not large as in the present case where $a_0 = 0.2$.

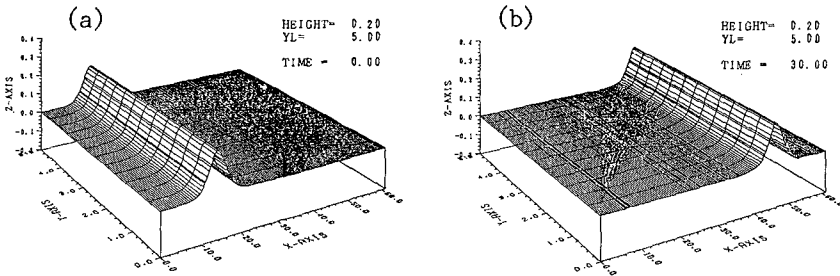

Fig. 2 Wave-form when the solitary wave is not bent initially.
(a) $t = 0$, (b) $t = 30$.

2.2 Scenario of 3-D Evolution

An example of the evolution of a bent solitary wave is shown in Fig. 3. All the parameters are the same as the previous case, the only difference being that the amplitude of the initial bend ϵ is set equal to 1 instead of 0. Figure 3a shows the bird's-eye view of the initial wave form, and the time evolution that follows is shown in Figs. 3b–3f. The scenario of the evolution may be summarized as follows:

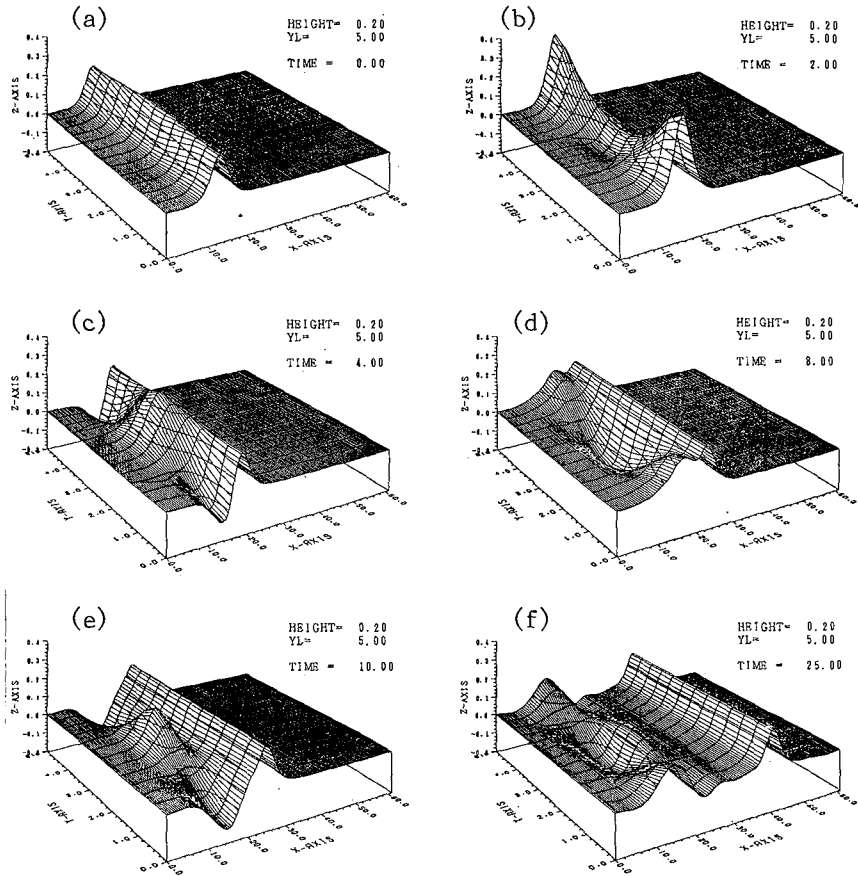

Fig. 3 3-D evolution of a bent solitary wave. $a_0 = 0.2$, $L_y = 5$ and $\epsilon = 1$.

(1) The waveheight spontaneously starts to increase around $y = 0$ and $y = L_y$ where the wave crest is made behind initially, while it starts to decrease around $y = L_y/2$ where the crest is put forward. As it is generally true for long waves that the higher waves propagate faster than the lower, this unevenness of the waveheight brings out such a distribution of propagation speed along the crest-line that would help the bent crest-line go back to a straight line. (Fig.3b)

(2) Around $y = 0$ and $y = L_y$ where the crest is now propagating faster because of the increased waveheight, the water just behind the crest appears not to be able to keep up with the crest, and as a result of that, a depression of water surface appears. On the other hand, around $y = L_y/2$, the water just behind the crest seems to be overtaking the crest which is now propagating by a reduced speed, and a swell up of water surface is observed behind the crest. (Fig.3c)

(3) The lateral distribution of the free surface displacement behind the crest-line that has appeared in (2) evolves into a standing wave-like oscillation. The period of oscillation coincides approximately with that of a linear long wave with wavenumber $k = 2\pi/L_y$. By this time, the recovery of a straight crest-line has been accomplished, and a 2-dimensional solitary wave with a straight crest-line is emerging out of the transient wave motion. (Figs.3d and 3e)

(4) The initial condition finally splits into two parts. One is a 2-D solitary wave with a straight crest-line which propagates steadily with a speed given approximately by $1 + a/2$, and the other is a standing wave-like oscillation which appears to stay around the position for all the time, the position where the wave was given initially. This difference between the propagation speed of these two parts brings out the appearance of a region with a calm free surface between them. This calm region grows wider as time goes on and the solitary wave propagates further from the initial position. (Fig.3f)

Figure 4a shows the top-view of the crest-line at various time-steps in which it can be seen clearly how the crest-line approaches a straight line. In order to see this phenomenon more quantitatively, we show in Fig.4b the evolution of a quantity X_{dev} defined by

$$X_{\text{dev}}(t) = \int_0^{L_y} \{x_c(y) - \bar{x}_c\}^2 dy, \quad (5)$$

where $x_c(y)$ is the x -coordinate of the crest-line in terms of y and \bar{x}_c is the average of $x_c(y)$. By its definition, X_{dev} vanishes when the crest-line is straight.

Fig. 4 (a) The top-view of the crest-line for $0 \leq t \leq 30$. (b) X_{dev} , i.e., the deviation of the crest-line from a straight line. (c) The evolution of the maximum and the minimum waveheight along the crest-line ($a_0 = 0.2$, $L_y = 10$ and $\epsilon = 1$)

Figure 4c shows the evolution of the maximum and the minimum waveheight along the crest-line. This figure shows clearly the spontaneous appearance of a nonuniformity of the waveheight right after the initial time, as well as its gradual relaxation and the return to a state of uniform waveheight.

2.3 L_y – Dependence

We've shown above that a solitary wave seems to have an ability to make its crest-line straight when it's bent initially by producing a nonuniform distribution of the waveheight along the crest.

There are two important quantities that characterize this phenomenon. One is the characteristic time-scale of the phenomenon and the other is the size of the highest wave that appears during the transient motion. Figure 5a shows the L_y -dependence of the characteristic time-scale which is defined as the time when $X_{\text{dev}}(t)$ of eq.(5) attains its first local minimum. In the same figure is also shown by a dashed line the period of oscillation of a linear long wave with wavelength L_y . The result shows that the longer the length-scale of the initial bend, the longer it takes to return to a straight crest-line.

Fig. 5 (a) L_y -dependence of the characteristic time-scale (b) L_y -dependence of the maximum waveheight that appears during the transient motion

The maximum waveheight that appears during the transition divided by the initial height is shown in Fig.5b as a function of L_y . This figure shows that the higher wave appears as the length-scale of the initial bend is shortened or as the curvature of the initial crest-line is increased. For the type of initial condition we are now using, we can get a wave which is 2.6 times as high as the initial wave by bending its crest-line such that $L_y=3$ and $\epsilon = 1$. This result strongly suggests that it might be possible to make a solitary wave break without decreasing the water depth but by just bending its crest-line somehow. We've also investigated the dependence of the phenomenon on the initial waveheight a_0

by changing a_0 from 0.1 to 0.5, but no appreciable change in the characteristic time-scale or the maximum waveheight was observed.

The crest-line of solitary waves that are observed on the beach are usually very long and nearly straight in spite of the uneven bottom topography over which they may have propagated. This might be related to the ability of a solitary wave as that shown above to keep its crest-line straight by adjusting the waveheight distribution along the crest when it is deformed by some external cause.

3. A Simple Model

In this section, we try to reproduce the phenomenon shown in the previous section by a simple model in order to understand intuitively the principle that underlies the phenomenon. The model the detail of which is explained below is derived by an analogy with the motion of an axisymmetric (or cylindrical) solitary wave.

The waveheight of a diverging axisymmetric wave which can be produced quite easily by throwing a stone into a pond is observed to decrease as the wave propagates outward and the crest-line of the wave is stretched. On the other hand, the waveheight of a converging axisymmetric wave which occurs when one hits a circular basin filled with water increases as the wave propagates inward and the crest-line is shortened. It is quite obvious that these changes of waveheight are the result of conservation laws.

3.1 Assumptions of the Model

Bearing this in mind, we now propose a very crude model to understand intuitively the 3-D evolution of a bent solitary wave. The followings are the assumptions on which the model is constructed;

- (1) Each point that constitutes the crest-line moves in the direction normal to the crest-line at that point with velocity v given by $v = (1 + a/2)$, where a is the local waveheight of the crest.
- (2) The waveheight a changes in such a way that *mass* or *energy* is conserved. (see Assumption (3) below.)

(3) The shape of normal cross-section at any point of the crest-line is similar to that of the K-dV soliton, and its horizontal length-scale is proportional to $1/\sqrt{a}$ when the local waveheight is a .

3.2 Evolution Equations

The shape of the crest-line and the distribution of the waveheight along it at time t is assumed to be described as $x = x(\sigma)$, $y = y(\sigma)$ and $a = a(\sigma)$, where σ is a parameter which plays a role of the *Lagrangian* coordinate. With this parametric representation of the crest-line, the Assumption (1) can be expressed as

$$\left. \frac{\partial \vec{x}}{\partial t} \right|_{\sigma} = \vec{v} = \{1 + a(\sigma)/2\} \vec{n}, \quad (6)$$

with

$$\vec{n} = (y_{\sigma} \vec{i} - x_{\sigma} \vec{j}) / \sqrt{x_{\sigma}^2 + y_{\sigma}^2}.$$

This is the evolution equation for the shape of the crest-line. On the other hand, the evolution of $a(\sigma)$ is governed by the Assumptions (2) and (3) which require the following relations to hold. When *mass* conservation is assumed,

$$a(x_{\sigma}^2 + y_{\sigma}^2) = \text{const.} \quad (7)$$

along a ray (i.e., $\sigma = \text{const.}$), while

$$a^3(x_{\sigma}^2 + y_{\sigma}^2) = \text{const.} \quad (8)$$

if *energy* conservation is assumed instead.

3.3 Result

Figures 6.a and 6.b show the top-view of the crest-line at various times and the evolution of X_{dev} defined by eq.(5), respectively, that are obtained by the model with *energy* conservation. Although the model is quite a crude one and there would be a lot of possibilities to elaborate on it, it nevertheless expresses, at least qualitatively, the approach of a bent crest-line to a straight line as shown by these figures.

Fig. 6 (a) The top-view of the crest-line for $0 \leq t \leq 40$. (b) X_{dev} , i.e., the deviation of the crest-line from a straight line. ($a_0 = 0.2$, $L_y = 15$, $\epsilon = 1$ and the energy conservation eq.(8) is assumed.)

Fig. 7 (a) L_y -dependence of the characteristic time-scale (b) L_y -dependence of the maximum waveheight that appears during the transient motion. \odot : model with mass conservation, \square : model with energy conservation, \triangle : SMCE.

The L_y -dependence of the characteristic time-scale and the maximum waveheight obtained by the present model are shown in Figs. 7a and 7b respectively. In these figures, the open squares show the result of the model with energy conservation, while the open circles show that of the model with mass conservation. The

result of the SMCE is also shown in the same figures by open triangles for the sake of comparison.

It can be seen from these figures that the model with *energy* conservation generally gives much better results than the model with *mass* conservation. Especially, the characteristic time-scale predicted by the model with *energy* conservation almost coincides with that predicted by the SMCE as shown in Fig. 7a. This reminds us of the well-known fact in the perturbation theory of the K-dV equation that the amplitude modulation of one-soliton induced by a small perturbation can be calculated correctly by using any of the infinite number of conservation laws except the first one which corresponds to the mass conservation. This somewhat peculiar fact can be explained in terms of the non-secular condition of the perturbation analysis. (see for example Tanaka (1980))

CHAPTER 68

FULL-SCALE MEASUREMENTS OF WAVE RUN-UP AT SEA DYKES

Uwe Sparboom 1)
Joachim Grüne 2)
Sven Grosche 3)
Mark Haidekker 3)

ABSTRACT

Wave run-up phenomena due to breaking waves acting on sea dykes are focussed in this paper. Field measurements at two locations of the North Sea Coast are reviewed and compared with full-scale investigations in the Large Wave Channel, Hannover. Commonly used design approaches on wave run-up at sea dykes are discussed. For some naturally shaped shallow wave spectra (Pierson-Moskowitz type) estimations are proposed for wave run-up, run-down and water front velocity in relation to the wave height and to the breaker number.

1. INTRODUCTION

Wave run-up and overtopping phenomena are mostly responsible for dyke failures during storm surge tides at the German North Sea Coast. Recently, this again was demonstrated at dyke profiles near Dagebüll harbor, Northfrisian Coast. Looking towards the discussed possible sea level rise in the near future, reliable wave run-up design criteria for sea dykes are very important.

Large Wave Channel-Joint Institution of the University of Hannover and the Technical University of Braunschweig,

Hannover University, Merkurstrasse 11, 3000 Hannover 21, Germany

Wave run-up field measurements at Eastfrisian sea dykes were reported by Erchinger (1974). An estimation of the maximum wave run-up - based on levelling the marker-line of flotsam after storm tides - was proposed by Niemeyer (1976). Results on wave run-up field measurements at the North Sea Coast, also correlated to synchronously measured wave spectra, were published by Coldewey (1982) and Grüne (1982).

In this paper, field measurements (Grüne, 1982) and full-scale measurements in the Large Wave Channel (Führböter, Sparboom and Witte, 1989) were compared with calculated wave run-ups using the empirical approaches derived by Wassing (1957) and by Hunt (1959). Extensions of the Hunt-approach which were published by van Oorschot and d'Angremond (1968) and by Battjes (1971) were also taken into account for comparison.

2. FIELD MEASUREMENTS

In order to verify empirically developed formulae field measurements on wave run-ups and wave spectra were carried out previously (Grüne, 1982). A special run-up probe was used at two different locations of the North Sea Coast (WANGEROOGE and EIDERDAMM). The investigated dyke profiles with 1:4 and 1:6 slopes were constructed by a sand core which was covered by an impermeable layer made from asphalt concrete (Fig. 1). The data of the storm surge measurements were analyzed in the time domain.

Figure 1. Dyke profiles with run-up gauges (Grüne, 1982)

Figure 2. Synchronous records of waves and wave run-ups

An example for synchronously measured records of the wave height and the wave run-up is given in Fig. 2 for a short time slice. Corresponding log-normal distributions of a nearly 15 minutes time interval are plotted in Fig. 3.

Figure 3. Log-normal distributions of 15 minutes records

Comparing measured and calculated run-ups it was found that the measured run-ups were considerably higher than the predicted run-ups. Two design formulae were used for the run-up with 2 % exceedance:

a) Wassing, 1957 $R_{98} = K \cdot H_{1/3} \cdot \frac{1}{N}$

with the empirical factor $K = 8$,
the significant wave height $H_{1/3}$
and the slope angle N .

b) Hunt, 1959 $R_{98} = C' \cdot \bar{T} \cdot \sqrt{G \cdot H_{1/3}} \cdot \frac{1}{N}$

with the empirical factor $C' = 0.5$,
the mean period \bar{T} ,
the acceleration due to gravity G ,
the significant wave height $H_{1/3}$
and the slope angle N .

Remark:

The original Hunt-formula (e.g. Techn. Advis. Comm., 1974) yields the run-up $R=0.4 \cdot \bar{T} \cdot \sqrt{gH} \cdot 1/N$ and is derived from experimental laboratory tests on smooth and uniform slopes. Applying this formula to field conditions the wave parameters usually are used as statistic values (\bar{T} and $H_{1/3}$). After Führböter (1976) the run-up estimation by Hunt should be increased by a factor 1.25 which goes back to a proposal presented by Vinjé during a meeting of the so-called North Sea Coastal Engineering Group in the year 1972. The empirical factor C' therefore becomes $C' = 1.25 \cdot 0.4 = 0.5$.

Results of the comparison were plotted in Fig. 4 for the WANGEROOGE location. For the 1:4 slope the mean K-factor (Wassing) increased up to 11.32 and the mean C' - factor (Hunt) increased up to 0.71. Results of the EIDERDAMM location were given in Fig. 5 for both slopes 1 : 4 and 1 : 6. Comparing the results for the 1:4 slope with those of the WANGEROOGE location a larger increase of the empirical factors is shown.

Figure 4. Comparison of measured and calculated wave run-up (after Grüne, 1982)

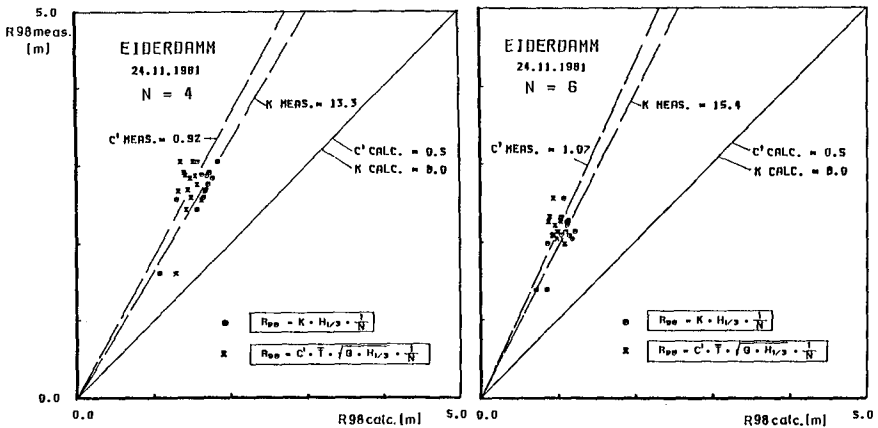

Figure 5. Comparison of measured and calculated wave run-up (after Grüne, 1982)

In order to compare the field measurements with the extended Hunt-approach established by van Oorschot and d'Angremond (1968), some field records of the WANGE-ROOGE location were additionally analyzed in the frequency domain in the same manner as the new data from full-scale laboratory investigations. The results will be discussed in chapter 4.2.

3. LARGE WAVE CHANNEL MEASUREMENTS

3.1 Test set-up

The Large Wave Channel (LWC) in Hannover allows to investigate wave attack phenomena in full-scale. The main dimensions of the channel are: depth 7.0 m; width 5.0 m and length 324 m. Regular and random waves can be generated up to wave heights of 2.5 m with a waterdepth of 5.0m. Details on the Large Wave Channel were published by Grüne and Führböter (1975). Design criteria and technical works were reported by Grüne and Sparboom (1982).

A cross-section of the prototype dyke slope which was investigated in the Large Wave Channel shows Fig. 6. The dyke core was constructed by sand. The compact cover layer was made by asphalt concrete with a smooth surface. Wave run-ups were measured by a special step gauge (Grüne, 1982). The waves were measured near the toe of the dyke slope by a wire gauge. The tests were carried out with a waterdepth of 4.8 m (SWL).

Figure 6. Test slope 1:6 in the Large Wave Channel (LWC)

3.2 Wave conditions

With reference to natural wave conditions at sea dykes two main test series were run (Führböter et al., 1989):

- a) regularly generated waves with wave heights up to 2.3 m and wave periods up to 15 s;
test duration: 110 waves

- b) irregularly generated waves; P-M-type spectra with significant wave heights up to 1.2 m and peak periods up to 11 s ;
test duration: nearly 25 minutes

For all generated waves an integrated absorption control system was applied to minimize wave reflexions at the wave generator. The wave parameters for all tests including the corresponding breaker numbers ξ (Iribarren number) are plotted in Fig. 7.

Figure 7. Wave test parameters for 1:6 dyke slope

3.3 Data evaluations

The measured data were analyzed in the time domain as well as in the frequency domain using the computer equipment (HP 1000/A 900) at the Large Wave Channel (Sparboom and Grosche, 1986/1987; Sparboom and Haidekker, 1987).

The test data for regular waves (Fig. 8) were characterized by mean parameters (\bar{H} , \bar{R} , \bar{T}). Because each regularly generated wave produced a run-up, the mean period had the same value for both signals.

The test data for irregular waves (Fig. 9) were characterized by mean parameters (\bar{H} , \bar{T}) and by extreme statistics (R_{98} , $H_{1/3}$). The waves were evaluated by the zero-down crossing method and the run-ups were found by crest values above SWL. An example of the calculated log-normal distributions of the synchronously recorded waves and run-ups is given in Fig. 10. Frequency characteristics (e.g. peak period T_p) were calculated using the frequency analysis (Fast Fourier Transformation method). One window had 8192 data points. The Nyquist frequency was 20 Hz and the number of degrees of freedom was 54 with respect to combined averaging.

Figure 8. Synchronous records of waves and run-ups

Figure 9. Synchronous records of waves and run-ups

Figure 10. Log-normal distributions of 25 minutes records

4. COMPARISON OF CALCULATED AND MEASURED WAVE RUN-UP

4.1 Regular waves

The so-called Delft-formula was derived by Wassing (1957). Regular waves with steepnesses of 5 and 7 percent were investigated in a small-scale model (Tab. 1). Another formula was published by Hunt (1959). After this formula the run-up depends linearly on the breaker number which contains the influence of the wave height, the wave length or wave period and the slope angle (Tab. 1).

In Fig. 11 the measured run-ups were compared with calculated ones using these two formulae. For plunging breakers the Hunt-approach underpredicts run-up about 20 percent and the Wassing-approach overpredicts run-up about 35 percent. As shown later, run-up phenomena under sea state conditions cannot be described sufficiently basing only on laboratory tests with regularly generated waves. The dynamic response due to a random process differs significantly from a response due to a regular process.

Figure 11. Comparison of measured and calculated wave run-up

4.2 Irregular waves

The formulae derived by Wassing and Hunt were extended to sea state conditions. From a practical point of view the extreme wave run-up mostly is defined by R 98 which means that the highest two percent of the wave run-ups are acceptable for overtopping. Van Oorschot and d'An-

gremond (1968) published results derived from spectral wave simulations in a small-scale model. They found that the run-up values vary with the spectral width parameter (formula see Tab. 2). According to the Rayleigh-distribution of waves and run-ups Battjes (1971) proposed coefficients for narrow and wide band wave spectra (Tab. 2).

In Fig. 12 some results of run-up values $R_{u,98}$ from field measurements by Grüne (1982) (WANGEROOGE location) and the results from full-scale measurements in the Large Wave Channel are compared with theoretical ones. The approach by Wassing -neglecting the wave period- is far from being reliable; the theoretical values are 60 percent underestimated. The Hunt/Battjes-formula -in the case of wide wave spectra- underestimates the run-up nearly 20 percent and the Hunt/v.Oorschot,d'Angremond-formula overestimates the run-up nearly 20 percent. The differences of the data seem to be caused by using different wave periods. Therefore in the opinion of the authors, for using the formulae the choice of the periods should be paid more attention. From various spectra in Fig. 13 it can be seen that the peak periods of both the waves and the run-ups seem to tend into the same range. A strongly smoothing procedure of the energy shape is exemplarily shown in Fig. 14 for one field and one LWC-test. The changes of the spectral density shapes are indicated by the transfer function with integrator characteristic. Higher frequencies of the

wave process are lost in the run-up response process. Lower frequencies are found for the run-up process which are not present in the incident wave process (see also Mase, 1988). In the range of the peak frequency a quasi linear relation between both processes seems to exist. Further detailed research work on this topic is recommended.

Figure 13. Corresponding wave and run-up spectra of LWC-tests

Figure 14. Spectral functions of waves and run-ups

5. WAVE RUN-UP, RUN-DOWN AND WATER FRONT VELOCITY AS A FUNCTION OF THE BREAKER NUMBER

In this chapter the results from the full-scale measurements with regular waves and with wave spectra at the prototype 1:6 dyke slope (Large Wave Channel) are referred to the well-known breaker number ξ as mentioned by Bruun and Günbak (1977). Wave run-up (Fig. 15) and run-down (Fig. 16) were calculated as relative values with reference to the wave height. The water front velocities (Fig. 17) were referred to $\sqrt{g \cdot H}$ (Roos and Battjes, 1976).

In the range of plunging breakers the data for regular waves as well as for irregular waves (Fig. 15) do not fit the relation $R_u = H \cdot \xi$ derived by Hunt (1959). If the wave spectra are described by $H^{1/3}$ (or $H^{1/2}$) and T_p , for the investigated wide banded Pierson-Moskowitz spectra which have a similar energy density shape as shallow water spectra (e.g. WANGEROOGE location) a rough run-up estimation is proposed for plunging breakers $0.5 < \xi < 2.5$:

$$\frac{R_{u,gs}}{H^{1/3}} = 1 + \xi \quad \text{with } \xi = \frac{T_p}{N} \cdot \sqrt{\frac{G}{2\pi \cdot H^{1/3}}}$$

$$\text{or } \frac{R_{u,gs}}{H} = 1.5 \cdot (1 + \xi) \quad \text{with } \xi = \frac{T_p}{N} \cdot \sqrt{\frac{G}{2\pi \cdot H}}$$

with N = front slope ($1/N = \tan \alpha$)
and G = acceleration due to gravity.

Figure 15. Relative wave run-up of Large Wave Channel tests

The relative run-down is shown in Fig. 16. The run-down of regular waves remains above SWL up to $\xi \approx 2.0$ whereas in the case of irregular waves the run-down always remains under SWL. For the investigated P-M-type spectra the wave run-down can roughly be described for plunging breakers $0.5 < \xi < 2.5$:

$$\frac{RD_{.98}}{H_{1/3}} = -0.23 \cdot \xi \text{ with } \xi = \frac{\Delta T_P}{N} \cdot \sqrt{\frac{G}{2\pi \cdot H_{1/3}}} .$$

Figure 16. Relative wave run-down of Large Wave Channel tests

The water front velocities (Fig. 17) were evaluated from the time records of the wave run-up signals (Fig. 8 and 9). The mean velocities were calculated with the time in which the run-up or the run-down reached the maximum or the minimum. The maximum velocities were found by the first derivative of the run-up/run-down signal. High velocity values were found -as expected- in the lowest range of run-down; they were acting roughly near SWL. Mean and maximum velocities due to regularly generated waves confirm earlier small-scale measurements by Roos and Battjes (1976) up to $\xi \approx 2.0$. It should be noted that relative velocities due to irregular waves are definitely larger than those found for regular waves. For the investigated spectra a rough estimation of the local maximum water front velocities (up and down the slope) may be given for plunging breakers $0.5 < \xi < 2.5$:

$$\frac{MAX V_{98}}{\sqrt{G \cdot H_{1/3}}} = 1.5 + 0.25 \cdot \xi \text{ with } \xi = \frac{\Delta T_P}{N} \cdot \sqrt{\frac{G}{2\pi \cdot H_{1/3}}}$$

with $max V_{98}$ = statistical value with two percent exceedance .

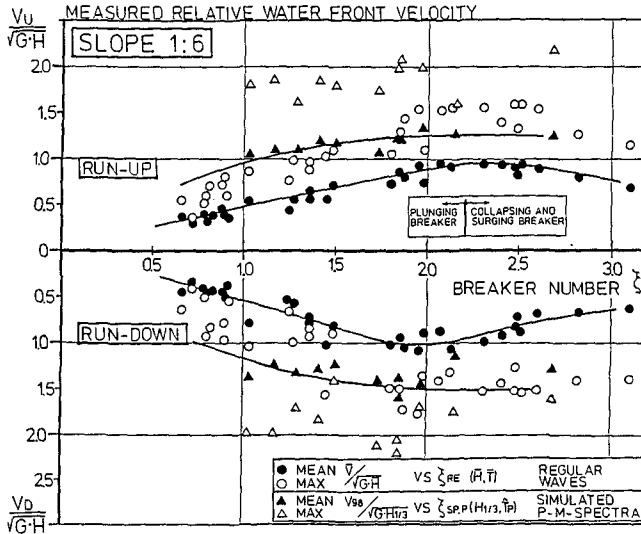

Figure 17. Relative water front velocities of Large Wave Channel tests

6. CONCLUDING REMARKS

The approach by Wassing (1957) disregarding the wave period cannot be used for real sea state conditions.

The approach by Hunt (1959) can be verified for full-scale and real sea state conditions. Nevertheless, the selection of the wave spectra parameter for the wave period and the wave height has to be investigated in more detail with different sea state conditions to enable a standardization for general application.

Results from measurements with regular waves even in full-scale do not describe the wave run-up process under sea state conditions sufficiently and should therefore not be used for practical engineering purposes.

7. ACKNOWLEDGEMENT

The authors would like to acknowledge very gratefully the German Research Foundation (DEUTSCHE FORSCHUNGSGEMEINSCHAFT) sponsoring the research program on safety and reliability of dykes and revetments for coastal protection (SFB 205 / A1). The project is running under supervision of Prof. Dr.-Ing. A. Führböter.

CHAPTER 69

STATISTICAL CHARACTERISTICS OF OFFSHORE CURRENTS

Michel K. Ochi*

ABSTRACT

This paper presents the analytical derivation of probability density functions applicable for tidal (high frequency components), residual (low frequency components), and total (the vector sum of tidal and residual) current velocities. The theoretical probability density functions are compared with histograms constructed from measured data. A method to estimate the extreme current velocities in a specified time period is presented by applying extreme value statistics.

INTRODUCTION

The magnitude of current velocity measured in offshore areas fluctuates randomly with frequencies covering a wide range from 0.0008 to 0.08 cycles per hour (period range from 1200 to 12 hours). Measured current data may be decomposed into high and low-frequency components. Here, high-frequency components are considered to be currents associated with tides, while low-frequency components (called residual currents) are those attributed to wind and all other environmental conditions.

It may be of considerable interest to obtain the statistical distributions applicable for the tidal (high frequency components), residual (low-frequency components), and total (the vector sum of tidal and residual) current velocities, and therefrom to estimate the extreme velocities expected to occur in a specified time period.

This paper presents the analytical derivation of probability density functions applicable for the tidal and residual as well as total current velocities. The theoretical probability density functions are compared with histograms constructed from measured data. Based on these probability density functions, extreme current velocities are estimated from knowledge of variances of high and low-frequency components in two rectangular directions.

High Frequency (Tidal) and Low Frequency (Residual) Currents

Offshore current velocity records, in general, represent the average velocities consisting of various frequencies measured during a certain time period. For example, Figure 1 taken from Reference 1 shows a portion of measured current velocities recorded at a 26 meter depth off Newfoundland, Canada. The data represent the hourly mean current velocities measured at 10 minute intervals in a dominant hourly current direction. Figure 2 shows a polar diagram indicating the magnitude and direction of the measured current velocities. Unfortunately, statistical information on high frequency (tidal) and low frequency (residual) current velocities cannot be obtained from Figure 2. Nor is it possible to obtain this information by simply separating the time history shown in Figure 1 into high and low frequency components, since the components thusly obtained merely represent the high and low frequency current velocities in the dominant hourly current direction. The tidal and residual currents flow independently in constantly changing direction.

Figure 1 Time history of current velocity

Figure 2 Polar diagram indicating the magnitude and direction of current velocity as a function of time

In order to obtain the statistical properties of tidal components and residual components of current velocity, it is first necessary to decompose the measured current velocity into two rectangular components as shown in Figure 3. Here, for convenience, we consider the East-West and North-South directions. Each of these two velocity components, denoted by U and V respectively, is then further decomposed into a high frequency (tidal) velocity component and a low frequency (residual) velocity component. In the present study, a cutoff frequency of 0.035 cycles/hour (28.5 hour period) is used to separate the two components [1]. This is because the results of spectral analysis of the records indicate that a small amount of energy exists beyond the 24.0 hour period (0.042 cycles/hour). Thus, the time history of current velocity constructed from measurements at one hour intervals is decomposed into the following four components:

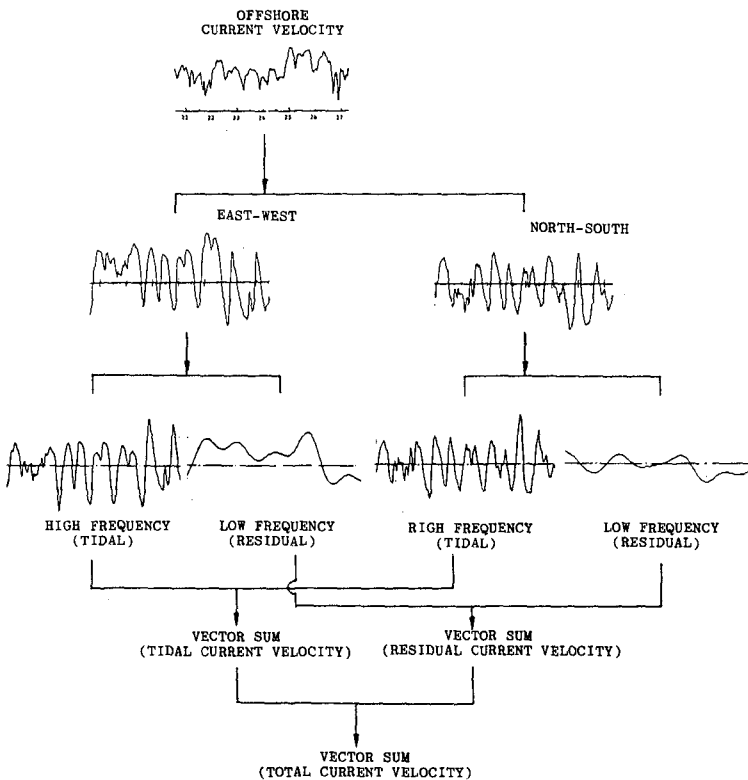

Figure 3 Diagram illustrating analysis of offshore current velocity data

In the East-West direction

- High frequency (tidal) component, H_u
- Low frequency (residual) component, L_u

In the North-South direction

- High frequency (tidal) component, H_v
- Low frequency (residual) component, L_v

From these four time histories, the magnitude of high frequency (tidal) velocity can be obtained by combining H_u and H_v in vector form, while that for the low frequency (residual) velocity is obtained by combining L_u and L_v . The current velocities thusly combined at one hour intervals, denoted by H and L, respectively, have individual directions and provide information on tidal and residual current velocities. The high and low frequency currents are hereafter referred to as tidal and residual currents, respectively.

