
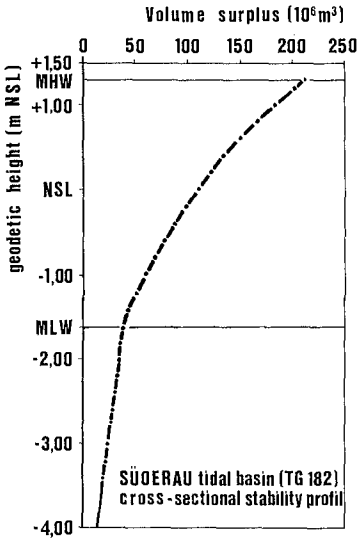

Fig. 11a: Stability profile of the Süderau tidal basin.

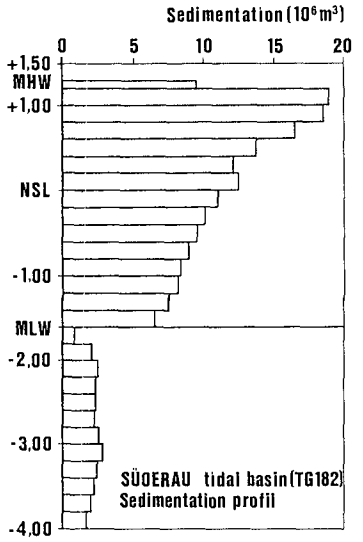

Fig. 11b: Sedimentation profile of the Süderau tidal basin.

flushing discharge from the Norderhever into the Süderau.

The sedimentation profile (Fig. 11b) shows the volume changes (sedimentation) to be expected per height interval. The sedimentation quantities per height interval are determined by simply taking differences from the stability profile summation curve. For sufficiently small height intervals, a functional curve for the sedimentation profile is obtained, which represents the derivative of the stability with respect to the geodetic height.

The stability criteria are also valid for parts of tidal basins. By means of appropriate incremental volume balances in a tidal basin from the coast towards the sea for different reference planes (e.g. MLW or MHW), longitudinal stability profiles are obtained. The latter provide a visual representation of the overall stability behaviour of the entire tidal basin. The longitudinal stability profiles of the Süderau for the reference planes MLW and MHW show that the tidal basin is not only in a state of non-equilibrium at its seaward boundary but also over the entire region, except for several unimportant cases of erosion in the immediate vicinity of the coast (see Fig. 12).

The amount of sedimentation to be expected in the Süderau may be visualized as a cube with a side length of approximately 6 km. It is not expected, however, that the amount of sedimentation predicted on the basis of the volume balances in the present state will actually occur. This will be the case as long as the tidally-induced flushing discharge from the Norderhever (see Fig. 10) continues to be effective. This flushing discharge has produced an artificial state of non-equilibrium which may only be removed when the flushing discharge is

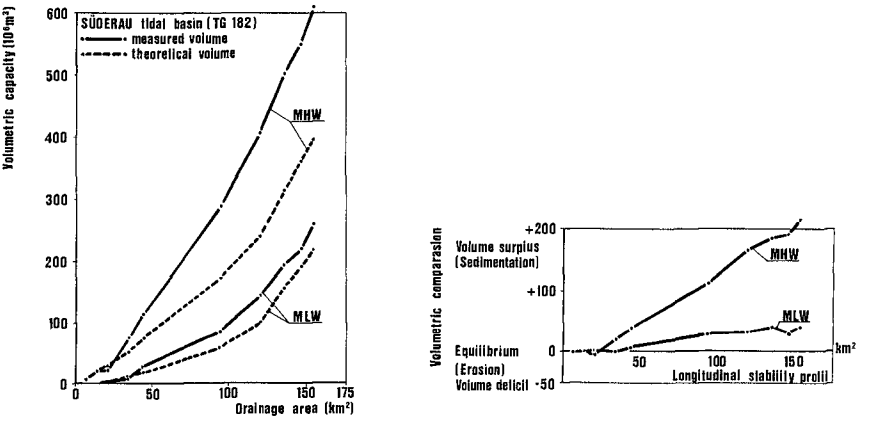

Fig. 12: Longitudinal stability profiles of the Süderau tidal basin.

prevented, as for example by means of an offshore dyke between the mainland and the Island of Pellworm (see Fig. 10). This dyke is being designed at present, and is expected to be constructed sometime after 1990.

5. Conclusion

The investigations described here show that it was possible to obtain a considerable improvement in the stability criteria so far known for tidal basins in the German Bight. This was done by taking into account the differences in the structure of the tidal basins with respect to varying tidal conditions and the separate evaluation of the creek and the flat section of the tidal basin.

The stability analysis for the Süderau tidal basin, that was undertaken as being representative of others, reveals not only the efficacy of the newly developed criteria and of the associated evaluation procedure, but also the possibility of applying it to tidal basins that have special boundary conditions as a result of particular hydrological and morphological developments.

ABSTRACT

Recently, a depth and current refraction model has been developed for the computation of directionally spread, random wave propagation in coastal regions (Booij et al., 1985). For the verification of the performance of this model laboratory measurements in a directional, shallow water wave basin were conducted. Specific attention was given to the verification of the new features of the numerical model, viz. the effects of directional spreading and ambient current field on the wave propagation and transformation process, and the change of characteristic spectral wave frequency due to wave dissipation processes.

1.0 INTRODUCTION

Since the late seventies it has become a policy in the Netherlands to verify the performance of nearshore wave propagation models (see e.g. Dingemans et al., 1984). Recently, the Delft Technical University has devised a depth and current refraction model on a grid including directional characteristics, HISWA, see also Holthuijsen and Booij (1986) in these proceedings. In contrast to the now generally accepted parabolic refraction-diffraction models, for this model it was chosen to disregard the diffraction part in order to include directional spreading of the wave field. Moreover, also the change of characteristic wave period has been modelled. Because from the previous verification studies only scarce information on directional spread is available, a special laboratory experiment has been set up in a new wave basin, equiped to generate directional, shallow water waves (Mynett et al., 1984).

The primary purpose of this study is the verification of the wave heights and the wave periods, including the effect of directional spread on the wave characteristics. A geometry consisting of a semi-cylindrical bank on a horizontal bottom has been chosen, so that these effects may be studied.
In order to separate the two-dimensional effects around the tip of the bank, refraction and diffraction, from the one-dimensional effects due to shoaling and wave breaking, also the case of the fully cylindrical bar has been included. Moreover, to obtain information on the variability of the wave field in the basin, also the case of constant depth is considered.
Here a first, concise report is given of the verification of HISWA against the laboratory measurements. A full report will appear elsewhere.

2.0 MATHEMATICAL FORMULATION OF HISWA

It is well known that the evolution of random wave fields can be described by

$$\frac{\partial A}{\partial t} + \dot{x}_i \frac{\partial A}{\partial x_i} + \dot{k}_i \frac{\partial A}{\partial k_i} = S, \tag{1}$$

where $A(\vec{k},\vec{x},t)$ denotes the wave action density, $\dot{x}_i \equiv dx_i/dt = \partial\Omega/\partial k_i$ is the group velocity, v_i, and $\dot{k}_i \equiv dk_i/dt = -\partial\Omega/\partial x_i$ is the rate of change of wave number due to refraction. Notice that the summation convention has been used with i = 1,2. The dispersion relation is given as $\omega = \Omega(\vec{k},\vec{x},t)$. When the medium in which the waves propagate does not depend on time explicitly, one has $\omega = \Omega(\vec{k},\vec{x})$, which case is taken here; in that case Ω is a Hamiltonian for the vector field $(\dot{x}_i,\dot{k}_i)$. In the case of an ambient current field $\vec{U}(\vec{x})$ one has

$$\Omega = \omega_r + k_i U_i , \qquad \omega_r = [gk\cdot\tanh kh]^{\frac{1}{2}}, \qquad k = |\vec{k}| ,$$

where $h(\vec{x})$ is the waterdepth. Then one has $v_i = c_{gi} + U_i$ and $c_{gi} = \partial\omega_r/\partial x_i$. Transforming from (k,x) space to the space (x,ω,Θ), with Θ the wave direction, and introducing the absolute energy density $\tilde{E}$ by $\tilde{E} = A\omega$, one obtains for the transport of energy along the vector field defined by the Hamiltonian Ω,

$$\frac{\partial \tilde{E}}{\partial t} + \frac{\partial}{\partial x_i}[\tilde{E} v_i] - \frac{\partial}{\partial \Theta}\left[\tilde{E}\left\{(c_g - \frac{c}{2})\frac{1}{h}\frac{\partial h}{\partial n} + \cos\Theta \frac{\partial U_1}{\partial n} + \sin\Theta \frac{\partial U_2}{\partial n}\right\}\right] = \omega S, \tag{2}$$

where $c = \omega_r/k$ and n is the direction in space normal to Θ.
This equation for the absolute energy becomes, after assuming time-independency ($\partial\tilde{E}/\partial t \equiv 0$, and thus stationary wave fields) and integration over ω between 0 and ∞ :

$$\frac{\partial}{\partial x_i}[\omega^{(A)} \cdot A^{(o)} \cdot \bar{v}_i] + \frac{\partial}{\partial \Theta}[\omega^{(A)} \cdot A^{(o)} \cdot \bar{C}_\Theta] = S_1, \tag{3}$$

where the mean quantities $\omega^{(A)}$, $A^{(o)}$, $\bar{v}_i$ and $\bar{C}_\Theta$ are defined by

$$A^{(o)}(\vec{x},\Theta) = \int_o^\infty A(\vec{x},\omega,\Theta)d\omega , \qquad \omega^{(A)}(\vec{x},\Theta) = A_o^{-1} \int_o^\infty \omega A d\omega$$

$$E^{(o)} = \omega^{(A)} A^{(o)} , \qquad \bar{v}_i = (1/E^{(o)}) \int_o^\infty \tilde{E} v_i \, d\omega,$$

$$\bar{C}_\Theta = -(1/E^{(o)}) \int_o^\infty \tilde{E} \left(c_g - \frac{c}{2}\right)\frac{1}{h}\frac{\partial h}{\partial n} d\omega + \cos\Theta \frac{\partial U_1}{\partial n} + \sin\Theta \frac{\partial U_2}{\partial n} , \qquad S_1 = \int_o^\infty \omega S d\omega.$$

Using Leibniz' rule and rewriting the result, a second equation is obtained:

$$\frac{\partial}{\partial x_i}[A^{(o)} \bar{v}_i] + \frac{\partial}{\partial \Theta}(A^{(o)} \bar{C}_\Theta) = \frac{1}{\omega^{(A)}}\left[S_1 - A^{(o)} \bar{v}_i \frac{\partial \omega^{(A)}}{\partial x_i}\right]. \tag{4}$$

Equations (3) and (4) are the basic equations for HISWA. The source term S_1 is implemented as $(\omega^{(A)}/\sigma^{(A)})S^{(o)}$, where $S^{(o)}$ denotes the change of energy and $\bar{v}_i \partial\omega^{(A)}/\partial x_i$ is interpreted as the change of the frequency

$\omega(A)$ and is prescribed as a function S_ω of the local data. For the inclusion of source terms $S^{(o)}$ and the numerical solution technique is referred to Holthuijsen and Booij (1986).

3.0 EXPERIMENTS

Wave basin

In a wave basin of 26.40 m width and 34 m length a wave generator is available, consisting of 80 flaps which can be driven independently of each other, with a total length of 26.40 m, see Fig. 1. After considering several geometries by numerical investigation, a geometry consisting of a submerged, semi-cylindrical bar on an otherwise horizontal bottom has been chosen, see Fig 1. As a check and for comparison, measurements have also been performed for the case of a submerged, fully cylindrical bar (extending over the whole width of the basin) and for the horizontal bottom situation. The unperturbed water depth is 40 cm. Opposite to the wave generator a wave absorbing gravel beach was made, with a slope of 1:7 and with the waterline at 30 m from the wave board.

Input wave conditions

The input conditions are varied according to the properties of the two-dimensional spectrum $S(f,\theta)$:

- the width of $S(f,\theta)$ in f;
- the width of $S(f,\theta)$ in θ
- the wave height Hm0;
- the incident wave direction, θ_o.

We have :

$$S(f,\theta) = E(f).D(\theta;f),$$

where we took JONSWAP-type spectra E(f) and a $\cos^m(\theta)$-type directional distribution:

$$E(f) = A_o \tilde{S}(\nu) \quad , \quad \tilde{S}(\nu) = \nu^{-5} \exp\left[-\frac{5}{4}\nu^{-4}\right] \gamma(\nu)$$

$$\gamma(\nu) = \gamma_o \exp\left[-\frac{(\nu-1)^2}{2\sigma}\right] \quad , \quad \nu = f/fm,$$

$$A_o = \alpha_o g^2 (2\pi)^{-4} f_m^{-5}; \qquad \sigma = 0.07, \ \nu \leq 1; \qquad \sigma = 0.09, \ \nu > 1$$

and

$$D(\theta;f) = B_2 \cos^m(\theta-\theta_o); \quad -\frac{\pi}{2} \leq \theta-\theta_o \leq \frac{\pi}{2}$$

$$= 0 \quad ; \text{ elsewhere.} \qquad B_2 = \frac{1}{\sqrt{\pi}} \cdot \frac{\Gamma\left(\frac{1}{2}m+1\right)}{\Gamma\left(\frac{1}{2}m+\frac{1}{2}\right)} .$$

Here γ_0 is the peak-enhancement factor and m is the exponent of the $\cos^m\theta$ directional distribution.

The input wave conditions, selected in such a way, that some of them are also useful for testing other wave propagation models, are chosen to be

Table 3.1 Input conditions.

Measuring devices

The water surface elevation was measured with a resistance type, temperature corrected wave gauge. The relationship between the depth of immersion of the vertical conductor and the output voltage is approximately linear. The deviation from linearity is less than 1% (relative error).
In order to detect the wave directionality, Delft Hydraulics has developed a wave direction meter in which a wave gauge as described above is combined with point measurement of two orbital velocity components in the horizontal plane. The device is a button-type instrument containing two orthogonal electro-magnetic velocity meters (Fig. 2). The measurement range is from -50 to + 50 cm/s. The stability is approximately 1 cm/s, the noise is better than 1 cm/s and the linearity deviation is less than 1% (relative error). The direction of the two velocity components was +45° and -45° to the orthogonal line from the wave generator.

Measurements

At 26 sites, as depicted in Fig. 3, wave height measurements are taken. At seven of these sites directional information is obtained from measurements of the two horizontal velocity components. Because of the large amount of information, and the fact that only three directional measuring devices were available, two repetitions of each run with a diffe rent lay-out of the instruments were necessary. The instruments at sites 10 and 15 were kept in place so that the reproducibility of the experiments could be assessed.

Current measurements have been performed for the semi-cylindrical bank situation for the cases 5 and 8, at 81 measuring sites located in a square grid pattern at intervals of 3 m. Three wave direction meters have been used for this purpose, which had to be replaced 26 times so as to cover all positions. At all positions the velocities were measured at half water depth. For three positions the velocities were measured at five different levels so as to obtain some information concerning the vertical structure of the velocity field. Moreover, two wave gauges have been used, which remained at the same place during all tests. At the toe

of the wave damping talus the mean water level was measured at ten dif ferent positions by means of a narrow connection tube and gauge-glass.

All cases as given in Table 3.1 have been run for the three different bottom topographies, except the current measurements which have only been performed for the semi-cylindrical bank configuration.

The various measurements are denoted by mexy, where x = 1, 2, or 3 indi cates the geometry (empty basin, cylindrical bank and semi-cylindrical bank respectively) and y gives the measurement condition (1-8) as listed in Table 3.1.

As an example of resulting spectra for me35 the spectra E(f) at site 10, close to the wave board and site 28, behind the bar are shown in Figures 4 and 5, together with the target (JONSWAP) spectra, scaled with the spectral peak and the peak frequency. The principal part of the spectrum closely follows the shape of the target spectrum. It is noted, however, that behind the bar a considerable second harmonic spectral peak in E(f) is observed, due to wave breaking over the bar. The variance of this second harmonic peak in the spectrum has been analyzed for seven sites. To characterize this peak we calculated the variance above the frequency f = 1.4 Hz, m0d2. For the measurements me35, me25 and me15 the rate m0d2/m0 has been given in the next Table, and m0 is the total variance.

$$m0d2 = \int_{1.4}^{3.125} E(f)df, \quad m0 = \int_{0}^{3.125} E(f)df.$$

	site	semi-cyl. me35	cyl. me25	empty basin me15
in front of bank	19	20.8	19.9	18.5
	10	20.0	18.5	17.7
	18	21.2	20.8	20.5
on bank	38	21.2	20.8	20.5
behind bank	39	37.1	51.5	17.6
	29	43.1	52.1	18.3
	28	60.9	51.0	17.8

Table 4.1 Values m0d2/m0 in %.

Inspection of the tabulated results, especially for me15, indicates that the contribution of the second spectral part is approximately 20% in the target spectra, which remains unaffected as the wave field propagates over the horizontal bottom. In the nearly one-dimensional case of wave breaking over the cylindrical bank the second spectral part grows relative to the primary spectral part; the energy densities become approximately equal. In the case of wave breaking over the semi-cylindrical bank the growth of the second spectral part relative to the primary spectral part varies with its position relative to the bank. These results indicate that the concept of one characteristic mean frequency is doubtful in such situations.

5.0 VERIFICATIONS

Boundary conditions and computations

Computations have been performed for all cases in Table 3.1 for both the semi-cylindrical and cylindrical bank geometry. The boundary conditions used as input in the numerical model have been determined from the corresponding measurement series. For the wave height the height Hm0 at site 10 has been taken ($Hm0 = 4\sqrt{m_0}$) and for the wave period T the average wave period, T_{m-10}, has been taken, defined as

$$T_{m-10} = m_{-1}/m_0 , \qquad m_j = \int_0^\infty f^j E(f)\, df$$

The moments m_j have been determined from the measured spectrum.

As the computed wave height behind the bar depends critically on the wave breaking parameter γ, the value for γ has been determined according to the algorithm as given by Battjes and Stive (1985), using T_{m-10} for the wave period. The bottom friction coefficient fw has been set at 0.01, a reasonable standard value.

Because the sidewards boundaries in the mathematical model are dissipative, the wave field close to these boundaries is distorted. Following Dingemans et al. (1984) for the parabolic wave model, a region with an apex of 20 degrees is taken to be a possibly distorted area; this followed also from initial computations with an empty basin. The computational region is now taken to be 50 m wide, instead of 26.40 m, the actual width of the wave basin.

Method of comparison

A relatively large amount of data has been collected, especially since we are dealing with measurements on a grid. The measurement parameters are the wave height Hm0, the wave period T_{m-10}, the main wave direction teta and the directional spread σ_o. In addition to a graphical comparison between measurements and computations, a more objective measure of correspondence was sought. To that end the approach of Willmott (1981, 1984) was adopted, in which a set of statistical measures is used. For all parameters mentioned the following procedure was followed; as an example it is elaborated here for the wave height.

The wave height field as obtained from the measurements mexy is to be compared with that from the corresponding computations; this is done at 26 sites where the wave height is compared with the computed wave height H at that site. In fact, from the computations output is generated in a square of 50 by 50 cm with midpoint the site in question, where 25 wave heights are given (see Sketch 1 below). For the comparison the mean value over the middle 9 points is used; the standard deviations are also computed, but are so low that in fact the wave height at the site alone could equally well have been taken.

```
x  x  x  x  x
x  x  x  x  x
x  x  o  x  x        Sketch 1
x  x  x  x  x
x  x  x  x  x
```

A direct comparison of the HmO and the H values is given by means of a scatter plot, which gives visual information on the correspondence. The statistical parameters recommended by Willmott (1981, 1984) are defined in the following way.

Consider a set of observations $\{O_i\}$ and predictions $\{P_i\}$, i=1,...,n. Then the mean absolute error, mae, and the root mean square error, rmse, are given by, with $\langle\cdot\rangle$ denoting the averaging operator,

$$\text{mae} = \langle|P_i - O_i|\rangle \qquad \text{and} \qquad \text{rmse} = [\langle(P_i - O_i)^2\rangle]^{\frac{1}{2}}.$$

With an ordinary least square regression $\hat{P}_i = a + bO_i$ the systematic and unsystematic part of the rms error, rmses and rmseu, can than be obtained as

$$\text{rmses} = [\langle(\hat{P}_i - O_i)^2\rangle]^{\frac{1}{2}} \qquad \text{and} \qquad \text{rmseu} = [\langle(P_i - \hat{P}_i)^2\rangle]^{\frac{1}{2}}.$$

The potential variance, PE, is given by

$$\text{PE} = \sum_i [\,|P_i - \langle O_i\rangle| + |O_i - \langle O_i\rangle|\,]^2$$

and an index of agreement, d, is given as

$$d = 1 - \frac{n \cdot \text{rmse}^2}{\text{PE}}; \qquad 0 \leq d \leq 1.$$

For d = 1 one has perfect agreement and for d = 0 none at all.

The parameters $\langle O_i\rangle$, $\langle P_i\rangle$, $s(O_i)$, $s(P_i)$, a, b mae, rmse, rmses, rmseu and d form a complete set for comparison purposes. Other variables can be derived from this set, see Willmott (1981, 1984). The bias for instance, is given by $(\langle P_i\rangle - \langle O_i\rangle)/\langle O_i\rangle$. It has to be stressed that a single parameter is in most cases not suited for model validation. Notice that these parameters are not scaled, apart from d.

Due to space limitations in the following the attention is restricted to case 5, for the semi-cylindrical bank. This particular choice is motivated by the fact that the conditions of case 5 come close to situations observed in nature and this case is one of the two primary cases around which the parameters are varied (the other one is case 2).

Wave heights

For case 5 a number of numerical model computations was made. One of the initial computations, ve35b, has been performed with starting values H = 10.42 cm and T = 1.17 s and wave breaking parameter $\gamma = 0.84$. The value of the latter parameter is determined according to the algorithm of Battjes and Stive (1985), so that the model may be considered untuned. The resulting wave heights H at the 26 sites are compared with the corresponding measured HmO values. A scatter plot of these values is given in Figure 6. Notice that the computed wave height values lie mostly below the measured ones; the bias is approximately -7%.

As can be expected in case of the semi-cylindrical bank geometry, a considerable current field is generated by the waves, especially due to wave breaking on the bar. Because the mathematical model also gives the

driving forces (in fact the gradients of the radiation stress components) for subsequent use in current models, such a wave driven current computation has been carried out and the resulting current field has been used in a second computation, ve35bs, in order to account for effects of current refraction on the wave field. The current field of a closely related computation, ve35a, where γ = .80 instead of .84 in ve35b, has been given in Fig. 7 and the stream function is given in Fig. 8. The resulting scatter plot of the pairs of wave heights at the sites is shown in Fig. 9. It is clear upon comparison of Figures 6 and 9 that inclusion of wave driven currents gives a closer correspondence between computed and measured wave heights. The bias has been reduced from approximately -7% to approximately -2%.

Because the wave generated current field has also been measured for case 5 for the semi-cylindrical bank geometry in 81 points 3 m apart, see Fig. 10, the measured current field can also be used for the wave propagation computations. The result of such a computation, ve35s1, has been given in the scatter plot of Fig. 11.

The statistical parameters for the computations ve35b, ve35bs and ve35s1 are given in the Table 5.1 below. For comparison the results for the fully cylindrical bank, computation ve25 (H = 10.23 cm, T = 1.17 s, γ = 0.83), are also included; H_c denotes the computed wave heights.

		ve35b	ve35bs	ve35s1	ve25
<Hm0>	[cm]	8.79	8.79	8.79	6.97
<Hc>	[cm]	8.22	8.65	8.55	6.91
s(Hm0)	[cm]	1.76	1.76	1.76	2.52
s(Hc)	[cm]	2.01	1.76	1.79	2.52
a	[cm]	-1.14	0.48	-0.09	-0.03
b	-	1.06	0.93	0.98	1.00
mae	[cm]	0.72	0.53	0.36	0.22
rmse	[cm]	0.92	0.66	0.50	0.28
rmses	[cm]	0.59	0.19	0.24	0.06
rmseu	[cm]	0.71	0.63	0.43	0.27
d	-	0.94	0.96	0.98	1.00

Table 5.1 Statistical parameters for wave height, over 26 sites.

These figures show that the correspondence between computed and measured wave heights becomes better with increasing accuracy of the current field. Concentrating on the mae and rmse deviation measures a continuous reduction is seen to occur from left to right in the Table. Whereas the accuracy of the wave height prediction in case ve35b (no current refraction) is already satisfactory (bias -6.6% and rmse = 10.5%), a large part of these deviations is due to the neglect of the wave-induced current field.

Taking the measured current field into account in the wave propagation computation, one has bias = -2.8% and rmse = 5.7%; as scaling parameter the value <Hm0> has been used. Considering the systematic part of the rmse deviation, rmses, it is seen that tuning is possible for better correspondence because the contribution to the mean square error due to systematic deviations is still 24% of the total mean square error; in

the optimal case this value should approach zero. It is stressed that the parameter setting has not been tuned to the measurements, only the boundary condition for the wave height and the wave period have been taken from the values at site 10, situated close to the middle of the wave board. Furthermore one single wave height was taken along the boundary, whereas, in the measurements some variation was obtained, primarily due to current refraction. It is noted furthermore that the nearly one-dimensional case, ve25, gives indeed the best results.

Wave periods

In order to be able to compare the computed wave periods, T_c, with the measured ones, it is necessary to derive the wave periods T_{m-10} from the measured wave spectra. This is done only for the 7 sites on which also the wave direction is available. The statistical parameters then become:

		ve35b	ve35bs	ve35s1	ve25
$\langle T_{m-10} \rangle$	[s]	1.11	1.11	1.11	1.12
$\langle T_c \rangle$	[s]	1.07	1.05	1.05	0.95
$s(T_{m-10})$	[s]	0.08	0.08	0.08	0.06
$s(T_c)$	[s]	0.11	0.13	0.13	0.22
a	[s]	-0.31	-0.25	-0.45	-2.41
b	-	1.25	1.17	1.35	2.99
mae	[s]	0.05	0.07	0.07	0.19
rmse	[s]	0.07	0.10	0.10	0.24
rmses	[s]	0.04	0.06	0.07	0.20
rmseu	[s]	0.06	0.08	0.07	0.13
d	-	0.85	0.72	0.76	0.41

Table 5.2 Statistical parameters for wave period, over 7 sites.

Compared with the results of the wave heights, the prediction of the wave periods is not so good. In order to check the deviations more accurately point by point comparisons are made, of which the results are given in the next Table. Here δ is the relative error $\delta = (T_c - T_{m-10})/T_{m-10}$.

	ve35b			ve25		
site	T_c	T_{m-10}	δ %	T_c	T_{m-10}	δ %

Table 5.3 Computed (T_c) and measured (T_{m-10}) wave periods at 7 sites.

As wave period changes are best checked with the fully cylindrical bank topography, the result of ve25 is more pertinent to this case than is the result of ve35b. In fact, the change in frequency can be better studied in a wave flume because directional spreading is not of importance

here (higly dissipative waves). It is seen that behind the bar the computed wave periods are about 30% too low. That the figures for ve35b are much better is due to the fact that, because of refraction, a considerable amount of "unbroken" waves reach the region behind the bar; this is especially true for the case ve35b, where no current refraction effects are included.

One should be aware of the simple adjustment of the wave periods, via some similarity approach, taking a very simplified spectral shape. It is clearly necessary to investigate the wave period adjustment further.

Wave directions

The measured values tetam are determined as follows. At each spectral frequency (of a total of 128) the wave direction θ is determined from the Fourier coefficients of the directional function by

$$\theta(f) = b_1(f)/a_1(f)$$

and the directional spread σ_o follows as

$$\sigma_o = \left[2\{1 - (a_1^2 + b_1^2)\}\right]^{\frac{1}{2}}.$$

The values θ_m follow from a simple average of the 10 values around the spectral peak frequency. The inaccuracy of θ_m is estimated to be up to about 4°, due to inaccuracy in the placing of the measuring device and the inaccuracy of the data.

site	me35 θ_m	ve35b θ_c	ve35bs θ_c	ve35s1 θ_c	me25 θ_m	ve25 θ_c
19	-5.6	0	-0.11	0.69	-4.14	0
10	1.34	0	-0.16	-0.06	2.47	0
18	-3.63	0	-0.16	0.15	-0.29	0.01
38	-13.88	-33.10	4.98	-13.18	-4.38	0.22
39	-3.37	-19.16	-4.73	-1.50	-7.54	0.22
29	-9.64	-22.74	0.01	-2.86	-6.35	-0.02
28	2.32	-21.00	-0.19	-7.54	1.06	-0.56

Table 5.4 Measured (θ_m) and computed (θ_c) wave directions.

The site 38 at the tip of the semi-cylindrical bank is the most sensitive one for checking the wave directions (in fact, the point was chosen because of this). It is seen from Table 5.4 that in this situation inclusion of current refraction is of utmost importance to a good prediction of wave directions. This can also be made clear visually from the Figures 12 and 13 where the vector plots of wave heights and directions are shown for the cases ve35a and ve35s1. Total refraction is much reduced when accounting for the wave driven current field. Especially the circulation cell near the head of the bar is important here. In the calculated current field as used in ve35bs this cell was apparently not calculated accurately enough, because the error in the calculated predominant wave direction remained about 20 degrees, but now in the opposite direction.

The values of the statistical parameters for the wave direction θ are:

	ve35b	ve35bs	ve35s1
$\langle\theta_m\rangle$	-4.6	-4.6	-4.6
$\langle\theta_c\rangle$	-13.7	-0.1	-3.5
$s(\theta_m)$	5.7	5.7	5.7
$s(\theta_c)$	13.6	2.8	5.1
a	-7.9	-1.3	-1.6
b	1.3	-0.3	0.4
rmse	14.0	8.5	5.4
rmses	9.2	8.2	3.4
rmseu	10.6	2.2	4.4
d	0.53	0.33	0.69

Table 5.5 Statistical parameters for wave directions.

It is seen from Tables 5.4 and 5.5 that value of the index of agreement d is quite low in all cases, as also follows from the linear regression coefficient b.

6.0 CONCLUSIONS

For wave height prediction the numerical model performs well: without taking the wave-generated current field into account the bias is -6.6% and the rms error is 10.5%. Taking the current field into account these values are -2.8% and 5.7% respectively. Notice that these values are obtained without any tuning of the model, i.e. the parameters are chosen beforehand according to known prescriptions, derived from other model investigations, where, moreover, a fixed frequency was chosen. Especially for the wave breaking parameter γ there are indications, also obtained from other models, that it should be chosen somewhat higher; this would result in a smaller negative, or positive, bias. As the figures are based on all 26 values, and values in front of the bank are of course much better, the accuracy is somewhat less than apparent from the given figures. Taking into account the 17 sites lying on and behind the bank, the result is bias = -7.8 versus -3.2% and rmse = 11.1 versus 5.1%.

For a good prediction of the principal wave direction the inclusion of the wave-generated current field is essential. The prediction of the wave period is less satisfactory, the decrease in T is too fast. The modelling of the change in frequency is too simple; a very schematized spectral shape is assumed and, moreover, the assumed similarity of spectral shapes is seen not to be valid in strong dissipation zones. The effect of wave breaking on the spectral shape is the loss of energy on the low frequency part and the generation of higher harmonics in the spectrum, see Figures 4 and 5. It can also happen that wave breaking is so strong that the wave energy in the original frequency band has totally disappeared and that only the higher harmonic peak in the spectrum remains; an example of this behaviour has been given in Figures 17 and 18 of Dingemans et al. (1984) for field measurements in the Haringvliet region, in the Rhine-Meuse estuary. It is necessary to model the transfer of energy to higher harmonics in the spectrum in order to be able to obtain a good prediction of characteristic wave period due to breaking of waves in shallow water.

The wave-induced current field prediction is quite good. Inclusion of such current fields has been shown to be necessary in some situation so as to obtain more accurate wave height predictions in shallow water regions. The modelling of wave and current fields, possible via an iterative computation procedure, needs further investigation. This may be important for coastal models with waves and tides, especially where the interaction between bottom changes and waves and currents is a very sensative process.

CHAPTER 82

FIELD MEASUREMENTS OF DUNE EROSION

J.S. FISHER, M. ASCE*
M.F. OVERTON, Asaoc. M ASCE**
T. CHISHOLM***

ABSTRACT

A series of field experiments was made to evsluate the use of s laboratory derived relationahip between the force in the wave uprush snd the erosion of besch dunes. Mesaurements of the awash velocity snd height st the dune face were used to compute a specific force parameter. This force term was correlated with the specific eroaion of the dune. A linear relationahip aimilsr to that found in the lsborstory waa determined with a R aquared vslue of .87.

INTRODUCTION

The prediction of dune retrest by storms is sn essentisl element of sny besch erosion model. Most of the current models uae some form of an equilibrium besch profile to determine the volume of sand eroded from the dune during s storm. These models have s common basis in the use of the Bruun Rule (Brunn 1954) which states that sa ses level riaes s besch will try to achieve the same profile it had previously. The profile will be ahifted upwards and towards the ahore using the material eroded from the beach to fill the required volume.

In terma of the application of this spproach to the dune, Edleman (1972) and Dean (1976) have both developed methoda which seem to give useful results for extreme events. In this caae the besch can be expected to resch an equilibrium profile. Vellings (1982) and Hughes and Chui (1981) have included phyaicsl model reaults in the application of this spprosch. More recently, Kriebel and Desn (1985) have improved the equilibrium profile model with the use of numericsl methods snd sdditional empirical analysis of storm eroded besches.

An slternstive method for the prediction of dune erosion waa proposed by Fisher and Overton (1984) where the erosion from each

*Prof. of Civil Engineering, North Carolins State University, Raleigh, North Carolina 27695-7908
**Assistant Prof. NCSU
***Grsduate Resesrch Assist., NCSU

individual swssh uprush is used to determine the dune erosion. The total storm erosion is a function of the frequency and intenaity of the awash. Thia spprosch does not require the development of s post-storm equilibrium profile.

Both approsches to the dune eroaion problem have merit. The equilibrium profile method is particularly will suited to long-term plsnning and the prediction of the erosion from extreme events. The wave swash spprosch enables one to estimste the impacts of smsller events for which the equilibrium profile may not be achieved. In order to develop a dune erosion model uaing the swaah characteriatica, it is necesssry to determine the relationahip between the swash and the dune scour. A seriea of laboratory and field experimenta as well as numericsl modeling have been used in this current research. Thia paper presents a portion of our results dealing with the results of the field studiea. Additionsl field resulta sre reported by Chisholm (1986). Young (1986) presents the initial laboratory reaults, and the numerical work is in Overton, Fisher and Fensish (1987).

BACKGROUND FOR FIELD EXPERIMENTS

The basic spprosch of this resesrch is that the total erosion of a dune during a storm can be viewed as the summation of the erosion from ths individual awash uprushes which impact the dune. The uprush is sssumed to behave as a bore characterized by its lesding edge velocity snd s characteristic height. When the bore reaches the toe of the dune, it scours sand and is reflected down the beach. The volume of sand eroded for each swash impact is probably s function of the swash hydraulics, the sediment size, dune geometry snd moisture content. The preaent laboratory reaesrch simplifies ths problem by only considering s single ssnd size snd a limited range of moisture contents.

In order to investigate the relstionship between the swash snd the dune scour, s series of laboratory experiments have been carried out, Young (1986). The experiments focused on the volume of sand eroded for individual bores in a 12 m flume. The bores were generated by releaaing water from a head tank with a quick opening gate. The water then traveled up sn inclined besch to the experimental dune. A number of different initisl head tank elevstions were used, thus generating different bore sizes st the dune.

The analysis of the results for 50 experiments with 10 different head tank levels yielded s linear relationship betwesn the force of the uprush at the dune snd the volume eroded. SVE is defined ss the specific volume eroded, cu m, snd SF is the specific forcs, N/m, exerted by the bore against the dune, defined by the mean of the product of the leading edge velocity squared and the msximum bore height while it is in contact with the dune. Figure 1 illustrstes the linear correlation between SVE snd SF for the laboratory tests. These data have s R squared vslue of .84.

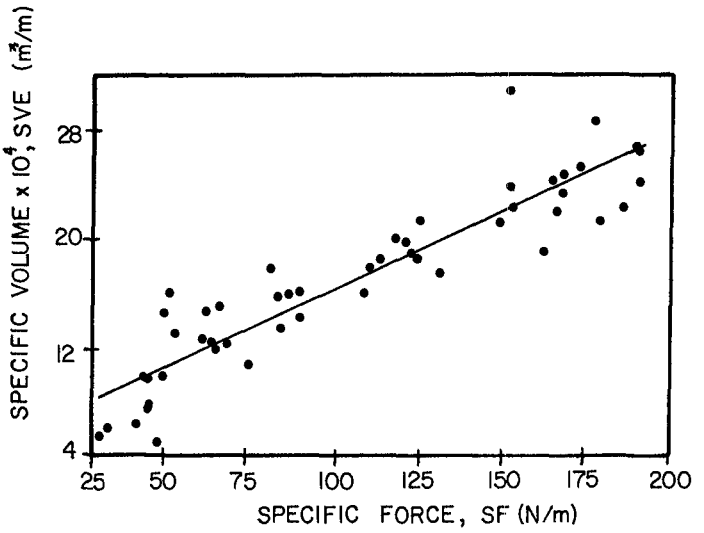

Figure 1. Linear correlation of apecific force and specific volume eroded for laboratory dune.

These results are for a limited number of laboratory experimenta. The dunes were all conatructed with the same size sand. Moiature content was not varied significantly, and the small scale meant that the force on the dune was relatively amall. A aeriea of field experiments waa therefore initiated in order to determine if thia or a similar relationahip could be found at scales more cloaely approximating prototype conditions.

DESCRIPTION OF FIELD EXPERIMENTS

The field experiments were made at the Field Reaearch Facility of the Army Corps of Engineera, Duck, North Carolina. The experiments consisted of the construction of a dune on the beach and the measurement of the rate of erosion by the wave swash as well as the hydraulic characteristics of this awash. Figure 2 is a schematic diagram of the field setup. A detailed description of the experiment is presented in Chisholm (1986).

The test dune is constructed at low tide with its toe at about the position of the mean tide level. No attempt is made to time the dune construction with extreme wave conditions. The experiment proceeds with whatever wave swash is present. The sand for the experimental dune is collected from the local dunes at the research pier. The dune is constructed between two vertical retaining walls. One side is made of a

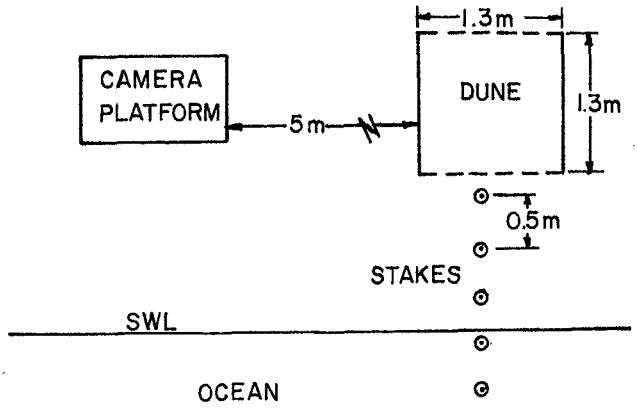

Figure 2. Schematic diagrsm of field aetup.

clesr plsstic (normsl to the shoreline) and the other of plywood. The former side has s grid on it, and both 35mm snd video pictures sre msde of the dune ss it erodes. The walls are 1.3 m spart, snd a typicsl dune is built to an elevstion of about 1 m. The dune is constructed in a series of diacrete stages. New sand ia plsced between the walls, compacted snd saturated by pouring water on it. This ia followed by the sddition of more sand, compaction and water. This process is continued until the desired elevstion is resched.

As the water level rises with the incoming tide the dune begins to be acoured snd eroded by the wave uprush. A video camera records both the changes in the dune (through the clesr plsstic wall) as well sa the swaah. Vertical stakes are placed in a line in front of the dune ss reference points for both the depth snd velocity of the swssh. These data sre also collected by the use of two capacitance wave gagea locsted along this same line in front of the dune. A still camers is used to photogrsph the dune profile sfter every msjor impact. These photographs are then used to calculste both the erosion for each uprush sa well ss the total eroaion for the entire experiment. Additional wave dsta including the significsnt period snd height sre collected ss part of the routine data collection progrsm by the Corps.

A typical experiment consists of the continuoua monitoring of the eroaion of the experimental dune during the time that the swaah reachea the dune, or until the dune is completely destroyed. The output from the capacitance gages is collected during the experiments on a portable computer with an analog to digital conversion system. The computer is powered by a generator, and is located in a truck on the beach. The data from these gages is used to to determine the height of the wave upruah juat prior to the time of impact with the dune. The actual velocity recorded is that of the leading edge of the bore. The volume of erosion for any single awash is determined from a comparison of the aequential still photographs. Theae pictures are digitized and volumes determined with a computer.

RESULTS

The results from four experiments during June 1986 are presented here. While other experiments were completed, these were the most succeasful in terms of the operation of the instrumentation and the construction of the dunea. Table 1 presents a summary of the conditions for each of theae four tests.

TABLE 1

WAVE DATA DURING DUNE EROSION TESTS

DATE	WAVE HEIGHT (M)	WAVE PERIOD (SEC)	TIDAL RANGE (M)
6/11	.33	14.2	.85
6/12	.41	10.6	1.05
6/25	.41	8.8	1.21
6/26	.58	7.2	1.01

The field data waa analyzed to see if a similar relationship exists between the specific force and eroaion for the field dunes. The data shown in Figure 3 for June 12 are typical for all of the tests. As with the laboratory analysis, the specific force is calculated as the product of the square of the leading edge velocity and the maximum bore height while it is in contact with the dune. Unlike the laboratory data, there is conaiderable scatter, and no significant correlation between the force and the erosion. There are several factors which may contribute to this poor correlation. The field data, including both the swaah heights and velocities, are very noisy. An additional factor haa

to do with the difference in the nature in the erosion of the field dune and the one built in the laboratory. In the field the dune continuea to erode with the rising tide. Unlike the laboratory dune, its face is not always vertical, but rather is highly irregular, continuing to change during the experiment. Thia irregular face meana that some uprush hit a vertical wall, othera a curved undercut surface, and still others a recently failed masa of sand. While data are not available to make definitive conclusions, it is probable that the same uprush will erode different volumea of dune sand depending on the nature of dune face.

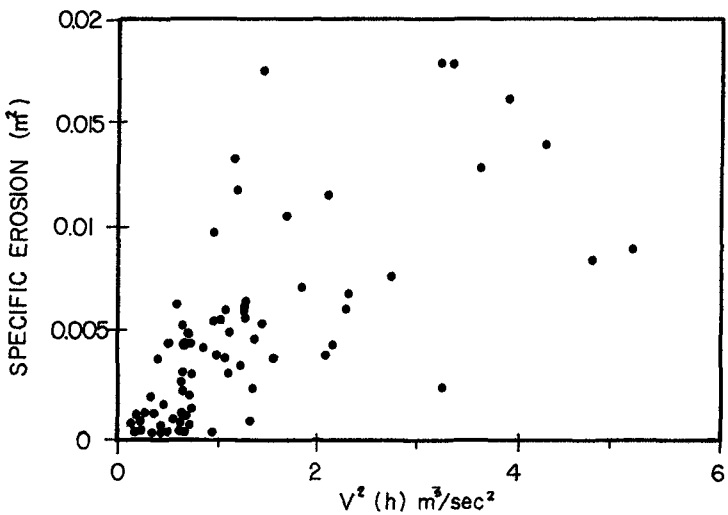

Figure 3. Specific erosion per individual swash force for June 12, 1986.

The scatter shown in Figure 3 was reduced by grouping the data according to intervala of force. Seven intervals were choaen: 0-0.5, 0.5-1, 1-1.5, 1.5-2, 2-3, 3-4, and greater than 4 N/M. For each interval, the average specific erosion was plotted against the average specific force. Figure 4 shows the linear correlation uaing theae intervals for the combined data for three experimenta, June 11, 12, and 26. (Due to a problem with the 35mm camera, the data for June 25 could not be analyzed on an individual swash baais.) There is an improved correlation (R squared equal to .75) between the specific erosion and

the specific force when these data are grouped by these intervals. The intervala obviously smooth out the scatter aaaociated with the individual surges and the irregular dune face. When viewed this way, the field data agree with the laboratory data in that there is a linear relationahip between the erosion and the force on the dune.

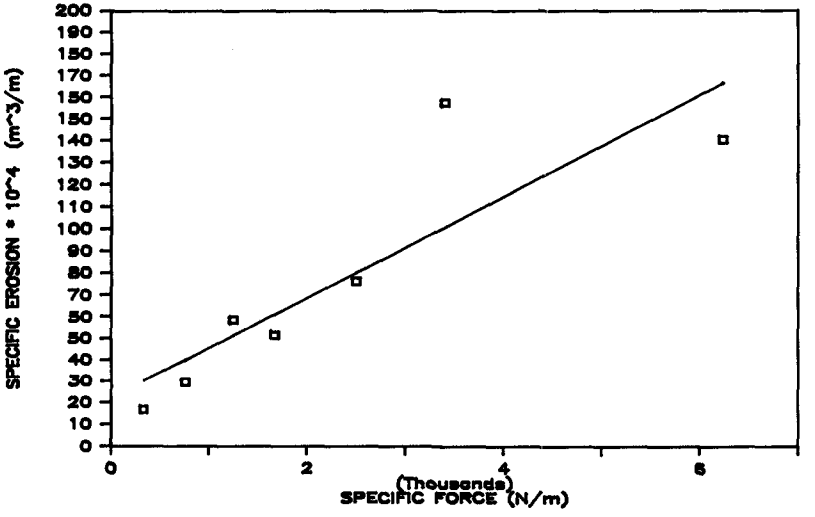

Figure 4. Specific eroaion va. specific force grouped by intervals, combination of June 11, 12, and 26.

From a practical point of view, the prediction of dune erosion based on individual swash bores is unreasonable. A method where the net dune erosion is determined from the cumulative effects of the swash would be more useful. Using the data from the four experimenta, one such method waa evaluated. The total specific erosion during the entire experiment waa plotted against the aummation of the individual specific force valuea, Figure 5. Only four data pairs are plotted, representing the four separate experiments. Aa with the data grouped by the force intervals, these data are also well correlated, R aquared equal to .87.

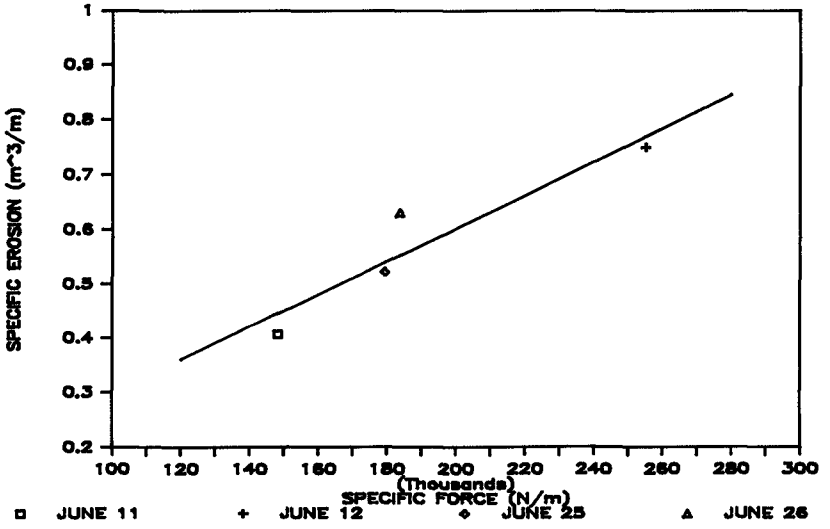

Figure 5. Total specific erosion va. summation of specific force for four experiments.

CONCLUSIONS

The primary objective of theae field experiments was to determine if the relationahip developed in the laboratory is valid for prototype scales. The resulta auggest that the general concept of relating the dune eroaion to the force of the upruah is reasonable. In particular, the good correlation (R aquared equal to .87) for the net dune erosion and the summation of the swash force on the dune provides reason to think that this approach may prove useful in the prediction of dune eroaion. Additional field test are needed for larger dunes and higher levels of awash force. Further resesrch is also needed in the mechanics of erosion, the role of moisture content, and root density from vegetation in the dune erosion process.

CHAPTER 83

Evaluation of Models of Nearshore Processes

C A Fleming*, B M Pinchin and R B Nairn**

Summary

The Canadian Coastal Sediment Study, known as C2S2, included numerous activities related to improving the measurement and prediction of sand transport in the nearshore zone. The data was used to evaluate a number of predictive techniques commonly used for coastal zone modelling for both alongshore and onshore/offshore sediment transport modelling. Field experiments were carried out at two sites. This paper is concerned with the first of these sites at Pointe Sapin, New Brunswick. Computed transport rates were compared with volumes of sand that accumulated in a sand trap formed by an offshore breakwater upstream of the mouth of Pointe Sapin harbour. The predictive techniques used were a parametric wave hindcasting model, a spectral wave refraction model, alongshore current predictors, seven of which rely on computed alongshore current distributions.

1 INTRODUCTION

The Canadian Coastal Sediment Study was a multi-departmentally sponsored research programme aimed at improving the knowledge of sand transport on beaches. The original objectives of the study were to develop instrumentation for measuring instantaneous rates of nearshore sand transport, to evaluate existing methods of measuring and predicting nearshore transport, to sponsor co-operative field studies and to encourage the development of new and improved nearshore transport predictors. The authors were contracted to carry out engineering predictions of waves, wave-generated currents and nearshore sediment transport of two sites: Pointe Sapin, New Brunswick and Pointe Deroche, Prince Edward Island. In addition they were contracted to compare these predictions to measurements made at Pointe Sapin between September and November 1983. This whole exercise implicitly involved the extensive application of numerical modelling of nearshore processes including wave hindcasting, wave induced currents and prediction of both alongshore and onshore/offshore sediment transport.

Pointe Sapin, New Brunswick is located at the northern entrance to the Northumberland Strait and that section of the coastline generally faces south-east. The site is exposed to waves generated in the Gulf of St Lawrence (See Figure 1) and is sheltered approximately from east to south by Prince Edward Island. Thus, the wave climate is dominated by waves approaching from the northeast quandrant. The beach at

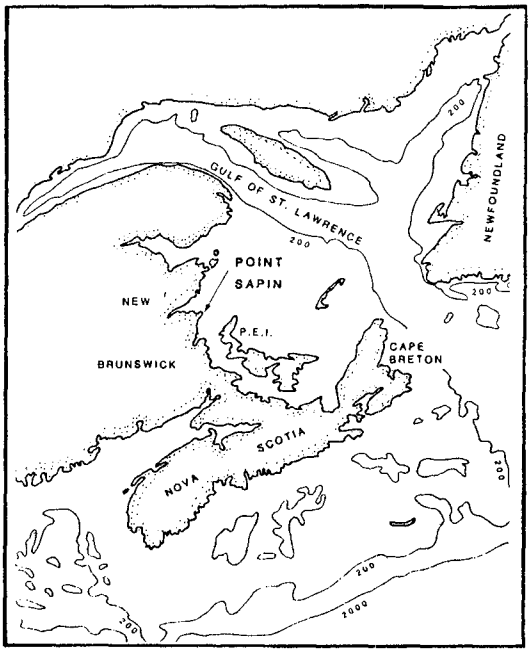

Figure 1: Location of Pointe Sapin

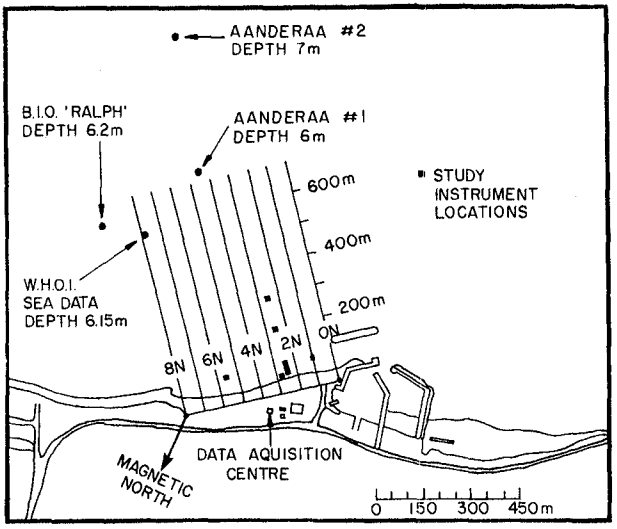

Figure 2: Survey Lines and Instrument Positions

Pointe Sapin is a wedge shaped body of sand between 2 and 3 metres thick on the backshore thinning to nothing between 60 and 75 metres offshore. Thus, the beach overlies a wide rock shelf which is composed of reddish-brown siltstone. The offshore bedrock is covered by a thin layer of gravelly sands. The sediments in the littoral zone are predominantly fine sand sized particles which are well sorted with a mean diameter between 0.18 and 0.25mm. Local deposits of pebbles do occur.

There is a small fishing harbour at Pointe Sapin which has suffered quite severe sedimentation problems in the past. As a result an offshore breakwater was constructed to act as a sand trap and this has been effective in significantly reducing the siltation problem. The offshore breakwater, the layout of which is shown in Figure 2, lies approximately 100 m off the main breakwater of the fishing harbour. It has been estimated that in an average year at least 60% of the littoral drift should be caught in the sand trap. The existence of the sand trap on the south side of the study site was one of the factors that led to the selection of this site. The mean tide range at the site is 0.9 metres and the tidal currents run reversing parallel to the coast with speeds generally less than 0.1 metre/sec.

2 FIELD MEASUREMENTS

The field programme at Pointe Sapin was carried out during the latter part of 1983. Many measurements were made, including offshore wave measurements 8.3km west of the site in 16.5m depth of water (Skafel, 1984), nearshore wave measurements (Aubrey and Spencer, 1984), nearshore current measurements and various sediment concentration devices all of which are summarised by Daniel, 1985.

In addition macro-scale experiments were carried out using a number of different types of bottom drifters as well as radioactive tracers. The sand trap was dredged clear immediately prior to the experiment and profile surveys of the sand trap area and adjacent beaches were carried out at regular intervals throughout the experiment period (Gillie, 1984 a).

3 PREDICTIVE TECHNIQUES

3.1 Wind Hindcasting

A parametric wave hindcasting model was used which included options to use four difference hindcasting models; SMB deep water, SMB shallow water, Derbyshire-Draper and JONSWAP. The wind data required is a time series of wind speed and direction, adjusted if necessary to a standard elevation above mean sea level. For each forward step of the hindcast an effective wave, defined by height, period and direction, is the resultant hindcast wave composed of a generated and a decayed wave train. The larger of the two components was treated as dominant in defining the wave period and direction.

The effective wave for each timestep was computed by examining the wind data and dominant wave conditions for a preceding duration time equal to the selected maximum wave generation sequence. Thus, by backstepping

through the data from the current record every combination of wind speed and duration is examined up to a limiting condition, in this case 2 days, or to a point where the wind direction differs from the average of the preceding sequence by an amount exceeding a defined wave divergence angle eg 22.5 or 45 degrees. The wave decay sequence was initiated either when a calm was encountered or when the wave divergence angle was exceeded. A number of wave decay functions were considered. (See Fleming et al, 1984)

3.2 Wave Transformations

The two principal components of the computational procedure are a wave refraction model and a post-processor that calculates the specteal transfer functions which in turn provide wave height coefficients and direction shifts from deep water to a shallow water point of interest.

The wave refraction model used was based on the highly efficient 'circular arc' technique allowing the high ray density backtracking for several frequencies from each point of interest to be carried out. The seabed was defined by ten digitized depth grids which varied in both overall dimensions and mesh size according to the water depth and proximity to the field investigation site.

The process of refracting a wave spectrum is based on the assumption that the wave energy flux in a frequency band will remain in that band as each component of the wave spectrum is transferred inshore. It is thus possible to discretise a deepwater directional wave spectrum and independently transfer it inshore applying appropriate shoaling coefficients. In this case the JONSWAP model was used. Its applicability to this site was verified by matching computed spectra with offshore spectra measured in 1982 (Fleming et al, 1984).

The direct application of this procedure to the offshore wave measurements led to a substantial over-estimation of inshore wave heights during one of the storms. This led to an investigation into energy dissipation mechanisms and as a result wave spectrum saturation for shallow water were incorporated into the wave spectrum transformation procedure. The shallow water equilibrium spectrum theories used were due to Kitaigorodskii et al, 1975 and Bouws et al, 1981. Comparative results are presented in Section 4.

3.3 Nearshore Sediment Transport

The inshore wave climate defined by the above procedure allowed calculation of alongshore sediment transport rates for the same breaker line, surf zone geometry and hence, alongshore current distribution for up to ten sediment transport models.

A complete description of the theories underlying the models used in these studies has been given (Fleming et al, 1984). This was based on an earlier publication (Fleming and Swart, 1982) in which the theory proposed by Longuet-Higgins was adapted to allow for contribution to the shear term by the longshore current itself and to rationalise the variation of friction coefficient as a function of beach slope and both wave and current friction factors. A similar treatment was carried out

based on Battjes (1974) theoretical approach. This is comparable to Longuet-Higgins approach for regular waves, but considers linear random waves together with the same momentum balance equation.

The friction factor for alongshore currents has been based on roughness length and it is this parameter that is most open to debate. In the absence of bed forms there are a number of different estimates for grain roughness and the one considered in this study has been proposed by Kamphuis (1975) as 2D90 (2D90 refers to the grain size for which 90% of the sediment distribution by weight is smaller). In the presence of ripples the roughness length may simply be taken as some multiple of the ripple height or the expression proposed by Swart (1976a) which includes both the ripple height and the ripple steepness. Whilst this formulation has relatively little data to confirm its validity it seems to have gained quite wide acceptance for lack of any more substantiated work. However, having adopted that expression the problem then shifts to applying a ripple height and length predictor.

Three different ripple models have been considered in this study. They are due to Mogridge and Kamphuis (1972), Swart (1976a) and Nielsen (1978). All three models may be used to determine both ripple height and ripple length as a function of local water depths, wave height, wave period, sediment size and relative density of the material. The formulations are essentially empirical and primarily based on physical models together with some limited field data.

The computational procedures were as follows:

i) The beach profile was divided into a number of representative sections of variable size.

ii) The inshore wave conditions were used to find the breaker position and corresponding properties. These were used in the bulk predictors.

iii) The mean wave height was calculated according to a Rayleigh probability function. The mean wave height was found by integrating the distribution truncated by the maximum possible wave.

iv) Wave and sediment characteristics were used to calculate ripple dimensions. This in turn provided data for the hydraulic bed roughness to be evaluated.

v) The wave and current parameters were used to calculate the alongshore current distribution across the profile.

vi) Wave properties, currents and the various coefficients calculated were used to determine bed shear stresses which in turn are used to drive some of the detailed prediction models.

vii) Each wave condition was taken in turn and running totals of gross and net transport and relative distribution kept as a running total.

Both bulk energy sediment transport predictors as well as detailed predictors were applied as outlined in Table 1.

	MODEL	GENERAL CLASSIFICATION
1	CERC Formula (1977)	Bulk energy model
2	Davies and Kamphius (1985)	Bulk energy model, includes grain size and beach slope
3	Sayao et al (1985)	" " " " " " " "
4	Engelund and Hansen adaptation by Swart (1976)	Based on bed and suspended loan concentrations with a background current, no incipient motion criterion
5	Willis (1978)	Adaptation of Ackers and White (1973), includes an incipient motion criterion
6	van der Graaf and van Overeem (1979)	Adaptation of Ackers and White (1973), includes an incipient motion criterion
7	Nielsen (1979) (for breaking waves)	Based on bed and suspended load concentrations with a background current, includes an incipient motion criterion
8	Nielsen (1979) (for non-breaking waves)	Ditto
9	Fleming (1977)	Ditto
10	Swart (Fleming & Swart, 1982)	Adaptation of Ackers and White (1973), includes an incipient motion criterion derived from a wide range of wave and current conditions

Table 1: General Description of Alongshore Sediment Transport Predictors

4 COMPARISONS OF MEASUREMENTS WITH PREDICTIONS

4.1 Offshore Waves

Figure 3 shows three sets of hindcast and measure wave heights and periods between the 21st and 31st October 1983 for one of the storms that occurred during the experimental period. Set (A) used the SMB deep water parametric hindcast model. It is seen that the hindcast wave heights were in reasonably good agreement with the measurement with the exception of the peak of the storm when the predictions grossly exceeded measurements. The hindcast wave periods were generally in good agreement with measurements throughout the period shown. Set (B) used the

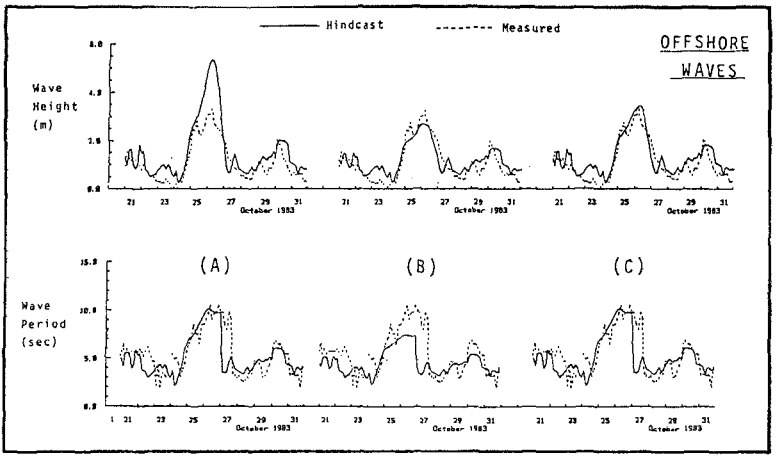

Figure 3: Hindcast and Measured Offshore Wave Data

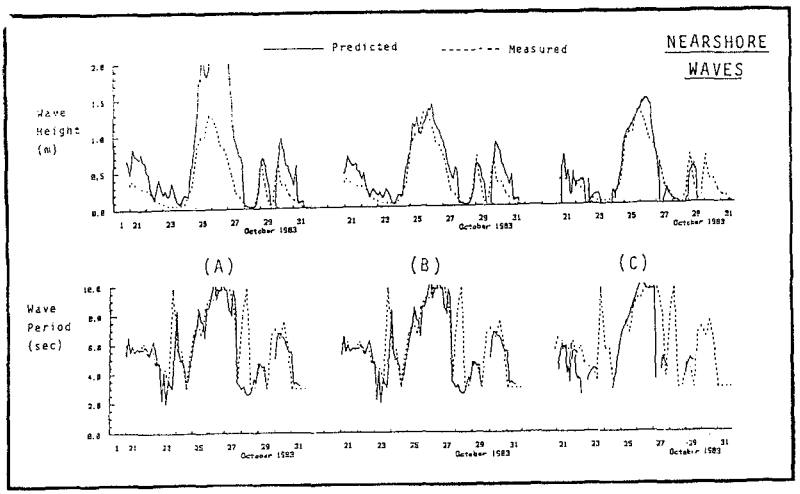

Figure 4: Hindcast and Measured Nearshore Wave Data

SMB shallow water parametric hindcast model. However, instead of using water depths characteristic of the entire fetch the water depth at the wave recording site (16m) has been used. it may be circumstantial, but the hindcast wave heights show much better agreement with measurements during the peak of the storm, but are little changed at other times. In contrast the hindcast wave periods became rather less than the measured particularly through the storm. At this point it might be noted that combination of SMB shallow for wave heights and SMB deep for wave periods would give a reasonably respectable result. The final set (C) was obtained by applying the SMB deep water hindcast model modified for spectral saturation which is a function of depth (Bouws et al, 1985). Here both the hindcast wave height and wave period show excellent agreement with measured values.

4.2 Nearshore Waves

The nearshore wave measurements were made in a little over 6 m mean water depth. Both deep water measured and hindcast wave sets were transferred to this shallow water site by applying the wave height coefficients and directions deduced from the spectral wave refraction model described in Section 3.2.

Figure 4 shows three sets of predicted and measured wave heights and periods between 21st and 31st October 1983 and can thus be compared directly with the previous figure. Set (A) represents the offshore measured waves transferred to shallow water by direct application of the spectral transfer results. It can be seen that the predicted wave heights were largely excessive by up to a factor of two for most of the record length, whilst the wave periods were in reasonably good agreement. Set (B) represents the offshore measured waves transferred to shallow water by application of spectral refraction results modified to include shallow water spectral saturation limits in each frequency band. Here it is seen that the predicted wave heights show excellent agreement with those measured. The wave periods remain largely un- changed and in good agreement with measured values. Set (C) represents the hindcast wave climate offshore which included saturation limits (ie Set (C) in Figure 3) transferred to the shallow water recording site by application of spectral refraction results modified to include shallow water spectral saturation limits as above. The agreement on wave height remains good but the wave period predictions appear to show a slight deterioration.

4.3 Alongshore Currents

The first storm during the experiment occurred between 24 October and 27 October 1983. Two of the current meter records were suitable, but not ideal, for testing purposes. The measured currents were on two

profiles (1.0N and 2.5N) both at a baseline offset of 86 m (see Figure 2). The points lie seawards of the point of maximum alongshore current velocity and there was no information with regard to distribution of current velocity across the profile.

Tests were carried out in a sequence that represents a progression from the simplest assumptions to those which incorporate all the relevant parameters. Only one example of the numerous test is given in Figure 5. In this case the match during the first half of the storm was quite good with the Battjes model. However, none of the model runs managed to predict the large currents at the two separate instruments during the latter part of the first storm. It seems apparent that currents measured after hour 50 were not wave induced and if it possible that this might be the case from as early as hour 25. Other types of currents might be wind-induced, tidal currents and large-scale ocean circulation.

While a quantitative assessment of the contribution of wind stress to longshore currents was not performed, an examination of wind velocities precluded this possibility. Tidal currents at Pointe Sapin are generally less then 0.1 m/sec (Gillie, 1985) and consequently could not have a significant influence on measured values. Large scale circulations were also ruled out as currents of a similar magnitude were not measured at the nearshore wave recorder site in 6 m of water. it was finally concluded that there was most likely some data logger error.

The second storm occurred between 4 and 7 November. In this case the results from two current meters on line 2.5 N at baseline offsets of 71 m and 86 m were compared to predicted results. The wave heights for this storm were rather less so that the measurements were even further down the tail of the cross shore distribution. An example of one of the predictions compared to measurement is shown in Figure 6.

4.4 Alongshore Sand Transport

The volume of sand transported during the two storms that occurred during the experimental period have been estimated by a number of investigators (Kooistra and Kamphuis, 1984, Morse, 1984 and Gillie, 1984) using both the profile surveys of the sand trap and adjacent beach as well as the radioactive sand tracer experiments. The estimate of net volume of sand transported during a particular event is dependent on whether only the sand trap itself is considered as the control volume or whether some part of the beach upstream of the sand trap should also be included. Considering the period of 22nd and 27th October estimated volumes vary from about 5000 cu m to nearly 11000 cu m. These figures do not account for efficiency of the sand trap. A reasonable estimate would increase the range to between 6500 m^3 to 13000 m^3 with an average magnitude of 10,000 m^3.

Less attention has been paid to the second storm which occurred betwen the 4th and 7th November 1983 and during which wave heights were not as large as for Storm 1. In this case estimates of volumes accumulated during the storm have varied between 2,000 m^3 (Gillie, 1984b), 2,600 m^3 $\pm$ 140 m^3 (Morse, 1984) and 3,100 m^3 (Kooistra and Kamphuis, 1984)

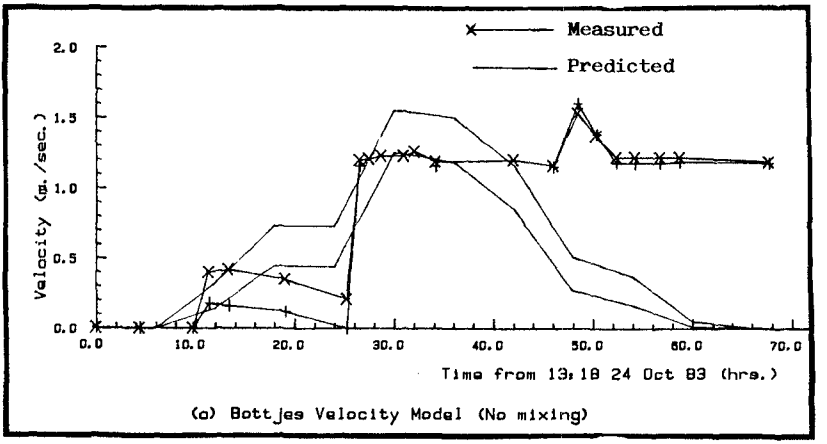

Figure 5: Predicted and Measured Alongshore Currents, Storm 1

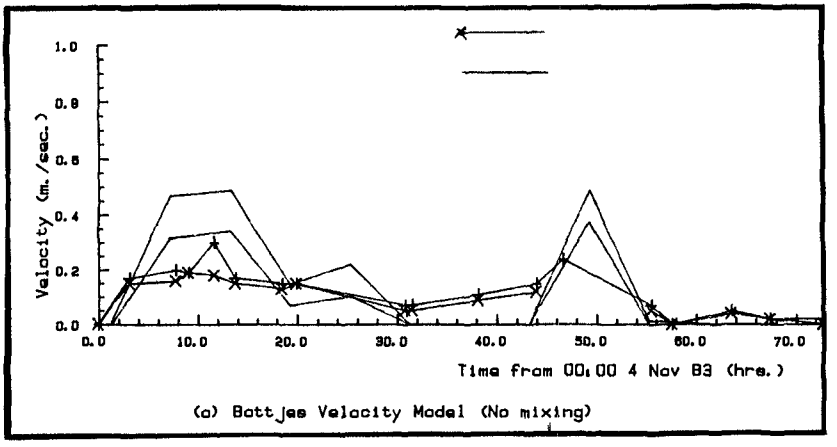

Figure 6: Predicted and Measured Alongshore Currents, Storm 2

A selection of the analyses that were carried out for each storm are given in Table 2. Many more variations and sensitivity tests and details can be found in the Pahse II report (Fleming et al, 1986). In the case of the second storm there were no deep water wave measurements.

Swart	1,186	118	2,698	34,040

Note: All runs use Battjas type alongshore current velocity distribution, variable water level, variable slope and an average sediment grading. Wave climate and ripple models vary as follows:

1 Hindcast using deep water SMB model, refracted inshore without saturation limits, S/L ripple roughness.
2 Measured deep water waves, refracted inshore without saturation limits, S/L ripple roughness.
3 Hindcast using deep water SMB model, refracted inshore with saturation limits, S/L ripple roughness.
4 Measured deepwater waves, refracted inshore with saturation limits, S/L ripple roughness.
5 Measured inshore waves, Swart/Lenhoff ripple roughness.
6 Measured inshore wave, Neilsen ripple roughness.

4.4.1 Storm 1

Referring to Table 2, Run 1 used a hindcast deep water wave climate refracted inshore using standard spectral transfer techniques It has been shown that this will have overestimated the wave heights quite considerably and the estimated transport volumes were correspondingly excessive. Run 2 was similar but used the measured deep water wave climate and hence gave an improved estimate, but still in excess of measured volumes. Run 3 was similar to Run 1 except that spectral saturation was included in the wave transformation to shallow water. Here, the predicted volumes for two of the detailed predictors lie within the range of volumes estimated for measurements. Similarly Run 4 was similar to Run 1 and predicted volumes for three of the detailed predictors fall within the estimated range and in general values for all models were closest.

Run 5 used the measured inshore wave records and generally gave lower predictions than Run 4 due to slightly lower wave heights. All of these runs used the ripple predictor adopted by Swart (1976a). Run 6 is similar to Run 5 except that the Neilsen ripple predictor has been used. Three of the detailed predictors gave reasonable results but others gave quite large over estimates.

Assimilating all of the results from the Storm 1 tests there are a number of observations that can be made:

(i) The Battjes longshore current velocity model used in conjunction with the Fleming and Swart (1982) friction factor gave consistent results.

(ii) For the bulk predictors tested the Queen's 2 predictor gave the closest net volumes transported to those measured in the field in all cases tested but the estimates in these investigations were higher than those made by Kooistra and Kamphuis (1984) for the Queen's 1 model.

(iii) The Nielsen (breaking wave) sediment transport model was the most stable of all of the detailed predictors tested and gave results very close to the measured volume even when the input parameters are varied quite widely.

(iv) The use of different ripple models in conjunction with the Fleming and Swart (1982) friction factor formulation is not strictly valid and will result in higher current velocities for grain roughness or the Nielsen ripple model.

(v) The need to accurately define the nearshore wave climate cannot be over-emphasised, the sensitivity of all predictors having been clearly demonstrated. In the absence of nearshore wave measurements a good wave transformation model is clearly required. In the absence of offshore wave measurements the quality of the result obviously rests almost entirely on the quality of the offshore wave hindcast.

4.4.2 Storm 2

Again referring to Table 2, Run 1,3,5 and 6 were for identical combinations of input parameters as previously described for Storm 1. In this case the inclusion of spectral saturation in the wave transformation to shallow water resulted in an under-estimate of transported volumes for all except the bulk predictors. The 'best' results for the detailed predictors was given for Runs 5 and 6 which correspond to the measured nearshore wave data with different ripple models. However, the bulk predictors gave excessive values for these combinations.

The overall observations relating to Storm 2 results are:

(i) The offshore wave hindcast for Storm 2 did not predict the magnitude and duraction of the waves very well. Consequently both sets of predictions made on this basis significantly underestimate the net volume of sand transported for many of the detailed predictors.

(ii) The bulk predictors overestimated the net transport voumes for all combinations of variables tested except the offshore wave hindcast cases which were known to underestimate the wave conditions. The Queen's 2 predictor gave marginally better results than Queen's 1.

(iii) The results for the detailed predictors are generally much closer to the measured field volumes.

(iv) The Nielsen (breaking wave) model was again the most stable of the detailed predictors under all conditions tested and gave predictions close to measured when nearshore measured wave data is used.

(v) The importance of accurately defining the nearshore wave climate was once again clearly demonstrated.

5 CONCLUSIONS

Wave hindcasts for the offshore measurement site showed that shallow water effects in 16m of water were relatively large. The accuracy of the prediction could apparently be improved significantly by introducing depth dependent energy saturation principles into the hindcast models. Computation of nearshore wave heights and directions on the basis of two dimensional spectral refraction techniques did not provide good estimates for the larger of two storm sequences measured. Again the inclusions of depth-dependent energy saturation modifications to the transformation process improved the predictions considerably. This is not a new application in this context (see for example Resio, 1978). Application of the frequency saturation principles into the wave transformation process can most conveniently be incorporated into the spectral transformation method. As far as the frequency saturation limits are concerned there remain a number of issues that need to be resolved.

The use of the Longuet-Higgins formulation for the distribution of alongshore currents had no advantage or showed no distinctly better fit to the recorded data than the Battjes type model. In fact it suffers one positive disadvantage in that it requires the definition of a mixing coefficient for which there are no real guidelines as to what are appropriate values for different conditions. It may be anticipated that in the case of the existence of offshore bars or beaches with predominantly plunging breakers there will be problems in applying models derived for plane beaches.

It is also abvious that the roughness model used in the sediment transport predictors as well as the alongshore current friction factor empirical relationship plays a very central role in determining the level of shear forces acting on the bed.

Finally turning to the question of the performance of the sediment transport models themselves. Amongst the bulk predictors the Queen's formulations clearly performed better than the CERC formula. For the detailed predictors the Ackers and White derivations appear to be extremely sensitive to current velocities particularly when they exceed a threshold of about 1 m/s. The latest of these derivations reported in Swart and Fleming (1982) appeared to give results closest to the measured values. The Engelund and Hansen adaptation gave results that were quite comparable to the Ackers and White adaptations, but generally overpredicted transport rates, not surprisingly as it does not contain any threshold of movement criterion. Nevertheless it is extremely simple to apply. Results from the Fleming and Nielsen based models were comparable for many conditions, but the latter have proved to be by far the most stable in this application. It is therefore concluded that the Nielsen based models gave the best overall performance of all the detailed predictors tested. That was not without some anomalies related to varying grain sizes and wave heights which appeared to change the bed roughness in the opposite sense to the other models.

To summarise predictions of alongshore transport rates have been made using both bulk energy and detailed predictors which rely on computed alongshore current distributions. A number of comparative estimates have shown (i) the sensitivity of the detailed predictors to the friction factors used which are indirectly dependent upon the ripple roughness model, (ii) the magnitude of error that would have occurred from using an unverified deep water wave hidncast model, (iii) the magnitude of error that would have resulted in using an offshore wave climate transformed by consideration of refraction alone and (iv) a close comparison in results between measured and predicted rates when the improved method of estimating the nearshore wave climate is used. It should also be noted that the best prediction of net volume transported were largely within the range of volumes deduced from various field measurements. However, there is considerable scope for improvement of the sediment transport predictors.

ACKNOWLEOGEMENTS

We gratefully acknowledge the support of Bert Pade and Peter Daniel, C2S2 study managers; Dave Willis, National Research Council; Chris Glodowski, Public Works Canada and other

members of the ACROSES committee. The information gathered by the numerous investigators during the Study has been invaluable in providing the required data. It has been a privilege to have taken part in the C2S2 research programme.

CHAPTER 84

VIRGINIA BEACH SAND SIZE AS BASIS FOR DESIGN OF ON-SHORE DREDGED MATERIAL DISPOSAL

Cyril Galvin*, M. ASCE, James W. Holton, Jr.**, M. ASCE, Ronald G. Vann***

ABSTRACT

Analyses of sand samples collected along and across the Atlantic Ocean shore of Virginia Beach, Virginia, suggest that sand placed on the shore should have a minimum median diameter of 0.20 mm to efficiently benefit the beach. Size analyses and shoreline change data show that the existing long-term beach replenishment by mechanical bypassing across Rudee Inlet and by truck-hauled sand from land sources is effective and necessary to maintain the shore along the commercial segment of Virginia Beach. The data also indicate that the northern segment of Virginia Beach shore, occupying more than half the distance between Rudee Inlet and Fort Story, is gaining sand. About two million cubic meters of sand to be dredged from the Atlantic Ocean Channel offshore of Virginia Beach will be suitable for placement on the beach.

INTRODUCTION

Background. Channel depths at the entrance to the Harbor of Hampton Roads, Virginia, are insufficient to accommodate modern, fully-laden colliers outbound from the harbor's large coal terminals at Norfolk and Newport News. Achieving sufficient depths will require dredging large volumes of sediment, including dredging the Atlantic Ocean Channel which extends southeasterly from the mouth of Chesapeake Bay (U.S. Army Corps of Engineers, 1985). Ordinarily, the most economical disposal of these dredged sediments is dumping at sea, but sand in the dredged material is a resource that might usefully be placed on nearby beaches of the City of Virginia Beach, Virginia.

At the time this work started, it was not known how much sand would be available from dredging the Atlantic Ocean Channel, and what characteristics were required to make its disposal on the beach a useful operation. The investigation under discussion differs from a typical beach fill project in that dredging will produce sand as a byproduct, and we determine if it would be beneficial to dispose of this sand on

* Principal Coastal Engineer, Box 623, Springfield, Virginia 22150.
** President, Waterway Surveys & Engineering, Ltd.
*** Chief, Dredging Management Branch, Norfolk District, U.S. Army Corps of Engineers.

the beach. The costs of such disposal are not treated here, but it is anticipated that the benefiting beach would bear the differential in cost (if any), compared to the cost of dumping at sea.

This particular investigation is the fourth of five similar investigations on the feasibility of disposing sand on beaches near two Hampton Roads entrance channels. These five investigations, performed under contract by Waterway Surveys & Engineering, Ltd (WS&E) with the Corps of Engineers, Norfolk District, include disposal from Thimble Shoal Channel on Fort Story beaches (WS&E, 1984a), on West Ocean View beaches (WS&E, 1984b), and on East Ocean View beaches (WS&E, 1984c), and disposal from Atlantic Ocean Channel on Virginia Beach (WS&E, 1986a), and on Sandbridge Beach (WS&E, 1986b). Previous technical reports on this study area include the beach profile study of Goldsmith, et al. (1977), four CERC papers by Harrison and associates all dated 1964, and engineering reports related to the Virginia Beach Erosion Commission work.

Purpose. This paper analyzes sand size along and across a ten-kilometer segment of the shore at Virginia Beach, Virginia. The analysis is used to understand how coastal processes affect the beach and, given this understanding, to judge whether sand to be dredged from the Atlantic Ocean Channel may be suitably placed there. The emphasis is on beach sand from Virginia Beach. Additional details on both the beach and Atlantic Ocean Channel sediments are in WS&E (1986a).

Location. The study beach is on the Atlantic coast of Virginia, south of the entrance to Chesapeake Bay (Figure 1). It extends from the south boundary of Fort Story, southward past the residential and commercial segments of Virginia Beach, across Rudee Inlet, to Croatan Beach (Figure 2). This shore trends about 10 degrees to 15 degrees west of north and is partially sheltered by the Virginia Barrier Islands to the north-northeast (Figure 1) and shoals at the Bay entrance. The effects of this shelter on the wave climate, along with the westerly trend of the shoreline, produce a net northward longshore transport at the study beach (opposite the regional southward trend of more exposed Atlantic sites). Mean annual breaker height is less than 0.6 meters and tide range is about 1.0 meters (Table 1). The Atlantic Ocean Channel is 6 to 12 kilometers offshore of the study beach (Figure 2).

Units. Metric units are used for distances, wave heights, and sand volumes (1 km = 0.6 miles; 1 meter = 3.3 feet; 1 cubic meter = 1.3 cubic yards). Since authorized project depths are given in feet, depths are identified first in feet, and then in meters. Two vertical datums are used: Mean Low Water (MLW) for channel depths and National Geodetic Vertical Datum (NGVD) for the beach and nearshore surveys. Sand sizes are given in millimeters (mm). The conversion from mm to phi units needed to design beach fills can be found in the Shore Protection Manual (U.S. Army Corps of Engineers, 1984). The Shore Protection Manual will be indicated hereafter as SPM.

** Extreme period is the wave period characteristic of the extreme height.

ATLANTIC OCEAN CHANNEL

Project depth in Norfolk Harbor Channel is -55 feet MLW (-16.8 m MLW), but due to sea conditions in the ocean, greater depths will be required in Atlantic Ocean Channel. The Corps of Engineers determined that, for the purpose of this investigation, it is assumed that the Atlantic Ocean Channel will be dredged to a depth of -62 feet MLW (-18.9 m MLW), including an allowance of 2 feet (0.6 m) for advance maintenance dredging. Channel width is taken as 305 meters.

For those design conditions, and the existing bathymetry, about 11.3 million cubic meters of sediment will be dredged from the Atlantic Ocean Channel (WS&E, 1986a).

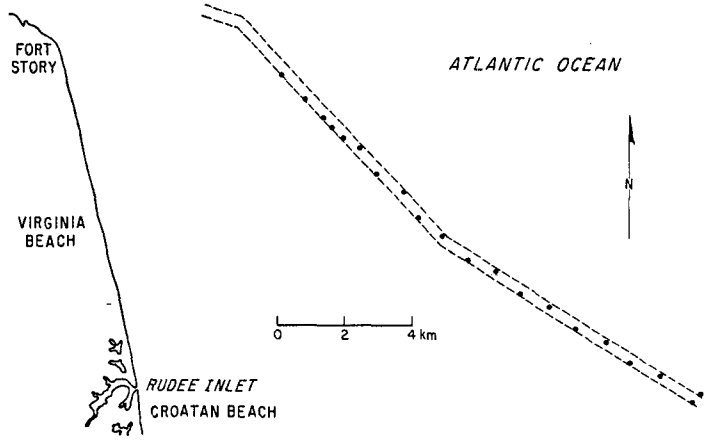

Figure 2. POSITION OF ATLANTIC OCEAN CHANNEL OFF VIRGINIA BEACH

To identify what types of material will be dredged, 21 cores were taken from the Atlantic Ocean Channel (Figure 2). Each core was logged and selected samples of the cores were sieved. These data were made available to WS&E for use in this investigation. Analysis of the logs indicates that about 54% of the material to be dredged is silty sand and sandy silt, 15% is sand and gravelly sand, 11% is a mixture of sand and silty sand, and the remainder is clay or other material.

Detailed examination of the logs and the sieve analyses indicates that about a third of the material to be dredged is sand with a median size of 0.20 mm or coarser, but at least a third of this 0.20 mm sand occurs in thin or isolated deposits that probably would not be economical to exploit, so that slightly less than 2 million cubic meters would be available for placement.

VIRGINIA BEACH

Because of the net northward longshore transport, the south end of the study beach is taken as the origin. The study beach begins at Croatan Beach, south of Rudee Inlet, even though the potential disposal area is north of Rudee Inlet (Figure 3), because Rudee Inlet interrupts northbound longshore transport. Inclusion of Croatan Beach permits an evaluation of the effect of that interruption on the reach needing the sand.

Rudee Inlet is a navigable inlet with a controlling depth of about -3 meters MLW under typical conditions. The inlet is bounded on the south by a jetty which serves as a breakwater and wier, providing shelter for a small hydraulic dredge to bypass sand coming over the wier section. A jet pump is also located north of the wier as a separate bypassing operation. The dredge and the jet pump are estimated cumulatively to bypass about 132,000 cubic meters per year (from Virginia Beach Erosion Commission, quoted in Langley McDonald, 1985). These estimates are based on hours of pumping time and an assumed concentration of sediment, rather than on direct measurement of the bypassed sand. The dredge does most of the bypassing.

North of Rudee Inlet is the highly developed 4-km commercial segment of the Virginia Beach shore where the beach is backed by a bulkhead or a seawall topped by a boardwalk. North of the boardwalk, the shore is backed by residential development and an increasingly broad strip of dunes.

The Virginia Beach shore has high value to the regional and state economy because of beach-related recreation. To maintain the beach, local and federal authorities have been replenishing the sand on a regular basis since 1951, at a long-term average rate from all sources of 190,000 cubic meters of sand per year. Sources include sand pits and stockpiles via truck hauls, and the littoral zone via dredging and the jet pump in Rudee Inlet. In the five years, 1981 through 1985, the average replenishment increased to about 260,000 cubic meters per year

(replenishment rates calculated from Langley McDonald, 1985). Placement by truck haul is usually done in the spring, and was done in April and May 1985, five months before the surveys and samples of this investigation. The dredge and jet pump operate intermittently all year.

The replenishment has had a marked effect on the condition of the beach, as can be seen by analyzing the shoreline change data of Everts, et al. (1983). Results of this analysis are shown in Figure 4 where the horizontal axis is distance north of Croatan Beach and the vertical axis represents accretion or erosion rates (erosion is negative). The long-term rate of change (1859-1980) is determined largely by conditions

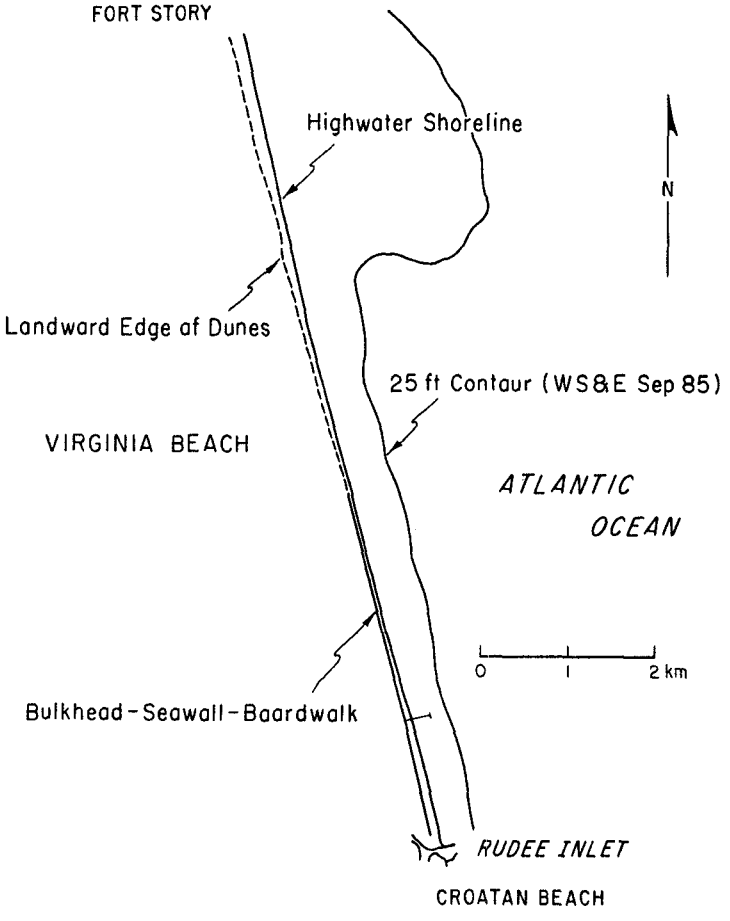

Figure 3. BOUNDARIES OF STUDY AREA

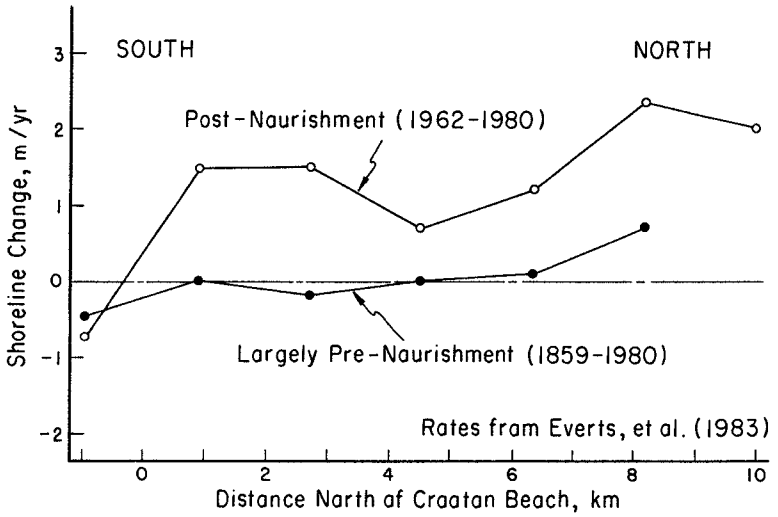

Figure 4. LONG-TERM RATES OF SHORELINE CHANGE

predating the beach replenishment, and the recent rate (1962-1980) is determined by conditions since the start of replenishment. The replenishment period clearly coincides with the onset of significant accretion (Figure 4).

The bathymetry offshore of Virginia Beach has a relatively normal slope from the shoreline to a depth of about -8 meters MLW (-25 feet MLW, Figure 3). At and seaward of this depth, the slope becomes unusually flat, typically 1 in 2000 for distances of at least 3 km. At the north end of the study area, there is a wide shoal (Figure 3) marked by the 25-foot depth contour. The origin of this shoal is probably related to the northward net longshore transport at Virginia Beach interacting with the tidal regime at the entrance to Chesapeake Bay. Whatever its origin, the shoal tends to shelter the study area from the full extreme of the Atlantic Ocean wave climate. This shoal may be responsible for the higher rates of accretion to the north of the study area in Figure 4.

The dimensions of the beach and the nearshore bathymetry are summarized on Figure 5, which is derived from surveys of profile lines performed by WS&E in late September and early October 1985. The horizontal axes of the figure indicates the relative south-to-north position of the surveyed profile lines, with tick marks indicating the even-numbered profile lines. The vertical axis of Figure 5 varies with the symbol, as discussed below.

Backshore width is indicated by open triangles on Figure 5, with each tick mark on the vertical axis equal to 50 feet (15.3 m). As

shown, backshore is widest at the north and south ends of the study area, but is absent over much of the central and southern half of the shore, in agreement with the history of erosion there.

Berm elevation is indicated by the filled triangles, with each tick mark equal to 5 feet (1.5 m) elevation above NGVD datum. The majority of the surveyed berms are at an elevation of about 2.0 to 2.2 meters (NGVD), with a tendency to be somewhat lower in the south and higher in the north.

Foreshore slope is indicated by open squares, with each tick mark on the vertical axis equal to 0.05. The range in slope is from about 0.05 in the south to between 0.10 and 0.18 in the northern half of the study area.

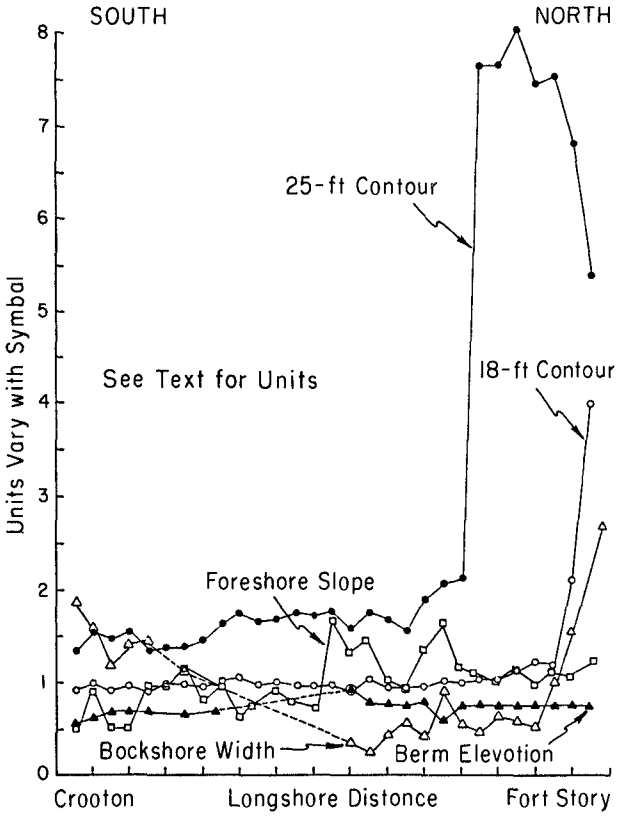

Figure 5. PROFILE CHARACTERISTICS AT VIRGINIA BEACH

The open and filled circles indicate distance to the -18 and -25 foot NGVD depth contours (-5.5 and -7.6 m), with each tick mark equal to 500 feet (153 m) from the shoreline. The abrupt seaward displacement of the contours off the north end of the study area indicates a relatively flat bottom where small changes in vertical elevation produce large changes in position of the contour.

SAND SIZE DISTRIBUTION

Experience with this and related sites (Ramsey and Galvin, 1977) suggests that sand on the typical beach profile can be adequately sampled from locations indicated on Figure 6 by surface grab samples taken during surveying. All 29 profile lines were sampled at the foreshore, and 11 of the 29 profile lines were sampled at the six sites indicated on Figure 6. A total of 86 surveyed samples were obtained in this way and sieved. Their median sand size is summarized in Table 2. A qualitative visual description of each sample is given in Appendix B of WS&E (1986a).

Figures 7 through 12 show longshore distributions of sand size for each of the six sample locations on Figure 6, beginning with the offshore sample (Figure 7) and moving landward to the foredune sample (Figure 12). The axes of these six figures are identical. The horizontal axis is distance north from Croatan Beach, in km. The vertical axis is sand size, in mm. Each figure shows three lines. The middle line is the D_{50}, or median, grain size of the sample; the top line is the size at which 16 percent of the sample is coarser; and the bottom line is the size at which 84 percent of the sample is coarser. The 16 and 84 percent sizes are shown because they are required for SPM beach fill design (in phi units).

Examination of the six figures shows similarities and differences in size from the different sample locations. The samples from offshore (-10 feet or -3 meters) are the most uniform in the longshore direction, have the lowest median size (about 0.18 mm), and the narrowest spread between D_{16} and D_{84}. The samples from the low tide terrace (Figure 8) and just seaward of the foreshore (Figure 9) tend to be more variable in the longshore direction, and show somewhat greater median sizes than the offshore samples, with a greater spread between D_{50} and D_{16} than between D_{50} and D_{84}, perhaps due to shell fragments and pebbles.

For nearly eight kilometers of the 10-km study beach, the foreshore samples (Figure 10) increase northward in median size. This is somewhat unusual in that size usually decreases in the downdrift direction. Several of the foreshore samples have the D_{50} size closer to the D_{16} size than to the D_{84}, a condition which is relatively uncommon in the population of sand samples. The mid-berm (Figure 11) and backshore (Figure 12) size distributions are similar to each other in overall shape, and differ from the foreshore size distribution (Figure 10). The similarities between mid-berm and backshore are shown by their relatively constant D_{50} and D_{84} sizes in the longshore direction and by the variation in D_{16} sizes (both have relatively high values of D_{16} between kilometers 1 and 4 and at kilometers 9 and 10). The dune samples tend

to have slightly finer D_{50} sizes than the mid-berm samples, being finer in seven of the ten samples north of Rudee Inlet (Table 2), which is consistent with a slight amount of wind sorting.

The overall trends in D_{50} are compared in Figure 13 for the offshore, foreshore, and mid-berm samples. This figure shows clearly the relatively low and constant values of D_{50} found offshore, the higher and relatively constant values of D_{50} on the berm, and the unexpected northward increase of D_{50} on the foreshore.

INTERPRETATION

There are four classes of data which should be integrated for a consistent interpretation of how coastal processes will affect disposal of Atlantic Ocean Channel sand on the study beach. These four include the shoreline change rates (Figure 4), beach replenishment amounts and dates (Langley McDonald, 1985), the profile characteristics (Figure 5), and the sand size distribution along and across the beach (Table 2, Figures 6 through 13).

Bypassing experience clearly indicates net longshore transport is from south to north. Thus, a south placement will get most use from the sand. The shoreline change data indicate erosion has (historically) been greater in the south, which also suggests disposal in the south. The existence of Rudee Inlet at the south end of the study beach suggests that placement should be north of its immediate zone of influence, to avoid shoaling in the inlet.

None of 54 sand samples from the subaerial beach had a D_{50} size less than 0.21 mm (see backshore, berm, and foreshore in Table 2). Only 6 of 21 samples from immediately seaward of the beach had a D_{50} size less than 0.20 mm (see seaward of the foreshore and low tide terrace in Table 2). In contrast, at the ten-foot depth, the highest D_{50} in eleven samples was 0.20 mm (one sample), and the average of the eleven samples was 0.17 mm.

These size data are interpreted to mean that, under prevailing conditions at Virginia Beach, sand must have a D_{50} of at least 0.20 to remain on the subaerial beach, i.e., to add to that part of the beach used in calculating economic benefits. This interpretation is supported by closer analysis of the foreshore size distribution on Figure 10. The foreshore at Croatan Beach, which is the first sample plotted on the left end of Figure 10, has a D_{50} of 0.38 mm and is the only sample south of Rudee Inlet. Of the first ten foreshore samples north of Rudee Inlet, only one is coarser than 0.25 mm. This abrupt drop in foreshore sand size from one side of the inlet to another is interpreted as an effect of the bypassing by dredge and jet pump; these bypassing operations withdraw sand from below water in the inlet (the inlet sand size is the first point on Figure 7) and discharge it on the foreshore north of Rudee Inlet. Since the below-water sand is shown to be fine, the sand discharged on the foreshore will be relatively fine. The distribution on Figure 10 shows this. This interpretation is relatively consistent with profile characteristics on Figure 5, where both foreshore slope and berm elevation are lower in the south end of the study area, as expected from finer sand beaches.

The position of the 25-foot contour (Figure 3 and Figure 5) coincides with the higher long-term accretion rates at the north end of the study area (Figure 4). It is somewhat puzzling that the subaerial beach at this site also has the coarsest sand (Table 2). However, the data are consistent if the offshore shoal represents the finer fraction winnowed from the sand carried northward by longshore transport and the

subaerial beach is the residual coarse material. At any rate, it is clear that the north half of the study beach is not in need of replenishment.

CONCLUSIONS

a. The best location to place suitable sand from the Atlantic Ocean Channel is in the south half of the study area, approximately in the segment from kilometer 1 to kilometer 4 on the horizontal scale used for Figures 7 through 13.

b. Efficient beach replenishment will require sand that has a median (D_{50}) size of at least 0.20 mm, when placed on the beach.

c. Design berm heights should be about 2.1 m above NGVD and expected foreshore slopes will be about 0.05 to 0.10, depending on the coarseness of the sand placed there.

d. Size analyses of surface grab samples from along and across the study beach provide simple but strong constraints on beach disposal design.

Acknowledgements. This paper is based on work done under contract DACW65-85-D-0037 with the Norfolk District, U.S. Army Corps of Engineers (see WS&E, 1985a, in References). The Project Manager for the earlier work was Richard Klein, Waterways and Harbors Section, Norfolk District. Data collection and analysis were assisted by James L. Overton, Mark Ricketts, Robert Taliaferro and Naren Tayal. Greg Hamadock, Law Engineering (McLean Branch), supervised the analysis of the beach sand. Herbert J. Bruder prepared all illustrations and Sheila Zukor typed several versions of the manuscript. Preparation of this report was paid for by the firms of Cyril Galvin, Coastal Engineer and Waterway Surveys & Engineering, Ltd.

CHAPTER 85

Federal Jetty and Sand Dike at the Entrance to Fire Island Inlet, New York

Cyril Galvin*, M. ASCE, Charles, J. Rooney**
and Gilbert K. Nersesian***, M. ASCE

ABSTRACT

Prior to construction at Fire Island Inlet, Fire Island was moving westward at more than 200 feet per year, the north shore of the inlet was eroding severely, and navigation in the inlet was difficult. The Federal Jetty, completed in 1941, and the sand dike, built in 1959, have halted the westward migration, eliminated the severe erosion, and partially improved navigation, with minimal maintenance or repair to the structures. There has been a large net accretion of sand east of the jetty and west of the dike, an unknown part of which is at the expense of shores to the west of the inlet. At the State Park on the south side of the inlet interior, erosion accelerated, probably because of the dike.

The middle and ocean segments of the 4750-foot Federal Jetty are now (1987) in good condition, although the design implies a stability coefficient for the quarrystone jetty head at time of construction that would now be considered risky. Stability has been promoted by a stone blanket under and east of the jetty, a thick stone apron seaward of the jetty, a low (8 feet MLW) crest, and armor stone that has been partially keyed in place. Damage due to scour, common at other single-jetty inlets, is absent here because longshore transport, which easily overtops the low crest, keeps the inlet channel away from the jetty. Although the two seaward segments of the jetty remain in good condition, the inshore segment of the jetty is in poor condition, despite its apparently sheltered location. The cumulative effects of waves, possibly channeled to the site along recurved spits during storms, have damaged 1200 feet, and tidal scour has destroyed about 230 feet. The damaged segment has a design cross section which is one-fifth and one-twelfth the cross sections of the jetty trunk and head.

The dike was constructed with sand dredged from the inlet, and its seaward shore was later armored by dumped riprap. The dike moved the tidal channel away from the north shore, shifted the ocean entrance of the inlet eastward (against the direction of longshore transport), and shortened the distance to the ocean.

INTRODUCTION

Background. Fire Island Inlet is a large permanent tidal inlet on the south shore of Long Island, New York, which connects Great South Bay with the Atlantic Ocean through an unusually long, shore-parallel channel (Figure 1). The entrance to the inlet is the site of two large coastal structures: the Federal Jetty constructed in 1939-1941 and the sand dike, known locally as The Thumb, constructed in 1959. Saville (1960) reviewed the history of these structures up to that time, based on personal experience. See also Gofseyeff (1953). An excellent recent view of both structures is the cover photo of the July 1986 issue of Shore & Beach, taken immediately after Hurricane Gloria made landfall in the vicinity (Terchunian, 1986).

The jetty fixed the position of the western end of Fire Island after that island had moved westward at a rate in excess of 200 feet per year for more than a century. The sand dike has alleviated severe tidal scour along the residential shore of the community of Oak Beach. Together, these structures have forced the inlet entrance into a relatively stable position. Neither structure has had major maintenance, despite the relatively exposed site. Perhaps because they have functioned well and almost without maintenance, these structures are not well known, either to the general public or to the coastal engineering profession.

Purpose. This paper identifies features in the design of the Federal Jetty and the sand dike that have made them functionally and structurally useful over a relatively long time. This knowledge is used to derive lessons which may be applied to coastal engineering projects elsewhere. Conclusions are based on historical information at the New York District, Army Corps of Engineers, and a knowledge of local coastal processes and existing conditions (Galvin, 1985).

Location. The south shore of Long Island, New York, is the northern part of the mid-Atlantic states in the United States. Long Island measures approximately 120 miles (192 km) from the entrance to New York Harbor on the west to Montauk Point on the east. Fire Island Inlet is at the western third of this shore, approximately 36 miles (58 km) east of the entrance to New York Harbor.

Units. Design data are taken from contract documents which use customary English units. Distances are in feet (1 foot = 0.305 meters) and rock weights are in pounds and (short) tons (1 pound = 2.2 kilograms; 1 ton = 0.907 metric tonnes). Locations are identified by surveyor's stations along the jetty centerline, so that Station 33+10, for instance, is 3310 feet measured along the curved jetty centerline from the inlet end of the jetty.

FEDERAL JETTY

Background. Construction of the Federal Jetty was a Depression-era project. The authorized jetty has the stated purpose of checking the westward littoral drift of sand and providing a greatly improved

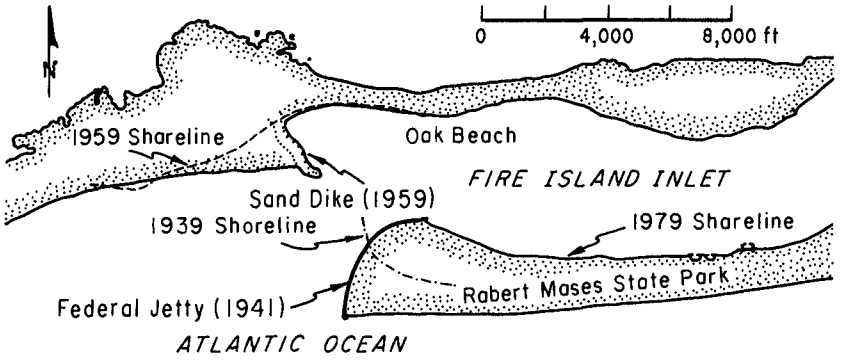

Figure 1. LOCATION OF FEDERAL JETTY AND SAND DIKE AT FIRE ISLAND INLET

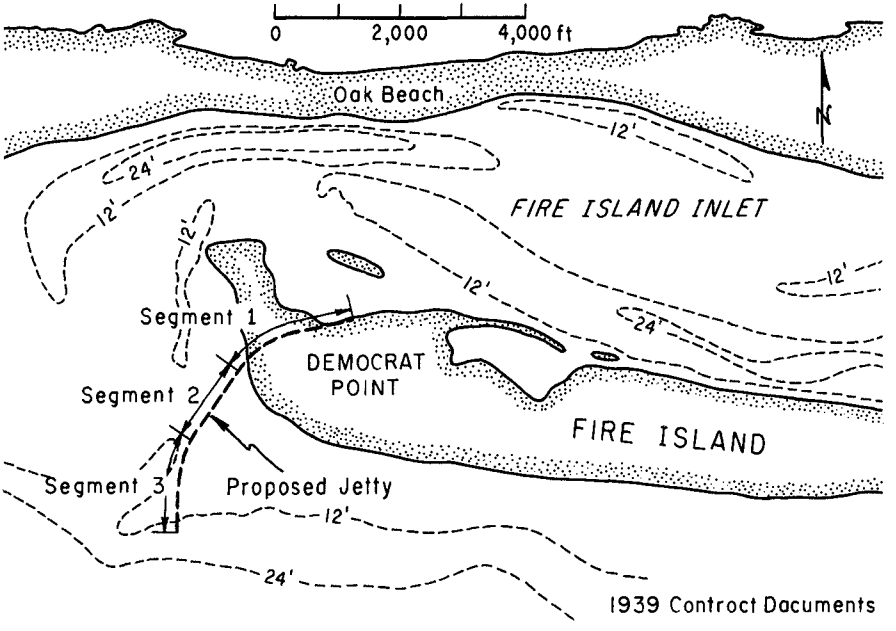

Figure 2. PLAN OF FEDERAL JETTY WITH 1939 SHORELINE AND BATHYMETRY

navigation channel (House Document 33, 75th Congress, 1st Session, Chief of Engineers to Chairman, Committee on Rivers and Harbors, paragraph 4, 13 May 1937). Apparently, appropriations took another year. On 28 September 1938, Robert Moses, President of the Long Island State Park Commission, announced that a jetty would be built at Fire Island Inlet by the Corps of Engineers for an estimated cost of $759,000 (New York Times, 29 Sep 38). (This estimated cost is the same as that in House Document 33.) The Moses announcement came only one week after the 1938 Hurricane, which remains the storm of record for much of Long Island, and it seems probable that the timing of the announcement was affected by that storm. As announced, construction was to be done during the next eight months, but after eight months, only the construction contract was ready. The contract was won by the firm of Spearin, Preston & Burrows, Inc. of New York and signed on 13 June 1939. Work began on 26 June 1939 and was completed on 15 April 1941, for a price that was approximately $75,000 less than the figure announced by Moses (District Engineer's Report, House Document 762, 22 Dec 48).

Design. Figure 2 shows the location of the jetty with respect to the preconstruction shoreline, redrawn from the 1939 contract documents. Total crest length was 4750 feet, and a submerged stone apron extended seaward for an additional 200 feet. The jetty was divided into three segments in plan. Segment 1 covered 2000 feet, crossing land that was exposed at low tide. Segment 2 covered 1350 feet, going from near the then existing shoreline out to a depth of about 8 feet. Segment 3 covered 1600 feet, including the 200 feet of submerged stone apron. Segments 1 and 3 are curved in plan, so that Segment 3 at the ocean is north-south, and Segment 1 at the inlet is almost east-west.

Depths are plotted from the plane of Mean Low Water (MLW), which was taken as 1.8 feet below the plane of mean sea level at the Sandy Hook, New Jersey, tide gage. Mean tide range is 4.1 feet at the ocean end of the jetty.

The design of the jetty is shown in longitudinal section in Figure 3 and in cross section in Figure 4. Noteworthy features of the longitudinal section (Figure 3) include the relatively low crest elevation (8 feet above MLW), and the stone blanket and apron at the seaward end. A stone blanket from 1 to 3 feet thick underlies the entire Segment 3 and extends landward to the 1939 -6 foot MLW contour, about 350 feet into Segment 2. Along the outermost 500 feet of the jetty, this blanket extended 50 feet east of the toe of the jetty side slope. For 200 feet along the centerline (extended) of the jetty, there was a stone apron 3 feet thick and approximately 90 feet wide.

Table 1 summarizes the stone weights and side slopes of the jetty.

Construction. We assume that the jetty was built according to contract plans, since the writers have not seen any as-built modifications of the contract drawings. Photos show that the contractor built

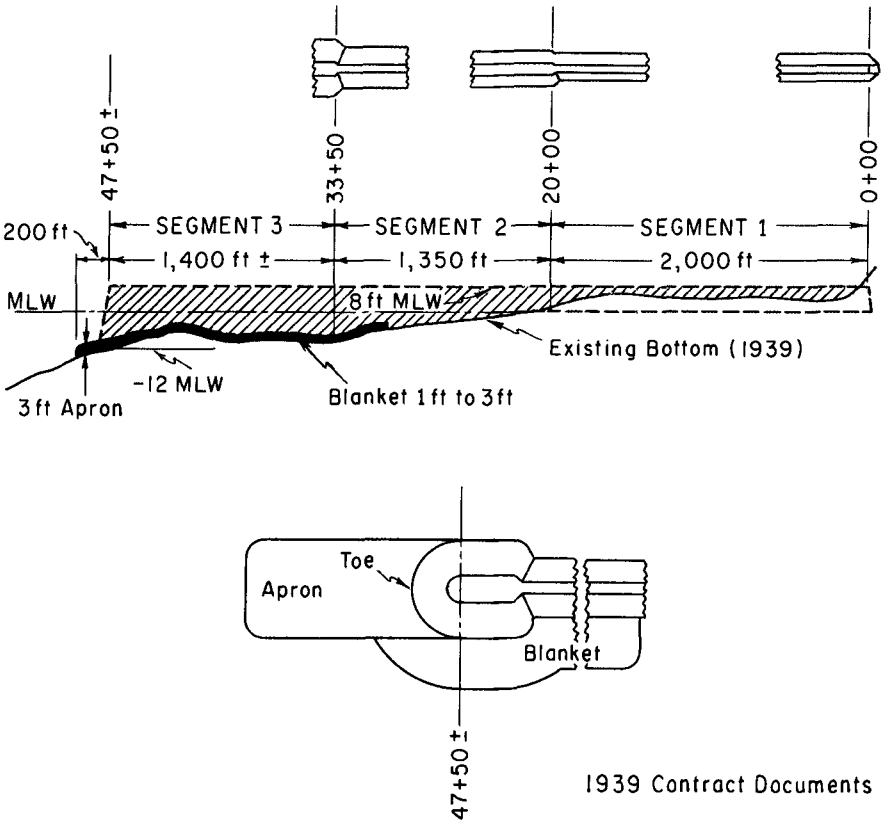

Figure 3. LONGITUDINAL SECTION ALONG JETTY CENTERLINE, WITH PLAN VIEWS OF SEGMENT TRANSITIONS AND SEAWARD END.

a pier at the inlet side of the western tip of Fire Island for unloading materials. A railroad was built on a wooden trestle along the line of the jetty. Stone was barged to the pier, loaded on flat bed rail cars, and taken to the active construction site. The core stone was tipped from the cars. Cap stone (armor stone) appears to have been removed and placed by crane.

Dated photos in the Corps of Engineers' records show that by 3 January 1940, core stone was being dumped at station 3+00 from the pile-supported railroad trestle. The core stone was being dumped into water beside the tracks, which is in agreement with the design (Figure 4) which calls for Section 1 to be excavated to MLW. The same photo shows what appear to be cap stone stockpiled along the route of the trestle. Later photos on 1 February 1940 show cap stone in place at Stations 1+60 and 0+15. At least at 0+15, the cap stone is immediately below the trestle beams, with only a few inches clearance.

*(outer 50 feet of Segment 3)

Aerial photos taken on 4 June 1940, 3 October 1940, 8 November 1940, and 10 April 1941 are included here as Figures 5, 6, 7, and 8. These photos were found in the records of the New York District Corps of Engineers (reprinted by permission of the New York Daily News). The photos were taken from the same relative position, and provide a good record of the advancing construction.

Figure 5 suggests that Segment 1 of the jetty (Figure 2) was essentially complete by June 1940, approximately a year after the contract was signed. At this time, the trestle was constructed to Station 33+00, which is approximately the seaward end of Segment 2, and core stone had been placed for about half of Segment 2. The trestle bents in Segment 2 are more than double the width of the railroad. The rails are confined to the west half of the bents. It is evident from close inspection of Figures 5 and 7 that temporary timber platforms were laid on the pile caps east of the track to support cranes that placed the cap rock.

Figures 6 and 7 show the trestle to dogleg to the right at the seaward end, and the track moves from the west side of the trestle to the east side of the trestle after passing the change in direction. Isolated piles in the water along the pre-dogleg line of track suggest that the dogleg replaces a wave-damaged section of trestle.

The survey included in the 1939 contract shows that the three-foot thick stone apron would be placed in depths of 12 to 14 feet. However, after placement of the apron, a December 1940 survey (with probings) in the New York District files shows depths from 15 to 20 feet above the stone apron for at least the outer 100 feet of the apron. Probably, the advancing jetty constricted the preconstruction pattern of tidal flow feeding the marginal flood tide channel (Figure 2), causing scour seaward of the tip of the jetty prior to placement of the apron.

The four photos show rapid accretion of the shore east of the jetty and some erosion immediately to the west. By the end of construction, sand freely overtopped the jetty (Figure 8), as it does today. Even at the start of construction, there was a large sand spit west of the jetty, and a recurved sand spit along the inlet which reattaches near Segment 1 (see top of Figure 5). A recurved spit such as shown in Figure 5 is common today after severe storms.

Present Conditions. The present condition of the jetty varies from remarkably good along Segments 2 and 3 to severe damage along Segment 1. Although it was anticipated that maintenance would cost about $25,000 annually (House Document 33, 75th Congress, 1st Session), little maintenance has actually been done. The District Engineer's report in House Document 672 (printed December 1948) states that repairs up to March 1947 totaled $600.00 (six hundred dollars), and that a total of $50,000 was to be spent on rock repair in 1948. Files in the Navigation Branch, Operations Division, state that 165 tons of rock were placed on the jetty in 1948. Notations on plans indicate that repairs were made at Station 20+00 and between 23+00 and

24+00. These locations are in Segment 2, not at the seaward end. No other repairs are known, either from the files or from the memory of knowledgeable persons. The 165 tons is a relatively small amount, occupying, for example, a little more than six feet of the Section 2 shown on Figure 4.

When constructed, Segment 1 was on land (Figure 2), and had a weak cross section (Figure 4 and Table 1). Segment 1 now shows damage both by waves and by tidal currents. Waves have damaged and penetrated behind the jetty for at least 1200 feet, eroding significantly into the dunes east of the jetty (Figure 9). This damage occurs in a relatively sheltered position within the inlet, but the recurved spits, pointing at or terminating at Segment 1, may provide a wave channel which can concentrate ocean waves on the jetty. (During storms, the recurved spits may be submerged, and refraction would concentrate wave energy above the spit, delivering the waves to the jetty.) Recurved spits on the inlet side of the jetty have been a common feature through time. These spits appear across the top of photos in Figures 5, 6, 7, and 8, with shapes and relative positions identical to those observed in recent years. A recurved spit intersecting the damaged length of Segment 1 was especially well developed after the severe northeast storm of 29 March 1984 (Galvin, 1984). Figure 9, based on a June 1984 photo, shows a remnant of this March 1984 spit. However, such a spit was not well developed after Hurricane Gloria (Terchunian, 1986).

Tidal scour from the ebb current flowing out of Great South Bay impinges on the inlet shore of Robert Moses State Park (Figure 1). Scour from this ebb current has severely eroded the shore of the park, and along with the shore, removed about 230 feet of the jetty, i.e. Station 0+00 to about Station 2+30. Since the design section is relatively light and no lower than 0 feet MLW elevation, Segment 1 has no resistance to undermining by the tidal current in a channel that is 20 feet deep or more.

It is worth noting that the east jetty at Shinnecock Inlet (two inlets east of Fire Island Inlet) shows similar damage (Dean and Maurmeyer, 1977) at the same relative positions as the wave and scour damage to Segment 1 of the Federal Jetty. At Shinnecock, however, there are no recurved spits.

At the ocean shore east of the jetty, there has been a large accretion of sand since the jetty was constructed. This is made evident by comparing the 1939 shoreline and bathymetry on Figure 2 with the recent shoreline (June 1984) on Figure 9. The present accreted condition was reached rapidly, probably by 1950, according to Saville (1960).

The area of sand in the spit west of the jetty is, surprisingly, relatively unchanged between the 1939 design condition (Figure 2) and the 1984 photo traced on Figure 9. However, this spit has shifted seaward, from a position adjacent to Segment 1 in 1939 to a position adjacent to Segment 3 in 1984 (compare Figures 2 and 9).

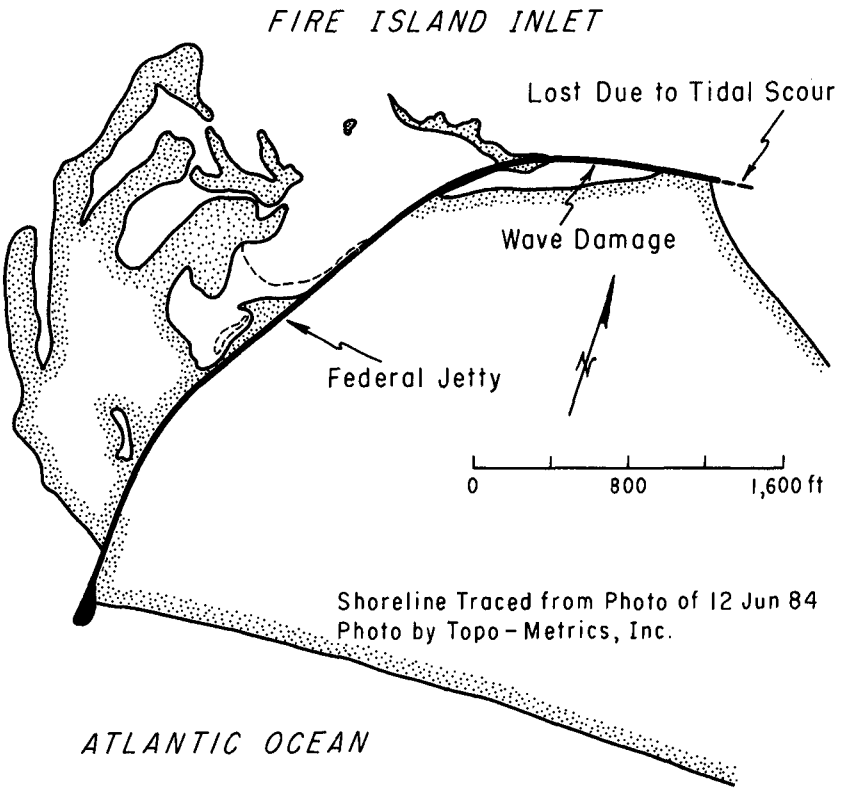

Figure 9. RECENT (1984) SHORELINE IN VICINITY OF FEDERAL JETTY

SAND DIKE

Erosion at Oak Beach. The community of Oak Beach, along the north shore of Fire Island Inlet, had a long history of erosion, mainly due to the deep tidal channel that existed along the shore (see the bathmetry on Figure 2). This erosion predated the construction of the jetty, and is one of the concerns addressed in House Document 33 (1937). The Town, County, and State had each attempted a solution to this problem prior to construction of the jetty, without success.

According to Saville (1960), proposed solutions were developed by the New York District in 1957, and these were reviewed by the Beach Erosion Board. At the time, Saville was himself one of the three civilian members of the Board (and consultant to the Long Island State Park Commission). The Board's review emphasized the need to deal with the tidal currents, ahead of anything else, including a model study.

Construction of Sand Dike. The adopted project required dredging sand from the inlet and placing part of it along the Oak Beach shore. After the project was approved (and apparently after the work had started), the Long Island State Park Commission in the fall of 1959 requested a change, to place the dredged material in a "closure dike" crossing the tidal channel. The Corps of Engineers approved this change on 16 November 1959, and the contractor placed 1,235,300 cubic yards of sand (pay quantity) in a dike (crest elevation 12 to 15 feet MLW) which closed off the channel (letter from New York District to North Atlantic Division, 2 May 61). Construction went from the seaward end of the dike landward (see Figure 1), and closure was complete on 3 and 4 December 1959 (Saville, 1960). This is remarkably swift movement on a major project without prior engineering or model studies. The changes are graphically shown by air photos identified as Figures 3 and 4 in the report of Kassner and Black (1983).

Subsequent History. The changes to this dike are indicated in part by the shorelines on Figure 10. Shortly after construction, local interests placed stone around the dike to armor it (mentioned in the 2 May 1961 letter, but not directly referred to by Saville, 1960). The dike initially had a boot-like shape, but most of the "foot" to the boot was eroded by 1965. The sequence of shorelines on Figure 10 suggest at least another effort at riprap revetment, after 1961. Since then the dike itself has been relatively stable, and its west side has been subject to much accretion (Galvin, 1985).

The effect of the dike on the channel is indicated by the shape and depth of the deepest part of the channel passing around the end of the dike (Figure 10). For most of the first decade after dike construction, the deepest part of the channel trended to the northwest. Gradually, however, the channel reoriented until now it has a northeast trend, and in the process, the old channel west of the dike was abandoned. The abandoned channel became the site of accretion as the ebb channel, forced eastward by the dike, bypassed a large part of the ebb tidal delta, which then accreted to shore. Analysis of the downdrift accretion is given in detail by Galvin (1985). The general bypassing process under natural conditions is discussed by FitzGerald (1983). The location of the ebb tidal delta and the shifting of the shoals in the inlet are shown in air photos by Barwis, et al. (1977).

DESIGN LESSONS

Stone Blanket and Apron. The one to three-foot layer of stone under the jetty provides both a foundation and a filter for the structure. The extension of the blanket east of the jetty probably prevented scour and reduced breaking waves during the time immediately after construction, before beach accretion. The extension of the stone apron seaward of the jetty also prevented scour immediately after construction, and probably still provides a floor for erosion during storms. The stone blanket seems a prudent requirement and the stone apron a necessary requirement for this structure. The data reinforce experience at other projects that scour must be expected

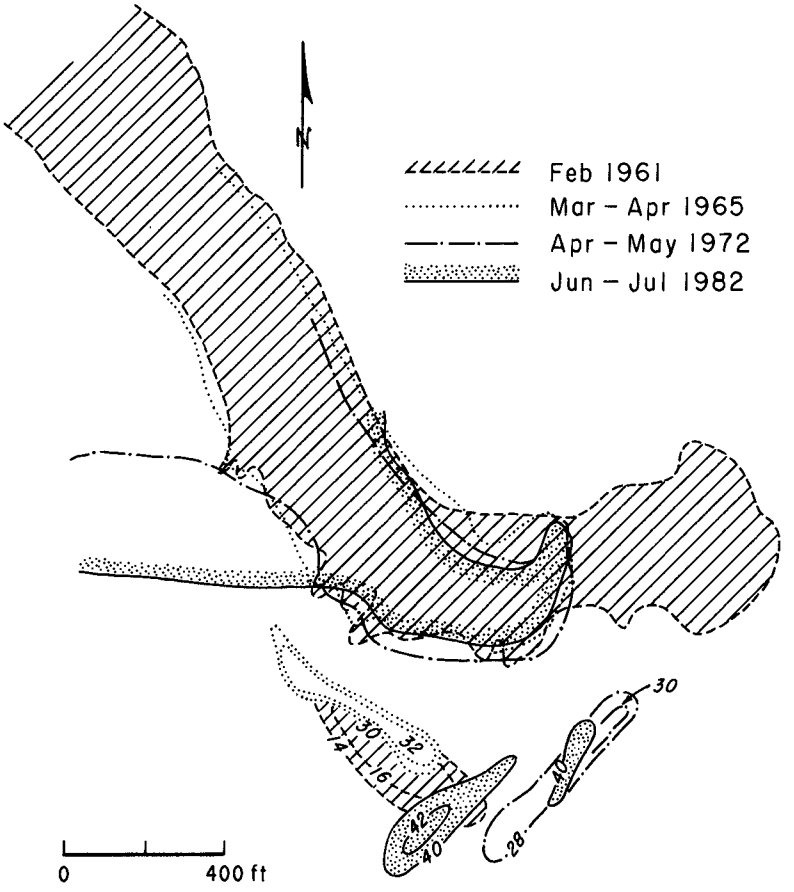

Figure 10. **SHORELINE CHANGES AND THE DEEPENING AND REALIGNMENT OF CHANNEL AT THE SAND DIKE.**

during construction, in front of the advancing jetty, prior to placement of the stone apron.

Design Wave Height. Using presently accepted practice in jetty design (U.S. Army Corps of Engineers, 1984, Shore Protection Manual, referred to hereafter as SPM), the jetty head at the Federal Jetty (as described in Table 1) would now be considered to have a questionable design. The most exposed direction is to the southeast. A profile to the southeast based on the December 1940 survey, after placement of

the stone apron, shows the toe of the jetty in a depth of 15 feet (MLW). Seaward of this depth, the mean slope is nearly flat for 100 feet or more (not steeper than 0.020).

If the 1940 profile governs during storms, breaker travel considerations (Galvin, 1969; SPM, page 7-10) indicate a breaker height of 19 feet may reach the jetty at high tide. (Given the low crest elevations, severe storm surges would submerge the jetty, reducing the potential damage.) Using this height in Hudson's equation, along with the design parameters in Table 1, suggests that WK_D is 42.5 tons. Since the design requires W to be at least six tons (Table 1), and the contractor is not likely to exceed this requirement by much, but is likely to save larger stones for the jetty head, it is estimated that the actual W in the jetty head is eight tons. This implies K_D equal to 5.3, a value which is relatively high for the head of a stone structure (Table 7-8, SPM). This high K_D may have developed due to partial fitting of the cap stone in place, and the practice of grading the core so that the larger core stone is on top. But the armor stone is only a single layer, according to the design. Alternatively, it is possible that, seaward of the jetty head, shoals filter out the very large waves, before they reach the jetty.

The design lesson from this analysis is that care in construction and a long-term shoaling trend may permit a stable jetty head built with nominally underdesigned armor stone.

Single-Jetty Design. It is well known that single jetties at tidal inlets often have scour problems (Kieslich, 1981), but these problems have been absent at the Federal Jetty. Experience at Fire Island Inlet suggests that single-jetty inlets are feasible if there is nearly unidirectional longshore transport, combined with a low crest that permits overtopping (Figure 8). The unidirectional transport at Fire Island is the result of the position of the New Jersey coast, west of Fire Island, which reduces the maximum fetch from the west. The effect of this limited fetch is well illustrated in Figure 7, where the west winds are strong enough to produce foam streaks through the jetty, but these winds have not been able to produce large waves. The long-term effect of this unidirectional westward transport is reflected in the overlapping planform of Fire Island Inlet (Galvin, 1970).

Sand Accretion. The Federal Jetty and the sand dike are both aligned perpendicular to shore. Present knowledge would anticipate the large accretion of sand on the ocean shore east of the jetty (Figure 1), but the major accretion west of the sand dike (Figure 10), on the downdrift side, would perhaps still be unanticipated today. The large volume of sand in the ebb tidal delta is the source of this accretion, and the eastward shift of the channel freed this sand to move ashore.

Shore Erosion. In the two decades after the sand dike was constructed, the inlet shore of Robert Moses State Park (Figure 1) eroded severely (Galvin, 1985). This erosion is probably a reaction of the

inlet system to construction of the Thumb. The large accretion west of the Thumb is not necessarily withdrawn from the littoral system, but may be shifted from the ebb tidal delta to shore. It is believed that sand now crosses the existing inlet channel by natural bypassing (Galvin, 1983), but how much of this sand reaches the downdrift shore of Jones Beach after passing the channel is not known. Thus, the sand dike has an undetermined responsibility for erosion of the recreational beaches to the west.

Role of Engineering Studies. The two major structures discussed in this paper were built without model studies or any of the environmental impact studies now necessary. A model study was subsequently made (Bobb and Boland, 1969), and this did not anticipate the major shoaling west of the sand dike that has since developed (Terchunian, 1986). The Federal Jetty has now (1987) endured without major repair for 46 years and the sand dike for 26 years. The sand dike was constructed on the basis of a major field change to a beachfill project already started.

The present paper, based on field inspection, knowledge of the local coastal processes, and a historical review of events leading to construction has yielded insight on coastal engineering design. Such retrospective studies would be useful on other projects. Considerably more technical detail on erosion, accretion, and dredging at Fire Island Inlet is given by Galvin (1985).

Acknowledgements. This paper is based on knowledge derived from earlier work completed under Contract DACW51-83-C-0005 with the New York District, Army Corps of Engineers. James R. Hill and Robert J. Hallermeier contributed significantly to the writing of the final report on that contract. G.K. Nersesian obtained valuable historical information from the files of the New York District, including the photos in Figures 5, 6, 7, and 8. We thank Eugene Ferrara of the New York Daily News for permission to reprint the photos, and Robert J. Hallermeier, John G. Housley, D. D. Davidson, Thorndike Saville, Jr., and Michael J. Piszker for comments on an earlier version of this manuscript. Herbert J. Bruder prepared all figures, and Sheila Zukor typed several versions of the paper. The preparation of this paper has been paid for by the senior author's consulting firm.

CHAPTER 86

Experimental investigation of the wave and current motion over a longshore bar.

J. Buhr Hansen[1] & Ib. A. Svendsen[1]

Abstract

The results presented in this paper are from a series of experiments in a wave flume modelling the onshore-offshore water motions over a bar bottom profile.

In a true 3-dimensional natural situation the flow of water over the bar varies along the coast. In the experiments the flow of water over the bar is simulated by a controlled discharge through the flume.

1. INTRODUCTION

On a beach with a longshore bar there will in general be a net flow of water over the bar profile caused by the incident waves. The longshore discharge in the trough behind the bar will increase along the coast in the flow direction until it is finally released as a rip current. This study concentrates on the analysis of the on shore wave and current motion over the bar with changing net flow of water into the trough behind the bar.

In Hansen and Svendsen (1984) and Svendsen (1984) the undertow caused by waves on a plane beach with no longshore current and consequently no net on shore flow of water has been investigated. A more detailed literature review may be found in these papers and in Dally & Dean (1986) and Svendsen (1986). For completeness may be added that recently the authors have come across a note by Iwata (1970) in which some of the aspects of undertow has been discussed.

The present study shall be viewed as the first step towards a description and understanding of the full 3-dimensional water motion inside the breaker line on coasts with a longshore bar. The paper concentrates on the results of laboratory experiments aiming at an experimental verification of the theoretical model presented in Svendsen & Hansen (1986) included in these proceedings of the 20th ICCE (in the following referred to as I).

The situation studied is indicated in Fig. 1. The waves are assumed to be perpendicular to the bar and the shoreline. It is so far uncertain how the net flow of water over the bar varies along the coast. In our wave flume experiments the wave and current motion in a cross section is analysed subject to changing net flow of water over the bar simulating the varying conditions along the coast.

[1]Institute of Hydrodynamics and Hydraulic Engineering, Technical University of Denmark, Bygning 115, DK-2800 Lyngby, Denmark

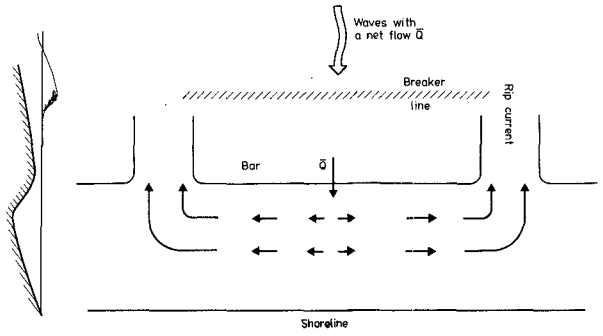

Fig. 1 The natural situation studied

2. EXPERIMENTAL SET-UP

The experiments were carried out in a 60 cm wide wave flume with a bar bottom profile, Fig. 2. The still water depth over the top of the bar is chosen to be approximately 0.6 • H, H being the wave height in relatively deep water. The net flow of water is generated artificially by a closed circuit circulation of water in the flume. The water is pumped from the trough shorewards of the bar - through the wave absorber - and fed back to the flume in front of the piston type wave generator. The water is sprayed onto the surface through 60 5 mm$^{\emptyset}$ holes in a 2 m long diffuser pipe placed above the water surface. The waves used through-out the experiments were generated as H = 12 cm, T = 2s using a non-sinusoidal time variation of the wave generator that yields a minimum of free harmonic disturbances. The still water depth in front of the wave generator was accurately adjusted to h_o = 340 mm in a situation with no waves but with the actual discharge being pumped through the flume[1].

The pumped discharge, Q, is in the series of experiments performed within the range 0 to 8 l/s. (The pumped discharge will be used as indicator of the net flow in the different tests.) The mean discharge per unit length of the coast is $\bar{Q} = 0.6 \cdot Q$. In Table 1 the actual mean current velocities $\bar{Q}/h$ in the different tests are given relative to

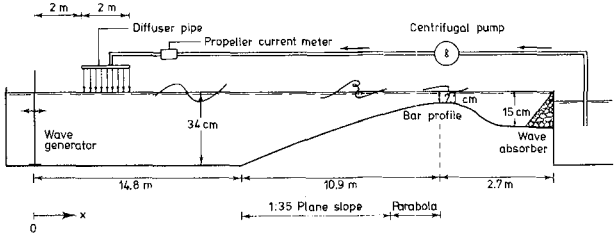

Fig. 2 Experimental set-up.

[1] During the tests the actual mean water depth in front of the wave-generator with both waves and current was 335 mm for the pumped discharges 0; 2.5 and 8.0 l/s but 329 mm for the discharge 5.0 l/s.

$\sqrt{gh}$ at different water depths, and relative to the measured wave particle velocity amplitude, $1/2(u_{w,c} - u_{w,t})$, at the bar crest. $u_{w,c}$ and $u_{w,t}$ are the wave particle velocities under the crest and through, respectively.

Q l/s	$\frac{\bar{Q}}{h\sqrt{gh}}$ at			$\frac{\bar{Q}}{h1/2(u_{w,c}-u_{w,t})}$ at
	'h=34omm'	breaking	bar crest	bar crest
0	0	0	0	0
2.5	o.0069	o.014	0.056	0.40
5	o.0141	o.03o	o.128	o.85
8	o.0219	o.050	o.181	1.36

Table 1. Wave and current combinations

The chosen system for flow generation in the flume has proven to be very succesfull since wave recording 1 m after the diffuser pipe has given heights $\bar{H}$ = 129 mm with a standard deviation of only 2 %. There is found no significant change due to changing discharge. The recorded wave height is 8 % greater than the wave height anticipated from the wave generator motion. This is due to the fact that the wave generator motion is calculated assuming a Stokes 2. order theory, while the Stokes parameter $UR = HL^2/h^3 \simeq 36$ indicates that a higher order theory ought to be applied.

3. EXPERIMENTAL TECHNIQUE AND DATA AQUISITION

For each discharge two independent sets of experiments were performed.

Initially a 'continuous' recording of the wave height H, the mean water surface MWS of set-up, b, and the wave celerity, c, was performed using the slowly travelling carriage technique described in Hansen and Svendsen (1979). In each of the test runs approximately 500 waves were recorded from 1 m after the diffuser pipe (x = 5 m) to 0.6 m after the bar crest (x = 26,3 m).

Subsequently a series of particle velocity measurements were made at selected vertical sections, and at a number of points between the bottom and the wave trough. In each of these tests simultaneous recordings were made by three wave gauges; One gauge at a fixed position 1 m in front of the diffuser pipe and two gauges 20 cm apart over the point of velocity measurement as indicated in Fig. 3. The velocities were recorded by a one component Laser Doppler Anemometer type DANTEC LDA04 with a 60 cm focussing distance which enabled the recordings to be taken in the middle of the wave flume.

The LDA analog output and the analog output from the three wave gauges were sampled by a computer based datalogging system every 15 ms, equivalent to 133 samples per wave period. A total of 30 waves were recorded in each test.

Particle velocity recordings are performed at 7 x-positions in the flume with one x-position (x = 18.81 m) before and 6 after breaking, the last one over the bar crest (x = 25,70 m). At each x-position the velocities are measured at 10-15 different levels, ζ, from 5 mm above

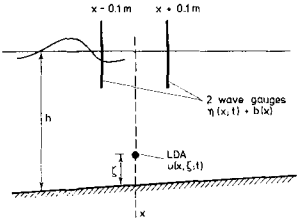

Fig. 3 Positioning of wave gauges and LDA measuring point.

the bottom to the wave through and in some cases to the MWS. Only horizontal particle velocities are recorded.

While the wave gauges are virtually unaffected by the presence of air bubbles in the water after wave breaking, bubbles may cause drop outs in the LDA signal. As the analog signal from the LDA system may be erroneous in case of drop outs, an electronic switch operated by the LDA lock detector output is installed between the LDA analog output and the datalogging system. This gives an easily detectable value (negative overflow in the ADC) in the sampled time series in case of drop out of the LDA signal. The drop outs may then be dealt with in the subsequent data analysis.

4. DATA ANALYSIS PROCEDURES

4.1 LDA drop outs, correction of erroneous data

The data analysis programme constructed to deal with the LDA drop outs and eventually other erroneous data operates on a three step basis

Step 1: The time series is scanned and all drop outs are detected. Single drop out data in otherwise valid series of data are replaced by the mean value of the two neighbour values.

Step 2: Of the remaining drop outs groups of min. 6 consecutive data (~ 0.1 s in time) are analysed for length and periodicity of occurence. In case of a reasonably well defined period of occurence and a reasonably constant drop out length these data are assumed to be recorded above the actual water surface and the velocities are set to zero.

Step 3: The remaining drop outs are replaced by the ensemble average figure calculated from the remaining data in the series. Further in this step all the time series are checked for obviously erroneous data due to neighbouring drop outs or electric noise. These are replaced by the ensemble average figures.

For the wave gauge recordings never more than 1 or 2 data within a series of 4090 are detected in step 3. For the velocity recordings well below the wave trough level a maximum of 2 % of the data are detected during the checking procedures, mainly in step 1.

When the velocity measuring point is above the wave trough level the number of erroneous data may be very high. Fig. 4 shows the first 4 periods of the processed velocity time series recorded 9 mm above trough

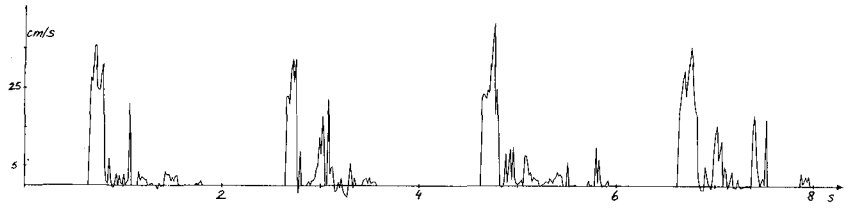

Fig. 4 Velocities recorded above the wave trough.

level at the crest of the bar where the wave height is 30 mm. In this whole series of 4090 data covering 30 wave periods 80 data are changed in step 1, 1900 set zero in step 2 and an additional 160 of the data are changed in step 3.

4.2 Main results from time series

All time series are analysed over an integer number of wave periods and the following figures determined:

1) The zero-up-crossing mean wave period: T = 2.00 s usually with a standard deviation below 0.03 s;
2) The mean value, $\bar{u}$ and b for the velocity and wave gauge recordings respectively;
3) The mean of the maximum values ($u_{w,c}$ and η_c) and minimum values ($u_{w,t}$ and η_t) relative to the mean value;
4) The RMS values relative to the mean (RMS(u_w) and RMS(η));
5) The mean 'wave heights'; and
6) The phase shift, or time lag Δt, between the signals from the two wave gauges used to determine the absolute wave celerity, $c_a = \Delta x/\Delta t$, with Δx = 0.2 m, cf. Fig. 3.

4.3 Separation of wave and turbulent components.

Although the waves are generated with a strictly constant wave period small and inevitable variations in the breaking may create appreciable variations in the period of each individual wave event, no matter how the period is defined. This implies difficulties in separating the turbulent part of the recorded signals from the (ordered) wave component. In fact the irregularities of both surface variation and particle motion makes it a non-trivial problem (even for strictly periodic waves) to decide what rightly is turbulence and what belongs to the wave motion (see also Svendsen, 1987).

In the present investigation we have used an ensemble average procedure to separate the turbulent part of the signal from the wave motion. This was found reasonable because the small variations in the wave periods mentioned above.

The ensemble wave component, $\tilde{\eta}$ and $\tilde{u}_w$ for surface elevation and velocity respectively, are then determined as the mean value of all 30 samples at the same phase of the wave. The standard deviation around each of the mean values represent the surface fluctuations, η', and velocity fluctuations (turbulence), u', respectively.

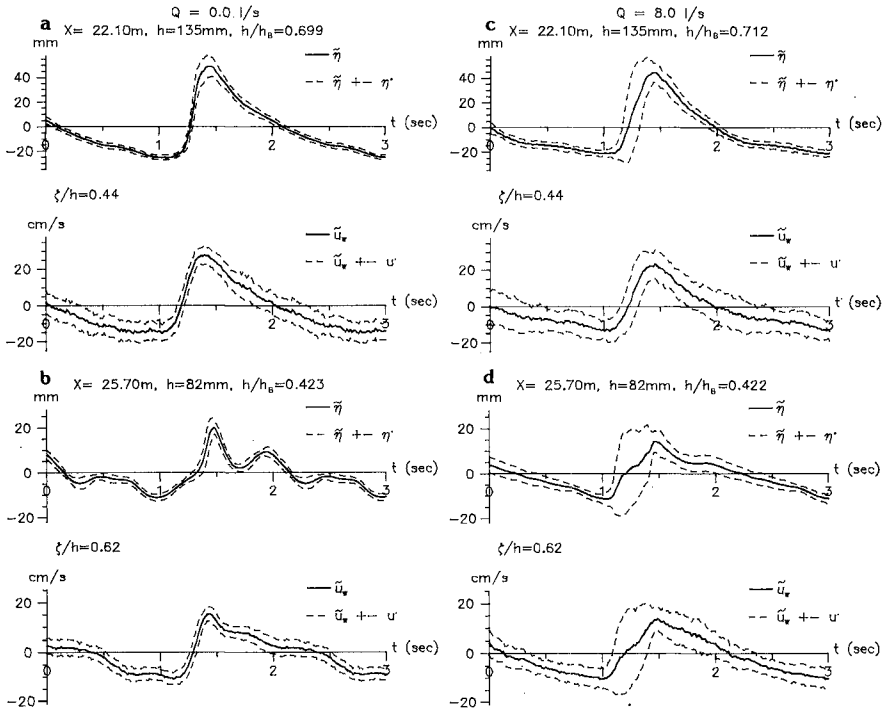

Fig. 5 Ensemble mean profiles for surface elevation, $\tilde{\eta}$, and wave particle velocities, $\tilde{u}_w$, at 2 positions for Q = 0 and 8 l/s.

In Fig. 5 are given the ensemble mean profiles for $\tilde{\eta}$ and $\tilde{u}_w$ from four different tests ($\tilde{\eta} \equiv 0$; $\tilde{u}_w \equiv 0$). The figure 5 further shows the surface fluctuations, η', and u'. In the cases a), b) and c) these are seen to be almost constant over the wave period. In Fig. 5 d), however, the level of fluctuations is considerably higher around the front of the wave than over the remaining part of the wave period. This tendency is observed only in the Q = 8 l/s case and only for measuring points with $h/h_B < 0.5$, where h_B is the breaker depth. For these points with $(\bar{Q}/h)/1/2(u_{w,c} - u_{w,t}) > .88$ the measured velocities are positive over the entire wave period, and the standard deviations on T is as large as 0.2•T. Consequently, in that case, the u' cannot be viewed as turbulence around the wave front, but over the remaining part of the profile the u' level is virtually unaffected by the variations of the wave period.

The chosen ensemble averaging procedure will always yield signal amplitudes smaller than the mean of the individual 'heights'. In the surf zone the height of the ensemble profile is in general 0.91 times the mean of the individual heights. However, in the tests with large variations of the wave periods the ratio is as small as 0.76.

4.4 Accuracy of experimental results

From experiments using the slowly travelling carriage technique reported by Hansen & Svendsen (1979) it is established that the recorded wave heights and water level changes is very accurate. This is also the case for the measured wave celerities up to the point of breaking. In the surf zone, however, the surface fluctuations may cause widely scattered c values. As the second type of experiments performed in this study determines the wave celerity from 30 consecutive waves instead of one wave these results show much smaller scattering and will be used throughout the study.

The wave height and water level changes from the two types of experiments are in Fig. 6 seen to be in close agreement. In figure 6 the 'continuous' wave recordings are compared with the mean values from all individual waves, $\bar{H}$ and b, recorded in the time series. The standard deviation on $\bar{H}$ is less than 2 mm and on the set-up's less than 0.3 mm in all positions but one (x = 21.23) which is the first measuring

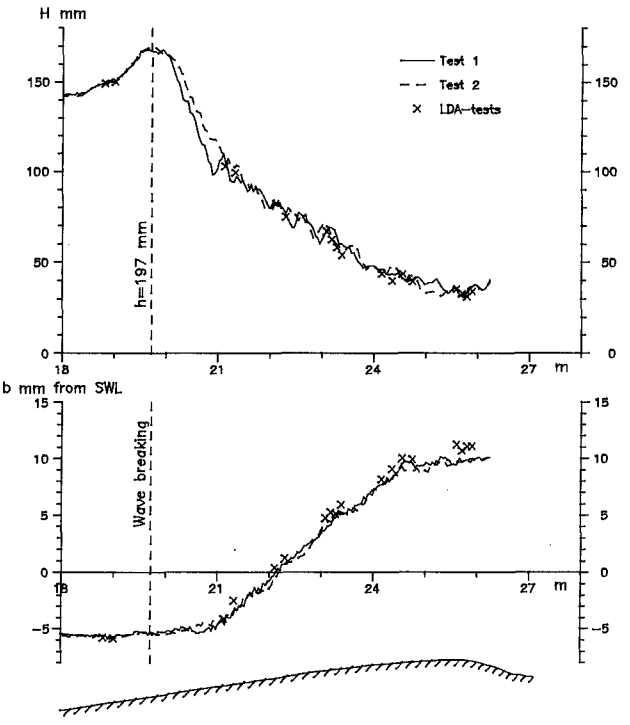

Fig. 6 Reproducibility of wave heights and water level changes for Q = 0. Test 1 and test 2 from 'continuous' wave recordings; LDA-tests are $\bar{H}$ and b from time series.

position after breaking. Fig. 6 is for the Q = 0 case, but the same tendency is clearly observed for other Q values.

Also the velocity measurements show a larger variation near the breaking point than elsewhere. The largest scattering obtained from repeating the same measurement several times is found at x = 21.23 m. Fig. 7 shows the results for the mean velocity, $\bar{u}$, (undertow) from a total of 7 test series. The large variation on the mean values indicates that the 30 waves used in each test is a too small number for a proper averaging at this point. At all other points the variance is much smaller and 30 waves define the mean sufficiently accurately. The results presented in the following chapter of this paper are taken as the mean value of all tests at any particular position and height.

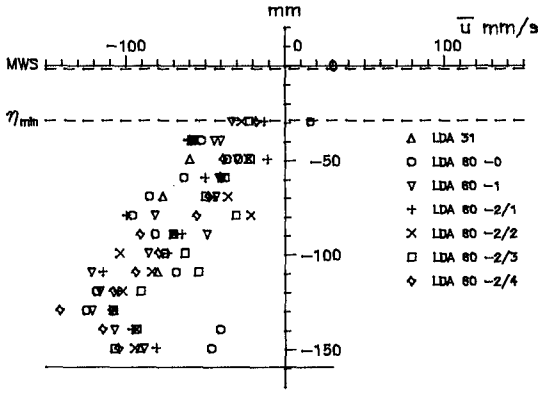

Fig. 7 Repeated measurements of undertow (Q = 0) at x = 21.23 m; h/h_B = 0,80

5. DISCUSSION OF RESULTS

5.1 Surface elevations

As the waves in front of the sloping bed are seen to be virtually unaffected by the superimposed currents this may be expected also to be the case about wave breaking where $(\bar{Q}/h)/\sqrt{gh} \leq 0.05$, see Tables 1 and 2. The point of wave breaking is defined as the point with $(H/h)_{max}$ in the 'continuous' wave recordings; the position varies from x = 19.34 m for Q = 2.5 l/s (h = 205 mm) to x = 19.82 m for Q = 8 l/s (h = 194 mm). When considering that small irregularities in the recorded waves may easily shift the position of $(H/h)_{max}$ point ± 20 cm (see Fig. 6) it is reasonable to conclude that the wave breaking is not significantly influenced by the current.

From the wave data at the bar crest included in Table 2 it appears that the decay of the waves over the surf zone and the set-up, b, are not significantly influenced by the current either. However, the H/h value at the bar crest seems to be increasing with increasing current, which might indicate that the intensity of the wave breaking is reduced with increasing flow velocity. These mechanisms are discussed more detailled in I.

All time series measurements in the surf zone are assumed to be within the inner region of the surf zone as defined in Svendsen et al (1978). This is analysed further in I.

Q	At breaking (from 'continuous' wave recording)				At bar crest (from time series)			
l/s	H_B mm	$\Delta b^{2)}$ mm	h_B mm	H_B/h_B	$\bar{H}^{1)}$ mm	$\Delta b^{2)}$ mm	h mm	$\bar{H}/h$
0	170	-0,6	197	o.87	33.o	16.5	82	o.41
2.5	163	-0,8	205	o.79	37.6	17.6	83	o.45
5	162	-0,5	198	o.82	33.4	15.3	76[3]	o.44
8	156	-0,8	194	o.80	38.5	15.6	82	o.47

1) $\sigma_{H/\bar{H}} \sim 0.1$ in all tests. 2) Relative to MWS at h_o = 340 mm
3) See footnote p. 2

Table 2 Wave characteristics at breaking and at the bar crest

The dimensionless wave energy flux, B_o, is from Fig. 8 seen also to be unaffected by Q, but is, on the other hand, seen to vary considerable over the surf zone with a maximum at $h/h_B \sim 0.6$ and $H/H_B \sim 0.45$. Fig. 8 and Fig. 9 are both included for later comparisons with the velocity measurements.

The absolute wave celerity, c_a, is significantly increasing for increasing discharge through the wave flume. As should be expected, however, the relative celerity c_r given by $c_r = c_a - U$ (where U is the current velocity averaged over the depth) is in Fig. 10 seen to be independent of the pumped discharge.

U is determined from the results given in Fig. 11 as the mean value of $\bar{u}$ from the bottom to MWS, where values above trough level have in most cases been obtained by extrapolation.

A possible interpretation of the results for c_r is that $c_r = \alpha\sqrt{gh}$. This has been used in I with an assumed constant α value. The measured c_r can also be said to agree well with the bore celerity, c_{bore}, as given by

$$\frac{c_{bore}^2}{gh} = 1/2 \frac{d_t \cdot d_c}{h^3} \left(d_t + d_c\right)$$

(eq. 44 in Svendsen et al (1978), where d_t and d_c are the water depth under wave trough and crest, respectively.

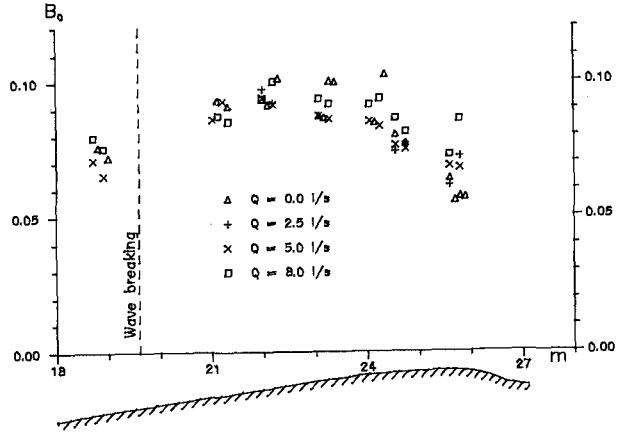

Fig. 8 $B_o = \overline{\tilde{\eta}^2}/H^2$ for the ensemble mean surface profiles .

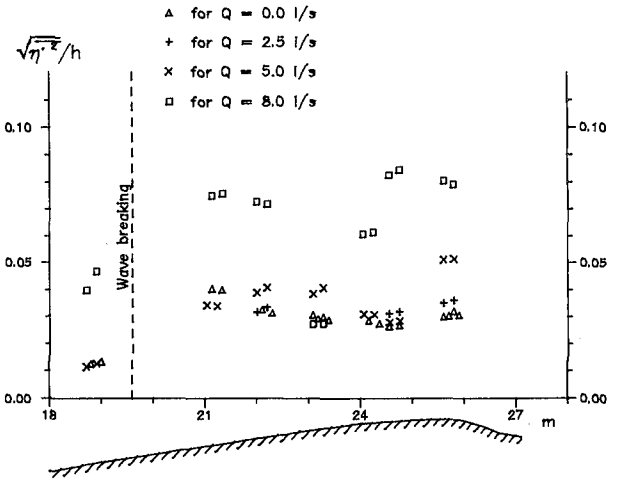

Fig. 9 Surface fluctuations η'.

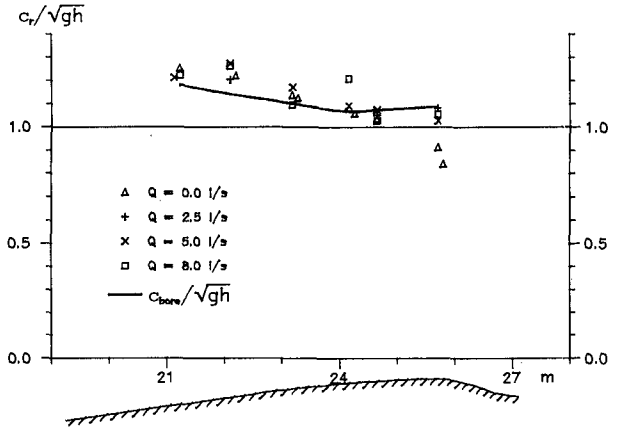

Fig. 10 Relative wave celerity

5.2 Particle velocities

Mean velocities are calculated from the time series as $\bar{u}$ over the total number of periods. The results are compiled in Fig. 11 for all horizontal and vertical positions and for the four different discharges through the flume. The mean velocities for different discharges all show similar depth variations. Only at the two positions closest to breaking (x = 21.23 m and 22.10 m) do the big scatter in the individual results obviously distort the general trend. As previously pointed out (see Fig. 7) the vigorous breaking and associated large variations from wave to wave in this regiuon causes a considerable scatter in the results when averaged over -only- 30 consecutive waves.

The volume flux, Q_s, due to the waves may also be determined from

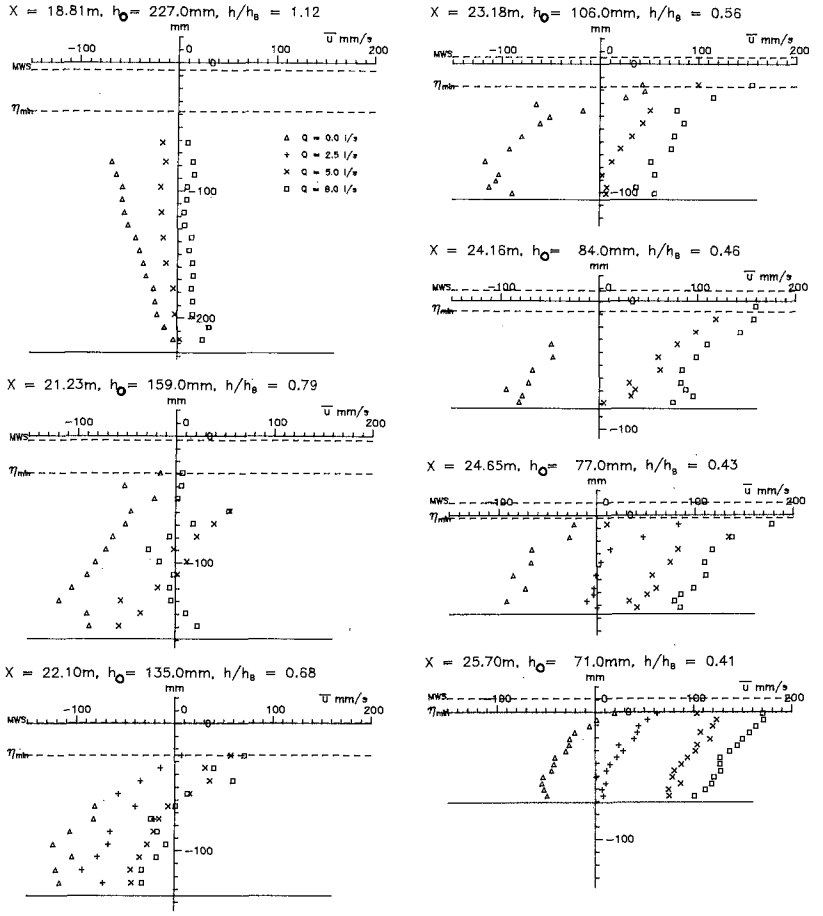

Fig. 11 Mean Eulerian velocities at 7 positions for four different Q values.

the measurements. The depth integrated, time averaged continuity equation reads $\bar{Q} = Q_c + Q_s$. Here Q_c is the mean discharge from bottom to MWS, $Q_c = U \cdot h$. As $\bar{Q}$ is known from the pumped discharge, Q_s can be determined and the results are given in Fig. 12. They show a considerable scatter indicating how delicate these calculations are and how sensitive they are to the accuracy of the recorded $\bar{u}$ or U values. This particularly applies to situations where U is primarily due to $\bar{Q}$ so that Q_s is determined as the difference between two large numbers.

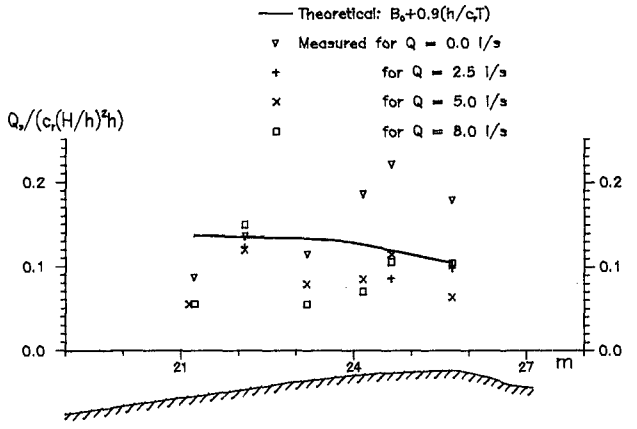

Fig. 12 Theoretical and 'measured' mass flux Q_s due to waves.

Fig. 12 also shows the values of Q_s used in I but calculated from the measured c_r and H as given in Fig. 8 and 10. The 'theoretical' Q_s values are generally higher than the measured values.

The wave particle velocities, $\tilde{u}_w$, for Q = 0 l/s and Q = 8 l/s are shown in Fig. 13. For the 2.5 and 5 l/s cases the picture is exactly the same.

The relation between the surface elevations η and the particle velocities u_w are to the lowest order of approximation

$$u_w = \sqrt{gh} \cdot \frac{\eta}{h}$$

or, when averaged over the period

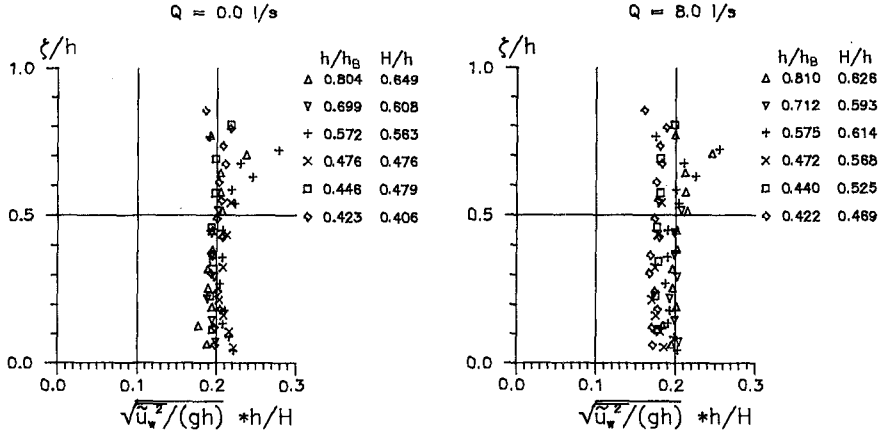

Fig. 13 Kinetic energy in ensemble mean wave particle motions.

$$\sqrt{\frac{\tilde{u}^2}{\frac{w}{gh}}} \cdot \frac{h}{H} \approx \sqrt{B_o}$$

When the velocities are calculated from the surface recordings using this relation (Fig. 8 shows $\sqrt{B_o}$ values ranging from 0.25 to 0.31) they are significantly overestimated.

The implication of this is that in the theoretical results in I B_o should only represent $\overline{\eta^2}$. Where B_o represents $\overline{u^2}$ contributions a smaller value than B_o should be used. A closer analysis is left for future studies.

The velocity fluctuations (turbulence) are shown in Fig. 14 for the two cases Q = 0 l/s and 8 l/s. The significant decrease in turbulence level for decreasing water depth found in the Q = 0 l/s case does not appear in any of the three other current situations.

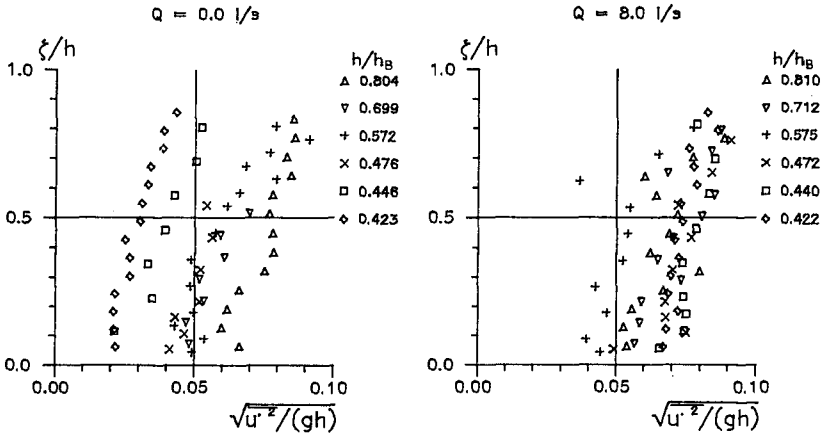

Fig. 14 Turbulent energy in recorded particle motions.

Svendsen (1987) has analysed other available data on surf zone turbulence. The total turbulent kinetic energy, k, may be estimated from u' component as

$$k = \frac{1}{2} \cdot \frac{1}{0.43} \overline{u'^2} = 1.08^2 \overline{u'^2}$$

(Svendsen (1987) eq. 3.1). The results given in Fig. 14 are from this seen to be in close agreement with the results of Stive & Wind's test No. 1 as analysed in Svendsen (1987). It is interesting to notice, that the level of surface fluctuations, $\overline{\eta'^2}/h^2$, as given in Fig. 9 are of the same order of magnitude as the $\overline{u'^2}/gh$ given in Fig. 14. The implication of this and other aspects of the turbulence will be analysed further.

The analysis of the results continues. The theoretical model given in I and the experiments reported here are used interactively to gain further insight into the problem studied.

TWO-DIMENSIONAL EMPIRICAL EIGENFUNCTION MODEL FOR THE ANALYSIS AND PREDICTION OF BEACH PROFILE CHANGES

T.-W. Hsu[1], S.-R. Liaw[2], S.-K. Wang[2] and S.-H. Ou[3]

ABSTRACT

A two-dimensional empirical eigenfunction model is proposed for the analysis and the prediction of beach profile change due to longshore and cross-shore sediment transports. Beach profile data from Redhill coast, Taiwan, measured every two months at 150 meters interval along the detached breakwaters are analyzed and the relative importance from two directions is investigated. Furthermore, by employing the method of Markov process and linear regression, a prediction model is formulated which takes into account the effect of breaking waves, bottom sediment and radiation stress of waves. This 2-D model is shown to be effective in the analysis and the prediction of beach changes near the coastal structures.

INTRODUCTION

The movement of coastal sediment can be decomposed into longshore component and cross-shore component. Longshore transport is defined as sediment transport parallel to the beach, while cross-shore transport is defined as transport perpendicular to the beach. These components are both significant in response to seasonal variations in the forcing parameters such as waves, tides, winds and currents. Therefore, beach profile changes due to longshore and cross-shore transport should be separated and represented as a time series in order to obtain a detailed understanding.

Winant et al.(1975) proposed a method to describe beach changes in terms of empirical eigenfunctions. The usefulness of the eigenfunctional representation was confirmed as a concise method of representing beach profile changes

(Aubrey, 1978; Aranuvachapun and Johnson, 1979). Uda and Hashimoto (1982) proposed a new model to analyze the beach changes due to longshore and cross-shore sediment transports. They used longshore eigenfunctions and cross-shore eigenfunctions to describe temporal variations of beach profile changes. However, the cross-shore eigenfunctions were taken as a time average in their analysis and only the longshore eigenfunctions changing with time. This implies that the beach profile change is independent of cross-shore sediment transport.

The aim of this paper is to extend Uda and Hashimoto's concept and proposes a 2-D empirical eigenfunction model for the analysis and the prediction of beach profile changes for temporal and spatial variation where both longshore and cross-shore sediment transport are significant. Field observation of beach profiles obtained from Redhill, Taiwan, are examined and the relative importance of beach changes from two orthogonal modes is also given. In addition, a prediction model is formulated by employing the method of Markov process and linear regression. The results of prediction model are compared with the existing models and measured data.

THEORETICAL FORMULATION

One-Dimensional Empirical Eigenfunction Method

The method has been described by Winant et al. (1975). In brief, an eigenfunction is expressed in the form of

$$h_{xt} = \sum_n e_{nx} C^*_{nt} \tag{1}$$

where the h_{xt} are the beach profile data, e_{nx} represent the spatial eigenfunctions, C^*_{nt} represent temporal eigenfunctions, and n represent the variation modes.

The spatial eigenfunctions form an orthogonal set as

$$\sum_n e_{nx}\, e_{mx} = \delta_{nm} \tag{2}$$

where δ_{nm} is Kronecker delta.

The spatial correlation matrix A is expressed as

$$A = \begin{bmatrix} a_{11} & a_{12} & a_{13} & \cdots & a_{1n} \\ a_{21} & a_{22} & a_{23} & \cdots & a_{2n} \\ \vdots & \vdots & \vdots & & \vdots \\ \vdots & \vdots & a_{ij} & & \vdots \\ \vdots & \vdots & \vdots & & \vdots \\ a_{n1} & a_{n2} & a_{nj} & \cdots & a_{nn} \end{bmatrix} \tag{3}$$

In which, the elements of matrix A are defined by

$$a_{ij} = \frac{1}{N_x N_t} \sum_t h_{it}\, h_{jt} \tag{4}$$

where N_x is the number of data points per profile, N_t is the

number of measured times. The matrix A possesses a set of eigenvalues λ_n and a set of corresponding eigenfunctions e_{nx} which are defined by matrix equation

$$A\, e_{nx} = \lambda_n\, e_{nx} \tag{5}$$

The temporal eigenfunctions are calculated with

$$C^*_{nt} = \sum_x h_{xt}\, e_{nx} \tag{6}$$

By defining $C_{nt}=C^*_{nt}/(\lambda_n N_x N_t)^{1/2}$, it can be shown that C_{nt} form an orthogonal set, and eq.(1) is rewritten as

$$h_{xt} = \sum_n (\lambda_n N_x N_t)^{1/2}\, e_{nx}\, C_{nt} \tag{7}$$

Analysis of 2-D Empirical Eigenfunction Method

Following Uda and Hashimoto (1982), we extend the 1-D empirical eigenfunction method to the 2-D bed elevation h(x,y,t), which is a function of offshore distance x, and longshore distance y at a certain time t. The expression of h(x,y,t) is as follow

$$h(x,y,t) = \sum_k e_k(x,t)\, e_k(y,t) \tag{8}$$

In this expression, $e_k(x,t)$ are the cross-shore eigenfunctions, $e_k(y,t)$ the longshore eigenfunctions, k the variation modes. Eq.(8), obviously, represents the variation of the beach profile configuration in terms of longshore and cross-shore distances at the specific time t. In some cases, such as the profile configuration around a coastal structure or a rhythmic topography, it is desirable to use the data of all profiles for the analysis of spatial characteristic beach changes instead of the single beach profile.

The cross-shore eigenfunctions form an orthogonal set as

$$\sum_x e_n(x,t)\, e_m(x,t) = \delta_{nm} \tag{9}$$

In order to generate the cross-shore eigenfunctions, like the correlation matrix A, a symmetric matrix B is formed with elements of

$$b_{ij} = \frac{1}{N_x N_y} \sum_y h(i,y,t)\, h(j,y,t) \tag{10}$$

where N_y denotes the total number of measured points alongshore. The matrix B are real matrix with a set of eigenvalues λ_k and a set of corresponding eigenfunctions $e_k(x,t)$

$$B\, e_k(x,t) = \lambda_k\, e_k(x,t) \tag{11}$$

The longshore eigenfunctions $e_k(y,t)$ which define the longshore changes of beach profile are evaluated as

$$e_k(y,t) = \sum_x h(x,y,t)\, e_k(x,t) \qquad (12)$$

In the analysis of beach profile changes due to longshore and cross-shore sediment transports, Uda and Hashimoto (1982) took the cross-shore eigenfunctions $e_k(x,t)$ to be independent of time and only let the longshore eigenfunctions $e_k(y,t)$ changing with time. This means that the nature of variations doesn't depend on cross-shore sediment transport. This paper allows $e_k(x,t)$ and $e_k(y,t)$ to vary with distance and time respectively. The expressions of $e_k(x,t)$ and $e_k(y,t)$ are given as follows,

$$e_k(x,t) = \sum_n (\lambda_n N_x N_t)^{1/2}\ e_k^n(x)\ C_{kx}^n(t) \qquad (13)$$

$$e_k(y,t) = \sum_m (\lambda_m N_x N_t)^{1/2}\ e_k^m(y)\ C_{ky}^m(t) \qquad (14)$$

where $e_k^n(x)$: cross-shore spatial eigenfunctions
$C_{kx}^n(t)$: cross-shore temporal eigenfunctions
$e_k^m(y)$: longshore spatial eigenfunctions
$C_{ky}^m(t)$: longshore temporal eigenfunctions

Formulation of the Prediction Model

In order to relieve forecast errors, the variation of beach profile subtracted the mean beach profile from the original data is used. By this method, the set $h(x,y,t)$ is expressed as

$$h(x,y,t) = \bar{h}(x,y) + \sum_k e_k'(x,t)\, e_k'(y,t) \qquad (15)$$

where $\bar{h}(x,y)$ is the temporal mean of the beach profile. A prime on the eigenfunctions indicates that these eigenfunctions are similar in data sets where the mean profile has not been removed. According to eqs.(13) and (14), $e_k'(x,t)$ and $e_k'(y,t)$ can be expressed, respectively, in the form of

$$e_k'(x,t) = \sum_n (\lambda_{nx} N_x N_t)^{1/2}\ e_k^{n'}(x)\ C_{kx}^{n'}(t) \qquad (16)$$

$$e_k'(y,t) = \sum_m (\lambda_{my} N_x N_t)^{1/2}\ e_k^{m'}(y)\ C_{ky}^{m'}(t) \qquad (17)$$

The fluctuations of beach profile are calculated as

$$h'(x,y,t) = h(x,y,t) - \bar{h}(x,y) \qquad (18)$$

$h'(x,y,t)$ was used to generate eqs.(16) and (17) by processing the procedure of the analysis of 2-D empirical eigenfunction method.

The predictands for prediction model always consist of a representation of the beach profile time series. Accordingly, it is necessary to forecast the next time step eigenfunctions $C_{n(j+1)}$ and let the spatial eigenfunctions $e_k(x)$ and $e_k(y)$ to be constants.

The Markov process based on Sonu (1973) and three forcing parameters were used here to estimate the temporal eigenfunctions $C'_{n(i+1)}$ in the prediction model. The simplest linear equations can be described as

$$\begin{aligned} C'_{1(i+1)} &= \overline{a_{11}}C'_{1i} + \overline{a_{12}}C'_{2i} + \ldots + \overline{a_{1n}}C'_{ni} + \overline{a_{1(n+1)}}F_{i+1} \\ C'_{2(i+1)} &= \overline{a_{21}}C'_{1i} + \overline{a_{22}}C'_{2i} + \ldots + \overline{a_{2n}}C'_{ni} + \overline{a_{2(n+1)}}F_{i+1} \\ &\vdots \\ C'_{n(i+1)} &= \overline{a_{n1}}C'_{1i} + \overline{a_{n2}}C'_{2i} + \ldots + \overline{a_{nn}}C'_{ni} + \overline{a_{n(n+1)}}F_{i+1} \end{aligned} \tag{19}$$

or

$$\begin{bmatrix} C'_{1(i+1)} \\ C'_{2(i+1)} \\ \vdots \\ C'_{n(i+1)} \end{bmatrix} = \begin{bmatrix} \overline{a_{11}} & \overline{a_{12}} & \ldots & \overline{a_{1n}} & \overline{a_{1(n+1)}} \\ \overline{a_{21}} & \overline{a_{22}} & \ldots & \overline{a_{2n}} & \overline{a_{2(n+1)}} \\ \vdots & \vdots & & \vdots & \vdots \\ \overline{a_{n1}} & \overline{a_{n2}} & \ldots & \overline{a_{nn}} & \overline{a_{n(n+1)}} \end{bmatrix} \begin{bmatrix} C'_{1i} \\ C'_{2i} \\ \vdots \\ F_{i+1} \end{bmatrix} \tag{20}$$

where $\overline{a_{11}} \ldots \overline{a_{n(n+1)}}$ are constant coefficients, F_{i+1} are the dimensionless forcing parameters for the next time step.

Three forcing parameters corresponding to breaking waves, features of bottom sediment transport and radiation stresses of waves were taken into account in the present method. The reason why these three parameters are chosen is that they have been used in the past with degrees of success to describe nearshore process. Based on Battjes (1974), the characteristics of breaking waves can be described by surf similarity parameter ζ defined by

$$\zeta = \tan\beta \; / \; (H/L_0)^{1/2} \tag{21}$$

where $\tan\beta$ is the bottom slope, H wave height, L_0 wave length in deep water. The features of bottom sediment transport can be classified by the parameter C proposed by Gourlay (1968)

$$C = H_0 \; / \; wT \tag{22}$$

where w is the fall velocity of sediment determined by the characteristics of sand and kinematic viscosity of the fluid and T is the wave period. The radiation stresses of inclined waves are written as (Bowen,1969)

$$S = \begin{bmatrix} S_{xx} & S_{xy} \\ S_{yx} & S_{yy} \end{bmatrix} = \begin{bmatrix} S_{rr}\cos^2\alpha + S_{ss}\sin^2\alpha & (S_{rr}-S_{ss})\sin\alpha\cos\alpha \\ (S_{ss}-S_{rr})\sin\alpha\cos\alpha & S_{rr}\sin^2\alpha + S_{ss}\cos^2\alpha \end{bmatrix} \tag{23}$$

with

$$S_{rr} = E(2n-1/2) \;, \quad S_{ss} = E(n-1/2) \;, \quad E = 1/8\,\rho g H^2$$

where r is the direction of wave propagation, s is the direction normal to the wave propagation, x is cross-shore coordinate, y is longshore coordinate, α is the angle be-

tween wave crest and beach, n is the ratio of wave group velocity to wave celerity, E is wave energy, ρ is density and g is gravity acceleration. A dimensionless wave energy was introduced for the consistent dimension of forcing parameters

$$E_0 = (1/8\ \rho g H^2) \ / \ (1/8\ \rho g H_0^2) \tag{24}$$

It is convenient to write eq.(19) in general matrix notation as

$$P = \overline{A} \cdot D \tag{25}$$

where P is the (m•N) matrix of m quantities to be predicted, D is the (n•N) matrix of n data parameters and $\overline{A}$ is an (m•n) coefficient matrix, N is the total number of observations of these quantities which are to be used in the prediction. The optimal form of the coefficient matrix $\overline{A}$ was determined by using the linear regression:

$$\overline{A} = C_{PD}\ C_{DD}^{-1} = (P \cdot D^T)\ (D \cdot D^T)^{-1} \tag{26}$$

where C_{PD} denotes the covariance matrix between the predict-and and data, C_{DD} is the auto-covariance matrix of the data, and T is the transpose operator.

The estimator of matrix P is used for both hindcast and forecast models. A hindcast model is defined as the estimate made from the same data and the predictand which are used to form the covariance matrix, whenas a forecast model is defined as the estimate made from the covariances formed from other data and predictand samples. According to Davis (1976), the hindcast skill can be represented by a predictability index S_H:

$$S_H = 1 - \frac{E(P-\hat{P})\ (P-\hat{P})^T}{E(PP^T)} \tag{27}$$

in which E represents the expected value operator, $\hat{P}$ denotes the estimated value. The hindcast skill increases with the higher value of S_H. On the other hand, the forecast ability was described by the mean-square-forecast error S_F:

$$S_F = \frac{E[h(x,y,t) - \hat{h}(x,y,t)][h(x,y,t)-\hat{h}(x,y,t)]^T}{E[h(x,y,t)][h(x,y,t)]^T} \tag{28}$$

where $\hat{h}(x,y,t)$ is the estimated bed elevation. A model is predictable with lower mean-square-forecast error.

FIELD DATA

Beach Profile Data

As shown in Fig.1, Redhill coast is located in the southern part of Taiwan and consists of eroding sandy bluffs ranging from 6 to 10 meters high. Fig.2 shows the detached breakwaters built on the shoreline to prevent waves from reaching the eroding shore.

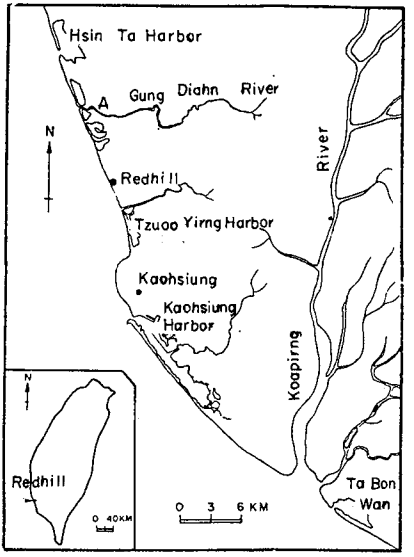

Fig. 1 Location of Redhill coast

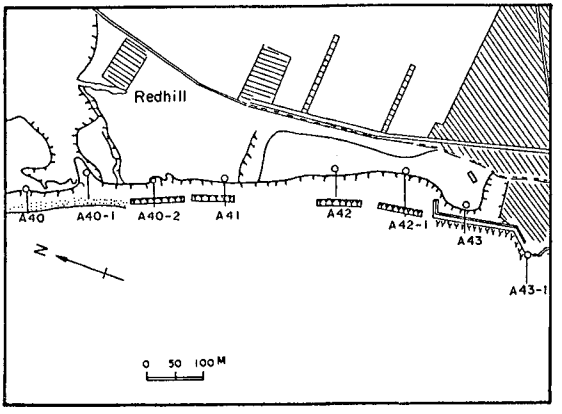

Fig. 2 Alignment of detached breakwaters and observed positions

The beach sand has median grain size of 0.28mm and submerged specific gravity of 1.6 Surveys of the beach profile have been conducted at every two months from 1982 to 1984. Each profile was measured at some intervals over a distance about 600m offshore. A detailed measurement was done on the foreshore part by using standard surveying method, while depth measurements on the offshore part were taken by cable lead.

Wave Climate of Redhill Coast

There are no wave data available at Redhill coast. The wave data observed at Ta Bon Wan located about 48km south of Redhill coast (Fig.1) have been used. The wave height at Ta Bon Wan was measured at the depth of 12.5 meters using a pressure wave gage. In winter, the prevailing direction of incoming wave at Ta Bon Wan is NNE, and waves from various directions were partly sheltered by land. The cumulative relative energy $P_E(\theta)$ is given by

$$P_E(\theta) = \frac{1}{m_0} \int_{-\pi/2}^{\theta} \int_0^{\infty} S(f,\theta)\, df\, d\theta \qquad (29)$$

where $S(f,\theta)$ is directional wave spectrum, f is angular frequency, θ is the azimuth measured counterclockwise, and m_0 is the total wave energy expressed as

$$m_0 = \int_{-\pi/2}^{\pi/2} \int_0^{\infty} S(f,\theta)\, df\, d\theta \qquad (30)$$

For NNE directional waves, the azimuths θ_1 and θ_2 were taken as -45° and 31° for Redhill coast and for Ta Bon Wan, respectively. The wave height ratio k_d between Redhill coast and Ta Bon Wan is determined by using SWOP directional spectrum

$$k_d = \sqrt{P_E(\theta_1) / P_E(\theta_2)} = 3.15 \qquad (31)$$

In summer, since the SW directional incoming wave is almost perpendicular to the coast, wave data from Ta Bon Wan can be directly applied to Redhill coast without any modification.

Based on Sawaragi (1982), the response of the beach to the various kinds of incident waves can be expressed in terms of a representative wave calculated by the following formulas:

representative wave period: $$T_S = \sum_i T_i\, p_i / P_T \qquad (32)$$

representative wave height: $$H_S^2 C_{gS} P_T = \sum_i C_{gi} H_i^2 p_i \qquad (33)$$

representative wave direction:
$$H_S^2 C_{gS} \sin\alpha_S \cos\alpha_S\, P_T = \sum_i H_i^2 C_{gi} \sin\alpha_i \cos\alpha_i\, p_i \qquad (34)$$

where H_i: component wave height
H_S: representative wave height
T_i: component wave period

T_s: representative wave period
α_i: component wave direction
α_s: representative wave direction
C_{gi}: representative wave group velocity
p_i: component probability
$P_T = \sum_i p_i$=total probability

RESULTS AND DISCUSSION

Results of Beach Profile Analysis

The 2-D empirical eigenfunction analysis was conducted by using the beach profile data collected at Redhill coast from December, 1982 to December, 1984. The total number of recording times is N_t=13 and that of calculating points N_x=20, N_y=8.

Fig.3(a) shows the cross-shore profiles of section A40-2 of the first three spatial eigenfunctions e_1^1(solid line), e_1^2 (dash-dot line) and e_1^3 (dash line). The temporal eigenfunctions are given by C_{1x}^1(solid line), C_{1x}^2(dash-dot line) and C_{1x}^3(dash line) as shown in Fig.3(b). The first spatial eigenfunction is interpreted as the mean beach function according to Winant et al.(1975). The time dependence of the mean beach function is almost constant, indicating a stable beach for Redhill coast. The second spatial eigenfunction has a minimum at the location of summer berm and a maximum in the area of winter bar. The negative value of the second temporal eigenfunction accounts for the sand migration up to the level of the summer berm, while the positive value indicates the movement of sand down beach to the winter bar and hence represents erosion on the beach. The third spatial eigenfunction has positive value in the broad region from shoreline to about 400m and negative value in the offshore region. The corresponding temporal eigenfunction is found to have positive values before December, 1983 and negative values after December, 1983.

The 2-D empirical eigenfunction method is also employed for the analysis of shoreline changes due to the construction of detached breakwaters. Based on Uda and Hashimoto (1982), the shoreline changes can be described in terms of the second longshore eigenfunctions $e_2(y,t)$. From Fig.4, we note that the second longshore eigenfunction changes with seaward advancement at the central side on which the detached breakwaters were constructed. The corresponding cross-shore eigenfunction $e_2(x,t)$ is shown in Fig.5, in which the cross-section of a detached breakwater is located about 30m in the x direction. Depositions of sand behind the detached breakwater is also found. Results of analysis reveal that the design and the construction of detached breakwaters are successful for beach preservation measures.

Fig.6(a) presents the first three longshore spatial eigenfunctions e_1^1(solid line), e_1^2(dash-dot line) and e_1^3 (dash line). The time variations of these functions as shown in Fig.6(b) are C_{1y}^1(solid line), C_{1y}^2(dash-dot line)

and C_{iy}^{3} (dash line). The temporal function C_{iy}^{1} shows almost no chang over the recording time. The other two eigenfunctions show no clear tendency. Perhaps more data are required for the analysis.

On the other hand, Winant et al. (1975) pointed out that each eigenvalue is representative of certain percentage of the mean square value of the data. Table 1 shows that the eigenvalues of longshore eigenfunctions are larger that those of cross-shore eigenfunctions, indicating that the longshore sediment transport has more effect on beach profile change than the cross-shore sediment transport does.

Prediction of Beach Profile Changes

It has been shown that the stability is an important consideration in the prediction of empirical eigenfunction method (Aubrey,1978). In this paper, two data sets of different sample lengths (N_t=10 and 12) were examined. The results of analysis show that the eigenfunctions are stable with respect to the length of the data (Wang, 1985).

Uda and Hashimoto (1982) calculated the shoreline change by one-line theory, and then the longshore eigenfunction $e_2(y,t)$ was calculated from shoreline changes. Since the nearshore zone is characterized by complex flow fields and fluid-sediment interactions, it is difficult to estimate quantitative shoreline changes by one-line simulation. The correlation between $e_2(y,t)$ and shoreline changes is not significant in present analysis as shown in Fig.7. In this paper, three parameters and computed beach configuration at each time step are used to predict temporal eigenfunctions, because they are easily to obtain from available wave data and beach profile data without any mathematical simulation.

Table 2 shows the mean square value of forecast error S_F for different models. The forecast skill of present analysis is better than 1-D model and Uda and Hashimoto's model, although its predictability S_B was lower as listed in Table 3.

Fig.8(a) and (b) depict two profiles of A40-2 and A41 and their estimates from three different models. It is seen that the prediction of 2-D model yields a better result than 1-D model and Uda and Hashimoto's model as compare to the measured profiles.

CONCLUSION

Field data of beach profiles taken over two years at Redhill coast were analyzed by employing the 2-D empirical eigenfunction method. The results indicate that beach profile changes due to longshore and cross-shore sediment transports are separable. A successful detached breakwater as beach erosion countermeasure is also verified. The prediction of 2-D model shows that the beach profile changes are predictable. It is also concluded that this 2-D model is shown to be effective in the analysis and the prediction of beach changes near coastal structures.

CHAPTER 88

TIME SCALE FOR MODELING BEACH CHANGE

by

Masahiro Ito[1] and Yoshito Tsuchiya[2]

1. ABSTRACT

A time scale in the similarity of beach change between model and prototype in transitional beach processes from an initial even slope to an equilibrium is developed using a series of small- and large-scale experiments in which the experimental conditions were set up with the scale-model relationship by the authors (1984). The time scale is obtained empirically as a function of experimental scale. Applied the proposed time scale and the scale-model relationship to model experiments, similarity of morphological beach change such as shoreline change and relative breaker point was well reproduced within the allowable range of experimental error. A semi-theoretical time scale is obtained from the continuity equation, the sediment transport rate, and the scale-model relationship of equilibrium beach profile in two-dimensional beach change. The relation between experimental and semi-theoretical time scale is discussed.

2. INTRODUCTION

Experimental technique for reproducing beach changes during time-dependent storm waves is desirable for beach erosion control and design of coastal structures. Some investigators have attempted to find the scale-model relationship and the time scale for beach change, however, scale-model relationship and time scale in transitional beach processes are not established well. Most of those studies had developed scale-model relationships by using major parameters which govern effectively beach changes. Noda (1972) discussed how the scale-distortion in vertical and horizontal scales and properties of beach material in models influence on the scale-model relationship. Vellinga (1982) carried out a number of small- and large-scale model tests for the dune erosion in Duch coast, Netherland caused during huge waves, and proposed a scale-model relationship with distortion and time scale by summarizing its results. Also, by applying the dynamic similarity condition and the dimensionless fall velocity parameter demonstrated by Dean (1973), Hughes (1983) studied the

2 Professor, Disaster Prevention Research Institute, Kyoto University, Kyoto, 611 Japan.

scale-model and time scale relationship. He examined the applicability of the proposed relationship to distorted model tests of coastal dune erosion in Panahadle, Florida due to a hurricane. As the result of the tests, the beach profile nearby the shoreline was only reproduced. Hallermeir (1985) proposed a distorted scale-model relationship which was introduced using the parameter composed of sediment and the fluid characteristics, and also discussed it including the scale-model relationships by Hughes and Vellinga. He was examined his relationship using two-dimensional large-scale models which were conducted at the Coastal Engineering Research Center, US Army. The scale-model relationships by Noda, Vellinga and Hughes include an effect of distortion in vertical and horizontal scales. These scale-model relationships have not been examined by verification tests.

The authors (1984) proposed an empirical scale-model relationship by considering the degree of experimental error which appears in model experiments. This scale-model relationship is that gives the relation between experimental scales such as wave properties, water depth in a wave tank which can be determined by the Froude law, and the grain-size scale of beach sand. By using the authors' scale-model relationship, we can be similar the beach profiles and breaking wave properties in the only equilibrium of model and prototype. Then the time scale which can hold the similarity between model and prototype during the transitional beach processes from an initial even slope to an equilibrium must be found.

3. SCALE-MODEL RELATIONSHIP FOR EQUILIBRIUM BEACH PROFILE

To find the scale-model relationship for two-dimensional equilibrium beach profile a series of small- and large-scale experiments was carried out in the following conditions:
(1) The vertical and horizontal length scales, such as scales for beach profile and water depth in a wave tank were taken the same (i. e., undistorted or geometric similarity). Both the vertical and horizontal length scales are subjected to Froude law.
(2) Wave characteristics such as wave height in deep water and period also are determined by the Froude law.
(3) The beach sediment in small-scale models was used sand or silica-sand with the same specific gravity as the sand used in the large-scale models. The grain-size scale $\lambda_d = (d)_m / (d)_p$, is chosen independently of the experimental scale, $\lambda_l = 1/n$, as mentioned in (1) and (2).

In accordance with the abovementioned (1), (2) and (3) small- and large-scale model experimental conditions are given. These experiments were carried out using the large two-dimensional wave tank (78m long, 1m wide and 1. 2m deep) and the medium one (28m long, 0. 5m wide and 1m deep). By arranging results of small- and large-scale model experiments, the similitude zone which indicates a good agreement between the model and prototype beach profiles at equilibrium was found as shown in Fig. 1. The scale-model relationship in Fig. 1 was rearranged for the conditions of $(d/H_0)_p < 0.01$ and $H_0/L_0 = 0.007 \sim 0.042$. We have also reported that the scale-model relationship shown by the dot-dashed line as the central

trend curve of the similitude zone can be expressed by the following empirical relationship

$$\frac{1}{\lambda_d} = 1.7^{a} \left(\frac{1}{\lambda_l}\right)^{b} \qquad (1)$$

where a=1, b=0.83 for the range of experimental scale $1 \geq \lambda_l \geq 1/2.2$, and a=0, b=0.2 for $\lambda_l > 1/2.2$.

4. EXPERIMENTS OF TRANSITIONAL BEACH CHANGES FROM INITIAL TO EQUILIBRIUM STATE

If we set up the experimental conditions of model and prototype so that the both relationships enter into the similitude zone shown in Fig. 1 {i.e., by Eq. (1)}, we are possible to similar the only equilibrium beach profiles between the two, but impossible to similar the beach change between the two in case of the transitional beach process from an initial even slope to an equilibrium. we find out experimentally the time scale relationship so that the prototype beach profile at the specified operation time can similar to the model beach profile which was selected up among experimental results in gradually increasingly wave operation time.

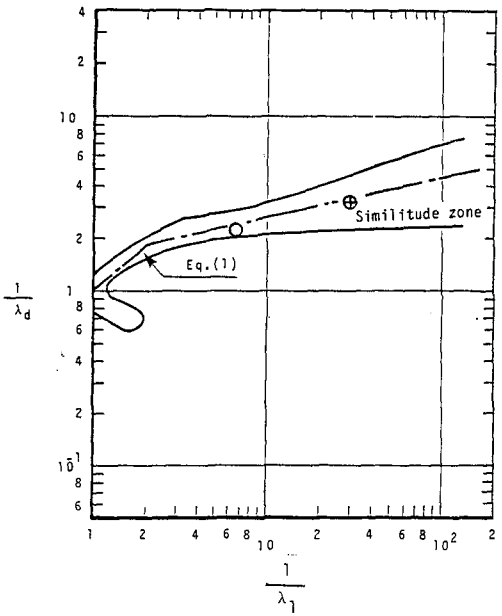

Fig. 1 Scale-model relationship by Ito & Tsuchiya for equilibrium beach changes with time scale relationship obtained by laboratory experiment.

By use of steady and regular waves in the two-dimensional large wave tank, beach changes as large-scale models (prototype) were measured intermittently until they reach from the initial even slope to an equilibrium state The experimental result and condition which Saville (1957) carried out a long time ago using a large wave tank, also is taken to be the prototype. In small-scale models, the vertical and horizontal lengths (experimental scale) such as wave properties and water depth in the wave tank were determined by the Froude law as mentioned in 3. (1) and (2). The sand and silica-sand to be used in the model were chosen according to Eq. (1) so that the grain-size scale enters within the similitude zone in Fig. 1. Model experiments were carried out until the beach profiles reach their equilibrium state for longer time, and beach changes and wave breaking properties during the experiments were measured intermittently. Model beaches in the medium wave tank were made initially the same beach slope with

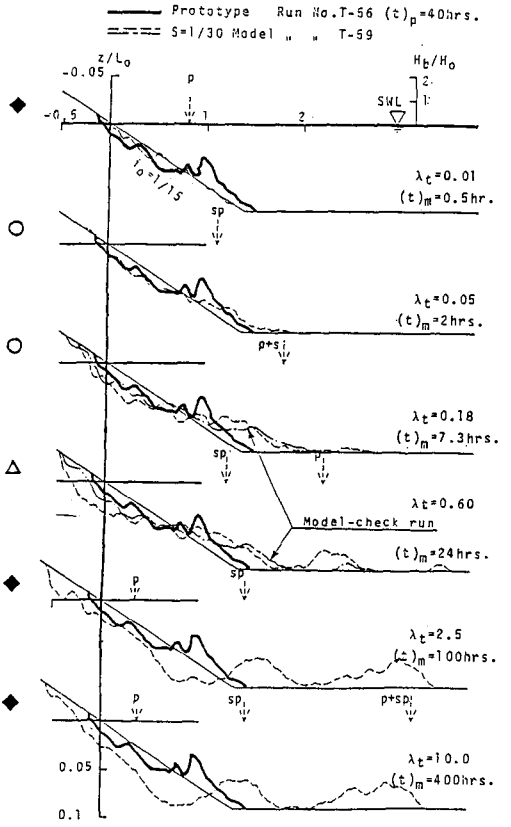
(a) Transitional beach change in model and prototype.

Fig. 2 Similarity comparison of the prototype beach profiles at the given time with temporarily varying model beach profiles (to be continued).

the corresponding prototype. An example of the experimental conditions determined by the manner mentioned is shown in Table 1.

As is seen in Fig. 1, these experiments are satisfied the similarity condition as indicated by the open circle for Run No. 3M-25 to Run No. 3 and the cross-circle for Run No. T-59 to Run No. T-56 (by Saville (1957)). Therefore, the only equilibrium beach profile between the two will become similar, but the similarity in transitional processes is uncertain. To define the similarity in transitional processes, prototype beach profile and breaking wave properties at the time, $(t)_p$=5hr, are compared with those in scale models during the times, $(t)_m$=0.39~23.3hr, as shown in Fig. (2). The position and the length



(b) Equilibrium beach profile in prototype.

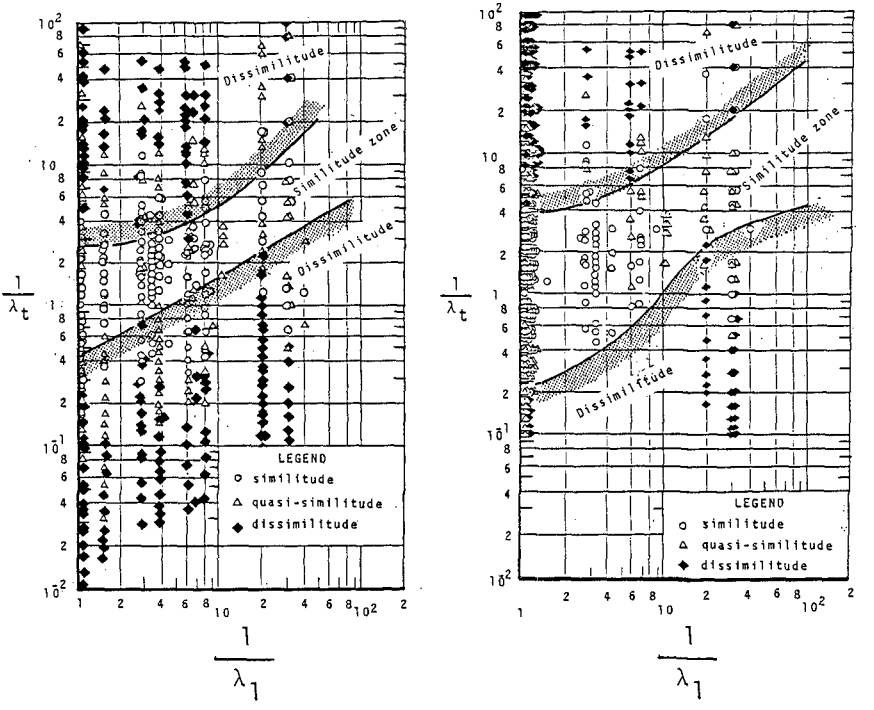
of allows in this figure indicate the breaking position and relative breaker height, H_b/H_0, and "P", "SP" and "SP+P" symbols indicate breaker types, plunging, spilling and intermediate between them, respectively. By considering the characteristics of experimental error, similarity of beach profiles and wave breaking properties are classified into three categories, *similitude* ("○"-mark), *quasi-similitude* ("△") and *dissimilitude* ("◆"). It is clearly recognized from Fig. 2 (a) that the judgement for similarity depends on the time scale, $\lambda_t=(t)_m/(t)_p$, and that the arrange of experiments which satisfy the relationship for the time-dependent similarity can easily be found. Also, Fig. 2 (b) shows the similarity comparison of the time-dependent beach profiles of the model, Run No. T-59 in Table 1 with Saville's prototype, Run No. T-56, in which the beach change is almost in equilibrium. By this way, in the case where the beach change of prototype is in transitional stage, non-equilibrium, the judgement results for similarity including the other experimental results are rearranged by λ_t^{-1} and λ_l^{-1} as shown in Fig. 3 (a). Furthermore, in



(a) Time scale for beach changes of model and prototype in transitional process.

(b) Time scale for beach changes of prototype only in equilibrium.

Fig. 3 Relationship between the time scale λ_t and the experimental scale λ_l for similarity in beach changes of model and prototype.

the case where the beach change of prototype is in equilibrium, the similarity comparison between the prototype (Run No. 56 in Table 1) and the time-dependent beach change of model (Run No. T-59) is shown in Fig. 3 (b), in which the results of other experimental results are also included. Median grain sizes of the sand and the silica-sand used in the model and prototype range of $(d)_m$=0.15~0.42mm and $(d)_p$=0.15~1.62 mm, respectively. The similitude /dissimilitude zones where the time scale relationship is/not achieved, are shown in Fig. 3 (a) and (b). The similitude zones are in Fig. 3 (a) and 3 (b) are not same, but a overlapped similitude zone can be found in Fig. 4. The similitude zone in Fig. 4 may be expressed by

$$\frac{1}{1.6\sqrt{\lambda_l}} \leq \lambda_t \leq \frac{1}{0.65\sqrt{\lambda_l}} \qquad (2)$$

It is noted in the figure that the dotted line which indicates the average tendency of Eq. (2) agrees closely with the Froude time scale

$$\lambda_t=\sqrt{\lambda_l}=\frac{1}{\sqrt{n}} \qquad (3)$$

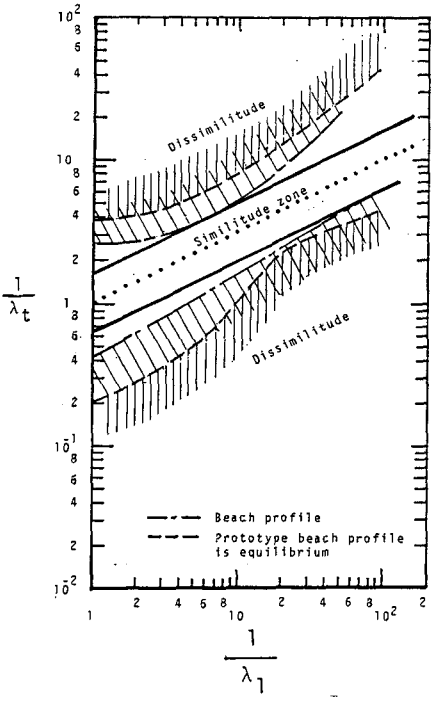


Fig. 4 Empirical time scale for modeling beach change.

5. APPLICABILITY OF THE TIME SCALE RELATIONSHIP PROPOSED

We set the experimental scale and grain-size scale of model for prototype by Eq. (1), and determine the wave duration operation time between the two by Eq. (3) which indicates the average tendency of similitude zone in Fig. (4). In case of this experimental manner, the relationship of the wave duration time in the model, $(t)_m$, and prototype, $(t)_p$, is given by

$$(t)_m=\frac{(t)_p}{\sqrt{n}} \qquad (4)$$

and the relationship of wave periods is

$$(T)_m=\frac{(T)_p}{\sqrt{n}} \qquad (5)$$

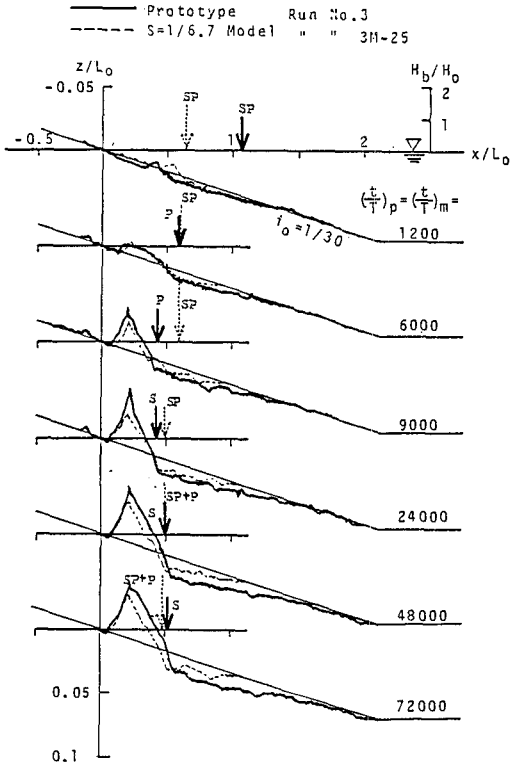

Fig. 5 Similarity of model and prototype beach changes reproduced by applying the time scale relationship.

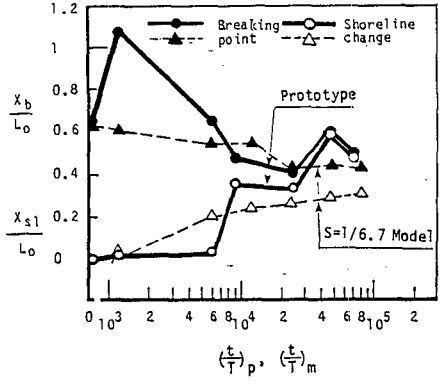

Fig. 6 Time changes of shoreline change and relative breaking position in the similarity experiments.

From Eqs. (4) and (5), we obtain

$$\left(\frac{t}{T}\right)_m = \left(\frac{t}{T}\right)_p \tag{6}$$

An example of the comparison between the beach change reproduced by model and prototype is shown in Fig. 5. At the same dimensionless times by Eq. (6), this figure illustrates changes of the beach profile and the breaking wave properties from an initial even slope to an equilibrium. Fig. 6 also shows in detail the reproduction of the shoreline change, X_{sl}/L_o, and the movement of breaking point, X_b/L_o in dimensionless form. The discrepancy between the two shown in the figure is less than the range of experimental error. From Figs. 5 and 6, it is recognized that the time scale relationship of Eq. (2) is available for the laboratory model for reproducing the transitional beach change in prototype.

6. TIME SCALE BY SEMI-THEORETICAL METHOD

We can introduce the time scale in beach change processes using the three relationships for two-dimensional beach change; 1) the continuity equation of beach change

$$\frac{\partial z}{\partial t} + \frac{1}{1-\Lambda}\frac{\partial q_x}{\partial x} = 0 \tag{7}$$

where q_x is the sand transport rate in the offshore direction, t the time, Λ the bottom sediment porosity, and z and x the vertical and horizontal coordinates, respectively; 2) the sand transport rate; and 3) the the scale-model relationship of equilibrium beach profile expressed by Eq. (1).

From Eq. (7), the time scale ratio in beach change between model and prototype is expressed by

$$\frac{t_m}{t_p} = \frac{\Lambda_m}{\Lambda_p}\frac{(q_x)_p}{(q_x)_m}\frac{z_m}{z_p}\frac{x_m}{x_p} \tag{8}$$

Denoting the scale ratio of model parameter to prototype parameter by $\lambda_{parameter}$, the experimental conditions mentioned in 3. (1) ~ (3) can be presented as

$$\left.\begin{aligned}
&\lambda_l = \lambda_x = \lambda_z = \lambda_{l_0} && \text{(Geometrical similitude)}\\
&\lambda_H = \lambda_{L_o} \\
&\lambda_T = \lambda_x^{1/2} && \text{(Froude law)}\\
&\lambda_S = 1 && \text{(Specific gravity of beach material is assumed to be the same in model and prototype)}\\
&\lambda_\nu = \lambda_\rho = 1 && \text{(Properties of fluid are the same in model and prototype)}
\end{aligned}\right\} \tag{9}$$

$$\left.\begin{aligned} \lambda_A &= 1 \\ \lambda_g &= 1 \end{aligned}\right\}$$

Rearranging Eq. (8) with Eq. (9), the following relationship is yielded

$$\lambda_t = \lambda_{qx}^{-1} \lambda_l^2 \tag{10}$$

For introducing the time scale using Eq. (10), the relationship which specifies exactly the on-offshore sand transport rate in beach change is necessary. Such a formulation of sand transport has not been obtained completely, but empirical relationships of sand transport in a bed load were proposed by Madsen and Grant (1976) and Tsuchiya et al. (1984) from experimental results. These relationships are only applicable in the offshore zone, not surf zone. Tsuchiya et al. proposed the relationship of Kalinske- Brown type

$$\frac{q_x}{U^* d} = K (\tau^* - \tau^*_c)^2 \tag{11}$$

where

$$\tau^* = \frac{U^{*2}}{sgd} \qquad \text{(Shields parameter)} \tag{12. a}$$

$$\tau^*_c = \frac{U^*_c{}^2}{sgd} \sim 0.05 \qquad \text{(Threshold Shields number)} \tag{12. b}$$

$$K = 1.7 \left(1 + \frac{300d}{2a_w}\right) \qquad \text{for} \frac{2a_w}{d} > 100 \tag{12. c}$$

where U^* is the shear velocity at the bed, U^*_c the critical shear velocity, a_w the orbital radius of water particle, and K the constant depending on the ratio of orbital diameter to grain size, $2a_w/d$. The shear velocity at the bed is expressed by

$$U^* = \sqrt{\frac{f_w}{2}}\, Ub_{max} \tag{13}$$

where f_w is the wave friction factor, Ub_{max} the one half of the maximum horizontal velocity of water particle in the vicinity of the bed $\{\pi H/(2T\sinh 2\pi h/L)\}$. By Swart (1976), the friction factor, f_w, is expressed by

$$\left.\begin{aligned} f_w &= 0.0025 \exp\left\{5.21 \left(\frac{a_w}{k_s}\right)^{-0.19}\right\} && \text{for} \quad \frac{a_w}{k_s} > 1.57 \\ f_w &= 0.3 && \text{for} \quad \frac{a_w}{k_s} < 1.57 \end{aligned}\right\} \tag{14}$$

where k_s is the roughness length of the bed which is nearly equal to the sand size. Consequently, the sand transport rate in a bed load by

Eq. (11) becomes

$$q_x = K U^{*5} s^{-2} g^2 d^{-1} - 0.08 K U^{*3} s^{-1} g^{-1} + 0.04^2 K U^* d \tag{15}$$

Substituting Eq. (13) into Eq. (15) and taking the scale ratio of the sand transport rate, we obtain

$$\left.\begin{aligned}
\lambda_{q_x} &= \lambda_K \quad \lambda_{f_w}^{5/2} \quad \lambda_d^{-1} \quad \lambda_H^{5} \quad \lambda_T^{-5} \quad \lambda_{\sinh\frac{2\pi h}{L}} \\
\lambda_{q_x} &= \lambda_K \quad \lambda_{f_w}^{3/2} \quad \lambda_H^{3} \quad \lambda_T^{-3} \quad \lambda_{\sinh\frac{2\pi h}{L}}^{-3} \\
\lambda_{q_x} &= \lambda_K \quad \lambda_{f_w}^{1/2} \quad \lambda_d \quad \lambda_H \quad \lambda_T^{-1} \quad \lambda_{\sinh\frac{2\pi h}{L}}^{-1}
\end{aligned}\right\} \tag{16}$$

Furthermore, combining Eqs. (10) and (16), and arranging those by Eq. (9), the time scale relationship can be given as

$$\left.\begin{aligned}
\lambda_t &= \lambda_K^{-1} \quad \lambda_{f_w}^{-5/2} \quad \lambda_d \quad \lambda_l^{-1/2} \\
\lambda_t &= \lambda_K^{-1} \quad \lambda_{f_w}^{-3/2} \quad \lambda_l^{1/2} \\
\lambda_t &= \lambda_K^{-1} \quad \lambda_{f_w}^{-1/2} \quad \lambda_d^{-1} \quad \lambda_l^{3/2}
\end{aligned}\right\} \tag{17}$$

It is clear from Eq. (17) that the time scale is subjected to the scale effect of $2a_w/d$ (λ_K), the scale effect of wave friction factor, λ_{f_w}, and the grain size scale, λ_d. Using the sand transport rate by Eq. (11), the time scale may be given by the condition which is satisfied simultaneously the three equations in Eq. (17).

On the other hand, Madsen and Grant proposed the dimensionless bedload sand transport rate in the half wave cycle, q_x/wd, using the Shields number, $\tau_{0m}/\rho sgd$, as

$$\frac{q_x}{wd} = 12.5\left(\frac{\tau_{0m}}{\rho sgd}\right)^3 \tag{18}$$

where w is the sediment fall velocity, ρ the fluid density, s the specific gravity of the sediment in water, and τ_{0m} the maximum bottom shear stress by

$$\tau_{0m} = \frac{1}{2} f_w \rho U_{bmax}^2 \tag{19}$$

Combining Eqs. (13) and (19), the scale ratio becomes as

$$\lambda_{q_x} = \lambda_{f_w}^{3} \quad \lambda_w \quad \lambda_d^{-2} \quad \lambda_s^{-3} \quad \lambda_H^{6} \quad \lambda_T^{-6} \quad \lambda_{\sinh\frac{2\pi h}{L}}^{-6} \quad \lambda_g^{-3} \tag{20}$$

The similarity relationship of the sediment fall velocity , as the authors (1984) considered already, may generally be expressed

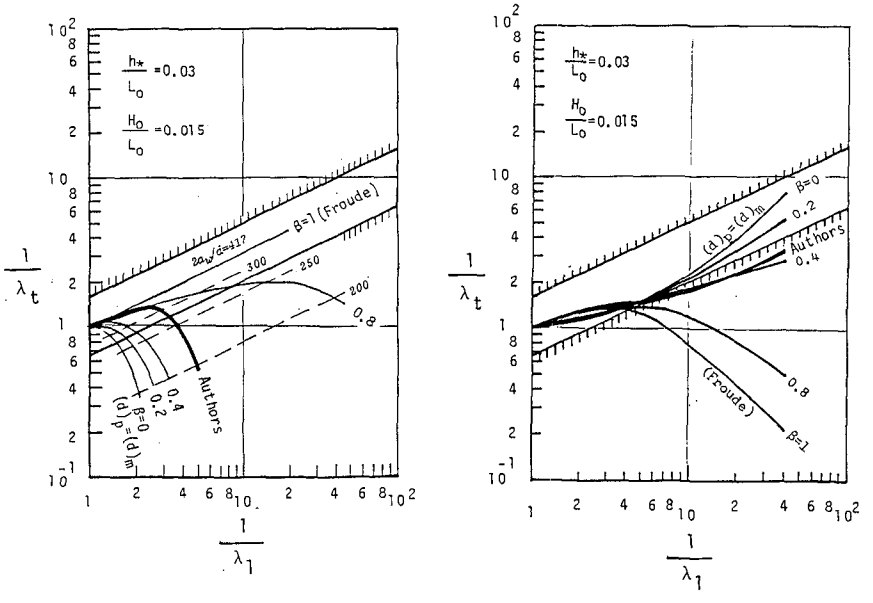
$$\lambda_w = \lambda_d^{n_w} \tag{21}$$

where n_w=2, 1, 2/3, and 1/2 for Stokes', Allen's, Karman's, and Newton's formulas of sediment fall velocity, respectively. Combining Eqs. (10), (20) and (21), and arranging it with Eq. (9), the time scale can be reduce to

$$\lambda_t = \lambda_{f_w}^{-3} \lambda_d^{2-n_w} \lambda_l^{-1} \tag{22}$$

It is recognized from Eq. (22) that the time scale relationship is influenced by the scale effects of the wave friction factor and grain size.

Now consider how the grain-size scale and the ratio of the orbital diameter of water particles to the grain size influence on the time scale. Eq. (1) may be expressed in a generalized form as



(a) Time scale calculated by using the sand transport rate by Tsuchiya et al.

(b) Time scale calculated by using the sand transport rate by Madsen and Grant.

Fig. 7 Comparison of the time scale obtained experimentally with the semi-theoretical time scale.

$$\lambda_d = \alpha \lambda_l^{\beta} \tag{23}$$

where

$$\left.\begin{aligned} \alpha &= \left(\frac{1}{1.7}\right)^a \\ \beta &= b \end{aligned}\right\} \tag{24}$$

Fig. 7 (a) shows the relationship between the time scale and the experimental scale which was calculated numerically using Eqs. (10), (11) and (23) in the experimental conditions of Run No. 3 in Table 1 and of the beach change at the dimensionless position of $h_*/L_0=0.03$. To understand the influence of grain-size scale on the time scale, the coefficient and exponent of Eq. (23) are changed in steps as $\beta=0$ {$(d)_m=(d)_p$}, 0.2, 0.4, 0.8, and 1.0 when $\alpha=1$; and $\beta=b$ when $\alpha=(1/1.7)^a$ {same to Eq. (1)} From Fig. 7 (a) the influence of grain-size scale for on the time scale can therefore be understood easily. Additionally, the effect of $2a_w/d$ is shown by the broken lines in the figure. The result calculated numerically using the sand transport rate by Madsen and Grant is shown in Fig. 7 (b) taking β as parameter. It is indicated from Fig. 7 that the grain-size scale influences considerably on the time scale.

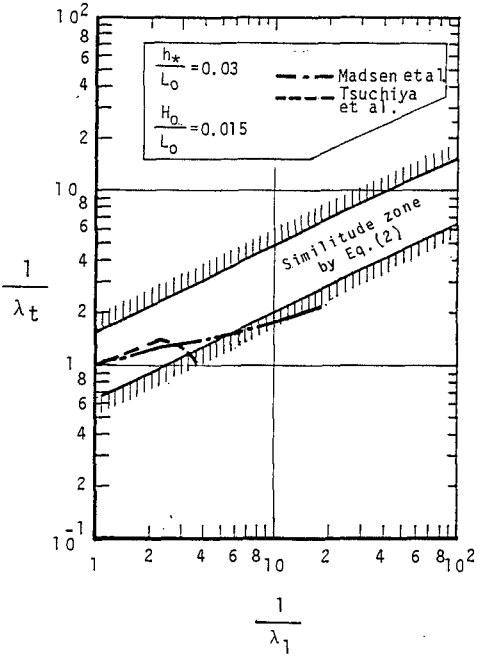


Fig. 8 Comparison of empirical time scale with semi-theoretical time scales.

Comparisons of the time scale relationship by Eq. (2) with the two semi-theoretical time scales mentioned in 6 are shown in Figs. 7 (a) and 7 (b). As is seen in these figures, there exists a quite difference between the two by the relationship of sand transport rate used in calculation. The difference in the time scale relationships is subjected to change in the exponent β in Eq. (23). The comparison of the time scale relationship by Eq. (2) with the semi-theoretical time scales which were obtained using the scale-model relationship of Eq. (1) is shown in Fig. 8. In the experimental scale range of $1 \geq \lambda_l > 1/4$, the semi-theoretical time scales agree well with the empirical time scale relationship proposed.

7. CONCLUSIONS

The main conclusions in this paper are summarized as;
(1) Based on the results of experiments which were conducted by applying the authors' scale-model relationship of Eq. (1), the empirical time scale relationship, which is held the similarity between the model and prototype in transitional beach change processes from an initial even slope to an equilibrium, was proposed by Eq. (2). The average tendency in the similitude zone for the time scale coincides nearly with the Froude time scale.
(2) The model beach processes which was set up using Eqs. (1) and (3) can well reproduce beach changes and breaking wave properties in prototype.
(3) The semi-theoretical time scale introduced by the continuity equation of beach change, the sand transport rate and the generalized scale-model relationship is not only subjected the grain size scale but the effect due to the wave friction factor and the ratio of orbital diameter of water particle to grain size of the bed material.
(4) Two semi-theoretical scales which were obtained by using the authors' scale-model relationship are a little different from those by formulas of sand transport rates, but agree well with the empirical time scale within the range of experimental scale, $1 \geq \lambda_t > 1/4$.

CHAPTER 89

LENGTHS OF RUNS OF JUST BREAKING AND BROKEN WAVES IN IRREGULAR WAVE TRAIN ON GENTLE SLOPES

Koichiro IWATA*
and
Shunji ITOH**

ABSTRACT

This paper is aimed to investigate theoretically and experimentally the variations of the probability distribution and mean values of the run length and total run length of just breaking and broken waves in an irregular wave train on gentle slopes. The theoretical model developed here is shown to be valid for evaluating the lengths of runs of just and broken waves from deep water up to the shoreline.

1. INTRODUCTION

Different from regular waves, the individual waves in an irregular wave train do not break at one specific location, but break at many different locations on sloping bottom, since their wave height and wavelength are different each other, in general. The estimation of the probability of successive breaking waves and its mean value is basically very important for coastal engineering problems. Although many theoretical models[1)-5)] have been proposed to estimate variations of the probability of wave breaking and wave statistics such as the mean, one-third and one-tenth largest wave heights, there has been no literature dealing with lengths of runs of just breaking and broken waves in an irregular wave train on sloping bottom.

With this background in mind, this paper is to discuss the variations of the probability of wave breaking and lengths of runs of successive just breaking and broken waves from deep

** M. Eng., Civil Engineer, Nitsuken-Design Co.,Ltd.,Civil Engineering Design Office, Osaka, Osaka 541, JAPAN.

water up to the shoreline on gentle slopes. First of all, the theoretical model is described to estimate the probability distribution and mean value of the lengths of runs of just breaking and broken waves for a given probability of occurrence of just breaking and broken waves. Next, a theoretical model is presented to estimate the probability of occurrence of just breaking and broken waves on gentle slopes. The numerical method combining the two theoretical models is proposed to evaluate the variation of the probability distribution and mean values of the lengths of runs of just breaking and broken waves for various kinds of waves on gentle slopes. Secondly, laboratory experiments are carried out to investigate the variation of the probability distribution and mean values of the run and total run lengths of just breaking and broken waves as well as to examine the validity of the numerical method on gentle slopes. The validity of the method proposed here is verified by the laboratory experiments. Using the method, the diagrams are presented to evaluate the variation of the mean run length and mean total run length of broken waves of 6 kinds of irregular waves on gentle slopes of 1/10,1/20,1/30 and 1/50.

2. DEFINITION OF RUN LENGTH AND TOTAL RUN LENGTH OF JUST BREAKING AND BROKEN WAVES

A run length of just breaking wave is defined by the sequence of a just breaking wave. A total run length of just breaking wave is defined by the number of waves between a group of just breaking waves and the next occurrence of a just breaking wave by the succeeding group of waves. The same definition is made to the run length and total run length of broken wave. *The just breaking wave* defined in this paper is an critical wave just at the inception of breaking and has little air bubble. *The broken wave* defined here includes waves in the transformation process immediately after the inception of breaking as well as air-entrained waves with a turbulent water surface. We permit here, however, for the sake of convenience of treatment that the broken wave includes the just breaking wave.

The run length (J_1) and the total run length (E_1) of the just breaking wave, in the case shown in Fig.1, are $J_1=3$ and $E_1=6$. On the other hand, the run length (J_2) and total run length (E_2) of the broken wave are $J_2=4$ and $E_2=6$, as indicated in Fig.1. It should be noted that the broken wave includes the just breaking wave, as stated above.

3. NUMERICAL METHOD

3.1 Estimation of run length and total run length

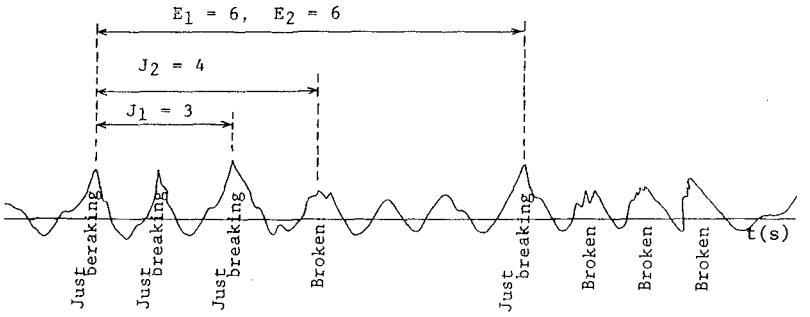

Fig.1 Schematic illustration of definition of run length and total run length of just breaking and broken waves.

Based on the random process which successive waves are uncorrelated, the probability distributions of run lenghts, J_1 and J_2 and total run lengths, E_1 and E_2 of just breaking and broken waves and their mean values, $\bar{J}_1$, $\bar{J}_2$, $\bar{E}_1$ and $\bar{E}_2$ are expressed by[6),7)]

$$\left.\begin{aligned} &P_1(J_1) = P_{JB}^{J_1-1} \cdot Q_{NB}\ ,\quad Q_1(E_1) = \left(\frac{P_{JB}\cdot Q_{NB}}{P_{JB}-Q_{NB}}\right)\left(P_{JB}^{E_1-1} - Q_{NB}^{E_1-1}\right) \\ &\bar{J}_1 = 1/(1-P_{JB}),\quad \bar{E}_1 = 1/P_{JB}(1-P_{JB}) \\ &P_{JB} + Q_{NB} = 1 \end{aligned}\right\}, \tag{1}$$

$$\left.\begin{aligned} &P_2(J_2) = P_B^{J_2-1} \cdot Q_N\ ,\quad Q_2(E_2) = \left(\frac{P_B\cdot Q_N}{P_B-Q_N}\right)\left(P_B^{E_2-1} - Q_N^{E_2-1}\right) \\ &\bar{J}_2 = 1/(1-P_B)\ ,\quad \bar{E}_2 = 1/P_B(1-P_B) \\ &P_B + Q_N = 1 \end{aligned}\right\}. \tag{2}$$

In Eqs.(1) and (2), $P(J_i)$ is the probability of occurrence of the run length J_i, $Q(E_i)$ the probability of occurrence of the total run length E_i, $\bar{J}_i$ the mean run length and $\bar{E}_i$ the mean total run length, where subsuffix i is either 1 or 2 and i=1 and i=2 mean respectively the quantity regarding the just breaking and broken waves. P_{JB} in Eq.(1) is the probability of occurrence of the just breaking wave, and Q_{NB} in Eq.(1) is the probability of non-occurrence of the just breaking wave. P_B and Q_N in Eq.(2) are the probability of occurrence and non-occurrence of the broken wave, respectively. Therefore, given P_{JB} and Q_{NB}, the probability distributions of run length and total run length of the just breaking wave, $P(J_1)$ and $Q(E_1)$, and their mean values, $\bar{J}_1$ and $\bar{E}_1$ are calculated with Eq.(1). Similarly, given P_B and Q_N, the probability distributions and mean values of run length and total run length of the broken wave are evaluated with Eq.(2).

3.2 Estimation of probability of occurrence of just breaking and broken waves

The theoretical model developed here to obtain P_{JB}, Q_{NB}, P_B and Q_N follows basically that of Sawaragi and Iwata[3]. Individual waves in an irregular wave train are assumed to be uncorrelated each other and to experience independently shoaling and breaking. In addition, once an individual wave breaks, the wave is assumed to keep broken up to the shoreline on gentle slopes.

(1) Shoaling condition:
The shoaling condition presented for regular waves, which is based on the linear wave theory, is employed,

$$\left.\begin{aligned} H_S &= K_S H_O \\ K_S &= \left(\tanh kh + kh(1-\tanh^2 kh)\right)^{1/2} \end{aligned}\right\} \qquad (3)$$

where K_S is the shoaling factor, Ho the equivalent wave height in deep water, H_S the wave height at the depth of h and k the wave number ($=2\pi/L$; L the wavelength at the depth of h).

(2) Breaking limit:
Modifying the breaking limit presented by Goda[2] for regular waves, the following equation is used for the 1st approximation,

$$H_b/Lo = 0.15(1-\exp(1.5\pi(h_b/Lo)(1-15S^{4/3}))) \qquad (4)$$

where H_b is the wave height at breaking point, h_b the still-water depth at breaking point, Lo the wavelength in deep water and S the bottom slope. Eq.(4) has been shown to provide a good approximation for the breaking limit of individual waves in an irregular wave train[8),9)].

(3) Mean water level variation from stillwater level:
The mean water level $\bar{\eta}$ at the depth of h is calculated by[10)],

$$\frac{d\bar{\eta}}{dx} = -\frac{1}{(\bar{\eta}+h)}\frac{d}{dx}\left(\frac{1}{8}\bar{H}^2\left(\frac{1}{2}+\frac{2kh}{\sinh 2kh}\right)\right) \qquad (5)$$

where $\bar{H}^2$ is the mean square wave height, x the horizontal distance and $\bar{\eta}$ the mean water level height from the stillwater level. In the numerical calculation, the following equation is employed in place of Eq.(5),

$$\left.\begin{aligned} \bar{\eta}_{j+1} &= \bar{\eta}_j - \frac{D_k}{(h+\bar{\eta})_{j+1/2}}\left(\bar{H}^2_{j+1} - \bar{H}^2_j\right), \\ (h+\bar{\eta})_{j+1/2} &= \left((h+\bar{\eta})_j+(h+\bar{\eta})_{j+1}\right)/2 \\ D_k &= \frac{1}{8}\left(\frac{1}{2}+\frac{2kh_j}{\sinh 2kh_j}\right) \end{aligned}\right\} \qquad (6)$$

where subsuffix j indicates the location of calculation.

(4) Probability of occurrence of just breaking and broken waves, P_{JB} and P_B:

As stated in Section 2, the broken wave includes the just breaking wave. Therefore, the probability of occurrence of the broken wave, P_B at the depth of h^* can be obtained by integrating the probability of occurrence of just breaking waves, P_{JB} from deep water to the water depth, h^*;

$$P_B(h^*) = \int_{h^*}^{\infty} P_{JB}(h)\, dh \quad . \tag{7}$$

The probability of occurrence of the just breaking wave, $P_{JB}(h)$ at the depth of h is determined by the ratio of the number of waves which satisfy the breaking limit to the total number of waves at the depth. Using Eq.(7), the probability of occurrence of just breaking waves, $(P_{JB}(h))_j$ between the depths, h_{j-1} and h_j can be described by

$$(P_{JB}(h))_j = ((P_B)_j - (P_B)_{j-1})/(h_{j-1} - h_j) \tag{8}$$

where h_{j-1} is larger than h_j, and $(P_B)_j$ and $(P_B)_{j-1}$ are the probability of occurrence of broken waves at the depth of h_j and h_{j-1}.

3.3 Procedure of calculation

Based on the previous studies[2),3)], the stillwater depth, h on the sloping bottom was divided into many numbers of portion, as illustrated in Fig.2. The non-dimensional variation of the stillwater depth, $\Delta h/Ho$ in the portion was varied according to the change of dimensionless stillwater depth, h/Ho. That is, $\Delta h/Ho$ =1.0, 0.25 and 0.1 were chosen for h/Ho=5-30, h/Ho=2-5 and h/Ho≤2, respectively. The calculation was done by the step-by-step method[2),3),7)], using the waves given at deep water as an input wave condition. Two kinds of waves such as the waves generated in a wave tank which will be mentioned later and the theoretically proposed waves expressed by Eq.(12) in Section 5.

The outline of calculation method in case of the experimental waves is described in this section. Assuming that the wave period and total number of individual waves are constant from deep water up to the shoreline, the variation of the wave height due to shoaling was calculated with Eq.(4) until the wave arrived at the shoreline. The wave which exceeded the breaking limit of Eq.(4) was treated as the broken wave. The probability

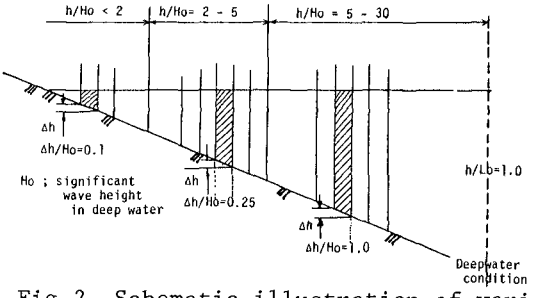

Fig.2 Schematic illustration of variation of Δh due to change of stillwater depth, h.

density corresponding to the broken waves was re-distributed, in proportion to that of non-broken waves, to the probability density of non-broken waves in order to determine $\bar{H}2$ and $\bar{\eta}$ with Eq.(6). The detailed calculation technique is referred to the references 2),3),7) and 9).

The probability of occurrence of broken waves, $P_B(h)$ at the water depth of h is obtained by the ratio of the total number of broken waves from deep water up to the depth, h to the total number of waves at the depth of h. The probability of occurrence of just breaking waves, $P_{JB}(h)$ between the depths, $h+\Delta h/2$ and $h-\Delta h/2$ can be calculated with Eq.(8),where Δh is a small quantity. In the calculation,Δh given by the following equation was employed to evaluate $P_{JB}(h)$,

$$\Delta h/Ho = (\Delta x/Ho)\ S = 1.5\ S$$

where Δx is a small increment of horizontal distance and Δx is taken 1.5 times the one-third largest wave height, Ho in deep water. The reason of this is that the width of coastal and offshore structures is around 1.5 times the design wave height. Using $P_B(h)$ and $P_{JB}(h)$ thus calculated, the probability distribution and mean value of lengths of runs of just breaking and broken waves are easily determined with Eqs.(1) and (2).

4. LABORATORY EXPERIMENT

4.1 Equipment and procedure

In the experiment, an indoor wave tank in 0.95m height, 0.7m width and 25m length at Nagoya University was used. The experimental set-up is illustrated in Fig.3. A flap-type wave generator controlled by Oil-Pressure Servo was installed at one end of wave tank. The water is perfectly shut out from the area behind the wave board. Therefore, the input electrical signal is smoothly converted to the wave motion. At the other end of wave tank, the wooden uniform slope was installed. Two kinds of slopes such as 1/15 and 1/30 were used. Three kinds of irregular waves (W.-2,W-3 and W.-4 in Table 1) were generated to have a Bretschneider spectrum as an expected spectrum. One irregular wave (W.-1 in Table 1)

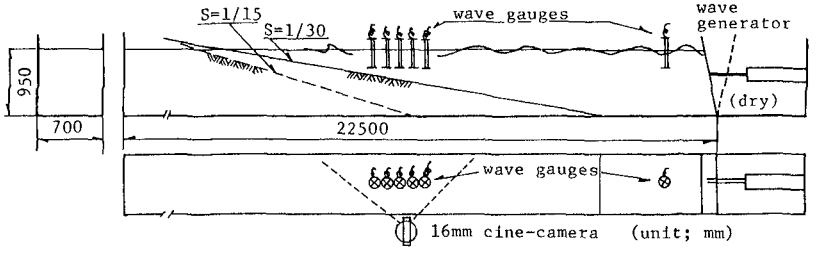

Fig.3 Schematic view of experimental set-up.

Table 1 Experimental waves

Bottom Slope	Case	$\bar{H}$ (cm)	$\bar{T}$ (s)	$H_{1/3}$(cm)	$T_{1/3}$(s)	Ho (cm)	Q_p	f_c (Hz)	Wave
1/15	Case 1	11.2	1.4	13.8	1.3	14.9	7.03	0.45	W.- 1
	Case 2	6.1	1.0	9.3	1.1	9.8	1.97	0.30	W.- 2
1/30	Case 3	8.4	1.0	12.5	1.1	13.4	1.80	0.35	W.- 3
	Case 4	3.9	0.9	6.0	1.1	6.4	1.52	0.30	W.- 4

$\bar{H}$; mean wave height, $\bar{T}$; mean wave period, $H_{1/3}$; significant wave height $T_{1/3}$; significant wave period, Ho; significant wave height in deep water Q_p; spectral peakedness, f_c; peak frequency of power spectrum

was generated to have double peaks on its power spectrum. Some of their spectral and statistic values are given in Table 1.

The water surface profiles were not only measured by capacitance-type wave gauges, but also simultaneously filmed, through glass side wall,by a 16mm high speed cine-camera (50 frames/s) in order to obtain the one-to-one correspondence between the waves in time domain and those in spatial one. This enabled us to omit noise-like small waves frequently observed in the surf zone as well as to classify clearly the waves into the just breaking, broken and unbroken waves. The measuring time of waves was about 12 minutes. Water surface profiles measured by the wave gauges were recorded on magnetic tapes. The irregular waves (W-1,W-2,W-3 and W-4) were generated 5 or 6 times so that the waves at 25 different points located from h=63cm up to near the shoreline were possible to be measured.

4.2 Data analysis

The irregular wave was analyzed by both the wave-by-wave and spectral analyses. The individual wave in an irregular wave train was defined by the zero-downcrossing method. The water surface profile was sampled at every 0.1 s. The wave power spectrum was calculated by B-T[11] method with data of 4800 points. The maximum lag number and degree of freedom were 80 and 120, respectively.

Anlayzing 16mm motion films by means of a film motion analyzer, all the individual waves were carefully classified into the just breaking, broken and non-broken waves. Special care was paid to determine the just breaking wave, since the just breaking wave is defined, as stated already, as the critical wave with little air at the inception of breaking. The breaking point and wave height at the breaking point were all determined by analyzing the 16mm motion films with help of wave data taken by the wave gauges. The high pass filter was used to eliminate the surf beat from wave profiles near the shoreline so as to definitely obtain the individual waves. The number of individual waves generated at the wave board in experiments was 420, 520, 595 and 550, for the waves of W.-1, W.-2, W.-3 and W.-4, respectively.

4.3 Results and discussion

Figure 4 shows one example of time series of successive 206 individual waves in the case of wave, W.-1, where symboles

□ and ■ indicate, respectively, the just breaking and broken waves. The wave without the symboles is non-broken wave. Therefore,most of individual waves at the depth of h/Ho=2.11 in Fig.4 are the non-broken wave. With the irrgular wave approaches to the shoreline, the number of the just breaking wave increases to a maximum and then decreases. The maximum occurrence of just breaking waves in Fig.4 is around h/Ho = 1.01. On the other hand, the number of the broken wave increases continuously as the irregular wave train propagates to the shoreline and most of the individual waves become the broken wave, as indicated in Fig.4.

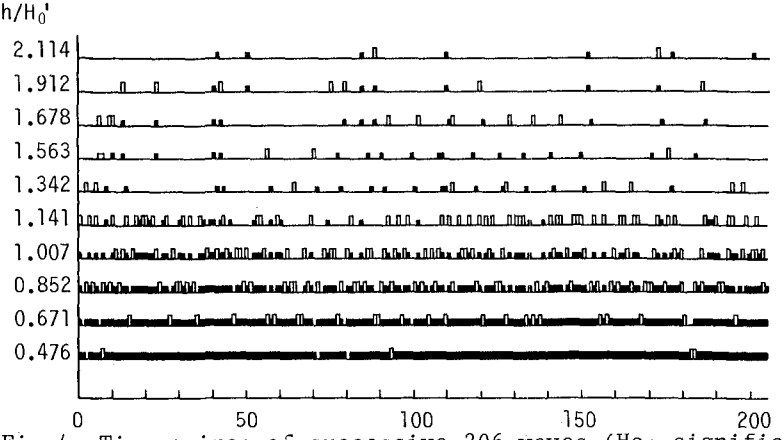

Fig.4 Time seires of successive 206 waves (Ho; significant wave height in deep water).

(1) P_{JB} and P_B

As shown in Fig.5, P_{JB} increases to a maximum and then decreases as the irregular wave approaches to the shoreline. The experiments showed that the maximum value of P_{JB} is 0.29 at h/Ho=1.14, 0.24 at h/Ho=1.00, 0.11 at h/Ho=0.83 and 0.14 at h/Ho=1.1, respectively, for the wave, W.-1,W.-2,W.-3 and W.-4. $P_{JB}(h)$ is given here by $P_B(h-\Delta h/2)-P_B(h+\Delta h/2)$,and $\Delta h=1.3H_o$, as in Eq.(10). The theoretical values estimated with Eqs.(3)-(10) are shown in Fig.5. At the same time, the theoretical values estimated with Eqs.(4)-(10) and Eq.(11) in place of Eq.(3) are shown for comparison. Eq.(11) was proposed as the shoaling condition for finite amplitude regular

$$\left.\begin{array}{ll} H/H_o = K_s & ; \quad gHT^2/h^2 \leq 30 \\ Hh^{2/7} = \text{const.} & ; 30 < gHT^2/h^2 \leq 50 \\ Hh^{5/2}(\sqrt{gHT^2/h^2} - 2\sqrt{3}) = \text{const.} & ; \quad gHT^2/h^2 > 50 \end{array}\right\} \quad (11)$$

waves by Shuto[12]. In Eq.(11), g is the gravitational acceleration, T the wave period. The theoretically estimated values agree quantitatively well with experimental ones. There are, however, some discrepancies about a maximum value of P_{JB} between the calculations and experimental values. The main reasons of this may be (i) Eq.(4) is not a better equation,

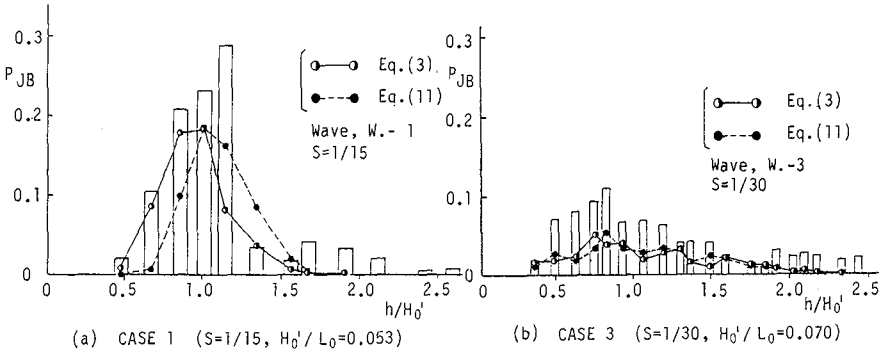

Fig.5 Variation of P_{JB} with decreasing of water depth.

and (ii) number of waves in the surf zone decreases, in the worst case, to 90% of the number of waves generated at the wave board in the experiment.

The probability of occurrence of broken waves, P_B becomes continuously large, as shown in Fig.6, as the wave approaches the shoreline. The agreement of calculated values with experimental ones is much better than the case of P_{JB}. It can be said that P_B is well predicted by the numerical model proposed in this paper. Figure 6 shows that 98% of the wave,W.-1 and about 80% of the wave, W.-3 are broken waves at the non-dimensional water depth h/Ho=0.5.

Figures 5 and 6 show that theoretical values estimated with Eq.(3) as shoaling condition seem to be in better agreement with experimental values more than ones estimated with Eq.(11) as shoaling condition.

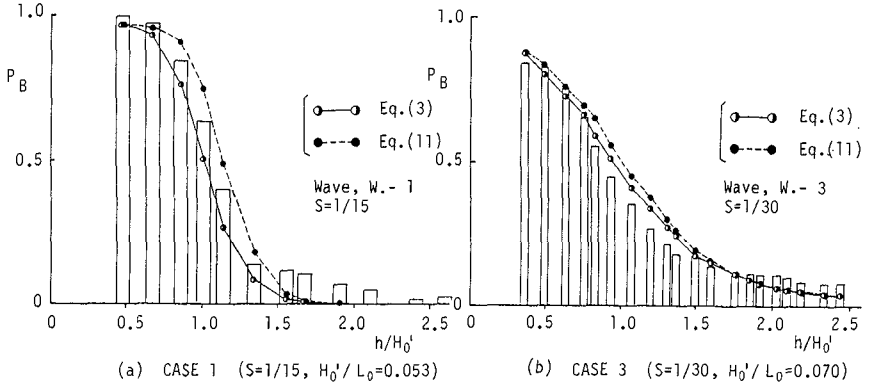

Fig.6 Variation of P_B with decreasing of water depth

(2) $P_1(J_1)$, $P_2(J_2)$, $Q_1(E_1)$ and $Q_2(E_2)$

Figures 7 and 8 show some examples of $P_1(J_1)$ and $Q_1(E_1)$, and $P_2(J_2)$ and $Q_2(E_2)$, respectively. Concerning $P_1(J_1)$, the probability of run length $J_1=1$, $P_1(1)$ is predominantly large, compared with $P_1(2)$ and $P_1(3)$. $P_1(3)$ is negligibly small even at h/Ho=1.066 where P_{JB} becomes maximal. On the other hand, the probabilities of total run lengths, $Q_1(1)$, $Q_1(2)$,$Q_1(3)$, $Q_1(4)$ and $Q_1(5)$ are the same order, although $Q_1(E_1)$ tends to decrease as E_1 becomes large.

The probability distribution of run length of broken waves, $P_2(J_2)$ differs from that of $P_1(J_1)$. $P_2(2)$,$P_2(3)$,$P_2(4)$ and $P_2(5)$ are comparatively large, compared with $P_2(1)$. In case of $P_1(J_1)$, $P_1(1)$ decreases to a minimum and then increases, and $P_1(2)$ and $P_1(3)$ increase to a maximum and then decrease as the waves advance to the shoreline (see Fig.9). In contrast, $P_2(1)$ decreases almost monotonously. The location where $P_1(1)$ becomes a minimum and $P_1(2)$, $P_2(2)$ and $P_2(3)$ take a maximum value correspond to the location at which P_{JB} becomes maximal. The theoretically estimated values are in good agreement with experimental values. The calculation method which employs Eq.(3) as the shoaling condition seems better than one using Eq.(11) to evaluate $P_1(J_1)$,$Q_1(E_1)$,$P_2(J_2)$ and $Q_2(E_2)$.

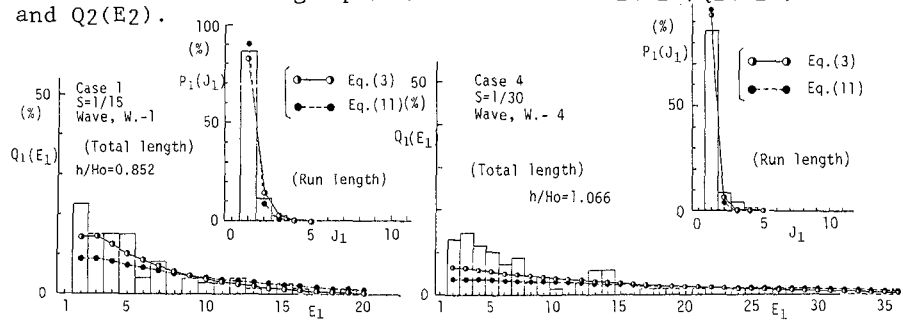

Fig.7 Probability distributions of J_1 and E_1.

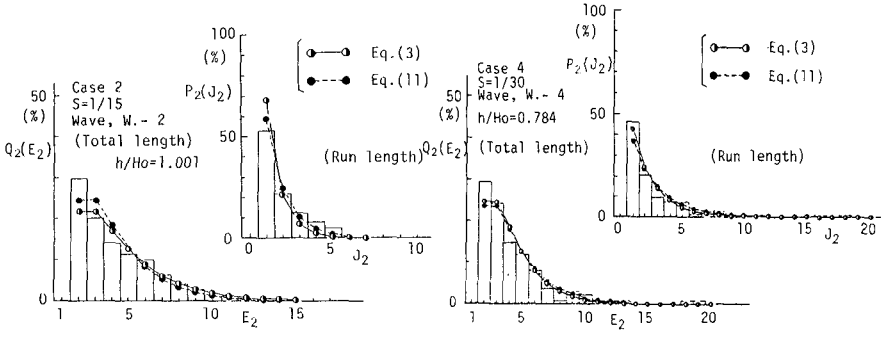

Fig.8 Probability distributions of J_2 and E_2.

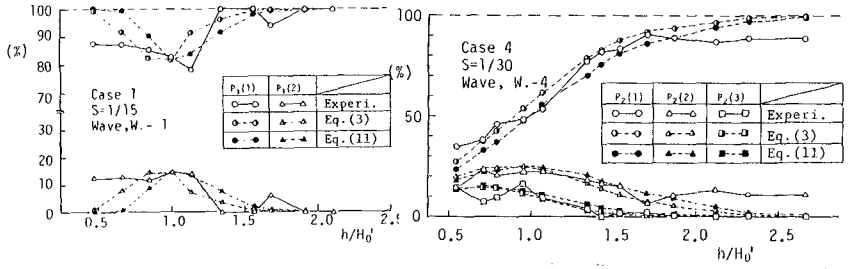

Fig.9 Variation of $P_1(1)$, $P_1(2)$, $P_2(1)$, $P_2(2)$, $P_2(3)$ with h/Ho.

(3) $\bar{J}_1$, $\bar{J}_2$, $\bar{E}_1$ and $\bar{E}_2$

The mean run length of just breaking wave, $\bar{J}_1$ never exceeds 2.0 from deep water up the shoreline, as shown in Fig.10. The maximum value of $\bar{J}_1$ was 1.33, as given in Table 2. This fact means that two waves never break successively on average. There is discrepancy between experimental and calculated values, especially around h/Ho≅1 at which PJB becomes maximal. This reason is that the theoretical model cannot estimate well PJB around h/Ho≅1 at which waves break most frequently.

The mean total run length of just breaking wave, $\bar{E}_1$ decreases to a minimum and then increases as increase of h/Ho, as shown in Fig.11. $\bar{E}_1$ is strongly related to PJB and $\bar{E}_1$ increases with decreasing of PJB. The difference between experiments and calculations is due to the reason that the theoretical model cannot estimate very well PJB, as stated above.

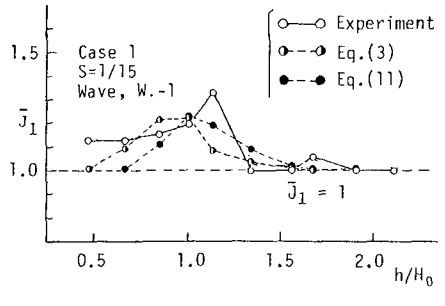

Fig.10 Variation of $\bar{J}_1$ with h/Ho.

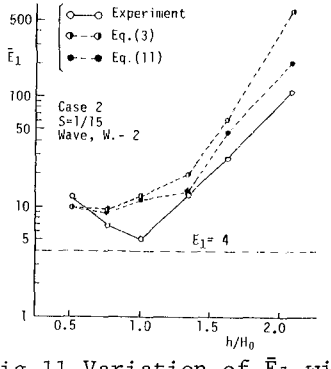

Fig.11 Variation of $\bar{E}_1$ with h/Ho.

Table 2 Experimental values of $\bar{J}_{1max}$, $\bar{E}_{1min}$ and $\bar{E}_{2min}$.

Bottom Slope	Case	Ho/Lo	$\bar{J}_{1max}$	$\bar{E}_{1min}$	$\bar{E}_{2min}$	Wave
1/15	Case-1	0.053	1.33	4.26	3.92	W.- 1
1/15	Case-2	0.050	1.25	5.07	4.14	W.- 2
1/30	Case-3	0.070	1.09	8.93	4.68	W.- 3
1/30	Case-4	0.031	1.24	8.12	3.89	W.- 4

Figures 12 and 13 show variations of $\bar{J}_2$ and $\bar{E}_2$ with h/Ho. The mean run length of broken waves, $\bar{J}_2$ increases continuously from 1 with h/Ho decreases. The variation of $\bar{J}_2$ with h/Ho is very similar to that of P_B. Since the theoretical model estimates very well P_B, the agreement between calculated and experimental values is very good. The variation of $\bar{E}_2$ with h/Ho is very similar to that of $\bar{E}_1$. $\bar{E}_2$ becomes minimal at the location where P_{JB} becomes maximal. According to Eqs.(1) and (2), the minimum value of $\bar{E}_1$ and $\bar{E}_2$ is 4. The minimum values obtained in the experiments was, as given in Table 2, more than 3.9, which is very close to 4. Therefore, it may safely be said that the random process model which considers no correlation between waves is a good model to evaluate accurately the lengths of runs of broken waves.

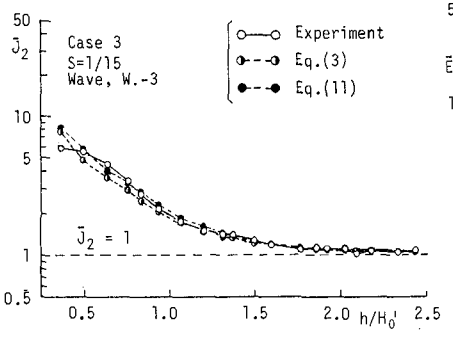

Fig.12 Variation of $\bar{J}_2$ with h/Ho.

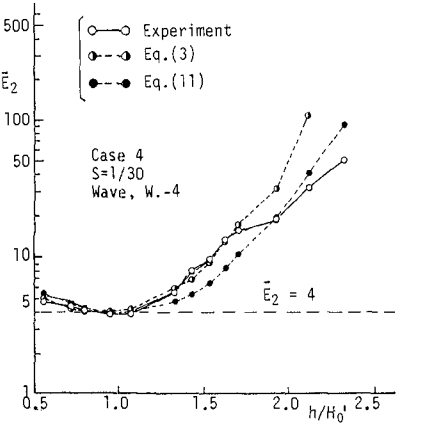

Fig.13 Variation of $\bar{E}_2$ with h/Ho.

5. DIAGRAMS OF $\bar{J}_2$ and $\bar{E}_2$

The theoretical model proposed in this study has been shown to evaluate well the lengths of runs of broken waves. Therefore, we try here to calculate the variation of the mean run and total run lengths, $\bar{J}_2$ and $\bar{E}_2$ with wave propagation from deep water to the shoreline on gentle slopes.

5.1 Calculation method

In the numerical calculations, 4 kinds of bottom slopes such as 1/10,1/20,1/30 and 1/50 and 6 kinds of waves such as Ho/Lo=0.002,0.005,0.01,0.02,0.04 and 0.08 were employed. The irregualr wave given by the following equation was employed as the deep water wave in order to obtain the diagram of $\bar{J}_2$ and $\bar{E}_2$.

$$P(H^*,T^*)=1.35H^*\cdot T^{*3}\exp\left(-\left(\frac{1}{4}H^{*2}+0.675T^{*4}\right)\right) \quad (12)$$

Here, $H^*=H/\bar{H}$, $T^*=T/\bar{T}$, and $\bar{H}$ and $\bar{T}$ are the mean wave height and period, respectively. The wave given by Eq.(12) was divided into 14400 rectangular meshes, i.e., 14400 individual

waves, as indicated in Fig.14. The wave in each grid,i.e., the individual wave is treated to experience shoaling and breaking. Once the wave breaks, the wave was assumed to keep broken up to the shoreline, and no correlation between waves was considered. The calculation method adopted was the same as that described in Section 3-1, and Eq.(3) was employed as the shoaling condition, since Eq.(3) was judged to be better than Eq.(11) as the shoaling condition, as stated in Section 4.

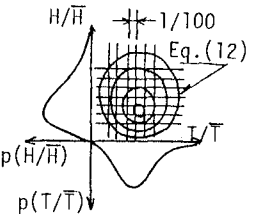

Fig.14 Joint probability distribution function of wave height and period.

5.2 Results and discussion

Figures 15 and 16 show variations of the mean run length, $\bar{J}_2$ and total run length, $\bar{E}_2$ with h/Ho on gentle slopes such as 1/10,1/20,1/30 and 1/50. $\bar{J}_2$ increases rapidly as h/Ho becomes small, as indicated in Fig.15. In addition, Fig.15 shows that the smaller the wave steepness,Ho/Lo and the gentler the bottom slope, the larger becomes h/Ho at which $\bar{J}_2$ grows up rapidly. Concerning to $\bar{E}_2$, $\bar{E}_2$ decreases to the minimum value of 4 and then increases as shown in Fig.16. The dimensionless water depth h/Ho at which $\bar{E}_2$ is minimal becomes larger as the wave steepness becomes smaller and bottom slope becomes gentler.

6. CONCLUDING REMARKS

In this paper, the variations of probability distribution, mean run and total run lengths of just breaking and broken waves on gentle slopes have been discussed, based on laboratory experiments and theoretical calculations. The theoretical model proposed here is shown to be valid and the random process model is powerful, especially for evaluating the characteristics of the probability distribution, mean run and total run lengths of broken waves.

ACKNOWLEDGEMENTS

CHAPTER 90

THE BOTTLENECK PROBLEM FOR TURBULENCE IN RELATION TO SUSPENDED SEDIMENT IN THE SURF ZONE

Peter Justesen[1], Jørgen Fredsøe[2] and Rolf Deigaard[3]

ABSTRACT

In the present paper the vertical distribution of turbulent kinetic energy k under broken waves is calculated by application of a one-equation turbulence model. The contributions to the energy level originate partly from the production in the wave boundary layer, partly from the production in the roller. Further on, the findings for k are used to calculate the vertical distribution of suspended sediment in broken waves.

INTRODUCTION

The vertical distribution of suspended sediment in the surf zone is of major importance for the evaluation of the rate of the longshore as well as the on-offshore sediment transport.

Outside the point of breaking, see Fig. 1, the presence of suspended sediment is restricted to the thin wave boundary layer. Models to describe this have been developed among others by Bakker (1974), Grant and Glenn (1983) and Fredsøe, Andersen and Silberg (1985).

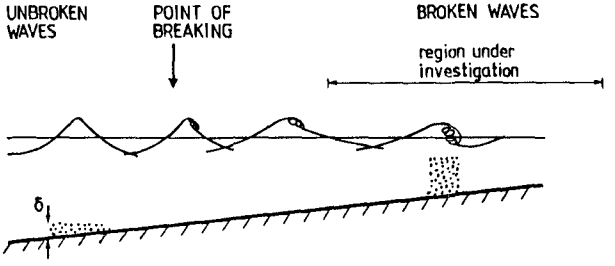

Fig. 1. Development of spilling breaker in the surf zone.

[1] M.Sc., Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Technical University of Denmark, Building 115, DK-2800 Lyngby, Denmark.

[2] Ph.D., Dr. Techn., Professor in Marine Hydraulic Engineering, ISVA, Technical University of Denmark.

[3] Ph.D., Senior Hydraulic Engineer, Danish Hydraulic Institute, Agern Alle 5, DK-2970 Hørsholm, Denmark.

Inside the point of breaking, the surface generated turbulence results in a much higher level of turbulent kinetic energy, especially close to the water surface, where the production of turbulence takes place around the surface roller. This leads to a significant increase in the amount of suspended sediment compared to unbroken waves of same height and period on the same water depth.

In the present paper, we consider the conditions for fully developed broken waves, where the energy loss can be approximated by that in a hydraulic jump. (Turbulent bore).

The transition region from breaking to fully developed broken waves is not included in the present analysis. In case of a plunging breaker, the turbulence may be extremely violent at the location where the breaking wave splashes through the water surface. Until now, this flow has not been satisfactorily described. In case of a spilling breaker, the present theory may be modified to describe also the region between breaking and fully broken waves. This will however require a more detailed description of the development of the surface roller during the initial stages of breaking.

SCOPE OF PRESENT WORK

The main purpose of the present paper is to include a detailed description of the distribution of turbulence in the analysis of the suspended sediment, especially in the overlap region close to the bottom where contributions to the turbulence level originate from the surface roller as well as from the near-bed wave boundary layer.

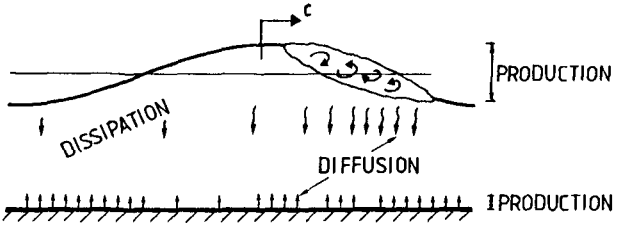

Fig. 2. Sketch of the location of production, diffusion, and dissipation of turbulent kinetic energy.

A first approach to solve this problem by application of a one-equation turbulence model for turbulent kinetic energy was proposed by Deigaard et al. (1986). In their model only the production of turbulence originating from wave breaking was included. Because this term is relatively well defined, the equation of motion could be avoided in the evaluation of the production term. As a result, the bottom generated turbulence was not directly included in the description, and Deigaard et

al. calculated the turbulence in the wave boundary layer independently using a simple model by Fredsøe (1984), in which the memory in turbulence is not included.

Because of the small thickness of the wave boundary layer, this might be a plausible approximation. However, the problem is how to combine the two contributions to get the total eddy viscosity. In Deigaard et al. (1986), the total eddy viscosity ε was estimated by

$$\varepsilon^2 = \varepsilon_b^2 + \varepsilon_t^2 \qquad (1)$$

where ε_b = eddy viscosity formed by production of energy in the wave boundary layer and ε_t = eddy viscosity formed by the production of energy in the water surface. Eq. 1 corresponds to summation of turbulent kinetic energy from the wall and the surface, respectively.

Especially in the overlap region where the level of turbulent kinetic energy is determined by both the surface and bed-generated turbulence a refined modelling of the level of k is needed. We refer to this region as the "bottleneck" region, because the level at this position is of extreme importance for how much sediment will be carried upwards to levels with higher turbulence. In the present theory, we use the transport equation for k to determine the distribution of k over the total depth. This analysis renders Eq. 1 redundant.

The advantage of the model by Fredsøe (1984) is that it is able to in a straightforward way to include the contribution of ε_b from a coexisting current in a three-dimensional motion. In this paper, the existence of such a current is disregarded. However, the present model can be extended to cover the combined wave current motion as long as this motion is restricted to a two-dimensional motion, see Deigaard, Justesen and Fredsøe (1986).

In the following description of the hydrodynamics and behaviour of suspended sediment, the bed is assumed to be plane and hydraulically rough. This restricts the present analysis to high values of the Shields parameter $\theta(> 1)$, according to Nielsen (1979). However, under storm conditions, where major parts of sediment transport takes place, this requirement is normally fulfilled.

HYDRODYNAMIC DESCRIPTION

Several attempts have been made in the past to describe the turbulence in the surf zone. Battjes (1975) has made a depth-integrated model for the turbulent kinetic energy and the eddy viscosity by assuming local equilibrium between the loss of energy from the waves and the dissipation of the turbulent energy. Svendsen and Madsen (1984) and Madsen and Svendsen (1983) applied the transport equation for turbulent kinetic energy to describe the longitudinal variation of the turbulence in a hydraulic jump or a bore. In this paper we shall calculate the eddy viscosity needed for the sediment calculations by use of the flow equation coupled with the transport equation for turbulent kinetic energy.

The flow kinematics are described by the equation of motion, which, neglecting convective terms, reads:

$$\frac{\partial U}{\partial t} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \frac{1}{\rho}\frac{\partial \tau}{\partial y} \tag{2}$$

U is the horizontal velocity, p is the pressure, and τ is the shear stress. The eddy viscosity ε is defined by

$$\frac{\tau}{\rho} = \varepsilon \frac{\partial U}{\partial y} \tag{3}$$

The turbulence is described by a one-equation turbulence model using the transport equation for the turbulent kinetic energy, k:

$$\frac{\partial k}{\partial t} = \frac{\partial}{\partial y}\left(\frac{\varepsilon}{\sigma_k}\frac{\partial k}{\partial y}\right) + \frac{PROD}{\rho} - C_1 \frac{k^{3/2}}{\ell} \tag{4}$$

According to Launder and Spalding (1972), the Prandtl number σ_k and the dissipation coefficient C_1 are taken to be $\sigma_k = 1$ and $C_1 = 0.08$. The length scale of the turbulence is to be prescribed. In the present model we have used ℓ given by:

$$\ell = \begin{cases} \sqrt[4]{C_1}\kappa y & \text{for } y < 0.07\,\dfrac{D}{\sqrt[4]{C_1}\kappa} \\ 0.07D & \text{for } y > 0.07\,\dfrac{D}{\sqrt[4]{C_1}\kappa} \end{cases} \tag{5}$$

κ is von Karman's constant ($\kappa = 0.40$). Close to the bed, ℓ has the variation normally used for boundary layer modelling, whereas it attains a constant value away from the bed to describe the conditions of free turbulence.

The coefficient of momentum diffusion, the eddy viscosity ε, is determined by the turbulent energy and the length scale:

$$\varepsilon = \ell \sqrt{k} \tag{6}$$

The production term, PROD, in the transport equation has two contributions. The first one is the production derived from the flow equation:

$$PROD = \tau \frac{\partial U}{\partial y} \tag{7}$$

This part of the turbulent production is most important in the wave boundary layer.

The second contribution is from the wave breaking. The details of the flow pattern in the surface roller is not modelled by the hydrodynamic model, and the production of turbulence in the surface roller is included in the transport equation by an analytical approximation introduced by Deigaard et al. (1986). The total energy dissipation due to the wave breaking is estimated from the energy loss in a hydraulic jump with the same height as the waves. The location of the production of turbulence is prescribed in the model on the basis of turbulence measurements in hydraulic jumps presented by Rouse et al. (1958). The turbulence originating from the wave breaking is dominant in the main part of the flow outside the wave boundary layer.

The boundary conditions for the k-equation are the no-flux condition at the surface:

$$\frac{\partial k}{\partial y}\Big|_{y=D} = 0 \tag{8}$$

and

$$k(z_0,t) = \frac{1}{\sqrt{C_1}}\,\varepsilon\,\left|\frac{\partial U}{\partial y}\right|,\quad z_0 = \frac{k_N}{30} \tag{9}$$

which expresses local equilibrium near the bed between production and dissipation of turbulent energy. k_N = bed roughness in Eq. 9. In addition, periodicity in the solution is required.

The pressure gradient in the flow equation is given by the free stream velocity, U_0:

$$\frac{1}{\rho}\frac{\partial p}{\partial x} = -\frac{\partial U_0}{\partial t} \tag{10}$$

The free stream velocity is estimated from linear shallow water theory:

$$U_0 = U_{1m}\sin\left(\frac{2\pi}{T}t\right) \tag{11}$$

By introducing these relations the following equation of motion is obtained:

$$\frac{\partial(U-U_0)}{\partial t} = \frac{\partial}{\partial y}\left(\varepsilon\frac{\partial U}{\partial y}\right) \tag{12}$$

The boundary conditions are (i) the no-slip condition at the bed

$$U(z_0,t) = 0 \tag{13}$$

and (ii) vanishing shear stress at the surface

$$\frac{\partial U}{\partial y}\Big|_{y=D} = 0 \tag{14}$$

Furthermore, periodicity in time is required.

THEORETICAL FLOW RESULTS

Two examples of the calculated instantaneous picture of the turbulent kinetic energy level for $a/k_N = 10^2$ and $a/k_N = 10^4$ are shown on the left hand side of Figs. 3 and 4, respectively. The production of surface generated turbulence has been set to zero in Figs. 3A and 4A in order to study the bed generated turbulence in the wave boundary layer alone. a = is the free stream amplitude and k_N the bed roughness. The variation in the x-direction (the direction of wave propagation) is obtained from the time variation by use of the relation

$$\frac{\partial}{\partial x} = -\frac{1}{c}\frac{\partial}{\partial t} \tag{15}$$

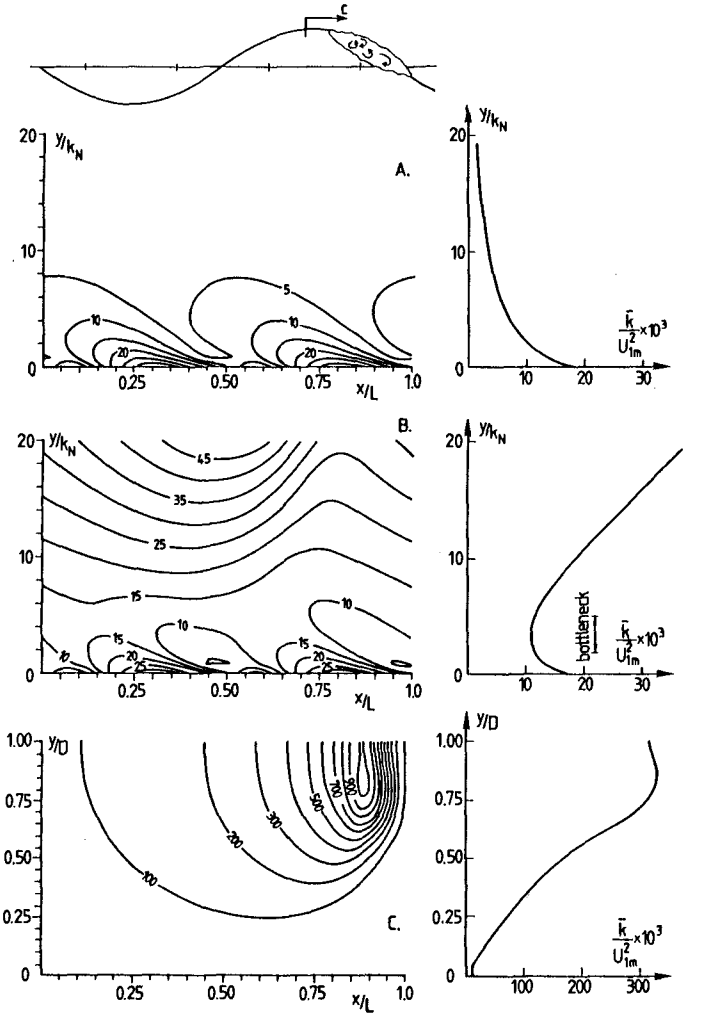

Fig. 3. Calculated distribution of turbulent kinetic energy (TKE) in unbroken and broken waves. Contour plots show the temporal variation of TKE, and the corresponding time-averaged levels of TKE are depicted on the right. A: Unbroken wave only with bottom-generated TKE; B: Near-bed region in broken wave; C: Total depth in broken wave. $a/k_N = 10^2$, $gT^2/D = 300$, $H/D = 0.5$. Levels of TKE indicated on contours are $\frac{\bar{k}}{U_{1m}^2} \times 10^3$.

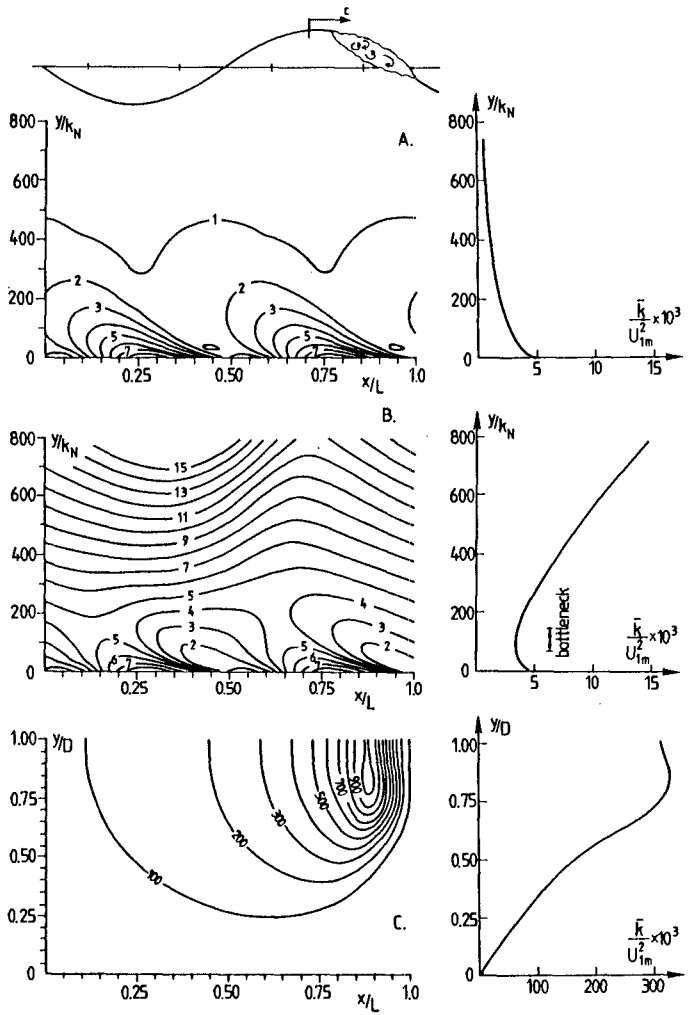

Fig. 4. Same as Fig. 3, but for $a/k_N = 10^4$, $gT^2/D = 300$, $H/D = 0.5$

It is seen that k has a maximum at the bottom, where the main production takes place. The shape of the contour plot is skew because it takes some time for the eddies to decay after being formed (mainly at the large outer flow velocities). The skewness is especially pronounced for small values of a/k_N, where the flow reverses rapidly. The pictures shown in Figs. 3A and 4A are experimentally verified by Hino et al. (1983) in case of a hydraulically smooth bottom.

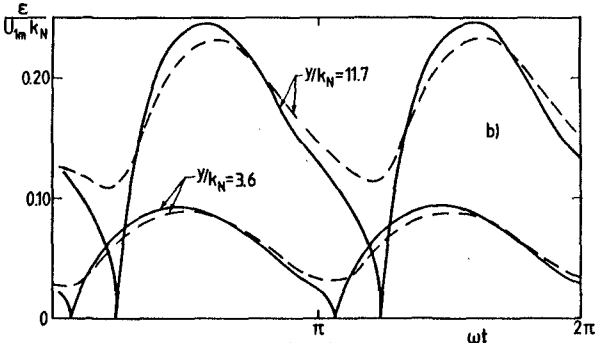

Fig. 5. Calculated temporal variation of eddy viscosity during one wave cycle in unbroken wave. - - - : one-equation model; —— : mixing-length theory. $a/k_N = 10^3$.

Fig. 5 shows the variation in the eddy viscosity during a wave cycle. The eddy viscosity is found from Eq. 6, and the importance of including a description of the behaviour of k is illustrated in Fig. 5 by comparing the predictions of a one-equation model with those of a mixing-length model, Bakker and van Doorn (1978). The implications of including a one equation model in the description of k are twofold: A: the time variation in ε is now predicted to be much smaller, because it takes time for the turbulent kinetic energy to decay, and B: the turbulence intensity increases further away from the bed at small values of a/k_N, because the turbulence level can now be built up with time.

In Figs. 3B, 3C and 4B and 4C contour plots of the instantaneous level of k, including the effect of turbulence formed around the roller, are shown. While the bottom turbulence has two peaks during one wave cycle (due to maximum flow velocity back and forth, respectively) the top generated surface has only one peak, just below the roller. In Fig. B, the detailed contour plots close to the bottom are depicted, while Fig. C shows the conditions over the entire depth. It is seen that the turbulence level is much higher far away from the bed than close to the bed.

On the right hand side of Figs. 3 and 4, the corresponding time-averaged values of k are shown. It is quite clear that a minimum (bottleneck) in k is present very close to the bottom, inside the wave boundary layer. This minimum in k is especially pronounced just below the roller, because it takes some time for the turbulence to penetrate downwards from the roller.

DESCRIPTION OF SUSPENDED SEDIMENT

The description of the vertical distribution of suspended sediment is based on the diffusion concept, for which the governing equation is the well-known

$$\frac{\partial c}{\partial t} = w \frac{\partial c}{\partial y} + \frac{\partial}{\partial y}\left(\varepsilon_s \frac{\partial c}{\partial y}\right) \tag{16}$$

where c = concentration by volume, t = time, w = fall velocity of suspended sediment, and ε_s = turbulent exchange factor for suspended sediment. In Eq. 16 the lateral diffusion term is neglected because the vertical gradient is much larger than the horizontal. ε_s is usually correlated to the eddy viscosity ε by

$$\varepsilon_s = \beta\varepsilon \tag{17}$$

where β is a constant of proportionality. Quite often, β is set equal to unity. Some experimental findings by van der Graaff and Roelvink (1984) suggest, however, that β is a function of the sediment properties: β increases with increasing grain size, and is normally somewhat larger than unity.

In the following calculations we have applied $\beta = 1$, so

$$\varepsilon_s = \varepsilon \tag{18}$$

If another value of β in Eq. 18 is adopted, the present results can still be applied by introducing a new fictive fall velocity

$$w_n = w\beta \tag{19}$$

because the vertical distribution depends only on the relative ratio w/ε_s.

Boundary condition at the bed: One of the major problems in steady current as well as in wave motion is to determine the bottom concentration c_b of suspended sediment. Here c_b is defined as the concentration of sediment a distance of about one to two grain diameters above the bed. Einstein (1950) suggested a kinematic approach, where the concentration of suspended sediment just above the bottom is directly related to the rate of the bed load transport.

Engelund and Fredsøe (1976) developed a model for c_b based on dynamic principles, describing how the fluid shear stress is transferred to the immobile part of the bed through the dispersive stress of the grains in suspension. An experimental result for the dispersive stress obtained by Bagnold (1954) was applied to calculate c_b.

The variation in c_b is obtained as a function of the Shields parameter, defined by

$$\theta = \frac{U_f^2}{(s-1)gd} = \frac{\tau_b}{\rho(s-1)gd} \tag{20}$$

s = relative density (2.65 for sand), g = acceleration due to gravity, d = mean grain diameter), cf. [8].

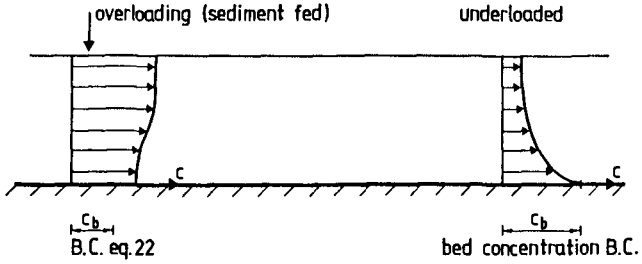

Fig. 6. Definition sketch of boundary condition for sediment concentration.

In two recent papers on suspended sediment in waves by Fredsøe et al. (1985) and Deigaard et al. (1986) the above mentioned method was applied to calculate the instantaneous value of c_b, based on the instantaneous value of θ

$$c_b = c_b(\theta) \tag{21}$$

The application of Eq. 21 seems reasonable from a physical point of view, since the theory behind the estimate of c_b is based on the assumption that c_b must have a certain value in order to transfer the fluid shear to the bed. However, in connection with a related topic, namely non-uniform river flow, Parker [16] discussed the above boundary condition, which he denotes the concentration boundary condition. In case of non-zero flux conditions, (i.e. erosion or deposition occurs in the bed) Parker instead applied a gradient boundary condition. This boundary condition was introduced because Eq. 21 gives physically unrealistic results in the case of overloading.

Let us consider the hypothetic case, in which the flow velocity is suddenly reduced from a certain steady value where $\theta = \theta_0$ to zero: in this case, Eq. 21 gives the result that c_b drops from $c_b(\theta_0)$ to zero instantaneously. However, all the sediment which is in suspension before the change in flow velocity occurs cannot settle faster than the settling velocity w. This means that in the still water, the time evolution in c_b is determined by

$$c_b(a,t) = c(a + \Delta y, t - \Delta t) \tag{22}$$

in which $\Delta y = w\Delta t$.

This equation simply states that the suspended sediment settles without changing its shape of the profile.

The example described above corresponds to the overloaded case. The underloaded case corresponds on the other hand to the flow situation where the fluid velocity is suddenly increased from zero to a certain flow velocity where $\theta = \theta_0$: here, it is possible for the bed concentration to adapt the new value $c_b(\theta_0)$ (disregarding inertia effects, which for sand are negligible)

because the suspended sediment just has to be transported a very small distance of the order of one grain diameter away from the bed. In this case, the sediment is not transported by diffusion, but by grain-grain interaction.

If we apply these considerations to the unsteady case under waves, an alternative boundary condition to the boundary condition Eq. 21 is

Underloading: Eq. 21

Overloading: Eq. 22

so the resulting boundary conditions become

$$c_b = \max \{c_b(\theta),\ c(a + w\Delta t,\ t - wt\} \tag{23}$$

In the wave case where the changes in flow velocity are continuous, Eq. 23 is still applied, as it describes the two extreme limits (for very fast varying flow) correctly.

Boundary condition at the surface: at the free surface, the flux of sediment is zero, or

$$\epsilon \frac{\partial c}{\partial y} + wc = 0 \quad \text{at } y = D \tag{24}$$

Periodicity in concentration: the time variation in c must be periodic, so

$$c(t,y) = c(t + T,\ y) \tag{25}$$

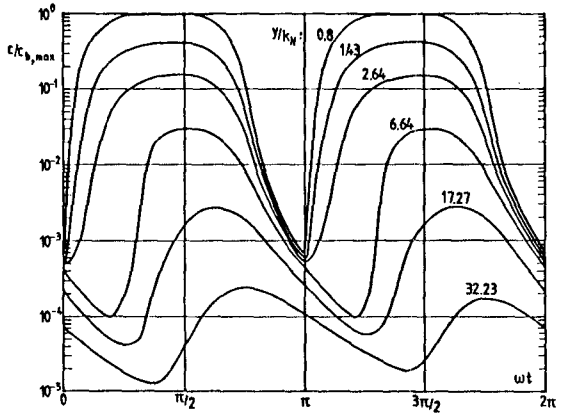

Fig. 7. Sediment concentration in different levels in a broken wave calculated as a function of time. $a/k_N = 10^3$, $gT^2/D = 300$, $H/D = 0.5$, $d = 0.2$ mm, $w/U_{1m} = 0.038$.

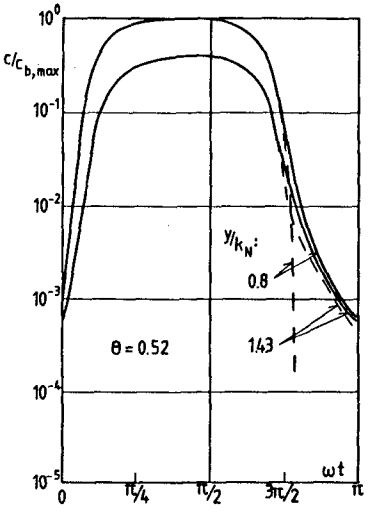

Fig. 8. Effect of choice of boundary condition for the sediment concentration. Solid lines indicate the same results as in Fig. 7 obtained using Eq. 23, whereas the dashed lines show results by using the bed concentration B.C.

THEORETICAL RESULTS FOR SUSPENDED SEDIMENT

Figs. 7 and 8 show the time-variation in the instantaneous value of concentration c of suspended sediment. It is noted from Fig. 7 that the concentration at a specific level is not totally identical in each wave half period. This can be explained by the former hydrodynamic calculations.

Fig. 8 shows the effect of the boundary condition selected: the dashed line in Fig. 8 is the result obtained by applying the bed concentration boundary condition, while the full drawn line is that obtained from Eq. 23. It is seen that the effect from different boundary conditions can be felt only a few grain sizes away from the bed.

Figs. 9 - 11 are related to the predicted vertical mean distribution c: in Fig. 9 the variation in c with a/k_N is depicted. The dashed line shows the results without wave breaking. In Figs. 10 and 11, the variation with gT^2/D and w/U_{1m}, respectively, are depicted.

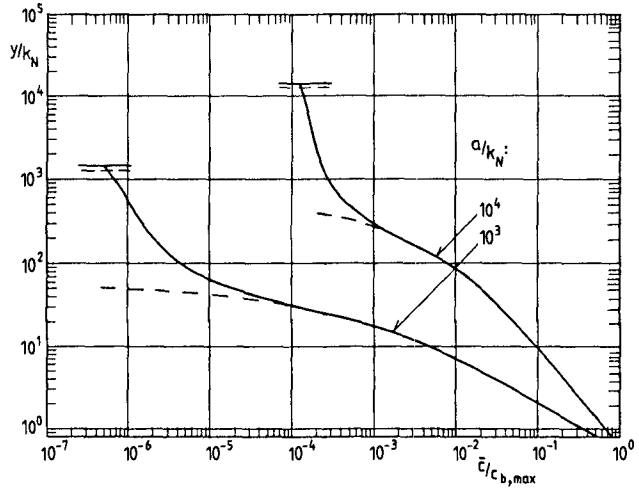

Fig. 9. Time-averaged concentration of suspended sediment as a function of depth for different values of a/k_N. GT^2/D = 300, H/D = 0.5, d = 0.2 mm, w = 0.025 m/s. Dashed lines indicate results for unbroken waves.

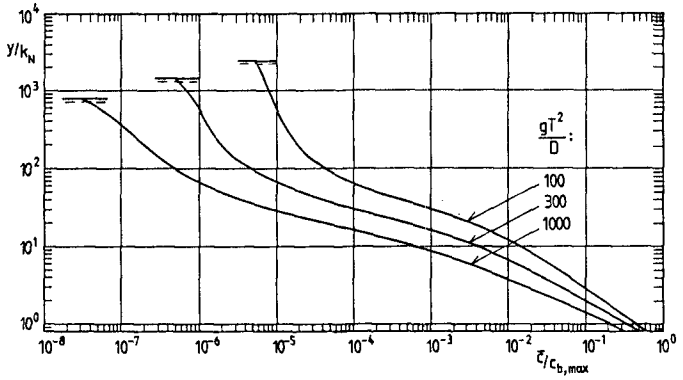

Fig. 10. Time-averaged concentration of suspended sediment as a function of depth for different values of gT^2/D. a/k_N = 10^3, H/D = 0.5, d = 0.2 mm, w = 0.025 m/s.

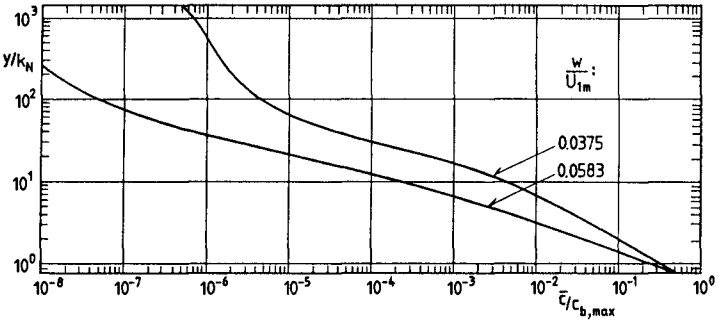

Fig. 11. Time-averaged concentration of suspended sediment as a function of depth for different values of w/U_{1m}. $a/k_N = 10^3$, $gT^2/D = 300$.

CHAPTER 91

Local Movements of Sand in the Surf Zone

Kazumasa KATOH[1] and Norio TANAKA[2]

Abstract

The fluorescent sand tracers are injected in a point in the surf zone. Core samples are taken from the sixteen points on the circumference with the time intervals of fifteen minutes for about five hours. At the same time, the horizontal two components of fluid velocities are measured at the injection point by using an electromagnetic currentmeter. The field observations have been carried out three times on two beaches facing to the Pacific Ocean. The relations between the local sand movements and the fluid dynamics are examined on the basis of the data obtained.

1. Introduction

The study on the local sand transport in the surf zone is regarded as one of the very important themes in the coastal engineerings, and it is earnestly hoped to make clear the actual conditions of sediment dynamics in the surf zone. There is, however, a major obstacle to further understanding of the local sand transport, or nearshore sediment dynamics, that is to say, the lack of instruments which can directly measure the sediment transport.

Nadaoka, Tanaka and Katoh (1981) developed the technique to use the fluorescent sand tracer for measuring the local sand movements in the surf zone, and examined its capability by applying it to the field, Ajigaura Beach in Japan. The result proved the technique quite promising, and we decided to explore its possibility further. The field observations with the fluorescent sand tracer have been carried on two beaches facing to the Pacific Ocean - Oarai Beach in 1981 and Sudahama Beach in 1982 and 1983, in Japan.

In this report, based on the data obtained by this method on these beaches, we examine the local sand movements such as the advection speed of sand tracer , the mixing depth into the sea bottom, the local sand transport rate, and so on.

2. Field Observations

2.1 Observation procedure

An outline of the observation procedure employed in the field using fluorescent sand tracer is as follows. First of all, a circle with the radius of 8.75 meters is established in the surf zone at an observation site. In practice, one pipe is set at the center of circle and sixteen pipes are set at the points which divide the circumference into sixteen arcs. An electromagnetic currentmeter is also set near the center of circle to measure the two horizontal components of the current velocity.

Three different colors of the fluorescent sand tracers, red, blue and yellow-green, are prepared in advance by utilizing the sand which have been previously removed from the beach face at the observation site. The observation starts at the time when one of the three colors of the tracers is injected at the center of circle. The remaining two colors of tracers are injected at the center at the time of one and two hours after the first injection, respectively. The volume of each sand tracer injected is 5 kilograms at a time. A sampling of the sand tracer at the sixteen points on the circumference is started 5 minutes after the first injection and is repeated with the time interval of 15 minutes, being 21 times for the typical case.

Core samples are taken at all the sixteen points as shown in Fig.1. The sampling procedure done by frogmen is as follows. (a) A transparent acrylic pipe of about 130 centimeters in length, 3.4 centimeters in inner diameter and 3 milimeters in thickness is brought to the sampling point by a frogman. (b) The acrylic pipe is pushed into the sea bottom by 20 to 30 centimeters. (c) The upper end of pipe is sealed with a rubber stopper. (d) The pipe is pulled out with the core sample inside it. (e) Immediately after it, the lower end of pipe is sealed with another rubber stopper, and the pipe is brought to the shore.

After removing the sea water, the core sample is slowly pushed out from the pipe onto a flat plate by using a piston. In almost all cases, the core sample was able to be taken out in a cylindrical shape without

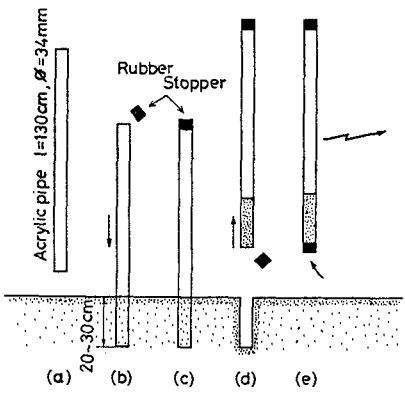

Fig. 1 Method of taking core sample.

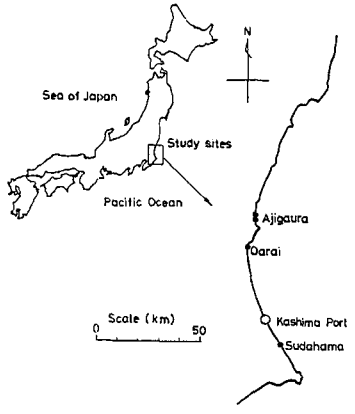

Fig.2 Location of study site.

Table 1 Summary of experiment conditions

Site	Experiment number	H_0 (m)	T_0 (s)	Tide level (m)	Tide level (m)	Clearance (cm)	Sediment d_{50}(mm) S_0, S_k
Oarai	8/31/81	0.52	6.0	0.16	0.77	12, 15	0.24
	9/ 2/81	0.38	5.7	0.36	1.07	8, 8	1.34, 1.12
Sudahama	7/28/82	1.50	8.5	1.03	0.78	12, 20	0.16
	7/29/82	1.20	8.8	0.86	0.90	17, 25	1.17, 0.99
	7/30/82	1.00	8.4	0.75	1.00	20	
Sudahama	8/24/83	1.02	5.7	0.26	1.31		
	8/25/83	0.85	7.5	0.32	1.13	13, 17	

being disturbed. The core sample is then sliced into 2 centimeters segments from the sea bottom to the depth of 12 centimeters. Each segment is well mixed, and about 40 % of its quantity is spread out in the shape of a circular plate having the diameter of 8 centimeters and the thickness of 0.15 centimeter on a flat plate in a pitch-dark room. Then, the number of the sand grains with each tracer color on the surface of the circular plate is counted ocularly under an ultraviolet light.

2.2 Sites of field observations

The tracer experiments were carried out three times on two beaches on the east coast of Japan - Oarai (autumn 1981) and Sudahama (summer 1982, summer 1983). These beaches are classified as micro-tidal beaches, because their tide ranges are about 1 meter. They are exposed to the full wave energy of the Pacific Ocean. The locations of these beaches are shown in Fig.2. An outline of each beach can be found elsewhere (Katoh et al., 1985). In total the tracer experiments were carried out for seven days. In this report, each experiment will be referred to by year, month and day.

General conditions of the sea during the field observations are listed in Table 1. The fifth and sixth columns give the tidal levels at the times of start and end of the observations above the datum line. A clearance listed in the seventh column is the vertical distance of the sensor of currentmeter from the sea bottom. The clearance was measured by using a scale or a palm and fingers of a frogman, repeating twice in almost all cases. The last column gives the medium diameter of sand (d_{50}), the sorting coefficient (S_0) and the skewness parameter (S_k) of the beach materials (quartz sand).

The observation was carried out at the ground elevation around the datum level, 0 meter, in each case. This is because of the fact that we could not help deciding the locations of almost the same water depth for the sampling works by the frogmen. The observation points were usually located inside the surf zone in all cases.

3. Characteristics of Waves and Currents

The two horizontal components of current velocities measured at the injection point were digitized at the interval of 0.1 second. Every two consecutive digital data are averaged to yield the smoothed data with the time interval of 0.2 second, which are utilized for analyses.

The representative values of currents, that is to say, the mean velocity, the principal direction of the incident waves (Nagata,1964), the skewness, the root-mean-square value of velocity fluctuation and a velocity atiltness in the principal wave direction, are calculated for every fifteen minutes.

A principal direction of the waves, θ_p, is defined as

$$\tan 2\theta_p = 2\overline{uv}/(\overline{u^2} + \overline{v^2}), \tag{1}$$

where u and v are the horizontal components of wave motions only, which are obtained by removing the steady state currents from the original data.

The velocity component in the principal wave direction U_p, being defined positive in the direction of wave propagation, can be obtained by the coordinate transformation with the angle of θ_p. The skewness is defined for U_p as

$$\sqrt{\beta_1} = \frac{1}{N}\sum (U_p)_i^3 / (U_p)_{rms}^3. \tag{2}$$

The velocity atiltness which is a new parameter originally proposed by Goda (1985) for the forward tilting of wave profile is calculated. The velocity profile of the forward tilting, when it is differentiated with respect to time, yields the up-and-down asymmetry in the acceleration profile, the magnitude of which can be evaluated by the similar way as the skewness as follow:

$$\sqrt{\gamma_1} = \frac{1}{N}\sum (\dot{U}_p)_i^3 / (\dot{U}_p)_{rms}^3, \tag{3}$$

where the overdot in the expression denotes the differentiation with respect to time.

For every observation, the arithmetic means of the representative characteristics of waves and the vectorial means of mean current velocities are calculated for the period from the time of injection to the end of observation, and the resultant values are listed in Table 2.

According to Table 2, the values of skewness in 7/28/82 and 7/30/82 are negative. As the velocity fluctuation due to waves U_p is defined as positive in the direction of wave propagations in these data analyses, the values of the skewness of U_p in the surf zone would be thought positive and large from the analogy of surface wave profiles. Therefore, It is a quite curious fact that the mean values of skewness are negative on Sudahama Beach. Their cause is examined here.

Figures 3 shows typical records of current variations in the case of negative skewness. The direction of the Y-component is almost the same as the direction of the incident wave propagation and that of the X-component is nearly parallel to the shoreline. The current velocity in the Y-component is featured with the existence of long-period fluctuations which have the period of about 80 to 100 seconds and the amplitude much greater than that of the short-period fluctuations corresponding to the motions of incident waves.

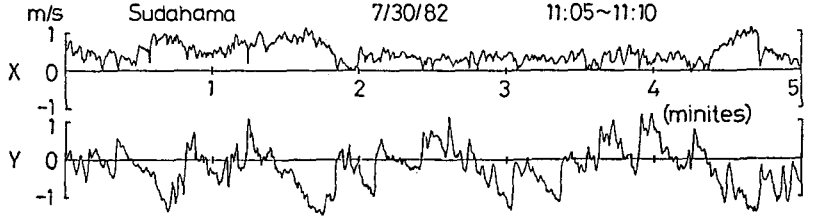

Fig.3 Typical segment of current records

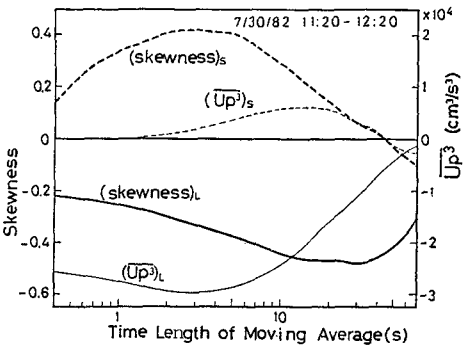

Fig.4 The values of skewness for the long period component and the short one.

By inspecting Fig.3 in detail, we can notice that the long-period components do not fluctuate sinusoidally but in the way that the velocity profile is flattened with longer duration in the positive side (onshore) and is sharpened with shorter duration in the negative side (offshore). Then, two analyses have been attempted for calculating the values of skewness. One analysis is to calculate the value of skewness, which is denoted by $(\text{skewness})_L$, for the smoothed velocity profile which is obtained by the application of the moving average technique; the averaging time length is

varied from 0.45 s to 70 s. Another is to calculate the skewness for the profile with removal of the smoothed profile, which corresponds to that of the relatively short-period components, and the resultant value is denoted by $(\text{skewness})_S$. These analyses have been done for the time series data of one hour. The result of analyses is shown in Fig.4, where the abscissa denotes the averaging time length. According to this figure, the values of skewness for the long-period components is always negative. Therefore, it is considered that the values of skewness for the long-period fluctuation are negative which make the values of skewness for the velocities combined of short and long-period components to be negative.

4. Characteristics of tracer movements

4.1 Advection speed and its direction

In order to estimate the advection speed and its direction of sand tracer, the following equations which have been derived by Nadaoka et al. (1981) are employed here.

Let $C(\omega,t)$ be the number of tracer particles in a core at the time t after the injection of tracer at a point of the direction ω on the circumference having a radius R (see Fig.5). Up to this time, tracer particles of $C(\omega,t)$ in number are considered to have moved from the center of circle to the circumference. It does not matter how tracer particles were transported there, whether in suspension or not, what happened with them on the way, and which way did they pass through. We are only concerned with the fact that they have moved there with the travelling time of t. Then the components of apparent travelling speed of tracer particles in the directions of η and ξ are given by $(R\cos\omega)/t$ and $(R\sin\omega)/t$, respectively. Furthermore, the mean advection velocity of tracer during the experiment can be defined by the following two components, u_m and v_m:

$$u_m = \frac{\int_0^\infty \int_0^{2\pi} C(\omega,t)\frac{R}{t}\cos\omega\, d\omega dt}{\int_0^\infty \int_0^{2\pi} C(\omega,t)\, d\omega dt}, \qquad (4)$$

$$v_m = \frac{\int_0^\infty \int_0^{2\pi} C(\omega,t)\frac{R}{t}\sin\omega\, d\omega dt}{\int_0^\infty \int_0^{2\pi} C(\omega,t)\, d\omega dt}. \qquad (5)$$

By using Eqs. (4) and (5), we have

$$V_t = (u_m^2 + v_m^2)^{1/2}, \qquad (6)$$

$$\theta_t = \tan^{-1}(v_m/u_m), \qquad (7)$$

where V_t is the mean advection speed of fluorescent sand tracer and θ_t is its direction.

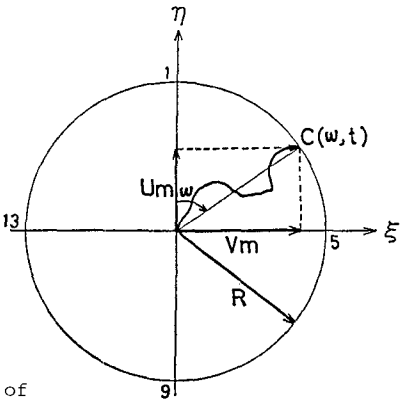

Fig. 5 Coordinate system.

In order to observe clear relations between the tracer advection and the characteristics of waves and currents, an oblique coordinate system which has been introduced by Nadaoka et al. (1981) will be used again. That is to say, the η axis is taken in the principal wave direction and the ξ axis is taken in the mean current direction, as shown in Fig.6. As these two axes generally intersect at an oblique angle, let the angle measured from the η axis to the ξ axis in the clockwise direction be ϕ_s.

Let us assume that the sand advection speed is V_t with the angle ϕ_t, which is defined in the same way as ϕ_s. Furthermore its two components in the directions of the mean current and the wave propagation are denoted by V_s and D, respectively, as shown in Fig.6. Then we have two equations as follows:

$$V_s = V_t \cdot \sin \phi_t / \sin \phi_s, \tag{8}$$

$$D = V_t \cdot \cos \phi_t \cdot (1 - \tan \phi_t / \tan \phi_s). \tag{9}$$

As all of physical quantities in the right-hand sides in Eqs. (8) and (9) can be estimated by Eqs.(1), (6) and (7) by utilizing the data measured, the values of V_s and D have been calculated and are listed in the first and the second columns in Table 3.

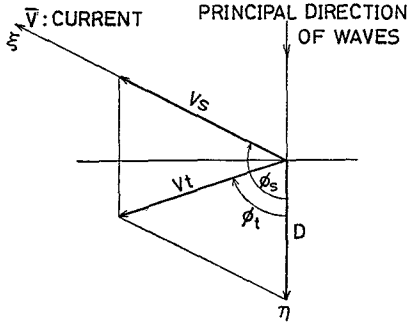

Fig. 6 Oblique coordinate system and definition of symbols.

Table 3 Tracer advection speed and mixing depth

		V_s (cm/s)	D (cm/s)	Mixing depth (cm)

8/25/83	3	-0.182	-0.299	6.53

4.2 Mixing depth of fluorescent sand tracer in the sea bottom

As pointed out by Komar and Inman (1970), Nadaoka et al.(1981) and Kraus (1985), a phenomenon of sand mixing in a layer from the sea bottom surface to some depth exists in the surf zone. The vertical distributions of fluorescent sand tracer are calculated for each tracer with all of the data, and the average mixing depth of 80% cut-off are also calculated and listed in the last column in Table 3. In this report the mixing depth is defined as the depth containing 80% of the

total tracer in a core, in the same manner as Nadaoka et al. (1981) and Kraus (1985).

5. Relations between Local Sand Transport and Fluid Dynamics

5.1 Advection speed of sand movement in the direction of mean currents

Nadaoka et al. (1981) obtained a semi-theoretical relationship of

$$\bar{V}_s = 0.01 * \overline{V_l}. \qquad (10)$$

where $\bar{V}_s$ is the mean advection speed of longshore transport and $\overline{V_l}$ is the average longshore current velocity, and they said with some field data that Eq.(10) is valid for the local sand transport.

The values of the advection speed of tracer in the direction of mean currents V_s and mean current velocity $\bar{V}$, which are listed in Table 3, are plotted in Fig.7. As seen in Fig.7, the data points, except one point which have relatively larger values of V_s, scatter around a straight line of

$$V_s = 0.01 * \overline{V}. \qquad (11)$$

Therefore the relation of Eq.(11) is considered to be reconfirmed here.

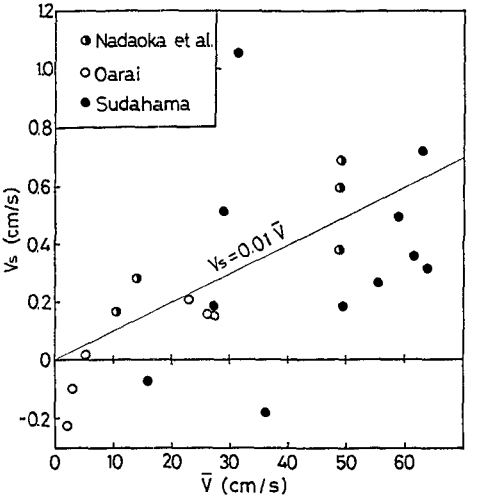

Fig. 7 V_s compared with $\bar{V}$.

5.2 Advection speed of sand movement in the principal wave direction

Nadaoka et al. (1981) showed that the dimensionless advection speed in the principal wave direction , $D/\sqrt{\overline{u^2}_p}$, can be explained by using the skewness parameter, which represents the feature of up-and-down asymmetry of velocity profile. Then, we tried to plot it against the skewness. The dimensionless advection speed, however, can be explained partially but not wholly by using only the skewness parameter (see Katoh et al., 1985), we need to take another parameter into account.

It might be said that the analysis in Nadaoka et al.(1981) has been done for one aspect of sand transport, i.e., bed load transport. Another approach for the explanation of the suspended load transport is thus necessary. Based on the data obtained in the surf zone, Sternberg, Shi, and Dowing (1984) reported that the frequency and duration of individual suspension events were strongly correlated with incident wave conditions, and the events of suspensions were in phase with bores propagating across the surf zone. Therefore, it is better to use a parameter representing the characteristic of the bores which have distinct features of the forward tilting both in the surface profile and in the velocity profile. Then, by using the velocity atiltness parameter (Eq.3), let us assume that the dimensionless advection speed

in the principal direction can be approximately expressed as follow:

$$D/\sqrt{\overline{U_p^2}} = a\cdot\sqrt{\beta_1} + b\cdot\sqrt{\gamma_1}\cdot(\dot{U}_p)^3_{rms} / g^3, \qquad (12)$$

where a and b are the coefficients and the second term in the right-hand side is normalized with the third power of the acceleration of gravity.

The transport direction of suspended load should be taken care, because the newly defined parameter is considered to be related to the concentration of the suspended load alone. According to the Shore Protection Manual, Coastal Engineering Research Center (1977), when the ratio of the deepwater wave height to the fall velocity of the beach sediment, H_0/w, is greater than wave period, T, the significant concentration of suspended load are expected to diffuse offshore and deposit in the offshore side. In the cases of the observations reported here, the fall velocity is of about 1.8 cm/s to 3.2 cm/s. If the period of incident waves, about 8 seconds (see Table 1), is taken for T, and 1.0 meter is taken for H_0, the value of H_0/w is apparently greater than T. Therefore, the suspended load is thought to be transported in the offshore direction.

The above consideration is applicable for the velocity fields due to the incident waves alone, but it is not so for the case in which the predominant long-period components coexist. In the latter case, the direction of the combined velocity depends almost on that of the long-period components. As seen in Fig.3, for example, when the long-period velocity components have a large positive value, the velocity combined with those of incident waves fluctuate mainly in the positive side. Under these conditions, a practice of taking the period of the incident waves as T is not appropriate, because the suspended load due to the passing of bores will be transported in the direction of the velocity of long-period components.

The direction of the net suspended load transport in the velocity fields containing the predominant long-period components will be inferred as follows. The values of skewness for the long-period velocity components are negative, which means that the total duration of the time when the direction of velocity is onshore is longer than that of offshore. The high concentration of suspended load occurs when the bores pass through. If the time interval between two arriving bores is constant, the frequency of the bores passing through a fixed point becomes larger during the time periods of onshore velocities than those of offshore ones, because the duration of the former is longer than that of the latter. This situation can be recognized in Fig.3. Therefore, the larger amount of sand is transported to the onshore direction in suspension, which yields the net onshore transport.

The sign of the coefficient b should be changed based on whether the predominant long-period components coexist or not with the incident waves. For this purpose, the values of skewness or U_p^3 can be utilized as a first step, because it is positive when the incident wave components are relatively large and is negative when the long-period components are relatively large. Thus, Eq.(12) is rewritten as

$$D/\sqrt{\overline{U_p^2}} = a\cdot\sqrt{\beta_1} + b\cdot \mathrm{sgn}(\sqrt{\beta_1})\cdot\sqrt{\gamma_1}\cdot(\dot{U}_p)^3_{rms} / g^3, \quad (13)$$

where $\mathrm{sgn}(\sqrt{\beta_1})$ takes the value of +1 or -1 depending on whether the skewness is positive or negative, and the value of redefined coefficient b should be a negative.

The value of $\overline{\dot{U}_p^3}$ can be obtained by multiplying the third power of $\sqrt{\overline{U_p^2}}$ by the skewness of the acceleration profile which are listed in Table 2. Using a regression analysis for Eq.(13) with the data listed in Table 2, we get the values of 0.024 and -85.1 for a and b, respectively. In turn, the value of the quantity in the right-hand side of Eq.(13) for each sand tracer has been calculated with the values of coefficients obtained, and it is plotted on the abscissa with the corresponding dimensionless advection speed on the ordinate in Fig.8.

Except three data points, the data are gathered around a straight line having the inclination of 0.85. The straight line is decided by applying the least squares method to the data excluding the three distant points so that the line should pass through the origin. By multiplying the coefficients a and b with the value of 0.85 we have the following relation:

$$D/\sqrt{\overline{U_p^2}} = 0.02\sqrt{\beta_1} - 72.4\cdot \mathrm{sgn}(\sqrt{\beta_1})\cdot \overline{\dot{U}_p^3} / g^3. \quad (14)$$

The first term in the right-hand side of Eq.(14) is considered to correspond to the bed load transport, while the second one to the suspended load transport. Equation (14) indicates that the directions of bed and suspended load transports are opposite each other, because $\overline{\dot{U}_p^3}$ usually takes a positive value.

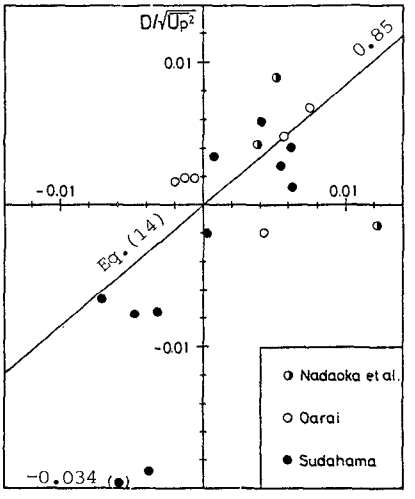

Fig.8 $D/\sqrt{\overline{U_p^2}}$ compared with the skewness and magnitude of forward inclination of velocity profile.

5.3 Mixing depth of sand tracer

Sunamura and Kraus (1985) presented the shear stress model to predict the average depth of wave-induced sediment mixing in the surf zone. The model shows that the mixing depth normalized with the sediment grain diameter is linearly related to the Shields parameter, which is proportional to the square of the velocity of the breaking waves. Then, let us examine whether this relation can be applied to the local mixing depth and the local velocities or not. The mixing depths listed in Table 3 are plotted against the mean-square values of velocities divided by the gravity of acceleration, $\overline{U_p^2}/g$, in Fig.9. Although some scatter is observed in the data points, the straight line drawn through the origin gives the result of

$$b = 2.5 * \overline{U_p^2}/g. \qquad (15)$$

Equation (15) can be rewritten with the local wave height by using the some assumptions as

$$b = 0.10 * H_{1/3}. \qquad (16)$$

This result is nearly same as that of Nadaoka et al. (1981) for the data obtained at Ajigaura Beach, in which the value of coefficient is about 0.08.

Furthermore, by asumming a constant sloping beach, h = x tanβ, and $\gamma = H_{1/3}/h = 0.6\text{-}0.65$ in the case of irregular waves in the surf zone, the average mixing depth in the surf zone can be estimated as follow:

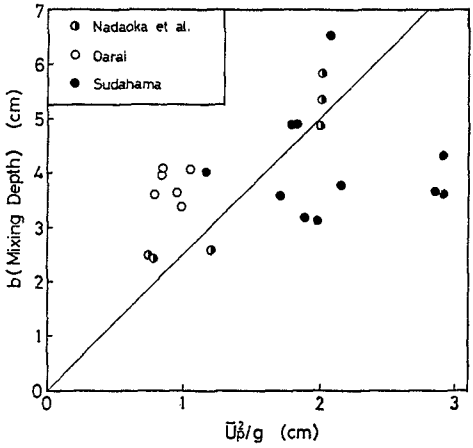

Fig. 9 Local mixing depth compared with $\overline{U_p^2}$.

$$\bar{b} = \frac{1}{X_b}\int_0^{X_b} b\,dx = \frac{1}{X_b}\int_0^{X_b} 0.10\cdot\gamma\cdot x\tan\beta\cdot dx = 0.05\cdot H_b, \qquad (17)$$

where X_b is the width of the surf zone and H_b is the significant wave height at the wave breaking point. The value of coefficient in Eq.(17) is of the same order as that in Sunamura and Kraus (1985), that is to say 0.027, but the former is about twice as large as the latter. At least in this report, the mixing depth should be expressed in terms of the velocity fluctuations as in Eq.(15), because the local wave height have not been measured in our observations.

5.4 Local sand transport rate

In much the same way as the bulk volume of longshore sand transport rate (Komar and Inman, 1970), a bulk volume of local sand transport rate per unit width Q_t is given by the equation

$$Q_t = b * V_t. \qquad (18)$$

The local advection velocity of the sediment V_t has been decomposed into the two components V_s and D in the directions of mean currents and the incident waves, respectively. The local sand transport rate is also decomposed into such two directions as follows:

$$Q_s = b * V_s, \qquad (19)$$

$$Q_D = b * D. \qquad (20)$$

By substituting Eqs.(11), (14) and (15) into Eqs.(19) and (20) respectively, we have

$$Q_s = \frac{0.0025}{g} * \overline{u_p^2} * \overline{v}, \tag{21}$$

$$Q_D = \frac{1}{g}[\ 0.05 \cdot \overline{u_p^3} - 181 \cdot \mathrm{sgn}(\overline{u_p^3}) \cdot (\overline{u_p^2})^{3/2} \cdot \overline{\dot{u}_p^3} / g^3\ ]. \tag{22}$$

The first term in the right-hand side of Eq.(22) mainly corresponds to the bed load transport, while the second one to the suspended load transport. Based on Eq.(22), further interesting discussions can be made. The mixing depth b is multiplied by the second term in the right-hand side of Eq.(14) to yield the contribution of suspended load to the total sand transport rate in Eq.(22). This operation looks strange because the mixing process is a phenomenon in the sea bottom, whereas the suspension of the bed material is that above the sea bottom. This apparent strangeness, however, may serve to understand the mechanics of sand transport in suspension in the surf zone.

For simplicity, let us pay our attention to one sand particle which has the same diameter as the others. The particle pausing on the sea bottom surface at first is suspended when the bore passes over it. Subsequently it is transported in suspension to some distance with the same velocity as the fluid one and deposit after several seconds on the sea bottom. Next, it is buried into the sea bottom due to the some mixing process of bed material. Then it losses an opportunity to be suspended again for a while. The time required for the particle to emerge again on the sea bottom surface becomes longer with increase in the mixing depth of the bed material. The elongation of the reappearance time reduces the apparent advection speed. This effect is already contained in the empirically obtained advection speed D (the second term of the right-hand side of Eq.14). While it is being buried in the sea bottom, the other particles which have been buried in the sea bottom to some depth initially at that point are successively suspended and transported to other points, of course with the same apparent advection speed as that of the particle we pay our attention to. The number of these particles suspended, or bulk volume of the particles, becomes large with increase in the reappearing time of our particle which is inferred to depend on the mixing depth b. Therefore, in order to obtain the total bulk volume of sand transport rate in suspension, the mixing depth b should be multiplied by the advection speed such as the second term in the right-hand side of Eq.(22).

Discussions have actively been held concerning whether the suspended load or the bed load transport is more important in the surf zone. For examples, Komar (1978) concluded that the suspended load is much less significant than the bed load transport, while Sternberg, Shi and Downing (1984) reported that all of the longshore transport at Leadbetter Beach could be accounted for by the suspended load transport. Let q_b and q_s be the absolute values of bed load and suspended load transport rate in the principal wave direction, respectively. They can be expressed from Eq.(23) as follows:

$$q_b = |0.05 \cdot \overline{u_p^3}| / g\ , \tag{23}$$

$$q_s = |181 \cdot (\overline{u_p^2})^{3/2} \cdot \overline{\dot{u}_p^3}| / g^4\ , \tag{24}$$

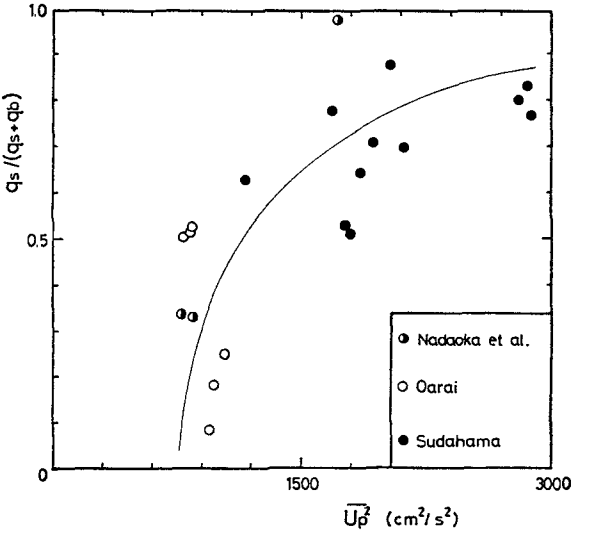

Fig. 10 Rate of suspended load transport compared with $\overline{U_p^2}$.

where sgn($\overline{U_p^3}$) is neglected because it has the absolute value of unity. Utilizing the values listed in Table 2, we can calculate the values of $q_s/(q_s + q_b)$ on the basis of Eqs.(23) and (24). The obtained values are plotted on the ordinate against the values of $\overline{U_p^2}$ on the abscissa in Fig.10. According to Fig.10, the ratio of the absolute suspended load transport to the total transport varies among the values of less than 0.1 to nearly 1.0 with a tendency of increase with the mean-square value of the velocity in the principal wave direction. From this tendency of increase, it can be inferred that the suspended load transport will become more significant under the high wave conditions.

6. Summary

The major conclusions in this report are as follows:

(1) It is reconfirmed that the advection speed of sand tracer in the mean current direction is about 1 % of the mean current velocity.

(2) The advection speed of sand tracer in the principal wave direction depends on not only the up-and-down asymmetry but also the before-and-behind asymmetry in the velocity profiles. The former asymmetry is considered to be related to the bed-load transport and the latter one to the suspended load transport. The magnitude of the before-and-behind asymmetry is evaluated by calculating the skewness for the acceleration profiles.

(3) The local mixing depth of the bed material is approximately proportional to the mean-square value of fluid velocities, which suggests the linear relationship with the local wave height.

(4) For the first approximation, the equations for the local sand transport rate are proposed which are restricted to the field conditions under which the observations have been carried out.

(5) The transporting conditions of suspended load are inferred so that the bed material may be transmittently transported in suspension in relatively short durations and be buried in the sea bottom due to the process of mixing of bed material during the remaining periods.

(6) The suspended load transport will become more significant under the high wave conditions.

The local sand transport rate equations empirically obtained in this study are not necessarily enough, because the local bottom slope, sediment characteristics, the critical velocity of the onset of sand movement and other factors are not taken into account and the assumption in the form of Eq.(13) is for the first approximation. Furthermore, it is a question whether the fluid velocities at the point of about 20 cm above the sea bottom is appropriate or not to be related with the sand transport rate. It is, however, clear for the local sand transport in the onshore-offshore direction that both the up-and-down and the before-and-behind asymmetry in the velocity profiles are important factors.

CHAPTER 92

APPLICABILITY OF SUB-SAND SYSTEM TO BEACH EROSION CONTROL

Yoshiaki KAWATA, M. ASCE* and Yoshito TSUCHIYA, M ASCE**

ABSTRACT

We performed experiments in the laboratory under controlled conditions in order to determine the applicability of a sub-sand filter system to the beach erosion control work. The filter system is used to control a flow condition at the sediment-fluid boundary. In the foreshore, it increases the inflowing velocity into the beach and thus results in increasing the threshold of beach sediment movement. The sub-sand filter system accelerates accretion of much beach sediment in the foreshore through the development of a berm under normal wave conditions. When wave conditions change from normal to stormy , it is also applicable to stabilize the beach profile, and thus decrease loss of beach sediment from the foreshore to the offshore.

INTRODUCTION

As Duncan(1964) pointed out, during flood tide the water level rises faster than the water table within the beach, so that the seaward edge of the water table slopes shoreward. Because of this, most of the sediment transported up the beach face by the swash during flood tide is deposited at the top of the swash limit. During ebb tide the enhanced backwash removes the sediment and deposits it on the shoreward side, where the backwash collides with the incoming surf and loses its transporting capacity. This mechanism has been investigated by many researchers in the field of coastal geomorphology. In the foreshore, the thin and wedge shaped layer of water in the wave uprush /backrush moves the sediment up and down the beach face. The depth of the beach sediment layer over the water table can control the rate of infiltration of sea water accompanied with wave run-up. This leads to changes of swash movement of sediment along the beach. The sub-sediment filter system is used to control the flow condition at the sediment-fluid boundary. In the foreshore, the system increases the inflowing velocity into the beach and thus results in increasing the

** Professor, Disaster Prevention Research Institute, Kyoto University, Kyoto, Japan

threshold of beach sediment movement. In the case of the laminar boundary layer, theoretical expression of the threshold of a sand under suction velocity is given by the authors (1984).

This protection technique has been developed by Chappell(1975) and Machemehl et al.(1976). In order to establish the sub-sand filter system as a means of beach erosion control, it is necessary to perform systematic experiments of beach changes under controlled conditions and to study increment of the threshold of sediment movement by the system. The objectives of this study are to investigate the effects of the system on the stability of beach profiles in the foreshore and to establish the applicability of the system to beach erosion control work.

EXPERIMENTS OF SUB-SAND FILTER SYSTEM

(1) Experimental apparatus

a) Solitary waves

The solitary wave tank shown in Fig. 1 is 21.6m long, 0.75m wide and 1.2m deep and has six trays in permeable slope to construct the sub-sand filter system. Suction pipes are connected to every tray and discharge rate is controlled by valves. Waves are generated automatically by a plunger with an eiectromagnetic cluch at intervals of 5 minutes 50 seconds. All experiments were run at a depth of 43.1cm. The permeable and impermeable beaches of slope 1/10 are constructed with sediment of mean diameter 0.350 mm. The experimental conditions are listed in Table 1, in which H is the wave height and u_s the suction velocity.

b) Monochromatic waves

Beach erosion control tests were carried out in a large wave tank (78m long, 1m wide and 1.5m deep) as shown in Fig. 2. A double hinged flatter type wave generator was used to generate regular waves. The wave period was varied by changing the running speed of the variable-speed drive unit thus enabling a continuous range from 0.5 s to 5 s. The wave height was changed with the eccentricity of the rod connecting the driving disk equipped at the generator. The test beach was 56m in length and was inclined at a slope of 1/30. The mean sediment diameter was 0.940mm. Sixteen pipes of diameter 5cm were used to construct the sub-sand filter system. They had a slit width of 1.5cm covered with fine mesh to prevent the passage of sediment. The header-pipe, of diameter 10cm, was coupled to the intake of a pump. The experimental conditions are listed in Table 2. Each run was further divided into two cases; a filtered experiment (hereafter referred to as A) and an unfiltered one (hereafter referred to as B).

(2) Measuring system

A capacitance type wave gauge and an ultrasonic depth sounder were attached to a movable carriage on the tank. This carriage moved at a speed of 10cm/s. The former was used to survey the bottom topography and the latter to determine the wave breaking point. The beach profile above still water level was obtained by using an improved point gauge.

(3) Procedures

To estimate the effects of the sub-sand filter system on the stability of a beach profile, it is necessary to compare the changes in the profile of an unfiltered beach with those in the profile of a filtered beach.

Each run was conducted in the following manner. First, the desired wave characteristics were established. Secondly, the beach was raked into its initial profile (1:10 for solitary waves and 1:30 for monochromatic waves) and the beach profiles were recorded. The pump for the filter system was operated at a constant flow rate during all tests.

CHARACTERISTICS OF BEACH CHANGES

(1) Beach Profile Changes by Solitary Waves

Some examples of the beach changes with respect to the number of solitary waves when equalling 200, 400 and 600 are shown in Fig. 3, in which a solid line and a dotted one are the beach profiles with and without filter operation respectively. The processes of the beach changes by solitary waves are as follows. At the beginning of the experiments, the shoreline retreated rapidly. A berm was formed in the foreshore and a step was formed in the inshore. In the case of

the larger wave heights such as in Run Nos. 3 and 4, ripples were generated on the step. Due to the sub-sand filter operation, the growth rate of the berm area with increment of the number of solitary waves was large in comparison with that under natural conditions. Therefore, the seaward slope of the berm with the filter became steep, and then the breaker scour formed at the onshore end of the step enlarged. Consequently, by the sub-sand filter operation, the deposition of sediment in the foreshore was developed, but the characteristics of the beach changes, such as shoreline recession and formation of a berm and a step, were not changed due to the filter operation.

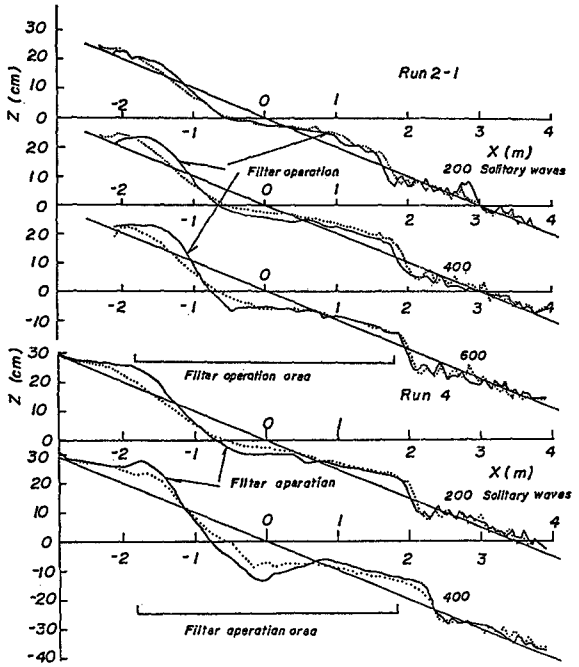

Fig. 3 Beach changes by solitary waves.

(2) Beach Profile Changes by Monochromatic Waves

Typical changes of beach profiles with time are shown in Fig. 4. From the experimental profiles in the nearshore zone in Run 7 (stormy wave condition), it was found that the beach profiles under filter operation are different to those under natural conditions. In the case of (B) (no filter operation), the small bar which was in the nearshore at t=5hr moved shoreward and developed, and changed to a large berm in the foreshore at t=10 hr. Finally, this berm came up to the beach crest and had two peaks. In the case of (A) (filter operation), the beach sediment movement in this area was not as simple as that in (B). Two small bars developed with time and moved shoreward, but the sizes and the moving speeds were very small in comparison with the former case. It was recognized that the sub-sand filter system reduces the sediment movement and stabilizes the beach changes in the nearshore zone.

In Run 8 (normal wave condition), from the view point of processes of berm development in the nearshore zone, existence of the sub-sediment filter system made no distinguishable difference to beach profile changes at t=7hr under natural conditions. After this time, the height of the berm in (A) was larger than that in (B), and then the shoreline advanced in the former case. From a budget of beach

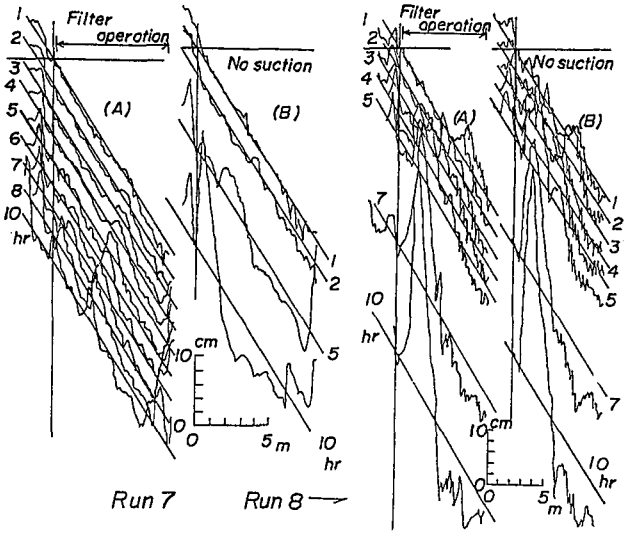

Fig. 4 Beach changes by monochromatic waves.

sediment in the nearshore zone, much sediment moved seaward in the offshore side of the berm and beach erosion occurred in the case of (B). Under the sub-sand filter operation, on the contrary, the accretion of beach sediment in the foreshore was found, because the seaward sediment movement was very controlled in the nearshore zone. It was also pointed out that under the filter operation, the beach profiles in the foreshore have a smooth surface due to the disappearance of ripples.

It is necessary to discuss whether the system is applicable or not when normal wave conditions change to stormy, because bottom roughness formed under the filter operation is very small. Under this bottom condition, incoming wave energy does not quickly dissipate and beach erosion will occur in the foreshore. Fig. 5 shows the results of the beach profile changes under the conditions mentioned above. The initial beach profile in Run 9 (stormy wave conditions) was the profile in which the filter was operated for ten hours in Run 8 (normal wave conditions). The changes of the beach profiles without the filter were very large in the foreshore, especially at the seaward slope of the berm, and much sediment moved seaward from this area. In contrast, the sub-sand filter system could stabilize the sediment movement, so that the changes of the beach profiles were smaller than those without the filter. It was found that the system is also effective, even if the wave conditions change to stormy.

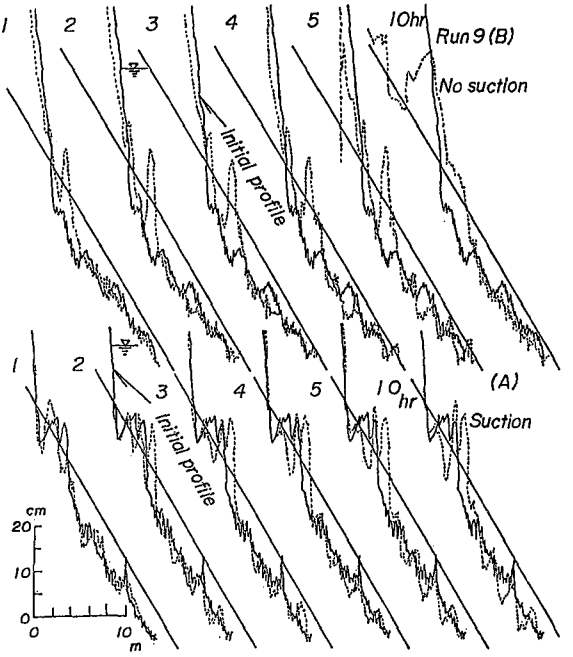

Fig. 5 Beach changes with changes of wave conditions from normal to stormy ones.

EFFECT OF SUB-SAND FILTER SYSTEM ON BEACH CHANGES

The development of a berm by solitary waves is shown as normalized beach profile A/A_a vs. H/h in Fig. 6, with the value of suction velocity u_s as a parameter. The symbol A is the area of the berm and A_a is the area of a right-angle triangle in which the length of the hypotenuse is the distance from a shoreline to a point of maximum runup height. It was found that in the range of the suction velocity, the effect of H/h on the berm size under the filter operation is about twice to four times greater than that under normal conditions. However, the growth rate of the berm with the increment of H/h is unaffected by any suction velocity in our experiments. The suction velocity which gives the largest value of A/A_a in the case of the experiments with 200 solitary waves does not coincide with the maximum velocity in any value of H/h.

The relationship between A/A_a and a dimensionless suction velocity u_s/w_f is shown in Fig. 7 with the value of H/h as a parameter. The symbol w_f is the settling velocity estimated by Rubey equation. In the case of H/h=0.250, the largest value of A/A_o is found at a moderate value of u_s/w_f both in 200 and 400 solitary waves. In other words, there is a most effective suction velocity in the growth of an underdeveloping berm. In the cases of H/h=0.167 and 0.203, the ratio A/A_a becomes nearly constant in the range of u_s/w_f of more than 0.25×10^{-3}. Under small wave conditions, the runup height and the rate of swash sediment transport are small, so that it is very difficult to make clear the effect of the filter. Consequently, the effect of the filter operation on the berm development depends on the runup height. Therefore, the most effective suction velocity will change with time.

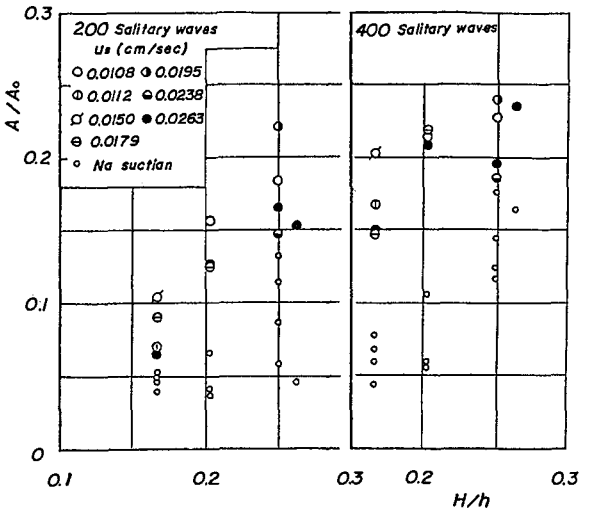

Fig. 6 Relationship between area of berm and ratio of wave height to water depth.

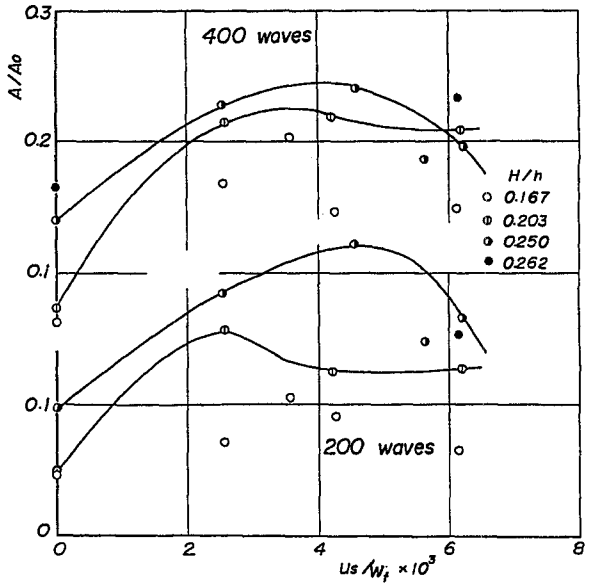

Fig. 7 Relationship between area of berm and suction velocity.

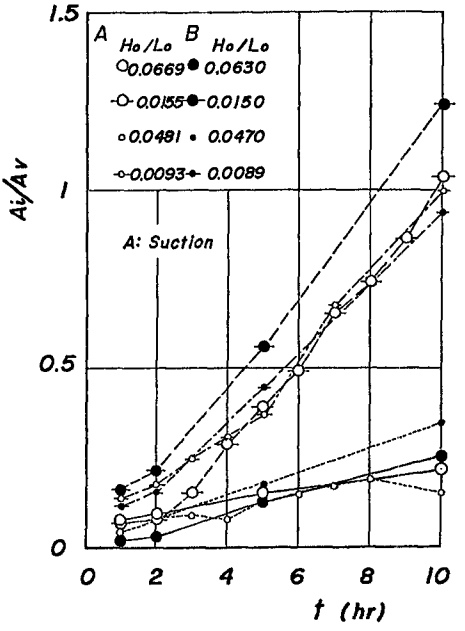

Fig. 8 Changes of budget of beach sediment in the foreshore with time.

The time development of the deviations of the dimensionless area A_i/A_v by monochromatic waves is shown in Fig. 8 with the wave steepness as a parameter. The symbol A_i is the amount of accretion and erosion areas (their absolute values) from the initial beach profile on the sub-sand filter system, and A_v is the area of a right-angle triangle in which the length of the hypotenuse is equal to that of the sub-sand filtered system. In our experiments with monochromatic waves, A_v is constant, because the length of sub-sand filter is 8m and the slope is 1/30, and so this value is 1.065 m^2. It is recognized that the changes of A_i/A_v with time in Run Nos. 6 and 8 (normal wave condition) are very large in comparison with those in Run Nos. 5 and 7 (stormy wave conditions), and this tendency continues until t=10hr. The values of A_i/A_v under the filter operation are smaller than those under natural conditions. This result is similar to that found by Machemehl(1976), though he defined the saturated and partially saturated zones (their boundary is a shoreline, and the area above still water level is defined as the saturated zone and the area below one is the partially saturated zone).

Fig. 9 shows the changes in the amount of accretion and erosion areas from the initial beach profile with time in Run 9. In this experiment, the initial profile was formed by the waves with a wave steepness of 0.0155. Even if the wave steepness changes from 0.0155 to 0.0481, the sub-sand filter reduces areas of accretion and erosion. The smaller value of A_i/A_v indicated that during the filter operation, the beach profile was more stable.

Fig. 10 shows the relationship between A_i/A_v and the wave steepness, with the duration of experiments as a parameter. As mentioned before, A_o in Machemehl's data is the saturated zone which is the area influenced with the filter below the still water level. It is found that the effect of the sub-sand filter system on the stabilization of the beach profile becomes very clear with the increment of the dura-

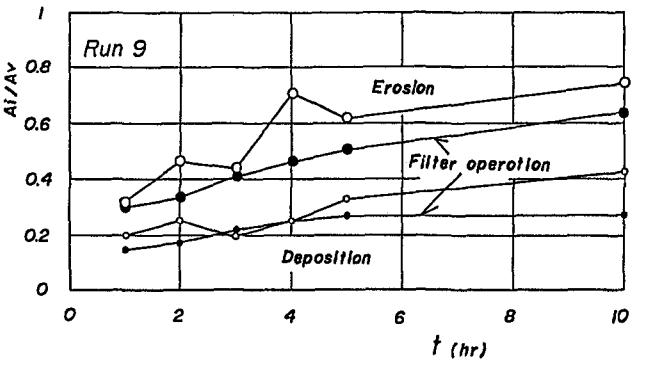

Fig. 9 Changes of budget of beach sediment in accompany with changes of wave characteristics

tion of the operation. Furthermore, the changes of A/A_o with time reduce and come to constant concomitantly with the increment of the wave steepness.

Above all, through our experiments concerning the effect of a sub-sand filter system on the stabilization of the beach profile, it is pointed out as follows: In cases of solitary waves and monochromatic waves with small wave steepness (swell wave conditions), the accretion in the foreshore grows very rapidly and leads to the formation of a berm under the filter operation. As the accretion area enlarged, the filter was not as effective so that a backrush did occur at the end of all our experiments. When the beach changes are caused by the waves with large wave steepness, the effect of the sub-sand filter system on the changes of accretion and erosion areas is not so

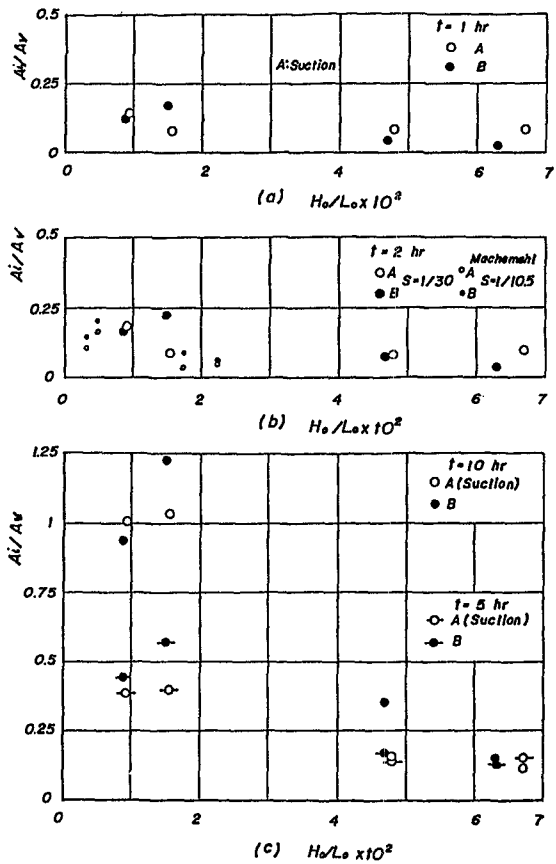

Fig. 10 Relationship between budget of beach sediment and wave steepness.

clear, but the filter did minimize the sediment movement in the area influenced by the filter in the nearshore zone. According to the experimental results of the beach changes under the filter operation, the roughness height become very small and it is very difficult to find ripples in the nearshore zone. In addition, the characteristics of beach profiles such as a stormy beach and a normal one do not change with the filter operation.

APPLICABILITY OF SUB-SAND FILTER SYSTEM

The most important point of the sub-sand filter systems in beach erosion control work is, of course, that the control work has high applicability to prevent or to mitigate beach erosion under any wave conditions. We discuss the applicability of the filter based on our experimental results. From Figs. 6, 7 and 8, the sub-sand filter system can accelerate accretion of much sediment in the foreshore through the development of the berm, so that it is accompanied by a shoreline advance. This characteristic shows the typical beach changes under normal wave conditions, so that this system encourages furthermore the beach changes with the duration of the wave action.

As is a well-known fact, the wave runup height become large with the decrease of the wave steepness. The swash movement of the beach sediment up and down the beach face can be largely controlled by the permeability of the beach, because the increased effective drag force creates a higher threshold for the sediment movement.

When wave conditions change from normal (swell wave) to stormy, the sediment of the berm in the foreshore moves seaward as the sediment in the offshore moves shoreward, and forms longshore bars, as shown in Fig. 4. Under the filter operation, the former sediment movement becomes inactive by the increment of the threshold. Therefore, the offshore sediment is greatly contributes to the formation of a longshore bar. In other words, loss of the sediment from the foreshore decreases. At the same time, the surface roughness mitigated by the filter operation in the foreshore does not lead to the enlargement of the beach erosion as shown in Fig. 9.

Our experiments were two dimensional in relation to cross-shore sediment transport, but saw-tooth movement of beach sediment due to waves with arbitrary wave angle will certainly be controlled by the system, so that the rate of longshore sediment transport is expected to reduce. As the results clearly show, the sub-sand filter system has high applicability to beach erosion control work.

CONCLUSIONS

We have developed the sub-sand filter system for beach erosion control work. The system has high applicability for stabilizing beach profiles in the foreshore, and consequently it is useful to reduce the offshore movement of beach sediment under any wave conditions.

CHAPTER 93

EVALUATION OF INCIDENT WAVE ENERGY IN FLUME TESTS

Eliezer Kit [1], Oded Gottlieb [2] and Dov S. Rosen [3], M. ASCE

ABSTRACT

A two dimensional model study, carried out for a structure in a flume using irregular waves, presents the problem of determining the relationship between the total incident wave energy attacking the structure and its response to that attack (displacements, forces, etc.) in various sea states. The total incident wave energy can be evaluated indirectly only, because the wave energy measured in the flume contains an extent of residual wave energy in addition to that generated by the wave machine. This residual energy consists of the re-reflected wave energy from the paddle of the wave machine, assuming the existence of quasi-stationary wave conditions in the flume. A method originally presented by Gravesen et al. (1974), was applied in this study to evaluate the total incident wave energy. In view of the results obtained by this method, a physically more sound refinement is proposed for the evaluation of the total incident wave energy (and characteristic wave height). Results of model tests were analyzed by the CAMERI refinement and compared with the Gravesen method and with a cross-spectral least squares method, separating incident and reflected wave spectra from wave spectra measured in the flume. Good agreement was found between the results obtained employing the CAMERI refinement and the cross-spectral least squares method. Advantages and drawbacks of these methods are indicated.

INTRODUCTION

The study of wave effects on structures in flumes using irregular waves, for example two dimensional breakwater stabilitiy studies, requires the determination of the incident wave energy in order to relate resulting wave effects (forces, displacements, overtopping, etc.) to the waves and by them to their probability of encounter.

Assuming quasi-stationary wave conditions in the wave flume, the incident wave energy (and the characteristic wave height) can be evaluated indirectly only, because the waves generated by the wave machine are partially reflected by the structure tested, then re-ref-

lected by the paddle of the wave machine back towards the structure and so on. Thus, a residual incident wave energy is added to the incident wave energy originally generated, resulting in a new total incident wave energy (and characteristic wave height).

Nowadays the most popular methods used for the determination of the incident wave energy in flume tests are as follows:
a) Division of the flume longitudinally into two (or more) sections of which one is used for the structural test, while the other is equipped with a mild sloping - wave absorbing beach and is used to measure the "incident" wave energy.
b) Two points cross spectral analysis, originally proposed by Goda and Suzuki (1976).
c) Three points least squares cross spectral analysis, proposed by Mansard and Funke (1980).
d) Preliminary determination of the coefficient of wave energy re-reflection using the method proposed by Gravesen et al. (1974), hereafter referred as the Gravesen method, or a refinement to it proposed by the authors in this article, referred as the CAMERI refinement.

The two points cross spectral method is based on the main assumption that irregular waves may be described as a linear superposition of an infinite number of discrete components, each with its own frequency, amplitude and phase. Another important assumption is that these components travel at their own individual phase velocity, described by the dispersion relationship. The method consists of measuring simultaneously the co-existing wave trains moving in opposite directions at two wave gauges located in constant water depth, close to each other and aligned parallel to the direction of wave propagation in the flume and cross spectral analysis to evaluate the incident and reflected spectra.

The third method attempts to overcome certain limitations of the two points cross spectral method such as limited frequency range, critical wave gauge spacing and high sensitivity to errors in the measurement of waves. It uses the two points method to measure the co-exsting wave trains moving in opposite directions at three or more locations of constant water depth (to prevent wave shoaling effects) and aligned on a line parallel to the direction of wave propagation in the flume. Spectral analysis of the signals at each wave gauge and cross spectral analysis between the signals of each pair of wave gauges by means of Fourier transform is done to express the wave activity at each wave gauge location in terms of an incident wave, a reflected wave and a noise signal. A least squares method is applied to resolve the Fourier expressions of the signals at each wave gauge in order to minimize the noise for all wave gauges.

The Gravesen method to determine the total incident wave energy is based on the preliminary determination of the re-reflection coefficient of wave energy from the paddle of the wave machine and on the evaluation of the coefficient of reflection of wave energy from the structure afterwards. This method and the proposed CAMERI refinement are described in detail in the following lines.

GRAVESEN METHOD

The evaluation of the coefficient of wave energy re-reflection is accomplished by preliminarily carrying out two separate series of tests in absence of the model structure investigated, but on the same bathymetry and for the same sea states to be generated on the model structure. The first series is performed with a non-reflective beach, while the second series is carried out with a reflecting vertical (rigid) wall, located at the position at which the model structure will be placed in the flume. Finally, the third series of tests is carried out with the model structure, under identical sea states as generated in the two preliminary test series.

For each sea state of any series of tests the assumptions of the cross spectral methods are also accepted. Consequently, the following expresions can be written by measuring the variance of the water elevation at a fixed position in any test:

$$Hm^2 = Hi^2 + Hr^2 \qquad (1)$$

where: Hm is the measured characteristic wave height,
Hi is the total incident characteristic wave height and
Hr is the reflected characteristic wave height.

The reflected energy coefficient Br and the re-reflection coefficient of wave energy Brr are derived from expressions (2) and (3) given below:

$$Hr^2 = Br * Hi^2 \qquad (2)$$

$$Hi^2 = Hg^2 + Brr * Hr^2 \qquad (3)$$

where: Hg represents the wave energy generated by the wave machine.

By inserting (2) in (3) and extracting Hi and then introducing the result in (1), the resulting expressions obtained are:

$$Hi^2 = Hg^2 * [\, 1 / (1 - Br * Brr) \,] \qquad (4)$$

$$Hm^2 = Hg^2 * [\, 1 / (1 - Br * Brr) \,] * (1 + Br) \qquad (5)$$

To determine the unknown values of the coefficient of re-reflection of wave energy from the wave machine paddle (Brr) and the incident wave energy generated by the wave machine (Hg), the Gravesen method assumes a Br value of zero (0) for the tests with a spending beach, which means that in the first series of tests it is assumed that Hm = Hg. In the second series of tests with the vertical wall, it assumes that Br takes the value of one (1). Hence, for each sea state it is possible to determine Brr since Hm remains the same as in the previous series of tests. Finally, in the third series of tests with the model structure, the reflection coefficient of wave energy (Br) from the structure and the total incident characteristic wave height (Hi) can be determined (see schematization in Figure 1).

Figure No. 2 - Testing set-up in preliminary testing series (Geometric model scale 1:65)

CAMERI REFINEMENT

The methods described above were considered for use in a two dimensional stability model study for the rehabilitation of the main breakwater of Ashdod Port (Rosen and Gottlieb - 1985). The design storm for this study included various sea states of increasing characteristic wave height. The higher sea states included a large fraction of waves which were expected to break or to be at near breaking point. Under such conditions non-linear effects may be strong and affect the reliability of cross spectral methods based on linear assumptions regarding wave profile and wave transformation. Therefore, the Gravesen method was considered an appropriate alternative. However, this method's assumption of Br = 1.0 from the vertical wall and the expectation of a different value for Brr from the paddle of the wave machine, did not seem physically justified. Consequently, two refinements were introduced to the Gravesen method:

a) In the testing series with a vertical wall, Br would be approximately equal to Brr, especially if a piston type wave machine is used.

b) The value of Brr to be used in the tests with the model structure, should be the average of the values of Brr obtained in the vertical wall testing series with low sea states only.

EXPERIMENTAL SETUP

A preliminary experimental study was conducted to investigate the applicability of the Gravesen method, the CAMERI refinement and the cross spectral least squares method in order to choose the most reliable method for the evaluation of the incident wave energy and characteristic height on the model breakwater.

The investigation was performed in one of CAMERI's wave flumes. Twelve resistance type wave gauges were used to measure the waves in the flume (two groups of three pairs located at two sites). The locations of the wave gauges were in two regions of mild bottom slopes of about 1:80 near the -17m and about 1:100 near the -23m contour lines. The wave generator was located in relatively deep water (-40m) and in the first series of tests a spending beach of rubberized coir material enclosed in wire mesh (slope 1:13) was placed at the end of the flume (see Figure No.2).

The shape of the spectral variance distribution of the synthetic time series was of a JONSWAP type with slightly modified values of the parameters (see Figure No.3). The duration of the sea states was varied (see Figure No. 4) to simulate storm development pattern from low to extreme conditions. The structure used in the preliminary investigation consisted of a smooth slope of 1:5, while the model study consisted of a tetrapod breakwater cross section with an initial slope of 1:1.33 (see Figure No.5).

DISCUSSION OF EXPERIMENTAL RESULTS

A set of typical results for the preliminary investigation is presented in Tables 1 and 2 based on the wave gauges located on the -17m and -23m contour lines respectively.

It should be noted that in the testing series with the vertical wall, the wave energy reflection coefficients (Br) obtained by the CAMERI refinement are in good agreement with the corresponding values evaluated by the cross spectral least squares method. Both methods give Br values between 0.65 to 0.70, while the Gravesen method assumes a Br value of 1.0. Furthermore, inspite of the fact that a vertical paddle piston type wave machine was used, re-reflection coefficients (Brr) of about 0.3 were obtained using the Gravesen method. These values were significantly different from 1.0, which was the value assumed for the reflection coefficient (Br) from the vertical wall.

The results obtained in the test series with the spending beach by the cross spectral method, confirm the prerequisite assumption of complete energy absorption by the spending beach for both Gravesen method and CAMERI refinement.

The wave energy reflection coefficients (Br) obtained for the 1:5 smooth slope structure, show that the values evaluated by the CAMERI refinement are in better correspondence with the cross spectral method than those evaluated by the Gravesen method.

Similar results from the actual stability model study with the tetrapod breakwater are given in Table 3.

The Br values evaluated by the various methods are plotted against the values determined by the cross spectral least squares method in Figure No.6.

Comparisons of the values of the characteristic incident wave heights evaluated using the various methods are presented in Figures No. 7 through 12 against the characteristic incident wave height values determined by the cross spectral least squares method.

Improved estimates of the total incident wave energy are obtained by the CAMERI refinement using more realistic reflection coefficients, for relatively low to moderate sea states.

It should be mentioned that the accuracy of the cross spectral method is limited in high sea states because the wave profile and the wave length are no longer well described by the linear theory , even if breaking does not occur. On the other hand some minor differences between the results are due to the fact that the wave gauges were not located in a constant depth zone.

The results indicate that better estimates are obtained for the high sea states with breaking waves, employing an average re-reflection coefficient obtained for the low sea states.

CONCLUSIVE REMARKS

The CAMERI refinement enables the evaluation of total incident wave energy (characteristic wave height) with almost no dependance on the bathymetry, easily providing real-time results, without any requirements for sophisticated software and comprehensive computer hardware. Its advantages versus the Gravesen method, result from a physically more sound approach, as proven by the analysis performed. Although the Gravesen method leads to lower estimates of the values of the total incident characteristic wave heights which might be considered to lead to conservative designs, the costs related to such conservative estimates, especially those of high sea states can not be reasonably justified.

The cross spectral least squares method provides off-line spectral distributions for incident and reflected waves, unavailable by the former approach, but it requires extensive computer resources and is of limited accuracy in the evaluation of high sea states with near breaking and breaking waves. Its use is also limited to horizontal or mild sloping sea bottoms. The results obtained using the CAMERI refinement can be used to verify results obtained by the cross spectral least squares method, increasing the reliability of the results of any flume study.

ACKNOWLEDGMENTS

The authors express their gratitude to E. Funke and J. Ploeg, Hydraulics Laboratory - National Research Council of Canada, for providing the cross spectral analysis computer programs.

The permission of Port Authority - Israel, to use and publish test results of wave data related to the Ashdod Port main breakwater rehabilitation model study, is gratefully acknowledged.

CHAPTER 94

Impact of Offshore Dredging on Beaches along the Genkai Sea, Japan

Haruyuki Kojima, Takeshi Ijima and Tadaaki Nakamuta*

ABSTRACT

Offshore dredging has been taking place in the coast of the Genkai Sea, Japan, since the early 1970's, which totaled more than 20 million cubic meters. In order to evaluate the impact of offshore dredging on shorelines as well as the adjacent sea bed, comprehensive coastal engineering studies were carried out over the last four years. The results obtained are not sufficient to establish a direct cause-and-effect relationship between offshore dredging and beach erosion; however, the correlation is sufficient to serve as a warning of a potentially serious problem. Moreover, the dredged holes above 30 meter depth are found to trap the sand from the neighboring bed, and considerable movement of sediment by wave action was observed above 35 meter depth. Thus, offshore mining that would minimize interruption of beach littoral system should be operated below 35 meter depth in the study area.

I. INTRODUCTION

A series of concave beaches separated by headlands forms the coast of the Genkai Sea in the northern part of Kyushu, Japan, as shown in Figure 1. These beaches have been considered to be stable because of the fact that they exist as sandy beaches without much supply of sediment from rivers. Since the early 1970's, owing to the increase in the demand for aggregate and restriction in the mining of gravel from rivers, sea bed at water depth of 15 to 40 meters has been dredged for the extraction of gravel and sand for use as aggregate in concrete. Recently, it was pointed out that beach erosion has been occurring and the cause is thought to be the possible effects of offshore dredging. Due to the possibility of a man-made cause, this erosion problem became an important issue in conserving valuable beaches in the study area and the impact of offshore mining on coastal morphology became public concern.

The objectives of this study are as follows:

(1) to identify historical shoreline changes and to evaluate characteristics of shoreline changes,

* Department of Civil Engineering Hydraulics, Kyushu University, 6-10-1 Hakozaki, Higashi-ku, Fukuoka 812, Japan

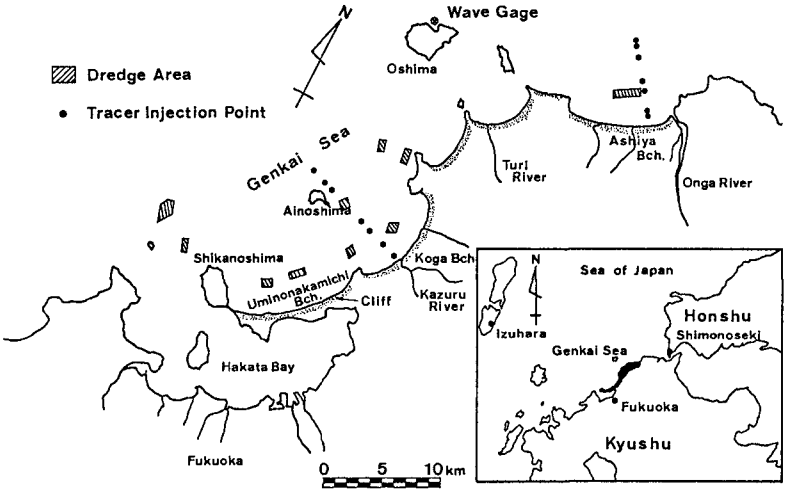

Figure 1 Vicinity Map of the Study Area

(2) to investigate causes of significant beach erosions and accretions through considering wave and climatic characteristics of the study area as well as data pertinent to human activities like offshore dredging and construction of coastal structures,
(3) to assess the link between beach erosion and offshore dredging and the effects of the present offshore dredging activities on the ambient beaches,
(4) to propose guidelines on how offshore mining should be conducted.

II. DATA COLLECTION

Several studies were carried out over four years 1981 to 1985 to obtain pertinent information on morphological changes and offshore dredging effects. They are:
(1) Meteorological surveys including compilation of wind data since 1896 and the number of typhoon attacks.
(2) Compilation of offshore wave data from 1975 to 1984 .
(3) Compilation of allowed volume of sand extraction from the sea bed between 1972 and 1983.
(4) Analysis of aerial photographs to determine historical shoreline changes.
(5) Hydrographic surveys over four years from 1981 to 1985 to obtain profile changes in beach and dredged holes.
(6) Fluorescent tracer studies and sea bed level measurements to acquire data on sediment movement.

III. DESCRIPTION OF THE STUDY AREA

3.1 Description of the Coastal Area

The study area is located in the northern part of Kyushu Island, one of the four main islands forming Japan, and bounded by Onga River to the east and Hakata Bay to the west. One of the major morphological characteristics of the coastline in this area is a series of concave beaches, divided by rocky promontories, resulting from formation of small valleys or basins due to submergence and emergence of land. These beaches stretches from 1 km to 15 km. Because of these headlands, movement of littoral sediment is confined at each concave beach; the supply of sediment from the neighboring beaches is considered to be insignificant.

Major sources of sediment supply in the study area are river and sea cliff. Using annual sediment yield per unit area of drainage basin, obtained from surveys of sediment trapped by reservoirs, and drainage area of each river basin, the total sediment production of each of the rivers was estimated. From this estimation Onga River may at maximum produce about 220,000m^3/year; sediment production of other rivers is considered to be negligible, being less than 10,000m^3/year(1). Sea cliff, another sediment source, is located at the east end of Uminonakamichi Beach, as shown in Figure 1. The cliff is 15 to 20 meters high and stretches about 1.5km along the shoreline.

3.2 Wind and Wave Characteristics

Wind and wave data compiled at Oshima between 1976 and 1980 were used to determine their characteristics. Wind velocity and direction frequencies are shown in Figure 2. The prevailing winds in the study area are from northwest during the winter season and out of the south-southeast during summer months. A dominant direction of strong winds with the velocity of over 10 meters/sec. (hereafter referred to as storm winds) is northwest at any season.

Figure 3 indicates seasonal occurrence frequencies of significant wave height and period. Severe waves with destructive energy occur during winter season. Taking into consideration the direction of storm winds, it is inferred that the prevailing high energy waves in the Genkai Sea are from northwest during winter months.