Figures 4 and 5 show examples of polar diagrams indicating the magnitude and direction of the tidal and residual current velocities, respectively, as a function of time. As can be seen in Figure 4, the tidal current velocities show approximately the same pattern of rotation as the measured current velocities shown in Figure 2. However, the residual velocity rotates very slowly clockwise through 180 degrees in approximately 20 hours in this example, and then rotates counter-clockwise through 90 degrees in approximately 12 hours. The residual current velocity does not have a consistently rotating directionality in contrast to the tidal velocity.

Figure 4 Polar diagram indicating the magnitude and direction of tidal (high frequency) current velocity as a function of time

Figure 5 Polar diagram indicating the magnitude and direction of residual (low frequency) current velocity as a function of time

It is noted that the tidal current and the residual current are statistically uncorrelated. The correlation coefficient between them is extremely small, on the order of 0.05. Hence, the possibility of simultaneous occurrence of large tidal current and large residual current is almost nil.

PROBABILITY DISTRIBUTIONS OF TIDAL AND RESIDUAL CURRENT VELOCITIES

The probability density function applicable for the tidal current velocity can be derived as follows: It is found from statistical analysis of measured data that both the East-West and North-South components of high frequency current velocities approximately follow the Gaussian probability distribution with zero mean and variance which is equal to the area under the spectral density function obtained for each direction [1]. It is also found that the East-West and North-South components, H_u and H_v , are statistically independent. Let us write the variance of H_u and H_v as σ_{HU}^2 and σ_{HV}^2 , respectively. Since the two random variables, H_u and H_v are statistically independent, the joint probability density function can be written as

$$f(H_u, H_v) = \frac{1}{2\pi\sigma_{HU}\sigma_{HV}} \exp \left\{ -\frac{1}{2} \left(\frac{H_u^2}{\sigma_{HU}^2} + \frac{H_v^2}{\sigma_{HV}^2} \right) \right\}, \quad (1)$$

$$0 \leq H_u < \infty, \quad 0 \leq H_v < \infty.$$

Let H be the vector sum of the two components. Then, H_u and H_v can be written as

$$H_u = H \sin\theta \quad H_v = H \cos\theta, \quad (2)$$

where θ = directional angle of H measured from North.

By applying the technique of changing random variables, the joint probability density function of H and θ can be obtained as

$$f(H, \theta) = \frac{H}{2\pi\sigma_{HU}\sigma_{HV}} \exp \left\{ -\frac{H^2}{2} \left[\frac{1}{\sigma_{HU}^2} + \left(\frac{1}{\sigma_{HV}^2} - \frac{1}{\sigma_{HU}^2} \right) \cos^2\theta \right] \right\}, \quad (3)$$

$$0 \leq H < \infty, \quad 0 \leq \theta \leq 2\pi.$$

The probability density function of the vector sum can then be obtained as the marginal probability density function of Eq.(3). That is,

$$f(H) = \frac{H}{2\pi\sigma_{HU}\sigma_{HV}} e^{-\frac{H^2}{2\sigma_{HU}^2}} \int_0^{2\pi} \exp\left\{-\frac{H^2}{2}\left(\frac{1}{\sigma_{HV}^2} - \frac{1}{\sigma_{HU}^2}\right)\cos^2\theta\right\} d\theta. \quad (4)$$

By expanding the exponential function and by integrating with respect to θ , we have

$$\begin{aligned} f(H) &= \frac{H}{\sigma_{HU}\sigma_{HV}} e^{-\frac{H^2}{2\sigma_{HU}^2}} \left[1 - \frac{H^2}{4}\left(\frac{1}{\sigma_{HV}^2} - \frac{1}{\sigma_{HU}^2}\right) + \frac{H^4}{64}\left(\frac{1}{\sigma_{HV}^2} - \frac{1}{\sigma_{HU}^2}\right)^2 + \dots \right] \\ &\sim \frac{H}{\sigma_{HU}\sigma_{HV}} e^{-\frac{H^2}{2\sigma_{HU}^2}} \cdot e^{-\frac{H^2}{4}\left(\frac{1}{\sigma_{HV}^2} - \frac{1}{\sigma_{HU}^2}\right)} \\ &= A \frac{H}{\sigma_{HU}\sigma_{HV}} \exp\left\{-\frac{H^2}{4}\left(\frac{1}{\sigma_{HU}^2} + \frac{1}{\sigma_{HV}^2}\right)\right\}, \end{aligned} \quad (5)$$

where A is a normalization factor to be determined such that the area under the probability density function becomes unity. It can be obtained as

$$A = 2\sigma_{HU}\sigma_{HV} \left(\frac{1}{\sigma_{HU}^2} + \frac{1}{\sigma_{HV}^2}\right). \quad (6)$$

Hence, the probability density function of tidal current velocity becomes

$$f(H) = \frac{H}{2} \left(\frac{1}{\sigma_{HU}^2} + \frac{1}{\sigma_{HV}^2}\right) \exp\left\{-\frac{H^2}{4}\left(\frac{1}{\sigma_{HU}^2} + \frac{1}{\sigma_{HV}^2}\right)\right\}. \quad (7)$$

This is the Rayleigh probability density function whose parameter is given as a function of the variances of the East-West and North-South components. Figure 6 shows a comparison of the probability density function given in Eq.(7) and the histogram of tidal current velocity constructed from measured data. Good agreement between them can be seen.

Figure 6 Comparison between histogram and probability density function of tidal (high frequency) current velocity

The probability density function of the residual current velocity can be derived through the same procedure as that used for the tidal current velocity. That is, by writing the variances of the East-West and North-South components of residual currents as σ_{LU}^2 and σ_{LV}^2 , respectively, the probability density function of the residual current velocity, L, can be given by

$$f(L) = \frac{L}{2} \left(\frac{1}{\sigma_{LU}^2} + \frac{1}{\sigma_{LV}^2} \right) \exp \left\{ -\frac{L^2}{4} \left(\frac{1}{\sigma_{LU}^2} + \frac{1}{\sigma_{LV}^2} \right) \right\} \quad (8)$$

A comparison between the probability density function and the histogram constructed from measured data is shown in Figure 7.

Figure 7 Comparison between histogram and probability density function of residual (low frequency) current velocity

PROBABILITY DISTRIBUTION OF TOTAL CURRENT VELOCITY

In this section, the probability density function of the vector sum of tidal and residual current velocities, hereafter called the total current velocity, will be derived. Here, the total current velocity is equal to the measured current velocity illustrated in Figure 1.

The magnitude of the total current velocity, denoted by C , can be written by the following vector sum of tidal and residual velocities:

$$C = \{ H^2 + L^2 + 2HL \cos(\theta_H - \theta_L) \}^{1/2}, \quad (9)$$

where H = magnitude of tidal current velocity, L = magnitude of residual current velocity, θ_H = directional angle of tidal current velocity, θ_L = directional angle of residual current velocity.

It was obtained in the previous section that the random variables H and L both follow the Rayleigh probability law. Hence, the probability distribution of the sum of the first two terms of Eq. (9), $(H^2 + L^2)$, can be obtained as follows:

It can easily be derived that the square of the Rayleigh probability distribution becomes the exponential probability distribution. That is, by writing H^2 and L^2 as H_* and L_* , respectively, we can derive the following probability density functions of H_* and L_* .

$$f(H_*) = \frac{1}{R_H} \exp\{-H_*/R_H\}, \quad f(L_*) = \frac{1}{R_L} \exp\{-L_*/R_L\}, \quad (10)$$

where

$$R_H = 4 / \left(\frac{1}{\sigma_{HU}^2} + \frac{1}{\sigma_{HV}^2} \right) \quad \text{and} \quad R_L = 4 / \left(\frac{1}{\sigma_{LU}^2} + \frac{1}{\sigma_{LV}^2} \right). \quad (11)$$

Since the random variables H and L are statistically independent [1], the probability density function of the sum of the random variables H_* and L_* , denoted by X , can be obtained as

$$\begin{aligned} f(x) &= \int_0^x \frac{1}{R_H} \exp\{-H_*/R_H\} \cdot \frac{1}{R_L} \exp\{-(x-H_*)/R_L\} dH_* \\ &= \frac{1}{R_H - R_L} \left(e^{-\frac{x}{R_H}} - e^{-\frac{x}{R_L}} \right), \quad 0 \leq x < \infty. \end{aligned} \quad (12)$$

Next, let us derive the probability density function of the third term of Eq.(9). For this, first the probability density function of $L \cos(\theta_H - \theta_L)$ is considered. Results of analysis show that the difference of the two angles $\theta_H - \theta_L$ scatters in random fashion over the range from $-\pi$ to $+\pi$; therefore, we may assume that $\cos(\theta_H - \theta_L)$ is a random variable and it has a uniform distribution over the range -1 to $+1$ with a density of $1/2$. It can also be assumed that the random variables L and $\cos(\theta_H - \theta_L)$ are statistically independent. Then the probability distribution of the product of $L \cos(\theta_H - \theta_L)$, denoted by Y , can be written as

$$f(y) = \begin{cases} \int_y^\infty \frac{1}{2} \frac{1}{L} f(L) dL & \text{for } y > 0 \\ \int_{-|y|}^\infty \frac{1}{2} \frac{1}{L} f(L) dL & \text{for } y < 0, \end{cases} \quad (13)$$

where $1/L$ is the Jacobian associated with the change of random variables, and $f(H)$ is given in Eq.(8). The probability density function $f(L)$ is symmetric with respect to $y=0$. Hence, we may write the function as

$$f(y) = \frac{1}{R_L} \int_{|y|}^\infty \exp \left\{ -L^2/R_L \right\} dL = \sqrt{\pi/R_L} \Phi \left(-\sqrt{2/R_L} |y| \right), \quad (14)$$

where $Y = L \cos(\theta_H - \theta_L)$ and R_L is given in Eq.(11).

The probability density function of $HL \cos(\theta_H - \theta_L)$ can be derived as the density function of the produce of two random variables H and $Y = L \cos(\theta_H - \theta_L)$ which are statistically independent. However, the derivation is extremely complicated in practice because of the density function $f(y)$. Hence, the probability density function $f(y)$ is approximated by the following normal probability density function:

$$f(y) = \sqrt{2/\pi R_L} \exp \left\{ -2|y|^2/R_L \right\}. \quad (15)$$

A comparison of Eq.(14) with its approximation given by Eq.(15) is shown in Figure 8 in which the random variable Y is non-dimensionalized by letting $Y = \sqrt{R_L}/2 X$.

By applying this approximation, the probability density function of $HL \cos(\theta_H - \theta_L)$, denoted by Z , can be derived from Eqs.(7) and (15). That is,

Figure 8 Comparison between $f(x)$ and its approximation by $(1/\sqrt{\pi})\exp\{-|x|^2\}$, where $y = \sqrt{R_1/2} x$ in Eq.(15)

$$f(z) = \int_0^u \frac{2}{R_H} \sqrt{\frac{2}{\pi R_L}} \exp\left\{-\frac{H^2}{R_H}\right\} \exp\left\{-\frac{2}{R_L}\left(\frac{z}{H}\right)^2\right\} dH$$

$$= \sqrt{\frac{2}{R_H R_L}} e^{-2\sqrt{\frac{2}{R_H R_L}} |z|}, \quad -\infty < z < \infty . \tag{16}$$

From the above equation, the probability density function of $2Z = 2HL \cos(\theta_H - \theta_L)$ which is the third term of Eq.(9) can be obtained. That is, by writing $2Z = W$, we have

$$f(w) = \frac{1}{\sqrt{2R_H R_L}} e^{-\frac{2|w|}{\sqrt{2R_H R_L}}}, \quad -\infty < w < \infty . \tag{17}$$

The probability density function of C^2 can now be evaluated as the density function of the sum of the two random variables X and W which are considered to be statistically independent and whose probability density functions are given in Eqs.(12) and (17), respectively. Since the random variable C^2 is positive only, we consider the following two cases for both of which the sum of X and W is positive.

(i) For $X > 0$ and $W > 0$.

By writing the random variable $C^2 = U = X + W$, we can derive the probability density function $f(u)$ from Eqs.(12) and (17) as

$$f(u) = \int_u^\infty \frac{1}{R_H - R_L} \left(e^{-\frac{x}{R_H}} - e^{-\frac{x}{R_L}} \right) \frac{1}{\sqrt{2R_H R_L}} e^{-\frac{2(u-x)}{\sqrt{2R_H R_L}}} dx$$

$$\begin{aligned}
 &= \frac{1}{\sqrt{2}} \left[\frac{1}{(\sqrt{2R_H} - \sqrt{R_L})(\sqrt{2R_L} - \sqrt{R_H})} e^{-\sqrt{\frac{2}{R_H R_L}} u} \right. \\
 &\quad \left. + \frac{\sqrt{R_H}}{(R_H - R_L)(\sqrt{2R_H} - \sqrt{R_L})} e^{-\frac{u}{R_H}} - \frac{\sqrt{R_L}}{(R_H - R_L)(\sqrt{2R_L} - \sqrt{R_H})} e^{-\frac{u}{R_L}} \right] \tag{18}
 \end{aligned}$$

(ii) For $x > 0$ and $W < 0$ but $U = X + W > 0$.

By writing $|W| = X - U$ in Eq.(17), we have

$$\begin{aligned}
 f(u) &= \int_u^\infty \frac{1}{R_H - R_L} \left(e^{\frac{x}{R_H}} - e^{\frac{x}{R_L}} \right) \frac{1}{\sqrt{2R_H R_L}} e^{-\frac{2(u-x)}{\sqrt{2R_H R_L}}} dx \\
 &= \frac{1}{\sqrt{2}} \frac{1}{R_H - R_L} \left[\frac{\sqrt{R_H}}{\sqrt{2R_H} + \sqrt{R_L}} e^{-\frac{u}{R_H}} - \frac{\sqrt{R_L}}{\sqrt{2R_L} + \sqrt{R_H}} e^{-\frac{u}{R_L}} \right] \tag{19}
 \end{aligned}$$

The sum of Eqs.(18) and (19) yields the probability density function of U . However, we consider only positive U in the above and discard the sum of the two random variables X and W for which U becomes negative. Hence, it is necessary to normalize the resultant probability density function so that the area under the density function is unity. By taking normalization into consideration, we have

$$\begin{aligned}
 f(u) &= L \left[\frac{1}{\sqrt{2}} \frac{1}{(\sqrt{2R_H} - \sqrt{R_L})(\sqrt{2R_L} - \sqrt{R_H})} e^{-\sqrt{\frac{2}{R_H R_L}} u} \right. \\
 &\quad \left. + \frac{2}{R_H - R_L} \left(\frac{R_H}{2R_H - R_L} e^{-\frac{u}{R_H}} - \frac{R_L}{2R_L - R_H} e^{-\frac{u}{R_L}} \right) \right], \quad 0 \leq u < \infty \tag{20}
 \end{aligned}$$

where

$$L^{-1} = \frac{1}{2} \frac{\sqrt{R_H R_L}}{(\sqrt{2R_H} - \sqrt{R_L})(\sqrt{2R_L} - \sqrt{R_H})} - \frac{2(R_H^2 - R_H R_L + R_L^2)}{(2R_H - R_L)(2R_L - R_H)} \tag{21}$$

Finally, by changing the random variable U to C where C is the square-root of U, we can derive the probability density function applicable for the total current velocity given in Eq.(9) as follows:

$$f(C) = L \left[\frac{\sqrt{2} C}{(\sqrt{2R_H} - \sqrt{R_L})(\sqrt{2R_L} - \sqrt{R_H})} e^{-\sqrt{\frac{2}{R_H R_L}} C^2} + \frac{4 C}{R_H - R_L} \left(\frac{R_H}{2R_H - R_L} e^{-\frac{C^2}{R_H}} - \frac{R_L}{2R_L - R_H} e^{-\frac{C^2}{R_L}} \right) \right], \quad 0 \leq C < \infty. \quad (22)$$

A comparison between the theoretical probability density function derived in Eq.(22) and the histogram of the total current velocity constructed from measured data is shown in Figure 9. Good agreement can be seen in the figure. The values of R_H and R_L of Eq.(22) are computed by Eq.(11) in which variances are evaluated through spectral analysis [1]. These are

$$\sigma_{HU}^2 = 334.3 \text{ (cm/sec)}^2, \quad \sigma_{HV}^2 = 293.7 \text{ (cm/sec)}^2, \\ \sigma_{LU}^2 = 248.7 \text{ (cm/sec)}^2, \quad \text{and} \quad \sigma_{LV}^2 = 214.2 \text{ (cm/sec)}^2.$$

Figure 9 Comparison between histogram and probability density function of total current velocity

Next, let us evaluate the magnitude of extreme current velocity expected to occur in 20 and 50 years. For this, the cumulative distribution function of the total current velocity is obtained by integrating Eq.(22) as follows:

$$\begin{aligned}
 F(C) &= \int_0^C f(C) dC \\
 &= L \left[\frac{\sqrt{R_H R_L}}{2(\sqrt{2R_H} - \sqrt{R_L})(\sqrt{2R_L} - \sqrt{R_H})} \left(1 - \exp \left\{ -\sqrt{\frac{2}{R_H R_L}} C^2 \right\} \right) \right. \\
 &\quad + \frac{2R_H^2}{(R_H - R_L)(2R_H - R_L)} \left(1 - \exp \left\{ -\frac{C^2}{R_H} \right\} \right) \\
 &\quad \left. - \frac{2R_L^2}{(R_H - R_L)(2R_L - R_H)} \left(1 - \exp \left\{ -\frac{C^2}{R_L} \right\} \right) \right] \tag{23}
 \end{aligned}$$

Then, by applying extreme value statistics, the probable extreme value most likely to occur in n-observations can be evaluated as a solution of the following equation:

$$\frac{1}{1 - F(C)} = n \tag{24}$$

Here, n is the number of samples in a specified time period. Since n = 1911 in 4 months for this example, the extreme values in 4 months, 20 years and 50 years are estimated as shown in Figure 10. For convenience, the logarithm of Eq.(24) is shown in the figure. The estimated extreme current velocity in 4 months is 76 cm/sec as compared with 74 cm/sec observed in the data. The extreme values expected in 20 and 50 years are 92.0 cm/sec and 94.5 cm/sec, respectively, as indicated in the figure.

Figure 10 Estimation of extreme current velocity in 4 months, 20 and 50 years

CONCLUSIONS

This paper presents the results of a study on stochastic analysis of offshore currents. The objective of the study is to estimate the extreme magnitude of offshore current velocities based on the probability density functions applicable for tidal (high frequency components), residual (low frequency components), and total (the vector sum of tidal and residual) current velocities. From the results of the analysis, the following conclusions are derived:

(1) It is found theoretically that the tidal (high frequency components) current velocity follows the Rayleigh probability law. The probability density function is given in Eq.(7). The parameter of the probability density function is given as a function of variances of high frequency components in two rectangular directions.

(2) Similarly, the magnitude of residual (low frequency components) current velocity follows the Rayleigh probability law and its density function is given in Eq.(8).

(3) The probability density function of the total current velocity (the vector sum of tidal and residual current velocities) is analytically derived as given in Eq.(22).

(4) The theoretical probability density functions are compared with histograms constructed from measured data and good agreement between them is obtained.

(5) A method for estimating the extreme value of the total current velocity expected in a specified time period is developed from knowledge of the variances of high and low frequency components in two rectangular directions.

ACKNOWLEDGEMENTS

This research was sponsored by the Office of Naval Research, Ocean Technology Program, through contracts N00014-88-K-0537 to the University of Florida. The author would like to express his appreciation to Drs. E.A. Silva and S.E. Ramberg for their valuable technical discussions received during the course of this project. The author is grateful to Dr. Max Sheppard for his kind help in obtaining the current data used in this study. The author also wishes to express his appreciation to Ms. Laura Dickinson for typing the manuscript.

CHAPTER 70

BREAKING AND REFLECTION OF A STEEP SOLITARY WAVE CAUSED BY A SUBMERGED OBSTACLE

Takashi Yasuda, Masanori Hara

ABSTRACT

A fully nonlinear potential flow theory is solved numerically but almost exactly for a solitary wave passing over a submerged obstacle by using BIM. Based on the numerical solutions, the reflection characteristics and the breaker type and criterion are made clear for a solitary wave up to breaking caused by a step.

1. INTRODUCTION

A sound knowledge on the transformation including the breaking of steep coastal waves over a submerged obstacle is important for planning and designing submerged coastal structures. However, few knowledge is obtained on the breaking caused by a submerged obstacle including a discontinuity in depth.

It has often been remarked that waves on beaches resemble solitary waves. In fact, steep coastal waves are demonstrated to be representable as a random train of solitons (Tsuchiya & Yasuda, 1986). Hence, it may be better to consider each wave crest as a solitary wave and investigate its transformation, rather than to examine directly that of steep coastal waves.

A computational model to be used here is based on BIM and has already developed by authors (1989). It can describe almost exactly the transformation up to overturning of the solitary wave propagating over a bed

* Prof., Dept. of Civil Eng., Gifu Univ., Gifu 501-11, JAPAN

** Eng., Civil Eng. Dept., Idemitsu Engineering Co., Ltd., 37-24 Shinden cho, Chiba 260, JAPAN

containing a submerged obstacle.

This study aims to make clear the breaker criterion and reflection characteristics of steep solitary waves passing over a step by using the computational model (Yasuda et al., 1989) which can describe almost exactly the transformation up to overturning of the solitary wave.

2. COMPUTATIONAL MODEL

In this study, the solitary wave given by the exact steady solution of fully nonlinear potential-flow theory is supposed over the planar of left side from the obstacle, and the still water is supposed over the obstacle and its right side planar in a two-dimensional domain. Further, the Cauchy integral theorem is introduced to solve Laplace's equation under the condition on the rigid boundary. The updating of the free surface profile and the velocity potential is based on the second-order Taylor expansion in a mixed Eulerian-Lagrangian formulation as well as Dold & Peregrine (1986).

3. VALIDITY OF THE MODEL

The first check of the time stepping accuracy is provided by examining the growth of the error energy defined by

$$E(t) = \frac{1}{2} \int_{-\infty}^{\infty} [\eta(x, t) - Y(x - ct)]^2 dx, \quad (1)$$

where Y is the surface displacement of the steady solitary wave mentioned above, c its propagation speed and η the water surface profile given by the present numerical solution. A test is made on the solitary wave in still water up to the dimensionless time $t\sqrt{g/h}=12$. Here, h is the undisturbed water depth and g the acceleration of gravity. While the wave has propagated on the distance of $15h$, $E(t)$ remains less than 3×10^{-5} in value. (Note, for comparison, that for the wave under consideration $(1/2) \int Y^2 dx = 0.42$.)

The second check is provided by examining the validity of the model against carefully controlled experiments in a wave tank (1m×1m×54m). The desired steep solitary wave is generated by using a servo-controlled, hydraulically activated wave maker. The

free surface displacement is measured with the capacitance-type wave gauges installed at three locations, P.1, P.2 and P.3 which are placed at the front of the obstacle, just behind of it and at the breaking point of the transmitted solitary wave, respectively. The breaking point is defined as the onset of the formation of a jet or bubble plume. The location of P.3(breaking point) is decided for each incident solitary wave by using a high speed video camera and observing the presence of the jet or bubble plume.

Figure 1 shows an example of the computed shape of the free surface at some evolution times. The initial wave-height H/h of the incident solitary wave is 0.4, and the relative height R/h and length B/h of the submerged breakwater model are $4/7$ and $24/7$, respectively. It is found that while the transmitted

Fig.1 Transformation of a solitary wave passing over a submerged break-water

solitary wave makes its front face overturn at the location of P.3, the reflected wave propagates backward as a small but noticeable solitary wave.

Figure 2 describes the temporal changes of the crest-height η_c/h and the horizontal water particle velocity U_c/\sqrt{gh} and the gradient angle of the front face θ at the top of the solitary wave shown in Fig.1. It is found that the gradient angle θ reaches -90 degrees and the front face becomes vertical at the onset when the top of the wave passes through the location of P.3 where the formation of a jet was observed in the experiment. Hence, the onset of overturning can be defined as the breaking point in the computational model.

Figure 3 shows the comparisons of the temporal surface elevation of the solitary wave shown in Fig.1 between the results computed by the model and the experimental results measured with the wave gauges installed at P.1, P.2 and P.3. The computed and measured profiles can not be quite distinguished up to the overturning location(P.3), nevertheless the formation of vortex was observed behind the end of submerged breakwater. This remarks that the numerical

Fig.2 Temporal changes of the quantities η_c/h , U_c/\sqrt{gh} and θ .

Fig.3 Comparisons with temporal water surface elevation between numerical and experimental results

results for the transformation of steep solitary waves over submerged obstacles are in excellent agreement with tank measurements up to overturning and the present model makes it possible not only to describe the transformation including overturning but also to predict the breaking point.

Further, in order to demonstrate the accuracy of the numerical solution obtained by using the present scheme, we carried out some numerical simulations of solitary waves propagating over a gently sloping bottom under the same initial wave-height H/h and bottom slope $\tan \theta$ with Papanicolaou and Richlen's experiment (1988). The breaker wave-height H_b/h was compared between the numerical results, where the breaker point is defined as the onset of overturning and experimental results by Papanicolaou and Richlen (for brevity P-R). Table 1 shows the results of the comparisons. It can be easily recognized from this table that the breaker wave-heights computed with the present model agree with those obtained by P-R within the error degree of 1%. This remarks that the breaking criteria could be established for the solitary waves without carrying out experimental works in a wave tank.

Table 1 Comparison with the breaker wave-height between the present numerical results and experimental ones by P-R

H / h	tan θ	H _b /h	
		Experi. (P-R)	Numeri.
0.2	0.0141	1.222	1.218
0.3	0.0126	1.086	1.077
0.4	0.0126	1.071	1.080

4. DEFORMATION UP TO BREAKING AND REFLECTION

Figure 4 shows the propagation processes of solitary waves up to breaking points. While the wave profile at the breaker point shown in Fig.4(a) seems to be a spilling breaker, the wave profile shown in Fig.4(b) could be regarded clearly as a plunging breaker. From these results, we can be convinced that both breaker types of spilling and plunging occur even in the case except for sloping bottoms and depend on a parameter ξ_s defined by authors (Yasuda, Hara & Sakakibara 1990) as

$$\xi_s^* = (R/h)/(H/h)^{2/5}, \quad (2)$$

where H denotes the initial wave-height of an incident solitary wave, h the still water depth in front of the rectangular step and R its height.

Further, we define a horizontally asymmetric parameter β_4

$$\beta_4 = \frac{-1}{2B} \int_{-B}^B \eta_x dx, \quad (3)$$

as the breaker type index, since the breaker type could be supposed to correspond directly to horizontal asymmetry. Here, the integral region B in the equation is indicated in Fig.5 Figure 6 shows the relation between the values of the parameter ξ_s of incident solitary waves and the parameter β_4 calculated from their wave profiles at breaker points.

Figure 7 indicates the backward propagation process of a reflected wave from a rectangular step. The reflected wave also seems to propagate as a steady solitary wave. Hence, we can easily define the reflection coefficient Kr of a solitary wave as a ratio

(a) Spilling breaker
 ($H/h=0.50$, $R/h=0.4$, $\xi_s = 0.032$)

(b) Plunging breaker
 ($H/h=0.36$, $R/h=0.6$, $\xi_s = 0.100$)

Fig.4 Temporal changes of wave profile of a solitary wave passing over a step

Fig.5 Region of integration for a horizontally asymmetric parameter β_4

Fig.6 Relation with the breaking of a solitary wave caused by a step between ξ_s^* and β_4

Fig.7 Backward propagation of a reflected wave from a step

of an incident wave-height H to a wave-height of the reflected solitary wave. Figure 8 shows the comparison of the relation of the reflection coefficient K_r to the relative step-height R/h between the computed results by the present model and the experimental ones by Seabra-Santos et al(1987). In the figure, a solid line indicates the result calculated by Lamb's formula

$$K_r = \frac{1 - \sqrt{1/(1 - R/h)}}{1 + \sqrt{1/(1 - R/h)}} \quad , \quad (4)$$

Fig.8 Relation of the reflection coefficient K_r from a step to its relative step height R/h

and a broken line denotes the theoretical result suggested by Yajima(1984) who solved the reflection problem of the KdV soliton using the inverse scattering method.

$$K_r = \frac{1}{4} \left\{ \sqrt{1 + 8 \frac{\sqrt{1/(1-R/h)} - 1}{\sqrt{1/(1-R/h)} + 1}} - 1 \right\}^2 \quad (5)$$

The regression curve is drawn with the following equation

$$K_r = 0.460(R/h)^{1.745} \quad (6)$$

It is made clear that the reflection coefficients obtained by the present model are independent of the amplitudes of incident waves as well as both the results of Lamb and Yajima, although they reveal the intermediate characteristics between eq.(4) and eq.(5). This remarks that the reflection coefficient of steady waves from a step is almost independent of the order of their nonlinearity but mainly depends on the relative step-height R/h alone.

5. BREAKING CRITERIA

Figure 9 shows the relation between the wave-height H/h of incident solitary wave of which front face

Fig.9 Relation of the presence of breaking caused by a step to the initial wave-height of incident solitary wave H/h and relative step-height R/h

overtURNS or not on a step and the relative step-height R/h . The solid line indicates the limiting wave-height H_c/h of the solitary wave which can be transmitted without breaking. The limiting wave-height is almost inversely proportional to the step-height. From the relation between H/h and R/h , the value of the critical step-height comes to light against each incident solitary wave which propagates over the step without breaking.

Figure 10 shows the breaking criteria of a solitary wave over a step, that is, the relation of the crest-height at the onset of breaking η_b/d and the limiting wave-height H_c/d to the relative step-height R/h . Here, d is the water depth on the step and is equal to $h-R$. It should be noted that the value of η_b/d is almost constant and is nearly 0.9, independently of the step-height. This remarks that the solitary wave having the crest-height under about 0.9 does not break on the step, even if the crest-height exceeds 0.78 which is the maximum crest-height of the steady solitary wave on a flat bottom. The solitary wave having the crest-height between 0.78 and 0.9 suffers fission on the

Fig.10 Breaking criterion of a solitary wave over a step

step, instead of breaking.

6. CONCLUDING REMARKS

It is verified through carefully controlled experiments that the present model enables us to compute very accurately the transformation of a steep solitary wave leading to breaking. Many numerical simulations using the model yield the breaker criterion and reflection coefficients of steep solitary waves over a step and further make clear the characteristics of reflected waves consisting of the positive solitary wave from the submerged breakwater.

7. ACKNOWLEDGEMENT

The authors wish to express their thanks to Dr. M. Tanaka of Gifu Univ. for his valuable advice.

CHAPTER 71

REPORT FROM THE NATO ARW ON WATER WAVE KINEMATICS, MAY 1989

by
Alf Tørum¹ and Ove T. Gudmestad²

ABSTRACT

A report is given on the NATO Advanced Research Workshop on "Water Wave Kinematics" held in Molde, Norway, 22 - 25 May 1989. The reports from the five working groups set up during the workshop are included in full.

1. INTRODUCTION

Water wave kinematics is a central field of study in ocean and coastal engineering. The wave forces on structures as well as sand erosion on coastlines and in the ocean are to a large extent governed by the local distribution of velocities and accelerations of the water particles.

Our knowledge of waves has generally been derived from measurements of the water surface elevations. The reason for this is that the surface elevations have been of primary interest and fairly cheap and reliable instruments have been developed for such measurements. The water wave kinematics has been derived from the surface elevation information by various theories. However, the different theories for the calculation of water particle velocities and acceleration have turned out to give significant differences in the calculated responses of structures. In recent years new measurement techniques have made it possible to make accurate velocity measurements. Hence, the writers deemed it to be useful to bring together a group of experts working actively as

¹ Head of Research/Professor. Norwegian Hydrotechnical Laboratory/Norwegian Institute of Technology, 7034 Trondheim, Norway.

² Dr. Scient/Dicipline Leader, Statoil, P.O. Box 300, 4001 Stavanger, Norway.

researchers in the field of water wave kinematics. These experts included theoreticians as well as experimentalists on wave kinematics. It was also deemed useful to include experts on the response of structures to have their views on what information is needed on water wave kinematics.

The objectives of the workshop were:

- to summarize research related to wave kinematics (state-of-the-art)
- to define approaches for design of safe and cost efficient offshore and coastal structures
- to exchange ideas and methodologies and to serve as a forum for idea generation
- to define further research needs and the most efficient methods to solve those needs.

A grant from NATO International Scientific Exchange Programme made it possible to hold a NATO Advanced Research Workshop in Molde, Norway, 22 - 25 May 1989. Additional funding was obtained from Statoil, Norway, the Royal Norwegian Council for Scientific and Industrial Research, Norway (NTNF) and from the Foundation for Scientific and Industrial Research at the Norwegian Institute of Technology, (SINTEF), Norway.

The workshop was organized as a series of lectures, including invited lectures, with discussions. Five working groups were also set up on five different subjects: Deep water waves, shallow water waves, breaking and freak waves, measurements and forces. The discussions and conclusions of the working groups were summarized in reports.

The scientific committee for the workshop had the following members:

Professor A. Tørum
Norwegian Hydrotechnical Laboratory/
Norwegian Institute of Technology, Norway.
Director of the Workshop.

Dr. Scient. O.T. Gudmestad
Statoil, Norway
Director of the Workshop

Professor R.G. Dean
University of Florida, USA

Professor D.H. Peregrine
University of Bristol, United Kingdom

Dr. S. Sand
Danish Maritime Institute, Denmark

60 persons from 13 different countries attended the workshop.

The proceedings from the workshop have been published by Kluwer Academic Publishers, The Netherlands. The title of the proceeding is "Water Wave Kinematics" with A. Tørum and O.T. Gudmestad as editors. 35 papers and 13 written short contributions are included in the proceedings. The proceedings also contain the reports of the working groups.

It is not possible within the framework of the paper to ICCE'90 to give proper justification to all the papers and discussions. However, it is felt that the summary reports from the working groups give state-of-the-art reports as well as recommendations for further research. They are therefore included in this paper.

2. REPORT FROM THE WORKING GROUP ON DEEP WATER WAVE KINEMATICS

2.1. INTRODUCTION AND SUMMARY

There are presently many wave kinematics procedures that are used by the offshore engineer to calculate design kinematics. These procedures include the highly nonlinear, two-dimensional breaking wave methods, the linear, random three-dimensional methods and others. In many cases the application determines the procedure to be used, e.g. for steel piled jacket (SPJ) static design the Stokes type procedures have traditionally been used. In other instances, the choice of the procedure depends on regulatory agency requirements, familiarity, available experimental verification, and also simplicity. The argument can be made that all these procedures have served the offshore industry well since there have been no major offshore platform failures that are directly attributed to wave kinematics inaccuracies. This success, however, may be due to general conservative approaches used in platform design, and to compensating factors. All procedures represent approximations to the real offshore kinematics problem, and as design procedures become more sophisticated, aiming to improve safety while reducing platform costs, there is a two-fold need (1) for additional verification and improvement of the various available procedures and (2) for development of procedures that solve satisfactorily the general problem of three-dimensional irregular waves with currents. The additional verification and establishment of ranges of applicability of present pro-

cedures is of utmost importance since some of the procedures, e.g. stretching methods for irregular waves, give significantly different kinematics in the wave crest region.

2.1.1. Statement of the problem

The general problem of wave kinematics and currents in deep water is quite complex, and needless to say it has not been solved. The physical model assumed for this discussion is deterministic (stochastic aspects of wave kinematics are not considered) and includes:

- regular or irregular finite height, non breaking waves
- wave conditions with or without energy spreading
- wave conditions with or without current.

In the case of waves only or waves with uniform current, the fluid is assumed irrotational and incompressible. For the case of nonuniform current with waves, the appropriate vorticity is assumed to be included. It is believed that any accurate solution to the analytical relationships describing this stated problem will give sufficiently accurate kinematics. Of course this will need to be substantiated with data.

2.1.2. Status

A satisfactory method for calculating kinematics in the general irregular wave with energy spreading cases that satisfies to high degree of accuracy Laplace's equation and boundary conditions is not presently available. For practical application, however, there are many analytical and empirical procedures that can be used depending on application. These procedures are backed up by varying degrees of experimental and/or analytical verification.

The extension of the two-dimensional wave procedures to three-dimensional waves is not straightforward neither from the analytical or technical nor from the wave input description side. Available solutions (empirical or low order analytical) are approximate, and, no extensive comparisons with data have been carried out.

The presence of storm tide or other non-uniform currents adds to the difficulty of the general wave only problem. Analytical solutions for regular waves (Stokes) with arbitrary current profiles are available. Also, empirical solutions are available for the general case, but those solutions can benefit from additional data.

2.1.3. Recommendations

Further measurements in the laboratory followed by carefully defined field tests are required. Test programs should be based on the need of the offshore industry. The industry should define the acceptable levels of accuracy in the kinematics, which would normally depend on application.

It is also required to develop analytical or numerical methods which solve the more general problem of kinematics for currents plus irregular, three-dimensional waves. In order to achieve this goal there is need for international cooperation and data sharing. Definition of standard bench-mark wave and current cases would also expedite verification of the procedures.

2.2. KINEMATICS MODELS

There are four major classes of wave kinematics problems that are discussed below which represent different levels of difficulty in the search for solutions. These are: two dimensional waves with and without current, three-dimensional waves with and without current.

2.2.1. Two dimensional waves

There is no kinematics procedure or theory presently available for the general case which satisfies the governing equations and the boundary conditions. The relatively new boundary integral methods hold promise but at present have computational and free boundary limitations.

Simple procedures (e.g. Wheeler stretching, delta stretching, Gudmestad method etc) which represent extrapolations of linear theory to finite height irregular waves have been successfully compared to available data according to published results. Since these procedures are basically empirical, their use far outside the range of wave parameters for which they have been verified should be done with caution. Additional kinematics data (laboratory and field) are needed in the wave crest to further verify and define the range of applicability of these methods. Theoretical efforts to assess the methods are also worthwhile.

There exist analytically robust procedures (Stokes methods, boundary integral methods, etc) to treat regular or or limited groups of waves with high accuracy although further testing against available data is necessary for these procedures, also. Verified methods

for using these procedures with irregular waves are yet to be established.

Numerical procedures (e.g. stream function, EXVP method, etc) that treat irregular single or multiple waves can also be used. These procedures fit with high accuracy one or both boundary conditions. The applicability of these procedures is limited by the assumptions they are based on (rigid shape or changing shape waves) and the required length of the wave trace that can be treated.

Linear theory could be used for low wave steepness or for elevations beyond one wave height below the deepest wave trough. Higher order theories (2nd order) are available and are applicable for low steepness. These theories, however, require additional comparisons with data, also.

2.2.2. Three dimensional waves

There is no general theory presently available apart from general linear wave theory and there is no procedure under development which is computationally efficient for the nonlinear case. Some of the available two-dimensional empirical procedures (stretching methods) may in principle be extended to the three-dimensional wave case. Test data will be needed to verify the accuracy of such extensions.

The linear wave theory could be used for the low wave steepnesses. Higher order numerical procedures (e.g. Forristalls KBCF-method) could be used if made computer efficient. Here also there is a need for data verification.

2.2.3. Current with waves

There is no analytical procedure available for the general case. There are, however, empirical procedures which are used by the offshore industry; these procedures have not been validated with data. For two-dimensional, steady regular waves and collinear current of arbitrary profile new theories exist and insight can be gained with these theories as to how waves interact with currents. Measurements are needed in the wave zone in particular to test the goodness of these various procedures.

2.3. RECOMMENDATIONS

The recommendations below address both short term and long term needs. The wave kinematics problem remains

still a challenging problem for the theorists and experimentalist, and will require good imagination to bring about new and improved solutions that can be put to use in offshore design.

2.3.1. Data

It is recommended that the industry clearly define the required accuracy of new data needed for the different applications. Laboratory measurements on kinematics for the following wave cases are needed:

- 2D regular waves and groups of waves for a larger range of parameters to verify analytical and numerical procedures;
- 2D irregular waves to verify and extend the test data base;
- 2D current with regular and irregular waves;
- 3D irregular waves in order to extend methods and procedures presently used for 2D waves;
- 3D irregular waves with current.

The laboratory tests should also aim towards definition of field tests which subsequently should be carried out.

2.3.2. Analysis methods

Research should concentrate on the following main tasks:

- Develop fully consistent 2D theory for irregular waves;
- Develop empirical procedures for current with waves;
- Develop fully consistent 2D theory for current with regular and with irregular waves;
- Extend empirical procedures from 2D to 3D,
- Develop higher order analytical and numerical procedures for 3D irregular waves with and without current;
- Clarify further the mean flow in the kinematics in waves.

2.4. COOPERATION

In order to successfully develop the analytical tools needed and to fully benefit from future testing in the laboratory and in the field, international cooperation is required. It is recommended that standard test cases be defined through the cooperation of the offshore industry and research institutions in order to verify procedures. For advancing the kinematics procedures, it

is essential that there be data sharing. Also, the offshore industry must continue to provide data for long term research projects at the institutions and the research institutions must continue to carry out basic research to solve engineering needs.

3. REPORT FROM THE WORKING GROUP ON SHALLOW WATER WAVE KINEMATICS

INTRODUCTION

The Working Group on Shallow Water Wave Kinematics (WGSWK) defined "shallow water" as extending from the conventional deepwater limit, $h/L_0 = 0.5$, to the shoreline. A decision was made to focus on the needs for the next two or so decades with criteria of methodology and data required by the designer and a generally improved understanding of the phenomena related to shallow water wave kinematics. Although of importance, wave hindcasting was not considered as within the Group's scope. Finally, in order to provide focus to our recommendations, only six problem areas have been selected for emphasis.

STATUS

The shallow water region is characterized as one of substantial nonlinearity, and directionality with the possibility of strong currents and large tidal fluctuations. At present, substantial variability in methodology ranging from ad hoc to sophistication is employed in the prediction of shallow water wave kinematics. The range of methodology encompasses regular vs irregular waves, deterministic vs stochastic representation and various methods of combining waves and currents. Although each of them can play useful roles, a better understanding is needed of the strength and relatively applicability and differences to be expected. Regulatory agencies prefer straight forward procedures suitable for codification. A need exists to develop and introduce procedures that have greater realism and physics and can be readily applied by industry.

The workshop addressed a number of problems relative to shallow water kinematics. It was concluded that for the case of regular waves without currents, existing wave theories are adequate. However, more emphasis needs to be directed to the problems of regular waves with a current which varies over depth. Of particular concern is the appropriateness of methods for predicting near surface kinematics. Due, in part, to the high nonlinearity of the surf zone and the significance of sediment transport in this area, more effort here is needed.

Other areas of research need are described in the following sections of this Working Group Report.

LONG-TERM CLIMATE DESCRIPTION

A Long-term climate description of a region is an important engineering activity which requires research in order to improve its reliability. In the absence of long-term widespread measurements, emphasis is thrown onto the use of recently developed shallow water codes such as -3 GWAM. The hindcasting is performed for adjacent deep water and wave energy is then radiated in towards the shallow water region. Inherent difficulties with this systematic approach centre around the influence of current-interaction, shoaling, and large variations of still water level with time. Areas of immediate research concern include the following:

- Algorithms to optimize long-term information whilst reducing the bulk of wind and pressure fields processed. (Such as sequential bootstrapping techniques and other sub-sampling procedures).
- Improving storage techniques for time-step and spatial interpolation.
- Statistical methods for addressing questions of simultaneity of water depth, current wave fields.

B. Although many platforms are equipped to record sea-state data, this is still done on a systematically intermittent basis (e.g. 20 minutes for each 3 hours). This appears to be satisfactory for most spectral and statistical requirements, but cannot be expected to record the more extreme events which may occur whilst the instruments are on stand-by. Without resorting to continuous recording, and hence involving storage and servicing problems, it would be highly desirable to develop methods of recording the extreme events in as much detail as possible.

WAVE TRANSFORMATION & DETERMINISTIC MODELS

A In the analysis of nearshore wave phenomena, the starting point will most often be information (e.g., the directional wave spectrum) of the wave field in deep water. Therefore, one needs wave transformation models that can transfer this information into the shallow water area of interest and to provide input for surf zone models.

The different model employed are chosen according to the scale and distance from the shore of the area under consideration:

- Outer area:
Depth-Current refraction models (linear)
Ray theory, finite difference
Mesh size 100 m - 1 km
Size of area modelled 25 km² - 1000 km²
- Intermediate area:
Models based on mild slope equation (linear, extended to include dissipation and boundary absorption) the parabolic approximation (linear or weakly nonlinear and dissipative).
Mesh size: 5 m - 20 m.
Size of area modelled: 1 km² - 25 km².
- Harbour areas:
Models based on "Boussinesq equation". (Weakly nonlinear).
Helmholz equation or 30 linear potential solutions
Mesh size: 5 m - 20 m.
Size of area modelled: < 5 km².

Research needs:

- Spectral model including refraction, diffraction, frequency shifts due to wave breaking.
- Generation of long waves by short waves, and their transformation.

B As the water depth becomes small and/or the waves become high, the analytical wave models cease to be valid: The prediction of maximum waves of constant form (with or without current) require the use of stream-function-like theories. In some cases these data can also be fitted to extreme wave data to account for the asymmetry found in nature. Asymmetry statistics or realistic methods of generalizing wave asymmetry should be developed. The wave models for prediction of kinematics under waves should be evaluation with high quality data.

2D models based on potential flow can now solve fully nonlinear problems from deep to shallow water. Up to now they are however limited:

- to the first breaking wave
- lack of a radiation boundary for arbitrary waves
- cannot model friction and flow separation

Research should be directed toward:

- introducing variety
- investigating post-breaking extensions of such models
- developing a free boundary (i.e. weakly reflective boundary conditions)
- 3D potential flow models

WAVE-CURRENT INTERACTION

Waves interact with current in a number of important, and often nonlinear ways within the upper frictionless part of the water column and through their combined friction at the bed. These strongly influence the wave propagation characteristics, the current distribution, the resulting sediment transport, and forces on structures. The State of the Art and the Research Needs on various modes of interaction are as follows:

A Refraction

At the moment, refraction of linear waves by horizontally sheared, vertical uniform currents can be calculated. It is however, necessary to extend these methods to nonlinear waves.

B Kinematics

Methods for the computation of regular nonlinear waves on codirectional vertically sheared currents have recently appeared. They should be extended to non-codirectional cases, and to random waves. Also, they should be combined with above mentioned item to predict refraction and kinematics due to horizontally and vertically sheared currents.

C Mass transport

Theories exist to calculate the mass transport of water near the bed for a laminar wave boundary layer in the absence of currents. These should be extended, first to the turbulent wave boundary layer, then to the case where an external (e.g. tidal) current is imposed.

D Bottom friction

Several theories exist to calculate mean and peak bed shear stresses due to sinusoidal waves superimposed on a current. These prediction methods need to be simplified (without offering much of their accuracy) to be applicable in wave phase averaged numerical wave and current models. Also, extensions should be made toward

irregular (frequency and direction) waves, breaking waves and to distinguish the wave propagation direction.

All the above topics require advances through theoretical and numerical methods, and laboratory and field measurements.

The topics require to be combined together to provide fully interactive 2D numerical models of wave and current fields, leading possibly (on the long term) to 3D models.

NONLINEAR DIRECTIONAL WAVE THEORY

A constant reoccurring problem in ocean engineering consists of finding the best choice for a given application between random, linear, directional wave theory and nonlinear unidirectional deterministic wave theory. Each approach seems to be optimal for some class of problems, but there are other types of problems for which neither is quite right. A nonlinear, directional, wave theory is sorely needed to bridge between the two extremes. In recent years, several new approaches to the problem have emerged. This, coupled with the increasing power of available computers, makes now an appropriate item to undertake the solution of this reoccurrent problem, both for deep and shallow water.

One potential direction of attack is to combine waves from several directions while forcing satisfaction of the wave equation and free surface conditions. A second direction consists of an iterative procedure which starts with a linear, directional sea surface and, in a stepwise fashion, proceeds to modify the surface toward a better satisfaction of free surface conditions while maintaining the proper directional spectrum and any conditioning constraints.

There probably are other alternatives also available. The development of such a general random directional wave theory would be of great value in future ocean engineering investigations.

SPLASH ZONE KINEMATICS

The wave kinematics at or near the free water surface are very critical in determining overturning moment and other load parameters in an offshore structure. It is difficult to make field measurements of wave kinematics in this zone since the measuring devices are alternately submerged and in the air. The abrupt shock to the instrument at the moment of passing through the air-water interface typically induces transients in the

measurements which are difficult to interpret. Measurements of forces in the splash zone experience similar shock problems. Non intrusive measurement scheme for both kinematics and forces need to be developed and studied.

From an analytical perspective relative to random, linear directional wave theory, the prediction of kinematics and forces for locations above mean water level are perplexing and create paradoxes within linear wave theory. Linear theory assumes infinitesimal amplitudes and so kinematics above mean water level are contradictory. If the theory is used without modification above mean water level, the velocities are overestimated in a part of the force regime critical to most structural computations. Various "stretching" schemes have been proposed and used, but these are quite "ad hoc" in nature and theoretically unsatisfactory. It would be much more desirable to have some scheme which closely satisfies the free surface boundary conditions.

Some experiments have been carried out to investigate splash zone kinematics and forces under laboratory conditions. Use of these results demands a knowledge of scale effects which for these processes are poorly understood. In field conditions also there is likely to be a thin wind-induced surface current which may locally enhance particle velocities and forces.

In summary there is a research need for (a) improved instrumentation for measuring forces and kinematics in the wave splash zone, and (b) more theoretically sound ways to modify random linear directional wave theory for loading points in the splash loading zone. (c) improved understanding of scale effects and (d) of the importance of wind-induced surface currents.

SURF ZONE HYDRODYNAMICS SEDIMENT TRANSPORT

To further our understanding of the processes that shape our coastline, it is essential that we understand the hydrodynamics of the surf zone. Of particular interest are the distribution over depth of wave induced longshore and onshore-offshore currents and the momentum fluxes which drive them. Advances in this area will enable more refined studies of sediment transport modes and rates.

As has been stressed by Dr. N. Barltrop during this workshop it is important to determine the appropriate wave theory to use for a particular study. Waves in the surf zone are non-linear. The hydrodynamics of the surf zone is further complicated by the geometry of the

bottom. Therefore it is suggested that shallow water wave theories (for constant and variable depth) be evaluated for applicability over various geometries (starting with planar and simple curved geometries and eventually extending to geometries which include bars). In parallel with the theoretical studies numerical approaches (such as the Stream Function Wave Theory or the Numerical Wave Tank) should be considered. Infragravity waves can also cause substantial velocity fluctuations and water surface displacements in the surf zone.

The turbulence associated with wave breaking causes the wave height to decay which is directly related to the momentum fluxes. Thus studies to determine the variation of eddy viscosity over depth and across the surf zone are essential. Another process to be further studied is the reforming of waves as they propagate over the troughs between bars.

Further research is also required in including the effects of the bottom boundary layer on the wave induced currents. In the area of sediment transport studies are required to model sediment transport across the surf zone and over depth. Shallow water symmetrical and asymmetrical waves and their interactions with currents should be considered as driving mechanisms.

Sediment transport driven by random waves is also an area requiring research efforts.

Better models to quantify longshore and crossshore sediment transport rates for suspended and bedload load transport are required. The threshold of motion and sediment pick-up rates are topics still requiring better understanding. One area of particular interest is the determination of the extent over depth of the breaking induced mixing and its effects on sediment transport. In this respect breaker types should be considered in analysis. Equilibrium beach profiles also need further research. To obtain a broader understanding of the mechanisms shaping coastal regions the sediment transport outside the surf zone requires attention. The study of the transport in this zone including tidal and storm surge currents is of importance. Surf zone and non-surf zone models of transport need to be connected in attempts to obtain a global model.

The verification of the results of the investigations suggested through laboratory and especially field testing is of utmost importance.

4. REPORT FROM THE WORKING GROUP ON BREAKING AND FREAK WAVES

DEEP-WATER BREAKING

Presentations at the workshop have included discussion of waves breaking in deep-water but details are only given in the context of wave tank simulations. Conventional measurements at sea do not distinguish broken from unbroken waves.

We wish to emphasize that the physics of breaking waves can differ between wave tanks and waves at sea. In particular, the most frequent and important occurrences of deep-water breaking are in wind-driven waves. The character of wind-driven waves varies with their age, but at any time breaking is intermittent and short-crested. This makes it difficult to quantify and measure breaking events.

Statistics of breaking would be invaluable. Some statistics of white caps have been collected and are clearly related to breaking events. Efforts to quantify the relation would be welcome and should be contrasted with statistics of breaking based on spectral distributions which only present the exceeding of a mathematical criteria. Such criteria need to be established from the physics of wind-wave interaction. An initial approach based on measurements following the mariner's type of observation is recommended, e.g. the percentage of braking waves as a function of wind speed, the size and duration of white caps, depth of air entrainment etc. We consider relations between sea state and Beaufort number could be confirmed and compared with modern wind casting methods.

Short-crestedness implies a need to account for three-dimensional breaking in multi-directional seas, but first the behaviour of ideal regular waves needs clarification both experimentally and theoretically.

The important effects of wind, with its pressure distribution driving the waves and the vorticity that wind drift induces in the surface layer have yet to be quantified, although, their qualitative importance has been demonstrated. This research is urgently needed since wave breaking is intimately linked with wave generation, and this linkage produces the most severe states that ships and offshore structures encounter.

We propose that measurements of breaking wind-waves be first conducted in wind-wave flumes, where it should be possible to measure all significant parameters,

though some development of instrumentation may be needed, especially to recognise wave breaking. In particular local properties worth measuring include elevation, velocity, vorticity, turbulent intensity, in both air and water as well as air or water entrainment. General properties to be examined include the type of breaking, three-dimensional structure and the role of breaking in frequency downshifting.

Theoretical studies need to be encouraged into quantifying the effects of surface drift and of three-dimensionality. Current numerical models can describe two-dimensional irrotational waves as they break. Addition of a layer of vorticity at the surface is feasible. Three-dimensional irrotational programs are likely to be developed but combination with vorticity seems unlikely in that case.

SHALLOW-WATER BREAKING

Breaking induced by bottom topography is a well-studied area because of its importance in all aspects of coastal engineering. For the purposes of this working group we ignore its implications for and interactions with surf-zone processes, other than the basic hydrodynamics. The presentations in the workshop reflect current research frontiers. That is investigation of the complex but deterministic flow field that occurs after breaking is represented by Tallent's detailed description of the eddies and splashes for a wave on a beach, the numerical modelling of wave behaviour before any splash occurs is described by Grilli and by Peregrine. These are all two-dimensional studies. For shallow-water breaking this limitation is not serious since such breaking is usually longcrested.

A number of substantial field experiments in the last decade are giving a good appreciation of surf-zone kinematics. However, for many practical purposes results from regular wave trains are used, often with extremely simplified models of the surf zone.

At the research level, many detailed aspects need study as mentioned below but the only major gaps in our knowledge concern the flow once breaking starts, until, on gentle slopes, the wave has become a turbulent bore; and the flow when breaking stops as when a broken wave enters deeper water. Further study is required because of the importance of the breaking phase in processes such as sediment transport, the generation of nearshore circulation which influences dispersion of pollution etc, the determination of set-up and run-up with relevance to flooding, and the severe conditions that break-

ing provides for structures such as breakwaters and sea walls.

Research is needed in the experimental area to clarify the strong effects of wind which at the present time are mainly recorded in books on surfing. Onshore winds lead to a dominance of spilling breakers, whereas offshore winds encourage plunging breakers. Several aspects of breaking need to be quantified, although we can recognise spilling and plunging breakers, intermediate cases are not readily described. That is, we still lack good definition for the relative size and strength of breakers.

The present initial studies on breaker structure need to be developed and extended since for many applications this is the most significant phase of wave development. There are still distinct experimental difficulties, and instruments or measuring techniques need to be developed, e.g. to measure air-water ratios.

Experiments and characterization of irregular waves as they break are required, especially on steeper slopes where backwash has a significant influence on breaker character.

Field observations have provided substantial data banks which can be usefully studied with further analysis and interpretation. We note however that conventional measurements can be of much greater value if simultaneous film or video records are made since it is not always easy to recognise wave breaking from other records.

Theoretical study is hampered by the difficulties of describing the breaking process, though there is a good chance of progress if the simple turbulence modelling of Svendsen and Madsen (1984) is developed. Verification of the potential flow models up to breaking by comparison with a wider range of experiments is desirable, and these models can be improved in a number of ways, e.g. inclusion of vorticity layers may mimic wind drift, or a sheared backwash flow.

Mathematical models of a simpler kind, such as those using the finite-amplitude shallow-water equations could provide insight into the interaction between the dominant waves and longer period waves (infra-gravity waves) whose origin may be in the surf-zone region and which have a dominant influence on run-up on gentle beaches.

FREAK WAVES

The workshop presentations of Kjeldsen and Sand give a good indication of the "state of the art" in this area. The following definition of freak waves has been proposed by Kjeldsen

$$H_{max}/H_s > 2.0$$

since this will in most cases (number of waves $n = 1000-2000$) represent a clear exceedance of the most probable maximum wave according to the Rayleigh distribution (c.f. Sand et al.). On the basis of observations in the Gulf of Mexico, the North Sea, the Irish Sea, off the coast of Norway, etc. it is believed that the phenomenon appears in both deep and shallow water, and is dependent on locality.

It is proposed that the following causes be further investigated:

Wave phenomenon causing freak waves:

- wave focusing
- waves arising from different directions
- super-position of waves of different scales

Amongst the physical causes are:

- topographical refraction, diffraction and reflection on different scales
- wave-current refraction
- colliding low pressure systems (e.g. collisions between polar lows and ordinary low pressures)
- combination of swell and wind seas
- response of the wave field to a turning wind field such as a hurricane

In many cases freak waves appear as a result of combinations of the phenomena mentioned above (see Kjeldsen).

Recommendations for future research are listed under the following headings:

- Full scale freak wave measurement program (selection of instrumentation, site platforms, etc)
- Extended analysis of existing data.
- Correlation of meteorological information and freak wave occurrence.
- Further description of freak wave categories as non-breaking, spilling or plunging breakers.

- Kinematic theory of 3-D freak waves (especially above MWL).
- Ultimate and accidental limit state design guidelines and possible forecasting for ships and the oil industry.

(See also recommendations given by ISSC on ship subject in August, 1988).

5. REPORT FROM THE WORKING GROUP ON MEASUREMENT OF WAVE KINEMATICS

5.1. INTRODUCTION

It was the position of this group that the other working groups in this workshop would provide the needs and justification for additional wave kinematics measurements. Consequently, our recommendations will focus more on the means of implementing measurements and making suggestions for improving the state-of-the-art. Given the very different natures of field and laboratory measurements requirements, this group felt it best to consider the requirements independently. It is important to note that our recommendation philosophy will not be limited to currently available methods and techniques but to also include technology and techniques that show promise for future wave kinematic measurements.

5.2. STATUS

5.2.1. Field

The quantity of field measurements available is inadequate and the quality, with respect to wave kinematics, is, in general, low. Furthermore, available measurements are often severely limited in usefulness due to the measurement locations, structural influence and lack of one or more velocity components. Instrument reliability is very uncertain as instruments are often improperly calibrated and maintenance and recalibration are infrequent or non-existing. Not infrequently, valuable information in severe storms is lost due to equipment failure.

5.2.2. Laboratory

In contrast to field measurements, the quantity and variety of laboratory measurements available is significant, but are still lacking in the important near-surface and bottom zones. The possibility of excellent quality in measurements is high given: the opportunity for assured reliable instrument operation through frequent testing and calibration; the disturbance to the flow, by

the measuring instrument or its support structure, can be made negligible or completely eliminated altogether; and that three-component measurements are attainable. Despite this, laboratory measurements must be viewed cautiously due to the possibility of improper modelling and uncontrollable tank effects.

5.3. USE OF MEASUREMENTS

5.3.1. Field

In general measurements are made for a specific purpose. Field measurements are though focusing on topics not covering the wave kinematics. Instead oceanographic knowledge is sought in order to define statistical parameters, for example:

- wave height
- tidal and ocean currents
- wind speed

However, time series of more severe events are in general available.

5.3.2. Laboratory

Laboratory experiments are, in general, conducted to verify the validity of theories and extensions to theories. Therefore laboratory measurements are, for the present, limited to unidirectional problems and most often to shallow or very shallow water cases since theoretical efforts are extensive here.

Laboratory measurements, therefore, do not cover the complex situation as found in nature that we attempt to learn more about.

5.4. MEASURING TECHNIQUES

5.4.1. Field

The most frequently used velocimeters are of the electromagnetic flow meter type. A few acoustic meters are also now available, their applicability to wave kinematics is uncertain. For current measurements, mechanical propeller meters are commonly applied for short term measuring programs. They are all kept at fixed positions by mounting directly to fixed structures or suspended from buoyant bodies. In general, none of the above mentioned meter types are suitable for measurements in the splash zone.

5.4.2. Laboratory

Commonly used types of velocimeters are electromagnetic, acoustic, and micropropeller meters. Optical techniques such as Laser Doppler Velocimetry have become increasingly used providing measurements without disturbing the flow.

5.5. RECOMMENDATIONS

5.5.1. Field

- a. Equipment operation should be kept at a level securing high fidelity, i.e. sufficient calibration and verification are needed.
- b. Equipment should be made durable.
- c. Measurements are to be taken at sufficient distance from structural influence. All three velocity components are needed.
- d. Equipment for near surface measurements needs development.
- e. Three-component LDV should be developed.

5.5.2. Laboratory

Techniques in general should be improved to allow for a more free choice in setting up an experiment. Whole-field measurements may prove excellent for verification after improvement of the recording and processing techniques. Maintenance and reliability should be given the utmost attention.

6. REPORT FROM THE WORKING GROUP ON FORCES

The discussions of this working group were an example of the dialogue and international co-operation that is personally rewarding for all participants and leads to valuable consolidation of the state-of-the-art and also points to future research needs.

This has been a workshop on water wave kinematics. Forcing on ocean and coastal structures is fundamentally related to kinematics - the two subjects should not be considered independently. However, the discussions of this working group were focussed on the issue of how knowledge of kinematics can lead to predictions of forcing. The discussions began with consideration of Morison's equation, and expanded to include other topics such as freak waves, laboratory standards, and the need

for an accessible complete information data base of field and laboratory data.

We have seen that the determination of force coefficients for an irregular wave case cannot be expected to follow from any regular flow situation. The case of coexisting waves and current should also be considered separately. It has been suggested that the use of random process theory to determine the variance and statistics of extreme Morison equation forcing in irregular waves leads to very encouraging results.

It is generally recognized that kinematics in the near field are more significant than those in the far field. Further study of wave effects on force coefficients is recommended.

More data is needed on force coefficients in situations typical of the real ocean environment. Continued research into force coefficients appropriate for: multi-directional seas, coexisting waves and currents, clusters of cylinders, and relative velocity situations, is recommended. The emphasis of this research should remain on understanding the physics of the forcing process, particularly the importance of kinematics in the near field.

Having called for more research and more data, the working group considers it important to recommend that the data be available to researchers around the world, and that it be reported in a sufficiently complete manner so that results from various sources may be compared. Probabilistic format and methods should be more systematically used in the processing and presentation of experimental results in order to:

- a) make them objectively comparable, and
- b) provide the information needed for reliability design methods.

A common data base for force coefficient values, together with the ability to inter-compare the results from various sources, would encourage more rigorous application of the Morison equation.

The accident at the Ekofisk field in 1984 in which a control room wall was damaged by a wave crest at least 22 m above mean water level has been mentioned by both Kjeldsen and Sand et al. This event provides graphic evidence that "freak" waves are a definite hazard to ocean structures. There is a need to learn more about the processes through which these waves are formed, their kinematics, and their probability of occurrence.

Efforts to understand the influence of crossing seas, topography, and co-existing current, on the frequency and formation of these extreme waves should continue. More good field data is needed to extend our understanding of "freak" waves. It has been suggested that the wave rider buoy is not capable of making these measurements.

A related topic is the forcing caused by breaking waves which may not necessarily be "freaks". Breaking and very steep asymmetric waves can exert significantly larger forces on ocean structures than steady symmetric waves of similar height and period. Such unsteady waves exist in real seas, and they should be considered by the designers of ocean structures. It is recommended that research into the probability of occurrence of wave breaking in a variety of realistic multidirectional seas should continue. It is also recommended that study of the forcing due to unsteady and breaking waves should continue.

A gap still exists between regulations - and therefore, engineering practice - and state-of-the-art research. There is a need for continual upgrading of design specifications to reflect advances made by the research community.

There was some discussion of the need for quality assessment of wave basin tests. Information of reflection characteristics, wave generator capabilities, and the vertical distribution of kinematics measured in the basin at various distances from the wave generator, should be documented and made available by basin operators.

More research on long waves and their influence on the slow drift motions of floating structures is recommended.

In summary, we would like to encourage the participants of the other working groups to continue to advance on many of the kinematics-related issues discussed at this workshop. This will help those of us in the forcing working group to solve some of our own problems. Expressed in a different way, learning more about hydrodynamic forcing on coastal and ocean structures is intimately linked to greater understanding of wave kinematics.

7. ACKNOWLEDGEMENT

The reports from the working groups presented in this paper has been reprinted from the proceedings of the NATO ARW (ref. 1). We acknowledge the permission of Kluwer Academic Publishers to reprint them.

CHAPTER 72

Prediction of the dimensions of a rip current system on a coast with bars

Julio Zyserman¹, Jørgen Fredsøe², Rolf Deigaard²

Abstract

A method to determine the dimensions of rip current systems (distance between rip currents, and width and depth of the rip channels) is presented for the case of a coast with longshore bars. The method is based on an overall sediment balance in the nearshore region. The balance is determined by application of a model for the wave-induced flow combined with a sediment transport model. The influence of the wave height, the wave period, and the direction of wave propagation, as well as of the sediment size is analyzed.

1. Introduction

Rip currents are strong narrow currents flowing seaward across the breaker zone, which return the water transported landward by the breaking waves. These currents influence the characteristics of the wave-induced flow and the associated sediment transport, and thereby the nearshore morphology. While a diversity of analytical and numerical models has been developed to determine the features of rip-current systems on plane beaches, the references regarding rip currents on coasts with longshore bars are rather scarce.

The main purpose of the present paper is to develop a method which can describe the characteristics of a rip-current system on a coast with bars taking an overall balance of the sediment transported in the nearshore region into account.