IV. SHORELINE CHANGES AND THEIR CAUSES

4.1 Historical Shoreline Changes

To quantitatively evaluate long-term shoreline alterations, numerous aerial photographs, taken from 1947 through 1982, were used, together with a digitizer which read positions of the water line on the aerials. After scale and tidal level were corrected, positions of the mean water shoreline were compared at every 50 or 100 meter interval in a consecutive yearly order. Rates of shoreline retreats or advances over three time periods were delineated for each

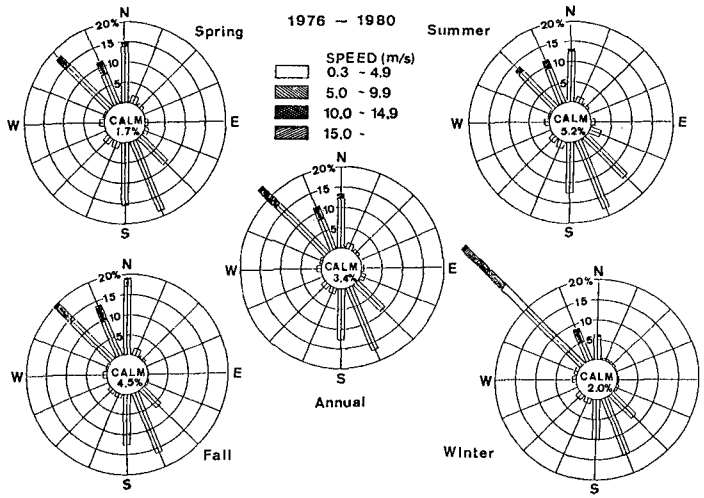

Figure 2 Seasonal Wind Roses

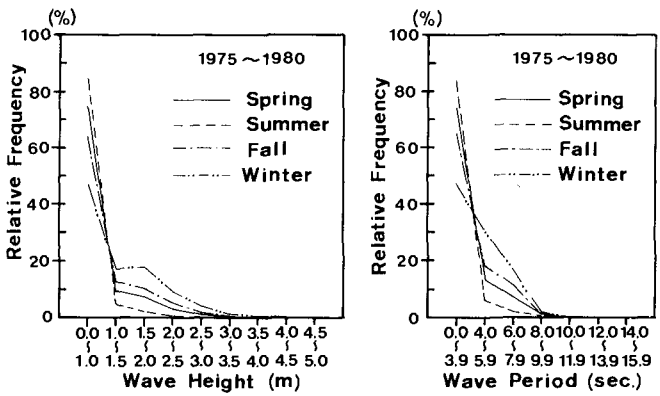

Figure 3 Seasonal Occurrence Frequencies of Significant Wave Heigh and Period

of the concave beaches (called Regions) in Figures 4 and 5. By averaging distances of the shoreline retreats or advances over small portions of each Region (called Areas) which were divided by considerations of spacial distribution patterns of the shoreline change rates plus the location of offshore dredging areas and coastal structures, yearly variations in average shoreline positions were acquired and are shown in Figure 6. Main results drawn from these changes are as follows:

(1) Between 1947 and 1961, a marked beach erosion with an average retreat of 45 meters occurred at the beaches in Region 5, the maximum shoreline recession being 85 meters, which took place in Area 3 of Region 5. For the same period

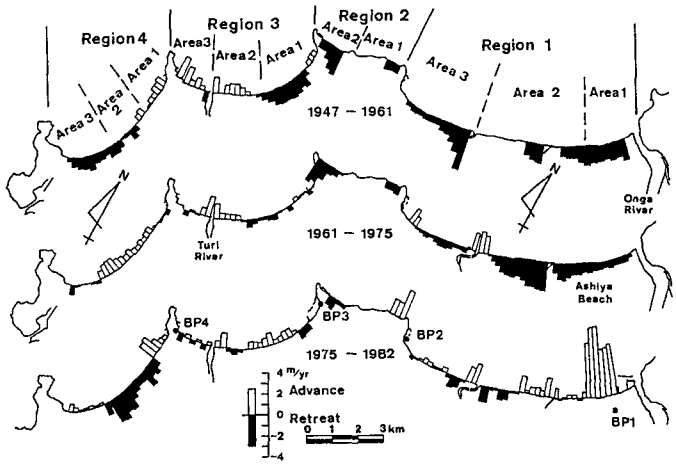

Figure 4 Distribution of Shoreline Change Rates in Regions 1 to 4

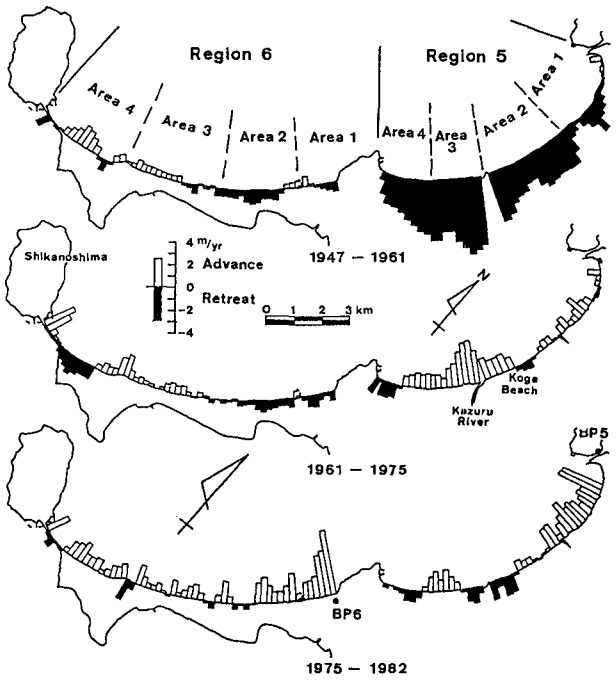

Figure 5 Distribution of Shoreline Change Rates in Regions 5 and 6

other beaches in Regions 1, 2 and 4 also had shoreline retreat ranging from 10 to 30 meters.
(2) Since 1961, most of the beaches have experienced a moderate erosion or stable condition, except for some of the beaches in Region 6 where shoreline receded sharply between 1966 and 1975.
(3) In Region 1, the beaches of Areas 2 and 3 had an erosional trend over 35 years from 1947 to 1982, whereas the beach of Area 1 showed a significant shoreline advance of 38 meters since 1975.
(4) The beaches in Regions 3 and 4, where the curvature of the concave beaches is rather big and an island called Oshima serves as an offshore barrier against the prevailing northwest waves (see Figure 7), indicated small shoreline variations being less than 20 meters over 35 years.

4.2 Causes of Significant Shoreline Changes

Possible causes of the significant shoreline changes identified above, especially beach erosion, are conceived of as follows:
(1) Exceptional intensity of wave impact
(2) Offshore dredging
(3) Construction of coastal structures.

In order to evaluate these factors, we performed extensive wave and weather surveys to determine an offshore wave condition which is regarded as the primary force altering beach configurations, and also collected information on the construction of coastal structures and volumes of the offshore dredgings. Because of the significance of storm-generated winds and typhoons in the overall scheme of coastal processes and erosion, the weather survey consists of two phases: (1) a compilation of data of storm winds with the speed of more than 10 meters/sec. and (2) an investigation of typhoon attacks experienced in the study area. These data were obtained from daily weather reports of the National Weather Service. Wave data measured at the depth of 20 meters offshore of Oshima(see Figure 1) were compiled from 1975 to 1981 for seven years.

Exceptional Intensity of Wave Impact

An attempt was made to correlate yearly fluctuations in the occurrence of both storm winds and severe waves with the trend of the beach erosion. Figure 8 shows occurrence frequencies of onshore storm winds with daily average speed of 5 meters/sec., high waves with significant height of over 3 meters and typhoon attacks which brought onshore storm winds in the study area. A tendency of the storm winds agrees quite well with that of the destructive waves; a remarkably high frequency of the storm winds between 1949 and 1959, thereby suggesting that abnormally strong wave energy may have exerted on the beaches. This period coincides with the occurrence of the severe beach erosion mentioned above.

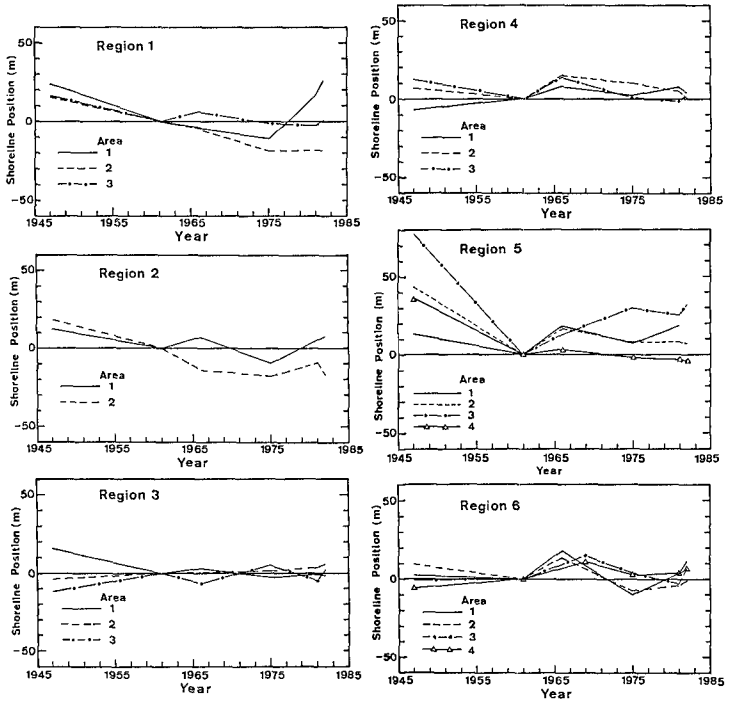

Figure 6 Shoreline Changes for Each Area versus Time

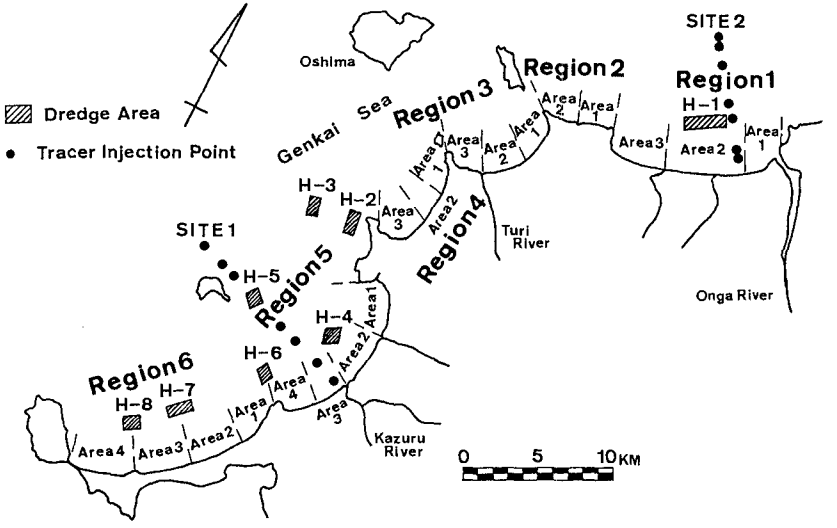

Figure 7 Locations of Areas, Dredging Sites and Fluorescent Tracer Injection Points

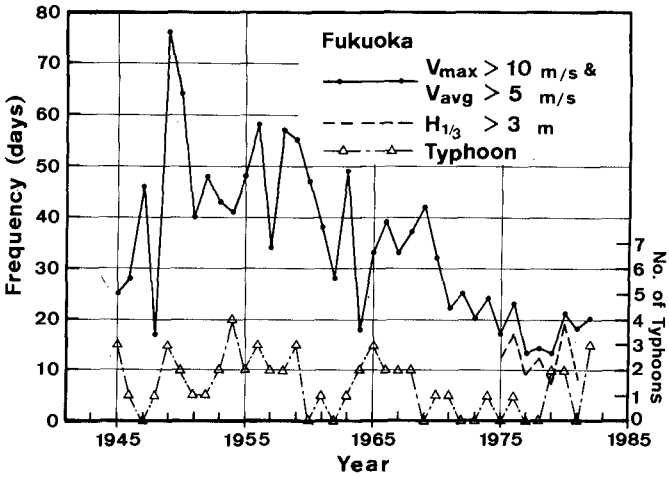

Figure 8 Frequencies of Storm winds, Waves and Typhoons

Thus, this beach erosion would most likely be caused by the exceptional intensity of wave impact.

Offshore Dredging

Annual variations in the dredging volumes were compared with the erosion trends to see if the possible effects of the offshore extraction on the beaches may be evaluated. Location of offshore dredging sites is delineated, in Figure 7, with respect to Areas where yearly shoreline changes were obtained for each Region. There are five Areas, offshore of which gravel and sand have been extracted at the depth of 15 to 20 meters; however, the mining site H-1 was excluded from this analysis because dredging started since 1982 and enough data have not been acquired yet. The average water depth of these four dredged holes are 18 meters for H-4, 25 meters for H-6, 16 meters for both H-7 and H-8.

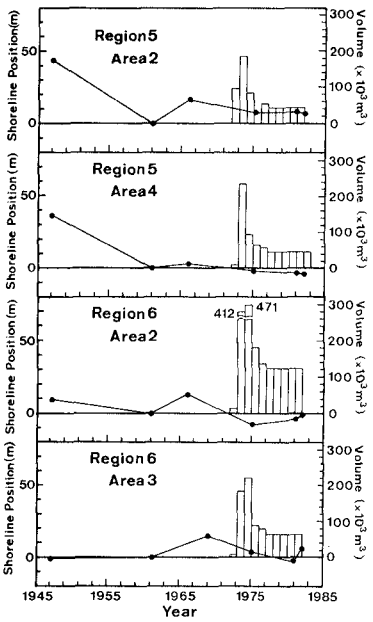

Figure 9 Relation between Shoreline Changes and Dredged Volumes

Figure 9 indicates a relation between annual Varia-

tions in dredged volumes and shoreline changes. Although the beaches in Region 5 had experienced an erosion trend before the gravel extraction, as seen in Figure 9, the beaches in Region 6 suffered a sharp shoreline recession after the offshore dredging started. Between 1966 and 1975 a shoreline recession rate for Area 2 of Region 6 was one of the severest in the study area over the nine year period, during which more than 0.8 million cubic meters of sand was dredged from the bed at 13 to 20 meters. This result therefore suggests the erosive effect of the dredging on the shorelines.

Coastal Structures

There are no data indicating severe shoreline retreat which may be attributed to the construction of coastal structures. However, drastic recovery from an erosion trend which took place on the beach of Area 1 in Region 1 may be a possible effect of the construction of six detached breakwaters in 1979.

V. ASSESSMENT OF THE PRESENT MINING ACTIVITIES

5.1 Profile Changes at the Dredged Holes

We conducted hydrographic surveys over four years from 1981 to 1985 to investigate profile changes at the dredged holes. In the surveys, an electronic positioning system and a sonic depth finder were used. Figure 10 shows typical beach profiles of four different holes dredged at several water depths. Beach profiles at and around dredge holes situated above the water depth of about 30 meters change substantially by piling up the holes with sediment. Profile changes at the dredged hole H-1 clearly illustrate infilling of the hole from the onshore side. Although profiles at greater depth and far offshore might involve considerable horizontal and vertical errors, changes in beach profiles at 35 to 40 meters seem to be insignificant and dredged holes there remain their shapes. Thus, the dredged trenches above, say, 30 meter depth in the study area may interrupt beach littoral system in that they serve as a trap to littoral sediment that would travel either onshore or alongshore. This depth is about twice as deep as the one obtained by Price, et al.(7) or much greater than the active zone of on-offshore movement which extends to about 10 meters, observed off La Jolla, California, by Inman and Rusnak(4). Although active on-offshore sediment movement in the study area would hardly be considered to extend to 30 meter depth, a considerable infilling of the holes with sand from the ambient bed does occur at that depth, which contributes to interception of the sediment supply to the upper portion of the beach and to steepening of a beach slope in the long run.

5.2 Sediment Movement

Fluorescent tracer experiments and observations of sea

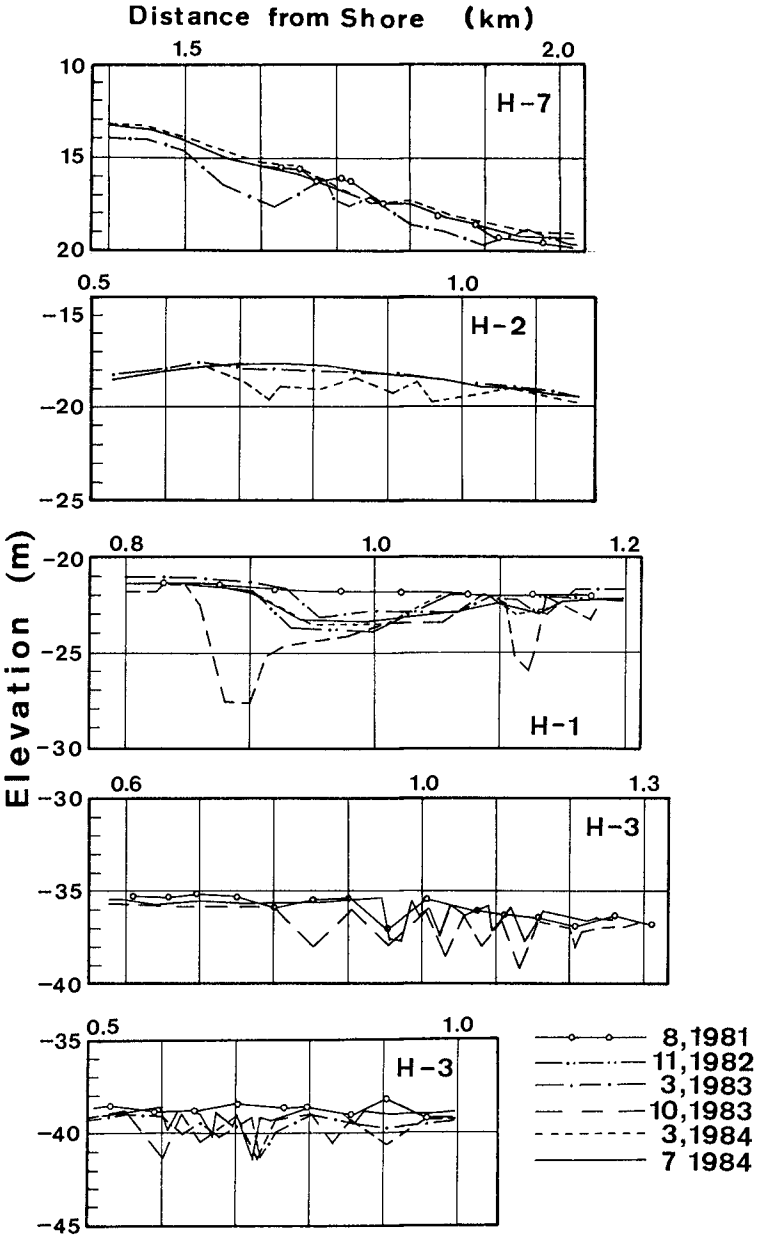

Figure 10 Profile Changes at Dredged Holes

bed levels were carried out to determine critical depth where general movement of sediment may occur. As shown in Figure 7, two locations were chosen for the experiments and fluorescent tracer and a series of graduated rods were placed at every 5 meter depth from the water depth of 10 to 40 meters. Beach profiles and median grain sizes at each 5 meter depth for two sites are shown in Figure 11. We observed tracer movement through taking underwater photographs and measured changes in bed level at the reference rods over three months during the winters of 1984 for SITE 1 and 1985 for SITE 2, the severest season with high waves. Wave data, taken off Oshima during the period of the 1984 measurement, is shown in Figure 12; there are no data for the 1985 measurement due to malfunction of a wave gage.

Figures 13 and 14 show movement of fluorescent tracers and changes in sea bed levels, respectively. Both results indicate that bottom sediment movement above 35 meter depth could be significant, whereas below that depth the movement minimum. This elaborates the result of profile changes at the dredged holes, as mentioned above. At all the observation points were seen sand ripples which form more symmetric shape than asymmetric one, and sea bed levels below 25 meter depth at SITE 1 changes noticeably between 38 and 53 days, during which the highest wave energy was exerted on the bed. These results imply that movement of sediment is more likely activated by wave action rather than unidirectional flow.

There are numerous equations describing sand motion initiation by wave action. It is of great interest for a coastal engineer to know which equations give a representative critical water depth at which sediment movement is considered to be negligible, so that offshore mining at that depth would have minimum adverse effects on the ambient sea bed. The generalized form of expression for critical water depth proposed by many researchers are written as :

$$\frac{H_0}{L_0} = \alpha \left(\frac{d_{50}}{L_0} \right)^m \sinh \frac{2\pi h}{L} \cdot \left(\frac{H_0}{H} \right)$$

where H and L are wave height and length, respectively, h is water depth, d_{50} is median grain diameter, α and m are constant, and subscript 0 indicates offshore condition. Ishihara and Sawaragi(5) proposed α=0.171 and m=0.25 for initial movement; Sato, Ijima and Tanaka(8) suggested α=1.35 and m=1/3 for general movement. Horikawa and Watanabe(3) introduced a more complex expression, based on conditions of bottom surface and boundary layer. In order to determine a critical depth, these three expressions plus recent works on threshold of sediment motion, done by Komar & Miller(6) and Hallermeier(2), were utilized together with the bottom orbital velocity computed from the linear wave theory.

Input parameters for calculation and computed results are shown in Table 1. Wave height and period are those with

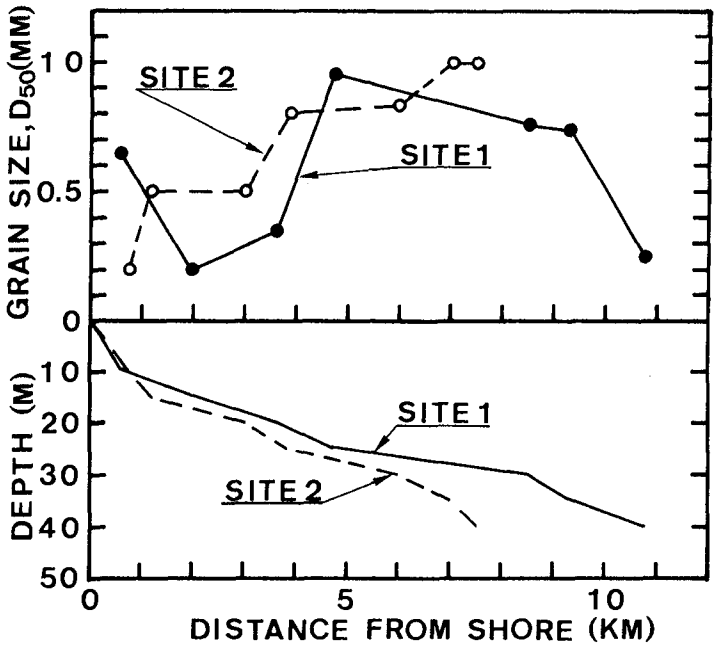

Figure 11 Beach Profiles and Median Grain Size Distribution at SITE 1 and SITE 2

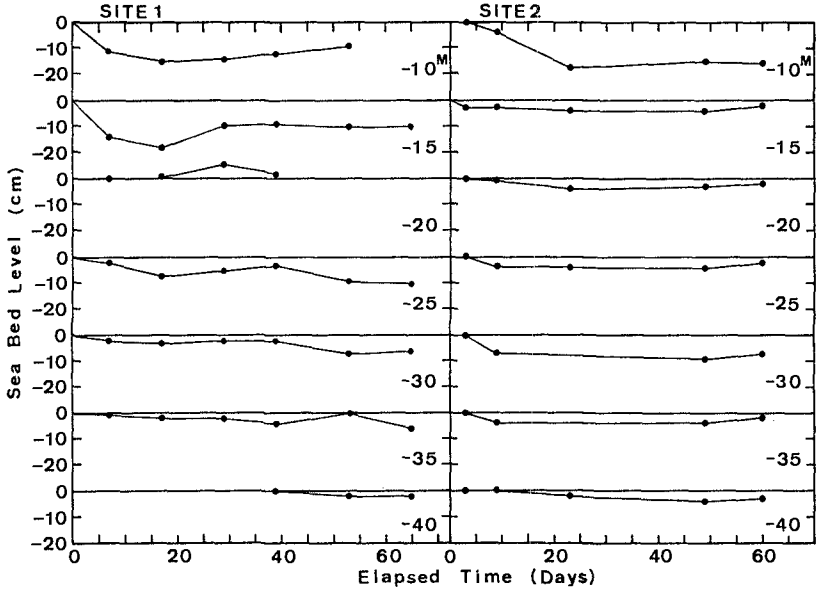

Figure 14 Changes in Sea Bed Levels at SITE 1 and SITE 2

the highest wave energy in Figure 12. The grain diameter was taken as an average value of median sediment grain diameters between 25 and 40 meter depth at SITE 1, as shown in Figure 11. In comparison with the actual measurement indicating a critical depth of 35 to 40 meters, the second and forth values in Table 1 show somewhat smaller and greater depth, respectively. The rest of equations give reasonable estimated depths for this case.

Table 1 Computation of Critical Water Depth

Input Parameters :

Wave Height = 4.58 m, Wave Period = 9.20 sec., d_{50} = 0.58 mm
Specific Weight of Sand = 2.64, Angle of Repose = 45 degree
Kinematic Viscosity = 0.0101 cm^2/sec.

3. Horikawa & Watanabe	37
4. Komar & Miller	49
5. Hallermeier	43

VI. CONCLUSIONS

Although the major cause of the severe beach erosions in the study area would most likely be the abnormally high frequency of destructive wave attacks inferred from the storm-wind data, the offshore dredgings do seem to result in a shoreline recession to some degree. Moreover, dredged holes above the water depth of about 30 meters are found to be refilled with sand which would be mainly transported from the onshore side, thereby interrupting beach littoral system by trapping sand which may travel in the on-offshore or alongshore direction and causing a steeper beach slope in the long run.

The data presented indicates a possible relationship between sand mining and the shoreline changes. Although the available data are not sufficient to establish a direct cause-and-effect relationship between offshore mining and beach instability, the correlation is sufficient to serve as a warning of a potentially serious problem. It is advisable, therefore, that the indiscriminate removal of sand from sea bed be avoided at such water depth that drastic beach profile changes occur. For the study area, it would be above the water depth of 35 meters.

ACKNOWLEDGEMENTS

The authors wish to thank engineers at the Harbor Division, the Prefecture of Fukuoka Department of Civil Engineering, for valuable cooperation and assistance in obtaining pertinent data and for permission to use some of the data. We also appreciated considerable contributions from each member of the Genkai-Hibiki Sea Beach Preservation Advisory Committee chaired by Professor Emeritus T. Ijima, Kyushu University.

CHAPTER 95

Undistorted Froude Model for Surf Zone Sediment Transport

by

D. L. Kriebel[1], W. R. Dally[1] and R. G. Dean[2]

Abstract

Small scale movable bed wave tank experiments were carried out according to undistorted Froude model laws with the sediment fall time, H/wT, as the governing parameter for scaling the model sediment. Four questions addressed in this study included: (a) the ability to reproduce larger scale model results for both erosional and accretive conditions, (b) the effects of more realistic concave upward initial beach profiles instead of the more usual planar initial slopes, (c) the criterion for onshore-offshore sediment transport, and (d) the capability of the model to simulate post-storm recovery.

Based on a comparison with large scale results of Saville (1957), it was found that the model provided good agreement for erosive conditions. For accretive conditions, the results were less conclusive although the general patterns of profile change were similar. The final beach profiles resulting from concave upward initial profiles were found to be substantially different from those for an initially planar profile. It appears that the initially planar profile unrealistically affects the breaker type and results in a more pronounced longshore bar and offshore slopes that are steeper than found in nature. Tests conducted to evaluate the criterion separating onshore-offshore transport suggested a higher value of the fall time parameter, H/wT, than was originally proposed by Dean (1973); this is interpreted to be due to scale effects in most of the model data used in the original development. Tests to simulate post-storm recovery were affected by the presence of "reflection bars" associated with a partial standing wave system. The reflection bars appear to strongly affect the sediment transport limiting the post-storm profile recovery. The most effective recovery was induced by continually changing wave conditions to maintain the wave breakpoint slightly landward of the bar crest.

Introduction

Simple and direct movable bed modeling laws are applied in a series of small-scale laboratory experiments on beach profile evolution. The basic criteria proposed by Dean (1985) and adopted in this study for modeling of surf zone processes are:

1) the model should be undistorted,

2) the model should be large enough to preserve the character of wave breaking processes and to avoid surface tension and viscous effects,

3) the scaling of hydrodynamic properties should be based on the accepted Froude criterion, such that the prototype to model length ratio, N_ℓ, and time ratio, N_t, are related as:

$$N_t = \sqrt{N_\ell} \tag{1}$$

4) The scaling of sediment properties should be based on preserving the fall time parameter, H/wT, where w is the sediment fall velocity, H is the wave height, and T is the wave period, such that the required fall velocity ratio, N_w, is given by:

$$N_w = \sqrt{N_\ell} \tag{2}$$

The proposed requirements are not new and are not universally applicable since many prototype situations cannot be practically replicated at small scale with an undistorted model. The criteria attempt, instead, to build upon what concensus may exist among modeling laboratories, primarily through reliance on the fundamental Froude model laws and the fall time parameter. In the recently proposed scaling laws for coastal movable bed models of Vellinga (1978) and Hughes (1983), preserving H/wT has resulted in successful duplication of prototype events during highly erosive storm conditions. Noda (1978) has found that preserving H/wT produces closer similarity than when the ratio H/d is preserved. Kamphuis (1982) also concluded that modeling based on the fall time parameter eliminates most of the scale effects associated with attempting to geometrically scale quartz sand grain diameters. By further specifying that the model should be undistorted, ambiguous definitions of length and time scales are eliminated, unrealistic augmentation of gravity forces are avoided, and interpretation of all physical quantities are clarified.

Objectives and Procedures

The overall goal of the study is to evaluate the usefulness of the undistorted Froude model, with sediment scaled according to the fall time parameter, for simulating beach profile evolution under specific erosive and accretive wave conditions. In order to test the proposed model laws, several sets of experiments were conducted to address specific objectives.

The first objective is to examine the ability of the model law to reproduce actual prototype-scale beach profile evolution. For this purpose, two experiments were conducted to simulate full-scale experiments by Saville (1957). The second objective is to examine the evolution of concave initial beach profiles compared to profiles with linear initial slopes for the same erosive and accretive wave conditions. The third objective is to examine the criterion for onshore-offshore sediment transport determined by Dean (1973) based upon the fall time parameter, or equivalently, the wave steepness, H_o/L_o, and a fall velocity parameter, $\pi w/gT$. Ten experiments were performed and the results compared to Dean's criterion as well as to results of prototype-scale experiments of Saville (1957) and Kajima et al. (1982). The fourth objective is to simulate conditions of post-storm beach recovery. A reference storm-barred profile was generated by elevated water levels and erosive wave conditions, then five experiments were conducted by lowering the water and subjecting the storm-generated breakpoint bar to accretive wave conditions.

The laboratory experiments were conducted in the Air-Sea flume at the University of Florida Coastal and Oceanographic Engineering Laboratory. The flume is 37 m long, 1.2 m deep, and 0.86 m wide. The wavemaker can generate regular or random waves; however, all experiments were performed using regular waves. A motorized cart that runs along rails mounted to the top of the tank carries a capacitance-sensing bottom profiler that is capable of resolving sand bed changes to within 2 mm. The sediment used in the experiments was a fine quartz sand with a median diameter of 0.15 mm. The mean fall velocity of the sand was found to be 1.8 cm/sec as obtained from a settling tube analysis.

Due to length restrictions, only a sampling of the figures can be presented in this paper. Much greater detail is available in Kriebel, Dally and Dean (1986).

Results and Analysis

a. Model Verification

The first series of experiments was designed to verify that the undistorted Froude model could reproduce prototype-scale events. Prototype conditions were taken to be two full-scale experiments conducted by Saville (1957) in a large wave tank 193.5 m long, 6.1 m deep, and 4.6 m wide. Saville's experiments were conducted using a linear 1:15 beach slope with 0.4 mm sand having an approximate fall velocity of 5.6 cm/sec. Based on the undistorted Froude model laws, the prototype to model fall velocity and time ratios are 3.1 while the length ratio is 9.6.

Two experiments were conducted, one under erosive wave conditions, the other under accretive conditions. In the erosion test, Saville's wave period was 5.6 seconds while the wave height in the flat section of the wave tank was 1.6 m. In the small-scale model, the wave period and the wave height in the flat portion of the tank were 1.8 seconds and 0.167 m respectively. The model surf zone was on the order of 4 m wide and seemed large enough to permit realistic wave breaking and transformation free of noticeable surface tension or viscous effects.

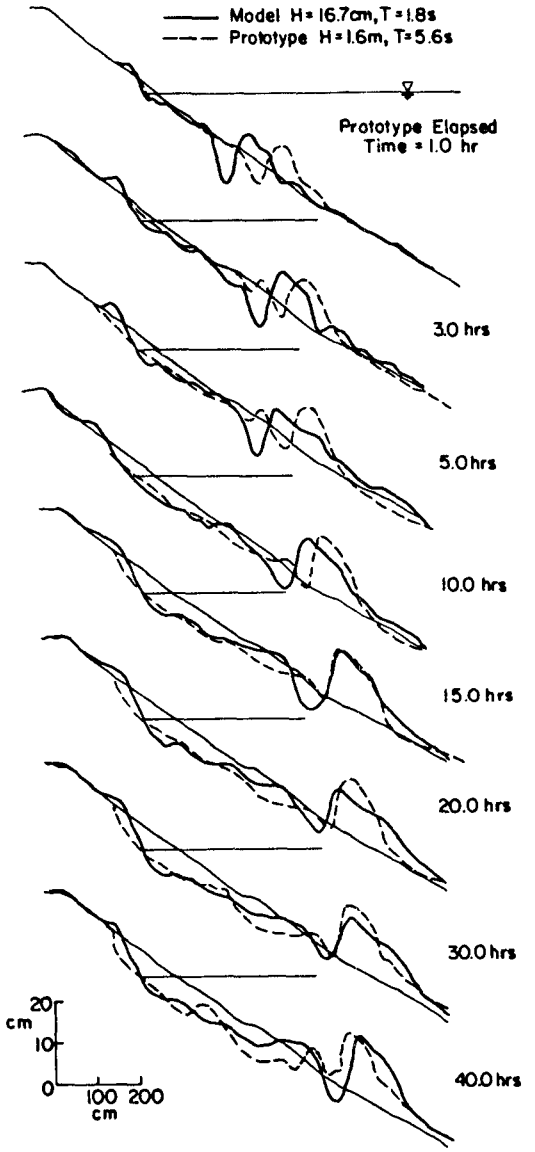

Figure 1. Beach Profile Evolution for Erosive Wave Conditions. Prototype Results Refer to Saville's (1957) Large-Scale Wave Tank Tests. Initial Planar Profile of 1:15 Slope.

In Figure 1, Saville's results are scaled according to the length scale and are compared to small-scale results. In general, the initial differences between the small- and large-scale model results are greater than at later times as equilibrium is approached. The final results at 40 hours are in good agreement and there is general similarity of the beach face slopes, the inner third of the surf zone, bar-trough geometries, and the offshore slopes. Offshore slopes in both model and prototype are approximately 1:5, and appear to be far steeper than natural offshore slopes.

In the second experiment, one of Saville's tests with constructive wave conditions was simulated. Saville's wave period and wave height in the flat section of the tank were 11.33 seconds and 1.28 m repectively. The required model parameters were T = 3.67 s and H = 0.13 m. Unfortunately, the wave generator in the model was not capable of generating a 13 cm wave at the required period, therefore, the maximum possible wave height of 8.5 cm was used. Results between model and prototype may then be compared in a qualitative sense only.

Figure 2 compares the profile evolution of the model and prototype. Despite the lack of similarity of wave heights, both profiles show the same general features with the building of a sizable berm and net onshore sediment transport. A problem encountered in the constructive wave test was severe wave reflection from the beach and re-reflection from the wave paddle. The reflection caused undulations or "reflection bars" in the outer profile, with bar crests located distinctly at the antinodes of the partial standing wave system. In Figure 2, three of these bars are noticeable over the offshore portion of the profile. The offshore bars seem to "lock up" sand and prevent effective onshore sediment migration from the toe of the slope to the berm as in the prototype.

b. Comparison of Results Using Concave Versus Linear Profiles

In an effort to achieve more realistic wave shoaling, wave breaking, and profile evolution, the 1:15 linear beach slope was abandoned in favor of a concave initial profile. As shown by Dean (1977), a profile shape which realistically represents non-barred profiles found in nature is:

$$h = Ax^{2/3} \tag{3}$$

where h is the depth at a distance x offshore and A is a slope parameter related to sediment fall velocity. Based on the initial experiments offshore slopes out to the breakpoint were fitted by an $Ax^{2/3}$ curve to establish a best-fit value of $A = 0.075\ m^{1/3}$. . The stable beach face slope was observed to be approximately 1:5. The new initial profile was therefore established with a 1:5 beach face slope to a point of tangency with the $Ax^{2/3}$ profile just below the still water level, beyond which the $Ax^{2/3}$ form was adopted.

For this initial profile, the same erosive and accretive wave conditions were repeated from the first experiments. The results corresponding to various elapsed times for the erosive case are shown in

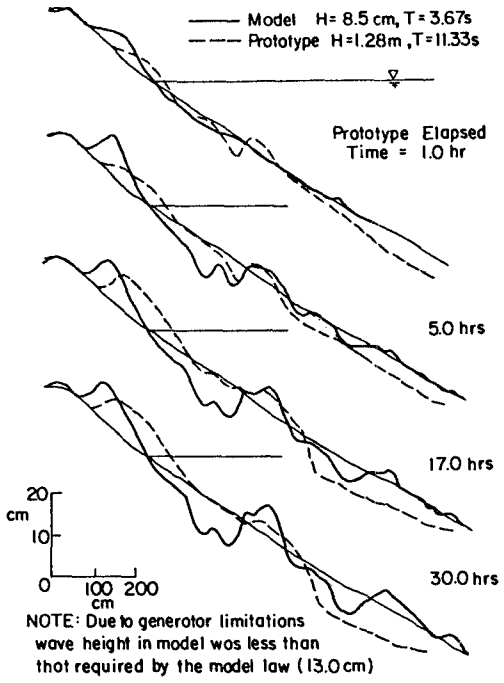

Figure 2. Beach Profile Evolution for Accretive Wave Conditions. Prototype Results Refer to Saville's (1957) Large-Scale Wave Tank Tests. Initial Planar Profile of 1:15 Slope.

Figure 3. Because of the mild offshore slope, waves broke in a spilling fashion during the first few hours of the test, in contrast to the plunging breakers observed in the 1:15 slope test. After 3 to 4 hours, waves began to plunge and a breakpoint bar became fully developed. From the beginning of the test, a broad symmetrical outer shoal grew steadily at a position well seaward of the breakpoint, seemingly due to increased sediment suspension over the rippled bed. As this bar grew, it began tripping waves in a spilling fashion between 10 and 11 hours. Waves then reformed before plunging on the inner bar, which moved shoreward due to the smaller reformed wave heights. Remarkably, the inner surf zone and beach face exhibited minor variation with only slight erosion over the test. It is noted that this offshore bar seems peculiar to this specific set of wave conditions and did not form under other erosive wave conditions.

In the case of low steepness waves beginning with an $Ax^{2/3}$ profile form, wave breaking was altered from surging-collapsing in the 1:15 test

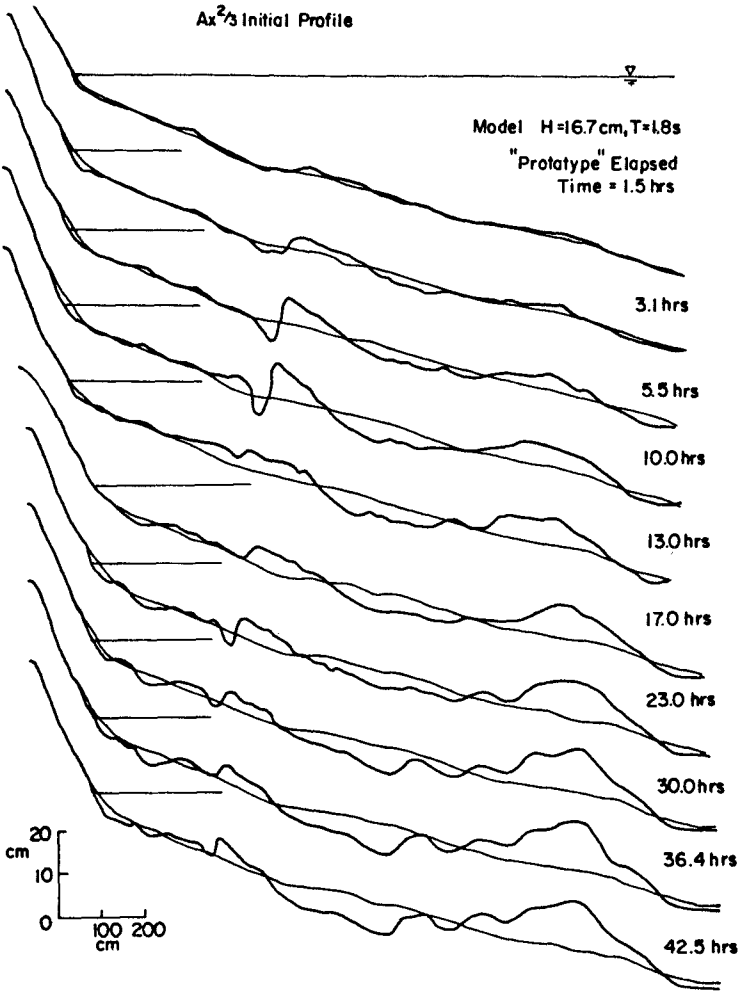

Figure 3. Evolution of Erosive Profile for $Ax^{2/3}$ Initial Profile.

to plunging. Only slight beach face accretion occurred but runup was nearly identical to the 1:15 test. The profile was dominated by multiple reflection bars and some cross-tank variations were present; however, little net onshore-offshore sediment transport occurred.

The effects of the initial profile form can be observed directly by superimposing the final profiles of the 1:15 and $Ax^{2/3}$ tests as shown in Figure 4. The most striking feature of the comparisons are the nearly identical beach face and inner surf zones despite the differences in initial profile forms and breaker type. Over the offshore regions the profiles are quite dissimilar, which may be attributed to different wave shoaling and breaking characteristics. To investigate further the role of bottom shape in wave transformation across the outer part of the profile, the breaker model by Dally, et al. (1985) was applied. Under erosive conditions for the initial profile of 1/15 slope, the model indicates rapid shoaling to an incipient breaker height of 19.8 cm at a mean water depth of 15.6 cm, i.e. $(H/h_b) = 1.27$, in accordance with the observed plunging breaker conditions. On the $Ax^{2/3}$ profile, the wave shoals very gradually until a height of 18.6 cm is reached in a mean water depth of 21.6 cm, $(H/h)_b = 0.86$, indicating a spilling breaker as observed at the beginning of the test. The same behavior is evident under accretive conditions. In general, wave shoaling and incipient breaking seem much more realistic on the $Ax^{2/3}$ profile as compared to the linear initial profile.

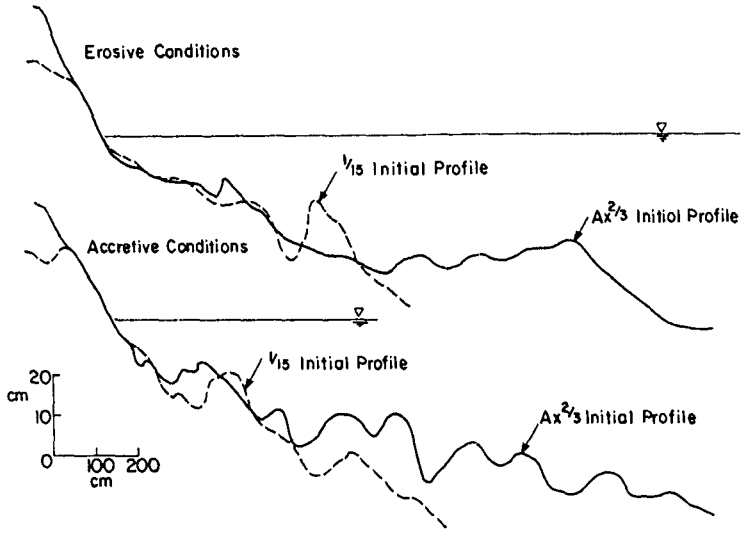

Figure 4. Comparison of Final Profiles Resulting from Planar (Slope 1:15) and $Ax^{2/3}$ Initial Profiles. (a) Erosive Conditions, (b) Accretive Conditions.

c. Model Experiments for Onshore-Offshore Transport

The major series of experiments was concerned with evaluating the undistorted Froude model against full-scale models for determining the criterion for the formation of storm or normal profile forms. Since the Froude model violates the Reynolds criteria, it was a priori expected that results of storm-normal profile tests would be skewed toward the formation of storm profiles, as it was found that onshore motion during constructive conditions is hindered by reflection problems while offshore motion under erosive conditions is enhanced by ripple-dominated suspension.

The framework adopted for the experiments was Dean's (1973) criterion for onshore-offshore transport:

$$\frac{H_o}{L_o} \begin{matrix} > \\ < \end{matrix} 1.7 \frac{\pi w}{gT} \qquad \begin{matrix} > \text{ offshore (storm profile)} \\ < \text{ onshore (normal profile)} \end{matrix}$$

or

$$\frac{H_o}{wT} \begin{matrix} > \\ < \end{matrix} 0.85 \qquad \begin{matrix} > \text{ offshore (storm profile)} \\ < \text{ onshore (normal profile)} \end{matrix}$$

Ten combinations of deepwater steepness and the fall velocity parameter, $\pi w/gT$, were selected. Starting with the $Ax^{2/3}$ initial profile, wave conditions were run for the prototype equivalent of 6 to 12 hours. Profiles were found to exhibit three forms, characterized by net onshore transport, net offshore transport, or a mixed response with simultaneous formation of a berm and offshore bar.

The initial and final profiles from individual tests are shown in Figure 5 and the results for direction of transport are given in Table 1. In general, profile changes are not as dramatic as typically observed on linear initial profiles, presumably since the initial concave profile is in quasi-equilibrium. In Figure 6, the small-scale results are augmented by available full-scale experimental results of Saville (1957) and Kajima, et al. (1982) and plotted in the same format as Dean's original criterion. As found by Dean (1973), a line with a 45° slope seems to reasonably separate storm and normal profiles and is given by:

$$\frac{H_o}{L_o} = c_1 \frac{\pi w}{gT}$$

or:

$$\frac{H_o}{wT} = c_2$$

where c_1 is found to be 4.0 to 5.0 and c_2, the critical value of the fall time parameter H/wT, is therefore 2.0 to 2.5. As expected, the undistorted Froude model exhibits slightly lower critical values than

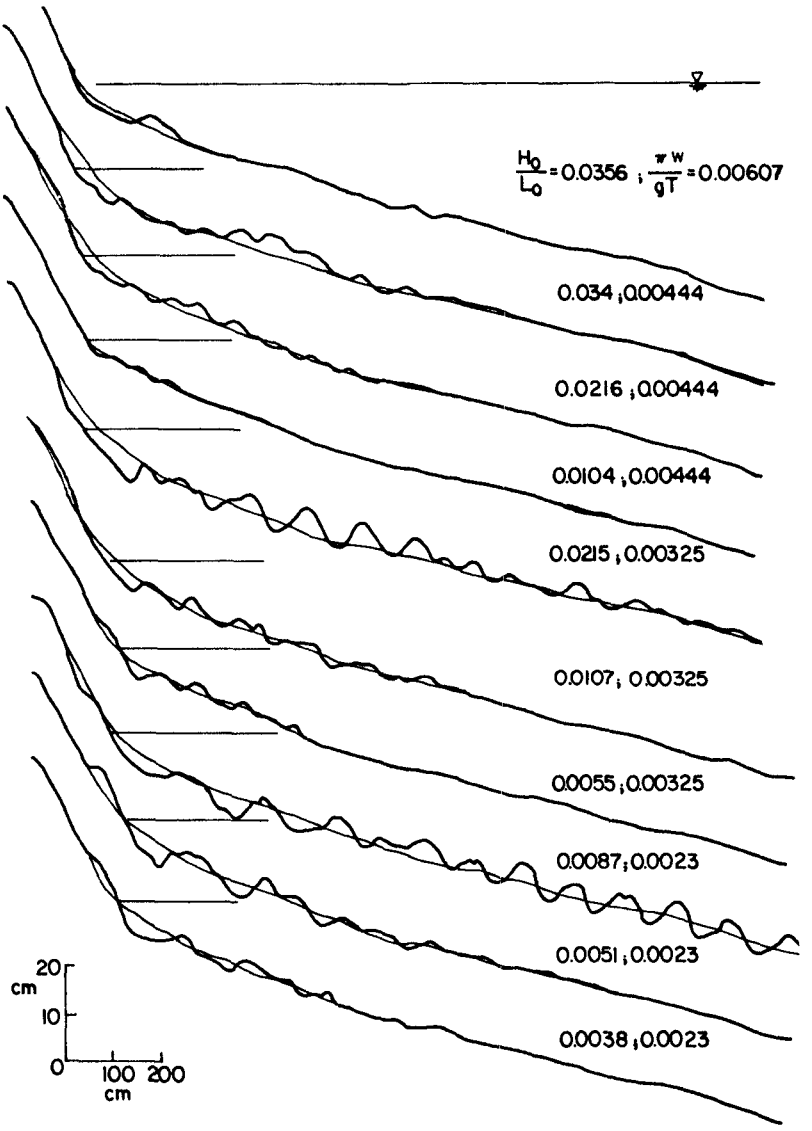

Figure 5. Final Beach Profiles for Test Series to Establish Criterion Separating Onshore and Offshore Sediment Transport. Initial $Ax^{2/3}$ Profile.

the full-scale experiments. The lower number in each range seems to represent the small-scale criterion while the upper number represents the approximate full-scale criterion, although more data is required to establish the criteria more exactly.

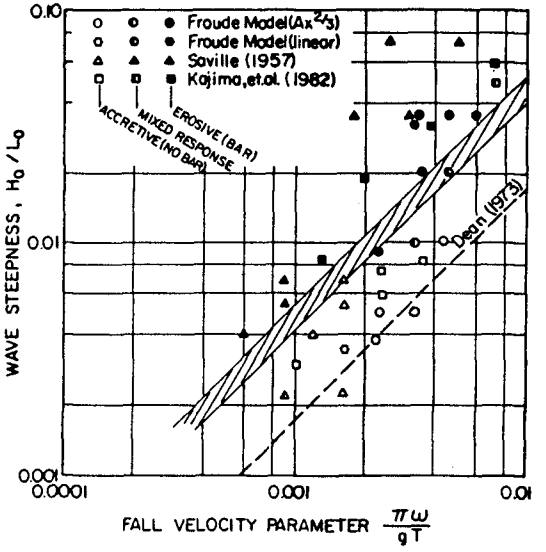

Figure 6. Conditions Separating Onshore and Offshore Sediment Transport Including Results of this Study, as well as Results of Prototype Scale Experiments of Saville (1957) and Kajima, et.al. (1982).

Reasons for the differences between the present criterion and Dean's original criterion are difficult to determine precisely but seem to be due to scale effects incorporated into Dean's original criterion. Other criteria for onshore-offshore transport also exhibit apparent scale effects from small to full scale. Kamphuis (1982) addresses possible scale-effects in small scale mobile bed models and attributes the greatest scale effects to the ratio of a characteristic length scale to the grain diameter, which governs bed roughness and bed geometry. He concludes, however, that it is impossible to determine the magnitude or source of scale effects with certainty. Despite the scale effects in the undistorted Froude model, results seem to agree reasonably with large scale results and are in much better agreement than other small-scale results with either unscaled sediment or unknown distortion effects.

d. Storm Bar Behavior Under Recovery Conditions

A final series of five experiments was designed to directly simulate the behavior of a profile, generated under storm wave conditions and an elevated water level, after the water level had returned to normal and lower steepness waves prevail. The storm profile was generated starting from the same $Ax^{2/3}$ profile used as the initial condition in the previous tests, except the water level was increased by 10 cm. The wave conditions of Saville's erosion test were then maintained for 3.87 hours to form a large breakpoint bar.

In this first test, the wave generator was set to maintain the erosive conditions with the water level returned to normal to see if any recovery would occur simply due to the drop in water level stranding the storm bar inside the new breakpoint. At the end of the test, nearly all traces of the storm bar had been eradicated and a new bar had formed offshore at the new plunge point that was identical to the initial bar. However, only a small berm has been constructed; and, on the whole, the beach face had not shown any signs of recovery and the inner surf zone had remained remarkably inactive.

The second test reduced the wave height so that the deepwater wave steepness was 0.01, while $\pi w/gT$ remained equal to 0.00325. This placed conditions in the recovery regime, according to Figure 6. This resulted in profile changes dominated by the formation of small scale reflection bars. For the first 3 hours the storm profile and bar retained their identity, with the reflection bars superposed on top. Ultimately, some material from the storm-generated bar moved landward to fill the trough and a small berm developed.

In the third recovery test, the deepwater steepness was reduced to 0.005, moving conditions further into the recovery regime. This produced a surging "breaker" at the toe of the beach face and substantial reflection. Energy conditions were so low that even after 8 hours, the original storm bar was still present. Except for a small transfer of material from the bar crest to trough, the storm bar was maintained much like a relict feature. A berm formed due to local onshore transport in the swash region.

In the fourth test, the deepwater wave steepness was returned to 0.01 while $\pi w/gT$ was reduced to 0.0023. According to Figure 6, this placed conditions in the transition between erosion and recovery. Wave conditions were such that the storm bar also caused breaking of the recovery waves, and as a result, much of the profile evolution consisted of a reworking of the bar material seaward. However, a substantial berm was constructed and fully developed within 3 hours.

In the fifth recovery test the deepwater steepness was reduced to 0.005, placing conditions within the recovery regime. The storm bar migrated landward over the first hour of the test and eventually stabilized at the breakpoint of the recovery waves. The berm grew until it stabilized at approximately 5 hours elapsed time, simultaneously with the appearance of reflection bars.

In a related experiment, using a linear initial profile, wave conditions were changed every 30 to 45 minutes to consistently maintain the breakpoint a few centimeters landward of the evolving bar. This test, shown in Figure 7, was the only test in which anything resembling complete shoreward bar migration onto the beach face was achieved. Apparently, under monochromatic wave conditions, complete bar migration requires "tuning" of the wave conditions toward smaller wave heights in order to continually promote the establishment of the bar landward of its previous position while ensuring that the previous bar is the source of sediment for the new bar.

Summary and Conclusions

Several sets of experiments were conducted to: 1) test a simple physical model scaling law for beach profile evolution, 2) investigate the effects of initial profile shape on profile evolution, 3) test the criterion of Dean (1973) for the formation of a storm profile versus normal profile, and 4) study the general behavior of a barred profile under recovery conditions. Only monochromatic waves were used in the experiments.

The model scaling law, based on Froude similarity and using sediment fall velocity as the controlling parameter, was found to reproduce beach profile evolution quite well under erosive conditions. Under constructive wave conditions simulation for portions of the profile seaward of the breakpoint is only moderately successful due to the improperly scaled boundary layer features and due to the persistent formation of fairly stable multiple bars associated with wave reflection.

For the same wave conditions, initial profile shapes of 1/15 planar slopes and $Ax^{2/3}$ produced dramatically different profile evolution and equilibrium shapes, especially offshore from the breakpoint. These differences are attributed to the different breaking behavior governed by different bottom slopes near the breakpoint. However, because depth limited breaking causes all waves to approach the same height regardless of incipient conditions, the inner surf zone and beachface showed remarkable similitude between the two tests. The concave profile was found to have more realistic wave shoaling and breaking characteristics and, on that basis, appears most useful for physical modeling.

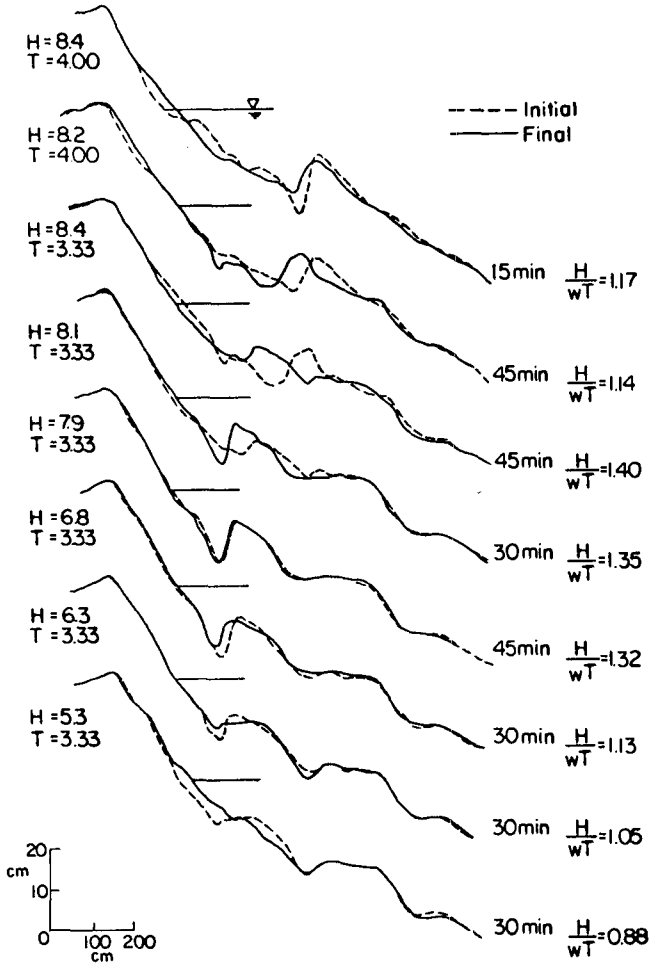

Figure 7. Beach Profile Recovery Resulting from Adjusting Wave Breakpoint to be Located just Landward of Bar Crest.

Model tests of the onshore-offshore criterion, when coupled with the prototype scale results of Saville (1957) and Kajima, et al (1982), resulted in a different criterion than that found by Dean (1973) based mostly on unscaled small-scale experiments. This criterion is more physically realistic, and the agreement of the undistorted Froude Model with prototype-scale experiments is satisfying but needs much additional model verification.

Direct simulation of a storm-barred profile with lowered water levels and constructive wave conditions indicates that onshore bar migration does not occur easily. Bar migration under monochromatic waves seems to require a specific set of finely tuned wave conditions such that the recovery breakpoint is always maintained just landward of the migrating bar. This can only occur due to a gradual reduction in wave height or due to changes in water depth due to tides.

Based on the undistorted Froude model, with monchromatic waves, beach recovery in qualitative or quantitative agreement with nature was difficult to attain. This is due to the aforementioned reflection problems, and scale effects in the bottom boundary layer and ripple formation. Preliminary tests with irregular waves were performed and seem useful for reducing wave reflection effects and for smoothing bottom ripples.

CHAPTER 96

Experimental study on on-offshore sediment transport of Accretive Beach

CHING-TON KUO* CHING-HER HWANG** I-CHOU TSENG***

1. INTRODUCTION

In treating coastal proceses, sediment transport is usually divided into along-shore and on-offshore components. It is believed that the on-offshore component has a prominant connection with short-term profile changes, observed during storm wave climates. Obviously its shift of sand plays a very vital role in shoreline migration. In other words, the beach profile has great bearing on coastal phenomena related to on-offshore sediment transport. As we know, there have been many studies on this kind of sediment transport rate, and considerable amount of knowledge on this problem has been accumulated so far. Yet it seems that we are still far from a reliable formulus to estimate the beach profile changes. The reason why is due to the complexity of mechanics of sediment transport. Therefore, the aim of this study is to examine experimentally the mechanism between on-offshore sediment transport and the deformation processes of two-dimensional beach profile. Then , a predictive model of the temporal and spatial distribution of net on-offshore sediment transport based on two-dimensional beach profiles and an equation of continuity of sediment transport is proposed. Various parameters of net on-offshore sediment transport in this model are discussed also.

2. THE CONTINUITTY EQUATION OF SEDIMENT TRANSPORT

The evaluation of net sediment transport in this study was on the the basis of continuity equation of sediment transport, assume the transport mode of sediment was just bed-load and there is no suspended sediment occurred. Therefore a coaser sand of 0.57^{mm} ϕ was used as a bed material in order to satisfy this theoritical consideration. Usually, sediment transport rate was measured directly by a sand trap during the last few decades. But due to such apparatus would cause severe disturbance to the fluid motion and the sediment movement. Instead the net rates of sediment transport were estimated by the continuity equation from the beach deformation data comparing with the initial profile. Attemp to find temporal and spatial the relationship between the net transport rate and wave condition were then made. Suppose a beach profile changes as given in Figure 1. By virtue of the conservation of bed material amount, the local net transport rate $q(x,t)$ per unit width is related to the bed elevation $h(x,t)$ measured from a certain datum as :

$$\frac{\partial h}{\partial t} = \frac{1}{1-\varepsilon} \frac{\partial q}{\partial x} \qquad \text{.....(1)}$$

in which ε is the sediment porosity. Therefore the effective net transport rate $Q(x)$ averaged over a time duration Δt of wave action is evaluated from the bed elevation change $\Delta h(x)$ by

$$Q = \frac{\bar{q}}{1-\varepsilon} = \int_{X_R}^{X'} \frac{\Delta h}{\Delta t} X' \qquad \text{.....(2)}$$

where X' is positively seaward and X_R means shoreward limit of beach deformation. Parameter definition is shown as Figure 2.

3. EXPERIMENTAL PROCEDURES

Experiments were carried out in a two-dimensional wave tank, 1 m wide, 1 m deep, 80 m long with a glass wall on one side of 30 m length at the end of tank. Figure 3 shows the general arrangement of the test equipment.

The experiments were performed using monochromatic waves generated by a flap-type wave maker installed at another end of the tank.

C2	2.0	8.4	0.015
C3	2.0	6.3	0.011

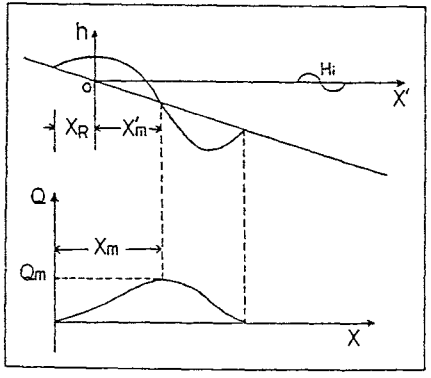

Fig.2 Coordinate system and notation

The incident wave height was measured by a capacitance type wave gage placed just offshore from the toe of the model beach. In order to make simply the experiments, tests were limited to a uniform initial beach profile of 1/30 and one coarse sand of 0.57^{mm} ϕ was used as a bed material mentioned above. Beach profile changes were measured by an electronic profile sensor to record the continuous profile data for every two hours within the testing duration of 18 ~ 20 hrs totally. Then, the temporal and spatial net rate of on-offshore sediment transport was evaluated from the beach profile changes.

Table 1 is a list of experimental cases. Various kinds of wave conditions were investigated for this test. Both the breaker height and local wave heights were also measured by a capacitance type wave gage mounted on a carriage capable of moving with constant speed along the centerline of the tank at the locations of 50 cm interval along the model beach in the middle of wave action. The horizontal distance from a base line on the model beach to the breaking position and the limited shoreward position of run-up were measured by ruler attached on grass wall.

4. EXPERIMENTAL RESULTS & DISCUSSION

Figure 4 (a)~(i) show the beach profiles at the end of wave action for all the cases listed in Table 1. It should be noted that profile changes are belong to the accretive type i.e. a shoreline progresses and no sand deposition takes place offshore. (Sunamura and Horikawa, 1974). The locations of breaking points are indicated by arrow symbols; dot line arrows for the initial stage and solid line arrows for the final stage. Experimental results indicate that the locations of breaking point progress shoreward as the accumulated time of wave increased, i.e. the breaker zone become narrowed gradually as shown in Fig 5 (a) ~(h) and its breaker type changed gradually also from spilling one to plunging breaker. Results also indicate that the maximum sediment transport rate take place arround the breaking point. Figure 6 (a) ~ (b) show some examples of the spatial and temporal distribution of the effective non-dimencsonal net transport rate Q/Qm evaluated from beach profiles mentioned above. It's seen that the

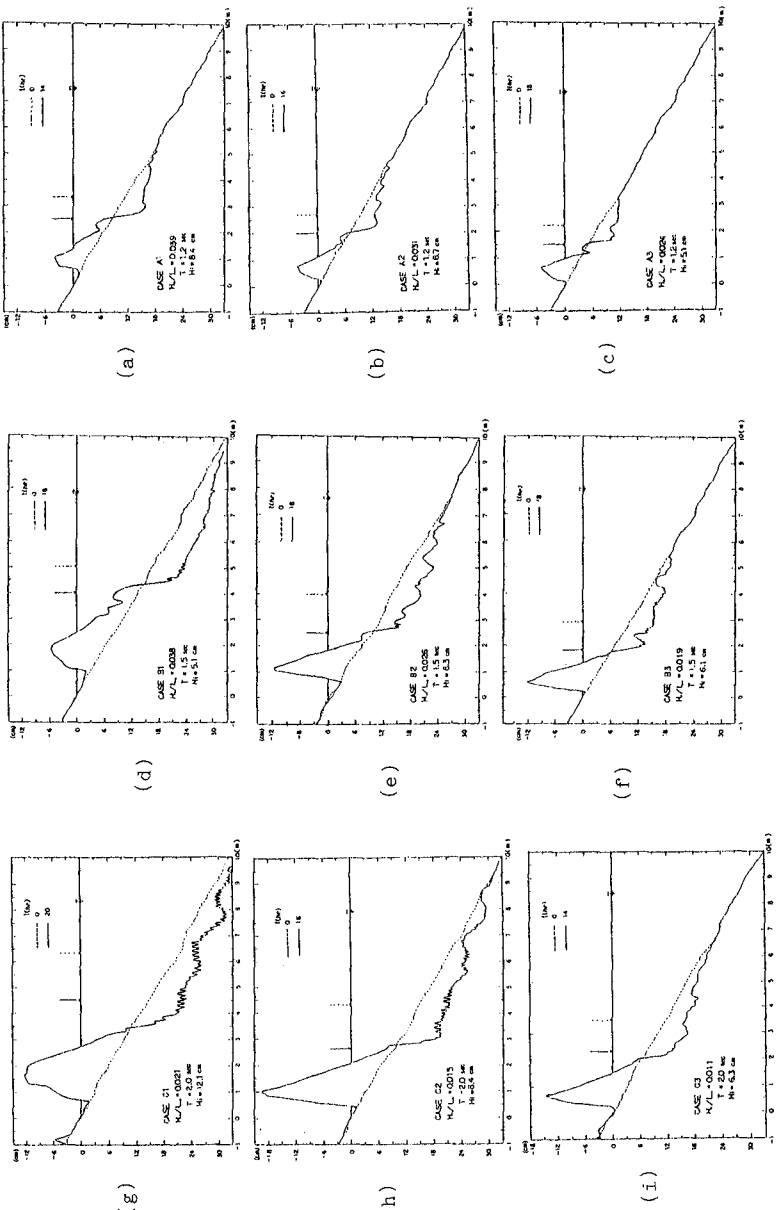

Fig.4 Beach profile after wave action

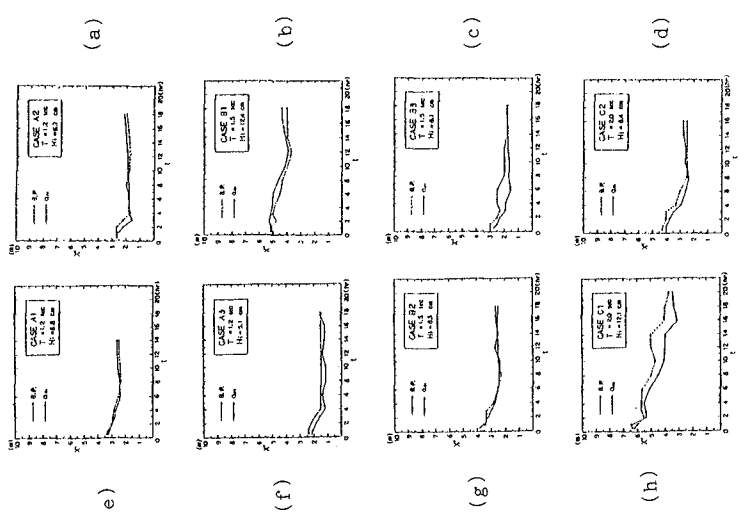

Fig.5 Spatial and temporal relationship between B.P. and Q_m

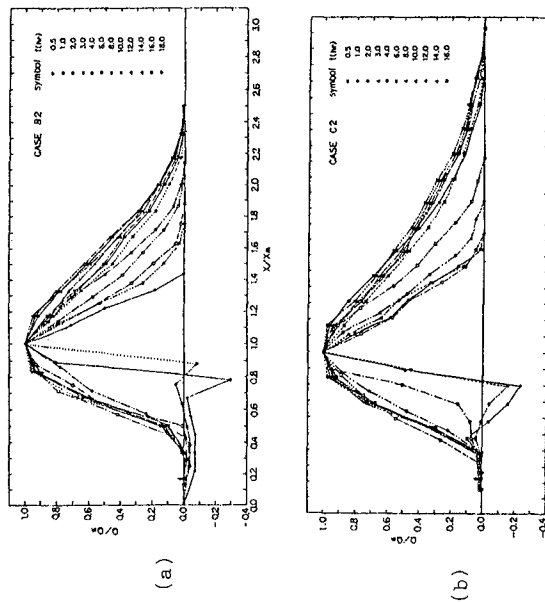

Fig.6 Spatial and temporal distribution of Q/Q_m

dimensionless distribution curves of sediment transport rate tend to steady after $t/T = 1.44 \times 10^4$, in which t is accumulated time of wave action and T is the incident wave period. Based on these data of each case an optimum curve was obtained to represent its characteristics as shown in Figure 7 (a)~(c). Then, a dimensionless sediment transport rate shown as Figure 8 for accretive beach were analyzed and relationship of parameters were shown also as figures 9~13. These experimental formulus were established ae follows:

$$Q/Qm = AM\bar{X}^{M-1} e^{-A\bar{X}^{M-1}} \quad ; \bar{X} > 1 \quad \ldots\ldots\ldots\ldots(3)$$

$$Q/Qm = C_6\bar{X}^6 + C_5\bar{X}^5 + C_4\bar{X}^4 + C_3\bar{X}^3 + C_2\bar{X}^2 + C_1\bar{X} + C_0 \quad ; \bar{X} < 1$$

and

$$C_6 = 32.31 \ , \ C_5 = -87.96 \ , \ C_4 = 79.23 \ , \ C_3 = -25.38$$

$$C_2 = 2.81 \ , \ C_1 = 0.01 \ , \ C_0 = 0.00$$

$$A = 15.16 \left(H_o/L_o\right) + 0.89 \quad \ldots\ldots\ldots\ldots\ldots\ldots(4)$$

$$M = 13.55 \left(H_o/L_o\right) + 2.52$$

in which

$$\bar{X} = X/X_m$$

$$Q_m/Q_o = 478.6 \left(t/T\right)^{-0.64} \ ; \ t/T \geq 1.44 \times 10^4 \ldots\ldots(5)$$

$$Q_o/Wod_{50} = 0.16 \, Ns^{1.51} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(6)$$

$$Ns = H/T \ / \sqrt{(s-1)gd_{50}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(7)$$

$$Xm'/H_o = 141.3 \left(t/T\right)^{-0.16} \ ; \ t/T \geq 1.44 \times 10^4 \ldots(8)$$

$$X_R/H_o = 0.771 \left(H_o/L_o\right)^{-0.537} \quad \ldots\ldots\ldots\ldots\ldots(9)$$

Where

5. APPLICATION OF THE NUMERICAL MODEL

Based on These experimental formulus mentioned above, then, a numerical model of two-dimensional accretive beach profile changes is presented. Figure 14 (a)$\sim$(c) are the examples of the comparison between this predictive numerical model and experimental results; solid line represents the numerical computational values and dot line represents the experimental results after 20 hours of wave action. Results indicate that the numerical model could be used to describe adequately on-offshore beach profile changes for the accretive beach.

6. CONCLUSIONS

The main conclusions of this study are summarized as follows:

(1) Experimental results indicate that final beach profile changes after 14 $\sim$ 20 hrs wave action respectively for all the cases are belong to the accretive type, i.e. a shoreline will progresses seaward and no sand deposition takes place offshore and predominant mode of sediment transport is the bed-load.

(2) When the time of wave action was increaed, the breaker zone width will become narrower and narrower and its breaker type will change gradually also from spilling one to plunging breaker.

(3) Results indicate that the position of maximum sediment transport rate will take place around the breaking point.

(4) On-offshore sediment transport rate is the function of Ns and t/T , and could be expressed as equation (3) to equation (9). When the acaumulated time of wave action are greater than $t/T = 1.44 \times 10^4$, its normalized non-dimensional spatial distribution of sediment transport rate could tend to be steady.

(5) Based on the experimental results, a predictive numerical model is presented and shown that this model could be used to describe adequately the on-offshore beach profile changes for accretive beach.

CHAPTER 97

NUMERICAL MODEL OF BREAKING WAVE AROUND A RIVER MOUTH

Jong-Sup Lee[+], Toru Sawaragi[++] and Ichiro Deguchi[+++]

ABSTRACT

Equations for wave kinematics and wave dynamics based on small amplitude wave theory have been used in the prediction of wave deformations and wave-indused currents. However, the applicability of the linear wave theory is questionable in a river mouth where forced wave breaking and strong wave-current interaction take place.

A numerical model based on the non-linear dispersive wave theory has been developed, the results by this model was compared with the values of the experiments and the linear theory. Wave transformations including shoaling, wave-current interaction and wave breaking by the model showed a good agreement with the experimental result. In the prediction of wave-induced currents, the excess momentum flux (Pxx) computed by the model has more reasonable value than the radiation stress (Sxx) calculated by the small amplitude wave theory.

1. INTRODUCTION

To predict wave deformation and wave-induced currents in a shallow water region is an important problem not only for a design of coastal structures but also for a prediction of beach deformations in near shore regions. In general, equations for wave kinematics and dynamics based on linear wave theory have been used to solve these problems. However, the applicability of the linear wave theory is questionable in a river mouth where forced breaking and strong wave-current interaction take place. Recentry, Boussinesq type equations have been often used in numerical modelling of short waves in shallow water regions (Abbott et al. (1978), Haugel(1980) and Haugel et al.(1982)) and the accuracy of these equations was discussed by Abbott et al.(1978) and McCowan (1982).

+ Assistant professor, Dept. of Ocean Eng., National Fisheries Univ. of Pusan, Korea.
++ Professor, Dept. of Civil Eng., Osaka Univ., Japan
+++ Assistant professor, Dept. of Civil Eng., Osaka Univ., Japan

In this paper, the applicability of Boussinesq type equations in surf zone dynamics was studied in the problems of wave transformations and wave-induced flows around a river mouth. Results by this model were compared with those of the experiments as well as the results calculated by linear model developed by Sawaragi et al.(1984).

2. BASIC EQUATIONS

Boussinesq equation derived by Peregrine (1967) in a variable water depth are written as follows, where we introduce the viscous term. Fig.1 shows the definition sketch of the coordinate system.

$$\frac{\partial \eta}{\partial t} + \frac{\partial M_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial M_j}{\partial t} + \frac{\partial}{\partial x_i}\left(\frac{M_i M_j}{h+\eta}\right) + g(h+\eta)\frac{\partial}{\partial x_j}\eta\delta_{ij} - \frac{\partial}{\partial x_i}\left(\nu\frac{\partial M_j}{\partial x_i}\right) + \tau_{bj}$$

$$= \frac{h^2}{3}\left[\frac{\partial}{\partial x_j}\left(\frac{\partial^2 M_i}{\partial x_i \partial t}\right) - \frac{M_i}{h+\eta}\frac{\partial}{\partial x_i}\left(\frac{\partial^2 \eta}{\partial x_j \partial t}\right)\right] \tag{2}$$

where $i,j = 1$ or 2
δ_{ij} = Kronecker's δ function
g = gravitational acceleration
ν = kinematic eddy viscosity
τ_{bj} = bottom friction
$M_i = U_i(h+\eta)$: depth integrated velocity, ie, mass flux per unit width

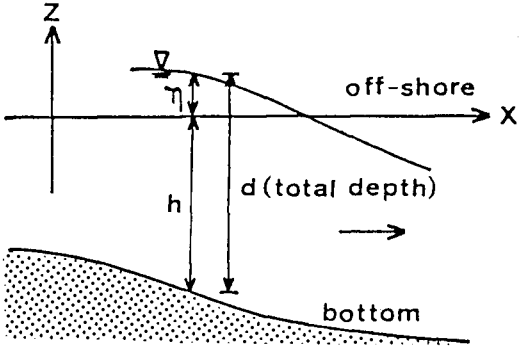

Fig.1 Definition sketch of coordinate system

Now, we define the mass flux per unit width M as a sum of staedy component M_o , phase averaged component of waves M' and turbulent component M''.

$$M_i = M_{oi} + M_i' + M_i'' \tag{3}$$

By using the above expression in eq.(1) and (2), the following equations for mean currents and waves are derived by the time averaging minipulation.

1) For mean currents

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial M_{oi}}{\partial x_i} = 0 \tag{4}$$

$$\frac{\partial M_{oj}}{\partial t} + \frac{\partial}{\partial x_i}\left(\frac{M_{oi}M_{oj}}{h+\bar{\eta}}\right) + g(h+\bar{\eta})\frac{\partial}{\partial x_j}\bar{\eta}\delta_{ij} + \overline{\tau_{bj}} + \frac{\partial p_{ij}}{\partial x_i}$$

$$- L_i = \frac{h^2}{3}\left[\frac{\partial}{\partial x_j}\left(\frac{\partial^2 M_{oi}}{\partial x_i \partial t}\right) - \frac{M_{oi}}{d}\frac{\partial}{\partial x_i}\left(\frac{\partial^2 \bar{\eta}}{\partial x_j \partial t}\right)\right] \tag{5}$$

where "$\overline{\quad}$" denotes the time averaged value, d is a total depth $h+\eta$, P_{ij} is a excess momentum flux by the wave motion, L_i is a lateral mixing term of momentum.

$$p_{ij} = \overline{M_i' M_j'}/(h+\eta) \tag{6}$$

$$L_i = \frac{\partial}{\partial x_i}\left(\frac{\partial M_{oi}}{\partial x_i}\nu - \frac{1}{h+\bar{\eta}}\overline{M_i'' M_j''}\right) \simeq \frac{\partial}{\partial x_i}\left(K_i \frac{\partial M_{oi}}{\partial x_i}\right) \tag{7}$$

where, τ_{bj} is a time averaged bottom friction term by waves and currents.

$$\overline{\tau_{bj}} = f_w\left(\frac{1}{2}\frac{M_{oj}}{h+\bar{\eta}} + \frac{M_j'}{h+\eta}\right)\left|\frac{1}{2}\frac{M_{oj}}{h+\bar{\eta}} + \frac{M_j'}{h+\eta}\right| \tag{8}$$

where, f_w is a bottom friction coefficient on the bottom.

2) For waves

$$\frac{\partial \eta'}{\partial t} + \frac{\partial M_i'}{\partial x_i} = 0 \tag{9}$$

$$\frac{\partial M_j'}{\partial t} + \frac{\partial}{\partial x_i}\left(\frac{M_i' M_j'}{h+\eta'}\right) + g(h+\eta')\frac{\partial}{\partial x_j}\eta'\delta_{ij} + (\tau_{bj} - \overline{\tau_{bj}})$$

$$+\frac{\partial}{\partial x_i}\left(\frac{M_{oi}M_j'}{h+\eta'}\right) + \frac{\partial}{\partial x_i}\left(\frac{M_i' M_{oj}}{h+\eta'}\right) + DM_j \tag{10}$$

$$= \frac{h^2}{3}\left[\frac{\partial}{\partial x_j}\left(\frac{\partial^2 M_i'}{\partial x_i \partial t}\right) - \frac{M_i'}{h+\eta'}\frac{\partial}{\partial x_i}\left(\frac{\partial^2 \eta'}{\partial x_j \partial t}\right)\right]$$

where, DM_j is the momentum dissipation term after wave breaking, it is expressed as :

$$DM_j = \frac{\partial}{\partial x_i}\left[-\nu\frac{\partial M_i'}{\partial x_i} + \frac{-\overline{M_i' M_j'} + \overline{M_i'' M_j''} - \overline{M_i'' M_j''}}{h+\eta'}\right] \tag{11}$$

From eq.(11), we see that the momentum dissipation after wave breaking and the Reynolds stress generated by wave breaking become a governing factor in wave-induced currents because the right hand side of eq.(11) includes the same term which appears in driving force and lateral mixing terms for mean currents. DM_j is evaluated by eq.(12) after Sawaragi et al.(1974).

$$DM_j=\frac{\partial}{\partial x_i}\left[K_i^*\frac{\overline{M_i'M_j'}}{(h+\eta')^2}\cdot(h+\eta')\right] \tag{12}$$

where, the momentum dissipation coefficient K_i has a value of 0.4 ~ 0.6, the 5th and 6th term in the left hand side of the eq.(10) indicates the effects of wave-induced interaction. The effect of the bottom friction is neglected in the wave equation.

3. NUMERICAL MODEL

The implicit method was used, then each time and space were taken as 2-level and central difference scheme respectively. The solution was obtained effectively by the Gauss Seidel interaction method with the A.D.I. double sweep algorithm.

To obtain the numerical solution of waves, the following linear offshore and onshore boundary condition are applied.
At offshore :

$$\eta_t'=a\cdot\sin[\sigma\cdot\Delta t\cdot n+k\cdot\Delta s(i-iE)] \tag{13}$$

where, **a** = amplitude of waves
$\sigma = 2\pi/T$
n = time step
k = wave number
ΔS = interval of grid

and

$$M_t'=-[\sqrt{g/h}\cdot\eta_t']\cdot h=-\sqrt{g\cdot h}\cdot\eta_t' \tag{14}$$

At onshore :

$$M'=(1-r)\sqrt{gh}\cdot\eta'$$
$$\eta'=-M'/\sqrt{gh} \tag{15}$$

where, r is a reflection coefficient. In order to determine the breaking point, the applicabirity of breaking criteria proposed by some investigators to the river mouth where strong wave-current interaction takes place are examined experimentally. Then we used the most adequate criteria in the calculations.

In the computation of mean currents, open boundary conditions at the river mouth(iS) and offshore(iE) are applied. They are given as follows :

$$\text{Open Boundary} \quad \begin{cases} M_{o\,is-1,j} = \text{River discharge}, & M_{o\,iE+1,j} = M_{o\,iE,j} \\ \bar{\eta}_{is-1,j} = \bar{\eta}_{is,j}\ , & \bar{\eta}_{iE+1,j} = 0 \end{cases} \tag{16}$$

As mentioned above, by calculating the waves and currents alternately,the effect of wave-current interaction is considered in waves and currents.

4. 2-D EXRERIMENTS AND NUMERICAL CALCULATION ON WAVE-CURRENT INTERACTION.

Littoral currents and water level around a river mouth are mainly affected by the relative strength of incident waves and river discharges. To investigate the effect of river mouth depth and run off on wave transformations and water levels we performed hydraulic experiments for wave-current interaction in a two dimensional wave tank. Then the results obtained by the experiments were compared with numerical results.

1) Experimental procedure and condition

The experiment was performed in the 2-D wave basin which has a 1/20 slope connected to river channel, 65cm in width and 23m in length, and the river discharge was supplied from the weir tank located in the upper part of the river channel. Fig.2 shows the experimental wave basin.

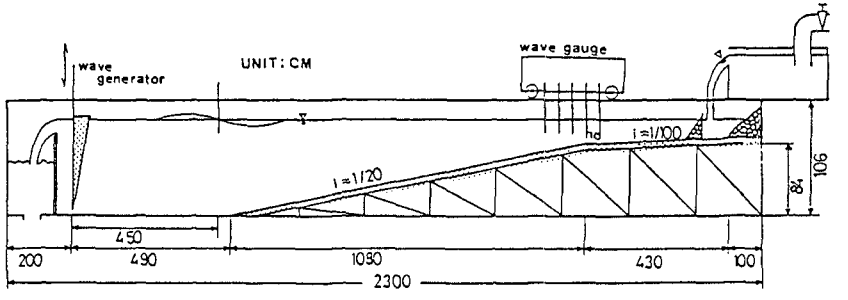

Fig.2 Wave tank and experimental set up

The wave height was measured at the intervals of 10cm by the capacitance type wave gauges equipped on platform car. Data were recorded by a data recorder with analog signals, and the data was analysed by the digital computer after the A-D conversion in 1/1000 sec interval.

We determined the experimental conditions by using a dimensional analysis. The experimental parameters are given as eq.(17).

$$\phi_3(h_o/H_o, q/(h_o\cdot\sqrt{gh_o}), i, H_o/L_o, x/L_o) = 0 \qquad (17)$$

where h_o : water depth in river mouth
H_o : wave height in offshore
T : wave period
i : slope
q : discharge per unit width
L_o : wave length in offshore
x : distance from the river mouth

Table 1 shows the experimental condition

$q_0 = q/(h_0'\sqrt{gh_0'})$, h_0': water depth at the river mouth from S.W.L.

2) Influence of the depth at river mouth affecting on wave transformation

Fig.3 shows the relationship between wave breaking depth and break height. In the figure, NATU-A and NATU-B are the results in the uniform slope beach which have not river channel.

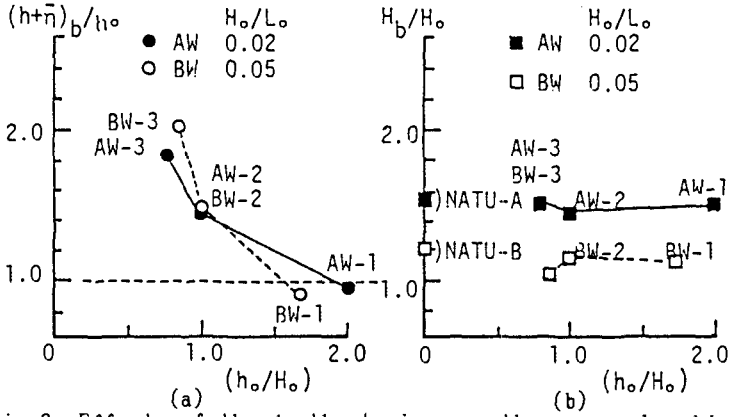

Fig.3 Effects of the depth at river mouth on wave breaking conditions

In Fig.3(b), we see that the break height is not affected by the depth at river mouth. The cases AW-1 and BW-1 of Fig.3(a) show that forced wave breaking took place in the river channel.

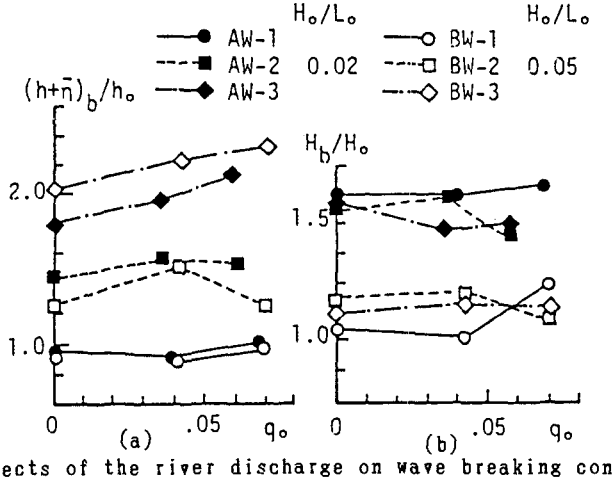

Fig.4 Effects of the river discharge on wave breaking conditions

3) Influence of currents on wave tranformation

Fig.4 shows the relation between the river discharge(q_o) and breaking condition. The results shown in Fig.4(a) show a tendency that the breaking point moves to offshore with increasing river discharge. However, in Fig.4(b), we see that the break height is not affected by the river discharge.

We also examined the applicability of wave breaking criteria to the coexistence field of waves and currents. Fig.5 illustrates the comparison of breaking heights measured by the experiment and the breaking criteria by Miche(eq.(18)) and Goda(eq.(19)).

$$H_b/L_b=0.142\ \tanh(2\pi h_b/L_b) \tag{18}$$

$$H_b/L_o=0.17\{1-\exp[-1.5\ \frac{\pi h_b}{L_o}(1+15\ \tan^{4/3}\beta)]\} \tag{19}$$

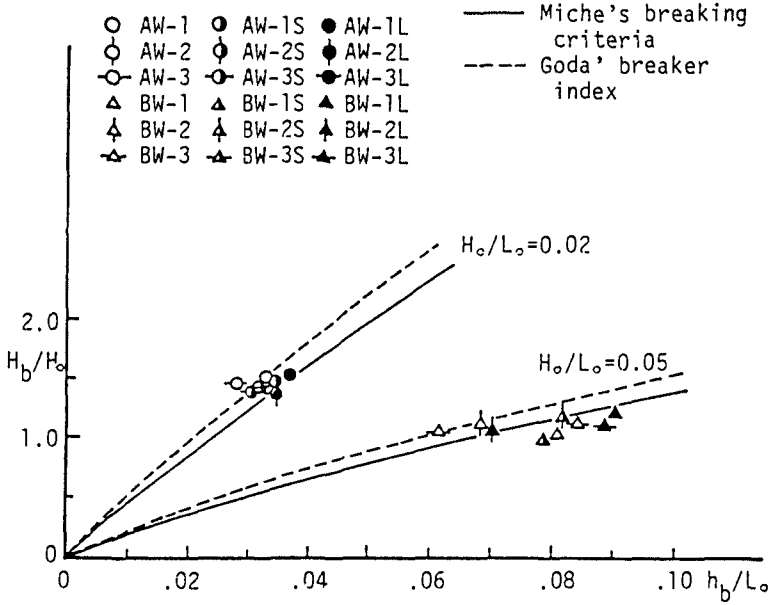

Fig.5 Comparisons between measured and predicted wave breaking conditions

From this figure, experimental results coincide well with both criteria regardless of the wave steepness.

4) Comparisons of numerical and experimental results.

In the preliminary calculations, it is found that the attenuation coefficient of the momentum after wave breaking K_1 in eq.(12) of 0.6 seems to be the most adequate for the prediction of wave transformation on a natural beach. So, we use this value together

with the Goda's breaking criterion in the following calculations.

Fig.6 shows the comparisons of measured and calculated wave heights and mean water levels in the cases where incident waves broke outside the river mouth (Cases AW-3 and AW-3L). Calculated results are shown by thick lines and measured results are indicated by circles. In the figure, calculated results based on the linear model (Sawaragi et al.(1984)) are also shown by thin lines. x = 0 at the horizontal axis corresponds to the location of the river mouth.

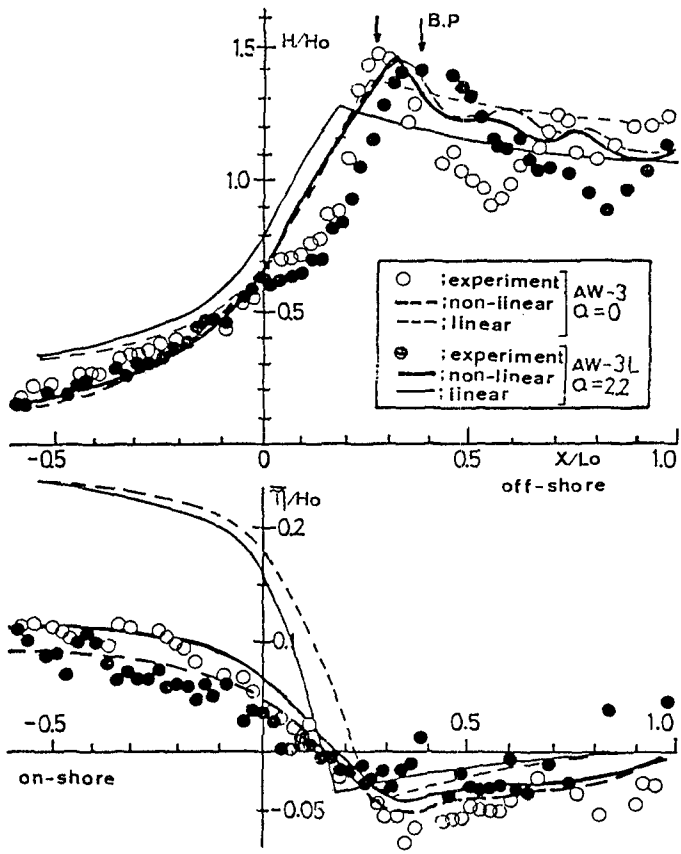

Fig.6 Comparisons between calculated and measured wave heights and mean water levels in the cases where waves broke outside the river mouth

It can be seen that although there are some discrepancies between the calculated and measured wave heights in the region of $0<x/L_o<0.3$, the calculated wave heights and mean water levels by the present model show good agreements with the experimental results regardless of the river discharge when compered with the predicted results by the linear model. Especially, the calculated mean water levels by the linear model give about two times larger estimetes of the experimental results.

Fig.7 illustrates time series of the surface displacements calculated 40cm outside and inside of the river mouth in the case of AW-3. From this figure, it is found that almost steady uniform waves are calculated after the generation of 6th wave.

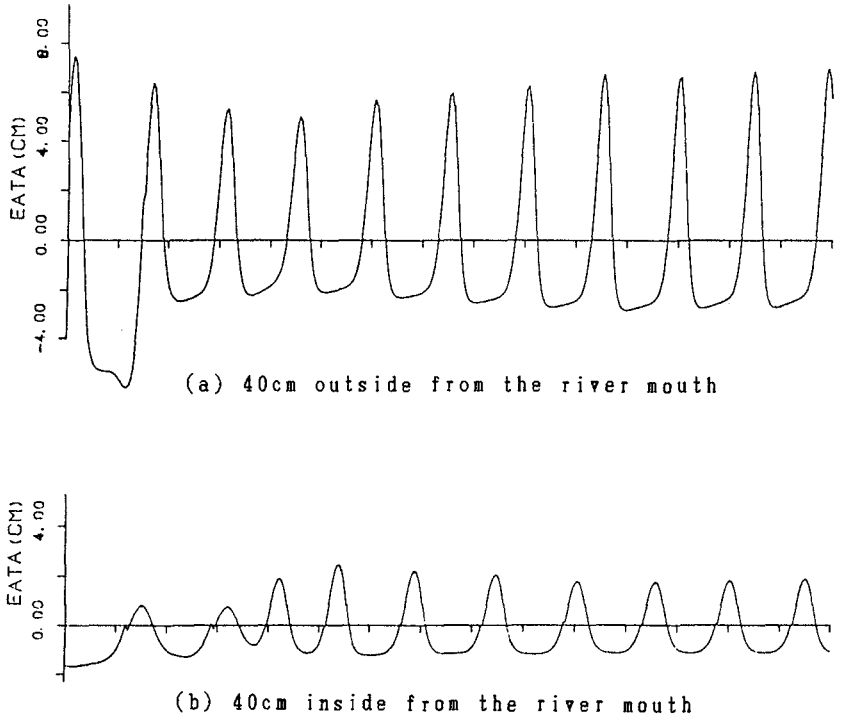

Fig.7 Simulated time series of surface elevation incide and outside of the river mouth

Fig.8 shows the comparisons of measured and calculated wave heights and mean water levels in the cases where the forced wave breaking took place in a river channel (AW-1 and AW-1L).

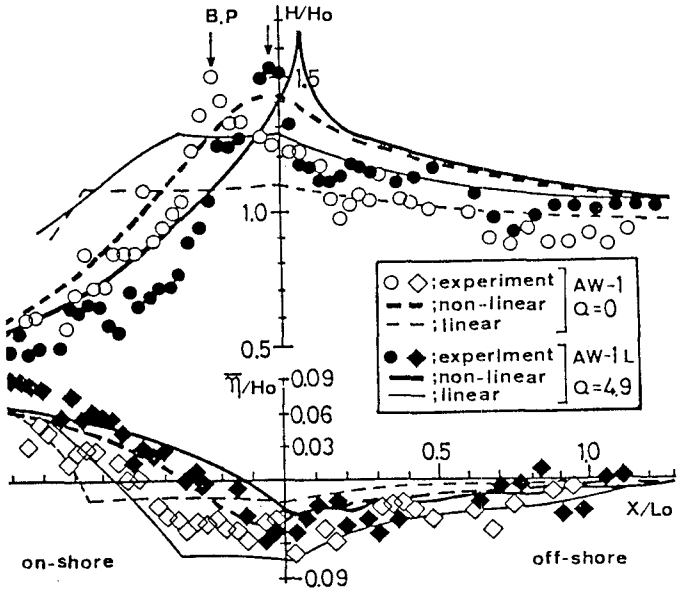

Fig.8 Comparisons between calculated and measured wave heights and mean water levels in the cases where waves broke in the river channel

In these cases, calculated wave heights by the present model no longer show good agreement with the experimental results. This disagreement comes from the difficulty in the determination of wave breaking condition in the river channel where the bottom slope is quite gentle. However, we can predict the closer experimental wave heights and mean water level by the present model than by the linear model.

As mentioned above, the linear model based on the linear wave theory overestimates the dis-placement of mean water level. On the contrary, the present model based on the non-linear wave theory offers good estimates of mean water level.

Fig.9 indicates the comparison between the excess monentum fluxes in the linear model S_{xx} and in the present model P_{xx} in thje case of AW-3. From this figure, the ratio of P_{xx}/S_{xx} becomes about 0.6 at around the break point and this results coincides with the results reported by Sawaragi et al.(1985).

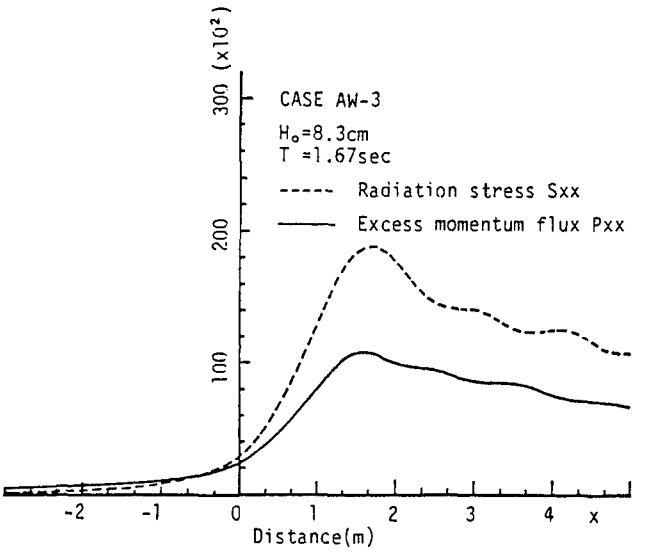

Fig.9 Comparison of P_{xx} and S_{xx}

6. CONCLUSION

In this paper, the authors applied Boussinesq type equations to simulate the wave field including wave breaking and wave-current interaction around a rivermouth.

The results simulated by the numerical model based on non-linear dispersive wave theory show good agreements with the experimental results in shoaling and wave-current interaction, and also in the prediction of wave breaking points and breaking heights it exhibits an improved results than those predicted by the linear model based on the linear wave theory.

CHAPTER 98

TURBIDITY - SEDIMENTATION IN CLOSED-END CHANNELS

Chung-Po Lin[1], Jonathan W. Lott[2] and Ashish J. Mehta[3]

ABSTRACT: In order to investigate the mechanism by which turbidity currents cause sedimentation in closed-end channels such as pier slips or residential canals, a laboratory investigation using fine-grained sediments was carried out. Two similar flume systems were used, each consisting of a main channel carrying sediment-laden flow and an orthogonally placed closed-end channel with a gate at the entrance. Characteristics of the turbidity current and sediment deposition in the closed-end channel were investigated following gate opening. Behavioral similarities between turbidity current and non-settling gravity currents were observed. Several properties, e.g. suspension concentration, showed exponential-type decay with distance. The ratio of sediment settling velocity to the densimetric velocity was found to be a useful parameter for comparing different test results. A relationship for estimating the sediment influx through the entrance is presented.

INTRODUCTION

Sedimentation problems in closed-end channels such as pier slips, tidal docks and residential canals have been reported extensively (Lin, 1987). In a detailed investigation carried out in pier slips at the Mare Island Naval Shipyard, San Francisco Bay area, Jenkins et al. (1982) showed in quantitative terms that the rate of sedimentation in the slips was measurably higher than that in the main channel to which the slips were connected. In general, mass transport associated with the tidal prism, wind-driven circulation and density-induced currents are mechanisms by which sediment enters the slip. Turbidity current is essentially driven by the difference in density between the sediment-laden outside waters and the relatively quiescent and sediment-free waters in the slip. The contribution to the total rate of sedimentation from this mechanism varies with the physical conditions; where tides are weak or when the sediment concentration outside is high, turbidity current becomes important as the source of sediment in the slip.

[3]Associate Professor, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611.

In the presently described laboratory study, only fine-grained sediments were used. The transport of such sediments, particularly where the tides are weak, as in much of Florida, is predominantly episodically controlled. There, fair weather suspended sediment concentrations are typically quite low, on the order of 5-20 mg/L. Therefore the major contribution to slip sedimentation occurs mainly during storms, when concentrations increase by one or two orders of magnitude. Flume experiments were therefore designed with this characteristic of sediment transport in mind. Two conceptually similar flume systems were used, one at the Waterways Experiment Station (WES) of the U.S. Army Corps of Engineers, Vicksburg, Mississippi, and the other at the University of Florida's Coastal Engineering Laboratory (COEL).

A closed-end channel of length L and width B, orthogonally connected to the main channel, is shown in Figs. 1a,b. A turbidity front of instantaneous length x_f measured from the entrance (x=0) occurs. The mean depth of water is H above the horizontal bottom (z=0). The sediment-laden main channel flow is fully turbulent and vertically well-mixed. The fluid density there is $\rho_w + \Delta\rho_o$, where ρ_w is the clear water density and $\Delta\rho_o$ is the density increment due to suspended sediment. Immediately inside the entrance a gyre zone occurs in which circulation is driven by lateral flow shear at the entrance. The vertically mixed flow is weakly turbulent there, and the distance of influence of the gyre is limited, being of the same order as channel width B. Almost immediately inside the entrance, deposition of sediment commences and the suspension density is lower than that in the main channel. The density difference, $\Delta\rho_1$, is therefore characteristically lower than $\Delta\rho_o$. It was found that for most of the front-related phenomena observed, $\Delta\rho_1$ was better representative of the driving force than $\Delta\rho_o$. Beyond the gyre the flow is predominantly viscous and stratified, with a clearly identifiable interface (z=η). Three characteristic features of the forward portion of the front are the nose ($z=h_1$), head (h_2) and neck (h_3).

Initially the gate was closed with equal water levels on both sides, but without sediment in the closed-end channel. The objective was to investigate both the behavior of the front and the characteristics of sediment deposition. Opening the gate to allow the turbidity current to move in is, in a sense, analogous to the generation of a relatively high concentration front during a storm, over very low concentration ambient conditions representing fair weather. In examining the physical phenomena, the focus was on understanding the basic transport mechanisms, without explicit consideration for prototype to model scaling. For the sake of reference, however, it may be noted that, given typical prototype pier slips or residential canals, the selected flume dimensions (noted later) could be considered to represent a prototype to model ratio on the order of 1:20 to 1:40.

A characteristic feature of the turbidity front is that given a sufficiently long channel, front motion generally slows down, and is ultimately arrested at a distance where the finest particles in suspension (at the entrance) settle out. The fluid density decreases up to the nose, where it almost equals that of clear water. A steady state exists, and there is an overall balance of forces involving the

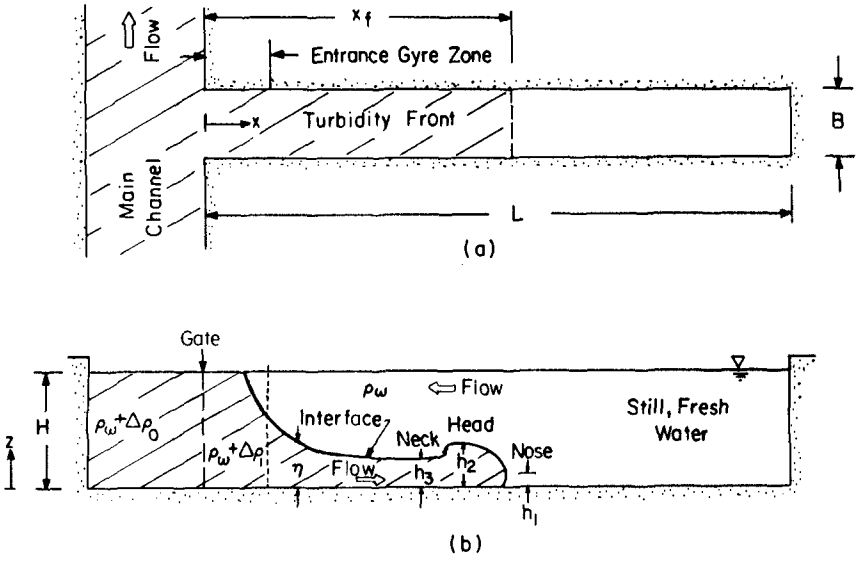

Fig. 1. Turbidity Front in a Closed-End Channel: a) Plan, b) Side View.

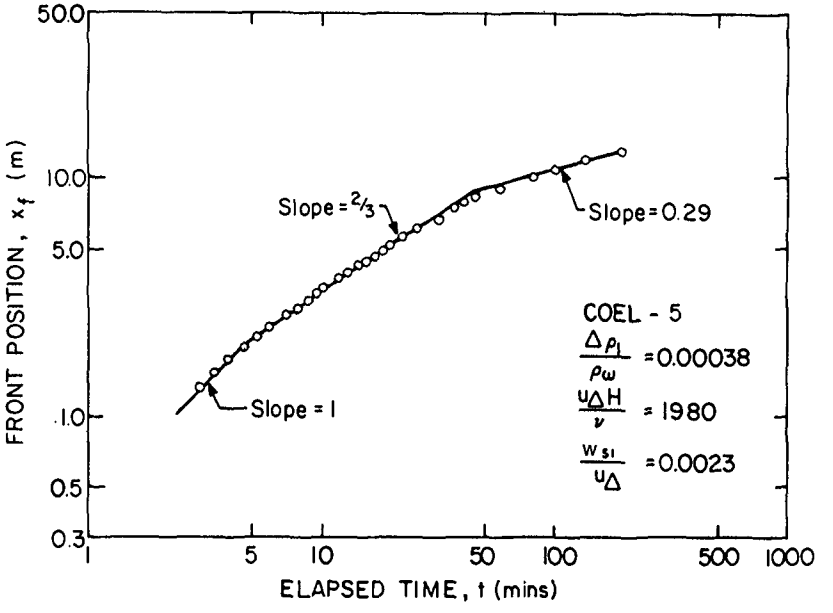

Fig. 2. Front Position with Elapsed Time after Gate Opening, Test COEL-5.

total density difference, water level set up in the channel and bottom friction. However, due to local force imbalance at different elevations above the bottom, sediment-laden water continues to enter through the lower half of the water column at the entrance, while an equal volume per unit time of almost sediment-free water leaves from the upper half.

METHODOLOGY

The three significant aspects of the phenomenon examined were: 1) the transient behavior of the propagating front after gate opening, 2) characteristics of the stationary front at steady state, and 3) rate of sedimentation. The scope of this paper permits only a brief presentation; details have been provided elsewhere (Lin and Mehta, 1986; Lott, 1986; Lin, 1987). In order to facilitate the investigation, three approaches were selected: 1) dimensional analysis for organizing the presentation of data, 2) numerical modeling to examine the transient and stationary front behaviors, and 3) simple analytic approaches to elucidate the stationary front behavior. Salient aspects are summarized below.

Dimensional Analysis

Dimensionless groups were developed for treating data for a number of different characteristics for the propagating as well as stationary fronts (Lin, 1987). One example will illustrate the point. The front speed, u_f, can be expressed as

$$\frac{u_f}{u_\Delta} = f\left(\frac{x}{H}, \frac{B}{H}, \frac{u_\Delta H}{\nu}, \frac{w_s}{u_\Delta}\right) \tag{1}$$

where ν is the kinematic viscosity of the fluid, and w_s is the sediment settling velocity. Furthermore, $u_\Delta = (g\ H\ \Delta\rho_1/\rho_w)^{1/2}$, where g is acceleration due gravity, is recognized as the densimetric velocity. Equation 1 indicates that the dimensionless front speed should depend on the front position, x/H, channel aspect ratio, B/H, densimetric Reynolds number, $Re_\Delta = u_\Delta H/\nu$, and the relative settling velocity, w_s/u_Δ. This relationship is analogous to the result for the speed of the saline front advancing against river flow having a velocity, u_r. In that case, w_s is replaced by u_r (Keulegan, 1966).

Numerical Modeling

A two-dimensional (x,z) time-varying mathematical model was developed to predict the vertical and longitudinal suspension concentration fields, based upon a solution of the equation of flow momentum, continuity and sediment mass conservation. Unlike the case of salinity intrusion which depends, amongst other factors, on the imposed river flow velocity, flow circulation in the present case is due solely to the imposed density difference between the main channel and the closed-end channel. The equation of momentum is therefore inherently coupled with that of sediment mass conservation; hence these equations, together with that of continuity, must be solved simultaneously. This was done using a finite-difference scheme with

appropriate fluid mechanical and sediment-related surface, interface and bottom boundary conditions, as well as no-flow condition at the closed-end, and constant suspension concentration at the entrance.

The coefficients in the model requiring specification were: 1) longitudinal and vertical momentum and mass diffusion coefficients e_x, e_z and ε_x, ε_z, respectively, and Manning's n for bottom roughness. In addition, two deposition-related parameters, the settling velocity, w_s, and the critical stress for deposition, τ_{cd} were required. The latter is equal to the bed shear stress, τ_b, below which all initially suspended sediment (having uniform properties) eventually deposits, while for all τ_b greater than τ_{cd} no deposition occurs. Resuspension of the deposit did not occur, hence was not considered.

The model was tested for stability and convergence. Spatial increments Δx = 0.5 m and Δz = 1 cm, and time-step Δt = 0.15 sec were selected for all test simulations. Data from test COEL-4 were used for model calibration. Some model applications are presented here. By invoking the Reynolds analogy, $e_x = \varepsilon_x$ and $e_z = \varepsilon_z$ were assumed. Since the relatively low concentration flow was laminar everywhere except in the small gyre zone near the entrance, e_z was selected to be equal to the kinematic viscosity of water, 10^{-6} m^2/sec. A value of 5 x 10^{-3} m^2/sec was found to be adequate for e_x. These values of the coefficients, applicable to homogeneous flows, were modified in the model for representing stratified flows, through appropriate formulations involving the gradient Richardson number (Lin, 1987). Manning's n was selected to be 0.030, which was close to that obtained from the Moody diagram. The median (by weight) settling velocity, w_s, of fine-grained sediments varies with sediment concentration; hence its value in the channel is space and time-dependent. Thus, for example, within the concentration range of interest it was found that $w_s = 0.000001C^{0.78}$ for kaolinite, where w_s is in m/sec and concentration, C, is in mg/L. This empirical relationship was derived from an independent set of tests in a settling column (Lott, 1986). It was found practical to select a constant value of w_s for each test, for simulation purposes. The value, w_{s1}, representing the condition of the entrance, was chosen. An evaluation of kaolinite deposition data in the channel yielded a value of 0.13 N/m^2 for the critical stress, τ_{cd}.

Analytic Development

The occurrence of a stationary front permits, for that purpose, a simplification of the governing equations, which can be solved to yield approximate results. An advantage these offer over numerical results is that they demonstrate, via comparison with data, the significance of the more important forces in explaining observations related to the flow field and the suspension concentration field. Space does not permit presentation of the relevant derivations which are given elsewhere (Lin, 1987). Illustrative results are given here.

Flow Velocity: A stationary front occurs under a balance between gravity and viscous forces. The length of the stationary front can be assumed to be considerably greater than the still water depth, H. The water layer above the front is considered to be sediment-free; all the

sediment being confined to the lower layer, with a uniform concentration. Under these conditions, momentum diffusion can be shown to be much more important in the vertical than in the horizontal direction. The closed-end causes a water surface slope to be set up, with the hydrostatic head balancing the excess pressure due to the density gradiant and the flow-induced bottom shear stress. In addition, inflow is balanced by outflow at every flow cross-section. Given the outflow velocity, u_s, at the surface, the following equations for the vertical profiles of the horizontal velocity, u, are obtained in the two layers:

$\xi < \zeta < 1$:

$$\frac{u}{u_s} = \frac{(1.5 - 0.375\xi)\,\zeta^2 - (3 - 0.75\xi)\,\zeta + 1}{-0.5 + 0.375\xi} \tag{2}$$

$0 < \zeta < \xi$:

$$\frac{u}{u_s} = \frac{(\zeta/\xi)^3 + (-3+1.5\xi^2-0.375\xi^3)(\zeta/\xi)^2 + (3-3\xi+0.75\xi^2)(\zeta/\xi)}{-0.5 + 0.375\xi} \tag{3}$$

where $\zeta = z/H$ and $\xi = \eta/H$.

Concentration Below Interface: The longitudinal variation of the depth-mean concentration in the lower layer, $\bar{C}_b$, can be examined by solving the steady state sediment mass transport equation. As a first order approximation only two terms need be considered: $u\partial C_b/\partial x$ and $w_s \partial C_b/\partial z$. Equating these terms amounts to balancing advective transport with gravitational settling. Experimental observations indicated an exponential-type decay for u and for w_s with distance (Lin, 1987). Therefore, $w_s = w_{s1} \exp(-\beta_1 x)$ and $u = u_1 \exp(-\beta_2 x)$ may be assumed, where subscript 1 for w_s and u refers to conditions at the entrance, and β_1, β_2 are empirical coefficients. Without presenting further details, it suffices to state the following resultant relationship for $\bar{C}_b$:

$$\frac{\bar{C}_b}{\bar{C}_{b1}} = \exp\left[-\beta \left(\frac{w_{s1}}{u_\Delta}\right)\left(\frac{x}{H}\right)\right] \tag{4}$$

where β depends on sediment properties. Investigations of lock exchange flows involving salinity-induced gravity currents suggest $\beta > 4$ (Lin, 1987).

Sediment Influx: The sediment influx rate at the entrance, $S = u_1 \bar{C}_1$, where $\bar{C}_1$ is the depth-mean concentration at the entrance. Experimental observations indicate that shortly after gate opening the flow velocity, u_1, approaches a constant value (Gole *et al.*, 1973; Lin, 1987). Furthermore, both the initial front speed, u_{f1}, and u_1 depend on u_Δ. Thus, increasing u_Δ implies increasing u_{f1} and u_1; in fact observations indicate $u_{f1} \simeq 0.5\, u_\Delta$. Likewise, $u_1 = \alpha u_\Delta$ may be assumed, where α is a proportionality constant. Therefore $S = \alpha u_\Delta \bar{C}_1$. Expressing $\Delta\rho_1$ in terms of $\bar{C}_1$, it can therefore be shown that

$$S = \alpha\left[\frac{gH}{\rho_w}\left(1 - \frac{1}{G_s}\right)\right]^{1/2} \bar{C}_1^{\,3/2} \qquad (5)$$

where G_s is the specific gravity of the sediment. It is interesting to note that given the sediment-type and water depth, S is proportional uniquely to the 2/3 power of sediment concentration at the entrance.

EXPERIMENTS

The dimensions of the closed-end channels at WES and COEL are given in Table 1. Also included are the imposed depth-mean concentration, C_o, in the main channel and the corresponding fluid density difference, $\Delta\rho_o$. Hydraulic arrangements were made to run each test for comparatively long durations (Lin, 1987). A total of 13 tests were carried out at WES and 14 at COEL. The longest test duration was 276 min in WES-13. Some difficulties were encountered in the WES tests in maintaining a constant water temperature during a test, owing to changes in the ambient air temperature. At COEL the flume was placed in a temperature-controlled environment. The test-mean temperature at WES ranged from 15.1 to 22.4°C, and at COEL from 18.9 to 26.7°C. In some tests, minor oscillations in otherwise steady flow speed and in suspension concentration in the main channel unavoidably resulted in data scatter.

Table 1. Summary of Experimental Conditions at WES and COEL

Flume	L (m)	B (m)	H (cm)	C_o (g/L)	$\Delta\rho_o \times 10^{-5}$ (g/cm^3)
WES	9.1	0.23	5.0-12.7	58-1878	3.4-114.7
COEL	14.7	0.10	8.0-10.6	250-3746	14.0-229.0

Seven fine-grained sediments together covering a wide range of physical and physico-chemical properties, were used; some cohesive and others nearly non-cohesive. The cohesive materials were flocculated, at fairly low salt concentrations in the fluid (Lin, 1987). Cohesive materials included kaolinite (median grain size 1 μm) and Cedar Key mud (2 μm). The others were flyash I (14 μm), flyash II (10 μm), flyash III (14 μm), Silica flour (7 μm) and Vicksburg loess (18 μm).

RESULTS

Front Characteristics

As in the case of the propagating front, for instance, of a salinity-induced gravity current, three distinct phases are found to occur during the movement of a turbidity front. These are the initial adjustment phase, the inertial phase and the viscous phase. These are

shown for COEL-5 (using kaolinite) in Fig. 2, in which the front position, x_f, is plotted against elapsed time after gate opening. The three phases are marked by lines of different slopes. During the first phase, of unit line slope, the front propagated at a constant speed, being motivated by the initial density gradient between the main and closed-end channels. During the second phase (line slope 2/3) inertia and gravity forces dominate, with the front speed, dx_f/dt, being proportional to -1/3 power of the elapsed time. For gravity currents, this -1/3 power dependence has been demonstrated both theoretically and experimentally (Rottman and Simpson, 1983). In the final phase, gravity and viscous forces entirely control front movement. The slope of 0.29 is slightly higher than 1/5 observed in the case of a gravity current, partly because of the effects of thermal gradients during this test (Lin, 1987).

In several tests, the first phase was too short to be recorded. Furthermore, the point of transition from the second to the third phase was found to be strongly dependent upon the dimensionless settling velocity, w_{s1}/u_Δ. Thus, for example in COEL-5, characterized by $w_{s1}/u_\Delta = 0.0023$, transition occurred at about 400 min. after gate opening, while in COEL-8 (using flyash III), with $w_{s1}/u_\Delta = 0.0208$, transition occurred at about 50 min. Thus, in the latter case, the relatively large particles settled out rapidly, leaving behind a slow moving, very fine particle suspension influenced by viscous drag.

Dimensional analysis suggested that the dimensionless initial front speed u_{f1}/u_Δ, would possibly depend upon the densimetric Reynolds number, Re_Δ, and the channel aspect ratio, B/H. Data plotted in Fig. 3 from all WES and COEL tests show a fair degree of scatter, but no clear trend of dependence of u_{f1}/u_Δ on either Re_Δ or B/H. Part of the reason for the scatter is believed to be the influence of the entrance gyre zone on front propagation. The gyre length in the x-direction was in the range of 0.2-0.4 m in WES tests and 0.1-0.2 m in COEL tests. Therefore, the speed at x=1 m in WES tests and 0.75 m in COEL tests, rather than at x=0, was conveniently selected as the initial front speed. Notwithstanding the data scatter problem, the mean value of u_{f1}/u_Δ is observed to be 0.43, which is fairly close to the value 0.46 obtained by Keulegan (1957) for salinity currents. A value of 0.50 is obtained theoretically (Yih, 1965). Since the effect of sediment settling is much less significant than that of the density gradient at the beginning, the correspondence between gravity and turbidity currents in this respect is not surprising.

In Fig. 4, the ratio of front nose height to head height, h_1/h_2 is plotted against the local head Reynolds number, $Re_h = u_f h_2/\nu$, for COEL tests (no data were collected at WES for this purpose). A trend of increasing h_1/h_2 with decreasing Re_h is evident. In other words, as might be expected, with increasing viscous drag relative to inertia, the nose becomes blunt, and nose height becomes greater relative to that of the head. In addition to COEL data, those on different types of gravity currents obtained from five other investigations have been included in Fig. 4 (Lin, 1987). The data of Lawson (1971) are shown by dashed lines indicating upper and lower bounds. These data, including those of Lawson's which are for gravity current in air, are observed to be entirely consistent with those from the present tests.

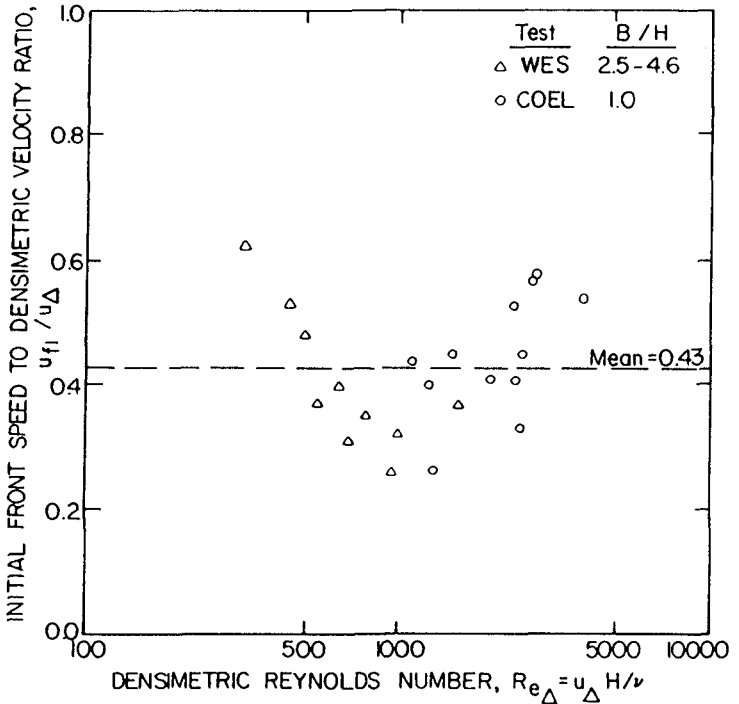

Fig. 3. Dimensionless Initial Front Speed against Densimetric Reynolds Number.

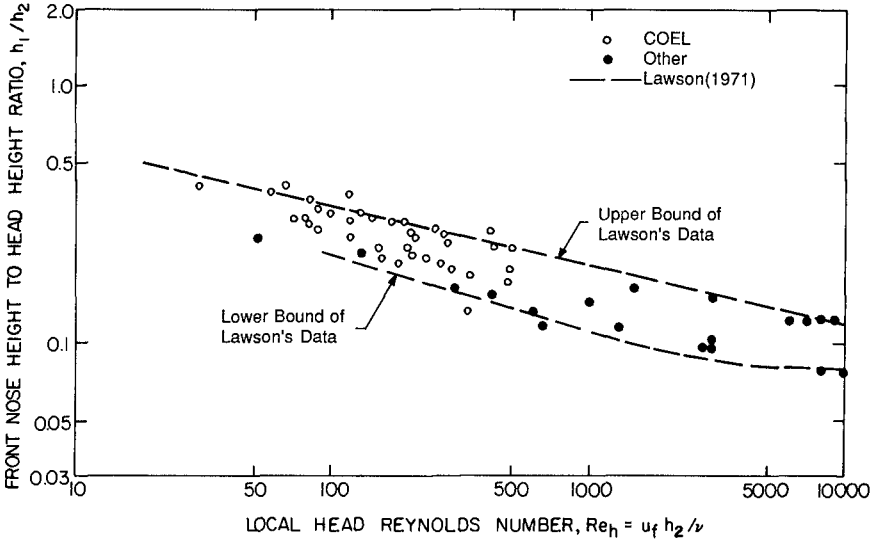

Fig. 4. Front Nose Height to Head Ratio against Local Head Reynolds Number.

Results presented by Lin (1987) indicate that the ratio of front head height to neck height, h_2/h_3, independent of the local neck Reynolds number, $Re_n = u_f h_3/\nu$, with a mean of 1.30. For salinity data at somewhat higher Reynolds numbers, Keulegan (1958) obtained a similar result with a mean of 2.08.

Velocity Profiles

For illustration, only results on the vertical velocity profiles at steady state, corresponding to a stationary front, are presented here. In Fig. 5, the dimensionless horizontal velocity, $u/|u_s|$ is plotted against the corresponding dimensionless elevation, $\zeta = z/H$. The data are for COEL-6 at x=1.8 m. Comparison has been made with numerical results as well as with analytically derived Eqs. 2 and 3. The numerical result is not affected by the boundary layer effects associated with the side walls of the channel. The data were obtained via a dye injection procedure such that the results were influenced both by the wall boundary and by lateral secondary currents. Limitations of the analytic solutions were noted previously. Inspite of these evident differences, the agreement between measured data, numerical and analytic results may be considered to be acceptable. The numerical and analytic results satisfy the steady state continuity requirement of equal discharge both ways. Experimental data are inaccurate in this respect.

Concentration Profiles

In Fig. 6, suspension concentration at elevation z=0.7 cm at five horizontal locations in COEL-5 are plotted as a function of time. At each location this elevation was below the corresponding elevation of the front interface. At each location, the concentration rises from nil ahead of the front to an eventual steady state value. Numerical results compare reasonably well with the data.

In Fig. 7, vertical concentration profiles for COEL-5 are plotted at 67 and 90 min. after gate opening. Five horizontal locations have been included. Agreement between data and numerical results (at 130 min) appears to be acceptable. The total height of each profile corresponds to the thickness of the turbid lower layer at that position and time.

Both the exponential nature of concentration decay with distance and the influence of the dimensionless settling velocity, w_{s1}/u_Δ, on the concentration profile is apparent in Fig. 8, in which the concentration ratio, $\overline{C}_b/C_{b1}$ at steady state is plotted against x/H on semi-logarithmic coordinates. Data from seven tests using kaolinite have been included. The exponential nature of the profiles is apparent. Three lines represented by different values of w_{s1}/u_Δ have been shown. Line slope is observed to increase with increasing w_{s1}/u_Δ, as would be expected since, for a given u_Δ, increasing w_{s1} implies increasing rate of deposition of sediment from suspension. These w_{s1}/u_Δ values (indicated on the lines) were obtained by best fitting Eq. 4 to data using β=7. It can be shown that this value of β corresponds to the ratio $u_1/u_{f1} = 0.57$, which is close to the value, 0.70, obtained experimentally by Gole *et al.* (1973). These w_{s1}/u_Δ

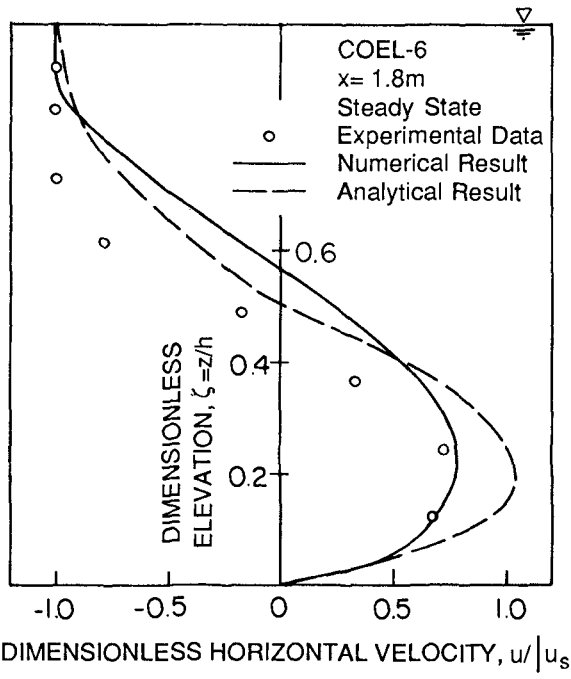

Fig. 5. Dimensionless Horizontal Velocity Profiles, Test COEL-6 at x=1.8 m.

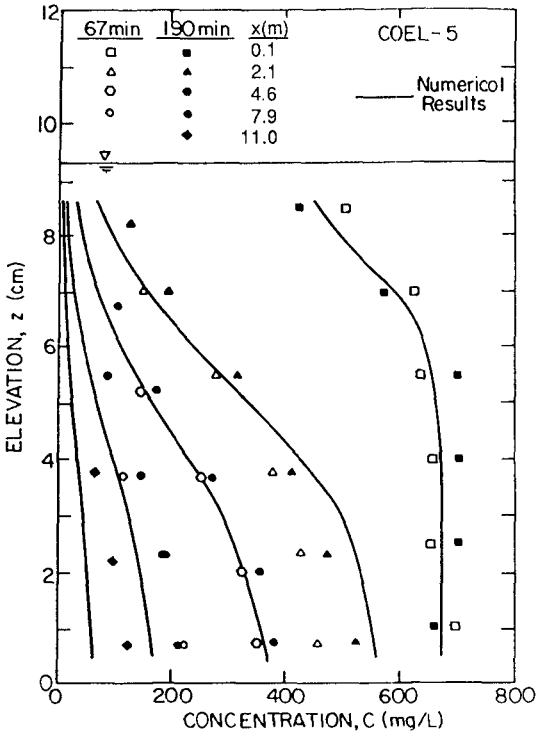

Fig. 7. Concentration Profiles at Steady State at Five Locations, COEL-5

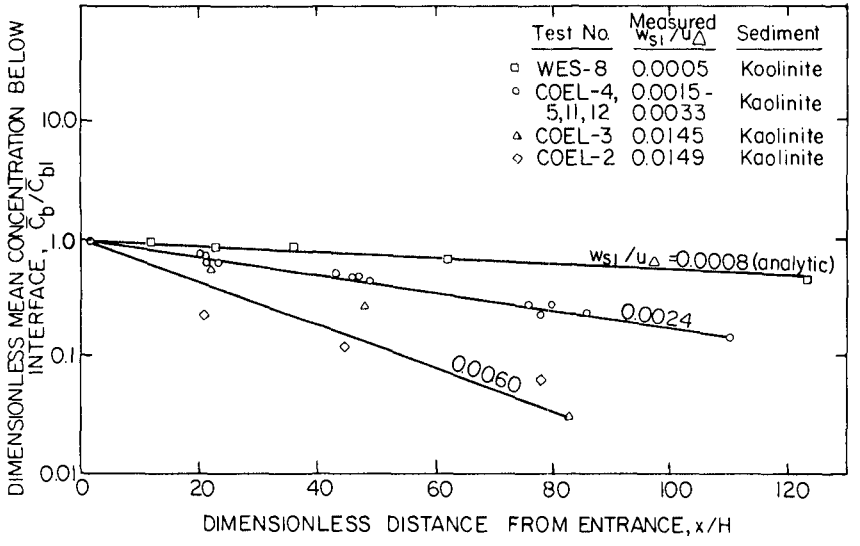

Fig. 8. Dimensionless Mean Conc.below Interface against Dist., Kaolinite

values differ from those based on measurement as given within the figure. The discrepancy increases with increasing w_{s1}/u_{Δ}, as a result of inherent limitation in applying Eq. 4 to data on sediment with a relatively large settling velocity. In such an event, for instance, the vertical concentration gradient becomes pronounced; hence the assumption of a uniform concentration, inherent in Eq. 4, is no longer reasonable.

Sediment Deposition and Influx

Sorting of sediment was characteristically observed in all tests in which relevant data were collected, with the grain size generally decreasing with distance from the entrance. Qualitatively, the same trend has been reported in prototype canals (Wanless, 1975). For nearly cohesionless sediment such as flyash, sorting measurably increased with increasing w_{s1}/u_{Δ}.

In Fig. 9, the rate of deposition, δ, is plotted against distance from the entrance for COEL-5. As would be expected, δ is observed to decrease rapidly with distance, once again suggesting an exponential decay. Agreement between measurement and numerical prediction is acceptable, except that there is a slight over-prediction.

Based upon the concept presented earlier, the rate of sediment influx, S, is plotted against entrance concentration, $\overline{C}_1$ in Fig. 10. A 3/2 power dependence of S on $\overline{C}_1$ is clearly evident in accordance with Eq. 5. Note that S represents a mean value, which was calculated by dividing the total deposited sediment mass in the channel by the test duration and the area of the lower half of the flow cross-section at the entrance. Since the turbidity front moved in fairly slowly during most of test duration except at the very beginning, S can be practically considered to represent the sediment influx rate as would occur at steady state. The coefficient 0.015 was calculated by selecting mean values of H = 8.8 cm and G_s = 2.55, for the twelve selected tests. The value α = 0.35 was empirically chosen, but this value can be shown to be consistent with the observations of Gole et al. (1973) that at steady state, the surface outflow velocity at the entrance is about 30% lower than the initial front speed (Lin, 1987).

CONCLUDING REMARKS

It is worthwhile noting in summary, that the turbidity current behaves generally in the same manner as a gravity current induced, for instance, by salinity, although there are evident differences, principally characterized by the ratio w_{s1}/u_{Δ}, a conveniently measurable parameter related to the turbidity current.

Although no attempt could be made in discussing model to prototype scaling problems because of evident reasons, it is noteworthy that by giving consideration to the basic fluid mechanical laws relating to the observed phenomena, a framework for future prototype investigation of a comprehensive nature is believed to have been established. Comparison may be made here between the present study and similar, very useful, previous investigations in laboratories on salinity-driven gravity currents.

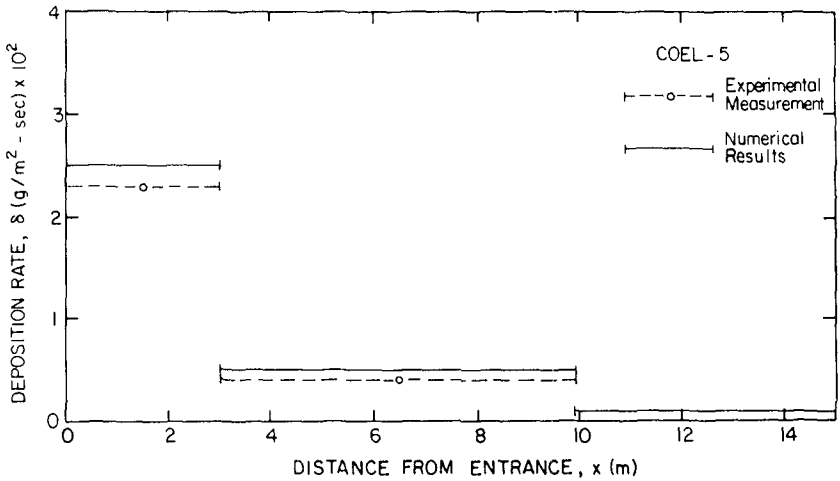

Fig. 9. Variation of Rate of Deposition with Distance, Test COEL-5.

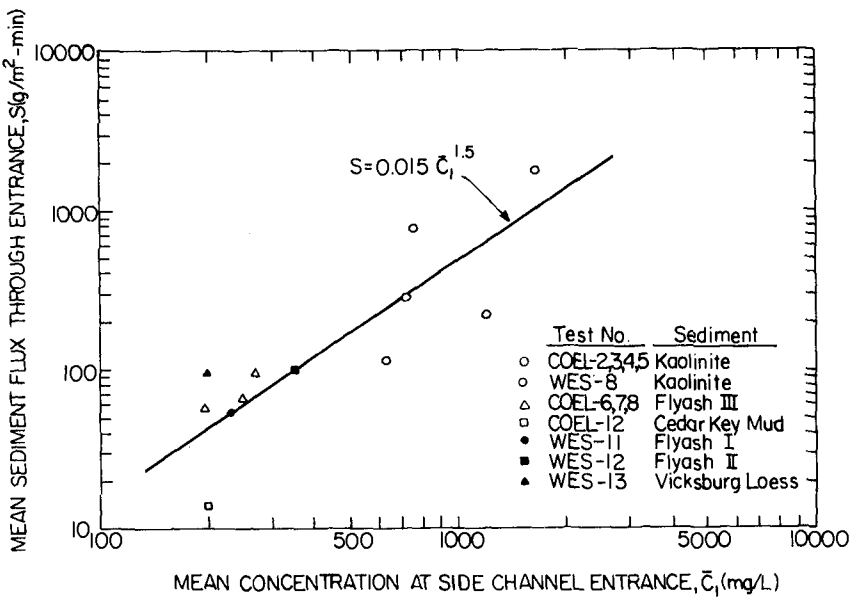

Fig. 10. Mean Sediment Flux as a Function of Depth-Mean Entrance Concentration.

From an engineering application viewpoint, Eq. 5 and its confirmation through Fig. 10 provide a simple means for computing the rate of sedimentation in closed-end channels. Its application to prototype canals seems highly promising, and deserves further consideration in that context.

ACKNOWLEDGEMENT

Support of the National Science Foundation (Grant No. CEE-84-01490), and the Hydraulics Laboratory of the Waterways Experiment Station, Vicksburg, Mississippi, is sincerely acknowledged.

CHAPTER 99

Closure of Tidal Channel in Land Reclamation

Chin-I Liu *

Ruey-Shyong Chang *

Abstract

The land reclamation of Lunwei subdistrict A in the development of Changhua Industrial Estate Project was commenced in May 1980. Fill sand was dredged by suction dredgers from borrow area and placed in the south and central parts of this subdistrict. Bamboo fence was used as sand retaining structure. In November, a new tidal channel occurred between two fill sand islands and across the head of seawall, it caused the increase of materials and the difficulty of construction of the seawall.

Closure of the tidal channel was completed by constructed a sand embankment dike with low cost materials such as; bamboo piles, bamboo mattress and sand bags.

1. Introduction

The Changhua Industrial Estate Project, located on the west coast of Central Taiwan on a stretch of tidal land, has a total area of about 6,292 hectares divided into six districts, namely, Shingkang, Yupu, Lunwei, Lukang, Fushin and Hanpao (Figure 1). The Yupu, Lunwei and Lukang districts with a total area of about 3,780 hectares were planned for phase 1 development to accommodate heavy industries such as machinery, steel, power and petrochemical.

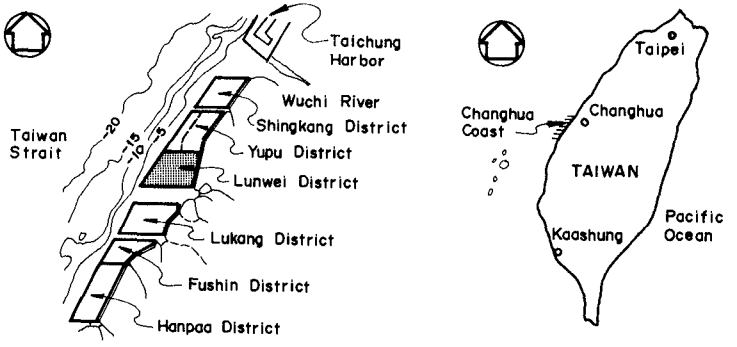

Figure 1 Key Plan of Changhua Industrial Estate

* Engineer, Sinotech Engineering Consultants Inc. No. 171, Sec. 5, Nanking East Road, Taipei, Taiwan, R.O.C.

The 406-hectare subdistrict A of the Lunwei district in the west has now been partially completed. Its development called for the construction of a 3,800 m long seawall and hydraulic fill of 18,800,000 m^3. A tidal channel runs southward through the center of this subdistrict and a sand bar lies west of the channel.

The development work commenced in May 1980. The rubblemound seawall was constructed from north to south along a planned line. Hydraulic fill was placed in the south and central parts of the subdistrict by using five suction dredgers positioned in borrow areas. By November 1980, a 2,700 m length of the seawall had been completed and the sand fill totaled about 4,000,000 m^3. In that month, a new tidal channel occurred between two fill sand islands and it flowed west through the head of the seawall. The original sea bed was scoured down to El.-8.0 m. As a result, the development work was slowed down and the quantities of seawall construction materials had had to be increased. Because the reclamation work must be completed in time to supply the future demand for land, closure of the tidal channel was considered the best solution, and a sand-made embankment dike was selected for this purpose. The dike was constructed within one tide cycle, involving 6 bulldozers and 100 workmen and using steel pipe piles, bamboo piles, mattress and sand bags as retaining structures.

This paper describes the formation and closure of the new tidal channel, the morphological variation and the low cost materials used.

2. Topography and Geology of Lunwei District

Figure 2 shows the boundary line and topography of the Lunwei district. On the north, the boundary is formed by the existing south seawall of the Yupu district, extending west for about 1 km; on the west by a 3.8 km long seawall which has been completed; on the south by a planned 4.8 km long revetment; and on the east by a planned inner dike, separated from an existing seawall by a proposed 200m wide waterway. The total area of the Lunwei district is 1,251 hectares.

A tidal channel runs NE-SW through the center of this district. The width of this 5.5 km long channel below El.-1.0 m ranges from 220 m to 550 m. The channel bed, with a 0.001 slope, has an elevation of -5.5 m at its deepest part, and the side slope is 1:10 below mean water level and 1:5 above mean water level.

The elevation of land on the east side of this tidal channel is +1.8 m, which dips gently on a 1:800 slope westward to the zero line of the channel.

A sandbar lies in a N-S direction along the west side of the tidal channel. Its highest elevation is +1.8 m in the northern part, sloping at 1:1,200 eastward to the tidal channel, and at 1:100 westward to El.-2.00 m. The slope to the south along the seawall line is 1:1,400, and that to the north is nearly flat.

The average elevation of the Lunwei district is about +0.3 m.

The geology of this district is divided into three zones. (1). The first zone is between the existing seawall and a line about 2.5 km to the seashore, which is an area of river deposit composed of yellowish gray fine sand and medium-grain sand in the top layer and fairly fine sand in the bottom layer. The grain size is from 0.2 mm to 0.5 mm. The second zone lies west of the first zone up to the low tide line. Coarser sand is found all over the place. The third zone is located at the river mouth, where the soil consists of silty-sand with a thin clay layer.

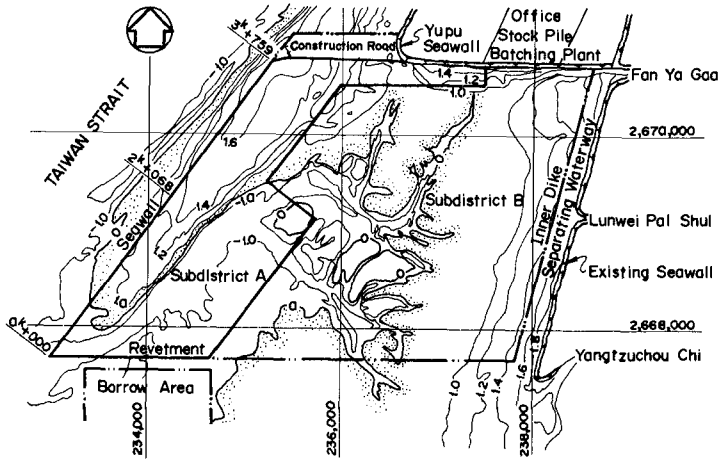

Figure 2 Topography of Lunwei District

3. Main Engineering Works

3.1 Land Reclamation

The Lunwei district is divided into two parts; subdistrict A and subdistrict B. Subdistrict A, with an area of 406 hectares, is planned to be filled to elevation +5.5 m, which will required about 18,800,000 m^3 of fill sand and 540,000 m^3 of cover material. For subdistrict B, which has an area of 845 hectares to be filled to elevation +4.2 m, about 32,000,000 m^3 of fill sand and 1,200,000 m^3 of cover material will be needed.

The reclamation work for subdistrict A started first. Fill sand is dredged from the proposed harbor basin and waterway to the south and east of this district respectively.

3.2 Seawall

The seawall line was set on the sandbar for easy construction

and to get the land needed. Typical section of the seawall are shown in Figure 3. Type A which has a sand core was adopted for the 1,691 m long northern section, while type B with a cobble core was used for the 2,068 m long sourthern section. The access road for the seawall was connected to the existing south seawall of the Yupu district. Bamboo fence was used as sand retaining structure for the sand core of type A seawall. Toe elevation was at El.+0 m, and synthetic mattress was placed between sand and cobble as filter to prevent sand from being sucked away by wave. Five-ton wave dissipation blocks were used to protect the seawall against storm wave.

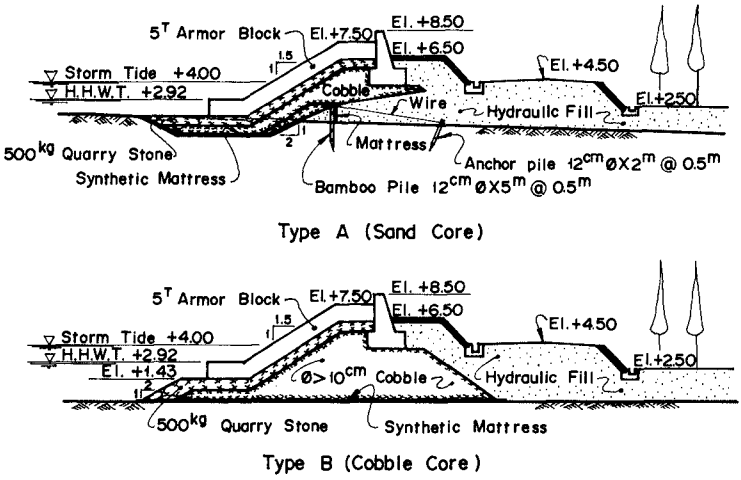

Figure 3 Typical Section of Seawall

4. Land Reclamation for Lunwei Subdistrict A

4.1 Distribution of Fill Sand

The total amount of fill sand required for Lunwei subdistrict A is about 18,800,000 m^3, which is supplied from borrow areas. Of this, about 17,200,000 m^3 is dredged from the south borrow area and the remaining 1,600,000 m^3 from the relocated tidal channel. The material for a 15 cm thick cover, totaling 540,000 m^3 in volume, comes from the Tatu mountain about 20 km away. (2).

4.2 Dredgers

Five suction dredgers with capacities as shown in Table 1 were used for the rclamation work. The arrangement of dredgers is shown in Figure 4.

Table 1 Characteristics of Dredgers

Name	Dimension (m)				Engine Power		Dia. of PiPe (")	Dredging Capacity (m^3/hr.)	Discharge Distance (Km)	Dredging Depth (m)
	Length	Width	Depth	Draft	Type	(HP)				
Taichun 1	34	11	3	1.8	Diesel	3,600	24	300-600	2.5	16
Taichun 2	58	18	3	2.1	Diesel	8,000	32	500-1000	5.5	20
Taichun 3	35	11	3	1.8	Diesel	3,000	24	300-600	2.0	16
Taichun 6	36	11.5	3	2.0	Diesel	3,000	24	300-600	2.0	20
Taichun 7	34	11	3	1.5	Diesel	3,000	24	300-600	1.8	16

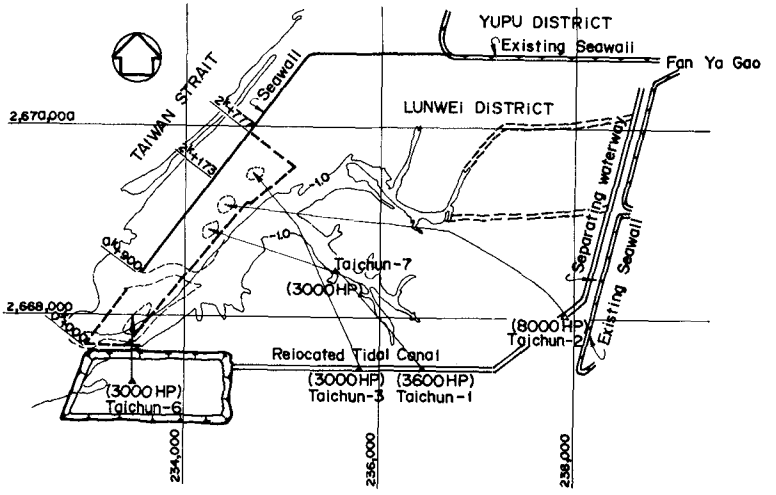

Figure 4 Arrangement of Dredgers for Land Reclamation

4.3 Sand Retaining Structure

Because construction of the seawall was from north to south, while the sand filling work proceeded from south to north. Bamboo fence of a simple type as shown in Figure 5 was used to retain the sand along the west and south boundaries. Bamboo fence consisted of bamboo pile, iron wire, anchor pile, bamboo mattress, etc. Two rows of bamboo fence were erected to prevent swell invasion.

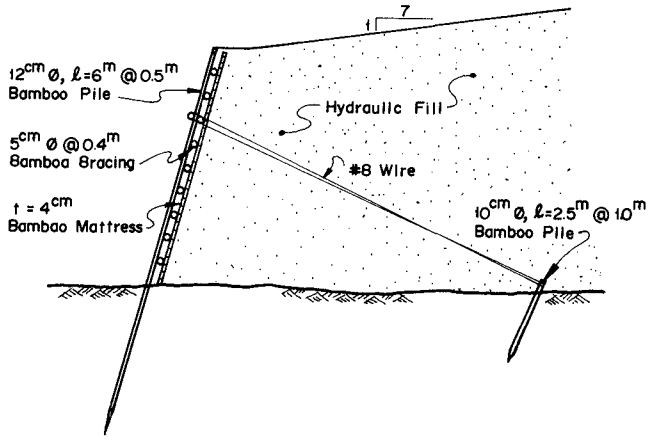

Figure 5 Typical Section of Sand Retaining Structure

5. Formation of Tidal Channel

The reclamation work for Lunwei subdistrict A was started in May 1980. Three 3,000 hp suction dredgers positioned in the south borrow area placed the fill sand in the southern part of this subdistrict. In July, one 3,600 hp and one 8,000 hp dredger positioned in the proposed relocation site for the tidal canal and the east waterway respectively placed sand in the middle part of the subdistrict. In October, two 3,000 hp dredgers in the south borrow area moved to the tidal canal to accelerate the dredging work, placing sand also in the middle part. Bulldozers were used for the earth moving work, which ran between the two sand islands at low tide, but in November the bulldozers could walk no more. The original sea bed was scoured, as even at low tide water still existed. The occurrence of the new tidal channel could be attributed to: (1) The bamboo fence used as retaining structure was partially destroyed by typhoon waves, so sand entered the original tide channel and reduced its flow section; (2) The two fill sand islands approached each other gradually and increased the tidal current velocity to scour the sea bed.

6. Morphological Variation

Figure 6 and Figure 7 show the morphological variation of the proposed closure section of the channel and the head of seawall. The deepest elevation was -6.0 m in the channel, and -8.0 m in the head of seawall.

The current velocity in the closure section was also measured under different tidal conditions. The maximum velocity was 2.25 m S^{-1} at the center during high tide. (3).

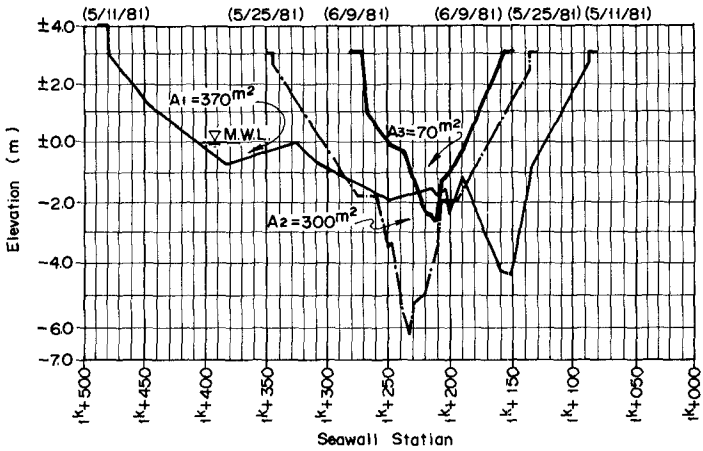

Figure 6 Morphological Variation of the Closure Section of the Tidal Channel

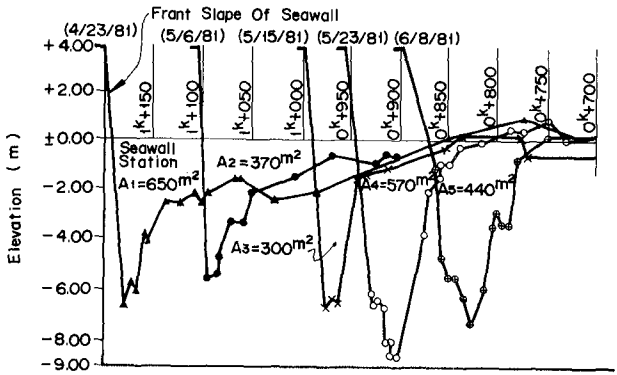

Figure 7 Morphological Variation of the Head of Seawall

7. Closure of Tidal Channel

7.1 Reasons for Closure of Tidal Channel

The scouring phenomenon occurred in November 1980, but land reclamation and seawall construction proceeded until May 1981. Due to the following reasons the closure of the tidal channel was decided.

(1) The scouring of seawall head resulted in construction diffi-

culty and the need for increased use of the construction materials.

(2) A large amount of the fill sand was washed away by tidal current.

(3) The typhoon season would come soon, so the finished part of the work must be preserved.

(4) The development work must be completed as soon as possible.

7.2 Construction of Closure Dike

Several field surveys were made to study the closure location and estimate the work quantity. After considering the construction feasibility, an upstream location was selected where the channel width was the narrowest, due to continued supply of sand. The selected closure date was June 10, 1981, the lowest tide time. Three alternative construction methods for the sand embankment dike were considered: (4).

(1) Use of steel sheet piles as temporary retaining structure and fill sand.

(2) Use of cobbles dumped from truck or barge.

(3) Use of bamboo piles and steel pipe piles as retaining structure and fill sand.

The last method was selected after comparing the material available, degree of difficulty of construction, and haul road condition. When the new channel occurred, about 78 sets of bamboo spurs were constructed along either bank for retaining sand and along the east side slope for reducing current velocity. Three 3,000 hp dredgers continuously supplied sand from each side to raise the channel bed from El.-6.0 m to El.-2.8 m. Prior to the closure date, about 10,000 m^3 of sand, 12,000 sand bags, 8"ϕ steel pipe piles, bamboo piles, mattresses, etc., were stocked on the banks for dike construction. At 10:00 p.m., June 9, 1981, the piling work started with the use of water jet during ebb tide, and bulldozers moved the sand from both banks to fill the dike until 5:00 a.m., June 10, 1981 when the dike was closed. Spurs made of bamboo piles and sand bags were constructed on the east slope to prevent scouring by the original tidal channel.

Eventually, the dike was completed, which has a top width of 10 m with top elevation at +3.0 m as shown in Figure 8.

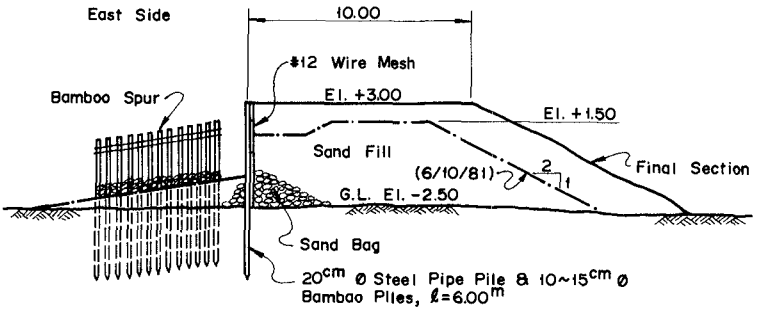

Figure 8 Typical Section of Embankment Dike

8. Conclusion

From our experience with this closure work the following conclusions can be drawn:

(1) Land reclamation from the south in this project has the advantages of higher dredging efficiency and ease of construction of the sand retaining structures, but this decision was risky, as it resulted in the need for closure of a new tidal channel.

(2) The success of the closure work was due to the dredgers' large capacity for supplying sand to reduce the channel depth, and to the use of spurs constructed of bamboo piles and sand bags to retain the fill sand and reduce the channel width so that the dike could be completed within one tidal cycle.

(3) The reclamation sequence must be carefully arranged. If the work started from inshore to offshore or proceeded simultaneously with seawall construction, the new tidal channel might not have occurred.

CHAPTER 100

Another approach to longshore current evaluation

M.A. Losada, A. Sánchez-Arcilla and C. Vidal

A simple model to predict the longshore current velocity at the breaker line on a beach with oblique wave incidence, is presented. The model balances driving and resistance terms (gradients of radiation and turbulent Reynolds stresses and bottom friction) to get a general expression for the velocity. This equation shows explicitely the influence of Iribarren's parameter on longshore current generation. It has been tested with field and laboratory data, obtaining a reasonable fit to measured values. The resulting (predictive) model is expected to be valid for any type of breakers though the calibration has been mainly done for spilling and plunging types, due to the scarcity of results for other breakers.

1.- INTRODUCTION

Longshore currents in the surf zone have been acceptably modelled using the radiation stress concept (Longuet-Higgins,1970). The longshore-trust (Nw/m^2) due to an oblique wave approach, given by the gradient of the radiation stress, is balanced (in stationary and longshore-uniform conditions) by bottom friction and horizontal mixing (Bowen, 1969), (Longuet-Higgins, 1970).

The gradient of the radiation stress is evaluated using sinusoidal theory (as a first approximation for slowly varying depths) and turns out to be proportional to the local rate of energy dissipation, D (Joules/(m^2 x sec)), regardless of its origin. Inside the surf zone a significant fraction of D comes from wave breaking because the turbulence associated to the breaking process is responsible for most of the dissipated energy. Bottom friction plays a minor role in this context, being important only in special cases (e.g. very steep and reflective profiles).

This means that turbulent horizontal mixing must be one of the most important factors in longshore-current generation because it accounts for a large part of the dissipated energy which controls the driving term.

Bottom friction turns out to be the main retardating term for the mean flow (e.g. Longuet-Higgins, 1970, Kraus & Sasaki, 1979). It depends on the type of granular material and resulting bed forms but also in the properties of the flow field defined in the fluid. These are, in turn, related to the bed geometry. It is, therefore, reasonable to expect a variation of the frictional stress with the existing level of turbulence (Fleming et al. (9)), defined (albeit simplistically) by the breaker type.

Turbulents horizontal mixing, the remaining retarding term in longshore-uniform conditions, is numerically less significant than bottom friction. This latter effect controls the magnitude of the resulting velocities while lateral mixing determines the profile (shore-normal) distribution.

All these points suggest that breaker type is closely related to longshore current generation. This implies that Iribarren's number, Ir, so far considered a parameter for definition of breaker characteristics, also plays an important role in longshore-current evaluation. A modified parameter, Ir θ, similar to the one used for oblique incidence in mound breakwaters (Losada et al., 1982), must be employed to include the effect of the angle of wave approach:

$$Ir_\theta = Ir \cos\theta = \left(\frac{g}{2\pi}\right)^{1/2} \cdot \frac{T \cdot \tan\beta}{(H_b)^{1/2}} \cdot \cos\theta \qquad (1)$$

in which:

H_b : wave height at the breaker line
T : wave period
$\tan\beta$: bottom slope
g : acceleration due to gravity.

The paper proposes an average evaluation of driving and resistance terms using the surf zone as a control volume and including the influence of breaker type througs Ir_θ. Turbulent stresses are calculated as proposed by Battjes (1975) while bottom friction is estimated with a linear law, based on the equations derived by Liu and Dalrymple (1978). The model has been tested with field and laboratory data from Putnam et al. (1945), Vitale (1981), Komar and Inman (1970) and Wu et al. (1985). The fit between predicted and measured velocities is satisfactory for usual values of the friction coefficient. The derived solution is shown to be valid for any type of breakers, therefore being more general than most of the previously published formulae, even though its field of application is restricted to planar beaches.

2.- LONGSHORE CURRENT FORMULATION

Longshore flow will be formulated using the vertically integrated, time-averaged mass and momentum conservation equations together with the simplifying assumptions of stationary and longshore-uniform conditions. With this approach, similar to the one used by Bowen (1969), the resulting longshore momentum equation is (Mei, 1983):

$$\frac{\partial S_{xy}}{\partial x} + \frac{\partial S'_{xy}}{\partial x} + R_{yb} = 0 \qquad (2)$$

in which:

S_{xy} = Excess momentum flux tensor due to wave fluctuations.
S'^{xy} = Excess momentum flux tensor due to turbulent fluctuations.
R^{xy}_{yb} = y-component of the horizontal shear stress on the bottom.

To obtain equation (2) from the momentum conservation law it has also been assumed that viscosity, bottom slope and wave slope were small (Mei, 1983). The coordinate system used is shown in figure 1. The x axis

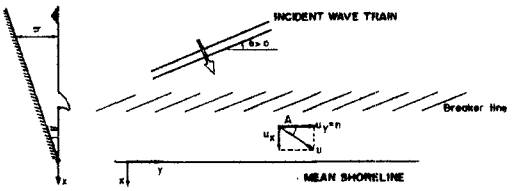

FIGURE 1.- DEFINITION SVETCH OF THE SURF ZONE IN A BEACH WITH LONGSHORE UNIFORM CONDITIONS. FOR A NEGATIVE ANGLE OF WAVE INCIDENCE θ, THE LONGSTORE CURRENT WILL BE ALONG THE NEGATIVE Y-AXIS

is normal to the shoreline and positive shorewards. The y axis is directed alongshore and is positive towards the right. The origin is situated at the mean-level shoreline.

The retarding terms inside the surf zone are, therefore, due to bottom friction and turbulent horizontal mixing (the equations are vertically integrated) with free surface stresses being neglected. It should also be remarked that equation (2) has been time averaged and, therefore, does not consider first order wave induced oscillatory motions with time scales comparable to the wave period.

The lateral mixing retarding term, $\partial S'_{xy}/\partial x$, is usually evaluated by means of the "eddy viscosity" aproximation of Boussinesq, von Schwind (24):

$$\frac{\partial S'_{xy}}{\partial x} = - \frac{\partial}{\partial x} \left(\rho \varepsilon \frac{\partial}{\partial x} (h + \bar{\eta}) V_1 \right) \qquad (3)$$

in which:

ρ = mass-density of sea water.
ε = horizontal eddy viscosity coefficient.
h = water-depth from the still water level.
$\bar{\eta}$ = mean water-level variation due to the waves.
V_1 = longshore component of the current velocity at the surf zone induced by breaking waves.

The resultant equation, (3), is entirely analogous to the ones obtained by Bowen (1969) and Longuet-Higgins (1964).

The radiation stress (associated to the wave induced oscillatory motion), S_{xy}, may be easily expressed as (Longuet-Higgins, 1964):

$$S_{xy} = F_x \frac{\sin\theta}{C} \qquad (4)$$

in which:

θ = angle between wave crests and bottom contours (figure 1).
C = phase speed of the waves.
F_x = energy flux normal to the shoreline, given by

$$F_x = E C_g \cos\theta = (1/8)\rho g H^2 C_g \cos\theta \quad (5)$$

in which:

H = sinusoidal wave-height (when considering irregular waves an equivalent H giving the same energy density, E, must be used).
C_g = group velocity of the waves.

Assuming, as first approximation, that Snell's law is valid throughout the surf zone, the driving term of the momentum equation may be written as:

$$\frac{\partial (S_{xy})}{\partial x} = \frac{\sin\theta_b}{C_b} \frac{\partial F_x}{\partial x} \quad (6)$$

in which b denotes values estimated at the breaker line.

The local average tangential stress (in the y-direction) exerted by the longshore flow in the bottom, R_{yb}, may be expressed by:

$$R_{yb} = \rho C_f < U_{ty} |\vec{Ut}| > \quad (7)$$

in which:

C_f = dimensionless bottom friction coefficient.
$|\vec{Ut}|$ = absolute value of the (total) current velocity vector at the surf zone
U_{ty} = y-component of the velocity vector.
$<>_{ty}$ = time-average operator.

Similar expressions for R_{yb} have been proposed in Liu and Dalrymple (1978) and Kraus and Sasaki (1979). The total velocity vector, $\vec{Ut}$, is composed of a steady part, associated to the current, and an oscillatory part due to the waves.

Using this decomposition and assuming that the oscillatory (wave induced) velocity is large when compared to the steady currents (wave induced or not) it is easy to obtain R_{yb} as, Liu and Dalrymple (1978):

$$R_{yb} = \rho C_f (\gamma/\pi) \sqrt{g(h+\bar{\eta})}\, V_1 (1 + \sin^2\theta) \quad (8)$$

in which:

γ = parameter varying (approximately) between 0.70 and 1.20 as a function of Ir (Battjes, 1974). It may be defined by:

$$\gamma = H_b/h_b$$

This expression, proposed by Liu and Dalrymple for weak currents, coincides with that used by Kraus and Sasaki (1979). It is also a

generalization of the one employed by Longuet-Higgins (1970) in which it was assumed that $\sin\theta << 1$. It seems advisable to retain the more general formulation (8), since, according to published results, significant changes in the final longshore-current value may appear even for moderate angles of wave incidence, θ_b.

The resulting longshore momentum equation is obtained substituting (8), (6) and (3) into (2):

$$\frac{\sin\theta_b}{C_b}\frac{\partial F_x}{\partial x} = -\rho C_f \frac{\gamma}{\pi}\sqrt{g(h+\bar{\eta})}\,V_1(1+\sin^2\theta) + \frac{\partial}{\partial x}\left(\rho\varepsilon\frac{\partial}{\partial x}((h+\bar{\eta})\,V_1)\right) \tag{9}$$

The two retarding terms on the right hand side of the equation are expressed in terms of very poorly known coefficients (C_f and ε respectively) often assumed constant through-out the surf zone. It, therefore, seems adequate to evaluate partial derivatives in an average sense, using a control volume extending from the breaker-to the shore line. With this approach ($\partial F_x/\partial x$), for example, is given by:

$$\frac{\partial F_x}{\partial x} = \frac{\theta - F_{xb}}{x_b} = \frac{F_{xb}}{x_b} \tag{10}$$

in which x_b is the width of the surf zone.

The eddy viscosity coefficient, ε, may be expressed as (Battjes, 1975):

$$\varepsilon = M.h^*\,(D/\rho)^{1/3} \tag{11}$$

in which:

M = dimensionless parameter expected to be of order one. Huntley (1976), obtained values for M in the range 0.3-2.0 for beaches of slope 0.1.

h^*= depth through which the turbulence extends. If $h^* = \delta h$, may be seen that for plunging breakers δ is near one while for other breaker type $0 < \delta < 1$. It is thus, clear that δ depends on $Ir\theta$.

D = mean rate of wave energy dissipation per unit area, given by

$$D = -(\partial F_x/\partial x) \tag{12}$$

Using average (integrated accross the surf zone) values for ε (ε_{ave}) and the bottom tangential stress and evaluating shore-normal gradients with the control volume approach it is easy to write (9) as:

$$-\frac{\sin\theta_b}{C_b}\frac{F_{xb}}{x_b} - 2\rho\varepsilon_{ave}\frac{V_{lb}}{x_b}\tan\beta\frac{6\gamma^2+8}{3\gamma^2+8} - \rho C_f\frac{\gamma}{\pi}(gh_b)^{1/2}\cdot (V_{lb}/\,)\,(1+(3/5)\sin^2\theta_b)) \tag{13}$$

in which:

tang β : bottom slope

$$\varepsilon_{ave} : M h^*_{ave} (F_{xb}/\rho_{xb})^{1/3} \simeq M\delta (h_b/2) (F_{xb}/\rho_{xb})^{1/3} \quad (14)$$

To obtain equation (13) sinusoidal theory (shallow water limit) and Snell's law have been used and $\bar{\eta}$, h and V_1 habe been assumed to vary linearly with x. For planar beaches (h = mx) $\bar{\eta}$ is usually considered to depend linearly on x (e.g. Longuet-Higgins and Stewart, 1964) while the linear profile for V_1 has also been proposed by several authors and seems adequate in this context in which the surf zone is considered as a whole in an average sense.

The available energy density at the breaker line (prior to dissipation) is:

$$E_b = E_{incident} - E_{reflected} = (1/8)\rho g H_b (1-K_r^2) \quad (15)$$

in which:

K_R : reflection coefficient, shown to be a function of Ir by Battjes (1974) for impermeable, rigid slopes.

It should also be remarked that the proposed value for the average bottom friction term coincides with the average tangential stress obtained from Longuet-Higgins formulation when $\sin^2\theta_b << 1$.

The longshore current velocity may be easily calculated from equation (13) which is linear in V_{lb}. Using (14) and (15) it is easy to obtain:

$$V_{lb} = \frac{V^*}{M \phi_M + C_f \phi_C} \quad (16)$$

in which:

V* : reference velocity given by:

$$V^* = \frac{(gH_b)^{1/2}}{4} \frac{\sin\theta_b (\cos\theta_b)^{2/3}}{\tan\beta^{4/3}} \quad (17)$$

ϕ_M : function given by:

$$\phi_M = \frac{8 + 6\gamma^2}{8 + 3\gamma^2} \frac{\delta}{\phi^{5/6}} \frac{1}{(1 + K_R^2)^{2/3}} \quad (18)$$

ϕ_C : function given by:

$$\phi_C = \frac{2}{3\pi} \frac{1 + (3/5)(\sin\theta_b)^2}{(1-K_R^2)(\cos\theta_b)^{1/3} (\tan\beta)^{7/3} \gamma^{1/2}} \quad (19)$$

Considering that γ, δ, K_R and $\tan\beta$ depend on $Ir\theta$ and assuming θ_b to be (numerically) slowly verying it may be written:

$$\phi_M = \phi_m(Ir\theta)$$
$$\phi_C \quad \phi_C(Ir\theta)$$

The structure of expression (16) for V_{lb} is, thus, similar to the formulae proposed by Thornton (1970), Bowen and Inman (1969), Bowen (1969), (1969), Longuet-Higgins (1970) and other authors, cf. Basco (1982). All these equations show a dependence on $(g H_b)^{1/2}$ which is maintained in the proposed model, in which the influence of $Ir\theta$ is clearly shown through V^*, ϕ_M and ϕ_C.

The obtained formulation should then be valid for any type of breakers, provided ϕ_M and ϕ_C as functions of $Ir\theta$, are known. However it would be convenient, from the point of view of calibration and practical applications, to derive a simpler expression. To do it consider that the orders of magnitude in (16) are (after substitution of standard, typical values for K_R, θ_b, γ and δ):

$$\phi_M = O(1)$$

$$\phi_C = O(\tan\beta^{-7/3}) = O(10^2) \quad \text{to} \quad O(10^4)$$

in which $\tan\beta$ has been assumed to be of order $O(10^{-1})$ to $O(10^{-2})$.

Assuming that M is $O(1)$ and C_f is $O(10^{-1})$ to $O(10^{-2})$ the order of magnitude of V_{lb} as given by (16) is:

$$O\left(\frac{V_{lb}}{V^*}\right) = \frac{1}{O(1) + C}$$

with:

$$C = O(C_f \phi_C) = O(1) \text{ to } O(10^3)$$

The samller values of C require large values of β with small values of C_f. This would correspond in Nature to a very steep beach with flat bottom of fine sand and will, therefore, not be found very often.

It seems, thus, reasonable to approximate V_{lb} by:

$$V_{lb} = \frac{V^*}{C_f \phi_{NC}} \tag{20}$$

in which ϕ_{NC} is a new function of $Ir\theta$, numerically similar to ϕ_C, but including the effect of horizontal mixing (i.e., the $M\phi_M$ term). In this final expression for V_{lb} the dependence on turbulent horizontal mixing is included through the $Ir\theta$ parameter which controls ϕ_{NC}. It seems a convenient result due to the difficulty in estimating eddy viscosity coefficients. The aim of the calibration process, developped in next section, will then be to determine ϕ_{NC} as a function of $Ir\theta$.

3.- CALIBRATION WITH FIELD AND LABORATORY DATA

The function ϕ_{NC} must include the lateral mixing effect while remaining of the same order of magnitude as ϕ_C. It may be obtained from equation (19) by retaining only the numerically most significant factors:

$$\phi_{NC} = \frac{1}{A\,(1 + K_R^2)\,(\tan\beta)^{7/3}} \qquad (21)$$

in which:

A : parameter expected to be of order O(1) representing the effect of turbulent mixing.

The final expression for V_{lb} is obtained from (20) and (21):

$$V_{lb} = (A/C_f)\; V^*\; (\tan\beta)^{7/3}\; (1-K_R^2) \qquad (22)$$

Substitution of V* from equation (17) gives:

$$V_{lb} = \frac{A}{C_f}\;\frac{(gH_b)^{1/2}}{4}\;\sin\theta_b\;(\cos\theta_b)^{2/3}\;(1-K_R^2)\;\tan\beta \qquad (23)$$

This formula is entirely analogous to the equivalent expression of Kraus & Sasaki (1979). The weak angular dependence mentioned by these authors (in addition to the factor $\sin\theta_b$) is here estimated as $(\cos\theta_b)^{2/3}$ while their slow variation with the mixing parameter P implies here a slowly varying A coefficient.

The proposed formule is also very similar to Komar's (1975) model. The 2.7 factor in the latter includes the $(A/C_f)\tan\beta$ term of the former, apart from some minor terms of scarce numerical significance ($\gamma^{1/2}$, $\cos\theta_b^{1/3}$, etc.). This implies a nearly constant value of A, in accordance with the results of Kraus et al. (1979), and a slow variation of the ratio $(C_f/\tan\beta)$. This point, also supported by Fleming and Stwart (9), can be explained considering that, for spilling breakers, ocurring on mild slopes with tanβ of order $O(10^{-2})$, the bottom will be rippled or flat with low sediment load and a value of C_f of order $O(10^{-2})$. Plunging breakers, on the other hand, will be move likely found on intermediate slopes ($\tan\beta$ of order $O(10^{-1})$) with and increased sediment load and C_f of order $O(10^{-1})$.

The constancy of the ratio $\tan\beta/C_f$, proposed by Komar (1975), is here reinterpreted as an Ir θ dependence of the C_f coefficient. This can be physically understood considering that the bottom friction coefficient depends on bed material and forms which are closely related to the flow properties in the area. These, in turn, vary with the breaker type and, thus, with Ir θ. Furthermore, when trying to evaluate the ratio $\tan\beta/C_f$ due attention must be paid to the fact than tanβ is distorted in hydraulic models, in which either it is kept artificially fixed (rigid-beds tests) or it is out of scale (mobile-bed tests). This point, together with possible variations of the ratio $\tan\beta/C_f$ for breakers other than spilling and plunging, suggests the convenience of including tanβ in the function of Ir θ

to be calibrated. This function, $X(Ir\theta)$, contains all unknown $Ir\theta$-dependent parameters appearing in equation (23). It may be, thus, written as:

$$X(Ir\theta) = (A/C_f)\ (1 - K_R^2)\ \tan\beta \cos\theta_b \qquad (24)$$

in which the factor $\cos\theta_b$ has been incorporated to reproduce the slope encountered by the obliquely incident waves.

The final expression for V_{lb} is obtained from (23) and (24):

$$V_{lb} = X(Ir\theta)\ ((gH_b)^{1/2})/4)\ \sin\theta_b\ (\cos\theta_b)^{-1/3} \qquad (25)$$

The average (accross the surf zone) longshore current velocity, V_{lave}, can then be estimated from (25) and the assumed linear (weak curvature) V_l profile:

$$V_{l\,ave} = 0.6 \times (Ir\theta)\ ((gH_b)^{1/2})/4)\ \sin\theta_b\ (\cos\theta_b)^{-1/3} \qquad (26)$$

The function $X(Ir\theta)$ has been calibrated with measured (field and laboratory data. It is proportional according to equation (24), to a ratio of lateral mixing to bottom friction effects. The former are related to the parameter A while the latter depend on the C_f coefficient. It is, therefore, reasonable to expect a family of $X(Ir\theta)$ curves varying with a mixing parameter defined here as A/C_f. Figures 2, 3 and 4 show the best-fit curves for laboratory (rigid and mobile-bed) and field data, respectively. These curves estimate $X(Ir\theta)$ from equation (26). The obtained bell shape (to be discussed in next section) is adequately reproduced using a linear times exponential equation, with two degrees of freedom, a, b:

$$X(Ir\theta) = a\,Ir\theta \exp(b\,Ir\theta) \qquad (27)$$

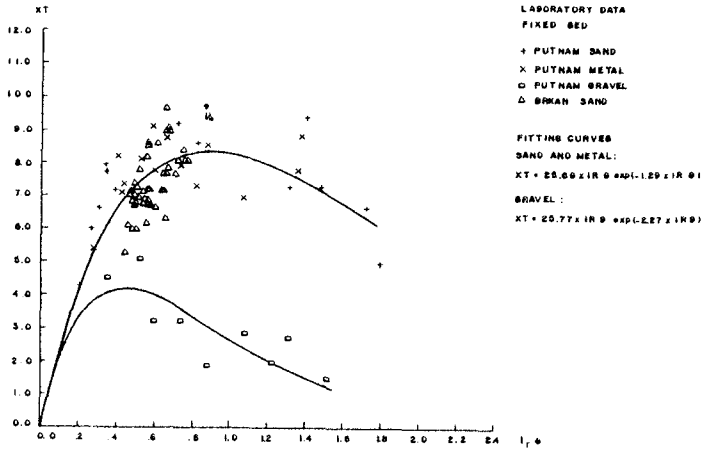

FIGURE 2.- BEST FIT $X(I_r\,\theta)$ CURVE FOR RIGID-BED (LABORATORY) DATA

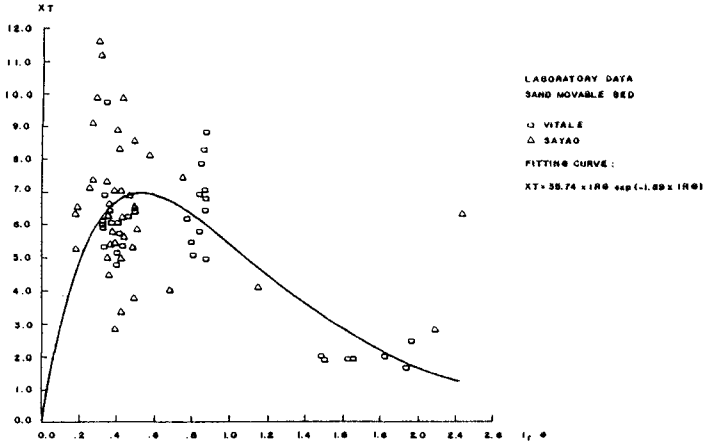

FIGURE 3.- BEST FIT X (I_r θ) CURVE FOR MOBILE - BED (LABORATORY) DATA

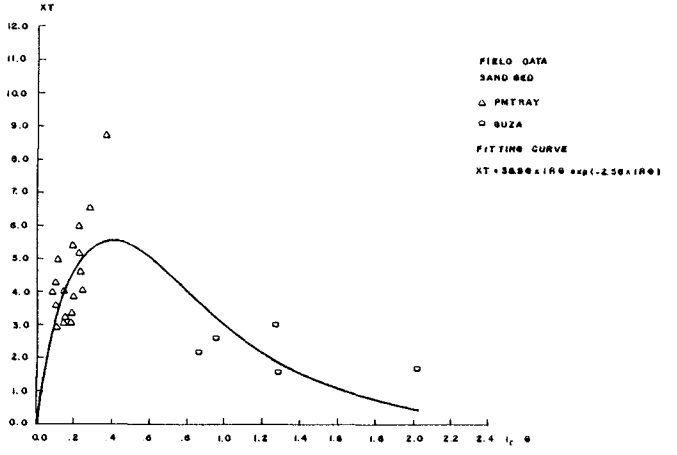

FIGURE 4.- BEST FIT X (I_r θ) CURVE FOR FIELD DATA

Theoretical predictions obtained with this family of $X(Ir\theta)$ curves and equation (26) appear in figures 5a,b and 6 corresponding, respectively, to rigid-bed, mobile-bed and field values. It is important to mention that only average longshore current velocities have been used in the calibration process. The reason was that most of the reported data were explicitely or implicitely defined as mean (accross the surf zone) velocities. Registered maximum values have been, thus, transformed to average velocities using a ratio, based on Longuet-Higgins (1970) profile distribution: $V_{l\,ave}/V_{l\,max}$ = 0.6.

In Vitale's data only tests with measured breaking wave heights have been used. Each velocity was calculated by averaging our sets of data, as presented in the original paper. Slope angle was measured directly from the original figures. The slope in Wu's data was that of the inner surf zone as obtained from the figures in the paper.

4.- DISCUSSION

The satisfactory fit of theoretically predicted values to experimental data illustrated the validity of the obtained expressions and the dependence of the longshore current on the Ir_θ parameter.

The control volume approach used to evaluate partial derivatives is consistent with the state-of-the-art knowdledge available for the C_f and M coefficients. The latter is generally accepted to be poorly known, while values used for the former, though sometimes not explicitely stated, are also rough estimates. Bottom friction in the surf zone is, in fact, a highly complex problem. The slope of the beach changes with wave and flow conditions; bed forms appear due, mainly, to wave action, changing the drag caused by surface roughness and introducing form drag as well as producing energy losses due to secondary currents; wave and current interactions cannot be often neglected which requires the evaluation of C_f for combined waves and currents in fully rough turbulent flow (Grant and Madsen (1979). The problem is further complicated by the sediment motion, because the mixture of water and sediment may not behave as clear water, which makes even more difficult and accurate determination of the boundary layer characteristics in this problem.

The changes in C_f with bed forms and material, sediment load and related parameters (Grant and Madsen, 1979, 1982) together with the uncertainties associated to many experimental values (arising from dificulties of measurement in the surf zone, ambiguous definition of velocities and wave heights, etc.) introduce significant errors in the data. This precludes any accurate fitting process which must, thus, be interpreted in a trend-like sense.

The behaviour of V_1 with Ir_θ may be obtained from equation (23). For high values of Ir_θ (corresponding to surging breakers) the amount of reflected energy increases with Ir_θ. This means that less energy is available to generate a longshore current and, thus, low values of V_1 should be expected for the uppermost range of Ir_θ. The other tail of the $V_1=V_1(Ir_\theta)$ curve corresponds to low values of Ir_θ and spilling breakers. Considering that the driving term is proportional to D (mean rate of wave energy dissipation per unit area) it is easy to understand that for very low values of Ir_θ the amount of energy to be dissipated (proportional to H^2) increases more slowly than the area for dissipation (proportional to the width of the surf zone). This means a slightly decreasing D which, in turn, implies a decreasing V_1 (after taking into account the effect of the retarding terms) for (low) decreasing values of Ir_θ.

The obtained bell slope for $V_e(Ir_\theta)$ applies to both mean and maximum longshore current velocities. The particulars of the curve will depend on bed and flow properties (figure 7). This behaviour also determines the bell-like sharpe of $X(Ir_\theta)$ which may be easily obtained from equation (25) or (26) introducing the known variation of V_1 and H_b with Ir_θ. This same trend for $X(Ir_\theta)$ can also be derived from equation (24) considering (A/C_f) as a mixing parameter with a maximum for spilling/plunging breakers and introducing the expected evolution of K_R and $\tan\beta$ with Ir_θ (figure 8).

The calibration process confirmed these results providing a family of $X(Ir_\theta)$

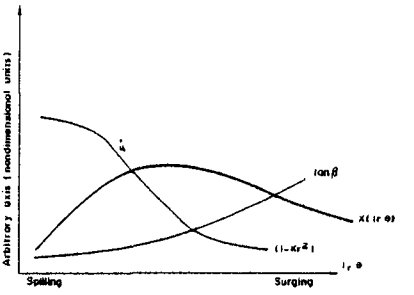

FIGURE 8.- SCHEMATIZATION OF THE EVOLUTION OF $\tan\beta$, $(1-K_R^2)$ AND $X(I_r\theta)$ WITH $I_r\theta$ (FOR DEFINITION OF SYMBOLS SEE TEXT)

curves depending on the mixing parameter, A/C_f. A good fit and low X values should, therefore, be expected for rigid-bed laboratory tests in which scales effects and reduced depths imply an overestimation of C_f and an underestimation of A. The obtained curves also show the increase in C_f (decrease in X) for gravel and coarse sand with respect to fine sand of smooth slopes (figure 2). Mobile-bed tests display larger dispersions due to difficulties associated to the control and adjustment of bed forms and slope for these models. The distorsion due to scale effects and out-of-scale bottom topography should also be considered when assessing the velocity of mobile-bed results (figure 3).

The same trend was found for field data in which the observed deviations of X for the lower range of $Ir\theta$ were attributed to the somewhat erratic behaviour of the A/C_f parameter in this range. This was attributed to the increasing degree of interaction among the various mechanisms acting on longshore current generation in field problems, which multiplied the difficulties associated to the control and estimation of parameters.

5.- CONCLUSIONS

A simple model to predict the longshore current velocity at the breaker line on a beach with oblique wave incidence is presented. From the proposed formulation the following conclusions may be drawn:

1.- The bell shaped dependence of the longshore current velocity on the amount energy dissipated, given by Iribarren's parameter, $Ir\theta$, is shown, even though the usual (spilling breaking) hypothesis, $\gamma = H_b/h_b$, is assumed to hold for all types of breakers. This suggests that $Ir\theta$ so far considered a parameter for definition of breaker characteristics, plays also an important role in longshore current generation.

2.- The structure of the obtained expression for the longshore current velocity is similar to the formulae proposed by other authors but includes (simultaneously) the effects of oblique incidence, bottom

friction, horizontal mixing and type of breakers. The final formula is, however, quite simple and can be reasonably used to predict velocities associated to any type of breakers. More experimental data are nevertheless required for calibration with collapsing and surging breakers.

3.- The $X(Ir_\theta)$ family of curves depend on a mixing parameter defined here by A/C_f. This ratio varies with bottom friction and the existing level of turbulence generated mainly at the free-surface but also including the contribution of the bottom boundary (bed forms, etc.).

This explains the greater dispersion of results obtained in mobile-bed tests and field measurements, corresponding to non-planar beaches. These cases do not fulfill the rather stringent hypotheses used to derive the model which should be, thus, applied with caution to these problems.

4.- The fit of theoretically predicted values to measured data is satisfactory, illustrating the validity of the obtained expressions. In particular, the ratio $\tan\beta/C_f$ appears to be weakly varying with Ir_θ, at least for spilling and plunging breakers. This suggests that C_f partially reflects the degree of turbulent mixing and gives more sense to the A/C_f parameter.

CHAPTER 101

Prediction of Properties of Marine Sand by In-Situ Measurement of Wave Induced Pore Pressure

Yoshihiko MAENO* and Takashi HASEGAWA**

ABSTRACT

The purpose of this paper is to predict the physical and mechanical properties of deposits near the surface of the seabed by in-situ measurements of the wave-induced pore pressure.

First, the wave-induced pressure both at the surface of the seabed and inside the seabed are examined by frequency analysis, to clarify the propagation characteristics of pressure in the seabed.

Secondly, a theoretical equation which gives the relationship between pore pressure fluctuation and wave pressure fluctuation is proposed.

Thirdly, the porosity of the seabed is predicted by the propagating characteristics of the pore pressure within the seabed based on the results of both the model tests by wave tank and the field measurements of the wave-induced pore pressure.

Finally, by fitting the theoretical equation to the spectral ratio of the in-situ measured pore pressure fluctuation to wave pressure fluctuation, the bulk modulus of the seabed and the degree of saturation are predicted.

INTRODUCTION

Wave-induced instabilities near the surface of the seabed, in which the deposit is confined at low pressure, is an interesting theme in coastal engineering. These instabilities are observed in many configurations, e.g., seabed slide, liquefaction of the seabed, moving of soil mass, shore process and so on. To analyze the stability of the seabed based on the theory of effective stress, knowledge of both the properties of the deposit and the wave-induced pore pressure developed in the seabed are needed. Many authors (e.g. Madsen, 1978; Yamamoto, 1977) have investigated the theory of predicting wave-induced pore pressure in a seabed by both theoretical considerations and in-situ measurements. The authors (1985a,1985b) also proposed an empirical equation evaluated by wave steepness to predict the wave induced pore pressure in the seabed. However, it is difficult to clarify the properties of the deposit near the surface of the seabed by element tests because of its low confined condition. Investigation through the in-situ measurement, therefore, is more desirable.

In this study, the physical and mechanical properties of the deposit are investigated by in-situ measurements of the wave-induced

pore pressure. The wave pressure at the seabed surface and the wave-induced pore pressure in the sand layer were measured at Nabae Beach in Wakasa Bay which is in the Sea of Japan off of Fukui Prefecture, Japan. The propagation characteristics of the wave-induced pore pressure were examined by the frequency analysis (Maeno and Hasegawa, 1985c). In particular, the spectral ratio of the measured wave-induced pore pressure fluctuation to the measured wave-induced pressure fluctuation at the seabed surface is noted as a powerful tool in examining the properties of the seabed deposit. Furthermore, the authors propose a theoretical equation which gives the relationship between the wave-induced pore pressure and the wave-induced pressure. The equation, which is a function of frequency, is compared with the spectral ratio. This equation is based on the assumptions that the seabed consists of fully saturated porous media and that the wave-induced pressure fluctuates at a frequency low enough to disregard the effects of viscous fluid.

THEORETICAL CORRELATION BETWEEN WAVE PRESSURE AND PORE PRESSURE

Correlation between Pore Pressure and Volumetric Strain

Many of the first order features in the relation between pore pressure and ground motion can be explained by the theory of elastic wave propagation (Mavko and Harp, 1984). As the saturated porous media consists of both solids and liquids, if it is assumed that the saturated sediments behave as a linear elastic solid and that the frequency of wave excitation is low enough that viscous fluid effects are negligible, the elastic wave-induced pore pressure is predicted to be proportional to the solid volumetric strain by the reciprocity theorem (Jaeger and Cook, 1969) of saturated porous media.

Therefore, the wave-induced pore pressure is related to the volumetric strain of the solid skeleton as given in Equation (1) (Jaeger and Cook, 1969).

$$p = \{ Kf(Ks-Kc)/[n(Ks-Kf)]\} \varepsilon \qquad (1)$$

where p is the pore pressure, is the volumetric strain of the solid skeleton, Ks is the bulk modulus of mineral grains costituting the solid skeleton, Kf is the bulk modulus of fluids, Kc is the bulk modulus of composites and n is the porosity.

Motion of Fluids in Porous Media

Biot(1956a,b) considered the motion of fluids in porous media and classified fluid motion into two mechanisms as follows. One is the motion induced by the relative acceleration between the solid phase and liquid phase; the other is induced by the pressure gradient caused by uneven compaction, and dissipated through the porous media according to Darcy's law. Both of them possess special individual features.

For example, the former is induced by both the compressional wave of the first kind and the shear wave and accelerates the solid skeleton. The force of inertia influences the phase lag between the fluid motion and the solid motion. The latter, called the local squirt

flow, is induced by the greater pressure gradient caused by the friction force between the liquid and the pore face when elastic waves are transmitted through the porous media. This pressure gradient depends on both the shape and the sinuosity of the pores.

Effects of Pore Shape on Fluid Motion

Biot(1956a,b) also considered the effects of the pore shape on frequency, depending on the force of friction. He examined pore shapes for the slit model and the round model. These models are understood by the aspect ratio of the section of pores. This ratio is assumed to be less than unity for the slit model and unity for the round model. These two pore shapes are extreme cases in the two poles. Although the pore shape in sediments is usually in the region between round and slit, it is reasonable to assume that round and slit models can be used to characterize the fluid motion.

Therefore, his elastic wave propagation theory is taken into account as the structure factor consists of both the shape and sinuosity of pores. However, this treatment of pore shape for wave propagation theory does not take into account the local fluid motion but, rather, takes into account the effects of pore shape on the local fluid motion by varying the value of the structure factor.

Biot(1962) also considered the squirt flow in porous media and investigated the effects of the shape and sinuosity of pores on the spectral ratio of the pore pressure to the volumetric strain. For the compressional wave of the first kind, the slit pore shape induces higher pore pressure than the round pore shape. For the first fluid motion, the spectral ratio of pore pressure to the volumetric strain increases with frequency. For the second fluid motion, that is a local squirt flow, the spectral ratio of pore pressure to the volumetric strain decreases for the round shape and increases for the slit shape as the frequency increases.

Correlation between Pore Pressure and Acceleration for Earthquakes

Mavko and Harp(1984) investigated theoretically the correlation between the pore pressure and the acceleration at the surface of the ground by relating both the horizontal and vertical acceleration to the volumetric strain during an S-wave train and a P-wave train respectively. For example, the spectral ratio of the pore pressure to the vertical acceleration at the surface of the ground during a P-wave train is defined in Equation (2).

$$P = \{zKf(Ks-Kc)/[nVp^2(Ks-Kf)]\}\,Ap \qquad (2)$$

where Vp is the velocity of the compressional wave of the first kind, Ap is the vertical component of the acceleration at the surface of the ground and z is the depth under the ground surface.

They analyzed both wave-induced pore pressure and the acceleration recorded during the 1980 Mammoth Lakes, California, earthquake sequence. Also they showed the spectral ratios of the pore pressure to the vertical acceleration and the horizontal acceleration during a P-wave train and an S-wave train, respectively.
During P-wave arrivals, there is a negative linear correlation between

the spectral ratio and the frequency. During S-wave arrivals, there is no linear correlation between the spectral ratio and the frequency. The spectral ratio decreases exponentially with the frequency. Assuming that P-waves consist mainly of the compressional wave of the first kind, since the spectral ratio of pore pressure induced by the compressional wave of the first kind to the vertical acceleration is shown to decrease linearly with the frequency, the pore shape is round and the fluid motion in the pores dominates the second model of fluid motion, that is the local squirt flow.

Theoretical Equation between Pore Pressure and Wave Pressure

The authors considered the spectral ratio which is defined as the ratio of the power spectrum of the wave-induced pore pressure fluctuation within the seabed to the spectrum of the wave-induced pressure fluctuation at the surface of the seabed. The correlation between the wave-induced pore pressure fluctuation within the seabed and the wave pressure fluctuation at the surface of the seabed under the plane strain condition is derived as follows.

The displacements of the seabed under the wave action are evaluated by Biot's elastic wave propagation theory (Yamamoto, 1981). However, the wave-induced motion of the seabed is a slow phenomenon according to Zienkiewicz's(1980) classification of Biot's dynamic and quasi-static formulation, because the seabed is composed of a sand layer and the period of the gravity wave is less than 1.0 Hz. The accelerations of both the solid and liquid phases are negligible for the formulation of this phenomenon. Then this formulation corresponds to formulations by the quasi-static consolidation theory. Therefore, the displacements are derived according to Biot's(1941) consolidation theory (Yamamoto, 1977).

Equations (4) and (5) give the displacements of the seabed (Yamamoto, 1977). The harmonic load is given in Equation (3).

$$T = P_0 \exp[i(Nx+\omega t)] \tag{3}$$

$$U = i\{m[i(1-2\nu)\omega''-1-2(1-\nu)N'']\exp(-Nz)/[-N''+i(1+m)\omega''] - [1-mN''/[-N''+i(1+m)\omega'']]Nz\exp(-Nz)+m\exp(-N'z)/ [-N''+i(1+m)\omega'']\}(P_0/2NG)\exp[i(Nx+\omega t)] \tag{4}$$

$$W = \{[1+m[1+(1-2\nu)(i\omega''-N'')]/[-N''+i(1+m)\omega'']\exp(-Nz) - [1-mN''/[-N''+i(1+m)\omega'']]Nz\exp(-Nz)-m(1+N'')\exp(-N'z)/ [-N''+i(1+m)\omega'']\}(P_0/2NG)\exp[i(Nx+\omega t)] \tag{5}$$

where

$$N'^2 = N^2+i\omega' \tag{6}$$

$$\beta = (1-\nu)/(1-2\nu) \tag{7}$$

$$\omega' = \omega/c \tag{8}$$

$$\omega'' = (\omega'/N^2) \tag{9}$$

$$c = (k/\gamma)/\{n/Kf'+(1-2\nu)/[2G(1-\nu)]\} \tag{10}$$

$$m = nG/[Kf'(1-2\nu)] \tag{11}$$

$$N'' = (N'-N)/N \tag{12}$$

$$1/Kf' = 1/Kf+(1-Sr)/Pa \tag{13}$$

and Kf' is the apparatus bulk modulus of the pore fluid, G is the shear modulus, ν is Poisson's ratio, ω is the angular frequency, k is the permeability, Sr is the degree of saturation, Pa is the absolute pore pressure, and U and W are the displacements in the x- and z-directions respectively.

The dilatational strain is given in Equation (14).

$$\begin{aligned}\varepsilon &= \partial U/\partial x + \partial W/\partial z \\ &= \{-[(1-Nz)(1+m)+m(1-2\nu)](-N''+i\omega'')\exp(-Nz) \\ &\quad +mN''\exp(-N'z)\}P_0\exp[i(Nx+\omega t)]/G[-N''+i(1+m)\omega'']\end{aligned} \tag{14}$$

The term of $P_0\exp[i(Nx+\omega t)]$ in Equation (14) is the harmonic fluctuation of the wave pressure at the surface of the seabed. Thus, Equation (14) shows the relationship between the volumetric strain and the harmonic fluctuation of the wave pressure at the seabed surface. Therefore, the relationship between pore pressure and harmonic fluctuation of the wave pressure at the seabed surface is obtained from Equations (1) and (14).

$$\begin{aligned}P &= Kf(Ks-Kc)\{-[(1-Nz)(1+m)+m(1-2\nu)](-N''+i\omega')\exp(-Nz) \\ &\quad +mN''\exp(-Nz)\}T/\{nG(Ks-Kf)[-N''+i(1+m)\omega'']\}\end{aligned} \tag{15}$$

METHOD OF FIELD EXPERIMENTS

In-situ measurements of wave-induced pore pressure were conducted at Nabae beach in Wakasa Bay, Fukui Prefecture, Japan, because the physical properties of the deposit and the seasonal change of the shore profile have been already measured at this site. Table 1 shows the properties of Nabae sand. Since the uniformity coefficient is 1.53, Nabae sand is fairly uniform. The grain size distribution of Nabae sand is uniform wherever samples are extracted.

Table 1. - Properties of Nabae Sand.

Specific gravity	2.70
Uniformity coefficient	1.53
Effective grain size	0.114 mm
Average grain size	0.160 mm
Permeability	0.023 cm/s

Figure 1 shows the system for measurements. In our preliminary experiments, pressure transducers were placed on the surface of the seabed and buried in the seabed on one straight line. The wave-induced pressure was measured simultaneously at both the surface of the seabed and at two different depths within the seabed. The wave pressure fluctuation was measured at the surface of the seabed, and the pore pressure fluctuation was measured in the seabed. In this

study, the wave-induced pore pressure was measured with a probe as follows. A pressure transducer with porous cap is fixed inside the probe at a point 15 cm from its tip. The probe has a length and diameter of 250.0 cm and 26.0 mm, respectively, and is tipped with a cone with a 30 degree angle. To clarify the properties of the deposit near the surface of the seabed where the confining pressure is fairly low, the wave-induced pore pressure was measured at a depth of 33 cm on August 9, 1985 and at a depth of 37 cm on August 10, 1985, below the mudline.

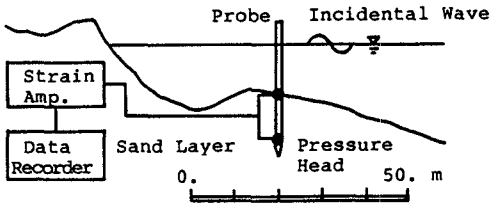

Figure 1. Experimental Set-Up of Field Measurements.

EXPERIMENTAL RESULTS AND DISCUSSIONS

Frequency Analysis of In-Situ Measurement

Figures 2(a) and 2(b) show the fluctuations of the wave-induced pressure at the surface of the seabed and the wave-induced pore pressure within the seabed. It can be seen from these figures that both the wave pressure and the pore pressure fluctuate similarly without any great difference, and that the high frequency component is significantly damped. This fact is made clearer when compared with the power spectrum in Figures 3(a) and 3(b).

The power spectrum decreases as the frequency increases. The conditions for Fourier fast transform(FFT) analysis are as follows: the sampling interval is 0.15 s; the number of sampling points is 1024; the Nyquist number is 3.33 Hz. There are no problems in examining a frequency component below 1.0 Hz.

Figures 4 and 5 show the coherence and the phase between the wave-induced pore pressure fluctuation within the seabed and the wave pressure fluctuation at the surface of the seabed, respectively. Figures 4(a) and 4(b) show that the coherence is unity in the frequency range less than 0.6 Hz and as the frequency increases to over 0.6 Hz the fluctuation increases. This fact suggests that the propagation characteristics of wave-induced pressure vary at a frequency of 0.6 Hz.

Figure 5(a) and 5(b) show that the phase is nearly constant, that is 0.5π in the frequency range less than 0.6 Hz, and as the frequency increases to over 0.6 Hz the fluctuation also increases. Since the phase represents the lag time multiplied by the angular frequency, the lag time between the two fluctuations increases as the frequency decreases. This fact indicates that longer periodic waves propagate easily into the seabed and affect the wave-induced instabilities of the seabed as previously mentioned.

(a) Measured on August 9, 1985. (b) Measured on August 10, 1985.

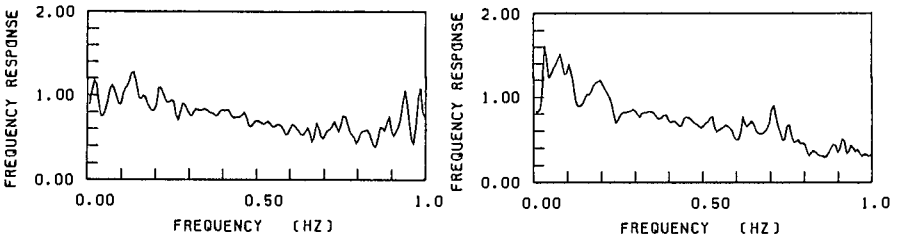
Figure 5. Phase between Wave Pressure and Pore Pressure.

Figure 6(a) and 6(b) show the frequency response. This figure demonstrates that the frequency response decreases linearly as the frequency increases with the greater fluctuation in the frequency range more than 0.6 Hz. This fact indicates that the low frequency component of the wave pressure fluctuation easily propagates into the seabed.



(a) Measured on August 9, 1985. (b) Measured on August 10, 1985.

Figure 6. Frequency Response between Wave Pressure and Pore Pressure.

Prediction of Porosity of Sediments

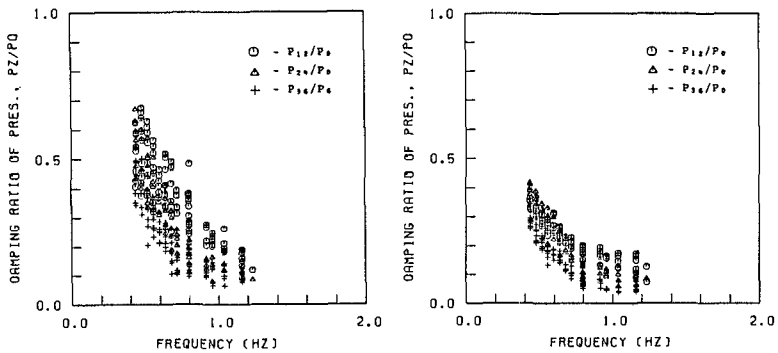
Many difficulties accompany the measurement of the seabed deposits. For example, the density logs used on land have problems in

performing the experiments in submarine, the method using sampling has disturbances of remolding and swelling, and the method using the radioactive log is now being developed to reduce the costs and the difficulty of operation. The simple method of the density log is proposed based on the propagating characteristics of the wave pressure into the seabed.

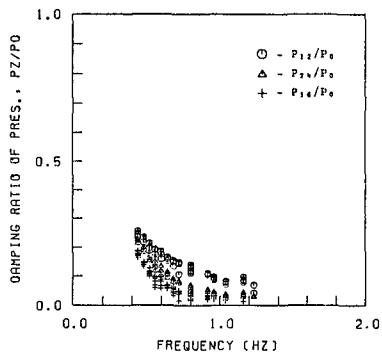
Stoll(1977) indicated that the attenuation of pressure within the seabed is understood by the mechanics both of the intergranular friction in the frame of the soil skeleton and the viscosity of the pore fluid moves in relation to the motion of the soil skeleton.

Since the frequency of the waves is less than 1.0 Hz and the seabed is composed of sand, the intergranular friction is predominant and the damping of the viscosity of pore fluid can be neglected.

The intergranular friction depends on the constitution of the soil skeleton. The density of the sand bed is chosen as the tool to decide this constitution. Therefore, the correlation between the damping and the density of the sand bed enables the prediction of the density of the sand bed.



(a) ρ_d = 1.55 tm^{-3} (b) ρ_d = 1.57 tm^{-3}



(c) ρ_d = 1.62 tm^{-3}

Figure 7. Effect of Frequency on Damping Ratio of Pore Pressure.

Figures 7(a) through 7(c) show the relationship between the frequency of the waves and the damping ratio, which is defined as the ratio of the measured pore pressure to the measured wave pressure at the surface of the bed, based on the results of our previous works (Maeno and Hasegawa, 1985b). In these figures, the subscript of P denotes the depth downward from the bed surface.

These figures show that the damping ratio decreases quadratically as the frequency increases. Since the damping ratio for the tide is infered to be unity, the damping ratio is unity at the frequency zero, and decreases with decreasing velocity as the frequency increases. This tendency is unique for a dense sand bed. However, the linear correlation between the damping ratio and the frequency can be assumed within the region of our experimental results.

Thus, Figure 8 shows the relationship between the gradient of this linear correlation and the density of the sand bed. In this figure, the gradient decreases with decreasing velocity as the density increases. This correlation can be drawn as the monotonous curve. This correlation is examined for the regular wave for various frequencies between 0.6Hz and 2.27Hz generated by the wave tank in laboratory experiments. However, the ocean waves are irregular. The damping of the non-linear waves must be defined. For the irregular waves, assuming that the damping ratio is defined as the spectral ratio of the pore pressure fluctuation within the seabed to the wave pressure fluctuation at the surface of the seabed, the correlation between the damping ratio and the density of the seabed is examined.

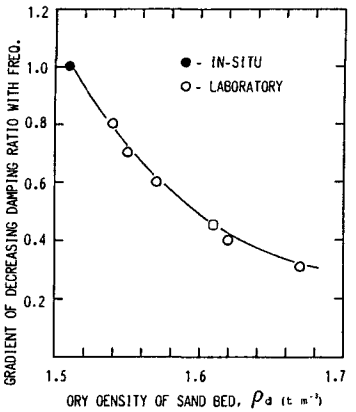


Figure 8. Relationship between Reduction Gradient of Damping Ratio and Dry Density of Sand Bed.

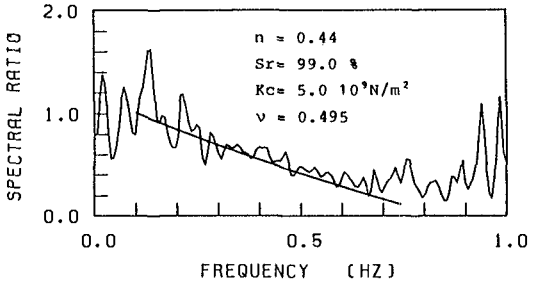
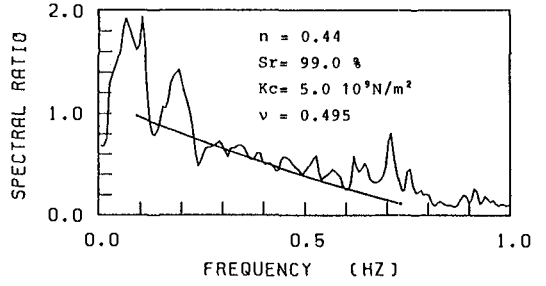
Figures 9(a) and 9(b) show the spectral ratio of the pore pressure to the wave pressure, which were measured at Nabae Beach in Wakasa Bay, Fukui Prefecture. In this figure, the spectral ratio decreases quadratically as the frequency increases. The linear correlation between the spectral ratio and the frequency can be assumed in the region less than 1.0 Hz. In this case, the gradient of this linear correlation is almost unity. The value of this gradient of in-

situ measurements, 1.0 is plotted on the approximate curve in Figure 8. The point determined on this curve indicates the density, 1.51 tm^{-3}. This value is infered to be the density of the seabed deposits.



(a) Measured on August 9, 1985.



(b) Measured on August 10, 1985.

Figure 9. Spectral Ratio between Wave Pressure and Pore Pressure.

Since the specific gravity of this sand is 2.70 as shown in Table 1, the porosity of the seabed deposits is obtained as 0.44. Based on Komura's(1961) study on the relationship between the porosity and the average grain size, the average grain size of Nabae sand, 0.160 mm indicates that the porosity of the bed is infered to be distributed between 0.35 and 0.45. Hamilton(1972) also indicates that the deposits of the mean grain size, 0.160 mm, has a porosity of almost 0.45. The predicted porosity, 0.44 is reasonable, because the seabed near the surface is loosest.

Therefore, assuming that the spectral ratio is equivalent to the damping ratio, the density of the seabed deposits can be obtained based on the experimental correlation between the damping ratio and the density of the bed.

Further field measurements for various sites make the verification of this prediction possible.

Comparison of Theoretical Equation with Spectral Ratio

Figures 9(a) and 9(b) show the spectral ratio of the pore water pressure fluctuation within the sand layer and the wave pressure

fluctuation at the surface of the sand layer. The spectral ratio decreases as the square of the frequency increases, because the frequency response between the pore pressure fluctuation and the wave pressure fluctuation decreases linearly as the frequency increases. The theoretical equation of the correlation between pore pressure and wave pressure is simulated using the parameters in Table 2.

Table 2. - Physical Parameters of Soils Used in Analysis

Bulk modulus of fluid, Kf	2.0 GPa
Bulk modulus of Mineral grains, Ks	36.0 GPa
Bulk modulus of composite, Kc	4.9-5.4 GPa
Poisson's ratio	0.495
Porosity, n	0.44

By fitting the theoretical Equation (15) to the spectral ratio, the properties of the seabed are examined, that is, the bulk modulus of composite, the porosity of the sand bed, the degree of saturation, the shear modulus and Poisson's ratio. The values of the porosity of the sand bed and Poisson's ratio can be assumed experimentally because they vary within a narrow range under the conditions in this investigation. The porosity is predicted to be 0.44 based on the considerations of the damping ratio of pore pressure as described in the previous section. Poisson's ratio of the saturated soil is in the region of 0.49 to 0.50 for the case of the shear modulus less than 1000 $kgfcm^{-2}$ (Ishihara,1970). And Poisson's ratio is predicted by Hamilton's(1979) Equation (16) consisting of the velocities of the compressional wave of the first kind and the shear wave measured in-situ in the seabed. In this case, Poisson's ratio is assumed to be 0.495.

$$\nu = \{(Vp/Vs)^2-2\}/2\{(Vp/Vs)^2-1\} \quad (16)$$

The shear modulus is derived by the bulk modulus of the composite and Poisson's ratio. The bulk modulus of the fluid and solid are assumed to have typical values as shown in Table 2.

Therefore, the values of the bulk modulus of composite and the degree of saturation can be determined by the theoretical equation which fits the spectral ratio.

In the low frequency range of less than 0.5 Hz, the theoretical value estimated by Equation (15) is in good agreement with those of the spectral ratio of in-situ measured wave-induced pore pressure fluctuation to the wave-induced pressure fluctuation at the surface of the seabed.

In this case, it is predicted that the bulk modulus of composite is between 4.9 GPa and 5.0 GPa and that the degree of saturation is between 97% and 99%. These values are compatible with Esrig and Kirby's(1977) results and those of other considerations.

Discussions

Since Nabae sand is a quite uniform marine sand, as shown in Table 1, the aspect ratio of the pore shape is predicted to be approx-

imately unity and the round model is chosen for the pore shape of this sand. Thus, the fluid motion includes the effects of the local squirt flow with the condition of high permeability.

The propagation characteristics of the wave pressure depend on both the compressional wave and the the shear wave based on Biot's consideration of pore shape. As the spectral ratio of the wave-induced pore pressure to the wave-induced pressure is consistent with the theoretical value predicted by the proposed Equation (15), which takes into account the effects of both the dilatational wave and the shear wave, the wave-induced effects are examined not only for the compressional wave but also the shear wave.

Many authors have investigated the mechanical and physical properties of the deposits in the seabed as described above. There are many difficulties in obtaining the properties of the deposits, for example the remolding and swelling of the samples caused by extraction from the seabed. By the in-situ measuring of the pore water pressure fluctuation within the seabed, information concerning seabed mechanics was derived from this study. Examination of the spectral ratio makes it possible to predict the properties of the deposits based on the theory of wave-induced pore pressure in porous media. Moreover, spectral ratio of the wave-induced pore pressure is similar to that of the earthquake induced pore pressure and both the spectral ratios can be related to each other. It is useful, therefore, to predict the propagation characteristics of earthquake induced pore pressure by the spectral ratio of wave-induced pore pressure.

CONCLUSIONS

The following conclusions were obtained :

1. The low frequency component of wave-induced pressure fluctuation propagates into the seabed as wave-induced pore pressure more easily than does the high frequency component.
2. The phase lag between the wave-induced pressure at the seabed surface and the wave-induced pore pressure within the seabed increases as the frequency decreases.
3. The theoretical equation which gives the relationship between pore pressure and wave pressure fluctuations is proposed.
4. The porosity of the seabed deposit is predicted by the damping ratio of pressure inside the seabed.
5. By fitting the theoretical equation to the spectral ratio between the wave-induced pore pressure and the wave-induced pressure at the seabed surface, the bulk modulus of composite and the degree of saturation can be determined. These values are compatible with those of theoretical and empirical considerations.

CHAPTER 102

LABORATORY STUDY ON TWO-DIMENSIONAL BEACH TRANSFORMATION DUE TO IRREGULAR WAVES

Nobuo MIMURA[1], Yukinori OTSUKA[2] and Akira WATANABE[3]

ABSTRACT

In the present study, effects of irregular waves on two-dimensional beach transformation and related phenomena were investigated through a series of laboratory experiments. Attempts were made to determine a representative wave of irregular wave trains which controlled individual phenomenon related to the two-dimensional beach profile change. It was found that the representative wave is different for each phenomenon. For the macroscopic beach profile change, it is the mean wave which represents whole incident waves. On the other hand, some of microscopic phenomena, such as initiation of sand movement and sand ripple formation, are controlled by larger waves in the wave train selectively, of which representative wave is the significant wave.

1. INTRODUCTION

There have been many studies on two-dimensional beach transformation and cross-shore sediment transport in and out of the surf zone. While a number of laboratory studies were performed on this subject, phenomena in real beaches could not be necessarily reproduced in wave flumes. The difference of phenomena in real beaches and laboratories is caused by several factors such as scale effect of physical model, three-dimensional effect of real topographic change, irregularity of real waves, etc. Among them, the effects of wave irregularity on the beach profile change have scarecely examined, since most of laboratory experiments were carried out by regular waves. While there are a few attempts to investigate bar formation and sediment transport rate under irregular waves such as by Tsuchiya and Inada(1974), and Wang and Liang(1975), complete understanding of this subject is beyond us. In order to connect the knowledge accumulated by historical laboratory studies with real phenomena, it is fundamentally important to determine the effects of wave irregularity on two-dimensional beach transformation.

1 Associate Professor, Department of Civil Engineering, Ibaraki University, Hitachi, Ibaraki 316, Japan
2 Kagoshima Prefectural Government, Kagoshima 892, Japan
3 Professor, Department of Civil Engineering, University of Tokyo, Tokyo 113, Japan

In the present study, a series of laboratory experiments were performed under the action of irregular waves. Beach profiles were measured at several time steps of wave action in an experiment. On the basis of these measurements of beach profiles, macroscopic profile change, threshold of sand movement, characteristics of sand ripples and net rate of cross-shore sediment transport were investigated. In order to examine the effects of irregular waves on these phenomena, results of the present study were compared with those from previous investigations of regular waves. While there are several ways to express the characteristics of irregular waves, the concept of representative wave was employed. As the representative wave, significant wave and mean wave were taken. It is a main objective to determine the representative wave for each phenomenon, which plays an almost same role as a train of irregular waves in generating the target phenomenon.

2. EXPERIMENTAL PROCEDURE

Laboratory experiments were performed in a wave flume, 19m long, 1m deep, and 0.8m wide, as shown in Fig. 1. A sandy beach was placed at one end of the flume. Two kinds of well-sorted quartz sand were used as bed materials: one is fine sand (Toyoura sand) with mean diameter, d_{50}, of 0.18mm, and the other coarse sand with d_{50} of 0.75mm. The wave flume was devided into two parts so that two tests with different bed materials could be carried out simultaneously. In order to make it easy to compare the results of the present experiments with those of regular wave studies, tests were limited to a uniform initial beach slopes of 1/10 or 1/20.

The wave generator used can produce irregular waves with any spectrum. In the present study, the Bretschneider-Mitsuyasu spectrum (Bretschneider 1968, Mitsuyasu 1970) was employed for incident waves. The general form of this spectrum, S, is

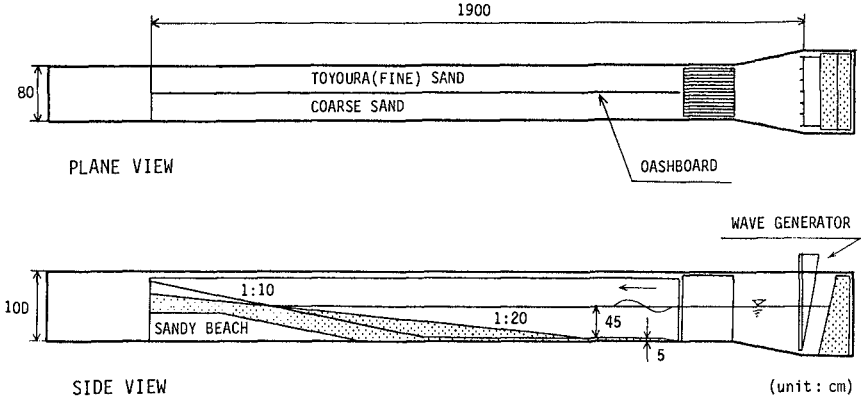

Fig. 1 Wave flume

$$S(f) = 0.257 H_{1/3}^{2} T_{1/3}^{-4} f^{-5} \exp(-1.03(T_{1/3} f^{-4})) \quad (1)$$

where f is frequency, and $H_{1/3}$ and $T_{1/3}$ are significant wave height and period. Keeping the spectrum of incident waves same, significant wave height and period were changed for each experiment. Consequently, twenty four experimental cases were chosen with combinations of two grain sizes, two initial slopes, and several ranges of representative wave height and period. Experimental conditions are summerized in Table 1.

In the course of each experiment, wave motion, sand movement, and beach profile were measured systematically. In order to measure beach profiles continuously and accurately, bottom profilers of electromagnetic type were used. The region coverd by this measurement is from a sufficient high point on the backshore where wave uprush could not reach to the offshore end of the sandy beach. Beach profiles were measured three times in a case, namely just before the start of wave action (0 hour), 3 and 9 hours after it. Net rate of cross-shore sediment transport was calculated from the data of beach profiles in a similar way developed by Watanabe et al.(1980). In the middle of wave action, wave profiles and near-bottom velocities were measured with intervals of 25 or 50 cm along the beach as well as an offshore point. Moreover, states of wave breaking and sediment motion were observed and recorded by using a video-tape recorder.

3. EXPERIMENTAL RESULTS AND DISCUSSIONS

3.1 Macroscopic Beach Profile Change

As the first topic of experimental results, macroscopic beach profile change will be discussed. Figures 2 (a) to (d) show the beach profiles and distributions of the net rate of cross-shore sediment transport for all the cases listed in Table 1. Beach profiles were obtained after 9 hour wave action and the net rate of sediment transport rate was evaluated from the difference of two successive beach profiles measured at 0 and 3 hours after wave action. Positive values of sediment transport rate indicates onshore transport and negative values are for offshore transport. In Figs. 2 (a) to (d), results are ranged as a parameter C increases, which was suggested by Sunamura and Horikawa(1974) for the classification of beach profiles. As the parameter C is closely correlated with the wave steepness, it can be said that the order of the results corresponds to that of wave steepness.

For the regular wave experiments, it has been reported that sandy beach transforms systematically into some equilibrium profile according to the conditions of incident waves. From Figs. 2, it is seen that beach profile shows a systematic change even under the conditions of irregular waves.

In cases of fine sand (Ser.A), beach profiles vary from accreting type to eroding type. Under the conditions of smaller C, therefore smaller wave steepness, berm forms on the foreshore for both cases with

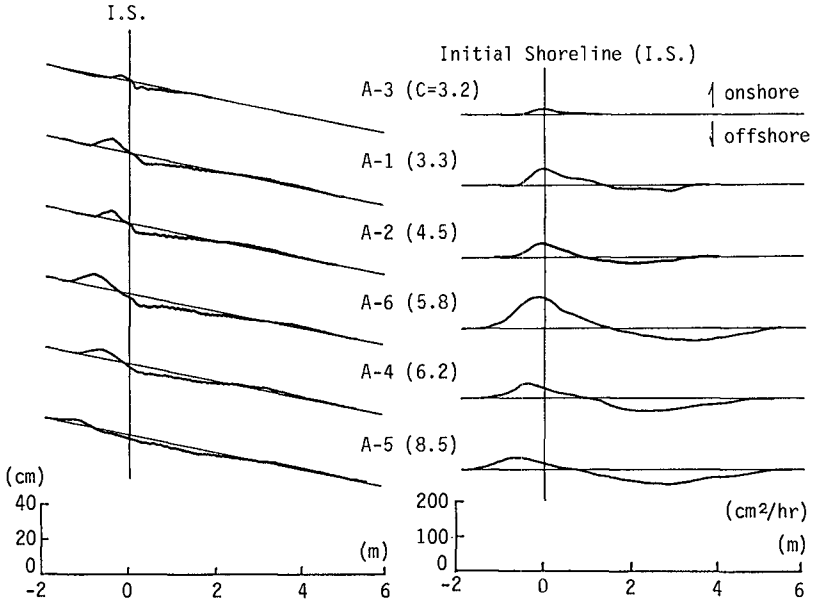

Fig.2 (a) Beach profiles and cross-shore sediment transport rate (initial slope=1/20, d_{50}=0.18mm)

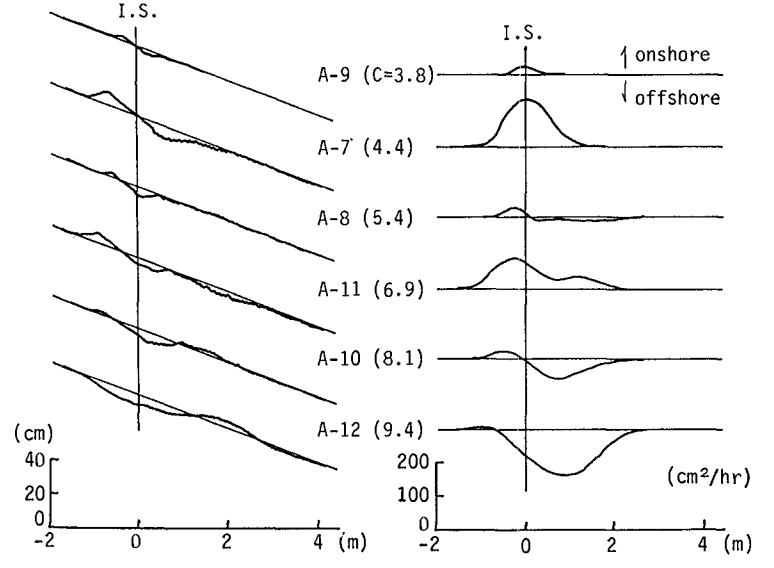

Fig.2 (b) Beach profiles and cross-shore sediment transport rate (initial slope=1/10, d_{50}=0.18mm)

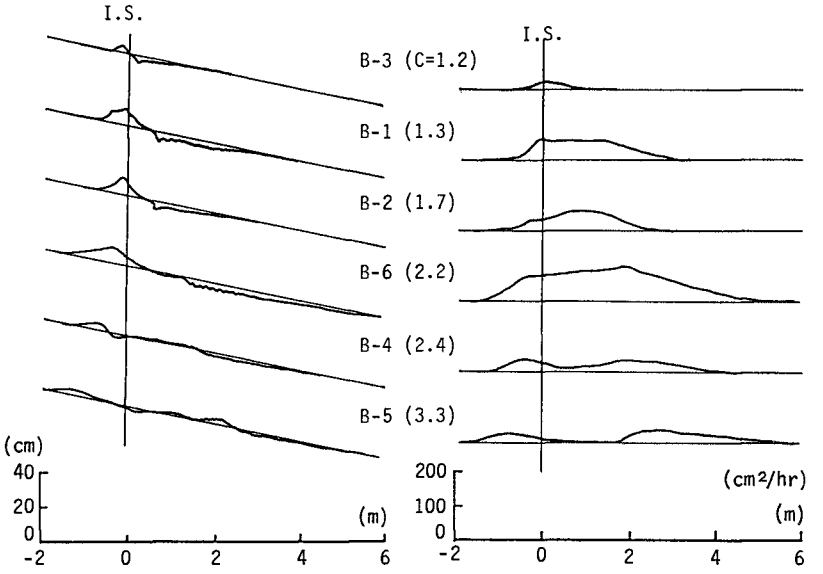

Fig.2 (c) Beach profiles and cross-shore sediment transport rate (initial slope=1/20, d_{50}=0.75mm)

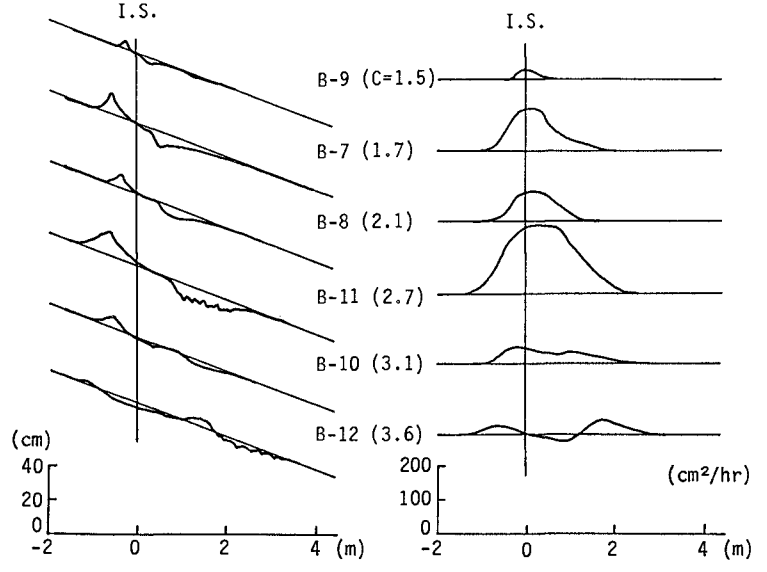

Fig.2 (d) Beach profiles and cross-shore sediment transport rate (initial slope=1/10, d_{50}=0.75mm)

initial slope of 1/10 and 1/20, and the direction of sediment transport is onshore in the whole region. As the value of C increases (wave steepness also increases), erosion of the foreshore begins and a bar becomes noticable. The sediment transport turns offshore. A complete eroding beach formed in Case A-12, of which incident waves were severest among the cases with initial slope of 1/10. In cases of coarse sand (Ser. B), eroding type of beaches did not appear because of the limitation of wave height and steepness. However, it can be seen that beach profiles and distributions of sediment transport rate vary in a systematic manner depending on the value of C.

It was observed that the progress of beach transformation was considerably slow in the present experiments comparing with regular wave cases. This tendency seems to be caused by wave irregularity. Namely, under the incidence of irregular waves, some waves may erode the beach, while other may act toward accretion. Coexistence of waves with conflicting actions yields the slow transformation of beaches. On the other hand, all waves have the same action under the regular wave conditions. Therefore, it should be noted that the beach transformation are accelerated in regular wave experiments.

3.2 Classification of Beach Profiles

It is well known that there are two typical types of natural beaches, that is bar (eroding) and step (accreting) type beaches. Many investigations have been performed to determine parameters classifying beach profiles, such as by Johnson (1949), Iwagaki and Noda (1962),

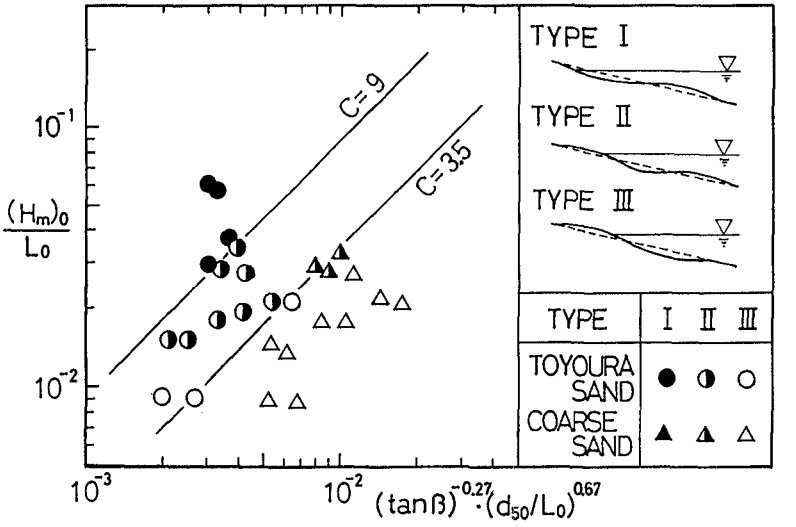

Fig. 3 Classification of beach profiles

Nayak (1970), Dean (1973), Sunamura and Horikawa (1974), and Hattori and Kawamata (1980). In the present study, adaptability of the classification of beach profile suggested by Sunamura and Horikawa is examined.

They classified beach profiles into three types based on the displacement of topography from the initial beach slope: Type I = a shoreline retrogresses and sand accumulates in offshore zone (eroding type), Type II = a shoreline advances and sand piles up offshore (intermediate type), and Type III = a shoreline progresses and no sand deposition takes place offshore (accreting type).

These three types are distinguished by a nondimensional parameter,

$$C = (H_0/L_0)\ (\tan\beta)^{0.27}\ (d/L_0)^{-0.67} \qquad (2)$$

where H_0 and L_0 are deep water wave height and length, $\tan\beta$ is initial beach slope, and d is grain diameter. Horikawa et al.(1975) determined the range of C parameter for each type on the basis of experimental results of regular waves as follows.

Type I: $10 < C$, Type II: $3 < C < 10$, Type III: $C < 3$.

Figure 3 shows the result of application of this classification to the present data given in Figs. 2. Figure 3 also includes the data of additional experiments performed in the same wave flume (Irie et al. 1985). For this application, mean waves were taken as the representative incident wave, that is, the values of ordinate and abcissa of Fig. 3 were calculated based on the wave height and length of the mean wave. It can be seen that this classification is effective for irregular wave cases, and that the mean wave gives considerably close criteria of classification as those for regular waves.

When the significant wave was used as the representative wave, the critical values of C moved from 3.5 to 5 and from 9 to 15 respectively. Therefore, it is concluded that the representative wave for the macroscopic beach profile change is the mean wave. This means that the macroscopic beach profile change is not controlled by a paticular group of waves, but by the whole incident waves.

3.3 Threshold of Sand Movement

As the threshold of sand movement, critical water depth was examined. It was determined based on a measured beach profile for each case, by judging the initiation point for the topographic change of the offshore region. Therefore, the critical water depth in the present study is for the general movement of sand particles, not for the initial movement.

The reference material were taken from the previous study by Horikawa and Watanabe (1967). Their method is certified to correspond with the results of laboratory experiments of regular waves.

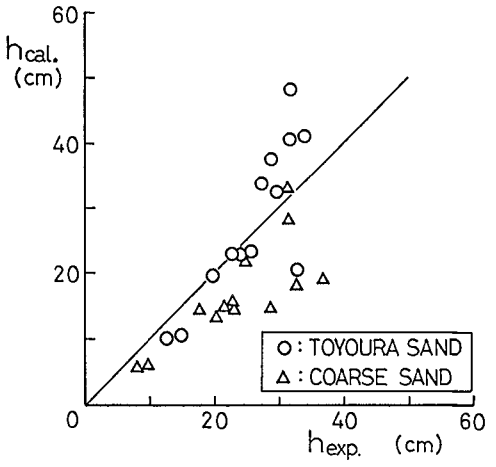

Fig. 4

Comparison of critical water depth between experiments and calculations

Figure 4 shows a comparison of the critical water depths obtained in the present experiments ($h_{exp.}$) and those of calculation by Horikawa and Watanabe's method ($h_{cal.}$). For this calculation, the quantities of significant wave were used. The agreement is considerably good in the region of small water depth, though the measured values tend to scatter as the water depth increases.

On the other hand, the mean wave gave forty percent smaller values of calculated critical depths, resulting in large disagreement with the measured values. Therefore, it is concluded that the representative wave for the threshold of sand movement is the significant wave. This conclusion seems to be as a matter of course, because sand grains cannot feel the influence of small waves in a deep area.

3.4 Characteristics of Sand Ripples

It has been certified that sand ripples play an important role in transporting sediment mainly through regular wave experiments. In the present experiments of irregular waves, sand ripples were observed in all cases of fine sand and a few cases of coarse sand. The most distinguishing feature is that the position and shape of sand ripples were considerably stable in spite that various waves passed over them one after another. Cloud of suspended sediment were often generated above the sand ripples, as seen in the regular wave experiments. It is recognized, therefore, that sand ripples are important for sediment transport also under the action of irregular waves.

In the present study, the initiation of formation and scales of sand ripples are investigated quantitatively. Among many studies on these subjects, the reference materials of regular wave experiments

were taken from the study by Riho et al.(1981).

In the regular wave study, Riho et al. determined the critical conditions of the ripple formation on the basis of two physical quantities: one is the ratio of orbital diameter of water particle at the bottom (d_0) to the median diameter of sand particles (d_{50}),and the other the Shields parameter. The orbital diameter, d_0, was evaluated from the wave profile based on the small ampritude theory. Moreover, in order to take the asymmetry of wave profile into account, they introduced a corrected orbital diameter, d_0', as:

$$d_0' = 4\alpha(1 - \alpha)d_0, \qquad \alpha = \eta_c/H \tag{3}$$

where η_c is amplitude of wave crest and H is wave height. The magnitude of Shields parameter, was calculated from the maximum velocity of water particle at the bottom.

Figure 5 shows the critical conditions of ripple formation. The left-hand side figure is for the significant wave and right-hand side figure is for the mean wave. In these figures, real lines indicate boundaries of ripple formation obtained in the present experiments and dashed lines are those given by Riho et al. for the regular wave experiments. It is seen that the significant wave gives closer values of both boundaries to those for the regular waves.

Figure 6 shows the relationship between the wave length of ripple (λ) and the orbital diameter of water particle (d_0') given by Fig. (3). Again, the left-hand side and right-hand side figures are for irregular wave and regular wave experiments respectively. In these figures, empirical relationships of λ with d_0' are shown: real lines are for irregular waves, and dashed lines are for regular waves. Refering to these figures, it is found that the orbital diameter calculated from the quantities of significant wave gives a considerably close relationship to that for regular waves. On the other hand, the agreement becomes bad, when the mean wave is used for the calculation of d_0'. Consequently, it can be concluded that the representative wave which controls the characteristics of sand ripples is the significant wave.

3.5 Cross-shore Sediment Transport Rate

Watanabe (1981) has proposed a formula for cross-shore sediment transport based on the concept of so-called power model.

$$\Phi = A(\Psi - \Psi_c)\Psi^{\frac{1}{2}} \tag{4}$$

where $\Phi = q/w_0 d$ is dimensionless transport rate, q is net rate of cross-shore sediment transport, w_0 is the settling velocity of sand particle, d is the grain diameter, $\Psi_c$is the critical Shields number for general movement of sands, and A is constant. This formula is based on an assumption that the amount of sand set in motion are considered to be propotional to the excess of Ψ over its critical value, Ψ_c. It was certified that Eq. (4) gives good agreement with the data of regular wave experiments with Toyoura sand, when A is 7 and Ψ_c is 0.11.

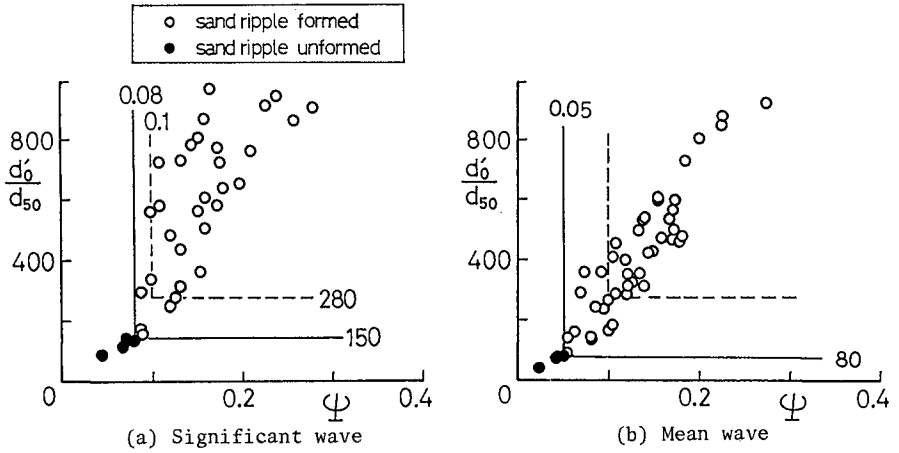

Fig. 5 Critical conditions for sand ripple formation

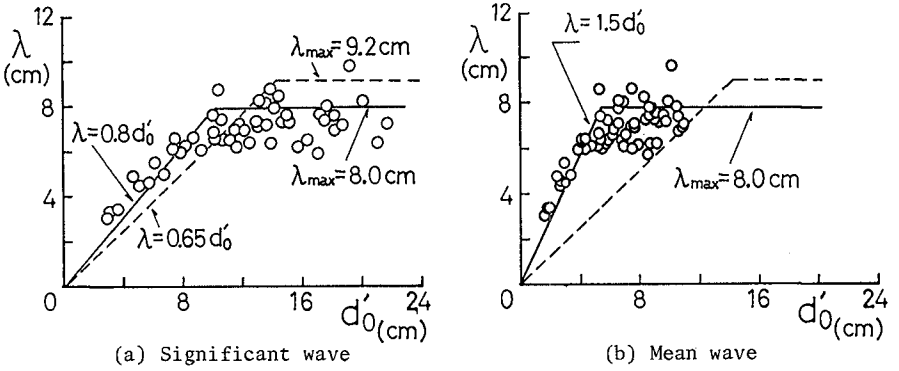

Fig. 6 Relationship between wave length of sand ripples and orbital diameter of water particle

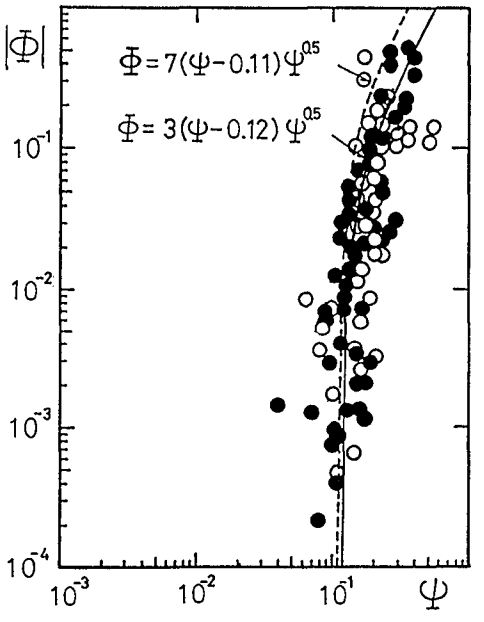

Fig. 7
Net rate of cross-shore sediment transport (Toyoura sand, d_{50} = 0.18mm)

Figure 7 shows the relationship between the non-dimensional sediment transport rate and the Shields parameter for the cases of fine (Toyoura) sand in the present experiments. In the figure, open and closed symbols indicate onshore and offshore transport respectively.

Experimental data do not so scatter, showing the same tendency as seen for regular wave experiments: namely, the value of Φ increases rapidly with the Ψ value while the latter is small, but its increase rate gradually diminishes as Ψ increases. It is very interesting that the Shields parameter is effective in expressing the sediment transport rate even under the irregular wave conditions. Eq. (4) again gives a good expression for the experimental data. However, the magnitude of the coefficient A seems to be somewhat smaller for irregular wave cases than for regular wave ones. This may indicate that the efficiency of wave power to set sand grains in motion reduces under the irregular wave conditions. This tendency corresponds to the slow speed of the beach transformation as mentioned before.

As for the representative wave, two of them gave very similar results. Therefore, the representative wave could not be specified for the sediment transport rate.

4. CONCLUSIONS

Through the present study, the effects of irregular waves on two-dimensional beach transformation were investigated. The examined subjects are macroscopic beach profile change and its classification, threshold of sand movement, characteristics of sand ripples and cross-shore sediment transport rate. The representative wave for each phenomenon were determined by comparing the results of the present experiments of irregular waves with those from regular wave studies. It is very interesting that there are two kinds of phenomena related to the two-dimensional beach transformation, which are controlled by whole incident waves or a group of large waves in a irregular wave train. These understandings are the important step to obtain a general view of beach transformation in real coasts.

CHAPTER 103

Coastal engineering studies for inshore mining of diamonds at Oranjemund

J P Möller*, K C Owen** and D H Swart*

ABSTRACT

This paper describes a diamond mining operation on the west coast of Africa in Namibia (South West Africa, see Figures 1a and 1b), where a sea-wall of normal beach sand has been built out to a distance of more than 300 m seawards of the original coastline. The wall which runs alongshore is maintained in the high energy environment, which is characterized by northbound longshore transport rates, by means of artificial suppletion at a rate of up to and more than 300 000 m^3/ month. Before embarking on the project the company had to be assured of the sand on the sand-wall; to allow completion of the project free of severe damage by wave action. This implied being able to predict the erosion rate of the sea-wall by the waves. The data set used consisted of wave measurements by Waverider and wave observations obtained from voluntary observing ships; aerial photographs at monthly intervals of the waterline in the study area; and soundings of the beach, sea-wall and nearshore topography by using a helicopter as a platform. Various methods of prediction and projection were used to quantify sediment movement

1. BACKGROUND

The diamonds have been deposited in a number of beaches on a narrow wave cut bedrock shelf. This series of beaches, itself formed by alternating transgressions and regressions of the sea, is covered by varying depths (up to 20 m) of marine sand overburden. The diamond deposits are continuous seawards and this paper addresses particularly the coastal engineering aspects of the mining methods used in this area adjoining the sea. In the 1970's various types of beach protection against wave attack were used to make mining of the beach area in the dry possible. These included interlocking concrete blocks and sheet-piles. Due to economic constraints and the requirement only being for temporary protection attention turned to using the sand overburden, which has to be excavated and dumped to expose the diamond gravels, to build the sea-wall. This structure has a crest width of 25 m, about 10 m above MSL and is progressively developed seawards.

* Sediment Dynamics Division, Coastal Engineering and Hydraulics, National Research Institute for Oceanology, CSIR, P.O. Box 320, Stellenbosch, 7600, Republic of South Africa.

** Assistant General Manager, Consolidated Diamond Mines (Pty) Ltd, P.O. Box 35, Oranjemund, 9000, Namibia.

The mining sequence becomes rather critical in as far as it relates to the distance over which excavated material is to be transported, this being one of the major expense items in the project. This implies that the area to be excavated and the length of sea-wall to be constructed or maintained should always be in close proximity.

The increase in beach slope causes increased offshore losses of material and the stability and construction of such a structure require close monitoring to ensure the safety of personnel and equipment and to make such a capital-intensive undertaking economical. An extensive monitoring programme which includes inshore bathymetric surveys, aerial photography, the analysis of sea-wall volumes and regular site visits by personnel and consultants was incorporated at an early stage.

At present the mine is at its maximum planned offshore limit and the mining programme is now even more strictly governed by the effect of the harsh littoral processes in the area. The regular monitoring of progress and changes in the nearshore coastal area ensures that the project proceeds optimally.

2. OVERVIEW OF AVAILABLE DATA

Wave Data

Oranjemund lies on a desolate part of the coast far from any major harbours and wave data from the area, before the project was started, were rather sparse. A Waverider station was set up in 1978 in 17 m of water depth to gather information for the design of a piled jetty in the surf zone in the mining area. In 1981 the station was moved to a water depth of 106 m and the CSIR has analysed the data from this station by standard methods.

As the Waverider does not record wave direction use had to be made of available Voluntary Observing Ship's (VOS) records that were collected between 1960 and 1979. Figure 1a shows the $1^{\circ} \times 1^{\circ}$ squares in which the VOS data available along the Southern African coast were grouped for the analysis. In Swart and Serdyn (1981) annual, seasonal and monthly analyses are shown for height, period and direction combinations. It was also possible to collect raw VOS data during the project by utilizing Cape Town based coasters that operated on the west coast.

The aim was to use Waverider and VOS data collected during a specific period and correlate these with the beach behaviour during the corresponding period.

Figure 2 contains a wave-height exceedance curve for the 106 m Waverider station at Oranjemund. It can be seen that the wave climate is fairly severe, with a once/year significant wave height of 5,6 m. Figures 3 and 4 show the wave height and period histograms for all data. On the basis of the VOS wave data a swell rose was compiled, as shown in Figure 5. The swell waves exhibit a strong south-easterly tendency, whereas the local wind field is more predominantly south-east (see Figure 6), which is alongshore.

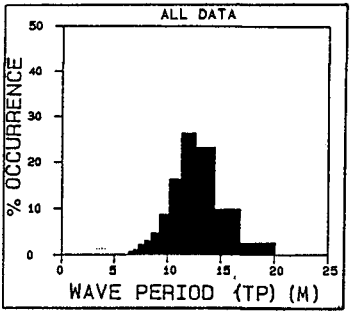

Fig.4

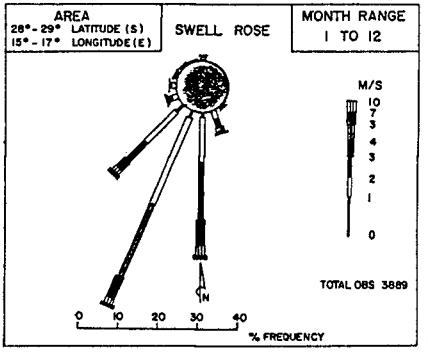

Fig.5

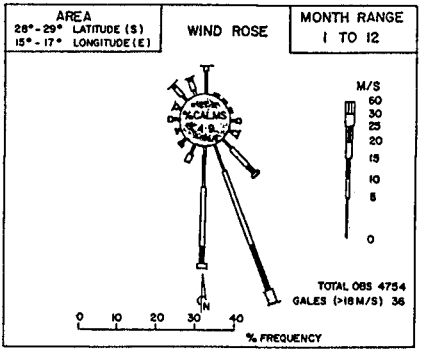

Fig.6

Surveys

The highly dynamic littoral zone along the mining area requires close topographical monitoring, especially in front of the sea-wall where substantial offshore losses could occur during stormy events.

A helicopter is used for the surveying, which is done with a lead-line and 3 theodolites. Beach and nearshore surveys have been carried out routinely at 3-monthly intervals for 10 years. Each survey, which includes a set of 7 lines for which records are available since the beginning of the project, consists of 23 lines that extend from the top of the sea-wall to ± 15 m below MSL.

Profiles, contour maps (Figure 7a) and difference maps (Figure 7b), which relate each survey to the preceding survey, are drawn for each survey. The difference maps clearly show areas of erosion or accretion between surveys which is of great help when trends in the coastal processes are to be studied.

Aerial Photography

Aerial photo mosaics are taken monthly and display beach form characteristics and operational features of importance to the design. The photography is done from a helicopter and a set of ground beacons is used for proper alignment while the camera is horizontal. This allows fairly accurate measurements to be made on the mosaics. Figure 8 shows, for example, the northward advance of the leading edge of the sea-wall in time.

Sand Samples

For the calculation of on/offshore and longshore transport capacities knowledge of the grain size distribution of the beach material is required. Initial sampling along the coastline over 35 km during 1979 indicated that the median grain size decreases towards the north. The median grain size typically varied from about 600 microns at the Orange River in the south to 350 microns 35 km north of the Orange River (see Figure 9). This has been verified by subsequent annual re-sampling.

Artificially Dumped Volumes

Up to 5 million cubic metres of overburden are excavated annually for sea-wall construction and maintenance. Diesel-driven dozers and scrapers are used for this work. It is essential that the schedule at which material is required for the construction and maintenance of the sea-wall matches the scheduled programme for overburden stripping. Figure 10 gives as an example the dumped volume during a 19-month period in 1985/86. During this period the average monthly dump rate was 300 000 m^3, which amounts to nearly 3 times the average northbound drift rate.

It is specifically relevant that due cognizance be taken of the fact that the natural net longshore transport capacity in the area is about 1,3 million cubic metres per year towards the north (see Chapter 3 below). The mining procedure is therefore directed to benefit

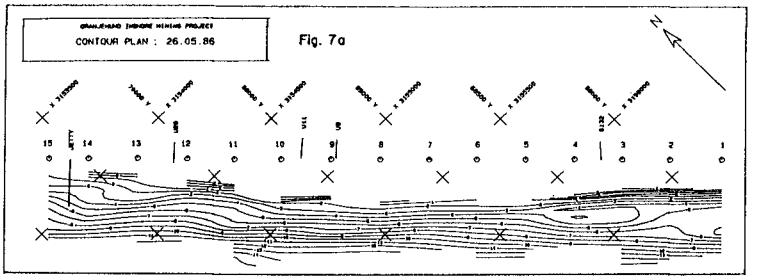

Fig. 7a

maximally from this natural mechanism of moving material.

3. INTERPRETATION OF PHYSICAL PROCESSES OPERATIVE IN THE COASTAL AREA

In order to assess the behaviour of a sea-wall such as that shown schematically in Figures 11, 12 and 1b, it is necessary to quantify the littoral processes in three different areas, namely,

- the area to the south of the sea-wall proper, which will be shown below to be the updrift area;
- the area in front of the sea-wall proper, and
- the area to the north (downdrift) of the sea-wall proper.

Updrift Area

The available wave data for the area clearly show a strong predominance of waves with a high angle of incidence from the south-southwesterly sector. As a result the littoral drift in the area is predominantly northbound. Swart in CSIR (1979) found on the basis of predictions with the SPM littoral drift predictor (SPM, 1973) that the gross longshore transport in the area is about 1,9 million cubic metres per year, with a net of 1,3 million cubic metres per year northbound. These extremely high values, which are the result of the high angles of incidence referred to above, have been verified by comparison with the rate of updrift infill at the first sea-wall, which was constructed in 1971. Figure 13 shows this verification in the form of a comparison between actual shoreline changes and the shoreline changes predicted with the assumption of a littoral drift rate as given above.

Figure 13 indicates that up to 50 per cent of the littoral drift arriving from the south bypasses into the area in front of the sea-wall proper. Obviously the magnitude (percentage) of the bypassed quantity depends on the degree of build-out of the sea-wall relative to the original waterline and the degree of change in the coastline orientation.

Area Seawards of Sea-wall

Prior to the initiation of inshore mining the sea-bed in the sea-wall area was characterized by a typically concave beach profile which shelved out at 6 m below mean sea level (MSL). The 6 m contour typically was situated about 300 to 400 m seawards of the mean waterline. Swart in CSIR (1979) showed that the plateau referred to here can be physically explained as the lower limit of the active profile development in the area where combined bed-load and suspended load takes place (Swart, 1974). Between the 6 m and 16 m contours the underwater slope was relatively steep at 1 in 30.

The foregoing means that any plans to build out a sea-wall into the nearshore area would be bounded on the seaward side by the sharp change in profile. In practice this meant that the maximum distance over which the mean water line could be shifted seawards was of the order of 200 to 300 m, just by considering the geometry of typical beach profiles found in the area. Obviously this would only be possible if artificial nourishment were to be added at the top of the profile to compensate for additional wave-driven seaward losses due to the

steepening of the beach profile. The studies described in this paper were aimed largely at quantifying these processes and determining practical limits for the beach build-out.

Figures 14 and 15 show examples of hydrographic profiles taken over a 4-year period across the beach in front of the sea-wall. Figure 14 was taken in the southern section of the sea-wall while it was still being built out to its maximum protrusion. Figure 15 depicts profiles in the area of maximum protrusion. The dramatic recent build-up of 180 m can be seen clearly. Prior to 1982 about 10 m of build-up had already taken place in this area, making the total build-up of the order of 300 m. As a reference Figure 16 contains beach profiles about 8 km north (downdrift) of any inshore mining activities. Reference to Figure 12 shows schematically how the sand balance is made up.

Downdrift Area

In the classical case of an obstruction to longshore drift one would expect downdrift erosion. However, in the case of the sea-wall, the processes operative in the area are completely different and merits special discussion. As a result of the artificial nourishment in the area of the sea-wall proper the magnitude of the northbound longshore drift is increased sharply in relation to the initial pre-sea-wall condition. Swart showed in CSIR (1979) that the extent of the increase in the longshore transport rate is a function of the degree of build-out from the original waterline, which is logical. For an offshore build-out of 200 m relative to the already partially built-out shoreline he predicted an increase in the amount of longshore transport of 250 per cent, which sounds very high.

Because the longshore drift potential returns to normal towards the north, as the effects of the inshore mining activities become less, it means that the excess material arriving from the sea-wall area in the south will deposit, thereby creating an area of substantial accretion to the north (downdrift) of the sea-wall proper. Figure 17 contains an example of the seaward growth in the shoreline during 1977 to 1982 at a location about 3 to 5 km to the north of the sea-wall position at that time. Simulations of downdrift shoreline change, performed with the one-line shoreline model of Pelnard-Considère (1954), modified to include longshore variations in wave height and beach profile and location, verified the longshore transport increase by 250 per cent, which was quoted above.

The sedimentation to the north of the sea-wall proper takes place in the form of a low washover fan at the level of a maximum wave run-up, which typically is about 2 to 4 m above MSL. One of the main outcomes of the study reported in this paper was to optimize the northward sea-wall advance such that the sedimentation to the north of the sea-wall can be used to maximum benefit as a platform for the building out of the sea-wall in that area.

4. MINING SEQUENCE AS RELATED TO COASTAL PROCESSES

On the basis of a detailed modelling of the physical coastal processes in the area, it was possible to optimize various aspects related

to the sea-wall (CSIR, 1983).

Mathematical models based on the onshore-offshore model developed by Swart (1974), the shoreline evolution theory of Pelnard-Considère (1954) and topographical changes have been and are still being used to predict the littoral response. The model on topographical changes referred to is similar to that developed by Perlin and Dean (1983) but it uses the Swart (1974) method for the prediction of onshore-offshore transport, which is well tried. The wealth of survey data allows for the easy calibration of the above-mentioned mathematical models and also supplies a unique data set showing how very steep and very much flatter beach profiles in close proximity react to the same incident waves.

Calculations were made to determine the extent of maintenance feeding which would be required for different sea-wall offset distances from the original shore. It was concluded that it would be possible to maintain a sea-wall in a position more than 300 m seawards of the original shoreline.

Typical components of a mining sequence strategy developed on the basis of the research are the following:

- the sea-wall should be actively maintained over a 600 m length, which is advanced northwards at 800 m per year;

- the volume of material required annually for sea-wall building and maintenance was theoretically predicted to have a minimum value of 2,7 million cubic metres, which contains 2 million for sea-wall building alone. The maximum predicted sea-wall maintenance is much higher than the minimum value of 0,7 million cubic metres and could be as high as 3 million cubic metres, making the total volume required 5 million cubic metres per year. Actual dumped figures to date fall within these bracketing values.

- The sea-wall is particularly vulnerable during spring high-tide and arrangements must be made to cope with an increased maintenance load during periods of spring tide.

5. SUMMARY AND CONCLUSIONS

In summary, it can be stated that a sea-wall which is maintained at Oranjemund at a distance of more than 300 m seawards of the original waterline, causes updrift accretion of between 50 and 100 per cent of the strong, net littoral drift of about 1,3 million cubic metres per year, which arrives from the south. In front of the sea-wall a beach profile steeper than the initial one is maintained by artificial nourishment. As a result the longshore drift rate in this area is increased more than twofold by the increased suspended load in the water column. To the north (downdrift) of the sea-wall proper the reduction of the drift rate back to normal leads to an area of sedimentation advancing northwards with the sea-wall.

On the basis of the understanding of the processes involved and the mathematical modelling of these processes an optimum mining strate-

gy was developed.

Apart from recommendations regarding the broad strategy for inshore mining, this ongoing study has regularly supplied inputs on the basis of the gathered data and model results which allowed an essentially non-marine project team to optimize their activities to cope with changes in the littoral environment.

In addition, the project can serve as a one-to-one scale beachfill test and could prove extremely useful to evaluate techniques for the design of beachfills.

CHAPTER 104

An Automated Measuring System to Registrate and Balance Suspended Sediment and Associated Parameters

Lothar J.R.Neumann *

The automated measuring system Oortkaten (AMO) was established in order to determine the balance of suspended sediment and associated parameters. Morphological and velocity weighted averaged samples are taken using the newly developed MOSTRA-Method. This results in a cross-sectional average value.

Introduction

Suspended sediments in rivers and estuaries are a nature phenomenen, but since one knows that this suspension is the carrier of heavy metals and other aggressive material, the answer to the question of its origin and behaviour becomes more and more important. In the beginning, measurements of suspended material and the estimation of transport rates were conducted by single measurements or by monitoring a river-section for a few days. Today we know that this kind of measuring cannot yield the results we need to estimate loads of suspended matter over long periods or even offers insights into the relations between suspended matter and associated parameters, such as temperature, oxygen, river discharge or current velocity.

The main problems for measurements in navigable waterways and the interpretation of data, in the past and even nowadays, are aggreviated by interuptions of passing ships, high costs for staff and material, especially for ship capacities, a lack of data to interpolate between single measurements and last not least inhomogeneities for example in the current velocity profiles or in other distributions in the river-cross-section.

In line with a KFKI-Projekt** permanent measurements of suspended matter should make it possible, to compute transport rates through a cross-section of an estuary. At the same time parallel measurements of associated parameters should answer the question as to their influence on changes in the suspended matter concentration data. Because no instrumentation was available to perform this tasks, an own system was developed, the Automated Measurement Station

** KFKI -Coastal Engineering Board of West-Germany

Oortkaten (AMO). Figure 1 shows the station during ebb.

Figure 1. Automated Measurement Station Oortkaten (AMO)

Location and Boundary Conditions

The operation position of the measurement device AMO is in the river ELBE near the village Oortkaten at streamkilometer 607.5. This location is on the West-German part of the river shortly before the splitt of the river into two river arms with the most important West-German harbour, The Hamburg Harbour, in between. (Figure 2). Here the river has a width of 525 m and a maximal depth of about 10 m.

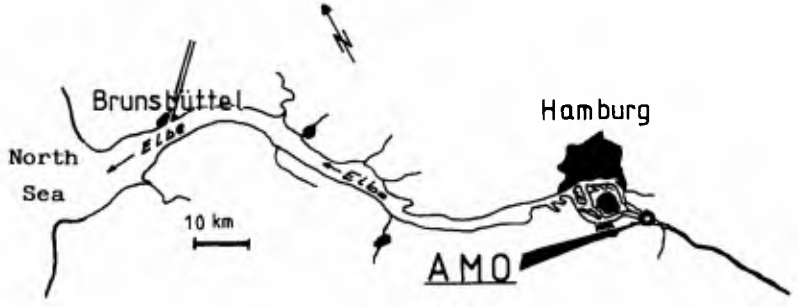

Figure 2. Location of the AMO.

The boundary conditions are important by using automatically working systems. For the location of the AMO the boundary condition are the following ones :

The M 2-tide is dominant, but the tide is influenced by the river-discharge. This leads to a mean duration of ebb for eight hours and four hours for flood. The mean tidal range is 3 m. The ebb current velocity in on an average of 0.9 m/sec with extrem values of 1.5 m/sec. During flood these values are 0.4 and 0.9 m/sec. The mean annual value for the river discharge is 700 m^3/sec, but in times of high water, values up to 3900 m^3/sec were measured. The water temperature is 0 to 25 degree Celsius, depending on the season, and normally there is ice on the river from January until the end of February. The concentration of oxygen varies from 5 - 11 g/m^3 and the suspended sediment concentration range is 15 - 35 g/m^3 with a part of ignition loss, which is with 35 %(+/-5 %) a very constant value.

Measurement Method

Besides waterlevel, current velocity and current direction, concentration of oxygen, pH-value, conductivity, optical attenuation and temperature, the system computes the discharge through the cross-section of the estuary. Watersamples are taken and analyzed seperately in a laboratory on suspended sediment concentration, grainsize distribution and ignition loss. These parameters respectively samples, are measured or collected by a new method called MOSTRA which stands for morphological and current velocity adequated measurement method.

By this method the measuring data of the parameter respectivly the samples are related to the water volume that passes through those parts of the river-cross-section, for which the measurement should be representative (Figure 3).

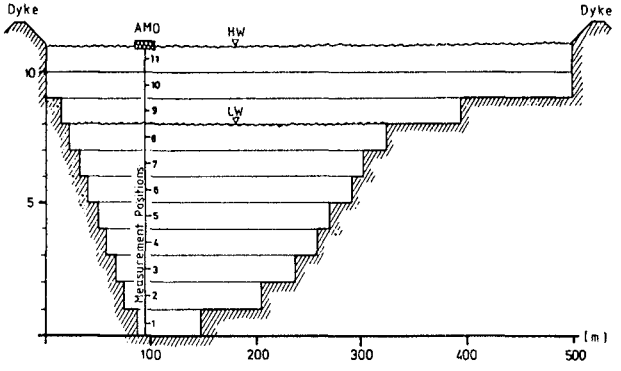

Figure 3. Schematical cross-section of an estuary.

The smaller the cross-section-part, for which the measurement should be representative, the better the dataone measure. If the distributions of the hydrographical parameters in the cross-section are very heterogenous, than it is necessary to measure in more than one profile. In any case representative measurements are necessary. These controls have to be conducted as often as possible with multi-point-measurements.

The knowledge of the cross-section-plane as a function of the water depth, as well as the current velocity for each single measurement position, are necessary requirements for the computation of the measured data. The function for the schematic cross-section (Fig.3) is shown in Figure 4.

For each single measurement position the measured data of the parameters are weighted by the relevant cross-section-plane (Fig.3) and the current velocity. In this way the measured data are related to the water volume, that passes through the relevant river-cross-section part during the measurement.

After having completed measurements at all positions of the profile, the data for each parameter are added and computed to mean values. The result are averaged data vertically integrated and related to the actually transported water volume.

The taking of samples must be related to the cross-section-plane only, because the sampling, depending on the current velocity -so called isokinetic sampling of water- is carried out by a system unit itself. The taking of samples according to the measurements of parameters is being achieved at every measurement position of the profile by the duration of the sample time (Fig.5). Figure 5 shows the extrem differences to an unweighted kind of taking water samples. The greater the gradient of a parameter in the vertical profile, the greater are the differences between the results of the different measurement methods. The complete mathematical background of this method is published by NEUMANN (1985).

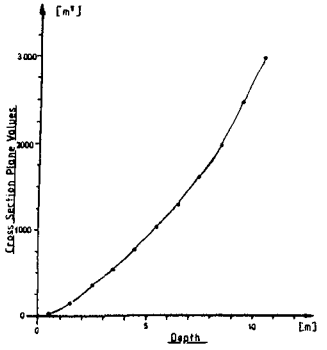

Figure 4. Cross-section-plane, function of waterdepth.

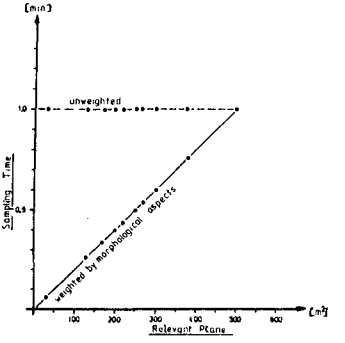

Figure 5. Sample time as a function of the relevant plane

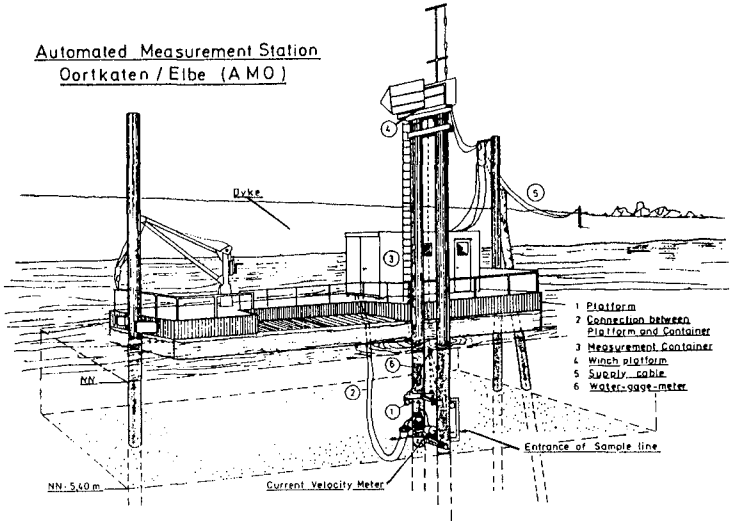

Figure 6. Principle view of the AMO.

Technical System

The Automated Measurement Station Oortkaten consists of several units (Fig.6). The sampling unit is placed on a platform, which is held between two piles and moves, operated by a winch up and down between surface and ground. From here a supply cable and two tubes cimbine the sampling unit through a pontoon with a container. This connection has a length of 18 m. Inside the container all other system are integrated. These are the units to store the samples, measure the parameters and a process-computer-system for operation control and data processing. The 20-feet-container is linked to the shore, which is 50 m away by supply cable for fresh water, electricity and telefon.

The sampling unit on the platform was developed to take the samples isokinetically, measure the current velocity and current direction. The entrances of the sample tube are fixed in the main directions of the river currents. This ensures the position of the AMO, where only alternating current directions occur. For measurements in regions with unsteady directions, a self-directing platform construction is necessary.

To reach the same current velocity at the entrances of the sampling tube as in the river, it is necessary to pump isokinetically. This is important, because flow behaviour of water is different from that of suspended particles. The water velocity is measured with an accoustic current velocity meter, type ME -SM 125, which controls a pump. At the AMO

a NETZSCH- mono-pump type 3-NU/10 is installed, which has an almost linear pumping characteristic between the pumping volume of 0 - 1000 cm^3 per minute. Based on this pattern a linear relation between the pumped water volumes and the current velocities are achieved.

Unit No.2, the sample collection-unit is installed insite the container. All mechanic equipment, as well as tanks and sample bottles are installed in one big box. The interior of this box is cooled down to 4 degrees Celsius to stop biological acticities in the samples. Inside the box several valves direct the water either to one of the collection tanks or back into the river. Two tanks are available and each of them has a capacity of 180000 cm^3. To seperate the suspendion of water and solid material a centrifuge is used. This ceperator type ALFA LAVAL LAPX 202 has a seperation-degree of 0.45 µm grainsize by 6000 rotations per minute. Beneath the tank and the centrifuge an assembly line, with 750 cm^3-sample-bottles is installed. It has a capacity of 64 bottles which garantuees a one-week-working-period of the AMO, because 2 bottles are filled after every half-tide.

The measurement of the parameters temperature, conductivity and pH-value occurs inside the container. The sensors of a multi-parameter-measurement-unit are provided with river water by one of the tubes, coming from a seperate pump, fixed on the moving platform.

The operation control of the single units of the AMO and their working together is aided by an integrated process-computer-system. The computer is in line with a telefon modem which gives the opportunity to control and change the working processes, or have a look at the measured data from a terminal at any place, where a telefon is available.

Sampling Process

Water sampling and measurement of associated parameters are taken every 20 cm between surface and ground of the river. These are done under the use of the MOSTRA-Method. From the platform, schematically shown on the left hand side in the figures 7a,b,c, river water is continuously pumped into the container. If the plateform reaches a measurement position, it stops and the water flow is being directed through an overflowtank or bypass back into the river, until the platform reaches the next position. According to the current velocity, the tank will be filled during a half-tide with 100 - 180 dm^3 river water.

When the current direction changes, the river flow is being directed to tank No.2 in the same way then before into No.1 (Fig.7a). Shortly before and after slack water it is possible that both velocity directions occur in different water depths. In this case the water flow is directed either into tank No.1 or No.2, according to the direction of the current.

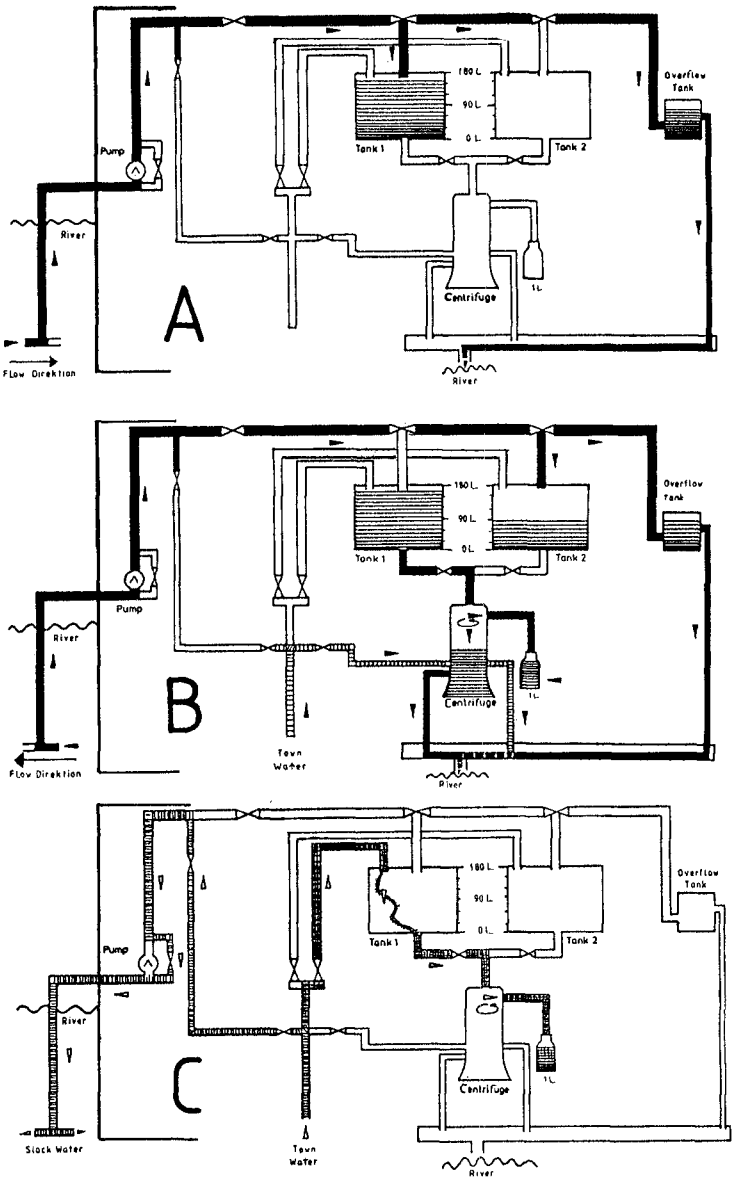

Figure 7. Sampling process of the AMO
a. Sampling of water
b. Centrifugation of sampled water
c. Washing and cleaning of the system

This interplay continuous until the new direction is measured at all measurement positions. Now the water flow is only being directed to tank No.2 and the bypass. Tank No.1 is now ready to be emtied.

In this moment, the centrifuge is started by the computer and the tank outlet-valve is opened. After the tank is completely emptied, the centrifuge content (a substratum of 0.5 dm^3) is filled into a sample bottle. An engine now starts the assembly line and a new bottle is placed beneath the outflow of the centrifuge (Fig.7b).

Tank No.1 and the centrifuge will now be washed with town water (Fig.7c) and the rinsing water is filled into the second sample bottle. After a new bottle has been brought into position, the cetrifuge will be switched off, and the tank outlet-valve be closed.

The whole process last 30 minutes, depending on the content in the tank. Parallel to the tanks the sample tube down to the platform in the river will be washed against the pumping direction to avoid obstructions.

All single phases of the process are computer aided and may be changed in every manner, so that shorter times for taking samples or other interferences are possible.

Recommendation

In line with a KFKI-projekt (CHRISTIANSEN, 1985) an automated measuring system (AMO) was established in order to determine the balance of suspended sediment and associated parameters. Morphological and velocity weighted averaged samples are taken using the newly developed MOSTRA-Method. This results in a cross-sectional average value.

The data of the system afford better answers about transport rates through the cross-section of a river, because the system even works in extrem situations, such as high water, stormy weather and heavy traffic.

CHAPTER 105

Changing of wave climate due to breaking on a tidal inlet bar

Hanz Dieter Niemeyer[+]

ABSTRACT

Changes of wave climate due to breaking on a tidal inlet bar are investigated by analysis of field measurements prosecuted offshore and onshore of the bar. Quantitative results for wave height reduction, period and length transformation and energy dissipation are presented as well as a study considering the dominating breaking criterion.

1. INTRODUCTION

The prevailing longshore drift along the East Frisian islands is eastward directionalized. The sand by passing the inlets leads to the configuration of the typical tidal delta: a number of shoals separated by channels leading from the updrift to the downdrift island like a chain. The landfall area of the sand on the downdrift island divides its beaches into an eroding and accretionary part. A very impressive example are the beaches of the island of Norderney (Fig. 1): Downdrift of the sand's landfall there are broad accretionary beaches while updrift the continuous erosion has forced man to build revetments and groynes, because the sand needed for supply is passing seaward. The only comforting thing is that the shoals act like a submerged breakwater on incident waves and attenuate especially the higher ones. In order to get quantitative information about this effect field measurements were carried out in the offshore area, on the island foreshore and in the tidal inlet of the island of Norderney (Fig. 2). The results gained up to now from these investigations are presented here.

(I: offshore, II: island foreshore, III: tidal inlet)

2. BOUNDARY CONDITIONS OF THE FIELD MEASUREMENTS

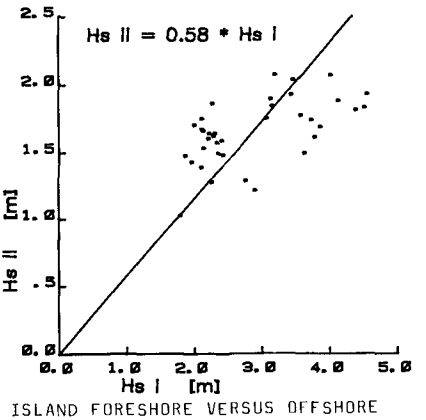
The tidal inlet Norderneyer Seegat is ebbdominated with mixed energy with reference to the classification of HAYES (1979). The mean tidal range is about 2.4 m changing on the average up to 0.7 m due to spring and neap tide. Set-up occuring during storm tides has until now reached the measure of some 3 m. The water depth due to MHWL at the three measuring stations is 12.1 m (offshore), 4.8 m (island foreshore) and 3.2 m (tidal inlet). The measurements were carried out with ultrasonic wave gages, which unfortunately do not always guarantee undisturbed data registration, because this measuring principle is very sensitive due to air

bubbles in the water. Further details considering the investigation area and especially its morphological boundary conditions have been published earlier (LUCK 1978; FITZGERALD, PENLAND + NUMMEDAL 1984).

3. WAVE HEIGHT REDUCTION

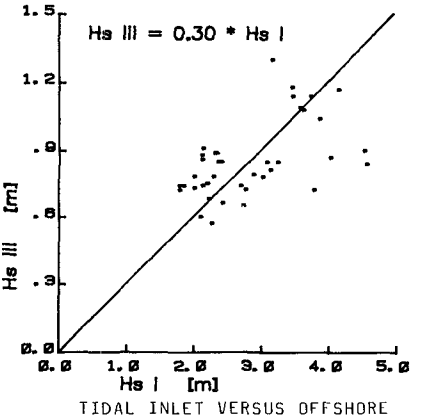
Comparing significant wave heights measured offshore and onshore of the tidal inlet bar makes their attenuation due to the crossing of the shoals evident, on the average there is a reduction of 42 % on the island foreshore and of 70 % in the inlet area in relation to offshore significant wave height (Fig. 3 + 4). But this general tendency is superimposed by a scattering of values due to variations of onshore parameters corresponding to offshore significant wave heights which nearly do not differ from each other.

Fig. 3



ISLAND FORESHORE VERSUS OFFSHORE SIGNIFICANT WAVE HEIGHT

Fig. 4



TIDAL INLET VERSUS OFFSHORE SIGNIFIKANT WAVE HEIGHT

The onshore wave heights also generally depend on the water level fluctuations in the investigation area: There is basically a tendency of bigger onshore significant wave heights for increasing water depths. But this relation is also characterized by a scattering of onshore wave heights occuring in coincidence with water depth, which have the some order of magnitude (Fig. 5 + 6). This process corresponds with the paradox of wave breaking on bars: For the same water depth an increase of offshore wave heights does not always effect an increase of those correspondently arriving onshore, but sometimes there is a decrease.

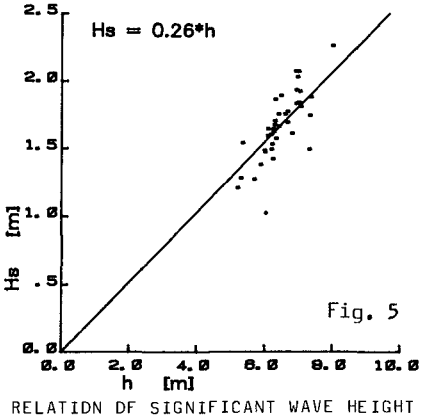


Fig. 5

RELATIDN DF SIGNIFICANT WAVE HEIGHT AND WATER DEPTH (ISLAND FDRESHDRE)

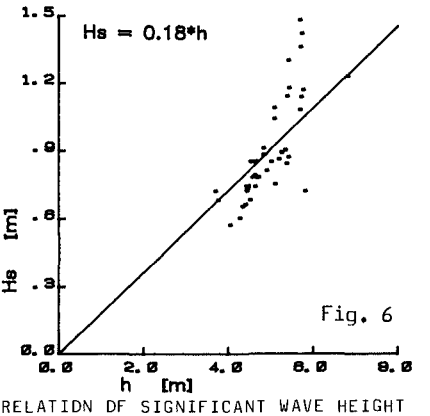

Fig. 6

RELATIDN DF SIGNIFICANT WAVE HEIGHT AND WATER DEPTH (TIDAL INLET)

This first interpretation of data leads to the conclusion that it is impossible to analyse the damping effect of a bar on wave height by taking into account only single related parameters. The interaction of the most important hydrodynamical and morphological boundary conditions governing this process, must be taken into consideration. As the shoals of a tidal inlet bar act on crossing waves like a submerged breakwater, the idea comes up to make use of the analytical formulation of boundary conditions, which was developped in previous research on this subject (ABDUHL KHADER + RAI 1980; JOHNSON, FUCHS + MORISON 1950). Additionally the investigations of DIEPHUIS (1957) on scale effects due the reproduction of wave breaking on bar in hydraulic models of small size were taken into account.

Transferring these results a statistical appromination has been developped considering the following boundary conditions: Wave height/water depth relation in the offshore region and additionally as well relative length shortening due to shoaling, wave steepness and relative water depth in the offshore area as the relations of the bar crest height to offshore water depth and shoal width to offshore wave length.

$$\frac{H_i}{H_a} = a_1\left(\frac{H_a}{h_a}\right)^{b_1} + a_2\left(\frac{H_a}{L_a}\right)^{b_2} + a_3\left(\frac{h_a}{L_a}\right)^{b_3} + a_4\left(\frac{g \cdot T_a^2}{L_a}\right)^{b_4} + a_5\left(\frac{h_a - h_R}{h_a}\right)^{b_5} + a_6\left(\frac{B_R}{L_a}\right)^{b_6}$$

First the regression analysis is carried out particularly for each boundary condition in order to differentiate their importance for wave height transmission across the bar by means of correlation coefficients (Table 1).

Table 1: Partial correlation coefficients for single boundary conditions of wave height transmission

AREA	WAVE HEIGHT	BOUNDARY CONDITION					
		H_a/h_a	H_a/L_a	h_a/L_a	$g \cdot T_a^2 \cdot L_a^{-1}$	$(h_a-h_R)/h_a$	B_R/L_a
ISLAND FORE-SHORE	H_{max}	0,773	0,138	0,530	0,280	0,421	0,578
	H_s	0,859	0,475	0,399	0,663	0,303	0,447
	H_m	0,851	0,263	0,628	0,621	0,258	0,653
TIDAL INLET	H_{max}	0,717	0,256	0,340	0,010	0,252	0,367
	H_s	0,764	0,347	0,464	0,192	0,146	0,481
	H_m	0,708	0,223	0,507	0,583	0,135	0,503

It is evident that offshore wave height/water depth ratio is the dominating boundary condition. All others are in comparison of less importance.

The results of this nonlinear multiple regression analysis are only demonstrated due to limited space for the significant wave heights: Measured and computed data show a rather good agreement (Fig. 7). In or-

Fig. 7

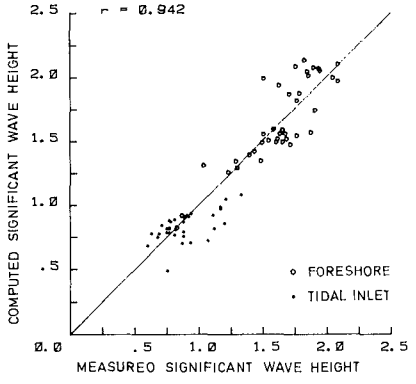

Fig. 8

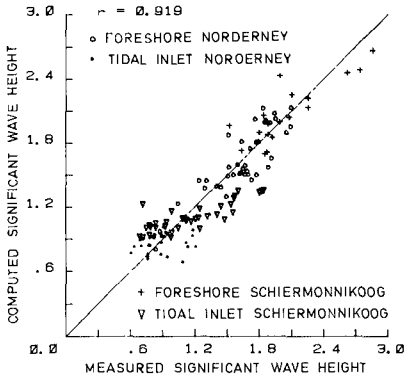


der to check, if this method is also useful for other areas with similar boundary conditions, a second wave data set from the region of the tidal inlet of the West Frisian island of Schiermonnikoog (MAD DELFZIJL 1983) is additionally taken into consideration. The function gained from the regression analysis does also fit the composited data of both areas (Fig. 8).

Summarizing these results it becomes obvious that the formulation of boundary conditions for wave breaking on tidal inlet bars and their functional relationship as developped here are not only applicable to these processes in the investigation area itself but also in other regions with similar morphological boundary conditions.

4. PERIOD AND LENGTH TRANSFORMATION

The breaking of waves on the bar does not only create a damping of their heights but also a transformation of their periods and length. Data analysis for these parameters was carried out in the same manner as for wave heights. The partial correlation coefficients for significant wave period and length are summarized in table 2, separately for the island foreshore and the tidal inlet:

Table 2: Partial correlation coefficients for single boundary conditions

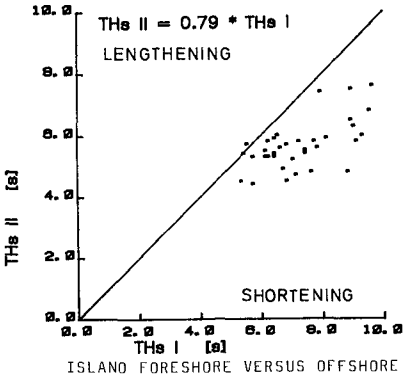
AREA	PARAMETER	BOUNDARY CONDITION					
		H_a/h_a	H_a/L_a	h_a/L_a	$g \cdot T_a^2 \cdot L_a^{-1}$	$(h_a-h_R)/h_a$	$8_R/L_a$
ISLAND FORE-SHORE	T_{Hs}	0,708	0,365	0,707	0,683	0,275	0,336
	L_{Hs}	0,754	0,471	0,754	0,717	0,400	0,435
TIDAL INLET	T_{Hs}	0,536	0,030	0,275	0,536	0,275	0,336
	L_{Hs}	0,582	0,047	0,582	0,554	0,400	0,435

Obviously period and length transformation due to breaking on the tidal inlet bar does not depend primarily on a single boundary condition as wave height transmission by the offshore wave height/water depth ratio. It is also evident that wave breaking on the bar is different on its parts which separate the island foreshore and the tidal inlet itself

from the offshore area. The transformation of periods and lengths do not depend to a similar extent on the same boundary conditions, which is apparently clear for offshore wave steepness.

A direct comparison of periods and lengths measured offshore and onshore of the bar (Fig. 9 + 10), shows that wave breaking on the bar leads to a decay of bigger offshore waves to shorter solitons (GALVIN 1972) or secondary waves (HULSBERGEN 1974).

Fig. 9a



ISLAND FORESHORE VERSUS OFFSHORE SIGNIFICANT WAVE PERIOD

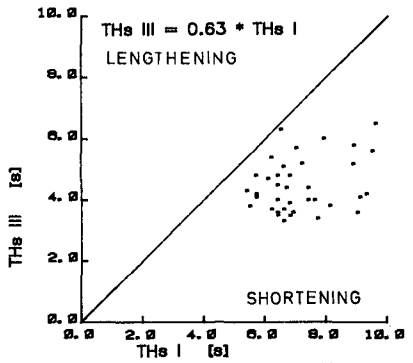
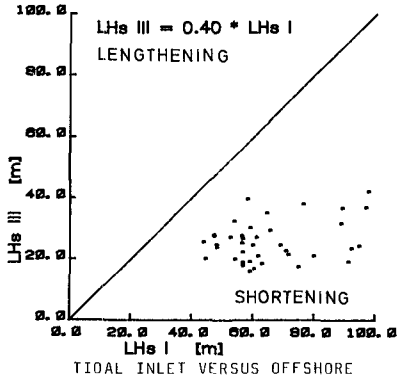
ISLAND FORESHORE VERSUS OFFSHORE SIGNIFICANT WAVE LENGTH

Fig. 10a



TIDAL INLET VERSUS OFFSHORE SIGNIFICANT WAVE PERIOD

Fig. 10b



TIDAL INLET VERSUS OFFSHORE SIGNIFICANT WAVE LENGTH

In analogy to wave heights the nonlinear multiple regression analysis was not only carried out for the data measured in the investigation area itself but additionally in connection with those from the region of the West Frisian Island of Schiermonnikoog. Due to limited space only the results of the last are quoted here (Fig. 11 + 12). The data fitting to the treated function is of less accuracy than for wave heights, especially for those from the tidal inlet of the Norderney Seegat. This result agrees well with the order of magnitude of partial correlation coefficients (Table 2). Probably this lack of accuracy is partly created by disturbances in data sampling due to failures of the measuring devices as mentioned before.

Fig. 11

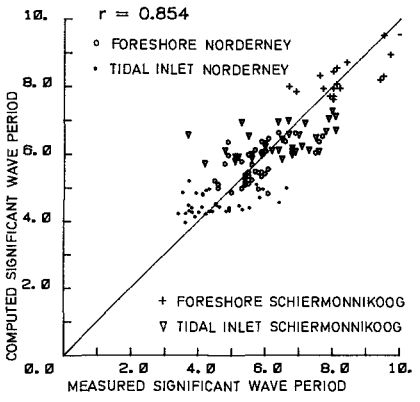


Fig. 12

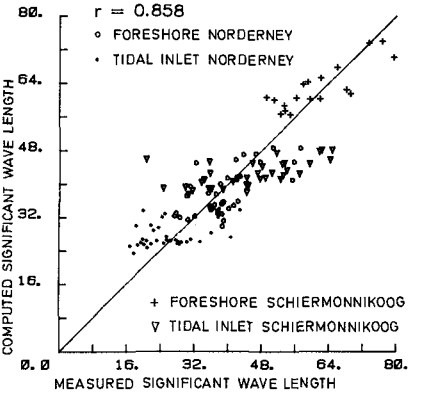

5. ENERGY DISSIPATION

5.1 ENERGETICALLY REPRESENTATIVE WAVES

The energy of a wave is defined as follows:

$$E = \frac{1}{8} \cdot \rho \cdot g \cdot H^2 \cdot L$$

FÜHRBÖTER (1974) suggested determining the power of a wave in terms of electricity:

$$N = 1{,}225 \cdot \rho \cdot g \cdot H^2 \cdot \frac{L}{T} \ (kw)$$

In order to compute the power of an energetically representative wave for measured time series in the offshore area of the German North Sea coast DETTE and FÜHRBÖTER (1977) made the following substitution:

$$\frac{L}{T} = c = \sqrt{g \cdot h}$$

Additionally they introduced the significant wave height H_s for the computation of wave power:

$$N = 1{,}225 \cdot \rho \cdot g \cdot H_s^2 \cdot g \cdot h \quad (kw)$$

But this solution includes two basic faults. Firstly the energetically representative wave height of a time series is in accordance with LONGUETT-HIGGINS (1953) H_{rms} and not H_s. Secondly the use of the approximation for shallow water wave celerity is restricted to values of relative water depth of

$$h/L_o \leq 0{,}05 \quad .$$

As well in the investigation area of DETTE and FÜHRBÖTER (1977) as at the measuring station in the offshore area of Norderney this assumption is not satisfied. Furthermore it seems to be convenient to consider the energy flux, represented by the ratio of wave group and phase velocity. Therefore the power of the energetically representative waves of all measured time series is computed in the following manner:

$$N = 1{,}225 \cdot n \cdot \rho \cdot g \cdot H_{rms}^2 \cdot c$$

$$c = \frac{g}{2\pi} \cdot T_m \cdot \tanh (k \cdot h)$$

A comparison of the results for data from the offshore area of Norderney with the computation method suggested by DETTE and FÜHRBÖTER (1977) shows, that their statement leads to an overestimation of wave power with hyperbolical character of about 400 % on the average (NIEMEYER 1983).

The determination of energy dissipation due to wave breaking is carried

out by comparing the power of the energetically representative waves of all time series measured correspondently offshore and onshore of the tidal inlet bar. In order to avoid an overestimation of longer waves the wave power is summarized per hour considering the possible number of waves which can occur during this unit of time due to their period.

Fig. 13

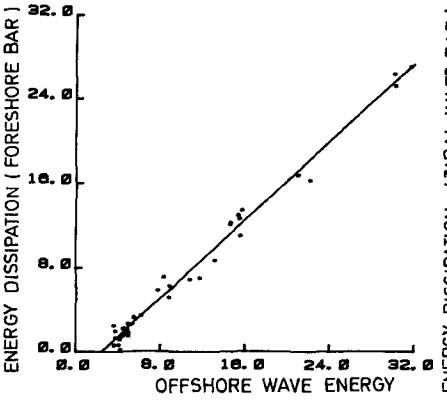

Fig. 14

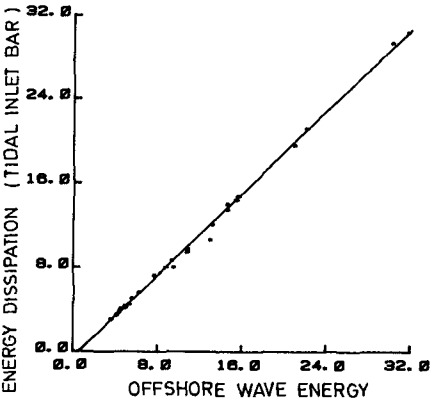

The numerical results of these computations indicate the enormous sheltering effect of the bar for its onshore areas against wave action. There is a strong linear relationship between offshore wave energy and energy dissipation due to breaking on the bar (Fig. 13 + 19): On the average 92 % of wave energy in the offshore area dissipates on the bar's shoals seaward of the tidal inlet and 70 % on those separating the island foreshore from the open sea. These differences in dissipative efficiency of the two parts of the bar, which correspond with wave height damping, could be easily explained by the distinction of its morphological features: The shoals seaward of the bar are higher, have a larger aerial extension and are closer to each other than those surrounding the island foreshore (Fig. 1 + 15). It seems furthermore noteworthy that energy dissipation on both parts of the bar increases with the same tendency as offshore wave energy.

Though there is a strong linear relationship between offshore wave energy and its dissipation on the bar, it is not similarly succesful to

Fig. 15:
Tidal inlet bar (foreground: tidal inlet; background: island foreshore)

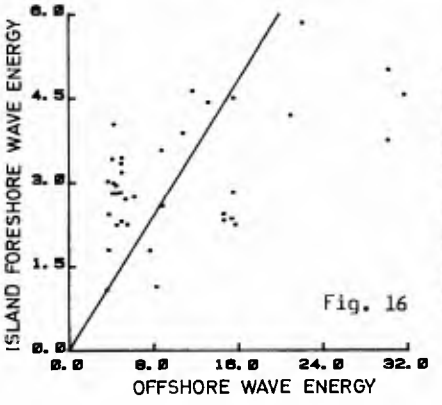

Fig. 16

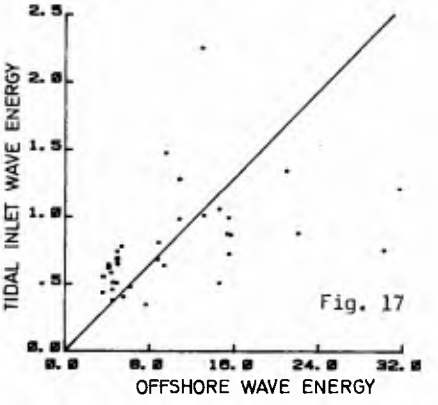

Fig. 17

use it for the derivation of the residual wave energy in the onshore areas (Fig. 16 + 17). There is a remarkable scattering of values due to divergence from the functional average. The reason might be that the residual wave energy is much smaller than both the offshore wave energy and its rate of dissipation due to breaking. So probably the derivation leads to small differences of large numbers. But it is noteworthy that the functional average is well in accordance with the average rate of dissipation derivated above.

5.2 ENERGY SPECTRA

As well as for energetically representative waves of measured time

series, investigations of energy dissipation due to wave breaking have been carried out by comparison of spectra, which have been measured correspondently offshore and onshore of the bar. The intention was to get not only information about energy dissipation but also about energy shifting to other frequencies.

The spectra of two runs are used here for such an exemplary comparison. One is representative for high the other for very high offshore wave conditions (Table 3). Corresponding to the meteorological boundary conditions the energy of spectrum No. 51 is five times greater than that of No. 24 and the relation of peak energy density is even ten to one (Fig. 18 + 19, Table 3). Comparing the spectra onshore of the bar these differences have become remarkably smaller. This result also proves the already established fact that an increase of wave energy in the offshore area leads always to a higher dissipation due to breaking on the bar. The dissipation is not only characterized by a decrease of total energy

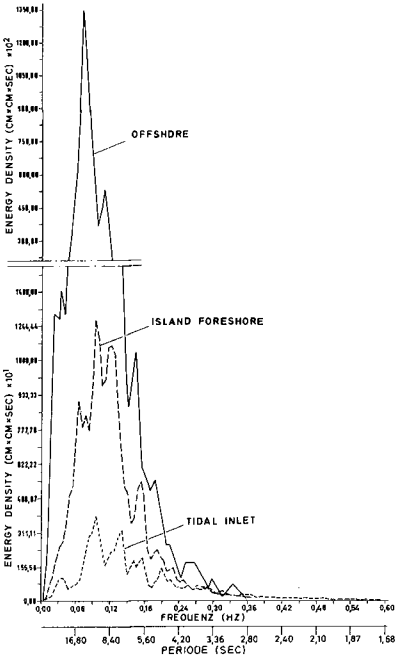

Fig. 18: Spectrum No. 51

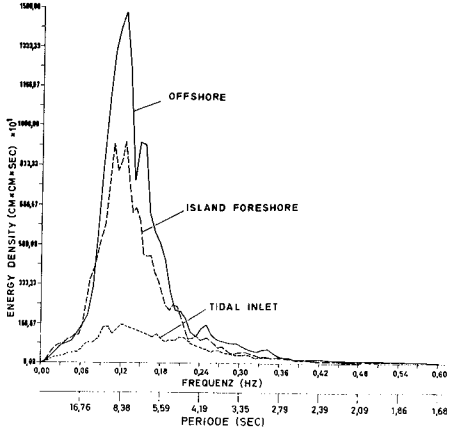

Fig. 19: Spectrum No. 24

Table 3: Comparison of Spectral Parameters

PARAMETER	RUN 24			Run 51		
	OFF-SHORE	ISLAND FORESHORE	TIDAL INLET	OFF-SHORE	ISLAND FORESHORE	TIDAL INLET
$E_{ges}(cm^2)$	5 616	3 654	1 150	25 644	5 182	1 602
$E_{fmax}(cm^2\ s)$	12 900	9 302	1 642	139 200	12 660	3 864
f_{max} (Hz)	0,128	0,127	0,122	0,080	0,093	0,087
T_p (s)	7,8	7,9	8,2	12,5	10,8	11,5
H_s (m)	2,11	1,71	0,95	4,53	2,04	1,19
T_{m02}(s)	5,5	5,7	4,3	7,2	6,3	5,1
ε	0,95	0,93	0,93	0,98	0,96	0,91
Q_p	1,44	1,40	1,01	1,71	1,16	1,08

but also and to a larger extent of the energy peak concentration leading to multi-peak spectra in the onshore areas. The decay of peak concentration intensifies the more firstly the higher the spectral peak concentration in the offshore area and secondly the higher the dissipative efficiency of the shoals. So for both spectra the dissipation of energy is in comparison on the shoals offshore of the tidal inlet itself much larger than on those seaward of the island foreshore. Also the change of the spectral shape due to the decay of the single peak to a number of peaks of similar order of magnitude occur on the island foreshore only significantly for spectrum No. 51 with its very high energy peak concentration.

Analogous high energy dissipation due to the same boundary conditions - high shoals with large areal extension close to each other and high energy concentration in the offshore wave spectrum - effects an energy shifting to higher frequencies (Fig. 20). Considering this result and the correspondent change of spectral shape it is remarkable that there is even nearly no change in peak frequency from the single peak offshore spectrum to the corresponding ones in the onshore areas of the bar with a multi-peak shape. Therefore it seems necessary to reconsider the interpretation of multi-peak spectra by only one peak frequency.

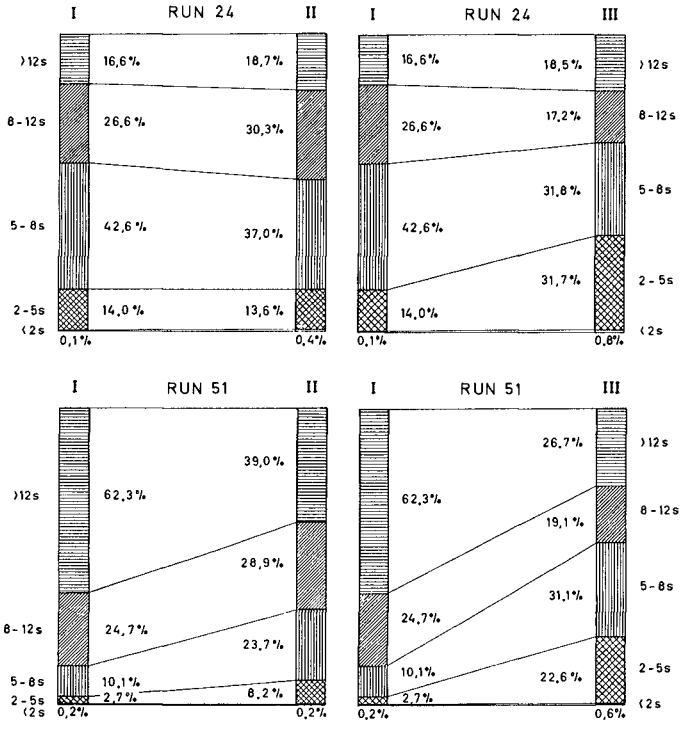

Fig. 20: Spectral energy shifting due to wave breaking on the bar

I: Offshore II: Island foreshore III: Tidal inlet

6. HYDRODYNAMICAL CAUSES FOR WAVE BREAKING

In order to evaluate the hydrodynamical causes for wave breaking on the bar, the two breaking criteria for shallow water were correspondently taken into account. Firstly the limit of wave height/water depth ratio for North Sea conditions (FÜHRBÖTER 1974; SIEFERT 1974) and secondly the critical wave steepness (MICHE 1944) were computed for the measured offshore wave data. Additionally their transformation due to shoaling was considered. The investigations are based on a fictitious water depth on the bar corresponding to the highest areas of the shoals.

Even for this water depth, which is rather small with respect to site conditions a large number of significant wave heights calculated due to shoaling would not break on the bar (Fig. 21 + 22). On the contrary many more of these fictitious significant wave heights would break taking the critical steepness limit (MICHE 1944) into consideration

(Fig. 23 + 24). This result leads to the conclusion that the dissipative efficiency of the bar does not only base on the restricted water depth on the highest part of its shoals but also and probably to a larger extent on shoaling water depth from the offshore area to the bar.

CHAPTER 106

NUMERICAL SIMULATION OF BEACH PROFILE CHANGES

Hitoshi Nishimura*
Tsuguo Sunamura**

ABSTRACT

This paper presents an overall numerical model for predicting beach profile changes due to waves. The local rate of net on/offshore sediment transport is empirically formulated as a function of the Ursell number and Hallermeier parameter. A sub-model of two-dimensional wave transformation includes the wave shoaling, breaking and damping in a surf zone. It is combined with another sub-model of beach profile change for the analyses of wave-profile interaction. The validity of the model is examined through hindcasting of profile changes observed in ordinary and prototype-scale flumes.

1. INTRODUCTION

In planning countermeasures against beach erosion, which is raising serious problems at many coast in the world, it is indispensable to understand the interaction between waves and beach profiles. This paper deals with a numerical model for the prediction of beach profile changes under given conditions of incident waves, bed material and initial profile. The process of profile change is simulated through repetitive calculation of two-dimensional wave transformation and net sediment transport due to waves. Similar trials were made also by Mizuguchi and Mori (1981) and Shibayama (1984).

For these years, trials have been made to establish a more advanced numerical model for analyzing three-dimensional beach processes. Nevertheless, studies on two-dimensional models such as beach profile models and shoreline models are meaningful particularly from the engineering point of view, since it seems to be impossible for the time being to apply a three-dimensional model to the analyses of long-term and/or wide-range beach transformations.

2. MODELING OF TWO-DIMENSIONAL WAVE TRANSFORMATION

Several methods are available for the numerical simulation of wave transformation in a shallow region. Among them, the simplest method based on the law of wave energy conservation will be most relevant here, since the calculation of local wave heights only is required in

* Associate Professor, Institute of Engineering Mechanics, University of Tsukuba, Sakura, Niihari, Ibaraki 305, Japan.
** Associate Professor, Institute of Geoscience, ditto.

modeling of this type. It is also to be borne in mind that the present model involves a net sediment transport rate formula, whose accuracy cannot be so high as yet.

For a steady field of uni-directional waves, the equation governing the variation of wave energy density is written as

$$\frac{\partial EC_g}{\partial x}+\Gamma=0 \tag{1}$$

where x is the shoreward coordinate, E is the wave energy density ($E=\rho gH^2/8$, ρ is the density of water, g is the gravitational acceleration and H is the wave height), C_g is the group velocity of waves, and Γ represents the wave damping mainly associated with breaking. Nishimura (1982) suggested that the wave height attenuation after breaking is well simulated, if the wave energy dissipation is assumed to be proportional to the energy density ($\Gamma=\alpha E$) with α regarded as a function of the water depth. Izumiya and Horikawa (1984) investigated the damping of waves more precisely to evaluate separately the effects of bottom friction and internal turbulence produced by breaking:

$$\Gamma=[\sqrt{2}(2n-1)C_f+C_t]\sqrt{\frac{2n-1}{\rho}\left(\frac{E}{d}\right)^3} \tag{2}$$

where n is the ratio of group velocity to phase velocity of waves, and d is the substantial water depth including wave setup.

The frictional coefficient C_f is normally assumed to take a value of the order 0.01. Another coefficient C_t, which represents the effect of turbulence in the surf zone, is given as

$$C_t=\beta_0\sqrt{nE/\rho gd^2-0.09} \tag{3}$$

where the value of β_0 is about 1.8, although it is affected by the bottom slope to a certain extent. The coefficient C_t is set to be zero before breaking or when $nE/\rho gd^2 < 0.09$. The breaking point is judged by use of the breaker indices given by Goda (1970).

For the numerical integration of Eq. (1), the variables are discretized and the equation is rewritten into a finite difference form. Computation points are uniformly distributed along the x-axis. Then, the wave energy (and, therefore, the wave height) at each point can be determined successively from the offshore to the shore, if the incident wave height and period are given.

Radiation stress accompanying monochromatic waves is easily evaluated from the energy density. Since the gradient of the stress balances with gravitational component of water surface slope,

$$\frac{\partial\zeta}{\partial x}+\frac{1}{\rho gd}\frac{\partial}{\partial x}\left[\left(2n-\frac{1}{2}\right)E\right]=0 \tag{4}$$

The surface elevation due to wave setup is given through the numerical integration of the above equation. In this case, Eqs. (1) and (4) have to be solved simultaneously, because the substantial water depth is the sum of ζ and the still water depth h. The amount of wave setup is actually very small except in a swash zone and it is sufficient to revise the values of ζ only when effective changes appears in d.

3. FORMULATION OF SEDIMENT TRANSPORT RATE

In order to measure a net sediment transport rate in a wave flume,

a tray method (Sunamura,1982) was employed. A rectangular tray, the width of which is equal to that of the flume, is divided into two equivalent compartments by a thin metal splitter having the tray width. The compartments are filled with equal mass of sediment to be tested. The surface of sediment is manually smoothed and the splitter is removed. Then waves are allowed to act for a certain period of time. After completion of wave action, the splitter is returned to the original position. The sediment is separately taken out from each compartment and weighed after complete drying. From the difference in sediment mass, the direction and rate of net sediment transport are determined at a fair level of accuracy.

A wave flume 12 m long, 40 cm high, and 20 cm wide was used. A plunger-type wave generator was equipped at one end of the flume, and a mortar-made uniform slope of 1/20 was installed at the other end. In this experiment, a tray (60 cm long and 2 cm deep) was fixed on the slope after removal of a part of the bottom. The tray was always exposed to the action of broken waves with heights ranging from 1.8 to 3.2 cm and periods from 0.8 to 2.4 s. Five kinds of well sorted sediment with approximately the same specific gravity (about 2.6) but different diameters (0.23, 0.41, 0.79, 1.3, and 2.9 mm) were used. The amount of sediment tested was 1500 g for each compartment. The surf zone data available were incorporated to form a sound base for establishing a transport rate formula which is applicable to the whole range of the nearshore zone.

The data were analyzed with the Ursell number U_r representing the skewness of water particle velocity profile and the Hallermeier (1982) parameter Φ indicating the intensity of sediment movement, where

$$U_r = HL^2/d^3 \quad \text{and} \quad \Phi = (a_0\omega)^2/\gamma' g D$$

in which L is the wave length, a_0 is the near-bottom orbital diameter, ω is the wave angular frequency of waves, D is the grain size of the sediment, and γ' is the specific gravity of immersed sediment.

Figure 1 is a plot of net sediment transport directions on the U_r - Φ plane, showing that

(1) net sediment transport takes place if $U_r > 230$,

(2) onshore transport occurs if $7000/U_r < \Phi < 0.13\,U_r$,

and (3) offshore transport occurs if $\Phi > 0.13\,U_r$.

A quantitative examination of the data plotted in the figure indicated that the normalized sediment transport rate Q/wD can be expressed as a function of Φ for a fixed U_r, where Q is the volume (with void) rate of net onshore sediment transport per unit shoreline length, and w is the fall velocity of the sediment. In order to determine the functional form, the values of Q/wD were plotted against Φ for each range of U_r values, as shown in Fig. 2. Although the critical parameter value for net sediment transport is given by $\Phi_c = 7000/U_r$, data analysis on a quantitative basis suggests that an approximation of $\Phi_c = 0$ is reasonable.

Thus, the following functional form was assumed:

$$\frac{Q}{wD} = -A\Phi(\Phi - 0.13U_r) \tag{5}$$

where A is a function of U_r. The curves were drawn in Fig. 2 as a result of the best fit of Eq. (5) to the data. In spite of considerable data scatter, it is observed that general trends can be described by

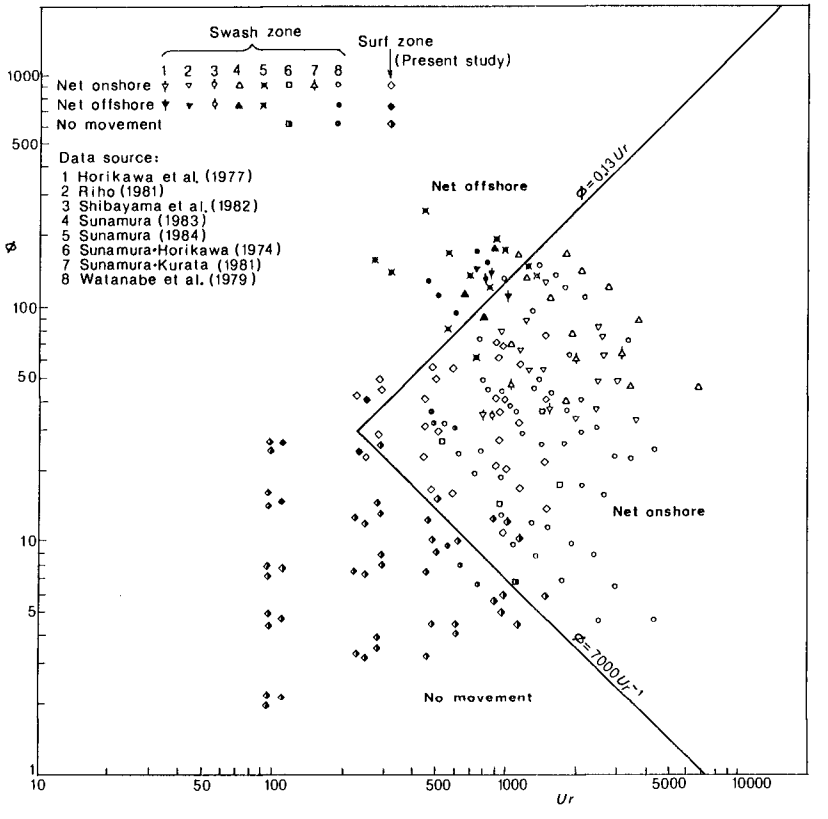

Fig. 1 Demarcation of net sediment transport directions.

this equation. A further plot showed that $A \sim U_r^{0.2}$, so that the following transport rate formula yields:

$$\frac{Q}{wD} = -BU_r^{0.2}\Phi(\Phi - 0.13U_r) \tag{6}$$

where B is a constant of the order 10^{-7} for laboratory tests of ordinary scale, and Q vanishes when $U_r < 230$.

Another set of data was obtained through prototype-scale experiments at the Central Research Institute of Electric Power Industry, Japan, and an investigation on these data indicated that B takes a value of the order 10^{-5} (Sunamura, 1984). As to this scale effect, however, a contradictive conclusion is derived from applications of the above formula as will be shown in Section 5. More studies are needed to fix the value of the coefficient.

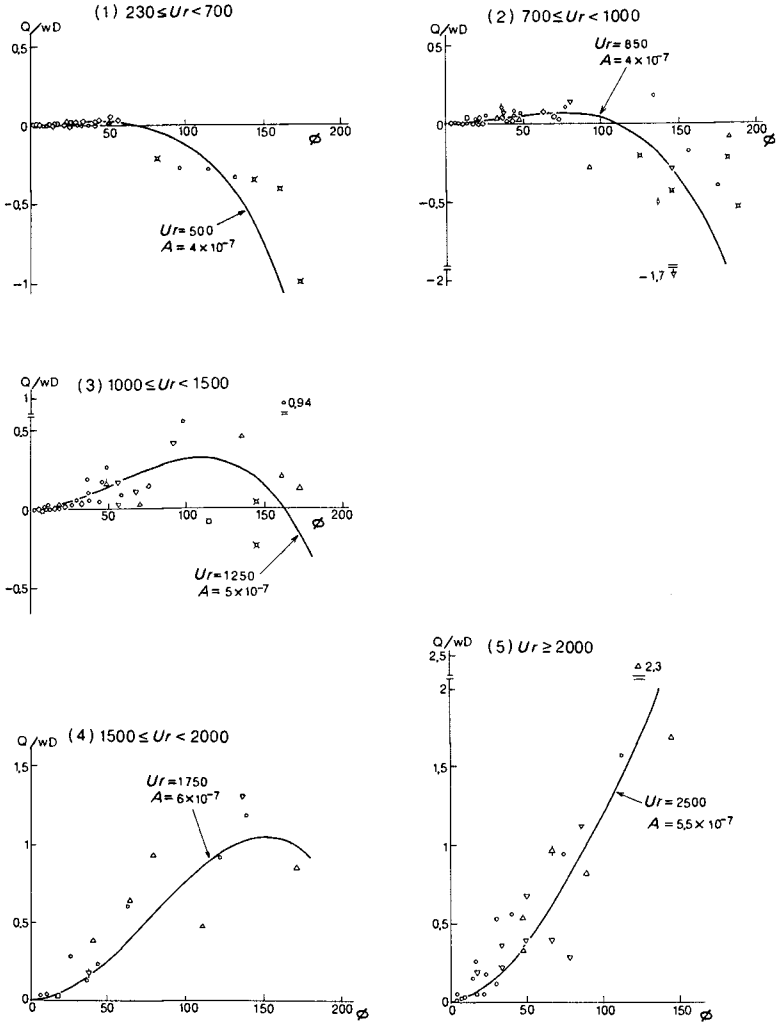

Fig. 2 Relationship between the normalized sediment transport rate Q/wD and the Hallermeier parameter Φ. (See the legend in Fig. 1 for symbols)

4. MODELING OF BEACH PROFILE CHANGES

The formula (6) gives the rate of net sediment transport as a function of local wave height and water depth, including no factor to represent the effect of bottom slope. As a consequence, a model simply based on the above formula may allow the generation of unrealistic local irregularities in the bottom topography. It is also impossible for the model to describe the reduction of net sediment transport which is normally observed as the beach profile approaches to an equilibrium slope.

On the basis of the above discussion, a term proportional to the excess bottom slope is introduced to give the effective sediment transport rate Q':

$$Q'=Q\mp\left(\left|\frac{\partial z}{\partial x}\right|-\beta_*\right)Q_* \tag{7}$$

where z is the bottom surface level and the modification is performed only when the absolute bottom slope exceeds the critical slope β_*. The scale of the modification Q_* is determined empirically as well as β_*. In the above expression, the inverse sign to that of $\partial z/\partial x$ is to be selected. Similar expression was used by Watanabe (1982) in his three-dimensional model.

Now, the continuity equation for bed material is written as follows:

$$\frac{\partial z}{\partial t}+\frac{\partial Q'}{\partial x}=0 \tag{8}$$

where t is the time.

Let the values of the wave height and the water and bottom surface levels be defined at computation points $x=i\Delta x$ $(i=0, 1, 2, \cdots)$ except those of the sediment transport rate which are defined at intermediate points $x=(i+1/2)\Delta x$. Then, the rise of bottom surface Δz_i during the time interval Δt at the i-th point is given as

$$\Delta z_i=-(Q'_{i+1/2}-Q'_{i-1/2})\Delta t/\Delta x \tag{9}$$

in which the values of variables at the intermediate points required for the calculation of Q' are obtained through interpolation from those at neighboring definition points.

Simulation of the beach profile change is achieved by repetitive computations of the wave height, sediment transport rate and bottom surface level. It is recommended to adjust the time interval Δt at each time step of computation so that the resultant maximum change in the bottom surface level may not exceed a given limit. In order to save the computer execution time, variation of the wave height is calculated only when effective changes appeared in the beach profile.

5. EXAMPLE COMPUTATIONS

First, the result of a movable bed experiment of ordinary-scale is used for the examination of the numerical model. The bed material was well sorted sand with the grain size of 0.18 mm and the specific gravity of 2.7. The fall velocity of the material is estimated from Ruby's formula at 2.4 cm/s for the temperature of 15°C. A uniform slope of 1/10 was installed in a wave flume 17 m long, 60 cm high, and 40 cm wide. The bed was fixed and horizontal in the offshore range, where the

water depth was 35 cm.

The slope was exposed to the continuous action of regular waves for 2 hours, and the profiles were measured several times after switching the wave generator off. A touch sensor was used for the measurement of the bottom level at every 5 cm along a longitudinal line. A representative profile was obtained through averaging profiles along 5 measuring lines at maximum, since the bottom topography was not necessarily uniform over the flume width. A typical bar was formed under the incident wave condition of 0.8 s in period and 6.7 cm in height.

Figures 3 show calculated wave height variations before and after the bar formation in comparison with experimental data. Calculated variations of the mean surface elevation are also shown by broken lines in the figures. The spacing of computation points Δx was fixed at 5 cm over the entire range of computation. A notable difference between the calculated and measured wave heights is found at their peaks near the breaking point. This is rather reasonable because the present model simulates the effective wave height which is proportional to the square root of wave energy density. Owing to the shoaling effect, a wave crest becomes steeper as it approaches to the breaking point, and a rapid increase in the apparent wave height is observed when it breaks.

Partial reflection of waves at the front slope of the bar causes a considerable undulation of wave height in the offshore range, as shown in the lower figure. A corresponding undulation also appears in the beach profile. Note that the wave reflection is not taken into account here in the computation. A more realistic results can be obtained through numerical integration of the decomposed mild slope equation with a dissipation term (Nishimura et al., 1983), although much more computational labor is required.

Figure 4 shows the beach profiles observed in the flume, whereas the results of numerical modeling is shown in Fig. 5. The profiles in Fig. 4 describe the very early stage of the observed process, involving already the major part of the profile changes. In the numerical computation, the parameter values such as $\beta_* = 0.1$ and $Q_* = 10^{-5}$ m^3/s were used, and the time interval Δt was adjusted in the range from 60 to 150 s. In spite of the comment in Section 3, the coefficient B was given the value of 10^{-5} here for the best fit to the measured profiles. The generation and development of a bar are well simulated by the numerical model, while the location of the bar is not correctly estimated.

As shown in Fig. 6, the rapid changes in the wave height and water depth result in the complicated variations of U_r and Φ values. The corresponding sediment transport rate is denoted by the broken line in Fig. 7. The solid line in the same figure shows the rate deduced from the observed profile changes. The peak of the former appears at the breaking point, whereas the peak of the latter is located on the back slope of the bar. In the numerical model, the predominant flushing effect appearing at the bar crest causes offshore shift of the bar and, consequently, that of the breaking point. Thus, the continuous and rather rapid move of the bar takes place. Such interactive deformations of waves and beach profile are often observed in a flume and in a field as well, although the speed of bar move is much lower.

The above-discussed defect of the model implies an inadequateness of the basic assumption that the rate of net sediment transport can be evaluated solely from local wave and topographic conditions. In fact,

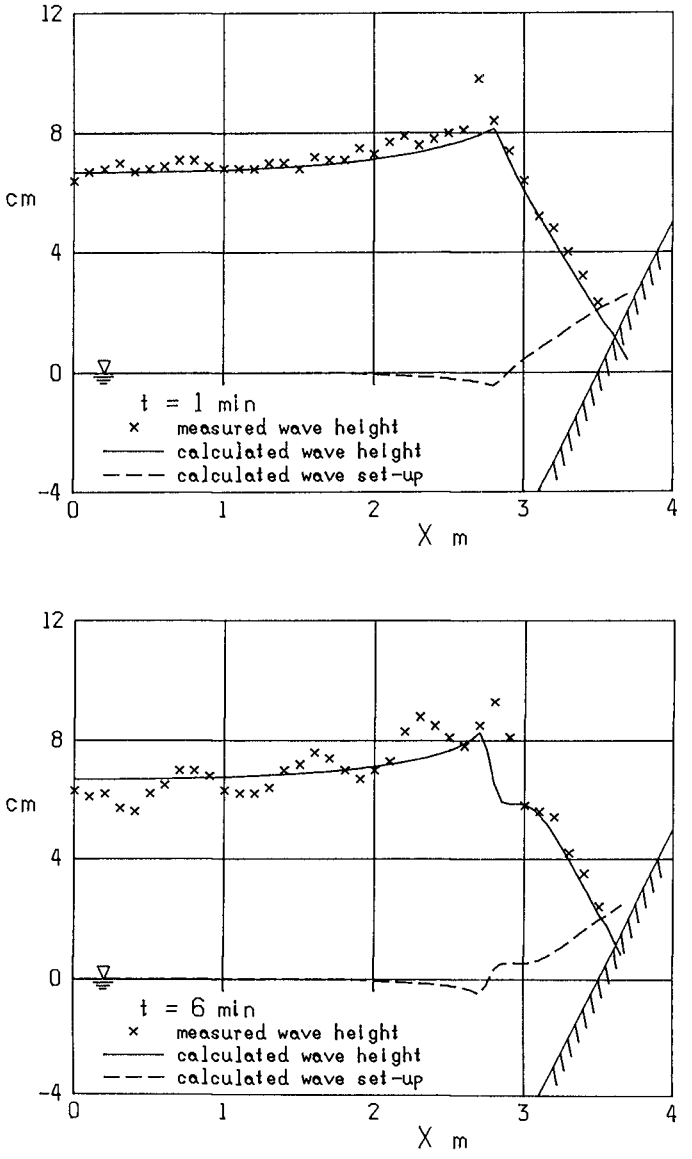

Fig. 3 Variation of the wave height and wave setup.

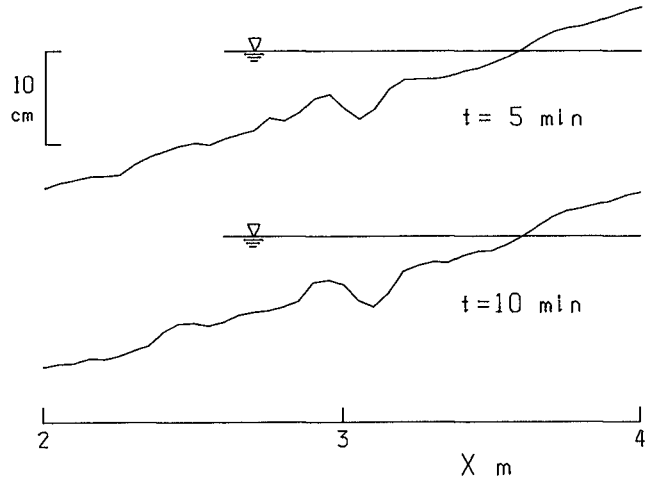

Fig. 4 Beach profiles observed in an ordinary-scale flume.

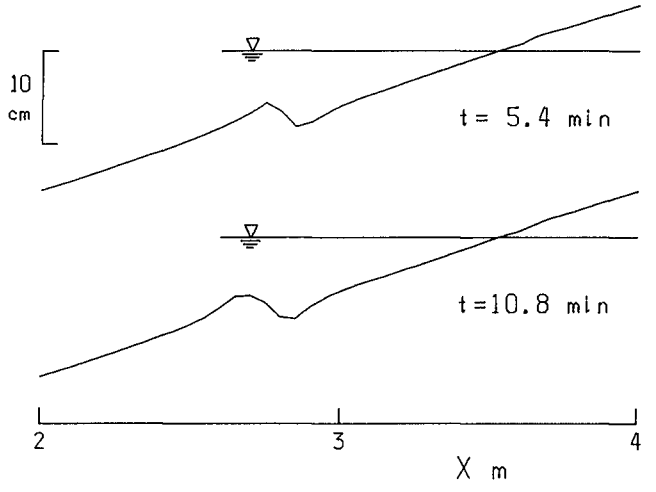

Fig. 5 Calculated beach profiles.

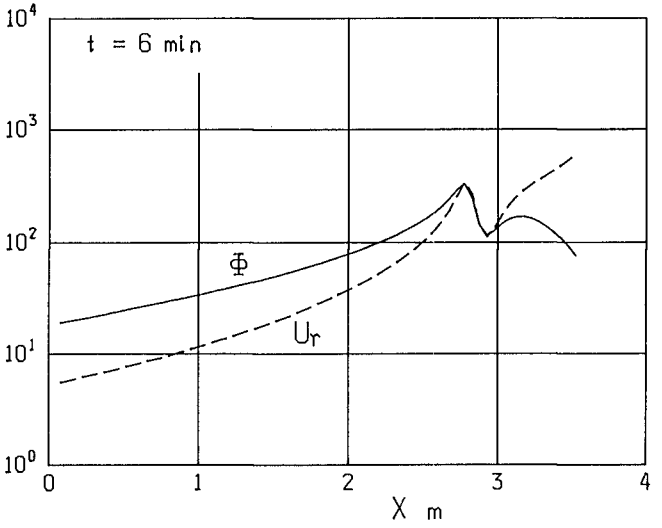

Fig. 6 Variations of the Ursell number U_r and the Hallelmeier parameter Φ.

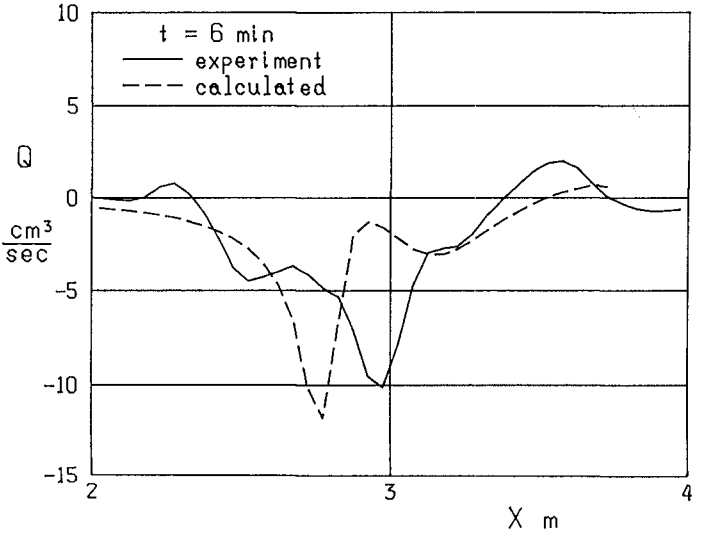

Fig. 7 Variation of the sediment transport rate.

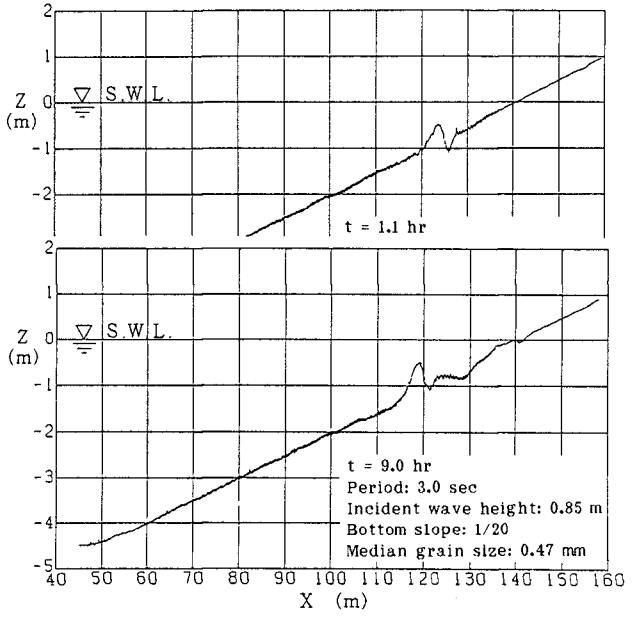

Fig. 8 Beach profiles observed in a prototype-scale flume.

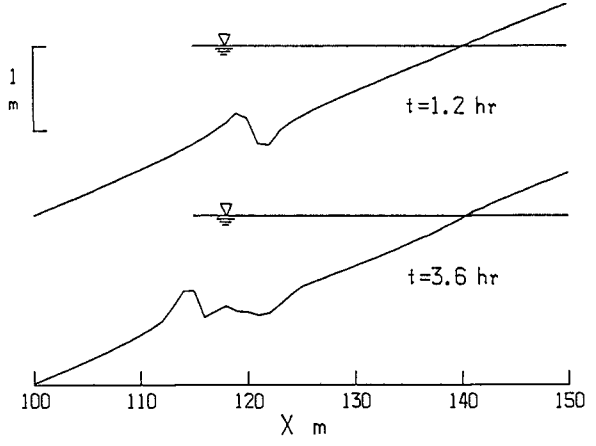

Fig. 9 Calculated beach profiles.

the intense near-bottom flows induced by plunging waves largely contribute to the bar and trough formation.

Figure 8 presents another example of beach transformation observed in the prototype-scale wave flume by Shimizu et al. (1985); experimental conditions are specified in the figure. The corresponding result of numerical hindcasting is shown in Fig. 9, which exhibits the similar tendencies to the preceding example. It is, however, interesting to point out that the numerical model well explain the generation of a secondary bar in the trough behind a main bar. In this example, the spacing Δx and the time interval Δt were expanded to 1 m and 10 ~ 30 min, and Q_* also proportionally to the maximum rate of net sediment transport. A note is that the value of coefficient B in the formula (6) was kept unchanged at 10^{-5} . It is thus concluded through these applications that the significant scale effect does not appear on this coefficient.

ACKNOWLEDGEMENTS

The authors are grateful to the Central Research Institute of Electric Power Industry, Japan, who kindly offered the experimental data for this study. The study was financially supported by the Science Research Fund of the Ministry of Education, Science and Culture, Japan, and also by the Project Research Fund of the University of Tsukuba.

CHAPTER 107

Design of beach nourishment scheme

K.W. Pilarczyk*, J. van Overeem**, W.T. Bakker***

1 Introduction

An artificial beach nourishment used to replenish an eroding part of a coast may seem expensive and the need for repetition may discourage coastal managers. However, careful considerations of capital and maintenance cost frequently prove that it may be, in fact, the optimum solution. An added advantage is that the recreational function of the beach is preserved.
In spite of a great number of research-reports and publications on coastal processes and beach nourishment, the practical applicability of this knowledge is still in an initial stage, i.e. formulating the general concepts and trying to test their validity and practical applicability.
On the other hand, the solution of many practical coastal engineering problems cannot wait until complete understanding of these processes and the existing knowledge on this subject (though limited) should be made available for designers and managers involved in coastal engineering.
This was the main reason for the Rijkswaterstaat (Dutch Public Works Department) to prepare a manual on artificial beach nourishment.

In 1983, this Department established the task-group 'Profile Formation of Beaches', with the aim to study the relevant aspects of beach nourishment. These aspects concern among other things the influence of a beach fill on the coastal morphology and the environment, and the design and execution of a beach nourishment scheme.
The members of the task-group originate from various governmental departments, research institutes (Delft Hydraulics) and private organisations (Volker Stevin Dredging, Zanen Verstoep Dredging Contractors). In addition to the members of the working-group some other persons and organizations (also outside the Netherlands) have contributed to the final report.
The results of the studies have been described in a Manual on Beach Nourishment (Manual, 1986). This manual contains both theoretical and practical information, and is intended for persons and organisations who are involved in the prevention of beach erosion. Nearly all available and relevant literature to this subject has been incorporated.
The actual paper reviews part of the contents of the Manual and summarizes aspects related to the aim, the different types and the design process of beach nourishment schemes.

* Rijkswaterstaat, Road and Hydraulic Engineering Division, The Netherlands
** Delft Hydraulics, The Netherlands
*** Rijkswaterstaat, Tidal Waters Division, The Netherlands

2 Contents of the Manual

The Manual presents a comprehensive overview of matters related to shoreline protection by artificial beach nourishment and has been written for any authority, organization or person responsible for assessment of measures to protect, maintain or extend coastal areas. Government bodies, planners, designers and contractors will find the basic information they need. The various aspects to develop a strategy of artificial beach nourishment will pass in review: background information on coastal processes and shoreline evolution, design requirements and parameters, design methods, execution methods, and environmental aspects are the major elements presented in this manual. Furthermore, a number of implemented schemes are evaluated to indicate the applicability and accuracy of present design methods and the gaps in knowledge of this moment. In addition inventories have been made of artificial nourishment projects both in and outside The Netherlands.

The final document consists of two separate reports. The Manual (1986) comprises basically the findings of the working group, whereas the Background Report (1986) is a compilation of relevant information gathered in the scope of this project. Thus the Manual can be used separately without the need to consult the Background Report.

"Manual on Artificial Beach Nourishment" deals with the basic information for planning and design of a scheme of artificial beach nourishment. Coastal processes, computational methods, design parameters and execution methods are discussed here. General conclusions and recommendations for the future are presented in the report.

"Background Information on Artificial Beach Nourishment" comprises the information and detailed data collected, and computations carried out during the study. Literature abstracts, questionnaires on past artificial nourishment projects, model descriptions, hindcast computations and the specific Dutch situation with respect to artificial beach nourishment are comprised by the report.

3 Type in view of the aim of beach nourishment

Artificial beach nourishment schemes are generally executed with the aim to protect the coastline against beach erosion and/or to enlarge the beach for recreational purposes.
The following examples of causes of beach erosion can be mentioned:

- interruption of longshore transport by coastal structures;
- reduction of sediment supply by rivers;
- dune and beach erosion by storm surges;
- shifting of tidal channels;
- alongshore migration of large sand waves;
- relative sea level rise;
- beach mining.

The different types of beach nourishment can be characterized by the location where the sand is placed in the coastal zone, viz.:

(a) position in cross-shore direction (at the back, on top or at the face of dunes, on the beach or on the offshore zone);
(b) position in alongshore direction (placed along the beach, a stock pile of sand, or a continuous supply of sand).

Which specific type to select, depends on the aim of the beach nourishment and/or the cause of beach erosion.

4 Design process of beach nourishment scheme

The design process for an artificial beach nourishment scheme is schematically given in Figure 1. For a proper definition of the type and scale of the beach erosion problem, an assessment should be made concerning the causes of beach erosion and the interests of the actual beach with respect to safety, recreation, environment and economy.

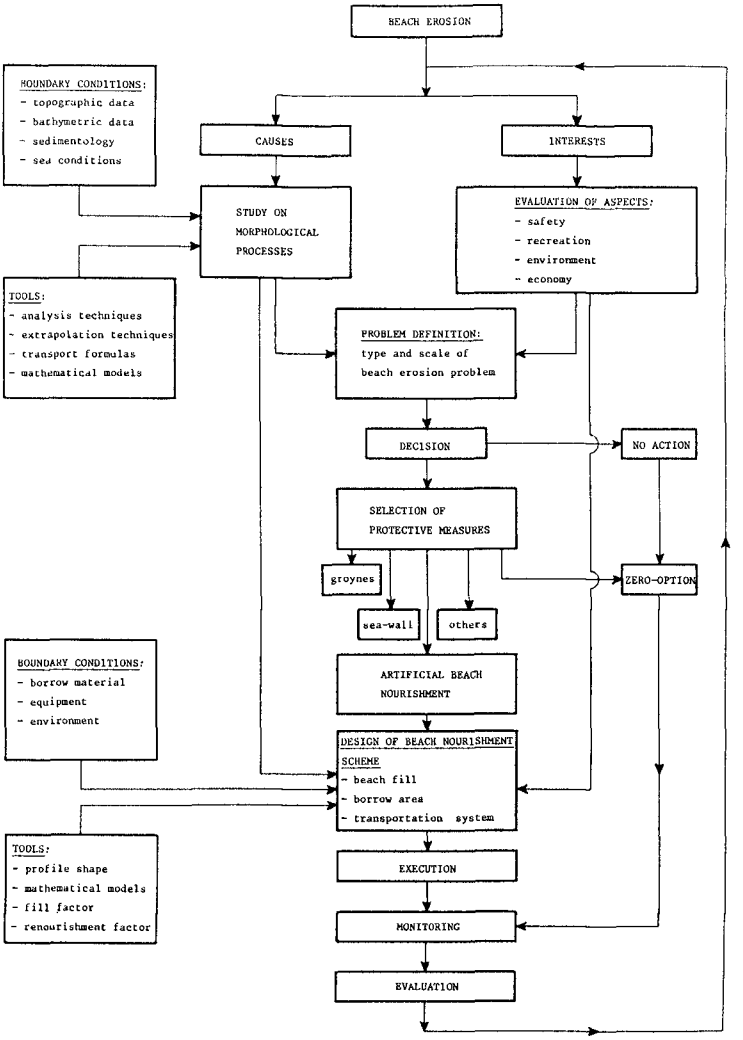

Figure 1 Process of design, execution and evaluation

The causes of beach erosion are determined in a study on morphologic processes, including the analysis of hydro-sedimentological data and the hind- and forecast of the coastal development by means of extrapolation techniques and mathematical models.
Once the problems have been defined, like short-term or long-term erosion (Figure 2), a decision can be made whether or not protective measures should be taken, and if so, which type of measures should be applied (beach nourishment, groynes, detached breakwaters, seawalls, revetments, etc.).

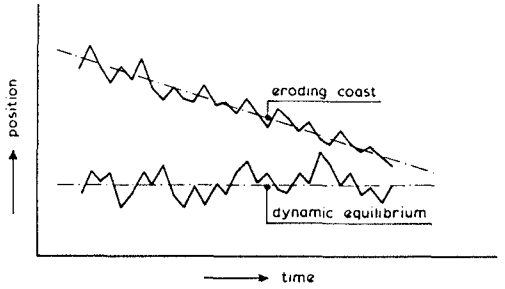

Figure 2 Short-term and long-term coastline variations

Aspects such as effectiveness, flexibility, spreading of cost, executi-on, harmony with nature, environment, etc., should be considered before selecting the protective measure (Figure 3).

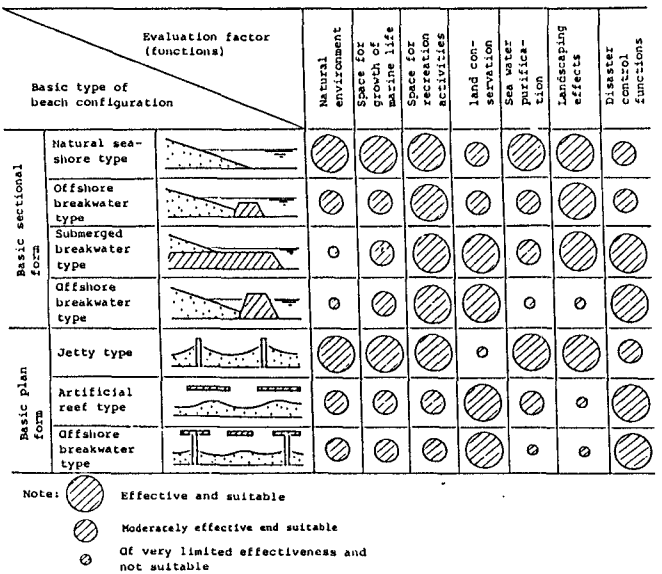

Figure 3 Selection of beach protection measure for project at Yokohama. (Kobayashi et al., 1985)

In this paper only attention is paid to the design of artificial beach nourishment schemes, for which three design elements can be distinguished, viz. the beach fill, the borrow area and the transportation system. The dimensions of the fill should be such that the effectiveness as a coastal protection is guaranteed during a pre-defined period of time. Different tools are available to determine the deformation of the fill as a function of the hydraulic boundary conditions and the applied borrow material (mathematical coastal morphology models, adjusted SPM fill factor and renourishment factor, see Manual (1986) and Shore Protection Manual (1984)).
The selection of the borrow area and the transportation system depends among other things on the available fill material, the influence of the borrow area on the coastline, the local conditions and regulations, the available equipment and the execution method.
It is recommended, that after execution of the beach nourishment, regular surveys are executed to monitor the behaviour of the beach fill and borrow area.

5 Design of beach fill

5.1 Introduction

A major question concerning the design of a beach nourishment is the determination of the required volume of sand, such that the beach fill satisfies the specified requirements during a specified time. As a result of the sand transport in the coastal zone, the beach fill will be reshaped, and possibly sand is leaving the area to be protected. In particular a sand fill placed on an eroding beach, which is the usual case, has a restricted lifetime.
For the design of a beach fill it seems convenient to make a distinction between cross-shore transport and longshore transport. The cross-shore transport is responsible for the shaping of the coastal profile till more or less an equilibrium form is attained. Due to this profile development a retreat of the shoreline may occur. Usually the longshore transport is the main agent in the reshaping of the planform of the beach fill. As a result of this reshaping of the planform sand may leave the coastal area to be protected, while on the other hand sand may also enter the protected coastal area.

5.2 Coastal profile of beach fill

The required volume of sand for a beach fill is to a large extent determined by the development of the coastal profile. In this connection different aspects can be considered, viz. the shape of the active profile as a result of the prevailing hydraulic forces, and the depth to which this profile will develop. Below this depth usually a transition zone has to be defined which meets the original profile.

Shape of active profile:

Many researches have studied the development of coastal profiles under wave attack in order to derive relations between profile shape, wave motion and sediment characteristics. Most of the derived relations are based on the results of small-scale tests in wave-channels. However, the inevitable scale effects and the strong schematization of the conditions in the model do not permit an exact extrapolation of the data to nature. The schematization applies to both the sedimentologic and the hydraulic conditions. In models mostly one type of sand is used as bed material,

whereas in nature the sediment characteristics vary often strongly along the profile. In addition the results of model testing have usually been obtained by applying fixed wave conditions, while in nature the wave conditions are quite variable. As a matter of fact the whole wave climate is responsible for the shape of the coastal profile, while also other factors play a role, like tides, surf beats, coastal currents, etc. Obviously the complexity of the factors has also caused that the analyses of measurements in nature have not led to applicable relations for predicting the shape of coastal profiles.

In case a former situation of the beach should be restored it is obvious to start from the coastal profile at that time, if available. The difference between this former coastal profile and the present profile then equals the volume of sand to be supplied per unit length of beach, provided that the borrow sand is similar to the native sand. If the former profile is not known it can be assumed that the coastal profile will develop according to the present profile up to a certain depth.

The native profile and its dynamics are important to estimate the eventual shape of the beach fill. From curve-fitting on numerous profiles Dean (1983) and Moore (1982) developed an usable relation representing the effect of the particle diameter on the beach shape (see Figure 4):

$$h(y) = Ay^m \approx By^{2/3} D^{1/3} \qquad (1)$$

where h is water depth, A is a constant roughly proportional to $D^{1/3}$ and should be determined for each particular case, D is particle diameter, y is distance from water line, m is exponent (usually assumed equal to about 2/3), B is an unknown factor which has to be determined for each specific case.

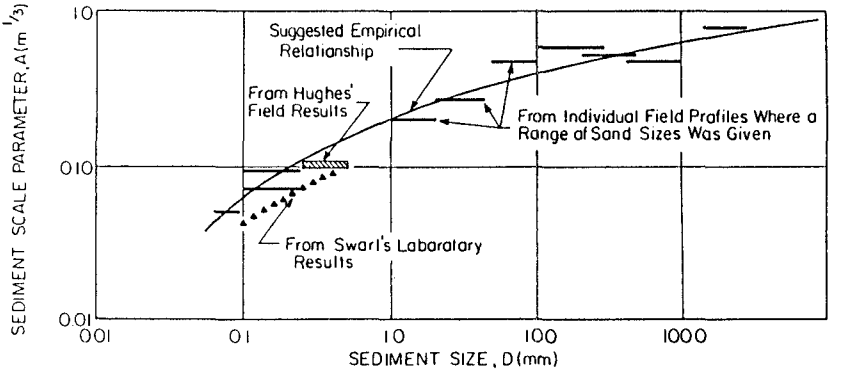

Figure 4 Value of A in $h = Ay^m$ versus sediment size (Dean, 1973, modified from Moore, 1982)

Generally the profile adapts itself rather quickly to the actual wave impact. Erosive profiles occur under severe wave conditions and lead to so-called bar profiles. Accretive profiles are characterized by moderate wave impact and are referred to as step-profiles. Graphs of Dalrymple and Thompson (1976) give a rather illustrative picture of the influence of the wave-grain size parameters on the slope of the profile, both for model and prototype conditions (see Figure 5).

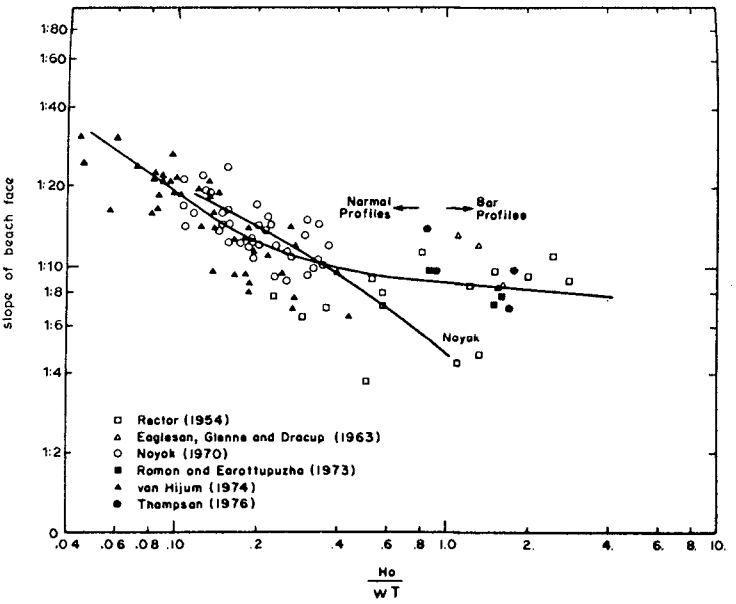

Figure 5 Beach slope versus fall velocity parameter (Dalrymple and Thompson, 1976)

Quite often the borrow sand will not be similar to the native sand, and then it is to be expected that the ultimate profile will differ from the present one. For an estimate of the new profile use can made of the scale relationship for the profile steepness as derived from extensive tests of dune erosion at different scales (Figure 6, see Vellinga (1982)). This relation is as follows:

$$\frac{n_l}{n_d} = \left(\frac{n_d}{n_w^2}\right)^{0.28} \tag{2}$$

in which n_l is the horizontal scale, n_d is the vertical scale, n_w is the scale of the fall velocity of the sand, which is related to the median grain diameter D_{50}.

Now the coastal profile of the replenished beach can be considered as a model of the present profile. The vertical scale n_d is directly related to the scale of the wave height thus $n_d = n_H$. Since the beach fill is subject to the same wave conditions as the present beach, it is clear that $n_d = 1$. Consequently:

$$n_l = n_w^{-0.56} \tag{3}$$

This relation should be read as follows. Suppose that the fall velocity of the native sand is w_1 and that of the borrow sand is w_2. If in the present profile the depth contour d is situated at a distance l_1 from

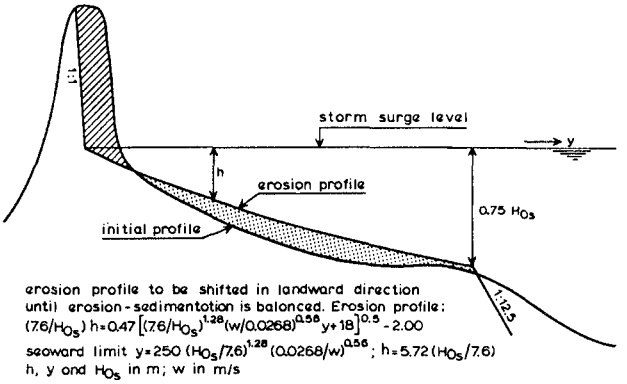

Figure 6 Erosion profile after storm surge (Vellinga, 1984)

the shoreline, then the distance of the same depth contour to the new shoreline of the replenished beach is determined by the relation:

$$\frac{l_1}{l_2} = \left(\frac{w_1}{w_2}\right)^{-0.56} \qquad \text{or} \qquad l_2 = \left(\frac{w_1}{w_2}\right)^{0.56} l_1 \tag{4}$$

The effect of this relation is illustrated in Figure 7. If the borrow sand is coarser than the native sand, thus $w_2 > w_1$, then the profile of the replenished beach is steeper than the original profile, and conversely. It is clearly shown that the use of coarse sand is profitable in view of the required volume of sand to obtain a certain widening of the beach.

It is observed that the method described above provides a fair estimate of the profile shape of the replenished beach. A condition, however, is that representative values for the fall velocity of the native sand and of the borrow sand are applied. This means that, because of the sorting effect of the waves, a large number of samples of the native sand has to be collected and analysed, and this may also apply for the borrow sand. Moreover, because of the handling of the borrow sand, finer parts may be washed out so that the median grain size increases. Because of these reasons an exact prediction of the equilibrium profile of the replenished beach is not possible.

Depth of active profile:

From Figure 7 it can be concluded that it is important to know to which depth the coastal profile will develop. This holds, in particular if the borrow sand is similar or finer than the native sand. In case the profile should develop unlimitedly in seaward direction enormous amounts of sand are needed to obtain a widening of the beach.

It should be stated beforehand that the seaward limit of the profile that is shaped by the action of the waves cannot be ascertained. In first instance the profile will extend rapidly by which sand is removed from the upper part of the profile to deeper water. If the lower limit

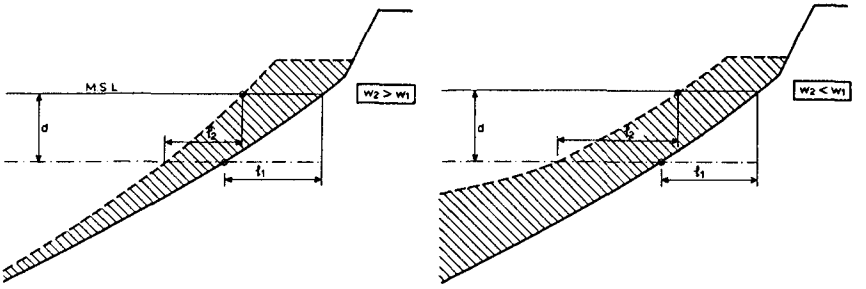

Figure 7 Effect of grain-size on profile steepness

of the developing profile has reached deep water only the infrequent higher waves are able to create offshore transport at that depth. So the development of the profile in seaward direction is slowing down with time, but it is not possible to determine when this process will stop. Nevertheless for the assessment of the quantity of sand needed for a specified widening of the beach, an idea should be achieved of the depth up to which the profile will develop. In case the fill sand is coarser than the native sand, the uncertainty in this depth does not play a prominent role in the determination of the required volume of sand, but it does if the borrow sand is finer.

For an estimation of the lower limit of the active coastal profile use can be made of the relations derived by Hallermeier (1978). He divides the coastal profile into three zones (see Figure 8):

- littoral zone up to depth d_1 with significant alongshore transport and intensive on/offshore transport throughout a typical year;
- shoal zone with significant on/offshore transport up to depth d_I, at which depth expected surface waves are likely to cause little sand transport;
- offshore zone where the surface wave effects on the bed are usually negligible.

In view of the definition mentioned above it is recommended to assume that the active coastal profile will develop up to a depth d_1 by wave action, although below this depth still significant cross-shore transport will occur.

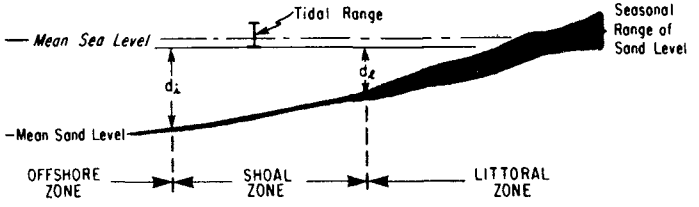

Figure 8 Zonation of seasonal beach profile (Hallermeier, 1978)

On basis of an analysis of available data Hallermeier arrives at the following relation for the lower limit of the littoral zone:

$$d_l = 2.28\ H_s - 68.5\ (H_s^2/gT_s^2) \tag{5a}$$

where d_l is water depth below low water level, H_s is the local significant wave height with a frequency of occurrence of 0.137% (12 hours per year) and T_s is the associated significant wave period.

Birkemeier (1985) has evaluated Hallermeier's method and on the basis of field measurements at the CERC's Field Research Facility in North Carolina. He suggests the relation:

$$d_l = 1.75\ H_s - 57.9\ (H_s^2/gT_s^2) \tag{5b}$$

For a Jonswap spectrum the relation $(H_s/gT_s^2)^{0.5} = 7.1 \times 10^{-2}$ holds good by approximation and for a Pierson-Moskovitz spectrum the relation $(H_s/gT_s^2)^{0.5} = 6.4 \times 10^{-2}$ can be assumed. By substituting these relations into Eq. (5a) it is found that $d_l = 1.93$ or $2.00\ H_s$ and into Eq. (5b) $d_l = 1.46$ or $1.51\ H_s$.
Unless the wave spectrum deviates significantly from the above mentioned spectra, it can be assumed for practical purposes that:

$$d_l = 1.75\ H_{s\ 0.137} \tag{6}$$

It is stressed that H_s pertains to the nearshore wave condition. In case wave condition are only known far offshore, computations are to be done for transferring these data to the nearshore zone.

Transition zone:

If the borrow sand is coarser than the native sand, then the profile of the beach fill may intersect the original profile at a level that is above the profile depth as defined above. In that case the coastal profile is completely fixed. However, in many cases the required intersection between the new and original coastal profile takes place at a lower level. In order to obtain this intersection a transition zone should be defined.
In first instance it seems reasonable to assume that the lower limit of this transition zone is located at the depth d_i so that the boundaries of the transition zone coincide with the boundaries of the shoal zone as defined by Hallermeier (see Figure 8). Hallermeier arrives at the following critical condition for the lower limit of the shoal zone:

$$\phi_c = (U_o^2/\Delta gD) = 8 \tag{7}$$

where U_o is maximum orbital velocity at the bed, Δ is specific density of sand in seawater (= 1.6), g is gravitational acceleration and D is median sand particle diameter.

In Equation (7) the value of U_o is computed according to the linear wave theory:

$$U_o = \pi H/T \sinh (2\pi d_i/L) \tag{8}$$

in which H is annual median significant wave height, T is average wave period associated with the median wave height and L is wave length.

From Equations (7) and (8) it follows that:

$$\frac{2\pi d_i}{L} = \text{arc sinh } \left(\frac{\pi H}{T\sqrt{8\Delta g D}}\right) \tag{9}$$

For known values of H, T and D the value of $2\pi d_i/L$ can be computed.

Measurements seaward of the mouth of the Haringvliet in the Netherlands at a depth of MSL-6 m yield an annual median significant wave height H = 0.55 m with a period T = 3.5 s. Thus for D_{50} = 200 μm the value of d_i = 5.8 m and for D_{50} = 100 μm the value is d_i = 7.1 m. However, the same measurements show that $H_{s\ 0.137}$ = 3.0 m, which means that d_1 = 6.0 m. So d_i and d_1 have virtually the same value in this case, which does not seem realistic. Obviously the relation between d_i, which is the lower limit of the shoal zone in deep water, and the annual median significant wave height does not hold for the observed wave climate in the mouth of the Haringvliet. The relations of Hallermeier are based mainly on wave observations along the U.S. coasts with low wave steepnesses.

Because the relation for the lower limit of the shoal zone, as derived by Hallermeier, cannot be generally applied for defining the lower limit of the transition zone, it is suggested that this lower limit is defined as:

$$d_i = (1.5 \text{ to } 2)\ d_1 \approx 3\ H_{s\ 0.137} \tag{10}$$

The thickness of the beach fill between the depths d_1 and d_i can be assumed to decrease linearly with distance (see Figure 9).

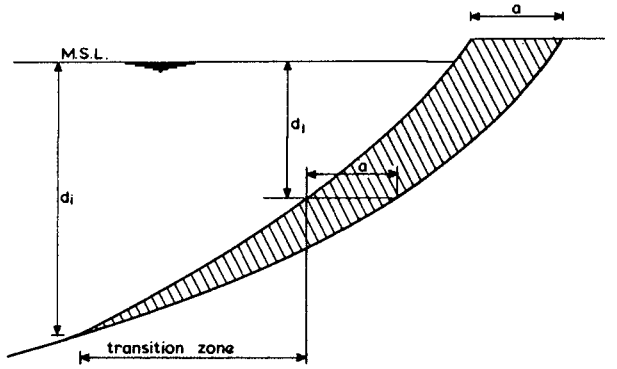

Figure 9 Profile of beach fill, borrow sand equal to native sand

5.3 Adjusted SPM fill factor and renourishment factor

In the Shore Protection Manual (1984) two models are recommended as design tools for beach fills. These models have been developed for the

condition that the textural properties of the borrow sand differ from those of the native sand. The aims of the two models can be defined as follows:

a. The adjusted SPM fill factor (R_A) is used to determine how much overage of borrow sand may be required.
b. The renourishment factor (R_J) is used to determine the relative frequency of renourishment.

Both beach fill models use the mean and sorting values of the composite grain size distributions of the native and the borrow sediments as basic input. This means that careful attention should be paid to the design of sediment sampling plans, since the quality of any beach fill calculation is, at best, only as good as the native beach and borrow composites have been determined. The number of samples to be analyzed for determining the composite grain size distribution depends on the variation of the materials and their individual properties.

Further it is observed that the models only take into account the effect of a possible difference between the properties of the native sand and the borrow sand. Consequently for the application of the models first other aspects of the design of a beach nourishment scheme should be determined, in particular the required volume of sand and the frequency of renourishment in case the properties of the borrow sand and the native sand are similar. For more information regarding the use of the factors reference is made to the Shore Protection Manual (1984).

5.4 Planform of beach fill and mathematical coastal morphology models

During and some time after the placement of a beach fill the reshaping of the coastal profile by onshore/offshore transport is usually the most noticeable phenomenon. However, at the same time the longshore transport will start to reshape the planform of the beach fill, which process may continue for a long period. The effect of the longshore transport on the planform of the beach fill is in particular perceptible at the transition between the replenished beach and the adjacent non-replenished beach. In Figure 11 the morphologic process at the end of a beach fill has been reflected schematically. Because of the replenishment the coastline has moved seaward and a transition zone develops where the direction of the coastline differs from the original direction. In case of a longshore transport from left to right, as drawn in the figure, this longshore transport will be larger in the transition zone due to this difference in coastline direction. The result is that erosion occurs along the left part of the transition zone and accretion along the right part. Because of these processes the transition zone will expand in both directions. If the longshore transport is from right to left, then the coastal development is the same as drawn in Figure 10.

An important question is to predict the dimensions of the initial beach fill, which are required to protect a coastal area during a desired guarantee period. Different methods are available, ranging from simple analytical to sophisticated mathematical, for the prediction of the morphological behaviour of the fill. In the simplest analytical theory, the coast is schematized by one line (Bakker, 1970).

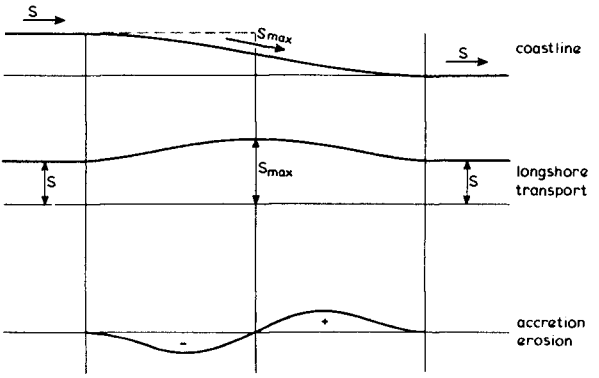

Figure 10 Schematic view of coastal processes at end of beach fill

An example of the one-line theory has been illustrated in Figure 11 for a beach fill with initially a rectangular shape (LxB). This figure shows the parameters B/b (ratio between the initial width B and the minimum required width b), A/a (ratio between the initial area A and the minimum area a) and x_o/L_o as a function of the dimensionless length ℓ/L_o, where ℓ is the length of beach to be preserved and $L_o = \sqrt{4(s/h)t}$, (s is the variation of the longshore transport per radian of coastline rotation, h is the schematized thickness of the active profile and t is time). It will be clear that the coastal stretch where the sand is supplied has to be larger than the area to be protected, in order to account for losses along the sides.

For instance, if the beach area (ℓxb) to be protected during 5 years is 5000 x 50 m^2, while the coastal constant s is 300,000 m^3/rad/yr and the height of the profile is 6 m, then the dimensionless length ℓ/L_o is 5000/1000 = 5. From Figure 12 it can be seen that the initial width of the area should be 1.1 x 50 = 55 m and the extra length at both sides of the fill (x_o) should be 1.2 x 1000 = 1200 m. Consequently the fill should have an area which is about 50% larger than the area to be protected (A/a ≈ 1.5).

This one-line method is rather a strong schematization of reality and the results should therefore be interpreted with care. More sophisticated models give the opportunity for more "taylor made" solutions, as presented in the Manual (1986).

6 Conclusions and recommendations

Generally, artificial nourishment turns out to be a feasible and attractive method to restore, protect, extend and maintain beaches. The essence of the reported advantages are flexibility and harmony with nature. This is concluded after review of literature on about 60 artificial nourishment projects (Manual, 1986).

Inevitably artificial beach nourishment will be applied in the future more and more as standard method for coastal protection and extension of recreational facilities. Whenever technically possible and economically feasible, it is recommended to accomplish the remedy on artificial supply rather than by fixed structures.

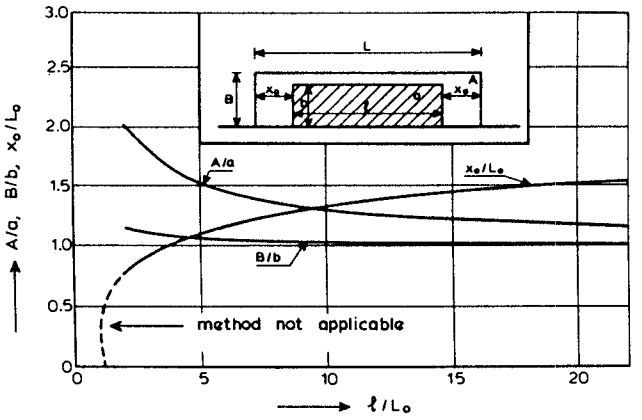

Figure 11 Optimal dimensions of sand supply according to one-line theory

An integral design method for artificial beach nourishment, including all relevant parameters, is not yet available. However, for separate aspects of the design of the beach nourishment various design tools are available, such as models for the prediction of the morphological behaviour of the fill and methods for the determination of the effect of different grain size characteristics.