2. The model for the wave-induced flow

Hydrodynamics in the uniform condition

Consider the situation shown in Fig. 1. A train of waves propagates obliquely towards a coast with a longshore bar. The bottom contours are straight, and parallel to the shoreline. The adopted system of reference is also shown in the figure. The x-axis is coincident with the still-water shoreline, and the y-axis has its origin at the coast and extends offshore. As the waves approach the coast, the effect of refraction makes the wave fronts turn, and the combined effects of shoaling and refraction do that the waves become steeper, until they break on the bar. The subscript "br" is used to indicate characteristics of a given variable at the line of breaking. The broken waves pass over the crest of the bar to the deeper water of the trough where the process of wave breaking is reduced or completely stopped. As the waves further propagate towards the beach, they are shoaled and refracted until they eventually break on the inner beach.

Under these conditions, a longshore current is generated by the breaking waves. The driving force for the

Figure 1. Definition sketch for uniform case.

current is provided by the cross-shore gradient of the shear component of the radiation stress tensor S_{xy} . Since the value of $\partial S_{xy} / \partial y$ is directly proportional to the rate of dissipation of wave energy (Longuet-Higgins, 1972), the forcing term and therefore the induced current will be greater where the dissipation of wave energy is more intense, i.e. in the vicinity of the lines of breaking.

The waves also cause a deviation of the mean water surface from the still water level. Seaward of the breaker line a depression of the mean water level or "set-down" exists, whereas a raise of the water surface with respect to the still water level or "set-up" appears in the surf zone.

As an example the velocity profile of the depth-integrated longshore current calculated over a bar-trough profile is shown in Fig. 2.

The calculation have been made for irregular waves, and the wave conditions have been determined by the model of Battjes and Janssen (1978) for the transformation of Rayleigh distributed waves, with the breaker index given by Battjes and Stive (1985).

Figure 2. Calculated profiles of longshore current, and the bar-trough profile.

Refraction was determined by application of Snell's law using the peak period of the irregular waves, and disregarding the influence of the currents on wave refraction. Bottom friction was modelled according to Fredsøe (1984), and the turbulent stresses were represented by the usual gradient diffusion of momentum, with the coefficient for lateral exchange of momentum given by Battjes (1983). More details about the representation of the forcing terms can be found in Zyserman (1989).

The variables were chosen as: deep water wave height $H_{rms,0} = 1.2$ m, peak wave period $T_p = 7.5$ s, mean direction of wave propagation in deep waters $\alpha_0 = 45^\circ$, distance from still water shoreline to the crest of the bar $y_B = 90$ m, still water depth over the bar $D_c = 1$ m, slope of the inner beach $\tan(\beta) = 0.02$, slope of the seaward face of the bar $\tan(\theta) = 0.01$, and mean diameter of the bed material $d = 0.20$ mm. The profile labeled as "without lateral mixing" in Fig. 2 was determined disregarding the cross-shore exchange of momentum.

Hydrodynamics in the non-uniform condition

Figure 3 shows the non-uniform coastal geometry. The cross section through the bar is similar to the uniform profile considered above, but the bar is interrupted by rip channels of width W_H and depth D_H , so that the length of the bar between adjacent holes is L_B . The rip channels are taken to have a rectangular section, where they cross the bar.

The waves still break on the bar, but the water depth in the channels is so large that the wave breaking here is much less intense than on the bar, if the waves break at all. The tendency to build up the wave set-up is therefore much stronger over the bars than in the channels.

This means that the mean water level is higher behind the bar than at the holes, and that a pressure gradient directed towards the rip channels exists. This pressure gradient will accelerate the mass of water at the trough in the longshore direction, until it turns seaward and flows through the holes in the form of a rip current. The amount of water discharged by the rips is compensated by the water flowing over of the bar into the trough.

The wave-induced currents can be described by means of depth-integrated equations for conservation of x-momentum and of y-momentum and the continuity equation. In the general form these equations read:

Figure 3. Definition sketch for the non-uniform case.

$$\rho h \left(\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} + g \frac{\partial \bar{\eta}}{\partial x} \right) + \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} - \frac{\partial T_{xx}}{\partial x} - \frac{\partial T_{xy}}{\partial y} + \bar{\tau}_{bx} = 0 \tag{1}$$

$$\rho h \left(\frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + g \frac{\partial \bar{\eta}}{\partial y} \right) + \frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y} - \frac{\partial T_{xy}}{\partial x} - \frac{\partial T_{yy}}{\partial y} + \bar{\tau}_{by} = 0 \tag{2}$$

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial (hU)}{\partial x} + \frac{\partial (hV)}{\partial y} = 0 \tag{3}$$

where U and V are the time-mean and depth-averaged components of the flow, t is time, h is the total depth $h = D + \bar{\eta}$, D is the local depth measured from the still water level and $\bar{\eta}$ is the water surface elevation, g is the acceleration of the gravity, S_{xx} , S_{xy} , and S_{yy} are the longshore, shear, and cross-shore components of the radiation stress tensor respectively, T_{xx} , T_{xy} , and T_{yy} are the analogous values of the Reynolds stresses produced by the turbulence, and $\bar{\tau}_{bx}$ and $\bar{\tau}_{by}$ are the components of the resulting bed shear stress over a wave period.

Solution of equations (1), (2), and (3) gives the three variables U, V , and $\bar{\eta}$ in the domain of interest.

A numerical solution of equations (1) to (3) requires large and laborious calculations, and considerable amounts of computing time. It has therefore been preferred to adopt some physically well based simplifying assumptions, in order to reduce the computations involved in the solution. This has been done because a large number of study cases involving different wave characteristics and shore configurations was to be analyzed.

The assumptions adopted are listed below. A detailed discussion of the procedure is given by Zyserman (1989).

- A steady state is considered.
- The diffusion of momentum due to turbulent fluctuations of the velocity is not taken into account.
- It is assumed that the wave characteristics are uniform alongshore between two holes.
- The cross shore discharge of water per unit length over the crest of the bar produced by the breaking waves q_w is given by

$$q_w = h_c V = h_c \sqrt{2g(\bar{\eta}_0 - \bar{\eta})} \quad (4)$$

according to Deigaard (1986). $\bar{\eta}_0$ is the value of the set-up for the uniform situation, $\bar{\eta}$ is the real value of the set-up, and h_c is the mean-water depth over the crest of the bar.

- It is assumed that the cross-shore component of the current V varies linearly behind the bar, and that cross shore discharge is constant offshore the bar:

$$V = V_{\max} y / y_B \quad \text{for } 0 < y < y_B \quad (5)$$

$$hV = \text{constant} \quad \text{for } y > y_B \quad (6)$$

V_{\max} being the maximum value of V in the through just behind the bar crest.

- The contribution of the wave set-up $\bar{\eta}$ to the total depth h is disregarded, so now $h = D$.
- The mean water surface behind the bar is horizontal.

With these simplifications, the set of three equations can be reduced to the following two partial differential equations:

$$\rho D \left(U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} + g \frac{\partial \bar{\eta}}{\partial x} \right) + \frac{\partial S_{xy}}{\partial y} + \bar{\tau}_{bx} = 0 \quad (7)$$

$$\frac{\partial(DU)}{\partial x} + \frac{\partial(DV)}{\partial y} = 0 \quad (8)$$

which can be solved by an iterative procedure.

The numerical solution is performed using a finite difference formulation of Eqs. (7) and (8). The unknowns are determined in a domain having the length of the bar L_B in the x-direction, and being bounded by the still-water shoreline and an offshore limit y_L , which is taken as the position where the value of $\partial S_{xy}/\partial y$ becomes smaller than a chosen limiting value.

The boundary conditions for the variables are:

$$U = 0 \quad \text{for } y = 0 \quad \text{and} \quad 0 < x < L_B \quad (9)$$

$$U = 0 \quad \text{for } y = y_L \quad \text{and} \quad 0 < x < L_B \quad (10)$$

$$V = 0 \quad \text{for } y = 0 \quad (11)$$

$$DV = \text{constant} \quad \text{for } Y_B < y < y_L \quad (12)$$

The boundary condition for $\bar{\eta}$ is determined from the expansion-loss of the rip current flowing through the rip channels:

$$\bar{\eta}_H = \frac{|\bar{v}_{rip}|^2}{2g} \quad (13)$$

The subscript "H" indicates a value of the variable determined at the hole, \bar{v}_{rip} is the velocity in the rip channel.

Figure 4 shows the longshore current velocity profiles obtained for $H_{rms,0} = 1.2$ m, $T_p = 7.5$ s, $\alpha_0 = 45^\circ$, $\tan(\beta) = 0.02$, $\tan(\theta) = 0.01$, $D_c = 1$ m, $L_B = 180$ m, $Y_B = 90$ m, $W_H = 22.5$ m, $D_H = 3$ m, and $d = 0.2$ mm. The velocity in the rip channel equals 1.22 m/s in this situation.

The results obtained can be compared with the velocity profile without lateral mixing of Fig. 2. The same data were used in the two examples, so the observed differences are due to the presence of the rip currents.

A striking difference is the smoothness of the velocity profiles in the case of non-uniform flow conditions, even when the effect of turbulent momentum transfer is disregarded. This is due to the cross shore flow which effectively transfers longshore momentum in the

Figure 4. Calculated longshore current flow in presence of rip currents.

cross shore direction. The shore parallel velocities on the bar are reduced because water from offshore continuously is moving into the field of driving forces from the wave breaking. Similarly the longshore momentum is convected into the trough, giving a continuous velocity profile.

The flow model which gives the flow field and the wave conditions in the near-shore area is used as basis for the sediment transport calculations.

3. The sediment transport model

The model used to calculate sediment transport has been described in detail in a series of papers by Fredsøe, Andersen, and Silberg (1985), and Deigaard, Fredsøe, and Hedegaard (1986a, 1986b), so only the main features of the model are presented here.

The total load transport of sediment per unit width q_t is determined as the sum of two contributions: the bed load transport q_b and the suspended load transport q_s .

The instantaneous bed load transport is related to the instantaneous dimensionless bed shear stress or Shield's parameter θ according to the findings of Engelund and Fredsøe (1976). θ is determined at each instant from the model developed by Fredsøe (1984) for the boundary layer in combined wave-current situations. The mean value of the bed transport during a wave period is then found by integration of the instantaneous values.

The concentration profile of suspended sediment is determined at every instant by solving the diffusion equation for the sediment. The turbulent exchange factor for the suspended sediment is taken equal to the eddy viscosity of the flow. The turbulent eddy viscosity is determined as the combination of contributions from the current boundary layer, the wave boundary layer and from the wave breaking.

The mean value of the suspended transport in the direction of the mean current over a wave period is determined by time-averaging the product between the concentration of suspended sediment and the total (current + wave) horizontal velocity in the direction of the current. This product is integrated between the bed level and the water surface to give the transport rate.

4. The prediction of the dimensions of the rip-current system

Based on the sediment transport calculations the dimensions of the bar-rip channel system is determined. The dimensions considered are: the bar length L_B , the width of the rip channel W_H and the depth D_H of the rip channel. The geometry of the system is then determined for a given bar profile, sediment characteristics and incoming wave conditions. Equilibrium conditions are assumed and no erosion or deposition must occur. The basis for the analysis are the sediment budgets for two cells, Fig. 5.

The sediment transported in the trough by the longshore currents flowing toward the rip must equal the amount of sediment flushed through the hole by the rip. This condition can be written as:

$$Q_{S,rip} = Q_{S,end} \quad (14)$$

Figure 5. Sediment balances.

The total amount of sediment transported over the bar must be equal to the amount of sediment transported toward the rip, giving:

$$Q_{S,inc} = Q_{S,end} \quad (15)$$

where the the sediment transport per unit width q_t has been integrated along the bar, and across the rip channel and the trough, in order to determine $Q_{S,inc}$, $Q_{S,rip}$, and $Q_{S,end}$, respectively.

These two conditions make it possible to determine the bar length L_B and rip depth D_H for a given value of the rip width W_H . The solution is made by iteration, calculation the ratio between the in- and outgoing sediment of each cell. An example of the calculations is shown in Fig. 6 with the following input data: $H_{rms,0} = 1.2$ m, $T_p = 7.5$ s, $\alpha_0 = 0^\circ$, $\tan(\beta) = 0.02$, $\tan(\theta) = 0.01$, $D_c = 1$ m, $L_B = \text{variable}$, $Y_B = 90$ m, $W_H = 22.5$ m, $D_H = \text{variable}$, and

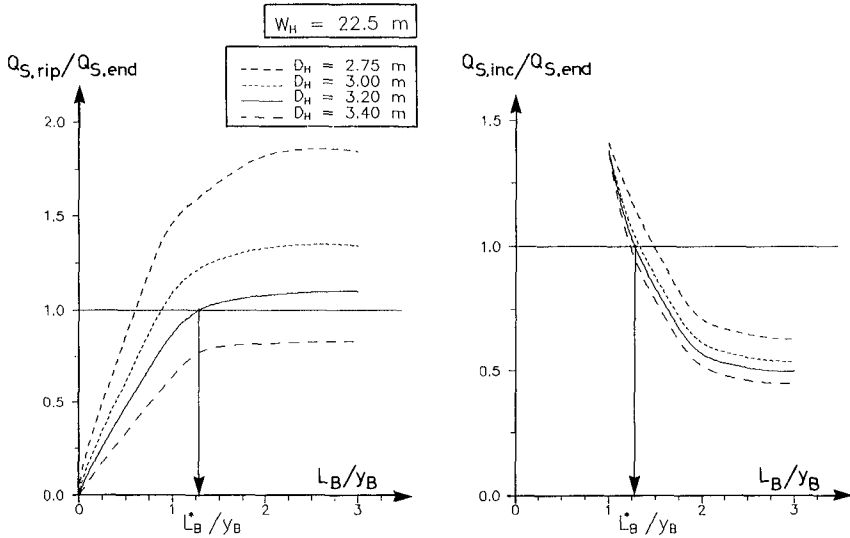

Figure 6. The determination of the length of the bar.

$d = 0.2$ mm. The solution in this case is found for $D_H = 3.2$ m and $L_B = 1.3 y_B = 120$ m.

When this method is applied for different widths of the hole W_H , it is possible to obtain a set of curves representing the equilibrium length of the bar L_B , the depth of the hole D_H , and the total sediment transport of the rip $Q_{S,rip}$ as functions of the width of the hole W_H , for a given wave situation, bar-trough profile, and bed material. Fig. 7 shows the equilibrium value of $Q_{S,rip}$ and D_H as function of and the width of the hole. The data are similar to Fig. 6, except for the wave approach angle which is now $\alpha_0 = 45^\circ$. The equilibrium bar length is very insensitive to changes in W_H being constant about $L_B = 1.37 y_B = 123$ m.

$Q_{S,rip}$ is a measure of the flushing capacity of rip channel, and the situation with maximum $Q_{S,rip}$ can therefore be taken as the optimal configuration where the rip current has the highest capacity to flush sediment in the seaward direction. This criterion gives a rip channel width of $W_H = 25$ m and a depth of $D_H = 2.8$ m.

A sensitivity analysis has been made to illustrate the influence that the wave height, the wave period, and the diameter of the bed material have on the solution. The situation illustrated in Fig. 7 with $\bar{\alpha}_0 =$

Figure 7. The determination of the dimensions of the rip channels based on $(Q_{S,rip})_{max}$.

45° is taken as Case I, and used as a basis for the comparison. All the other cases are obtained by changing the value of one of the independent variables with respect to its value in this case. Case II is the situation already considered in which the angle of wave incidence was changed to $\alpha_0 = 0^\circ$. In Case III the wave height is taken as $H_{rms,0} = 2$ m. In Case IV the wave period is taken as $T_p = 10$ s, and in Case V the grain size is taken as $d = 0.4$ mm, giving $w = 0.05$ m/s. The results are presented in Table 1.

An alternative criterion for determining the rip channel width has been proposed by Skou and Fredsøe (1990). The idea is that nature should select the

Case	$H_{rms,0}$ (m)	T_p (s)	$\bar{\alpha}_0$ (°)	d (mm)	L_B (m)	W_H (m)	D_H (m)
I	1.2	7.5	45	0.20	123	25	2.80
II	1.2	7.5	0	0.20	120	25	3.00
III	2.0	7.5	45	0.20	146	11	5.25
IV	1.2	10.0	45	0.20	126	23	3.15
V	1.2	7.5	45	0.20	123	43	1.65

$$D_C = 1 \text{ m} \quad Y_B = 90 \text{ m} \quad \tan(\beta) = 0.02 \quad \tan(\theta) = 0.01$$

Table 1. The equilibrium dimensions as function of the input parameters.

condition giving the maximum slope of the $Q_{S,rip} - W_H$ curve, as this represents the maximum strength of the response of the system to a perturbation imposed on it. If for instance the width of the channel is reduced by a random infill of sediment, then the increase of $Q_{S,rip}$ due to the decrease in W_H is a measure of how fast the rip channel will erode to reestablish the equilibrium. Fig. 8 illustrates the application of this criterion to Case III, giving $W_H = 17.6$ m and $D_H = 3.6$ m.

Figure 8. Determination of the dimensions of the rip channels based on $(dQ_{S,rip}/dW_H)_{max}$.

5. Conclusions

A method for determining the features of a stable shore when a rip-current system exists on a bar-trough shore profile has been developed. The calculated characteristics of the coast comprise the length of the bar or spacing between rip currents L_B , and the dimensions of the rip channel: width W_H and depth D_H .

The method reproduces some characteristics of the rip-current systems that can be observed in nature fairly well, such as the larger distance between rip channels and the deeper holes associated with heavy breakers, see Case III of Table 1.

No perceptible influence of the grain diameter on the length of the bar was found, but coarser grains led to wider and shallower holes. It was also determined that waves of normal incidence produce slightly shorter bars and deeper holes than waves of oblique incidence.

CHAPTER 73

SCALE EFFECTS IN BREAKING WAVES

Toumazis¹, A.D. and Anastasiou², K.

Abstract

A breaking wave model, which is partly physical and partly analytical, is proposed. This model is based on observations that up to a certain moment the wave presents a long, smooth, horizontal, cylindrical edge, which then segments due to surface tension effects. A disturbance on a cylindrical surface, withdrawn from the influence of gravity, becomes unstable when its wavelength exceeds the circumference of the cylinder. The rate of growth of the instability, is a function of the radius of the cylinder and the wavelength of the disturbance. Using the theory describing the evolution of the assumed hyperbolic shape of the tip of a breaking wave, the radius of the cylindrical edge is approximated to the radius of curvature of the hyperbola. The model describes the three-dimensional evolution of the curling wave crest. Scale effects are then derived which show good agreement with experimental results.

Introduction

During the overturning process of a breaking wave, the plunging jet is in a state of free fall. Assuming that the wave is two-dimensional, with no transverse inertial forces, and air friction is negligible, surface tension is the predominant force acting on the fluid particles.

Under similar ambient conditions, the behaviour of the overturning face of the breaking wave is the same to that of a liquid cylinder. If a liquid cylinder is constructed and liquid is drawn out gradually, the diameter of the cylinder decreases until the length of the cylinder becomes just about three times as great as its diameter. Soon afterwards instability begins, and the cylinder alters its form; it narrows at the waist, so passing into an unduloid and the deformation progresses quickly until the cylinder breaks in two, and its halves become portions of spheres. This behaviour is due to surface tension effects. Plateau (1863) established experimentally that the distance between the spheres is proportional to the diameter of the cylinder. In the case of a very long cylinder, when many spheres are formed, the parts between consecutive

dilations or constrictions undergo identically and simultaneously the same modifications as described above (fig. 1).

Fig. 1 Stages of the segmentation of a liquid cylinder

Plateau (1863) also noted that the phenomenon of the formation of lines and their resolution into spherules is not confined to the case of the rupture of the equilibrium of liquid cylinders; it is always manifested when one of the liquid masses, whatever may be its figure, is divided into partial masses. The phenomenon is also produced when liquids are submitted to the free action of gravity.

Worthington (1908) discussed the effect of surface tension on breaking waves. He observed that a wave that has just impetus enough to curl over and break, up to a certain moment it presents a long, smooth, horizontal, cylindrical edge, from which, at a given instant, are shot out a large array of little jets which speedily break into foam, and at the same moment the back of the wave, hitherto smooth, is seen to be furrowed and combed (fig. 2). He proposed that these jets are due to the segmentation of the cylindrical rim according to Plateau's law, and the ridges between the furrows mark the lines of easier flow determined by the jets. Further observations of this phenomenon were made by Toumazis (1989) from video and photographic records.

Fig. 2 Diagrams of a breaking wave (Worthington 1908)

Regarding scale effects in breaking waves, Fuhrboter (1986) studied impact loading by breaking waves on slopes and found that scale effects do exist.

Skladnev and Popov (1969) measured impact pressures induced by waves breaking on a slope in a more systematic way. Waves of the same steepness but of wave height ranging between 3 and 120 cm were tested. Prototype conditions were considered the ones with the 120 cm wave height. The results were presented in graphical form (fig. 3). The abscissa is the ratio of the model to the prototype (120cm) wave heights and the ordinate is the ratio of the model to the prototype impact pressure factor K_p , defined as the ratio of the measured pressure to the static pressure ρgh , where h is the wave height. From these results it is evident that, it is not permissible to use Froude criteria to scale up experimental results on breaking waves with model breaker height less than about 0.5m.

Fig. 3 Effects of wave height on the relative wave pressure value in the wave impact zone. (Skladnev and Popov, 1969)

Stive (1984) reached the same conclusion, stating that in order to avoid disturbing influence of the surface tension on the amount of air absorption in the broken wave, the incident wave height in the model must exceed approximately 0.5m.

The primary objective of this work is to formulate a model for the effects of surface tension on breaking waves and to establish a quantitative threshold beyond which scale effects are negligible. It will be shown that this threshold agrees well with available experimentally derived indicators.

Surface Tension Effects on Free Falling Liquid Cylinders

Any small disturbance on a liquid cylinder may be considered, according to Fourier's theorem, as the summation of a series of sinusoidal wave disturbances. The surface area of the cylinder will change whereas the volume of the liquid

remains the same. As surface tension results in contracting the volume to the minimum possible surface area, an increase of the surface area due to the disturbance will be opposed by surface tension, whereas a contraction of the surface will be enhanced. The criterion for stability is therefore the change of surface area for a given volume after the appearance of a small disturbance. In the following derivations the effects of only one sinusoidal disturbance will be considered, bearing in mind that the principle of linear superposition must be applied when a full range of Fourier components must be taken into account.

If a cylinder with radius r is slightly deformed so that

$$y = r + a \cos \frac{2\pi}{L} x \quad (1)$$

where x is measured parallel to the axis, y is the distance normal to the axis, a is the amplitude of the deformation, and L is the wavelength of the deformation. Plateau (1863) showed that the cylinder is stable if

$$L < 2 \pi r \quad (2)$$

The theory is hereby extended to consider a sector of a liquid cylinder with a slight sinusoidal deformation

$$y = r + a \cos(kx) \quad , \quad \text{where } k=2\pi/L \quad (3)$$

The mean surface area between two consecutive crests, σ , is then

$$\sigma = r \theta + \frac{1}{2} r \theta a^2 k^2 \quad (4)$$

where θ is the angle between the radii of the sector. Assuming the volume of water in the cylindrical sector remains the same, the mean volume S is

$$S = \frac{1}{2} \theta r^2 + \frac{1}{4} \theta a^2 \quad (5)$$

Combining the two expressions for σ and S ,

$$\sigma = \sqrt{2 \theta S} + \frac{\theta}{4} \frac{a^2}{r} (k^2 r^2 - 1) \quad (6)$$

The surface area of the undisturbed liquid ($a=0$) is,

$$\sigma_0 = \sqrt{2 \theta S} \quad (7)$$

Therefore, the change in the surface area is,

$$\sigma - \sigma_0 = \frac{\theta}{4} \frac{a^2}{r} (k^2 r^2 - 1) \quad (8)$$

If $k.r > 1$ the surface area increases and hence the liquid is stable, while if $k.r < 1$ the surface area decreases and instability results.

The obtained result is independent of the angle θ . The cylinder is a special case of the considered case, with $\theta=2\pi$. Plateau (1864) and Rayleigh (1878) reached the same result by considering the cylindrical shape as the initial condition.

The mode of falling away from unstable equilibrium necessarily depends on the small deformations to which the system is subjected. In an ideal situation of no deformations, even if $L>2\pi r$ the cylinder would still be in equilibrium. In practice however, some kinds of disturbances are always present. Although all disturbances corresponding to $L>2\pi r$ are unstable, the rate of change of the shape due to each wavelength, L is different.

Assuming that the amplitude of the disturbance, a , once unstable, grows exponentially with time, that is

$$a = a_0 e^{qt} \quad (9)$$

where a_0 is the initial amplitude, Lord Rayleigh (1878) showed that for a cylindrical surface,

$$q^2 \approx \frac{T}{\rho r^3} \left[x^2 - \frac{9}{8} x^4 + \frac{7}{24.3} x^6 - \frac{25}{210} x^8 + \frac{91}{211.3.5} x^{10} \right] \quad (10)$$

where $x=kr=2\pi r/L$. For given r , all disturbances with wavelength, L , less than $2\pi r$ ($2\pi r/L>1$) are stable. For L greater than $2\pi r$ the disturbances grow with time, the fastest growing one having $L\approx 9r$.

Gravity and Inertial Effects

The mathematical description of the free surface area of a two-dimensional overturning wave, as governed by inertial and gravitational forces, was presented by Longuet-Higgins (1980). A frame of reference was used in which the x -axis is longitudinal horizontal, in the same direction as the propagation of the wave, the y -axis is transverse horizontal and the z -axis is vertical. The saddle-point, the point where the pressure gradient vanishes, follows a free fall trajectory. Its motion therefore satisfies

$$x = x_1 + U (t-t_1) \quad (11)$$

$$\text{and} \quad z = z_1 - 1/2 g (t-t_1)^2 \quad (12)$$

where x_1 , z_1 , t_1 and U define the initial coordinates, time and horizontal velocity respectively. The tip of the wave is approximated by the hyperbola

$$\frac{x^2}{\alpha^2} - \frac{z^2}{\beta^2} = 1 \quad (13)$$

Taking γ to represent the angle between the asymptotes, δ the angle of rotation of the principal axes, and r the radius of curvature at the tip of the breaker (fig. 4),

$$\tan \frac{\gamma}{2} = \frac{\beta}{\alpha} \quad (14)$$

$$r = \left| \frac{\beta^2}{\alpha} \right| \quad (15)$$

Fig. 4 Hyperbola approximating the tip of the wave.

Given the initial conditions, the two-dimensional evolution of the crest of the wave as depicted in Fig. 5 may be completely described, as shown by Longuet-Higgins (1980). It should be noted that in this reference there is a misprint in equation 5.8; the term f^2 should be included in the numerator of the right hand side.

The Proposed Model for the Breaker

Worthington's proposition (1908) is adopted as the fundamental assumption on which the presented model is based. That is, the crest of the overturning wave presents a long, smooth, horizontal, cylindrical edge.

The horizontal cylindrical edge, in the state of free fall, is modified in a manner governed by surface tension principles. The radius of the cylindrical edge is assumed to be independent of surface tension effects and only governed by inertial and gravitational forces. The formulations derived by Longuet-Higgins (1980) are therefore applicable to this problem. The radius of the cylindrical edge (Worthington, 1908) is equated to the radius of curvature of the hyperbolic edge of the wave (Longuet-Higgins, 1980). The proposed model is therefore a combination of two distinct analytical descriptions. The problem is studied by considering the evolution of monochromatic sinusoidal disturbances on the tip of an overturning wave.

Consider a small sinusoidal disturbance of amplitude a_0 , and wavelength L , on a liquid cylindrical edge. Surface tension considerations suggest that the amplitude of the disturbance will start growing when the wavelength, L , exceeds $2\pi r$, with an exponential rate of growth, $a_t = a_0 \exp(qt)$ (equation 9). The value of q is obtained from equation 10. For a cylindrical edge with a continuously varying radius, r , it is more appropriate to rearrange equation 9 so that,

$$a_{t+\delta t} = a_t \exp(q \delta t) \quad (16)$$

Given the initial conditions of the overturning wave, that is the conditions at breaking point, the evolution of the breaker shape is computed. For any time t , the values of the variables δ and γ as defined by Longuet-Higgins (1980) are thus obtained. These values together with the coordinates of the point of intersection of the axes of the hyperbola, which are determined from equations 11 and 12 describe completely the evolution of the tip of the breaker in the two-dimensional plane of the wave. The radius of curvature of the tip of the breaker is equal to

$$r = \left| -\frac{\beta^2}{\alpha} \right| = r_0 \tan^{3/2}(\gamma/2) \quad (17)$$

Assuming that the rate of increase of the amplitude of a disturbance on the tip of the breaker is the same as that for a cylinder, as derived by Rayleigh (1878), the amplitude of a disturbance of wavelength L is then obtained using equations 16 and 10.

Figure 5 shows the time dependent characteristics of six distinct sinusoids with the same initial amplitude. It is clear that, as the radius of curvature of the curling wave crest decreases with time, the long disturbances start growing first. The rate of growth of the amplitude decreases with increasing wavelength of the disturbance (eqn. 10). A long wavelength starts growing early and slowly, whereas a short wavelength starts growing late and rapidly. There is consequently a particular wavelength which attains the maximum amplitude at the instant of hitting the water surface. This predominant wavelength is therefore a function of the type and size of the breaker (initial radius of curvature, breaker height and horizontal velocity) and the form of the initial disturbance.

Short wavelengths are in general associated with small breaker heights and small radii of curvature at the tip of the breaker. The duration of overturning is short. Sinusoidal disturbances of long wavelengths although unstable, grow very slowly and the short duration of overturning does not allow them to become dominant. The smaller the breaker, the shorter the predominant wavelength.

On the other hand, big breakers have large radii of curvature even at plunging point. Disturbances of short wavelengths do not become unstable. As a result, the bigger the breaker, the longer the predominant disturbance.

Derivation of Scale Effects from the Proposed Model

As it has already been noted, in breaking waves apart from the gravitational and inertial effects, surface tension also plays a significant role. In scaling surface tension effects the ratio of the inertial to the surface tension forces must be the same. The Weber number

$$W_e = u \sqrt{(l\rho/T)} \quad (18)$$

must be the same in both prototype and model conditions, where ρ and T are the density and surface tension of the fluid, u and l are velocity and length scales respectively.

Fig. 5 Evolution of six sinusoids, of different wavelength, on the tip of an overturning wave.

It is evident that the Froude and Weber criteria cannot be satisfied simultaneously. In model tests involving breaking waves, Froude scaling is usually the adopted criterion, as it models satisfactorily the overall conditions, although the details of the breaking process are not fully modelled. It is of vital importance, in the interpretation of the model test results, to know how the non-scaling of surface tension effects affects the prototype conditions.

The developed physical/computational model, which takes into consideration both gravitational and surface tension effects, is now used to quantify scale effects in breaking waves. Consider a wave breaking in shallow water (fig. 6), which has the following characteristics

$$\begin{aligned} L_b &\sim T \sqrt{gh} & (19) \\ \text{and } H_b &\sim h & (20) \end{aligned}$$

where \sim means order of, L_b is the wavelength of the breaking wave, T is the wave period, h is the water depth at breaking point, and H_b is the breaker height.

Fig. 6 Breaking wave in shallow water depth.

In order to determine the angle γ when the forward face of the wave becomes vertical, the assumption is made that the backward face of the wave is straight such that,

$$\tan \gamma \sim \frac{L_b}{H_b} = \frac{T\sqrt{gH_b}}{H_b} = T \sqrt{\frac{g}{H_b}} \quad (21)$$

The initial conditions are therefore

$$\gamma_0 \sim \tan^{-1} \left(T \sqrt{g/H_b} \right) \quad (22)$$

$$\delta_0 \sim 1/2 \gamma_0 \quad (23)$$

$$r_0 \sim 1.4 H_b \quad (24)$$

The duration of overturning is equal to the time required for a free fall from height H_b

$$t_b \sim \sqrt{2H_b/g} \quad (25)$$

For a given breaking wave height, H_b , and wave period, T , the evolution of a transverse sinusoidal disturbance on the wave crest, with wavelength L , and amplitude a_0 , is traced up to plunging point. The ratio of the amplitude of the disturbance at plunging point, a_p , to the initial amplitude, a_0 , i.e. a_p/a_0 , is a measure of the surface tension effect on the wave breaking process for the assumed wavelength of initial disturbance.

When the above procedure is followed for a range of wavelengths of disturbance, the maximum value of a_p/a_0 , corresponding to the predominant wavelength of disturbance, is deduced. Any given breaker is therefore associated with a predominant wavelength of disturbance, whose amplitude at plunging point is amplified by the factor a_p/a_0 .

Figure 7 presents the computed values of the ratio a_p/a_0 for a wide range of wave conditions. The variation of this ratio reflects the effects of scaling. A constant value for a_p/a_0 implies that the shape of the breaker does not change between large and small waves.

Fig. 7 Model results showing the relative growth of predominant disturbance as a function of breaker height.

It is evident from this plot that, surface tension effects are the same for breaking waves bigger than about 0.5m in height, whilst they become increasingly important for smaller waves. This observation suggests that, assuming the curling face of the wave retains a hyperbolic shape, big waves, which have small curvatures, do not feel the surface tension forces. This is in agreement with the broad characteristics of surface tension; surface tension is a molecular effect which becomes important for high curvatures.

The presented model is in agreement with the experimental results of Skladnev and Popov (1969) and Stive (1984), who both found that scale effects do exist for breaking waves smaller than 0.5m high. The results from the present model and the available experimental observations, however, appear to disagree with regard to the following point. The present model predicts no segmentation of the tip of the wave for big waves, whilst the experimental results suggest that big waves are highly aerated and spayed, whilst in small waves aeration is negligible or does not occur at all (Skladnev and Popov,

1969). This apparent contradiction may be justified by considering the 0.5m cut-off point as the point at which the physical process of wave overturning changes. For breaker heights up to 0.5m, the global surface tension effects are more significant than the microscopic ones. For bigger waves, as the results from the proposed model suggest, the global surface tension effects are negligible.

The radius of curvature of an assumed irregularity on the tip of the wave is very small compared to that of the tip of the breaker. When unstable, the short wavelength disturbances grow much faster than the longer ones. These properties imply that, the short sinusoidal transverse disturbances, which are stable from the macroscopic point of view, are now unstable and fast growing. They thus prevail on the tip of the wave. The described process is illustrated in figure 8. The evolution of the same monochromatic disturbance is presented, as predicted from the numerical model, for four different radii of curvature. The fast growth of the disturbance associated with the small radii of curvature is evident. Irregularities on the tip of the breaker, therefore tend to produce closely spaced jets. These jets are easily observed on the curling crest of two-dimensional overturning waves, breaking in both deep and shallow water conditions.

Fig. 8 Evolution of a transverse disturbance ($L=40\text{mm}$), on 4 waves of different curvatures: $r_0 =$ a) 14mm, b) 12mm, c) 10mm, d) 8mm. Time interval = 0.02 seconds.

Critical Assessment of the Proposed Model

The accuracy of any model depends on the validity of the assumptions inherent in the modelling. In the proposed model two distinct theories are used, the first one dealing with the segmentation due to surface tension effects, and the second with the stretching of the tip of the plunging jet, due to gravity and inertia effects.

The formulations on surface tension used in the proposed model are based on linear theory. Non-linear solutions have been developed since the original formulations by Plateau and Rayleigh. Bogy (1979) presented a literature review on the problem of the segmentation of liquid jets. Recent theories take into account finite amplitude disturbances, non-linear interactions, viscosity and air friction. The approximations inherent in the proposed model are such that the use of linear theory in describing surface tension effects is quite reasonable.

Regarding the formulations derived by Longuet-Higgins (1980) on the change of form of the tip of the curling wave, no experimental work has been done to test the theory. The reason for the absence of such a work becomes apparent when one looks at photographs showing the overturning process. The curling face loses its continuity, as it spreads into jets and the free surface boundary is no longer two-dimensional, making the description of the cross sectional profile a most difficult task. The theory and assumptions however, on which the derivations are based are reasonable and, overall, the results are broadly in agreement with observations.

The assumptions inherent in the proposed model introduce their own limitations. Firstly, it is assumed that the tip of the overturning wave behaves like a horizontal liquid cylinder. The surface tension formulations for liquid cylinders are based on the assumption that there is no flow across the surface of the cylinder, a condition which is not necessarily valid in a breaking wave. The effect of this assumption is that the model is strictly applicable to the very tip of the wave crest.

The ridges formed at the back of the wave are not treated by the proposed model. Their formation may be explained by the physics on which the model is built. The back of the wave has its own radius of curvature and any transverse disturbance on its surface will grow or diminish according to surface tension principles. The segmentation of the tip of the wave spreads in the vicinity of the crest. The long wavelengths of the enhanced transverse disturbances are further amplified, as the radius of curvature at the back of the wave is longer than at the tip. These disturbances appear as ridges, or channels of easier flow according to Worthington's (1908) terminology, spaced at wider intervals as their distance from the tip of the breaker becomes greater.

A further assumption built in the model is that the two theories used, namely surface tension and gravity, do not affect each other. That is, the radius of the cylinder is not modified by the growth of the disturbance. This assumption affects mostly the short disturbances which rapidly form thin jets, in which case the horizontal cylinder loses its physical meaning.

Conclusions

Surface tension has been shown to play an important role in the overturning stage of a breaking wave. During this stage, any unstable disturbances on the tip of the breaker will grow as the curling face follows a free fall trajectory. The effects of the two main forces, namely gravity and surface tension have been combined together to produce an analytical/numerical model that describes the evolution of the overturning face of a breaking wave.

The initial conditions of the overturning face were related to the breaker height and period, after making certain approximations. The most important result derived from the model is that breaking characteristics are independent of surface tension effects, for breakers larger than 0.5m high, a result which is in agreement with earlier experimental results.

CHAPTER 74

Comparison of Wave Hindcast Methods for Lower Gulf of Thailand

Sutat Weesakul¹
Supot Charulakana²

Abstract

The practical wave hindcast methods namely, SMB (Sverndrup-Munk-Bretchneider), PM (Pierson-Moskowitz) and SPM 1984 (Shore Protection Manual) were evaluated and accessed for their accuracy using the one year recorded of the available oceanographic data at the lower gulf of Thailand in 1987. It was found that all models show the comparable accuracies of significant wave height (H_s) and significant wave period (T_s) but SPM (1984) rather gave the lowest root mean square error when H_s exceeds 1 m. The empirical formulae of land-wind velocity relationship was simply established in a exponential form. The value of constants in the expression between the 5 meteorological stations on land in the southern part of Thailand and the offshore platform were obtained as well. Using the land-wind velocity empirical formulae and a selected wave hindcast method to predict H_s and T_s , the better result was obtained by the low RMSE value.

Introduction

In developing countries, long term wave record is always lacked due to the high cost of instrument used. This make the unreliable of wave forecasting from the limited number of data for planning and design of coastal projects. A wave hindcast model utilizing local wind velocity will provide more quantitative data of wave climate. The design parameters of two large ports in Thailand is also obtained from the result of wave hindcast models. The selection of appropriate models is quite important and it will govern the project cost. In this study, the result of practical wave hindcast models were compared with the real field measurement to access their accuracy. The empirical relationships of land-wind velocity were established in order to improve the wave hindcast

¹D.Eng, Dept. of Civil Eng, Faculty of Engineering, Chulalongkorn University, Bangkok 10330, Thailand

²Graduate Student, ditto

procedure at specific sites. The better result was obtained and shown with the lower root mean square error for both wave height and period.

Procedure

A comparison of three wave hindcast models was carried out using the oceanographic information recorded at the offshore platform at the lower gulf of Thailand during a period of one year in 1987. The available data were significant wave height, period, wind velocities and their direction respectively. Fig.1 shows the location of offshore platform. The conventional Sverdrup-Munk-Bretschneider (SMB) model was compared with the Pierson-Moskowitz (PM) model and with the relatively new model from shore protection Manual (SPM, 1984).

The SMB wave hindcast model was used as the standard method for wave prediction and its procedure was published and referred to SPM (1977). The PM wave hindcast model was an accepted method and Silvester (1977) and Muangman (1973) described the detail for hindcast deep water wave height and period including the energy transfer concept from the previous wind velocity. Recently, the standard method for wind wave prediction in Shore Protection Manual (1984) was changed. The simplifying equation was based on the parametric approach of Hasselmann et al (1976). This method will refer to as SPM (1984) and it will be tested for its accuracy as well.

The significant data for wave hindcast method was wind direction and velocity overwater or oversea. The problem in wave hindcast method in practical is that how to transform the available recorded overland wind velocity to the overwater wind.

In this study, land-wind velocity relationship was empirically formulated using the Meteorological information observed at the 5 stations at the southern part of Thailand and the offshore wind velocity data. Since the altitude of the meteorological station was not much higher than the sea level, the data between overwater and overland wind velocity was related instead of using pressure gradient. Lag time of wind data was also taken into considered and computed by measuring the distance between the platform and each land station in different wind direction and divided by average velocity. The lag time was used to select the over land data which corresponded to over water wind.

Results

The significant finding from the study will be highlighted associated with the example results herein.

Comparisons of Wave Hindcast Models

The results of all three wave hindcast models were shown by

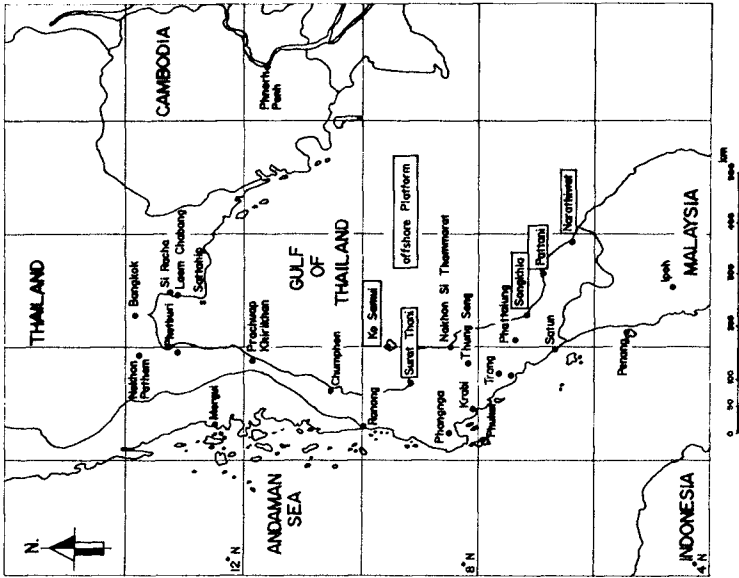

Fig. 1 Location of the Study Area

Fig. 2 Comparison of Predicted and Observed $H_{1/3}$ and $T_{1/3}$ in March 1987

comparing predicted and observed values of significant wave height and period. In Thailand, there are 3 seasonal classified by wind direction. The wind from North East Monsoon always blow from period of December to March. The South West Monsoon start from June to September. Finally the transition period is from April to May and October to November. Examples taken from March, July and December 1987 were depicted in Figs.2 to 4. The predicted values from SPM (1984) were rather overestimated when wave height exceeds approximately 1 m. while the rest is underestimated. The wave period showed the same trend while that from SMB and PM were underestimate. The accuracy of each models were accessed using the root mean square error (RMSE). Figure 5 showed RMSE of wave height and period. SPM (1984) has the less RMSE of wave height compared with the rest when its value exceeds 1 m. while the wave period show scatter RMSE for and model. However, the accuracies in predicting wave height and wave period were comparable for all models. In addition, It was found that most of the time wave condition was duration limited case independent of method used.

Land-Wind Velocity Relationship

Relation of over water wind velocity, i.e at the offshore platform, and that of over land, i.e at the nearby 5 meteorological station on land, were simply established and expressed as

$$R_L = a+b.exp(c.U_L) \quad (1)$$

Knowing over land wind velocity (U_L), the over water wind velocity (U_W) can be computed using the ratio $R_L (=U_W/U_L)$ in the above equation. Fig.6 shows land-wind velocity relationship. Table 1 summarizes the constants, a, b and c, of each stations. It was found that the ratio R_L increased as the station more away from shoreland.

A better result of wave hindcasting, using the over land wind data and the above equation, are depicted in Fig.7. The RMSE reduced from 0.595 m. to 0.383 m. and 6.676s to 5.025s for both significant wave height and period. The improved accuracy are 55% and 33% respectively.

Conclusions

Wave climate at a specific site in the study area can be predicted using the empirical formulae of land-wind velocity relationship and a selected wave hindcast model. Any models give the comparable accuracies of the wave hight prediction but SPM (1984) rather give the high value when wave height exceeds 1 m. with the less RMSE compared with the rest and most of the time the wave period is somewhat lower than the measured one. The procedure described above is useful and practical for engineering application in developing countries which deal with coastal problems since local wave climate is necessarily and basically needed when few field date is available.

CHAPTER 75

Developing Wave-Current Boundary Layers

Richard R.Simons¹
Andreas G.Kyriacou²

Abstract

When applied to real engineering problems, mathematical models of combined wave-current flows usually assume that both wave and current properties remain in a quasi-steady state. Shear stresses and other flow parameters are calculated for instantaneous values of wave height and current strength, regardless of the changes being induced by tides, winds, or wave grouping.

This paper describes tests carried out in a wave flume to investigate velocity profiles, bottom shear stresses and water surface characteristics under gradually developing flow conditions, such as those created when a group of waves is superimposed onto a pre-existing current or when a steady current is added to a train of regular waves. Results indicate that, at laboratory scale, the water surface characteristics adapt within a few wave periods to changes in superimposed waves or current, but that mean velocity profiles and shear stresses may take considerably longer to respond to the new flow conditions.

Introduction

In the assessment of sediment transport at the seabed or in the design of structures to stand in coastal waters, a large number of mathematical models

¹Lecturer, Civil Engineering Dept, University College London.

²Project Manager, Santa Fe Laboratory, UCL, London WC1E 6BT
ENGLAND

are now available to describe the local wave and current processes. Approximately thirty of these models include the effects of wave-current interactions, and their calibration has generally been based on the assumption of a quasi-steady relationship between the wave properties and the current strength [Simons et al. (1988)]. In practice, with coastal hydrodynamics dominated by cyclic tidal currents and storm-generated currents and waves, this is not the case, although it remains to be shown whether the quasi-steady approach gives an adequate prediction. Some models [Christoffersen and Jonsson (1985); Davies, Soulsby and King (1988)] have included the effects of unsteady currents, but these are the exceptions. The DSK (1988) model predicts a rapid change in boundary layer characteristics if the net flow rate, rather than the driving pressure gradient, is maintained after the addition of the waves. However, if instead, the pressure gradient is held constant, then the change to stable wave-current conditions is far less rapid.

The present paper describes a laboratory study aimed at measuring the characteristics of developing flows, in particular looking at the rate at which bottom shear stresses and water surface properties in wave-current flows adapt to varied currents and isolated wave groups.

Wave-Current Interaction

Before going on to consider cases where current strengths are being varied or where short groups of waves are being superimposed on a current, it is worth noting the results from previous studies carried out under "steady" combined wave-current conditions, when regular waves of constant height propagate onto a steady unidirectional current.

Results from earlier experiments in flumes and in the field indicate that the properties of both waves and currents are changed from their separate values. These observations have been used to calibrate and to confirm the physical assumptions necessary in the derivation of wave-current mathematical models. For instance, the addition of wave-induced oscillatory motion has been shown to be capable of inducing orders-of-magnitude increases in the apparent bed roughness and the bottom shear stress felt by the mean current, although the mean

velocity profile retains a logarithmic region [Bakker & Doorn (1978); Brevik & Aas (1980); Kemp & Simons (1982), (1983); Tanaka, Chian & Shuto (1983)]. Turbulence intensities determined from the fluctuations about the ensemble averaged velocities are increased within the oscillatory boundary layer; Simons et al. (1988) found that the increase in u' is of the same order as the increase in u_* defined from the mean velocity profiles.

As a result of the extra frictional resistance at the bed, it has been demonstrated in flume tests that the mean water level slope increases if a constant volume flow rate is to be maintained. Also, rates of wave energy dissipation change in the presence of co-existing currents. Simons, Grass & Kyriacou (1988) showed that attenuation rates decrease if waves propagate over a following current, but that they can increase if the current flows against the direction of wave propagation. It was suggested that this phenomenon could be explained in terms of a wave friction factor, using the definition proposed by Jonsson (1966).

Experiments

The present test programme was performed in a recirculating laboratory flume 610 mm wide and 30 m long, with a still water depth of 300 mm and a horizontal bed roughened with 10 mm limestone chippings. A two channel laser Doppler anemometer was used to determine instantaneous Reynolds stresses and simultaneous horizontal and vertical velocities. The experimental set-up was similar to that described by Simons et al. (1988).

During the test programme, 10 different developing flow cases were investigated, where waves were gradually superimposed onto an existing steady current or vice versa. Seven tests involved running a steady current for one minute, adding waves for 6 minutes, then returning to the current-only state for a further minute. In the other three tests, waves were first propagated through still water for a minute, a current introduced gradually over an 80 second period and run for a further 5 minutes, then the waves turned off and a steady current left to flow for another minute. The experimental conditions are set out in **Table 1**.

Each test was repeated 10 times, with the 2-channel

Run	Initial State:			Superimposed flow:			Final state:

Table 1. Parameters for the developing flow tests.

laser anemometer set at different heights above the bed. Water surface (wave height and MWL) was also recorded simultaneously at 10 points along the flume in 3 groups such as to make it possible to identify and compensate for reflected waves moving back up the flume from the beach. Water surface data were recorded on computer disc every 140ms through a high speed analogue to digital converter, while velocities were stored on magnetic tape for subsequent processing.

In order to analyse the results from these varied flow tests, it was necessary to develop a series of computer programmes capable of synchronizing a large number of independent data files. Each of these files contained a time series of velocities or Reynolds stresses at the chosen measuring positions through the boundary layer, from which full depth profiles of mean velocity, turbulence and Reynolds stress could be generated at different stages through the tests (using appropriate short-term averaging). Simple ensemble-averaging was not possible because of the imposed variation in the "mean" velocities. Time series of MWL and wave height at 3 widely spaced locations along the flume were also required, from which it was possible to derive information on wave attenuation and mean water

surface slope. This process was complicated by having only 10 simultaneous sets of water surface data, closely spaced in three groups (5m, 15m, and 25m from the wave paddle) from which to interpret the significance of reflected waves in the flume.

Two wave periods [0.7s, 1.0s.] and two wave heights [25mm, 40mm.] were considered in combination with three co-directional currents [75mm/s, 190mm/s, 250mm/s].

Results

Fig.1 Boundary layer profiles of horizontal velocity at 30s intervals after the superposition of waves [T=1s;].

In the tests where waves were superimposed onto a pre-existing steady current, it was found that the mean velocity profile took approximately 200 wave periods to stabilize under the new combined flow conditions. The increase in shear stress at the boundaries slowed the mean current, causing a redistribution of flow across the channel. Fig.1 shows mean velocity profiles at 30 second intervals after generation of the first wave at the paddle 15 m upstream. Despite the scatter caused by

such a short averaging period, the mean velocities can be seen to be more or less established in a stable profile after 150s; over the next 50s, velocities increase towards their initial current-only values near mid-depth, but with slower flow maintained near the bed and at the surface. It should be remembered here that the mean velocities reflect not just the superimposed current flow but also wave-induced mass transport.

Fig.2 Development of Horizontal Oscillatory Velocities at 30s intervals after the start of wave generation.

In order to determine orbital velocity amplitudes and turbulence intensities during the transitional period after the addition of the waves, a second order curve fit was applied to the unprocessed velocity data to establish the oscillatory component. The short term mean velocity and the reconstituted 2nd order orbital velocity were then subtracted from the raw data, leaving the turbulent velocity fluctuations. The root-mean-square of these short samples (5 s; 30 s) were then used to quantify the instantaneous turbulence intensities.

The same procedure was applied to horizontal and vertical velocity components and to Reynolds stresses. Fig.2 shows the variation in horizontal orbital amplitude through the depth at time intervals corresponding to those in fig.1; the wave motion was found to be stable after the generation of 20 or so waves.

Fig.3 Development of Horizontal Turbulence Intensities at 30s intervals after waves are superimposed.

Profiles of turbulence intensity through depth showed considerable scatter, as the 30s averages plotted in fig.3 demonstrate. The profile containing the highest values near the bed relates to data sampled early in the test, and is probably attributable more to the change in mean velocity during the initial 30s sample rather than to real turbulence. Careful study of the profiles of u' and v' could justify a conclusion that stable wave-current conditions have been established after 30 or so wave periods, but such a view must be taken as tentative.

Fig.4 Variation in water surface elevation when waves are added to a steady current: a) 5m from the wave paddle; b) 25m from the wave paddle.

Turning now to the behaviour of the water surface, fig.4 records the water surface movement at the measuring station closest to the wave paddle (top) and near the beach, 20m. downstream (bottom). Using the second order curve-fitting routine, it was possible to analyse these data further to yield time series of wave heights (fig.5) and "mean" water levels (fig.6) for the corresponding tests. These results confirm earlier observations that the mean water level slope is increased by the addition of waves. Figs.4 and 6 both show the water level rising at the paddle end of the flume by between one and two millimetres, with a corresponding fall at the beach end. This change takes approximately 30s. to stabilize, whereas wave heights build up to a constant value within three or four seconds of the arrival of the first wave. The regular oscillation apparent in the MWL traces is due to the use

Fig.6 Time series of mean water level 5m from the paddle when waves are added to a steady current.

Fig.5 Time series of wave heights 5m from the paddle when waves are added to a steady current.

of a digitizing interval which does not exactly repeat at the same phase each wave cycle.

Fig.7 Time series of wave heights 5m from the paddle when waves are added to a steady current.

All the results described above relate to the first series of tests where waves are added to a pre-existing current. Analysis is still to be completed for the tests where a current was gradually imposed onto regular waves. However, fig.7 shows the water surface movement at the 5m position along the flume during one of these runs. Despite the great care exercised in opening the current control-valve, a seiche wave has clearly been set up in the flume. This emphasizes the difficulty in carrying out and analysing data from these unsteady tests.

Conclusions

From the profiles of mean velocity and turbulence characteristics, it has been shown that stable wave-current conditions may not be established until nearly

200 waves have passed the LDA measuring position. However, a far more rapid time-scale (say 15 wave periods) was evident in the changes in hydraulic gradient along the flume induced by the addition of waves to a current.

These results suggest that care needs to be taken when using wave-current models in coastal engineering for the prediction of mean velocities and consequential sediment transport rates if wave conditions are changing rapidly. However, a quasi-steady approach appears appropriate where changes in wave characteristics and mean water levels are the only consideration.

CHAPTER 76

INCORPORATION OF WAVE EFFECTS IN A 3D HYDROSTATIC MEAN CURRENT MODEL

H.J. de Vriend¹⁾ and N. Kitou²⁾

Abstract

The consistency of the mathematical formulation of a 3D hydrostatic current model for coastal areas is discussed. At various points, widely accepted concepts and formulations are shown to lead to inconsistencies, and more consistent alternatives are proposed. Besides, some essential lacunae in our physical knowledge of 3D wave-driven currents are indicated.

Introduction

Nearshore currents have a three-dimensional structure, which plays an important part in coastal dynamics. Mathematical models in this field ought to take this into account. Especially if the wave-induced "cross-shore" sediment transport is concerned, descriptions of the near-bed current velocity based on a 2D depth-integrated current model will fail (cf. De Vriend, 1986). Also 2D-vertical models will fail in many practical cases, by lack of longshore uniformity. Quasi-3D models, coupling a 1D-vertical and a 2D depth-integrated model to describe a 3D current field, may bring relief here. This type of models, however, needs further substantiation before being ready to describe nearshore currents (Arcilla et al., 1990; Svendsen and Putrevu, 1990). Fully 3D current models, therefore, have their part to play here, if it were only as a reference for simpler models (e.g. Q3D).

The present paper describes the incorporation of wave-effects into a 3D-hydrostatic mean current model. It concerns the form and the consistency of the basic mathematical formulation, rather than the actual numerical implementation.

Model concept

We will start from a 3D hydrostatic current model, with the vertical plane mapped onto a rectangle via the so-called sigma-trans-

-
- 1) DELFT HYDRAULICS, P.O.B. 152, 8300 AD Emmeloord, The Netherlands
 - 2) Demokritos Univ. of Xanthi, Dept. of Civil Engrg., 67100 Xanthi, Greece

formation. It is essential for the concept presented herein, that the vertical is discretized into a fixed number of steps (layers), the uppermost of which covers at least the full height of the sea waves (Fig. 1).

Fig. 1 Discretization of the vertical plane

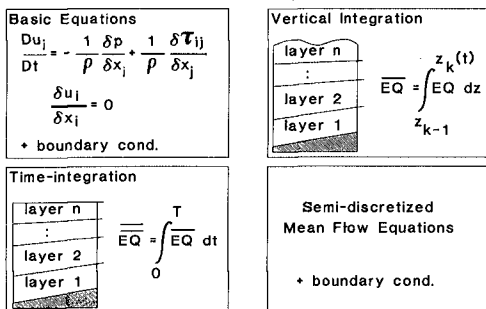

Fig. 2 Derivation of semi-discretized wave-averaged equations

The net wave effects are included in the constituting equations for the mean current by formal integration of the Reynolds equations over the vertical elements of the computational grid and over the time scale of the waves (Fig. 2).

The resulting semi-discretized equations contain a number of wave residual terms, viz.

- mass flux terms in the equation of continuity,
- mass flux terms in the momentum equations, and
- wave-induced effective stresses in the momentum equations.

Besides, the waves influence the turbulent exchange of momentum and the effective bottom shear stress.

In the next sections, we will discuss these effects one by one, supposing the wave parameters to be given, i.e. we will not go into the matter of fully interactive wave-current systems.

Wave-induced mass flux

In the case of periodic waves, the wave-averaged equation of continuity contains no net wave-effects in layers entirely below the wave trough level, i.e. in all layers but the one adjacent to the water surface.

The wave-averaged equation for this top layer reads

$$\frac{\partial \Delta_k}{\partial t} + \frac{\partial}{\partial X_i} \left(U_{i,k} \Delta_k + \frac{M_i}{\rho} \right) + T.T. = 0 \tag{1}$$

in which:

- t = time,
- X_i = horizontal co-ordinates (i=1,2),
- Δ_k = thickness of the k-th layer,

- $U_{i,k}$ = horizontal mean velocity components, averaged over the k-th layer,
- M_i = wave-induced mass flux components,
- ρ_i = mass density of the fluid,
- T.T. = terms related to the sigma-transformation.

The wave-induced mass flux components in this equation are defined by

$$M_i = \frac{1}{T} \int_t^{t+T} dt \int_{z_{n-1}}^{z_n} \rho \tilde{u}_{i,n} dz \tag{2}$$

in which T denotes a significant time scale of the wave motion, long enough to yield a meaningful average, $\tilde{u}_{i,n}$ is the wave orbital velocity in the top layer, and n is the index of this layer.

On the basis of a wave theory, Eq. (2) can be elaborated in terms of wave field parameters (height, direction, etcetera). We will discuss this in a later section.

At the physical level, Eq. (2) means an extension with respect to 2D-vertical and 2D-horizontal situations: the mass flux can give rise to 3D circulations, as is illustrated in Fig. 3.

Figure 3 3D effect of wave-induced mass flux

Wave-induced momentum flux

The procedure outlined in Figure 2, when applied to the momentum equations, yields residual wave-effects through the non-linear advection terms. Using

$$\frac{1}{T} \int_t^{t+T} dt \int_{z_{k-1}}^{z_k} u_{i,k} u_{j,k} dz = U_i U_j \Delta_k + U_i \frac{M_i}{\rho} + U_j \frac{M_j}{\rho} + \frac{1}{T} \int_t^{t+T} dt \int_{z_{k-1}}^{z_k} \tilde{u}_{i,k} \tilde{u}_{j,k} dz \quad (3)$$

we can split the residuals of the horizontal advection terms into a mean-flow part, a mass-flux related part (two terms), and a part that contributes to the radiation stress.

The vertical advection term also yields a wave-residue, which should not be disregarded a priori (also see Svendsen and Lorenz, 1989, and Deigaard and Fredsøe, 1989).

The resulting semi-discretized equation for the k-th layer reads

$$\begin{aligned} \frac{D}{Dt} \left(U_{i,k} \Delta_k + \frac{M_i}{\rho} \right) + (U_i W)_{z_{k-1}}^{z_k} = \\ - g \Delta_k \frac{\partial z_s}{\partial X_i} + \frac{1}{\rho} \frac{\partial}{\partial X_j} (\Delta_k \bar{\tau}_{ij,k}) + \frac{\bar{\tau}_{i,z}}{\rho} \Big|_{z_{k-1}}^{z_k} + \\ + \frac{1}{\rho} \frac{\partial}{\partial X_j} (\Delta_k \bar{\sigma}_{ij,k}) - \langle \tilde{u}_i \tilde{w} \rangle \Big|_{z_{k-1}}^{z_k} + T.T. \end{aligned} \quad (4)$$

in which:

W = mean vertical velocity component,

g = acceleration due to gravity,

z_s = water surface level,

$\bar{\tau}_{ij}$ = Reynolds stress components in vertical planes,

$\bar{\tau}_{i,z}$ = Reynolds stress components in horizontal planes,

$\bar{\sigma}_{ij}$ = wave-induced effective stress,

\tilde{u}_i, \tilde{w} = wave-orbital velocity components,

T.T. = terms due to the co-ordinate transformation.

The mass flux component, non-zero in the top layer only, is defined by (2). The definition of the wave-induced effective stress reads

$$\bar{\sigma}_{ij,k} = \frac{1}{T} \int_t^{t+T} \frac{dt}{\Delta_k} \int_{z_{k-1}}^{z_k} \rho \tilde{u}_{i,k} \tilde{u}_{j,k} dz + \frac{\delta_{ij}}{T} \int_t^{t+T} \frac{dt}{\Delta_k} \int_{z_{k-1}}^{z_k} (\bar{p} - \rho \langle \tilde{w}^2 \rangle) dz \quad (5)$$

in which \bar{p} denotes the instantaneous hydrostatic part of the pressure and δ_{ij} is the Kronecker delta.

In general, the wave-induced mass flux will be small as compared with the mass flux related to the mean flow. If not, the mean flow velocity will be so small, that the advection terms are negligible, anyway. We will therefore disregard the mass-flux related residual advection terms.

The remaining residue of wave-induced horizontal advection basically acts as an effective stress, comparable to the Reynolds stress. In depth-integrated models, it adds up to the radiation stress (Longuet-Higgins and Stewart, 1964); in the present 3D model, this stress is distributed over the vertical. Consequently, the wave-induced current forcing, composed of the divergence of the effective stress and the vertical advection residue, also has a vertical distribution.

In addition to the wave-induced terms in (4), which vanish in the absence of waves, there are also wave-influenced terms, which are just modified by wave effects. The shear stress terms are of this type, and so are the near-bed boundary conditions.

In the next sections, we will discuss how the mass flux, the effective stress and the wave-induced current forcing can be elaborated in terms of global wave field properties, such as energy density, energy dissipation rate, etcetera. The other wave-influenced terms will receive further attention in a later section.

Evaluation for harmonic waves

Wave-induced mass flux

Using linear wave theory, Eq. (2) for the wave-induced mass flux can easily be elaborated to

$$M_i = \frac{E}{c} e_i^w \quad (6)$$

in which E is the energy density of the wave field, c is the wave celerity, and e_i^w denotes the components of the unit vector in the direction of wave propagation.

Wave-induced forcing ("classical" approach)

In depth-integrated models, it is customary to evaluate the radiation stresses on the basis of linear wave theory for a quasi-uniform domain (mild-slope approximation).

When applied to the present vertically resolved model, this theory yields for the effective stresses

$$\begin{aligned} \bar{\sigma}_{ij,k} &= \left(N - \frac{1}{2}\right) E f_{ij}(z_k) + \frac{1}{2} \delta_{kn} E \\ \langle \tilde{u}_{i,k} \tilde{w} \rangle &= 0 \end{aligned} \quad (7)$$

in which N is the ratio of group and phase celerity, and f_{ij} is a function of z only. Note that the last term of the expression for $\bar{\sigma}$ exists only in the top layer.

The corresponding wave-induced driving force per unit area (henceforth called "force", as the term "stress" has already been used for the effective stress tensor) can be elaborated to

$$F_{i,k} = \frac{D}{c} e_i^w f_D(z_k) - \frac{1}{2} \frac{\partial E}{\partial X_i} f_E(z_k) + \dots \tag{8}$$

in which D denotes the dissipation rate of the wave field, and f_D and f_E are functions of z only.

Figure 4 Decomposition of wave-induced force ("classical" theory)

The wave-induced force according to (8) can be split into three parts, viz. (also see Fig. 4)

- a surface part: $F_{s_i} = - \frac{1}{2} \frac{\partial E}{\partial X_i}$ (9)

- a depth-invariant part: $\bar{F}_i = h \frac{\partial}{\partial X_i} \left\{ \frac{(n-\frac{1}{2})E}{h} \right\} + \frac{1}{2} \frac{\partial E}{\partial X_i}$ (10)

- a depth-varying part: $F_{z_i} = \frac{E}{h} f_1(z) + \frac{1}{2} \frac{\partial E}{\partial X_i} f_2(z) + \frac{D}{c} f_3(z)$ (11)

The depth-invariant part of the force is fundamentally unable to drive a circulation current and is therefore disregarded here. The depth-varying part is basically able to drive a circulation, but it is usually assumed weak enough to be disregarded. This leaves the surface part, which acts at the mean water surface like a wind stress. It corresponds with the force at the wave trough level in various undertow models (Svendsen, 1984; Stive and Wind, 1986).

According to Eq. (9), the force will be non-zero in non-breaking (e.g. shoaling) wave fields. This is a major inconsistency of the model. If there is no ambient current and no wave breaking, all of the above results stem from a description of an ideal fluid in irrotational motion. The surface force resulting from this theory, however, will give rise to an infinite vorticity when applied to an ideal fluid body.

Wave-induced forcing (revised theory)

In a genuinely uniform situation, there will be no gradients in global parameters, such as E, and hence there will be no surface force and no inconsistency. From a practical point of view, however, a model should cover more than this trivial case.

Any deviation from uniformity in the "classical" model gives rise to the aforementioned inconsistency. Upon closer investigation, this is basically due to the assumption of quasi-uniformity of the domain and the global wave field parameters, which underlies the description of the vertical structure of the wave motion in the "mild-slope" approximation (Berkhoff, 1976):

$$\begin{Bmatrix} \tilde{\eta} \\ \tilde{u} \\ \tilde{p} \end{Bmatrix} = \begin{Bmatrix} \hat{\eta} \\ \hat{u}(z) \\ \hat{p}(z) \end{Bmatrix} \cos\chi \quad \text{with: } \chi = \omega t - kX \quad (12)$$

$$\tilde{w} = \hat{w}(z) \sin\chi$$

In this approximation, each of the amplitude functions \hat{u} , \hat{p} and \hat{w} is strictly similar in every vertical of the domain. Spatial non-uniformities only affect their scaling.

In order to achieve consistency of the model, we shall relax the mild-slope approximation. Going back to irrotational motion in a domain with a mildly sloping bottom and weakly non-uniform global wave parameters, we can take the classical solution as a basis and perturb this for small non-uniformities. In a horizontally 1D case, oriented along the X-axis, this yields in a first-order approximation (see De Vriend and Kitov, 1990, for further details)

$$\tilde{\eta} = \hat{\eta} \cos\chi \quad (13)$$

$$\tilde{u} = \hat{u}(z) \cos\chi + f_u \left(\frac{\partial z_b}{\partial X}, \frac{\partial z_s}{\partial X}, \frac{\partial k}{\partial X}, \frac{\partial \hat{\eta}}{\partial X}; z \right) \sin\chi \quad (14)$$

$$\tilde{w} = \hat{w}(z) \sin\chi + f_w \left(\frac{\partial z_b}{\partial X}, \frac{\partial z_s}{\partial X}, \frac{\partial k}{\partial X}, \frac{\partial \hat{\eta}}{\partial X}; z \right) \sin\chi \quad (15)$$

in which the functions f_u and f_w depend linearly on the gradients of the global parameters z_b , z_s , k and $\hat{\eta}$.