The performance and deformation of artificial beach fills, which significantly affect the coastal geometry, can be predicted with different tools, ranging from simple to complicated, depending on the boundary conditions of the actual situation. It is foreseen that in future use will be made of two-dimensional horizontal and (quasi) three-dimensional coastal morphological computer models to evaluate the effect of artificial beach fills and to select via comparative computations the optimum location and shape. At the same time it must be stressed that the presently available techniques (long-term coastal monitoring, fill- and renourishment models, profile shape formulations and one- and multi-line models) certainly suffice in the proper cases.

Conclusions about the performance of a fill are often based upon observed changes of only a restricted section of the profile above a certain elevation. Although profile development may extend to greater depths than surveyed, in many cases a reasonable idea is obtained of the performance of the fill. However, it is stressed that surveying of only the subaerial section certainly is insufficient.
Both gradients in longshore transport and severe wave impact generally cause the reported losses. The quantity of sand loss depends on the surveyed profile lengths; therefore care should be taken with the definition of beach loss, since material which is transported further offshore is not necessarily lost for the beach development. Gradients in longshore transport are mostly responsible for "real" losses. It should be stressed that no strict guide-lines can be presented regarding the measurements to be carried out for the evaluation of a beach replenishment project.

Official procedures to attune different projects are still tiresome. In future it will become more necessary to try to use the sand, which comes available from other planned or ongoing dredging projects, for artificial beach nourishment. Material from maintenance dredging should be used after a close examination of its characteristics. Maintenance dredging is normally the removal of siltation which is most of the time odorous and contains a large percentage of fines, which makes it unsuitable for beach nourishment schemes. However, granular material from capital dredging work should well be suitable and could reduce the total coast of a planned nourishment scheme. Therefore it makes sense to enhance the cooperation between the various governmental agencies, who are in charge of such civil engineering projects.

The results of this study underline once again the statement that "still, the more is learned about coastal processes, the more it is realized how little is known yet". Because of the complexity of the problem and its world wide importance, close international co-operation in this field is strongly recommended.

CHAPTER 108

Analysis of a Beach Quality Problem

Gordon K. Prestedge*, M.ASCE and
Christopher A. Fleming**

A study was recently undertaken to investigate sediment transport on a section of coastline where recreational beaches have experienced periodic erosion. Alongshore, onshore/offshore and aeolian sediment transport processes were investigated and quantitative transports predicted with the aid of calibration using surveys and aerial photographs. This paper describes the study and the recommendations proposed for beach quality improvements.

Introduction

Recreational Beaches at Port Elizabeth, South Africa, consist of small sandy areas on an otherwise rocky section of the Algoa Bay coastline (Figures 1 and 2). The natural beaches, Pollok, Hobie and Humewood (shown on Figure 2) have been plagued by loss of sand and exposure of cobbles and rock sub-strata at times. Poor quality of the beaches particular during peak summer periods has become a matter of considerable public concern. A study was initiated to investigate the macro sediment regime on this coastline, understand the root cause of the problem and put forward proposals for beach improvement measures. The possibility that stabilisation of the headland bypass dunefield in 1968 at Cape Recife has aggravated the problem as well as the impact that a proposed boat launching facility would have on the adjacent beaches was also considered.

Nearshore Wave Data

To be able to determine the wave conditions at the nearshore sites of interest it was first of all necessary to select appropriate offshore wave data. Offshore wave data was obtained from measurements at the site of oil exploration platforms that had been operating for several years in an area south-west of Algoa Bay. Significant wave heights and peak energy wave periods obtained from the Waverider records were combined with concurrent visual observations of wave direction taken from the rig. The deep sea wave rose is shown in Figure 1. The data set of wave height, period and direction for the deep ocean conditions obtained in this way provided an excellent definition of deep ocean wave conditions which were refracted on a record-by-record basis to thirteen nearshore calculation positions along the study coastline. Wave refraction was undertaken using wave ray back-tracking and three-dimensional spectral transfer techniques (Abernethy et al, 1975).

* Associate, Watermeyer, Legge, Pièsold & Uhlmann, Cape Town, Republic of South Africa
** Director, Sir William Halcrow & Partners, Swindon, United Kingdom.

In view of the shape of Algoa Bay and the fact that the majority of energy in the deep ocean was contained in the south-west quadrant, it was important to ensure that a pure refraction model would correctly represent the nearshore wave conditions on the study coastline. An investigation using a combined refraction/diffraction model (Southgate, 1981) as well as pure diffraction (Sommerfeld, 1896) was investigated. It was found that pure diffracted energy would be small in the area of interest for waves with deep ocean directions from the south-west quadrant and for predominant wave periods. Owing to the gently shelving nature of the seabed at Cape Recife, the majority of wave energy would reach the area of interest during south-westerly conditions by refraction alone.

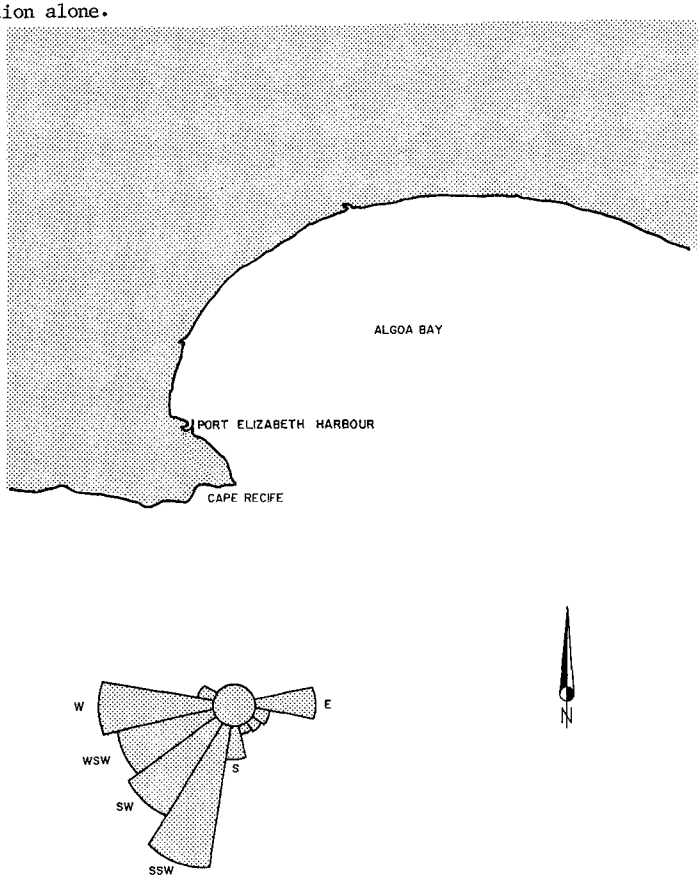

Figure 1. Locality Map and Deep Ocen Wave Energy Rose

Figure 2. Aerial Photograph of Study Coastline

The study coastline is exposed to locally generated wind waves from the easterly sector. A check was therefore carried out using a parametric wind wave hindcasting model to ensure that the locally generated wind wave components were adequately represented in the deep ocean wave data.

Nearshore wave energy roses on the study coastline are shown on Figure 3.

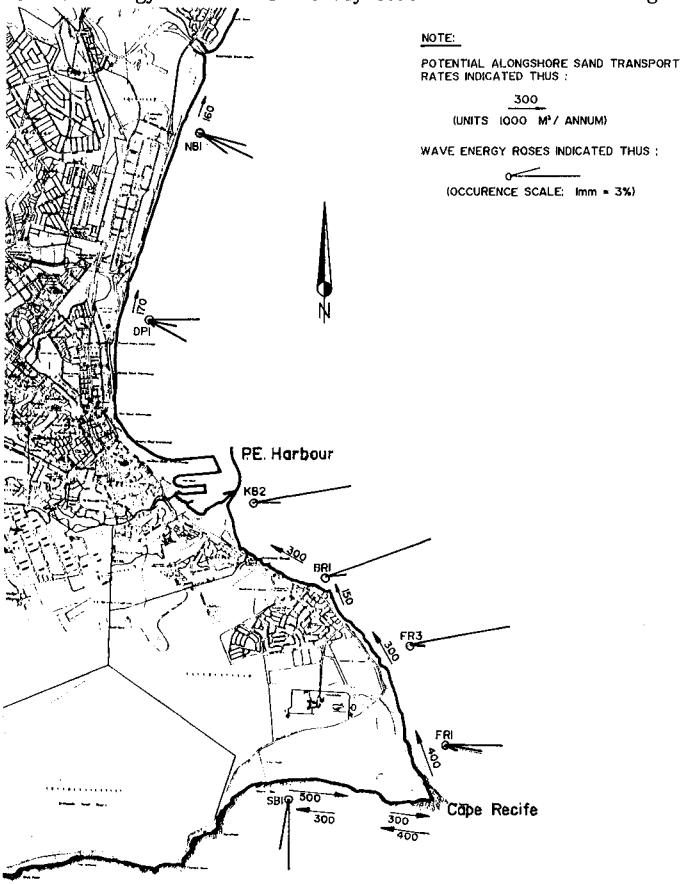

Figure 3. Nearshore Wave Energy Roses and Potential Alongshore Transport Rates

Alongshore Sediment Transport

Alongshore sediment transport was evaluated using three alongshore sediment transport theories after thirteen theories, both bulk and detail predictors had been investigated. The three detailed predictor theories used were as follows:

- Engelund and Hansen as adapted by Swart
- Neilsen
- Swart and Lenhoff (Swart, 1980)

The wave data was arranged in statistical groups of 15° directional increments, 0,5m wave increments and period increments ranging from 1 to 3 seconds. The wave data used represented an average year based on all available deep ocean data. For the detailed predictor type transport models each profile was divided into a number of sand transport zones. From each transport zone local wave conditions were determined from the nearshore wave statistics at the nearshore calculation positions and from refraction and shoaling between the calculation positions and the transport zones. The location of the breaker line was determined by considering refraction and shoaling in relation to input data.

Transport rates obtained from the theories were compared with historical information on the rate of accretion at Kings Beach, the location of which is shown in Figure 2. Port Elizabeth harbour was constructed in 1931 and has formed a total barrier to alongshore transport in this area. Various surveys of the area have been carried out over the years and this has permitted the volume of sand trapped south of the harbour to be quantified. The results are shown in Figure 4. From this information and harbour records (which indicated that a certain amount of sand has permeated the breakwater and has been removed by dredging from the harbour side of the breakwater), a best estimate of the average alongshore sand transport rate at King's Beach of 180 000 cubic metres per annum was established.

The headland bypass dunefield at Cape Recife was stabilised in 1968. It had been suggested that that may have been the cause of beach erosion problems. However dune stabilisation does not appear to have signficantly affected the rate of accretion of sand at King's Beach in recent years. An aeolian transport analysis (Swart, 1985) of the rate at which sand was likely to have been transported across the headland bypass dunefield to the study coastline prior to stabilisation, was undertaken. It was found that the rate of supply of sand from such sources was likely to have been of the order of about 30 000 cubic metres per annum.

It appears therefore that approximately 150 000 cubic metres of sand is at present still being fed to the study coastline from the area west of Cape Recife by wave-induced transport around the gently shelving seabed area in the vicinity of the Cape.

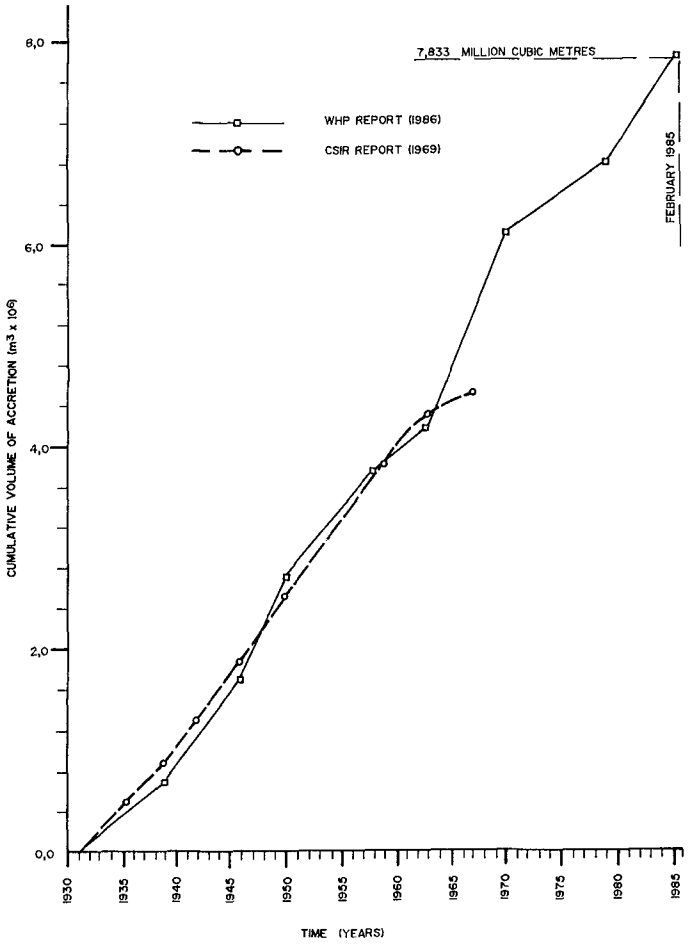

Figure 4. Cumulative volume of Accretion at King's Beach

Theoretically predicted transport rates were calibrated with the aid of data obtained from accretion at King's Beach and it was found that in order to match measured alongshore transport rates, consideration had to be given to saturated wave spectra effects in shallow water after Bouws et al 1985 who developed the TMA spectrum by applying the Kitaigorodskii et al 1975 depth dependant term to the Jonswap spectrum. In this case a nominal nearshore water depth of 6m was used. Considerations of similar analyses for all the shoreline sections led to the derivation of a sand budget based on the variation in alongshore transport obtained from the model. Alongshore sand transport rates are shown in Figure 3.

A large portion of the study coastline is rocky so that it is important to distinguish between the "potential" alongshore sand transport rate and the actual alongshore sand transprot rate. Sand can only be transported at the calculated potential transport rate if sufficient sand exists on the coastline. If insufficient sand exists such as on a rocky coastline, then the actual transport rate would be less than the potential rate and limited to the rate of supply of sand to the coastline from further updrift. The rate of supply is currently estimated to be 150 000 cubic metres per annum despite the stabilisation of the headland bypass dunefield at Cape Recife. Potential transport rates of up to 450 000 cubic metres per annum were calculated.

The apparent net transport rate from east to west in the area immediately west of Cape Recife, is hypothetical since during conditions that produce transport to the east, sand is carried past the headland and northwards along the study coastline and that sand is not available to be moved westwards under westerly transporting conditions.

It was found that for all conditions alongshore transport was northwards on the study coastline between Cape Recife and the harbour.

Onshore/Offshore Sediment Transport

Onshore/offshore sediment transport (Swart, 1985) was used in a qualitative application to examine the response of the beach to storm waves. Calibration required in order to obtain quantitative results was not possible in this case in view of the presence of cobbles and bedrock close to the beach surface which at present prevents full development of the equilibrium profiles. Observations of the beaches after recent major storms were however useful for comparison with theoretical predictions and for evaluating the depth of sand cover required to accommodate beach profile fluctuations without exposing rocky and sub-strata cobble layers.

The beach quality problem accordingly appeared to be the result of a lack of retention of sand on the beaches and not the result of a lack of supply of sand to the coastline.

Beach Processes

It is concluded that the only reason why Pollok Beach, Hobie Beach and Humewood Beach exist is that each is formed by a rocky headland behind which sand is trapped (pocket beaches). If these headlands did not exist there would be no beaches. The rocky headlands are not large enough to trap sufficient sand to ensure sandy beaches under all normal weather conditions. During locally generated wind waves from the east and south-east, the steep storm waves move sand offshore and expose the bedrock and cobbles frequently.

The object of the proposed recommendations are therefore to extend the natural rocky headlands responsible for the creation of the beaches and thereby trap a larger reservoir of sand and in turn enable the beaches to respond to the cyclic onshore/offshore movement of sand under normal storm conditions. This solution would be one of emulating the natural processes and simply trapping larger volumes of sand on the beaches and reducing the occurrence of stony beaches to rare occasions after very stormy seas.

Proposals had also been made previously for the construction of a small boat harbour on this section of coastline and these proposals were investigated in relation to the observed nearshore beach processes. It was advised that a large harbour should not be constructed as this would tend to cut off the alongshore sand transport to beaches downdrift. Furthermore all beach structures should be of minimal length and care should be taken that structures did not divert sand offshore particularly in areas where the seabed dips steeply seawards.

Proposed beach improvements at Pollok Beach, Hobie Beach and Humewood Beach are shown in Figures 5, 6 and 7 respectively. Improvements proposed at Hobie Beach were augmented with an offshore breakwater to improve the launching of small sailing boats from that beach.

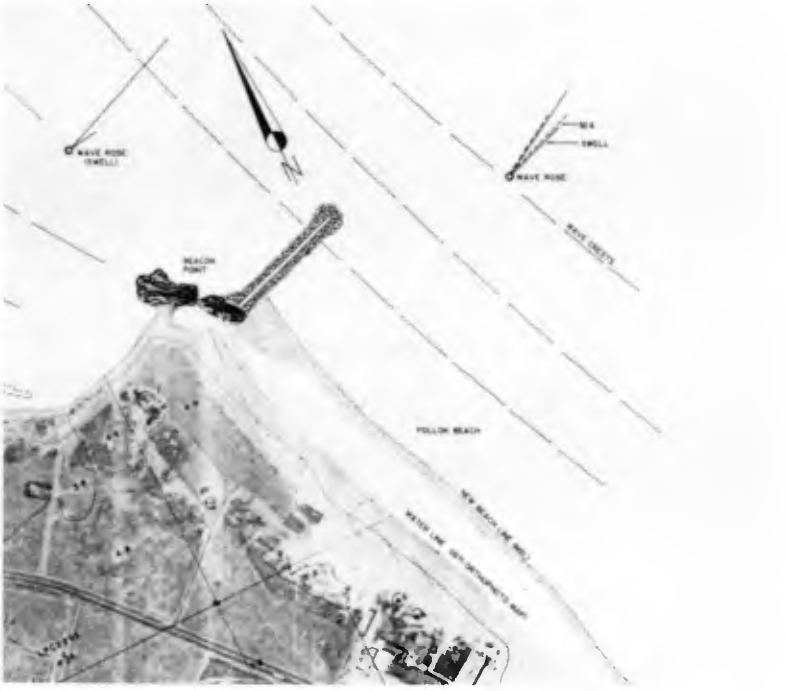

Figure 5. Proposed Headland Extension at Pollok Beach

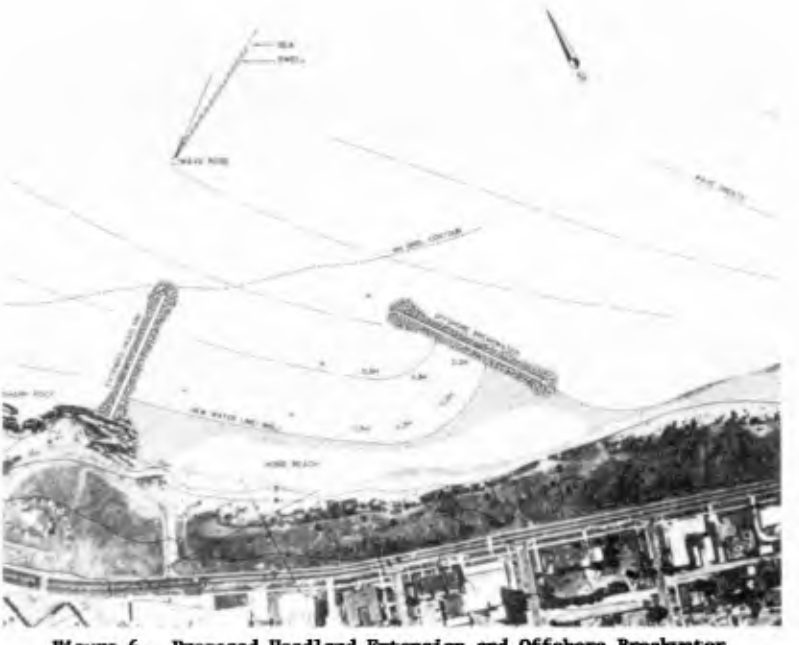

Figure 6. Proposed Headland Extension and Offshore Breakwater at Hobie Beach

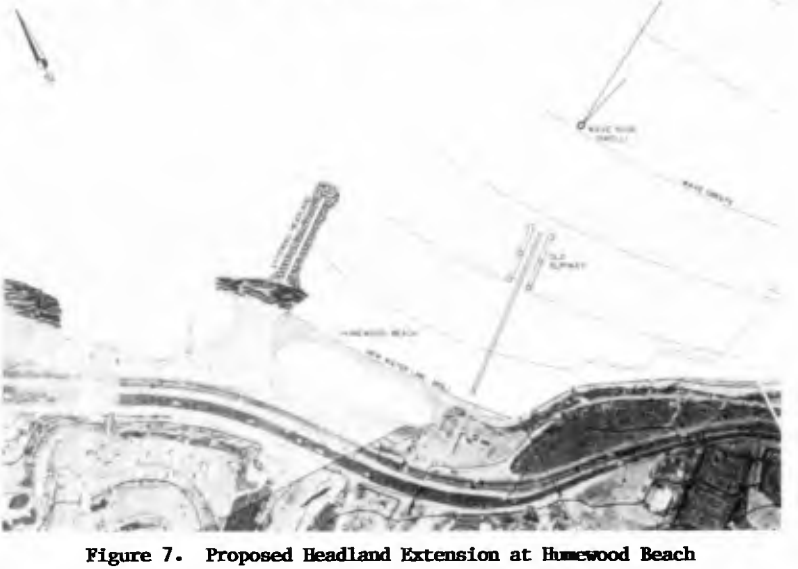

Figure 7. Proposed Headland Extension at Homewood Beach

Conclusions

Beach erosion problems on the southern beaches of Port Elizabeth were found to be caused by an inadequate reservoir of sand on the beaches. The existing reservoir was found to be unable to accommodate the natural beach changes which occur in response to variations in the wave climate. Extensions of the rocky headlands at these beaches would result in more sand being held on the beaches. It was found that an adequate supply of sand is supplied to the study coastline and transported along the coast by wave action to fill and maintain the beaches after the headland structures are built.

CHAPTER 109

LABORATORY STUDY ON SAND TRANSPORT OVER RIPPLES DUE TO ASYMMETRIC OSCILLATORY FLOWS

Shinji Sato* and Kiyoshi Horikawa**

ABSTRACT

Mechanism of sand movement due to asymmetric oscillatory flows was investigated through experiments. Measurements of bed forms, suspended sand concentration and net sand transport rate were carried out by using an oscillatory flow tunnel. The process of entrainment and suspension of sand above asymmetric ripples was quantitatively described. The geometry of ripples and the net sand transport rate in regular and irregular flows were expressed in terms of hydraulic parameters characterizing the oscillatory flow. Two-dimensionality of ripples was found to be an important factor in the estimation of the net sand transport rate.

1. INTRODUCTION

In order to predict sediment transport and wave attenuation over a sand bottom, it is of great importance to understand the geometry of bed forms and the mechanism of sand suspension. Sand ripples are frequently observed to be asymmetric in shallow water region where velocity histories near bottom become asymmetric owing to the nonlinearity of surface waves and superimposed currents. The asymmetry of flows and ripples is considered to exert crucial influences on the direction and the net rate of sand transport in the on-offshore direction. Although several models have been proposed for the sand transport rate over ripples on the basis of experimental results [*e.g.* Sunamura(1980)], the validity of these models is not fully verified owing to the lack of reliable data of the sand transport rate.

The present study attempts to investigate the sand movement over ripples due to asymmetric oscillatory flows. A series of experiments are conducted under the conditions of regular and irregular asymmetric oscillations by using an oscillatory flow tunnel. Detailed measurements of bed forms are carried out for each run of the experiments to elucidate characteristics of the sand ripple geometry and the net sand transport rate. The influences of the asymmetry and the irregularity of velocity histories on the shape of ripples as well as the resultant net sand transport rate are discussed for a wide range of conditions. The process of sand suspension under asymmetric oscillations is also described through the measurements of the suspended sand concentration.

2. EXPERIMENTAL PROCEDURES

2.1. FACILITIES AND CONDITIONS OF EXPERIMENTS

Experiments were performed in an oscillatory flow tunnel which consisted of a loop of closed conduits and a hydraulically-driven piston whose motion was arbitrarily controlled by input voltage signals. A section of the tunnel was covered with glass side walls and removable acrylic ceilings. The beds in this section were composed of wooden plates as

* Research Associate, Dept. of Civil Eng., Univ. of Tokyo, Bunkyo-ku, Tokyo, 113 JAPAN.

** Professor, ditto.

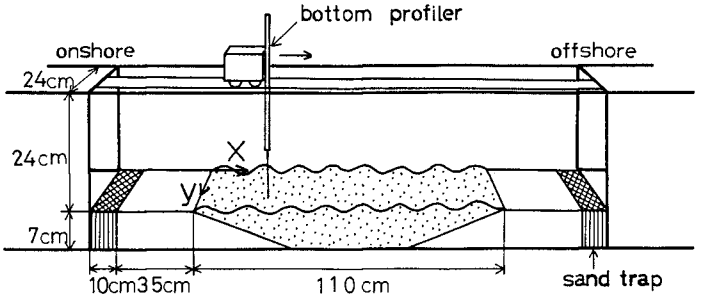

Fig. 1 Experimental set-up.

illustrated in Fig. 1. The central region of the beds was lowered with mild slopes at both ends, in which well-sorted sand with median diameter 0.18 *mm* was filled to make initially flat test bed. Sand traps were installed at both ends in order to trap the sand that would otherwise move out of the test section.

Experiments were carried out for regular and irregular oscillations. The input signals were simulated by using a digital computer, in which time histories of the displacement of water particles under waves were calculated on the basis of linear and nonlinear wave theories. Velocity histories of regular oscillations were simulated on the basis of the fifth-order Stokes or the third-order cnoidal wave theory. Six signals involving various degrees of nonlinearity were created, in which three signals were simulated by using the Stokes wave theory and the other three signals were simulated by the cnoidal wave theory. Figure 2 shows a typical velocity history calculated by the cnoidal wave theory, in which u_c is the maximum onshore velocity, $\hat{u}$ is the total amplitude of the velocity variation and ω is the angular frequency of the oscillation.

It is also of importance to understand the sand movement under irregular oscillations. However, it is not easy to calculate the velocity variations due to nonlinear irregular waves. In order to incorporate the effect of the nonlinearity in a simple manner, wave-by-wave approach was attempted in the present study. Since each wave crest propagates like an independent wave in the very shallow water region, velocity variations can approximately be calculated by applying the regular wave theory to each wave. On assuming the Bretschneider-Mitsuyasu spectrum, variations of the surface elevation were numerically simulated. Each wave was defined by means of zero-up-crossing method and a series of couples of wave heights and periods were obtained. Velocity histories of each wave were then calculated by using the Stokes or the cnoidal wave theory on the assumption that each wave was an independent regular wave. Velocities of each wave were connected at zero-up-crossing points to produce a continuous velocity history as shown in Fig. 3.

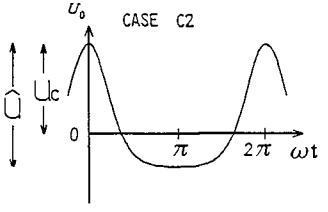

Fig. 2 Velocity history of regular asymmetric oscillations.

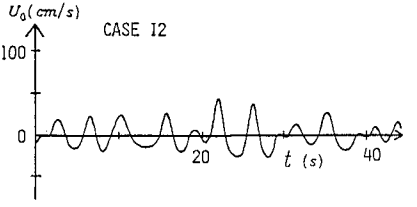

Fig. 3 Velocity history of irregular asymmetric oscillations.

Experimental conditions are listed in Table 1, in which T is the mean period of the oscillatory flows and d_0 is the mean total displacement of the oscillations. The total number of experimental cases is 50 cases for regular oscillations and 25 cases for irregular oscillations.

2.2. NET SAND TRANSPORT RATE

Measurements of bed forms and the net sand transport rate are of practical importance in connection with the calculation of beach profile change. In order to estimate the net sand transport rate over large-scale steady-state ripples in a high accuracy, the following procedures were developed in the present study by combining sand traps and detailed measurements of the bed topography.

(1) Initially flat test bed is exposed to the action of oscillatory flows until steady-state bed forms develop.

(2) Bottom profiles of the test bed are measured in detail and sand transported out of the test bed is removed.

(3) The action of the oscillatory flow is continued for an additional duration Δt.

(4) Bottom profiles are measured again and the sand transported out of the test bed is collected, which is dried for 24 hours in a drying kiln.

The difference of sand surface level $\Delta h(x,y)$ (positive accretion) and the dry mass of sand collected at onshore and offshore ends, m_{on} and m_{off}, are evaluated through the procedures described in the above. Mass conservation of sand leads to

$$(1-\lambda_v)\int_0^B\int_0^L \Delta h dx dy + (m_{on}+m_{off})/\rho_s = 0 \tag{1}$$

where (x,y) indicate the coordinates as in Fig. 1, B and L are the width and the length of the test bed respectively, $\lambda_v(=0.4)$ is the porosity of the sand and ρ_s $(=2.64g/cm^3)$ is the density of sand. The net sand transport rate q_x at x (positive onshore) is evaluated by

$$q_x(x) = \left(\int_0^B\int_0^x (1-\lambda_v)\Delta h dx dy + m_{on}/\rho_s\right)/(B\Delta t) \tag{2}$$

Table 1 Experimental conditions.

Regular oscillations

	$u_c/\hat{u}$	T(s)	d_o(cm)	
RL	0.5	1 - 7	5 - 65	sinusoidal oscillations
S1	0.555	3 - 5	17 - 51	simulated by the Stokes wave theory
S2	0.570			
S3	0.626			
C1	0.639			simulated by the cnoidal wave theory
C2	0.722			
C3	0.831			

Irregular oscillations

	$u_c/\hat{u}$	T(s)	d_o(cm)	
IL	0.5	3.90	16 - 51	symmetric oscillations
I1	0.52	3.68	27 - 51	asymmetric oscillations
I2	0.60			
I3	0.68			

The net sand transport rate free from the disturbances created at the both ends of the test bed was estimated by means of these procedures. In order to make accurate evaluation of sand volume change, bottom profiles were measured in detail along ten measuring lines with a bottom profiler installed on a self-moving carriage. It was found that the ratio of the residue of Eq. (1) to the evaluated net sand transport rate was about 10 % even for a case in which three-dimensional ripples were developed. The error of the evaluation of the net sand transport rate in the present experiments was therefore considered to be less than 10 %, which was excellent compared with other methods attempted in the previous studies.

2.3. CONCENTRATION OF SUSPENDED SAND

In order to understand the process of sand suspension, the concentration of suspended sand was measured for a case in which typical two-dimensional ripples were developed. The measurements were carried out under asymmetric oscillation of signal C2 with the period and the total displacement of the oscillation being 3 *s* and 24.1 *cm* respectively. Variations of sand concentration were measured at about 100 points above an asymmetric ripple with a light-absorption-type probe whose diameter was 0.3 *cm* at the end of the sensor. Measuring points were arranged in a grid whose spacings were 1 *cm* in x direction and 0.5 to 2 *cm* in z direction. The measuring points closest to the bed were set at 0.5 *cm* above the bed, which was found critical in order not to cause the local scour. Variations of the concentration and the displacement of the piston were simultaneously recorded for 40 *s* and were then converted to digital values with an interval of 0.04 *s*.

3. THE GEOMETRY OF RIPPLES

Sand ripples developed in asymmetric oscillatory flows are generally asymmetric as illustrated in Fig. 4; the flank of a ripple facing onshore being steeper than the other. Since the formation of sand ripples plays an essential role in the sand transport, it is firstly of significance to understand characteristics of sand ripples.

Small scale ripples were developed at the beginning of the ripple formation from initially flat bed. It required 5 to 40 minutes under regular oscillations and 15 to 90 minutes under irregular oscillations until steady-state ripples were developed. The irregularity of waves thus tended to delay the formation of steady-state ripples. This is because the action of each wave is not always effective for the formation of the resultant ripple geometry since the size and the intensity of lee vortices were not uniform under irregular waves.

Two-dimensional ripples as shown in Fig. 4 were developed in 45 cases. Three-dimensional ripples were observed in the other 30 cases in the flow with large Reynolds numbers. Since mechanics of sand movement changes drastically over two- and three-dimensional ripples, it is firstly of importance to understand the condition for the occurrence of two- and three-dimensional ripples.

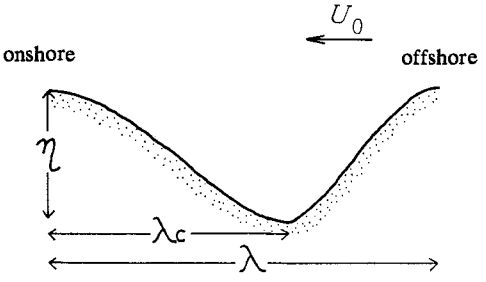

Fig. 4 Schematic diagram of an asymmetric ripple.

Two-dimensionality of wave-generated ripples was systematically discussed by Carstens *et al.*(1969), in which the range of two-dimensional ripples was found to be

$$d_0/D < 1550 \tag{3}$$

where D is the sand diameter. Lofquist(1978) undertook further experiments using an oscillatory flow tunnel and suggested that the two-dimensionality of ripples was dependent on two parameters, d_0/D and $U_0^2/[(\rho_s/\rho-1)gD]$, in which U_0 was the amplitude of velocity histories, ρ was the density of water, and g was the gravity acceleration. Kaneko(1981) classified characteristics of ripples by using $U_0^2/[(\rho_s/\rho-1)gD]$ and D/δ, in which δ was the thickness of the Stokes layer. Transition from two- to three-dimensional ripples was also discussed by Vongvisessomjai(1984), in which relationships for the geometry of ripples in oscillatory flows were proposed in terms of a parameter $U_0/\sqrt{(\rho_s/\rho-1)gD}\cdot d_0/(2D)$.

Relationships between characteristics of ripples and various hydraulic parameters were examined, including new data obtained under the conditions of asymmetric and irregular oscillations [Sato(1986)]. It was found that the most essential parameters to describe characteristics of ripples were d_0/D and the Shields parameter Ψ defined by,

$$\Psi = \frac{1}{2} f_w \frac{U_0^2}{(\rho_s/\rho-1)gD} \tag{4}$$

in which f_w was the friction factor proposed by Jonsson(1966) which was evaluated on the assumption that the bottom roughness was equal to the sand grain diameter.

Figure 5 shows the classification of ripples developed in sinusoidal oscillations in terms of d_0/D and Ψ. Three-dimensional ripples are developed under conditions with large values of d_0/D and Ψ. The boundaries between two- and three-dimensional ripples are well described by the broken lines.

The classification of ripples in asymmetric flows is also made by using d_0/D and Ψ. Figure 6 shows the classification of ripples in asymmetric flows, in which the Shields parameter is evaluated by the following equation:

$$\Psi_{rms} = \frac{1}{2} f_w \frac{(\sqrt{2}u_{rms})^2}{(\rho_s/\rho-1)gD} \tag{5}$$

where u_{rms} indicates the root mean square value of the velocity history.

The wavelength and the wave height of ripples are also formulated in terms of d_0/D and Ψ. Sato(1986) analysed data of ripples obtained in wave flumes, in oscillatory flow tunnels and on natural beaches, in which functional relationships between the ripple geometry and hydraulic parameters were derived as

$$\lambda/d_0 = 1.4(d_0/D\cdot\Psi^{1/2})^{-0.146} \tag{6}$$

$$\eta/\lambda = 0.191(1-(\Psi/0.6)^2) \tag{7}$$

for two-dimensional ripples in regular oscillations and

$$\lambda/d_0 = 350(d_0/D\cdot\Psi^{1/2})^{-1} \tag{8}$$

$$\eta/\lambda = 0.158(1-(\Psi/0.6)^2) \tag{9}$$

for three-dimensional ripples in regular oscillations. Relationships for the conditions of irregular oscillatory flows were expressed by

$$\lambda/d_0 = 3.55(d_0/D\cdot\Psi^{1/2})^{-0.292} \tag{10}$$

for $d_0/D\cdot\Psi^{1/2}<650$ and Eq. (8) for $d_0/D\cdot\Psi^{1/2}>650$, and

$$\eta/\lambda = 0.191(1-\Psi/0.6) \tag{11}$$

where values of d_0 and Ψ were evaluated using significant waves.

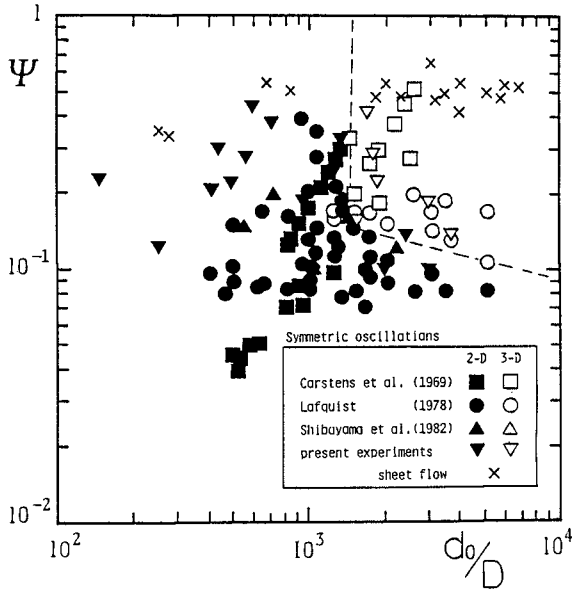

Fig. 5 Occurrence of two- and three-dimensional ripples in sinusoidal flows.

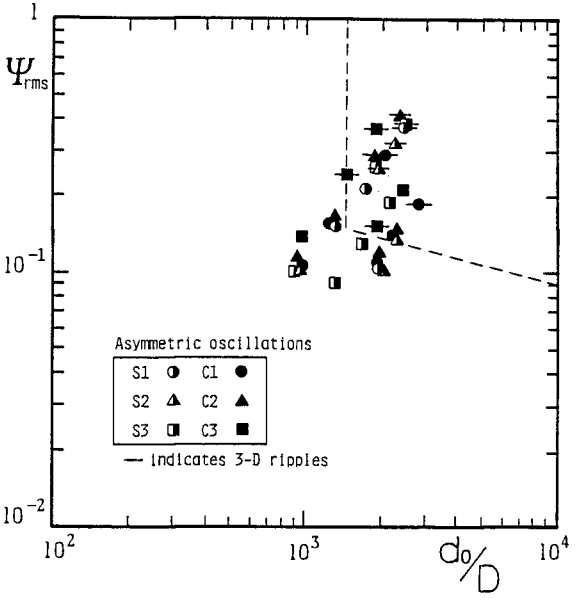

Fig. 6 Occurrence of two- and three-dimensional ripples in regular asymmetric flows.

Figure 7 shows the relationship between λ/d_0 and $d_0/D \cdot \Psi_{rms}^{1/2}$ for the data obtained in the present experiments by using sinusoidal and regular asymmetric oscillations together with existing data in sinusoidal oscillatory flows with sand whose diameter was about 0.2 *mm*. Values of λ/d_0 for two- and three-dimensional ripples are well expressed by Eqs. (6) to (9) with no significant deviations between data in sinusoidal flows and data in asymmetric oscillations.

Figure 8 shows the relationship between the ripple steepness η/λ and the Shields parameter. Values of η/λ are almost constant for both sinusoidal and asymmetric oscillations

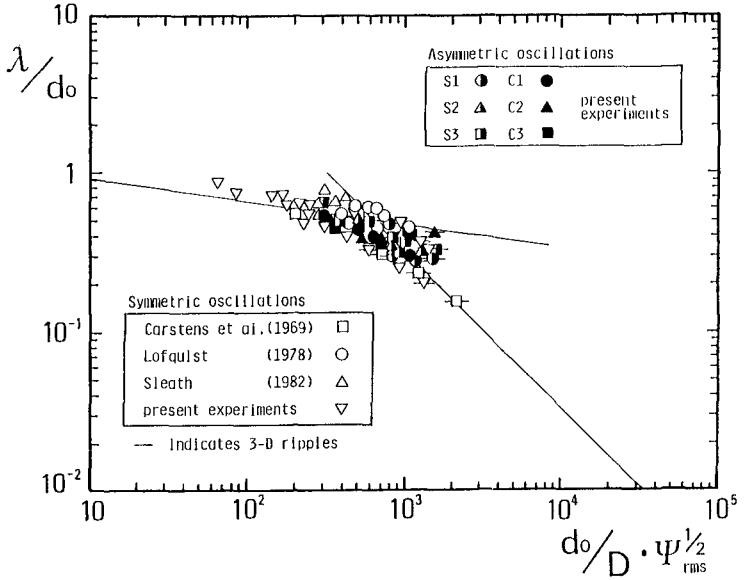

Fig. 7 Relationships between λ/d_0 and $d_0/D \cdot \Psi^{1/2}$ for ripples in regular oscillations.

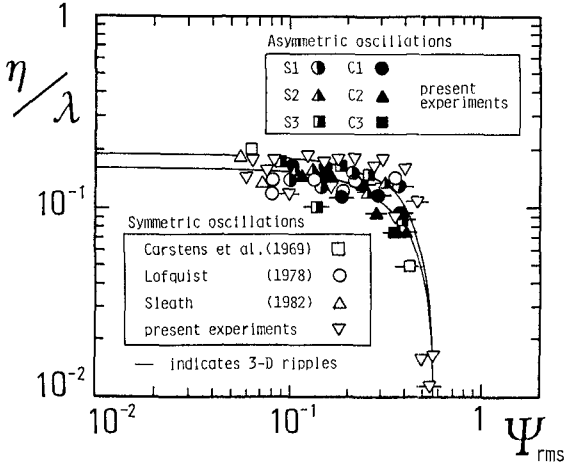

Fig. 8 Relationships between η/λ and Ψ for ripples in regular oscillations.

except in the transition region to the sheet flow. It is confirmed that the ripple steepness in asymmetric oscillatory flows can be consistently predicted by using the Shields parameter.

Figures 9 and 10 show the geometry of ripples in irregular oscillations. It is noticed that the geometry of ripples in irregular flows are also analysed consistently by using two parameters d_0/D and Ψ when these parameters are evaluated by using significant waves. It is found that the wavelength of ripples developed in irregular oscillations is almost the same with that in regular oscillations but the ripple steepness reduces considerably in irregular oscillations, which is consistent with the analysis made by Nielsen(1981).

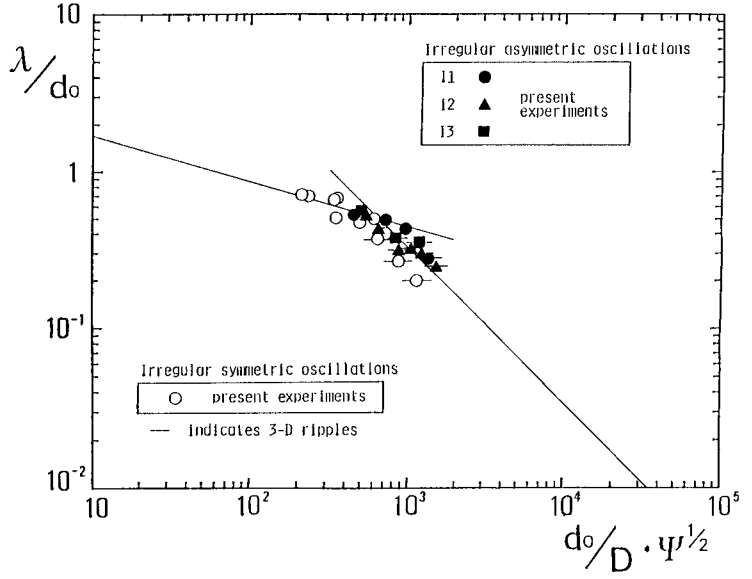

Fig. 9 Relationships between λ/d_0 and $d_0/D \cdot \Psi^{1/2}$ for ripples in irregular oscillations.

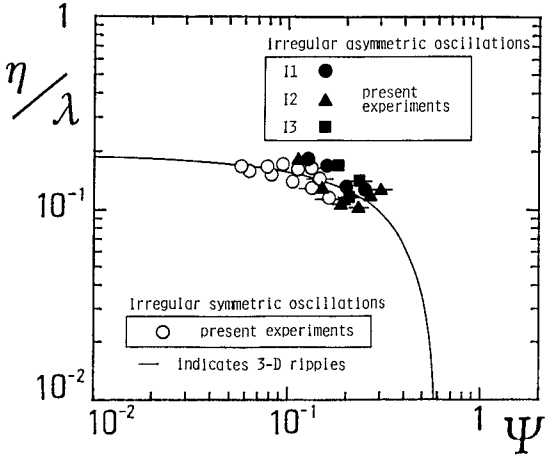

Fig. 10 Relationships between η/λ and Ψ for ripples in irregular oscillations.

The asymmetry of ripples is also of great importance since it exerts strong influences on the formation of lee vortices and in turn on the amount of the net sand transport. Figure 11 shows the relationship between the asymmetry of ripples and that of velocity histories. Data of ripples obtained in the previous experiments by using the same facilities are plotted together. The asymmetry of ripples increases linearly with the asymmetry of velocity histories until it reaches a critical value. On the assumption that the curve of the onshore-facing flank of a ripple is a sinusoidal curve whose maximum slope angle is equal to the repose angle of the sediment ϕ_r, the maximum of the ripple asymmetry is expressed by

$$\left(\frac{\lambda_c}{\lambda}\right)_{max} = 1 - \frac{\pi}{2}\frac{\eta/\lambda}{\tan\phi_r} \tag{12}$$

If values of η/λ and ϕ_r are approximated by the mean values of data in the present experiments, 0.16 and 33 ° respectively, the maximum asymmetry of ripples is estimated as

$$\left(\frac{\lambda_c}{\lambda}\right)_{max} = 0.61 \tag{13}$$

The above relation appears to explain the trend of the experimental data in strongly asymmetric oscillatory flows.

4. DISTRIBUTION OF SUSPENDED SAND CONCENTRATION

It was observed in the experiments that suspended sand clouds of high concentration were formed above two-dimensional ripples and that the sand transport in suspension appeared to contribute as the essential portion of sand movement. In order to predict the sand transport rate over ripples, it is of great concern to estimate the magnitude and the distribution of suspended sand concentration.

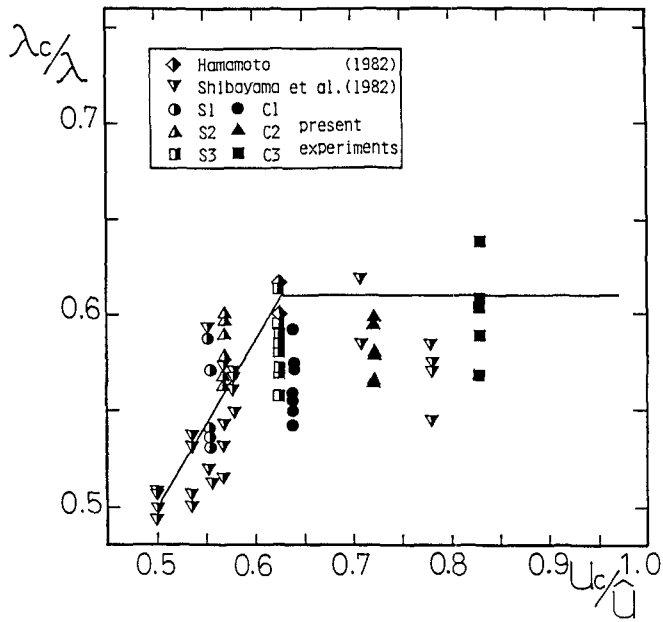

Fig. 11 Relationships between the asymmetry of ripples and the asymmetry of velocity histories.

Distributions of the equi-phase mean concentration were evaluated in order to understand the spatial and temporal variations of suspended sand concentration. Figure 12 illustrates distributions of the equi-phase mean concentration during one period. A suspended sand cloud is formed above the steeper flank of a ripple ($\omega t=\pi/5$) when the direction of the flow is onshore. The cloud is then thrown up over the ripple crest after the flow direction changes ($\omega t=3\pi/5$) and transported offshore. The formation of a sand cloud is not appreciable during the period when the direction of the flow is offshore. The resultant net sand transport therefore becomes to the offshore direction in asymmetric oscillatory flows. It is concluded that the essential portion of sand suspension occurs during the period when the flow direction is onshore. Sand suspension by the strong onshore flow is therefore considered to be of importance in the estimation of the net sand transport rate under asymmetric oscillations.

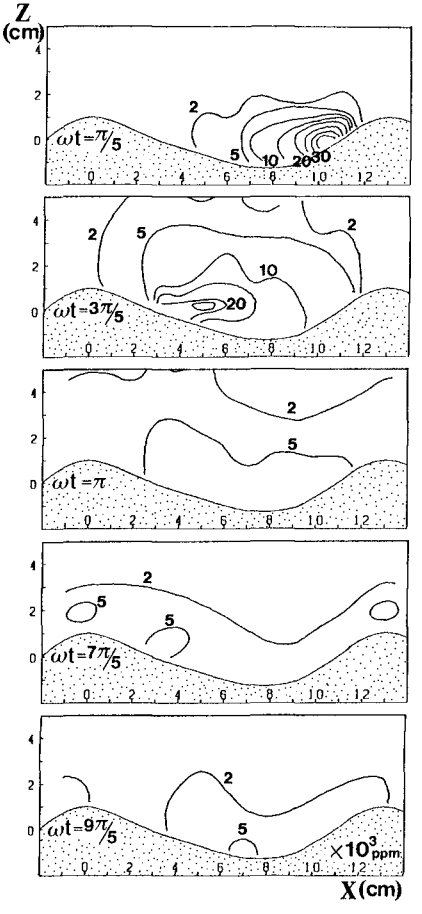

Fig. 12 Distributions of equi-phase mean concentration of suspended sand.

5. NET SAND TRANSPORT RATE

Figure 13 illustrates measured profiles of steady-state ripples developed in a case in which the oscillation was produced by a signal C2. The figure on the bottom indicates the spatial variation of the net sand transport rate q_x evaluated by Eq. (2). The arrows at both ends, $x=0\ cm$ and $x=110\ cm$, represent the volume of trapped sand. Values of q_x are regarded to be almost constant in the central region of the test bed, in which the net sand transport rate free from the disturbance produced at both ends can be estimated. The periodic variations in q_x are considered to be due to the movement of sand ripples. The net sand transport rate Q was therefore evaluated as a mean value of q_x over a region of one wavelength of a ripple at the center of the test bed.

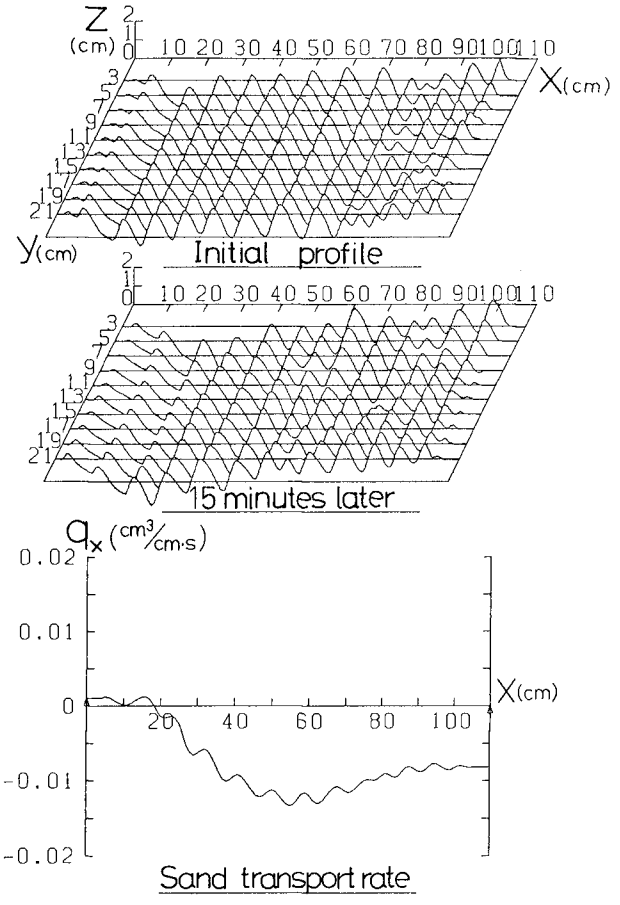

Fig. 13 Measured profiles of bed forms and the net sand transport rate.

Figure 14 shows the variation of the net sand transport rate at various stages in the development of ripples from initially flat bed. Measurements of bottom profiles and collections of trapped sand were conducted at $t/T=150$, 450, 750 and 1050. The net sand transport rate Q was small but positive at the initial stage of ripple formation in which the sand was observed to move dominantly as bed load. The direction of the net sand transport gradually tended to be in the offshore direction with the increase of sand suspension enhanced by the development of ripples until it reached a steady state at $t/T=600$. Since the time required for the development of steady-state ripples is generally considered to be small compared with the duration of steady-state waves on natural beaches, it is practically of significance to elucidate the net sand transport rate over steady-state ripples.

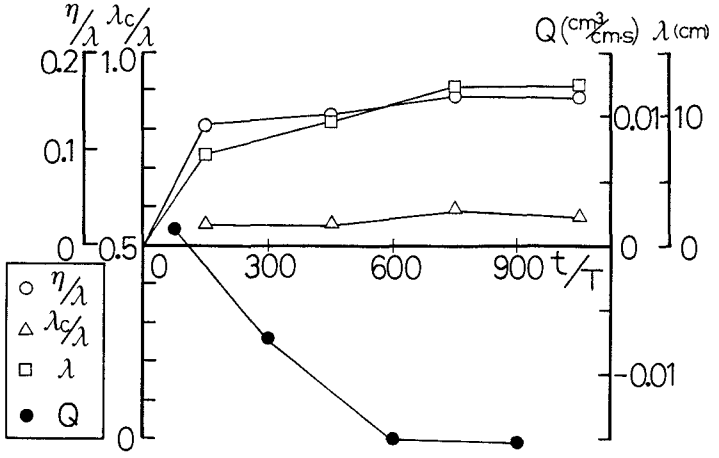

Fig. 14 Variations of the ripple geometry and the net sand transport rate with the development of ripples.

The net sand transport rate over steady-state ripples was in the offshore direction for all the cases in the present experiments. Since sand suspension occurred dominantly above the steeper flank of ripples when the flow direction was onshore, the resultant net sand transport rate was considered to be strongly dependent on the maximum onshore velocity u_c. Figure 15 shows the relationship between the following dimensionless net sand transport rate Φ and the Shields parameter Ψ_{on} evaluated by using u_c:

$$\Phi = \frac{Q}{w_s D} \tag{14}$$

$$\Psi_{on} = \frac{1}{2} f_w \frac{u_c^2}{(\rho_s/\rho - 1) g D} \tag{15}$$

The solid line represents the following empirical relation proposed by Watanabe(1982) on the basis of laboratory experiments of two-dimensional beach deformation

$$|\Phi| = 7(\Psi - \Psi_c)\Psi^{1/2} \tag{16}$$

where $\Psi_c(=0.11)$ represents the threshold of the Shields parameter for the general movement of sand particles. The relation proposed by Madsen and Grant(1976) for the sand transport rate during a half period is also depicted by the broken line,

$$|\Phi| = 12.5\Psi^3 \tag{17}$$

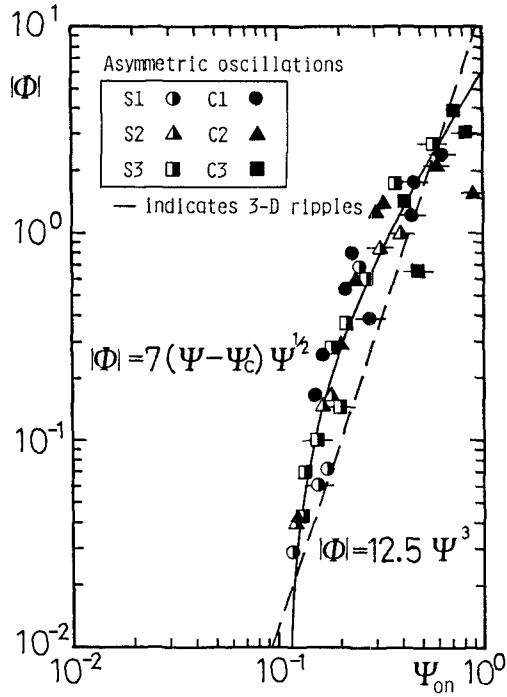

Fig. 15 Relationships between the net sand transport rate and the Shields parameter.

It is found that measured transport rates are expressed well by Eq. (16) for a wide range of conditions. The differences due to the degree of the asymmetry of velocity histories are not recognized but two-dimensionality of ripples appears to be an important factor.

Figure 16 is a comparison between measured net sand transport rates $|\Phi_m|$ and transport rates $|\Phi_c|$ calculated by Eq. (16). The transport rate over two-dimensional ripples exceeds the calculation a little, while the transport rate is found to decrease considerably over three-dimensional ripples. This is considered to be consistent with the observation that sand suspension by coherent vortices is not significant when three-dimensional ripples are developed.

The net sand transport rate under irregular oscillations can be estimated by considering the contributions of each wave in a similar manner with that for the cases of regular oscillations. The net sand transport rate is calculated by

$$\Phi = (\sum_i \Phi_i T_i)/(\sum_i T_i) \tag{18}$$

where T_i represents the period of each wave and Φ_i is the calculated transport rate for each wave calculated by Eq. (16). Figure 17 shows the comparison of measured net sand transport rate $|\Phi_m|$ and the transport rate $|\Phi_c|$ calculated by Eq. (18). Calculated values agree fairly well with measured values for the cases in which two-dimensional ripples were developed. Transport rate decreases considerably under the conditions of three-dimensional ripples.

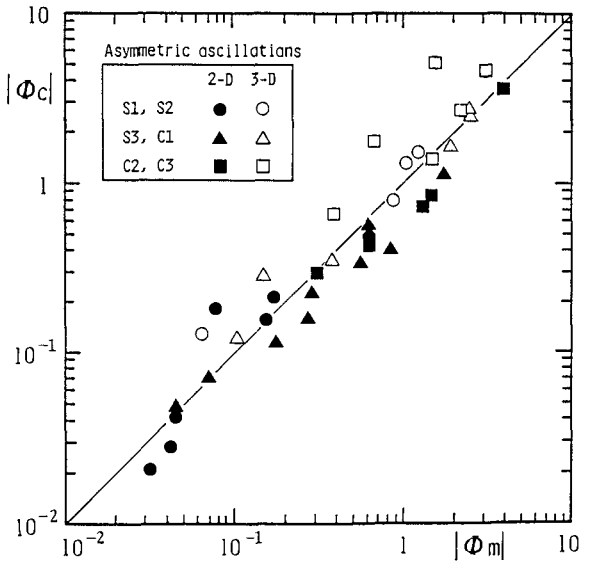

Fig. 16 Comparison of the measured and the calculated net sand transport rate (regular oscillations).

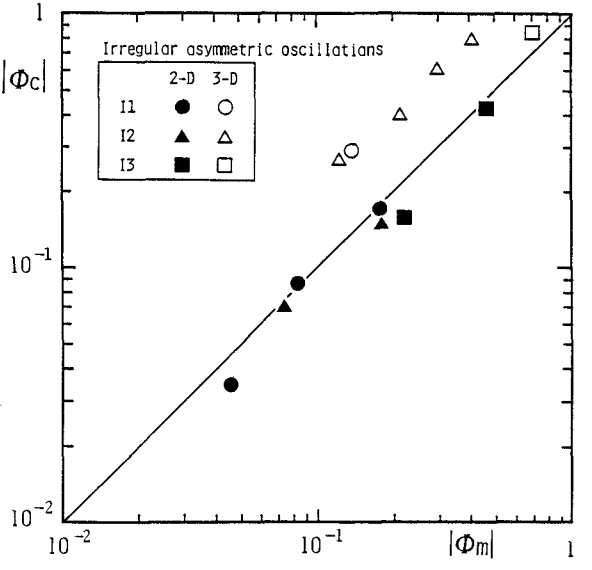

Fig. 17 Comparison of the measured and the calculated net sand transport rate (irregular oscillations).

6. CONCLUSIONS

The mechanism of sand movement due to asymmetric oscillatory flows was investigated on the basis of laboratory measurements. Characteristics of the ripple geometry and the net sand transport rate were discussed in terms of hydraulic parameters characterizing the oscillatory flow. The geometry of ripples in asymmetric oscillations was described by two parameters d_0/D and Ψ for both regular and irregular oscillations. The asymmetry of ripples was found to be dependent on the asymmetry of velocity histories and the repose angle of the sand. The measurements of suspended sand concentration revealed that the asymmetry of flows and ripples exerted strong influences on the formation of sand clouds and that the entrainment of sand by the strong onshore flow was important in the estimation of the sand transport. The net sand transport rate over steady-state ripples was expressed by the Shields parameter based on the maximum onshore velocity. It was found that the net sand transport rate decreased considerably over three-dimensional ripples. Further studies are expected on the measurements under the conditions of much larger bottom shear stresses and the simulation of the nonlinear velocity variation under irregular waves.

CHAPTER 110

MODELING TURBULENT BOTTOM BOUNDARY LAYER DYNAMICS

Y. P. Sheng*, Member ASCE

ABSTRACT

This paper presents a modeling approach aimed at soving a complete hierarchy of turbulent bottom boundary layers which are often encountered in practical coastal and oceanographic engineering problems. The practical problem is extremely complex due to the presence and interaction of competing processes. A comprehensive model is thus needed to first provide fundamental understanding of a variety of turbulent bottom boundary layers before any simple model for the complex problem can be meaningfully constructed. This paper presents a comprehensive second-order closure model of turbulent transport and in addition, discusses some applications of the model to wave boundary layer, wave-current boundary layer, sediment-laden boundary layer and two-dimensional boundary layer. Example is provided to show how such a comprehensive model may be used to guide the development of a simple model.

I. INTRODUCTION

Flow in coastal waters is generally turbulent. A thorough understanding of the dynamics of turbulent bottom boundary layers is of paramount importance in the field of coastal and oceanographic engineering. For quantitative estimation of sediment transport rate and optimal design of structures in coastal waters, it is essential to first estimate the hydrodynamic forces acting on the ocean bottom which may be flat or complicated by the presence of bedforms or structures such as pipelines (Figure 1). The hydrodynamic forces can be produced by slowly varying currents (due to wind or tide) or short-period oscillatory currents (due to linear or nonlinear short-period waves) or a combination of both. When hydrodynamic forces exceed certain critical values, bottom sediments may be eroded and carried into the water column and, consequently, significant suspended sediment concentration and vertical concentration gradient may be produced thus leading to modification of the flow.

Simple Models or Comprehensive Models?

Dynamics of turbulent bottom boundary layers in coastal waters is extremely complex because of the coexistence of many competing mechanisms in turbulent flows: short-period wave, stratification, wave-

*Coastal & Oceanographic Engr. Dept, Univ. of Fla., Gainesville, 32611

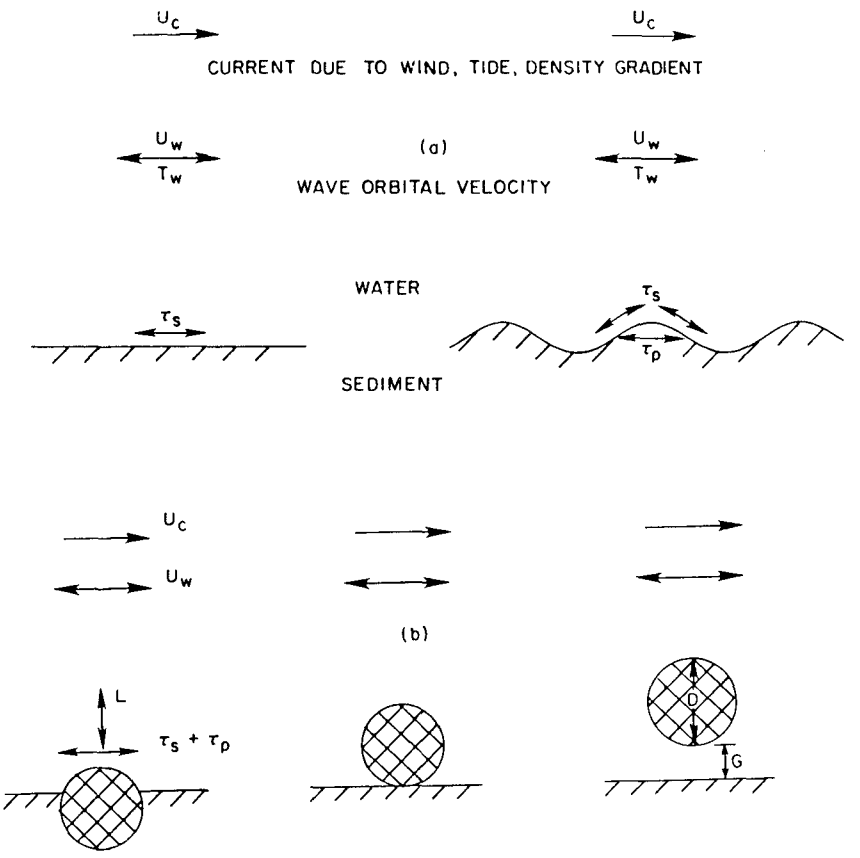

Figure 1 Bottom boundary layer flow over (a) flat and wavy bottom, and (b) flat bottom with pipelines.

current interaction, nonlinearity, and two-dimensional and even three-dimensional effects due to the presence of complex structures or bedforms. A comprehensive model capable of accurately resolving the complex turbulent boundary layer dynamics is urgently needed to provide physical insight and to solve practical engineering problems. Such a model must contain the proper physics of the major competing mechanisms and hence, cannot be necessarily "simple". Despite this fact, however, engineers faced with the complex practical problems in coastal sediment transport and structural design have generally favored the development and use of the so-called "simple" analytical or numerical models which, unfortunately, are often developed at the expense of compromising physics. Indeed, the literature is abound with such "simple" analytical and numerical models for some of the processes described above. For example, since the early eddy-viscosity model of Kajiura (1968), numerous similar eddy-viscosity

models have been developed to simulate turbulent wave boundary layers. Eddy-viscosity models for wave-current interaction (e.g., Bakker and Van Doorn, 1978; Grant and Madsen, 1979) and stratified flow (e.g., Long, 1981) have also been attempted. While these models for individual processes could be calibrated to produce "good" results when sufficient data exist and under limiting conditions, these models generally fail to work when two or more of the competing mechanisms coexist or when little data exist and "prediction" is required. This is primarily due to the grossly simplified turbulence parameterization contained in these simple models, where the turbulence is typically assumed to be always in equilibrium with the mean flow and hence the turbulent transport is modeled as a local diffusive process only. Moreover, simple eddy-viscosity models developed for different processes cannot be readily superimposed for application to complex problems. Nevertheless, simple models continue to be developed and used. For example, forces on bottom pipelines have generally been estimated by using the simple but empirical Morison's equation (Sarpkaya and Isaacsen, 1981), which largely ignores the physics.

Modeling Approach

In order to develop meaningful simple analytical or numerical models for turbulent boundary layers and coastal sediment transport, one must start from comprehensive models which do not make ad-hoc assumptions about the processes described above. This paper describes such a comprehensive second-order closure model of turbulent transport which has been previously applied to simulate wave boundary layer (Sheng, 1982 and 1984) and wave-current interaction (Sheng, 1984). Such a comprehensive model, because of the added physics it contains, can simulate the individual processes without ad-hoc parameter tuning, and hence, is useful for understanding and predicting the complex turbulent boundary layer dynamics when many competing mechanisms coexist or when little data exist. In the long run, we can use the physical insight gained from these comprehensive models to provide guidelines for development of meaningful simple analytical or numerical models.

Model Validation

Previous eddy-viscosity models for wave boundary layers and current-wave boundary layers could only be calibrated against mean flow quantities. On the other hand, Sheng (1984) compared the results of a second-order closure model with both the mean and turbulent quantities within turbulent bottom boundary layers. This is a very important point—when modeling complex turbulent flow phenomena, model results must be compared with turbulence data. Comparison of model results against mean flow data alone and/or quantities of second-order importance (e.g., mass transport) is insufficient to judge the quality of the model. While the second-order mass transport may have some meaning in wave theory or laboratory study of wave boundary layer (Sleath, 1984), in practical situations the negligible mass transport velocity is easily overwhelmed by the tidal currents or wind-driven currents, hence, it is extremely hard to discern and is of questionable practical importance.

This Work

In addition to a brief review of the complete second-order closure model, this work also discusses two simplified versions of the model which are useful under certain conditions. Some recent applications of the second-order closure model to simulate wave boundary layers, wave-current boundary layers, sediment-laden bottom boundary layers, and two-dimensional effects are discussed.

II. MODELS OF TURBULENT FLOWS

Instead of presenting model equations which are only valid for a particular process of interest, this work will present the following general equations which are valid for turbulent flows where more than one of the processes (e.g., stratification, wave-current interaction, nonlineartiy, stratification, and 2-D or 3-D effects) are present. Anticipating applications to 1-D, 2-D, axisymmetric and even 3-D flow situations, the model equations are given in tensor notation.

Mean Equation

Reynolds-averaged equations for the mean flow quantities in an imcompressible fluid in the presence of rotation are:

$$\frac{\partial U_i}{\partial x_i} = 0 \tag{1}$$

$$\frac{\partial U_i}{\partial t} + \frac{\partial U_i U_j}{\partial x_j} = -\frac{\partial \overline{u_i u_j}}{\partial x_j} - \frac{1}{\rho_o}\frac{\partial p}{\partial x_j} - g_i\frac{\tilde{\rho}}{\rho_o} - 2E_{ijk}\Omega_j U_k + \frac{\partial}{\partial x_j}\left(\nu\frac{\partial U_i}{\partial x_j}\right) \tag{2}$$

$$\frac{\partial \phi}{\partial t} + \frac{\partial U_j \phi}{\partial x_j} = -\frac{\partial \overline{u_j \phi}}{\partial x_j} + \frac{\partial}{\partial x_j}\left(\kappa\frac{\partial \phi}{\partial x_j}\right) \tag{3}$$

where U_i and u_i are the mean and fluctuating velocity components, $\tilde{\rho}$ and ρ are the mean and fluctuating components of density, E is permutation tensor, Ω is earth's rotational speed, ν is the kinematic viscosity, κ is the kinematic diffusivity, and Φ and ϕ are the mean and fluctuating temperature (or salinity). An equation of state is needed to relate $\tilde{\rho}$ and Φ.

It is apparent that the above equations are not closed unless additional information is given for the second-order correlations $\overline{u_i u_j}$ and $\overline{u_j \phi}$. Models which provide information on $\overline{u_i u_j}$ and $\overline{u_j \phi}$ are called turbulence models.

Existing models for turbulent transport can be grouped into two categories: those which employ the turbulent (or eddy) viscosity/diffusivity concept, and those which do not.

Eddy-Viscosity Models

The eddy-viscosity/diffusivity concept assumes that, in analogy to the viscous stresses and fluxes in laminar flow, the turbulent stresses and heat or mass fluxes are proportional to the mean velocity and temperature or concentration gradients, respectively. In tensor notation, the concept is:

$$-\overline{u_i u_j} = \nu_t\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right) - \frac{q^2}{3}\delta_{ij} \tag{4}$$

$$-\overline{u_i \phi} = K_t \frac{\partial \Phi}{\partial x_i} \tag{5}$$

where ν_t and K_t are respectively the eddy viscosity and diffusivity, and $q^2 = \overline{u_i u_i}$ is twice the turbulent kinetic energy (k). Unfortunately, ν_t and K_t are not fluid properties but depend strongly on the state of turbulence and may vary considerably across the flow, from time to time, and from one flow to another. Despite the simplicity of its concept, however, the precise value/formula for the eddy viscosity is not necessarily simple to determine. One often hears such remarks in a technical paper or presentation: "What kind of eddy viscosity is needed in order that the model results agree with data?" Thus, eddy viscosity is essentially a convenient "tuning parameter" for many people who do not wish to deal with turbulence in a rigorous fashion. One is cautioned that a "well tuned" eddy viscosity formula for one process/problem cannot be readily applied to another process/problem. In addition, the concept breaks down completely in flow regions where the flux is against the gradient of the transported quantity. Such counter-gradient-flux regions occur quite frequently in turbulent flows.

Second-Order Closure Models

This type of turbulence model uses transport equations for the turbulence stresses $\overline{u_i u_j}$ and fluxes $\overline{u_j \phi}$ such that the eddy-viscosity concept does not have to be introduced. The transport equations for a second-order closure model (e.g., Sheng, 1982), following a procedure outlined by Donaldson (1973), are presented in the following in terms of $\overline{u_i u_j}$, $\overline{u_i \rho}$ and $\overline{\rho\rho}$:

$$\frac{\partial \overline{u_i u_j}}{\partial t} + U_k \frac{\partial \overline{u_i u_j}}{\partial x_k} = -\overline{u_i u_j}\frac{\partial U_j}{\partial x_k} - \overline{u_j u_k}\frac{\partial U_i}{\partial x_k} - g_i \frac{\overline{u_j \rho}}{\rho_o} - g_j \frac{\overline{u_i \rho}}{\rho_o} \tag{6}$$

$$- 2E_{ikm}\Omega_k \overline{u_m u_j} - 2E_{jmk}\Omega_m \overline{u_k u_i}$$

$$+ v_c \frac{\partial}{\partial x_k}\left(q\Lambda \frac{\partial \overline{u_i u_j}}{\partial x_k}\right) - \frac{q}{\Lambda}\left(\overline{u_i u_j} - \delta_{ij}\frac{q^3}{3}\right) - \delta_{ij}\frac{2bq^3}{3\Lambda} + \nu\frac{\partial^2 \overline{u_i u_j}}{\partial x_k^2} - \frac{2a\nu\overline{u_i u_j}}{\Lambda^2}$$

$$\frac{\partial \overline{u_i \rho}}{\partial t} + U_j \frac{\partial \overline{u_i \rho}}{\partial x_j} = -\overline{u_i u_j}\frac{\partial \tilde{\rho}}{\partial x_j} - \overline{u_j \rho}\frac{\partial U_i}{\partial x_j} - \frac{g_i \overline{\rho\rho}}{\rho_o} - 2E_{ijk}\Omega_j \overline{u_k \rho} \qquad (7)$$

$$+ v_c \frac{\partial}{\partial x_j}\left(q\Lambda \frac{\partial \overline{u_i \rho}}{\partial x_j}\right) - \frac{Aq}{\Lambda}\overline{u_i \rho} + \kappa\frac{\partial^2 \overline{u_i \rho}}{\partial x_j^2} + \frac{a\kappa\overline{u_i \rho}}{\Lambda^2}$$

$$\frac{\partial \overline{\rho\rho}}{\partial t} + U_j \frac{\partial \overline{\rho\rho}}{\partial x_j} = 2\overline{u_j \rho}\frac{\partial \tilde{\rho}}{\partial x_j} + v_c \frac{\partial}{\partial x_j}\left(q\Lambda \frac{\partial \overline{\rho\rho}}{\partial x_j}\right) + \kappa\frac{\partial^2 \overline{\rho\rho}}{\partial x_j^2} - \frac{2bsq\overline{\rho\rho}}{\Lambda} \qquad (8)$$

where the last 5 terms in Eq. (6), the last 4 terms in Eq. (7), and the last 3 terms in Eq. (8) are "modeled" terms. For example, in Eq. (6), the term containing v_c is a diffusion term, the term containing q/Λ is a tendency-toward-isotropy term, while the last 3 terms are dissipation terms with the last 2 terms vanishing at high Reynolds number. The model constants, $v_c = 0.3$, $b = 0.125$, $a = 3$, $A = 0.75$, and $s = 2.8$, are determined by comparing model simulations with a wide variety of critical laboratory experiments where only one or two of the modeled terms is dominant, and remain fixed for any new model application (Sheng, 1986a). Thus the model is sometimes termed an invariant model.

An equation for the turbulence macroscale Λ is needed to close the system of equations (1) through (8):

$$\frac{D\Lambda}{Dt} = 0.35\frac{\Lambda}{q^2}\overline{u_i u_j}\frac{\partial U_i}{\partial x_j} + 0.6bq + 0.3\frac{\partial}{\partial x_i}\left(q\Lambda\frac{\partial \Lambda}{\partial x_i}\right) - \frac{0.375}{q}\left(\frac{\partial q\Lambda}{\partial x_i}\right)^2 - \frac{0.8\Lambda}{q^2}g_i\overline{u_i \rho} \qquad (9)$$

It is useful to derive an equation for q^2 from Eq. (6):

$$\frac{\partial q^2}{\partial t} + U_k\frac{\partial q^2}{\partial x_k} = -2\overline{u_i u_k}\frac{\partial U_i}{\partial x_k} - 2g_i\frac{\overline{u_i \rho}}{\rho_o} + v_c\frac{\partial}{\partial x_k}\left(q\Lambda\frac{\partial q^2}{\partial x_k}\right) - \frac{bq^3}{\Lambda} + \frac{\partial^2 q^2}{\partial x_k^2} - \frac{2a\nu q^2}{\Lambda^2} \qquad (10)$$

Simplified Second-Order Closure Models

Equations (6), (7), (8) and (9) constitute the so-called "Reynolds stress model" and is the most complete second-order closure model. These dynamic equations contain much more physics of the turbulent flow than the eddy-viscosity model, or first-order closure

model. Although the solution of these equations requires considerable computational effort, simplifications of the equations can sometimes be introduced in practical applications to reduce the computational effort. For example, if the time scale of mean flow is large compared to that of turbulence, "quasi-equilibrium" approximation may be introduced such that only Eqs. (9) and (10) are needed to represent the dynamics of turbulence, while Eqs. (6), (7) and (8) are replaced by a set of algebraic equations where the total derivative and diffusion terms are neglected. If, in addition, the turbulence does not change significantly over Λ, the "super-equilibrium" approximation is valid such that Eqs. (6), (7) (8) (9) are replaced by a number of algebraic equations. Such simplified second-order closure models are used to represent the vertical turbulence in the three-dimensional hydrodynamic model of coastal and estuarine circulation (Sheng, 1986b).

III. SECOND-ORDER CLOSURE MODELING OF WAVE BOUNDARY LAYERS

Wave Boundary Layer

The Reynolds stress model as presented above has been applied to simulate the wave boundary layer of Jonsson and Carlsen (1976). The one-dimensional version of the model was used and hence the equations become considerably simplified, since only vertical gradients appear in the equations. Boundary layer approximation was invoked and the free-stream oscillatory currents are balanced by a lateral pressure gradient which is imposed throughout the boundary layer. Results shown in Sheng (1982) and Sheng (1984) demonstrated that the Reynolds stress model was able to faithfully simulate the mean velocities at various phase angles and the phase lag of mean velocities at different vertical levels. In addition, comparison of the model results vs. computed Reynolds stress data indicated the lack of temporal resolution of mean velocity measurements.

Logarithmic Layer

Perhaps one of the most important model results is the explicit computation of the instantaneous logarithmic layer. It is a well known fact that the velocity distribution within a homogeneous and steady-state bottom boundary layer follows the logarithmic variation:

$$u = \frac{u_*}{k} \ln\left(\frac{z}{z_o}\right) \tag{11}$$

where k is the von-Karmen constant, u_* is the friction velocity and z_o is the roughness height, while the turbulent fluxes are more or less uniform within the layer. In the presence ot density stratification due to variation in temperature, salinity and/or suspended sediment concentration, the thickness of the logarithmic layer (or constant flux layer) may be significantly modified. In addition, the presence of a body force such as pressure gradient may also significantly alter the thickness of the logarithmic layer. Jonsson and Carlsen (1976) could not measure their turbulence directly and hence assumed a fixed logarithmic layer thickness of 6.3 cm. Results of the Reynolds stress

model clearly indicate a much thinner logarithmic layer, as shown in Figure 2, which is modulated by the pressure gradient associated with the free-stream oscillatory flow. The instantaneous Reynolds stress at three levels (0.5 cm, 1 cm and 4 cm above the bottom) and two phase angles as shown agree well with model results.

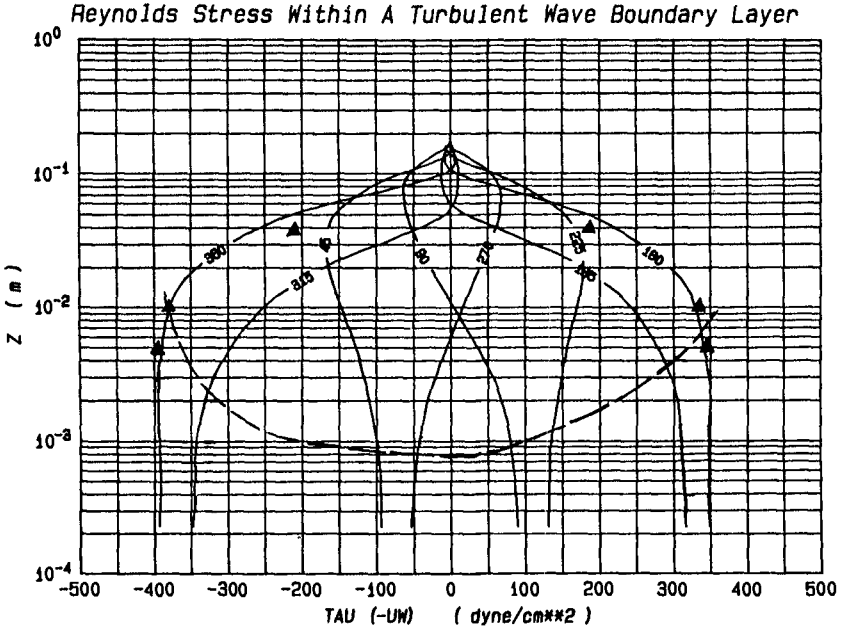

Figure 2 Reynolds stress within Jonsson and Carlsen's wave boundary layer. ——— : model; ▲'s: data; ----- indicates the approximate edge of the logarithmic layer.

Eddy Viscosity

The presence of the logarithmic layer is validated by the model, thus the eddy viscosity near the bottom can be found to scale with ku_*z, where z is the distance above the bottom:

$$\nu_t = \frac{\tau}{\partial u/\partial z} = \frac{\rho u_*^2}{u_*/kz} = \rho u_* kz \qquad (12)$$

Since u_* is a function of time, ν_t must be a function of time and space. This explains why almost all of the previous eddy-viscosity models, which use either spatially varying or temporally varying eddy viscosity, fail to faithfully reproduce Jonsson and Carlsen's wave boundary layer data (Sheng, 1986a). However, Eq. (12) is not valid outside the logarithmic layer.

Another reason why eddy viscosity is a poor concept for studying turbulent boundary layers is visualized in Figure 3 which shows the eddy viscosity calculated from Jonsson and Carlsen's data via $\nu_t = \tau/(\Delta u/\Delta z)$. It is apparent that the eddy viscosity is often scattered and may become negative which is physically meaningless. The solid lines represent the eddy viscosity computed from the results of the Reynolds stress model via $\nu_t = \overline{ww}\,\Lambda/q$.

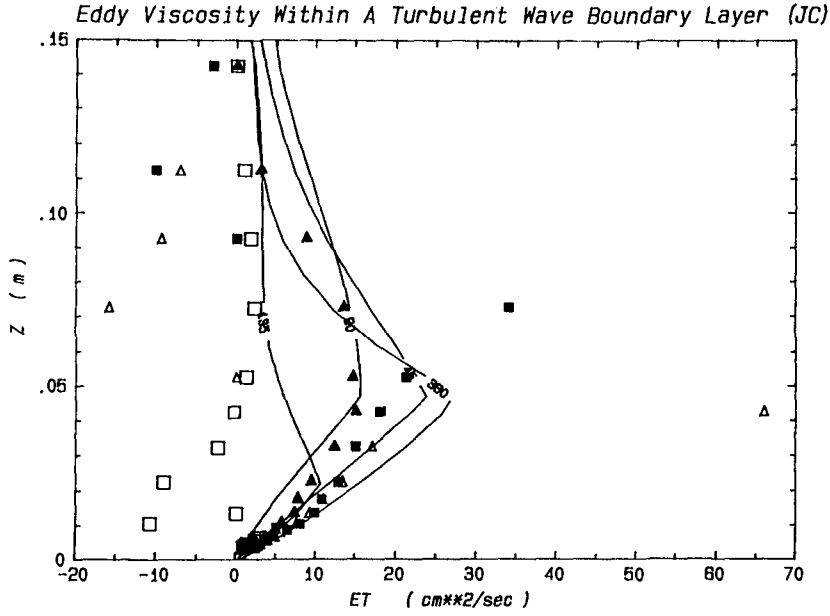

Figure 3 Eddy viscosity computed from Jonsson and Carlsen's data (Δ, , Δ,) and computed from the model results via $\overline{ww}\,\Lambda/q$.

Simplified Second-Order Closure Models for Wave Boundary Layer

Recently, the "quasi-equilibrium" and "super-equilibrium" versions of the second-order closure model were applied to simulate Jonsson and Carlsen's wave boundary layer (Sheng, 1987). The "quasi-equilibrium" results compared very well with data while the "super-equilibrium" results did not do as well. However, this in no way implies that the simplified second-order closure models are sufficient for simulating all turbulent wave boundary layers, since the state of turbulence may vary from one boundary layer to another and from one problem to another.

Other Wave Boundary Layers

Sheng (1984) simulated the turbulent bottom boundary layer underneath a cnoidal wave and found strong asymmetric behavior in the predicted mean velocities and Reynold stresses. The maximum Reynolds stress was found to be 50% higher than that produced by a simple sinusoidal wave boundary layer.

Another interesting wave boundary layer experiment was conducted by Hino, et al. (1983). It was reported that the measured turbulent intensities increased substantially while the flow changes from the acceleration stage to deceleration stage. Again, results of the Reynolds stress model agree well with data (Sheng, 1987).

IV. WAVE-CURRENT BOTTOM BOUNDARY LAYER

Kemp and Simons (1982) measured the mean and turbulent quantities within the turbulent bottom boundary layer underneath a wave propagating with the current. They found that for smooth bed, the turbulent stresses produced by the wave alone and the current alone can be superimposed to give the total stress for the wave-current case. For rough bed, however, the wave-current interaction is highly nonlinear and the turbulent stressed due to current and wave cannot be linearly superimposed. Although their experiments appear to contain 2-D and 3-D effects in the vicinity of the roughness elements (due to the relatively small ratio between particle displacement and roughness A_{bm}/k_s), it is interesting to compare the results of a 1-D Reynolds stress model against their data. As an example, comparison in terms of the maximum vertical varinace is shown in Figure 4, where the model results were for the case of WCR5. Notice the generally good agreement between data and model results, except in the vicinity of the roughness elements where 2-D effect is important.

V. SEDIMENT-LADEN BOTTOM BOUNDARY LAYER

The second-order closure model has been recently applied to simulate the effect of suspended sediment concentration on the boundary layer flow structure and to improve the determination of erosion/deposition relationships from laboratory experiments (Sheng, 1987).

VI. TWO-DIMENSIONAL EFFECT

Most bottom boundary layer models, including those cited above, are one-dimensional and hence cannot be expected to work when two dimensional effect due to bedforms or structures is present. DuToit and Sleath (1981) measured velocity measurements close to rippled beds in oscillatory flow and compared their data with three 1-D models (Kalkanis, 1964; Kajiura, 1968; Bakker, 1974). The agreement between data and model results was found to be rather poor. In 2-D flows, profile drag becomes important in addition to the skin friction drag. Vortex generation and shedding play an important role in the two-dimensional bottom boundary layer dynamics, but are simply not resolved in the one-dimensional models.

As an example, the 2-D version of the second-order closure model was used to simulate the flow and separation behind a backward facing step. As shown in Figure 5, the computed mean velocity and Reynolds stress distribution compare well with data at various downstream distances X behind the step with height H. The Reynolds stress distribution shown is in the vicinity of the flow reattachment point. It should be pointed out that for such a complex problem, a "simple" eddy-viscosity model simply does not exist.

The 2-D version of the Reynolds stress model can be applied to simulate the wave boundary layer or wave-current boundary layer over a wavy bottom. It should be pointed out that such model will be able to correctly resolve the nonlinear inertia terms, without treating it as "second-order" effect as in the 1-D model.

VII. CONCLUSIONS

The dynamics of turbulent bottom boundary layers in coastal waters is extremely complex because of the simultaneous presence of such competing processes as stratification, short-period wave, wave-current interaction, nonlinearity, and two-dimensional effects. Numerous "simple" (from the point of view of computational effort) models for individual processes (e.g., a pure wave boundary layer) have been developed in the past. Unfortunately, many of these models were developed with ad-hoc empiricism and hence one cannot superimpose the simple models for application to complex problems. In order to ultimately derive simple analytical or numerical models of the complex overall problem, a comprehensive model must be first constructed and used to gain physical insight and to provide guidance for formulating simpler models.

A comprehensive second-order closure model of turbulent transport is presented here. Model applications to a variety of bottom boundary layers (wave boundary layer, wave-current boundary layer, sediment-laden boundary layer, and two-dimensional boundary layers) are discussed. The model is capable of simulating the measured mean and turbulent quantities. Simplified versions of the second-order closure model are available and can be applied to some problems. An example was provided to demonstrate the fact that an eddy-viscosity model is meaningful only if it is derived based on sound understanding of turbulent flow.

For meaningful model validation, model results must be compared with measured turbulence data instead of mean flow data only.

CHAPTER 111

SEDIMENT TRANSPORT DUE TO BREAKING WAVES

Tomoya Shibayama, A.M. ASCE *
Akihiko Higuchi ** and
Kiyoshi Horikawa, M.ASCE***

ABSTRACT

In the surf zone, the agitation of the bed materials by breaking waves is strong and the suspended sand concentration in the vicinity of the wave plunging point is extremely high. Sand movement in this region was observed and sand concentration was measured in a wave flume. The sand movement in the region was divided into the following two categories: 1) sand suspension due to the large vortex which is created by wave plunging, and 2) sand deposition under turbulent flow. The condition for exciting this suspension process was considered and the result was well explained by the two parameters which are the deep water wave steepness and the bottom slope. Then a numerical model of the sediment suspension process was formulated and the process was well simulated by the model.

1. INTRODUCTION

In recent years, many attempts have been made to formulate cross-shore sand transport and resultant beach transformation. However many of these treatments are based of oscillatory wave motion and the resultant bed shear stress. In order to analyze sand transport within the surf zone more precisely, the dynamics of breaking waves must be understood more clearly. In the surf zone, agitation due to wave breaking lifts the bed material and places it into suspension and the suspended sand concentration in the vicinity of the breaking point is extremely high. Fig. 1 shows the schematic view of the sand movement process in this region. The purpose of the present paper is to describe the nature of sand movement under breaking waves.

The present work was stimulated by the following two studies. Dean (1973) treated the problem of sand suspension at the wave breaking point and gave critical values of two parameters which govern the sand

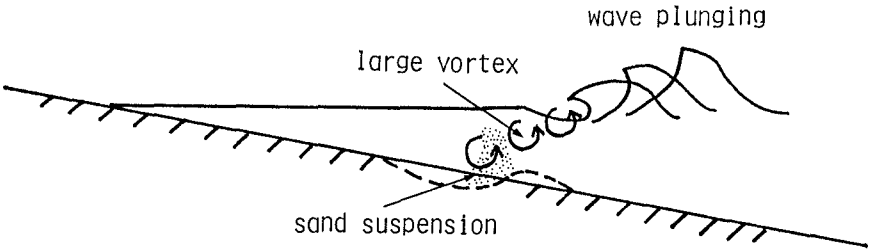

Figure 1: Schematic View for Sand Suspension due to Wave Plunging.

transport direction at the wave breaking point. The two parameters are the wave steepness and the ratio of fall velocity to wave period. Sawaragi and Iwata (1974) investigated the mechanism of wave breaking and reported the nature of plunging waves. They described the physical mechanism of the "horizontal roller" which is the large vortex created by the wave plunging. In the present study, the sand suspension process will be explained in relation to the action of the large vortex.

2. CONDITIONS FOR SEDIMENT SUSPENSION

Wave breaking over a movable bed sometimes results in sand suspension due to agitation caused by the wave plunging. In order to determine the condition when this kind of sand suspension occurs, laboratory experiments were performed for a wide range of flow conditions. In the experiment, two wave flumes, termed A and B, were used. Flume A was 11 m long, 0.2 m wide and 0.3 m deep. Flume B was 25 m long, 0.8 m wide and 1.5 m deep. Sand with median diameter 0.2 mm was used for bed material. In both flumes, sand was placed to form an initial beach profile of uniform slope. The conditions of the experiments performed are summarized in Table 1 together with the conditions of Shibayama and Horikawa (1982).

In order to investigate the water particle movement, polystyrene of diameter 1 mm or 2 mm and specific gravity 1.02 were injected into the water. The motion of sand particles and polystyrene particles in the vicinity of the breaking point was recorded using a 16 mm movie camera. By analyzing the film, the motion of sand particles and the characteristics of the large vortex could be examined.

From the observation, the effect of large vortex itself to sediment suspension, not the small scale turbulence, was found to be the main mechanism to cause the sand suspension at the wave plunging area. Fig. 2 shows the critical values of the bottom slope and deep water wave

steepness for the creation of a large vortex due to wave plunging. The result of Sawaragi and Iwata (1974) are also shown in the figure. The solid line in the figure defines the boundary between the large vortex and no-large vortex region. The dashed line in the figure shows values of the similarity parameter, I_r, (Battjes, 1975) defining the transition between spilling and plunging breakers, given by $I_r = i_0/(H_0/L_0)^{1/2} = 0.5$ (dashed line in the figure) where i_0 is the initial bottom slope and H_0/L_0 is the deep water wave steepness. As seen from the figure, the two boundaries are different. The customary definition of wave breaking type was based on surface profile appearance at the point of breaking. However from the view point of sediment suspension, it is more important whether a breaking wave produces a large vortex or not. The solid line is more important than the dashed line for describing sand movement in the wave breaking area.

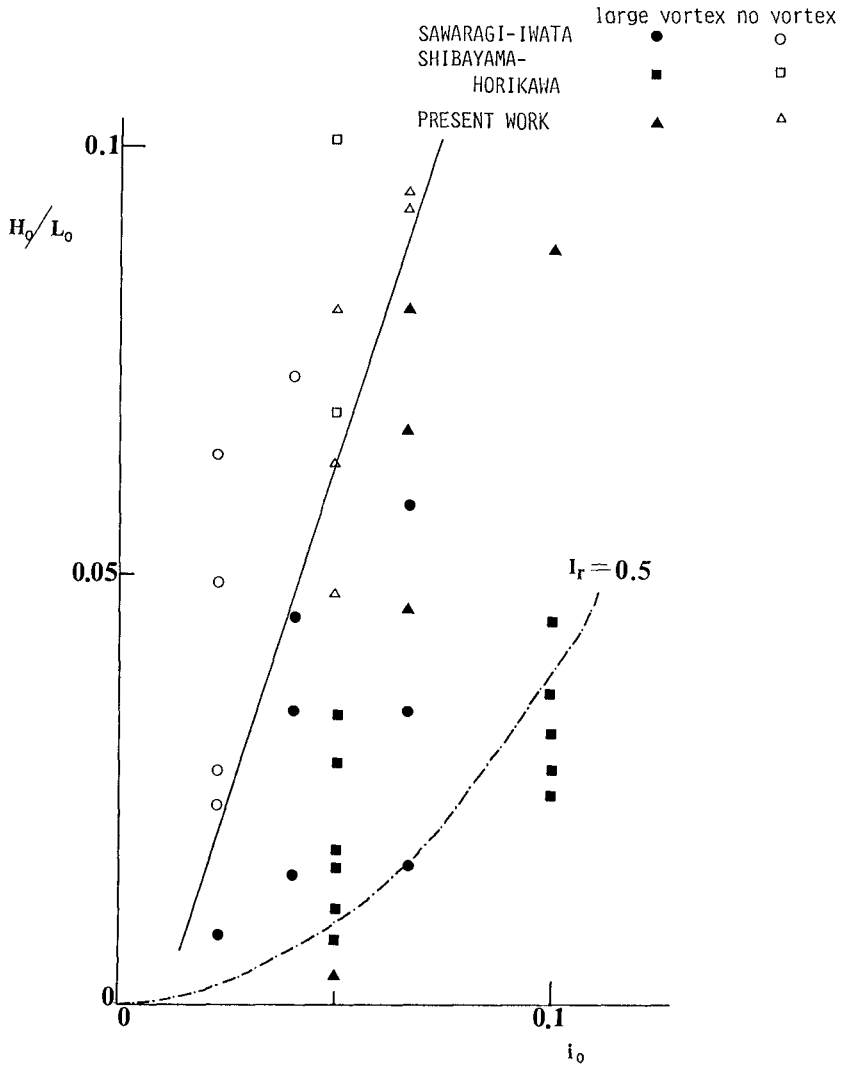

Figure 2: Conditions for Creation of Large Vortex.

From the figure, the necessary wave condition for producing sand suspension due to the mechanism described in the present paper can be determined. This condition is necessary but not sufficient to produce suspended sand. For sand suspension, another condition is required: sand particles must be small, or light enough to be moved or suspended by the velocity field created by the large vortex. However, this condition has not yet been described in a quantitative manner.

3. SAND MOVEMENT AND CONCENTRATION DISTRIBUTION

In experiment B-1, a 35-mm camera utilizing a shutter speed of 1/30 s was used and sand particle pathlines were obtained by tracing the film. The reason why we chose this condition was to minimize the effect of air bubbles. If the wave period is long, air bubbles created by wave plunging go up to the surface in early wave phase, and therefore we can measure sand concentration without the effect of air bubbles thereafter. Figures 3 (a-1) to (a-6) show the experimental results. In this figure, the formation process of the suspended sand cloud can be seen. The arrows indicate the velocity vector of the sand particle movement, the dotted region denotes the cross-sectional area of sand cloud, with one dot representing one sand particles in the photographs.

The sand movement process can be described as follows: (a) Immediately after the wave crest passes the inspection section in the flume, the large vortex created by wave plunging touches bottom. Sand particles on the bottom start into suspension due to the arrival of the vortex (Phase a-1); (b) The suspended sand cloud increases in size and a high concentration area is formed (Phase a-2); (c) Suspended sand particles diverge and some of them are deposited on the bottom (Phase a-3); (d) Suspended sand grains move offshore and some particles are deposited on the bottom (Phases a-4 and a-5); and (e) The next wave crest arrives and a portion of the previously suspended sand particles move onshore (Phase a-6). Figure 3—(A) shows the time history of water surface elevation measured at Point x (observation point indicated in Fig. 3, a-1). The numbers in Fig. (A) indicate the wave phase at the time of each measurement.

Figure 3(b-1) to (b-6) shows the time series of the sand concentration distribution for the the same experimental run. The sand concentration was measured with a Iowa type concentration meter (Nakato et al.,1977), which optically measures the concentration. The probe consists of a 6 mm diameter emitter and detector, separated by a distance of 10 mm. The concentration was obtained at 71 points in the wave breaking area and the equi-phase-mean value over 15 waves were obtained. The equi-phase-mean value should be used because the suspension process fluctuates somewhat from one wave period to the next. In order to calculate equi-phase-mean value of the concentration, each

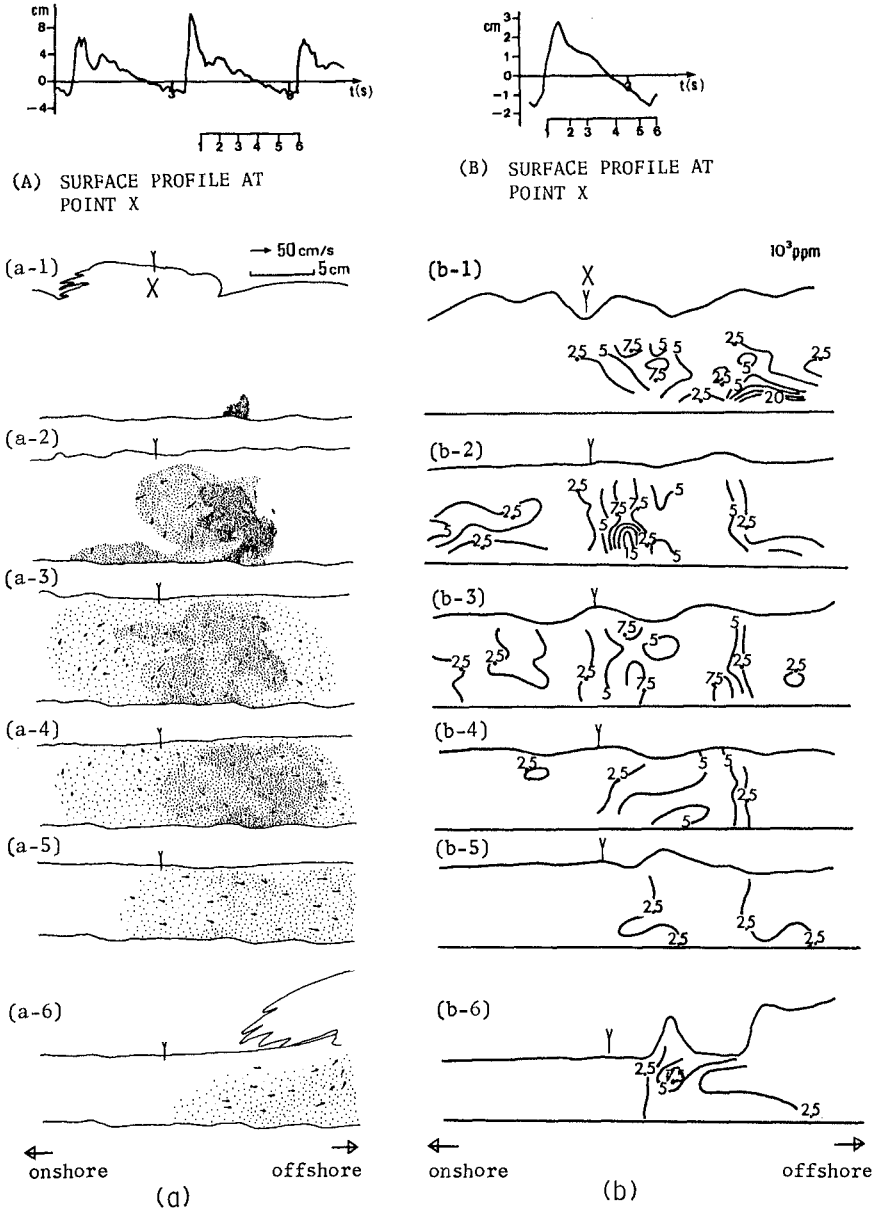

Figure 3: Suspended Sand Movement and Corresponding Sand Concentration.

wave period was divided into 90 intervals. The equi-phase-mean values was obtained by averaging the concentration over 15 waves for each phase. For the wave phase i,

$$\bar{c}(\theta_i) = \frac{1}{N}\sum_{n=1}^{N} c_n\ (\theta_i) \qquad (1)$$

where $\bar{c}$:equi-phase-mean concentration, i:wave phase, $\theta_i = 2\pi i/90$, $i=1,\cdots 90$, n:number of the wave, $n=1,\cdots 15$. From this figure, we can see a high concentration area which corresponds to the location of the suspended sand cloud. The equi-phase-mean value of the water surface are also displayed.

It should be mentioned that the laboratory results discussed here are limited to the case of regular waves traveling onto a beach of initial constant slope. Although the experiment was started with a constant sloping beach, a bottom trough formed due to the action of the plunging waves and the water depth at the wave plunging point became greater as time went on. The result was that the agitation of the bottom material due to wave breaking diminished as time went on. For the present experiments, the initial beach profile was set to form a uniformly sloping beach. Each experiment was allowed to proceed until the bottom becomes somewhat deformed, i.e., less than 100 waves for the present case, then the experiment was stopped and the bottom was smoothed to a uniform slope again. Thus the interaction between the profile change and wave transformation is believed to be negligibly small.

The gradient of wave pressure in the horizontal direction (cross-shore distance) in the breaking area might be considered to play a role in sand movement. Madsen (1974) analyzed this effect and concluded that the pressure gradient alone may affect bed stability but is not great enough to remove sand particles from the bed. Therefore, the pressure gradient appears to be only a secondary factor to control the amount of sand set in motion during the sand suspension process.

4. A SIMULATION MODEL

In order to formulate a simulation model of the sand movement, the following two processes should be evaluated. The first one is the sand suspension process due to a large vortex and the second one is the process of sand transport in turbulent motion. We first consider suspension rate due to a large vortex.

(1) A model for sand suspension rate

The total amount of suspended sand in the sand cloud can be calculated for each phase by integrating the concentration for the area of the sand cloud. Figure 4 shows the result indicating sand mass per one centi-meter width for the same experimental run with Figure 3. In the figure, surface profile history is also indicated. From the figure, we can observe that the total amount of suspended sand rapidly increases after passage of the wave crest and subsequently decreases gradually as part of the sand cloud is deposited on the bottom. If we neglect the rate of sand falling to bed in the sand suspension process, we can estimate the rate of sand suspension from the gradient of sand mass curve. Then a pick up rate is modeled as

$$f(t) = A \sin(2\omega t + \varphi) \qquad (2)$$

where A is the constant, ω is angular frequency and φ is the phase shift. And we will consider the range $f(t) > 0$ and $0 < \omega t + \varphi/2) < \pi$ only. Here the empirical constant A was determined by the previously described sand mass curve of Figure 4 as the gradient of the curve for the first suspension period.

(2) A model for sand movement and velocity measurement in wave breaking region

Next we will consider suspended sand movement in the turbulent field. Here, sand velocity was modeled as the sum of water particle velocity including turbulence and the sediment particle fall velocity. This assumption was called "zero order solution" by Nielsen (1984) and he discussed the validity of the assumption. Then sand movement was simulated by means of the Monte Carlo method. The motions of sand particles were calculated by integrating the velocity of sand particles.

In order to evaluate sand movement, the information of velocity field is required in the wave breaking area. In general, the velocity can be divided into the following three components (Okayasu et al., 1986), which are (1) steady flow, (2) periodic motion (which include wave motion and large vortex), and (3)turbulence. A laboratory experiment was performed by using a wave flume which was 23 m long, 0.8 m wide and a step type beach profile was used. The profile consisted of a 1/10 slope and a flat bed. The reason why we chose this type of beach topography was to fix the breaking point of each wave. Figure 5 shows the beach profile used and the arrangement of measuring points. The measuring area was from 0.5 cm to 14.5 cm above the bottom and 80 cm long in an on-offshore directed vertical plane. The measuring points were arranged to make 2 cm grids. In total, 328 measuring points were set in the test section.

A hot film velocimeter with a split type probe was used to measure

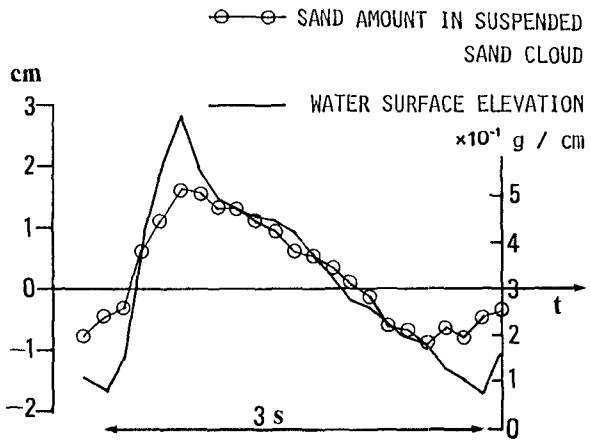

Figure 4: Phase Change of Sand Amount in Suspended Sand Cloud.

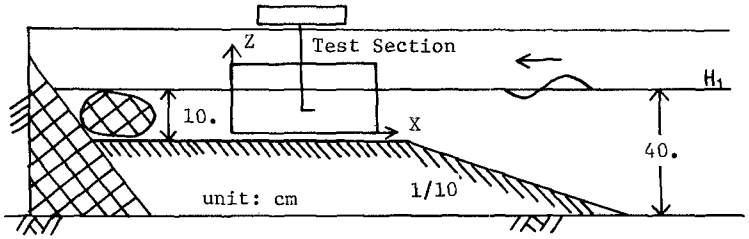

$T = 1.55$ s $H_0/L_0 = 0.020$ $H_1 = 6.95$ cm

Figure 5: Experimental Set-Up and Condition for Velocity Measurement.

the time history of two-dimensional velocity vector. By using the velocimeter, we can obtain two components of velocity data, which are one component of velocity histories with plus or minus sign and an absolute value of the other component. Therefore we cannot get full information about the signs of two components. In the present case, the sign of the on-offshore component velocity was not determined. It was reversed once in every wave period according to the surface profile. The velocity data were sampled every 10 ms and were converted into digital data. The equi-phase-mean values of velocity over 30 periods were calculated. Each wave period was divided into 150 intervals and the equi-phase-mean value was obtained as an average of the velocity value at the same phase of every wave. The turbulence component was determined as the deviation from the equi-phase-mean value.

Figure 6 shows the resultant measured velocity field, which are steady flow, periodic component and turbulent intensity of vertical velocity component at the phase immediately after the wave plunging. The turbulent intensity of horizontal velocity component was also obtained but not illustrated in the figure. From the figure, we can obviously observe a large scale vortex by velocity vectors. The high turbulent region is in good agreement with the vortex region indicated by velocity vectors.

(3) Simulation results

Figure 7 shows an example of simulation result of sand particle distributions. First, sands were suspended from the initial suspension area which is shown in the figure, according to the time history of pick-up function. The initial suspension area was supposed to locate 4 cm above the bottom for the present case. Sands diverged according to velocity field which include turbulence. Here, the velocity characteristics such as the steady flow, the equi-phase-mean velocity and the turbulent intensities between the grid points were determined by means of linear interpolation between the grid points. Sands formed suspended sand cloud and moved to offshore. Sands which fell down to the level of 2.5 cm above the bottom were considered to fall on the bed and they are not indicated in the figure. Figure 8 shows example of sand particle pathlines. Here also we can identify the location of suspended sand cloud area. The sand particle pathlines exhibit the same tendency to the laboratory phenomena which is the formation and the movement of suspended sand cloud under the function of the organized motion in turbulence.

The present model is elementary one and was done as the first trial. It can be concluded that the present model is promising for the future development. For further improvements, precise modeling of pick up rate and velocity field is required.

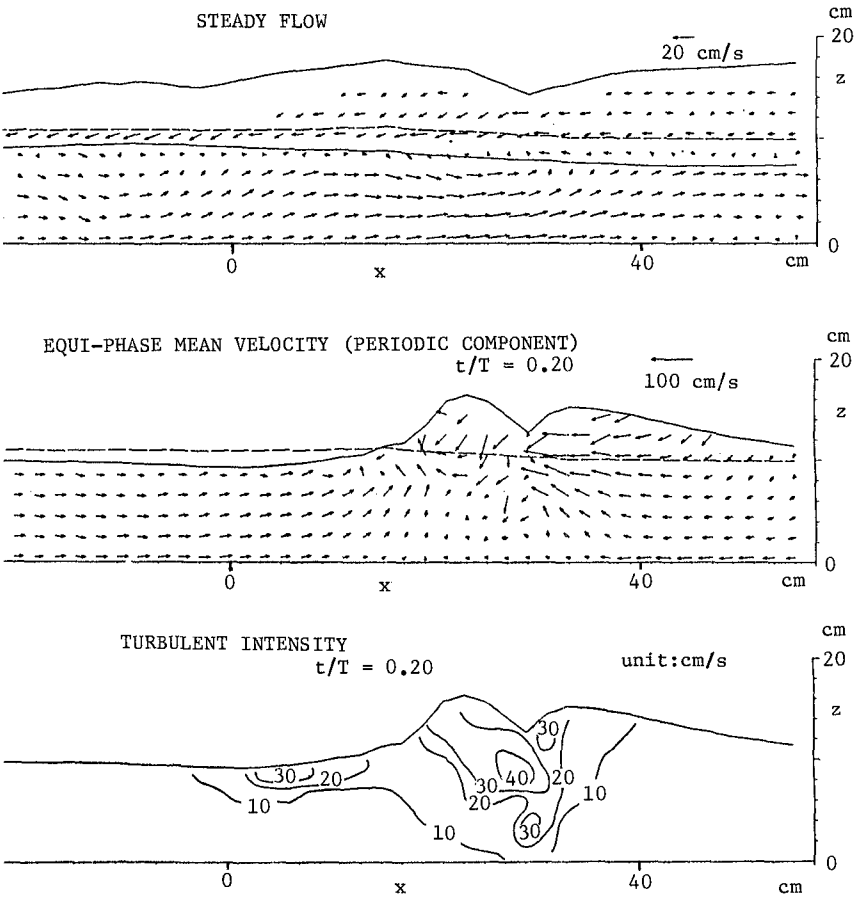

Figure 6: Measured Velocity Field.

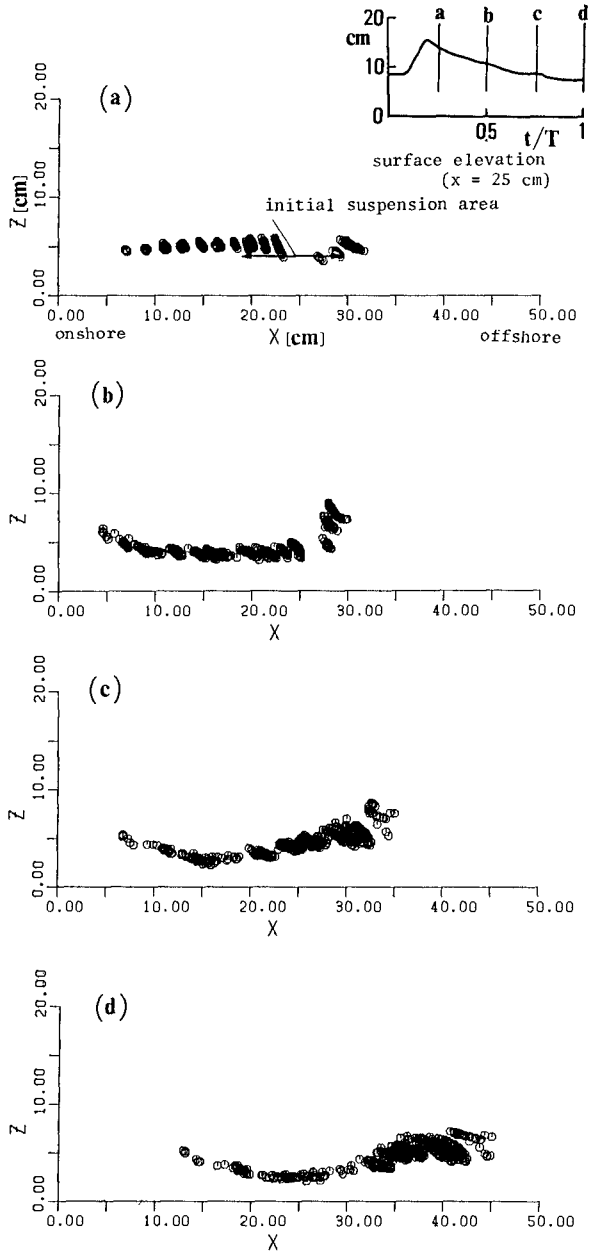

Figure 7: Examples of Sand Particle Distribution.

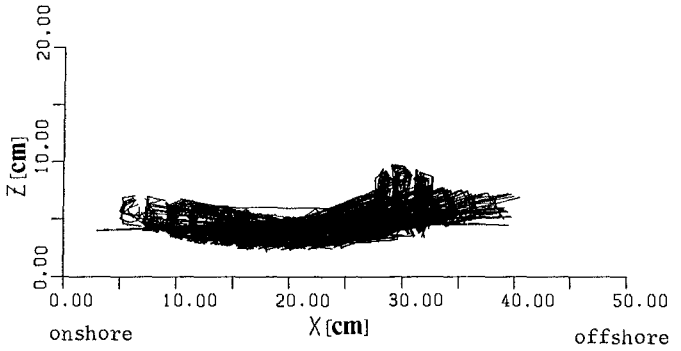

Figure 8: Examples of Sand Particle Pathlines.

The air bubbles have possibility to give an important effect to formation of suspended sand cloud (personal communication with Dr. P. Nielsen). The air bubbles which are created by wave plunging produce upward flow in wave breaking area when they go up to the water surface after the large scale vortex disappears. The upward flow produced by the bubbles transports sand particles upward and therefore diverges sands to upward directions. This effect should be examined more precisely by laboratory experiments as a next step.

5. CONCLUSIONS

The formation of a large vortex induced by plunging waves was found to be one of the necessary conditions for sand suspension caused by breaking waves. The condition for the vortex formation is determined by deep water wave steepness and bottom slope. The movement of suspended sand was divided into two processes; (1) suspension due to the large vortex and (2) sand transport in the turbulent flow. An appropriate modeling of the two processes was performed and simulation results were obtained. The results are not satisfactory but judged to be promising for the further improvement.

ACKNOWLEDGMENTS

The authors thank to Dr. N. Mimura of Ibaraki University, and Mr. A. Okayasu of the University of Tokyo for their co-operations in performing the experiment of Section 4-(2). This study was financially supported by a grant in aid for scientific research, No. 59750405, Ministry of Education, Science and Culture, Japanese Government, which is granted for the first author.

CHAPTER 112

SHORE PROCESS ALONG THE COAST OF IWO-JIMA

Toshiyuki Shigemura*,M.ASCE

Abstract

Iwo-jima is a small isolated volcanic island located in the Pacific Ocean. Due to the continuous upheaval of the island, foreshore area of this island has been increasing since 1911.

Investigation is made to clarify the variation of the foreshore area of this island by analyzing the various field data obtained during the past three years.

Analyses reveal that the foreshore area is currently increasing at an approximate rate of 180,000 square meters per year due to the unusual upheaval of the island exceeding 45 centimeters per year although seasonal variation of the foreshore area reaches 300,000 square meters.

1. Introduction

Iwo-jima is a small volcanic island located in the Pacific Ocean about 1250 kilometers south of Tokyo (24°45' to 24°49'N, 141°17' to 141°21'E). This island is situated at the southern tip of the Izu-Ogasawara volcanic arc which runs almost parallel to the longitude of 140°E.

Figure 1 shows the present topography of Iwo-jima. To show the beach evolution occurred during the past seven decades, shoreline in 1911 is shown in this figure as a reference. Surface area and shoreline length of this island are currently 23.2 square kilometers and 24.3 kilometers, respectively.

The island is relatively flat with an average of 110 meters except for the area around the Mt. Suribachi. The surface is mostly covered with thick vegetation and there are no rivers on

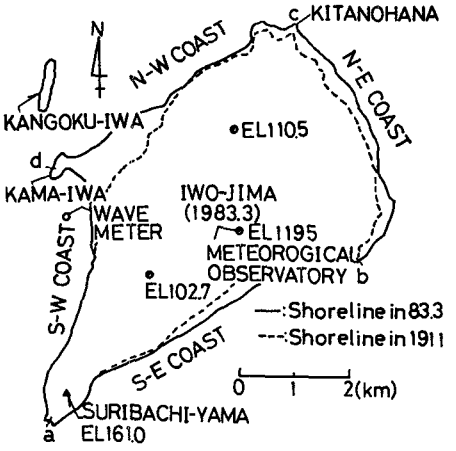

Figure 1. Present topography of Iwo-jima

*Professor, Dept. of Civil Eng., National Defense Academy, 1-10-20 Hashirimizu, Yokosuka, Kanagawa 239, Japan

this island. Thus, few sources of sediments seem to exist in and around the island. However, most of the coast is rimmed by sandy beach, approximately 200 meters wide. Further, quite surprisingly, the shoreline has been advancing seaward year by year since 1911. The author and his colleagues have analyzed old maps, charts and aerial photographs of Iwo-jima, and found that the shore area has increased roughly 3.2 square kilometers during the past seven decades. They also found that this increase was caused by the unusual upheaval of this island, approximately 30 centimeters per year(Shigemura et al, 1984). These are the characteristics of so called a long term variation of the shore area in Iwo-jima. However, the shore area is varying continuously within shorter period, which is important to know from the engineering point of view.

This paper intends to clarify the characteristics of the short term variation of shore area in Iwo-jima by analyzing various field data obtained during the past three years since 1982.

2. Field measurements

To investigate the short term variation of the shore, the following field surveys have been made during the past three years since 1982:

(1) Photographing of the shoreline by a helicopter
(2) Traversing and levelling surveys of the shore
(3) Measuring of the waves by a supersonic wave meter
(4) Collection of wind and tidal data

Details of these field surveys will be described in the following sections.

2-1. Photographing of the shoreline by a helicopter

To get the data of the shoreline variation, aerial photographs of entire shoreline have been taken since November 1982, using a helicopter of JMSDF (Japan Maritime Self Defense Force) stationed there. By the end of September 1985, 19 sets of photographs were taken in total, which were taken at an altitude of 2000 meters except for one set of photographs.

2-2. Traversing and levelling of the shore

To get the data of upheaval and variation of the foreshore area of the island, traversing and levelling surveys have been done on the entire shore of the island since August 1982. These surveys were made at least twice a year, using the 53 measuring points located on the backshore at intervals of roughly 300 meters (figure 2).

2-3. Measurement of the waves by a supersonic wave meter

Wave data has been measured since May 1982 by a supersonic wave meter installed about 450 meters off the west coast

of Iwo-jima at a depth of 12 meters (see figure 1). These data were recorded for 10 minutes every two hours until November 7, 1983 when the typhoon #17 washed the meter away. Thus, waves were measured for 19 months.

2-4. Collection of wind and tidal data

Both wind and tidal data were not measured in each of the field surveys since meteorological data has been measured at the central part of this island since 1968 by JMSDF and tidal data has been recorded at the foot of the Mt. Suribachi since December 1980 by the Japan National Research Center for Disaster Prevention (JNRCDP). These wind data will be used to produce the seasonal wind diagrams covering the period of the field surveys.

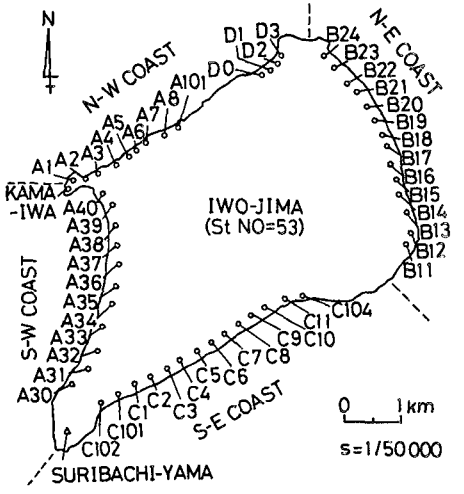

Figure 2. Mesuring points on the backshore of Iwo-jima

Further, the tidal data will be used to refer the elevation of bench mark placed at the foot of the Mt.Suribachi for the levelling survey.

3. Analyses of field data

3-1. Variation of the surface area of Iwo-jima

As mentioned previously, 19 sets of aerial photographs have been taken by a helicoter during the past three years. Table 1 summarizies the details of the photographing.

Unfortunately, most of these photographs were taken with some inclination. Thus, the following procedures were taken to determine the shorelines in each photographed date from these photographs:

(1) Each set of the film was processed into a series of slides.

(2) Five reference maps with a scale of 1/4000 were reproduced from the aerial photographs taken in March 10, 1983 (figure 3).

(3) Each of the reference maps was placed on a special table designed so that it may rotate around three axes, and slides were projected onto it.

(4) After rotating the table until several points on the map fitted with the corresponding points on the projected slide, the shoreline was drawn successively on the reference map.

Table 1. Details of the photographing of the shoreline

No.	Data	Time	Altitude	Tide	Remarks
1	Nov.25,'82	13:35-14:35	2000 m	84.0 cm	inclined photos

11	Jun.12,'84	11:00-12:00	2000 m	16.0 cm	inclined photos
12	Jul.11,'84	11:00-12:00	2000 m	20.0 cm	inclined photos
13	Sep.05,'84	09:15-10:15	2000 m	40.0 cm	inclined photos
14	Oct.07,'84	15:30-16:30	2000 m	70.0 cm	inclined photos
15	Nov.16,'84	09:30-10:30	2000 m	56.0 cm	inclined photos
16	Mar.01,'85	09:00-10:00	2000 m	75.0 cm	inclined photos
17	May 27,'85	09:00-10:00	2000 m	76.0 cm	inclined photos
18	Jul.12,'85	09:00-10:00	2000 m	46.0 cm	inclined photos
19	Sep.04,'85	14:30-15:30	2000 m	48.0 cm	inclined photos

Shorelines determined in this way, were processed by a special AD convertor and the position of each shoreline was digitalized every 2 millimeters or 8 meters on the actual spot. Based on this data, the surface area of the island on each photographed date was calculated.

Figure 4 shows the variation of the surface area of Iwo-jima during the past three years.

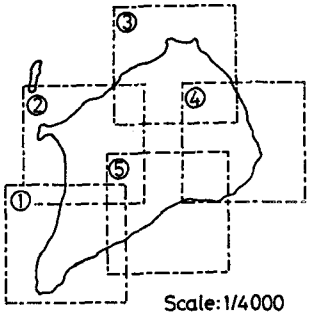

Figure 3. Reference map of Iwo-jima

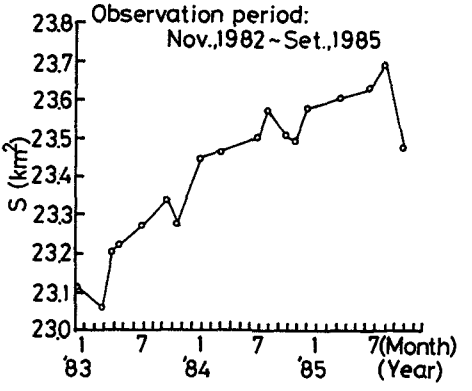

Figure 4. Variation of the surface area of Iwo-jima

Figure 5 shows the current variation of the surface area together with the one occurred before 1982(Shigemura et al, 1984).

From figure 4 and 5, the folloing facts can be seen:
(1) The surface area of Iwo-jima has kept increasing since 1911, although the increasing rate is not constant but varies with time.
(2) Surface area began to increase drastcally in 1952 and kept increasing until 1968 at an approximate rate of 140,000 square meters per year. By the end of 1981, the surface area increased roughly 3.2 square kilometers as compared with the surface area in 1911.
(3) Surfce area is currently increasing at an approximate rate of 180,000 square meters although there is a considerable variation in its magnitude.

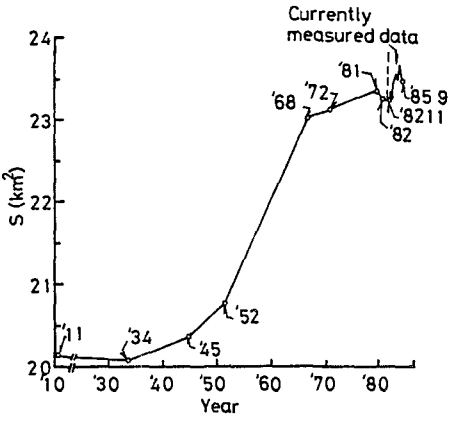

Figure 5. Variation of the surface area of Iwo-jima since 1911

3-2. Upheaval of Iwo-jima

Since August 1982, both traversing and levelling surveys have been made six times along the entire bachshore of the island. Table 2 summarizes the periods in which the surveys have been made.

Table 2. Periods in which surveying has been made

No.	Period
1	Jul.23,'82 to Aug.09,'82
2	Jun.08,'83 to Jun.28,'83
3	Feb.09,'84 to Feb.20,'84
4	Nov.16,'84 to Dec.05,'84
5	Mar.09,'85 to Mar.28,'85
6	May 14,'85 to May 31,'85

All of these surveys have been made with the aid of the 101 Topographic Battalion of the Japan Ground Self Defense Force (JGSDF).

Figure 6 shows the variation of the relative upheaval height, ΔH of each measuring point shown in figure 2, which was determined on the basis of its elevation measured in the first survey (August,1982).

Figure 7 shows the cumulative upheaval height of the backshore of Iwo-jima in the same period which was determined by simply averaging the elevations of the 53 measuring points shown in figure 2. Further, figure 8 shows the cumulative upheaval height of Iwo-jima presented by Kosaka and

his colleagues(Kosaka et al,1979). They determined the upheaval height by comparing the elevations of several points shown in old maps and charts and by analyzing their own data of levelling which was performed four times during the period between 1968 and 1978.

From figure 6, 7 and 8, the following facts can be observed:

(1) Upheaval of Iwo-jima is not uniform along the coast but varies considerably in both time and location.

(2) Iwo-jima upheaved drastically during the period between February 1984 and November 1984 at the rate exceeding 1 meter per year.

(3) Iwo-jima is currently upheaving at an approximate rate of 45 centimeters per year, which is greater than that observed during the period between 1952 and 1968.

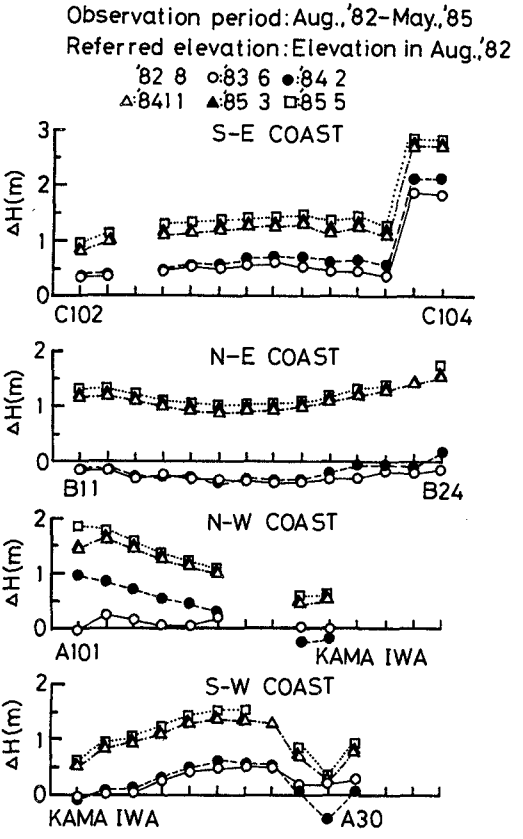

Figure 6. Variation of the relative upheaval height, Δ H of each mesuring point

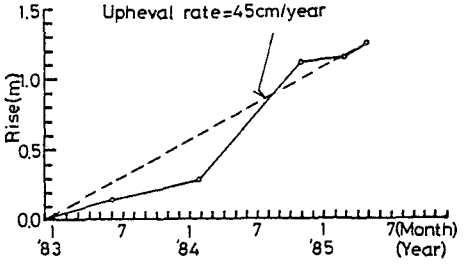

Figure 7. Cumulative upheaval height of Iwo-jima

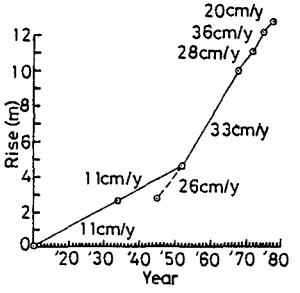

Figure 8. Cumulative upheaval height (After Kosaka et al, 1979)

3-3. Wave characteristics in Iwo-jima

As mentioned in section 2-3, waves were recorded for 19 months after May, 1982. These records were processed at a sampling interval of 0.5 second by an A-D convertor, and wave height and period were determined by applying the zero up crossing method on these processed data.

Table 3 summariges the seasonal distribution rate of significant waves whose height and period are in the given ranges of their magnitudes.

Table 3. Seasonal distribution rate of the significant waves in Iwo-jima

Season	H 1/3(m) 0-1	1-2	2-3	<3	T 1/3(s) <6	6-8	8-10	<10
Spring	62	36	1	1	29	51	16	4
Summer	70	20	4	6	21	42	21	16
Fall	73	14	7	6	8	43	27	22
Winter	59	35	6	0	31	49	16	4

Table 4 summarizes the maximum height and the significant period of the waves recorded while the typhoons were hitting Iwo-jima.

Table 4. Values of H max and T 1/3 of the waves recorded while typhoons were hitting Iwo-jima

#17	Nov. 2,'83	0200	lack of data		985mb	NNE1030km	30.0m/s	NNW

In this table, figures in the column of No. indicate the names of tyhoons, and the information in the column of location indicates direction and distance to the center of a typhoon from the island. Further, does the letters in column of θ indicates the advancing direction of each typhoon.

From these tables, the following facts can be seen:

(1) Dominant waves in Iwo-jima are those whose significant heights are less than 1 meter and whose significant periods are less than 8 seconds through the year.

(2) High waves whose significant height is greater than 3.0 meters and whose significant period is greater than 10 seconds appear in summer and fall.

(3) Huge swell whose maximum height is roughly 10 meters and whose significant period is greater than 12 seconds will hit Iwo-jima when a typhoon with a central pressure less than 940 millibars pass within a region of 600km far from Iwo-jima.

Huge swells of this size usually hit Iwo-jima several times per year. Characteristics of these waves were also reported at the 19th ICCE(Shigemura et al, 1984)

3-4. Wind characteristics in Iwo-jima

As mentioned in section 2-4, JMSDF has been recording the wind data every three hours, since 1968.

By analyzing the wind data recorded in 1983, 84 and 85, seasonal wind diagrams were produced.

Figure 9 shows the seasonal wind diagrams. From this figure, the following wind characteristics can be observed:

(1) East winds are dominant in spring, summer and fall. South winds are the secondarily dominant in spring and summer.

(2) N-E winds are dominant in fall and winds ranging from NE to N are dominant in winter.

(3) Approximately 3% of the total winds analyzed are the high winds whose veloities exceed 10 meters per second. These winds blow from the direction ranging from SE to SSE in summer although they blow from the direction ranging from NNW to NE in fall and winter.

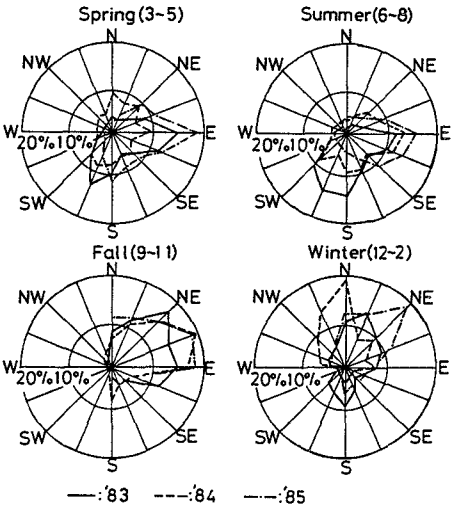

Figure 9. Seasonal wind diagrams in Iwo-jima

These results agreed well with the ones obtained by analyzing the wind data recorded in Iwo-jima during the period between 1968 and 1977(Shigemura et al,1984).

4. Variation of the foreshore area in Iwo-jima

Through the primary analyses, it was found that Iwo-jima was currently increasing its surface area at a rate greater than that occurred before 1982. Further, it was proved that this increase was surely caused by an unusual upheaval of this island.

To see the variation of the surface area more clearly, relative values of the surface area on each photographed date was determined on the basis of the surfase area on March 10, 1983. These values will be called ΔS in the following discussion. ΔS may indicate the increase of the foreshore area if the increase of the surface area is caused

by a continuous upheaval of the island.

Regression analysis was made on the data of ΔS over time. Figure 10 shows the variation of ΔS during the past three years. In this figure, the straight line indicates the regression line of ΔS over time and the symbol of square indicates a deviation of ΔS from its corresponding value predicted by the regression line, which will be referred to as dS in the following discussion. Further, the symbol of black circle shows the relative upheaval height, ΔH.

Regression analysis revealed that the foreshore area was currently increasing at an approximate rate of 180,000 square meters per year although dS scatters considerably along the regression line.

Suppose the increasing rate of 180,000 square meters per year was brought by the current upheaval of the island, dS may indicate the variation of the foreshore area caused by the other factors besides upheaval, namely waves and currents. It is difficult to find a definite trend in the variation pattern of dS. However, the following facts can be observed from this figure:

(1) dS tends to increase from spring to summer and from fall to winter, but to decrease from summer to fall and from winter to spring, respectively.

(2) The range of the variation of dS is approximately 250,000 square meters per year at most.

These findings are the characteristics of the short term or the seasonal variation at least, of the entire foreshore area of Iwo-jima.

Analysis was further proceeded to examine the local effect on the short term variation of dS. To see the local effect, the coast was divided into four sections as shown in figure 11. These sections were designated S-E coast, N-E coast, N-W coast and S-W coast, respectively.

Similar analysis was made on the data of ΔS in each section. Figure 12 shows the analytical results. In this figure, straight lines indicate the regression lines of ΔS over the time in each coast. Further, the symbol of square indicates the relative upheaval height, ΔH and the symbol of white circle represents ΔS. This figure clearly shows that there is a certain analogy among the variation

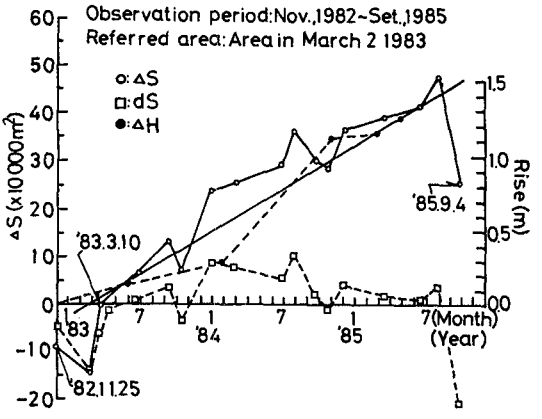

Figure 10. Variation of relative surface area, ΔS in each coast

patterns of ΔS in each coast.

To see this more precisely, variation of dS was checked similarly. Figure 13 shows the short term variation of dS in each coast. From this figure, the following facts were observed:

(1) Variation of dS is generally much greater in both the S-E and N-W coasts compared with that in both the N-E and S-W coasts. Namely, that reaches approximately 300,000 square meters in the former coasts during the period from spring to fall. However, that is usually 150,000 square meters at most in the latter coasts throughout the year.

(2) dS in both the S-E and S-W coasts shows quite similar and rhythmical patterns seasonally. dS in both the N-E and N-W coasts also shows quite similar variation patterns. However, these patterns are not as rhythmical seasonally as they are in the S-E and S-W coasts.

(3) There exist a certain phase lag between the variation patterns of dS in the S-E coast and that in the S-W coast. Similar phase lag is found between the variation patterns of dS in the N-E coast and that in the N-W coast, too.

(4) Variation pattern of dS in the S-E coast is almost opposite to that in the N-W coast.

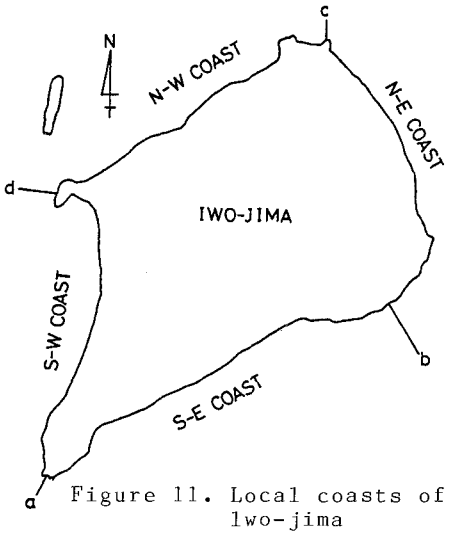

Figure 11. Local coasts of Iwo-jima

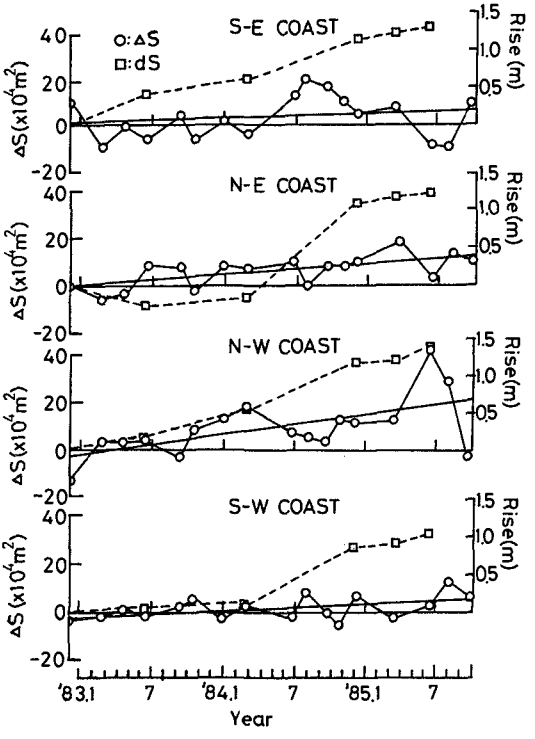

Figure 12. Variation of ΔS in each coast of Iwo-jima

Similarly, variation pattern in the N-E coast is almost opposite to that in the S-E coast.

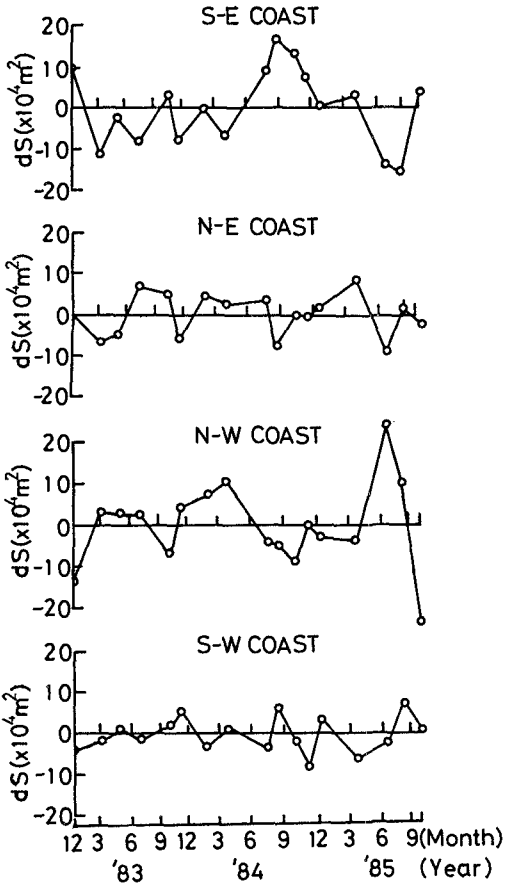

Figure 13. Variation of dS in each coast of Iwo-jima

5. Conclusions

Variation of the foreshore area in Iwo-jima was investigated by analyzing the 19 aerial photographs of the shoreline, land surveying data and wind and wave data which were all obtained through the field surveys performed during the past three years.

As a result, it was found that the foreshore area was currently increasing at an approximate rate of 180,000 square meters per year as a whole, due to the continuous

upheaval of the island exceeding 45 centimeters per year. Further, it was found that two different patterns appeared locally in the variation of the foreshore area and that in S-E and N-W coasts, variation of the foreshore area reached 300,000 square meters seasonally.

CHAPTER 113

REDUCTION PROCESS OF CROSS-SECTIONAL AREA AT RIVER MOUTH

Takuzo Shimizu*, Kosuke Kondo** and Ryoichi Kajima***

ABSTRACT

Reduction processes of the cross-sectional area at a river mouth were investigated on the basis of numerical simulations and field measurements, in order to predict the possibility of closing of the mouth of the Samegawa River, Fukushima, Japan. As a result, it was found that the decrease in tidal prism, induced by a reduction of the cross-sectional area, had an important effect on the closing of the river mouth. By considering this effect and estimating the sediment transport rate properly, a practical prediction model was successfully established for simulating the reduction processes of the cross-sectional area at the river mouth.

1. INTRODUCTION

A jetty was constructed on the northeastern side at the mouth of the Samegawa River, Fukushima, Japan, in order to prevent increased heated water from the Nakoso Thermal Power Station from affecting the river's fishery. After the jetty construction, the heated water is separately and directly discharged into the Pacific Ocean through an open channel excavated about 500 m northeast of the river mouth through the sand spit which extends along the shore in front of the power station (Figure 1).

One of the most important influences of the jetty construction is the reduction of the cross-sectional area at the river mouth, induced by the decreased discharge passing through it. However, since many factors, such as waves, nearshore currents, tidal flows, inherent river flows, and heated water discharge are involved in complicated sediment transport around the river mouth, beach changes or closing processes near the river mouth are not yet completely predictable.

This study aims to elucidate the mechanism of the interaction between hydraulic factors, especially tidal change and topographical changes at the river mouth, and to establish a prediction model of the reduction processes of the cross-sectional area.

2. OUTLINE OF FIELD INVESTIGATION

2.1 Study Area

Field investigations were carried out around the mouth of the Samegawa River, located on the Pacific coast in the southern part of Fukushima Prefecture (Figure 1). The sandy beach stretches from southwest to northeast in front of the river mouth. A rocky shoal exists only near the Ryugu Headland at the northeast end of the shore. The bottom contours are parallel to the shoreline and the bottom slope is as gentle as 1/70. The Samegawa River is a small and rapid river having a catchment area of 600.9 km^2 and an average bottom slope of 1/50 to 1/70. The river surface area influenced by tides was about 73,400 m^2 before the jetty construction and now is about 53,600 m^2.

According to the wave climate data observed by the Ministry of Transport over a five-year period from 1981 to 1985 off the Onahama Harbour, about 9 km northeast of the study area, the mean significant wave height is 1.0 m, the mean significant wave period is 8.1 s, and the occurrence frequency of wave heights beyond 2.0 m is less than 6 %. Wave directions, obtained by visual observations twice daily with a transit from the roof of the Power Station, are limited from ESE to SSE. The dominant direction is SE, normal to the shore, and its frequency reaches about 81 %.

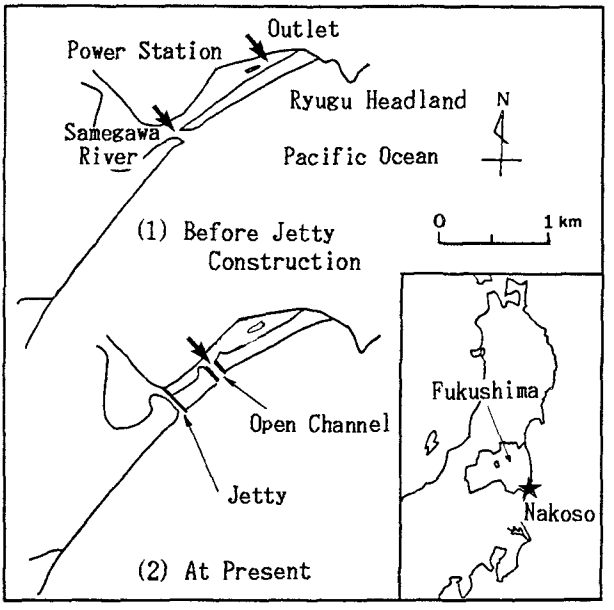

Figure 1 Study Area Location Map.

2.2 Field Investigation Program

The jetty construction was undertaken in August 1982 and completed in May 1985. Field investigations were carried out over a period of approximately five years, beginning in October 1980. The field investigation program consisted of:

(1) coastal topography surveys (about 4 times/year),
(2) cross-sectional area surveys at the river mouth (about once a month),
(3) 25-hour continuous readings of current and water level, during which water temperature and salinity were measured twice (16 times/5 yeras),
(4) nearshore current observations (occasional), and
(5) fluorescent sand tracer experiments (3 times/5 years).

Topographical changes and hydraulic characteristics were studied mainly using the data obtained in (2) and (3) above.

3. TOPOGRAPHICAL CHANGES AT RIVER MOUTH

3.1 Position of River Mouth

Figure 2 shows aerial photographs of the past and the present around the mouth of the Samegawa River. The position of the mouth before the jetty construction had a tendency to shift toward the northeast. Before the extreme flood event in September 1977, it had been located at the Ryugu Headland about 1.5 km northeast from the present position. This shift of the river mouth location is because the most effective wave energy arrives from the southeast direction, driving the net littoral sediment transport northeastward.

In the fluorescent sand tracer experiments carried out twice on the southeastern shore, most of the tagged grains were found along the shoreline extending from the injection points to the river mouth, although longshore currents were not always directed to the northeast. This is attributed to many complicated influences of the incident wave direction, the tidal elevation, the sea-bed topography, the river discharge and so on. This result suggests that not only the longshore currents but also the sediment transport in the swash zone play important roles in the sand spit extension around the river mouth.

3.2 Change of Cross-sectional Area

Figure 3 shows time histories of the cross-sectional area A from October 1980 to March 1985, together with variations of wave energy flux P, inherent river discharge Qr, and heated water discharge Qp. The solid curves in the corss-sectional area diagram are the results of simulations mentioned later.

It is seen in this figure that the cross-sectional area was forcibly and abruptly enlarged by every extreme flood event. After that it was gradually reduced and finally came to a state of dynamic equilibrium. This kind of variation pattern is common and repeated.

Figure 2 Aerial Photographs of Study Area.

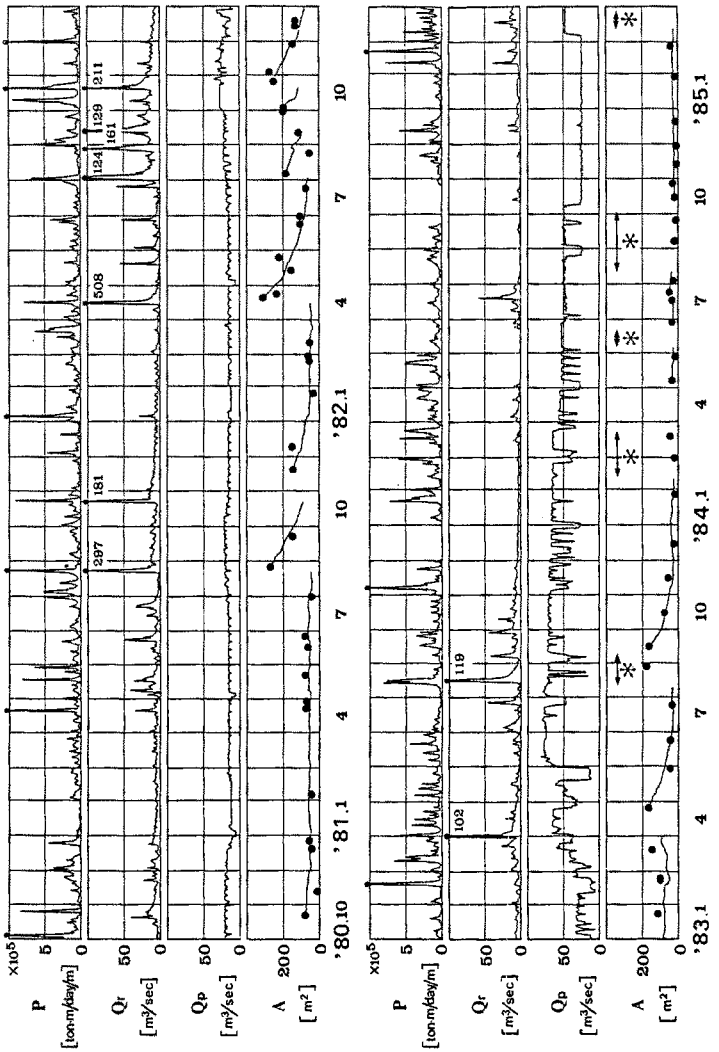

Figure 3 Time Series of Wave Energy Flux P, Inherent River Discharge Qr, Heated Water Discharge Qp and Cross-sectional Area A.
(● : Observation, —— : Calculation, * : Under Dredging)

The equilibrium area was about 50 m^2 before the jetty construction but after then decreased to about 20 m^2 because of the decrease in the total discharge passing through the river mouth caused by the separation of the heated water. Recently, maintenance dredgings have been carried out a few times a year, but not during fishing seasons for sweetfish in spring and salmon in autumn. The cross-sectional area was at the minimum of 11.8 m^2 with a width of 12.7 m in November 1984. This is partly because it was during the salmon fishing season and, importantly, because there were no extreme flood events throughout the year.

Next we investigate shape characteristics of the cross-section. The relationship between the area and the width of the minimum cross-section is close to that of a triangular cross-section rather than that of rectangular one (as Ogawa et al. (1984) has already pointed out). We however assume that the cross-section is rectangular, in order to make easy the use of the relationship between the width and the mean depth in numerical simulations.

The relationships between the cross-sectional area A and the width B or the mean depth h were calculated on the basis of the field surveys by regression analysis. The results are shown as follows:

$$B = 1.83\ A^{0.8} \quad \text{(correlation coefficient 0.91)} \tag{1}$$

$$h = 0.55\ A^{0.2} \quad \text{(correlation coefficient 0.48)} \tag{2}$$

The width shows a fairly good correlation with the area. On the other hand, the mean depth data observed after the jetty construction scatter around the above relationship. This is because the increased river discharge causes scouring adjacent to the jetty instead of enlarging the width.

4. HYDRAULICS AT RIVER MOUTH

4.1 Water Level and Discharge at River Mouth

The water level and the discharge at the river mouth are affected mainly by tidal flows and inherent river flows, aside from the wave set-up. Especially the tidal flow was supposed to be predominant under ordinary conditions but not during extreme flood events. To examine this, sixteen field observations were carried out, in which both the water level and the horizontal velocities were measured for 25 hours running, mainly during spring tide. In this section we report results of the above measurements.

Two or three two-component electro-magnetic current meters were placed about 1 m above the bottom on the minimum cross-section of the river mouth. In order to determine the ratio of the mean velocity at the measurement points to the cross-sectionally averaged velocity, another way of measurement using a propeller-type flowmeter was carried out at about 20 to 30 points spaced on the same cross-section once during flood tide and once during ebb tide. In every case there was no evidence of much spatial asymmetry in the flow, and therefore it can be

considered that data obtained by the electro-magnetic current meters were representative of the cross-sectionally averaged velocities. The water level variations were measured every 30 or 60 minutes by visual observation using poles installed near the electro-magnetic current meter.

Figure 4 shows an example of time series of the water level and the discharge at the river mouth. The highest water level is approximately equal to the coean's high tide level, whereas the lowest does not fall to the ocean's low tide level. Although the ocean tide changes nearly sinusoidally, the water level at the river mouth changes asymmetrically with the ebb period being longer than the flood period.

Figure 5 shows the relationship between the measured high and low water levels at the river mouth and those calculated by the Meteorological Agency at Onahama Harbour. Figure 5 indicates that the above-mentioned tendency becomes apparent when the width of the river mouth is less than approximately 60 m.

Tidal prism is defined, in general, as the gross volume of water entering or exiting an inlet during ebh or flood tides. According to the results of the field observations, it has been confirmed that tidal prism can be estimated by multiplying the difference of water level change at the river mouth by the river surface area under the influence of tides. Therefore, the decrease in tidal range results in a substantial decrease in tidal prism.

Table 1 lists mean annual values of inherent river discharge, heated water discharge, tidal discharge, and total discharge passing through the river mouth. The total discharge was calculated at the sum of the former three. Since the jetty construction in 1983, there has been no heated water discharge through the river. The tidal discharge was estimated by the following method:

(1) The lowest water level at the mouth is estimated by using the two different relations, equation (a) and (b), according to the width beyond or below 60 m as shown in Figure 5.
(2) The tidal prism during a half tidal cycle is calculated by multiplying the difference between the highest and the lowest water levels by the river surface area.
(3) The tidal discharge is then obtained by averaging the tidal prism over the half tidal cycle.

The tidal discharge thus calculated is not strictly true becuase the ebb and flood periods are assumed to be equal, ignoring the actual difference between the two.

The total flow rate passing through the river mouth decreased from a yearly average value of 50 to 60 m^3/s before the jetty construction to about 20 m^3/s after the construction. This is not only because the heated water was separated, but also because the decrease in the river surface area induced the decrease in tidal prism.

4.2 Numerical Model

As discussed in the preceeding section 4.1, the water level at the river mouth does not fall as low as the sea water level during ebb tide. As a result the tidal prism decreases so that the width of the river mouth is reduced to less than about 60 m. In the Samegawa River the inherent river discharge is small and the tidal prism shares 70 to 80 % of the total flow rate.

In this section we estimate the decrease in tidal prism by taking into account head losses due to friction and at the entry, exit and bend.

The numerical model developed in this study is essentially similar to that used in the analysis of a sea-inlet-bay system (e.g. see Bruun (1978)). Consider such a model of the river mouth as the tidal-influenced water surface area connected with the sea through a channel with uniform rectangular cross-section. Assuming that the velocity in the channel is constant and that the tidal wavelength is much larger than the channel length, the one-dimensional equation of motion along the channel axis can be expressed as:

$$du/dt + gd\eta/dx + I_f + I_\ell = 0 \tag{3}$$

$$d\eta/dx = (\eta - \eta s)/\ 2\ell \tag{4}$$

$$I_f + I_\ell = g\, n^2 |u|u\ /\ R^{4/3} + fc|u|u\ /\ 2\ell \tag{5}$$

where u is the average velocity (positive into the upstream direction), g is the acceleration of gravity, η is the water level at the river mouth, ηs is the sea water level, ℓ is the channel length, A is the cross-sectional area, I_f is the bottom friction term, I_ℓ is the term of head losses except frictional loss, R is the hydraulic radius, n is Manning's friction coefficient, and fc is the head loss coefficient at the entry, exit and bend.

The continuity equation can be used as expressed in equation (6), assuming that the river water level rises and falls uniformly at any time.

$$A\,u + Qr = S\,d\eta/dt \tag{6}$$

where A is the cross-sectional area, Qr the inherent river discharge, and S the river water surface area taken as independent of the water level. The validity of equation (6) has been verified in the practical sense by field measurements.

Relating equations (4), (5) and (6) to (3) and eliminating the velocity u, the following ordinary differential equation of the second order with respect to η can be obtained.

$$\frac{d^2\eta}{dt^2} + \left\{\left(\frac{fc}{2\ell} - \frac{g\,n^2}{R^{4/3}}\right)\frac{S}{A}\left|\frac{d\eta}{dt} - \frac{Qr}{S}\right| - \frac{B}{A}\frac{d\eta}{dt}\right\}\left(\frac{d\eta}{dt} - \frac{Qr}{S}\right) + \frac{Ag}{S\ell}(\eta - \eta s) = 0 \tag{7}$$

in which the time variation of Qr is assumed to be slow enough to ignore. Equation (7) can easily be solved numerically by using the Runge-Kutta-Gill method. The stationary solution can be obtained by calculating repeatedly for several tidal cycles from certain initial conditions. The initial conditions used in this model are $\eta = \eta s + \Delta\eta$, $d\eta/dt = Qr/A$, at $t = 0$, where $\Delta\eta$ is the displacement of backwater given by the result of non-uniform flow calculation. The sea tide is assumed to be sinusoidal.

Calculation of the variation of the water surface elevation by the above method leads to the result that the high water in the river becomes lower than that in the ocean and the time of high water in the river lags behind that in the ocean. These are natural results caused by nonlinear head losses and are observed in a general sea-inlet-bay system. However, these results are inconsistent with those of the field measurements, which indicate that both the high water level and its time in the river are approximately equal to those in the ocean. Probably, this is because the depth of the channel and the depth of the river surface area influenced by the tide are not large enough as compared with the ocean tidal range. Therefore, the variation of the water level at the river mouth from the time of the ocean's high tide elevation is calculated under the initial conditions, as mentioned previously, whereas it is approximated using an appropriate fifth-order function, from the time when the calculated level becomes lowest or equal to the ocean's tide, to the time of the next high water level.

An example of the result of the numerical simulation is shown in Figure 4. The solid curves show the calculated time series of water level and discharge at the river mouth. In spite of simplicity of the model presented here, the calculated values correlate well with the observed ones. In the other cases, the decrease in tidal prism can be estimated within ±10 % error by properly choosing the head loss coefficient fc and the channel length ℓ.

4.3 Effect of Decrease in Tidal Prism

This section presents effects of the width variation on the total discharge and the sediment transport rate at the river mouth by using the numerical model discussed in section 4.2.

First the variation of the absolute flow volume during a tidal cycle (12.5 hours) as caused by the change in the width is investigated. The relationship between the width and the mean depth obtained in section 3.2 is used.

Figure 6 shows the results of three cases of tidal ranges:(1) 1.45 m of the mean spring tidal range, (2) 0.91 m of the range between the mean higher high and the lower low water levels, and (3) 0.33 m of the mean neap tidal rnage, with no inherent river discharge. The discharge passing through the river mouth decreases exponentially as the width decreases. For example, at spring tide when the width is 5 m, the discharge decreases to about one third that for conditions of 100 m width, in which the water level at the river mouth changes simultaneously with that in the ocean.

Next, the effect of the width variation on the gross volume of sediment transport rate for a tidal cycle is shown in Figure 7, in which comparison is made with that in the cases of the same tidal change at the river mouth as that in the ocean. A Bagnold-type formula, equation (8), proposed by Watanabe (1982) was used to calculate the transport rate.

$$q_r = K_r (u_*^2 - u_{*c}^2) |u| / g \tag{8}$$

in which q_r is the volume transport rate including the sediment porosity, u_* is the friction velocity, u is the flow velocity, and K_r is the dimensionless coefficient. The assumptions used in this calculation are (1) the critical Shields parameter is 0.06, (2) the grain diameter is 0.25 mm, (3) the dimensionless coefficient K_r is 1.0, and (4) the friction velocity is estimated using the turbulent logarithmic velocity profile law.

It is generally seen that the sediment transport rate increases rapidly as the width decreases, because the flow becomes fast. However, when the width becomes narrower to some extent, the sediment transport rate is forced to become much smaller than that in the case of the same tidal change as in the ocean. For example, it becomes 1/10 to 1/100 at spring tide when the width is less than 20 m.

5. NUMERICAL SIMULATION OF REDUCTION PROCESS OF CROSS-SECTION

5.1 Prediction Model

Shuto and Aota (1980) originally proposed a numerical model predicting the time variation of the cross-sectional area at a river mouth and Ogawa et al. (1984) further developed the model. In these models the cross-sectional area was assumed to change owing to sediment

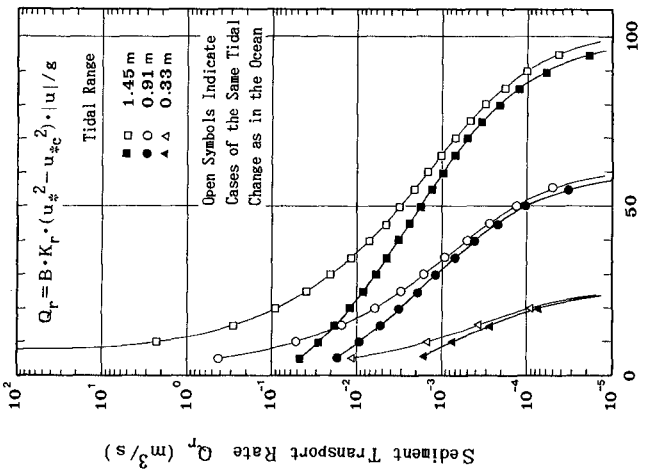

Figure 7 Effect of Width Variation on Sediment Transport Rate.

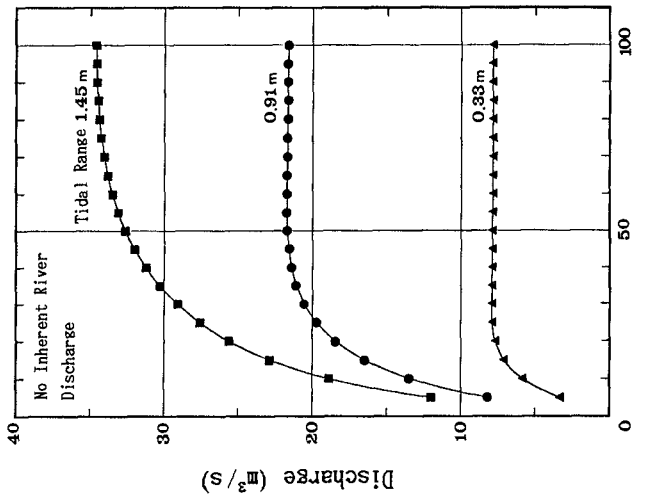

Figure 6 Effect of Width Variation on Discharge.

outflow caused by the river flow and sediment inflow caused by waves (as shown in Figure 8). However, vagueness remains in the physical meaning of the two coefficients involved in the sediment transport formulas; i.e. values of the coefficients suitable for the observed changes are different for different periods at the same place.

We now introduce the effect of the decrease in tidal prism, induced by a reduction of the cross-sectional area at the river mouth, into the prediction model. In this model the instantaneous sediment outflow caused by the river flow is calculated using the water level and velocity estimated by the numerical hydraulic model (discussed in section 4.2) and the total volume of sediment outflow over a tidal cycle from the high tide to the next high tide is evaluated. On the other hand, the volume of sediment inflow is estimated using the wave conditions at the breaking point. Then the variation of the cross-sectional area is simulated for every tidal cycle on the basis of the balance of the two kinds of sediment transport.

The governing equation for sediment mass conservation at the river mouth is expressed as

$$L\, dA/dt = q_r\, B - q_w\, B \tag{9}$$

in which q_r, q_w are the volume transport rates of sediment outflow and inflow, L is the width of the sand spit, A is the cross-sectional area, and B is the width of the river mouth.

The sediment outflow is given by equation (8), and assumed to act so as to maintain the cross-section independently of the flow direction.

The sediment inflow is simply expressed by equation (10), because it is difficult to estimate it quantitatively by taking account of the mechanism of sand motion.

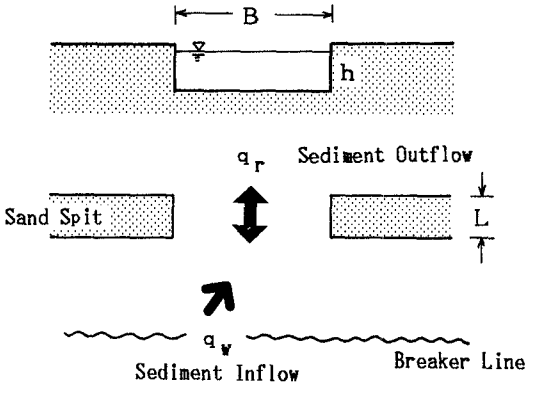

Figure 8 Schematic Diagram of Sediment Transport at River Mouth.

$$q_w = K_w H_b^{1.5} \tag{10}$$

in which H_b is the significant wave height at the breaking points, and K_w is a dimensional coefficient. This expression is obtained by considering that the sediment transport rate in the surf zone is proportional to the wave energy flux at the breaker line and dividing it by the width of the surf zone. The breaker height H_b is estimated using the following formula proposed by Sunamura (1983),

$$H_b/H_o = (\tan\beta)^{0.2} (H_o/L_o)^{-0.25} \tag{11}$$

where H_o is the significant wave height in deepwater, L_o is the wavelength in deepwater, and $\tan\beta$ is the bottom slope.

According to the results of the previous studies and the fluorescent sand tracer experiments, the coefficients K_r and K_w are expected to be of the order of magnitude of 10^0 and 10^{-5} respectively.

The reults of the simulation are shown in Figure 3. Calculation was terminated during extreme flood events causing the abrupt enlargement of the cross-section, and during dredging. With constant values of the coefficients, $K_r = 1.0$ and $K_w = 2.5 \times 10^{-5}$ ($m^{0.5}/s$), the results show a good agreement with the observed changes in the reduction processes at the river mouth. These values of the coefficients used in the simulation are the same order of magnitude with those mentioned above.

5.2 Possibility of River Mouth Closing

In order to examine the possibility of closing, the relationship between the significant wave height in deepwater and the width of the river mouth in a state of dynamic equilibrim ($dA/dt = 0$) is investigated. Figure 9 shows the results obtained under three conditions of tidal ranges with no inherent river discharge. When the wave height is placed above the curve of a reference tidal range at a reference width, the cross-sectional area becomes smaller and in the opposite case it becomes larger.

Since the width of the Samegawa River is now 10 to 30 m, it can be seen that the mouth of the river expands and contracts repeatedly in response to waves and tides. Therefore, it can be concluded that the present cross-section reaches an approximate equilibrium and that complete closure will not occur.

6. CONCLUDING REMARKS

As a result of this study based on the field measurements as well as numerical simulations, it has been found that the closing process has the following mechanism: a cycle that commences with a reduction of the cross-sectional area induces a decrease in tidal prism resulting in a substantial decrease in sediment outflow, and this decreased sediment outflow causes a further reduction of the cross-sectional area as the last phase before another cycle begins again. By considering this

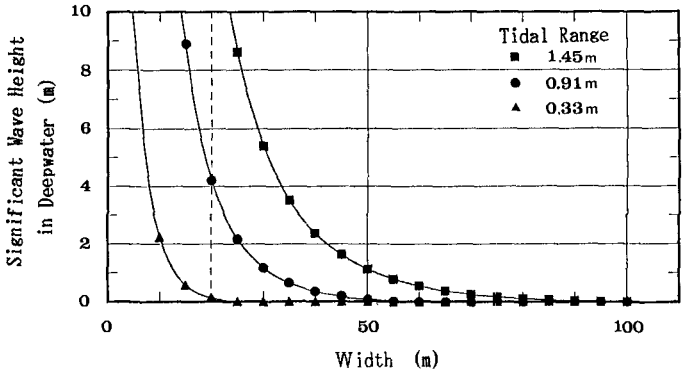

Figure 9 Relationship between Significant Wave Height in Deepwater and Width of River Mouth in a State of Dynamic Equilibrium.

mechanism, it has become possible to reasonably simulate the topographical changes of the river mouth.

However, the prediction model of the reduction process presented here is a simple one-dimensional model and it is impossible to simulate the variation of the sand spit width. Therefore, it is important to properly choose such parameters as to represent the plane configuration of the sand spit and the cross-sectional shape of the channel, on the basis of topographical surveys.

ACKNOWLEDGEMENTS

We would like to express our deep appreciation to H. Kaburagi and Y. Matsubara of the Joban Joint Power Co., Ltd. for the support they lent to this study and for their permission to publish this paper. We would also thank Prof. A. Watanabe of University of Tokyo for his useful suggestion in preparing the manuscript.

CHAPTER 114

A MODEL FOR CROSS-SHORE SEDIMENT TRANSPORT

M.J.F. Stive*

ABSTRACT

A model for cross-shore sediment transport due to random waves is described which adopts a vertically integrated transport description for sheetflow situations. The formulation of the transport as a function of the instantaneous velocity field is based on the approach of Bailard (1981). This approach assumes in essence that the instantaneous transport is proportional to some power of the instantaneous near-bottom velocity. Implementation of this transport description in a time-dependent model requires a formulation of the time-mean and some low order moments of the near-bottom velocity field. An initial formulation based on a monochromatic, second order Stokes wave representation is presented. The model is checked on the basis of both field and laboratory data. Some consequences for further study are indicated.

1. INTRODUCTION

Observation of sediment transport due to random waves on a two-dimensional beach indicates that one of the more important mechanisms under active surf conditions may be the transport of sediment by the time mean, seawards directed flow near the bottom induced by the breaking of waves. It was shown (Stive and Battjes, 1984) that this mechanism is so dominant that a vertically integrated model incorporating this mechanism alone describes the bottom variations in an active surf zone to a satisfactory, first approximation. Extension of this model with other transport mechanisms is a logical step towards a more complete cross-shore sediment transport model. Here some first suggestions are made to extend the model with transport due to the asymmetry of the wave motion, so that also a mechanism for onshore transport is included.

2. TRANSPORT FORMULATION

Since we are interested in a transport formulation which takes also the effects of wave asymmetry into account, it is essential to adopt a formulation describing the instantaneous transport. A simple approach would be to assume that the instantaneous sediment transport rate, q, is proportional to some power of the local relative velocity between the bed and the fluid outside the boundary layer. For example,

$$q(t) = A\, u(t) |u(t)|^n \qquad (1)$$

where $u(t) = u_b \cos\omega t$ + higher harmonic terms, with u_b the orbital velocity amplitude just outside the boundary layer and ω the angular frequency.

* Senior Researcher, Delft Hydraulics, P.O. Box 152, 8300 AD Emmeloord, The Netherlands.

The latter approach has been elaborated consistently for surf zones on a plane sloping beach by Bailard (1981), who extended the work of Bailard and Inman (1981). Based on Bagnold's (1963) energetics concept these authors use as a starting point a description of the instantaneous sediment transport basically in the form of Equation (1), extended with the effect of a bottom slope. Bailard (1981) distinguishes between bedload transport in a granular-fluid shear layer of a thickness in the order of the wave boundary layer and suspended transport in a layer of greater thickness, typically in the order of several centimeters. For the bedload transport the power n as introduced by equation (1) is given as 2, while for the suspended transport it is given as 3. Here the formulation is reduced for application in the cross-shore direction which yields the instantaneous total load sediment transport equation (see also Bailard, 1982):

$$i(t) = i_B(t) + i_S(t) = \rho c_f \frac{\varepsilon_B}{\tan\phi}\left[|u(t)|^2 u(t) - \frac{\tan\beta}{\tan\phi}|u(t)|^3\right] + \rho c_f \frac{\varepsilon_S}{w}\left[|u(t)|^3 u(t) - \frac{\varepsilon_S}{w}\tan\beta\,|u(t)|^5\right] \quad (2)$$

where i is the total cross-shore immersed weight sediment transport rate (composed of the bedload transport rate, i_B, and the suspended load transport rate, i_S), ρ is the water density, c_f is the drag coefficient for the bed, $\tan\beta$ is the slope of the bed, ϕ is the internal angle of friction of the sediment, w is the sediment's fall velocity and ε_B and ε_S are bedload and suspended load efficiencies, respectively. The efficiency factors ε_B and ε_S denote those (constant) fractions of the total power produced by the fluid motion which are expended in transporting. The immersed weight sediment transport rate is linked to the volumetric transport rate q by

$$q = \frac{i}{(\rho_s - \rho)gN} \quad (3)$$

where ρ_s is the sediment density, g the gravitational acceleration and N the local volume concentration of solids.

The above sediment transport formulation uses vertically integrated equations. As a consequence, the sediment transports are assumed to respond to the near bottom water velocity in an instantaneous, quasi-steady manner. This assumption is probably valid for most natural beaches with prevailing sheet flow conditions and incident wave periods in excess of 5 seconds approximately.

Another uncertainty in the transport formulation concerns the use of bedload and suspended load efficiency factors. Although constant values have been found adequate for certain types of flow, the estimation of their optimal values, and their possible variations with the type of flow considered leaves at least some quantitative uncertainty.

3. WAVE INDUCED CROSS-SHORE FLOWS

Given the variation of the cross-shore velocity field the mean cross-shore sediment transport rate may in principle be calculated from the time averaged Equation (2):

$$\langle i \rangle = \rho\, c_f \frac{\varepsilon_B}{\tan\phi}\left[\langle |u|^2 u\rangle - \frac{\tan\beta}{\tan\phi}\langle |u|^3\rangle\right] +$$

$$+ \rho\, c_f \frac{\varepsilon_S}{w}\left[\langle |u|^3 u\rangle - \frac{\varepsilon_S}{w}\tan\beta\,\langle |u|^5\rangle\right] \qquad (4)$$

The total velocity u is decomposed into a near-bottom, mean (overbar) and an oscillatory (tilde) flow component,

$$u = \bar{u} + \tilde{u} \qquad (5)$$

Conceptual simplifications follow by assuming that the oscillatory velocity is due to a single plane wave of frequency ω and some small nonlinear harmonics:

$$\tilde{u} = u_m \cos\omega t + u_{2m}\cos 2\omega t + \ldots \qquad (6)$$

in which $u_m > u_{2m} > \ldots$

Using Equations (5) and (6) in Equation (4) yields:

$$\langle i \rangle = \rho c_f u_m^3 \frac{\varepsilon_B}{\tan\phi}\left[\psi_1 + \frac{3}{2}\delta_u - \frac{\tan\beta}{\tan\phi}(u3)^*\right] +$$

$$+ \rho c_f u_m^4 \frac{\varepsilon_S}{w}\left[\psi_2 + \delta_u (u3)^* - \frac{u_m}{w}\varepsilon_S \tan\beta\,(u5)^*\right] \qquad (7)$$

in which the relative current strength, δ_u, is

$$\delta_u = \bar{u}/u_m \qquad (8)$$

and ψ_1 and ψ_2, represent non-dimensional velocity moments, defined as

$$\psi_1 = \langle \tilde{u}^3\rangle / u_m^3 \qquad (9a)$$

$$\psi_2 = \langle |u|^3\, \tilde{u}\rangle / u_m^4 \qquad (9a)$$

The even velocity moments $(u3)^*$ and $(u5)^*$ are defined as:

$$(u3)^* = \langle |u|^3\rangle / u_m^3 \qquad (10a)$$

$$(u5)^* = \langle |u|^5\rangle / u_m^5 \qquad (10b)$$

Retaining first order in the relative current strength and odd moments only three velocity moments may be simplified further, i.e.

$$u_m^4\, \psi_2 \simeq \langle |\tilde{u}|^3\, \tilde{u}\rangle + 3\bar{u}\langle |\tilde{u}|^3\rangle \qquad (11)$$

$$\text{and } u_m^3 (u3)^* \simeq \langle |\tilde{u}|^3\rangle + 3\bar{u}\langle |\tilde{u}|\tilde{u}\rangle \qquad (12a)$$

$$u_m^5 (u5)^* \simeq \langle |\tilde{u}|^5\rangle + 5\bar{u}\langle |\tilde{u}|^3\tilde{u}\rangle \qquad (12b)$$

Inspection of the above expressions indicates that we need to evaluate the mean return flow and the oscillatory velocity moments.

Mean return flow

It has been hypothesized by Dyhr-Nielsen and Sørensen (1970) that the seaward directed returnflow or undertow in the surf zone -which compensates for the shoreward directed mass flux above wave trough level- is driven by the imbalance between the vertically non-uniform wave momentum flux on the one hand and the vertically uniform pressure gradient on the other hand. Quantitative evaluations of these ideas leading to models for the circulation have been presented by e.g. Dally (1980), Svendsen (1984), and more recently by Stive and Wind (1986). These cross-shore flow models are all based on a periodic wave formulation. To apply these models in the case of random waves Stive and Battjes (1984) have shown that satisfactory results are obtained, by simply applying the periodic formulation to that fraction of the waves that are breaking.
An evaluation applying this idea to Stive and Wind's model and a generalization to the case of quasi-3D current models has recently been made by De Vriend and Stive (1987). The formulation for the purely 2DV (two-dimensionally vertical) case has been adopted here. It is described below leaving out the rather large number of analytic expressions for which the reader is referred to the paper.

In order to derive the wave-mean cross-shore current, the water column is divided into three layers, viz. a surface layer above the wave trough level, a middle layer and a bottom layer. Stive and Wind (1986) propose to consider only the area below the wave trough level, and to take account of the surface layer effects via an effective shear stress at the trough level, compensating for the momentum decay above it, and via the condition that the net undertow must compensate for the mass flux in the surface layer. This means that the surface layer model is reduced to the formulation of the effective shear stress and the mass flux. The bottom layer velocity due to non-breaking waves is assumed to be similar to Longuet-Higgins' (1953) "conduction solution" for progressive waves. For breaking waves, Stive and Wind (1986) show that assuming a zero bottom shear stress leads to acceptable predictions of the current outside the wave boundary layer. This means that for this part of the current the bottom layer as such can be left out of consideration. Thus the problem has been reduced to solving the velocity in the middle layer from the horizontal momentum balance, both for the case of breaking and of non-breaking waves. In both cases the prescribed shear stress at the wave trough level provides an upper boundary condition, whereas the lower boundary condition follows from the zero shear stress approximation (breaking waves) or from matching with with bottom layer solution (non-breaking waves). The integral condition of continuity can be used to determine the remaining unknown constant (the bottom shear stress for non-breaking waves, the mean return current velocity for breaking waves).