Substituting this result into the expressions for the effective stresses yields

$$\bar{\sigma}_{ij,k} = (N - \frac{1}{2}) E f_{ij}(z_k) + \frac{1}{2} \delta_{kn} E \quad (16)$$

$$\langle \tilde{u}_{i,k}, \tilde{w} \rangle = (N - \frac{1}{2}) E f_E \left(\frac{\partial z_b}{\partial X}, \frac{\partial z_s}{\partial X}, \frac{\partial k}{\partial X}; z \right) + f_E(z) \frac{\partial E}{\partial X} \quad (17)$$

in which f_{ij} and f_E are functions of z only, and f_E depends linearly on the gradients of z_b , z_s and k . Note that, unlike Eqs. (14) and (15), the effects of the amplitude variation are separated and yield the energy-gradient term of (17).

Also note that (16) is identical to (7), i.e. in a first-order approximation the residue of the horizontal momentum flux is not affected by the global non-uniformities.

In contrast with the classical theory, however, the vertical momentum flux is deviating from zero now!

Although we have only derived the revised theory for a 1-D case, it seems reasonable to assume, that similar results will be found when applying the same idea to horizontally 2-D situations.

Let us therefore assume, without formal proof, that in such a situation the vertical momentum flux contribution (17) can simply be rotated into the direction of wave propagation.

In that case, elaboration of the wave-induced driving forces yields

$$F_{i,k} = \frac{D}{c} e_i^w f_D(z_k) + \text{irrot. terms} \quad (18)$$

The irrotationality of the last terms in this equation refers primarily to the horizontal plane, but, upon closer inspection, these terms are also irrotational (uniformly distributed) in the vertical. Hence this part of the force is basically unable to drive a circulation current and can be disregarded here. The remaining part is proportional to the energy dissipation rate of the wave field (cf. Longuet-Higgins, 1970; Battjes, 1988), and it turns out to be concentrated in the top layer, where the $\langle \tilde{u}\tilde{w} \rangle$ -term reaches its highest value and where the dissipation actually takes place (Fig. 5).

Figure 5 Decomposition of wave-induced force (revised theory)

The inconsistency of the classical model has now been removed: if the flow is inviscid, there is neither dissipation, nor wave-induced current forcing. Apparently, the vertical momentum flux term, which is the only part of the forcing influenced by the present extension of the wave model, plays a key role in achieving consistency (cf. Svendsen and Lorenz, 1989, for waves on a sloping bottom, and Deigaard and Fredsøe, 1989, for breaking waves). This may seem to be in contrast with Stive and Wind's (1986) observation, that the $\langle \tilde{u}\tilde{w} \rangle$ -term, when evaluated on the basis of measured data, is relatively small. We would like to point out, however, that the principal effect of this term is concentrated in the top layer of the fluid, between the troughs and the crests of the waves. Stive and Wind's data set does not extend to this area.

Role of bottom friction and wind-input

Although the formal derivation of (18) is based on the inviscid flow assumption, the wave boundary layer can easily be included. There, again, the $\langle \tilde{u}\tilde{w} \rangle$ -term plays a prominent part (Longuet-Higgins, 1953; also see Craik, 1982): it yields the driving force of the boundary layer streaming.

In general, the forcing will be located where the dissipation of organized motion actually takes place (cf. Nairn et al., 1990). As illustrated by Fig. 6, this will be in the surface layer for wave-breaking and wind-input (negative dissipation!), in the bottom boundary layer for bottom friction, and probably throughout the water column for wave-turbulence interaction in an ambient turbulent flow.

It may be clear, that in a depth-integrated current model outside the surf zone the contributions of the various types of wave energy dissipation ought to be weighted according to their location in the vertical. They cannot simply be piled up in a current-driving body force, which is implicitly assumed (via the assumptions under-

lying the depth-averaging) to be uniformly distributed over the vertical. This would imply too much emphasis on the forcing associated with bottom friction, and too little on the wind-induced forcing. Unfortunately, this is exactly what is done when putting the results of a wave model, including effects of wind-input and bottom friction, into a classical radiation stress and wave-induced force computation, and driving a depth-averaged current model with the resulting forces. Models of this type covering large areas with mainly non-breaking waves should therefore be considered with caution.

Figure 6

Location of wave-induced current forcing

Evaluation for broken waves

Roller concept

According to a concept introduced by Svendsen (1984), a broken wave of the spilling type can be considered as a harmonic carrier wave with a surface roller at its front face. This roller introduces an additional complication for the surf zone.

Since the roller moves with the wave celerity c , its contributions to the wave-averaged fluxes of mass, momentum and energy are given by (also see Deigaard and Fredsoe, 1989)

$$\text{mass flux: } \rho \frac{Ac}{\lambda} \tag{19}$$

$$\text{momentum flux: } \rho \frac{Ac^2}{\lambda} \tag{20}$$

$$\text{energy flux: } \rho \frac{Ac^3}{\lambda} \tag{21}$$

where λ denotes the wave length and A the cross-sectional area of the roller. According to Svendsen (1984), the latter quantity can be estimated at $0.9 H_{cw}^2$, if H_{cw} is the height of the carrier wave.

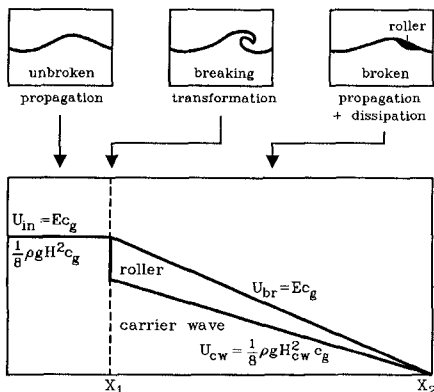

The total mean energy flux due to a broken wave follows from

$$E_{br}c_g = \frac{1}{8} \rho g H_{cw}^2 c_g + \rho \frac{Ac^3}{\lambda} \tag{22}$$

in which c_g is the group celerity of the waves. With the above approximation of A and the shallow water approximation of the phase and group celerities, this leads to (cf. De Vriend and Stive, 1987)

$$E_{br} = E_{cw} \left(1 + 7 \frac{h}{\lambda} \right) \tag{23}$$

Both (22) and (23) express, that there is a difference between the energy contents of the carrier wave and the broken wave as a whole, due to the contribution of the roller (Fig. 7).

Hence it makes a difference, whether we describe the waves by their bulk energy density, e.g. by solving an energy balance equation including a dissipation term, or by the height of the carrier wave, e.g. via a breaker height criterion. In the former case, the roller effect is already included in the computed energy density, E_{br} , whereas in the latter case the roller contribution has to be accounted for explicitly.

Figure 7 Energy flux due to broken waves

Wave-induced mass flux

The wave-induced mass flux, found by adding the contributions of the carrier wave and the roller, reads

$$M_{br} = \frac{E}{c} + \rho \frac{Ac}{\lambda} \tag{24}$$

or, making use of Eq. (23) and the underlying assumptions,

$$M_{br} = \frac{E_{br}}{c} \tag{25}$$

Apparently, the mass flux, at least in this approximation, can be expressed in terms of the bulk energy density of the broken waves, without any additional term to account for the roller contribution.

Note, however, that this is only valid as long as the shallow water approximation applies to c and c_g .

Wave-induced forcing

Eq. (18) gives the wave-induced forces in terms of the energy dissipation rate, including the effect of breaking. Hence, it is the most convenient to derive these forces from a wave model that describes the decay of the bulk energy density by solving an energy balance equation including dissipation. In that case, the roller contribution in D needs not be calculated explicitly.

If the wave model describes the height of the carrier wave, e.g. via the breaker height criterion $H_{br} = yh$, the dissipation rate has to be calculated from

$$D = - \frac{\partial}{\partial X} \left[\frac{1}{8} \rho g H_{cw}^2 c_g + \rho \frac{Ac^3}{\lambda} \right] \tag{26}$$

Here the roller contribution has to be taken explicitly into account.

Wave influence on turbulence effects

Waves also exert their influence on the mean current through turbulence and boundary shear stress. Non-breaking waves affect the

near-bed water motion and the bed shear stress (for instance, see Van Kesteren and Bakker, 1984, or Davies et al., 1988), and they are also suspected to interact with the turbulence higher up in the water column.

Broken waves introduce an additional turbulence production mechanism, which can be of significant influence in a large part of the vertical (Justesen et al., 1986), and possibly also in the horizontal (Wind and Vreugdenhil, 1986).

In the transition zone, where waves start breaking, there is a transformation of organized wave motion, through overtopping and roller formation, into turbulence. Nairn et al. (1990) show, that this transition process should be taken into account when modelling the currents in this zone.

Starting from the Boussinesq hypothesis, so from a scalar eddy viscosity, there is a range of turbulence models and bed stress models at our disposal. Very few of these models, however, include wave effects in a well-validated manner.

Without going into details, we will consider three types of models, indicate how wave effects can be included and assess the state of the art.

Partial-slip model

Leendertse (1987), in his 3D-hydrostatic current model, uses a combination of a constant eddy viscosity and a partial-slip condition at the bottom

$$\nu_t \left. \frac{\partial U}{\partial z} \right|_{z_b} = A |U_1| U_1 \quad (27)$$

in which the factor A is the key element of the model. It has to be derived from known shear stress descriptions, such as Chezy's or Manning's model.

This technique, sometimes referred to as Bazin's method, has proved rather successful in plane or slightly disturbed steady shear flow (e.g. in rivers and well-mixed estuaries; Engelund, 1974). As far as we know, it has never been shown to work equally well for strongly distorted oscillatory shear flow.

When attempting to apply this concept to the coastal situation, with its strongly distorted 3D flow and its complex shear stress relationships, the determination of A becomes rather laborious, if possible, at all. In view of the rather weak physical basis, the effort to further work out this concept seems not justified.

Algebraic eddy viscosity model

Algebraic eddy viscosity models are widely used in engineering applications. Very often, this is combined with a similarity assumption, which, for a simple pressure-driven shear current, boils down to

$$\nu_t = \bar{\nu}_t f_v(z) \quad (28)$$

A parabolic shape function f_v , combined with appropriate boundary conditions, leads to the well-known logarithmic velocity profile. The depth-invariant scaling factor, $\bar{\nu}_t$, reflects the turbulence production mechanism. In plane shear flow, for instance, $\bar{\nu}_t$ is proportional to the bottom shear velocity.

A way of including wave effects into this type of model is to adjust \bar{v}_t for wave-induced turbulence generation. In principle, this can concern only turbulence generated at the bottom, since other production mechanisms are likely to correspond with other vertical shape functions. This means, that breaker-generated turbulence is not included, nor the interaction of waves and turbulence throughout the water column.

It may be possible to model the various wave-effects on turbulence separately and to superimpose the results. The eddy viscosity is a non-physical artefact, which is unsuited for superposition, but superimposing turbulence kinetic energy contributions seems a defensible case (Deigaard et al., 1986).

At the eddy viscosity level, this would mean a quadratic composition

$$v_t = \left[\left\{ \bar{v}_t f_v(z) \right\}_{\text{bottom}}^2 + \left\{ \bar{v}_t f_v(z) \right\}_{\text{breaking}}^2 + \dots \right]^{\frac{1}{2}} \quad (29)$$

shear

In practical model applications, a vertical resolution which is sufficient to describe the details of boundary layers is seldomly feasible. In those models, the boundary layer is described with a separate, semi-analytical boundary layer model, which is matched with the numerical solution, e.g.

$$U = \frac{U_*}{\kappa} \ln \frac{z}{z_0} \quad (30)$$

in which U_* denotes the wall shear velocity and z_0 is the point of zero intersection of the velocity profile. In general, z_0 is given in terms of roughness parameters, and the matching with the numerical model goes via U_* .

Waves are known to influence both quantities: they tend to enhance the effective wall shear stress, and they shift the point of zero intersection of the mean velocity further away from the wall (see, for instance, Van Kesteren and Bakker, 1984).

Higher-order turbulence closure

A more sophisticated way of describing turbulence is the so-called higher-order closure, based on one or more coupled transport equations for turbulence properties, such as the kinetic energy. Typical examples are the k-model (e.g. Deigaard et al., 1986) and the k- ϵ model (e.g. Wind and Vreugdenhil, 1986).

Higher-order turbulence models have proven their value for intra-wave current modelling (e.g. Davies et al., 1988). At the level of wave-averaged current modelling, however, their present applicability is limited by a lack of basic knowledge. Possibly important turbulence production mechanisms (wave-turbulence interaction) are still poorly known, and the knowledge of the intra-wave processes has hardly been parameterized in terms of mean-current and global wave properties.

On the other hand, depth-averaged models including wave breaking as a source of turbulence production (Battjes, 1983; Wind and Vreugdenhil, 1986) seem to work well. It has to be pointed out, however, that these models have only been tested critically for the inner surf zone, where this type of production is predominant.

For other areas, wave-averaged higher order turbulence models have not yet been substantiated.

Conclusions

The principal conclusions from the work presented herein can be summarized as follows.

- The wave-induced mass flux has to be included in the equation of continuity for the top layer. It will not always be compensated by a return current in the same water column, but can give rise to 3D circulations.
- The $\langle \bar{u}\bar{w} \rangle$ -term in the wave-averaged momentum equation plays an essential part in the consistency of the model in spatially non-uniform situations.
- The classical mild-slope approximation leads to inconsistency of the model, because it yields inappropriate estimates of the $\langle \bar{u}\bar{w} \rangle$ -term. An extended linear wave model for mildly non-uniform situations leads to consistent results.
- Wave-induced current forcing is located there, where the wave energy dissipation actually takes place. This means, that the forcing due to spilling breakers takes place near the water surface, and that forcing associated with bottom dissipation takes place near the bottom.
- The necessity to include a roller contribution when modelling wave-driven currents depends on whether the bulk energy density of the breaking waves is described, or the carrier wave height. Only in the latter case, a roller contribution has to be taken explicitly into account.
- So far, the application of higher-order turbulence models in wave-averaged current models is not supported by sufficient physical knowledge, except maybe for very specific situations.

Acknowledgement

The major part of the work presented herein was carried out during the second author's stay at DELFT HYDRAULICS, in 1988, which was co-financed by the University of Xanthi, Greece. The results will be implemented and utilized by both authors in Project 0035-C, "G6 Coastal Morphodynamics" of the Marine Science and Technology (MAST) Programme of the Commission of the European Communities.

CHAPTER 77

Nonsteady computations of undular and breaking bores

A.F.Teles da Silva ¹ and D.H.Peregrine ²

1. Introduction

A bore occurs when water with local depth h_1 , say, moves over shallower water with depth h_2 , necessarily moving at a lower speed, in a scale in which horizontal distances are a few times bigger than either h_1 or h_2 . The bore is the region of transition between the two uniform depths and speeds. If the slopes are initially gentle, the bore gets gradually steeper and develops into one of three types depending on the ratio $\Delta = \frac{h_1-h_2}{h_2}$. For small enough values of Δ , $\Delta < \simeq 0.3$, the bore front develops into a smooth succession of long waves. The difference between the upstream and downstream levels is fitted with undulations which are long at the front and short at the back. These are called undular bores. For big enough values of Δ , $\Delta > \simeq 0.7$, bore fronts break and the whole bore takes the aspect of a turbulent breaking zone extending over some depths and advancing at a constant speed (over a flat bed); outside this turbulent zone the water is flat. For intermediate values of Δ breaking and turbulence at the front precede a train of smooth undulations. Here the difference in level between upstream and downstream is fitted partially with breaking and turbulence in the front and partially with undulations. these bores are called undular breaking bores.

The classical bore theory, Lamb (1932) article 187, supposes a well developed bore advancing at constant speed and calculates the fluxes of mass, momentum and energy across the bore in a frame of reference moving with the bore speed. It is shown that if mass and momentum are preserved, energy must be necessarily lost. Benjamin and Lighthill (1954), applied this approach, within the approximation of Kortweg & De Vries' equation, to the first

¹ Instituto de Matemática, Univ. Fed. do Rio de Janeiro & Lab. Mec. Fluidos, Prog. Eng. Mec., COPPE, CP68503, CEP21910, Rio de Janeiro - RJ, Brazil

² School of Maths, Univ. of Bristol, Bristol BS8 1TW, England

undulation of an undular bore; they show that, if mass momentum and energy are preserved, the wave is necessarily a solitary wave, if energy is lost the wave is a cnoidal wave. A limitation to the applicability of the classical approach to the whole of an undular bore is that, at any time, the flow at its back is unsteady; because new undulations are continually forming and growing, turning the bore into an intrinsically unsteady phenomenon even if waves in the front assume a nearly steady aspect. Hence, in order to understand the bore as a whole, with its upstream and downstream regions, the evolution must be followed from an initial state. The simplest unsteady model is provided by shallow water equations; although, these are unable to predict undulations because vertical components of velocity are neglected. A higher order unsteady modelling is obtained by either Boussinesq's or Kortweg & De Vries' equations. Peregrine (1966), using a smooth transition as initial state, integrates Boussinesq's equations, numerically, in order to follow the evolution of gentle undular bores. The characteristic formation of smooth undulations is compared with the continuous steepening predicted by shallow water theory. Using K. & De V.'s equation, Gurevich & Pitaevskii (1973), calculate analytically, an asymptotic solution valid for large values of time, the evolution of a step like initial condition. It is found that the separation between successive crests increases logarithmically and the height of the solitons at the head of the bore is 2Δ for an initial step of magnitude Δ .

In the present work we model the unsteady evolution of an initially gentle transition using a completely nonlinear mathematical formulation. The only approximations are the ones inherent to perfect fluid modelling. The flow is described by a potential of velocities ϕ which at any time obeys to:

$$\nabla^2 \phi = 0 \quad (1)$$

$$\phi_t + \frac{1}{2} \nabla \phi^2 + gY = 0 \quad \frac{D\mathbf{R}}{Dt} = \nabla \phi \quad (2)$$

$$\phi_y = 0 \quad (3)$$

$$\lim_{x \rightarrow -\infty} Y = h_1 - h_2 \quad \lim_{x \rightarrow \infty} Y = 0$$

$$\lim_{x \rightarrow -\infty} \nabla \phi = (U_1, 0) \quad \lim_{x \rightarrow \infty} \nabla \phi = (U_2, 0) \quad (4)$$

(1) is to be valid inside the fluid region; equations (2) are to be satisfied on the free surface which is described parametrically by $\mathbf{R} = (X, Y)$ to allow for overturning, g is the acceleration of gravity; equation (3) is valid on the flat bed placed at $y = -h_2$; the four

equations (4) are valid on the extremities, $x = \pm\infty$ and h_1, h_2, U_1 and U_2 are given constants. Moreover we re scale distances by the downstream depth h_2 and accelerations by the acceleration of gravity g . The evolution of the free surface is calculated by a numerical method which is a modification of Dold & Peregrine's (1986) boundary integral scheme from the initial free surface profile

$$Y = \frac{\Delta}{2}[1 - \tanh(\alpha X)] \quad (5)$$

For most of the computations the value of α has been set to $\alpha = 0.25$.

2. Numerical Results

Figure 1a shows the evolution of a strong bore, for $\Delta = 0.8$, for times 0, 2, 4, 6, 8, 10, 12 and 14, (from top to bottom in that order). Figure 1b shows the bore overturning at time 14.95. Figure 2a shows the evolution of an undular breaking bore, for $\Delta = 0.35$, for times 0, 10, 20, 30, 40, 60 and 70, with a vertical magnification of 10. This bore breaks at time 71.9; the breaking crest is shown in Figure 2b.

In order to assess the influence of Δ on the bore evolution we follow the growth of the first wave. Figure 3 shows graphs of height of the first crest, (x axis), against time, (y axis), for several values of Δ : 0.1, 0.2, 0.25, 0.28, 0.3, 0.3125, 0.325, 0.35, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.2 and 1.5 (from bottom to top). Waves have been followed until time 140, for cases in which breaking did not occur, and until the moment when a slope of 90° first appear. Waves can, approximately, be grouped into three types:

- i*) the crest grows towards an asymptotic value;
- ii*) the crest first behaves as if in *i*) and then steepens and rapidly breaks;
- iii*) the crest grows at an accelerated rate until breaking.

These types correspond to the three bore types: undular, breaking and undular breaking. More details of the computations are given in Table 1. Table 1, below, gives the nondimensional time of breaking, t_b , which is the time when a slope of 90° first appear, in $\sqrt{\frac{h_2}{g}}$ units; the height of breaking y_b ; the horizontal distance travelled before breaking, x_b , in h_2 units. The front of the stronger bores break at a height that is slightly bigger than the original ($= \Delta$); also shown in Table 1 are H_1 and H_2 which are the distances from the first and second crests to the bed, respectively, divided by $1 + \Delta$, (upstream level); for Δ greater than 0.7, H_2 is nearly 1. meaning that secondary undulations almost cease to exist. As Δ grows beyond 1.5,

Figure 2a

Figure 2b

Figure 3

Figure 4

H_1 approaches 1.0; for higher values of Δ the bore breaks before a single wave forms; these facts also appear in the values of $\theta_1, \theta_2, \theta_3$ and θ_4 which are respectively the maximum slopes, in degrees, of the front and back faces of the first and second waves. Note that after breaking the values of H_1 will be reduced.

Δ	t_b	x_b	y_b	H_1	H_2	θ_1	θ_2	θ_3	θ_4
0.325	131.7	164.4	0.87	1.42	1.28	81.5°	26.4°	11.9°	11.1°
0.35	71.9	88.7	0.89	1.40	1.19	88.5°	25.3°	4.3°	3.0°
0.4	45.3	56.2	0.93	1.40	1.12	84.9°	23.0°	1.2°	0.5°

3.0	-.	-.	-.	1.03	1.00	91.8°	-.°	0.0°	0.0°

Table 1

According to Benjamin and Lighthill (1954) the first wave of a well developed bore is a solitary wave. We expect the computed bores either to break or to develop into solitary waves. For this reason we compare properties of first waves in the bore with properties of solitary waves. Figure 4 shows graphs of mass of the first wave against wave-height for values of Δ equal to 0.1, 0.2, 0.25, 0.28, 0.3, 0.3125, 0.325, 0.35, 0.4, 0.5 and 0.6 (from bottom to top); also shown is the same relationship for the same range of solitary waves for comparison (the longer curve starting at the origin). Some remarkable facts can be observed: waves which are not going to break tend to assume the mass of a solitary wave even if wave-lengths at this stage, $t \leq 140.$, are all less than 4.5 depths; this fact have equally been observed for phase speed and maximum slope; waves which break have more mass than the maximum possible for solitary waves. Nonbreaking waves in Figure 4 tend to approach the solitary wave curve in a way that enables a rough estimate of asymptotic heights of undulations of nonbreaking bores. On this basis we conjecture that $\Delta \simeq 0.3$ is the highest limit for undular bores.

Another result about the evolution of bores is shown in Figure 5 where curves of wave-length of the first undulation is plotted against

Figure 5

Figure 6

time; the wave-length of the first wave has been calculated as twice the horizontal distance from the crest to the trough just behind. A feature of Figure 5 that is important in the comparison with experiments is that bores undulations stretch faster for the gentler bores.

4. Comparison with weakly nonlinear results

In order to assess ranges of effectiveness of weakly nonlinear modelling we calculate the evolution of the initial free surface condition (5) using both shallow water and Boussinesq's equations and compare the results with the ones obtained by means of fully nonlinear calculations. Shallow water equations provide a good approximation for the initial stages of steepening of initially gentle bore fronts; for large values of Δ , where secondary undulations are not present, shallow water equations remain accurate for slopes up to $\simeq 20^\circ$. Boussinesq's equations are more suitable to model the initial stages of evolution of very small undulating bores. Figure 6 shows the comparison with shallow water equations for the initial condition (5) with $\alpha = 0.125$ and $\Delta = 2.0$; times shown are 4.0, 6.0, and 8.0 (from top to bottom).

There is a good agreement until time 6.0 when slopes are $\simeq 20^\circ$; after this point shallow water equations predict a too quick steepening and breaking.

Figure 7 shows a comparison between results from Boussinesq's equations (dashed lines) and full nonlinear computations (full lines) for $\alpha = 0.25$, time = 50 and $\Delta = 0.1, 0.2$ and 0.3 (from top to bottom). Boussinesq's equations overpredict undulation growth, bore speed and number of undulations in a way that errors increase with Δ and time for a fixed value of α .

5. Comparison with experiments

Favre (1935) conducts experiments in a canal 75.58m long and 0.41m wide; from Favre's experiments we are specially interested in his first and third sets in which depth of water is $\simeq 0.2050m$ and $\simeq 0.1075m$, respectively. Results for 0.2050m of depth compares well with our computational experiments. In this set Δ varies from 0.062 to 0.278 depths. It is found that, at the end of the tank, after travelling for about 300 depths, the first waves acquire a nearly steady aspect; final wave-lengths range from $\lambda = 10.8$ depths to $\lambda = 8.6$ depths. Of special interest for comparisons are the bores with $\Delta = 0.202$ and $\Delta = 0.278$ depths which produce waves that at the end of the canal are respectively 0.395 and 0.570 depths of height. According to results in Figure 3 we can expect our calculated bores with $\Delta = 0.2$ and $\Delta = 0.28$ depths to produce solitary waves which are $\simeq 0.41$ and $\simeq 0.62$ depths high respectively. These figures

Figure 7

are respectively 3.8% and 8.8% higher than Favre's; the small differences can still be accounted for viscous dissipation of long waves travelling over long distances.

For depth 0.1075*m*, Favre's third set, viscous effects are more conspicuous and results do not match as well with our calculations. In this set Δ ranges from 0.080 to 0.500 depths. One mismatch appears in the measured wave-lengths. In the previous set, undulations at the bore front for $\Delta = 0.238$ have a wave-length of 9.024 after travelling for about 300 depths; in depth 0.1075*m*, with a bore with $\Delta = 0.230$, a wave-length of 8.47 depths is found at the end of the canal which is about 600 depths long. In a completely inviscid situation we should expect this later bore to attain greater wave-lengths for two reasons: gentler bores should stretch faster and bores continually stretch as they travel further; (see Figure 5). The results of Figure 5 are confirmed by Favre's experiments of the same set. Another important difference between our inviscid results and Favre's third set is the breaking, spilling, of the bore front for $\Delta = 0.281$, at a distance of about 350 depths from the start of the canal; in his first set the bore with $\Delta = 0.278$ produces waves which are 0.570 depths high; one could expect smaller waves for $\Delta = 0.281$ because of a stronger viscous dissipation in shallower waters; this wave must break at a height smaller than 0.6 depths which is too small when compared with results for y_b in Table 1.

6. Bores on water of constant vorticity

Favre's results for depth 0.1075*m* are certainly more affected by viscosity than these for depth 0.2050*m*. One of the effects of viscosity is dissipation of energy; but the sole dissipation of energy cannot be accounted for differences found in the comparison between inviscid results and Favre's experiments. Another important manifestation of viscosity, for long waves, is the shedding of vorticity generated at the boundary layer on the bed. Negative vorticity produced at the bed is difused into the fluid and its distribution varies with time and location which makes mathematical modelling a difficult task. For mathematical convenience we adopt a simple model in which vorticity is a constant. A perturbation in a 2D flow with constant vorticity can be represented by a potential flow. Hence, in order to introduce constant vorticity into the flow, we modify the boundary value problem for the potential ϕ given in equations (1) to (4) adding to the first and second equations (2), the terms:

$$-\omega(Y\phi_x - \psi)$$

to the left hand side of the first of equations (2), where ω is the value for the constant vorticity and ψ is a complex conjugate of ϕ

and

$$-\omega Y_i$$

to the right hand side of the second of equations (2).

Despite the simplicity of constant vorticity modelling, features of the third set of, depth = 0.1075m, of Favre's experiments are present in our computations. Figure 8 shows the evolution of wave-length with time for irrotational and rotational bores: the full line curves are irrotational bores for $\Delta = 0.25$, upper curve, and $\Delta = 0.28$, lower curve; the dashed lines are rotational bores: for $\Delta = 0.28$ and $\omega = -0.125$, upper curve, and for $\Delta = 0.25$ and $\omega = -0.25$, lower curve. The two irrotational bores show the usual pattern in which the lower one is longer at any given time. Negative vorticity affects wave-lengths: the rotational bores are shorter than the corresponding irrotational ones, moreover the lower rotational bore, $\Delta = 0.25$ is made shorter by the use of stronger negative vorticity, $\omega = -0.25$ compared with $\omega = -0.125$. Another feature reproduced by constant negative vorticity modelling is breaking at smaller wave-heights; Figure 9 shows breaking of two bores with $\Delta = 0.8$, the dashed line bore is irrotational and the full line one moves in water of vorticity $\omega = -0.25$; the legend to the graph belongs to the rotational bore and the profile shown is for time 12. Results in Table 1 show that the corresponding irrotational bore breaks (with an angle of 90°) at time 14.4 and its crest is, at the moment of breaking, at $x = 20.5$, hence negative vorticity causes premature breaking. About the profile of the bore $\Delta = 0.281$, Favre comments that it has the shape of a cycloid; such a comment cannot apply to irrotational waves. Figure 10 compares the profiles of the first two undulations of two bores, both with $\Delta = 0.25$; the one in dotted lines is an irrotational bore and the one in full lines represents the profile of a bore with vorticity $\omega = -0.25$. We notice that not only wave-lengths are shorter but crests are more peaked and troughs are flatter.

Positive vorticity has an opposite effect: Undulations tend to get longer, acquire a round sinusoidal shape and break at bigger heights when compared with irrotational ones. Bores which move up estuaries, probably, travel on water in which vorticity is mainly positive, generated by the boundary layer of the downstream river current. These bores should look rounder and move faster than bores running over still water.

7. Conclusions

Comparisons between Favre's first and third sets of experiments show that depth of water and width of the channel play an important role on results. Sandover and Zienckiewicz (1957), conducted experiments on bores for channel depths of 2", 3", 4" and 6". They present

results for nondimensional discharge of water against wave-height at the end of the canal. These results show that for the same discharge wave-heights consistently increase with channel depth. They also show results for a channel in which the bed is rough and crests at the end of the canal are consistently lower when compared with results for the same discharge and depth on smooth beds.

Favre's and Sandover and Zienkiewicz's results show that interaction with the boundary layer at the bed may be important in the analysis of results of experiments with bores. The presence of a boundary layer has two important effects: dissipation of energy and generation of vorticity. Dissipation of energy contributes to lower wave heights and the presence of vorticity will have an effect on breaking, on wave-lengths, on wave shape and on the limit on maximum Δ for undular bores.

Results in Figure 4 and Table 1 lead to the conclusion that maximum height of bores divided by upstream depth, H_1 , grows with Δ for $\Delta < \simeq 0.3$ and then decay for breaking bores, ($\Delta > \simeq 0.3$). The limiting figures 0.3 and 0.7 have been found through an irrotational modelling; how this figures will change in real situations may depend on average values of vorticity. In situations in which vorticity is negative, as it happens in bores running over still water, the only vorticity is produced at the bed by the undulations, these figures will be smaller. In situations in which the bore moves upstream a current, the average vorticity can be positive and the limiting waves higher.

CHAPTER 78

Experimental and Numerical Study on Solitary Wave Breaking

Hitoshi Nishimura¹ and Satoshi Takewaka²

Abstract

Interior flow fields under drastically transforming solitary waves were visualized and recorded using a high-speed video system. Flow velocities were estimated by tracing fluid particles through spatial correlation analysis of video images. A Lagrangian equation system was successfully employed to numerically simulate two-dimensional wave transformations in a vertical plane.

Introduction

In these years, remarkable progresses have been achieved in techniques for analyzing nearshore wave transformation. However, our knowledge on the fundamental mechanism of wave breaking is rather limited as well as on after-breaking wave transformation. Existing breaking indices are by no means enough for application to a complicated field of composite and/or irregular waves. For future study of this problem, introduction of new methods is of particular importance in both experimental and theoretical approaches.

Since wave transformation such as breaking is quite unstable, exactly the same phenomenon cannot be reproduced even in a well-designed wave flume. It is therefore difficult to obtain an entire picture of interior fluid motion by repeating velocimeter measurements. At least, the accuracy of thus obtained velocity distribution cannot be sufficient for succeeding estimation of pressure, vorticity, and so forth. In this

¹ Professor, Inst. of Eng. Mechanics, Univ. of Tsukuba, Tsukuba, Ibaraki, 305, Japan.

² Research Associate, Dept. of Civil Eng., Tokyo Inst. of Tech., O-okayama, Meguro, Tokyo, 152, Japan.

context, observation and measurement with visual devices are much more promising.

On the other hand, a Eulerian equation system is normally employed in computational approach to two-dimensional fluid motions. Numerical schemes in the Eulerian framework, however, have a weakness in handling moving boundaries. Note that the fluid motion under a wave is essentially prescribed by surface conditions and that the surface profile rapidly deforms under a breaking condition. Although the Lagrangian equations have some disadvantages in particular in their numerical integration process, they may provide a useful means for wave transformation analysis, allowing much more rigorous treatment of surface boundaries.

Methods of Picture Analysis

Techniques of flow visualization and video image analysis are employed here to investigate the hydraulic mechanisms of solitary wave runup on a vertical wall and its breaking on a uniform slope. Once if a precise velocity field in a wave is obtained, then corresponding distributions of pressure, vorticity, etc., will be easily deduced.

A conventional method of neutral buoyancy float tracing is not quite appropriate for such a purpose. It is not easy to keep the floats with finite sizes in suspension and they may not move in the same manner as water particles. The number of floats is limited for computerized tracing and, furthermore, their location cannot be well controlled. A flow field is more conveniently visualized by densely scattering small solid particles in the fluid. In this case, flow velocity at an arbitrary position is estimated from the variation of a local brightness pattern through either temporal or spatial correlation analysis.

Figure 1 describes the principle of temporal correlation analysis (for example, Miike et al., 1986), in which time-series data of brightness variations at adjacent two points are compared. Time-lag between the variations is considered to be the traveling time of a water particle for the distance between these two points. The flow direction can also be detected since the correlation will be highest between two points along a local path-line. This method is suitable to real time measurement of flow velocity at a fixed point, but is not applicable to strongly unsteady flows, requiring steady shift of brightness variation for a finite time interval.

The spatial correlation analysis (for example, Kimura and Takamori, 1986), in principle, is more similar to the normal float tracing. A recorded image of visualized fluid at each time is converted into a matrix of digital brightness gradation data at all the pixels. A small square body of fluid is specified by a reference frame fixed in a matrix, whereas a test frame with the same size is moved in another matrix for an adjacent time as shown in Figure 2. The spatial correlation between brightness patterns in these two frames is evaluated in terms of the correlation coefficient R defined by

Figure 1. Temporal Correlation Analysis

Figure 2. Spatial Correlation Analysis

$$R = \frac{\sum (m_i - \bar{m})(n_i - \bar{n})}{\sqrt{\sum (m_i - \bar{m})^2 \sum (n_i - \bar{n})^2}} \quad (1)$$

where m_i and n_i represent the brightness gradations at the i -th pixels in the reference and test frames, and \sum and $\bar{\quad}$ respectively denote summation and average over the frames. Higher correlation will be obtained as the test frame gets closer to the new location of the fluid body in question. Spatial displacement of the fluid body during a prescribed time interval is thus estimated. This method is adopted in the following, since it is obviously applicable even to unsteady flows.

When brightness variation is smooth both in time and in space, introduction of gradient method is recommended to notably reduce the computational load for the above-explained fitting test. Provided that the apparent brightness of a water particle is kept unchanged as it moves, the total derivative of the brightness B should vanish: that is,

$$dB/dt = B_t + UB_x + VB_y \quad (2)$$

where t is the time, x and y are the horizontal and vertical coordinates, U and V are the velocity components in the x - and y -directions, and suffices denotes partial derivatives. The above relationship gives the flow direction from temporal and spatial gradients of brightness.

It should be also noted that the angle of fluid particle rotation can be directly detected by rotating the test frame and seeking for better fit, where the brightness values have to be interpolated for the pixels in the rotated frame. The local vorticity can be thus estimated possibly more accurately than from velocity gradients. Pre-processing of image data using filters may be helpful in these advanced analyses (Huang, 1981).

Experimental Setup and Data Processing

For each case of experiment, either a vertical wall or a uniform slope were installed in a wave flume 17m long, 40cm wide and 60cm deep. A solitary wave was generated by a single forward motion of a piston-type wave board driven by compressed air. In order to lessen the effect of parallax in video recording, the flume width was reduced to 10cm by a partition wall with a gradual contraction in front of the wave generator.

The time-scale of the present experiments required the use of high-speed monochromatic video system, by which 1000 scenes can be recorded per second. A scene was resolved into 256x256 pixels when converted to a

matrix of digital brightness gradations. Flow was visualized by scattering yellow polyethylene beads with diameter of roughly 0.5mm in the water. The beads are originally heavier than water, but their specific gravity is adjustable by heating because of gas containment. The density of bead distribution was determined on trial and error basis so as to produce the best video images. The material of background wall and the directions of lighting had also to be carefully decided. Reflected lights from water surface and basin walls badly disgrace the reliability of image data.

Figure 3 shows the outline of data acquisition and processing system, where the arrows indicate the flow of data. A set of digitized image data is enormous in its volume, while a high-speed video tape can be rewound only several times. Obtained analogue data, therefore, were first copied on a normal tape, and only necessary parts of the data for each analysis were stored on a hard disk after A-D conversion. For efficient processing of data by a micro-computer, it is desirable to write programs in a machine language.

Results of Experiments

Photo 1 shows video images describing runup and return flow motions of a solitary wave on the vertical wall. This can also be regarded as the formation process of a standing wave. It was observed that the lower layer water starts to fall slightly before the maximum runup height is reached. A very slender runup profile is thus formed. After that, the crest water gets into nearly

Figure 3. Data Acquisition and Processing System

free fall motion and plunges into lower water layer, yielding a vortex motion at the foot of the wall. Slow replay of video record in fact well exhibit such details of rapid wave deformation. A result of image analysis is given in Figure 4, which shows an instantaneous flow field in the rising stage. Obvious misevaluations of velocity appear at several points in the figure. In the fitting tests, the frame size of 9×9 pixels were adopted, and displacements of water particles were evaluated in pixel unit. More precise velocities will be obtained by estimating sub-pixel fractions of displacements through two-dimensional interpolation.

(a) $t = 6.46s$ (b) $t = 6.56s$ (c) $t = 6.64s$ (d) $t = 6.84s$

Photo 1. Solitary Wave Runup on a Vertical Wall

Photo 2 shows a visualized breaking motion of a solitary wave on the 1/20 slope. A shadow region appears under the overturning wave crest, since light source was located on the upper flange of wave flume. Figure 5 is an example of obtained velocity field. The velocity vectors were plotted only for the points where larger correlation coefficients than 0.7 was obtained in the fitting tests. This criterion of minimum reliability could not be attained for the shadow region, indicating the fatal importance of lighting technique for thorough estimation of velocities over the whole region.

Lagrangian Equation System

For theoretical treatment of fluid motion in a vertical plane, it is here assumed that the fluid is inviscid and incompressible. A further assumption is that only the gravity is exerted as an external force.

The continuity equation in the Lagrangian framework is given as

$$X_a Y_b - X_b Y_a = J \quad (3)$$

where a and b are the Lagrangian parameters to identify a water particle, X and Y are the horizontal and vertically upward coordinates to indicate the location of the water particle at an arbitrary time, J is at most a function of a and b , and suffices again denotes partial derivatives. The above equation is differentiated with

Figure 4. Observed Flow Velocities in a Solitary Wave Running Up on a Vertical Wall

(a) $t = 5.140s$

(b) $t = 5.165s$

Photo 2. Solitary Wave Breaking on a Uniform Slope

respect to time t to yield

$$U_a Y_b - U_b Y_a - V_a X_b + V_b X_a = 0 \tag{4}$$

in which the velocity components U and V are simply related to X and Y as

$$U = X_t, \quad V = Y_t \tag{5}$$

On the other hand, the momentum equations are written as

$$X_{tt} X_a + (Y_{tt} + g) Y_a = -P_a / \rho \tag{6}$$

$$X_{tt} X_b + (Y_{tt} + g) Y_b = -P_b / \rho \tag{7}$$

where P is the pressure, g is the gravitational acceleration, and ρ is the fluid density. Elimination of force terms in the above equations through cross-differentiation and single integration of the obtained equation with respect to time lead to the following law of vorticity conservation.

$$U_a X_b - U_b X_a + V_a Y_b - V_b Y_a = C \tag{8}$$

where C is an arbitrary function of a and b .

Figure 5. Observed Flow Velocities in a Breaking Solitary Wave

For simplicity, a and b are defined as the positional coordinates of a fluid particle at a reference time $t=0$ when the fluid is at rest. It is most convenient to define the coordinate system in such a way that either a or b takes a constant value along every boundary. For a solid boundary, the expression of boundary configuration in terms of X and Y by itself gives a kinematic condition. Along a free surface, $P=0$ is imposed as a dynamic condition, which can be easily rewritten in terms of the other unknown variables with reference to the momentum equations (6) and (7).

Numerical Simulation Using Lagrangian Equations

Numerical analysis with experimental verification is a useful means for investigating the detailed dynamics of wave transformation. Behavior of surface waves is essentially governed by the boundary conditions at the free surface. Although the Lagrangian coordinate system is possessed of a definite advantage in describing a moving boundary (Chan, 1975), it has been rarely employed in wave computations, perhaps because of 1) second order derivatives with respect to time involved in the equations of motion, 2) nonlinearity of both the equations of motion and continuity, and 3) weakness against large deformation of computational grids. These difficulties, however, became less significant nowadays as computational technology rapidly progressed. For this sort of simulation, two alternative formulations are available.

One is a velocity solution method, where the continuity equation (4) and the irrotationality constraint (8) are discretized and solved simultaneously with given boundary conditions for velocity components at all the grid points. The computation proceeds to the next time step through integration of Eq. (5). It is obvious that this method is applicable only to irrotational fluid motion.

The other is a pressure solution method, in which the original set of equations is directly treated, that is, discretized pressures in the momentum equations (6) and (7) are determined so that the resultant deformation of every fluid particle satisfies the continuity equation (3). This formulation for the pressure yields in principle a Poisson-type equation, which is numerically solved through easier operation of matrices with a smaller dimension. Furthermore, the pressure formulation is more flexible in taking into account secondary factors such as fluid viscosity and surface tension. A shortcoming of this formulation lies in weaker constraint against the generation of non-physical vorticity,

which often results in computational instability of checkerboard-split type.

It proved from trial computations of the solitary wave transformations that two methods mentioned above yield no significant difference in their results. Computed distributions of velocity and pressure for the case of solitary wave runup are shown in Figure 6, where both the coordinates and pressure are nondimensionalized with the still water depth as length-scale. Water particles are either at rest or slowly falling except near the wave crest as observed in the corresponding experiment. Extremely mild pressure gradient in the upper layer gives a theoretical background to the observed free-fall motion of crest water. The computation fails immediately after this as fatal distortion of computational grids emerges in the crest region.

Computed velocity and pressure in the breaking wave are shown in Figure 7. Mild pressure gradient in the crest region implies less dynamical interaction between water particles. Further decrease in the local pressure will lead to a free motion of the crest water and possibly to air entrainment. On the contrary, verti-

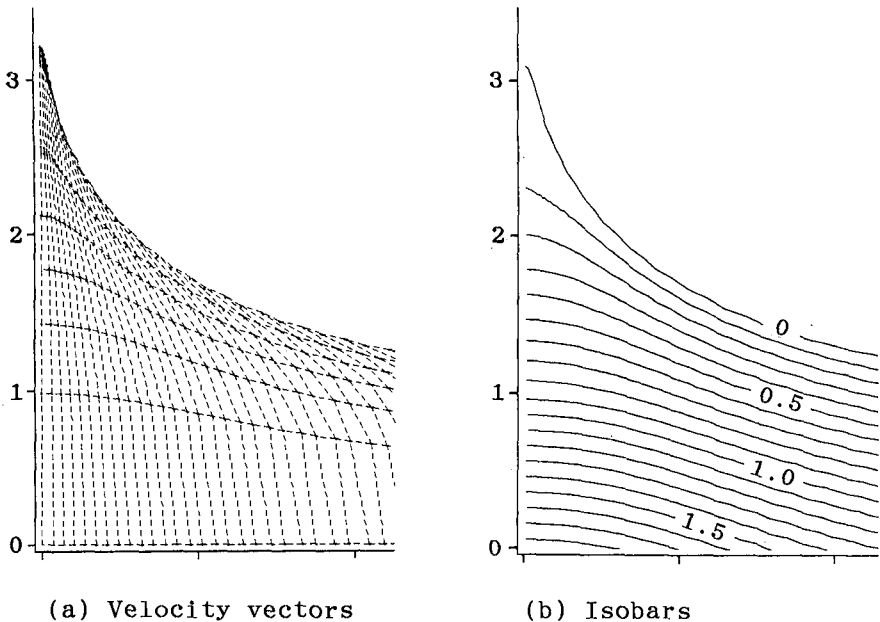

Figure 6. Computed Distributions of Velocity and Pressure in a Solitary Wave Running Up on a Vertical Wall

and possibly to air entrainment. On the contrary, vertical pressure gradient at the foot of the breaker front is rather steep, providing a good circumstance for sediment suspension. In general, numerical simulation excluding the effect of surface tension allows unrealistic formation of a sharp plunging nose.

(b) Isobars

Figure 7. Computed Distributions of Velocity and Pressure in a Breaking Solitary Wave

Concluding Remarks

For better understanding of wave breaking phenomena, combined experimental and theoretical investigations are required particularly on their dynamical aspects with more attention to the process of local pressure reduction. The spatial correlation analysis of video images provides a useful means in such studies as well as the numerical analysis in the Lagrangian framework. The accuracy of velocity estimation by means of image analysis is expected to largely improve in the near future as video systems with higher resolution become available.

CHAPTER 79

WAVE REFLECTION BY A NUMBER OF THIN POROUS PLATES FIXED IN A SEMI-INFINITELY LONG FLUME

S. W. TWU¹ and D. T. LIN²

ABSTRACT

The reflection of small-amplitude surface waves by a number of vertical porous plates is investigated. The plates are fixed in a semi-infinitely long channel of constant depth. Analytic solutions in dimensionless closed form are presented for the surface wave profiles in the several regions separated by these plates. And from them the reflection coefficient is obtained. Three cases, one to three porous plates, are evaluated. The results show that for incident waves in the range of $1/20 < \text{water depth/wave length} < 1/2$, it is appropriate to maintain the spacing between every two adjoining plates, and between the end wall and its nearest plate at a value of 0.88 times the water depth. As two or three porous plates are used for damping wave, an arrangement would be more effective if the front porous plate has a larger porosity and the back one has a smaller porosity. Several experimental tests for these porous-plate wave absorbers are conducted and the reflection coefficients are measured by using Goda's method. It is found that the theoretical solutions agree fairly well with the experimental results.

I. INTRODUCTION

The reflection and transmission of small-amplitude surface waves by a thin vertical barrier were first studied by Dean (1945). In Dean's analysis, the vertical barrier was submerged in water with its top edge at a distance below the free surface. Since then, several similar problems have been analyzed by authors, such as Wiegel (1960), Newman (1965), Mei (1969), Macaskill (1979), etc. In most of their analysis, the obstacles are assumed to be placed in a spacious water area without any boundary effect. It is known that if there is any other structure existing around the barriers, such as a back wall, the estimating results will be different. Chwang (1984) analyzed the reflection of small-amplitude surface wave by a thin porous plate fixed near the end of a semi-infinitely long channel of constant depth. Chwang found that as the distance

between the porous plate and the channel end wall (l) is equal to a quarter wave length plus a multiple of half-wave length of the incident wave, then the reflected wave amplitude is reduced to a minimum. In water areas where the waves have a variety of wave length, it is unlikely to keep a constant value for l/λ (λ the wave length). Then in this situation, The problems of how the spacing between the porous plate and the end wall may affect the reflection coefficient if a single plate is used, and what might be the appropriate spacing among these plates if a number of porous plates are adopted are investigated in this paper.

II .THEORETICAL CONSIDERATION

Three thin porous plates are assumed to be located in a semi-infinitely long channel of constant depth shown in Figure 1. The first plate is located at $x=0$, the second at $x=-l_1$, the third at $x=-(l_1+l_2)$, and the end wall at $x=-(l_1+l_2+l_3)$. An incident wave propagating in the negative x direction toward the porous plates is represented by

$$\eta_i = a \sin (\omega t + K_0 x) \dots \dots \dots (1)$$

where η_i is measured from the undisturbed mean free surface at $y=h$, K_0 is the wave number, ω is the circular wave frequency and a is the incident wave amplitude which is assumed to be very small in comparison with the water depth(h).

Fig.1. Sketch of three porous plates in a semi-infinitely long flume.

The fluid in the channel is assumed to be inviscid and incompressible, and its motion irrotational. Therefore, the velocity potentials $\Phi_j(x,y,t)$ exist in all regions and the velocity of the fluid can be expressed as

$$\vec{V}_j = \nabla \Phi_j \quad (j=0,1,2,3) \dots \dots \dots (2)$$

where the subscript j refers to the j th fluid region. Region (0) represents the region $x>0$, region (1) represents $-l_1 < x < 0$, region (2) represents $-(l_1+l_2) < x < -l_1$, and region (3) represents $-(l_1+l_2+l_3) < x < -(l_1+l_2)$. The velocity potentials satisfy the two-dimensional Laplace equation

$$\nabla^2 \Phi_j = 0 \quad (j=0,1,2,3) \dots \dots \dots (3)$$

The linearized free-surface kinematic and dynamic condition are, respectively

$$\frac{\partial \Phi_j}{\partial y} = \frac{\partial \eta_j}{\partial t} \quad \text{at } y=h \quad (j=0,1,2,3) \dots \dots \dots (4)$$

$$\frac{\partial \Phi_j}{\partial t} + g \eta_j = 0 \quad \text{at } y=h \quad (j=0,1,2,3) \dots \dots \dots (5)$$

Where g is the gravitational constant . From equation (4) and (5) we obtain the linearized free-surface condition for the velocity potentials Φ_j

$$\frac{\partial^2 \Phi_j}{\partial t^2} + g \frac{\partial \Phi_j}{\partial y} = 0 \quad \text{at } y=h \quad (j=0,1,2,3) \dots \dots \dots (6)$$

The normal velocity of the fluid must vanish at the bottom of the channel. Hence

$$\frac{\partial \Phi_j}{\partial y} = 0 \quad \text{at } y=0 \quad (j=0,1,2,3) \dots \dots \dots (7)$$

Let the normal velocity of the fluid passing through the porous plate from region 0 to region 1 be $W_1(y,t)$, that from region 1 to region 2 be $W_2(y,t)$ and that from region 2 to region 3 be $W_3(y,t)$. Then, the boundary conditions on both sides of each thin porous plate are

$$\frac{\partial \Phi_j}{\partial x} = -W_1 \quad \text{at } x=0 \quad (j=0,1) \dots \dots \dots (8)$$

$$\frac{\partial \Phi_j}{\partial x} = -W_2 \quad \text{at } x=-l_1 \quad (j=1,2) \dots \dots \dots (9)$$

$$\frac{\partial \Phi_j}{\partial x} = -W_3 \quad \text{at } x=-(l_1+l_2) \quad (j=2,3) \dots \dots \dots (10)$$

The end wall is assumed to be solid and vertical, and the normal velocity vanishes at the wall. Therefore

$$\frac{\partial \Phi_3}{\partial x} = 0 \quad \text{at } x=-(l_1+l_2+l_3) \dots \dots \dots (11)$$

It is assumed that the flow inside the porous plate obeys the Darcy's law. Hence the flow velocity inside the porous plate W is

linearly proportional to the pressure difference between the two sides of each porous plate.

$$W_1(y,t) = \frac{b_1}{\mu} (P_0 - P_1) \quad \text{at } x=0 \dots\dots\dots(12)$$

$$W_2(y,t) = \frac{b_2}{\mu} (P_1 - P_2) \quad \text{at } x=-\ell_1 \dots\dots\dots(13)$$

$$W_3(y,t) = \frac{b_3}{\mu} (P_2 - P_3) \quad \text{at } x=-(\ell_1 + \ell_2) \dots\dots\dots(14)$$

where μ is the dynamic viscosity and b_1, b_2, b_3 are material constant, having the dimension of length. The hydrodynamic pressures $P_j(x, y, t) (j=0, 1, 2, 3)$ are related to the velocity potentials through the linearized Bernoulli equation

$$P_j = -\rho \frac{\partial \Phi_j}{\partial t} \quad (j=0, 1, 2, 3) \dots\dots\dots(15)$$

where ρ is the density of the fluid. Since the incident wave is a periodic wave, the velocity potentials, porous flow velocities and the hydrodynamic pressures are assumed to have a time factor $\exp(i\omega t)$.

$$\Phi_j = \phi_j(x, y) \exp(i\omega t) \quad (j=0, 1, 2, 3) \dots\dots\dots(16)$$

$$\bar{w}_j = w_j(y) \exp(i\omega t) \quad (j=0, 1, 2, 3) \dots\dots\dots(17)$$

$$P_j = p_j(x, y) \exp(i\omega t) \quad (j=0, 1, 2, 3) \dots\dots\dots(18)$$

Here, a complex expression is used and only the real parts should be taken to represent physical quantities.

The solutions of equation (3), satisfying boundary conditions (6), (7), (11) for each region are, respectively,

$$\begin{aligned} \phi_0 = & A_0 \cosh K_0 y \exp(ik_0 x) + A_0^* \cosh K_0 y \exp(-ik_0 x) \\ & + \sum_{m=1}^{\infty} A_{0m}^* \cos K_m y \exp(-K_m x) \dots\dots\dots(19) \end{aligned}$$

$$\begin{aligned} \phi_1 = & B_0 \cosh K_0 y \exp(ik_0 x) + \sum_{m=1}^{\infty} B_{0m} \cos K_m y \exp(K_m x) \\ & + B_0^* \cosh K_0 y \exp(-ik_0 x) + \sum_{m=1}^{\infty} B_{0m}^* \cos K_m y \exp(-K_m x) \\ & \dots\dots\dots(20) \end{aligned}$$

$$\begin{aligned} \phi_2 = & C_0 \cosh K_0 y \exp(ik_0x) + \sum_{m=1}^{\infty} C_{0m} \cos K_m y \exp(K_m X) \\ & + C_0^* \cosh K_0 y \exp(-ik_0x) + \sum_{m=1}^{\infty} C_{0m}^* \cos K_m y \exp(-K_m X) \end{aligned} \dots\dots\dots(21)$$

$$\begin{aligned} \phi_3 = & D_0 \cosh K_0 y \cos K_0(x + \varrho_1 + \varrho_2 + \varrho_3) \\ & + \sum_{m=1}^{\infty} D_{0m} \cos K_m y \cosh K_m(x + \varrho_1 + \varrho_2 + \varrho_3) \dots\dots\dots(22) \end{aligned}$$

where the first term on the right hand side of equation (19) corresponds to the incident wave. A_0 is the incident wave constant and is related to the incident wave amplitude, a , by

$$A_0 = \frac{ag}{\omega \cosh k_0 h} \dots\dots\dots(23)$$

k_0, k_m ($m=1, 2, 3, \dots\dots\dots$) satisfy the dispersion relation

$$\omega^2 = gK_0 \tanh K_0 h = -g K_m \tan K_m h \dots\dots\dots(24)$$

Noting that $\cosh k_0 y$ and $\cos K_m y$ ($m=1, 2, 3, \dots$) form a complete set of orthogonal functions over the range from $y=0$ to $y=h$, substituting equations (19)~(22) into equations (8) ~ (11) by using equations (12)~(18), then equating the coefficients of terms with the same function, we obtain

$$A_{0m}^* = B_{0m} = B_{0m}^* = C_{0m} = C_{0m}^* = D_{0m} = 0 \dots\dots\dots(25)$$

($m=1, 2, 3, \dots$)

$$\left. \begin{aligned} \frac{A_0^*}{A_0} &= F_1^* + i F_2^* \quad , \quad \frac{B_0}{A_0} = F_3^* + i F_4^* \\ \frac{B_0^*}{A_0} &= F_5^* + i F_6^* \quad , \quad \frac{C_0}{A_0} = F_7^* + i F_8^* \\ \frac{C_0^*}{A_0} &= F_9^* + i F_{10}^* \quad , \quad \frac{D_0}{A_0} = F_{11}^* + i F_{12}^* \end{aligned} \right\} (26)$$

in which

$$F_1^* = \frac{F_9 F_{11} + F_{10} F_{12}}{F_{11}^2 + F_{12}^2} \quad , \quad F_2^* = \frac{F_{10} F_{11} - F_9 F_{12}}{F_{11}^2 + F_{12}^2}$$

$$\begin{aligned}
 F_3^* &= \frac{-2G_1 (F_7 F_{11} + F_8 F_{12})}{F_{11}^2 + F_{12}^2} , & F_4^* &= \frac{-2G_1 (F_8 F_{11} - F_7 F_{12})}{F_{11}^2 + F_{12}^2} \\
 F_5^* &= \frac{-2G_1 (F_5 F_{11} + F_6 F_{12})}{F_{11}^2 + F_{12}^2} , & F_6^* &= \frac{-2G_1 (F_6 F_{11} - F_5 F_{12})}{F_{11}^2 + F_{12}^2} \\
 F_7^* &= \frac{-4G_1 G_2 (F_3 F_{11} + F_4 F_{12})}{F_{11}^2 + F_{12}^2} , & F_8^* &= \frac{-4G_1 G_2 (F_4 F_{11} - F_3 F_{12})}{F_{11}^2 + F_{12}^2} \\
 F_9^* &= \frac{-4G_1 G_2 (F_1 F_{11} + F_2 F_{12})}{F_{11}^2 + F_{12}^2} , & F_{10}^* &= \frac{-4G_1 G_2 (F_2 F_{11} - F_1 F_{12})}{F_{11}^2 + F_{12}^2} \\
 F_{11}^* &= \frac{-8G_1 G_2 G_3 F_{12}}{F_{11}^2 + F_{12}^2} , & F_{12}^* &= \frac{-8G_1 G_2 G_3 F_{11}}{F_{11}^2 + F_{12}^2}
 \end{aligned}$$

in which

$$G_1 = \frac{\rho \omega b_1}{\mu k_0} , \quad G_2 = \frac{\rho \omega b_2}{\mu k_0} , \quad G_3 = \frac{\rho \omega b_3}{\mu k_0} \dots\dots(27)$$

G_1, G_2 and G_3 are known as porous-effect parameter(Chwang 1984) for the three porous plates, respectively,

$$\begin{aligned}
 F_1 &= (G_3 - 1) T_3^* (T_1 T_2 - T_1^* T_2^*) + G_3 T_3 (T_1^* T_2 + T_1 T_2^*) \\
 F_2 &= G_3 T_3 (T_1 T_2 - T_1^* T_2^*) - (G_3 - 1) T_3^* (T_1^* T_2 + T_1 T_2^*) \\
 F_3 &= (G_3 + 1) T_3^* (T_1^* T_2^* - T_1 T_2) - G_3 T_3 (T_1^* T_2 + T_1 T_2^*) \\
 F_4 &= G_3 T_3 (T_1 T_2 - T_1^* T_2^*) - (G_3 + 1) T_3^* (T_1^* T_2 + T_1 T_2^*) \\
 F_5 &= (2G_2 - 1) F_1 + (T_1^2 - T_1^{*2}) F_3 + 2T_1 T_1^* F_4 \\
 F_6 &= (2G_2 - 1) F_2 - 2T_1 T_1^* F_3 + (T_1^2 - T_1^{*2}) F_4 \\
 F_7 &= (T_1^{*2} - T_1^2) F_1 + 2T_1 T_1^* F_2 + (2G_2 + 1) F_3 \\
 F_8 &= -2T_1 T_1^* F_1 + (T_1^{*2} - T_1^2) F_2 + (2G_2 + 1) F_4 \\
 F_9 &= -(2G_1 - 1) F_5 - F_7 , & F_{10} &= -(2G_1 - 1) F_6 - F_8 \\
 F_{11} &= F_5 - (2G_1 + 1) F_7 , & F_{12} &= F_6 - (2G_1 + 1) F_8
 \end{aligned}$$

$$\begin{aligned}
 T_1 &= \cos k_0 \varrho_1 , & T_2 &= \cos k_0 \varrho_2 , & T_3 &= \cos k_0 \varrho_3 \\
 T_1^* &= \sin k_0 \varrho_1 , & T_2^* &= \sin k_0 \varrho_2 , & T_3^* &= \sin k_0 \varrho_3
 \end{aligned}$$

(j) From equation (5), we have the free-surface equation for region

$$\eta_j = - \frac{1}{g} \frac{\partial \Phi_j}{\partial t} \quad (y=h) \quad j=0,1,2,3 \dots\dots\dots(28)$$

Substituting equation (16) into (28) , by using equation (19), (25) and (26), then taking the real part, we obtain the free-surface elevation, ζ_0 , for region(o)

$$\zeta_0 = R_e (\eta_0) = a [\sin(\omega t + k_0 x) + F_1 \sin(\omega t - k_0 x) + F_2 \cos(\omega t - k_0 x)] \dots\dots\dots(29)$$

in which

$$a = \frac{\omega A_0 \cosh k_0 h}{g}$$

The first term on the right hand side of equation(29) represent the incident wave , and the second and third term represent the reflected wave with a wave amplitude a_r as

$$a_r = (F_1^2 + F_2^2)^{1/2} a \dots\dots\dots(30)$$

If we define the reflection coefficient as ratio of wave amplitude of the reflected to incident wave , then we have the reflection coefficient C_r as

$$C_r = (F_1^2 + F_2^2)^{1/2} \dots\dots\dots(31)$$

The free-surface elevation for regions (1) , (2) and (3) could also be obtain in the same way. They are respectively

$$\zeta_1 = a [F_3 \sin (\omega t + k_0 x) + F_4 \cos (\omega t + k_0 x) + F_5 \sin (\omega t - k_0 x) + F_6 \cos (\omega t - k_0 x)] \dots\dots\dots(32)$$

$$\zeta_2 = a [F_7 \sin (\omega t + k_0 x) + F_8 \cos (\omega t + k_0 x) + F_9 \sin (\omega t - k_0 x) + F_{10} \cos (\omega t - k_0 x)] \dots\dots\dots(33)$$

$$\zeta_3 = a \{ F_{11} \sin \omega t \cos [k_0(x + \varrho_1 + \varrho_2 + \varrho_3)] + F_{12} \cos \omega t \cos [k_0(x + \varrho_1 + \varrho_2 + \varrho_3)] \} \dots\dots\dots(34)$$

The first and second term in equation (32) , (33) represent waves progressing from right to left, with amplitude $(F_3^2 + F_4^2)^{1/2} \cdot a$ and $(F_7^2 + F_8^2)^{1/2} a$ for regions (1) and (2), respectively. The third and fourth term are waves from left to right with amplitude $(F_5^2 + F_6^2)^{1/2} a$ and $(F_9^2 + F_{10}^2)^{1/2} a$, respectively. In region (3) , the wave is in a situation of fully standing wave , with the same wave amplitude in both directions.

III .THEORETICAL RESULTS

Based on equation (31), the theoretical reflection coefficient is computed. Letting $\varrho_2 = \varrho_3 = 0$ we obtain the theoretical reflection coefficient for a single porous plate , showing the same result as Chwang's (1984). The porous plate produces the smallest reflection coefficient if the single porous plate is located at a distance of $m/4$ times the wave length ($m=1,3,5, \dots$) in front of the end wall. Letting $\varrho_3 = 0$ we obtain a case for two porous plates. For a constant value of $\varrho_2/\lambda = 0.25$, the relationship between C_r and ϱ_1/λ is calculated and shown in Figure 2 . With four G values presented

Fig.2. Reflection coefficient versus l_1/λ for two porous plates with $l_2/\lambda=0.25$.

, it shows that the two porous plates produce the smallest reflection coefficient if the distance between the two porous plates is maintained at a distance of a multiple of half wave length. For $G=2$ a zero reflection coefficient can be reached. In the case of three porous plates, letting $l_3/\lambda=0.25$ and $l_2/\lambda=0.5$ the relationship between C_r and l_1/λ is presented in Figure 3. Again, it is found that as long as the distance between the first and second plate is maintained at a multiple of half wave length, the best wave absorption can be observed. For $G=3$, a zero reflection coefficient can be obtained. From the above-mentioned cases, it is concluded that the best wave absorption could be achieved by locating every porous plate at a position where a clapotis node may occur. Both porous plates in Figure 2, or three porous plates in Figure 3, have a uniform G value for each solution curve. Now,

Fig.3. Reflection coefficient versus l_1/λ for three porous plates with $l_2/\lambda=0.5$, $l_3/\lambda=0.25$.

we shall see what would happen if we use different G values for the two or three porous plates. Firstly, each plate of the two-porous-plate wave absorber is placed at where a clapotis node may occur. And two cases are calculated. One of them is that the first plate has a G value twice as large as that of the second plate. The other case has a reverse arrangement. Their results are shown in Figure 4 by the curve indicating C_r versus G. It is easily seen that for two porous plates with different G values, whether the first or the second plate has a larger porous-effect parameter does not have any effect on the reflection coefficient, if each

Fig.4. Comparison of reflection coefficient between two arrangements of two porous plates.

plate is located at a position where a clapotis node may occur. However, if one of the plates is not located at such a position, a different phenomenon happens. This can be seen in Figure 5, in which the first porous plate is not located at such a position. It is indicated that the two-porous-plate wave absorber with a larger G value for the first porous plate than for the second porous plate always give a lower reflection coefficient than the one with reverse G values. The same phenomenon also happens in the three-porous-plate wave absorber. Figure 6 shows the case of three porous plates having each plate located at a position where a clapotis node would occur. And it is observed that whether the porous plates have an increasing order or decreasing order of G values from the front to the back of the wave absorber does not have any effect on the reflection coefficient. But in Figure 7, in which only one

Fig.5. Comparison of reflection coefficient between two arrangements of two porous plates.

of the three porous plates is located at the particular position mentioned above, the reflection coefficient is quite different. The wave absorber with decreasing order of G values for those plates along the incident wave direction tends to give a lower reflection coefficient in comparison with the increasing order case. According to the previous statement, we know that it is the most efficient way to locate each porous plate at a position where a clapotis node may occur, if a number of porous plates are adopted. However, in actual situation it is impractical to maintain a porous plate at such a position because of the variable incident wave length. The nondimensional parameter Q_s/λ is evidently a variable rather than

Fig.6. Comparison of reflection coefficient between two arrangements of three porous plates.

Fig.7. Comparison of reflection coefficient between two arrangements of three porous plates.

a constant. Therefore, a value of another dimensionless parameter Q_s/h is more suitable to be sought in an attempt to find a proper spacing among those plates. For incident waves corresponding to the range $0.095 < \omega^2 h/g < 3.13$, the reflection coefficient of the wave absorber has been calculated for various values of Q_s/h from 0.05 to 1.0. And it is found that whether it contains one, two or three porous plate(s), the wave absorber gives a more homogenous lower reflection coefficient as $Q_s/h=0.88$. The reflection coefficient of these cases at this particular value of Q_s/h will be shown later in section (IV) and compared with the experimental results.