In De Vriend and Stive (1986) these middle-layer solutions are considered in detail, for non-breaking waves, for breaking waves and for a random breaking wave field, respectively. In the latter case part of the waves are breaking, say a fraction $\tilde{Q}_b$ ($0 \leq \tilde{Q}_b \leq 1$). If mutual interaction between the waves is left out of consideration, this means that the secondary current velocities for the breaking and the non-breaking waves have to be added with appropriate weight factors.

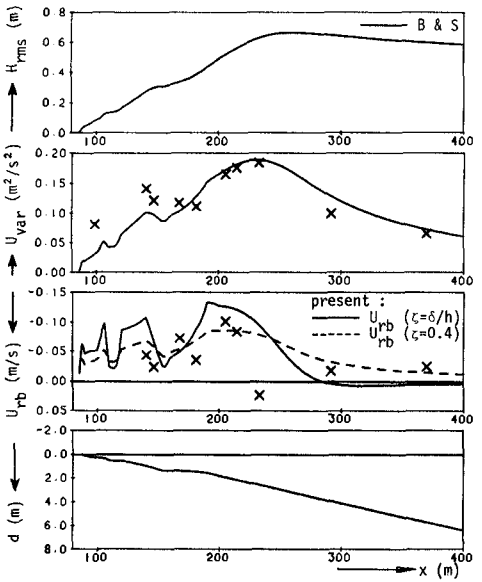

Fig. 1 Wave-induced undertow: comparison with NSTS measurements Nov. 20, 1978 at Torrey Pines beach (after Guza & Thornton, 1985); profile of bottom elevation below MSL (d), cross-shore undertow velocity (U_{rb}), variance of horizontal orbital velocity (U_{var}), and rms wave height (H_{rms}) versus distance normal to shore (x). Data points: measured values. Curves: computation with the models, see legend; B & S is Battjes and Stive (1985), present is present model, where U_{rb} ($\zeta = \delta/h$) is the undertow on top of the bottom boundary layer and U_{rb} ($\zeta = 0.4$) is that at 0.4 times the water depth.

To conclude this section a comparison is made with a field data and laboratory data. The field data are from the NSTS campaign at Torrey Pines Beach (Guza and Thornton, 1985). The wave energy decay prediction model (Battjes and Stive, 1985) was calibrated ($\alpha = 5.0$ and $\gamma = 0.5$) on the basis of the measured orbital velocity variance in the frequency range $0.05 < f < 0.5$ Hz. The velocity measurements were conducted at elevations of 0.4 m to 1.0 m above the bed. Taking account of the inherent inaccuracy of the measured, mean cross-shore velocities, the agreement is good, for the magnitude as well as for the cross-shore distribution of the velocity.

The laboratory data concern a more complicated depth profile (with two bars) under random wave attack. The wave energy decay prediction is again after the above mentioned model, but now according to the suggested parameterization The velocity measurements were conducted at an elevation of 0.05 m above the bed. Assuming that the accuracy of the measured, mean cross-shore velocities is relatively high the agreement in this case is less good. It is expected that the observed discrepancy is mostly due to the difficulty in predicting the breaking wave fraction on a barred beach (see the comparison between measurements and computations of $\tilde{Q}_b$).

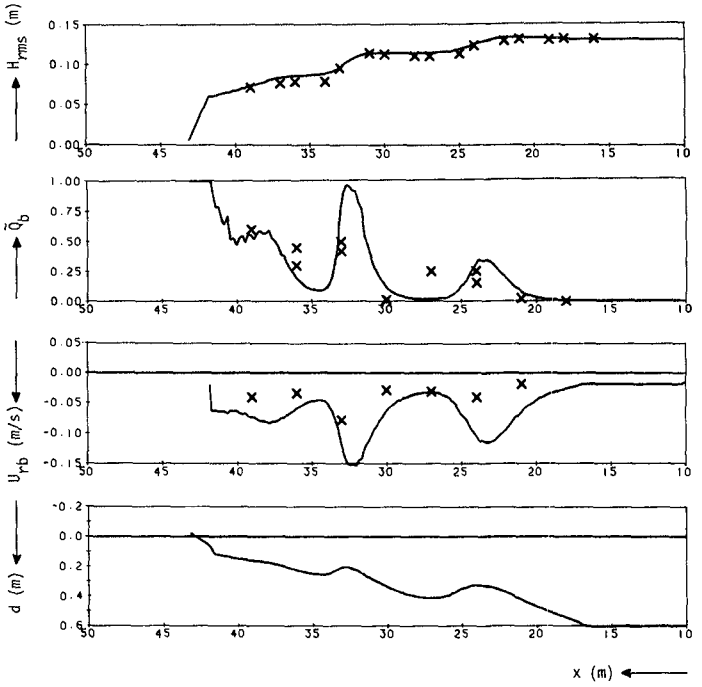

Fig. 2 Wave-induced undertow: comparison with flume measurements: profile of bottom elevation below MWL(d), cross-shore undertow velocity (U_{rb}), fraction of breaking waves ($\tilde{Q}_b$) and rms wave heights (H_{rms}) versus distance normal to shore (x).
Data points: measured values. Curves: computation with the model, where U_{rb} is the undertow at 0.05 m above the bottom.

Oscillatory velocity moments

From the evaluation of the present transport formulation it appears that the following low order oscillatory velocity moments are of importance:
- the four lowest even moments $\langle\tilde{u}^2\rangle$, $\langle|\tilde{u}|^3\rangle$, $\langle\tilde{u}^4\rangle$, $\langle|\tilde{u}|^5\rangle$, which are non zero for symmetric velocities,
- the two lowest odd moments $\langle\tilde{u}^3\rangle$, $\langle|\tilde{u}|^3\,\tilde{u}\rangle$, which are zero for symmetric velocities.

The latter moments are the most difficult to estimate: they are nonzero only for nonlinear waves such as actually occur nearshore. The shoreward velocities in such waves are typically stronger and of shorter duration than the offshore flows, leading to nonzero values for the odd moments.

A theoretical evaluation of the even moments for a random, linear sea (Gaussian model) is given by Guza and Thornton (1985). The theoretical moments are compared to field observations from the NSTS study. Their results indicate that even moments do not critically depend on cross-shore velocity asymmetry. This is due to the fact that also for symme-

tric velocities these terms are nonzero. At the present stage we will therefore rely on the Gaussian estimates for the even moments.

The odd moments are zero for a symmetric velocity field, but can be nonzero for asymmetric (nonlinear) motions. A relevant nonlinear property is the asymmetry of the wave surface about the horizontal axis. For nonbreaking waves this asymmetry may to a first approximation well be predicted on the basis of a horizontal bottom, nonlinear wave theory, assuming that due to gradual bottom variations the waves locally behave as on a horizontal bottom (see Flick et al, 1981). However, in the horizontal bottom, nonlinear wave theories the phases of the harmonics are locked to zero and there is no vertical wave profile asymmetry possible. This asymmetry about the vertical plane is an essential property of the sawtooth shaped breaking waves in the surf zone. These theories are deficient in this respect and thus unsuitable for calculations of odd velocity moments which depend critically on phase. To illustrate this we calculate the two lowest order odd moments assuming that the velocity fluctuation is described by a second order approximation with a locked but nonzero phase between the two components:

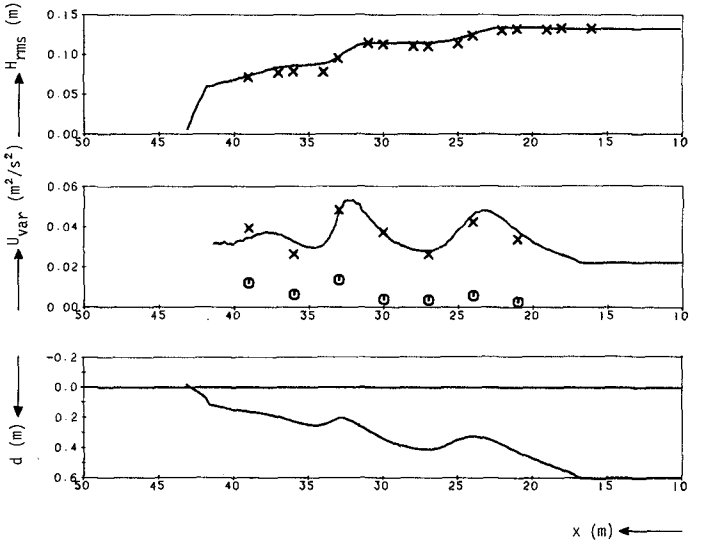

Fig. 3 Wave-induced near-bed velocity variance: comparison with flume measurements; profile of bottom elevation below MWL(d), oscillatory horizontal velocity variance (U_{var}) and rms wave height (H_{rms}) versus distance to shore (x).
Data points: measured values, the circles indicate U_{var} in the frequency range 0-0.25 Hz. Curves: computations with the model.

$$\tilde{u} = u_m \cos \omega t + u_{2m} \cos (2\omega t + \phi_2) \qquad (14)$$

in which $u_m > u_{2m}$. After some algebraic manipulation it may be show that to lowest order the two odd velocity moments are given by:

$$\langle \tilde{u}^3 \rangle = \frac{3}{4} u_m^2 u_{2m} \cos \phi_2 \tag{15a}$$

$$\langle |\tilde{u}|^3 \tilde{u} \rangle = \frac{12}{5\pi} u_m^3 u_{2m} \cos \phi_2 \tag{15b}$$

An interesting perspective now arises when we combine these results with the following observations. In the inner surf zone where the breaking waves are quasi-steady the relative phase of the second harmonic increases smoothly toward the asymptotic value (see Flick et al, 1981):

$$\phi_2 \to \pi/2 \tag{16}$$

Thus, according to Eq. 15a, 15b, the odd velocity moments for breaking waves vanish ultimately.

At this point we may specify our wave decay model which predicts linear and nonlinear properties necessary to derive the velocity moments. As a starting point Battjes and Stive's (1985) wave decay prediction model is adopted to yield the cross-shore variation of the variance of the wave elevation. Given the wave variance, linear theory may be applied to provide the near-bottom velocity variance and thus the even velocity moments based on the Gaussian model. The odd velocity moments are estimated from the nonbreaking fraction of waves only, assuming that the contribution of the breaking waves is negligible in view of the above conclusions. To provide results from this model we use the second order Stokes expansion with

$$\tilde{u} = u_m \cos \omega_p t + \frac{3}{4} \frac{u_m^2}{c} \sinh^{-2}(k_p h) \cos 2\omega_p t \tag{17}$$

and choose $u_m = u_{rms}$ from the consideration that the monochromatic representation of the random wave field should have to same variance.

We conclude with a comparison between the above theory and the same laboratory measurements used earlier in the undertow comparison. Firstly, the velocity variance prediction may be checked from Fig. 3. It appears that the linear, Gaussian estimate is quite accurate. Secondly, the prediction of the remaining low order velocity moments may be checked from Fig. 4. It is noted that all moments are normalized by the variance, that the even moments are based on the linear, Gaussian estimate and that the odd moments are based on the nonlinear, monochromatic estimate. Here it appears that the prediction of the lowest order moments are reasonable given all assumptions made but that the discrepancies increase with increasing order of the moments as could be expected.

4. COMPUTATION OF TRANSPORT AND BOTTOM CHANGES

In the present model the local mean, volumetric cross-shore sediment transport rate, $\langle q \rangle$, is calculated according to the following expressions, where use has been made of expressions (4) and (8)...(12):

$$\langle q \rangle = B_{as} \langle q_{as} \rangle + B_{un} \langle q_{un} \rangle - B_{sl} \langle q_{sl} \rangle \tag{18a}$$

$$\langle q_{as} \rangle = F_B \psi_1 + F_S \psi_2 \tag{18b}$$

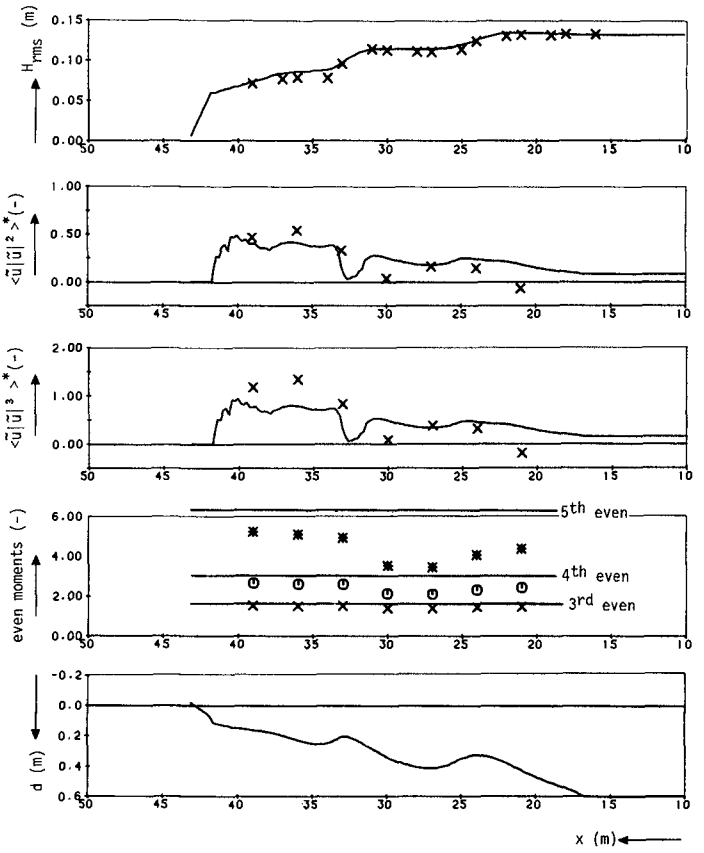

Fig. 4 Wave-induced near-bed velocity moments: comparison with flume measurements; profile of bottom elevation below MWL (d), normalized odd and even moments and rms wave height (H_{rms}) versus distance to shore (x).
Data points: measured values. Curves: computations with the model, where the even moments are according to the linear, Gaussian model.

$$\langle q_{un} \rangle = F_B \frac{3}{2} \delta_u + F_S \, 4\delta_u \, (u3)^* \tag{18c}$$

$$\langle q_{sl} \rangle = F_B \frac{\tan\beta}{\tan\phi} (u3)^* + F_S \frac{u_m}{w} \varepsilon_S \tan\beta \, (u5)^* \tag{18d}$$

$$F_B = \frac{c_f u_{rms}^3 \varepsilon_B}{\Delta g N \tan\phi} \tag{18e}$$

$$F_S = \frac{c_f u_{rms}^4 \varepsilon_S}{\Delta \, g \, N \, w} \tag{18f}$$

Here c_f is the drag coefficient equal to $\frac{1}{2}f_w$ with f_w the friction factor as defined in Stive and Battjes (1984) and B_{as}, B_{un} and B_{sl} are proportionality constants which should be O(1) if the description is right. The free parameters in the above expressions are ϵ_B and ϵ_S which for cross-shore transport are given by Bailard (1982) on the basis of field observations as 0.10 and 0.02 respectively. These values are adopted here.

The cross-shore variation of the local, mean sediment transport may now be calculated with the above expressions (18a...f) given the results of the wave height decay and kinematics model. Through application of the mass balance for the sediment (of which the properties are assumed constant) the bottom changes may be calculated. This procedure may be repeated for the new beach profile. In the numerical evaluation a second order Runge-Kutta algorithm is used in the wave decay model and a modified Lax scheme in the bottom change calculations. As a boundary condition on the waterline the present formulation yields $\langle q \rangle = 0$.

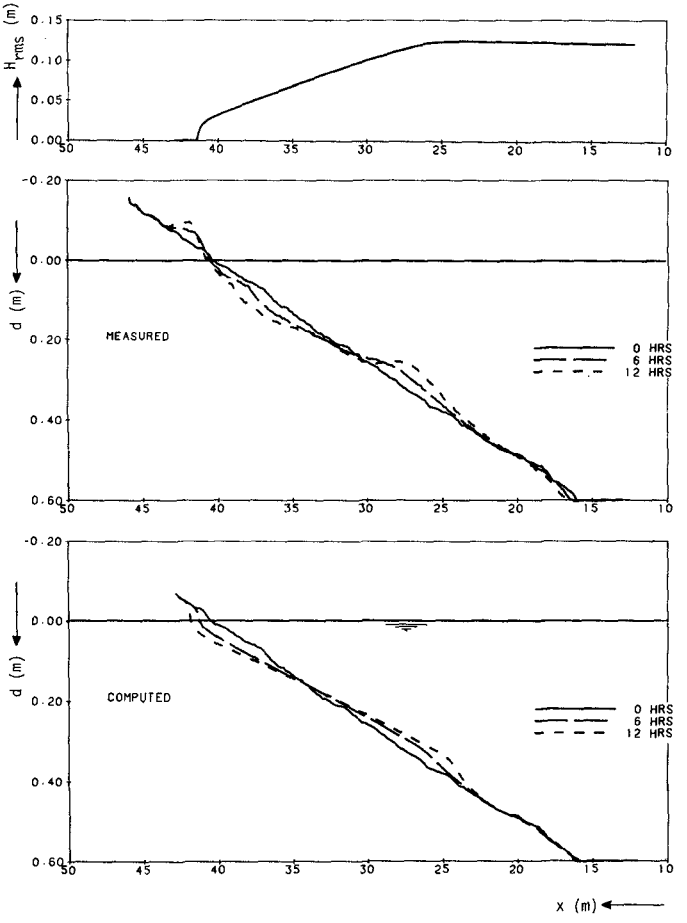

Fig. 6 Deformation of initially plane beach due to random waves: comparison with flume measurements; profiles of bottom elevation below MWL (d) and rms wave height (H_{rms}) versus distance to shore (x).

5. MODEL VERIFICATION

For the purpose of verification of the present model, a comparison was made with available field data, and laboratory measurements were carried out. The field data set concerns observed bar formation and deformation in an estuary region in the South of the Netherlands, the socalled Voordelta, which occurred after closure of one of the Southern Dutch estuaries. The profile deformation in cross-shore direction is appreciable (see Figure 5). The comparison between the hindcast results and the measurements is satisfactory, despite the fact that the wave climate and

hydraulic conditions were schematized to one value for the incident wave characteristics and a fixed waterlevel. The proportionality constants B_{as}, B_{un} and B_{sl} were set at 1.0. Some characteristic parameters of this case are collected in Table 1 below.

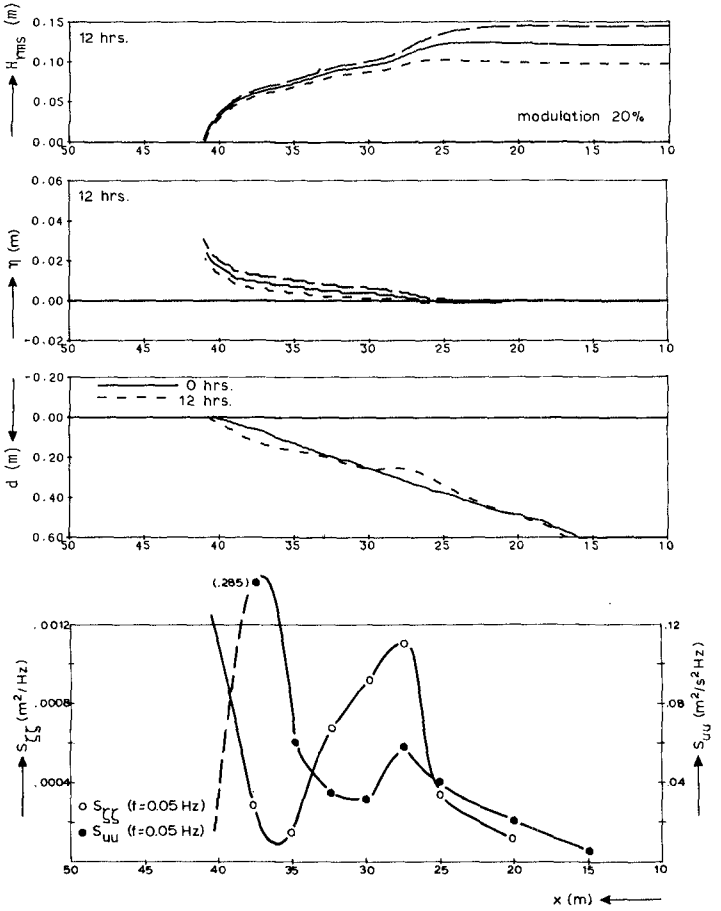

Fig. 7 Low frequency energy on the initially plane beach: computed wave height and set-up modulation and measuerd, resonant 1/2 long wave mode between surf zone's outer region and the shore.

The laboratory measurement programme involved the collection of surface elevation, near-bottom velocity and profile deformation data on two beach profiles -one initially plane and the other barred- under random wave attack (see Table 1 for some characteristic parameters). The velocity data on the barred beach were used in the earlier presented comparisons with the theoretical wave-induced cross-shore flows. The resulting beach profile deformations - restricted to the plane beach case due to space limitations - are compared with the model predictions here.

Fig. 6 gives the measured and computed profile deformation after 6 hrs and 12 hrs on the initially plane beach. It appears that the main erosion and sedimentation patterns agree, also quantitatively (the proportionality constants were all set on 2.0). Here we ignore the small sedimentation in the swash zone above the waterline, a process which is not included in the present model. An important discrepancy, however, is found in the horizontal and vertical development of the sedimentation in the surf zone's outer region. The measurements indicate a more pronounced development of an offshore bar, eventually with a negative shoreside slope. Similar indications of the absence of these developments in the model are found by the results for the profile deformations of the initially single-barred beach. The present model is unable to predict the development of the bar's shore side.

case	profile	grain diameter (μm)	$H_{rms,incident}$ (m)	f_p (Hz)
field	deltaic bar	225	1.50	0.17
laboratory	plane	90	.123	0.50
laboratory	single bar	90	.081/.133	0.50/0.50

Table 1 Characteristic parameters field and laboratory cases

Analysis of the discrepancies has resulted in strong indications that resonant surf beat modes may be the cause of the shoreside bar developments. Some results in support of this are given furtheron. First, we discuss possible surf beat sources. An inventory of the literature on this topic yields two "natural" sources (1, 2) and two "laboratory" sources (3, 4), viz.

(1) the release of or forcing by group-bound long waves due to wave breaking (Longuet-Higgins and Stewart, 1964);
(2) forcing by the time variation of the initial breaking region due to wave-grouping (Symonds and Bowen, 1984);
(3) wave paddle reflection of flume bound long waves;
(4) parasitic, wave paddle generated free long waves.

The third of these sources can be eliminated in the present measurements since the method of active wave absorption was adopted (Kostense, 1984). Discrimination between the other sources is very difficult: in all cases amplitudes and frequencies are closely related and proportional to the wave group characteristics. Whichever source is responsible, the following observation is of importance. On the initially plane beach a resonant ½ wave surf beat mode develops (see Fig. 7) between the water line and the outer surf zone, at which latter position the undertow deposits sand. The interesting, yet not well understood fact is that this mode is resonant. This is not expected by any theory, but the results in Fig. 7 for the modulated wave height indicate that both first two mentioned surfbeat sources can explain a forcing. Also, for the barred beach similar -although more complicated- observations were made.

Obviously, this is a relevant mechanism which should be included in a model. It is noted though that compared to a natural situation the relevance of this development may be somewhat overemphasized, i.e. with the timescale being approximately 4 the above storm wave conditions with fixed water level would have to be strictly constant for two days.

6. DISCUSSION AND CONCLUSION

In this paper a first suggestion is made to extend the earlier formulated model for offshore sediment transport due to undertow (Stive and Battjes, 1984) with the effects due to horizontal asymmetry in the wave motion. To arrive at these results it was necessary to model some low order odd moments of the near-bottom velocity field. An initial formulation based on a monochromatic, second order Stokes wave representation is shown to give a reasonable, first approximation to the odd velocity moments, but obviously the formulation needs improvement.

The odd velocity moments were readily used in the transport formulation of Bailard (1981). This concerns a vertically integrated description of the sediment transport in sheetflow conditions, which assumes that the instantaneous transport is proportional with some power of the instantaneous near-bottom velocity. The validity of this approach for natural surf zones needs further investigation.

A check was made of the ability of the model to predict beach profile deformations. Reasonable agreement was found in the general patterns. However, it appears that in an erosive situation only the onset of the bar formation in the outer surf zone is indicated by the model, whereas subsequent bar growth is not well predicted. The growth is believed to be associated with resonance of particular long wave modes forced by wave grouping effects. This phenomenon needs further investigation, before it can be included in a dynamic cross-shore sediment transport model.

It is finally noted that analysis of this model for several realistic cases has resulted in the following conclusions. There are two main contributions to the sediment transport, viz. that induced by the undertow yielding offshore transport and that induced by the wave-asymmetry yielding onshore transport. In low-frequency or swell conditions the latter dominates and in high-frequency or storm conditions the former dominates. These conclusions coincide with the common suggestions that low-frequency waves build up a coast and that high-frequency waves erode it.

ACKNOWLEDGEMENT

This work was done as a part of the TOW Coastal Research Programme of the Ministry of Transport and Public Works (Rijkswaterstaat) of the Netherlands. The author wishes to thank Dr. H.J. De Vriend for the many helpful discussions and Dr. J.A. Battjes for his critical review of the manuscript.

CHAPTER 115

BEACH CHANGE AROUND DETACHED BREAKWATERS DUE TO ARTIFICIAL NOURISHMENT OF BYPASSED SAND

SUYAMA, H*., T. UDA** and T. YOSHIMURA***

ABSTRACT

Field experiment of sand bypassing was conducted on the Shimoni–ikawa Coast in Toyama Bay. The materials of 5900m^3 dredged on the updrift coast of the harbor were thrown into behind the detached breakwater. After the nourishment detailed surveys of the bottom topography around the breakwaters, wave observations and tracer tests using colored concrete blocks were carried out in order to investigate the movement of the nourished sand. Temporal and spatial changes of the shoreline positions and the sectional area of the beach in the shoreward zone of the detached breakwater are examined. It is found through the field experiment that the materials nourished behind the detached breakwater were carried slowly in the longshore direction by the westward littoral drift, dominating on the coast, without the outflow of sand through the openings of the breakwaters. It is concluded that the detached breakwater is useful to control the on–offshore sand movement and to retain the sand behind the detached breakwater.

I. INTRODUCTION

The Shimoni–ikawa Coast, located in Toyama Bay and formed by the fluvial sediment supply of the Kurobe River for an alluvial fan, has experienced severe beach erosion for a long time. On the east end of the coast Miyazaki Fishery Harbor has been constructed since 1947, and the balance of littoral transport directing westward was lost due to the presence of the breakwater. The shoreline advanced on the updrift side of the breakwater and the shoaling in the harbor entrance was caused by the sand movement around the tip of the breakwater, whereas the downdrift beach was eroded. In foreign countries sand bypassing method is frequently used to solve the beach erosion and accretion simultaneously, but in Japan the applied cases of the method are rather few.

Ministry of Construction and Fishery Agency performed a cooperative field study on the method to solve these problems, including sand bypassing system, in 1983 and 1984, taking the case of the Shimoni–ikawa Coast into a characteristic example.

This paper mainly summarizes the result of the field investigations conducted by Ministry of Construction. The aim of the study is to investigate the effectiveness of

sand bypassing for a way which can solve the problems of the beach erosion and accretion near the harbor simultaneously through the field experiment. The second is to examine the function of the detached breakwater for a structure which can control the abrupt diffusion of the nourished sand by the field experiment.

Ⅱ. FIELD EXPERIMENT OF SAND BYPASSING

The field experiment was carried out on the Shimoni－ikawa Coast located in Toyama Bay (Fig. 1). The coast is one of the famous coasts eroded severely in Japan, and various countermeasure works against beach erosion have been conducted. In recent years the beach has still been eroded, and the settlement of the concrete armour units of the detached breakwaters and the scouring of the sea bottom in front of the sea wall are considerably large. Bottom contours around Miyazaki Fishery Harbor is shown in Fig. 2. Sandy beach extends on the east coast of the harbor, and to the contrary there is no sandy beach on the west coast. Instead, coastal revetments and many detached breakwaters are placed along the coastline to protect the coast. The coastlines east of Miyazaki Fishery Harbor and west of the river mouth of the Sasa River run almost in the east－west direction. Both coastlines have the discrepancy of the shoreline position of around 1km in the on－offshore direction at the downcoast of Miyazaki Fishery Harbor. The discrepancy of the shoreline positions is considered to be formed by the beach erosion. First, the position of the mouth of the Kurobe River historically moved westward and the sand supply of the river decreased on the coast, and hence the beach was eroded by westward littoral drift with the lack of the sand supply. Secondly, westward littoral drift was obstructed by the presence of the breakwater of Miyazaki Fishery Harbor.

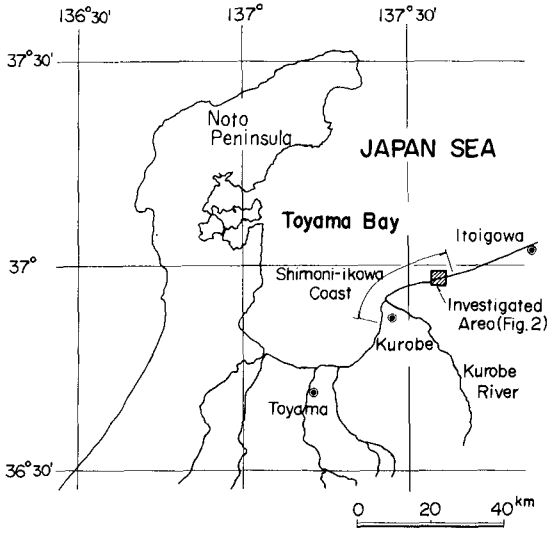

Fig.1 Location of Shimoni－ikawa Coast.

The transportation of sand was conducted by the following method. First, beach materials were dredged on the updrift site of the breakwater of Miyazaki Fishery Harbor, and were carried to 2 . 5 km downdrift location from the harbor by land (Fig. 2). The materials of 5900m³ were thrown into behind the detached breakwater. For the transportation method, dump trucks of 11 tons were used, since the materials mainly consist of gravels and the transportation by sea is thought to be difficult because of high waves in winter, although various methods were examined at first. The transportation were carried out for 34 days from October 13 to December 7 in 1983. Artificial nourishments behind the detached breakwater were conducted 6 times dividedly between November 4 and December 7 in 1983 as summarized in Table 1 .

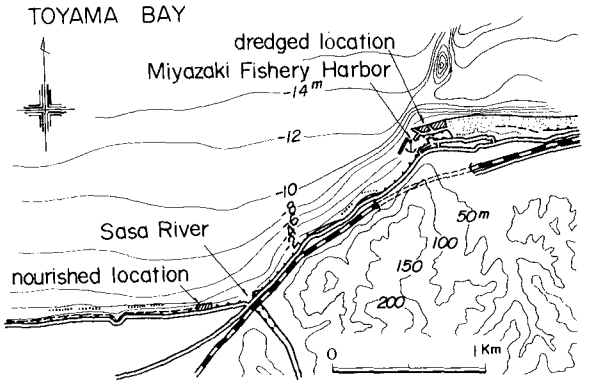

Fig.2 Bottom contours around Miyazaki Fishery Harbor.

Table 1 Nourished amount of sand.

Date	Nov. 4	Nov.10	Nov.16	Nov.17	Nov.29	Dec. 7
nourishd volume	1,050m³	1,100	1,100	530	1,060	1,060
accumulated volume	1,050m³	2,150	3,250	3,780	4,840	5,900

The location of the artificial nourishment was planned at the downdrift coast next to the fishery harbor at first, because of the short transportation distance. However, the nourishment was finally conducted behind the detached breakwater located about 2.5 km west of the harbor, considering the following two reasons. First, the nourishment at the location next to the harbor was anxious about the influence to the fishery, since the coast is a good fishing ground of production of the kelp. Second, the combined method of the construction of the detached breakwater and the artificial nourishment is considered to be effective in order to control the movement of the

The direction of the coastline is taken for the reference line of the figure. It is found that waves are frequently incident from clockwise direction to the normal of the shoreline. Under these conditions, westward longshore sediment transport should prevail.

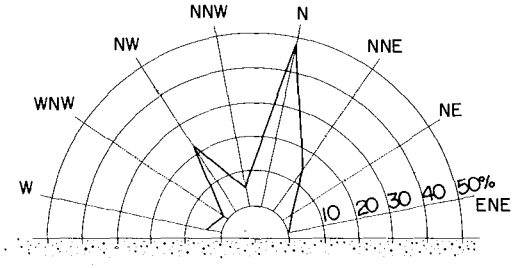

Fig.4 Wave direction measured during November 4 through April 13, 1984 off the nourished location.

Ⅳ. FIELD TEST OF ARTIFICIAL NOURISHMENT

Here, the changes of the shoreline positions, beach profiles and sand volumes obtained by the field experiment of the artificial nourishment are described. First, the alignment of the survey lines of the sounding around the nourished location is shown in Fig. 5. The soundings of wide region were conducted at 40m intervals along 26 survey lines between a and z placed alongshore. The artificial nourishment was carried out behind the detached breakwater located at No.174. The sounding was carried out widely westward from the nourished location instead of ones centered at the nourished breakwater, because the predominant direction of littoral drift is westward and large beach change was expected in the west region. On the other hand, 40–m–interval of the sounding is considered to be too wide near the nourished location, because large beach change might be observed and therefore the soundings of 10 m intervals behind the nourished breakwater and 20 m intervals behind the adjacent breakwaters were selected.

Regarding the beach changes due to the artificial nourishment, bottom contours around the detached breakwaters are compared first. Figure 6 shows the bottom contours measured between October 13, 1983 and January 21, 1984 after the nourishment. The maximum depth behind the breakwaters was about 2 m below the mean sea level before the nourishment. The shoreline behind the detached breakwater protruded remarkably as shown in the bottom contours of December 7 after the completion of the nourishment, and at the same time it began to accrete behind the adjacent breakwater. Furthermore, it is found from the bottom contours until January 21 that the beach change at the openings is small and the tombolo behind the nourished breakwater began to be eroded. To the contrary behind the adjacent breakwater sand accumulated and the scale of the tombolo became large with time.

nourished sand and to prevent the outflow of sand toward the offshore zone, so that the field investigation of the system is valuable for the test of the future measure against beach erosion.

Calculating the actual cost of the transportation of the materials by the price in 1983, the total cost of the transportation and the nourishment was about 10 dollars/m^3 (1 \$≒162¥). The rate of the transportation of the materials was 244m^3/d, since 11-ton dump trucks ran between two locations 40 times a day. More frequent transportation between two locations was difficult because of the environmental influence produced by the passage of the dump trucks in a small town.

Ⅲ. WAVE CONDITIONS DURING FIELD INVESTIGATIONS

Wave conditions during the field investigation of the artificial nourishment were observed at Tanaka Observatory located 5.6km west of the nourished location. Visual observation of wave direction off the nourished detached breakwater was also done. Temporal change of the daily mean of the significant wave height and wave period measured by an ultrasonic wave gauge placed at 15 m deep position off the coast is shown in Fig. 3. During the nourishment between November 4 and December 7, fairly high wave ($\bar{H}_{1/3}$=2.5m and $\bar{T}_{1/3}$=12.9s) attacked the coast on November 20. Besides, several high waves were observed after December 7 when the artificial nourishment was completed. For example, $\bar{H}_{1/3}$=2.30m ($\bar{T}_{1/3}$=5.8s) on December 12 in 1983, $\bar{H}_{1/3}$=3.2m ($\bar{T}_{1/3}$=9.0) on January 17 and $\bar{H}_{1/3}$=2.8 m ($\bar{T}_{1/3}$=11.6s) on January 18 in 1984. Regarding the seasonal change of wave conditions, wave height is high during November through April due to winter storms and calm between May and the midst of August, that is, the wave height becomes smaller than 0.5 m. Wave height and wave period show distinctive seasonal changes. Long-period high waves and short-period low waves appear in winter and summer, respectively.

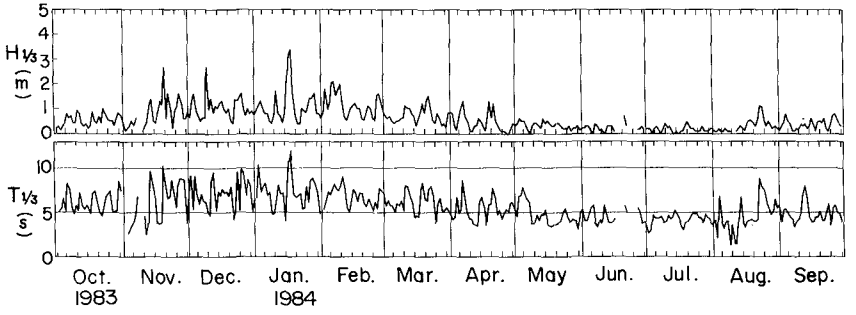

Fig.3 Temporal change of the daily mean of significant wave height and wave period measured at Tanaka Observatory.

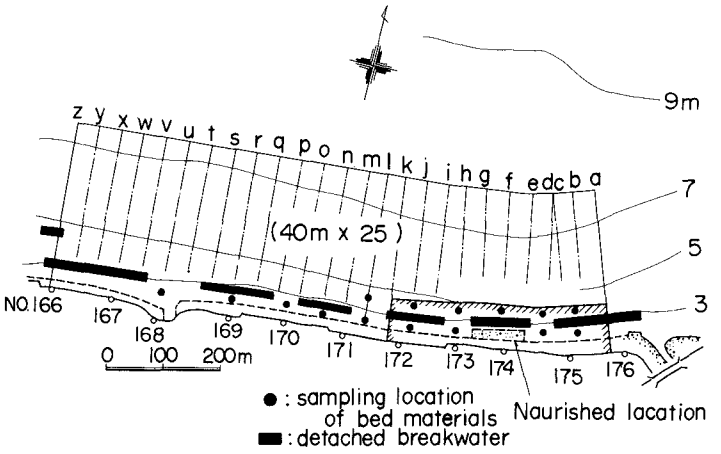
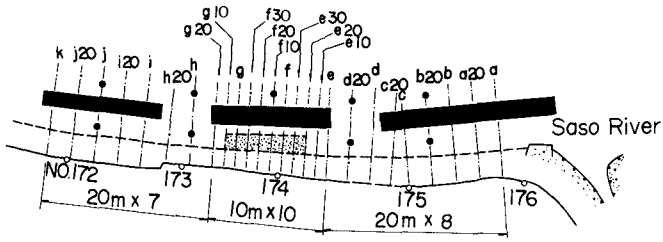
Wave direction off the nourished location was visually measured during November 4, 1983 through April 13, 1984 from top of the coastal revetment (Fig. 4).



(a) Sounding of wide region



(b) Sounding of narrow region

Fig.5 Scope of the soundings around detached breakwaters.

Figure 7 expresses the longshore changes of the shoreline positions and the sectional area of the beach at some survey lines near the nourished location. The reference date of these changes is selected on October 13, 1983 before the nourishment. The change of the sectional area, $\triangle A$, is calculated in the shoreward zone of the detached breakwater. Besides, the porosity inside the wave breaking works placed along the shoreline was assumed to be 50% in the calculation of the sectional area. The shoreline retreated at the nourished location, although once there was a large projection of sand, and the shoreline behind the adjacent detached breakwater advanced. It is found that the shoreline change is abrupt in the beginning of change, but soon it began to slow down with time. The change of the sectional area corresponds with that of the shoreline positions very well, so that it is understood that the shoreline position becomes a good parameter in expressing the change of the sectional area. However, some small differences are noted at survey lines located at

the openings of the breakwaters (for example at survey line h). The region where △A is small is restricted to a narrow zone between the survey line i and h, although the region of small shoreline change is considerably wide. This means that sand can accumulate in a shallow zone in the openings of the detached breakwaters, even if the shoreline does not advance.

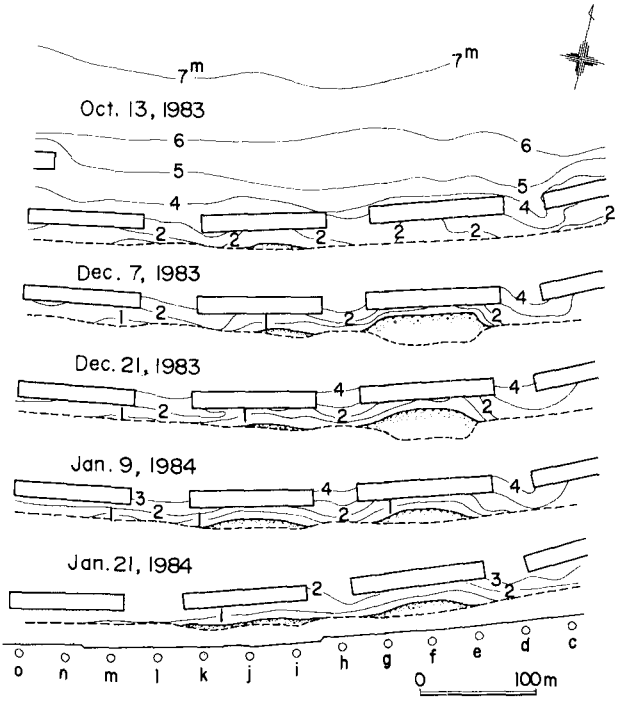


Fig.6 Comparison of bottom contours around detached breakwaters.

The characteristic change of the beach profiles corresponding to the changes of the shoreline positions and sectional area as described above is expressed in Fig. 8. The profies of survey line f, located behind the nourished detached breakwater, is shown. In the profile of December 21, 1983, expressing the beach topography of 14 days after the nourishment, a large amount of sand accumulate in front of the wave breaking works to the onshore end of the detached breakwater, keeping mild slope. Then the beach, of which elevation is between 1.8 m and −1.5 m above the mean sea level, was eroded at this location. It is found that the maximum depth of the eroded beach was restricted within the shallow water zone behind the detached breakwater.

A good correlation is observed between the change of the shoreline positions, △y, and that of the sectional area, △A, as shown in Fig. 7, so that the relationship between △y and △A is examined as in Fig. 9. The solid and open circles are the data obtained in the eroded region behind the nourished breakwater and the accreted

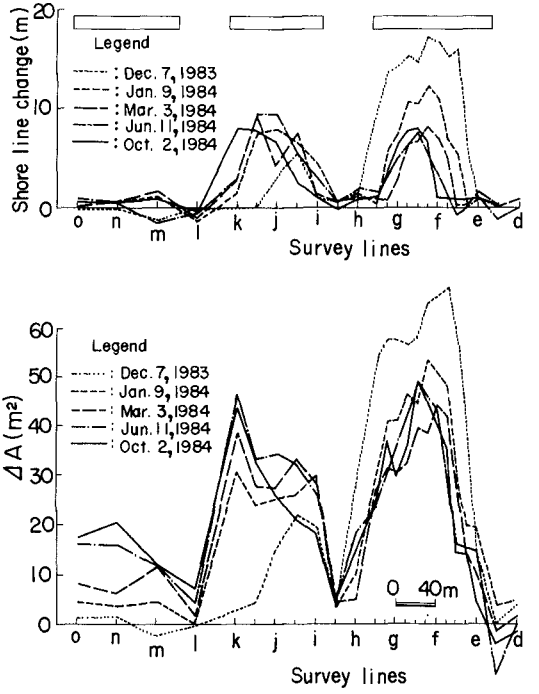

Fig.7 Longshore distributions of shoreline change, △y, and change of sectional area, △A.

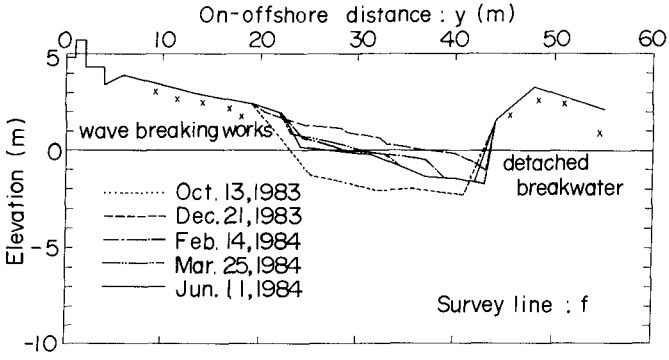

Fig.8 Change of cross section of the beach behind the breakwater (survey line : f) .

region next to the breakwater, respectively. A relation stands between $\triangle A$ and $\triangle y$ with the correlation coefficient of 0.97.

$$\triangle A = 2.6\ \triangle y + 3.5 \qquad (1)$$

where $\triangle A$ and $\triangle y$ have m^2 and m unit, respectively. The regression coefficient of $\triangle A$ and $\triangle y$ is equal to the characteristic height of the beach changes due to littoral transport.[1] Equation (1) shows that the areal change of a section of the beach can be expressed in terms of the change of the shoreline position, and that the characteristic height is equal to 2.6 m. The value is small compared with the one obtained on the other coast. For example, it is around 8 m on the Suruga Coast in Suruga Bay facing the Pacific Ocean.[1] The reason is such that the beach changes are confined within the shallow water zone behind the breakwater in this field experiment.

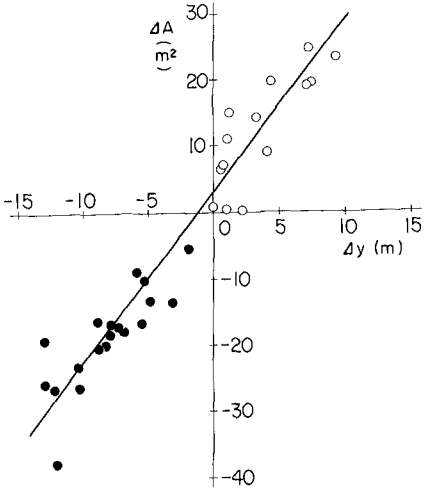

Fig.9 Correlation between the change of the sectional area, $\triangle A$, and that of the shoreline position, $\triangle y$.

Next, temporal changes of the shoreline positions and the sectional areas will be discussed in detail as shown in Fig. 10, since the overall relationship between these variables has already known. The abscissa shows the date of the sounding, and the ordinates are the change of the shoreline position in m-unit and that of the sectional area in m^2-unit, respectively. Changes at 26 survey lines between c and o are shown in the figure. Survey lines between e through g_{20} are located just on the nourished breakwater, and survey lines between i through k are located on the adjacent detached breakwater. The shoreline advanced abruptly between e_{10} and g_{20} during October 13 through December 7 due to the nourishment. At the same time the shoreline at i_{20} and j behind the adjacent detached breakwater advanced without the

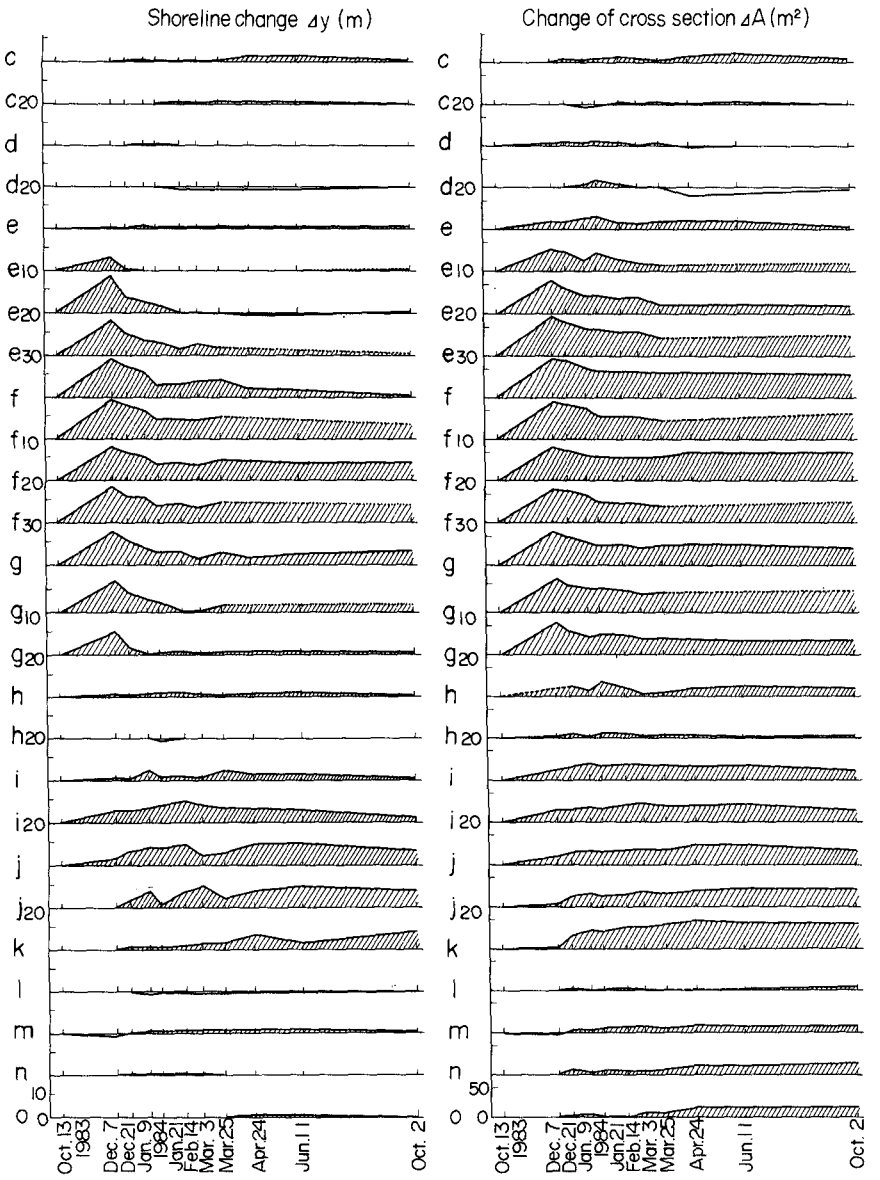

Fig.10 Temporal and spatial change of the shoreline position.

shoreline changes in the opening between the breakwaters. This means that part of the nourished sand were carried quickly westward by the longshore transport with the initiation of the artificial nourishment, and deposited behind the adjacent detached breakwater. Besides, it should be noted that the shoreline did not advance behind the detached breakwater located east of the nourished location, e.g. survey line c and c_{20}. The shoreline change agrees well with the change of the sectional area, and the sectionl area increases with the advance of the shoreline position. In the vicinity of the openings of the breakwaters, for instance at survey lines e, e_{10}, g_{10}, g_{20}, i and i_{20}, the sectional area is considerably large, although the shoreline change is comparatively small. It is found that sand accumulate below the sea surface without the advance of the shoreline. Moreover, the changes of the shoreline position and the sectional area since December 7 were rapid at first, and then the rate of changes decreased with time. Two reasons are considered. First, high waves attacked the beach under the winter storm condition at first, but gradually it became calm wave condition as shown in Fig. 3. Secondly, the rate of change of the nourished form was rapid in the beginning, since nourished sand had a projecting form, even if the artificial nourishment was conducted behind the breakwater.

V. RELATION BETWEEN VOLUME CHANGE AND LONGSHORE COMPONENT OF ENERGY FLUX OF WAVES

In the planning of the beach nourishment behind the detached breakwater, it is important from the technical point of view to know whether there is a possibility of outflow of sand through the openings of the detached breakwater toward the offshore zone or not. Because the sand amount to be needed for the creation of tombolo depends upon both the sand retained behind the breakwater and the loss of sand due to the on–offshore sand movement. Therefore the volume changes in various regions were calculated from the survey data and were summed up as in Fig. 11. In the figure the volume change in each period were normalized by the total volume change, 8152m^3, between October 13, 1983 before the nourishment and December 7 right after the nourishment. In order to obtain the volume change the volume of the materials deposited inside the wave breaking works has to be counted, and for the purpose the porosity inside the wave breaking works was assumed to be 50%. The volume change until December 7 is 2252m^3 greater than the nourished volume of 5900m^3, although both volumes should coincide each other. As for the reasons of the difference, several posibilities are considered such that the assumption of the porosity of 50% was not appropriate, the sounding on October 13 had some error, or the calculation of the total volume of the nourished sand had also some error. However, it is difficult to investigate the problem in detail, so that the volume change of sand is compared by the relative ratio with respect to the total volume change between October 13 and December 7.

Regarding the volume change of sand until October 2 , 1984, it is understood that almost all amount of the nourished sand were retained behind the detached breakwaters and the loss of sand into offshore zone was small, taking account of the

total volume of sand from the nourished location to the second detached breakwater. Comparing the volume changes of sand in each region, the volume behind the nourished detached breakwater had about 80 percent of the total volume in the beginning, but soon it decreased with time. The rate of the volume change was large at first, and then became small. To the contrary the sand volume behind the adjacent breakwater increased rapidly. These changes are considered to be due to the cause that the sand were carried alongshore by the longshore sand transport directing westward in a shallow region behind the detached breakwater. Finally it is concluded that the nourished sand were retained behind the detached breakwater and were useful for the formation of tombolo.

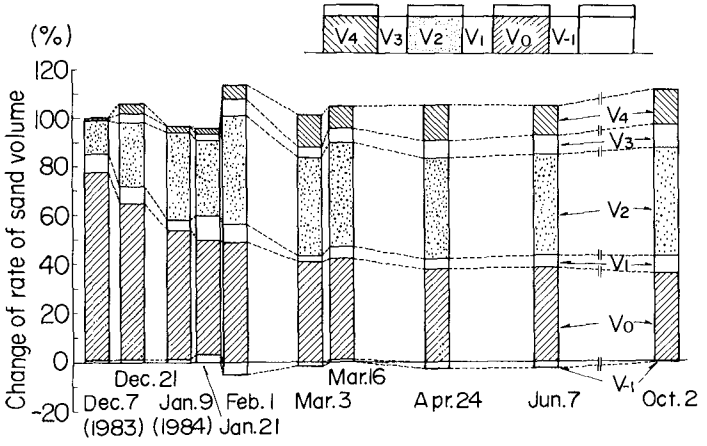

Fig.11 Temporal change of rate of nourished sand volume.

Next, the relationship between the longshore component of the energy flux of waves and the volume change of sand behind the nourished and west detached breakwaters are investigated as shown in Fig. 12. The energy flux of waves are evaluated at a depth of 5 m off the detached breakwater. The energy flux was obtained by the following method. First, wave height at the position of 15 m deep off the nourished location is calculated from the observed data of Tanaka Observatory, considering wave refraction due to the change of the bottom topography. Regarding the wave direction data, the results of the visual observation are assumed to be the input data at the same position, although the accuracy of the visual measurement may not be so high. If the visual observation data are lacking due to the difficulty of the observation under the storm wave conditions, the wave direction at the nourished location was estimated from the data of the visual observation of the wave direction at Tanaka Observatory. Due to the charcteristics of wind velocity and the restricted fetch at Tanaka Observatory, the possibility of the generation of waves having longer period than about 5 seconds in Toyama Bay is very rare, so that waves, having

longer period than 5 seconds and being incident from the west of point of Noto Peninsula are assumed to be incident from the direction connecting Tanaka Observatory with the point of Peninsula. After the incident waves at a depth of 15 m were decided, wave shoaling between 15 m and 5 m off the nourished location was calculated, and finally the energy flux of waves was obtained.

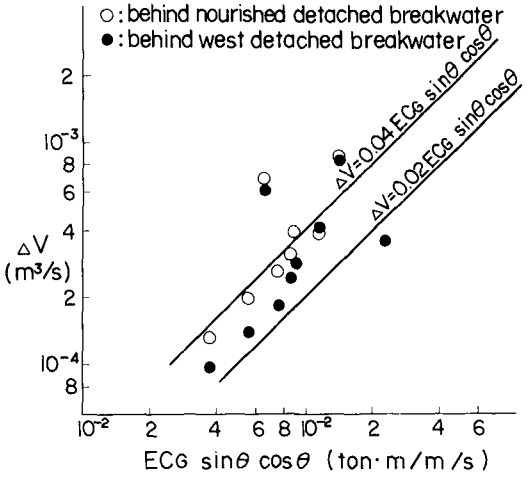

Fig.12 Relation between the longshore component of the energy flux of waves and volume change of sand.

In Fig. 12 the coefficient between the volume change of sand and the longshore component of the energy flux of waves was found to be 0.02-0.04, although it is difficult to compare the value with the past results of the coefficient directly because the longshore component of the energy flux of waves in Fig. 12 is not estimated at the breaking point. The value is one order smaller than the Savage coefficient. In the field experiment the beach changes were mainly confined within behind the detached breakwater, and the wave height behind the breakwaters is small compared with the exposed beach, so that the movement of the bed materials is restricted under the wave conditions and the coefficient is thought to become small.

Ⅵ. RESULTS OF TRACER TEST

In order to examine the direction of the littoral drift around the detached breakwater, tracer test using colored concrete blocks was conducted on December 7 in 1983 after the beach nourishment had just finished. Colored concrete blocks of around 30m³ were placed on the surface of the nourished sand, and the movement was examined by the sampling test of 11 times until October 2 , 1984. The number of the colored concrete blocks was counted directly along the shoreline. For the colored concrete, high strength concrete mixed with the red pigment was used in order to

confirm the easiness of the distinction of colored blocks along the shore and the abrasion resistence. The colored concrete blocks were broken into fine pieces of about 15 cm diameter. The compresive strength of these concrete was around 900kg/cm² at the field test.

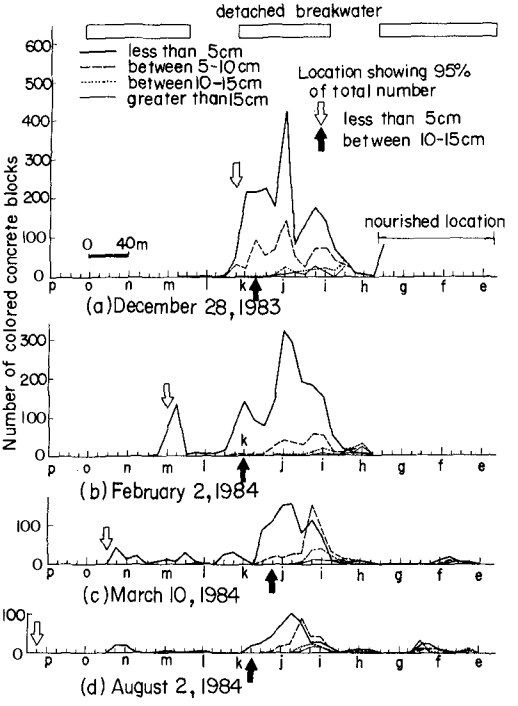

Fig.13 Longshore distribution of number of colored concrete blocks.

Longshore distribution of number of the colored concrete blocks is shown in Fig. 13 with the classification of each grain size of the recovered samples. The number is counted every 10 m intervals alongshore. The arrows in the figure designate the location showing 95% of the total number counted from the west end of the nourished position. Tracers of the grain size less than 5 cm moved westward definitely with time, and they reached to the point P distant about 350m from the nourished location. On the other hand the movement of tracers of larger grain size is slower compared with the case of the smaller grain size. The region where the tracers of the grain size smaller than 5 cm were recovered coincides with the one where large beach changes were observed, so that it is found that the maximum distance of the movement of the nourished sand during the observation period is about 350m.

Ⅶ. CONCLUSIONS

In this study the field experiment of sand bypassing was done on the Shimoni–ikawa Coast in Toyama Bay. Finally the following conclusions were obtained.

(1) In the field experiment the sand nourished behind the detached breakwater were carried slowly in the longshore direction without the outflow of sand through the openings of the detached breakwaters. It is concluded that the detached breakwater is useful to control the on–offshore sand movement and to retain the sand behind the detached breakwater.

(2) On the Shimoni–ikawa Coast tombolos were not formed behind the detached breakwaters, because after the severe erosion of the coast the sand supply to the coast was small. It is found that they can be formed by the nourishment of sand bypassed from the updrift coast. The formation of tombolo is considered to be useful for the prevention of wave overtopping, because the depth near the shore becomes smaller due to the presence of tombolo.

(3) The coefficient between the volume change of sand and the longshore component of the energy flux of waves was found to be 0.02-0.04.

(4) The direction of littoral transport was confirmed to be westward due to the tracer test using colored concrete on the coast. It was also found that the fine tracer were carried more rapidly than coarser tracer.

ACKNOWLEDGEMENT

This study was conducted under the commitee's guidance, of which members consist of Prof. Y. Tsuchiya, Disaster Prevension Research Institute, Kyoto University for the chairman, Prof. N. Shuto, Tohoku University, Prof. H. Noda, Tottori University and the delegates of the government offices. Authors would like to thank Prof. Y. Tsuchiya, Prof. N. Shuto and Prof. H. Noda for many useful discussions.

CHAPTER 116

The Interaction of Waves and Currents over a Longshore Bar

I.A. Svendsen & J. Buhr Hansen *

Abstract

A two-dimensional model for waves and steady currents in the surf zone is developed. It is based on a depth integrated and time averaged version of the equations for the conservation of mass, momentum, and wave energy. A numerical solution is described based on a fourth order Runge-Kutta method. The solution yields the variation of wave height, set-up, and current in the surf zone, taking into account the mass flux in the waves.

In its general form any wave theory can be used for the wave properties. Specific results are given using the description for surf zone waves suggested by Svendsen (1984a), and in this form the model is used for the wave motion with a current on a beach with a longshore bar. Results for wave height and set-up are compared with measurements by Hansen & Svendsen (1986).

1. Introduction

On a beach with a longshore bar the wave breaking over the bar is usually combined with a net shoreward mass flux which, in a three-dimensional flow situation, feeds longshore currents.

Both field observations and experiments indicate that the longshore current is much stronger in the shore-parallel channel or "trough" behind the bar than on the bar itself. Thus for almost shore-normal waves the motion over the bar can be nearly two-dimensional, at least till a point somewhere around or after the bar crest.

The net flow over the bar and in the trough behind was studied theoretically by Bruun (1963) and later by Dalrymple (1978), who was able to determine the largest possible distance between two successive rip currents. A similar analysis was made by Deigaard (1986). These considerations, however, apply to the creation of the rip over an, in principle, uniform and unbroken bar. Once the rip current has established an opening in the bar the position of the rip is locked to this opening, at least over times long enough for the flow pattern to be considered quasi-steady. Thus the question becomes: how much water flows over the bar with the waves, and how does the net flux influence waves, set-up, etc.?

* Institute of Hydrodynamics and Hydraulic Engineering, Technical University of Denmark, DK-2800 Lyngby, Denmark.

In the present paper we approach these problems theoretically by considering the above-mentioned two-dimensional situation of shore-normal incident waves and a shore-normal current with discharge $\overline{Q}$. In an accompanying paper by Hansen & Svendsen (1986) (denoted by I in the following) this situation is modelled experimentally. The net discharge $\overline{Q}$ is added to the waves well offshore of the slope and runs out through the permeable wave absorber which replaces the actual beach. Thus in this experiment the longshore flow in the trough is not represented.

In choosing this arrangement we implicitly assume that in a prototype situation the magnitude of $\overline{Q}$ will be determined by the distance between the rips and by the position of our two-dimensional flow section relative to the position of the rip currents.

The mathematical numerical model developed is based on the depth integrated, time averaged equations of continuity, momentum, and energy as derived by, e.g., Phillips (1977). These equations apply for a very general combination of waves and currents. In the model, the wave properties, such as radiation stress, mass flux, and energy flux are represented by dimensionless coefficients chosen in a way which makes them depend only weakly on water depth, wave height, and wave period.

The general form of the model allows these coefficients to be determined by any chosen wave theory. In the present application, however, the coefficients are developed using the description of breaking waves suggested by Svendsen (1984a). In that paper, and in Svendsen (1984b) and Hansen & Svendsen (1984), wave height, set-up, and undertow were analysed for breaking waves with no net flow. This is now generalized to include the effect of currents following (or opposing) the waves. This also implies including the effect of the undertow in the wave-current interaction, although in the present form of the model it is only done in a depth-averaged sense.

Finally is presented a comparison with the experimental results for wave heights and set-up over a barred profile described in more detail in I. This is combined with a discussion of the inaccuracies in the theoretical approach as revealed by the comparison.

2. The Basic Equations

The type of model in question belongs to the group of models which consider only the depth integrated equations averaged over a wave period. Thus the effect of the waves on the conservation equations is represented by depth integrated, time averaged quantities, such as (in the continuity equation) the mass (or volume) flux created by the waves, the radiation stress, and (in the energy equation) by the energy flux and the mean energy dissipation per unit of time and area of the bottom.

2.1. Conservation of Mass

Following Phillips (1977) (although with a different notation) we use the definitions shown in Fig. 1. An x,z-coordinate system has its origin in the undisturbed water surface SWL, and the instantaneous water surface elevation $\eta(x,t)$ is measured from the local mean water surface MWS so that the temporal mean of η is zero.

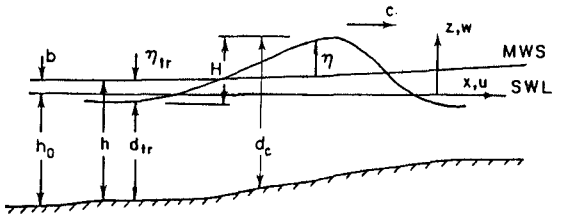

Figure 1. Definitions used.

The horizontal particle velocity u(x,z,t) is divided into two parts u_w (wave) and U (current) defined so that

$$u = u_w(x,z,t) + U(z) \quad ; \quad \overline{u}_w = 0 \tag{2.1}$$

where $\overline{\ }$ means average over a wave period.

We define a depth mean value of U(z) by

$$U = \overline{\frac{1}{h}\int_{-h_0}^{b+\eta} U(z)dz} \tag{2.2}$$

and the volume flux due to the wave part u_w of the motion then becomes

$$Q_s = \overline{\int_{-h_0}^{b+\eta} u_w \, dz} = \overline{\int_{\eta_t}^{b+\eta} u_w \, dz} \quad *) \tag{2.3}$$

where η_t is the (negative) surface elevation in the wave trough. The total mean volume flux $\overline{Q}$ can then be written

$$\overline{Q} = \overline{\int_{-h_0}^{b+\eta} u \, dz} = Q_s + Uh \tag{2.4}$$

Eq. (2.4) is the equation for the conservation of mass.

2.2. Conservation of Momentum

In the present study we will consider only the quasisteady problem of a time-independent current. We also assume that in the depth-integrated and time-averaged momentum and energy equations U(z) can be replaced by U. We can then use the momentum and energy equations given by Phillips (1977).

Following Phillips we define the radiation stress by

*) Notice that this definition of Q_s differs slightly from that by Svendsen (1984b), who used u instead of u_w in (2.3).

$$S'_{xx} = \overline{\int_{-h_0}^{b+\eta} \rho(u_w^2 - w^2)dz} + \frac{1}{2}\rho g\overline{\eta^2} - \frac{\rho Q_s^2}{h} \tag{2.5}$$

where w is the vertical velocity, and ' in S'_{xx} indicates the inclusion of the Q_s-term. This term is actually $O(H^4)$, which is small in ordinary Stokes waves, and it was omitted by Mei (1983). I turns out even in surf zone waves, where H/h = 0.6, to be rather unimportant.

With these definitions and simplifications the horizontal momentum equation can then be written in the following form

$$\frac{d}{dx}\left\{\rho\frac{\overline{Q}^2}{h} + S'_{xx}\right\} + \rho gh\frac{db}{dx} + \overline{\tau}_b = 0 \tag{2.6}$$

which, except for the $\overline{\tau}_b$-term, is the same as Phillips' expression (3.6.11).

2.3. Conservation of Energy

We define the energy flux E_f due to the waves only by

$$E_f = \overline{\int_{-h_0}^{b+\eta} \left\{p_D + \frac{1}{2}\rho(u_w^2 + w^2)\right\} u_w \, dz} \tag{2.7}$$

where p_D is the dynamic pressure defined as

$$p_D = p + \rho g(z - b) \tag{2.8}$$

The energy density E in the waves is

$$E = \overline{\int_{-h_0}^{b+\eta} \frac{1}{2}\rho(u_w^2 + w^2)dz} + \frac{1}{2}\rho g\overline{\eta^2} \tag{2.9}$$

and the total mean dissipation per m^2 bottom and per second is termed $\mathcal{D}$.

The energy equation for the wave motion then becomes

$$\frac{d}{dx}\left\{E_f + UE - \frac{1}{2}\rho\overline{Q}\left(\frac{Q_s}{h}\right)^2\right\} + S'_{xx}\frac{dU}{dx} - \overline{\tau}_b U = \mathcal{D} \tag{2.10}$$

This form also corresponds to Phillips' Eq. (3.6.19) except for the term $\overline{\tau}_b U$, which is the dissipation at the bottom due to the current*). In the surf zone, however, this contribution is very small relative to the total dissipation $\mathcal{D}$, and hence we shall omit it in the numerical computations. $\mathcal{D}$ also includes the dissipation in the bottom boundary layer due to the oscillatory motion, and also that contribution will be ignored in this paper. This implies that $\mathcal{D}$ simply is assumed to equal the breaker disspation.

The two equations (2.6) and (2.10) may be considered generalised versions of the momentum and energy equations often considered in the surf zone

$$\frac{dS_{xx}}{dx} = -\rho gh\frac{db}{dx} - \overline{\tau}_b \quad , \qquad \frac{dE_f}{dx} = \mathcal{D} \tag{2.11}$$

*) See Christoffersen & Jonsson (1980).

Like these two equations, (2.6) and (2.10) can be solved for b and H^2 provided the wave properties are described in terms of h, b, and H^2. Notice, however, that since

$$h = h_0 + b \tag{2.12}$$

even Eqs. (2.11) are complicated.

3. Dimensionless Wave Quantities

As mentioned in the introduction the wave quantities Q_s, S'_{xx}, E_f, and E must all be determined by some wave theory. This also applies to the energy dissipation $\mathcal{D}$ and the mean bottom shear stress $\overline{\tau}_b$. To facilitate a rational approach to this problem we define dimensionless forms of these quantities.

For Q_s, S'_{xx}, E_f, and E we introduce the following dimensionless quantities

$$B_Q = Q_s h/c_r H^2 \tag{3.1}$$

$$P' = S'_{xx}/\rho g H^2 \tag{3.2}$$

$$B = E_f/\rho g c H^2 \tag{3.3}$$

$$B_E = E/\rho g H^2 \tag{3.4}$$

We see that for linear theory these four quantities would depend only on h/L (L being local wave length defined as cT). In nonlinear waves, and particularly breaking waves, the dimensionless quantities will depend also on the wave height, but only weakly so.

The energy dissipation $\mathcal{D}$ is non-dimensionalized by defining D as

$$D = 4\ hT_a/\rho g H^3 \tag{3.5}$$

which is inspired by the idea that the dissipation in breaking waves resembles that in a bore.

The same definitions (except B_Q) were used by Svendsen (1984a), who suggested simple expressions for their form for surf zone waves. Before actually limiting the computations to a particular way of describing the breaking waves we first develop the numerical scheme used for the solution. Thus in the following we simply assume that

$$(B_Q,\ P',\ B,\ B_E,\ D) = f(x) \tag{3.6}$$

where f(x) includes dependence on wave height H, set-up b, and more detailed wave properties such as shape of surface profile, velocity, and pressure distributions, etc. Hence also results for linear theory could be used (although it may not be expected to represent the wave details well).

In the present formulation of the problem we consider $\overline{Q}$ as known (equal to the discharge supplied by the pump). Hence the net current velocity U can be determined from the continuity equation (2.4) as

$$U = \frac{\bar{Q}-Q_s}{h} \tag{3.7}$$

The mean bottom shear stress $\bar{\tau}_b$ will be discussed in Sect. 6.

4. The Numerical Procedure

Christoffersen & Jonsson (1980) showed that for Stokes waves the energy equation for the wave motion corresponding to (2.10) can be written as an equation for conservation of wave action, namely for the steady case considered here as

$$\frac{d}{dx}\left(\frac{E}{\omega_r}(U + c_{gr})\right) + \frac{\mathcal{D} - \bar{\tau}_b U}{\omega_r} = 0 \tag{4.1}$$

where c_{gr} is the Stokes group velocity. This version of the energy equation, however, was derived utilizing the special properties of linear waves and hence cannot be used for the general nonlinear waves considered in this paper. We therefore choose to solve (2.6) and (2.10) directly for b and H^2 respectively.

The numerical solution is obtained by a fourth order Runge-Kutta method. This requires that the two differential equations (2.6) and (2.10) with (3.1) through (3.5) substituted are written on the form

$$\frac{db}{dx} = f_b(x,b,H^2) \quad ; \quad \frac{dH^2}{dx} = f_H(x,b,H^2) \tag{4.2}$$

Since, however, the dimensionless coefficients in general are unknown functions of b and H^2 the form (4.2) cannot be obtained in a strict manner.

We therefore utilize the assumption that the dimensionless coefficient depends only weakly on H. To further simplify the problem we also assume that the additional terms in (2.6) and (2.10) due to the current are small too. For the numerical computations we therefore isolate db/dx and dH^2/dx from the main terms in (2.6) and (2.10), that is the terms included in (2.11). We then accept that derivatives of the dimensionless coefficients, the current, and the Q_s-terms contain db/dx and dH^2/dx. In the computations these db/dx and dH^2/dx are then evaluated only at each grid point, not at intermediate points in each integration interval as the Runge-Kutta method prescribes.

The equations for db/dx and dH^2/dx derived according to these assumptions may be described by introducing the following definitions

$$\alpha = c_r/\sqrt{gh} \tag{4.3}$$

$$D' = D\,\frac{H^2}{h}\,\frac{H}{h}\,\frac{1}{4T_a\alpha\sqrt{g/h}\,B} = \frac{\mathcal{D}}{\rho g c B} \tag{4.4}$$

$$f_1 = \left[\frac{\bar{Q}^2}{gh^3}h_x - \frac{\bar{\tau}_b}{\rho g h}\right] \Big/ \left(1 - \frac{1}{2}P\left(\frac{h}{h}\right)^2\right) \tag{4.5}$$

$$g_1 = \frac{H^2}{E_f}\left[\frac{1}{2}\rho\bar{Q}\,\frac{d}{dx}\left(\frac{Q_s}{h}\right)^2 - S'_{xx}\frac{dU}{dx} - \frac{d}{dx}(EU)\right] \tag{4.6}$$

We then get:

$$\frac{db}{dx} = F_b \tag{4.7}$$

$$\frac{dH^2}{dx} = F_H \tag{4.8}$$

where

$$F_b = -\frac{P'}{h}\frac{D' + H^2\left(\frac{P'_x}{P} - \frac{B_x}{B} - \frac{1}{2}\frac{h_{ox}}{h}\right) + g_1}{1 - \frac{1}{2}P'\left(\frac{H}{h}\right)^2} + f_1 \tag{4.9}$$

$$F_H = D' - \left(\frac{1}{2}\left(\frac{h_{ox}}{h} + \frac{F_b}{h}\right) + \frac{B_x}{B}\right)H^2 + g_1 \tag{4.10}$$

f_1 and g_1 represent the small terms mentioned above. We see that, in addition to contributions that vanish with the net flow $\bar{Q}$, there are terms associated with $\bar{\tau}_b$ or U which for $\bar{Q} = 0$ represents the undertow. Except for the $\bar{\tau}_b$-term all these terms are calculated by differentiating analytically the expressions given in the following Section 5. In the computations we assume that $dB_0/dx = d\alpha/dx = 0$ (see I), and for computation of b_{n+1} and H^2_{n+1} at points x_{n+1}, f_1 and g_1 are evaluated only at x_n.

The fourth order Runge-Kutta scheme for two simultaneous equations is given in, e.g. Hildebrand (1974, 2nd ed.) p. 291.

5. Determination of the Wave Quantities

The mathematical-numerical description presented so far does not presume anything about how the wave properties Q_s, S'_{xx}, E_f, E, and $\mathcal{D}$ are determined. As mentioned a description of the phase motion of the waves must be involved, and most often sinusoidal waves have been used to determine the radiation stress and the energy flux for a wave with a given height and period. Examples are Huang & Wang (1980), Dally et al. (1984), Izumiya & Horikawa (1984). But also solitary waves and cnoidal wave theory have been used.

For the present applications we determine Q_s, S'_{xx}, E_f, and E by using the model for surf zone waves suggested by Svendsen (1984a).

The basic assumption is that the actual horizontal particle velocity in the oscillatory motion shown in Fig. 2a can be approximated by a constant velocity u_0 everywhere except in the surface roller (Fig. 2b). Here the velocity is assumed to be equal to the phase velocity c, since the roller represents a body of water which is carried with the wave. It is furthermore assumed that the pressure is hydrostatic.

Following Svendsen (1984a) we also assume that u_w can be approximated by

$$u_w \simeq c_r \eta/h \tag{5.1}$$

where c_r is the wave speed relative to the water.

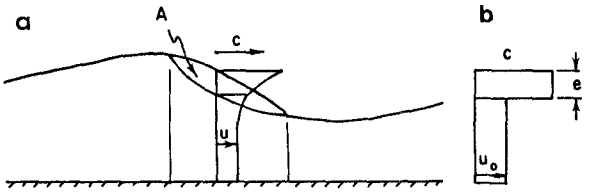

Figure 2. Actual and assumed velocity profiles.

The inaccuracies this leads to are analysed in some detail in I.

c_r, U, and the wave speed c_a observed from a fixed point are related by

$$c_a = c_r + U \tag{5.2}$$

From the definition (2.3) for the volume flux Q_s due to the waves we then get the following for B_Q (defined by (3.1))

$$B_Q = B_0 + B_r \frac{gh}{c_r^2} \tag{5.3}$$

where

$$B_0 \equiv \overline{\left(\frac{\eta}{H}\right)^2} \tag{5.4}$$

$$B_r = \frac{A}{H^2} \frac{c_r}{gT_r} \tag{5.5}$$

Here A is the vertical cross-sectional area of the roller. Svendsen (1984a) found $A/H^2 \sim 0.9$. T_r is the relative wave period which is related to the absolute period T_a through (5.2) by $L \simeq c_r T_r = c_a T_a$. (Notice that owing to the different definition of Q_s, the result for Q_s differs by a factor h/d_t from the result given by Svendsen (1984b). d_t is the water depth under the wave trough, Fig. 1.)

Similarly, we get from the definition (2.5)

$$P' = B_0\left(\frac{1}{2} + \frac{c_r^2}{gh}\right) + B_r - \frac{c_r^2}{gh}\left(\frac{H}{h}\right)^2 B_Q \tag{5.6}$$

(2.7) yields for B

$$B = B_0 + \frac{1}{2} B_r \tag{5.7}$$

and finally, (2.9) yields

$$B_E = \frac{1}{2}\left\{B_0\left(1 + \frac{c_r^2}{gh}\right) + B_r\right\} \tag{5.8}$$

Equations (5.3) - (5.8) together with (3.1) - (3.4) determine Q_s, S'_{xx}, E_f, and E in the momentum and energy equations ((2.6 and (2.10) respectively) for a wave of given height H and phase velocity c_r at depth h.

As in Svendsen (1984a) we will assume that α in (4.3) is constant throughout the surf zone. This is further discussed in I. An alternative - and perhaps more natural - choice would be to assume that c_r equals the speed of a bore with height H. However, in I it is found that the difference is small, and α constant is much simpler to use in the derivations.

Following Svendsen (1984a) we assume that the energy dissipation can be determined as the dissipation in a bore of the same height as the wave. This results in

$$\mathcal{D} = - \rho g \frac{c_r}{L} h \frac{H^3}{4 d_t d_c} \tag{5.9}$$

where d_t and d_c are instantaneous water depths below the wave trough and the wave crest respectively. In establishing this analogy to the bore it is assumed that adding a uniform current to the wave or the bore does not change the breaking process. Therefore, the phase velocity in (5.9) is the relative velocity c_r.

Eq. (5.9) is substituted into the definition (3.5) and we utilize that (5.2) implies

$$T_r = T_a (1 + U/c_c)^{-1} \tag{5.10}$$

This then yields

$$D = - \frac{h^2}{d_t d_c} \frac{1}{1 + U/c_r} \tag{5.11}$$

This expression illustrates that for a current U > 0 following the wave the dissipation decreases relative to a wave of the same absolute period T_a and vice versa for a wave on an opposing current, as one would expect from the corresponding change in wave steepness.

6. The Mean Bottom Shear Stress

The mean bottom shear stress $\overline{\tau}_b$ occurs in the time-averaged momentum equation (2.11). Svendsen et al. (1987) showed how $\overline{\tau}_b$ can be determined from the undertow, which is patched to the flow in the (oscillatory) bottom boundary layer to satisfy the no-slip condition at the bottom. This implies that to determine $\overline{\tau}_b$ we must first determine the velocity distribution over depth of the undertow (which here means the current velocity profile U(z)). Their results for $\overline{\tau}_b$ are equivalent to

$$\overline{\tau}_b = \frac{1}{2} \rho f_w u_{wbm} U_b \tag{6.1}$$

where f_w is the wave friction factor, u_{wbm} is the particle velocity amplitude at the bottom, and U_b the current velocity at the bottom (i.e. outside the boundary layer).

In the present version of the model we will approximate (6.1) by

$$\bar{\tau}_b = \frac{1}{2} \rho f_w u_{wbm} U \tag{6.2}$$

(U given by (2.2)). As the measurements in I show, this is not always a good approximation and may for small U even lead to (small) $\bar{\tau}_b$ values of the wrong sign. The total error on b, however, is estimated not to exceed 20% of this already very small contribution (in numbers less than 0.2•1.2 mm of a total set-up of ~15 mm for the experiments in I).

For u_{wbm} we have used the forward velocity amplitude

$$u_{wbm} = c \frac{\eta_c}{H} \frac{H}{h} \tag{6.3}$$

and f_w is found from Jonssons's diagrams to be $\sim 2 \cdot 10^{-2}$.

7. Comparison with Experimental Results for Waves and Currents Over a Longshore Bar

Numerical experiments have been carried out with the model for the wave-current flow over the longshore barred profile investigated experimentally in I.

In these experiments the still-water depth h_0 is given by (all units in m)

$x < 14.78$ $\qquad h_0 = 0.340$

$14.78 < x < 22.96$ $\qquad h_0 = 0.340 - (x - 14.78) \cdot 0.0280$

$22.96 < x$ $\qquad h_0 = 0.0705 + (x - 25.70)^2 \cdot 5.53 \cdot 10^{-3}$

This corresponds to a plane bottom with slope $h_x = 0.0280 = 1 : 35.7$ between $x = 14.78$ and $x = 22.96$, succeeded by a parabola with summit (bar crest) at $x = 25.70$.

The numerical experiments described here were made with the following (fixed) parameter values (see I):

$A/H^2 = 0.9$; $B_0 = 0.090$

$\eta_c/H = 0.60$; $\alpha = 1.0$

$\Delta x = 0.1$;

Formally, A/H^2 represents the roller, and the value of 0.9 was obtained from deep water measurements (see Svendsen, 1984a).

The choice of B_0 constant and $\alpha = 1$ may be refined on the basis of the experimental results in I. The formulas for the coefficients show that changes in B_0 or α will effect results in much the same way.

The discussion is mainly restricted to the wave height and the set-up variations. Fig. 3 shows a comparison of wave heights for the four $\bar{Q}$-values for which measurements are reported in I, and Fig. 4 shows the set-up. Two sets of computations are shown:

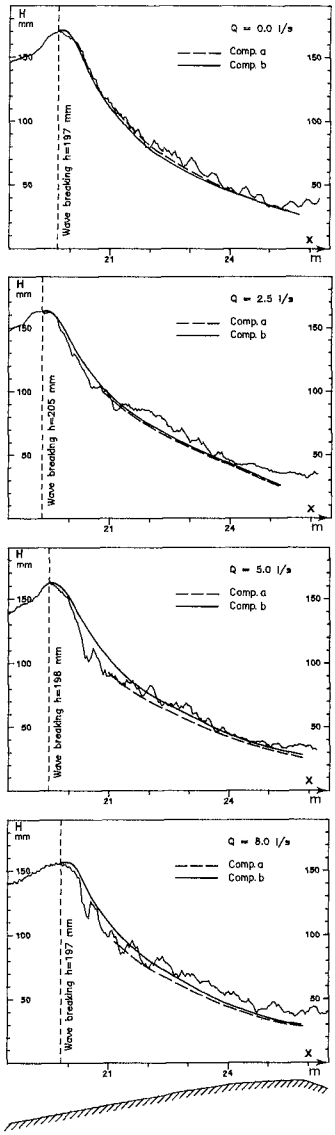

Figure 3. Comparison of measured and computed wave heights.

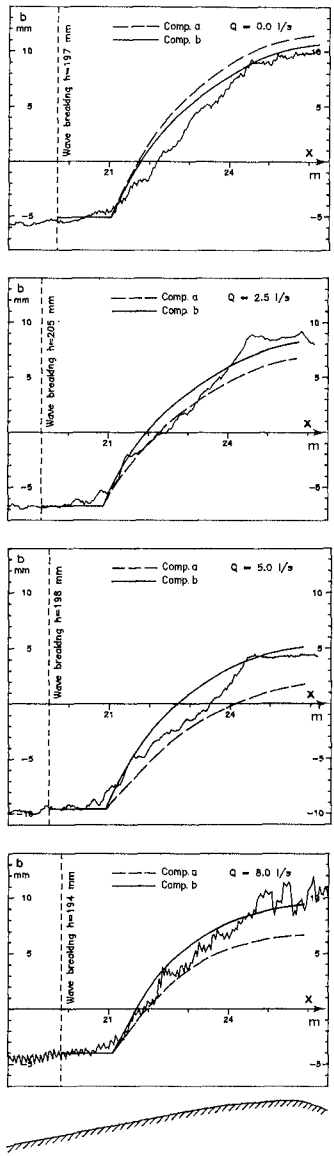

Figure 4. Comparison of measured and computed set-up values.

a) Computations starting at $h_o = 0.8\ h_{oB}$. This point was found by Svendsen (1984a) to correspond to the end of the transition region, in which the collapse of the wave creates an almost constant S_{xx} in spite of the decrease in wave height.

b) Computations starting from the breaking point. In this case the dissipation has artificially been made to grow gradually from 0 at the breaking point and asymptotically approach the value given by (5.9). The expression used is

$$\mathcal{D} := \tanh\left(0.4\ \frac{x - x_B}{h_{oB}}\right)\mathcal{D} \tag{7.1}$$

which implies that at a distance of five times h_{oB} $\mathcal{D}$ has reached 96% of the full value. This modification does not model the simultaneous transitions in S'_{xx} and E_f, and hence (7.1) is combined with the assumption $b_x = 0$ in $x_B < x < x_t$ (x_t representing the transition point). For a more detailed discussion of the transition region reference is made to Basco (1986).

7.1. General Comparison

It is seen from Fig. 3 that the wave height variation is quite accurately predicted by the model with a slight tendency to too low values. It may also be noted that, in spite of the fact that computation a) starts at the transition point with a wave height which is somewhat different from the height obtained by computation scheme b) at that point, the wave heights obtained near the bar crest by the two schemes are nearly the same.

Also the set-up values over the bar crest are in reasonable agreement with the measurements, whereas there is a general tendency to too high b-values in the region between the transition point and the bar crest. In particular, it is noticed that immediately after the transition point the computations have db_x/dx significantly larger than the measurements.

As should be expected, the set-up variation depends strongly on the wave heights. This can be seen by comparing the set-up variations from a) and b) in the four cases and noting that in some cases the wave heights from computation b) are larger than those from a), in some not: the computed set-up variations follow the same pattern. The coupling from set-up to wave height is simply represented by the fact that the set-up represents an increase in depth, which for sufficiently small h_0 may be appreciable.

7.2. The Influence of the Currents

The computations all use measured values of H and b as initial values, and it is seen that in the experiments there are small differences in the mean water level at the breaking point for the four cases. These are caused by small variations in the total amount of water in the flume required to obtain the same mean water depth with the current only.

Computations with the model show that these small differences in the mean water depth do not influence the wave heights and the set-up in the region studied. Therefore, we may get an estimate of the actual effect the current has on the set-up by comparing the set-up variations relative to a common starting point. This is done in Fig. 5, which also shows the wave height variations (see also I, Table 2).

Both wave height and set-up are seen to be almost unaffected by the current.

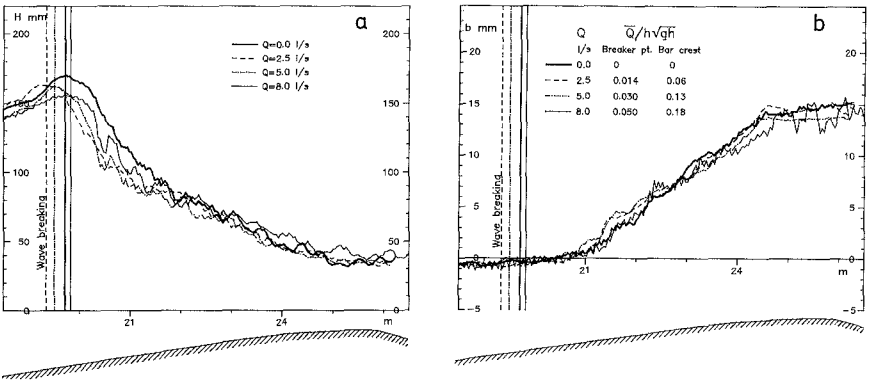

Figure 5. Wave heights (a) and set-up (b) measured for four different values of $\overline{Q}$.

From these results one might jump to the conclusion that the currents have only a negligible effect on the wave conditions. A closer inspection and numerical experiments show that this is too much of a simplification. The extra terms in the equations are important. They just happen nearly to balance each other for the conditions studied.

For the wave heights the behaviour is quite different from a situation with non-breaking waves. The mechanism seems to be that an increase in wave height will also cause an increase in the dissipation and in the energy flux. Hence there is a strong conservatism built into the system at this point, as computations a) and b) also indicated.

For the set-up the mechanism is different: There is no stabilizing effect which parallels that of the dissipation. It is found that the interaction terms in the momentum equation decrease the set-up slightly for all $\overline{Q}$-values, and the bottom shear stress amplifies this by causing a similar decrease in the set-up (up to about 1.2 mm for $\overline{Q} = 8$ ℓ/s). A somewhat stronger effect, however, of the current is caused by the (seemingly) small changes of the wave height described above. That this is the case can be verified in the numerical model by running experiments with the current effect suppressed in one equation and not in the other.

It is particularly interesting to notice that the total set-up Δb at the bar crest measured relative to the water level at the breaking point varies only slightly with the current condition. The measured and computed values are shown in Table 1 below. Considering the many approxima-

tions which the model represents, the very good agreement with the measured values for Δb must be considered fortuitous, as is also suggested by the deviations for the set-up at other x-values.

Notice that the integrated effect of $\overline{\tau}_b$ changes sign when the current increases. This is because shortly after breaking the undertow dominates the (nearbottom) flow ($\overline{\tau}_b < 0$). For large values of $\overline{Q}$ this situation is reversed further shorewards for continuity reasons.

Table 1. Total difference Δb between water level at breaking and over the bar crest.

Discharge $\overline{Q}$ (ℓ/s)	Computation b), $\overline{\tau}_b = 0$	Computation b), $\overline{\tau}_b$ from (6.2)	Measured
0	1.52 cm	1.57 cm	1.55 cm
2.5	1.52 cm	1.51 cm	1.61 cm
5	1.49 cm	1.43 cm	1.42 cm
8	1.39 cm	1.27 cm	1.45 cm

7.3. Inaccuracies in the Predicted Set-Up

The set-up is a direct measure of the variation in shore-normal radiation stress, and the variation of the radiation stress in general is closely associated with the generation of surf zone currents (also in the 3D case). It must therefore be considered an essential condition for a surf zone model that it is able accurately to predict the set-up. At the same time, the set-up is fairly easy to measure and hence a convenient quantity to test models against.

As mentioned earlier Fig. 5 shows that for all $\overline{Q}$-values there is a tendency that the model overestimates the growth rate of the set-up immediately after the transition point (where the momentum equation is switched on in the computations). This inaccuracy was not observed when a model based on the same principles (but without a current) was applied to waves on a plane slope (Svendsen, 1984a). Although the general agreement with measurements might be considered acceptable, and better than other surf zone models, the deviation in db/dx is important. It will cause rather significant discrepancies when db/dx is applied as input for determination of the vertical velocity distribution for the current (see, e.g. Svendsen et al., 1987).

A closer analysis of the situation in the region around the transition point indicates that a major reason for the deviations is related to the abrupt switch between S'_{xx} constant in the transition zone and the rapidly changing S'_{xx} following from the bore description for the inner region. In real waves this transition will of course be gradual.

8. Conclusions

A two-dimensional model for the wave-current interaction in the surf zone has been established. It is based on depth-integrated time-averaged equations of continuity, momentum, and energy. As a description of the

breaking waves is used a generalized form of the method developed by Svendsen (1984a). In principle, however, any wave theory can be used for determination of the coefficients describing the wave properties in the model. The effect of the bottom shear stress is included.

Numerical results for wave heights and set-up are compared with measurements for a bar-type profile. In general, the agreement is found to be quite good although there is a region shortly after the transition point with less accuracy for the set-up.

Finally, the effects of the different elements of the model are discussed.

CHAPTER 117

Prediction of wind-driven transport rates

D H Swart*

ABSTRACT

The rate of wind-driven sand movement in a dune field is an important parameter needed to establish management strategies for sand dune fields. Until recently not much attention has been given in engineering circles to the possible effect of wind-blown sand transport. However, there is a wealth of literature on the subject which goes back as far as 1936. A study of literature reveals that there are at least 16 formulae for the prediction of the aeolian transport rates which are readily available. This paper describes a technique which utilizes these 16 formulae in the most effective manner for predicting the best estimate of the **potential** wind-blown transport rate. Restrictions on the applicability of the method are discussed and fields for further research are recommended.

1. BACKGROUND

Sediment pathways and sediment budgets in the coastal zone often depend on the balance between wave- and current-driven sediment movement in the nearshore region and wind-driven transport of sand through driftsand areas connecting adjacent bays or embayments. The management of these areas often relies on knowledge of the relative magnitude of the transport in the underwater and driftsand areas.

Evaluation of the merit of stabilizing a driftsand area is a case in point. On the one hand the stabilization may be essential to prevent inundation of townships or valuable agricultural land by driftsands. On the other hand this same driftsand field may be a vital source of sand supply for the beaches downwind of the driftsands. A proper decision about the extent and method of stabilization can then only be made once a reliable estimate has been made of the amount of wind-driven sand movement that could potentially take place annually.

However, the prediction of the aeolian sand transport can only be as good as the wind data. This is frequently a problem. Data of sufficient quality and of long enough duration are needed. A recording period of at least one year and preferably longer is required. Usually such data are only available at focal points for development along the coast with the result that in the case of remote sites one frequently has to resort to the use of visual estimates of wind statistics gathered by lighthouse keepers or to measured data from sites which may be totally unsuitable for application to the site under consideration.

* Head, Sediment Dynamics Division, National Research Institute for Oceanology, CSIR, P.O. Box 320, Stellenbosch, 7600, Republic of South Africa.

Visual estimates of wind characteristics have been made regularly by Voluntary Observing Ships (VOS) since 1960. The estimates are incorporated in six-hourly weather observations of these ships and relayed to the major weather forecasting bureau. Because the deck officers who compile the weather observations are mostly experienced seamen the quality of their estimates is usually good. A vast number of the VOS wind observations for the period from 1960 are available and these cover the entire South African coastline. On the basis of a comparison between VOS wind data and anemometer recordings from shore-based stations Swart (1986) concluded that VOS wind data can be transformed into representative wind statistics on land in the coastal zone.

This paper summarizes the available techniques for the prediction of wind-driven transport, which are based on plane-bed transport situations, and investigates means of applying these techniques to the turbulent wind field situations encountered in driftsand areas.

2. AEOLIAN TRANSPORT PREDICTORS

2.1 General

The predictors for the magnitude of potential aeolian sand transport which have traditionally been used most extensively are those of Bagnold (1941), Kawamura (1951) and O'Brien (1936). More recently Hsu (1971a) and Mossa (1980), amongst others, developed modified predictors. Notwithstanding the large time span between the development of the various formulae, they are all very similar in appearance and in the wind transport rates which are predicted.

The reason for the similarity of appearance of the different formulae is that the mechanism which causes the wind-blown transport of sand is well understood. As soon as the shear stress exerted by the wind field on the sand surface exceeds a critical value, grains start to move. Although certain researchers neglect the critical shear stress in their formulation, all formulae equate the potential aeolian sand transport to some function of the shear stress.

The predicted wind transport rates are similar because the empirical coefficients in the different formulae were updated as more data became available.

This section contains a summary of the equations developed by the researchers mentioned above. To facilitate their easy application all these formulae were transformed into metric units and the transport rates expressed in cubic metres per metre per second, by assuming a porosity of 0.7 in the sand body before transport takes place. The limitations of the predictors will be given here to the extent it is given in the original publications. A more in-depth discussion of each of the 16 formulae can be found in Swart (1987a).

These formulae all relate to the situation where the wind is blowing over a **dry** sand surface, whereas this is obviously not always the case in nature. Therefore, the effect of moisture in the sand on the transport is discussed briefly in Section 2.3. More details can again be found in Swart (1987a).

The following symbols are used extensively in the eguations:

S_a = potential aeolian sand transport rate, expressed in $m^3/m/s$;
u_{*w} = the shear velocity at the sand surface due to wind action, expressed in m/s, which is equal to $(\tau_o/\rho_a)^{1/2}$;
u_{*wc} = critical value of shear velocity above which movement takes place, in m/s;
τ_o = total shear stress at the sand surface due to wind action;
ρ_a = mass density of air in kg/m^3 (1.29 kg/m^3);
ρ_s = mass density of sand in kg/m^3 (2 650 kg/m^3);
g = gravitational acceleration in m/s^2 (9.8 m/s^2);
D_{50} = median grain diameter of sand, in m.

The shear velocity u_{*w} can be determined from the wind velocity profile above the sand surface. The way in which this is done for cases in which the velocity profile is not specifically measured, such as would be the case when predictions are being done, is open to discussion. This aspect will be dealt with in Section 3.

In most of the original publications the potential aeolian sand transport rate is denoted by q and is expressed in g/cm/s. The shear velocities u_{*w} and u_{*wc}, where subscript w incidentally refers to wind, are called u_* and u_{*c} in the original publications and are given in cm/s. The mass densities are given in g/cc in the original papers and the gravitational acceleration is expressed in cm/s^2. All these cgs units have been transformed into metric units for this paper, as indicated above. Symbols used only occasionally will be defined in the text.

2.2 Predictive Formulae

Bagnold (1941) found a formulation for the potential aeolian transport on the assumption that grains move downwind with a bouncing motion near the sand surface. By using data presented by Bagnold (1954), Iwagaki (1958) and Kubota et al. (1982) regarding the empirical constant, the following formula (in metric units) is found:

$$S_a = 0.052\, D_{50}^{0.5} \left(\frac{\rho_a}{g}\right) u_{*w}^3 \quad \text{(in } m^3/m/s\text{)} \qquad \ldots(1)$$

It appears that the data on which the coefficient in equation (1) is based can be summarized as follows:

Range of D_{50} : 0.20×10^{-3} m to 0.40×10^{-3} m
Range of u : 0.14 m/s to 2.85 m/s.

Kawamura (1951) assumed that the shear stress at the sand surface is composed of two components, namely, that caused by the wind and that caused by the impact of saltating and moving sand particles. By using the incipient motion criterion of Bagnold (1941) and experimental data of Kawamura (1951), Horikawa and Shen (1965) and Kubota et al. (1982) the original Kawamura formula can be written as:

$$S_a = 8.24 \times 10^{-4} \left(\frac{\rho_a}{g}\right) (u_{*c} - u_{*wc}) (u_{*w} + u_{*wc})^2 \quad \ldots(2a)$$

(in $m^3/m/s$)

where

$$u_{*wc} = 0.1\left[\left(\frac{\rho_s - \rho_a}{\rho_a}\right) g D_{50}\right]^{1/2} \quad \ldots(2b)$$

The range of conditions for which this formula is valid is the same as that for the Bagnold formula, namely:

Range of D_{50} : 0.20×10^{-3} m to 0.40×10^{-3} m
Range of u_{*w} : 0.14 m/s to 2.85 m/s.

O'Brien and Rindlaub (1936) developed an empirical formula on the basis of field experiments which was transformed by Horikawa (1981) and the present author to

$$S_a = 5.473 \times 10^{-5} (u_{*w} + 0.108)^3 \quad \ldots(3)$$

for $u_{*w} > 0.20$ m.

The range of conditions for which this formula is valid, is as follows:

Range of D_{50} : $D_{50} = 0.20 \times 10^{-3}$ m
Range of u_{*w} : ~ 0.20 m/s to 0.60 m/s.

Hsu (1971a, 1971b, 1972, 1973, 1974a, 1974b) developed on the basis of field measurements a relationship between a shear Froude number and the potential aeolian sediment transport. Empirical coefficients were determined by using laboratory and field data of Bagnold (1941), O'Brien and Rindlaub (1936), Zingg (1952), Kawamura (1951), Horikawa (1960), Belly (1962) and Kadib (1964, 1965).

It can be written in metric units as:

$$S_a = 3.434 \times 10^{-9} \exp(4\,970\, D_{50}) \left[\frac{u_{*w}}{(g D_{50})^{1/2}}\right]^3 \quad \ldots(4)$$

(in $m^3/m/s$).

The range of conditions for which this formula is valid, is as follows:

Range of D_{50} : 0.15×10^{-3} m $\leq D_{50} \leq 1.0 \times 10^{-3}$ m
Range of u_{*w} : 0.18 m/s $\leq u_{*w} \leq$ 2.85 m/s.

Hsu (1974a) only shows a range of u_{*w} extending to 1.0 m/s, but the tests with high wind shear velocities, performed by Kubota et al. (1982), provided another data point which is in agreement with equation

(4), which in effect extends the range of u_{*w} to the value shown above.

Mossa (1980), working under the guidance of Hsu, reanalysed the data which led to equation (4) and found a slightly modified formulation, which is given below although it does not really add any new information over and above that already reported:

$$S_a = 3.475 \times 10^{-9} \exp(4\,910\, D_{50}) \left[\frac{u_{*w}}{(g\, D_{50})^{1/2}}\right]^3 \qquad ...(5)$$

(in $m^3/m/s$).

The range of variables is the same as that for the original Hsu formula.

Chiu (1970) used measurements of wind-driven transport rates at different levels above the sand surface, which he integrated over depth, to obtain an expression for the total wind-driven transport rate. He then used data by Bagnold (1941), Zingg (1952), Horikawa (1960), Belly (1962) and Kadib (1964) to generalize his results to include a range of grain sizes and values of the sorting coefficient s (where $s^2 = D_{75}/D_{25}$). In metric form his results finally lead to:

$$S_a = 5.5 \times 10^{-4} f(s,D_{50}) (2.13 + 0.39\, u_{*w}) \left(\frac{\rho_a}{g}\right) u_{*w}^3 \qquad ...(6a)$$

$f(s,D_{50})$ is for one formulation of Chiu taken as unity and in the other as

$$f(s,D_{50}) = \exp\left(-1.78 \times 10^{-3} (s^2 - 1)^{1/2}\, i\left[\frac{s^3}{D_{50}} (1.6641 - s^2)^2\right]^{1.1}\right) \qquad ...(6b)$$

with $i = 1$ for $s < 1.29$ and $i = -1$ for $s \geq 1.29$.

The range of values of the variables to which these expressions apply is:

Range of D_{50} : 0.145×10^{-3} m $\leq D_{50} \leq 1.0 \times 10^{-3}$ m
Range of u_{*w} : 0.24 m/s $\leq u_{*w} \leq$ 1.35 m/s
Range of s : $1.01 \leq s \leq 1.41$.

Kadib (1964, 1965, 1966) investigated the concepts developed by Einstein (1950, 1953) for the description of sediment motions by flowing rates, and concluded that turbulence, "particle hiding" and flow variation are also important parameters in aeolian transport, as well as in addition also the effect of saltating sand grains on the threshold of particle motion. Kadib assumed that the relationship between the dimensional sediment load intensity Φ and a dimensionless parameter ψ_* which related the submerged particle weight and the lift force on the particle, derived by Einstein for water flow, is also valid for air flow. In addition, he expressed both the particle hiding and the effects of particle impact on the force balance as a correction to the

lift force. He used his own data as well as that of O'Brien and Rindlaub (1936), Zingg (1952), Horikawa (1960) and Belly (1962) to determine this correction factor. His results are given graphically in Kadib (1965). In order to make the method more widely applicable, Swart (1987b) evaluated the high shear data of Kubota et al. (1982) in the same manner described above and performed curve-fitting to the combined graphical results. The final result was obtained:

$$S_a = 8.25 \times 10^{-4} \rho_s \Phi \left(\frac{\rho_s - \rho_a}{\rho_a}\right)^{1/2} (gD_{50}^3)^{1/2} \qquad ...(7a)$$

(in $m^3/m/s$).

where

$$\Phi = \begin{cases} 0 & \text{for } \psi_* \geq 25 \\ 29[\psi_*^{-2.66} - 1.912 \times 10^{-4}] & \text{for } 10 \leq \psi_* < 25 \\ 6.497\ \psi_*^{-2.05} & \text{for } \psi_* < 10 \end{cases} \qquad ...(7b)$$

$$\psi = \left(\frac{\rho_s - \rho_a}{\rho_a}\right) \left(\frac{gD_{50}}{u_{*w}^2}\right) \qquad ...(7c)$$

$$\psi_* = \frac{\xi}{I} \psi \qquad ...(7d)$$

$$\frac{\xi}{I} = \begin{cases} 2.5 - 0.125\psi & \text{for } \psi \leq 10 \\ 6.265\ \psi^{-0.7} & \text{for } \psi > 10 \end{cases} \qquad ...(7e)$$

More details of the above formulations can be found in Swart (1987a, 1987b).

On the basis of the data included in Kadib (1965) and those on high shear velocities added in this study, the range of application of the Kadib method is as follows:

Range of D_{50} : 0.145×10^{-3} m $\leq D_{50} \leq 1.0 \times 10^{-3}$ m
Range of u_{*w} : 0.24 m/s $\leq u_{*w} \leq$ 2.89 m/s.

Nakashima (1979) studied, with reference to the control of blown sand under field conditions, wind-driven sand transport, with specific reference to the threshold shear velocity and its dependence on grain size, particle shape parameter and the water content of the sand surface. Some very interesting aspects of Nakashima's work are referred to in Sections 2.3 and 2.4 and are discussed in more detail in Swart (1987a). The potential transport over a dry sand surface, as given Nakashima and expressed in metric units, is given by:

$$S_a = 1.79 \times 10^{-3} D_{50} u_{*w} \rho_s \left[\left(\frac{u_{*w}^2 \rho_a}{gD_{50}\rho_s}\right)^{0.8} - 0.03\right] \qquad ...(8)$$

On the basis of the data contained in Nakashima (1979), the range of application of equation (8), is as follows:

Range of D_{50} : 0.22×10^{-3} m $\leq D_{50} \leq 1.61 \times 10^{-3}$ m
Range of u_{*w} : 0.2 m/s $\leq u_{*w} \leq$ 1.6 m/s
Range of $s_1 = (D_{84}/D_{16})^{1/2}$: $1.246 \leq s_1 \leq 1.802$.

Tsuchiya and Kawata (1972, 1975) performed a rigorous, theoretical treatment of all aspects related to saltation of sand grains. In the 1972 paper the various elements of the theory were compared to data, and good agreement was found. In the 1975 paper three different theories were derived on the basis of the various saltation processes described in the original paper, which can in metric units be written as:

$$(1) \quad S_a = 0.5\, u_{*w}\, D_{50}\, (\lambda)^{1/2}\, a_r\, a_1\, F_1\, (\tau_* - \tau_{*c}) \qquad \ldots(9a)$$

$$(2) \quad S_a = u_{*w}\, D_{50}\, F_2\, (\tau_* - \tau_{*c}) \qquad \ldots(9b)$$

$$(3) \quad S_a = u_{*w}\, D_{50}\, F_3\, (\tau_* - \tau_{*c}) \qquad \ldots(9c)$$

In the above F_1, F_2 and F_3 and λ, a_r and a_1 are parameters defined in the original publication by Tsuchiya and Kawata (1975). Furthermore, τ_* is the bed shear defined as:

$$\tau_* = \frac{u_{*w}^2}{(\rho_s/\rho_a - 1)\, g\, D_{50}} \qquad \ldots(9d)$$

and τ_{*c} is the critical shear stress assumed equal to 0.01, which corresponds exactly with equation (2b).

The expressions (9a) to (9c) were derived from first principles in the 1975 paper and as such place no restrictions on the range of applicability, although saltation must of course take place for the theory to be valid. However, the various elements of the theory have been compared in the two papers referred to above with data covering the following range of variables:

Range of D_{50} : 0.144×10^{-3} m $\leq D_{50} \leq 0.715 \times 10^{-3}$ m
Range of u_{*w} : 0.054 m/s $\leq u_{*w} \leq$ 1.22 m/s.

Zingg (1952) did wind tunnel experiments to investigate the relationships between wind speed and shear velocity at the sand surface on the one hand and between shear velocity and sediment transport. He obtained a modification of the original formula by Bagnold (1941);

$$S_a = 0.023\, D_{50}^{0.75}\, (\rho_a/g)\, u_{*w}^3 \qquad \ldots(10)$$

The range of variables on which this expression is based, is as follows:

Range of D_{50} : 0.20×10^{-3} m $\leq D_{50} \leq 0.715 \times 10^{-3}$ m
Range of u_{*w} : 0.3 m/s $\leq u_{*w} \leq$ 1.82 m/s.

Zanke (1978) separated bed-load q_b and suspended load and q_s from each other and demonstrated that an earlier theory for the prediction of sediment transport under uniform current flow (Zanke, 1978) is

valid for air flow as well. In the latter case he calibrated the theoretical expressions against field data gathered on the German North Sea coast, and then checked the resulting formulae against data of Exner (1928), O'Brien and Rindlaub (1936) and Kadib (1965).

Zanke (1980) proposes that the total transport is given by one of the following two versions:

$$S_a = \begin{cases} q_b + q_s \\ q_b \end{cases} \qquad \ldots(11a)$$

where the expressions for bed load and suspended load are as follows:

$$q_b = 1.5 \times 10^{-6} \left(\frac{v_1^2 - v_{c1}^2}{w^2}\right)^2 D_*^4 \, \nu \frac{1}{p} \qquad \ldots(11b)$$

and $$q_s = 1.5 \times 10^{-6} \left(\frac{(v_1^2 - v_{c1}^2)(v_1^2 - v_{l1}^2)}{w^4}\right) D_*^4 \, \nu \frac{1}{p} \qquad \ldots(11c)$$

where ν is the kinematic viscosity of air, p is the porosity, taken to be equal to 0.7 by Zanke, and v_1 is the wind velocity at 1 cm above the sand surface, obtained from measurements of wind speed 10 m above the surface by assuming a logarithmic velocity profile.

D_* is a dimensionless grain diameter;

$$D_* = \left\{\frac{(\rho_s/\rho_s - 1)g}{\nu^2}\right\}^{1/3} D_{50} \qquad \ldots(11d)$$

The range of variables used to establish equations (11) is:

Range of D_{50} : $D_{50} = 0.24 \times 10^{-3}$ m.

The theory was, however, tested against data collected by O'Brien (1936), Kadib (1965) and Exner (1928). This extends the range to:

0.145×10^{-3} m $\leq D_{50} \leq 1.0 \times 10^{-3}$ m

Range of v_{10_m} (velocity at 10 m) $v_{10} \leq 20$ m/s.

The range of u_{*_w} in the measurements of O'Brien, Kadib and Exner referred to above is 0.2 m/s to 2.89 m/s.

Horikawa et al. (1983), in a useful summary of available formulae for the prediction of wind-blown sand transport, concluded that most formulae failed to predict accurately transport rates in the case of sands with a wide grain size distribution, characterized by a sorting coefficient u_c (= D_{60}/D_{10}) >> 1. Swart (1987b) used the first tentative results of Horikawa et al. (1983) to reanalise the original data used to establish all the formulae given herein and obtained the following:

$$S_a = K_{MBKS} \left(\frac{\rho_a}{g}\right) (u_{*w} - u_{*wc}) (u_{*w} + u_{*wc})^2 \quad ...(12a)$$

This Modified-Bagnold-Kawamura-Swart formula is identical to the Kawamura formula (equation (2)) except for the coefficient, which is given by:

$$K_{MBKS} = 5.49 \times 10^{-4} \; u_{ca}^4 \left(\frac{D_{50a}}{D_{50}}\right)^{-0.5} \left(0.02 \left(\frac{D_{50}}{D_{50_r}}\right) + 0.08\right) (u_c - 1)^{-2/3} \quad ...(12b)$$

where D_{50_r} = reference grain size = 0.2×10^{-3} m

$$D_{50a} = \beta u_* + 2.4 \times 10^{-3} \quad ...(12c)$$

If $D_{50a} > D_{50}$ then $D_{50a} = D_{50}$

$$\beta = 1.5 \times 10^{-4} (1 - \sigma_u) \quad ...(12d)$$

$$\sigma_u = \frac{D_{60}}{D_{90}}$$

$$u_{ca} = \alpha u_* + 1.5 \quad ...(12e)$$

If $u_{ca} > u_c$ then $u_{ca} = u_c$

$$\alpha = 1 - \sigma_u$$

The range of variables on which this formulation is based, is as follows:

Range of D_{50} : 0.145×10^{-3} m $\leq D_{50} \leq 1.0 \times 10^{-3}$ m
Range of u_{*w} : 0.054 m/s $\leq u_{*w} \leq$ 2.89 m/s
Range of D_{60}/D_{10} : $1.02 \leq D_{60}/D_{10} \leq 1.988$
Range of D_{60}/D_{90} : $0.662 \leq D_{60}/D_{90} \leq 0.988$

2.3 Transportation of moist sand

It is not the purpose of this paper to review the transportation of moist sand by wind action. However, because the sand is frequently moist when wind speeds capable of moving dry sand occurs, it is necessary to study this phenomenon. Horikawa, Hotta and Kubota (1982b) presented an excellent review of work done to date on blown sand on wetted sand surfaces. From this review it is clear that:

(1) The problem of blown sand on wetted sand surfaces has not been conclusively studied yet and a number of problem areas still remain to be solved.

(2) Wind-driven sand transport depends, amongst other things, on the water content of the sand layer, humidity, air temperature and solar radiation. It will be very difficult ever to use these

parameters on a routine basis for the prediction of wind-driven transport rates because of the scarcity (non-existence) of parallel statistics on the various variables. It is nonetheless important to quantify the effect on the transport rate of these variables.

(3) In trying to predict the mechanism of blown sand on wet sand surfaces it will be necessary to know to what depth the sand is wetted by a rainfall of known intensity and duration as well as the manner in which the sand bed will dry out again. The rôle of sand characteristics, humidity, wind speed, air temperature and solar radiation needs to be addressed in this respect.

(4) It would appear that the main differences between blown sand on wet and dry sand surfaces is that the critical wind speed when sand movement starts is increased on a wetted sand surface and that the variation of sediment concentration is different. It would, however, appear that as a first estimate the Kawamura type formula could be used for blown wet sand, provided that a modified incipient motion criterion is used. The results given by Horikawa et al. (1982a,b), Hotta et al. (1984) and Nakashima (1979) in this regard indicate that there is a wide divergency in the available data, perhaps because of the difficulty of accurately defining and measuring the moisture content in the sand bed.

(5) More controlled measurements under laboratory conditions as well as field experiments are required to address the points raised above.

2.5 Discussion

This chapter has reviewed the available formulations for the prediction of blown sand on dry and wet surfaces. At present the best that can be done is to predict the transport of blown sand on a dry surface which, for ease of reference, is termed the **potential** sand transport. Apart from the problem of wet sand surfaces which was addressed in Section 2.3, there are a few other aspects which are particularly relevant to field application of the techniques, which will require systematic study. The two most important of these are:

(1) The effect of the topography of the sand surface over which the wind blows on the shear velocity and the magnitude of the blown sand volume. To date little work has been done in this respect, but reference can be made to Nakashima (1979), Svasek and Terwindt (1974) and Harmse (1985).

(2) The effect of vegetation cover has not been addressed quantitatively. Particularly in the case of blown-sand control or dune management this aspect, coupled with the previous point on topography, is of major importance. In this respect reference can be made to Fryberger et al. (1984), Illenberger (1986) and Swart and Reyneke (1987).

3. DETERMINATION OF SHEAR VELOCITY

Most of the formulae given in the previous chapter relate sand transport to the shear velocity at the bed. Mostly the shear velocity has to be computed on the basis of wind speed measurements at some distance above the sand surface. It is assumed that a logarithmic velocity profile exists, although this aspect still has to be addressed in the case of sand transport through dune fields where the dune height may be higher than 50 m. A number of different formulations, all of an empirical nature, exist in the body of literature referred to in Chapter 2. For the purpose of uniformity all the data used to determine these different relationships were plotted together in the form of a graph relating shear velocity with the wind speed at 2 m above the sand surface. This graph is shown here as Figure 1.

The best fit through the data points is given by

$$u*_w = 0.0275\ u_2^{1.25} \qquad \ldots(13)$$

where u_2 is the wind speed at 2 m above the sand surface.

The scatter in the data is encompassed by an upper and a lower envelope at a distance of plus or minus 20 per cent from the line defined by equation (13). This expression is used together with the logarithmic velocity law for all work reported on in this paper.

4. COMPARISON BETWEEN VOS WIND DATA AND SHORE-BASED ANEMOMETER RECORDS

In the determination of a sand budget as part of some preliminary engineering design it is often necessary to establish the contribution of the wind-driven component of sand transport to the overall budget. Under such circumstances the situation frequently arises that reliable wind statistics are not available in the close proximity of the area under consideration. It has been found quite useful then to rely, as a first approximation, on anemometer data recorded by Voluntary Observing Ships (VOS) in the coastal waters off the study site.

Swart (1987c) has shown that a reasonable similarity exists between the wind direction variation offshore and at the coast (see Figure 2). Obviously major topographic features modify the offshore wind climate but as a first estimate this is a reasonable assumption. In addition, he showed that the VOS wind speed is generally higher than that recorded at land-based anemometer stations. However, a comparison of all available shore-based anemometer wind speed data with corresponding VOS data showed that a good first estimate of wind speed can be obtained by

$$v_2 = 0.6\ v_{VOS} \qquad \ldots(14)$$

(see Figure 3).

The purpose of the foregoing is not to suggest that there is no need for shore-based anemometer data, but only to provide first estima-

tes in the case of feasibility studies. In the final instance the variability of the wind field along the coast in sympathy with topographical variations is such that the only reliable results on aeolian transport will be those based on long-term wind data gathered on site.

5. SUMMARY OF PROCEDURES

The problem to be addressed is that 16 different formulae for the prediction of wind-driven sand transport on a dry sand surface were given in Chapter 2. Each of these have a different field of applicability. It has not been possible to demonstrate conclusively that any one of these formulations is clearly superior or inferior to the rest. The method described below gives a technique which allows the establishing of a good best estimate of the wind-blown transport rate.

For any given value of wind speed the wind speed is converted via the logarithmic law to a representative height above the ground of 2 m. The potential sediment transport rate is predicted for each of the 16 formulae and the answers ordered from the highest to the lowest. The highest 3 values and the lowest 3 are then rejected and the average of the central 10 estimates is then used as the predicted potential wind-blown transport rate according to the technique. Figure 4 gives an idea of the scatter involved for the case of D_{50} = 300 μm and v = 15 m/s.

For normal application wind statistics from an anemometer of given height above the ground would serve as input data along with grain size details. It has been shown that data obtained from Voluntary Observing Ships can be used to obtain a good first estimate of the coastal wind climate. The results obtained from the analysis are represented in a creep diagram which is really an inverted rose.

Figure 5 gives an example of the aeolian creep diagram. It is possible to quantify the aeolian sand budget either on the basis of such a diagram or by using a tabular representation of the results.

6. FIELD VERIFICATION OF TECHNIQUE

The formulae given in Section 2, with the exception of those by Tsuchiya and Kawata (1975), were derived empirically. The empirical coefficients in the various formulations are therefore based on laboratory results or individual field experiments. This does not, however, give any indication of how any of these techniques will behave when applied to long-term wind statistics. For this purpose the method of application outlined in Chapter 5 was tested against long-term wind-data in situations where the sand drift was also known.

The method has been applied to a number of sites around the South African coast, amongst others the dune fields around Port Elizabeth and the dune fields on the South West African coast in the vicinity of Walvis Bay (see Figure 7). Measurements of dune advance rates at both these sites have been used to verify the technique. **Port Elizabeth** data indicate gross eastbound transport rates of 68 $m^3/m/yr$ at Cape Recife (McLachlan, pers. com.), whereas Prestedge (pers. com.) estimates the net eastward movement in the area at 45 $m^3/m/yr$ for the

period 1972 to 1981. East of the Sondags mouth McLachlan estimates, on the basis of dune advancement, a net eastbound transport rate of 35 to 42 $m^3/m/yr$ and a shoreward movement of about 30 $m^3/m/yr$. The latter figure was revised by Illenberger (1986) to 22 to 30 $m^3/m/yr$. Predictions with the technique described herein show the following potential rates:

Northbound:	gross	27 $m^3/m/yr$
	net	18 $m^3/m/yr$
Eastbound :	gross	78 $m^3/m/yr$
	net	45 $m^3/m/yr$

Calculations by Swart (1986) show variations in the predicted annual drift rate of a factor 3 on a year-to-year basis over an eleven-year period due to the variability of the wind field (Figure 6).

Walvis Bay data by Le Roux show northward volumetric dune advance rates of 120 $m^3/m/yr$ in the lower Kuiseb valley. Calculations with two different sources of wind data show northward aeolian transport rates of 109 and 122 $m^3/m/yr$ respectively. The good correspondence is shown in Figure 8.

7. CONCLUSIONS

This paper reviews the quantitative techniques for the prediction of windblown sand transport. The main conclusions reached are the following:

(1) Sixteen different techniques were identified which can be used to predict potential wind transport rates over dry, unvegetated sand surfaces.

(2) None of these is clearly superior or inferior to the others. Therefore a computational scheme was developed which utilizes the central ten predictions out of an ordered (high to low) set of 16 predictions for a given set of boundary conditions.

(3) By application to two prototype examples where long-term data are available, it was shown that the method can be used to give accurate predictions of aeolian transport rates, provided that reliable wind statistics are available.

(4) It was shown that Voluntary Observing Ships' wind data provide a good, first estimate of the uncontaminated wind field on the coast, provided that there are no major topographical features such as mountains to deflect the wind patterns locally.

(5) The method described in this paper supplies potential windblown transport rates and neglects the effect on the transport of air temperature, the humidity, the moisture content of the soil, which is related to the amount and intensity of the rainfall, the salt content of the sand, the percentage of vegetation cover of the sand and the topography of the ground over which the wind is blowing.

8. RECOMMENDATIONS

It should be clear from the above that although the technique described supplies a reliable estimate of the potential windblown transport rate, there are still a number of factors which need to be researched further in detail before it will allow the prediction of prototype transport rates under variable prototype conditions. Much of this research is already underway. Factors which demand particularly urgent attention are those listed under item (5) in Chapter 7. Every effort should be made to co-ordinate the activities in this respect of the various researchers actively working toward understanding the effect of these parameters on the windblown transport rate.

CHAPTER 118

BEACH CHANGES BY STORM WAVES

Ichirou Takeda* and Tsuguo Sunamura*

ABSTRACT

Monitoring of beach profiles was carried out during one-year period at two sites located 3 km apart along a Pacific beach, Japan. These two sites are composed of beach sand with different grain size: 0.76 mm and 0.26 mm. It was found that the shoreline did not move even in storm wave events at the site with 0.76-mm sand, where the "seesaw mode" profile change took place in the subaerial portion of the beach. It was also found that the shoreline was not always retreated by storm waves at the 0.26-mm sand site, where the "parallel mode" profile change dominated, at the time of presence of bars working as a submerged breakwater to protect the beach from erosion.

INTRODUCTION

It is generally considered that storm waves erode beach material and transport offshore causing shoreline recession on a coast with dominant cross-shore sediment transport. In some cases, however, no shoreline retreat occurs even in the event of storm waves. There have been few systematic studies on such a phenomenon. The present study purposes to investigate this problem based on one-year consecutive monitoring of beach changes and incident wave characteristics.

STUDY AREA AND DATA ACQUISITION

Beach monitoring was carried out at Naka Beach, Ibaraki Prefecture, Japan (Fig. 1). The beach, facing the Pacific Ocean, is an approximately straight coast with a north-south oriented shoreline 5 km long. The beach sediment is

*Institute of Geoscience, University of Tsukuba, Ibaraki 305, Japan.

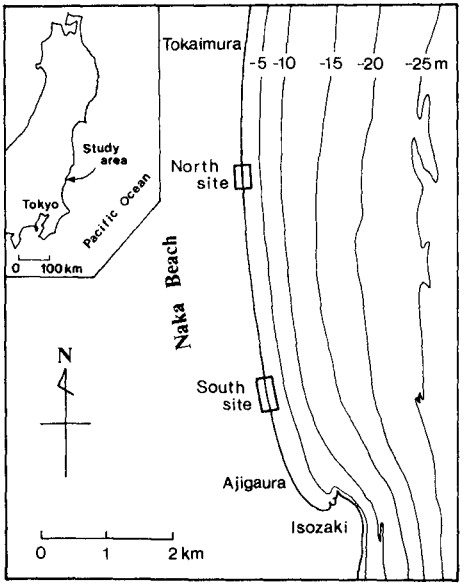

Fig. 1 Study area and two monitoring sites.

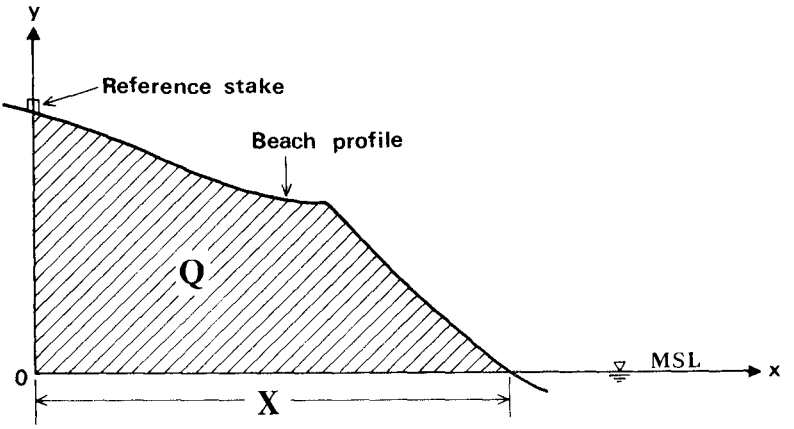

Fig. 2 Schematic diagram showing beach width and subaerial beach sediment volume

composed of coarse sand in the northern part of the beach and fine sand in the southern part (Takeda, 1984). The shoreline of the study area is stable on a long-term basis (Tanaka et al., 1973). The direction of long-term longshore sediment transport would be southward, but cross-shore sediment transport dominates for short-term beach changes. No man-made coastal structures have been constructed on the beach.

An outer bar is always located nearly parallel to the shoreline, and an inner bar only develops under certain physical conditions. The average bottom slope is 0.011 to a water depth of 20 m, and is almost constant along the beach. No significant alongshore difference in incident wave characteristics has been observed. The beach is in a microtidal environment, a maximum tidal range is 1.4 m and a mean is about 1 m.

Two monitoring sites, 3 km apart, were established along this beach (Fig. 1). They are called North Site and South Site. North Site has an alongshore length of 300 m and South Site has a 500 m length. The mean grain size of the beach material was 0.76 mm at North Site and 0.26 mm at South Site. Reference stakes were installed along the shoreline on the highest part of the beach. Sixteen stakes were set up at an interval of 20 m at North Site and eleven stakes were installed at 50-m interval at South Site.

Beach profiles were surveyed perpendicular to the general shoreline trend from each stake to the surf zone using a telescopic level, a surveyor's rod, and a tape. The survey was conducted at an interval of once or twice per week for a period of one year beginning August 28, 1980.

Based on the beach survcy results, the beach width and the subaerial beach sediment volume, defined in Fig. 2, were calculated. In this figure, the x-axis extends offshore on mean sea level from the origin which is located at the intersection with the y-axis extending upwards through a reference stake. The beach width, X, is the horizontal distance between the origin and the point at which the beach profile meets the x-axis. The subaerial beach sediment volume, Q, is the cross-sectional area (hatched area) bounded by the beach profile, the x-axis, and the y-axis. Averaged values of X and Q over 16 survey lines for North Site and 11 lines for South Site were obtained, and they were denoted by $\bar{X}$ and $\bar{Q}$, respectively.

The two quantities, $\bar{X}_*$ and $\bar{Q}_*$, are defined as:

$$\bar{X}_* = \bar{X} - \bar{X}_0 \quad (1)$$

$$\bar{Q}_* = \bar{Q} - \bar{Q}_0 \quad (2)$$

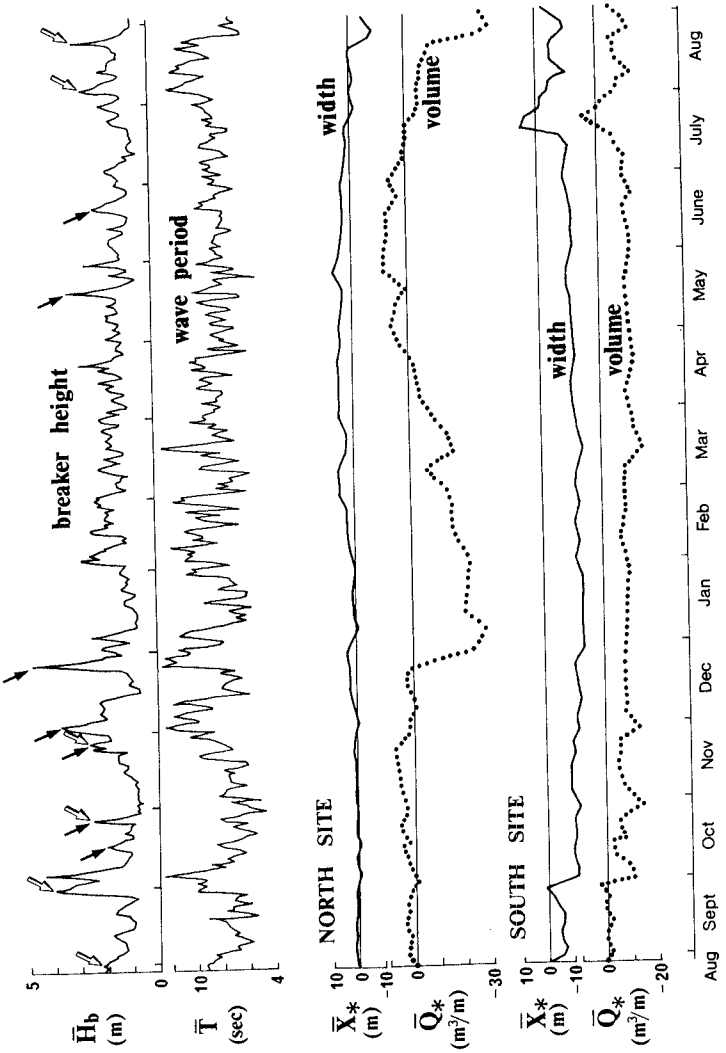

Fig. 3 Time-series data of waves and beach characteristics.

where $\bar{X}_0$ and $\bar{Q}_0$ are values of $\bar{X}$ and $\bar{Q}$ of August 28, 1980, the first day of the investigation, respectively.

Waves were measured by an ultrasonic-type wave gage installed about 10 km south of the study area at a water depth of 21 m. Continual wave records obtained over 20 minutes for every two hours were available. Based on the wave records, daily averages of deepwater significant wave height and period were obtained. Daily averages of significant breaker height, $\bar{H}_b$, were calculated using the following relationship (Sunamura, 1982):

$$\frac{H_b}{H_0} = (\tan \beta)^{0.2} \left(\frac{H_0}{L_0}\right)^{-0.25} \quad (3)$$

where H_b is the breaker height, H_0 and L_0 are the deepwater wave height and length, respectively, and $\tan\beta$ is an average nearshore bottom slope.

Time-series data of $\bar{X}_*$, $\bar{Q}_*$, $\bar{H}_b$, and daily averages of significant wave period, $\bar{T}$, are shown in Fig. 3.

RESULTS AND DISCUSSION

Beach Erosion Pattern

The time-series data of $\bar{X}_*$, $\bar{Q}_*$, and incident waves (Fig. 3) illustrate that the characteristics of subaerial beach change in the event of storm waves is different between the two sites. Namely, the pattern of change in $\bar{X}_*$ is the same as that in $\bar{Q}_*$ at South Site, while the change pattern of $\bar{X}_*$ is different from that in $\bar{Q}_*$ at North Site.

At South Site, storm waves simultaneously decreased both $\bar{Q}_*$ and $\bar{X}_*$. This change pattern was observed at storm events shown by open allows in Fig. 3, i.e., storms in late September, 1980; late October, 1980; late November, 1980; early and late August, 1981. Such a subaerial beach change is schematically shown in Fig. 4-(A); that is, storm waves decrease the beach width and the subaerial beach sediment volume at the same time, and the "parallel mode" profile change takes place.

A typical example of this type of profile change actually observed at South Site is shown in Fig. 5. The solid line indicates the profile before the storm waves (with a maximum of $\bar{H}_b$ = 2.7 m) in late November, 1980. The step had a height of about 0.3 m. The dashed line shows the after-storm profile. As shown in Fig. 5, the storm wave action decreased both the subaerial beach sediment volume as well as the beach width.

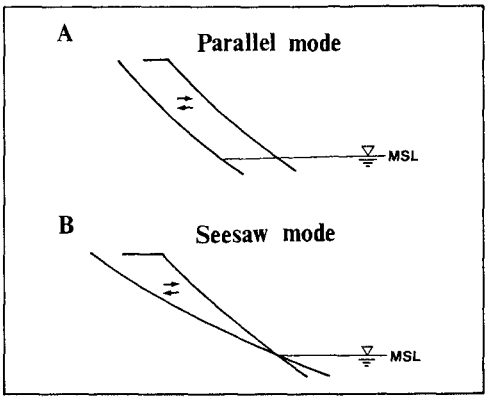

Fig. 4 Schematic diagram showing subaerial beach changes.

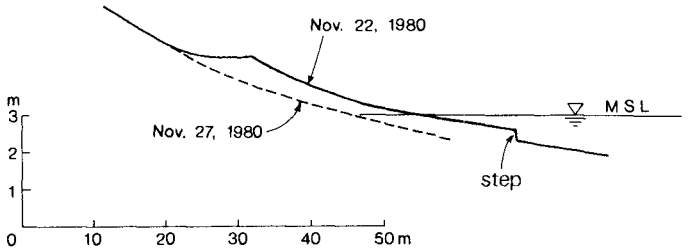

Fig. 5 Typical beach erosion pattern observed at South Site.

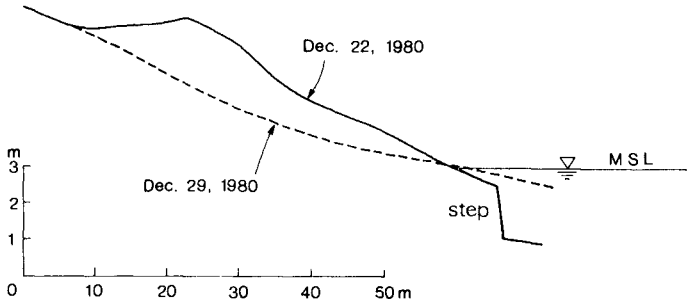

Fig. 6 Typical beach erosion pattern observed at North Site.

On the other hand, storm waves decreased $\bar{Q}_*$ but they did not decrease $\bar{X}_*$ at North Site. This change pattern was observed at storm events shown by solid allows in Fig. 3, i.e., storms in middle and late October, 1980; late November, 1980; early and late December, 1980; middle May, 1981; and late June, 1981. This subaerial beach change is shown in Fig. 4-(B). In spite of that subaerial beach material is eroded away by storm waves, the shoreline advances or does not change, and the "seesaw mode" profile change occurs in the subaerial portion of the beach.

Figure 6 shows an actual example of the seesaw mode profile change occurred at North Site due to the storm waves with $(\bar{H}_b)_{max}$ = 4.8 m on December 25, 1980. The pre-storm profile (solid line in Fig. 6) had a step with a height of about 1.5 m. The storm waves markedly decreased the subaerial beach sediment volume, whereas the shoreline position did not retreat but advanced. The surf zone could not be surveyed due to high waves, but it was observed through wading that the eroded subaerial beach material deposited near the shoreline.

The difference in the two patterns of beach profile changes are due to the scale of a step formed under calm-sea conditions before the attack of storm waves. Larger steps usually developed at North Site, where beach material eroded by storm waves was not transported offshore but deposited just in front of the step, and no shoreline retreat occurred as schematically shown in Fig. 7-(B). The height of steps formed at South Site was much smaller. Eroded material was not deposited near the shoreline, but transported seaward to build up an inner bar in the surf zone, and the shoreline retreated [Fig. 7-(A)].

Beach Response of South Site to Storm Waves

It was often observed that the South Site beach also was not always eroded by large storm waves. For example, the beach was severely eroded by the action of storm waves in late September, 1980, but the beach was not significantly eroded by the storm in late December, 1980, which was the highest storm waves during the one-year survey period (Fig. 3). A similar phenomenon could also be recognized at the storm events in early February, late April, and middle May, 1981. Figure 3 shows that this phenomenon always occurred when the beach had a low $\bar{Q}_*$-value, that is, the beach was poor in the subaerial beach sediment volume. Beach material eroded from the subaerial portion of the beach had been transported offshore and formed an inner bar in the surf zone as schematically shown in Fig. 7-(A). It can be considered that such an inner bar is closely related to the condition for beach erosion.

Moreover, if the inner bar effects the condition for beach erosion, the outer bar also probably affects beach erosion. Because energy of waves arriving at the beach is greatly influenced by the position and water depth of a bar (Carter and Balsillie, 1983). The position of the outer bar in this study area was greatly changed by the action of the largest storm waves on December 25, 1980. The bar, located 70 to 120 m offshore before this day, was moved further offshore and thereafter its location was kept between 150 to 250 m in offshore distance. The time-series data (Fig. 3) were split into two parts on this day for the purpose of examining the critical condition for beach erosion.

In order to express the existence or nonexistence of inner bar, a dimensionless parameter, Q_R, is introduced, which is defined as:

$$Q_R = \frac{\bar{Q}_* - Q_{min}}{Q_{max} - Q_{min}} \tag{4}$$

where Q_{max} and Q_{min} are the maximum and minimum values of $\bar{Q}_*$ during the one-year investigation period, respectively. The parameter Q_R, which shows a relative subaerial beach sediment volume, is a value ranging from 0 to 1. A berm-developing beach state (fully accretionary state) has larger Q_R-values compared with an inner-bar forming beach state (erosional state), and a bar-welding beach state takes intermediate values.

The magnitude of storm waves can be expressed by a dimensionless coefficient, k, in the following equation (Sunamura, 1984; Takeda, 1984):

$$\frac{H_b}{gT^2} = k\frac{D}{H_b} \tag{5}$$

where D is the grain size of beach material, and g is the gravitational acceleration.

Because (1) wave climate changes in time and (2) beach change is most sensitive to larger waves during one interval of two consecutive beach profiling, $(\bar{H}_b)_{max}$ and $\bar{T}_{max}$ were substituted for H_b and T in equation (5), respectively:

$$\frac{(\bar{H}_b)_{max}}{g\bar{T}_{max}^2} = K\frac{D}{(\bar{H}_b)_{max}} \tag{6}$$

where $(\bar{H}_b)_{max}$ is the maximum value of daily average breaker height during one interval between surveys, $\bar{T}_{max}$ is the average wave period of the day giving $(\bar{H}_b)_{max}$, and K is a dimensionless coefficient. The larger value of K means the

higher wave-intensity resulting in net offshore sand transport in the surf zone (Sunamura, 1984).

Using two parameters, Q_R and K, the critical condition for beach erosion was examined. Figure 8 is a plot of data obtained before December 25, 1980 (the outer bar was located near the shoreline). Beach accretion or erosion is determined by the change in subaerial beach sediment volume $\bar{Q}_*$ during one survey interval, i.e., an increase in $\bar{Q}_*$ is defined as accretion, while a decrease in $\bar{Q}_*$ is defined as erosion. In Fig. 8, the open symbol indicates accretion and the solid symbol denotes erosion. Data showing small change in $\bar{Q}_*$ less than 1.0 m^3/m were excluded from the plot. Although some overlapping of the data points is seen, the erosion-accretion demarcation can be described by the solid curve. The figure shows that no erosion takes place even for the case of larger K-value when the beach has lower Q_R-value. Namely, the beach is not likely to be eroded even by the large storm waves when an inner bar develops. This suggests that the inner bar protects the beach acting as a submerged breakwater.

Figure 9 is a plot of data obtained during the period when the outer bar was located further offshore. A similar tendency to the former case is found. These two results show that the existence or nonexistence of an inner bar is closely related to the critical condition for beach erosion.

Comparison of Figs. 8 and 9 indicates the influence of the outer bar on beach erosion. The demarcation curve in Fig. 9, compared with Fig. 8, is plotted in the lower-left area. This suggests that less severe storm waves can erode the beach when the outer bar is located offshore. The water depth of bars increases with increasing offshore distance (Keulegan, 1948). Because the outer bar located closer to the shoreline has smaller water depth, such an bar is likely to protect the beach acting as a submerged breakwater like the above-mentioned inner-bar case. On the other hand, the outer bar located offshore can not effectively work as a submerged breakwater to protect the beach from erosion.

CONCLUSIONS

The data of beach monitoring shows that the seesaw mode profile change dominates at the coarse sand beach (North Site) and the parallel mode profile change takes place at the fine sand beach (South Site). In the case of seesaw mode profile change, little significant shoreline retreat occurs in the event of storm waves. It is found that the presence of inner bar and the location of outer bar greatly influence the subaerial beach change occurring on the fine sand beach.

CHAPTER 119

NUMERICAL SIMULATION OF TURBULENT WAVE BOUNDARY LAYERS

J. H. Trowbridge[1], A.M.ASCE, C. N. Kanetkar[2] and N. T. Wu[3]

ABSTRACT: This paper reports numerical computations of fully rough turbulent boundary layers produced by first and second order Stokes waves. The computations are based on a mixing length turbulence closure and on a slightly more sophisticated turbulent kinetic energy closure. The first order results compare well with existing laboratory results. Reversal of the second order steady streaming under relatively long waves, which has been predicted analytically, is also predicted in the numerical results. The steady second order velocity field is found to become fully established only after a development time on the order of a few hundred wave periods. Both the first and second order results indicate that advection and diffusion of turbulent kinetic energy play a minor role in determining the Reynolds averaged velocity field.

INTRODUCTION

A quantitative understanding of turbulent wave boundary layers is necessary for coastal engineers concerned with dissipation of wave energy, wave-induced sediment transport, and the effect of waves on large-scale, slowly varying currents. This study is confined to the case of fully turbulent boundary layers produced by weakly nonlinear waves near fixed hydrodynamically rough boundaries. The boundary roughness elements are assumed to be small compared to the boundary layer thickness.

Previous analytical studies (Kajiura, 1968; Grant and Madsen, 1979; Brevik, 1981; Myrhaug, 1982; Trowbridge and Madsen, 1984a), numerical studies (Bakker, 1974; Johns, 1975; Bakker and van Doorn, 1978), experimental studies (Jonsson, 1966; Jonsson and Carlsen, 1976; Bakker and van Doorn, 1978; Kamphuis, 1975) and semi-empirical analyses (Jonsson, 1966) have clarified the physics of the first-order problem. This is the purely oscillatory case corresponding to linear wave theory. By using relatively simple analytical solutions based on eddy-viscosity models, or numerical results based on Prandtl's mixing-length theory, one can predict with confidence the Reynolds-averaged velocity field, boundary shear stress and energy dissipation for the first-order case.

[1]Assistant Professor, Dept. of Civil Engrg., University of Delaware, Newark, DE 19716.
[2]Central Water and Power Research Station, Pune, India.
[3]Graduate Student, Dept. of Civil Engrg., University of Delaware, Newark, DE 19716.

The second-order solution, which incorporates the effect of wave nonlinearity, is not as well established. The quantity of particular interest in the second-order problem is the steady streaming, or steady current which is generated in the boundary layer due to frictional dissipation of energy and nonlinearity. The asymmetry in the velocity field and bottom shear stress are also of interest in transport problems. Longuet-Higgins (1958) assumed that the effective viscosity is constant from the point of view of a moving fluid particle, although he allowed it to vary with mean particle position. He was able to show that under this restriction, the steady streaming just outside the wave boundary layer has the same value as in laminar flow. This value is independent of the molecular viscosity, and it is always in the direction of wave propagation. A later similar study, based on a time-invariant viscosity with a particular vertical structure, was reported by Johns (1970) with similar results. Later Johns (1977) reported a study based on a more realistic turbulent kinetic energy closure, but he neglected the second-order properties of the pressure field outside the boundary layer. In addition, he found that the steady streaming outside the boundary layer was zero. This result contradicts the laminar solution and existing analytical solutions, and will be discussed below in more detail. Trowbridge and Madsen (1984b) reported an analytical study based on a detailed, physically based eddy viscosity model, and found that the steady streaming produced by Stokes waves is in the direction opposite that of wave propagation for relatively long waves. Jacobs (1984) obtained a similar result by using an analysis based on Saffman's turbulence model.

Trowbridge and Madsen (1984b) found that their predictions of the steady streaming were sensitive to the eddy viscosity model. They used two models: one in which time variation of the viscosity extended throughout the boundary layer, and one in which the time variation of the viscosity was confined to a thin layer near the boundary. Example results are shown in Figure 1, indicating that predictions of the steady streaming are quite sensitive to the model used. The two models produced nearly indistinguishable results in the first order problem, and hence could not be judged on this basis.

Observations of the second-order properties of wave boundary layers are scarce. Bakker and Van Doorn (1978) reported a study carried out in a laboratory wave basin, in which the horizontal velocity was measured inside the boundary layer. In order to obtain turbulent flow at relatively small laboratory scales, Bakker and van Doorn had to use roughness elements which were quite large compared to the boundary layer thickness, and therefore the relevance for comparison with the theoretical studies quoted above is limited.

This paper reports a numerical study of turbulent wave boundary layers, based on Prandtl's mixing-length model and on a slightly more sophisticated turbulent kinetic energy closure, which was originally suggested by Prandtl (e.g., Schlichting, 1979), developed by several researchers, and summarized, for example, by Reynolds (1976). The purposes of this study are the following: (1) to clarify the physics of the second-order turbulent wave boundary layer; and (2) to give insight for developing a simpler analytical model which can be used as

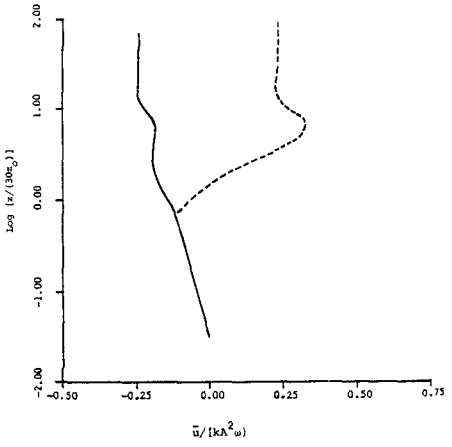

Figure 1. Mean velocity $\bar{u}$ as a function of vertical coordinate z based on the analyses reported by Trowbridge and Madsen (1984b). Solid line, first model; dashed line, second model. $kh = 0.50$, $A/(30z_o) = 179$.

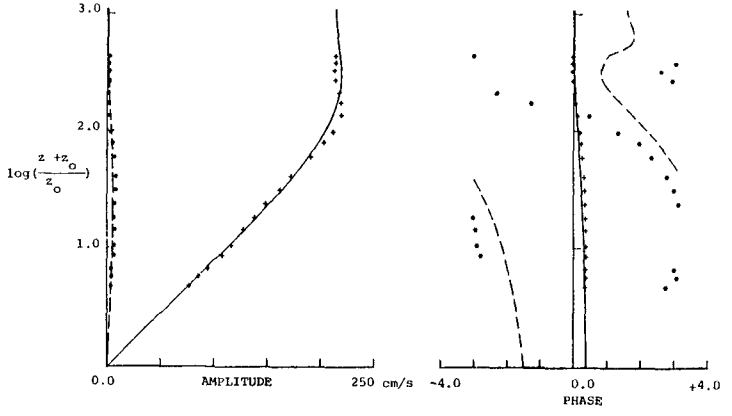

Figure 2. Computed amplitude and phase of the first and third harmonics of the horizontal velocity based on the mixing length model, compared with measurements reported by Jonsson and Carlsen (Test 1). Solid line, first harmonic; dashed line, third harmonic; asterisk, measurement. $30\ z_o = 1.59$ cm.

the basis for future studies involving more complicated processes.

GOVERNING EQUATIONS

The flow to be considered is produced by a regular train of plane waves which is described locally by Stokes' second-order solution. The governing equations are the boundary layer approximation to the 2-D Reynolds-averaged mass and momentum equations. These are

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \tag{1a}$$

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + w\frac{\partial u}{\partial z} = \frac{\partial U}{\partial t} + U\frac{\partial U}{\partial x} + \frac{\partial}{\partial z}\frac{\tau}{\rho} \tag{1b}$$

(e.g., Tennekes and Lumley, 1972) where x is the horizontal coordinate, positive in the direction of wave propagation, z is the vertical coordinate, positive upward with z equal to zero at the fixed bed, t is time, (u,w) is the Reynolds-averaged velocity vector inside the boundary layer, U is the horizontal velocity outside the boundary layer, τ is the Reynolds shear stress, and ρ is the fluid density. The corresponding boundary conditions are the no-slip conditions at the bed and the no-stress condition far away from the bed:

$$u = w = 0 \qquad \text{at } z = 0 \tag{2a}$$

$$\tau \to 0 \qquad \text{as } z \to \infty \tag{2b}$$

The unsteady component of U is determined by Stokes' second-order solution, which is

$$U - \bar{U} = A\omega\cos(\omega t - kx) + \frac{3}{4}\frac{kA^2\omega}{\sinh^2(kh)}\cos[2(\omega t - kx)] \tag{3}$$

(e.g., Dean and Dalrymple, 1984). Here an overbar denotes a time-averaged quantity, A is the near-bottom excursion amplitude, ω is the radian frequency, k is the wave number, and h is the water depth. The steady component of U is determined by the mechanics of the boundary layer, and hence is not known initially.

An additional equation necessary for the turbulence closure is the boundary layer approximation to the turbulent kinetic energy equation, which is

$$\frac{\partial}{\partial t}\left(\frac{1}{2}q^2\right) + u\frac{\partial}{\partial x}\left(\frac{1}{2}q^2\right) + w\frac{\partial}{\partial z}\left(\frac{1}{2}q^2\right) = \frac{\tau}{\rho}\frac{\partial u}{\partial z} + \frac{\partial D}{\partial z} - \epsilon \tag{4}$$

(e.g., Tennekes and Lumley, 1972) where $(1/2)\,q^2$ is the Reynolds averaged turbulent kinetic energy per unit mass, D is the vertical flux of kinetic energy due to turbulent "diffusion," and ϵ is the Reynolds averaged dissipation per unit mass.

The leading terms in (1b) are the temporal acceleration terms and the stress term, and the leading terms in (4) are the time deriva-

tive term and the three terms on the right side (production, diffusion and dissipation). In both equations, the advective terms are order kA compared to the leading terms, and the neglected terms are order $k\delta$ compared to the leading terms, where δ is the boundary layer thickness. The viscous terms are neglected in both equations because they are small everywhere compared to the other terms for the case of hydrodynamically rough bed.

An important simplification is achieved by using the condition of periodicity in space and time. By using this condition together with the mass conservation equation to determine the vertical velocity, one can write equations (1b) and (4) as follows:

$$\frac{\partial u}{\partial t} - \frac{u}{c}\frac{\partial u}{\partial t} + \frac{1}{c}\frac{\partial u}{\partial z}\int_0^z \frac{\partial u}{\partial t}\,dz = \frac{\partial U}{\partial t} - \frac{U}{c}\frac{\partial U}{\partial t} + \frac{\partial}{\partial z}\left(\frac{\tau}{\rho}\right) \tag{5a}$$

$$\frac{\partial}{\partial t}\left(\frac{q^2}{2}\right) - \frac{u}{c}\frac{\partial}{\partial t}\left(\frac{q^2}{2}\right) + \frac{1}{c}\frac{\partial}{\partial z}\left(\frac{q^2}{2}\right)\int_0^z \frac{\partial u}{\partial t}\,dz = \frac{\tau}{\rho}\frac{\partial u}{\partial z} + \frac{\partial D}{\partial z} - \epsilon \tag{5b}$$

where c is the wave speed. Equations (5) involve derivatives with respect to z and t only, rather than x, z and t.

TURBULENCE CLOSURES

We shall discuss results based on two turbulence closures. The first is Prandtl's mixing length model, which is

$$\tau = \rho\, \ell^2(z)\, \left|\frac{\partial u}{\partial z}\right| \frac{\partial u}{\partial z} \tag{6}$$

Here $\ell(z)$ is a vertical length scale which must by specified. We shall use simply

$$\ell = \kappa(z + z_o) \tag{7}$$

where κ is the Karman constant and z_o is the bed roughness scale. The turbulent kinetic energy equation is not needed for this closure, and the governing equations are simply (5a) and (6).

The second closure is a slightly more sophisticated turbulent kinetic energy closure. In this closure, the stress is written

$$\tau = c_2\, q\, \ell \tag{8}$$

where c_2 is an empirically determined constant, and the length scale $\ell(z)$ must be specified. As before, we shall use (7). The diffusion and dissipation terms are modeled by

$$D = c_2\, c_3\, q\, \ell\, \frac{\partial}{\partial z}\left(\frac{q^2}{2}\right) \quad ; \quad \epsilon = c_1\, q^3/\ell \tag{9a}$$

where c_1 and c_3 are constants. The boundary conditions for q are

$$q \to 0 \quad \text{as} \quad z \to \infty \quad ; \quad q^2 = c_4\, |\tau/\rho| \quad \text{at } z = 0 \tag{9b}$$

where c_4 is an empirical constant. The constants have been determined by other researchers by comparison with observations made in steady flows. We shall use the following values: $c_1 = 0.054$, $c_2 = 0.38$, $c_3 = 0.59$, $C_4 = 7$ (Reynolds, 1976).

It can easily be shown that the turbulent kinetic energy closure reduces to the mixing length model if temporal rate of change, advection, and diffusion of turbulent kinetic energy are neglected. The mixing length model can therefore be regarded as being based on a simplified turbulent kinetic energy balance in which production balances dissipation.

SOLUTION METHOD

As noted above, the advective terms on the left and right sides of (5a) and the left side of (5b) are order kA compared to the leading terms. In Stokes waves, kA is a small quantity, and the advective terms may be neglected for the purpose of a first approximation, yielding

$$\frac{\partial u}{\partial t} - \frac{\partial}{\partial z}\left(\frac{\tau}{\rho}\right) = \frac{\partial U}{\partial t} \tag{10a}$$

$$\frac{\partial}{\partial t}\left(\frac{q^2}{2}\right) - \frac{\partial D}{\partial z} - \frac{\tau}{\rho}\frac{\partial u}{\partial z} + \epsilon = 0 \tag{10b}$$

These equations are consistent with Stokes first order solution (linear waves). With the use of one of the turbulence closures discussed above, these equations may in principle be solved subject to the appropriate boundary conditions, with $\partial U/\partial t$ determined from the first term in (3). This solution is purely oscillatory and contains only odd harmonics of the fundamental Fourier component, i.e., terms with periods of T, T/3, T/5,etc., where T is the fundamental wave period.

Once a first-order solution is obtained from (10), the small advective terms in (5) may be estimated from the first-order solution. Equations (5)can be written

$$\frac{\partial u}{\partial t} - \frac{\partial}{\partial z}\left(\frac{\tau}{\rho}\right) = \frac{\partial U}{\partial t} - \frac{U}{c}\frac{\partial U}{\partial t} + \frac{u}{c}\frac{\partial u}{\partial t} - \frac{1}{c}\frac{\partial u}{\partial z}\int_0^z \frac{\partial u}{\partial t}\, dz \tag{11a}$$

$$\frac{\partial}{\partial t}\left(\frac{q^2}{2}\right) - D - \frac{\tau}{\rho}\frac{\partial u}{\partial z} + \epsilon = \frac{u}{c}\frac{\partial}{\partial t}\left(\frac{q^2}{2}\right) - \frac{1}{c}\frac{\partial}{\partial z}\left(\frac{q^2}{2}\right)\int_0^z \frac{\partial u}{\partial t}\, dz \tag{11b}$$

With the advective terms determined by the first order solution, and with the terms involving U determined by both terms in (3), the right sides of equations (11) are known. By using one of the turbulence closures discussed above, one may in principle solve equations (11) subject to the appropriate boundary conditions. This procedure yields a solution consistent with Stokes' second order solution for the wave field. To this level of approximation, the boundary layer solution consists of a large, purely oscillatory, first order part, containing only odd harmonics of the fundamental Fourier component, and a smaller second order part, containing even harmonics of the fundamental Fourier component, as well as a steady component.

Equations (10) and (11) resemble coupled heat equations, each containing an unsteady term, a diffusion term, and various source and sink terms. These equations can be solved subject to the appropriate boundary conditions by means of a fully implicit, finite control volume procedure described in detail by Patankar (1980). In deriving this procedure, one integrates the governing equations across a small control volume of height Δz and considers the fluxes of momentum and turbulent kinetic energy across the interfaces of each control volume. The scheme leads to a numerical time-stepping procedure in which one solves iteratively for the spatial distribution of velocity and kinetic energy at each time step.

In the computations described below, we used a vertical grid with a spacing varying as the cube of the distance above the solid boundary, and we applied the conditions at infinity at a finite distance above the boundary equal to A. In most computations we used 360 time steps per wave period and 51 grid points, and our convergence criterion was that the last iteration must yield values within approximately one part in 10^4 of the previous iteration. We found that computations carried out on this basis yielded results which were nearly identical to results obtained with larger numbers of grid points and time steps, and with a stronger convergence criterion. We began the computations from rest, and we found that the first order solution reached a periodic state after roughly six to ten periods. The second order solution required a much larger time to reach a periodic state, as discussed below.

FIRST ORDER RESULTS

As discussed in the Introduction, the first order solution for the case of a fixed bed with roughness elements small compared to the excursion amplitude is fairly well established on the basis of existing experimental, theoretical and semi-empirical studies. The purposes of presenting additional first order results here are to show that the numerical solutions reproduce available observations, and to compare the results produced by the two different turbulence closures.

Figure 2 shows vertical distributions of amplitude and phase of the first two nonzero Fourier components in the first-order velocity field. The Figure also shows observations reported by Jonsson and Carlsen (1976, Test 1). The computations in Figure 1 are based on the mixing length closure. Figure 3 shows a comparison of results based

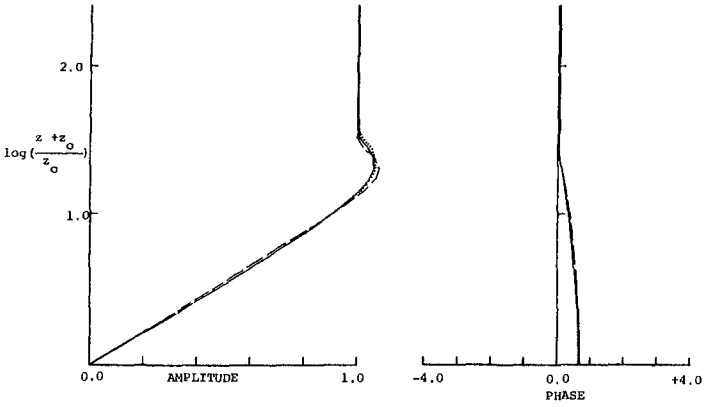

Figure 3. Computed dimensionless amplitude and phase of the first harmonic of the horizontal velocity. Solid line, mixing length model; dashed line, time rate of change of turbulent kinetic energy equal to production minus dissipation; dotted line, turbulent kinetic energy closure. $z_o/A = 0.004$.

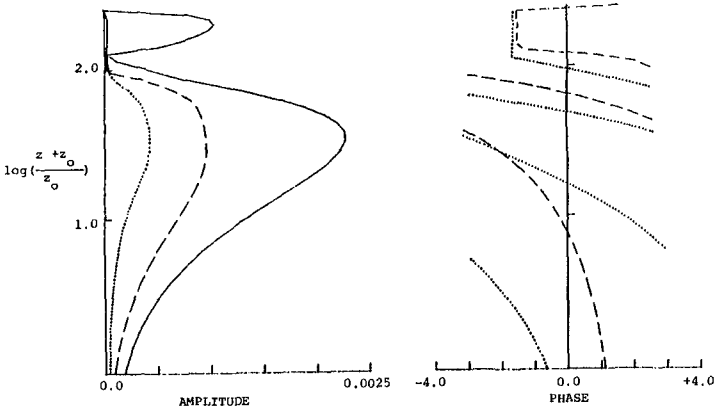

Figure 4. Computed amplitude and phases of the first three nonzero Fourier components of the first order eddy viscosity, normalized by A and ω, based on the mixing length model. Solid line, mean component; dashed line, second harmonic; dotted line, fourth harmonic. $z_o/A = 0.004$.

on the mixing length model and on the turbulent kinetic energy closure. Both closures reproduce the experimental observations well, and the results based on the two closures are nearly indistinguishable from each other. A small improvement in the agreement between computations and observations is possible if one uses a more physically reasonable length scale than that given by (7). This point is well understood based on previous theoretical studies (Kajiura, 1968; Brevik, 1981; Trowbridge and Madsen, 1984a) and will not be pursued here.

We thought initially that because wave boundary layers are an unsteady phenomenon, the most important parts of the first-order turbulent kinetic energy balance might be unsteadiness, production and dissipation, because diffusion is known to be relatively small in steady turbulent flows near solid surfaces (e.g., Tennekes and Lumley, 1972). Neglect of the diffusion term in the turbulent kinetic energy balance leads to a simplified solution, because in this case no boundary conditions are necessary for the turbulent kinetic energy. We found, however, that computations based on a simplified model without the diffusion term are only slightly different, but slightly worse from the point of view of comparison with experiments, than computations based on either the mixing length or kinetic energy closures. We therefore abandoned this approach.

Figures 4 and 5 show computations of the eddy viscosity, ν_T, which is defined by

$$\tau = \rho \, \nu_T \frac{\partial u}{\partial z} \tag{12}$$

In the mixing length closure,

$$\nu_T = \kappa^2 \, z^2 \left|\frac{\partial u}{\partial z}\right| \tag{13a}$$

and in the kinetic energy closure

$$\nu_T = c_2 \, q \, \ell \tag{13b}$$

The results in Figures 4 and 5 are very close. This is a convincing demonstration that the mixing length and kinetic energy closures give nearly identical results in the first order problem, because computations of eddy viscosity are more sensitive to the closure model than are computations of velocity.

The conclusions based on the first order results presented here are the following: (1) both turbulence closures reproduce the observations quite well; and (2) advection and diffusion of turbulent kinetic energy, which are the processes neglected in the mixing length model, have no significant effect on the Reynolds averaged motion.

SECOND ORDER RESULTS

Existing analytical models (Trowbridge and Madsen, 1984b) indicate that predictions of the second order boundary shear stress and the

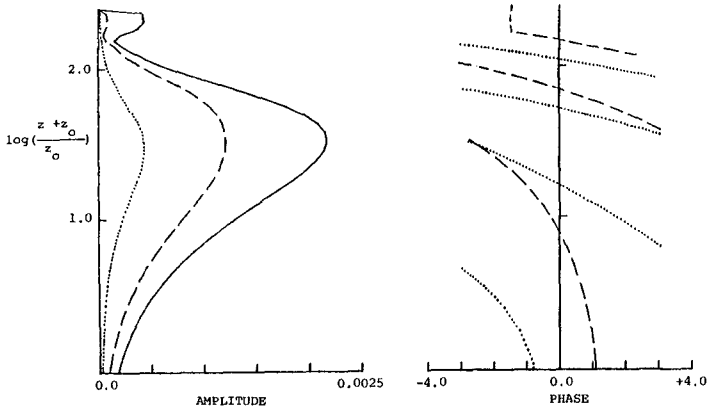

Figure 5. Computations as in Figure 4 based on the turbulent kinetic energy closure.

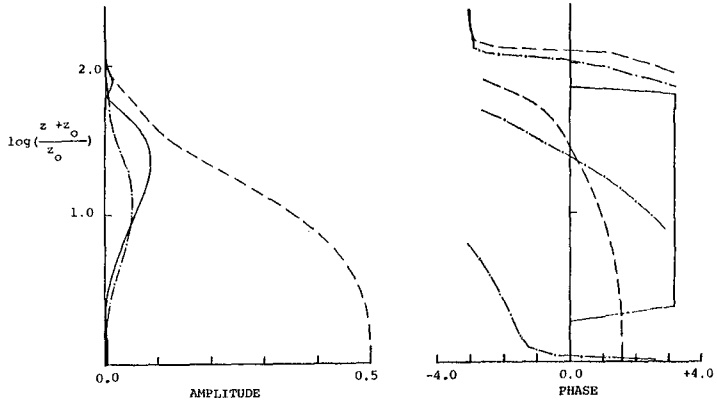

Figure 6. Computed amplitudes and phases of minus the second order forcing term on the right side of (11a), normalized by $kA^2\omega^2$, based on the mixing length model. Solid line, mean component; dashed line, second harmonic; dashed-dotted line, fourth harmonic. $z_o/A = 0.004$, $kA = 0.2$, $kh = 1.0$.

unsteady component of the velocity inside the boundary layer are relatively insensitive to the particular eddy viscosity model used. In discussing the second order results, we shall therefore concentrate on the steady streaming. Because there is no significant mean pressure gradient in an oscillatory wave field, the steady motion is forced solely by the nonlinear advective terms on the right side of equation (11a). In general, these terms contain a mean component plus components at even harmonics of the fundamental frequency. Figure 6 shows the vertical distribution of the amplitudes and phases of the forcing function on the right side of (11a). The dominant forcing occurs at twice the frequency of the first order wave field, but the mean forcing is clearly evident. Throughout most of the boundary layer, the mean forcing is in the direction of wave propagation, but near the outer edge of the boundary layer the mean forcing is in the opposite direction. Outside the boundary layer, of course, the mean forcing is zero.

In carrying out the second order solution, we began the computations from rest, as in the first order solution. The solution for the velocity profile appeared to become nearly periodic after approximately six to ten periods. For those short times, we found mean velocity profiles which approached zero outside the boundary layer, similar in this respect to Johns' (1977) computations. Computations carried out over larger times, however, showed that the mean velocity inside the boundary layer continues to evolve for a long period, gradually reaching a steady state only after a few hundred periods. Figure 7 shows the mean velocity at several different times after the start of the motion, indicating the gradual approach to a positive, steady profile at very large times. At small times, the velocity outside the boundary layer is in the direction opposite that of wave propagation. This behavior is explained by the fact that the mean forcing is negative near the outer edge of the boundary layer. Initially, the boundary layer thickness is small, and the vertical transport of momentum due to Reynolds stresses is small compared to the mean forcing. Consequently, at small times the fluid at the outer edge of the boundary layer acts like a frictionless fluid under the action of a mean, negative, distributed body force. The resulting velocity is negative until the effect of the solid boundary diffuses outward far enough to begin moving the fluid forward. The results in Figure 7 are believed to be qualitatively correct with possible quantitative discrepancies due to recovery from initial conditions and the finite computational domain.

The velocities shown in Figure 7 correspond to kh equal to 1.0, or waves in water of intermediate depth. In this case, the mean velocity at large times is in the direction of wave propagation. Figure 8 shows similar mean velocity profiles for kh equal to 0.5, corresponding to relatively long waves. As in Figure 7, the gradual approach of the mean velocity to a steady state is evident. In Figure 8, however, the mean velocity is in the direction opposite that of wave propagation. This figure confirms qualitatively the reversal of the steady streaming under long waves which was found analytically by Jacobs (1984) and Trowbridge and Madsen (1984b).

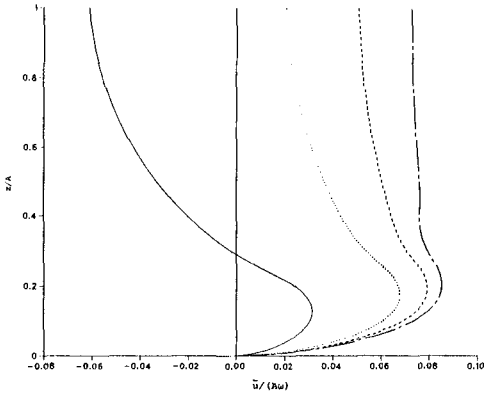

Figure 7. Computed mean velocities at several different times after the start of the motion. From left to right, the curves correspond to t/T = 10, 30, 50, 100. z_o/A = 0.004, kA = 0.2, kh = 1.0.

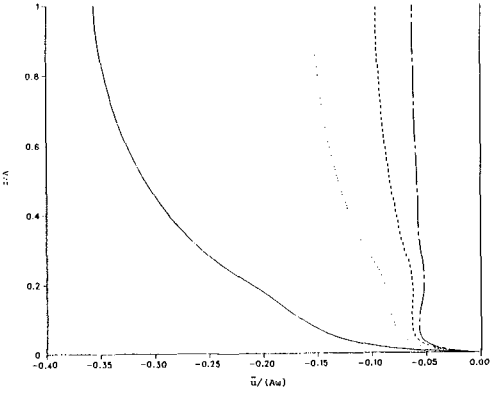

Figure 8. Computations as in Figure 7 for kh = 0.5.

Because of the long time periods required for the mean velocity to reach a steady state, numerical simulations of the second order problem based on implicit time-stepping procedures are very time-consuming. Our present results indicate, however, that computations based on the mixing length closure are nearly identical to computations based on the turbulent kinetic energy closure. Figures 7 and 8 are based on the mixing length model, and at relatively short times (of order ten wave periods) there is no significant difference between these results and the computations based on the turbulent kinetic energy closure.

The conclusions based on the second order computations are the following: (1) reversal of the steady streaming produced by relatively long waves is confirmed qualitatively; (2) the two turbulence closures give very similar results, indicating that processes in the turbulent kinetic energy equation other than production and dissipation have no significant effect on the Reynolds averaged velocity and stress; and (3) the time-averaged motion requires a very long time to reach a steady state. Conclusion (3) implies that the averaged motion may not become steady during time periods over which a natural wave field can be considered stationary. Consequently, it may be necessary to consider the history of the wave field when considering low frequency boundary layer motions produced by natural waves. In laboratory basins, where controlled, stationary conditions are possible for long times, the mean motion might have time to reach a steady state, if experiments are carried out for long enough periods.

A SIMPLE ANALYTICAL MODEL

For the purposes of studying more complicated processes, such as sediment transport, a simple analytical model which captures the main features of the flow is preferable to a more complicated, although possibly more consistent, numerical solution. One of the purposes of the numerical study reported here is therefore to guide development of realistic analytical models. The following very simple analysis is essentially the argument of Jacobs (1984) in a slightly more straightforward form. It is based on a mean momentum balance derived by Longuet-Higgins (1958) and on the assumption of a constant friction factor.

The mean momentum balance derived by Longuet-Higgins (1958) is, to second order,

$$\bar{\tau}_b = -(\overline{uw})_{z=\infty} \tag{14}$$

where τ_b is the boundary shear stress. Use of the mass equation and the condition of periodicity in space and time shows that the vertical velocity may be written

$$w = \frac{1}{c} \int_0^z \frac{\partial u}{\partial t} \, dz \tag{15}$$

Substitution of the first order momentum balance (10a) yields

$$w = \frac{z}{c} \frac{\partial U}{\partial t} + \frac{1}{\rho c} (\tau - \tau_b) \tag{16}$$

to first order. Substitution of (16) into (14) and use of the boundary conditions (2) gives

$$\overline{\tau_b} = \frac{1}{c} \overline{\tau_b U} \tag{17}$$

correct to second order. If we assume that a constant wave friction factor f gives an adequate representation of the boundary shear stress, we have

$$\tau_b = \frac{1}{2} f \rho U|U| \tag{18}$$

Substitution of (3) and (18) into (17) yields, after straightforward algebra, the following result for the steady streaming just outside the boundary layer:

$$\bar{U} = \frac{2}{3} \frac{\overline{U^2}}{c} \left[1 - \frac{3}{4} \frac{1}{\sinh^2(kh)} \right] \tag{19}$$

correct to second order. Equation (19) is the result obtained by Jacobs (1984). This result agrees fairly well with the present numerical computations, and it indicates a reversal of the steady streaming produced by long waves. It is noteworthy that (19) is independent of the boundary roughness.

The above analysis may be used to calculate the time-varying boundary shear stress in a manner which incorporates the presence of the steady streaming consistently, although approximately.

CHAPTER 120

TRANSIENT RIPPLE FORMATION AND SEDIMENT TRANSPORT

By Suphat Vongvisessomjai,[1] M. ASCE, L.C.J. Munasinghe,[2] and P.P. Gunaratna[2]

ABSTRACT

A knowledge of sediment transport rates due to wave action is essential for an understanding of various coastal engineering problems. Many problems have to be resolved before successful measurement can be made for sediment transport rates due to waves.

Since gradients of sediment transport cause changes of beach morphology, the sediment transport rate outside breaker can be determined from measured beach changes. Measurements of ripple growth and migration yield their mathematical descriptions in the same manner as those of surface waves. Expressions of sediment transport rates are then derived.

It is found from the study that the sediment transport rates are strongly controlled by the rates of growth and migration of ripples.

INTRODUCTION

Passage of water waves over an erodible bed of sands produces an oscillatory sediment transport. Due to wave action, the initially straight bed is deformed into wavy undulations known as ripples. These ripples will grow in height and length until they attain in equilibrium geometry for a set of wave-beach characteristics. The phenomenon of ripple formation due to wave action is of considerable interest due to a resulting contribution to sediment transport. In addition, the ripples on the bed significantly affect wave attenuation, wave induced current and beach profile. Not much data on transient ripple formation and migration are presently available despite the fact that they are needed to determine the sediment transport rate due to ripple migration.

The objectives of this study are to quantify the growth and migration of ripples due to wave action normal to beaches outside breaker lines from experimental results in a wave flume, and to determine the resulting rate of sediment transport. Since the offshore sediment transport does not yield a well defined ripple migration, only the onshore ripple migration and sediment transport are presented. This report is prepared from two master theses of Gunaratna (1984) and Munasinghe (1985).

SURVEY OF EARLIER WORK

Reviews will first be made on geometries of stable, not transient, ripples generated by oscillatory flows and followed by rates of sediment transport generated by oscillatory flows.

---

[1] Professor and [2] Graduate Students, Div. of Water Resources Engrg., Asian Inst. of Tech., P.O. Box 2754, Bangkok 10501, Thailand.

Ripple Geometry.- Ripple geometries generated by oscillating bed were first tested by Bagnold (1946) and Manohar (1955). Prototype ripples were measured by Inman (1957) and Dingler (1974). Extensive laboratory tests on ripple geometries were made by Mogridge and Kamphuis (1972). Analysis was made on ripple geometries by Vongvisessomjai (1984) using published and supplementary data tested by the author. These studies reveal that, when the bed shear stress of an oscillatory fluid exceeds the critical value required for initial motion on a flat sediment bed, rolling grain ripples will slowly form; as the shear stress increases, the height and length of ripples will also increase accordingly. The growing ripples continue to enlarge as the bed shear stresses reach higher values until optimum condition is reached. Beyond this stage, the ripple height will decay, while its length remains practically constant or decays slowly.

Empirical Rate of Sediment Transport.- Almost all empirical formulae of sediment transport rates were developed from oscillating bed data, only that proposed by Vongvisessomjai (1986) was developed from wave flume data.

Manohar (1955) employed an oscillating bed of sediment to study regimes of sediment transport, ripple geometries and rates of sediment transport. He found the governing parameter of all the phenomena to be

$$\psi_1 = \frac{U_{1m}}{[(s-1)g]^{0.4} (\nu D)^{0.2}} \quad \text{.....(1)}$$

in which U_{1m} = maximum orbital velocity of fluid just outside boundary layer; s = relative density of sediment; g = gravitational acceleration; ν = kinematic viscosity of fluid; and D = mean or median diameter of sediment.

In order to obtain rates of sediment transport, he generated asymmetrical motion by changing the angular frequencies of a flywheel driving the oscillating bed when it was at its extreme positions, while he held the amplitudes of the excursions constant. These asymmetrical motions yield a net sediment transport, the sediment being collected in a tray set into the sediment bed.

Kalkanis (1964) and Abou-Seida (1965) developed a relationship between the flow intensity ψ_2 and the bed load intensity ϕ_*, using the principle of Einstein's theory (1950) for sediment transport in open channels and introducing the effect of wave motion on the bed sediment. Their experimental data were obtained on oscillating beds. They found that Einstein's bed load equation for sediment transport in open channels was the same as that describing sediment transport induced by oscillating beds. This was so when the mean fluid velocity in open channels, used in defining ψ_2, was replaced by the amplitude of the oscillating bed velocity U_a, calculated at a distance 0.35D from the mean level of the bed.

$$\psi_2 = \frac{1}{\frac{U_a^2}{(s-1)gD}} \quad \text{.....(2)}$$

and

$$\phi_* = \frac{q_s'/\gamma_s}{D\sqrt{(s-1)gD}} \quad \text{.....(3)}$$

in which q_s' = the dry weight rate of the gross sediment transport per

unit width; and γ_s = the sepcific weight of the bed sediment. When U_a is correlated with U_{1m}, their relationship is $U_a \doteq 0.625U_{1m}$.

Madsen and Grant (1976) re-analyzed data of Manohar (1955) Kalkanis (1964) and Abou-Seida (1965) and expressed the volumetric rate of gross sediment transport, mornalized by the settling velocity and the diameter of the sediment, as function of the Shields parameter. They stated that in Kalkanis (1964) and in Abou-Seida (1965) ripples might have been present, and for Manohar (1955), ripples were present. However, the Shields parameter was computed using Jonsson's friction factor (1966) and based on grain diameter.

Sleath (1978) used a motion picture camera to determine the instantaneous and mean sediment transport rates averaged over a half cycle induced by an oscillating bed on flat sediment beds. From his data and those of Kalkanis (1964) and Abou-Seida (1965) he obtained an expression for the mean volumetric rate of the gross sediment transport per unit width q_v' from his data and those of Kalkanis (1964) and Abou-Seida (1965):

$$\frac{q_v'}{\omega D^2} = 47(\psi_* - \psi_{*c})^{3/2} \quad \text{.....(4)}$$

in which ψ_{*c} = the critical value of Shields parameter ψ_* for initial motion; $\omega = 2\pi/T$ = angular velocity; and T = period of oscillation. His expression of the friction factor was the same as that obtained by Jonsson (1966) and his equivalent sand roughness was taken to be the sediment grain size. Note that Grant and Madsen (1982) found a remarkable difference between friction factors of immobile and mobile beds with sediment suspension.

Sleath's instantaneous sediment transport rate $q_v(t)$ for sand and gravel was

$$q_v'(t) = \frac{8}{3} q_v' \cos^3(\omega t + \alpha) \left|\cos(\omega t + \alpha)\right| \quad \text{.....(5)}$$

in which t = the time; $q_s^* = (1-\beta)\gamma_s q_v^*$; β = porosity of bed sediment; and α = the phase lag of the local velocity behind the water surface

$$\alpha = 0.15 + 0.000018 \frac{q_v'}{\omega D^2} \left(\frac{a_{1m}}{D}\right) \frac{U_{1m}}{(\omega\nu)^{1/2}} \quad \text{.....(6)}$$

in which $a_{1m} = U_{1m}/\omega$ = nearbed amplitude of water particle excursion.

Kobayashi (1982) derived a criterion for the initiation of sediment movement on a gentle slope by balancing the forces acting on a sediment particle lying on the slope. A relationship for the instantaneous rate of the bed load transport on a gentle slope, which was quite similar in form to that of Madsen and Grant (1976), was then derived from a simple and quasi-steady analysis of the motion of sediment particles. His theory was in reasonable agreement with experiments, conducted on horizontal beds by Kalkanis (1964), Abou-Seida (1965) and Sleath (1978).

Vongvisessomjai (1986) found from analyses of sediment transport data from oscillating beds and wave flumes that they were different. The sediment transport rate developed from wave flume data was as follows:

For bed load transport ($Fd_* < 4$)

$$\phi_* = \frac{q_s'/\gamma_s}{D\sqrt{(s-1)gD}} = 0.0002\, Fd_*^3 \quad \text{.....(7)}$$

For total load transport ($Fd_* > 4$)

$$\phi_* = \frac{q_s'/\gamma_s}{D\sqrt{(s-1)gD}} = 0.0015\, Fd_*^{3/2} \quad \text{.....(8)}$$

in which the densimetric sediment Froude number $Fd_* = U_{1m}^2/[(s-1)gD]$.

METHODOLOGY

Basing on a theoretical model to explain the formation of wave-generated sediment ripples presented by Kennedy and Faclon (1965) in which a profile of ripple bed $z(x,t)$ was represented by a moving sinusoid of varying amplitude $\eta(t)$ and a constant ripple length, a time dependent ripple length $\lambda(t)$ is used in this study as follows:

$$z(x,t) = s_o x + \eta(t) \sin\left\{\frac{2\pi}{\lambda(t)}\left[x - \int_o^t C_r(t)dt\right]\right\} \quad \text{.....(9)}$$

in which x is the horizontal coordinate; t is time; s_o = beach slope; $C_r(t)$ is the celerity of ripple.

The growth rates of ripple height $\eta(t)$ and ripple length $\lambda(t)$ of Equation (9) are found from experimental results in a wave flume to be the same as

$$\eta(t) = \eta_{max}\{1 - \exp[-B^*(\frac{t}{T})]\} \quad \text{.....(10)}$$

and

$$\lambda(t) = \lambda_{max}\{1 - \exp[-B^*(\frac{t}{T})]\} \quad \text{.....(11)}$$

in which η_{max} is the maximum height of ripple; λ_{max} is the maximum length of ripple; B^* is the dimensionless growth of ripple; and T is the wave period. Information of geometry of equilibrium ripples has been provided by Vongvisessomjai (1984).

Sediment Transport Rate Due to Ripple Growth.- A simple rate of sediment transport q_r is determined only from ripple geometry developed from an initially straight bed excluding the information on ripple migration as

$$q_r = \frac{d}{dt}\left[(1-\beta)\gamma_s \int_o^{\lambda/2} z(x,t)dt\right]$$

$$= \frac{2}{\pi}\gamma_s(1-\beta)\frac{B^*}{T}\eta_{max}\lambda_{max}\exp[-B^*(\frac{t}{T})]\{1-\exp[B^*(\frac{t}{T})]\} \quad \text{.....(12)}$$

in which β is the porosity of sand on the bed. The maximum value of the above rate of sediment transport at time $t_{max} = 0.693T/B^*$ is

$$q_{rmax} = \frac{0.5}{\pi T}\gamma_s(1-\beta)B^*\eta_{max}\lambda_{max} \quad \text{.....(13)}$$

Figure 1 shows an example of transient growth of ripple height, Eq. 10, and its corresponding sediment transport rate due to ripple growth, Eq. 12. Sediment transport rate due to ripple growth and migration will be presented as follows.

The celerity of ripple $C_r(t)$ of Equation (9) is found from experiments to follow several patterns:

(a) a similar pattern to the growth rate of ripple as

$$C_r(t) = C_{rmax}\{1-\exp[-C^*(\frac{t}{T})]\} \quad \text{.....(14a)}$$

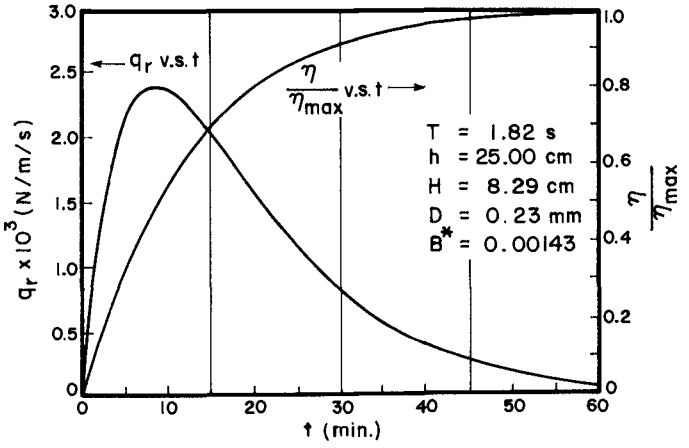

Figure 1. Transient Growth of Ripple Height and Its Sediment Transport Rate

in which C_{rmax} is the maximum celerity of ripple and C^* is the dimensionless migration rate of ripple.

(b) a growing-decaying pattern as

$$C_r(t) = At^m \exp(-Bt^n) \quad \text{.....(14b)}$$

in which A, B, m and n are empirical constants.

(c) a constant celerity as

$$C_r(t) = \bar{C}_r \quad \text{.....(14c)}$$

The rate of sediment transport per unit width $q_s(x,t)$ can be expressed in terms of the ripple bed profile $z(x,t)$ of Equation (9) as

$$\frac{\partial q_s(x,t)}{\partial x} + \gamma_s \frac{\partial z(x,t)}{\partial t} = 0 \quad \text{.....(15)}$$

The rate of sediment transport per unit width $q_s(x,t)$ can then be determined from the above equation using the measured bed profile $z(x,t)$ i.e. Equations 10 11 and 14a and a boundary condition of the instantaneous rate of sediment transport per unit width $q_s(t)$. These analytical solutions will be presented as follows.

Sediment Transport Rate Due to Ripple Growth and Migration.- Solving for $q_s(x,t)$ by integrating Eq. 15 with respect to x where the bed profile $z(x,t)$ is described by Eq. 9 yields

$$q_s(x,t) = \gamma_s \left[\frac{\lambda}{2\pi} \left(\frac{\eta}{\lambda} \frac{d\lambda}{dt} + \frac{d\eta}{dt} \right) \cos\left\{ \frac{2\pi}{\lambda} \left(x - \int_o^t C_r \, dt \right) \right\} + \left(\eta C_r + \frac{\eta}{\lambda} \frac{d\lambda}{dt} x - \frac{\eta}{\lambda} \frac{d\lambda}{dt} \int_o^t C_r \, dt \right) \sin\left\{ \frac{2\pi}{\lambda} \left(x - \int_o^t C_r \, dt \right) \right\} \right]$$

$$+ f(t) \quad \ldots\ldots\ldots\

EXPERIMENTATION AND RESULTS

Experimentation.- Experiments were conducted in the Hydraulic Laboratory of the Asian Institute of Technology. The major apparatus consisted of a wave flume (1m x 1m x 40m) with a flap-type wave generator, capacitance wave gauges connected to an amplifier and a chart recorder.

Various wave characteristics were tested on 1:20 and 1:10 slopes of medium sand (D_{50} = 0.41 mm) and on 1:20 slope of finer sand (D_{50} = 0.23 mm). Wave profiles along the flume were recorded at the start, middle and end of each run while reading of sand accummulation in sand trap were made at 5 minutes, 15 minutes, 25 minutes, etc. Observations of ripples and bed profile changes were made at various locations along sloping beds at mean water depths h = 17, 27, 32, 37, and 42 cm at various time intervals. Table 1 lists the experimental condition which was plotted in Figure 4 as compared with the onshore-offshore criterion of Sunamura and Horikawa (1974) confirmed that most of the runs were onshore transports.

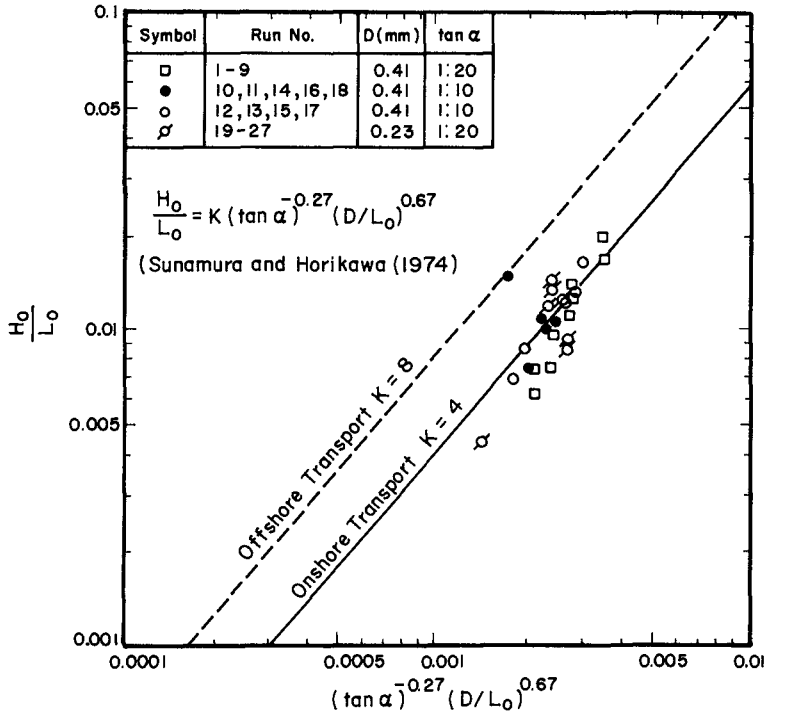

Figure 4. Experimental Condition

Experimental Results.- Experimental data were then used to determine the growth rate of ripples B^*, the geometry of the maximum ripples, η_{max} and λ_{max}, and the celerity of ripples. Since a systematic pattern of ripple migration could not be obtained, the time average celerity $\bar{C}_r$ and the maximum celerity C'_{max} of ripple migration were presented. These obtained empirical results were found to correlate well with the densimetric sediment Froude number $Fd_* = U_{1m}^2/[(s-1)gD]$ and the relative bed smoothness $a_* = a_{1m}/D$, in which $U_{1m} = \pi H/[T \sinh(2\pi h/L)]$ = nearbed water particle velocity; H = wave height; h = mean water depth; L = wave length; $a_{1m} = U_{1m}/\omega$ = nearbed amplitude of water particle excursion; $\omega = 2\pi/T$ = wave angular velocity; T = wave period; s = relative density of sand with respect to water; g = gravitational acceleration; D = median diameter of sand. Denoting the obtained results (B^*, η_{max}/a_{1m}, λ_{max}/a_{1m}, $\bar{C}_r/C$ and C'_{max}/C where C = celerity of the surface wave) by Y, their relations with Fd_* and a_* are

$$Y = k\, Fd_*^i\, a_*^j \quad \text{..... (19)}$$

Table 2 summarizes the empirical constants k, i and j obtained from regression analyses. Most of j for medium sand equal zero implies that the obtained results are independent on a_* but dependent on Fd_* only. Examples of these relationships for medium sand are shown in Figures 5-7 respectively for B^*, η_{max}/a_{1m} and λ_{max}/a_{1m}, $\bar{C}_r/C$ and C'_{max}/C.

TABLE 2.-Empirical Constants k, i and j of Eq. 19

Parameter Y	Medium Sand (D = 0.41 mm)			Finer Sand (D = 0.23 mm)		
(1)	k (2)	i (3)	j (4)	k (5)	i (6)	j (7)
B^*	1.77×10^{-6}	-0.394	1.68	1.82×10^{-4}	0.432	0.366
η_{max}/a_{1m}	0.464	-0.324	0	16.0	0.325	-0.951
λ_{max}/a_{1m}	2.79	-0.328	0	60.6	0.183	-0.800
$\bar{C}_r/C$	3.16×10^{-6}	1.25	0	1.40×10^{-6}	0.271	1.22
C'_{rmax}/C	6.20×10^{-6}	1.25	0	5.34×10^{-7}	0.717	0.500

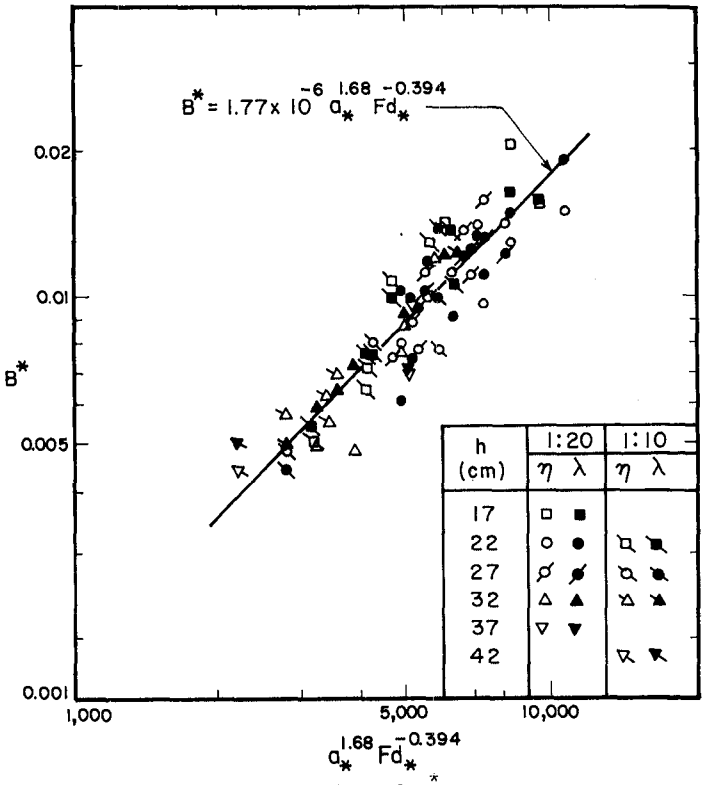

Figure 5. Correlation of B^* Versus $a^{1.68} Fd_*^{-0.394}$ for Medium Sand

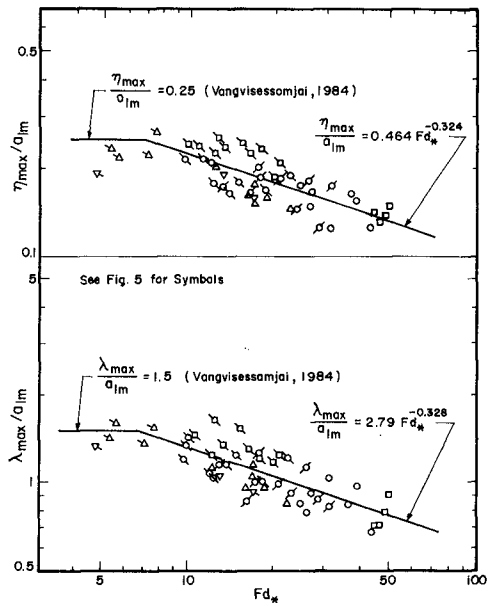

Figure 6. Correlation of Maximum Ripple Geometry Versus Fd_*

Sediment Transport Rate.- The averaged net sediment transport rates $\bar{q}'_{vexp}$ measured in the trap at 5, 15 and 25 minutes as listed in Table 1 were found to be of the same magnitudes of those computed from ripple growth and migration. These measured transport rates were found to be about 30 to 60 per cent of the empirical rate, Eq. 8, for medium sand of Run Nos. 1-18 while they were about 5 to 30 per cent of Eq. 8 for finer sand of Run Nos. 19-27 which were in the ranges of transition and offshore transport shown in Figure 1.

Basing on the same growth rate of ripple, the sediment transport rate due to ripple growth, $q_{rmax} = 2.4$ N/m/s as shown in Figure 1, was much smaller than that due to ripple growth and migration, $q_s(x,t) \doteq \pm 20$ N/m/s for Cases II to IV and about equal to that of Case I with $C_r = 0$ as shown in Figures 3a to 3d.

CONCLUSIONS

From this study of the trasient formation and migration of ripples, and the resulting sediment transport; the following conclusions could be drawn:

1. Growth rates of ripple height and length were found to follow the exponential form of Equations 10 and 11 respectively.
2. Celerities of ripple migration were found to have several patterns, Equations 14a, 14b and 14c, only the time averaged and maximum values were presented. More experiments would be required to quantify this phenomenon.
3. Empirical rate of sediment transport due to waves should be used with great care. Characteristics of ripple growth on a horizontal bed were rather uniform along the bed with negligible ripple celerity, therefore, the sediment transport rate should be negligible. However, a tray set into sediment bed would cause non-uniformity and thus traps a gross sediment transport forward and backward at either edge of the tray; this rate of transport of the mobile sediment could be calculated from expression for sediment transport rate due to ripple growth, Eq. 12.
4. On a sloping beach, characteristics of fluid, ripples and sediment transport rate were nonuniform and varied along the slope. Outside the breaker, the turbulence was smaller than that inside with less suspended sediment, the onshore transport rate here could be computed from the expression of sediment transport rate due to ripple growth and migration, Eq. 18.

ABSTRACT

Oue to the sheltering effect of the Wai-San-Ding Sand Barrier, the hydraulic condition of the putia harbor site is quite favorable. Since the relatively well-protected location of the Putai harbor area with regard to both waves and wind, no special navigational problems have to be envisaged.

The wave energy of the Putai harbor site is computed from the measured waves by considering the refraction effect down to breaking line. As the lack of wave records, the wind speed is used by applying the regression equations among the wave height, period and wind speeds, and then compute the wave height and period for obtaining the breaking wave energy. Therefore the total breaking wave energy (P_l) of the whole year along the Putai harbor coast is summated.

The littoral transport rate (I_l) is calculated from the mesh method by comparing the echo-sounding maps of two continuous different years. Therefore, the relationship of P_l and I_l is correlated in the Putai harbor site.

1. Introduction :

Pu-Tai harbor site area is located along the coast of Chia-Yi county, it faces to the Taiwan Strait, the bay area is about 900 hectoare. There is an large scale sand barrier 22 km long, 3-km wide, located on the NW of Pu-Tai bay, and then the barrier forms good wave sheltering effect to the bay.

The field records of wind condition at Pu-Tai from Nov., 1982 to Oct., 1983 show that the winter monsoon in December mainly blows the wind from NNE,N and NNW directions, etc., and with the stronger wind speed. In January, the prevailing wind directions are the same as those in December and totally 90% of occured frequency. The strongest wind occurs in N direction, and then in NNE direction also in February, wind overwhelmingly occurs in NNE, N, NNW directions which are in total 80% of occurred frequency. Wind in N direction occurs very frequently, but wind velocity of N and NNW directions is stronger. In March, wind comes more often from WNW, NW and NNW directions which totally reach up to 60%. Wind speed is highly reduced such that the occurrence of wind with speed stronger than 5 m/sec is only 17%. The wind in April occurs often from northerly direction, while in May, it comes from

southern direction. From the long-term data, summer monsoon blows from April to August, the direction is from south, while wind speed is quite small. The prevailing wind direction is NNE to NNW blows during Winter monsoon from September to Next March.

From the wave measurement, the maximum wave height reaches 1.8 m, commonly wave height locates between 20 cm to 80 cm: while wave period is between 4 sec to 8 sec. Wave Rider is installed in the NW direction of the offshore area near-15 m deep; while KSK cassette type wave meter installed at the proposed harbor mouth. The measurement shows that wave height decays obviously from offshore toward harbor mouth; especially for the big wave, it decays almost 50%; while wave period becomes longer when wave reaches harbor area.

The distribution of significant wave heights and significant wave periods in June, 1983 indicates wave height appearing from 25 cm toward 1.25 cm; while wave period is from 2 sec to 8 sec; they are located in the lower value. They show during summer time, navigational condition is quite well in the Pu-Tai harbor area.

The measured wave distribution in December at the Pu-Tai Offshore (-15m) which locates the South-West of the promontory delta. Even in December, the significant wave height is in the range of 30 cm to 80 cm, the corresponding significant wave period is between 3 sec to 8 sec. In such case, the NE winter monsoon waves decay rapidly due to the sheltering promontory delta area. The measured results show that there is perfectly calm sea surface for ship anchoring in the Pu-Tai bay area.

The winter monsoon waves recorded at the proposed harbor area becomes smaller compared to the offshore zone; while period shows a little longer due to the scan from KSK cassette recorder has the tendency to collect significant wave and neglect the smaller wave, therefore, commonly two waves scan to record as one wave such that period becomes longer.

Pu-Tai proposed harbor entrance is located in the SW direction of Ueng Tau, and there is a wide natural sheltering Wai-Shan-Ding Barrier Island in the NW direction, therefore, it has a good condition for wave prevention from northerly direction. According to the records of the winds at Au-Ku meteorological station, the winds occur most frequent in the direction of NNE (40.2%) and then ENE (22.2%). The hurricane waves in SSW to W directions affect the site most significantly and therefore they are selected as the design waves of the proposed harbor which are 7 m of height and 12-15 sec of period. As the results from computer processing show, the waves in SSW direction diverge mostly (and with K=0.45) as they approach the vicinity of the proposed harbor site. Otherwise, the waves (with T 1/3=14.5 sec) in SW direction converge lightly at the same position. Generally speaking, the waves in other directions diverge as they approach the proposed site, therefore, the proposed site is convenient and suitable. Fig. 1-1 shows the wave refraction drawing of Pu-Tai harbor site with wave direction of SSW and wave period T 1/3=14.5 sec. It has the same decaying tendency with that of the field measured waves.

Figure 1-1 The wave refraction drawing of Pu-Tai site

ID : SSW T : 14.5 Sec

2. The calculation of the alongshore breaking wave energy: The wave data are recorded by the wave gauge at the depth -15m per 2 hours in 1983 at Putai offshore area.

The wave is affected by the effects of shoaling, refraction, bottom friction and percolation. By neglecting the effects of bottom friction and percolation.as wave is propagating toward the surf zone,therefore the breaking wave height is equal to H = HoKrKs where Kr and Ks are refraction coefficient and shoaling coefficient respectively. The mathematical representation is as follows

$$Kr = (Bo / B)^{1/2} \tag{2.1}$$

$$Ks = (Cgo / Cg)^{1/2} \tag{2.2}$$

where B is the separation of the wave rays and prefix "o" represents the characters of deep water. As the bottom slope is smaller than 1/10 then Kr and Ks could be calculated from the four equations derived by Chao,Y.Y.(1970) as follows

$$C^2 = \left(\frac{G}{K}\right) \tanh kh \tag{2.3}$$

$$\frac{dB}{ds} = \frac{1}{c}\left(\sin\theta \frac{\partial c}{\partial x} - \cos\theta \frac{\partial c}{\partial y}\right) = -\frac{1}{c}\frac{dc}{dB} \tag{2.4}$$

$$H_o (C_g)_o B_o = H\ C_g B = \text{constant} \tag{2.5}$$

$$\frac{dB}{ds} - P^{(1)} \frac{dB}{ds} + P^{(2)} B = 0 \tag{2.6}$$

$$P^{(1)} = \frac{1}{c}\left(\cos\theta \frac{\partial c}{\partial x} + \sin\theta \frac{\partial c}{\partial y}\right) \tag{2.7}$$

$$P^{(2)} = \frac{1}{c}\left(\sin^2\theta \frac{\partial^2 c}{\partial x^2} - 2\sin\theta\cos\theta \frac{\partial^2 c}{\partial x \partial y} + \cos^2\theta \frac{\partial^2 c}{\partial y^2}\right) \tag{2.8}$$

where D is water depth, θ is the angle between X axis and wave direction, S is the distance along wave ray and C is the phase velocity. Use numerical method to get

$$D_{n+1} = D_n + \left(\frac{\partial D}{\partial x}\right)_n dx + \left(\frac{\partial D}{\partial y}\right)_n dy + \frac{1}{2}\left(\frac{\partial^2 D}{\partial x \partial y}\right)_n dx dx + \left(\frac{\partial^2 D}{\partial x \partial y}\right)_n dx dy + \frac{1}{2}\left(\frac{\partial^2 D}{\partial x \partial y}\right)_n dy dy \quad (2.9)$$

$$P_{n+1} = (4-2P_n^{(1)}\Delta S^2)/(2-P_n^{(1)}\Delta S)\ \theta_n - (2+P_n^{(1)}\Delta S)/(2-P_n^{(1)}\Delta S)\ B_{n-1} \quad (2.10)$$

The subscript "n" represents the value of the nth calculation, as shown in Fig.2.1, where X axis is taken parallel to the shoreline. Developing these numerical calculations to get "THE WAVE CHARACTER COMPUTING PROGRAM", (Hou etc., 1980) the wave characters such as Kr, Ks, H, Cg and θ could be found out at any water depth h=D. Since $\theta = \frac{\pi}{2} - \alpha$ as shown in Fig.2.1 then $(P_1)_b = \frac{1}{8}\rho g H_b^2 (c_g)_b \cos\theta_b \sin\theta_b$ is the alongshore breaking wave energy.

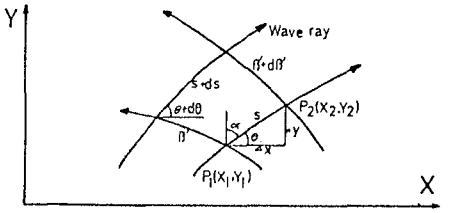

Figure 2.1 The diagram of the wave refraction.

Since there is no records of wave direction at -15m depth, the incident wave direction is found out by the above program using the deep water incident wave direction which is the wind direction as the wave gauge serves.

Consider only the waves which are moving onshore could cause littoral transporting. The waves which have the same incident direction are summed up. The root mean square value of their heights and the mean value of their periods are found out. Therefore, the total onshore acting waves are compiled to θ equivalent waves which have the "rms" wave height Hrm , mean wave period T. This is because

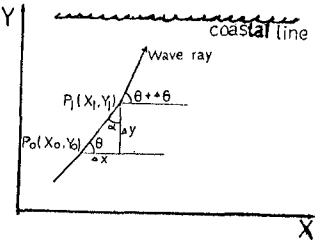

Figure 2.2. The diagram of the wave refraction.

$$(P_l)_b \propto H^2 \cos\theta\sin\theta \propto H^2 \sin 2\theta$$

$$\sum_{i=1}^{M} (P_l)_{bi} \propto \left(\sum_{i=1}^{M} H_i^2\right)\sin 2\theta = M H_{rms}^2 \sin 2\theta \quad (2.11)$$

Where M is the number of the waves which have the same wave direction , and H_{rm} is represented as

$$H_{rms}^2 = \frac{1}{M}\sum_{i=1}^{M} H_i^2 \quad (2.12)$$

To compute the alongshore breaking wave energy, the input data including the water depths of the grid points, the water depths and the coordinates of the incident points, the Hrm values and the T values of the equivalent waves with the incident wave direction at the depth -15m of the Putai offshore area, are all considered.

3. Computation Model between Wind and Waves

The paper is based on the winds and measured waves record, and then obtain their relationships. By using the 2nd order polynomial regression equation to work as the model for wind speed to compute wave height and wave period. From the above model and the measured wind records of the Pu-Tai Coast, the insufficient data could be supplied.

The computation procedure is described as follows.

1) To find out the statistical relationship between waves and winds for each month. By applying the records of wind speeds and wind directions, and the measured wave data from February to May., the relations among the wind speeds vs wave heights and wave periods correspondently at the same time could be reduced.

The wind speeds below 5 m/sec are neglected, since they have not significant effect to produce wave. To get rid of the small values of wind speeds and then compute the mean value, variance and correlation coefficient of each month. The statistical value is listed as the Table 3.1.

Table 3.1. Statistical Analysis of V, H & T.

	Wind Speed V(m/sec)		Wave Height Hrms(cm)		Correlation Coefficient of H vs T
month	Mean μ_V	Variance	Mean μ	Variance	TH
February	7.60	1.72	17.38	4.80	0.20
March	7.76	2.45	17.10	5.31	0.55
April	6.85	1.61	21.24	11.11	0.01
May	6.34	1.15	14.33	4.47	-0.20

In the Table 3.1, the mean is expressed as

$$U_X = \frac{1}{N}\sum_{i=1}^{N} X_i \qquad (3.1)$$

The variance is expressed as

$$\delta_x = \frac{1}{N}\sum_{i=1}^{N} (X_i - \mu_x)^2 \qquad (3.2)$$

and the correlation coefficient is expressed as

$$S_{xy} = \frac{\sum_{i=1}^{N} [(X_i - \mu_X)(Y_i - \mu_y)]}{\sqrt{\sum_{i=1}^{N} (X_i - \mu_X)^2 \sum_{i=1}^{N} (Y_i - \mu_y)^2}} \qquad (3.3)$$

From the above table, it is known that the correlation between wind and waves is so so perfect, the better one is in March, those of February and May are the next, the value in April is not so good correlation. The reason for fair correlation is due to the coastal geomorphological effect by the large Wai-San-Ding Sand Barrier, therefore winds and waves intrude into the Pu-Tai Bay area and show obvious refraction and energy diffusion. The effect of wave sheltering and shoaling is much complicated; while, in March, April and May, due to monsoon transitiond zone, the wind directions are changeable. For the avobe reasons, they cause the correlation coefficient be not so large. Except that, the time delay between wind and wave has some negative effect.

2) To find out the polynomial regression equations of wind speed vs wave height, and wind speed vs wave period. The correlations between winds and waves in February and in May are much better, and their wind directions are quite stable, therefore, February is considered as the base for computing the winter monsoon waves., while May is taken as the base for computing the summer monsoon waves. By using the least square method, and then the polynomial regression equations are obtained.

Let $X_1, X_2, X_3, \ldots, X_n$ as the n units of wind speed value.

$Y_1, Y_2, Y_3, \ldots, Y_n$ as the n units of corresponding wave height and wave period values.

as the constants of the m^{th} order polynomial regression equation.

$$X = \begin{bmatrix} 1 & X_1 & X_1^2 & X_1^3 & \cdots & X_1^m \\ 1 & X_2 & X_2^2 & X_2^3 & \cdots & X_2^m \\ \vdots & & & & & \vdots \\ \vdots & & & & & \vdots \\ 1 & X_n & X_n^2 & X_n^3 & \cdots & X_n^m \end{bmatrix}$$

$$Y = \begin{bmatrix} Y_1 \\ Y_2 \\ \vdots \\ \vdots \\ Y_n \end{bmatrix} \qquad A = \begin{bmatrix} A_o \\ A_1 \\ A_2 \\ \vdots \\ A_m \end{bmatrix}$$

The following relationship is obtained

$$X^T X A = X^T Y \qquad (3.4)$$

where X^T is the Transposed Matrix of X.

Solving "A" from EQ.(4), then the constants of the m^{th} order regression eguations of wave height vs wind speed, and of wave period vs wind speed correspondingly of each month are attained.

Wave period and wave height could be calculated by Eg.(5) and Eg.(6).

$$H = a_o + a_1V + a_2V^2 + \ldots \ldots + a_mV^m \quad (3.5)$$

$$T = b_o + b_1V + b_2V^2 + \ldots \ldots + b_mV^m \quad (3.6)$$

where V is the wind speed.

From wind and waves data of February and May, by using the above method, the following regression eguations are obtained.

1. In February
   a. For the 1^{st} order regression equation (i.e. m=1)
      $H = 13.08 + 0.57V$ (3.7)
      $T = 11.12 + 0.10V$ (3.8)
   b. For the 2^{nd} order regression equation (i.e. m=2)
      $H + -3.73 + 4.95V - 0.27V$ (3.9)
      $T = 12.00 - 0.39V + 0.014V$ (3.10)
   c. For the 3^{rd} order regression equation (i.e. m=3)
      $H = -29.87 + 14.93V - 1.48V + 0.047V$ (3.11)
      $T = 11.34 + 0.14V - 0.016V + 0.0012V$ (3.12)
2. In May
   a. For the 1^{st} order regression equation (i.e. m=1)
      $H = 11.15 - 0.76V$ (3.13)
      $T = 0.11 + 0.55V$ (3.14)
   b. For the 2^{nd} order regression equation (i.e. m=2)
      $H = 52.53 - 11.00V + 0.75V$ (3.15)
      $T = -2.87 + 3.31V - 0.20V$ (3.16)
   c. For the 3^{rd} order regression equation (i.e. m=3)
      $H = 75.02 - 21.22V + 2.27V - 0.073V$ (3.17)
      $T = -18.31 + 10.33V - 1.24V + 0.050V$ (3.18)
      Units H : cm, T : sec, V : m/sec
      After comparing with each other, the 2^{nd} order regression eguations are suitable and selected as the computation model.

Analytical Results

To compute the other month's wind speed and convert to wave height and wave period, data are wind records of November and December of 1982, July and August of 1983 from Putai meteorology station and records of September and October of 1983 from Ao-Ku coastal station. By using the winter computation model, wind records of September, November, December and January are converted into wave heights and wave periods. While wind records of September, November, December and January are converted into wave heights and wave periods. Similarly, wind records of July and August are applied by using the summer computation model to get waves correspondently. After all waves are acquired, by using

computation model of wave energy (Hou etc., 1984), then monthly wave energy are obtained and the results are shown in Table 3.2.

Table 3.2. Wave Energy monthly and daily in Putai Harbor Site

month / Wave Energy	July	August	Sept.	Oct.	Nov.	Dec.	Jan.	Unit
Monthly Wave Energy	14,960	14,530	12,670	13,380	13,470	18,250	16,830	$\frac{\text{ton-m}}{\text{m-month}}$
Daily Mean wave Energy	483	469	422	448	449	589	543	$\frac{\text{ton-m}}{\text{m-day}}$

To reduce wave energy of twelve months of the whole year, then they are shown in Fig.3.1 and Fig.3.2 and June shows heavy wave energy, since hurricane waves attacking, during this month, along the Putai coast.

4. Relationship between total Wave Energy and Littoral Transport Rate

Based on the analyzed result, it is found out the alongshore wave energy is 287,000 ton-m/m-yr, the corresponding littoral transport rate is 1.3×10^3 m^3/m-yr. The profile change of the Putai Bay area are shown from Fig4.1 to Fig.4.8. From the equation $I_l = K(P_l)_b$, the value of K is then become 3.5×10^{-3}. Therefore, the equation $I_l = 3.5 \times 10^{-3}(P_l)_b$ is applied to the Putai harbor site area. From the profile change of 1963, 1967 and 1980 they show that scour occurring along the Wai-San-Ding sand barrier due to supply of river sediment becomes less.

5. Conclusion and Suggestion

1) Applying the energy approach for unidirectional steady flow (Bagnold, 1963), derive out the relationship between the alongshore breaking wave energy and the littoral immered weight transport rate as $I_l = K(P_l)_b$. K is function of wave height, bottom slope, the grain size and the sediment transport pattern. It increases as the grain size decreases or it does either there exists are ocean current in the predominant littoral transport direction or under the action of the bigger waves. This reveals that the larger part of wave energy is supplied to transport sediment as the wave energy becomeslarger. This is shown by the empirical relationship $I_l = 0.154(P_l)_b$. But for a coast, such as the Taichung coast, where the oceanographic condition is so steady that the alongshore breading wave energy fluctuates slightly, the relationship between I_l and $(P_l)_b$ could be written as $I_l = K(P_l)_b$, where K is constant. Then the Putai coast has the relation of $I_l = 0.0035(P_l)_b$. This eguation could be applied for the coast of similar oceanographic conditions and beach characteristics to estimate the littoral transport rate. Such that the harbor planning and the shore protection could be based on.

2) Littoral transport study along the upstream and downstream of the Wai-San-Ding sand barrier (Hou, 1985) and the wave decaying and refracting of the Putai new port (Hou etc, 1984), has been deeply discussed. However, this paper deals with the measured data of wind speed, wind

direction and waves, then detail analyses are made to obtain the whole yearly alongshore wave energy. The littoral transport rate is obtained from the data of hydrographic survey. Therefore, the formula of $l_{\ell}=3.5 \times 10^{-3}(P_{\ell})_b$ is very appropriate for computing the littoral transport rate. The field measured data is very precious, since coastal area is widely surveyed, and very delicate, accurate instrument is used.

3) The model of wave height and wave period is deduced from wind speed. It's really a convenient and effective predict model for wind wave. Therefore, it could be applied and referred to ocean and coastal engineering use. However, the applicability of different wind conditions under different seasons need to be carefully considered.

4) The coefficient of littoral transport rate, K value, could be furtherly reconfirmed by comparing with the yearly dredging quantity of the Pu-Tai New Port. and then be modified.

5) As the shelf wind waves entering into the offshore due to the effect of Wai-San-Ding sand barrier, and then wave diffraction is shown, waves will turn around their direction, especially during winter season. Therefore, waves come from NNE and N directions will turn into NNW direction and then dissipate over the beach. It's really the features of local wind wave in the Putai harbor site. Therefore, the computation of wave energy along Putai coast, the offshore wave direction should be thoroughly considered.

6) Based on the calculation of wave energy along the Taichung harbor coast (Hou, etc, 1980) her yearly wave energy is sheltered by than that of the Putai harbor site. Since, the wave sheltering due to the Wai-San-Oing Sand Barrier, the offshore wave energy decays and decreases largely as it reaches the Putai harbor site.

CHAPTER 122

MATHEMATICAL MODELLING OF WAVE-INDUCED NEARSHORE CIRCULATIONS

DONGHOON YOO[1] and BRIAN A. O'CONNOR[2]

The paper presents a mathematical model for describing wave climate and wave-induced nearshore circulations. The model accounts for current-depth refraction, diffraction, wave-induced currents, set-up and set-down, mixing processes and bottom friction effects on both waves and currents. The present model was tested against published experimental data on wave conditions within a model harbour and shown to give very good results for both wave and current fields. The importance of including processes such as advection, flooding and current-interaction in coastal models was demonstrated by comparing the numerical results without each process to the results from the complete scheme.

1. INTRODUCTION

Wave-induced nearshore circulations are the result of complex processes driven by gravity water waves. When waves approach either the shoreline or man-made coastal structures, processes of shoaling, refraction, diffraction, dissipation and wave-current interaction occur. When waves propagate closer to the shoreline or diffract behind a breakwater, nearshore currents are produced by the excess momentum flux of the waves (radiation stresses). The nearshore currents are then modified by bottom friction and mixing processes, particularly in the surf zone. An additional effect produced by the presence of the waves is a change in mean water level, called set-up and set-down.

The last two decades have seen tremendous developments in the study of nearshore circulations induced by waves, with the establishment of various wave models and the use of more realistic closure models of bottom friction and mixing processes. Although recent numerical models have enabled a mathematical formulation of many of the nearshore processes to be made, a comprehensive model, which is able to describe all engineering situations, has yet to be developed. The model presented in the present paper is an attempt by the authors to improve the engineering modelling of complex nearshore processes.

In the present paper, an attempt is made to refine the classical ray model including the effects of diffraction and current-interaction, see also Yoo and O'Connor[13]. Thus, the new ray model is able to deal with large or small scale areas involving caustic zones and/or

diffraction in the lee of coastal structures. The wave field is defined at regular grid points, and hence any interpolation procedure often required for ray tracking method is avoided.

2. KINEMATICS OF REFRACTIVE AND DIFFRACTIVE WAVES IN SLOWLY VARYING CURRENT FIELD

For a plane wave, the wave number vector K_i and the wave frequency σ are given, respectively, by the spatial gradient and the time derivative of the phase function D. The local values of the slowly varying wave number vector and the frequency of the nearly plane wave may also be described by the same definitions, and the kinematic conservation is obtained from the definitions:-

$$\frac{\partial K_i}{\partial t} + \frac{\partial \sigma}{\partial x_i} = 0 \tag{1}$$

along with the zero-vorticity equation:-

$$\frac{\partial K_i}{\partial x_j} = \frac{\partial K_j}{\partial x_i} \tag{2}$$

where t is time, x is the cartesian coordinate and i,j=1,2 as in conventional tensor notation.

When the waves propagate on a current we also have the Doppler relation:-

$$\sigma = \sigma_0 + K_i U_i \tag{3}$$

where σ is the apparent or observed angular frequency, σ_0 is the intrinsic or Doppler-shifted angular frequency and U is the current velocity.

Waves generally appear to be propagating on still water in the moving frame of reference. All the relevant equations for the wave field are valid, therefore, on the moving frame of reference and the dispersion relation can be used in the form:-

$$\sigma_0^2 = gk \tanh kd \tag{4}$$

where g is the acceleration due to gravity, d is the water depth and k is the separation factor, which is the same as the wave number K (eiconal) for non-diffractive waves.

Battjes[1] discovered that the wave number K is not eiconal to k when diffraction occurs and produced the following relation:-

$$K^2 = k^2 + \delta^* = (1 + \delta)k^2 \tag{5}$$

where

$$\delta^* = \frac{1}{a} \frac{\partial^2 a}{\partial x_i^2} \tag{6}$$

$\delta = \delta^*/k^2$ and a is the wave amplitude. The wave number vector is not affected by a translation of coordinates. Thus equation (5) will be valid without modification for waves on a current.

It is then realised that

$$\sigma = \sigma\{\sigma_0(k,d),\ K_i(k,\delta^*),U_i\} \tag{7}$$

where the variables in the brackets are independent of each other. Differentiating equation (7) with respect to x_i using the chain rule and inserting it into equation (1) with the zero vorticity equation (2) produces the kinematic conservation equation for the wave number vector K_i:-

$$\frac{\partial K_i}{\partial t} + (R_j + U_j)\frac{\partial K_i}{\partial x_j} + S\frac{\partial d}{\partial x_i} + K_j\frac{\partial U_j}{\partial x_i} - \frac{R}{2ka}\frac{\partial^3 a}{\partial x_i \partial x_j^2} = 0 \tag{8}$$

where R_j are the intrinsic group velocity components given by

$$R_j = \frac{K_j}{k} R \tag{9}$$

$$R = \frac{1}{2}(1 + G)\frac{\sigma_\theta}{k} \tag{10}$$

$$S = \frac{G}{2}\frac{\sigma_\theta}{d} \tag{11}$$

$$G = \frac{2kd}{\sinh 2kd} \tag{12}$$

Here the second order derivatives of amplitude curvature are ignored. The last term of equation (8) expresses the diffraction effect on the transformation of kinematic wave properties. It further corrects the number of waves per unit length, depending on the gradient of amplitude curvature. Existing ray theories lack this term, and hence such methods fail to ensure kinematic conservation when diffraction occurs.

3. DYNAMICS OF WAVES AND TURBULENT CURRENTS

The major equations governing the dynamic motion of waves and turbulent currents derive from the conservation equations of motion. The wave-period and depth-averaged forms of the governing equations are as follows (see Yoo[12] for details):-

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x_i}(d\,U_i) = 0 \tag{13}$$

$$\frac{\partial U_i}{\partial t} + U_j\frac{\partial U_i}{\partial x_j} + \frac{1}{\rho d}\frac{\partial S_{ij}}{\partial x_j} + g\frac{\partial \eta}{\partial x_i} + \frac{|U|}{d}C^{U_i}U_i = \frac{\partial}{\partial x_j}\epsilon_j\frac{\partial U_i}{\partial x_j} \tag{14}$$

$$\frac{\partial a}{\partial t} + \frac{1}{2a}\frac{\partial}{\partial x_i}\{(R_i + U_i)a^2\} + \frac{S_{ij}}{\rho g a}\frac{\partial U_j}{\partial x_i} + C^a a^2 = 0 \tag{15}$$

where η is the wave-period-average surface elevation, ρ is the water density, ϵ_j are eddy mixing coefficients, C^U is the bottom friction coefficients associated with U_i, C^a is the bottom friction coefficient associated with a, and S_{ij} are the radiation stresses given by

$$S_{ij} = < \int_{-h}^{\zeta} (\rho \tilde{u}_i \tilde{u}_j + p \delta_{ij}) dz - \int_{-h}^{\eta} p_0 \delta_{ij} dz > \quad (16)$$

where ζ is the instantaneous surface elevation, h is the bottom elevation, $\tilde{u}$ is the wave particle velocity, p is the dynamic pressure, p_0 is the hydrostatic pressure and δ_{ij} is the Kronecker delta.

If it is assumed that the wave field is independent of the turbulent current field in such a way that any input or output of wave energy due to turbulent motion is made in an indirect way, the wave motion may be described by a potential formulation.

If we define the wave velocity potential by the equation:-

$$\tilde{u}_\alpha = - \frac{\partial \varphi}{\partial x_\alpha} \quad (17)$$

where $\alpha = 1,2,3$, from the Laplace and Bernoulli equations for the linear sinusoidal waves we have:-

$$\varphi = \frac{ga}{\sigma_0} \frac{\cosh k(h+z)}{\cosh kd} \cos D \quad (18)$$

where z is the water elevation. Substituting Equation (17) with Equation (18) into Equation (16) yields:-

$$S_{ij} = \frac{1}{2}\{(1 + \delta)(1 + G) \frac{K_i}{K} \frac{K_j}{K} + G \delta_{ij}\}(\frac{1}{2} \rho g a^2) \quad (19)$$

Equation (19) is the general expression for the radiation stresses of refractive and diffractive waves.

The four depth and wave-period averaged equations (8, 13, 14 and 15) form the basis of the present model and describe the wave and current fields in interacted flow. Equations (13) and (14) describe the current field, while equation (15) describes the wave field, when considered along with equation (8). It is also clear from the above equations that any solution of the proposed model requires proper estimation of the coefficients C^U, C^a and ϵ_j. In the surf zone, wave heights are eventually controlled by breaking, and a breaking criterion has commonly been used to limit wave height. In the present investigation, improved closure sub-models for evaluating such parameters are used. They are outlined in the following section.

4. CLOSURE SUBMODELS

MIXING PROCESS

Though many researchers seem to have realised that the mixing process in the surf zone should be related to the amount of wave energy dissipated by breaking, only Battjes[2] derived the velocity scale of turbulence from any sort of parameter directly related to the wave breaking. He found the cube root of the energy dissipation rate to be a proper measure of the velocity scale for turbulent eddy viscosity. He also suggested that the characteristic size of eddies would be primarily restricted by their vertical extent rather than their horizontal extent. This fact is well known in the field of river engineering. Many experimental and field measurements have indicated the strong depth-dependency of both horizontal and vertical eddy viscosity (see Fisher, et al. [5]).

Since the present wave amplitude equation (15) is of a transient form, the dissipation rate induced by wave breaking can easily be evaluated by checking to see if breaking has occurred, using a breaking criterion. If the wave amplitude given by equation (15) exceeds the breaking limit, the excess energy is considered to contribute to mixing processes. Otherwise, mixing processes would not be directly influenced by wave breaking.

The cube root of the energy dissipation rate, divided by fluid density, might be called the 'dissipation speed', since the square root of the bottom shear stress, divided by fluid density, is called the '(bottom) frictional velocity'. This concept is useful for considering the eddy motion of pure oscillatory flow or combined wave and current flow. Since significant amount of eddy motion is expected from bottom friction, even in the surf zone, a velocity scale for the eddy viscosity should also be related to the bottom friction. However, while a frictional velocity has been successfully used for modelling mixing process in uni-directional channel flows, it is of no use for oscillatory flow since the wave-period-average bottom friction of oscillatory flow vanishes.

In the present surf zone studies, the contribution of the bottom friction on the eddy motion is taken into account by regarding the combined breaking and frictional dissipation speed as the proposed velocity scale for the eddy viscosity. The inclusion of the bottom friction improves the Battjes' eddy viscosity model, which displays a sharp discontinuity at the breaking point.

The turbulent motion is also assumed to be anisotropic, and hence some allowance for directional preference is made in the model when describing the eddy viscosity. It has been assumed that the eddy viscosity has an ellipsoid form, of which the semi-major axes is determined by 60% of the total energy dissipation and the minor axes by 20%. The details are found in the recent work of Yoo[12].

BOTTOM FRICTION

Bottom friction has been recognised as one of the most important factors balancing the forces driven by radiation stresses in the nearshore circulation system. Due to this recognition, several numerical modellers have made efforts to evaluate more precisely the period-average bottom friction of the combined flow. However, in their approaches the friction factor was kept constant over the whole domain and its value seems to have been determined somewhat arbitrarily by the modeller's own personal view of the problem.

Fortunately, several detailed models now exist for evaluating the bottom shear stress of combined interacting wave and current flows. However, the majority of these models are too complex or involve time-consuming computer methods which are unsuitable for use in an engineering model of coastal circulations where many calculations have to be performed at a large number of grid points. The present authors have, therefore, taken one of the simpler "detailed models", that due to Bijker[4], and have modified it to include the effects of the reduction in mean current speed due to the presence of the waves. The modification also enabled expressions to be produced for the total energy dissipation rate and enhanced wave energy dissipation rate and the coefficients C^U and C^a.

The improved Bijker approach, see Yoo[12] and O'Connor and Yoo[9] for further details, was tested against results from other detailed models. It was shown to be as good as the more complex models and to be better than the existing simpler models but to take up little computation time. It was therefore adopted for the present model.

BREAKING CRITERION

The transformation of waves in the surf zone is eventually controlled or limited by wave breaking which results from the loss of stability of wave formation and in turn provides a major contribution to surf zone mixing processes. It has been common practice to describe the breaking process by a simple criterion which allows the wave growth only up to a certain limit.

Miche's criterion[8] has been widely used for numerical computation due to its mathematical reliability and broad coverage from deep to shallow water. In the late 1960's it was realised from experimental evidence that beach slope influenced the breaking mechanism and criterion. To include the slope effect, Miche's criterion was reworked by Battjes & Janssen[3] as follows:-

$$(Ka)_b = \frac{\pi}{7} \tanh (q\ Kd)_b \qquad (20)$$

where $q_b = (7/\pi)\ \gamma_b$ and γ_b is the ratio of wave amplitude to the water depth at the breaking point $(a/d)_b$. In this formulation, they also matched equation (20) with the breaking criterion for solitary waves in very shallow water, i.e., when $kd \to 0$ to find the value for q_b.

The factor q_b or γ_b may also be evaluated by empirical equations related to the bed slope. However, the existing relations do not take into account the current-interaction effect, which can be significant in the nearshore circulation system. Based on a theoretical reasoning, a new surf zone parameter β, applicable to the current-interacted situation, was developed by the authors. The parameter β is the relative intensity of the residual kinematic group velocity to the depth-mean energy propagation velocity. In the combined flow we may replace them by the absolute velocities, i.e.

$$\beta = \frac{R - P}{R + U_w} \tag{21}$$

where R is the relative kinematic group velocity, P is the depth-mean energy propagation velocity and U_w is the current velocity in the wave direction. Using the new parameter, a number of experimental data sets were examined and the following relation found (Yoo[12]):-

$$q_b = 0.8 + \tanh (90\beta) \tag{22}$$

Equation (21) also expresses that waves are liable to be more easily broken when they encounter an opposing current as the surf parameter reaches a higher value than when they propagate with a following current.

5. NUMERICAL MODELLING

The combined wave and current flow in coastal areas has been described by the set of Eulerian conservation equations, that is, equations (8) and (15) for the wave field and equations (13) and (14) for the current field. The bottom friction coefficients C^U and C^a and the mixing coefficients ϵ_j are defined using closure models, while the wave amplitude is given by equation (15), unless the breaking criterion of equation (20) shows a limited wave height at which point excess wave energy is transferred to mixing processes.

Due to several complicated non-linear terms in the equations, the solution of the system is best achieved by using numerical techniques. Finite difference explicit schemes are employed for solving both wave and current equations, since the full interaction between waves and currents is taken into account. It is here emphasised that the long and complex procedure of solving large number of simultaneous equations at each time step negates the large time step allowed by implicit schemes and drastically reduces the efficiency of implicit methods. Therefore, explicit schemes are chosen for the present work.

The angled derivative explicit (ADE) scheme, which was introduced by Flather & Heaps[8] for tide modelling, is used for solving the current momentum equations, while an upstream differencing scheme is used for solving the wave equations. Since waves are assumed to be progressive, the 'upstream' differencing scheme, which controls the direction of differencing by the direction of the progressive motion, was found to be an excellent choice for the wave equations (see Yoo[12] and Yoo & O'Connor[13] for details).

The solutions of finite difference forms of the governing equations are obtained by providing initial and boundary conditions. Tests with the model showed that the best arrangement was a 'cold start' for the current field with a flat water surface and zero current velocity everywhere and a 'hot start' for the wave field, that is, the wave variables over the modelled area were set to be the same as the inflow boundary values. Tests also showed that the initial errors were quickly damped down particularly in the surf zone, by imposing a breaking criterion which prevents excessive build-up of wave energy. No-flow condition was applied to the inflow boundary at the offshore end as well as to the land boundary.

In order to cope with situations involving the 'wetting' and 'drying' of computational grids, the Flather and Heaps' scheme[6] is employed in the present model, which tests the wet condition at each velocity point instead of each elevation point. It can allow the flooding from any direction and generally ensures mass continuity during a transition period from wet to dry or dry to wet. Unrealistically high velocities were found on steep slopes when the condition changed from wet to dry. This was improved by imposing a sensible depth, below which the flow velocity was put to zero, see Yoo[12].

6. MODEL APPLICATION

The present model has been tested against several well-controlled experiments with satisfactory results (Yoo[12]). The present paper presents a set of results obtained on a model breakwater study. The experiments were conducted by Gourlay[7] to study the nearshore circulation produced behind a semi-detached breakwater normal to the direction of wave approach (see Fig. 4 of Gourlay[7]). The beach behind the breakwater was formed of concrete. In the sheltered area behind the breakwater, it was curved with a constant radius centred on the breakwater tip. The water depth offshore of the beach was maintained at 20 cm throughout the tests. The inflow wave conditions were a = 45.5 mm and T = 1.5 seconds with waves propagating normal to the breakwater.

The investigation area was resolved by finite difference meshes of Δx = 0.185 m and Δy = 0.2075 m with 41 meshes in the x direction and 34 meshes in the y direction (see Fig. 1). The left-hand side of the training wall in front of the breakwater was not included in the computation domain and the inflow wave condition was imposed along the line at the offshore end of the training wall. The time step chosen was 0.005 seconds to ensure computational stability.

A value of 0.001m was chosen for the effective roughness height of the concrete in the model. Several trials with the model showed that the dimensionaless mixing coefficients M_b = 2.0 and M_f = 4.0 gave the best solution for the present case. The value of M_b = 2.0 is similar to that (M_b = 3.0) found by Visser[11] using experimental results for a uniform beach.

Fig. 2 shows the time variations of the wave amplitude, current velocity and mean surface elevation at the inshore points A and B (see Fig. 1). While the mean surface elevation still substantially

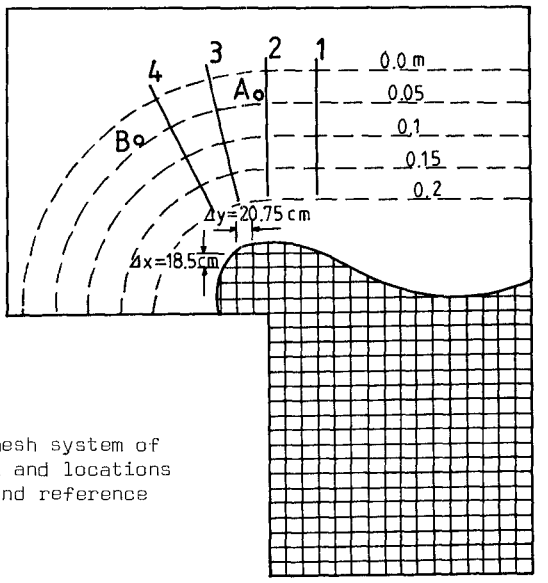

Fig. 1 Finite difference mesh system of Gourlay's wave tank and locations of cross-sections and reference points

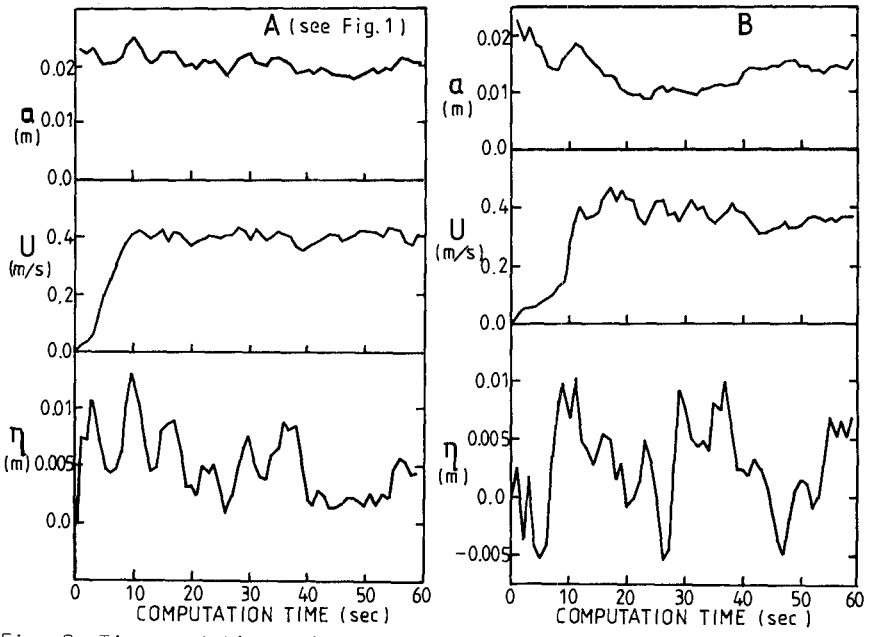

Fig. 2 Time variations of wave amplitude, current velocity and mean surface elevation at locations A and B.

oscillates up to 60 seconds, both wave amplitude and current velocity soon fully develop within a short period. It is interesting to note that at location B the wave amplitude gradually decreases below 0.01m up to 24 seconds, then slowly increases over 0.013m up to 40 seconds and finally remains relatively constant during the rest of the computation period. This changing history of the wave amplitude is certainly caused by the current interaction effects, which seem to alter the wave environment significantly over the whole area.

From Fig. 2, it is believed that the steady state is reached roughly at around 40 seconds. It was, therefore, decided that the result at 50 seconds was likely to be the final solution for the flow field in the present case. The results at time 50 seconds are shown in succeeding figures; wave height distribution in Fig. 3 and wave-induced currents in Fig. 4. The computed results are compared with the experimental data in plan and detailed comparison of the current values is made on several cross sections (refer to Fig. 1 for the details of the location of the cross sections). The agreement between the model and the experiment results is seen to be very good overall.

The computed wave height distribution is seen to be very similar to the experimental one (see Fig. 3). Some minor deviations are found in the middle of the right-hand side of the tank and in the left-hand corner behind the breakwater. Higher values at the left-hand corner in the lee of the breakwater seem to be due to reflection from the beach, while lower values in the middle of the right-hand side may be caused by the non-linear effect of wave transformation near the breaker zone.

The computed current pattern agrees quite well with the experimental one, both qualitatively and quantitatively (see Fig. 4). The computed main gyre behind the breakwater is located at a similar position to the experimental one, being located about 0.5m further inside the breakwater, while even the small eddy motion at the left-hand corner behind the breakwater is well represented by the present model. The detailed comparison of the currents on several cross sections shows the quite good agreement of the model results with the experimental ones in both offshore and inshore regions. In offshore regions, the model slightly over-estimates the current velocity, while inside the surf zone slightly under-estimates it. But the difference is considered acceptable, in view of likely errors in the measurement of conditions in the physical model and the limitation of grid resolution.

The model was finally employed for demonstrating the significance of the role of each term; advection, current-interaction and flooding. This can be best achieved by producing the computational results excluding each term and comparing them with the results from the experiments or the complete scheme. The computation results at 50 seconds are shown in Fig. 5, together with the results from the complete scheme. Problems were found when excluding the advection terms of the momentum equation. The flow developed so rapidly near the coastline that eventually the whole system became unstable at a

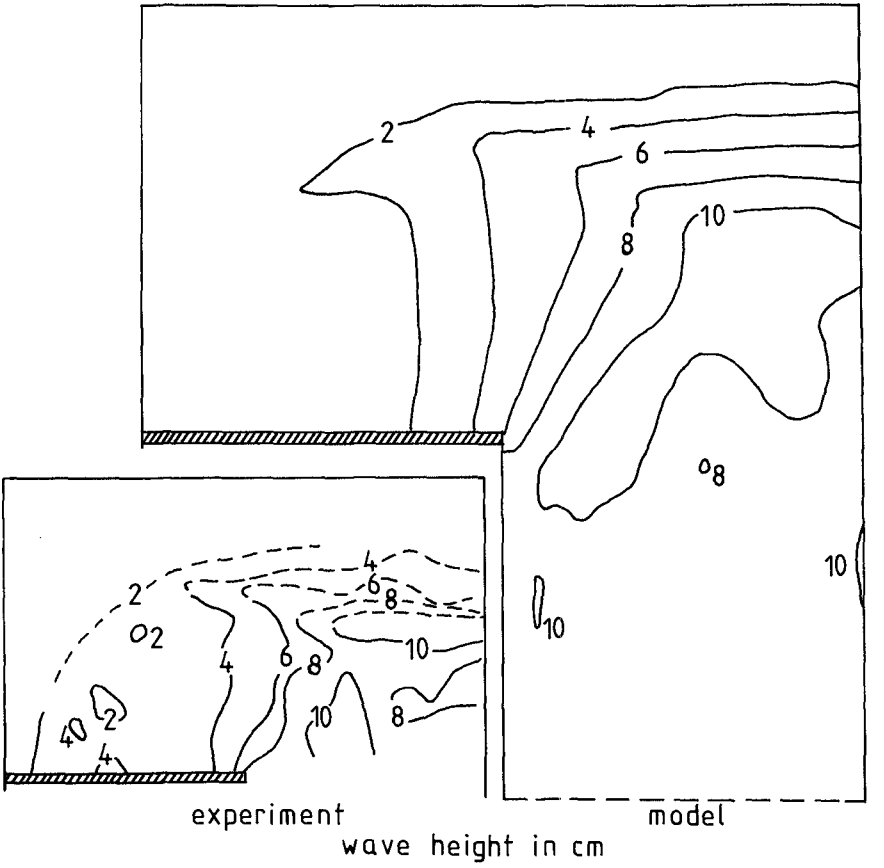

Fig. 3 Comparison of wave height between Gourlay's experiment and the present model

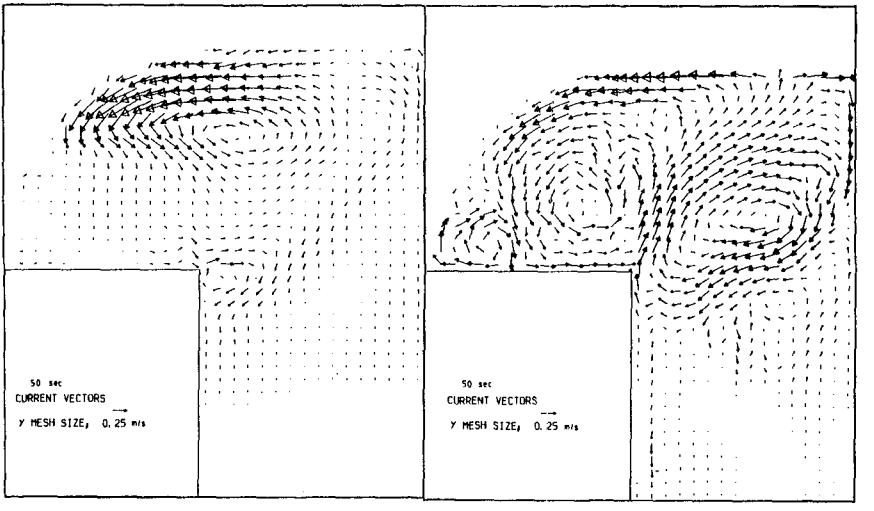
(1) complete (2) no-advection



(3) no-current-interaction (4) no-flooding

Fig. 5 Velocity distributions of wave-induced currents from different versions of the present model

run time of about 18 seconds. Therefore, the intermediate result at 15 seconds after the start of the computation is presented for the no-advection case.

Both schemes of no-advection and no-current-interaction are incapable of representing the small eddy motion at the left-hand corner behind the breakwater, while the centre of the main gyre is located a considerable distance from the experimental one. A totally wrong current pattern is thus given by the no-advection and no-current-interaction schemes. By contrast, the no-flooding scheme seems to have described the current pattern nearly as well as the complete interaction one. However, it generally over-estimates the current velocity particularly near the coast; the maximum velocity of the main gyre being predicted at over 65 cm/sec compared with about 50 cm/sec from the experiment, and the maximum velocity of the small gyre at over 25 cm/sec compared with about 10 cm/sec in the experiment. Therefore, if flooding is not included in the model, it is clear that incorrect answers will be obtained for both elevation and current velocity and, indirectly, for mixing coefficients.

7. CONCLUSION

The present work has been concerned with the development of an engineering computer model for evaluating both wave and current fields, particularly when they interact with each other as in the surf zone. The present wave model is fully based on ray theory, which has been extensively used in evaluating wave condition in field situations. The major deficit of existing ray models is that they are incapable of handling caustic or diffractive waves and hence the results are of limited use in areas with complex topography.

The present paper has shown how diffraction effects may be taken into account together with current-interaction effects. The authors' early works[12,13] proved the capability of the present ray model for handling caustic waves, while the present paper demonstrates the model's ability for evaluating the wave-current flow fields in breakwater situation while fully accounting for diffraction and the interaction between waves and current. The model is shown to give very good results for both wave and current fields.

Comparison of model and laboratory tests illustrate the effects of current interaction on wave transformation as well as the current field itself; non-linear advective accelerations on momentum transfer; and flooding of flat zones due to set-up. When any one of the above processes is excluded, the current pattern is shown to be strikingly different from the experimental result or the complete, computer model result.

CHAPTER 123

Wave and Current Interactions in Shallow Water

By Sung B. Yoon[1] and Philip L-F. Liu[2]

1. Introduction

Interactions between waves and currents are common and important phenomena in the coastal zone. Coastal currents, such as longshore currents, rip currents, and river flows, can significantly change wave heights and directions of wave propagation. Consequently, the design for shoreline protection measures must be adjusted accordingly.

Various theories for wave-current interactions exist and have been reviewed by Peregrine and Jonsson (1983). Most of these theories are developed for large-scale currents where the length-scale for the current variation is much greater than the typical wavelength. These theories cannot be applied to the coastal currents which are small-scale currents.

In this paper, the interactions between currents and nonlinear shallow water waves are investigated. Boussinesq equations are used to derive evolution equations for spectral wave components. The current intensity is assumed to be larger than the leading wave orbital velocity and smaller than the group velocity. The length-scale of the current is much shorter than those assumed in the existing large-scale theories.

To facilitate numerical computations, the parabolic approximation is applied and a simplified model is developed. A numerical example is given for the refraction and diffraction of cnoidal waves over a rip current on a sloping topography. Both normal and oblique incident cases are examined.

2. Boussinesq Equations

In the present study, the current velocity is assumed to be stronger than the leading order wave orbital velocity. Using ω as the characteristic wave frequency, a_0 as the characteristic wave amplitude and h_0 as the characteristic water depth, the following dimensionless variables are introduced:

[1]Graduate Research Assistant, [2]Professor and Associate Dean of Engineering College

Joseph DeFrees Hydraulics Laboratory, School of Civil and Environmental Engineering, Cornell University, Ithaca, NY 14853

$$t = \omega t \quad , \quad (x, y) = \frac{\omega}{\sqrt{gh_o}} (x , y) \quad , \quad h = h / h_o \quad ,$$

$$\xi_w = \xi_w/(\epsilon h_o) \quad , \quad \vec{u}_w = \vec{u}_w/(\epsilon \sqrt{gh_o}) \quad ,$$

$$\xi_c = \xi_c/(\mu^2 h_o) \quad , \quad \vec{u}_c = \vec{u}_c/(\mu \sqrt{gh_o}) \quad , \tag{1}$$

where

$$\epsilon = a_o/h_o \ll 1 \quad , \quad \text{and } \mu^2 = \omega^2 h_o/g \ll 1 \quad , \tag{2}$$

are small parameters and are assumed to be in the same order of magnitude. In equation (1) $\vec{u}_w$ denotes the depth-averaged horizontal wave velocity vector, while $\vec{u}_c$ represents the current velocity vector. ξ_w and ξ_c represent the free surface displacements associated with wave and current field, respectively. The Boussinesq equations can be written in the following dimensionless form:

$$\frac{\mu^2}{\epsilon} \vec{u}_c \cdot \nabla \vec{u}_c + \frac{\mu^2}{\epsilon} \nabla \xi_c + \frac{1}{2} \frac{\mu^4}{\epsilon} \nabla [\nabla \cdot (h \vec{u}_c)]^2 + \frac{\partial \vec{u}_w}{\partial t} +$$

$$\epsilon \vec{u}_w \cdot \nabla \vec{u}_w + \mu (\vec{u}_c \cdot \nabla \vec{u}_w + \vec{u}_w \cdot \nabla \vec{u}_c) + \nabla \xi_w -$$

$$\mu^2 \frac{\partial}{\partial t} \{\frac{h}{2} [\nabla \cdot (h \vec{u}_w)] - \frac{h^2}{6} \nabla (\nabla \cdot \vec{u}_w)\} = 0(\mu^4) \quad , \tag{3}$$

$$\frac{\mu}{\epsilon} \nabla \cdot [(h + \mu^2 \xi_c) \vec{u}_c] + \frac{\partial \xi_w}{\partial t} + \mu \nabla \cdot (\xi_w \vec{u}_c) +$$

$$\nabla \cdot [(h + \epsilon \xi_w + \mu^2 \xi_c) \vec{u}_w] = 0(\mu^4) \quad . \tag{4}$$

Note that in equations (3) and (4) the length scales for the wave field, current field and the topographical variation are all in the same order of magnitude, namely the typical wavelength. If the water depth is assumed to vary slowly, i.e. $\nabla h \sim 0(\mu)$, the momentum equation (3) can be simplified to be

$$\frac{\mu^2}{\epsilon} \vec{u}_c \cdot \nabla \vec{u}_c + \frac{\mu^2}{\epsilon} \nabla \xi_c + \frac{\partial \vec{u}_w}{\partial t} + \epsilon \vec{u}_w \cdot \nabla \vec{u}_w +$$

$$\mu (\vec{u}_c \cdot \nabla \vec{u}_w + \vec{u}_w \cdot \nabla \vec{u}_c) + \nabla \xi_w - \frac{\mu^2 h^2}{3} \nabla (\nabla \cdot \frac{\partial \vec{u}_w}{\partial t})$$

$$= 0(\mu^3) \quad . \tag{5}$$

We assume that the free surface displacement and the velocity vector for the wave field can be written as a Fourier series with the fundamental frequency ω, i.e.,

$$\xi_w = \frac{1}{2} \sum_n \xi_n \, e^{-int} \quad ,$$

$$\vec{u}_w = \frac{1}{2} \sum_n \vec{u}_n \, e^{-int} \quad , \tag{6}$$

where $n = \pm 1, \pm 2, \cdots$ and $(\xi_{-n}, \vec{u}_{-n})$ are the complex conjugates of $(\xi_n, \vec{u}_n)$. Substitutions of equation (6) into equations (4) and (5) and collections of terms for different Fourier harmonics yield:

$$\nabla \xi_c + \vec{u}_c \cdot \nabla \vec{u}_c + \frac{\epsilon^2}{4\mu^2} \sum_s \vec{u}_s \cdot \nabla \vec{u}_{-s} = 0(\mu^3) \quad , \tag{7}$$

$$\nabla \cdot [(h + \mu^2 \xi_c) \vec{u}_c] = 0(\mu^3) \quad , \tag{8}$$

where $s = \pm 1, \pm 2, \cdots$, and

$$-i n \vec{u}_n + \nabla \xi_n + \mu (\vec{u}_c \cdot \nabla \vec{u}_n + \vec{u}_n \cdot \nabla \vec{u}_c) + \frac{\epsilon}{2} \sum_s \vec{u}_s \cdot \nabla \vec{u}_{n-s} + i n \mu^2 \frac{h^2}{3} \nabla (\nabla \cdot \vec{u}_n) = 0 \ (\mu^3), \tag{9}$$

$$-i n \xi_n + \nabla \cdot [(h + \mu^2 \xi_c) \vec{u}_n] + \mu \nabla \cdot (\xi_n \vec{u}_c) + \frac{\epsilon}{2} \sum_s \nabla \cdot (\xi_s \vec{u}_{n-s}) = 0(\mu^3) \quad . \tag{10}$$

Equations (7) and (8) govern the current velocity $\vec{u}_c$ and the corresponding mean free surface displacement ξ_c with the influences of the wave field. On the other hand, equations (9) and (10) describe the wave field, ξ_n and $\vec{u}_n$ $(n = \pm 1, \pm 2, \cdots)$, which is affected by the current field. The current field can be split into two parts:

$$\vec{u}_c = \vec{q} + \mu^2 \vec{q}_2 \tag{11}$$

$$\xi_c = \eta + \mu^2 \eta_2 \tag{12}$$

where $(\vec{q}, \eta)$ represent the velocity vector and free surface displacement without the influence of waves and $(\vec{q}_2, \eta_2)$ denote the small corrections on currents due to waves. Substituting equations (11) and (12) into equations (7) and (8) yields

$$\nabla \eta + \vec{q} \cdot \nabla \vec{q} = 0 \quad , \tag{13}$$

$$\nabla \cdot (h \vec{q}) = 0 \quad , \tag{14}$$

and

$$\nabla \eta_2 + \vec{q} \cdot \nabla \vec{q}_2 + \vec{q}_2 \cdot \nabla \vec{q} + \frac{\epsilon^2}{4\mu^4} \sum_s \vec{u}_s \cdot \nabla \vec{u}_{-s} = 0 \quad , \tag{15}$$

$$\nabla \cdot (h \vec{q}_2 + \eta \vec{q}) = 0 \tag{16}$$

Substitutions of equations (11) and (12) into equations (9) and (10) yield the following equations

$$-i n \vec{u}_n + \nabla \xi_n + \mu (\vec{q} \cdot \nabla \vec{u}_n + \vec{u}_n \cdot \nabla \vec{q}) + \frac{\epsilon}{2} \sum_s \vec{u}_s \cdot \nabla \vec{u}_{n-s} + i n \mu^2 \frac{D^2}{3} \nabla (\nabla \cdot \vec{u}_n) = 0(\mu^3) \quad , \tag{17}$$

$$-i n \xi_n + \nabla \cdot (D \vec{u}_n) + \mu \nabla \cdot (\xi_n \vec{q}) + \frac{\epsilon}{2} \sum_s \nabla \cdot (\xi_s \vec{u}_{n-s}) = 0(\mu^3) \quad , \tag{18}$$

where

$$D = h + \mu^2 \eta \quad , \tag{19}$$

is the total water depth. The small terms in the current field, η_2 and $\vec{q}_2$, do not affect the accuracy of the wave field.

From equations (17) and (18) the following simple relationships can be found:

$$\vec{u}_n = - \frac{i}{n} \{\nabla \xi_n - \frac{i\mu}{n} [\vec{q} \cdot \nabla (\nabla \xi_n) + \nabla \xi_n \cdot \nabla \vec{q}]\} + 0(\mu^2) \quad , \tag{20}$$

$$\nabla \cdot \vec{u}_n = i n \frac{\xi_n}{D} + 0(\mu) \quad . \tag{21}$$

Multiplying D on the both sides of equation (17) and taking divergence of the resulting equation, we obtain a wave equation for ξ_n:

$$\nabla \cdot (D \nabla \xi_n) + n^2 \xi_n + i n \mu (\nabla \cdot \vec{q}) \xi_n + i n \mu \vec{q} \cdot \nabla \xi_n -$$

$$\frac{\mu^2 n^2 D^2}{3} \nabla^2 \xi_n + \mu \nabla \cdot [D (\vec{q} \cdot \nabla \vec{u}_n + \vec{u}_n \cdot \nabla \vec{q})] +$$

$$\frac{\epsilon}{2} \sum_s [D \nabla \cdot (\vec{u}_s \cdot \nabla \vec{u}_{n-s}) + i n \nabla \cdot (\xi_s \vec{u}_{n-s})] = O(\mu^3), \quad (22)$$

in which equations (18) and (21) have been used.

In summary, solutions for the current velocity $\vec{q}$ and the mean free surface displacement η can be obtained by solving the shallow-water equations (13) and (14). The wave field can be obtained by solving the nonlinear wave equation (22) with appropriate boundary conditions. The effects of the current field on the wave field are included in equation (22). The modification in the current field due to the wave field can be found from equations (15) and (16).

3. Parabolic Approximation

Consider the cases where the dominating wave propagation direction is in the x-direction. The free-surface displacement for the n-th harmonic can be written as

$$\xi_n = \psi_n (x, y) \exp [i n \int \frac{1}{\sqrt{d(x)}} dx] \quad , \quad (23)$$

where $\psi_n (x, y)$ is the amplitude function and d(x) is a reference depth which is a slowly varying function in x. We adopt the usual parabolic approximation that the length-scale of the amplitude function in the wave propagation direction is larger than that in the lateral (y -) direction, i.e.,

$$\frac{\partial \psi_n}{\partial x} \ll \frac{\partial \psi_n}{\partial y} \quad , \quad \frac{\partial^2 \psi_n}{\partial x^2} \ll \frac{\partial \psi_n}{\partial x} \quad . \quad (24)$$

To be more specific, we assume that the current field may be rotational and has a length scale which is slightly longer than the wavelength.

$$O(\frac{\partial U}{\partial y}) \sim O(\frac{\partial V}{\partial x}) \sim O(\alpha) \quad ,$$

$$O(\frac{\partial U}{\partial x}) \sim O(\frac{\partial V}{\partial y}) \sim O(\mu) \quad . \quad (25)$$

where (U, V) are the components of $\vec{q}$ in the x- and y-direction respectively. The small parameter α is assumed to be $O(\mu^{2/3})$.

Furthermore, the topographical variation is assumed to be much weaker than the current variations, i.e.,

$$O(\frac{\partial D}{\partial x}) \sim O(\frac{\partial D}{\partial y}) \sim O(\mu^2) \quad . \tag{26}$$

Consequently, we specify that

$$O(\frac{\partial^2 \psi_n}{\partial x^2}) \sim O(\mu^3) \text{ and } O(\frac{\partial^2 \psi_n}{\partial y^2}) \sim O(\alpha^2) \quad . \tag{27}$$

Substituting equations (20) and (23) into equations (22) and using the order of magnitude estimates, equations (25) - (27), we obtain the following parabolic wave equation for ψ_n:

$$2 i n (\frac{D}{\sqrt{d}} + 2 \mu U) \frac{\partial \psi_n}{\partial x} + D (1 + \mu \frac{U}{\sqrt{D}}) \frac{\partial^2 \psi_n}{\partial y^2} +$$

$$[\frac{\partial D}{\partial y} + 2i \mu n V + 2\mu \sqrt{D} (\frac{\partial V}{\partial x} + \frac{\partial U}{\partial y})] \frac{\partial \psi_n}{\partial y} +$$

$$\{i n \frac{\partial}{\partial x} (\frac{D}{\sqrt{d}} + 2 \mu U) + n^2 [1 - \frac{D}{d} - \mu \frac{U}{\sqrt{d}} (1 + \frac{D}{d}) +$$

$$\frac{\mu^2 n^2 D}{3} - \mu^2 \frac{U^2}{D}] - i n \mu^2 \frac{V}{\sqrt{D}} \frac{\partial U}{\partial y}\} \psi_n =$$

$$\frac{\epsilon}{2D} \sum_s n (n + s) \psi_s \psi_{n-s} + O(\mu^3) \quad , \tag{28}$$

where $D/d = 1 + O(\mu^2)$ is assumed.

4. A Numerical Example

In this section we employ the parabolic equation obtained in the previous section to study the propagation of shallow water waves over rip currents. The current velocity satisfying the shallow water equations (13) and (14) and the corresponding topography can be expressed as:

$$h = (30 - x)/30 \quad ,$$

$$U = -C_2 (30-x) \exp - [(30 - x)^2/C_3^2 + y^2/C_4^2]/2 \quad ,$$

$$V = -\sqrt{\frac{\pi}{2}}\, C_1 \left[2 - \left(\frac{x - 30}{C_3}\right)^2\right] \exp - \left[(30 - x)/\sqrt{2}\, C_3\right]^2 \operatorname{erf}\left[y/(\sqrt{2}\, C_4)\right]. \tag{29}$$

for $\sqrt{2}\, C_3 < (30 - x) < 30$, and

$$h = \sqrt{2}\, C_3/30 \quad ,$$

$$U = -\frac{\sqrt{2}}{e}\, C_2\, C_3 \exp - \left[y/(\sqrt{2}\, C_4)\right]^2 \quad ,$$

$$V = 0 \quad , \tag{30}$$

for $(30 - x) \leq \sqrt{2}\, C_3$, where C_1, C_2, C_3 and C_4 are constants. In the present computations, the following values are used: $C_1 = 0.078$, $C_2 = 0.049$, $C_3 = 7.98$ and $C_4 = 1.596$. The velocity profile is shown in Figure 1. Note that the depth is a constant in the region $x > 18.715$.

The incident wave train contains three harmonics $\psi_1 = 0.9988$, $\psi_2 = 0.0475$ and $\psi_3 = 0.0019$. The small parameters along the initial line are $\epsilon = 0.02$ and $\mu^2 = 0.361$. Thus, initially the incident wave is almost a linear dispersive system.

Using the linear wave ray theory, we plot the ray pattern of a normal incidence over rip currents (Figure 2). Because of wave refraction, caustics occur along the centerline of the rip currents; the ray theory becomes invalid. The present numerical solutions are shown in Figure 3. The linear solutions are obtained by ignoring the nonlinear terms in equation (28). The basic features of the wave height distribution are similar in linear and nonlinear results. However, the detailed free surface profiles are quite different since the nonlinear theory solutions contain higher harmoncis as seen in Figure 3c. A plot of the instantaneous contours of positive free surface displacement is given in Figure 4. The features illustrating the larger amplitudes along the centerline of the rip currents and the wider trough are clearly demonstrated.

Numerical results are also obtained for the case of an oblique incident wave train with the angle of incidence 30° along the initial line. The ray pattern is displayed in Figure 5 which shows oscillatory pattern in caustics. This feature is confirmed by the present numerical solutions as shown in Figure 6. The corresponding free surface profiles using linear and nonlinear theories are given in Figure 7. On the lee side of the rip current the nonlinear results show a faster phase velocity.

CHAPTER 124

2DH COMPUTATION OF TRANSIENT SEA BED EVOLUTIONS

Huib J. de Vriend*

ABSTRACT

The interaction between the constituent models for waves, currents, sediment transport and bottom level changes in a class of compound 2DH mathematical models of transient sea bed evolutions in the coastal zone is investigated mathematically, using the theory of characteristics and a harmonic analysis technique. This leads to contrary indications as to the importance of including diffraction in the wave model and to the unambiguous conclusion that the bottom slope effect on the sediment transport is indespensable for the mathematical system to be inherently stable. This conclusion is shown to imply that depth-integrated current model are insufficient to describe the flow in this type of morphological computations for the nearshore zone or complex coastal areas.

INTRODUCTION

In recent years, the progress in the physical understanding and the mathematical modelling of the water and sediment motion in coastal areas has enabled the numerical simulation of these phenomena to become a widely applied and useful tool in coastal hydraulics and coastal zone management. Besides, they seem to have brought the mathematical modelling of the integrated effect of these phenomena, the 3D morphological evolution of the sea bed, within reach. Various research institutes, all over the world, are making substantial research efforts in this field (see e.g. Fleming et al., 1976; Watanabe, 1982; Coeffé et al., 1982; McAnally et al., 1984; Yamaguchi et al., 1984; De Vriend, 1987a,b).
One of the cornerstones in the development of mathematical models of transient sea bed evolutions is a thorough physical knowledge, of the elementary phenomena tide, waves, currents, sediment motion and sedimentation/erosion, as well as their interactions (also see De Vriend, 1987a). The present paper attempts to contribute to this last field of knowledge, which still exhibits significant lacunae.
After the description and the mathematical formulation of the class of models to be considered, the interaction between the constituent models is analysed mathematically and the sensitivity of the model to some major simplifications in the constituents is assessed. Finally, conclusions are drawn on the applicabitlity.

GENERAL OUTLINE OF THE MODELS

The models concern 3D transient morphological evolutions in coastal areas. Basic elements are depth-integrated wave and current models, local sediment transport formulae and the sediment balance.

*Delft Hydraulic Lab., Delft, The Netherlands

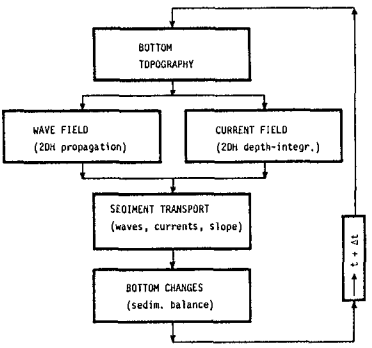

Fig. 1 Flow chart of investigated models

Fig. 1 gives an aggregate flow chart of the interconnection of these elements. Although the present analysis concerns systems of differential equations and the behaviour of their solutions, this flow chart also pertains to their elaboration in a numerical model, so that it can be considered as describing a computational procedure.

Fig. 1 shows that the constituent models are connected in series, with feedback via the bed topography only. This is a simplification of reality, as it ignores other feedback mechanisms, such as current refraction. On the other hand, it focuses attention on the morphological interaction to be investigated.

Another important simplification is the absence of wave dissipation. This means that wave-driven currents are left out of consideration as a mechanism through which the waves can interact with the other components of the system. The principal remaining interaction mechanism for the waves is the stirring of sediment. From a practical point of view, this is a fairly limitative assumption, but on the other hand the interaction analysis should be built up step by step. After the analysis for currents alone (De Vriend, 1987a,b), this is another step on a much longer way to go.

WAVE MODEL

The most general formulation of the wave models to be considered is based on the mild-slope equation for linear monochromatic unidirectional gravity waves (Berkhoff, 1976). Ignoring current refraction and dissipation, this equation can be written as

$$\frac{\partial}{\partial x}\left(cc_g \frac{\partial \Psi}{\partial x}\right) + \frac{\partial}{\partial y}\left(cc_g \frac{\partial \Psi}{\partial y}\right) + k^2 cc_g \Psi = 0 \qquad (1)$$

in which: x, y = cartesian co-ordinates in the horizontal plane,
c = phase celerity of the waves,
c_g = group celerity of the waves,
k = wave number and
Ψ = complex wave potential.

Substitution of the wave-type expression

$$\Psi(x,y) = \mathrm{Re}\left[a(x,y)\exp\left\{i\Phi(x,y)\right\}\right] \qquad (2)$$

in which $i = \sqrt{(-1)}$ and the amplitude and phase functions $a(x,y)$ and $\Phi(x,y)$ are real, leads to the eikonal equation

$$\left(\frac{\partial \Phi}{\partial x}\right)^2 + \left(\frac{\partial \Phi}{\partial y}\right)^2 = k^2 + \frac{1}{cc_g a}\left[\frac{\partial (cc_g)}{\partial x}\frac{\partial a}{\partial x} + \frac{\partial (cc_g)}{\partial y}\frac{\partial a}{\partial y}\right] + \frac{1}{a}\left[\frac{\partial^2 a}{\partial x^2} + \frac{\partial^2 a}{\partial y^2}\right] \qquad (3)$$

and the transport equation

$$\frac{\partial}{\partial x}\left(cc_g a^2 \frac{\partial \Phi}{\partial x}\right) + \frac{\partial}{\partial y}\left(cc_g a^2 \frac{\partial \Phi}{\partial y}\right) = 0 \qquad (4)$$

For purely refracting wave fields (geometric optics approximation), the last two terms of (3) drop out and the equations can be reduced to (also see Appendix I)

$$\frac{\partial}{\partial x}(k \sin\Theta) - \frac{\partial}{\partial y}(k \cos\Theta) = 0 \qquad (5)$$

$$\frac{\partial}{\partial x}(E\, c_g \cos\Theta) + \frac{\partial}{\partial y}(E\, c_g \sin\Theta) = 0 \qquad (6)$$

in which Θ denotes the direction of wave propagation and $E = \frac{1}{2}\rho g a^2$ is the energy density of the wave field.
Both the complete refraction/diffraction equations (3) and (4) and the refraction equations (5) and (6) will be investigated in their interaction with the other components of the model.

CURRENT MODEL

In order to avoid unnecessary complications, the current model includes a number of simplifying assumptions, most of which can be shown to have no essential influence on the interaction (De Vriend, 1985):

- depth-integrated formulation in terms of depth-averaged velocities,
- almost-parallel flow (no secondary currents),
- rigid-lid approximation for the free surface,
- no horizontal diffusion or dispersion of momentum,
- no wave influence on the bottom shear stress,
- bottom shear stress acting in the depth-averaged flow direction,
- no coriolis acceleration,
- no external driving forces, and
- steady flow.

Under these assumption, the flow model can be written as

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial x} - \frac{\tau_{bx}}{\rho h} \qquad (7)$$

$$u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial y} - \frac{\tau_{by}}{\rho h} \qquad (8)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + u\frac{\partial h}{\partial x} + v\frac{\partial h}{\partial y} = 0 \qquad (9)$$

in which: u, v = depth-averaged velocity components
p = total pressure (piezometric head * spec. weight)
ρ = mass density of the fluid
h = water depth
τ_{bx}, τ_{by} = bottom shear stress components.

For the system of equations to be closed, the bottom shear stress has to be related to the other dependent variables in the system. The present analysis requires no further specification than

$$\frac{\tau_{bx}}{\rho h} = ru; \quad \frac{\tau_{by}}{\rho h} = rv \quad \text{with} \quad r = \text{fnct}(u_t, h); \quad u_t = (u^2 + v^2)^{\frac{1}{2}} \qquad (10)$$

The flow model (7) through (10) will only be considered in its complete form, as the effects of simplifications have been investigated before (De Vriend, 1985 and 1987a).

SEDIMENT TRANSPORT MODEL

As was stated before, the sediment transport model is basically restricted to sediment transport formulae. Especially in coastal areas, where a large part of the transported sediment is suspended load, this can be a rather limitative assumption, though not necessarily fatal (c.f. Van Banning et al., 1987). Nevertheless, this type of model is choses, not only from the step-by-step philosophy, but also because transport formulae are widely used in practice. All the same, systems including suspended load models remain to be investigated (cf. Lin et al., 1984).
In addition to this restriction, it is assumed that, apart from the bottom slope effect,

- the magnitude of the transport is a function of the current velocity, the water depth and the wave height (and possibly other quantities that are not figuring as dependent variables in the present system),
- the direction of the transport coincides with the depth-averaged flow direction, and
- the magnitude of the transport is independent of the derivatives of the dependent variables.

This leads to the following mathematical formulation of the transport without bottom slope effect;

$$S'_x = \frac{u}{u_t} S'_t \; ; \; S'_y = \frac{v}{u_t} S'_t \text{ with } S'_t = \text{fnct } (u_t, h, E) \tag{11}$$

in which S'_x and S'_y are the components of the transport vector and S'_t denotes its magnitude.
The near-bottom sediment transport is influenced by the bottom slope, via the downslope gravitational force, acting on the bed load, and via the vertical component of the near-bed velocity, acting on the suspended load. These effects can be incorporated via the following approximative adjustments (cf. Koch et al., 1981 and Bailard, 1981):

$$S_t = S'_t \left(1 - \beta_1 \frac{\partial z_b}{\partial s}\right) \text{ and } \tan\alpha \triangleq \frac{S_y}{S_x} = \tan\delta - \beta_2 \frac{\partial z_b}{\partial n} \tag{12}$$

in which z_b denotes the bottom level, and s and n are stream-oriented and stream-normal horizontal co-ordinates (metric), respectively; δ is the depth-averaged flow direction.
Depending on the transport concept, the factors β_1 and β_2 are equal (Bailard, 1981) or not (Koch et al., 1981) and vary with the wave and current parameters. For simplicity, they are chosen equal and constant, i.e. $\beta_1 = \beta_2 = \beta$, so that (11) and (12) can be elaborated to

$$S_x = S'_t \left(\cos\delta - \beta \frac{\partial z_b}{\partial x}\right) \text{ and } S_y = S'_t \left(\sin\delta - \beta \frac{\partial z_b}{\partial y}\right) \tag{13}$$

provided that the bottom slopes are small compared with β^{-1}.

BOTTOM LEVEL CHANGES

The rate of change of the bottom level follows from the conservation of sediment mass

$$(1 - \varepsilon_p) \frac{\partial z_b}{\partial t} + \frac{\partial S_x}{\partial x} + \frac{\partial S_y}{\partial y} = 0 \tag{14}$$

in which ε_p denotes the porosity of the bottom. This part of the model

is quite unambiguous and, if combined with a transport formula, leaves no room for alternative formulations.

LINEARIZATION OF THE SYSTEM

Equations (3), (4), (7) through (10), (11), (13) and (14) basically from the mathematical model equations, although additional expressions have to be given for c, c_g, k, h, r and S'_t in terms of the dependent variables Φ (or Θ), a (or E), u, v , p and z_b. It is not necessary, however, to have these expressions explicity. The analysis of the system concerns the linearized equations in the vicinity of an arbitrary point in the solution space. If the values of the dependent variables at this point are indicated by the suffix "o", a non-linear relation like the sediment transport formula, for instance, is approximated by

$$S'_t(u_t,h,E) \approx S'_{t_o} + (u_t-u_{t_o})\left.\frac{\partial S'_t}{\partial u_t}\right|_o + (h-h_o)\left.\frac{\partial S'_t}{\partial h}\right|_o + (E-E_o)\left.\frac{\partial S'_t}{\partial E}\right|_o \qquad (15)$$

For each of the non-linear additional expressions, it is sufficient to specify the derivatives with respect to the relevant dependent variables.

After some elaboration of the equations, the most convenient way to specify the necessary quantities of this type turns out to be the specification of

$$T_1 \triangleq \frac{1}{1-\varepsilon_p}\left[\frac{h}{S'_t}\frac{\partial S'_t}{\partial h} - 1\right] \; ; \; T_2 \triangleq \frac{1}{1-\varepsilon_p}\left[\frac{u_t}{S'_t}\frac{\partial S'_t}{\partial u_t} - 1\right] \; ; \; T_3 \triangleq \frac{1}{1-\varepsilon_p}\frac{a}{S'_t}\frac{\partial S_t}{\partial a} \qquad (16a)$$

$$C_h \triangleq \frac{h}{c}\frac{dc}{dh} \; ; \; C_{gh} \triangleq \frac{h}{c_g}\frac{dc_g}{dh} \; ; \; R_u \triangleq \frac{u_t}{r}\frac{\partial r}{\partial u_t} \; ; \; R_h = \frac{h}{r}\frac{\partial r}{\partial h} \qquad (16b)$$

Since the wave number in the present wave models is inversely proportional to the phase celerity c, the relation between k and h is sufficiently characterized by k_o and C_h. Finally, the rigid-lid approximation provides the linear relation

$$h = z_s - z_b \qquad (17)$$

in which z_s is the prescribed elevation of the rigid lid.

Making use of these relations and definitions, and considering T_1, T_2, T_3, C_h, C_{gh}, R_u and R_h as constants in the vicinity of the point "o", the system of equations can be elaborated as described in Appendix I. The resulting system contains two equations describing how the wave field responds to small changes in the bottom topography, three equations describing how the current field responds to such changes and one equation describing how the bottom elevation responds to small changes in the wave and current fields. This last equation reads (also see: De Vriend, 1987b):

$$\frac{\partial z_b}{\partial t} + (T_2 - T_1)\frac{S'_t}{h}\left[\frac{u}{u_t}\frac{\partial z_b}{\partial x} + \frac{v}{u_t}\frac{\partial z_b}{\partial y}\right] - \beta S'_t\left[\frac{\partial^2 z_b}{\partial x^2} + \frac{\partial^2 z_b}{\partial y^2}\right] + T_2\frac{S'_t}{u_t^3} +$$

$$+ \left[-v^2\frac{\partial u}{\partial x} + uv\frac{\partial u}{\partial y} + uv\frac{\partial v}{\partial x} - v^2\frac{\partial v}{\partial y}\right] + T_3\frac{S'_t}{a}\left[\frac{u}{u_t}\frac{\partial a}{\partial x} + \frac{v}{u_t}\frac{\partial a}{\partial y}\right] = 0 \qquad (18)$$

This can be considered as an advection/diffusion equation for the bottom level, in which the last two terms, representing the effects of the wave and current fields, act as source terms. It shows that the bottom evolu-

tion must have a partly propagative, partly diffusive character, the former due to the non-linearity of the transport formula (otherwise the factor T_2-T_1 equals zero), the latter due to the bottom slope effect on the transport.

CHARACTERISTICS ANALYSIS

The system of equations derived in Appendix I can be analyzed with the theory of characteristics (Courant et al., 1961; also see Flokstra, 1981), which provides information on the elementary behaviour of the bottom changes, such as the celerity of bottom disturbances. Application of this technique to the same system without waves revealed (De Vriend, 1987b), that the bottom evolution has a propagative character if the bottom slope effect on the sediment transport is ignored. Even though in that case the transport is directed exactly downstream, bottom disturbances will not only propagate downstream with the well-known 1D celerity derived by De Vries (1969) and also showing up in Eq. (18): like an elementary disturbance in the water surface of a pond, they will also expand in all directions, in a peculiar star-shaped pattern (see Fig. 2).

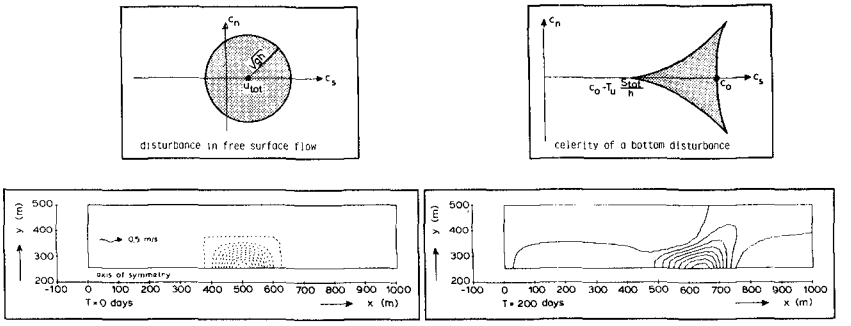

Fig. 2 Celerity patterns in 2DH models. Top left: current and surface wave. Top right: current and alluvial bottom. Bottom: numerical simulation of elementary bottom evolution.

Although formally the propagative character vanishes when the bottom slope effects are included (vide the diffusive character these effects introduce into Eq. (18)), numerical experiments have shown the typical celerity pattern to remain recognizable in the bottom evolution, like it is in the numerical experiment shown in Fig. 2. Therefore, a characteristics analysis with the bottom slope effects disregarded is expected to provide relevant information on the elementary bottom evolution, also in the presence of waves.
Application of the characteristics analysis to the present extensive system is a cumbersome task, which cannot possibly be described here. A detailed description and a discussion of the technique are given in a recent publication by the author (De Vriend, 1987b). Here only some of the results will be given. As the sustaining numerical experiments are awaiting the completion of an appropriate computer program, these results are presented with some reserve.

If the complete mild-slope equation is incorporated in the model, the bottom celerity components with respect to the stream-oriented co-ordinate system are given by

$$c_s = (T_2-T_1)\frac{S_t'}{h} + T_2\frac{S_t'}{h}\xi;\quad c_n = T_2\frac{S_t'}{h}\eta \tag{19}$$

in which the parameters ξ and η are related by

$$\eta^4 + (2\xi^2 - 5\xi - \tfrac{1}{4})\eta^2 + \xi(\xi+1)^3 = 0 \tag{20}$$

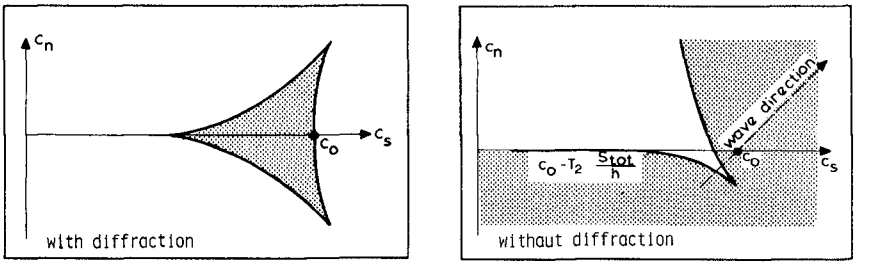

Fig. 3 Influence of wave diffraction on bottom celerities

These expressions, represented graphically in Fig. 3 (left), are exactly the same as for the case without waves. So the celerity is qualitatively independent of the way the sediment transport is influenced by the wave height: T_3 does not figure in (19) or (20). Quantitatively, the celerity does depends on the wave height via S_t'.
If the sediment transport depends on the angle between the wave and current directions the agreement with the case without waves is disturbed. So the conclusion is sensitive to the type of transport formula.

An entirely different celerity pattern can emerge when using simplified wave models. As this pattern is determined by the highest derivatives of the dependent variables in the various equations, disregarding diffraction leads to an essentially different system in this respect.

With the refraction equations (5) and (6), instead of (3) and (4), the expressions for the bottom celerity components read

$$c_s = (T_2-T_1)\frac{S_t'}{h} + T_2\frac{S_t'}{h}\xi + \frac{1}{2}C_{gh}T_3\frac{S_t'}{h} + \frac{1}{2}C_hT_3\frac{S_t'}{h}\xi^* \tag{21}$$

$$c_n = T_2\frac{S_t'}{h}\eta + \frac{1}{2}C_h\,T_3\frac{S_t'}{h}\eta^* \tag{22}$$

with the parameters ξ, η, ξ^* and η^* related by

$$\xi = (1-X)(2X-1) \text{ and } \eta = \pm 2X\left[X(1-X)\right]^{\frac{1}{2}} \tag{23}$$

$$\xi^* = X^4\,\frac{X^3(1-X)^3 - \left[X\xi\sin(\Theta-\delta)\cos(\Theta-\delta) + \eta(1-X)\sin^2(\Theta-\delta)\right]^2}{(1-X)^2\left[X^2\cos(\Theta-\delta) + \tfrac{1}{2}\eta\sin(\Theta-\delta)\right]^4} \tag{24}$$

$$\eta^* = 2X^6\,\frac{X\xi\sin(\Theta-\delta)\cos(\Theta-\delta) + \eta(1-X)\left[\sin^2(\Theta-\delta) - \tfrac{1}{2}\right]}{(1-X)\left[X^2\cos(\Theta-\delta) + \tfrac{1}{2}\eta\sin(\Theta-\delta)\right]^4} \tag{25}$$

in which the parameter X goes through all values between 0 and 1. Note that (23) is equivalent to (20), so that the celerties (21) and (22) consist of two parts, one corresponding with the case without waves and one proportional to T_3, the latter also depending on the angle between

the wave and current directions.
Fig. 3 (right) gives an example of this celerity pattern, for

$T_1 = -2$; $T_2 = 2$; $T_3 = 2$; $C_h = 0.5$; $C_{gh} = 0.375$ and $\Theta - \delta = 45°$

corresponding with the adapted Engelund-Hansen transport formula (Van de Graaff et al., 1979) and the shallow water wave celerities.
The resulting celerity pattern is essentially different from the one with diffraction included: it is no longer a closed curve and, consequently, the area of influence has become semi-infinite. On closer inspection, this behaviour is related to an essential property of purely refracting wave fields: if a wave ray encounters a bottom disturbance, its entire further course is influenced, and so is the wave height along this part of the ray (see. e.g. Dingemans, 1985).
Caution is required when interpreting these results in terms of applicability of types of wave models in the computation of transient morphological evolutions. The results suggest that a refraction model as described by Eqs. (5) and (6) be not applicable. It has to be noted, however, that the characteristics analysis focuses attention on a single aspect of the bottom evolution, viz. the celerity of small disturbances. It is thinkable that this aspect is irrelevant to certain situations. Only numerical experiments for well-selected test cases can show this.

HARMONIC ANALYSIS

In addition to the characteristics analysis, a harmonic analysis can be utilized to investigate the interaction between the constituents of a compound morphological model (cf. Deigaard, 1983 and Tsujimoto et al., 1985). It provides information on the propagation and amplification/damping of harmonic bottom waves. In principle, it can be applied to the transient morphological processes, considering the bottom-wave evolution in time, as well as to the equilibrium bottom topography, considering the variation of harmonic modes in space (cf. Struiksma et al., 1985).

So far, the harmonic analysis of the system including wave effects has only been successful for the transient processes. Like the characteristics analysis, this technique considers the linearized system, for simplicity about the point $(\Theta_o,\ a_o,\ u_o,\ v = 0,\ p_o,\ z_b = 0)$
in the solution space. The resulting system is given in Appendix I.
The technique of the harmonic analysis is well-known: harmonic perturbations of the type

$$z_b = \hat{z}_b \exp\{i(k_t t + k_x x + k_y y)\} \tag{26}$$

with k_t complex and k_x and k_y real, are substituted into the linearized system of equations, to yield a system in $\hat{\Theta}$, $\hat{a}$, $\hat{u}$, $\hat{v}$, $\hat{p}$ and $\hat{z}_b$, with k_t, k_x and k_y as parameters. The condition under which there is a non-trivial solution gives a relation between k_t, k_x and k_y, from which k_t can be solved if k_x and k_y are given.
In order to have a reference for the wave effects, this technique will first be applied to the system without waves. Without going into the algebraic operations, the result reads

$$\mathrm{Re}(\zeta_c) = \sigma\left\{-1 + \frac{4A_c\sigma^2\nu^2(\sigma^2+\nu^2) + 2B_c\nu^2[\sigma^2 + (1+Ru)\nu^2]}{4\sigma^2(\sigma^2+\nu^2)^2 + [\sigma^2 + (1+Ru)\nu^2]^2}\right\} \tag{27}$$

$$\mathrm{Im}(\zeta_c) = D_c(\sigma^2+\nu^2) + \frac{2A_c\sigma^2\nu^2\,[\sigma^2 + (1+Ru)\nu^2] - 4B_c\sigma^2\nu^2(\sigma^2+\nu^2)}{4\sigma^2(\sigma^2+\nu^2)^2 + [\sigma^2 + (1+Ru)\nu^2]^2} \tag{28}$$

$$\text{with:}\quad \zeta_c = \frac{k_t}{2(T_2-T_1)r_o}\ ;\ \sigma = \frac{u_o}{2r_o}k_x;\ \nu = \frac{u_o}{2r_o}k_y \tag{29}$$

$$A_c = \frac{T_2}{T_2-T_1}\ ;\ B_c = \frac{T_2}{T_2-T_1}\,\frac{1+R_u-R_h}{2}\ ;\ D_c = \frac{\beta}{T_2-T_1}\,\frac{2r_o h_o}{u_o} \tag{30}$$

Note that this system contains two important physical length scales (also see Struiksma et al., 1985), viz. the adjustment length of the flow, λ_w, and the adjustment length of the bottom, λ_s, given by

$$\lambda_w = \frac{u_o}{2r_o} \quad \text{and} \quad \lambda_s = \beta h_o \tag{31}$$

The second term in the expression for $\mathrm{Im}(\zeta_c)$ is easily shown to be negative if $A_c > 0$, and $R_h < 0$, as is usually the case. This means,that for $D_c = 0$, i.e. in the system without bottom slope effects, all modes are unstable. So this system has no stable solution (cf. De Vriend, 1985). For $D_c > 0$ (negative values are not realistic), the additional term in (28) is positive, i.e. the bottom slope effect on the sediment transport has a damping effect on bottom disturbances, as it should according to the bottom level equation (18). Besides, the additional term increases with the resultant wave number, so this damping effect will be stronger for shorter waves (which have steeper slopes).
As an example of how this works out quantitatively, Fig. 4 gives a graphical representation of (27) and (28), with and without bottom slope effects. The values of the constants correspond with the Engelund and

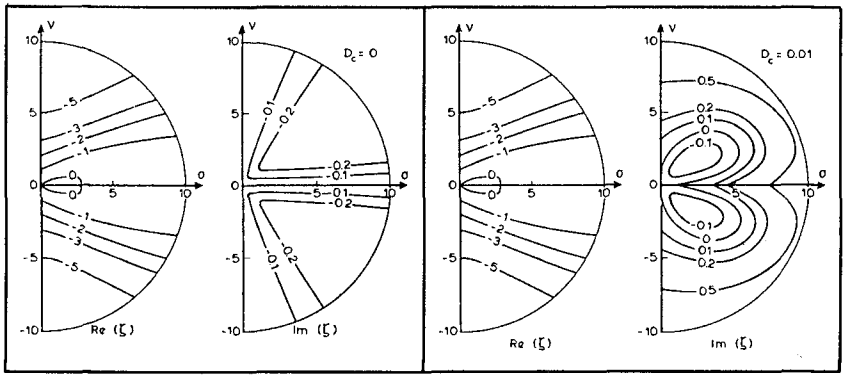

Fig. 4 Initial growth rate of harmonic bottom disturbances (current only)

Hansen transport formula ($T_1 = -1$, $T_2 = 4$) and Chezy's bottom friction law ($R_u = 1$, $R_h = -1$, $r_o = gu_o/[C^2h]$). In the case with bottom slope effects, D_c was chosen 0.01, which corresponds with $\beta \approx 4$. For $D_c = 0$, $\mathrm{Im}(\zeta_c)$ is always negative, indeed, whereas for $D_c \neq 0$, $\mathrm{Im}(\zeta_c)$ is only negative in two relatively small areas, representing fairly long bottom waves. The existence of such unstable modes is not necessarily unrealistic (Deigaard, 1983; also see Struiksma et al., 1985 and De Vriend, 1987a).

When applied to the system including waves, the harmonic analysis yields the following result

$$\mathrm{Re}(\zeta_w) = \sigma\{-1 + \frac{4A_w\sigma^2\nu^2(\sigma^2+\nu^2) + 2B_w\nu^2[\sigma^2+(1+R_u)\nu^2]}{4\sigma^2(\sigma^2+\nu^2)^2 + [\sigma^2+(1+R_u)\nu^2]^2} + \frac{4C_w\gamma^2\chi^2 - E_w(\phi^2+\chi^2)^2}{4\gamma^2\phi^2-(\phi^2+\chi^2)^2}\} \tag{32}$$

$$\mathrm{Im}(\zeta_w) = D_w(\sigma^2+\nu^2) + \frac{2A_w\sigma^2\nu^2[\sigma^2+(1+R_u)\nu^2] - 4B_w\sigma^2\nu^2(\sigma^2+\nu^2)}{4\sigma^2(\sigma^2+\nu^2)^2 + 5\sigma^2 + (1+R_u)\nu^2]^2} \tag{33}$$

with:

$$\zeta_w = \frac{k_t}{2(T_2-T_1+\frac{1}{2}C_{gh}T_3)r_o}\ ;\ \phi=\sigma\cos\theta_o+\nu\sin\theta_o;\ \chi=\sigma\sin\theta_o-\nu\cos\theta_o \tag{34}$$

$$A_w = \frac{T_2}{T_2-T_1+\frac{1}{2}C_{gh}T_3}\ ;\ B_w = A_w\frac{1+R_u-R_h}{2};\ D_w = \frac{\beta}{T_2-T_1+\frac{1}{2}C_{gh}T_3}\frac{2r_o h_o}{u_o} \tag{35}$$

$$C_w = \frac{\frac{1}{2}C_h T_3}{T_2-T_1+\frac{1}{2}C_{gh}T_3};\ E_w = \frac{\frac{1}{2}C_{gh}T_3}{T_2-T_1+\frac{1}{2}C_{gh}T_3};\ \gamma = \frac{u_o}{2r_o}k \tag{36}$$

Apart from the coefficients, these expressions are very much the same as in the case without waves: the only difference is an additional term in the expression for Re(ζ). This implies that the amplification/damping behaviour of the bottom disturbances remains qualitatively the same, with a predominant role for the bottom slope effects.

As a quantitative example, Fig. 5 gives graphical representations of (33) and (34), without and with bottom slope effects ($D_w = 0$ and $D_w = 0.01$, respectively), without and with diffraction ($\gamma = 0$ and $\gamma = 30$, respectively).

The values of the constants are chosen the same as in the example in Fig. 3, viz. $T_1=-2$, $T_2=2$, $T_3=2$, $C_h=0.5$, $C_{gh}=0.375$, but now with $\theta_o=0°$ (waves and current in the same direction) and with $R_u=1$ and $R_h=-1$ (Chezy). Apparently, the diffraction effect on Re(ζ_w) is rather small, especially for the longer modes.

These results suggest that the incorporation of diffraction in the wave model should have a minor effect on the elementary behaviour of bottom disturbances. However, caution should be exercised, again, when interpreting these results in terms of applicability of types of wave models. The analysis focuses attention on the evolution of small harmonic bottom perturbations, starting from the linearized system of equations. Besides, the indication it gives is contrary to the one given by the characteristics analysis. This does not imply that the two analyses yield contradictory results, since they consider different aspects (amplitude behaviour and propagation behaviour, respectively). Which of these aspects is decisive for the sensitivity of the model to diffraction is still not clear. Numerical model tests and further research are needed in order to arrive at definite conclusions.

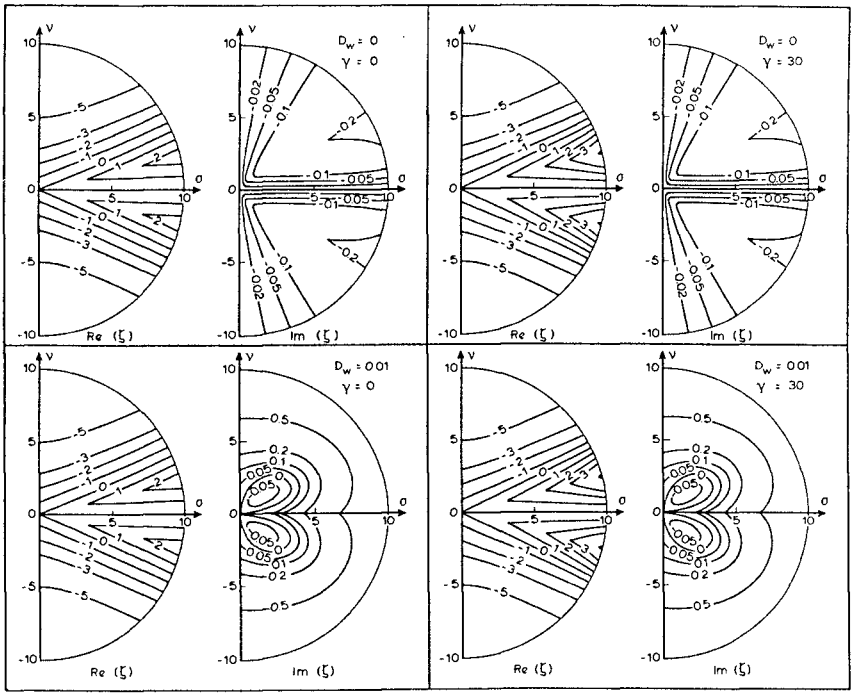

Fig. 5 Influence of wave diffraction on initial growth rate (waves + currents)

DISCUSSION

The investigated system, though including the principal interacting constituents (waves, currents, sediment transport, bottom level changes), is still a highly simplified representation of reality. For instance, the interaction via the response of wave breaking and the induced currents to morphological changes is left out of consideration. Especially in the surf zone, this seems to be an interaction of primary importance.

Nevertheless, the present analyses are practically relevant. If the dissipation of wave energy by breaking is formulated according to Battjes et al., (1978) and the corresponding driving forces per unit area are taken proportional to the dissipation density divided by the phase celerity (Longuet-Higgins, 1970; Dingemans et al., 1987), the relevant terms in the wave and current models are easily shown not to contain the highest derivatives of the dependent variables. Hence this interaction has no effect on the bottom celerity pattern found from the characteristics analysis. The harmonic analysis with this interaction included is still in progress, but is has already become clear that the bottom slope effect on the sediment transport is still a major (if not the only) damping agent in the system.

Another limitation of the present work is, that only linearized systems are considered. When there is a better outlook on the composition and the validity of mathematical models of transient 3D sea bed evolutions, their non-linear behaviour, including the possibility of bifurcations and chaotic behaviour, will have to be investigated.

The harmonic analysis of all variants and extensions of the model that have been investigated so far, clearly indicates that the bottom slope effect on the sediment transport is indispensable in the computation of transient morphological evolutions. If this slope-reducing mechanism is included, however, also the principal slope-generating mechanisms have to be taken into account, if it were only not to wind up with a zero beach slope.
In the nearshore zone, the onshore transport due to the asymmetry of the near-bottom orbital motion is a major slope-generating agent, as appears from investigations of coastal profile evolutions (Stive, 1986; De Vriend, 1986). A fascinating corroboration of this statement, though for edge waves instead of sea or swell, was given by Holman et al. (1982).
On the other hand, the wave-induced undertow in the surf zone causes an off-shore, so usually down-slope transport that is mostly stronger than the asymmetry-induced on-shore transport there (De Vriend et al., 1986). So, once the asymmetry-induced transport is included in a model of near-shore morphological evolutions, the transport due to the undertow, and hence the undertow itself, cannot be left out of consideration. This means that a depth-integrated current model is not sufficient for this kind of situations.
In most of the practical applications, the model area extends beyond the nearshore. Outside the surf zone, the undertow is absent and the waves induce only a much weaker drift current. The asymmetry-induced transport is found wherever the waves "feel" the bottom (so usually in large parts of the model), but it decreases as the water depth increases. This does not imply, that at deeper water the bottom slope effect is the only remaining cross-stream mechanism and that, consequently, a depth-integrated current model suffices. In the complex situations to which 2DH models use to be applied, the flow is curved almost as a matter of course. Besides, sand coasts without strong winds are rare and the coriolis-effect is present almost everywhere. Hence secondary flows due to wind, curvature and the coriolis-effect will occur and exert their influence on the sediment transport and the morphological changes. So in these cases the application of depth-integrated current models is disputable, as well.
This negative conclusion regarding depth-integrated current models does not mean that 2DH flow computation facilities are useless for morphological computations. Experience with river bend modelling (Struiksma et al., 1985) and recent investigations on the modelling of 3D nearshore currents (De Vriend et al., 1986) make clear, that without too limitative assumptions, the flow can be described with a standard depth-integrated model, extended with a simple profile technique for the secondary flow.

CONCLUSIONS

The two methods used to analyse the interaction between the constituents of the present class of compound 2DH mathematical models of transient sea bed evolutions yield contrary indications on the importance of diffraction in the wave model.

The harmonic analysis unambiguously shows, that the bottom slope effect on the sediment transport (via gravitation and via vertical advection) is indispensable for inherent stability of the mathematical system.
The necessity to include this bottom slope effect implies, that the influence of the asymmetry of the wave-induced orbital motion and of secondary flows has to be taken into account, as well. Consequently, depth-integrated current models are insufficient to describe the flow in models of 3D morphological evolutions, in the nearshore zone and in complex coastal areas.
Depth-integrated current models extended with a simple profile technique to describe the secondary flow appear to be suited for this kind of applications.

ACKNOWLEDGEMENTS

The investigations described herein were part of the TOW Coastal Research Programme, financed by the Netherlands Government and conducted jointly by the Ministry of Transport and Public Works (Rijkswaterstaat), Delft Hydraulics and the Technical University Delft. The author gratefully acknowledges Mr. M.W. Dingemans for his lessons in wave-field theory.

APPENDIX I - ELABORATION OF THE CONSTITUENT EQUATIONS

If the right-hand member of the eikonal equation (3) is named κ^2, this equation can be replaced by

$$\frac{\partial \Phi}{\partial x} = \kappa \cos\Theta \text{ and } \frac{\partial \Phi}{\partial y} = \kappa \sin\Theta \qquad (37)$$

Then the compatibility conditions for these phase function derivatives and the transport equation (4) can be elaborated to the linearized system

$$L_2(\Theta) - \frac{k^2}{\kappa^2}\frac{C_h}{h} L_1(h) + \frac{1}{2\kappa^2} L_1\left(\frac{\nabla^2 a}{a}\right) + \frac{C_h + C}{2\kappa^2 ha} gh\, L_1\left(\frac{\partial a}{\partial x}\frac{\partial h}{\partial x} + \frac{\partial a}{\partial y}\frac{\partial h}{\partial y}\right) + \text{h.o.t.} = 0 \qquad (38)$$

$$- L_1(\Theta) + \frac{2}{a} L_2(a) + \frac{1}{2\kappa^2} L_2\left(\frac{\nabla^2 a}{a}\right) + \left[\frac{C}{gh} + \left(1 - \frac{k^2}{\kappa^2}\right)\frac{C}{h}\right] L_2(h) + \\ + \frac{C_h + C}{2\kappa^2 ha} L_2\left(\frac{\partial a}{\partial x}\frac{\partial h}{\partial x} + \frac{\partial h}{\partial y}\frac{\partial h}{\partial y}\right) + \text{h.o.t.} = 0 \qquad (39)$$

in which ∇^2 denotes the Lapalician and "h.o.t." indicates higher order terms in the derivatives of a and h. The operators L_1 and L_2 are defined as

$$L_1 = \cos\Theta \frac{\partial}{\partial x} + \sin\Theta \frac{\partial}{\partial y} \quad \text{and} \quad L_2 = \sin\Theta \frac{\partial}{\partial x} - \cos\Theta \frac{\partial}{\partial y} \qquad (40)$$

The flow equations (7) though (10) remain unaltered, except for the linearization of the bottom shear stress

$$\frac{\tau_{bx}}{\rho h} = \left(\frac{\tau_{bx}}{\rho h}\right)_o + (u-u_o)\, r_o + \left(u_t - u_{t_o}\right) \frac{u_o r_o}{u_{t_o}} R_u + (h-h_o) \frac{u_o r_o}{h_o} R_h \qquad (41)$$

and a similar expression for the y-component.

Substitution of the linearized expression for the sediment transport, (15), into (12) and (13) and subsequently into the sediment balance equation (14) yields, after some elaboration and making use of the equation of continuity (9), the advection/diffusion equation (18).

Equations (38) through (41) and (7) through (9) form a representation of the system in which all derivatives refer to the dependent variables Θ, a, u, v, p and z_b (or h).
If this system is linearized about the point $(\Theta_o, a_o, u_o, v=0, p_o, z_b=0)$ in the solution space, i.e. if the x-axis is oriented downstream and the undisturbed bottom is horizontal, it can be written as

$$L_2(\Theta') + \frac{C_h}{h_o} L_1(z_b') + \frac{1}{2a_o k_o^2} L_1(\nabla^2 a') = 0 \qquad (42)$$

$$- L_1(\Theta') - \frac{C}{gh_o} L_2(z_b') + \frac{2}{a_o} L_2(a') + \frac{1}{2a_o k_o^2} L_2(\nabla^2 a') = 0 \qquad (43)$$

$$u_o \frac{\partial u'}{\partial x} = - \frac{1}{\rho}\frac{\partial p'}{\partial x} - (1 + R_u)\, r_o u' - R_h \frac{u_o r_o}{h_o} h' \qquad (44)$$

$$u_o \frac{\partial v'}{\partial x} = - \frac{1}{\rho}\frac{\partial p'}{\partial y} - r_o v' \qquad (45)$$

$$\frac{\partial u'}{\partial x} + \frac{\partial v'}{\partial y} - \frac{u_o}{h_o}\frac{\partial z_b'}{\partial x} = 0 \qquad (46)$$

$$\frac{\partial z_b'}{\partial t} + (T_2 - T_1) \frac{S_{t_o}}{h_o} \frac{\partial z_b'}{\partial x} - \beta S_{t_o} \nabla^2 z_b' - T_2 \frac{S_{t_o}}{u_o} \frac{\partial v'}{\partial y} + T_3 \frac{S_{t_o}}{a_o} \frac{\partial a'}{\partial x} \qquad (47)$$

in which the primes indicate the deviation of the relevant quantity from the solution in point "o" in the solution space. The operators L_1 and L_2 are given by (40), with $\Theta = \Theta_o$.
The system (I.9) through (I.14) is subject to the harmonic analysis.

CHAPTER 125

Dynamic stability of rock slopes and gravel beaches

J.W. van der Meer* and K.W. Pilarczyk**

Abstract

More than 150 tests have been analyzed in order to describe the dynamically stable profiles of rock slopes and gravel beaches under wave attack. Relationships between profile parameters and boundary conditions have been established. These relationships have been used to develop a computer program. This program is able to predict the profiles of slopes with an arbitrary shape under varying wave conditions, such as those found in storm surges and during the tidal period.

Introduction

An extensive research program has been performed on the static and dynamic stability of rubble mound revetments, breakwaters and gravel beaches. The results of the first part of this program, which dealt with static stability, were presented at the 19th International Conference on Coastal Engineering (Van der Meer and Pilarczyk, 1984). New stability formulae were given mainly based on statically stable rubble mound revetments with an impermeable core. Rubble mound breakwaters with a permeable core were subsequently tested and results were presented at the Breakwaters '85 Conference, (Van der Meer, 1985). A complete analysis of this part of the research (the static stability) was given by Van der Meer (1986-1 and 1986-2). Based on more than 250 tests, two practical stability formulae were given which take into account the wave period, storm duration and permeability of the structure.

The second part of the research program, dealing with dynamically stable structures and profile development, forms the subject for the present paper. About 150 tests have been analyzed.

Dynamic stability

Most breakwaters and revetments are designed in such a way that only little damage is allowed for in the design criteria, damage being defined as the displacement of armour units. This criteria demands large and heavy rock or artificial concrete elements for armouring. A more economic solution can be a structure with smaller elements, profile development being allowed in order to reach a stable profile.

The $H_s/\Delta D_{n50}$ parameter can be used to give the relationship between different structures, see Figure 1, where: H_s = significant wave height, Δ = relative mass density and D_{n50} = nominal diameter of average stone mass.

* Delft Hydraulics, P.O. Box 152, 8300 AD Emmeloord, The Netherlands
** Road and Hydraulic Engineering Division, Rijkswaterstaat, P.O. Box 20904, 2500 EX The Hague, The Netherlands

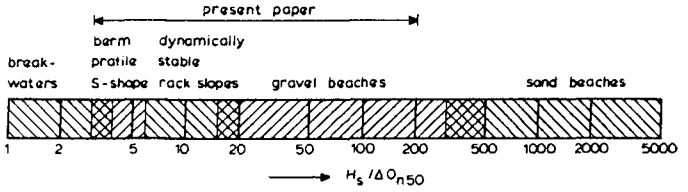

Figure 1 Type of structure as function of $H_s/\Delta D_{n50}$

Small values of $H_s/\Delta D_{n50}$ give structures with large armour units. Large values imply gravel beaches and sand beaches. Figure 1 gives the following rough classification:

- statically stable breakwaters: $H_s/\Delta D_{n50} = 1 - 4$
- berm breakwaters and S-shaped profiles: $H_s/\Delta D_{n50} = 3 - 6$
- dynamically stable rock slopes: $H_s/\Delta D_{n50} = 6 - 20$
- gravel beaches: $H_s/\Delta D_{n50} = 15 - 500$
- sand beaches: $H_s/\Delta D_{n50} > 300$

The area given by $H_s/\Delta D_{n50} = 3 - 200$ will be discussed in the paper.

Governing variables

The object of this paper is to show how the dynamic profile is influenced by the strength and load parameters. The governing strength parameter variables are:

stone size, grading of the stone, shape of the stone, initial slope and shape of the foreshore.

In the paper the size of armour units or gravel is referred to as the average mass of graded rubble or gravel, W_{50}, or the nominal diameter, D_{n50}, where:

$$D_{n50} = (W_{50}/\rho_a)^{1/3} \quad (1)$$

where: D_{n50} = nominal diameter (m)
W_{50} = 50% value of the mass distribution curve (kg)
ρ_a = mass density of stone (kg/m^3)

The relative mass density of the stone in water can be expressed by:

$$\Delta = \rho_a/\rho - 1 \quad (2)$$

where: Δ = relative mass density (-)
ρ = mass density of water (kg/m^3)

The grading of the stone is expressed here by D_{85}/D_{15}, where the subscripts refer to the 85 and 15 percent value of the sieve curve, respectively. The shape of the stone can be angular, rounded or flat. The initial profile can vary from a uniform slope to a berm profile or a structure with a low crest.

The governing load parameter variables are:
significant wave height H_s, average wave period T_z, storm duration given by the number of waves, N, and water level (tide).

Test equipment, materials and procedure

Tests were conducted at Delft Hydraulics in a small scale 1.0 m wide, 1.2 m deep and 50 m long wave flume and in the large Delta flume which is 5.0 m wide, 7.0 m deep and 230 m long. Random wave generators were used equipped with a system for measuring and compensating for waves reflected at the wave board. With this system standing waves and basin resonance were avoided. A surface profiler on a computer controlled carriage was developed for the investigation. This profiler is described in more detail by Van der Meer and Pilarczyk (1984).

Broken stone or gravel was used for the tests. The nominal diameter ranged from 4 mm upto 27 mm and the wave height from 0.13 m up to 1.7 m. Each complete test consisted of a pre-test sounding of the slope, a test of 1000 waves, an intermediate sounding, a test of 2000 more waves and a final sounding.

Test programme

The present research on dynamic stability can be divided into three parts:

- The research of Van Hijum and Pilarczyk (1982) on gravel beaches for which $H_s/\Delta D_{n50}$ was in the range 15 - 30, see Figure 1. The results of this research have been included in the present analysis. The research included also three-dimensional tests, resulting in derivation of a longshore transport formula for gravel.
- $H_s/\Delta D_{n50} \approx 3 - 15$. This range was investigated in the small scale flume. The influence of all the governing parameters mentioned above were investigated in this range.
- $H_s/\Delta D_{n50} \approx 30 - 200$. This range can only be investigated on a large scale since small scale investigations would give unacceptable diameters in the order of 1 mm and smaller, for which the fall velocity of the material becomes more important than the diameter. This range was tested in the Delta flume, by using 19 mm and 4 mm gravel and a wave attack with $H_s = 0.5 - 1.7$ m.

The research of Van Hijum and Pilarczyk (1982) resulted in 43 tests. About 120 dynamically stable tests were conducted in the small scale flume. Nine tests were performed in the Delta flume on dynamic stability.

Results

Each test resulted in two measured profiles in addition to the initial profile, one after a wave attack of 1000 waves and one after 3000 waves. A first analysis was done by comparing profiles for various tests. The conclusions from this analysis were used to develop a model for the dynamic profile. Relationships were subsequently derived to describe this model as a function of the boundary conditions.

Figure 2 shows the profiles measured for three tests. The initial slope was a 1:5 uniform slope, the wave period was $T_z = 1.75$ s and the diameter was $D_{n50} = 0.011$ m for all tests. The significant wave heights were $H_s = 0.129$, 0.188 and 0.237 m respectively; the lowest wave height in fact produced the smallest changes in slope. From Figure 2 it can be concluded that the wave height has a large influence on the profile.

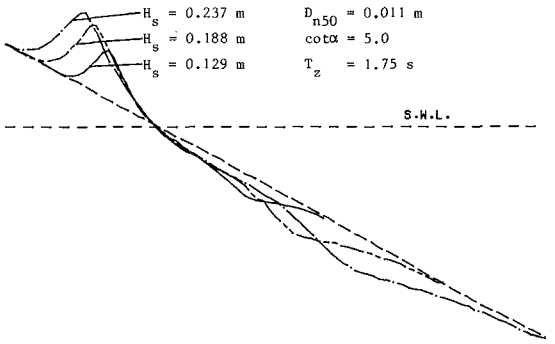

Figure 2 Influence of wave height

Figure 3 shows the influence of the wave period; the initial slope was again a 1:5 uniform slope and the nominal diameter was D_{n50} = 0.011 m. The significant wave height for all three tests was H_s = 0.13 m. The wave periods were T_z = 1.32, 1.77 and 2.52 s; the shortest period in fact produced the smallest changes in slope. A similar conclusion can be drawn as for the wave height namely that the wave period has a large influence on the profile. From Figures 2 and 3 can be seen that the wave height and wave period have the same order of influence on the slope.

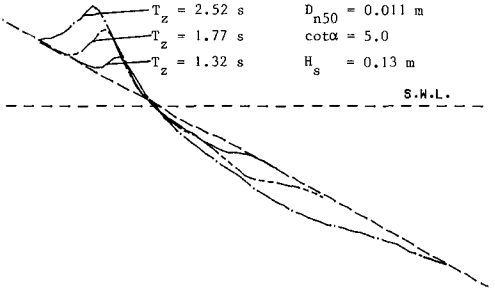

Figure 3 Influence of wave period

By analysis it was shown that the storm duration (the number of waves N) and the diameter (D_{n50}) also had a large influence on the dynamic profile. For small diameters, however, it was concluded that some parts of the profile, for example the crest height, were not influenced by the diameter.

In most tests the initial slope was a 1:3 or 1:5 uniform slope. In other tests a berm breakwater was tested with a 1:3 upper slope, a horizontal berm above, at, or below the still water level, and a 1:1.5 slope for the lower part. Low crested structures were also tested. Figure 4 shows a comparison of two tests with the same boundary conditions, but with different initial slopes. The initial slopes were a 1:3 uniform

slope and a berm breakwater with the berm at the still water level. The wave height was H_s = 0.19 m, the period T_z = 2.5 s and the nominal diameter was D_{n50} = 0.0257 m. The figures are compared by plotting the profiles at the same intersection with the still water level.

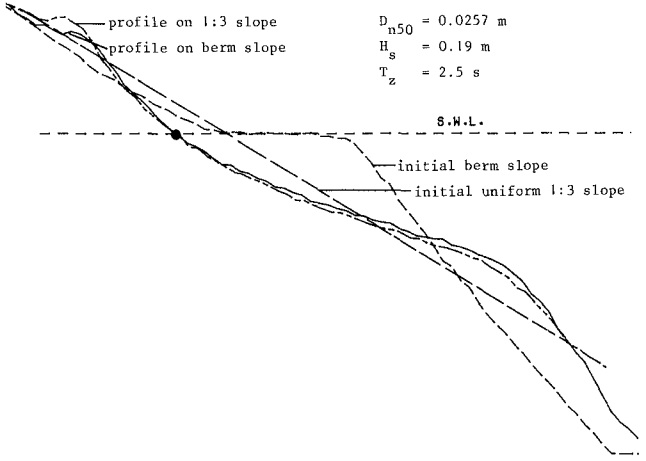

Figure 4 Influence of the shape of the initial slope

The conclusion is clear. In spite of the different initial slopes, the same profile is reached for a large part of the total profile. This part ranges from the crest to the transition to a steep slope (the step) at the deep water end of the profile. Figure 5 gives the same profiles for a 1:5, a 1:3 and a 1:1.5 uniform initial slope. Only the upper and lower parts of the profile are in fact dependent on the initial slope. The direction of transport of material and the position of the profiles is, of course, largely influenced by the initial slope.

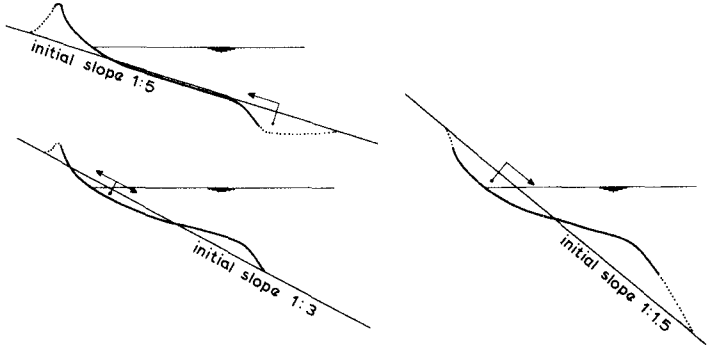

Figure 5 Profile obtained with different initial slopes

The same conclusion can be drawn from the results of the tests in which the influence of tide was investigated. Figure 6 gives the results

of one of these tests. Three profiles were measured during the test, two at high water and one at low. The wave height (H_s = 0.128 m) and period (T_z = 1.73 s) were constant during the test. The final profile in Figure 6, the second high water, is almost the same as the first, the first high water profile. In fact, the profile changed directly with changing water level.

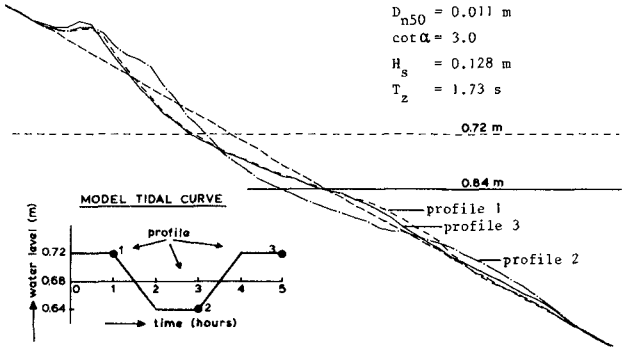

Figure 6 Influence of tide

Static stability is largely dependent on the initial slope, as is clearly expressed by the well known Hudson formula. Of course, for dynamically stable structures which are almost statically stable, the initial slope has also influence on the profile. It can be stated that, for $H_s/\Delta D_{n50} < 10 - 15$ the initial slope has influence on the profile.

From the analysis it could be concluded that the wave spectrum shape had no or only minor influence on the profile, provided that the average wave period was used to compare the tests, and not the peak period. The same conclusion was found for static stability by Van der Meer and Pilarczyk (1984). The grading of the material also has no or only minor influence on the profile, using the nominal diameter, D_{n50}, as a reference.

Summarizing, from the comparison of profiles it was concluded that wave height H_s, wave period T_z, number of waves, N, and nominal diameter D_{n50}, all have influence on the dynamic profile.

The spectrum shape and the grading of the material have no or only minor influence; the initial slope has no influence on a large part of the profile for $H_s/\Delta D_{n50} > 10 - 15$.

Development of a model of a dynamic profile.

On the basis of the conclusions described above a model was developed to describe the dynamic profile. Two points on the profile are very

important. These are shown in Figures 7 and 8, where profiles for a 1:3 and 1:2 uniform slope are illustrated schematically. The first point is the upper point of the beach crest and the second point the transition below SWL from the gentle part to a steeper part. The local origin is chosen at the intersection of the profile and the still water level.

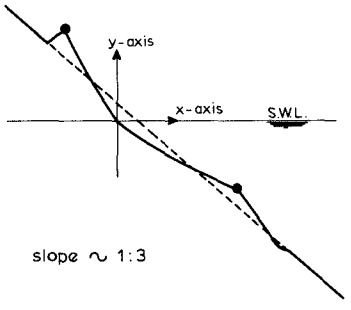

Figure 7 Schematized 1:3 profile

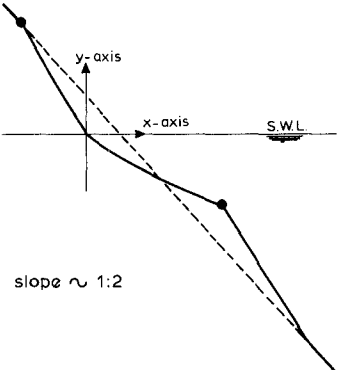

Figure 8 Schematized 1:2 profile

Figure 9 shows the model for a dynamic profile. A 1:5 uniform initial slope is shown with a high beach crest and a step. The profile is schematized by using a number of parameters all of which are related to the local origin or to the water level. The beach crest is described by the height, hc, and the length, lc. The transition to the step is described by the height, hs, and the length, ls. Curves, described by power functions, start at the local origin and go through these two points. The run-up length is described by the length, lr. The step is described by two angles, β and γ. Finally, the transition from β to γ is described by the transition height, ht.

The final analysis must result in relationships which describe the above profile parameters as a function of the boundary conditions. The height and length parameters lr, hc, lc, hs, ls and ht can be related to the nominal diameter, D_{n50}, or to the wave height, H_s, in order to get dimensionless parameters.

Development of relationships

First the influence of the storm duration was analyzed. Long duration tests (up to 25,000 waves) and the ratio of the parameters after 1000 and 3000 waves were used. The influence of the storm duration can be described by:

$$par = aN^b \tag{3}$$

where: par = lr, hc, lc, hs, ls or ht
a and b are curve-fitting coefficients.

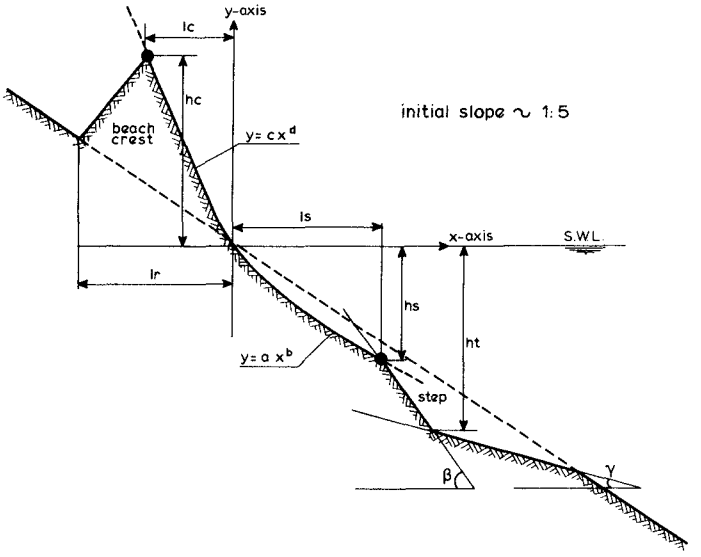

Figure 9 Model for dynamic profile

The coefficient b was established for each parameter. A dimensionless parameter, including the storm duration, can be expressed by:

$$par/D_{n50}N^{b} \quad \text{or} \quad par/H_{s}N^{b}$$

For the height and length parameters this resulted in:

- run-up length : $lr/D_{n50}N^{0.05}$ or $lr/H_{s}N^{0.05}$
- crest height : $hc/D_{n50}N^{0.15}$ or $hc/H_{s}N^{0.15}$
- crest length : $lc/D_{n50}N^{0.12}$ or $lc/H_{s}N^{0.12}$
- step height : $hs/D_{n50}N^{0.07}$ or $hs/H_{s}N^{0.07}$
- step length : $ls/D_{n50}N^{0.07}$ or $ls/H_{s}N^{0.07}$
- transition height: $ht/D_{n50}N^{0.04}$ or $ht/H_{s}N^{0.04}$

The parameter which is most influenced by the storm duration is the crest height hc, where the power coefficient amounts to 0.15. The remaining governing variables are the wave height and wave period. If the height and length parameters are related to the wave height, the remaining variable is only the wave period. This wave period can be described in a dimensionless form by using the wave steepness H_s/L_z, where $L_z = gT_z^2/2\pi$. By doing this the influence of the diameter has been ignored. As already concluded, this might be the case for high $H_s/\Delta D_{n50}$ values (above 15 - 30). One has then to determine the following relationship:

$$par/H_{s}N^{b} = f\ (H_s/L_z) \qquad (4)$$

If the diameter influences the height or length parameter it is reasonable to relate these height and length parameters and also the wave height and period to the nominal diameter. The wave height can be described by the $H_s/\Delta D_{n50}$ or the N_s-number which has also been used for static stability analysis, Van der Meer (1984). The wave period can be related to the nominal diameter by the following expression:

$$\text{dimenionless wave period} = \sqrt{g/D_{n50}}\ T_z \tag{5}$$

From the analysis of the profiles it was concluded that wave height and period had similar effect on the profile. This conclusion results in a combined parameter, HoTo, for the wave height and wave period.

$$\text{HoTo} = H_s/\Delta D_{n50} * \sqrt{g/D_{n50}}\ T_z \tag{6}$$

Using this parameter, HoTo, the following relationship should be established for each length or height parameter:

$$\text{par}/D_{n50}\ N^b = f(\text{HoTo}) \tag{7}$$

Equations (4) and (7) are the basis for the description of the profile parameters. Figure 10 shows Equation (4) for the crest height, hc, for several HoTo values > 1000. Since all the HoTo values lie on the one curve, irrespective of their individual values, this implies that different diameters fit the same relationship which in turn means that indeed the crest height is not influenced by the diameter for these particular HoTo values.

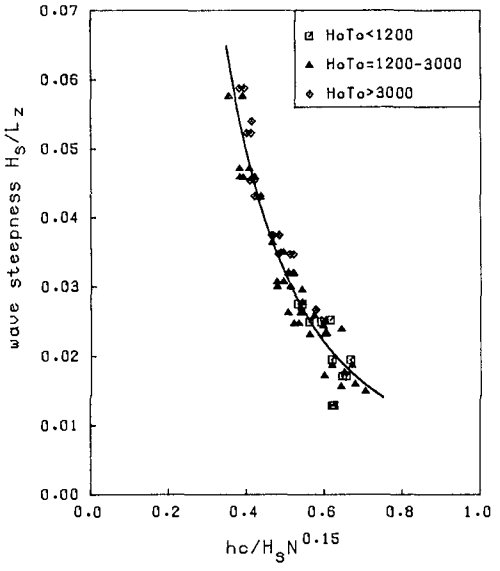

Figure 10 Relationship between crest height, hc, and wave steepness, H_s/L_z

Figure 11 shows the results for the crest length, lc, as a function of the wave steepness. Here different diameters show a different relationship. It is clear that, for this length parameter, the influence of the diameter cannot be ignored, even not for very small grain sizes.

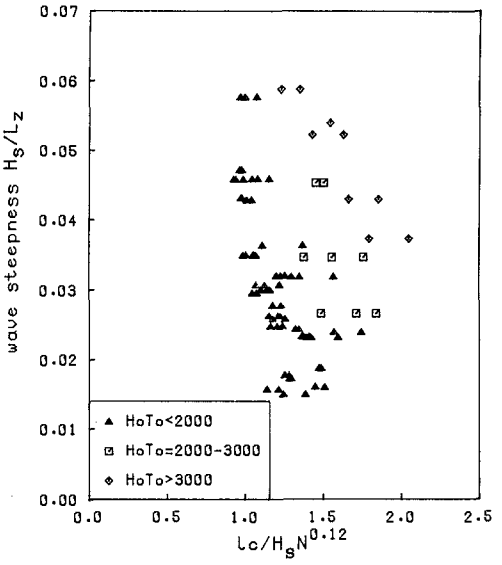

Figure 11 Relationship between crest length, lc, and wave steepness, H_s/L_z

Figure 12 shows again the crest length, lc, but in this case for the complete area for dynamic and static stability; this is achieved by using a logarithmic scale. For HoTo values smaller than 100 the slopes are stable as required in the traditional breakwater design. For HoTo values higher than 100,000 the transition area to sand beaches is entered. The highest point in the figure was found using 4 mm gravel with a wave height of about 2 m. On the horizontal axis the crest length, lc, is now related to the grain diameter instead of the wave height. Figure 12 shows also that for the transition to static stability, the lower part of the figure, the initial slope becomes important. The curves show a small difference between a 1:3 and 1:5 uniform slope.

Figures of the type shown in Figures 10 to 12 where plotted for each parameter. For all height parameters (hc, hs and ht) a relationship such as Equation (4) was established for high HoTo (HoTo > 1000-2000) values:

- crest height : $hc/H_sN^{0.15} = 0.89\ (H_s/L_z)^{-0.5}$ see Figure 10 (8)
- step height : $hs/H_sN^{0.07} = 0.22\ (H_s/L_z)^{-0.3}$ (9)
- transition height: $ht/H_sN^{0.04} = 0.73\ (H_s/L_z)^{-0.2}$ (10)

For the length parameters (lr, lc and ls), relationships for high HoTo values were established according to Equation (7):

- run-up length: $HoTo = 2.9\ (lr/D_{n50}N^{0.05})^{1.3}$ (11)

- crest length : $HoTo = 21\ (lc/D_{n50}N^{0.12})^{1.2}$ see Figure 12 (12)

- step length : $HoTo = 3.8\ (ls/D_{n50}N^{0.07})^{1.3} + 180$ (13)

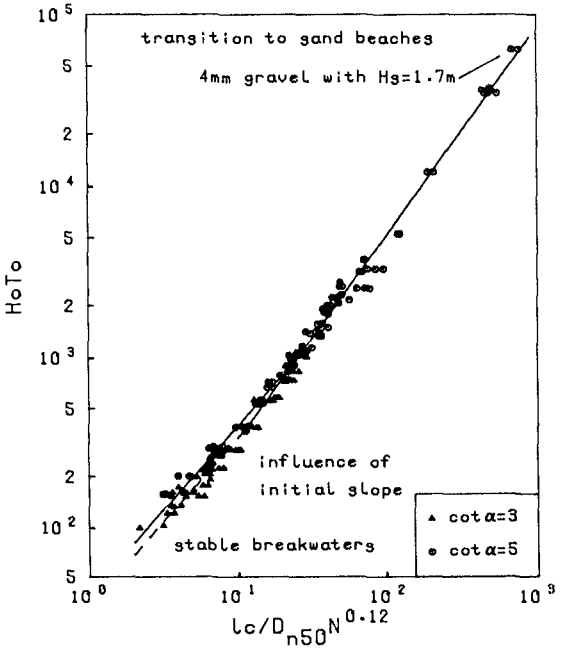

Figure 12 Relationship between crest length, lc, and HoTo

For lower HoTo values (HoTo < 1000 - 2000) an equivalent slope angle was introduced into the equations. To summarize two relationships were established for each length or height parameter, describing the influence in the lower and higher HoTo area. Relationships for the angles β and γ were also established.

Curves described by power functions start at the local origin, and go through the points described by hc and lc and by hs and ls, repectively, see Figure 9. From regression analysis it follows that the curves can be described by:

$y = a\ x^{0.83}$ below SWL, and (14)

$y = a\ (-x)^{1.15}$ above SWL (15)

where the coefficients a are determined by hc, lc and hs and ls.

Verification of the model

All the relationships for the height and length parameters, the power curves, the two angles β and γ and the method used to establish the equivalent slope angles for lower HoTo values were used to develop a computer program. This program can be used to calculate the profile, starting from an arbitrary slope and with varying water levels (tide) and wave conditions.

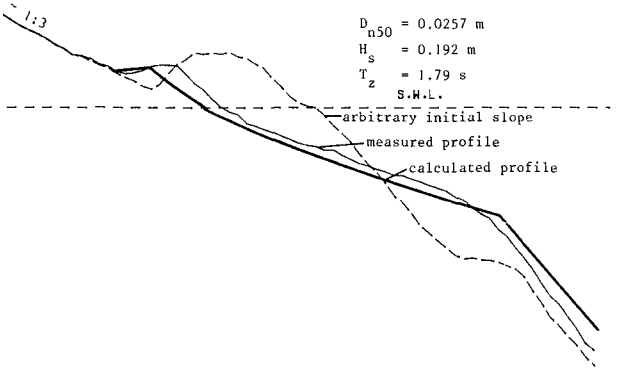

Figure 13 Measured and calculated profile developed from an arbitrary initial slope

In one test the man who constructed all the models was asked to build an arbitrary slope in the way he preferred. Figure 13 shows the slope he constructed and the measured and computed profile. The initial slope had an upper slope of 1 in 3 and a lower slope, with some irregularities, varying between 1 in 1.5 and 1 in 2. Figure 14 shows the calculation procedure and the results of the computer model. First the profile is calculated with the local origin at the intersection of the initial profile with the still water level. It is clear that this is not the right position of the profile, but it shows that the model parameters are independent of the initial slope and that the profile can be drawn anywhere. By means of an iteration process the profile was moved along the still water level untill the mass balance was fulfilled. The profile in the middle of Figure 14 was obtained after the fifth iteration and the profile on the left shows the final position.

Figure 13 shows the comparison between calculation and measurement. Some differences exist, but it can be concluded that the agreement is reasonable.

Figure 15 shows the calculation of the profiles for the same boundary conditions as those described for Figure 6, where the influence of tide was investigated. Here again the calculated profile at the end of the tide, Profile 3, is very similar to that for the first profile, Profile 1. The agreement between measurement (Figure 6) and calculation (Figure 15) is very good.

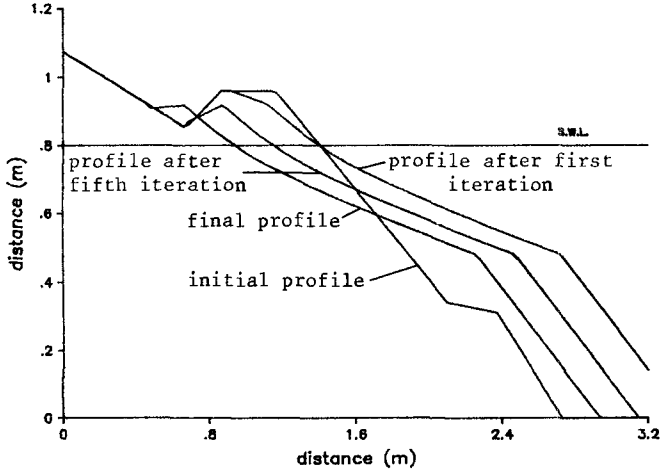

Figure 14 Calculation of dynamic profile

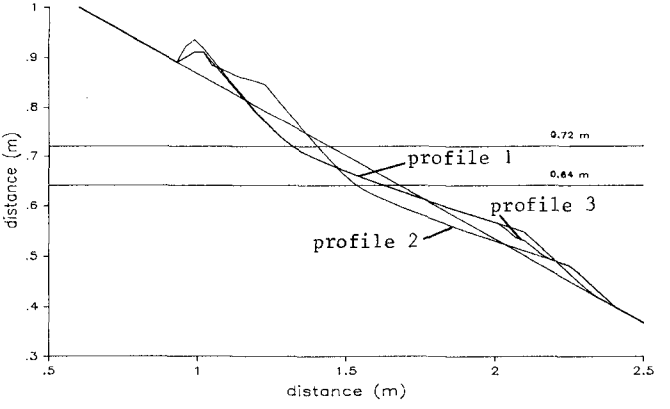

Figure 15 Verification of test shown in Figure 6 (tide)

Applications

The model can be used to describe the behaviour of rock and gravel beaches, including the influence of storm surges and tides. It can also be used to predict the stable profile for a berm type breakwater. The length of the gentle part of a berm type breakwater can be estimated and also the position of this part below the still water level. Another application is the prediction of the behaviour of core and filter layers under construction when a storm hits the incomplete part of a breakwater.

Special attention should be payed to structure with small diameters. The limitation of applicationis determined by the longshore transport under oblique wave attack. Van Hijum and Pilarczyk (1982) have derived a longshore transport formula for gravel. This formula was also described by Pilarczyk and Den Boer (1983).

Conclusions

More than 150 tests have been analysed to develop a computer model which is able to describe dynamically stable profiles. Initially conclusions were drawn by comparing profiles. These conclusions were then used to schematize the profile. The parameters for the schematized profile were then related to the boundary conditions. These relationships were used to develop a computer model and this model was verified using the test results.

Wave Transmission across Submerged Near-Surface Breakwaters

Clark B. Adams[1] and Choule J. Sonu, Ph.D.,[2] Members, ASCE

Abstract: Wave transmission across a submerged breakwater at Santa Monica, California, is examined through a three-dimensional model test. The results agree with empirical criteria previously proposed by Tanaka (1976).

Introduction

In 1983, El Niño came to California. By the time it left, over 20 piers and breakwaters had been damaged, countless beaches had lost sand, and new records for high tide levels had been set. At Santa Monica, the municipal pier was severely damaged. The seaward 120 meters of the pier were completely destroyed as were 110 meters of the adjoining Newcomb Pier. This occurred despite the fact that a submerged breakwater partially protects the pier from offshore swell.

The submerged breakwater was to figure prominently in repair alternatives considered by the City as they sought a plan most responsive to their needs. A major issue was whether to rebuild the breakwater and utilize its protective ability in developing the pier repair plans or to concentrate the reconstruction effort in strengthening the pier and avoid expending resources on the breakwater. To aid in making this decision, the City's consultant, Daniel, Mann, Johnson, & Mendenhall (DMJM), commissioned a three-dimensional model study of the site to investigate the effect that various breakwater configurations had on the alternative pier designs.

This paper compares the data on wave transmission across the submerged breakwater at Santa Monica obtained from the model study to results of wave transmission studies presented by Tanaka (1976). The Santa Monica data tend to corroborate Tanaka's results, suggesting their use in design application.

Setting

Santa Monica is part of the Los Angeles metropolitan area. Figure 1 shows the location of the site. The breakwater and pier are at the head of Santa Monica Bay, a broad open body of water bounded by the Santa Monica Mountains to the north and the Palos Verdes Peninsula to the

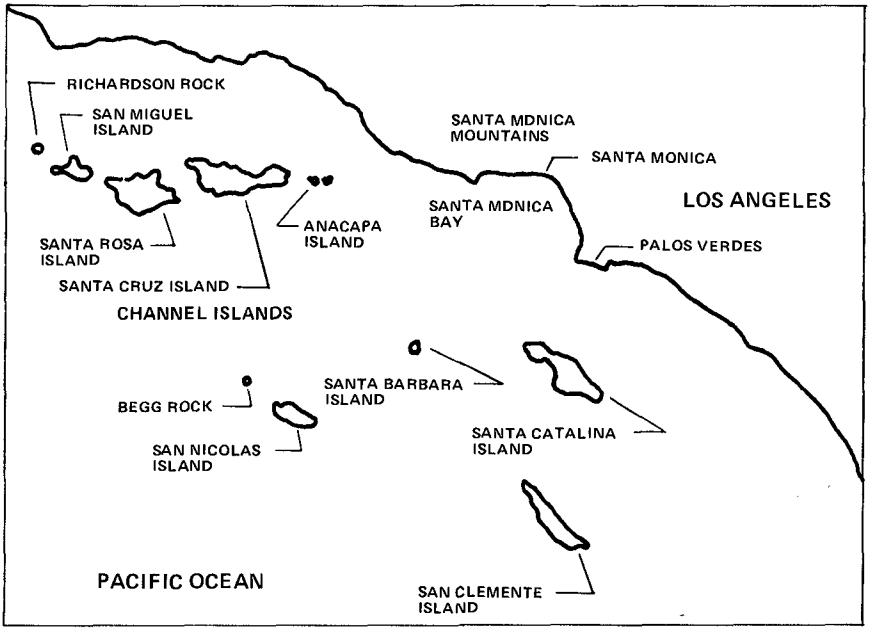

Figure 1. Site Location

south. The site is partially protected from offshore swell by Santa Catalina Island, Santa Barbara Island, San Nicolas Island, the Channel Islands, and Point Conception.

The Santa Monica shoreline is a broad sandy beach at the base of a 9 to 12 meter high bluff. Littoral transport is generally toward the south. Man-made structures such as the Santa Monica breakwater, the Marina del Rey jetties, and the Redondo Harbor breakwater interrupt this flow of sand at several points along the bay until the Redondo submarine canyon finally traps most of the remaining littoral drift at the southerly end of the bay and diverts it offshore.

History

A review of the history surrounding the Santa Monica breakwater will help in understanding several unusual aspects of its configuration. Man-made structures began to be constructed on Santa Monica Beach as early as the 1870s. The first structure on record was a small pier located near the site of the present pier. By 1876, a railroad pier supported by a substantial number of pilings had been built. In 1908, the first municipal pier was built; it failed 12 years later. The present municipal pier was built in 1921.

The Santa Monica breakwater was constructed in 1933 and 1934 by the City to provide a pleasure boat anchorage. The breakwater was

constructed parallel to the shoreline about 610 meters long and was located about 610 meters offshore. Figure 2 illustrates the breakwater configuration as it was constructed. The top elevation was 3 meters

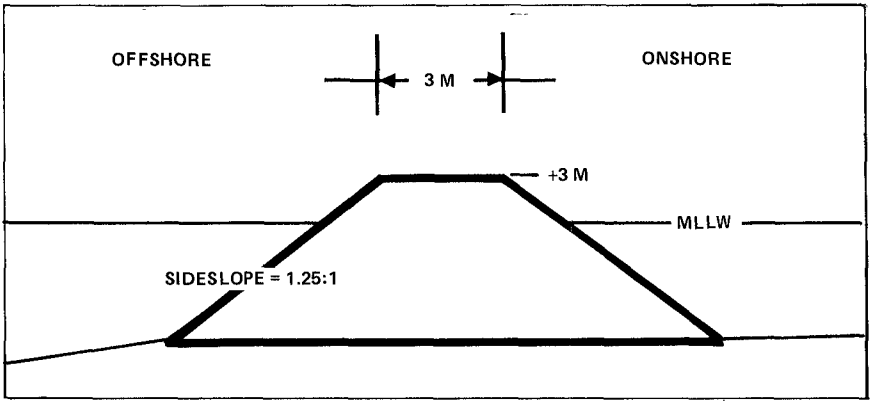

Figure 2. Original Santa Monica Breakwater Configuration

above mean lower low water (MLLW) and had a crest width of 3 meters. It had fairly steep sideslopes of 1.25 horizontal to 1 vertical. A rapid siltation of the anchorage followed the breakwater construction, and the beach behind the breakwater began advancing seaward. By 1937, as many as 245 anchorages had been lost to siltation. At the same time, the breakwater began deteriorating, and there are accounts of wave damage creating a gap in the breakwater as early as August 1934.

Based on survey data of a typical cross-section 30 meters from the northern end contained in the damage survey report of the Federal Emergency Management Agency dated July 21, 1983, the breakwater lost approximately 0.3 meter of its crest height after the first year of construction, another one meter by 1956, and an additional 0.2 meter by 1972. A survey of this breakwater after the 1983 storms showed the crest elevation of this section had lowered another 3 meters since 1972, although it is difficult to determine if the reduction was due to the storm or if it occurred gradually throughout the 11-year period. Figure 3 shows the site in 1975 and 1983 and illustrates the relative position between the pier and the breakwater. The shoreline bulge in the lee of the breakwater seen on the 1975 picture has retreated by 1983, possibly as a result of the deterioration of the breakwater. Figure 3 also illustrates the damage to the pier caused by the 1983 storms.

The 1983 configuration is illustrated in Figure 4. The crest height is -1.6 meters MLLW and the crest width at that level is 13.4 meters. Material from what was the upper portion of the breakwater has fallen down, creating a more stable sideslope of 2 horizontal to 1 vertical.

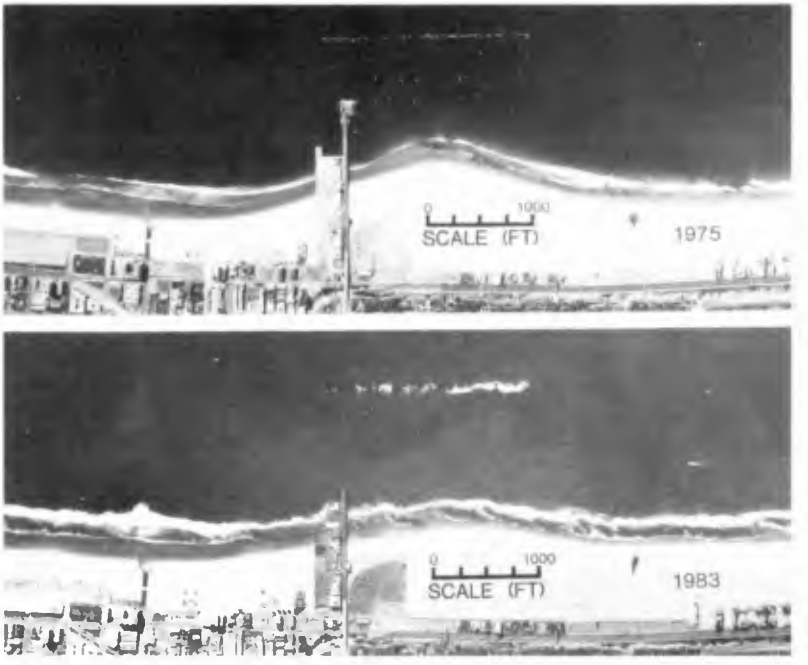

Figure 3. Comparison of Shorelines for 1975 and 1983

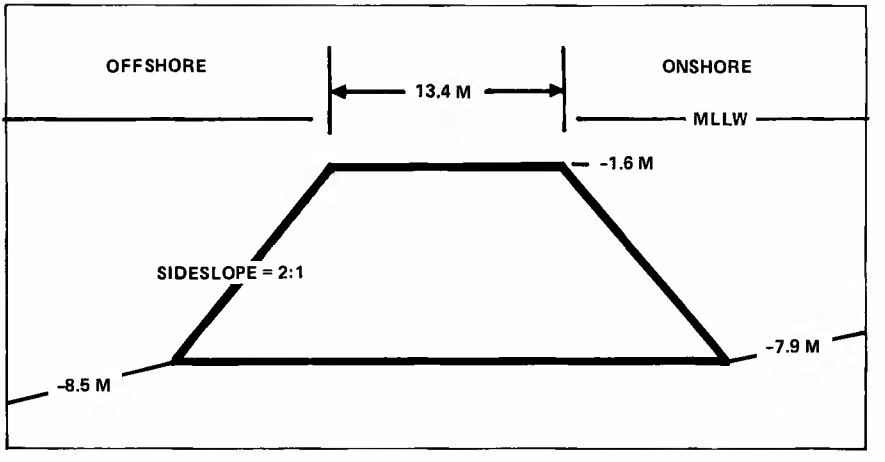

Figure 4. 1983 Breakwater Configuration

This was the condition of the breakwater when DMJM began its analysis. The breakwater was essentially submerged, especially at high tide, although the crest elevation was nonuniform in height and projected above the water surface in several locations. These complications played a role in the decision to utilize a model study in analyzing the wave action on the pier.

Model Study

The three-dimensional hydraulic model study was conducted by the Offshore Technology Corporation to determine the protection provided to the pier by various breakwater configurations. The results of the existing submerged configuration are analyzed in this paper. The model scale was 1 to 50. It covered an area of 37 meters by 24 meters, which represents 1,850 meters by 1,200 meters in prototype. Five breakwater configurations were modeled using rocks approximately scaled from the size specified in the prototype. Waves were directed at the site from three different directions, three different tide levels were studied, and six different significant wave heights were used.

The model bathymetry was constructed to model bathymetric survey data obtained in December 1983. Gravel was used to build up the model floor, and the final 0.025 meter finish layer was made of mortar. The prototype breakwater had a quarry run core, an underlayer of 900 kilogram (1 ton) stone, and an armor layer of 7,800 kilogram (8.6 ton) stone arranged in one and two layers. The model used a pea gravel core, 7 gram concrete aggregate for the underlayer, and 80 gram concrete aggregate for the armor layer. The stone size was modeled correctly, although the model armor was heavier than necessary to model the prototype rock. This was considered acceptable because the tests were conducted primarily to determine wave patterns and wave heights at the pier rather than armor unit stability.

The submerged breakwater had (prototype) crest elevations ranging from -1.8 meters MLLW to +1.8 meters MLLW and crest widths ranging from 11 meters to 24 meters. Waves were directed at the breakwater at an angle 13 degrees north of normal (235° azimuth). Water levels of 3.0 meters and 2.6 meters (prototype) above mean lower water were used in conjunction with tests of significant wave heights of 3.4, 3.9, 3.0, 1.9, 4.1, 3.2, and 1.9 meters. The waves were generated with periods having a frequency distribution matching the spectrum recorded on offshore wave recorders during the storm that damaged the pier.

Wave heights in the model were measured using capacitance-type wave gauges. Wave gauge locations were concentrated in the vicinity of the pier, although a wave gauge immediately behind and another in front of the breakwater are of particular interest in this paper.

Previous Studies

Researchers have conducted investigations of wave transmission across permeable structures for over 30 years. Some of the earliest work may have been studies of wave filters used in front of laboratory wave

generators. Saville (1963) examined a number of structures with crest elevations near the still water level for a proposed breakwater at Point Loma, California. Goda (1969) tested impermeable breakwaters for transmission by overtopping and developed an expirical equation to predict transmission coefficients which was found to be a function of the breakwater freeboard. Cross and Sollitt (1971) presented a semiempirical treatment for overtopping of subaerial breakwaters in which transmission coefficients depend on the breakwater freeboard to wave runup ratio. Keulegan (1973) studied vertical faced permeable breakwaters. Sollitt and Cross (1976) developed an analytical-empirical model for transmission through permeable breakwaters. Madsen and White (1976) presented a model of wave transmission and reflection for subaerial rubble-mound breakwaters. Seelig (1980) combined the model for transmission through permeable breakwaters of Madsen and White (1976) with prior work on transmission by overtopping.

Tanaka (1976) found the wave transmission coefficient related to the relative submergence depth and the relative crest width. His work is unique in that it deals with a continuous spectrum of breakwater crests, including both negative and positive clearance, while at the same time considering a broad range of crest widths. The continuous spectrum of crest heights was particularly useful for our purpose because, depending on the restoration scenario, the breakwater might function alternatively as a partially submerged or partially emerged structure at different phases of the tide. The broad range of crest widths was likewise

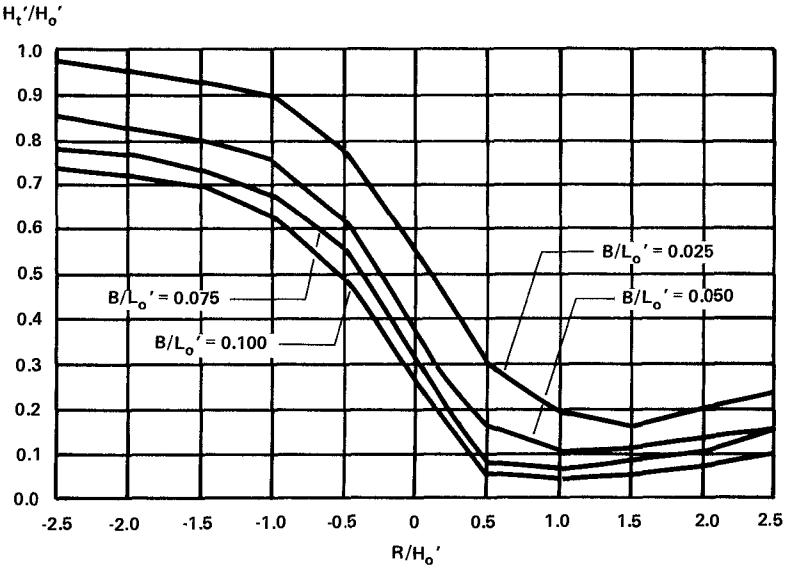

Figure 5. Results of Tanaka Study

appealing because the scenario included both the existing deteriorated broad-crested breakwater and rebuilt highly emerged narrow-crested configurations. The crest width to wave length ratio ranged from 0.025 to 0.8.

As shown in Figure 5, Tanaka's criteria give the transmission coefficients H_t/Ho' as a function of B/Lo and R/Ho', that is, as a function of crest width clearance, wave period, and wave height where B is the crest width, Lo is the deepwater wave length, R is the crest clearance, Ho' is the equivalent deepwater unreflected wave height, and H_t is the transmitted wave height. Tanaka found that for values of R/Ho' less than about -1.0, the breakwater produced little reduction in wave height and the transmission coefficient was not highly dependent on R/Ho'. For values of R/Ho' between -1.0 and +1.0, changes in R/Ho' produce large changes in transmission coefficient. For values of R/Ho' greater than +1.0, the breakwater was effective in reducing the wave height but the transmission coefficient was not highly dependent on R/Ho' and wave reflection was significant.

Comparison of Data

The general approach used in this paper is to compare the results from the Santa Monica model study to the results presented by Tanaka to see if his criteria predict the Santa Monica results. Figure 6 shows the Santa Monica results and the values that were obtained by applying Tanaka's criteria superimposed on the graph shown in Figure 5.

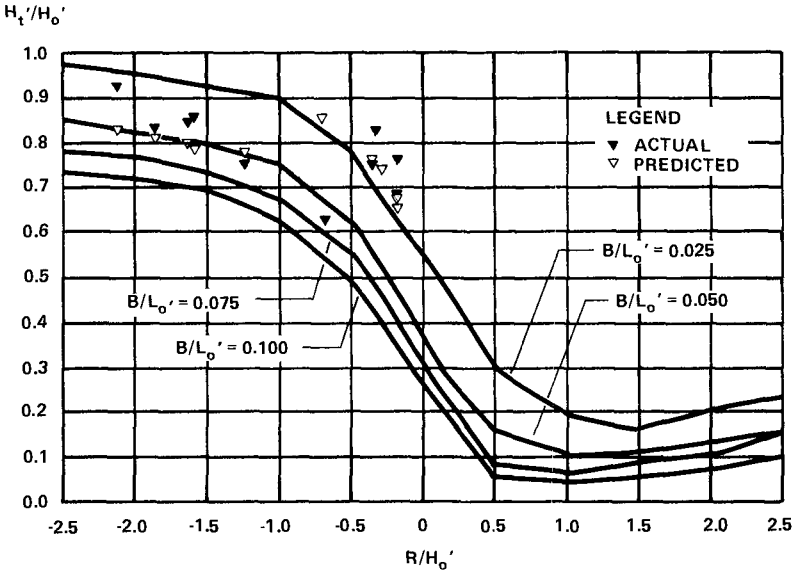

Figure 6. Santa Monica Data Comparison

Because Tanaka's criteria are based on monochromatic waves, our wave data were reduced to comparable parameters. Wave data in the Santa Monica tests were processed by the zero downcrossing method to obtain a frequency spectrum at each gauge. After several trials, it became apparent that parameters consisting of a significant wave height defined by

$$H_s = 4.0\ (m_o)^{1/2}$$

$$\text{where } m_n = \int_0^\infty f^n S(f)\,df$$

$$S(f) = (1/2)\ a^2(f)$$

$$a = \text{amplitude}$$

$$f = \text{circular frequency}$$

and a peak period provided the best agreement with Tanaka's results.

It is interesting to note that with a crest elevation of 1.5 meters below MLLW, the breakwater offers little attenuation for waves under 4.6 meters in height.

Figure 7 shows the predicted values of the transmission coefficient plotted against the values of the transmission coefficient measured in the Santa Monica model study. The figure shows the degree to which

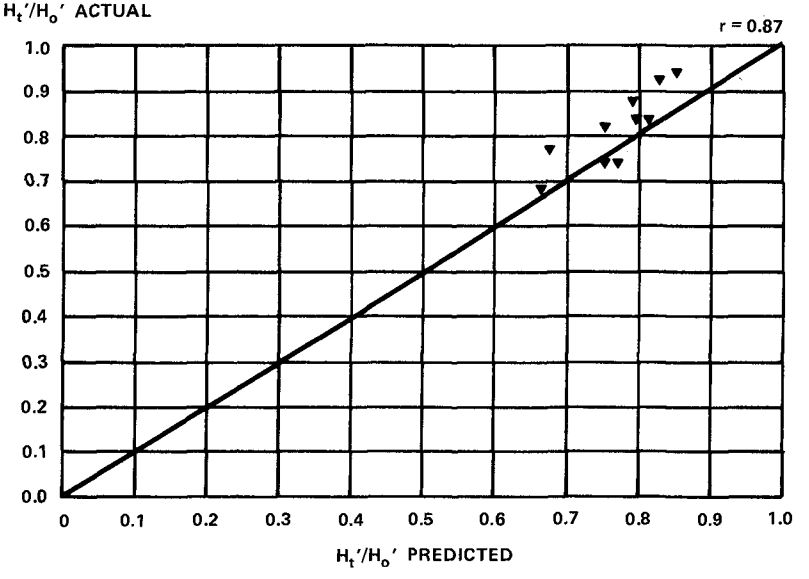

Figure 7. Actual vs Predicted Transmission Coefficients

Tanaka's criteria predict actual results. A perfect correlation would occur if all the data points fell on the diagonal line. Here we found r, the Pearson Product Moment Correlation Coefficient, to be equal to +0.87, essentially corroborating the criteria by Tanaka.

The figure indicates that the predicted transmission coefficients underestimate the actual results observed in the model test. This is demonstrated by the fact that most of the plotted points fall above the 45° diagonal line rather than being distributed evenly on either side. An interesting future study would be to determine if diffraction around the end of the breakwater in the Santa Monica model was the cause of this result.

Conclusions

Our conclusions are that the Santa Monica model data agree with the trend of Tanaka's findings. The correlation coefficient, a measure of this agreement, is +0.87. This conclusion lends credence to the use of Tanaka's curves as design tools when investigating submerged breakwaters. Tanaka's curves underpredict the transmission coefficients found in the Santa Monica model tests, so some care must be used in applying the curves. We also determined that except for very large waves, the existing breakwater at Santa Monica is not effective in attenuating wave height.

ACKNOWLEDGMENTS

The authors would like to acknowledge the City of Santa Monica for its support in making this study possible and the Offshore Technology Corporation for its role in conducting the model study.

CHAPTER 127

A PROCEDURE FOR THE ANALYSIS AND DESIGN OF CONCRETE ARMOR UNITS

W.F. BAIRD*, J.S. READSHAW*, R.D. SCOTT* AND D.J. TURCKE**

ABSTRACT

A rational approach to the design of rubble mound breakwaters that incorporates both the hydraulic stability and the structural integrity of individual concrete armor units is presented. A key element of this improved design procedure is the development of instrumentation to measure loads occurring on armor units in a physical model of a breakwater. Numerical methods have been employed to determine stresses throughout the armor unit once the loads are known and interaction design curves were developed from measured data. These interaction curves provide a useful assessment of the structural integrity of the armor units. The curves clearly demonstrate the overall factor of safety associated with the armor unit and the expected mode of failure. Based on the results of this type of analysis, the cost effectiveness and safety associated with different design alternatives may be explored and a breakwater that is both hydraulically and structurally efficient may be designed.

INTRODUCTION

The use of concrete armor units has become increasingly widespread, especially as rubble mound breakwaters have been constructed at locations where quarried rock of sufficient size was not available. In recent years, however, the armor layers of many breakwaters throughout the world have been severely damaged. This damage has often led to a breach of the breakwater structure rendering it only partially effective; the financial costs of such damage have sometimes totalled into the hundreds of millions of dollars. In certain cases, these breakwater failures have been attributed to the breakage of the individual concrete armor units. These problems have arisen because the research and development of concrete armor units has tended to focus on the hydraulic stability of the units with little or no consideration given to the structural integrity. Guidelines do not exist to aid the engineer in the structural design of armor units as there is a complete lack of knowledge of the nature and magnitude of the forces that may occur on the units in the breakwater environment.

The damage that has occurred on many breakwaters has clearly demonstrated the inadequacy of existing design procedures for

*W.F. Baird & Associates Coastal Engineers Ltd., 38 Antares Dr., Suite 150, Ottawa, Canada, K2E 7V2.
**Department of Civil Engineering, Ellis Hall, Queen's University, Kingston, Canada.

concrete armor units. A rational design procedure for breakwaters must encompass many facets of engineering endeavour including hydraulic, structural, geotechnical and materials engineering. The ultimate goal of an effective design scheme is to improve the hydraulic and structural efficiency of the armor layer, leading to more cost effective breakwater structures.

A comprehensive approach to the design of concrete armor units is presented in this paper. A key component of this design method was the development of instrumentation to determine the structural response of armor units in a physical model when subjected to simulated prototype wave attack. The structural integrity of the armor unit may be assessed once stresses and strains occurring in the unit can be quantified. The design of a unit is facilitated by the development of interaction diagrams which display armor unit structural strength and the unit's load response, and clearly demonstrate the overall factor of safety associated with a selected unit.

THE DESIGN PROCEDURE

Baird and Hall (1983) first suggested an alternate design procedure for concrete armor units that assesses both the hydraulic stability and structural adequacy of the individual units once the forces exerted on the units are defined. This procedure has been adapted in this report and is presented in Figure 1. Such a procedure represents a natural extension of current modelling practice and incorporates the load measuring instrumentation scheme discussed in the next section.

Referring to Figure 1, the first step in the design of any breakwater is to define the environmental conditions to which it will be exposed; the most important factor being the wave climate. An initial design for the breakwater must then be developed on the basis of experience or with the use of design formulas such as Hudson's equation. The selection of the armor unit will depend on a number of variables such as performance data reported in the technical literature, costs, and construction considerations.

The design is then tested using a physical model and modified until the selected armor units are hydraulically stable under the design wave conditions. At this stage, all of the units are assumed to remain structurally sound.