IV. EXPERIMENTAL TESTS

Three kinds of porous plates with different G values have been used for the model tests. They are (i) Plate No.1 : a stainless steel screen with 7 strings per cm, (ii) Plate No.2 : four layers of plate No.1 attached together, (iii) Plate No.3 : a layer of sponge of one cm in thickness and a plate No.1 attached together. To determine the material constant b of the porous plates, a water tank with a water head of 3 cm is used. The porous plate is placed at the outlet of the water tank, and the flow velocity passing through the porous outlet is measured. From equation (12) or (13), (14), we have.

$$\frac{W}{\gamma} = \frac{b}{\mu} \left(\frac{\Delta p}{\gamma} \right) \dots\dots\dots(35)$$

in which $\frac{\Delta p}{\gamma}$ represents the water head in tank . Based on equation (35) , with μ , γ , $\frac{\Delta p}{\gamma}$ and W being known, the material constant can be calculated. The material constant thus obtained for the porous plates is as follows:(i)porous plate No.1: $b=1.49 \times 10^{-6}m$, (ii) porous plate No.2: $b=1.01 \times 10^{-6}m$, (iii) porous plate No.3: $b=3.25 \times 10^{-7}m$. Substituting the material constant for these porous plates into equation (27), the porous-effect parameter is obtained. And based on this , the theoretical reflection coefficient is computed. Finally , several comparisons between the theoretical solution and the experimental result are made.

Experiments for the wave reflection by the wave absorber are conducted in a 75 m long wave flume with a cross section of $1.2m \times 1.0m$. Two wave gauges are located in front of the wave absorber at proper positions suggested by Goda . Then the experimental reflection coefficients are calculated by Goda's method for separation of the incident and reflected waves. The advantage of Goda's method is that there is no need to adjust the positions of the two wave gauges whenever the wave period changes . Let $\Delta \ell$ be the distance between the two wave gauges and X_1 the distance between the first porous plate and its nearest wave gauge . Goda suggests

$$X_1 \geq 0.1 \lambda_{max}$$

$$0.05 \lambda_{max} < \Delta \ell < 0.45 \lambda_{min}$$

In the experimental test a water depth of 50 cm is adopted. Wave period varies from 0.85 to 3 secs and the wave length varies from 112.0 to 639.6 cm. Hence, $X_1=120cm$ and $\Delta \ell=40cm$ used here are both within the Goda's suggested range . In measuring the reflection coefficient two different ways have been conducted. One of them is fixing the wave period at a constant , 2 secs, and then varying the distance between the porous plate and the end wall. This is conducted for a case of single porous plate . The ℓ/λ value has been changed from 0.5 to 1.5 with an interval of 0.05 and its result is shown in Fig 8 . Whereas the other is fixing ℓ/h at a

Fig.8. Reflection coefficient versus ℓ/λ for single porous plate with wave period=2.5.

Fig.9. Reflection coefficient versus $\omega^2 h/g$ for single porous plate.

constant and then changing the wave period during the experiment and its results are shown in Figure 9 to 13. In all these figures the theoretical value is presented by curve and the experimental result by dot. Figure 8 shows the reflection coefficient in terms of Q/λ for a single porous plate with material constant $b = 1.01 \times 10^{-6} \text{m}$. It is found that the experimental data agree very well with the theoretical solution. The wave absorber gives the lowest reflection coefficient if the porous plate is located at where the clapotis node may take place, i.e. $Q/\lambda = 1/4, 3/4, 5/4, 7/4, \dots$. Figure 9 to 13 show the reflection coefficient in terms of $\omega^2 h/g$ with $Q_s/h = 0.88$, which is the proper spacing found after series of calculation. Figure 9, 10, 11 are the results for single porous plate, two porous plates and three porous plates, respectively, with the same material constant, $b = 1.01 \times 10^{-6} \text{m}$, for all these porous plates. Good agreement is found between the theoretical solution and the experimental result. It is observed that a three-porous-plate wave absorber is more effective in damping wave than a two-porous-plate one, and the two-porous-plate wave absorber is also more effective than the single-porous-plate one. Figure 12 shows the reflection coefficient for a two-porous-plate wave absorber with different material constants for the plates, one with $b = 1.01 \times 10^{-6} \text{m}$, the other with $b = 3.25 \times 10^{-7} \text{m}$. Two arrangements have been performed, one with the larger b value for the front porous plate and the smaller b value for the back one, the other with the reverse order. Results of this two arrangements have been presented in this figure. It is shown, both theoretically and experimentally, that an arrangement with a larger b value for the front porous plate and a smaller b value for the back plate tends to give a lower reflection coefficient than the arrangement with a reverse order does. For a three-porous-plate wave absorber, a similar phenomenon can be found by referring to Figure 13. Their material constants are $1.49 \times 10^{-6} \text{m}$, $1.01 \times 10^{-6} \text{m}$, $3.25 \times 10^{-7} \text{m}$, respectively. It is also found that the case that has a decreasing order of material constant for the porous plates gives a lower reflection coefficient, thus works better in wave absorption, than the other case does. In general speaking, theoretical curves in Figure 12 and 13 agree well with the experimental results. But the agreement is not as good as that in previous figures. This is because the present wave absorbers contain a porous plate No.3 each, with material

Fig.10. Comparison between the theoretical solution and the experimental result for two porous plates.

Fig.11. Comparison between the theoretical solution and the experimental result for three porous plates.

constant $b = 3.25 \times 10^{-7} \text{ m}$, which is a sponge attached together with a steel screen. This porous plate bends as the waves pass through. And this bending motion causes a discrepancy from the theoretical assumption that these porous plates are fixed in place, thus leading to a little worse agreement between the experimental data and the theoretical value.

Fig.13. Comparison between the theoretical solution and the experimental result for two arrangements of three porous plates.

V. CONCLUSIONS

To damp wave by porous plate structure, the locations and the number of porous plates and the arrangement of material constant all play an important role in estimating the reflected waves from the structure. According to theoretical analysis, the best location for a porous plate is a position where a clapotis node may take

place . This measure could be applied to a wave absorber containing more than one porous plate . But in practical consideration ,it is much unlikely to choose a clapotis-node location for a porous plate because of the variable wave length.In this situation it is preferable to take a distance of 0.88 times the water depth for the space between any two adjoining porous plates, and between the end wall and its nearest one . In water areas with waves of varied wave periods, more than one porous plate would be more effective in wave damping than a single porous plate as long as the locations of the plates are properly selected . Likewise , a wave absorber containing more than two porous plates would be more effective than that containing only two porous plates . Furthermore, if more than two porous plates are adopted and an arrangement is used such that the material constants for these porous plates are in a decreasing order from the front to the back of the wave absorber, it would give a very low reflection coefficient.

CHAPTER 80

MODELING OF WAVE TRANSFORMATION ON SUBMERGED BREAKWATER

Somchai Rojanakamthorn¹, Masahiko Isobe², and Akira Watanabe³

ABSTRACT

A mathematical model of wave transformation over a submerged permeable breakwater is developed on the basis of the equations for waves on a porous layer which are newly derived under the mild-slope assumption. The model equation is given as a two-dimensional elliptic equation analogous to the mild-slope equation on an impermeable bed. The model of wave breaking on a submerged permeable breakwater is proposed on the basis of the modified mild-slope equation. The validity of the model is confirmed through comparison with the experiments for a trapezoidal breakwater and with strict solution for a rectangular breakwater.

I. INTRODUCTION

A submerged breakwater has been shown as an effective wave control structure with less environmental impacts. Prediction of the wave transformation over a submerged permeable breakwater and the resultant effects on wave action is important in planning and designing structures for the coastal protection. So far, investigations have mostly been carried out on the basis of laboratory and field experiments such as Dattari *et al.* (1978). Though some theoretical studies were made by Liu (1973) and others, a simple and general predictive model has not been established yet.

In this study, a model equation is derived based on the mild slope assumption to analyze the transformation of waves over a submerged permeable breakwater. The resultant equation is given as a two-dimensional elliptic equation and is analogous to the standard mild-slope equation for an impermeable bed. A mathematical model based on the present mild-slope equation is used to compute the wave transformation for a general bottom configuration. The applicability of the model is demonstrated through comparison with laboratory data obtained from model experiments in a wave flume. The validity of the model is also examined by comparing with the strict solution for a rectangular submerged breakwater.

II. MODELING OF WAVE TRANSFORMATION

The mathematical derivation of the basic equation for the transformation of non-breaking waves over an inclined porous layer is given in Rojanakamthorn *et al.* (1989). In the following, the derivation is briefly reviewed and the model of breaking wave transformation is formulated.

2.1 Wave Transformation over an Inclined Porous Layer

The analytical approach starts with the formulation of the wave transformation over a horizontal porous layer. A definition sketch is shown in Fig.1 in which the depth of water, h_1 , and the thickness of the porous layer, $h_p = h_0 - h_1$, are constant. The governing equations describing the motion of an incompressible fluid inside the porous medium under the assumption of irrotational flow can be shown by Eqs.(1) and (2) in terms of the seepage velocity potential ϕ_s and pressure p_s .

$$\nabla^2 \phi_s = 0 \tag{1}$$

$$C_r \frac{\partial \phi_s}{\partial t} + \frac{1}{\rho}(p_s + \gamma z) + f_p \sigma \phi_s = 0 \tag{2}$$

where C_r is the inertia coefficient, ρ the mass density of water, γ the unit weight of water, f_p the linearized friction factor, σ the angular frequency of the periodic wave motion, $\nabla = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$ the gradient operator, and $\partial/\partial t$ the partial differential operator with respect to time. The friction factor f_p is evaluated from the Lorentz' condition of equivalent work. The relationship can be expressed as

$$f_p = \frac{\int_V \int_0^T \left(\frac{\epsilon^2 \nu}{K_p} |\vec{u}_s|^2 + \frac{\epsilon^3 C_t}{\sqrt{K_p}} |\vec{u}_s|^3 \right) dt dV}{\sigma \int_V \int_0^T \epsilon |\vec{u}_s|^2 dt dV} \tag{3}$$

in which \vec{u}_s is the seepage velocity vector, ϵ the porosity of the medium, ν the kinematic viscosity, K_p the permeability, C_t the turbulent friction coefficient, V the volume under consideration, and T the wave period.

Equations (1) and (2) represent the Laplace equation and the unsteady Bernoulli equation for a seepage flow, respectively. The equations for the flow outside the porous medium can be obtained by substituting the coefficient C_r by unity and the friction

factor f_p by zero. The governing equations yield a potential flow problem. An analytical solution is derived for a monochromatic progressive wave train. The solutions for the velocity potentials were obtained as follows.

$$\phi = \frac{ig\eta}{\sigma} \frac{\epsilon \sinh(kh_p) \exp\{k(z+h_1)\} - \delta \cosh\{k(z+h_1)\}}{\epsilon \sinh(kh_p) \exp(kh_1) - \delta \cosh(kh_1)} \tag{4}$$

$$\phi_s = \frac{ig\eta}{\sigma} \frac{\cosh\{k(z+h_0)\}}{\epsilon \sinh(kh_p) \exp(kh_1) - \delta \cosh(kh_1)} \tag{5}$$

where

$$\eta = a \cdot \exp\{i(\sigma t - kx)\} \tag{6}$$

$$\delta = \epsilon \sinh(kh_p) - (C_r - if_p) \cosh(kh_p) \tag{7}$$

in which a is the amplitude of the incident wave prescribed at $x = 0$, g the gravitational acceleration, and $k = k_r - ik_i$ the complex wave number which is determined from the following relationship.

$$\sigma^2 = gk \frac{\epsilon \exp(kh_1) \sinh(kh_p) - \delta \sinh(kh_1)}{\epsilon \exp(kh_1) \sinh(kh_p) - \delta \cosh(kh_1)} \tag{8}$$

It is noted that without a porous layer the above results reduce to the following linear wave solution (9) and the dispersion relation (10).

$$\phi = \frac{ig\eta}{\sigma} \frac{\cosh\{k(z+h_0)\}}{\cosh(kh_0)} \tag{9}$$

$$\sigma^2 = gk \tanh(kh_0) \tag{10}$$

A mild-slope equation is then derived for an inclined porous layer in a general bottom configuration. Referring to Fig.2 in which waves propagate over a submerged permeable breakwater, the governing equations derived from the equations of an incompressible fluid are expressed in terms of the amplitudes of velocity potentials as

$$\nabla_h^2 \Phi + \frac{\partial^2 \Phi}{\partial z^2} = 0 \quad , \quad \nabla_h^2 \Phi_s + \frac{\partial^2 \Phi_s}{\partial z^2} = 0 \tag{11}, (12)$$

where $\nabla_h = (\partial/\partial x, \partial/\partial y)$ is the horizontal gradient operator, and

Fig.2 Definition sketch; waves propagating over a submerged permeable breakwater.

$$\Phi = (ig\hat{\eta}/\sigma)G(z) \quad , \quad \Phi_s = (ig\hat{\eta}/\sigma)H(z) \tag{13},(14)$$

in which $\hat{\eta}$ is the complex amplitude of the water surface displacement, and

$$G(z) = \frac{\epsilon \sinh(kh_p) \exp\{k(z + h_1)\} - \delta \cosh\{k(z + h_1)\}}{\epsilon \sinh(kh_p) \exp(kh_1) - \delta \cosh(kh_1)} \tag{15}$$

$$H(z) = \frac{\cosh\{k(z + h_0)\}}{\epsilon \sinh(kh_p) \exp(kh_1) - \delta \cosh(kh_1)} \tag{16}$$

Equations (13) to (16) are assumed to be applicable to the slowly varying depth condition by using the local values of k , h_0 , h_1 and h_p . The mild-slope equation is derived by the vertical integration of Eqs.(11) and (12) after multiplying by appropriate functions.

$$\int_{-h_1}^0 \left[G \left(\nabla_h^2 \Phi + \frac{\partial^2 \Phi}{\partial z^2} \right) \right] dz + \int_{-h_0}^{-h_1} \left[\epsilon(C_r - if_p)H \left(\nabla_h^2 \Phi_s + \frac{\partial^2 \Phi_s}{\partial z^2} \right) \right] dz = 0 \tag{17}$$

By utilizing the relevant boundary conditions and the solutions of Φ and Φ_s with the form of Eqs.(13) to (16) are invoked and the variations of depth are taken into consideration, Eq.(17) is thus expressed as

$$\begin{aligned} & \nabla_h \int_{-h_1}^0 G^2 \nabla_h \hat{\eta} dz + \int_{-h_1}^0 k^2 G^2 \hat{\eta} dz \\ & + \epsilon(C_r - if_p) \left[\nabla_h \int_{-h_0}^{-h_1} H^2 \nabla_h \hat{\eta} dz + \int_{-h_0}^{-h_1} k^2 H^2 \hat{\eta} dz \right] \\ = & - \left[\int_{-h_1}^0 G \nabla^2 G \hat{\eta} dz + G \nabla_h G \cdot \nabla_h h_1 \hat{\eta} \right]_{-h_1} \\ & + \epsilon(C_r - if_p) \left\{ \int_{-h_0}^{-h_1} H \nabla_h^2 H \hat{\eta} dz + H \nabla_h H \cdot \nabla_h h_1 \hat{\eta} \right\}_{-h_1} \\ & + H \nabla_h H \cdot \nabla_h h_0 \hat{\eta} \Big|_{-h_0} \Big\} \end{aligned} \tag{18}$$

The assumption of slowly varying depth, *i.e.*, the mild slope assumption is imposed. The contributions of the terms on the right-hand side of Eq.(18) which are the second order of the bottom slope are considered negligible. The following elliptic equation is finally obtained.

$$\nabla_h(\alpha \nabla_h \hat{\eta}) + k^2 \alpha \hat{\eta} = 0 \tag{19}$$

where

$$\alpha = \alpha_1 + \epsilon(C_r - if_p)\alpha_2 \tag{20}$$

$$\alpha_1 = \beta_1^2 h_1 [(\beta_2^2/2kh_1)\{1 - \exp(-2kh_1)\} - (\beta_3^2/2kh_1)\{1 - \exp(2kh_1)\} - 2\beta_2\beta_3] \tag{21}$$

$$\alpha_2 = \frac{1}{2}\beta_1^2 h_p \left\{ 1 + \frac{\sinh(2kh_p)}{2kh_p} \right\} \tag{22}$$

$$\beta_1 = [\epsilon \exp(kh_1) \sinh(kh_p) - \delta \cosh(kh_1)]^{-1} \tag{23}$$

$$\beta_2 = \epsilon \exp(kh_1) \sinh(kh_p) - (1/2)\delta \exp(kh_1) \quad (24)$$

$$\beta_3 = (1/2)\delta \exp(-kh_1) \quad (25)$$

Equation (19) is the mild-slope equation describing wave transformation on a mildly sloping porous layer and is an extension of the standard mild-slope equation derived by Berkhoff (1972) for an impermeable bed.

2.2 Breaking Wave Transformation on a Submerged Breakwater

(1) Modified mild-slope equation on porous layer

A submerged breakwater usually has a principal function of premature breaking of high waves to diminish the heights of waves transmitted to the shore. To develop a general predictive model for the breaking wave transformation, Eq.(19) is modified by incorporating an energy dissipation term as

$$\nabla_h(\alpha \nabla_h \hat{\eta}) + (k^2 \alpha - i\sigma \alpha f_D) \hat{\eta} = 0 \quad (26)$$

where f_D is an energy dissipation function. The energy dissipation function f_D due to wave breaking will be derived on the basis of energy equation.

(2) Energy dissipation function of breaking wave

For a uniform porous layer and water depth condition, the value of α is constant and independent of horizontal coordinates. Equation (26) then reduces to

$$\nabla_h^2 \hat{\eta} + (k^2 - i\sigma f_D) \hat{\eta} = 0 \quad (27)$$

The complex amplitude of the water surface displacement is now defined in terms of wave amplitude a as

$$\hat{\eta} = a \cdot \exp(-i\chi) \quad (28)$$

where χ is the phase angle.

Substituting Eq.(28) into (27) and grouping the real and imaginary terms, we obtain

$$\nabla_h \chi \cdot \nabla_h \chi = k_r^2 \{1 - (k_i/k_r)^2\} + (1/a) \nabla_h^2 a \quad (29)$$

$$\nabla_h (a^2 \nabla_h \chi) = -(2k_i k_r + \sigma f_D) a^2 \quad (30)$$

The contribution from the last term in Eq.(29) may be considered negligible and the ratio k_i/k_r may be small, and hence Eq.(29) is approximated as

$$\nabla_h \chi = (k_r \cos \varphi, k_r \sin \varphi) \quad (31)$$

where φ is the wave angle. If a unidirectional wave is considered, Eq.(30) reduces to

$$\frac{\partial}{\partial n} (a^2) = -(2k_i + \frac{\sigma f_D}{k_r}) a^2 \quad (32)$$

where n represents the coordinate in the direction of wave propagation.

Equation (32) is an energy equation of waves propagating over a horizontal porous layer in which the wave energy is dissipated due to porosity and wave breaking. The

standard mild-slope equation describing the transformation of breaking waves on an impermeable bed is shown by Eq.(33).

$$\nabla_h(cc_g \nabla_h \hat{\eta}) + (k^2 cc_g - i\sigma f'_D) \hat{\eta} = 0 \tag{33}$$

where f'_D is the energy dissipation function, c the wave celerity, and c_g the group velocity. The energy dissipation function f'_D due to wave breaking was proposed by taking into account the processes of wave decay and recovery (Watanabe and Dibajnia, 1988).

$$f'_D = \alpha_D \tan \zeta' \sqrt{\frac{g}{h}} \sqrt{\frac{\vartheta' - \vartheta'_r}{\vartheta'_s - \vartheta'_r}} \tag{34}$$

where

$$\vartheta' = (|\hat{\eta}|/h), \quad \vartheta'_s = 0.4(0.57 + 5.3 \tan \zeta'), \quad \vartheta'_r = 0.4(|\hat{\eta}|/h)_b \tag{35}, (36), (37)$$

in the above equations α_D equals 2.5, $\tan \zeta'$ the bottom slope at the breaking point, and the subscript b denotes the value at the breaking point. The parameters ϑ'_s and ϑ'_r are expressed according to the results of experiment.

Under the same condition of uniform water depth, an energy equation of breaking wave transformation is derived in a similar fashion. The equation is expressed as

$$\frac{\partial}{\partial n}(a^2) = -\frac{f'_D}{c_g} a^2 \tag{38}$$

Supposing that the mechanism of energy loss due to wave breaking on a submerged permeable breakwater is similar to those on an impermeable bed, we obtain the following expression through comparison of Eqs.(32) and (38).

$$f_D = (k_r/\sigma c_g) f'_D \tag{39}$$

Equation (39) gives an energy dissipation function due to wave breaking on an inclined porous layer. Here, an effective depth is introduced to take into account the porosity of the structure.

$$h'_1 = h_1 + \epsilon h_p \tag{40}$$

The energy dissipation function due to wave breaking on a submerged permeable breakwater is finally expressed as

$$f_D = \frac{k_r}{\sigma c_g} \cdot \alpha_D \tan \zeta \sqrt{\frac{g}{h'_1}} \sqrt{\frac{\vartheta - \vartheta_r}{\vartheta_s - \vartheta_r}} \tag{41}$$

where $\tan \zeta$ is the equivalent bottom slope at the breaking point which is defined as a mean slope in the distance $5(h'_1)_b$ offshoreward from the breaking point, and

$$\vartheta = (|\hat{\eta}|/h'_1), \quad \vartheta_s = 0.4(0.57 + 5.3 \tan \zeta), \quad \vartheta_r = 0.4(|\hat{\eta}|/h'_1)_b \tag{42}, (43), (44)$$

Fig.3 Breaking wave condition on submerged permeable breakwater.

Fig.4 Comparison of breaking wave condition.

(3) Breaking criterion

Wave breaking is usually detected from the condition which is determined by breaking indices. The information of wave breaking on a submerged permeable breakwater is scarce. Therefore, the wave breaking phenomena were preliminary investigated through a series of laboratory experiments.

The model experiments of submerged permeable breakwater were conducted with two sizes of gravel on a uniformly sloping bed and a horizontal bottom. The porosity of gravel were 0.39 and 0.44, respectively. On the basis of the experimental results, an empirical formula for the condition of wave breaking on a submerged permeable breakwater is proposed.

$$H_b/L_0 = 0.127 \tanh\{k_0(h_1)_b\} \tag{45}$$

where H_b is the wave height at the breaking point, L_0 the deep water wavelength, $k_0 = 2\pi/L_0$ the deep water wave number, and $(h_1)_b$ the depth of breakwater surface at the breaking point. The agreement of Eq.(45) with the experimental results is shown in Fig.3. The breaking wave condition in Eq.(45) has a similar form as that presented by Miche (1951).

$$H_b/L_b = 0.142 \tanh\{k_b(h_1)_b\} \tag{46}$$

in which L_b is the wavelength at the breaking point, and $k_b = 2\pi/L_b$ the breaking wave number. Equation (45) is plotted in comparison with Eq.(46) in Fig.4. It is shown that both equations give almost the same results for breaking wave height. However, the definition of the breaking wavelength and wave number for a submerged permeable breakwater is implicit. For the sake of the present application, Eq.(45) will be adopted as an index to detect the wave breaking.

2.3 Numerical Computation

A method of numerical computation is utilized for the computation of wave transformation in general breakwater configurations. A detailed description is also given in Rojanakamthorn *et al.* (1989). The governing equation is discretized by using a finite difference scheme. In this paper, a two-dimensional problem as in the wave-flume experiments is analyzed to examine the validity of the present model. Then, Eq.(26) reduces to

$$\frac{d}{dx} \left(\alpha \frac{d\hat{\eta}}{dx} \right) + (k^2 \alpha - i\sigma \alpha f_D) \hat{\eta} = 0 \quad (47)$$

The study area is divided into grids in the x-direction and a finite difference form of Eq.(47) is formulated. The computation is performed with the following boundary conditions. At the offshore boundary, an open boundary condition is imposed in which the water surface displacement is composed of incident and reflected wave components. Under the assumption of linear superposition, the complex amplitude of the water surface displacement is expressed as

$$\hat{\eta} = a_i \exp(-ik_0 x) + a_r \exp(ik_0 x) \quad (48)$$

where a_i and a_r represent the amplitudes of incident and reflected waves, respectively, and k_0 the complex wave number at the offshore boundary.

At the shoreline boundary, a non-reflective condition is imposed by considering that the wave energy is dissipated due to breaking on the shore. Therefore, the water surface displacement is the resultant of the transmitted waves.

$$\hat{\eta} = a_t \exp(-ik_{sh} x) \quad (49)$$

where a_t is the amplitude of transmitted waves, and k_{sh} the wave number in the shoreline region.

The solutions are obtained through an iteration. An initial value of the friction factor f_p is first assumed with zero energy dissipation due to wave breaking, $f_D = 0$. With a given incident wave condition, the complex wave number k at every grid is calculated from Eq.(8) via an iteration technique. The coefficient α is next evaluated from Eqs.(20) to (25) and then coefficients of the amplitudes $\hat{\eta}$ at every grid are determined. This results in a set of linear equations which can be solved by using the method of Gauss elimination. Wave breaking on the breakwater is then examined by Eq.(45) and the energy dissipation due to wave breaking is included from Eqs.(41) to (44). The calculation is iterated until the convergent results are obtained. The friction factor f_p is next evaluated from Eq.(3). The computed value of f_p is compared with the assumed one and the computation is iterated when required.

Fig.5 Definition sketch; waves propagating over a rectangular submerged breakwater.

For irregular waves, a technique of individual wave analysis is utilized. The advantage of this technique has been clarified in the analysis of wave breaking. In the computation, individual waves are defined from an irregular wave train through zero-downcrossing method and the transformation of each wave component is calculated.

2.4 Rectangular Submerged Breakwater

The validity of the mild-slope equation is examined by comparing with an analytical solution for a rectangular submerged permeable breakwater. A breakwater of finite width B is considered as shown in Fig.5. A monochromatic incident wave encounters the breakwater face at $x = 0$. Then, some part of the wave energy is reflected while the other part is transmitted through the breakwater. The flow field is separated into three regions. The solution in each region is shown in terms of unknown amplitudes as follows.

Region I ($x < 0$)

$$\begin{aligned} \phi_I = & \{a_i \exp(-ikx) + a_r \exp(ikx)\} \frac{\cosh\{k(z+h_0)\}}{\cosh(kh_0)} \exp(i\sigma t) \\ & + \sum_{m=1}^{\infty} a_{rm} \exp(k_m x) \frac{\cos\{k_m(z+h_0)\}}{\cos(k_m h_0)} \exp(i\sigma t) \end{aligned} \quad (50)$$

Region II ($0 < x < B$)

$$\phi_{II} = \sum_{n=0}^{\infty} [a_{1n} \exp(-ik_n x) + a_{2n} \exp\{ik_n(x-B)\}] G_n(z) \exp(i\sigma t) \quad (-h_1 < z < 0) \quad (51)$$

$$\phi_{sII} = \sum_{n=0}^{\infty} [a_{1n} \exp(-ik_n x) + a_{2n} \exp\{ik_n(x-B)\}] H_n(z) \exp(i\sigma t) \quad (-h_0 < z < -h_1) \quad (52)$$

Region III ($x > B$)

$$\begin{aligned} \phi_{III} = & a_t \exp\{-ik(x-B)\} \frac{\cosh\{k(z+h_0)\}}{\cosh(kh_0)} \exp(i\sigma t) \\ & + \sum_{m=1}^{\infty} a_{tm} \exp\{-k_m(x-B)\} \frac{\cos\{k_m(z+h_0)\}}{\cos(k_m h_0)} \exp(i\sigma t) \end{aligned} \quad (53)$$

In the above equations, a_{rm} and a_{tm} represent the amplitudes of evanescent modes of reflected and transmitted waves, a_{1n} and a_{2n} the amplitudes of progressive and evanescent modes of the transmitted waves through the front face and reflected waves from the rear face of the breakwater, and

$$G_n(z) = \frac{\epsilon \sinh(k_n h_p) \exp\{k_n(z + h_1)\} - \delta_n \cosh\{k_n(z + h_1)\}}{\epsilon \sinh(k_n h_p) \exp(k_n h_1) - \delta_n \cosh(k_n h_1)} \tag{54}$$

$$H_n(z) = \frac{\cosh\{k_n(z + h_0)\}}{\epsilon \sinh(k_n h_p) \exp(k_n h_1) - \delta_n \cosh(k_n h_1)} \tag{55}$$

in which

$$\delta_n = \epsilon \sinh(k_n h_p) - (C_r - i f_p) \cosh(k_n h_p) \tag{56}$$

The wave number k is determined from Eq.(10) while k_m and k_n can be determined from Eqs.(57) and (58).

$$\sigma^2 = -g k_m \tan(k_m h_0) \tag{57}$$

$$\sigma^2 = g k_n \frac{\epsilon \exp(k_n h_1) \sinh(k_n h_p) - \delta_n \sinh(k_n h_1)}{\epsilon \exp(k_n h_1) \sinh(k_n h_p) - \delta_n \cosh(k_n h_1)} \tag{58}$$

In Eqs.(50) to (53), unknown parameters are a_r , a_{rm} , a_t , a_{tm} , a_{1n} and a_{2n} . These unknowns are solved with the boundary conditions, namely the continuity of pressure and mass flux at the interfaces. The orthogonality of the eigenfunctions is utilized. After mathematical manipulations, the amplitudes a_{1n} and a_{2n} can be solved from the following equations.

$$\begin{aligned} & \sum_{n=0}^{\infty} \left[a_{1n} \left\{ \left(1 + \frac{k_n}{k} \right) \lambda_{10n} + \left(C_r - i f_p + \epsilon \frac{k_n}{k} \right) \lambda_{20n} \right\} \right. \\ & \left. + a_{2n} \exp(-i k_n B) \left\{ \left(1 - \frac{k_n}{k} \right) \lambda_{10n} + \left(C_r - i f_p - \epsilon \frac{k_n}{k} \right) \lambda_{20n} \right\} \right] \\ = & \frac{2a_i}{\cosh(k h_0)} \left\{ \frac{h_0}{2} + \frac{\sinh(2k h_0)}{4k} \right\} \tag{59} \end{aligned}$$

$$\begin{aligned} & \sum_{n=0}^{\infty} \left[a_{1n} \left\{ \left(1 + \frac{i k_n}{k_m} \right) \lambda_{3mn} + \left(C_r - i f_p + \epsilon \frac{i k_n}{k_m} \right) \lambda_{4mn} \right\} \right. \\ & + a_{2n} \exp(-i k_n B) \left\{ \left(1 - \frac{i k_n}{k_m} \right) \lambda_{3mn} \right. \\ & \left. \left. + \left(C_r - i f_p - \epsilon \frac{i k_n}{k_m} \right) \lambda_{4mn} \right\} \right] = 0 \quad (m = 1, 2, 3 \dots) \tag{60} \end{aligned}$$

$$\begin{aligned} & \sum_{n=0}^{\infty} \left[a_{1n} \exp(-i k_n B) \left\{ \left(1 - \frac{k_n}{k} \right) \lambda_{10n} + \left(C_r - i f_p - \epsilon \frac{k_n}{k} \right) \lambda_{20n} \right\} \right. \\ & \left. + a_{2n} \left\{ \left(1 + \frac{k_n}{k} \right) \lambda_{10n} + \left(C_r - i f_p + \epsilon \frac{k_n}{k} \right) \lambda_{20n} \right\} \right] = 0 \tag{61} \end{aligned}$$

$$\sum_{n=0}^{\infty} \left[a_{1n} \exp(-ik_n B) \left\{ \left(1 - \frac{ik_n}{k_m} \right) \lambda_{3mn} + \left(C_r - if_p - \epsilon \frac{ik_n}{k_m} \right) \lambda_{4mn} \right\} + a_{2n} \left\{ \left(1 + \frac{ik_n}{k_m} \right) \lambda_{3mn} + \left(C_r - if_p + \epsilon \frac{ik_n}{k_m} \right) \lambda_{4mn} \right\} \right] = 0 \quad (m = 1, 2, 3 \dots) \tag{62}$$

where

$$\lambda_{10n} = \int_{-h_1}^0 G_n(z) \cosh\{k(z+h_0)\} dz, \quad \lambda_{20n} = \int_{-h_0}^{-h_1} H_n(z) \cosh\{k(z+h_0)\} dz \tag{63}$$

$$\lambda_{3mn} = \int_{-h_1}^0 G_n(z) \cos\{k_m(z+h_0)\} dz, \quad \lambda_{4mn} = \int_{-h_0}^{-h_1} H_n(z) \cos\{k_m(z+h_0)\} dz \tag{64}$$

The amplitudes of reflected and transmitted waves a_r and a_t are then calculated from Eqs.(65) and (66).

$$a_r = \frac{1}{\frac{2}{\cosh(kh_0)} \left\{ \frac{h_0}{2} + \frac{\sinh(2kh_0)}{4k} \right\}} \sum_{n=0}^{\infty} \left[a_{1n} \left\{ \left(1 - \frac{ik_n}{k} \right) \lambda_{10n} + \left(C_r - if_p - \epsilon \frac{k_n}{k} \right) \lambda_{20n} \right\} + a_{2n} \exp(-ik_n B) \left\{ \left(1 + \frac{k_n}{k} \right) \lambda_{10n} + \left(C_r - if_p + \epsilon \frac{k_n}{k} \right) \lambda_{20n} \right\} \right] \tag{65}$$

$$a_t = \frac{1}{\frac{1}{\cosh(kh_0)} \left\{ \frac{h_0}{2} + \frac{\sinh(2kh_0)}{4k} \right\}} \sum_{n=0}^{\infty} \{ a_{1n} \exp(-ik_n B) + a_{2n} \} \{ \lambda_{10n} + (C_r - if_p) \lambda_{20n} \} \tag{66}$$

The reflection and transmission coefficients, K_r and K_t , are by definition equal to the absolute value of ratio of the complex wave amplitudes.

$$K_r = |a_r/a_i|, \quad K_t = |a_t/a_i| \tag{67}$$

Equations (59) to (67) are the strict analytical solution for a simple rectangular submerged permeable breakwater.