The next step in the design sequence is to determine the forces and/or the structural response of the armor units in the breakwater model. The response to both static and quasi-static loads can now be measured by a specially instrumented armor unit, which is discussed in the next section of this paper. The instrumentation system measures the internal bending and torsional moments at one location in the armor unit. The present investigation focuses on the dolos unit but the application of such techniques is not limited to this particular form of armor

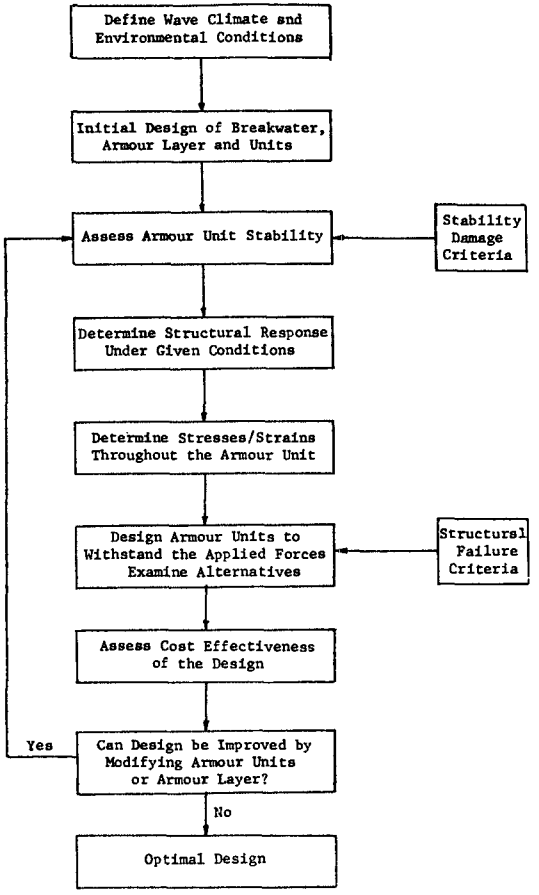

Figure 1 The Design Procedure

unit but to many units where bending and torque may be induced. As well, other similar types of instrumented units can be easily developed. Several instrumented units are placed at various locations in the armor layer and a series of tests conducted with the measured forces/stresses continually monitored.

The measured data are scaled to prototype and the individual armor units must then be analyzed with respect to the scaled forces or stresses. Generally, the armor unit's structural response can only be determined at a specific location on the unit. These stresses must be examined statistically and are then extrapolated to other locations to determine extreme stresses in the most critical regions within the armor unit. This may be achieved most easily by numerical analysis techniques such as the finite element method.

Once the critical stresses are known, the armor unit is designed to resist the applied extreme loading conditions. This entails the adoption of structural failure criteria and safety factors as is done with all structural design. Several alternatives can be examined, including alterations in the geometry and materials of the unit. Different means of increasing the strength of armor units that may be explored include the use of reinforcing, prestressing, fibre-reinforcing and high strength concretes. The effects of such changes on the structural strength of individual armor units may be readily assessed using standard analytic procedures in structural engineering. A sufficient margin of strength should be retained in the unit so that any potential dynamic loads may be resisted, such as may occur during handling and placement, and due to impacts caused by direct wave action, by inter-unit impact and by projectiles.

An important stage in the design procedure is to assess the design and its various alternatives in terms of cost effectiveness. In current design procedures, the economic benefits of altering the structural strength of armor units could only be assessed qualitatively as there was, up until now, no means of evaluating just how strong the units should be.

Finally, the overall breakwater design must be examined in terms of possible modification to either the armor unit or armor layer design. For example, altering the breakwater geometry or modifying the shape of the armor units themselves may be more cost effective than increasing the strength of the individual units.

The design process for concrete armor units outlined above will result in an optimum breakwater design that is both hydraulically and structurally sound under the given wave conditions. This design procedure is analogous to conventional structural engineering practice whereby the loads on a structure are initially defined, stresses throughout the structure determined, and the structure designed to resist the applied loadings.

THE ARMOR UNIT LOAD CELL

The key element in the design procedure discussed above is the load cell or load measuring system. The basis of this system is a thin-walled aluminum tube, which is instrumented with strain gauges and then inserted at the mid-shank location of a model armor unit (in this case a dolos) constructed of a steel-fibre reinforced epoxy, as shown in Figure 2. Strain gauges mounted on the tube measure all of the surface strains due to bending and torsion. Since dolosse primarily experience stresses due to bending and torsion, as exhibited by prototype testing and by the nature of their shape, the axial and shear stresses are considered to be of secondary importance. Details of the design, calibration and evaluation of the instrumentation scheme may be

Figure 2 The Armor Unit Load Cell

found in Scott, Turcke and Baird (1986) and Scott (1986).

The tubes which are inserted are of a different diameter, shape and material than the dolos shank, thereby violating complete similitude, but were designed such that the bending and torsional rigidity of the section were properly scaled from prototype. Such techniques have previously been suggested for structural models by Le Mehaute (1965) and Murphy (1950). Thus, bending and torsional strains were properly scaled but axial and shear strains were distorted. This technique allowed the measurement of strains under even the smallest loads. The output voltages of the strain gauge circuits that measure the bending moments and torques are calibrated against known loading conditions. Thus, two orthogonal moments and torques are measured directly by the system. This creates, in effect, an armor unit "load cell". The net result is that bending moments and torques can be established with a high degree of accuracy at one section in the armor unit under different load conditions.

Two dolosse having overall lengths of 203 mm and 106 mm were constructed using this force measurement scheme. The model units were made of a steel-fibre reinforced epoxy material, Devcon Plastic Steel, modified by the addition of lead pellets to make the density equivalent to that of concrete. This epoxy was utilized because it could be easily cast and then machined and worked in similar manner to any soft metal. Other materials could have been employed if they had a density similar to that of the prototype concrete.

The two dolos load cells were calibrated by the application of static point loads at various locations on the armor units and the strain gauge output measured; this procedure is employed in the calibration of any load transducer. A linear relationship was established between gauge output and the bending or torsional moments.

The calibrations were repeated prior to each test series to ensure that the load cells' characteristics had not changed in time. The calibrations were also performed prior to and subsequent to the application of the waterproofing, and showed that the water protection system had no effect on the load measurements.

An extensive series of tests were designed to fully evaluate the performance of the measurement system in both a dry environment and in the dry/wet environment of a hydraulic flume. Specific objectives of the test program were to examine both the sensitivity and accuracy of the load cell for measurement of forces in a model breakwater. The tests were divided into three categories: (1) static tests under self-weight loading; (2) static tests in a model breakwater; and (3) tests in a hydraulic flume. The results of the tests in the first category were compared against theoretical computations of moments and torques to determine the accuracy of the load cells.

The second set of tests examined the static forces on an amour unit due to placement and settlement in a breakwater. It was noted from the preliminary results that up to 25% of the structural capacity of the dolos unit can be utilized to resist these static loads. Such information is important for the proper design of armor units and may be readily extracted from physical models for different breakwater configurations.

The final set of evaluation tests employed a single instrumented unit rigidly mounted on a smooth slope. These tests were conducted to determine the effect of changes in wave height and location on armor unit response under controlled experimental conditions where the fluid flow was not as complex as which occurs in the breakwater environment.

The evaluation tests demonstrated the viability of the load measurement scheme for determining the structural response of armor units in the breakwater environment. This system had numerous advantages:

i) proper distribution of mass throughout the model,
ii) extremely high sensitivity levels with good accuracy in small scale models,
iii) excellent protection from environmental influences,
iv) flexibility of use: the same instrumentation could be employed in different types and sizes of armor units.

ANALYSIS AND DESIGN OF A BREAKWATER

A typical breakwater of conventional design was selected for the model investigation. The breakwater model was constructed in a two-dimensional hydraulic flume at a length scale of 1:40 as shown in Figure 3.

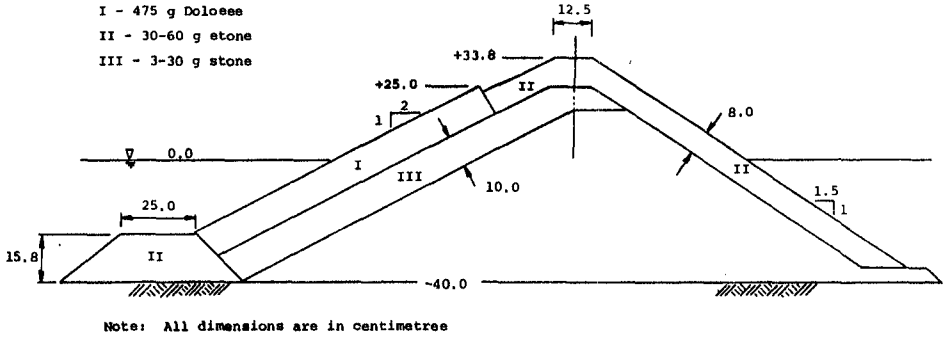

Figure 3 The Breakwater Model

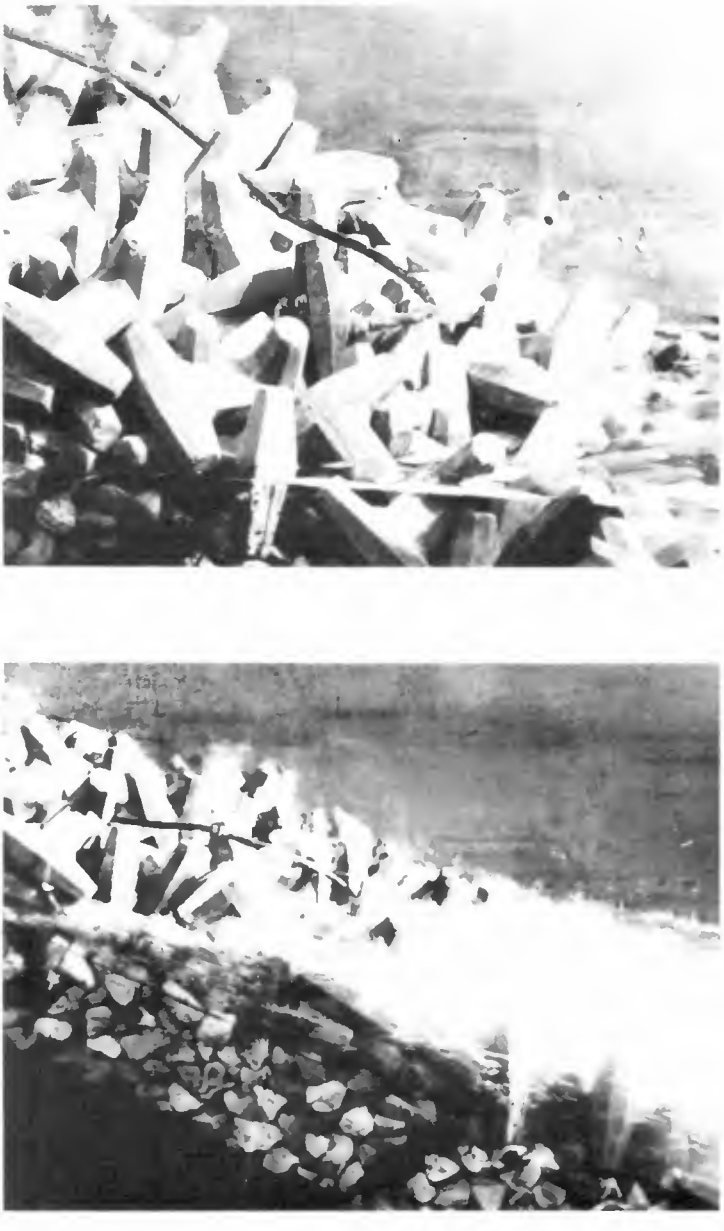

Figure 4 Photographs of the Breakwater Test

The primary armor layer was formed of 475 gram dolosse placed in two layers. At the specified scale, these units corresponded to 30 tonne units in prototype. During the test program, the structure was subjected to regular waves of height 24 cm and a period of 1.75 seconds, corresponding to a wave height of 9.6 metres and a period of 11.1 seconds in prototype. Assuming a K_d value of 15.9 (i.e. two layers of randomly placed dolosse, non-breaking waves, less than 2% damage (no rocking)), Hudson's formula yields a dolos weight of 24.3 tonnes for the given wave conditions [U.S. Corps of Engineers (1984)]. Thus, the 30 tonne units used in the model were hydraulically stable. This was supported by observations during the breakwater tests, in which little or no rocking of the dolos units was observed. The photographs of Figure 4 show the instrumented unit positioned in the armor layer and the breakwater being subjected to wave action.

Tests were conducted at twelve different locations in the armor layer; six were in the top layer and the remainder in the bottom layer. Prior to each test, the instrumentation was zeroed and calibrated. The unit was then placed in the armor layer and the static load response measured. The internal forces were monitored and graphically displayed when the model breakwater was subjected to wave action. Both the nature and magnitude of the forces were examined. These forces are created by both the inertial and drag forces of the water during wave breaking, uprush and downrush. A typical response of the armor unit to wave attack is shown in Figure 5 where the measured response for the two orthogonal bending moments and torque have been plotted against time. The repeatability of the peak signals with the wave period was excellent in all tests and the levels of the static forces may be noted on the plot. There was also excellent correlation of the peak signals from test to test at any one location.

Figure 6 displays some of the results of the test series. Here, torque has been plotted against the vector sum of the orthogonal bending moments for the maximum response recorded in each test as obtained from the time history plots of the internal forces.

Throughout the test series, the load cell performed with a high degree of reliability, and the waterproofing protected the instrumentation even under the severe environmental conditions of the model breakwater. The load cell exhibited high sensitivity levels and was able to measure even the small induced forces of static loading. The presence of lead wires to the instrumented unit did not pose any difficulties in the tests and did not affect the stability of adjacent units.

The next step in the design procedure, once the structural response is known in the model, is to assess whether structural failure will occur and how the armor units may best be designed to resist the induced forces in prototype. Several activities

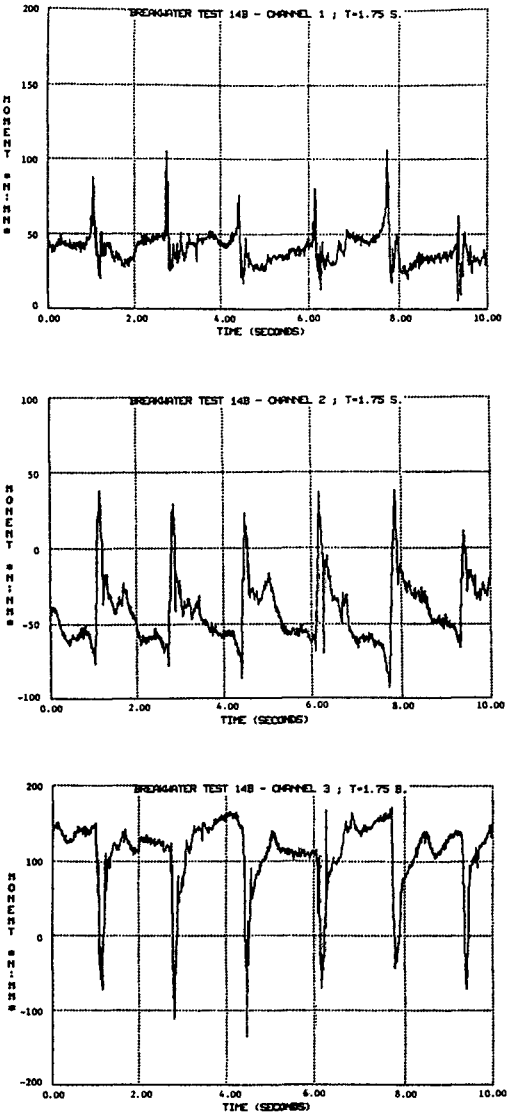

Figure 5 Typical Response of the Local Cell to Wave Attack

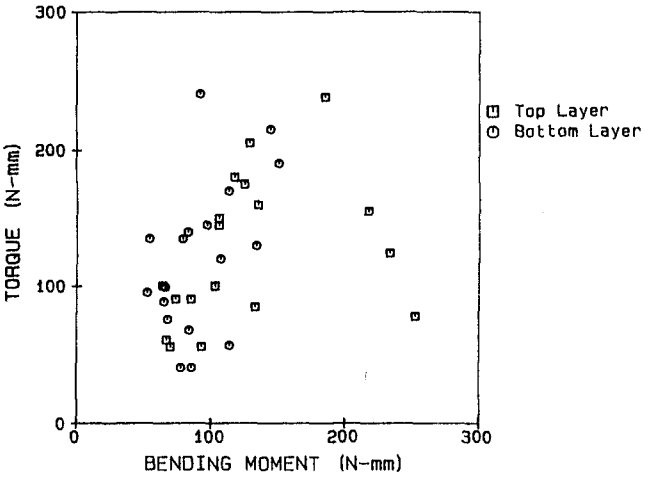

Figure 6 The Peak Internal Forces Measured

are essential to achieving this goal. First, the model forces/stresses must be scaled to prototype using the appropriate scale factors. Second, certain failure criteria for the designed armor unit must be identified and compared to the scaled data. Third, as the forces/stresses cannot be measured at all locations within the armor unit, approximate stress distributions must be determined throughout the unit.

Using the appropriate scaling relationship, the moment and torque levels in the prototype were computed. In order to determine if the combined effect of the moment and torque would cause a section to fail, a failure criteria had to be established. This led to the development of an interaction equation, based on the concrete failure theory of Cowan (1953, 1955), relating failure in the dolos shank composed of plain concrete under the combined actions of bending and tension:

$$\left(\frac{M}{M_{cr}}\right) + \left(\frac{T}{T_{cr}}\right)^2 = 1$$

where:

$$M_{cr} = 0.1597\ (Rh)^3\ f'_t$$

$$T_{cr} = 0.2140\ (Rh)^3\ f'_t$$

M_{cr} and T_{cr} are the pure bending moment and pure torque that would induce cracking in the dolos shank, R is the waist ratio, h is the dolos size and f'_t is the direct tensile strength of the concrete. The above expression is valid within the dolos shank; however, many dolos failures have been known to occur at the fluke-shank interface of the unit. Therefore, it was necessary to extrapolate the measured response to other regions in the

armor unit. This was achieved by means of numerical analysis using the finite element method where the stress increase at the fluke-shank interface was examined under different extreme loading and boundary conditions. The finite element grid used for the dolos unit is shown in Figure 7.

A typical result is displayed in Figure 8 where the peak moments and torques at the fluke/shank interface are plotted along with the failure curve for concrete strengths of 30 MPa and 40 MPa. It can be seen very clearly that the results for some of the units lie outside the safe region and, therefore, these units would have failed. These test results showed that despite using armor units which were hydraulically stable under the incident wave conditions, structural failure would occur, consequently demonstrating the inadequacy of the dolos armor unit as designed for this particular application. Fatigue has not been considered, though it can be a very likely source of problems in the breakwater environment.

The next stage in the analysis was to redesign the armor units to withstand the applied forces. This could be achieved by either altering the geometric shape of the unit, increasing the size of the unit or increasing the structural strength of the unit. The strength of concrete may be augmented by numerous means, such as by the use of reinforcing, prestressing, high strength concrete or fibre-reinforcing. These are just a few examples of the different design alternatives and does not by any means represent a comprehensive examination into the various design possibilities. An example of the effect of using reinforcing steel to increase the structural capacity of the dolos unit is shown in Figure 9.

The cost effectiveness of the various alternatives may now be truly examined because the structural requirements can be quantified. Such information is essential to the development of different design alternatives.

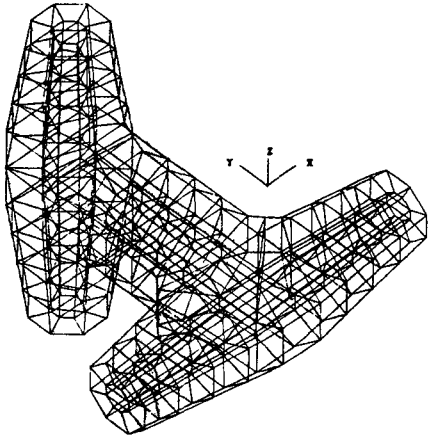

Figure 7 The Dolos Finite Element Method

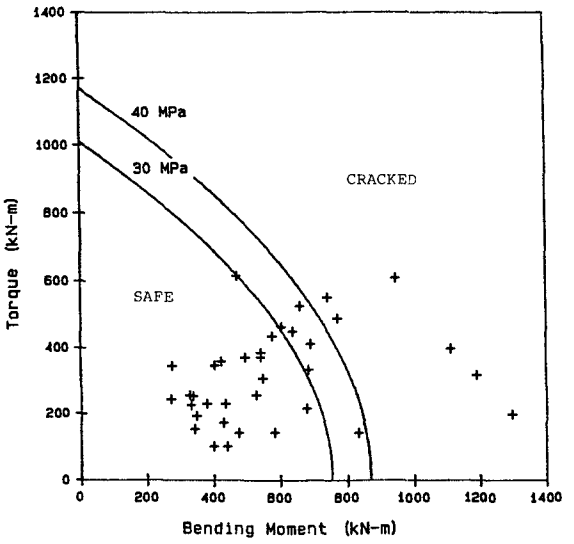

Figure 8 Peak Forces at the Fluke/Shank Interface

CONCLUSIONS

A rational procedure for the design of concrete armor units has been presented. A unique "load cell" was developed which measures the structural response of armor units in a standard breakwater model. This permits the structural integrity of the armor units to be assessed through the use of interaction curves, thus clearly demonstrating the overall factor of safety associated with the armor unit and the expected mode of failure.

Such a procedure represents the application of existing technologies and a comprehensive engineering approach to the design of rubble mound breakwaters. Some features of the design method are:

1) Methods of standard structural engineering practice are followed where first the loading conditions are assessed and the structure designed to resist the applied loads.
2) Numerical analysis techniques such as the finite element method are employed.
3) It is an extension of current design practice where physical models are utilized.
4) Materials technology and failure criteria are examined.

Consequently, an effective design scheme is available which incorporates both the hydraulic and structural considerations of a breakwater structure and , thus, can provide more cost effective solutions.

CHAPTER 128

SCOUR AROUND STRUCTURES

ECO W. BIJKER*, Member ASCE

Abstract

The physics of scour around structures and especially underneath pipelines is discussed. It is demonstrated that a combination of current and waves with an equal bottom shear stress as a uniform current gives lower scour rates than a single current with the same bottom shear stress.

The principle of the performance of scale series is discussed and it is shown that this method has still some weak points.

1. Introduction

When a structure is placed in water on an erodable bottom and is subject to a current or wave field, scour will most likely occur around the structure. It is difficult to predict this scour because the scour process is even more complicated than the normal transport process. In this paper the various processes and prediction methods will be discussed for pipelines on a sandy bottom because a lot of data is available from an extensive research carried out within the framework of the Dutch Marine Technology Research (MaTS).

At present it is possible to predict the current pattern around a structure, c.q. the pipeline, by numerical models. These models can also calculate the rate of turbulence and the bottom shear stress. Modelling of transport processes is, however, still very difficult [Leeuwestein and Wind (1984) and Leeuwestein et al. (1985)]. Good progress is made in obtaining a reliable description of the transport and scour phenomena.

As long as the final goal is not yet reached, physical model tests can offer a solution, not only for predicting scour values but also for obtaining a better insight in the physical processes. However, with physical modelling serious and well known scaling problems will arise. A method to cope to some extent at any rate with that problem, is the application of scale series. In this procedure a set of models with varying scales is applied and the results, for instance measured values of the scour, are extrapolated to values for scale 1:1.

---

* Professor of Coastal Engineering, Delft University of Technology, P.O. Box 5048, 2600 GA Delft, The Netherlands

This should give the correct answer. Since this extrapolation is rather difficult, often an attempt is made to determine for each test the best possible scale factor for the scour. In the ideal case all predicted scour values should give then the same value. Even in the case this ideal is not reached, the extrapolation of these 'up-scaled' values is much more easy than of the observed test values. This principle is demonstrated in Figure 1.

In this paper this procedure is worked out for the scour around pipelines and the possible deficiencies which are still inherent to this method are discussed.

2. Physics of scour

A basic difference exists between the scour caused by current and waves.

i. In a current field, normally a continuous transport exists. In this case the basic condition for the equilibrium situation in the immediate vicinity of the structure, so for the equilibrium scour hole configuration, is that the transport gradient, $dS(x)/dx = 0$. When the current is so low that in the undisturbed current field no transport occurs, the scour around the structure, c.q. underneath the pipeline, will develop until also in the vicinity of the structure the transport is zero. So again $dS(x)/dx = 0$. (See Figure 2.)

ii. Under the influence of an orbital wave motion hardly any continuous transport occurs. In this case the scour process is determined by the excursion distance of the sediment particles through the orbital motion. The amplitude of the sediment motion is closely related and even almost equal to the amplitude of the orbital motion of the water at the bottom. (See Figure 3.)

Moreover, another difference exists between the development of scour by only current or by waves. This is caused by the fact that in the case of only current, the scour will take place by an accelerated current which has subsequently a relatively low rate of turbulence. The bottom shear will be, however, higher than in the case of a uniform flow, since the boundary layer is not yet adjusted. This effect, of the adjustment of the boundary layer, does not occur for the situation with only waves, since the boundary layer under waves must be adjusted continuously. This effect is almost equal for the undisturbed wave motion and for the wave motion in the scour area.

For the combination of waves and current this effect is also noticeable. The bottom shear stress of the combined effect of waves and current can be written as

$$\tau_{cw} = \tau_c + \tfrac{1}{2}\hat{\tau}_w = \tau_c \left(1 + \frac{\hat{\tau}_w}{2\tau_c}\right) \qquad (1)$$

in which τ_c = bottom shear stress by current; $\hat{\tau}_w$ = amplitude of bottom shear stress by waves; τ_{cw} = combined bottom shear stress [Bijker (1966 and 1971)].

Since in the scour area τ_c increases relatively more than $\hat{\tau}_w$, the

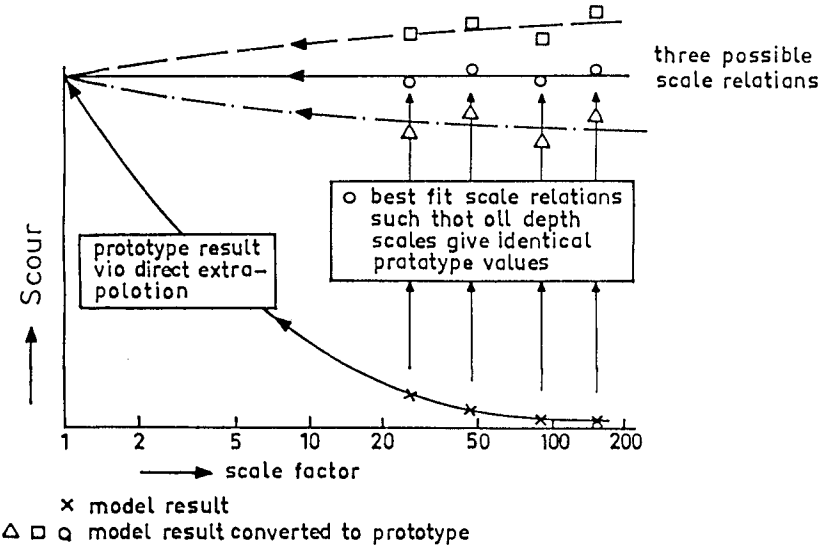

Fig. 1 Philosophy of a scale series

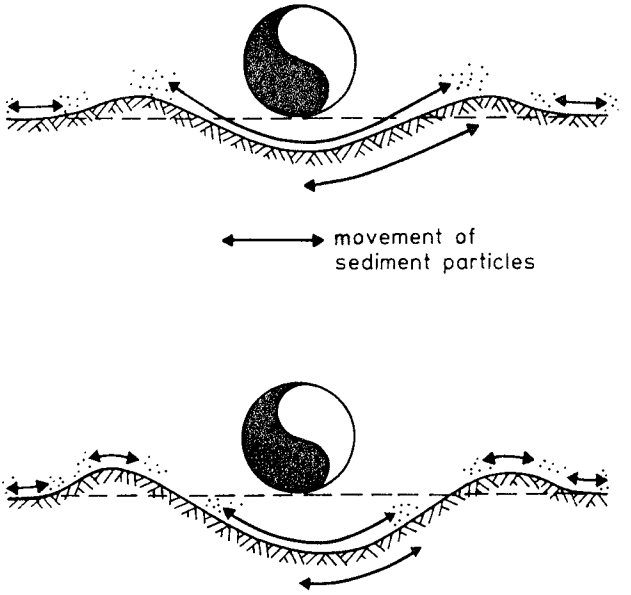

Fig.3 SCOUR DUE TO WAVES.

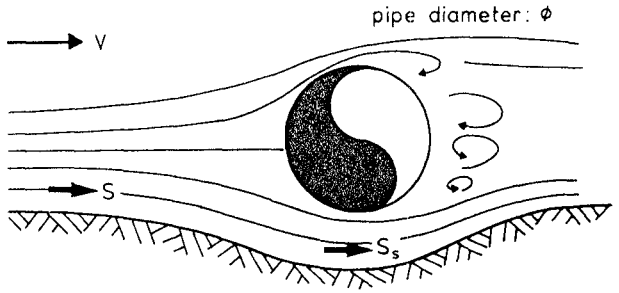

Fig. 2 SCOUR AS RESULT OF CURRENT

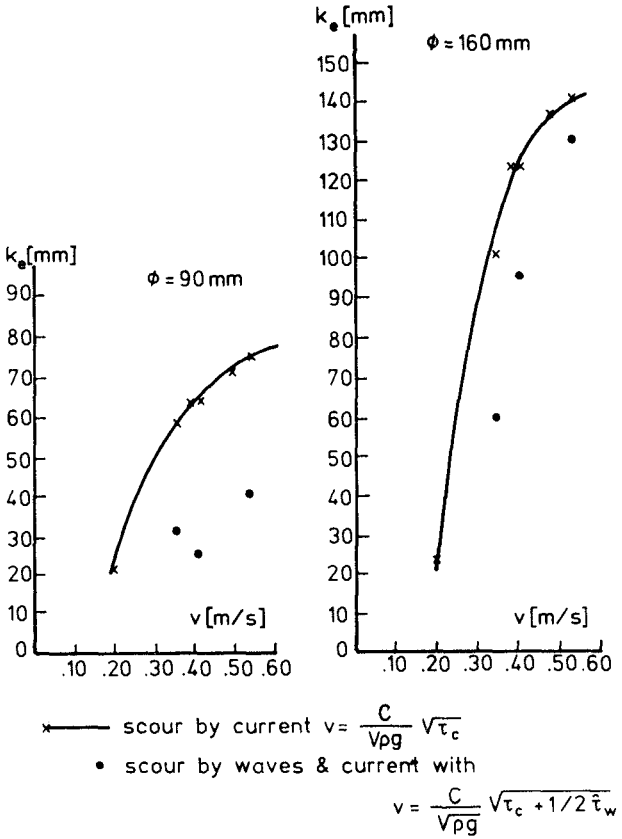

Figure 4. SCOUR FOR CURRENT AND CURRENT + WAVES.

factor by which the transport due to current is increased by wave motion is in the scour area less than in the undisturbed area.

The scour will be, therefore, less and this is demonstrated by tests in which scour has been subjected to a current and to a combination of current and waves with an equal bottom shear stress in the undisturbed area.

The velocity in the case of only current should be

$$v_1 = C\sqrt{\frac{\tau_{c,1}}{\rho g}} \qquad (2)$$

in which C = the Chezy bed resistance factor.

In the case of the combination of a current and waves, the current should be less, resulting in a bed shear $\tau_{c,2}$, so that

$$\tau_{c,w} = \tau_{c,1} = \tau_{c,2} + \tfrac{1}{2}\hat{\tau}_w \,. \qquad (3)$$

The scour occurring under these conditions should be compared with scour $k_{e,1}$ occurring by the velocity

$$v_1 = C\sqrt{\frac{\tau_{c,2} + \frac{1}{2}\hat{\tau}_w}{\rho g}} \,. \qquad (4)$$

The results are shown in Table 1 which gives the observed scour values for various combinations of waves and currents. The values v_1 of a single current giving the same resulting shear stress as the combination of waves and current are given with the corresponding scour values.

The results are also presented in Figure 4. Apart from the test with $v_2 = 0.40$ m/s and $\hat{u}_b = 0.15$ m/s, the scour underneath a pipeline subjected to a combination of waves and currents is less than the scour when the pipeline is subjected to a single current v_1 with the same bottom shear stress as v_2 and $\hat{u}_b$.

For a continuous transport the bottom changes can be described by

$$\frac{\partial}{\partial t}\left[\int_{z_b}^{z_s} c(x,z,t)\cdot dz\right] + \frac{\partial S(x,t)}{\partial x} + (1-p)\frac{\partial z_b(t)}{\partial t} = 0 \qquad (5)$$

in which $c(x,z,t)$ is the sediment concentration at place x, height z and time t, z_b is the height of the bottom, z_s = height of the water level, or any level above which $\frac{\partial}{\partial t}\left(c(x,z,t)\right) = 0$; $S(x,t)$ is the total sediment transport per unit of width at place x and time t, and p = the porosity of bottom material.

Equation 5 demonstrates that scour will not only occur as a result of $\partial S/\partial x$, but also because more sediment can go into suspension. This is especially important in those cases where the material brought into suspension can be transported outside the area of expected scour. This is of great importance for the scour around structures when locally material can be brought into suspension and then can be

transported by a continuous current.

This phenomenon also explains the difference in scour patterns in front of a vertical wall with coarse and fine bottom material [de Best et al. (1971), Irie and Nadaoka (1984)] .

3. Formulation of sediment transport

Sediment transport formulae can be written in the following general form:

$$\phi = f(\psi), \tag{6}$$

$$\text{in which } \phi = \frac{S}{\sqrt{g\Delta D^3}}, \tag{7}$$

with S = transport per unit width; g = acceleration of earth gravity; D = grain size of sediment and Δ = relative density of sediment;

$$\text{and } \psi = \frac{\tau}{\rho g \Delta D}, \tag{8}$$

with τ = bottom shear stress.

$$\text{For current } \psi_c = \frac{\kappa\, v_t^2}{g\Delta D} = \frac{\bar{v}^2}{C^2 \Delta D}, \tag{9}$$

with v_t = velocity just above laminar sublayer at er/33 and $\bar{v}$ = mean velocity, averaged over the depth

$$\text{and for waves } \psi_w = \frac{f_w \hat{u}_b^2}{2g\Delta D}, \tag{10}$$

with $\hat{u}_b$ = amplitude of the orbital velocity at the bottom and f_w = bottom friction factor of Jonsson [Jonsson (1966)] .

For the case of a combination of current and waves, ψ_c should be replaced by ψ_{cw}, which can be written as

$$\psi_{cw} = \psi_c + \tfrac{1}{2}\psi_w \tag{11}$$

[Bijker (1966, 1971)] .

Some sediment transport formulae are:

Meyer-Peter, Mueller

$$\phi = 13.3\,(\psi_c - 0.047)^{1.5} \tag{12}$$

Kalinske-Frijlink

$$\phi = 5\sqrt{\psi_c}\, e^{-0.27/\psi_c} \tag{13}$$

Paintal

$$\phi = 10.9\; 10^{18}\, \psi_c^{16} \quad \text{for } \psi_c < 0.05 \tag{14}$$

$$\phi = 21.7\, \psi_c^{2.5} \quad \text{for } \psi_c > 0.05 \tag{15}$$

Engelund and Hansen

$$\phi = \frac{C}{g} \psi^{5/2} . \qquad (16)$$

All above descriptions can, over a limited velocity range, be simplified to

$$S = \alpha v^{\beta} , \qquad (17)$$

in which α is a non-dimensionless coefficient. This simplification is used for the derivation of simple scale relations used in the scale series. A close analysis of the above quoted formulae shows that α is mainly determined by D and that the influence of the velocity and the type of transport, viz. : mainly bed load or mainly suspended load, or a combination of these two, are represented by the value of β .

For low transport rates, mainly in the form of bed load, β is larger, 0 (6), than for high transport rates with a large ratio of suspended load over bed load, 0 (2 or 3).

4. Prediction of scour by current through a scale series

In Chapter 1 it has been stated that, in order to be able to extrapolate the measured scour values for the various model pipes, c.q. structures to scale 1:1 , an as accurate as possible scale for the scour should be found. This requires a good choice for the velocity scale belonging to the various scales of the structure. The correct value of this scale is, moreover, at any rate necessary for a good performance of the model test. In the ideal case the transport scale is constant over the entire area, that is upstream and downstream and around the structure.

So, $$n_S = n_{S_s} , \qquad (18)$$

in which n_S = transport scale factor = prototype value over model value and the subscript s denotes the value at the place of maximum scour. This leads in this case through Equation (17) to

$$n_{(\alpha\, v^{\beta})} = n_{(\alpha_s\, v_s^{\beta_s})} . \qquad (19)$$

Equation (19) leads to a value of n_v and in some cases also to a relation of n_v to n_l .

From the discussion in Chapter 3 , α proves to be determined mainly by the grain size of the sediment. Since the material in the scour area will not differ much from that in the undisturbed area; $n_\alpha = n_{\alpha_s}$.

In order to make the computations not too complicated, n_β and n_{β_s} are assumed to be 1 . This is only so when the type of transport in the model is equal to that in the prototype. Since this is not completely true, the derived scale relation will not be the 'ideal' one. However, when the relation is consistent, extrapolation through a continuous curve to the prototype condition, $n_l = 1$, will be possible.

Equation (19) in this case can be written as

$$n_v^{\beta} = n_{v_s}^{\beta_s} \qquad (20)$$

Normally the relation between v_s and v is known. For a vertical pile $v_s = 2\,v$, which would lead to

$$n_v^{\beta} = 2^{\beta_s}\, n_v^{\beta_s} \quad . \tag{21}$$

For the tests with pipelines the situation differs somewhat since a pipeline with a larger diameter will force more water through the gap underneath the pipeline. The ratio between the velocity underneath the pipeline and the undisturbed velocity is, therefore, a function of the pipeline diameter ϕ.

Tests have shown that this ratio can be described by

$$v_s/v = \phi^{0.2} \quad . \tag{22}$$

In this case Equation (20) [Leeuwestein (1986)] can be written as

$$n_v^{\beta} = n\left(v\,\phi^{0.2}\right)^{\beta_s} = n_v^{\beta_s}\, n_\phi^{0.2\,\beta_s} \quad , \tag{23}$$

$$\text{or} \quad n_\phi = n_v^{p} \quad , \tag{24}$$

$$\text{with} \quad p = \frac{\beta - \beta_s}{0.2\,\beta_s} \quad . \tag{25}$$

Reasonable values for β and β_s are 5 and 3 respectively. The value of β_s is chosen lower than β because a numerical analysis by the Delft Hydraulics Laboratory revealed that underneath the pipeline a greater ratio of suspended load over bed load exists than in front of the pipe [Leeuwestein and Wind (1984)].

In that case $p = 3.3$ and subsequently

$$n_\phi = n_v^{3.3} \quad . \tag{26}$$

Another possible scale relation is based on Froude modelling of the flow pattern, so

$$n_\phi = n_v^{2} \quad . \tag{27}$$

The procedure to determine the scour underneath a pipeline of ϕ = 500 mm for an undisturbed current velocity of 0.7 m/s is as follows.

For various pipe diameters ϕ, ranging from 10 to 100 mm, the scour is measured for velocities of 0.2 , 0.3 , 0.35 and 0.4 m/s. The results are shown in Figure 5. For each value of the velocity, the velocity scale (with respect to v = 0.7 m/s) is determined and from that velocity scale the scale for the pipeline n_ϕ is calculated through Equation (24). When this exercise is performed for $p = 2$ and $p = 3.5$, a velocity in the test of $v = 0.35$ m/s, leading to $n_v = 2$, gives values of $n_\phi = 4$ and 11.3 respectively. In this way a set of scour values under pipelines with varying scales with regard to the pipeline of 500 mm and 'realistic' values of the tests-velocities is obtained. These points form the lower line of Figure 6. Exrapolation

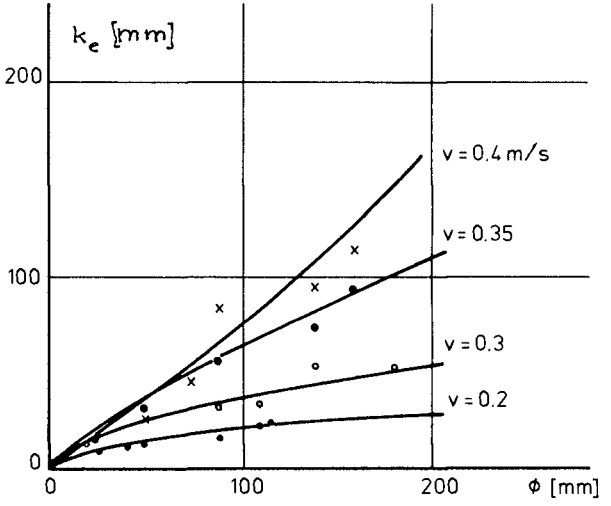

Figure 5. MEASURED SCOUR DEPTHS (CURRENT).

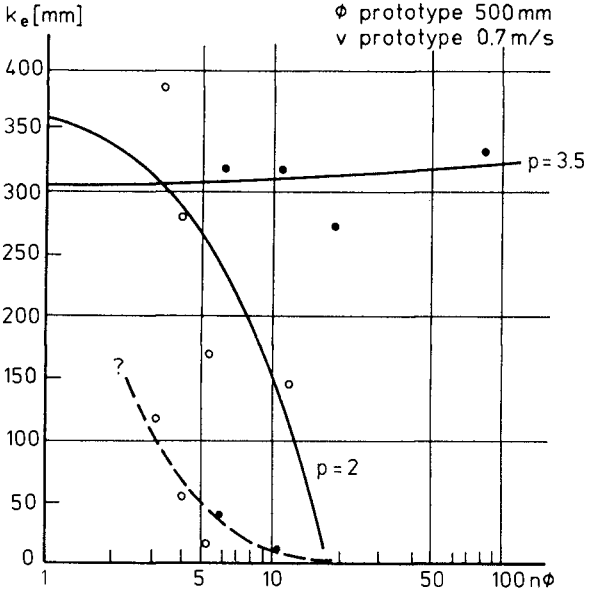

Figure 6. SCOUR BY CURRENT (MATS DATA).

of this line to $n_\phi = 1$ would give the expected scour for a pipe of 500 mm and a velocity of 0.7 m/s. This extrapolation is, however, easier when the observed scour values are multiplied with the expected scale factor of the scour. For the 'ideal' velocity scale this factor will be equal to n_ϕ . The lines obtained in this way for p = 2 and 3.5 are also given in Figure 6. Extrapolation is done by a linear regression analysis. In Chapter 6 the results will be discussed more in detail.

The same exercise has been done for the data of Kjeldsen, which are summarized in Figure 7. The final result is shown in Figure 8.

5. Prediction of scour by means of scale series for waves

In principle the same procedure as for a current is followed. However, in order to make a first estimate for p in $n_\phi = n_v^p$, a somewhat different procedure has to be followed, since the principle of scour around a structure by waves is basically different from that by current (see Chapter 2).

In the case of scour by waves no continuous transport of any importance exists. The criterium that $\partial S/\partial x = 0$ and, therefore, the requirement that n_S in front of the structure should be equal to n_{S_s} in the scour hole is irrelevant.

In the ideal situation $n_{k_e} = n_\phi$ and since the current pattern around the structure is determined to a great extent by the pressure around the structure, c.q. underneath the pipe, $n_\phi = n_{\hat{u}}^2$.

According to the physics of the scour underneath a pipeline as discussed in Chapter 2 , the amplitude of the orbital motion should be reproduced on the scale of the pipeline; n_ϕ . When the wave period is reproduced on $n_\phi^{\frac{1}{2}}$, this requirement also leads to $n_{\hat{u}} = n_\phi^{\frac{1}{2}}$.

The scale series have been performed with values of p = 1 , 1.5 and 2 . The original test results for scour by waves are given in Figure 9 and the final results for the scale series in Figure 10. The scour for the prototype pipeline of ϕ 500 mm and $\hat{u}_{b,pr} = 1$ m/s then is 187 , 205 and 210 mm which is reasonable close together. These values are, as could be expected, much less than the values obtained for a steady current of comparable value.

6. Discussion

For the pipeline of 500 mm in a steady current of 0.7 m/s, data are available from full scale tests in the large flume of the Delft Hydraulics Laboratory. The MaTS data give for p = 2 a value of k_e = 355 mm and for p = 3.5 a value of k_e = 302 mm. As a matter of fact, these two values should have been equal. Moreover, the full scale test gives a value of only 220 mm.

One of the reasons for this 'low' value of 220 mm probably is that the tests in the large flume have not been run long enough. In Figure 11 the results of these tests are shown. These results indeed give the impression that extension of the test with v = 0.7 m/s would have given somewhat larger values for the scour.

Another reason could be the layout of the test as shown in Figure 12. The feeding of the sand by controlled dumping in the flume some 50 m upstream of the pipe, could have led to a too high suspended load and,

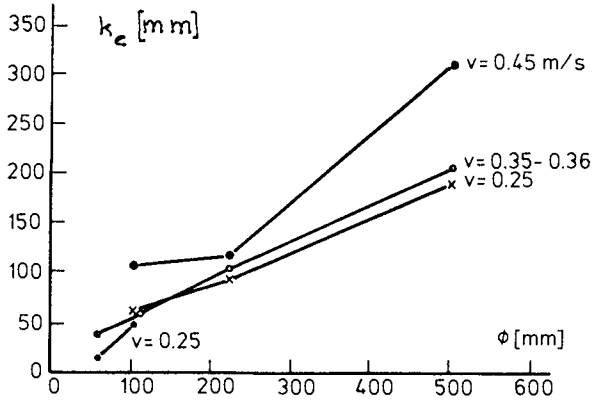

Figure 7. KJELDSEN SCOUR DATA.

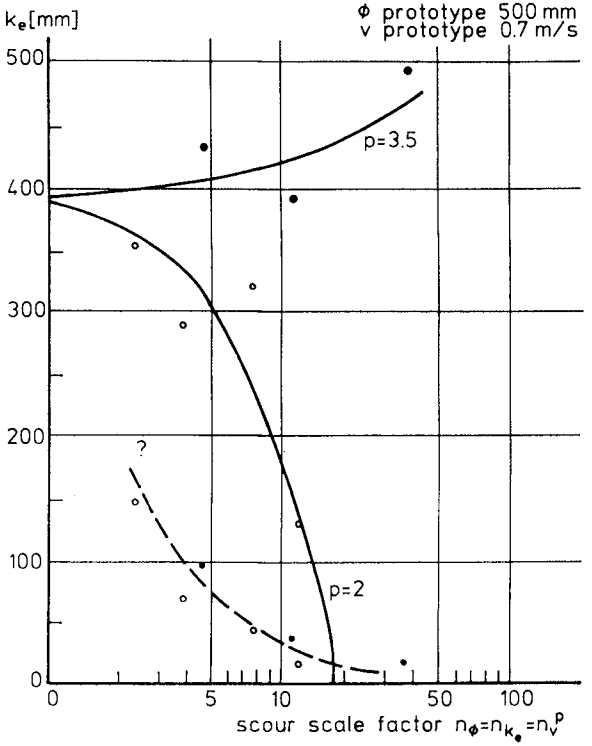

Figure 8. SCOUR BY CURRENT (KJELDSEN DATA).

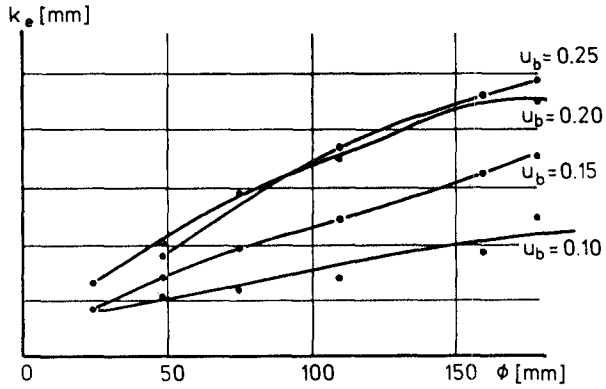

Figure 9. MEASURED SCOUR DEPTHS (WAVES).

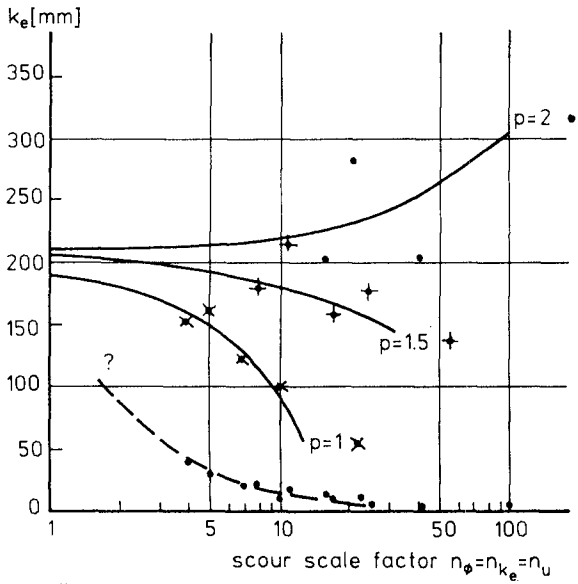

Figure 10. SCOUR BY WAVES.

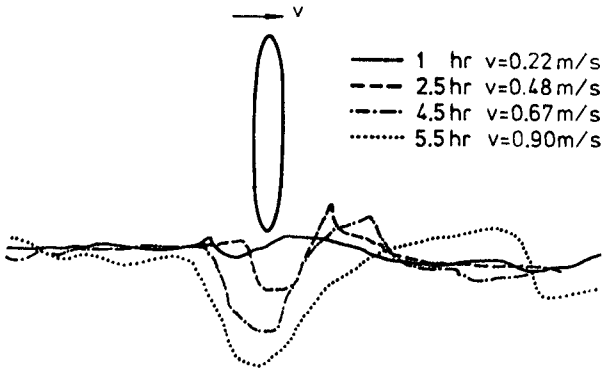

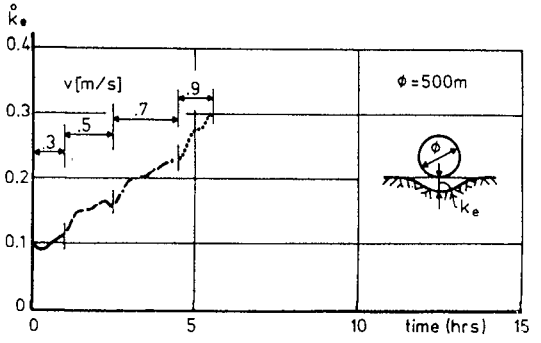

Figure 11. SCOUR MEASUREMENTS IN LARGE FLUME of D.H.L. (de Voorst).

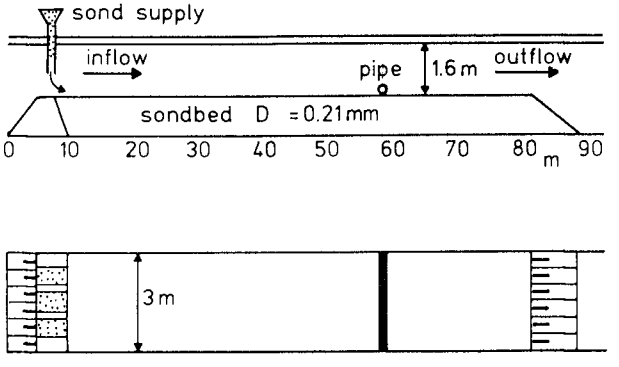

Figure 12. LARGE FLUME D.H.L. (de Voorst).

therefore, to too high sand supply to the scour hole. This also led in some cases to the formation of very large dunes.

Also the Kjeldsen data lead to values of the scour of the order of 390 mm, which is higher than predicted by the formula of Kjeldsen,

$$k_e = 0.97 \left[\frac{v^2}{2g}\right]^{0.2} \phi^{0.8} \qquad (28)$$

This would give $k_e = 266$ mm .

Of course, this value corresponds rather well with the direct extrapolation of the Kjeldsen data. However, it is not sure that this extrapolation is allowed, because the transport mechanism is changing when the velocity is increased so much from the values of the Kjeldsen data.

This also demonstrates the weak point of every scale series. It is well possible that extrapolation to the required prototype value will change the transport mechanism so fundamentally that extrapolation by a continuous curve is not allowed any more. Therefore, utmost care in the application of scale series is still necessary.

The ultimate procedure for scour prediction will be, therefore, in the nearby future the use of numerical models based on a description of the transport and scour processes through basic physical research.

CHAPTER 129

Durability of Rock Armour on Coastal Structures

A P Bradbury BSc *
N W H Allsop BSc MICE +

Abstract

This paper summarises many of the recent advances in the testing of rock quality for coastal structures. Advanced work on armour profile and armour unit shape descriptors is identified. A set of assessment methods for monitoring armoured slopes in the field are described, with examples drawn from recent monitoring exercises. The paper concludes by describing future directions of research in this field.

1 Introduction

Rock of mean unit weight within the range 2 to 20t is frequently used to protect or armour coastal structures such as breakwaters and sea walls. These structures are usually designed to dissipate much of the incident wave energy in flow over and through the rough and porous armour layer. Within such armour layers, each individual armour unit must therefore be capable of resisting the forces due to wave action, and must withstand mechanisms of chemical and physical deterioration operating in the marine environment. Historically the design of such armour layers required the use of rock judged to be "hard and durable", although few engineering tests were established to quantify the potential durability of the rock from any particular source. In this context durability may be defined as the capability of remaining useful for the original purpose. A more limiting definition, and that used in this paper, might require the material to remain at or above a defined level of usefulness, as given by armour layer performance and stability, over the full design life of the structure.

Recently a series of simple engineering tests have been developed to help quantify the potential durability of rock armour to be used on coastal structures, see Fookes & Poole (Ref 1). Appropriate acceptance values for each test have been advanced, based upon measurements of performance both in service and in the laboratory, see Poole et al, and Allsop et al (Refs 2, 3).

In most design work it has usually been assumed that the armour layer will remain at its original performance and stability levels throughout its design life, often about 30 to 50 years. However, it has been noted that rock armour on some structures has often not been as durable as had been hoped or anticipated. Many examples of early

* Scientific Officer, Coastal Structures Section
+ Principal Scientific Officer, Coastal Structures Section, Maritime Engineering Department, Hydraulics Research, OX10 8BA, UK.

deterioration reducing the stability and effectiveness of the armour have been identified (Ref 1). At some sites the rock available may be of inferior quality and will therefore be more likely to deteriorate under the action of waves, tides and other environmental factors. Alternatively, the design of the armour layer may itself allow significant levels of armour movement, giving rise in turn to impact and abrasion damage. Such movement might be envisaged at the design stage, as on rock berm breakwaters, see Baird & Hall (Ref 4), or on dynamically stable rock slopes, see Van der Meer & Pilarczyk (Refs 5, 6). On more conventional structures these high levels of armour movement may not however be expected, and will consequently not have been allowed for in the design. This may occur if the wave climate has been under-estimated, or if the structure is otherwise under-designed. A few design methods do envisage some armour movement, and the extent and rate of armour unit removal may be calculated, see Allsop et al (Ref 7) and Thompson & Shuttler (Ref 8). None, however, allow the deterioration of the armour layer performance or stability to be predicted.

Similarly, all design methods for rock, or concrete, armouring assume implicitly that the armour unit size and shape will remain constant throughout the structure life. To compound the problem, the methods used for monitoring completed structures offer relatively little assistance in quantifying the performance in service of an armour layer, or of its constituent armour units.

A number of techniques are presently being developed in the UK to assist the designer of rock armoured coastal structures to predict the likely deterioration of the armour over the design life of the structure. These techniques include rock quality testing, hydraulic model studies, and field monitoring methods. It is hoped that these techniques will allow the designer to adopt either of two different strategies, depending upon the client's administrative and financial position.

In situations where little or no maintenance will be possible, the designer may choose to use an over-size armour calculated to remain within acceptable stability levels throughout the structure design life. The initial size of the armour will be specified allowing for a possible level of deterioration. Such a design approach will allow the benefits and costs of importing a hard and more durable rock to be compared with the alternative use of less durable local material. Long-term consequences of different construction and armour placement techniques might also be assessed.

Where low initial cost is required, but provision may be made either for maintenance or refurbishment, the designer may choose an alternative strategy. In this situation the structure may be armoured using the best material locally available. Measurements of the rock quality using engineering tests, together with estimates of the severity of local degradation processes, possibly derived from monitoring other local structures, will then allow predictions to be made of the rate of armour layer deterioration. From this, the designer may then estimate the frequency of maintenance or

refurbishment requirements. Such estimates may be somewhat uncertain initially. Advanced monitoring techniques are therefore being developed to allow the degree, and hence rate, of deterioration to be quantified.

In any review of the technical literature it may be noted that the terms "damage" and "armour layer damage" are used by various authors with somewhat different meanings. In particular "damage" has often been taken to mean the permanent extraction of an armour unit from its original position in the armour. Such a definition does not, however, permit the quantification of more gradual deterioration, such as the fracture or progressive abrasion of armour units in situ. For this paper, and it is hoped for subsequent work, two definitions of damage are suggested:

(a) armour unit degradation - deterioration/change of armour unit size and/or shape from an original or an idealised size/shape;

(b) armour layer damage - deterioration of an armour layer from an original or idealised state leading to changes in the hydraulic performance and/or stability of the armour layer.

2 Recent Developments

2.1 Rock quality assessment and engineering tests

A wide range of engineering tests are available to quantify material properties such as strength, hardness, abrasion, and chemical resistance. Of these, some tests have been developed by researchers at Queen Mary College (QMC) for the testing of rock, principally intended for use as roadstone or aggregates, but more recently also for use on coastal structures as rock armour. In such applications the rock will be subject to processes of mechanical and chemical deterioration. These processes include impact, abrasion, freeze/thaw, salt crystallisation and leaching, and have been discussed fully by Fookes & Poole, and Poole et al (Refs 1, 2). The use of standard engineering tests is however of little benefit to the designer unless the test results can be related to prototype performance.

In a recent study, a wide range of rock types and prototype structures was studied. Rock from sites in the UK, Arabian Gulf, and east coast of Australia was subjected to a range of engineering tests. The results of these tests were correlated with experience of performance, particularly of rounding, spalling or fracturing. This project yielded a suggested suite of tests with appropriate acceptance values. These studies have been reported fully by Allsop et al (Refs 3, 7). Some aspects of the tests, the acceptance values suggested, their limitations and use, are discussed further with examples in Section 3 below.

It may be noted, however, that the rock available in some circumstances may be of low potential durability. The use of simple accept or reject criteria only for the supply of rock armour may therefore not be particularly helpful. Techniques that allow the in

service life of the available rock to be estimated will be more useful to the designer. A simple example of this approach has been presented recently by Fookes & Thomas (Ref 9). They describe the assessment of locally available rock in the course of a brief site visit. None of the rock easily available would pass the criteria suggested in References 2 and 3, and time was not available for a comprehensive test programme. A set of ad-hoc and qualitative assessment techniques was developed to allow the selection of the best material available. Engineering tests for point load strength, water absorption, and apparent specific gravity were used, together with a comprehensive understanding of the local geology, and of the processes of weathering and hardening. The potential useful life of the rock selected was estimated from the performance in service of various local coastal structures. In particular, assessments of armour stone rounding in service were made using a visually estimated score of relative roundness. In their brief appraisal, Fookes & Thomas demonstrated the potential use of engineering tests for rock quality assessment, together with in service performance monitoring of existing structures, as part of the design process for rock armouring. Since their appraisal, conducted in 1984, there have been further developments in monitoring techniques and in the quantification of the state of rock armour layers, and these are discussed in Sections 2.2 and 4 below.

2.2 Slope and shape monitoring techniques

Classic design methods for rock armouring envisage the construction of armour layers of fixed slope angle(s), thickness and layer porosity. The armour units within the layer are generally described only by the median unit weight, or by upper and lower limiting weights. Such simple descriptors do not, however, allow the hydraulic performance or stability levels of the armour layer to be fully quantified. Nor do they provide a particularly appropriate framework within which to monitor changes to the armour either in the field or in the laboratory.

Recently Latham & Poole (Ref 10) have advanced a set of more sophisticated techniques for the numerical description of the state of an armour layer. They have identified a range of descriptors intended to quantify the armour profile at both macro and micro levels. The descriptors have been tested using experimental profiles formed with glass balls or aggregate particles. Latham & Poole have described the use of high and low pass filters to the data. High pass filtering is clearly useful where particle shape and surface roughness are important. Conversely, low pass filtering may be used to reveal settlement or subsidence of the profile. It is however acknowledged that any relation between the properties of the armour layer profile and its hydraulic performance is as yet unquantified. The data rate required, at around 15-20 points per armour unit, also demands an automated measuring technique. This may be appropriate in the laboratory, but is not yet possible in the field. To accelerate data acquisition, researchers at both QMC and Hydraulics Research (HR) are actively pursuing video image processing techniques, some of which might be capable of digitising armour layer profiles directly.

Further advanced work is also continuing at QMC on the description of particle shape and roughness. Both of these factors considerably influence the hydraulic performance and the stability of the armour layer. Historically relatively little attention has been paid to particle shape. Qualitative terms such as cubic, angular, flat, and rounded, have often been used to describe shape. In some instances ratios of maximum and minimum perpendicular dimensions have been measured, or limiting values suggested. In few instances have the effects of particle shape been quantified. In no example known to the authors has armour unit shape or roughness been quantified and related numerically to armour performance or stability. In an effort to help overcome these problems, Latham and Poole have developed a number of sophisticated descriptors for particle shape and roughness. Preliminary work suggests that a single total roughness parameter might be used to assess many of the effects of armour unit shape on hydraulic performance and stability. A surface texture factor has also been derived for use in quantifying changes in armour unit texture and roughness. Again, automated data collection methods, such as video image analysis, have been investigated.

3 Rock Quality Tests

A suite of engineering tests have been used to assess the durability of the rock fabric, in rock armouring, on coastal structures. The tests have been adapted to analyse the effects of the physical and chemical degradation mechanisms operating in the marine environment; in particular the mechanisms causing abrasion, fracturing and spalling of the armour. The tests selected and the recommended acceptance value for each test are given below.

Recommended Acceptance Values for Quality Control Tests

Test	Recommended Acceptance Value
Aggregate impact value	25 maximum
Franklin point load index	$4MN/m^3$ minimum
Water absorption	2.5% maximum
Specific gravity	2.6 minimum
Magnesium sulphate soundness loss	12% maximum
Fracture toughness	$0.7MN/m^{3/2}$ minimum

The sulphate soundness and water absorption tests are used to assess the effects of salt water on the degradation of the armour. This is particularly important in situations where the rock has a high clay mineral content, such as in clay cemented sandstones or in weathered igneous rocks. Absorption and soundness tests have proved to be particularly useful in assessing the relative performance of various low strength rocks (Ref 9). The sulphate soundness tests induce swelling pressures within the rock fabric, causing accelerated disaggregation of the minerals. The specific test used in this study is a modified version of the ASTM soundness test. Magnesium sulphate is used in preference to sodium sulphate, as it produces more repeatable results, due to the single form into which magnesium sulphate crystallises.

The specific gravity of the rock is also of particular importance, in its stability against wave induced movement. Empirical design formulae for rock armoured structures indicate that more dense rock will be more stable than less dense rock of otherwise similar characteristics (Ref 7).

The Franklin point load test is used as a measure of tensile strength of the rock fabric. This test is particularly useful, since it requires no specimen preparation and can be carried out with portable test apparatus. It should, however, be noted that a fairly wide scatter of results may be obtained from this test. A sufficiently large sample of specimens should therefore be tested, to ensure that the results are statistically valid. Other tests have been considered as a measure of tensile strength; in particular the test for fracture toughness using the single edge notched beam method. This test provides results which correlate well with breakwater armour performance, and with the other engineering tests. Accurate specimen preparation and expensive testing equipment are, however, required for this particular test. Additionally, some difficulties have been experienced in preparing test specimens of coarse grained rocks (such as granites), where the test provides less reliable results. Whilst it is felt that this test does provide useful additional information on the rock quality, the additional costs and time taken tend to mitigate against its use.

The aggregate impact test is used as a measure of the potential for the disaggregation of the rock fabric by rock impact. This type of degradation typically occurs where armour is allowed to rock under wave action, or is subject to impact by suspended materials. Other tests have also been used to examine the wear resistance of the rock, including the Los Angeles abrasion test, an especially developed roller mill test, and the aggregate abrasion test. Whilst none of the tests have yet been fully calibrated against structure performance, general guidelines for the aggregate abrasion test have been drawn from the standards used in roadstone selection and experience drawn from a number of coastal structures.

The acceptance values tabulated above have been suggested on the basis of the in service performance of a range of rock types. In instances where the rock does not meet the specifications, in one or more of the tests, the full range of results should be considered carefully. Additionally, large scale inherent weaknesses in the rock, such as natural joints and bedding planes, which may affect armour unit size should also be considered. Only after careful analysis of the implications of any deficiencies in the rock should a decision be made to accept or reject the material.

In many instances, where the only rock available is of marginal or inferior quality, the tests may be used as a guideline to the performance of such material. Modifications to the design may sometimes be made to allow for the use of inferior quality of materials in the design. Further calibration data is, however, still required to allow the performance of substandard rock to be predicted with any degree of confidence.

The case studies outlined below illustrate some limitations of the durability tests and discuss the implications of results, suggesting appropriate modifications to the designs wherever necessary. A range of test results achieved in recent studies is shown in Table 1.

Two coarse granites from Spain have been examined, both of which exhibit good results in all but the Aggregate Impact Value test (AIV), where values of 30 and 41 were achieved - both above the recommended maximum of 25. These high values are clearly a function of the extremely coarse crystals of which these rocks are composed, and the angular nature of the aggregate size samples tested. The high impact values imply that the rock is less resistant to impact than might be desirable and suggest that abrasion, caused by movement of armour, or attrition by suspended sediment might cause fairly rapid rounding of the rock.

Rock type 4, (Table 1), exhibited an AIV of 41. Whilst the other test results were within acceptable limits, they were not so high as to imply a high level of durability. The shape characteristics of the armour, which was virtually cubic, and the absence of inherent planes of weakness in the armour did, however, allow a tight placement of the armour, thus reducing the likelihood of impacts from rocking movements. Hydraulic model tests conducted previously for a specific use had shown the rock armour to be very stable. The rock could therefore be expected to remain reasonably immobile under most wave conditions, and should therefore only suffer abrasion damage due to attrition by suspended sediments. By allowing a minimal over-design of rock weight, and ensuring that the armour is tightly packed, such rock of otherwise marginal quality should perform to an acceptable level.

The use of rock quality testing, together with hydraulic model tests may be illustrated by an example of a recent study for the rehabilitation of a vertical sea wall using rock armour. Two sources of rock were considered, the properties of which are given in Table 1 (rock types 1 and 2). Both rock types exhibited good results in all of the rock fabric tests. However, the large inherent weaknesses due to jointing in the carboniferous limestone indicated that the rock armour might break into smaller pieces if subjected to movements under wave action. The proposed construction method was considered carefully in the placement of rock in the hydraulic model. During testing, noticeable levels of armour rocking were recorded. The client was advised both on the hydraulic consequences of the design and the proposed construction method, and also on the implications of the anticipated armour movement on the selected rock armour type. As a result of the hydraulic model studies and the rock durability tests, it was possible to give advice on a suitable method of construction, to increase the packing density of the armour and thus reduce potential movement of the inferior quality rock.

4 Monitoring Techniques

Most conventional damage assessment techniques have been concerned solely with the evaluation of the proportion of armour units extracted permanently from the armour, resulting in cavities or voids. This is

Table 1: Rock properties

Rock Type	Location	Apparent Relative Density t/m^3	Water Absorption %	Magnesium Sulphate Soundness %	Franklin Point Load Index	Aggregate Impact Value	Aggregate Abrasion Value
1 Carboniferous Limestone	Westleigh UK	2.70	0.6	0.1	7.4	20	10.2
2 Gritstone (greywacke)	Triscombe UK	2.66	0.1	9.5	13.8	10	4

8 Granodiorite	Gothenburg Sweden	2.85	0.3	4.1	8.0	19	3.9

perhaps an over simplification of armour layer damage, since a number of significant, but more gradual degradation processes are not considered. The type of damage or degradation may vary according to a number of controlling factors.

(a) Environmental factors; such as waves, tidal range, temperature, salinity.
(b) Armour shape and size.
(c) Armour interlock.
(d) Rock quality.

An inspection method has been developed that allows the simultaneous appraisal of the effects of each of these elements. The methods used in this study are based closely on those developed by researchers at QMC and described by Allsop et al (Ref 3). A number of categories of armour layer damage have been identified, allowing the principle mechanisms of damage to be clearly defined on each structure. A brief description of each of the damage categories is given below.

The most obvious form of armour layer damage is the void or cavity, as considered by more conventional damage assessment methods. Fractures in armourstones may occur when the armour is permitted to move freely under wave action and/or where there are large inherent planes of weakness in the rock. Subsize armour may be defined as armour which is below specification size. This may occur as a result of poor quality control during construction, or may result from fracturing whilst in service. The final damage category used in this method of damage description is unstable armour. This is loosely defined as armour which is visibly mobile under wave action. Unstable armour is often characterised by rounded or abraded edges resulting from rocking movements, and is frequently observed on newly constructed structures, where initial placement may allow the armour to move freely. Such a condition is, however, usually temporary, as unstable armour tends to stabilise or is removed completely from the armour layers by wave action.

These armour layer degradation descriptors have been used in a monitoring method which aims to give a fuller description of armour layer damage than methods used previously. No sophisticated equipment is required to carry out surveys, but the method is, at present, limited to the sections of the structure that are surface emergent. Data is collected within carefully selected, delineated areas, each of which must be of sufficient size to provide a statistically valid sample of the armouring. The size of sample areas is dependent upon armour size and the freeboard of the structure. As a guideline, sample areas should contain a minimum of 100 armourstones. Similarly, the number and location of sample areas needed depends upon the size and exposure of the structure. Where possible, separate sets of measurements should be made for the intertidal and supratidal zones of the structure. Sample areas should be referenced to local fixed points, to allow relocation on subsequent surveys.

Surveys are conducted by counting the number of armour units in each of the damage categories. The most useful expression of damage is given by the total number of armour units in each category, expressed as a percentage of the total number of armour rocks in the study area.

A number of other damage assessment methods have also been considered (Ref 11). Expression of the degree of armour unit interlock may be a useful indicator of the integrity of the armour layers. A descriptor known as co-ordination number has been used to evaluate block interlock. This is simply defined as the average number of armourstones in contact with each individual armourstone in the sample.

Comprehensive monitoring programmes have been instigated using these measurement techniques. Several structures have been surveyed, covering a range of degrees of exposure to wave conditions and structure types. Some important aspects and conclusions drawn from the inspections are given below.

Port Talbot breakwater main arm was chosen for study, as a structure of typical rubble mound construction, exposed to a fairly severe wave climate. The main breakwater is approximately 2km long, changing alignment twice along its length, and is subject to a particularly large tidal range of approximately 8 metres. Sample areas were selected at locations of varying exposure - according to water depth and breakwater alignment, and separate sets of measurements were recorded in the intertidal and supratidal zones. The results of the first survey are shown in Table 2. A marked contrast in armour layer damage occurs between the intertidal and supratidal zones. Certain sections of the structure have degraded more rapidly than others, particularly in the intertidal zone. Sample area 3 (Table 2) has suffered far greater damage than other sections of the structure. This area is in a more exposed location, in deeper water and facing the predominant wave direction. The predominant category of armour layer damage on this structure is cavities. This is largely due to the severe wave conditions to which the structure is exposed. The rock armour is of relatively good quality, as is evidenced by the relatively low proportion of fracture damage. However, degradation by fracturing is significantly greater on the more exposed section of the structure, where more movements are likely to occur.

The revetment at Herne Bay, Eastcliff III is a recently constructed (1986) riprap armoured structure. Armour has a W_{50} of 850kg and the rock armour type is a granodiorite from Sweden. The properties of the rock are given in Table 1. An extremely low level of armour layer damage was measured on the first survey (Table 3). Good quality control during construction is evidenced by the absence of subsize armour. The quality of the rock appears to be very good, with little evidence of abraded or fractured armour. It should, however, be noted that the structure had not been subjected to a winter storm season at the time of the survey. Whilst overall armour layer damage was low, unstable armour figured prominently as a damage type. This might reasonably be expected on a newly constructed structure. Initial

Table 2: Breakwater Damage Assessment - Port Talbot

Sample No	No of Rocks	Fractures (%)	Cavities (%)	Subsize Armour (%)	Unstable Armour (%)	Total (%)	Co-ordination No
1 Supratidal	492	0.4	4.1	0.2	0.4	5.1	4.4
Intertidal	368	0.8	10.6	0.3	5.4	17.1	4.1

Table 3: Breakwater Damage Assessment

Location	No of Rocks	Fractures (%)	Cavities (%)	Subsize Armour (%)	Unstable Armour (%)	Total (%)	Co-ordination No
Port Talbot	2712	1.1	9.4	1.5	0.8	12.8	4.2
Stornoway	693	1.4	1.7	2.2	3.0	8.3	4.6
Herne Bay Eastcliffe III	828	0.2	2.2	0	1.7	4.1	4.9

settlement and removal of any unstable blocks during the first winter may well result in a reduced proportion of damage, in this particular category, on the next survey. The relatively wide grading of rock armour made measurement of the co-ordination number difficult, and where the rock grading was reduced in median size, at the less exposed end of the structure, the rock was too small to make measurement of the co-ordination number practicable. A series of levels were also taken along profile lines running from toe to crest of the structure.

The structure monitored at Stornoway airport is also armoured with riprap. The median rock size is, however, larger than that at Herne Bay, with a W_{50} of 1 tonne. This structure had been in existence for some years prior to the first damage survey, but sections of the structure had been repaired only a few months before the survey took place. The rock type used on this structure is a Lewisean gneiss, which often includes large inherent planes of weakness in the armourstones. This is evidenced in the damage analysis (Table 3) by the proportion of fractured armourstones in the samples. Cavities were infrequent, since most of the damage to the structure had recently been repaired. A relatively high proportion of structure damage occurred either as subsize armour or as unstable armour. This may be explained, to some extent, by the fact that the structure was a little unusual, in that it had undergone recent rehabilitation. Prior to repair the structure had a large number of cavities, due to armour removal. When armourstones are extracted it is quite common for units surrounding the voids to move to new positions, often reducing the size of the voids, and also reducing interlock between armourstones. In some instances the voids are reduced to a size such that the replacement rock cannot be placed in a stable position during repair. Alternatively, armour below the original specification size must be used to fill the voids, thus maintaining a reasonable degree of interlock. Whilst this may explain the reasons for the presence of some subsize armour on the structure, some of the armour has clearly degraded in situ as a result of fracturing along the planes of weakness in the rock.

Data collected in this study can be used to provide a detailed analysis of armour layer damage. By identifying the proportions, quantities and locations of each of the damage types, scheduled maintenance can be planned. If surveys are carried out on a regular basis, problems of gradual degradation that might otherwise go undetected may be identified. As more data becomes available, it should provide a basis for the selection of appropriate materials and construction techniques at the design stage, or allow revised placement techniques or material standards to be adopted during the repair of existing structures.

5 Recommendations

The work described in this paper has identified a number of techniques of use to the designer or owner of rock armoured coastal structures. A set of engineering tests has been developed to allow the identification of durable rock, and to grade available material for potential durability. Field monitoring techniques using a minimum of equipment have been described that quantify changes both to the

armoured slope and to individual armour units. A range of numerical descriptors have been defined and tested for armour profiles, and for armour unit shape and roughness.

Two further areas of research may now be identified. Armour unit shape and surface roughness clearly influence both the hydraulic performance and the stability of an armoured slope. Now that numerical descriptors are available for particle shape and roughness, it should be possible to conduct a series of hydraulic model tests to relate hydraulic performance and stability parameters directly to those for armour unit shape and roughness.

Also of importance to the prediction of armour layer performance is the quantification of changes to armour unit size and shape under the chemical and mechanical deterioration processes of the marine environment. This will require the quantification of rates of deterioration, such as rounding, in relation to the original rock material properties, wave climate and environmental parameters.

6 Acknowledgements

The work on which this paper is based has been funded in part by the Department of the Environment and the Ministry of Agriculture, Fisheries and Food. The authors are also grateful for the assistance of Dr J P Latham and Dr A B Poole of Queen Mary College, and Mr T J Austin of Canterbury City Council, and for the advice of Mr M W Owen, Manager of the Coastal Engineering Group, Hydraulics Research.

CHAPTER 130

THE INFLUENCE OF WAIST THICKNESS OF DOLOSSE ON THE HYDRAULIC STABILITY OF DOLOSSE ARMOUR

by
Hans F. Burcharth *
Torben Brejnegaard-Nielsen **

ABSTRACT

The paper presents results from experiments with Dolosse having the same mass and volume but with different waist thickness to height ratios. The armour was exposed to irregular waves simulating one storm with increasing wave heights and the effect of waist to height ratio on the hydraulic stability was studied. A low packing density of approximately 0.65 was used corresponding to a two-layer armour with high porosity.

From the results it is concluded that the hydraulic stability of Dolos armour is not very sensitive to variations in the waist to height ratio. Only for damage levels exceeding displacement of approximately 5% of the armour blocks in the most exposed area there seems to be a significant decrease in hydraulic stability with increasing waist to height ratio. Thus the waist ratio only influences the residual hydraulic stability.

Based on a short discussion of stressed in armour units it is concluded that design criteria solely based on movements of armour units as observed in hydraulic models are not adequate for the assessment of structural integrity of the units.

The paper also presents the results of each stability test as well as the scatter and the distributions. The large scatter found underlines the need for adoption of more restrictive safety factors than generally used in rubble mound breakwater design. It also supports the idea of a probabilistic approach in the design process.

INTRODUCTION

The recent failures of major rubble mound breakwaters have demonstrated the need for developments in breakwater design and construction. The problem is highly complex as the loads on the breakwaters and the response to match are typical stochastic wide-banded processes. On that background all parameters involved in breakwater design certainly have to be considered and their relative importance evaluated. One parameter of great importance is the mechanical strength of concrete armour units.

* Professor of Marine Civil Engineering, University of Aalborg, Denmark.
** Consulting Engineer, London, UK.

It is evident and well documented that the relative strength of concrete armour units decreases with the size of the armour units (Burcharth, 1981a), (Burcharth, 1981b), and (Silva, 1983).

Generally in complex types of armour units the stress level due to flow forces and static (gravity) forces increases linearly with the characteristic length (e. g. the height of the armour unit) while the stress level due to impacting units increases with the square root of the characteristic length. The relative importance of these stresses depends on the geometry of the units and their position on the slope, cf. Fig. 1.

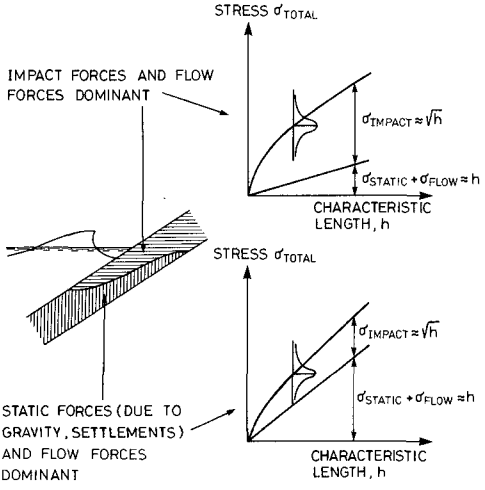

Figure 1. Qualitative representation of stresses in complex armour units as function of the size (length) of the units.

It follows from this that a design criterion solely based on movements of armour units in a hydraulic scale model is not adequate for the assessment of the structural integrity of the armour units.

Because of the size dependent stress level, one must either increase the strength of the units and/or apply a milder design criterion (e. g. a certain degree of rocking instead of displacements) when dealing with larger units.

In the case of complex types of armour units such as Dolosse, one way of increasing the strength is to increase the crosssections, i.e. apply a larger waist thickness to height ratio, r = d/h, see Fig. 3. However, by doing so the hydraulic stability will be changed too, which must be considered in the design. Thus, the relationship between the waist ratio and the hydraulic stability must be known. Scholtz et al. (1982) studied this relationship for Dolosse exposed to regular waves.

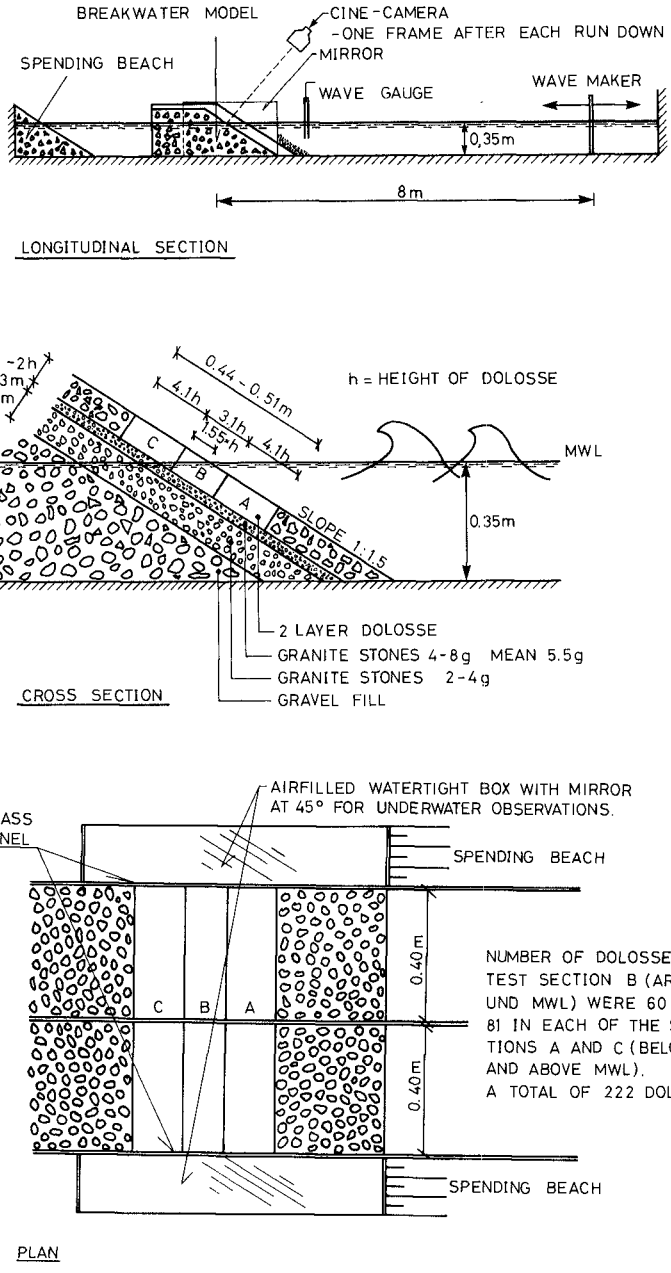

Figure 2. Test set-up.

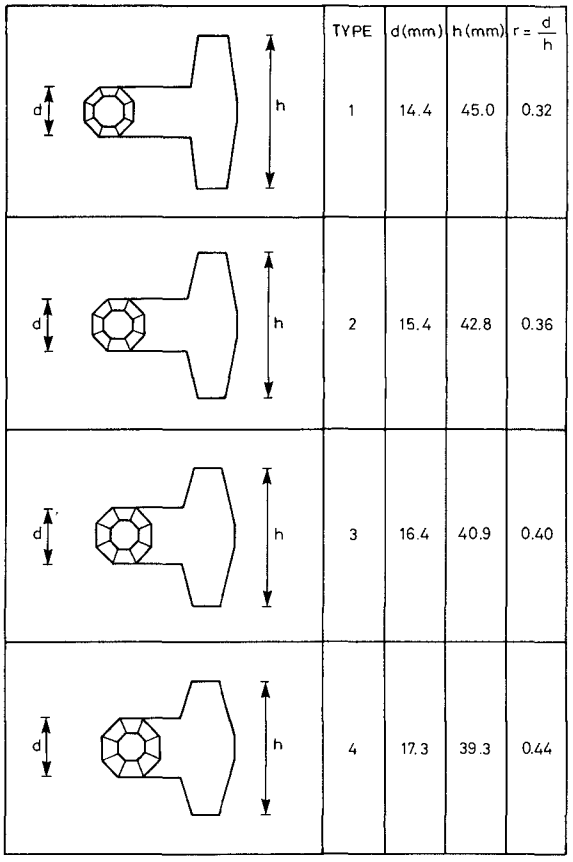

Figure 3. Geometry of model Dolosse.

In the present work the same hydraulic stability dependence is studied in irregular, two-dimensional waves for waist ratios of r = 0.32, 0.36, 0.40, and 0.44.

MODEL LAY-OUT

The tests were carried out in a 5 meter wide wavebasin, equipped with a spending beach, Fig. 2. As the total width of the model was only app. 1.6 meter, the wave reflection from the model was negligible.

The model was built in two separated sections to allow for a comparative study, where one section in all tests was armoured with Dolosse with a waist ratio of 0.32 used as a reference.

Each of the test sections was divided into three sub-sections called above, around and below mean water level. The Dolosse were placed randomly with a loose hand in two layers. For each test a total number of N = 222 Dolosse were applied in each section of 11.3 h x 0.40 m, where h is the height of the Dolos. Four types of Dolosse having the same volume and made of cement mortar with a mass density of ρ_a = 2.24 t/m^3 were tested. The geometry is given in Fig. 3. The theoretical volume of the Dolos is 14.2 cm^3, but pores in the surface made the actual volume V = 13.7 cm^3.

The packing density of the armour, defined as $\varphi = N\, V^{2/3}$, where N is the number of blocks per unit area, was 0.61, 0.64, 0.67, and 0.70 for waist ratios, r = 0.32, 0.36, 0.40, and 0.44, respectively. This corresponds to a two-layer armour with loose packing and high porosity. The increase in φ with r compensates for the otherwise increasing openness (exposure of filter layer stones) with increasing r. This, however, also means increasing amount of concrete per unit area with increasing r.

Generally a larger packing density in the order of 1.0 is recommended, but here the low values were chosen deliberately to represent the worst conditions in a real breakwater situation where uneven distribution of Dolosse on the slope can occur.

Cement mortar was applied in order to represent the prototype surface roughness as closely as possible. The tests were performed with irregular waves generated with a piston type wave maker on basis of a 5 parameters JONSWAP-spectrum.

$$S(f) = \alpha g^2 (2\pi)^{-4}\, f^{-5} \exp\left(-\frac{5}{4}\left(\frac{f}{f_p}\right)^{-4}\right) \cdot \gamma^{\exp\left(-\frac{1}{2}(f-f_p)^2/\sigma^2 f_p^2\right)}$$

with the four parameters;

f_p = 0.83 Hz
σ = 0.07 for $f < f_p$
σ = 0.09 for $f \geq f_p$
γ = 3.3

The fifth parameter α was used as a gainfactor to establish the desired significant wave-height $H_s = 4\sqrt{m_o}$, where m_o is the variance of the surface elevation.

Five values of H_s were chosen such that rocking of single blocks and displacements of several blocks would appear for the smallest and the largest H_s values, respectively. The values of H_s are given in Table 1 together with the parameter $\xi = (H_s/L_{H_s})^{-0.5} \tan\alpha$, where L_{H_s} are the wavelength corresponding to H_s and $\tan\alpha$ the slope.

Table 1. H_s and ζ values applied in the model tests.

Level	1	2	3	4	5
H_s (mm)	43	59	67	83	94
ζ	3.9	3.3	3.1	2.8	2.6

The duration of each test was 20 min. corresponding to approximately 1200 waves.

TEST PROCEDURES

Three series of tests were performed each containing the reference Dolosse (r = 0.32) and one of the other three block types. To evaluate the scatter each series consisted of five repeated (independent) tests, cf. Table 2, in each of which the wave height was increased corresponding to the above mentioned five levels of H_s.

Table 2. Test program.

Serie	1	2	3
Block type	r = 0.32, r = 0.44	r = 0.32, r = 0.40	r = 0.32, r = 0.36
No. of independent tests	5	5	5
No.of wave levels in each test	5	5	5

For each wave level in each test visual observations of the rockings and displacements in each of the sub-sections A, B, and C were made by 2 persons simultaneously by means of a special mirror system (Fig. 2). The mirror system allowed underwater observations throughout the running tests.

As a supplement single frames were taken by a cine-camera, which was activated when the water level during down-rush was approximately at the lowest level.

Two modes of movements were observed namely the rocking of the blocks (moving without translation) and the displacement of the blocks (moving with translation).

It was very clear from the testing that realistic information on the number of units rocking and being displaced cannot be obtained without the possibility of continuous underwater observations.

TEST RESULTS

In the Figures 4 to 7 the observed stability in terms of relative numbers of rocking and displaced units is depicted as functions of H_s, H_s/h and the stability number

$$N = \frac{\rho_a H_s^3}{M(\rho_a/\rho_w - 1)^3} = \frac{H_s^3}{V(\rho_a/\rho_w - 1)^3}$$

where ρ_a and ρ_w are the mass density of the Dolos and the water, respectively, and M and V are the mass and the volume of the Dolos, respectively.

N^3 can be derived from Hudson's formula as $K_D \cot\alpha$, where K_D is the Hudson stability factor. However, K_D should not be used for Dolos because the hydraulic stability is practically independent of the slope angle for $1 < \cot\alpha < 3$, which means that Hudson's formula is not valid for Dolos armour (Brorsen et al., 1974). However, to facilitate comparisons with the many published K_D values for Dolos also a K_D scale is shown in the figures.

To illustrate the scatter in the experimental results also the standard deviation over the mean value is shown for the various wave levels. Moreover, each test result is shown as a dot to visualize the actual distributions of the test results. It might be seen that these distributions can be fitted to the Poisson type distributions. It should be mentioned that these distributions, which represent the movements of the armour units, are different from the still unknown distributions related to the stresses in the units.

The figures illustrate the well known fact that the damage to the Dolosse armour is most severe in area B around the mean water level.

Despite its lack of consideration of the strength of the armour units, a design criterion corresponding to app. 5% of the units being displaced (within the levels SWL $\pm$ H_s) is often used. It is interesting to see that this compares to app. 10% of the units rocking and to H_s/h-values in the range 1.5-1.7 corresponding to K_D-values in the range 6.5-7.5. These K_D-values are lower than generally recommended. The reason for this discrepancy is probably that in many model tests the set-up did not allow underwater inspection of the movements of the armour units, which means that milder degrees of damage were recorded. Another reason might be lack of control of the reflected waves in some flume tests. Also the low packing density used in the present tests might have some influence on the K_D values, cf. the following conclusions.

Figure 8 shows a comparison of the stability of the four types of Dolosse. A decrease in stability with increasing waist ratio r is seen, but only for the more severe wave conditions, say $H_s/h > 1.5$ or $N^3 > 10$. For the smaller values of H_s/h there are only minor, non-systematical differences between the stabilities of the various shapes of Dolosse.

COMPARISONS AND CONCLUSIONS

Tests were performed on the hydraulic stability of Dolosse with waist thickness to height ratios of r = 0.32, 0.36, 0.40, and 0.44 exposed to irregular waves. It can be concluded that the hydraulic stability is decreasing with increasing waist ratios but only for high degrees of damage, i.e. damage levels exceeding displacements of approximately 5% of the blocks in the most exposed area. Thus the waist ratio only influences the residual hydraulic stability of the armour. The reduction in the hydraulic stability is probably due to the relatively quicker loss of effective permeability ("reservoir effect") and interlocking ability for units

with large waist thicknesses (Burcharth et al., 1983).

The same trend but more pronounced was found by Scholtz et al. (1982). However, they used regular waves in the experiments such that a comparison cannot be made directly. Brorsen et al. (1974) found that irregular waves of H_s will cause the same degree of damage as regular waves with the height $H \cong 0.8H_s$.

A comparison of the present results with the results of Scholtz et al. gives $H \cong 0.6H_s$ for the same damages. An explanation for a part of this discrepancy is probably that Scholtz et al. did not use a technique which allowed underwater inspection of the movements of the armour units. This means that the present tests certainly will show a larger number of moving units (other things equal) and thus a lower stability of the Dolos armour, because all units are kept under observation during the tests.

Moreover, Scholtz et al. used a packing density of 1.00 for the Dolos armour while a range of 0.61-0.70 was used in the tests presented here. The difference should, according to tests in regular waves by Zwamborn et al. (1982), compare to a reduction in wave height of approximately 6% for the lower packing density.

It should also be noticed that damage levels expressed in terms of the relative number of moving units are dependent on the actual number of units in the section under observation, i.e. dependent on the size of the section and the packing density. For example by increasing the packing density from 0.65 to 1.0 the relative number of moving units will decrease by app. 50% but of course only if the actual number of moving units is independent of the total number of units in the section, which is not the case.

A similar comparison of the present results with the results obtained by Brorsen et al. (1974) and Burcharth (1979) for regular waves and Dolos packing densities of 1.0 shows approximately the same relationship $H \cong 0.6H_s$ as mentioned above. This again is mainly due to the fact that the set-up of these tests did not allow continuous underwater inspections. It is believed that the relationship $H \cong 0.8H_s$ is the more realistic although based on the tests by Brorsen et al. where underwater inspection was impossible. This is because these tests are a comparative study where exactly the same observation technique was used on both regular and irregular waves and because it is reasonable to assume the same proportionality between the total number of moving units and the observed number of moving units for both regular and irregular wave conditions.

The presented results indicate that in areas of the armour layer where impacts are the dominant loads it is possible to obtain a balance between the hydraulic stability and the structural integrity also for the very large Dolosse of say 40 t or more by increasing the waist ratio. However, because stresses due to static (gravity) forces and flow forces increases more rapidly with the size of the units than stresses due to impact forces it might well be that for the armour layer as a whole the structural integrity cannot be obtained.

The large scatter in the experimental results underlines the need for adoption of more restrictive safety factors than generally used in rubble mound breakwater design. It also supports the idea of a probabilistic approach in the design process (Nielsen et al., 1983).

CHAPTER 131

STUDY OF STATISTICAL CHARACTERISTICS OF IRREGULAR WAVE PRESSURE ON A COMPOSITE BREAKWATER

by

Chien-Kee Chang* and Ching-Her Hwang**

ABSTRACT

Wave pressure is the most important external force for the design of breakwater. During recent years, there has been considerable development in the technology of vertical face breakwater; however, there is no reliable method to compute wave forces induced by irregular waves. The purpose of this study is to obtain statistical characteristics of irregular wave pressure distribution from the data of model tests.

The results of this study shown that vertical face breakwater under the action of irregular waves, some waves are reflected, so that the next wave breaks a critical distance resulting in a rapidly rising shock pressure on the breakwater. On the average, the wave pressure increase with incoming wave height, but the maximum wave force does not necessarily occur for the largest wave height. It can be occurred for serval larger wave group in an appropiate phase composition. The irregular wave pressure distribution on the breakwater is quite uniform; the ratio of tested and calculated wave pressures decreases with the reduction of relative crest height of breakwater.

Goda formula can predict the total horizontal force of the upper part of breakwater quite well except exetreme shock pressure occurred by non-breaking waves. Wave forces calculated by Miche-Rundgren and Nagai wave force formula are about 10% cummulated exceeding percentage of wave force obtained from model test.

Introduction

Sainflou (1928) drived a wave pressure formula for standing wave by using trochoidal wave theory. Sainflou formula has been widely used in calculating non-breaking wave forces for the past years. Rundgren (1958) by using Miche higher order wave theory and taking wave reflection into consideration, proposed Miche-Rundgren wave pressure formula for non-breaking waves. Nagai (1968) adopting small amplitude

* Deputy Director, Institute of Harbor and Marine Technology, Taiwan, R.O.C.

** Associate Researcher, Institute of Harbor and Marine Technology, Taiwan, R.O.C.

wave theory and test results suggested wave pressure formula according to three different relative depths. Goda (1974) suggested wave pressure computation method by taking the expected sliding proposed by Ito, into consideration and using the maximum wave height.

Lundgren (1974) studied the vertical face of composite type breakwater to reduce shock pressure by using irregular waves. When shock forces occur, they are functions of the ever varying combinations of wave shape. Hence they must be analyed statistically. The results show that the statistical distribution is often linear in a semilogarithmic diagram.

Katsutoshi (1984) studied random wave forces on upright section of breakwater, the test results show that for non-breaking wave trains, peak pressure can be predicted quite well by Goda formula to the joint distribution of wave height; the respective wave force defined as the same ways for the wave height can be predicted by Goda formula by using the corresponding respective wave. But, in case of breaking waves, the maximum pressure is far exceed the value predicted by Goda formula.

Experiment

A wind flume 100^{m} long, 1.5^{m} wide, 1.5^{m} deep, equipped with irregular wave generator, wind blower and circulation as shown in figure 1. Wave gauges, pressure gauges are interfaced on line with data acquisition system. The sampling rates for stage I and II are 45 samplings/sec. and 200 samplings/sec. respectively. The diameters of pressure transducer used for stage I and II are 8^{mm} and 1.8^{mm}.

Typical cross section is shown in figure 2. Two linear model scales 1/49 and 1/25 are used for stage I and II respectively. For the first stage, water depth range from 33.0^{m} to 37.5^{m}; wave heights are from 8.0^{m} to 16.5^{m}; the corresponding wave periods change from 12.0^{sec} to 14.6^{sec}. At the second stage, water depths vary from 10.5^{m} to 18.5^{m}; wave heights change from 3.0^{m} to 7.0^{m}; and wave periods are from 8.0^{sec} to 12.0^{sec}.

Test Results

Typical form of incident wave spectrum is shown in figure 3; cummulated exceeding percentage of wave height distribution is shown in figure 4. Time series of waves and corresponding pressure density are illustrated in figures 5 and 6 for the first and second stages respectively. Figure 5 shows that incident significant wave height 13.24^{m}, water depth 37.5^{m}, the relative water depth is 2.83. In general, it seems deep enough to prevent shock pressure induced by breaking waves; but, it occurs shock pressure at time 19.4^{sec}, when several larger waves attack the breakwater continually. It should be noted that the wave form is upside down in this figure. In the second stage, figure 6 shows that wave pressures are in phase with water level in front of the breakwater. Although, the relative water depth 2.85 (14.25/5.0) is almost equal to that of the first stage 2.83; but there is no shock pressure occurs in this test run.

The cummulated exceeding percentage of wave force for typical cases are shown in figure 7. Figure 8 shows comparision of wave forces acting on the same cross section for different test conditions. The force distribution on the vertical face breakwater shows quite uniform.

Wave forces calculated by different formula for wave height obtained from model test are plotted against the test results as shown in figure 9. Although, Goda formula can not predict wave pressure at a single point; but it can obtain the total horizontal force of the upper part of the breakwater quite well, except very exetreme shock pressure occurred by non-breaking waves. Wave forces calculated by Miche-Rundgren and Nagai formula is about the maximum one-tenth of the wave force (F10%) obtained from model tests.

From linear fitting curve, F1% and F10% are wave forces which occurred at cummulated exceeding percentage of 1% and 10% respectively. Figure 10 shows the ratio of wave forces between model test and formula computation (F_t/Fc). F_t is either F1% or F10% and Fc represents wave force calculated by Goda formula Fg. Miche-Rundgren formula Fm and Nagai formula Fn. The ratio Ft/Fc decreases with the decreasing of relative crest height d_c/y_c as shown in figure. Figure 10 shows when lower crest height of the breakwater, wave force formula predict larger wave force than those obtained in model tests. When d_c/y_c greater than 0.85, the ratio F_t/F_c varies from 0.9 to 1.0.

Conclusion

1. The maximum wave pressure does not necessarily occur for the largest wave height; the incident and reflected of a group of larger waves may induce the maximum pressure.

2. Under the action of irregular waves the pressure distribution acting on vertical force breakwater is quite uniform.

3. For non-breaking incident waves reflected by vertical wall, shock pressure can be occurred by an appropriate phase composition.

4. The ratio of wave forces obtained from model tests and calculated by different wave force formula decreases with the decreasing of relative crest height of breakwater.

5. Goda wave force formula can predict the maximum wave force in a wave train, except very exetreme shock pressure occurred by non-breaking waves. Wave forces calculated by Miche-Rundgren and Nagai formula are about 10% cummulated exceeding percentage of wave force obtained form model tests.

CHAPTER 132

THE RELATIONSHIP BETWEEN WAVE LENGTH AND WEIGHT OF ARMOUR BLOCKS

by

Kuo-Quan Chen*, Ruey-Chy Kao**, Frederick L.W.Tang***

ABSTRACT

Every coastal engineer realizes that the weight of armour blocks decided by Hudson's formula is safe enough for short steep waves, however, suffering damage from long period swells, even though the incidental wave height is the same. Several corrections have been made and submitted to ICCE as well as in other occasion. The authors try to explain analytically the influence of wave length on the design weight of armour blocks and justify by much of experiments in order to offer new formula and graphs for practical application.

INTRODUCTION

Armour blocks used as effective protection on seashore or structures, the wave energy absorbed due to its surface roughness, porosity and stability, when wave attacked. While an appropriate design of weight of armour unit, it is difficult to derive from theory because of many factors and conditions which conducted to

select it. [1]. Generally, the most frequently used formla, today, modified by Hudson(1959) and given by

$$W = \frac{\rho_s \quad g \quad H^3}{K_d \left(\frac{\rho_s}{\rho} - 1 \right)^3 \cot \theta} \qquad (1)$$

Where: W = armour blocks design weight

ρ_s, ρ = mass density of blocks and sea water

K_d = stability number

θ = slope angle of riprap facing offshore.

H = wave height at the location of the breakwater without wave breaking.

Its popularity comes from the limited variable of parameters and convinient to use.

From the viewpoints of safety and economics, design of armour unit used as shore protection, selection of the type, arrangements and its weight are the main consideration factors. Some armour unit, developed with spescial characteristis on its shapes and arrangements, but the weight of armour unit depends on equation (1), though it's safe enough for short waves, the damage occured from long waves occassionally. Especially for the waves caused by Typhoon on the sea area around Taiwan during summer and fall every year.

In accordance with the expiriences abovementioned, the authors try to consider wave period as an important factor as design of appropriate weigut of armour unit. For wave energy is under various influences, such as wave height, wave length, etc, ie, $E = \rho$ (ρ, g, H^2, L). From the point, the authors developed fundamently the

design equation for armour blocks involved the effect of wave period on stability, and justified by experiments for practical applications.

Some papers described armour blocks effected under irregular waves recent time, mostly based on Hudson's formula [8][10], However, Pilarczyk and Boer (1983), [7][11], developed series of stability formula, under random wave attacked, of which the parameters included wave period, number of waves, armour grading, spectrum shap, groupiness of waves and permeability of the core, etc. The abovementioned subjects were rubble mound but not armour unit, especially for artificial armour unit was lacking to make mention of. The authors have performed much expiriences on study and design of coastal and harbor engineering, [2,3,4,5,6,9,12] and realized that it is necessary to develop an application formula from the fundamentally studies.

ANALYSIS

If the weight of armoured block, on slope angle θ, is W, density ρ_s in air, then the vertical component force is $(1 - \frac{\rho}{\rho_s})$ W cos θ, therefore, the drag force (F_1) of aumour block against incoming waves express as follows, if μ as friction coefficient between block and mound. (Fig. 1)

$$F_1 = (1 - \frac{\rho}{\rho_s}) W (\mu\cos \theta - \sin \theta) \text{----------} (2)$$

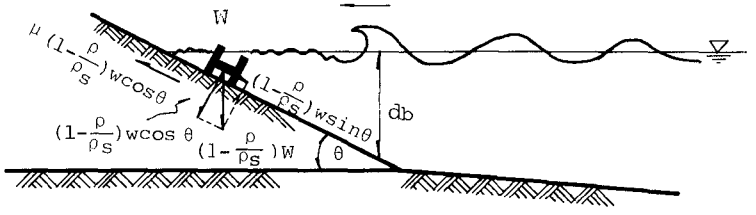

Fig. 1 Definition

The volume of armour block $V = \frac{W}{\rho_s g}$ is direct proportional to the cross sectional area of vertical direction of incoming waves, ie, proportional to $V^{2/3}$. if wave velocity v, then amour block attacked by wave force will be:

$$F_2 = C_D \rho v^2 \left(\frac{W}{\rho_s g}\right)^{2/3} \text{----------(3)}$$

Irribarren derived from velocity of long wave, under the stability conditions of armour block, $F_1 \geq F_2$. ie,

$$\left(1 - \frac{\rho}{\rho_s}\right) W \left(\mu\cos\theta - \sin\theta\right) = \frac{1}{2} C_D \rho g H \left(\frac{W}{\rho_s g}\right)^{2/3} \text{----(4)}$$

Irribarren's formula

$$W = \frac{K' \mu^3 \rho_s g H^3}{\left(\frac{\rho_s}{\rho} - 1\right)^3 \left(\mu\cos\theta - \sin\theta\right)^3} \text{----------(5)}$$

Where, $K' = C_D^3/8\mu^3$, C_D = drag coefficient.

In the case of a definite cross section, μ, ρ_s, ρ, and θ may be regarded as constant but C_D will be different according to the shape of block and velocity.

Let

$$C = \frac{1/8 \ \rho_s g}{\left(\frac{\rho_s}{\rho} - 1\right)^3 \left(\mu\cos\theta - \sin\theta\right)} \text{----------(6)}$$

Consequently

$$W = C C_D^3 H^3 \text{----------(7)}$$

H is to be replaced by H' under water level

$$H' = \frac{\pi H^2}{L_o \left(\sinh \frac{2\pi d}{L} \right)^2} = \frac{2\pi H^2}{L \sinh \left(\frac{4\pi d}{L} \right)} \qquad (8)$$

Substitute (8) to (7)

$$W = C C_D^3 H^6 \frac{\left(2\pi/L \right)^3}{\sinh^3 \left(4\pi d/L \right)} \qquad (9)$$

A non-dimensional expression is worked out as follows

$$\frac{W}{\rho_s g C_2 C_D^3 H^3} = \frac{\left(H/L \right)^3}{\sinh^3 \left(4\pi d/L \right)} \qquad (10)$$

Where

$$C_2 = \left[\frac{\pi}{\left(\frac{\rho_s}{\rho} - 1 \right) \left(\mu \cos \theta - \sin \theta \right)} \right]^3 \qquad (11)$$

This will be a new formula if the coefficients μ and C_D are selected properly which authors will be measured by experiments.

EXPERIMENT INVESTIGATION

In order to verify under the conditions of the armour blocks attacked by incoming waves, equation (10) and (11) in which friction coefficient μ and drag coefficient C_D included.

The values of μ and C_D which is obtained by a series of experiments.

Test on friction coefficient, it measured friction between block and mound under water, due to the block considered as submerged condition when wave attacked. The test layout as Fig.2, the value

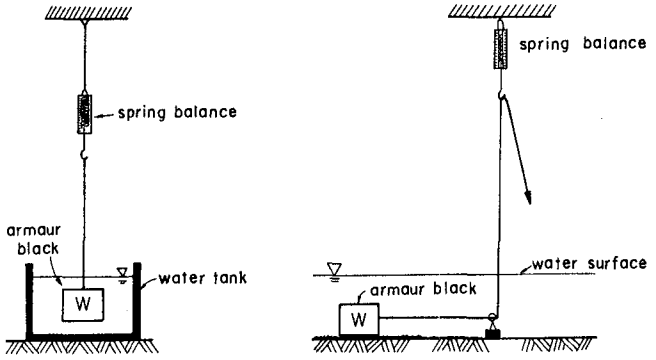

Fig. 2 Test of Friction Coefficient

of μ was obtained in average value of repeated experiments, as table 1.

Table-1 Friction Coefficient

Types	Wa (grf)	Ww (grf)	f (grf)	μ
HOLTRIPOD	74.9	42.5	61.67	1.4511
HEXA-HOLLOW TRI-LEG	46.1	30.1	50.00	1.6667
	67.4	45.0	75.00	1.6667
	84.9	57.5	83.75	1.4565
	110.9	72.5	103.57	1.4286
	137.6	79.1	119.45	1.5101

Another test on drag coefficient C_D, due to C_D related to reynoulds number of flow, authors tried to express volume of block as 2/3 order of characteristic length, using falling velocity experiment to find out the falling velocity, the instrument as Fig.3

and Photo-1, tested blocks namely Holtripod and Hexa-Hollow Tri-leg (Photo-2).

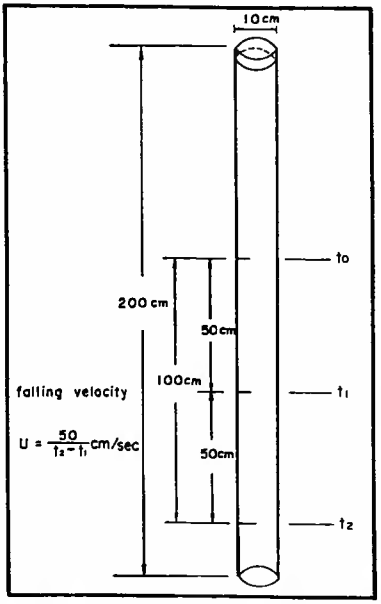

Fig. 3 Test on Falling Velocity

Photo-1 Test Instrument of Falling Velocity

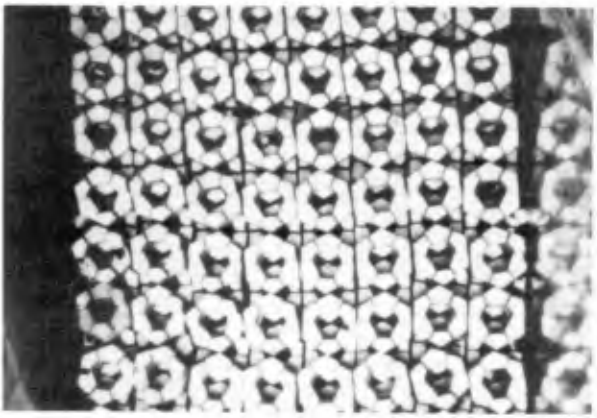

Photo-2 Model Blocks

The value of falling velocity of every model block obtained by measuring average of 30 repeated experiments, defferent weight of 4 blocks to be tested. These value were substitute to equation (13) and obtained C_D as table-2.

$$(\rho_s - \rho) g V = \frac{1}{2} \rho g v^2 C_D v^{2/3} \quad \text{----------(12)}$$

$$\Rightarrow C_D = 2 \left(\frac{\rho_s - \rho}{\rho} \right) g \frac{v^{2/3}}{v^2} \quad \text{----------(13)}$$

Where V = Volume of armour blocks

v = falling velocity

Using value of μ and C_D substitute to equation (10) and (11), it was calculated for varying relative depth d/L and wave steepness H/L and then plotted on theoretical curve in Fig. 4.

CONCLUSIONS

1. According to abovementioned analytical calculations and experiments, equation (10) namely

$$W = \rho_s\, g\, C_2\, C_D{}^3\, H^3\, (\, H/L\,)^3 / [\sinh(\, 4\pi d/L\,)]^3$$ is to be applied

in practical design, while C_2 in equeation (11) is known for the same type of blocks and definite design profile, the coefficient μ and C_D should be determined by the experiments having been

performed by the authors.

2. From the outcomes of calculations and experiments, it is obvious that wave length has marked effect on the design weight of armour blocks. In experiments, the influence of relative depth even greater than steepness. This reality reveals the fact that to determine the weight of armour block by wave height only will be deficient.

3. Based on this fundermental results, the authors will try to modify the value of drag coefficient C_D for futher studies, such that measuring flow condition of armour block under the design wave length, for practical application.

NOTE, DEFINITION

W	: armour block design weight	(kgf/m^3)
ρ_s	: mass density of block	(kg/m^3)
ρ	: mass density of sea water	(kg/m^3)

CHAPTER 133

Wave Trapping by Breakwaters

by Robert A. Dalrymple[1], M. ASCE, James T. Kirby[2], A.M. ASCE and Daniel J. Seli[3]

ABSTRACT: The refraction of water waves around the heads of breakwaters can lead to large wave heights along the sheltered side of the structure. These waves are shown to be edge waves, trapped on the breakwater, based on the comparison of laboratory data and linear edge wave theory.

Introduction

Water waves experience refraction, diffraction and shoaling on a breakwater. On the seaward side of the structure, wave breaking and reflection, due to the steep sides, often dominate the wave environment along the trunk of the structure. When the angle of incidence is large (with respect to the normal to the breakwater), Mach stem reflection can occur. It is this side of the structure, which receives the most attention by engineers. On the leeward side of the breakwater, the wave climate is supposed to be reduced, and the wave field dominated by diffraction. However, the rounded head of a breakwater can cause a significant amount of wave energy to be refracted onto the leeside of the breakwater, forcing the waves to be trapped there. These trapped waves then propagate along the breakwater into the sheltered region, with wave heights far larger than expected (they can exceed the wave heights on the seaward side of the breakwater). These waves are edge waves and decrease in size only due to frictional and percolation damping along the breakwater. Fortunately the edge motion decreases rapidly away from the breakwater, so that the sheltered area is unchanged, except along the breakwater. These edge waves, with their greatest amplitudes occurring at the waterline, may be large enough to warrant their consideration in design; particularly for large structures.

This paper examines the mechanisms for wave trapping by breakwaters, showing several model predictions of the phenomenon (using both an edge wave model and a parabolic combined refraction/diffraction model) and then laboratory data are presented to show the presence of these trapped waves, verifying that they are edge wave motions.

It has been known for a long time that the head of a breakwater is the location of wave focussing due to refraction of the waves over the submerged rounded portion of the terminus of the breakwater. Waves incident on the head of the breakwater are refracted around the structure in such a way as to create regions of very high waves on the shoulder of the structure. Palmer (1960) cites several breakwaters in the Hawaiian Islands that required repair due to this focussing. For the Nawiliwili breakwater, the extensive submerged head of the structure caused so much focussing of the waves that the waves broke and formed a jet of fluid on the lee side of the breakwater. Magoon (1984) has referred to this as the "Palmer jet". While the intent of this paper is not the discussion of the Palmer jet, it is a manifestation of the wave focussing that creates the trapped wave motion.

Smith (1986), presenting a methodology for breakwater design for the Corps of Engineers, points out that the complicated flow field in the vicinity of the breakwater head creates a design situation which is a "highly subjective and empirical process". Clearly more research into the behavior of waves in this region is important.

Theoretical Considerations

Wave-trapping on the Downwave side of Breakwaters

The simplest method for examining wave trapping by refraction around the head of the breakwater is through the use of Snell's Law. If we consider the trunk of the breakwater as a long steep beach, with parallel contours, then Snell's law applies for the refraction of the waves.

$$\frac{\sin \theta}{C} = \frac{\sin \theta_o}{C_o} \tag{1}$$

Here the subscripts denote offshore conditions. If a wave is reflected from the structure at a large angle and propagates from shallow to deep water, the wave propagation angle increases with depth. If this angle goes to 90°, then the wave is reflected from the deep water back into the shallow water (and back onto the breakwater). Due to the steepness of the breakwater, the waves, as they refract shoreward, once again reflect seaward, and the process continues. (Camfield (1982) has discussed this trapping mechanism with regard to reflective structures on straight shoreline.)

If the waves reach a 90° angle at the toe of the structure, then Snell's law reduces to

$$\sin \theta_c = \frac{C_c}{C_t} \tag{2}$$

where C_t is the wave speed at the toe of the structure and the angle, θ_c, is the critical angle. Therefore for a given depth on the breakwater, if the wave angle exceeds θ_c, then the waves will be trapped. The mechanism for inducing the waves to approach the trunk of the structure with large angles of incidence is of course the refraction at the head of the structure. See Figure 1.

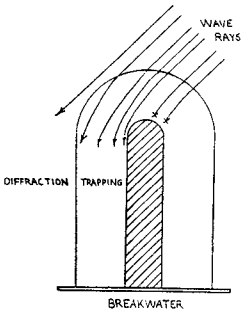

Figure 1. Schematic of Wave Trapping

It is in principle possible to determine the incident angle for wave trapping on a breakwater. Mei (1985) examines the capture of waves by circular islands, which can serve as an analog to the rounded head of a breakwater. For islands with very mild nearshore slopes, Pocinki (1950), all of the waves which cross the submerged bathymetry of the island eventually hit the island's shoreline. For islands with steeper nearshore slopes, less of the incident waves refract into the islands. This would be true for breakwaters. For waves normally incident on a breakwater, some percentage of the waves which pass the head of the structure will be captured; this percentage increasing with decreasing nearshore slope.

The trapped wave motion can be described by edge wave theory, which describes waves, which travel along a beach, rather than incident from offshore. These waves have been studied extensively by Guza (1985), who discussed the state of the art. Recently, Yeh (1986) reports laboratory verification of the edge wave theories to higher order. The dispersion relationship for a small amplitude edge wave on a planar beach of constant slope is

$$\sigma^2 = g \lambda \sin (2n+1)\beta \tag{3}$$

where σ is the angular frequency of the waves, $\sigma = 2 \pi/T$, λ is the wave number of the edge wave, $\lambda = 2 \pi/L$, where L is the wave length, g is the acceleration of gravity and β is the beach slope. Here n is the modal number, which describes how many zero crossings may occur in the wave profile in the offshore direction. Thus for a given breakwater slope and incident wave period the wave length of the edge waves can be determined. The free surface displacement of a zeroth mode standing edge wave can be described by an exponential function in the "offshore" (normal to the breakwater) direction (y):

$$\eta(x,y,t) = A e^{-\lambda y} \sin (\lambda x) \cos (\sigma t) \tag{4}$$

If the water depth at the toe of the structure is not too deep, then the edge waves are affected by the change in slope from the sloping structure to the bottom slope. The above dispersion relationship is no longer valid and therefore another means is necessary to find the wave length. Kirby, Dalrymple and Liu (1981) present a

finite difference procedure for solving the mild-slope equation for edge waves. This procedure was used here to compute wave lengths of laboratory waves, although it was found for the depths and slopes used here that Eq. (3) is quite accurate.

The mild-slope equation for periodic waves on an arbitrary beach profile can be written as

$$p\,\eta_{yy} + p_y\,\eta_y + (\sigma^2 q - \lambda^2\,p)\,\eta = 0 \tag{5}$$

where the subscripts denote derivatives and the water surface displacement is assumed to be

$$\hat{\eta} = \eta(y)\cos(\lambda x)\cos(\sigma t) \tag{6}$$

and $$p = C\,C_g$$

$$q = C/C_g$$

Here C and C_g are determined from linear wave theory, based on the local depth. By introducing the variable, $\zeta = \eta y$, Kirby et al. reduced the problem to an eigenvalue problem, as $\zeta \to 0$ as $y \to 0$ and $\zeta \to 0$ as $y \to \infty$. It then becomes a matter of finding the correct value of λ for the given wave period and beach profile. Holman and Bowen (1979) solved this problem using a shooting method, which involved many iterations for each mode of the edge wave motion. Using a finite difference technique, Kirby et al. were able to obtain all edge wave modes at one time, without iteration.

The solution follows by dividing the offshore distance, x, into a number of discrete intervals, from 0 to a large number representing infinity. Expressing Eq. 5 in finite difference form (using central differences), a tri-diagonal eigenfunction equation results.

$$\{A\}\,\{\zeta_i\} = \lambda^2\,\{\zeta_i\} \tag{7}$$

where {A} is a coefficient matrix and ζ_i are the discretized dependent variable. (This equation is slightly simpler than Kirby et al. as we have divided through by $p_i y_i^2$.) Solving the eigenvalue problem, using standard mathematics libraries (ISML), yields the eigenvalues, λ, which are the alongshore wave length of the edge waves, and the forms of the associated eigenfunction.

Wave Propagation Modelling

A refraction-diffraction model is capable of modelling the behavior of waves in the vicinity of the breakwater. In fact, the presence of the edge wave motion along the breakwater was first observed by the model, developed by Kirby and Dalrymple (1983, 1986). The parabolic model can be described as a solution to the following complex differential equation:

$$A_x - i(k-k_o)A + \frac{1}{2C_g} C_{g,x} A - \frac{i}{2C_g \sigma} (CC_g A_y)_y = 0 \qquad (8)$$

where the water surface displacement, η, is given by

$$\eta = \mathrm{Re}\ \{A(x,y)\ e^{i(k_o x - \sigma t)}\} \qquad (9)$$

and $i = \sqrt{-1}$. Here k_o is a representative wave number for the region of interest. This model is developed in finite difference form and solved by the Crank-Nicolson procedure. The results of the model are the complex amplitude, A, from which the instantaneous water surface or the transmission coefficient can be found. The reader is referred to the above papers and Kirby and Dalrymple (1984) for more details on the model, REF/DIF 1.

Laboratory Experiments

The Ocean Engineering Laboratory of the University of Delaware has a directional wave basin, with dimensions of 20m x 20m x 1.1m and a thirty element wave generator along one wall. The wave paddles, driven by Mavilor 600 servo-motors, can create waves in different directions as they are individually programmable using an HP 1000 computer.

A model breakwater with 2:3 slopes was built in the basin with a rounded head and a trunk length of 2.41m. The width of the breakwater trunk at the bottom was 2.1 m. The water depth of the basin was 0.36m. The angle of incidence of the waves was 37.8°. See figure 2. A reflecting wall was placed at the downwave end of the breakwater to prevent waves from flanking the structure, producing spurious effects, and to enhance the edge waves by reflection. This produced a partial standing edge wave pattern along the trunk of the breakwater on the downwave side.

Wave data was taken at four locations, using resistance wire gages. Gages were calibrated before and after each experiment to ensure accurate conversion of voltage data to elevation data. In front of the breakwater, the incident wave was measured at location A in figure 2. Then three wave gages were located on a transect

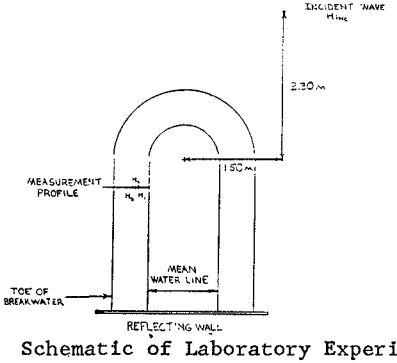

Figure 2. Schematic of Laboratory Experiment

normal to the breakwater axis, spaced 0.155m, 0.22 m, and 0.295 m from the still water line. This transect is also shown on the figure. Four separate wave periods were used for the tests. The wave heights at the wave gages were obtained for a given wave train.

Table 1 contains the wave data for the various tests, where T is the incident wave period and H_i is the incident wave height. In Table 2, the measured wave heights at the three shore-normal gages (with H_1 being the most inshore gage) are shown along with the measured spacing between the crests of the standing wave pattern along the breakwater, Lr. (This distance is one-half of the edge wavelength.)

TABLE 1. INCIDENT WAVE CHARACTERISTICS

TEST	T(s)	H_i(m)	θ(°)
234	1.00	0.068	37.8
227	1.30	0.057	37.8
212	1.35	0.091	37.8
230	1.40	0.068	37.8

TABLE 2. MEASURED WAVE DATA

Test	H_1(m)	H_2(m)	H_3(m)	L_r(m)
234	0.123	0.0860	0.0406	0.44
227	0.218	0.165	0.104	0.77
212	0.145	0.0930	0.0673	0.80
230	0.119	0.0630	0.0343	0.80

Comparing the wave heights at the innermost wave gage (H_1) for the different tests shows that there is a preferential amplification of the wave motion trapped along the breakwater. Dividing the wave height, H_1, by the incident wave heights for the four tests, we obtain the following ratios: 1.8, 3.8, 1.6, 1.7. The amplification of the waves along the trunk of the breakwater is clearly significant, with the 1.3 s. test (#227), showing almost a four-fold increase in wave height. This is thought to be due to the reflection that may occur at the breakwater head. The presence of the reflecting wall at the downwave end of the breakwater forces a partial standing wave system for the trapped waves. If the waves for test 227 are more efficiently

reflected by the change in bathymetry at the head of the structure, then a more resonant situation occurs.

In Table 3, two comparisons are shown with the data and the results from the theoretical edge wave model. The measured spacing of the antinodes of the partial standing edge waves is related to λ by $\lambda = \pi / L_r$. Column 2 and 3 show the comparison of the data and the numerical model, respectively. The average error is 8.3%. The discrepancy is not likely to be attributed to wave nonlinearities, as the nonlinear terms in the dispersion relationship act to increase the wave length (Guza and Bowen, 1976). It should also be noted that for these tests, the effect of the break in slope at the toe of the breakwater is negligible. Calculating the edge wave length using the dispersion relationship for constant slope, Eq. 3, results in a maximum 2% discrepancy with that predicted with the numerical model.

TABLE 3. COMPARISON OF DATA TO NUMERICAL MODEL

TEST	L_r(m)	L_p(m)	E (%)	$\lambda_{m1}(m^{-1})$	$\lambda_{m2}(m^{-1})$	$\lambda_p(m^{-1})$
234	0.44	0.47	−6.8	7.97	7.14	6.63
227	0.77	0.81	−5.2	5.3	3.88	3.87
212	0.80	0.86	−7.5	5.44	3.92	3.64
230	0.80	0.91	−13.8	8.89	3.92	3.43

In columns 5 and 6 of Table 3, the λ determined from the laboratory data is calculated two ways. Column 5 is the wave number calculated by π/Lr. In column 6, the wave number is found by a least squares fit to the three measured wave heights for each test, found by minimizing the total error, E:

$$E = \sum_{i}^{3} (H_i - A\, e^{-\lambda y_i})^2$$

for A and λ. There is a discrepancy between the two measures of λ. In Column 7, the value obtained from the numerical calculation is shown. The A values found by the least squares method for the four tests, which are a measure of the wave height at the shoreline, are 0.448, 0.509, 0.326, 0.464 m in order of increasing wave period.

In figures 3 and 4, the wave heights for four tests are shown on semi-log scale. According to the edge wave theory, the zeroth mode edge wave should decay exponentially, with a slope equal to the wave number, λ. The measured data are shown with a corresponding straight

line, which corresponds to the best fit line found by minimizing E, given above, for A alone, with λ given by the numerical model of Kirby et al. (Col. 7, Table 3). The agreement between the slope of the data and the straight lines in three of the tests (excepting test 230) indicates that the offshore decay of the measured wave motion is well described by an exponential behavior, as occurs with edge waves.

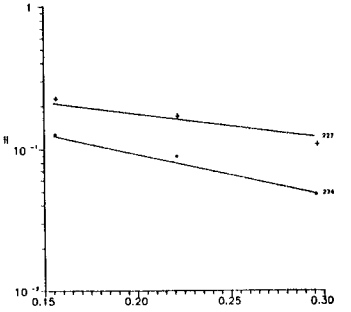

Figure 3. Wave Height Decrease with Offshore Distance for Tests 234 and 227.

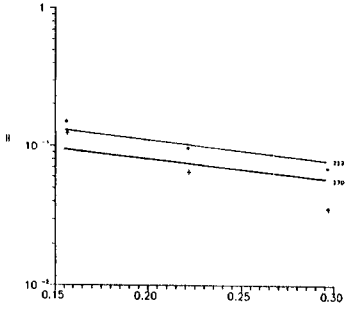

Figure 4. Wave Height Decrease with Offshore Distance for Tests 212 and 230.

In figure 5, the results of the refraction/diffraction calculation are shown. In this case, there is no reflective barrier at the end of the breakwater and thus the edge waves are progressive. For ease in modelling, two breakwaters are used. One situated on the upwave lateral boundary of the model and another on the downwave side. See Fig. 6. This permits the modelling of both the seaward and the downwave sides of the breakwater at the same time; although care must be taken to ensure that the structures are separated far enough so that the reflection from the downwave breakwater does not affect the upwave structure. Further, although the slope of the breakwater remains the same as in the physical model test, a 5 cm wall is assumed to exist along the water line, to ensure no wave breaking. The corresponding bathymetry is shown in figure 6. It should be obvious

from the figure 5 that the edge wave motion becomes trapped onto the downwave side of the breakwater. (Despite appearances, the edge waves do not increase in amplitude with distance along the breakwater. They just become more prominent, as they go deeper into the diffraction zone.)

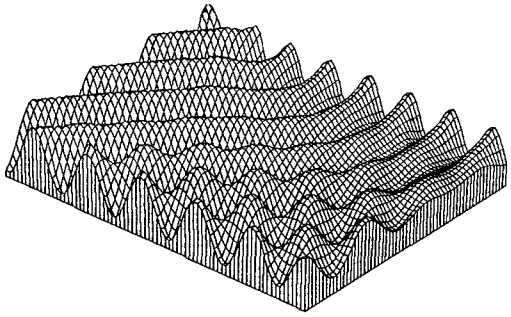

Figure 5. Instantaneous Water Surface Elevation Around Breakwaters.

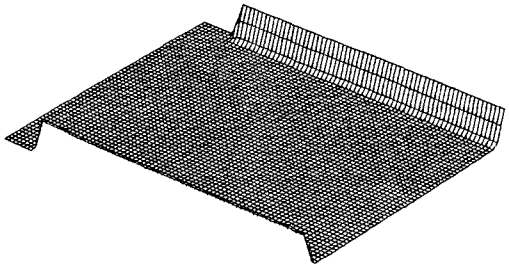

Figure 6. Bathymetry for Figure 5.

It can be presumed that should the edge wave motion on breakwaters become important, there are means to reduce their amplitudes. Clearly artificial roughness reduces their size. Another method of reducing their size is to reduce the amount of trapping that occurs. This can be done by reducing the amount of submerged head to refract the waves. Another possibility is to induce breaking on the head or to make a discontinuity in the breakwater bathymetry. In figures 7 and 8, the breakwater head is altered by adding a circular tip, which extends beyond the trunk width of the breakwater. This change reduces the amount of wave energy which can propagate around the structure.

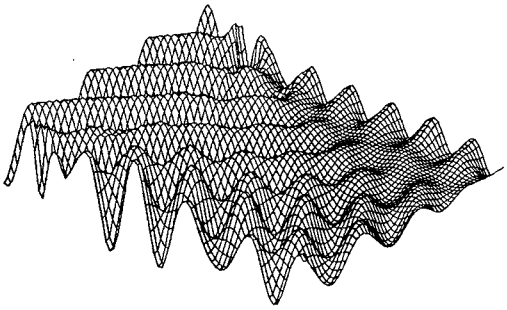

Figure 7. Instantaneous Water Surface Elevation for Rounded Head Breakwater.

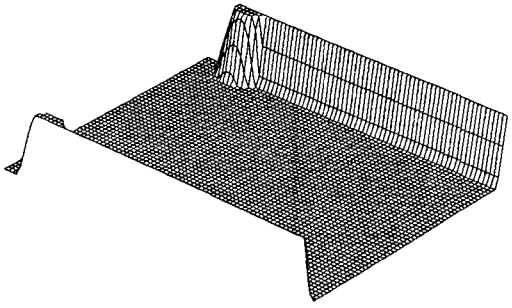

Figure 8. Bathymetry for Figure 7.

Conclusions

Waves, propagating around the head of a breakwater, can be channelled onto the lee side of the structure, where they will propagate, in the absence of friction, as edge waves. The laboratory data, obtained on a model breakwater, show trapped wave motion, which has the wave length and offshore dependency corresponding to edge waves.

Should this motion be of significance in the field (for large breakwaters), there are means to explore to reduce the amount of wave trapping that can occur. Further, by adding damping to the breakwater and reducing its reflectivity, the size of these waves can be reduced.

Acknowlegments

This material was based upon work supported by the National Science Foundation under Grant MSM 8114826. Mr. Douglas W. Coffin's help in the early stages of the laboratory work is gratefully appreciated.

CHAPTER 134

ULTIMATE RESISTANCE OF VERTICAL PLATE ANCHORS IN CLAY

Braja M. Das,[1] M., ASCE, and
Miguel Picornell,[2] A.M., ASCE

Abstract

Laboratory model test results for the ultimate pullout resistance of vertical square anchors embedded in saturated or near saturated clay have been presented. The undrained shear strength of the clay and the embedment ratio of the anchors have been varied. Based on the model test results, an empirical parametric relationship for estimation of the ultimate pullout resistance of shallow and deep square anchors has been presented.

Introduction

Vertical anchor plates (Fig. 1) are generally used for construction and design of waterfront structures such as sheet pile bulkheads. More recently, a number of studies relating to the ultimate pullout resistance of vertical anchor plates embedded in sand have been published (1,4,5,6,8, 9,10). Most of the important findings have been summarized in a paper by Das (1). In contrast, very few attempts have so far been made for evaluation of the ultimate resistance of vertical plate anchors embedded in saturated clay (ϕ=0 concept). The purpose of this paper is to present the results of some laboratory experimental studies for the ultimate pullout resistance of square anchor plates in saturated or near saturated clay soils.

Previous Studies For Ultimate Resistance of Vertical Anchors in Clay (ϕ=0 Concept)

When an anchor plate embedded in a clay soil is being subjected to an ultimate pullout load Q_u (Fig. 1), the failure surface in clay in front of the plate may extend to the ground surface. This will be the case when the embedment ratio H/B (H=depth of embedment of the anchor plate; B= height of the anchor plate) of the anchor plate is small. This type of anchor is referred to as a shallow anchor.

[2]Assistant Professor in Civil Engineering, The University of Texas at El Paso, El Paso, Texas, 79968, U.S.A.

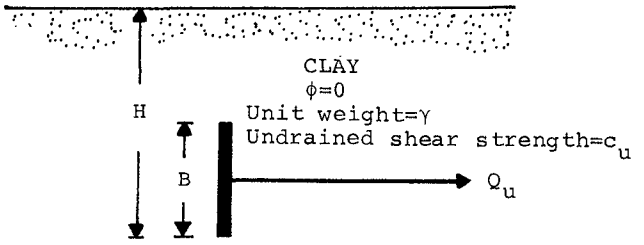

Figure 1. Vertical anchor plate.

However, if H/B is relatively large, local shear failure in the clay around the anchor will take place, and the failure surface in the soil will not extend to the ground surface. This type of anchor is referred to as a deep anchor. For shallow strip anchors with H/B<about 2, Teng (11) has suggested that

$$Q_u = L(P_p - P_a) \tag{1}$$

where L = length of the anchor plate at right angles to the cross section as shown in Fig. 1
P_p, P_a = Rankine passive and active force per unit length of the anchor in the front and the back, respectively

For ϕ=0 condition

$$P_p = \tfrac{1}{2}\gamma H^2 + 2c_u H \tag{2}$$

and

$$P_a = \tfrac{1}{2}\gamma H^2 - 2c_u H \tag{3}$$

where γ = unit weight of the clay
c_u = undrained shear strength

Combining Eqs. (1), (2), and (3)

$$Q_u = 4c_u HL \tag{4}$$

For anchor plates with limited length-to-height ratios (i.e., L/B≤about 5 to 6), the resistance derived from the sides of the plate during pullout needs to be accounted for. For such cases, Teng (11) suggested that

$$Q_u = 4c_u HL + 2c_u H^2 \quad \text{(for H/B<about 2)} \tag{5}$$

Mackenzie (7) conducted a number of laboratory model

tests on strip anchors in two different clay soils. According to this study and Tschebotarioff (12), the ultimate resistance of vertical anchors with dimensions B×L can be conveniently expressed in a nondimensional form as

$$F_c = \frac{Q_u}{BLc_u} \tag{6}$$

where F_c = breakout factor

Figure 2 shows the average variation of F_c with H/B as obtained by Mackenzie (7). It needs to be pointed out that

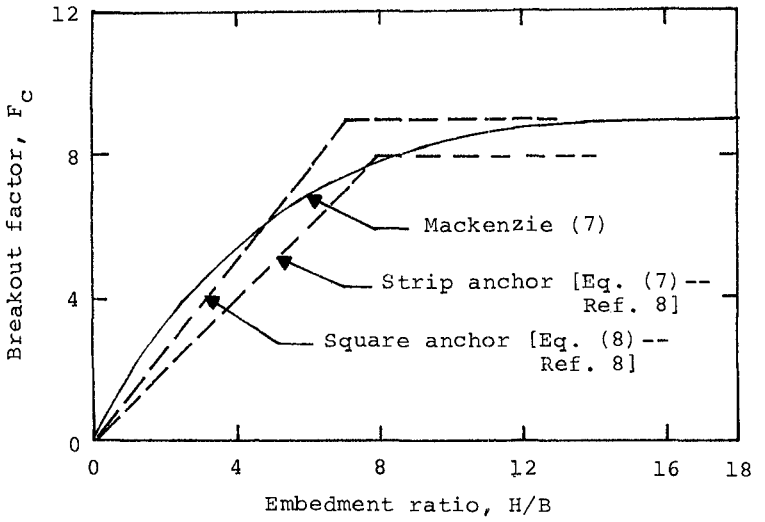

Figure 2. Breakout factor variation with embedment ratio from previous studies.

the magnitude of F_c increases with H/B up to a maximum value ($F_c=F_c^*$) at $H/B=(H/B)_{cr}$. For $H/B>(H/B)_{cr}$, the magnitude of the breakout factor remains practically constant (i.e., F_c^*). So, anchors with H/B less than or equal to $(H/B)_{cr}$ may be referred to as shallow anchors; and when the embedment ratio is greater than $(H/B)_{cr}$, they may be referred to as deep anchors. For Mackenzie's tests, the magnitudes of $(H/B)_{cr}$ and F_c^* are about 12 and 8.5, respectively.

Meyerhof (8) has suggested that conservative estimates of the breakout factor F_c with embedment ratio may be given as

$$F_c = 1.0(H/B) \leq 8 = F_c^* \quad \text{(for strip anchors)} \tag{7}$$

and

$$F_c = 1.2(H/B) \leq 9 = F_c^* \quad \text{(for square anchors)} \tag{8}$$

For comparison purposes, these relations have also been plotted in Fig. 2. The present study relates primarily to the determination of the breakout factor variation of square anchors only.

Laboratory Investigation

Laboratory model tests for determination of the ultimate pullout resistance of vertical square anchors were conducted with two steel model anchor plates measuring 38.1 mm × 38.1 mm and 50.8 mm × 50.8 mm (B×L). Each of the plates had a thickness of 9.5 mm.

The model tests were conducted in a box measuring 0.915 m × 0.508 m × 0.915 m (height). The sides of the box were braced to avoid lateral yielding.

Two clayey soils (referred to as Soil A and Soil B) collected from the field were used for the present tests. Soil A had 78% passing No. 200 U.S. sieve, with liquid and plastic limits of 32 and 19, respectively. Similarly, Soil B had 68% passing No. 200 U.S. sieve. The liquid and plastic limits of Soil B were 39 and 14, respectively. Based on the Unified soil classification system, both soils belonged to the group CL. The soils were initially pulverized in the laboratory, and desired amounts of water were added to them. After thorough mixing, the moist soils were transferred to several plastic bags. The bags were then sealed and kept in a moist curing room for about a week before use.

A schematic diagram of the laboratory test arrangement is shown in Fig. 3. In order to conduct a test, the desired anchor plate was rigidly attached to a steel rod. The rod, in turn, was attached to a steel cable. The cable passed over a pulley attached rigidly to the side of the box. The other side of the cable was attached to a load hanger.

For conducting a test, the moist soil from the plastic bags was poured into the box and compacted in 50.8mm thick layers to the desired height. The compaction was done in sections by using a flat-bottomed rammer. After compaction, step loads were placed on the load hanger, and the corresponding horizontal movements of the anchor were observed by a dial gauge. A time lapse of 5-8 minutes was allowed between the placement of each step load. This time lapse between the step loads was allowed to take primary creep into account. Loading continued until failure occurred.

A total of five series of tests were conducted in the laboratory. Other details of the tests are presented in

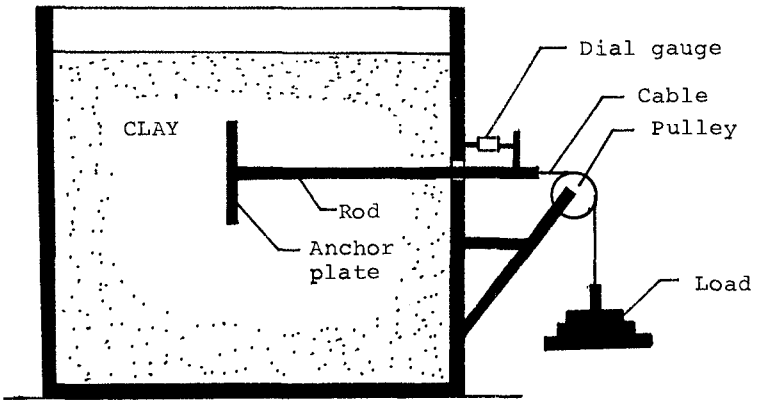

Figure 3. Schematic diagram of the model test arrangement in the laboratory.

Table 1. It may be noticed from this table that the larger model anchor plate measuring 50.8 mm × 50.8 mm was used for tests in softer clays.

Table 1. Model Test Details

Test series	Soil	Plate width, B (mm)	Properties of compacted soil (Average values)			
			Moist unit weight, γ (kN/m^3)	Moisture content (%)	Degree of saturation (%)	Undrained shear strength, c_u (kN/m^2)
1	A	50.8	19.65	24.5	97	20.3
2	A	38.1	20.76	17.6	94	42.4
3	B	50.8	19.03	28.5	98	12.5
4	B	38.1	20.29	18.5	92	28.1
5	B	38.1	20.65	16.2	93	52.0

Typical net load (Q) vs. horizontal displacement of the anchors as obtained from the laboratory tests are shown in Fig. 4. For all tests reported herein (a total of 41), a

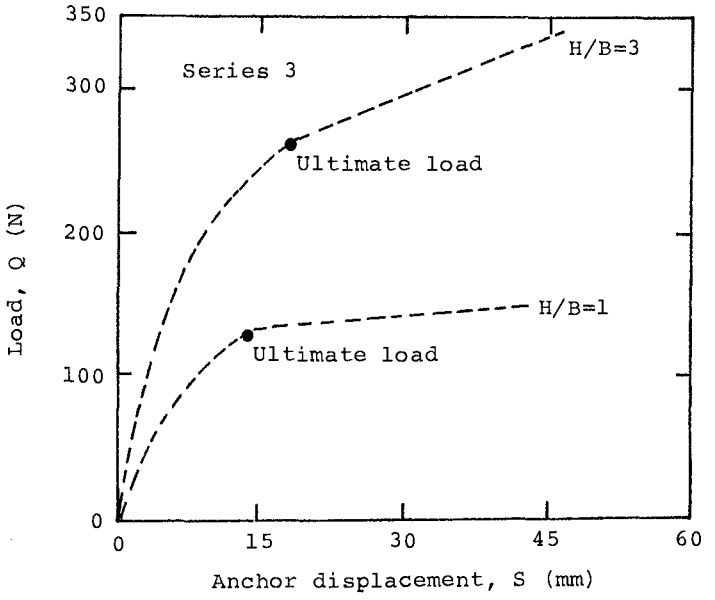

Figure 4. Typical net load vs. anchor displacement diagrams as obtained from the laboratory.

peak failure load was not observed. This is somewhat similar to the load-displacement plots obtained for local shear type of failure in soil in the bearing capacity tests of shallow foundations. The ultimate load for a given anchor pullout test is defined as the net load at which the load-displacement plot became practically linear (i.e., $\Delta Q/\Delta S$ became minimum). The net ultimate pullout loads for all tests conducted under this program are plotted in Fig. 5.

Model Test Results

Critical Embedment Ratio, $(H/B)_{cr}$

The relationship of the breakout factor for a rectangular anchor is given in Eq. (6). For square anchors, B=L; hence, the breakout factor

$$F_c = \frac{Q_u}{B^2 c_u} \tag{9}$$

By substituting the experimental values of the net ultimate load (Q_u), B, and c_u in the right-hand side of Eq. (9), the

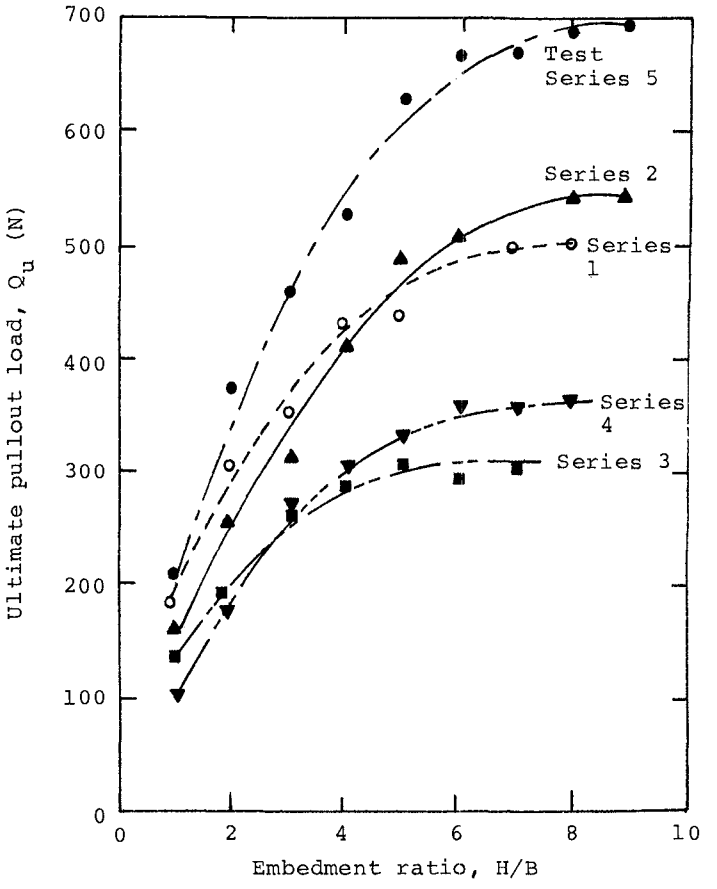

Figure 5. Ultimate pullout load for the model tests.

experimental values of the breakout factor F_c for all tests have been determined and have been plotted in Fig. 6. As expected, for a given test series the magnitude of the breakout factor increases with the embedment ratio H/B up to a maximum value and remains constant thereafter. Based on the average curves, the critical embedment ratios $(H/B)_{cr}$ at which the magnitude of F_c $(=F_c^*)$ becomes constant are also shown in Fig. 6. It can be seen from this figure that, for a given anchor plate, i.e., B/L=constant, $(H/B)_{cr}$ is not a constant. It is a function of the undrained shear strength of the clay in which tests are being conducted. The variation of the critical embedment ratios as determined from Fig. 6 have been plotted in Fig. 7 as a function of the undrained shear strength of the clay. The average plot in

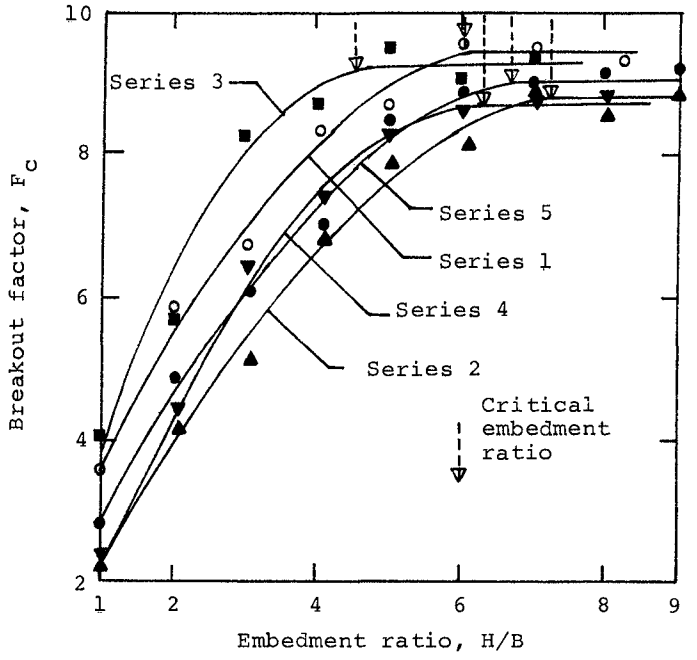

Figure 6. Variation of the experimental breakout factor.

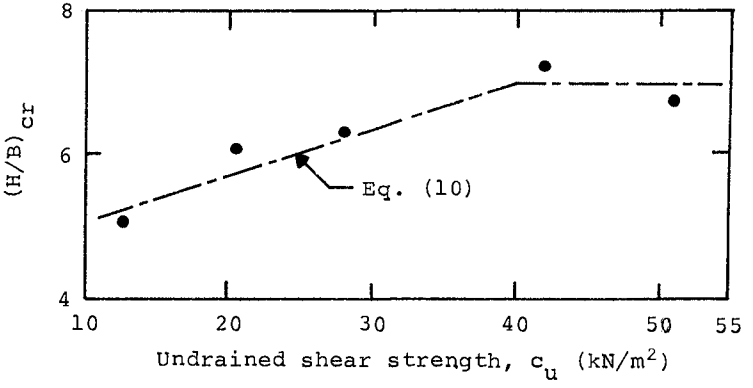

Figure 7. Variation of experimental $(H/B)_{cr}$ with c_u.

this figure can be approximated as

$$(H/B)_{cr} = 4.33 + 0.067c_u \leq 7 \qquad (10)$$

where c_u is in kN/m^2

Variation of Maximum Breakout Factor, F_c^*

As previously mentioned, the breakout factor for deep anchors is a constant, i.e., $F_c=F_c^*=$constant. Figure 8 shows the plot of the experimental variation of F_c^* as obtained

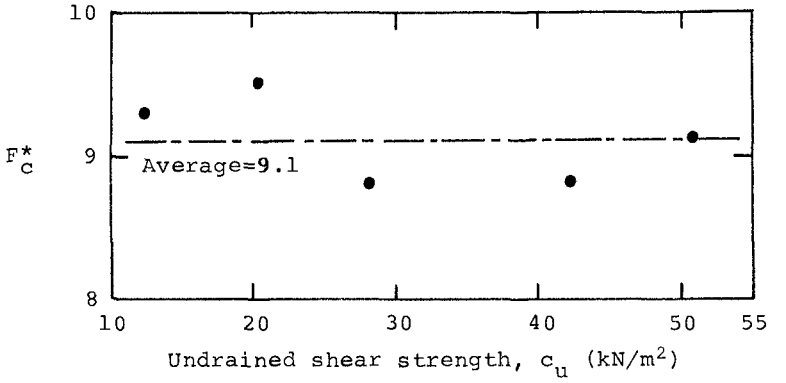

Figure 8. Experimental variation of F_c^* with c_u.

from the present tests with c_u. Based on this figure, it appears that F_c^* varies between 8.8 to 9.5, with an average of about 9.1. This indicates that F_c^* is not a function of the undrained shear strength of the soil and is similar to the magnitude of the bearing capacity factor N_c for square and circular foundations on saturated clay ($\phi=0$ condition). Hence, considering the errors involved in the laboratory tests of this type, the value of F_c^* may be assumed to be equal to 9.

Parametric Relationship for Breakout Factor of Shallow Foundations

In the process of developing a procedure for the estimation of the ultimate uplift capacity of shallow horizontal anchors embedded in saturated clay, Das (2,3) proposed a nondimensional parametric relationship which appears to be useful for the present problem under consideration.

The two parameters under discussion are as follows:

$$\alpha = F_c/F_c^* \tag{11}$$

and

$$\beta = \frac{(H/B)}{(H/B)_{cr}} \tag{12}$$

Using the above definitions, the experimental variation of β/α and β for each average plot of F_c vs. H/B as shown in Fig. 6 have been determined and are shown in Fig. 9. Although there is some scattering, all points in Fig. 9 appear

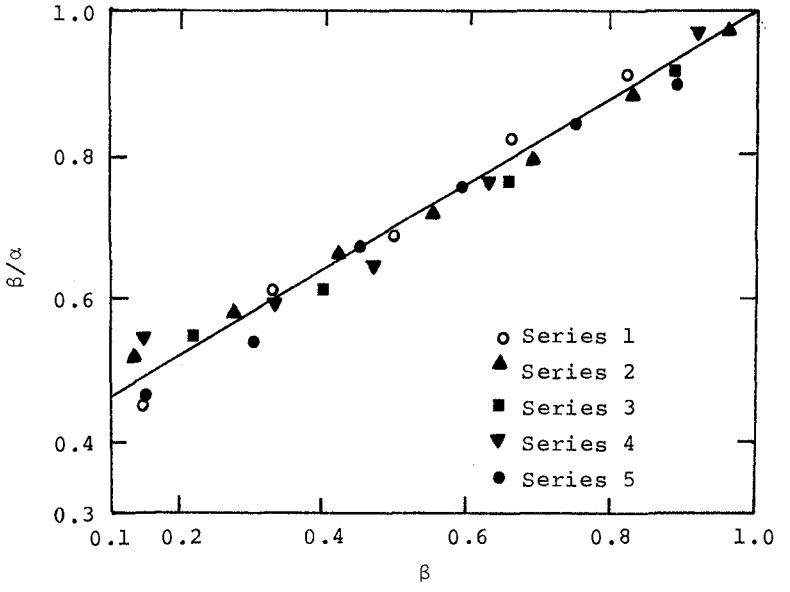

Figure 9. Variation of β/α with β--experimental results.

to fall in a narrow range. The average plot can be expressed in the form

$$\beta/\alpha = 0.4 + 0.6\beta \tag{13}$$

or

$$F_c = F_c^* \left\{ \frac{(H/B)/(H/B)_{cr}}{0.4+0.6[(H/B)/(H/B)_{cr}]} \right\} \leq F_c^* \tag{14}$$

Hence, once $(H/B)_{cr}$ is determined from Eq. (10), the value can be used in the preceding equation to obtain the breakout factor. However, based on previous discussions, if F_c^* is taken as 9, then

$$Q_u \simeq 9c_u B^2 \left\{ \frac{(H/B)/(H/B)_{cr}}{0.4+0.6[(H/B)/(H/B)_{cr}]} \right\} \leq 9c_u B^2 \qquad (15)$$

Conclusions

A number of laboratory model test results on square vertical anchors in clay (ϕ=0 concept) have been presented. Based on the model test results, the following conclusions can be drawn:

1. The ultimate pullout resistance of a vertical anchor can be expressed in the form of a nondimensional breakout factor, F_c.

2. The magnitude of the maximum breakout factor F_c^* is approximately equal to 9 for square anchors.

3. The critical embedment ratio increases with the undrained shear strength of clay; however, for stiff clays the magnitude of $(H/B)_{cr}$ is about 7.

4. The variation of the breakout factor with embedment ratio in clays of various consistencies can be expressed by a single nondimensional parametric equation [Eq. (15)].

CHAPTER 135

COASTAL ARMORING: EFFECTS, PRINCIPLES AND MITIGATION

by

R. G. Dean*

ABSTRACT

An attempt is made to conduct a rational assessment of the potential adverse effects of coastal armoring on adjacent shorelines and to propose methodology for mitigation, where appropriate. Specific attention is directed toward claims that armoring causes: profile steepening, increased longshore sediment transport, intensified local scour, transport of sand to substantial offshore distances, etc. The assessment presented here is based on a combination of sound principles and the availability or lack of laboratory and field data to either support or refute the claims. Although it is found that data relating to coastal armoring effects are sparse, conclusions can be drawn. There seems to be no factual data to support the contentions that armoring causes profile steepening, increased longshore transport, transport of sand to a substantial distance offshore, or significantly delayed profile recovery following a severe erosion event. Armoring does have the potential to cause intensified local scour both in front of and at the ends of an armored segment. Reasons for these effects, based on knowledge of response of a natural profile, are presented. Additionally, armoring which projects into the active surf zone can act as a partial barrier to the net longshore sediment transport, thereby causing downdrift erosion.

Methodology is presented for quantifying the appropriate mitigation for a particular armoring situation. The proposed mitigation is the annual placement of sand in the vicinity of the armoring to offset its potential adverse effects. The two potential adverse effects addressed in the methodology include the reduction of sediment supplied to the system as a result of the armoring and the blockage of longshore sediment transport by a protruding armoring installation.

INTRODUCTION

Coastal armoring in the form of seawalls or revetments is usually designed to be located along sandy shorelines which are either experiencing an erosional trend or which are subject to substantial seasonal

*Graduate Research Professor, University of Florida, Coastal and Oceanographic Engineering Department, Gainesville, FL 32611 and Director, Division of Beaches and Shores, Florida Department of Natural Resources, Tallahassee, FL 32303.

swings and/or storm-induced fluctuations that could conceivably endanger upland structures.

Coastal armoring, once regarded as a relatively desirable means of achieving shoreline stabilization, has recently been the focus of much attention including various concerns over possible adverse effects to the adjacent beach system, see for example Kana and Svetlichny (1982). An analysis of the available literature demonstrates that definitive laboratory or field data are sparse, thereby providing a fertile ground for conjecture and misinformation. Placed along a shoreline with an erosional trend, armoring can perform its intended function of upland stabilization while the adjacent shoreline segments continue to erode. The resulting offset between stabilized and unstabilized segments may be interpreted incorrectly that the armoring has caused the adjacent erosion. Coastal armoring does have the potential of causing adverse effects to the adjacent shoreline. In situations where coastal armoring is contemplated, it is important to recognize, and where possible to quantify and perhaps mitigate for these adverse effects. Specific alleged adverse effects of coastal armoring include: (1) offshore profile steepening, (2) intensified local scour, (3) transport of sand to a substantial distance offshore, (4) adverse downdrift erosion, and (5) delayed post-storm recovery. The coastal engineering profession has a responsibility to develop an improved understanding of the interaction of coastal armoring with the nearshore sand transport system in order to allow jeopardized structures to be protected where warranted without causing adverse effects to adjacent shorelines.

ASSESSMENT

The two possibile bases that can be used to assess the effects of coastal armoring include sound principles and data either from the laboratory or the field. A principle is present below followed by a discussion of processes and available data relevant to various possible armoring effects.

Principle

The strongest principle that can be applied in any discussion of coastal processes is that of sediment conservation. Clearly, coastal armoring neither adds to nor removes sand from the sediment system, but may be responsible for the redistribution of sand and may prevent sand from entering the system. As an obvious and immediate application of this principle, if as has been contended, coastal armoring causes profile steepening through nearshore erosion, then that same volume of sand must be transported to and deposited elsewhere. It is important to keep the principle of sand conservation in mind in reviewing the interaction of coastal armoring with the adjacent shoreline and offshore profile.

Laboratory and/or Field Data Relating to Various Possible Effects

Offshore Profile Steepening - Some have claimed that steeply sloping revetments, vertical seawalls and even steep dunes cause an associated increased wave reflection and sand to be eroded and

transported and deposited so far offshore that it is effectively "lost" to the littoral system. Increased wave reflection can clearly occur as a result of coastal armoring; however, there does not appear to be a mechanism for an associated offshore transport to significant depths nor is there evidence to support such transport.

While wave reflection can cause shore parallel bars in the laboratory, primarily for monochromatic waves, the existence of reflection bars in nature does not appear to be well-documented or at least highly prevalent. Moreover, the hydrodynamics associated with wave reflection does not offer an obvious explanation for offshore sediment transport. It appears that the behavior of a beach in nature is dependent primarily on the amount of sand in the nearshore system as compared to that for the equilibrium profile. Under normal conditions, the profile fronting seawalls and natural beaches will be the same up to the location of the seawall. If waves were completely reflected, it is acknowledged that the onshore and offshore forces on a sediment particle must be completely balanced and for this limiting condition, no tendency for onshore or offshore motion could exist. The equilibrium profile in this case could only be the superposition of barred topography on an otherwise horizontal bottom.

Storm-Induced Intensified Local Scour - Local scour under normal wave conditions has been addressed in the preceding section. During conditions of elevated water levels and high storm waves, the equilibrium profile requires sand to be transported seaward, both along natural and armored shorelines. Some of this material will be deposited as an offshore bar. Consider first a two-dimensional case as would occur in a wave tank. Because the armoring "denies" upland material for bar formation, this material is obtained from as near a location to the natural source as possible, i.e. immediately adjacent to the base of the seawall. This explanation is illustrated in Figure 1. Thus, during storms, it is expected that increased scour would occur at the toe of the vertical seawall. This is consistent with data presented by Kriebel, et.al. (1986) for post-Hurricane Elena profiles in which, relative to natural profiles, accentuated toe scour occurred at the base of seawalls, see Figure 2.

Extending to three dimensions, the above discussion of shoreline response during storms, since immediately in front of armoring there is insufficient sand to satisfy the "demand" of the offshore bar, the shore parallel downward slope to the area immediately seaward of the unarmored segment, combined with the mobilizing effects of breaking waves causes sediment to flow from the region offshore of the natural shoreline to that offshore of the armored segment. The effect of this interaction is to cause an additional "erosional stress" adjacent to the armoring with the magnitude of this stress increasing with the length of the armoring. This interaction is illustrated in Figure 3 and is consistent with post-Hurricane Eloise measurements as reported by Walton and Sensabaugh (1979), see Figure 4.

Projection of Armoring into the Active Surf Zone - If an isolated armored segment is constructed on an eroding shoreline where a substantial longshore sediment transport exists, the armoring will in time project into the surf zone and will act as a groin to block the

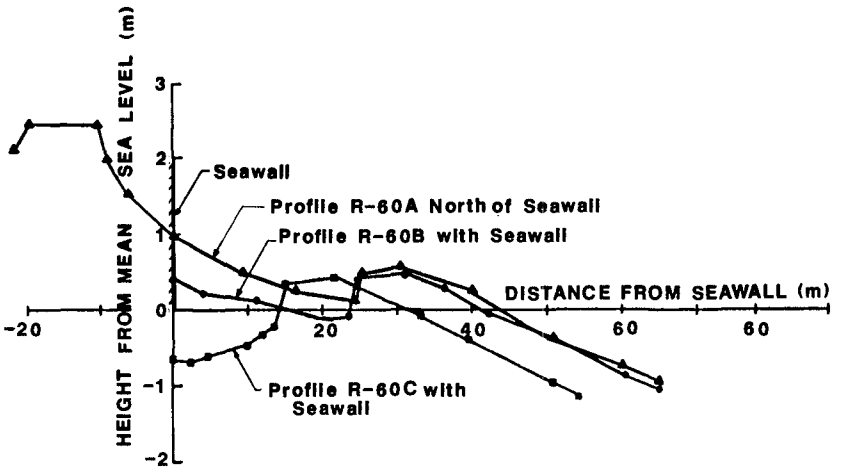

Figure 2. Comparison of Response of Natural and Seawalled Profiles to Hurricane Elena, September, 1985. (From Kriebel, et.al., 1986).

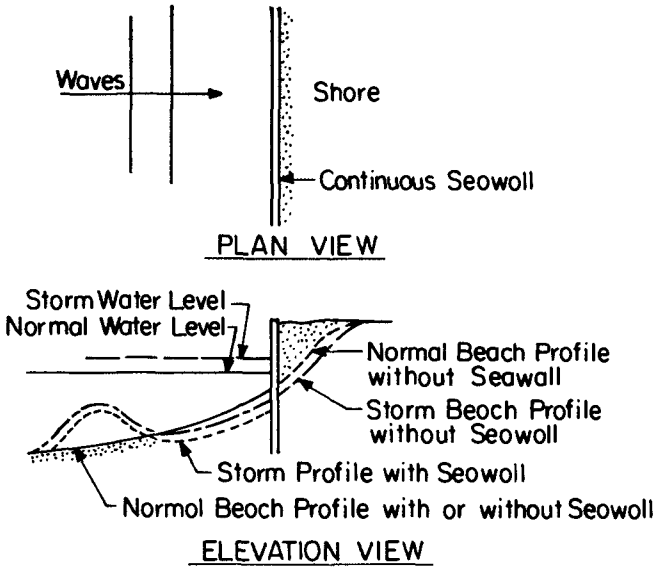
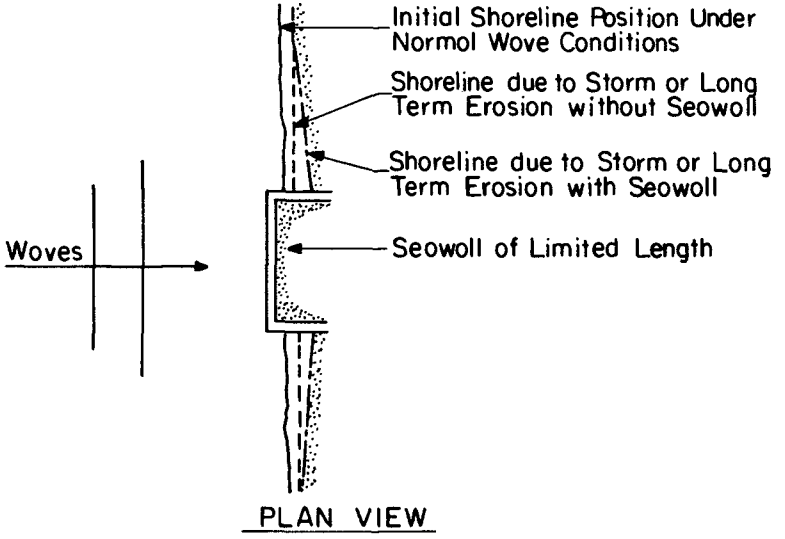
net longshore sediment transport. The annual deficit of sediment downdrift of the armoring will be the sum of that blocked by the projecting armoring and that not yielded by the upland protected by the armoring. The downdrift annual deficit will thus increase with (a) the length of the armoring, and (b) time as a result of increasing projection into the surf zone thereby blocking a greater and greater fraction of the longshore sediment transport. A simple method will be presented later to quantify approximately the downdrift deficit.

Effect of Wave Reflection on Longshore Sediment Transport - It has been argued that wave reflection from a seawall causes greater longshore sediment transport in front of the seawall and thus a local steepening of the profile. As presented in the discussion on "Principle" if this were the case, one would expect this effect to contribute to an equivalent deposition downdrift of the armoring, since greater quantities of sediment would be transported in the longshore direction in front of the armoring, but the transporting capacity of the waves would not be increased downdrift of the armoring. Contrary to the hypothesis that wave reflection causes increased longshore sediment transport, a rational argument can be advanced that the effect of wave reflection is to reduce the longshore sediment transport. Clearly, for an idealized shoreline with straight and parallel bottom contours, the total net longshore thrust, F_L, can be determined from momentum flux considerations as

$$F_L = \frac{\gamma H_o^2}{32} (1 - \kappa_r^2) \sin 2\alpha_o \qquad (1)$$



a) Qualitative Effects of Continuous Seawall on Storm Beach Profile.



b) Effect of Seawall of Limited Length on Storm or Long-Term Beach Planform.

Figure 3. Two- and Three-Dimensional Effects of a Seawall on Beach System during Storms.

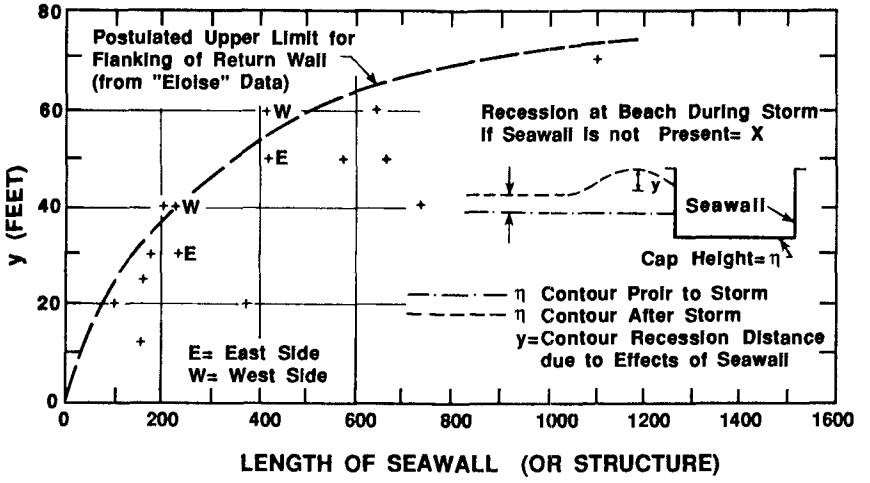


Figure 4. Additional Bluff Recession Due to Seawalls. Based on Post-Hurricane Eloise Field Observations by Walton and Sensabaugh.

in which κ_r represents the reflection coefficient as measured seaward of the surf zone, γ is the specific weight of sea water, and α_o is the deep water wave direction relative to a normal to the bottom contours. Thus for larger reflection coefficients, the total longshore thrust is reduced. Counter arguments are that there is an increase in the longshore current because the very shallow water portion of the profile provides much of the retarding force and that even with a reduced total longshore thrust, the currents and associated sediment transport can be increased. Clearly, this is a complex problem and deserves careful consideration prior to reaching a conclusion.

Interference with Post-Storm Recovery - Wave reflection from coastal armoring could be the cause of a delayed post-storm recovery. Although this hypotheses has been proposed, it is again helpful to look to nature to attempt to address this question. First if the presence of coastal armoring were responsible for a delayed post-storm recovery, there should be ample evidence in the form of deposits remaining seaward of armoring and armored shorelines in front of which the contours are displaced landward relative to the adjacent shorelines. Data presented by Kriebel, et.al. (1986) from Hurricane Elena supports an equally rapid or nearly equally rapid recovery adjacent to coastal armoring. Moreover, observations by Mr. Ralph Clark immediately after Hurricane Elena (September, 1985) and approximately eight months later (May, 1986) indicate that recovery had occurred to at least the pre-storm condition. Figure 5 presents a somewhat representative pair of photographs taken immediately after Elena and eight months later; inspection of these photographs supports natural beach recovery even in front of vertical seawalls.

Summary Assessment Based on Principles and Available Data

Based in part on the discussion above, Table I presents a summary assessment and evaluation of some common perceptions concerning the effects of coastal armoring.

PROPOSED APPROXIMATE PRINCIPLES

Based on the foregoing discussion and observations of cases of armoring in nature, the following two approximate principles are proposed:

1. In a two-dimensional situation in nature with wave and sediment conditions not conducive to formation of an offshore bar, the beach profile seaward of an armored segment does not depend on the presence of the armoring, but depends almost entirely on the equilibrium beach profile vis-a-vis the amount of sand available to form this profile.

2. In a two-dimensional situation in nature with wave and sediment conditions conducive to formation of a longshore bar, the additional volumetric scour immediately fronting the armoring will be less than or equal to that volume of material that would have been provided through erosion by that portion of the profile upland of the armoring if the armoring were not present.

MITIGATION

It has been noted that coastal armoring can cause adverse effects to adjacent shorelines, primarily through: (1) depriving the littoral system of material that would have been provided if erosion of the upland had not been prevented by the armoring, (2) blockage of the longshore sediment transport by armoring projecting into the active littoral zone, and (3) during storms due to sediment being drawn from adjacent profiles to replace that prevented from being eroded by the armoring.

In principle, it would appear desirable to assess the potential adverse effects of each armoring considered and to condition the construction on appropriate mitigation to offset these adverse effects. The mitigation would be the annual addition of sand to volumetrically compensate for that denied the adjacent shorelines by the armoring. This concept is illustrated by Figure 6, where installation of armoring without any mitigative sand placement will result in adverse effects to the shoreline, but with increasing annual volumes of sand added, the combination of armoring placed plus mitigative sand added become a benefit. The focus of this section is to recommend methodology for identifying the "neutral" point where the annual mitigative sand placement just offsets any adverse effects of the armoring. Two effects will be considered: (1) the reduction in sand supply through prevention of erosion, and (2) the blockage of sediment transport by a projecting revetment.

Reduction of Upland Sediment Supply by Armoring - Consider the situation presented in Figure 7 in which the erosional trend is, R, in

Table I. ASSESSMENT OF SOME COMMONLY EXPRESSED CONCERNS RELATING TO COASTAL ARMORING

Concern	Assessment	
Coastal armoring placed in an area of existing erosional stress causes increased erosional stress on the beaches adjacent to the armoring.	TRUE	By preventing the upland from eroding, the beaches adjacent to the armoring share a greater portion of the same total erosional stress.
Coastal armoring placed in an area of existing erosional stress will cause the beaches fronting the armoring to diminish.	TRUE	Coastal armoring is designed to protect the upland, but does not prevent erosion of the beach profile waterward of the armoring. Thus an eroding beach will continue to erode. If the armoring had not been placed, the width of the beach would have remained approximately the same, but with increasing time, would have been located progressively landward.
Coastal armoring causes an acceleration of beach erosion seaward of the armoring.	PROBABLY FALSE	No known data or physical arguments support this concern.
An isolated coastal armoring can accelerate downdrift erosion.	TRUE	If an isolated structure is armored on an eroding beach, the structure will eventually protrude into the active beach zone and will act to some degree as a groin, interrupting longshore sediment transport and thereby causing downdrift erosion.
Coastal armoring results in a greatly delayed post-storm recovery.	PROBABLY FALSE	No known data or physical arguments support this concern.
Coastal armoring causes the beach profile to steepen dramatically.	PROBABLY FALSE	No known data or physical arguments support this concern.
Coastal armoring placed well-back from a stable beach is detrimental to the beach and serves no useful purpose.	FALSE	In order to have any substantial effects to the beaches, the armoring must be acted upon by the waves and beaches. Moreover, armoring set well-back from the normally active active shore zone can provide "insurance" for upland structures against severe storms.

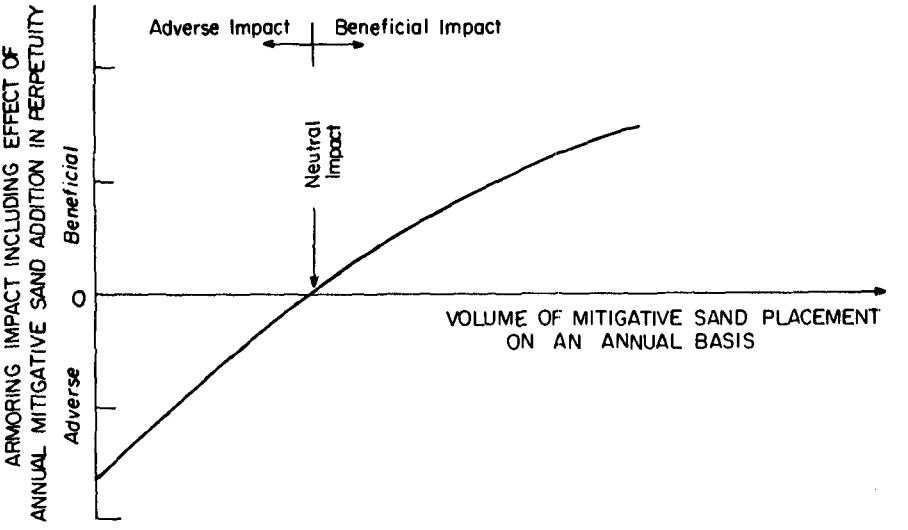

Figure 6. Effect of Annual Mitigative Sand Placement in Reducing the Adverse Impact of a Coastal Armoring Project.

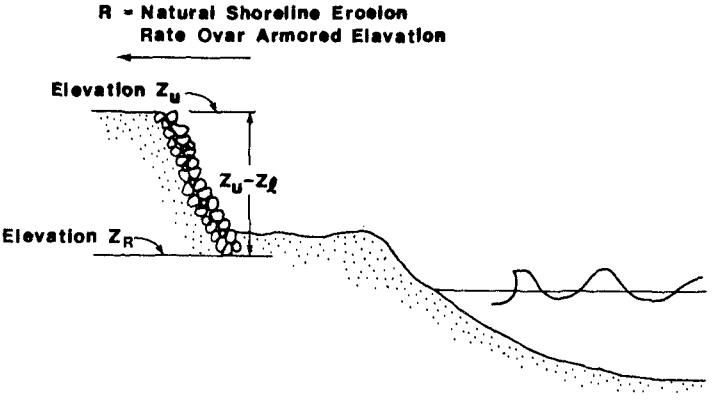

Figure 7. Definition Sketch. Describing Basis for Armoring Mitigation Due to Prevention of Upland Supply by Erosion.

m/yr and the armoring extends from a lower elevation, Z_ℓ, up to Z_u and the length of the armoring is ℓ. For this case, the required annual mitigative sand placement, Ψ_1, to achieve a neutral effect is

$$\Psi_1 = (Z_u - Z_\ell)(R)(\ell) \tag{2}$$

As an example, if the erosional trend rate is 1 m/yr, the length of the armoring is 100 m and the armoring extends from a lower elevation, Z_u, of 0 m to an upper elevation, Z_u, of 5 m, the annual volumetric mitigative requirement

$$\Psi_1 = (5-0)(1)(100) = 500 \text{ m}^3/\text{yr}.$$

Interruption of Longshore Sediment Transport - A coastal armoring constructed on an eroding coastline will eventually protrude into the active surf zone where it will cause a partial blockage of the longshore sediment transport with the familiar pattern of deposition and erosion updrift and downdrift of the armoring, respectively. This problem is complicated as the rate of impoundment will increase annually with the ultimate potential of blocking the entire net longshore sediment transport.

The volume of storage can be estimated by several different approaches. For purposes here, two different bases will be presented and it is recommended that an average of the two be used. For both, it is assumed that the updrift impoundment planform is linear and aligned with the incoming waves, see Figure 8.

The first method considers the profile in the storage area to be the same as that along the unperturbed beach. The additional annual volumetric storage rate, Ψ_{2_a}, can be shown to be

$$\Psi_{2_a} = \frac{(B + h_*)}{\tan\theta} \, b \, R \tag{3}$$

in which B = berm height, h_* = profile closure depth, R = long-term erosion rate, b = projection of armoring beyond unperturbed shoreline, and θ is angle of the wave crest approach relative to the unperturbed beach. Lacking specific information, a value of $\tan\theta = 0.1$ appears reasonable. It is noted that the projection distance b increases with time in accordance with $b = b_o + Rt$, in which b_o is the projection at the initial time and t is the number of years into the future.

The second method assumes that the profile modifications extend only out to the solid oblique line shown in Figure 8. Figure 9 shows profiles of the unaffected and assumed affected profiles for the second method. Clearly the second method represents an underestimate of the impounded volume whereas the first method is an overestimate. The equation for the annual rate of increased volume storage, Ψ_{2_b}, is

$$\Psi_{2_b} = \frac{1}{\tan\theta} \left(B + \frac{3}{5} h'\right) b \, R \tag{4}$$

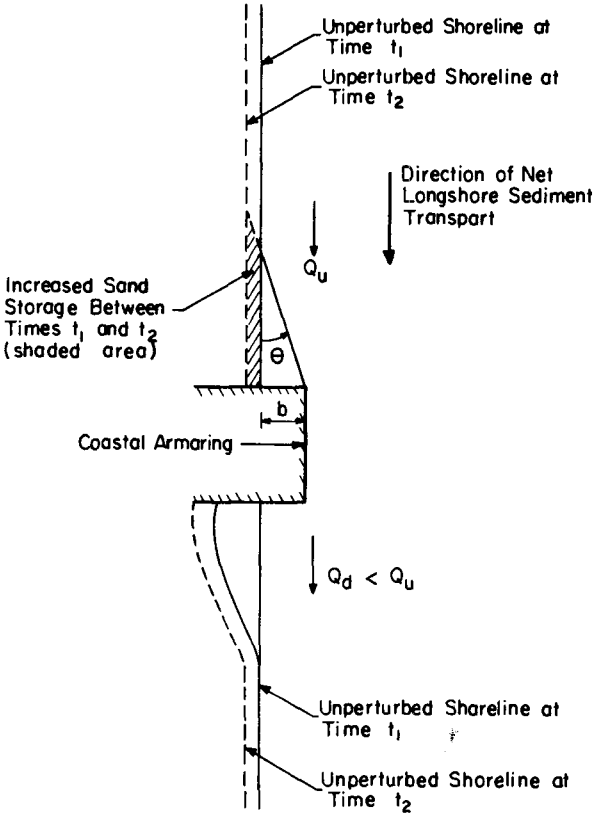

Figure 8. Illustration of Sand Storage by Coastal Armoring Projecting Beyond the Unperturbed Shoreline.

in which h' is the depth that would be present at the toe of the seawall if the seawall were not present. Eq. (4) incorporates the assumption of an equilibrium profile of the form $h = Ax^{2/3}$, in which h is the water depth at a distance x offshore and A is a scale parameter determined for the natural profile of interest. The parameter A has dimensions of $(\text{length})^{1/3}$ and for fine to medium sands is on the order of 0.1 $m^{1/3}$ (0.15 $ft^{1/3}$). Alternatively, h' can be estimated at a distance b along an unperturbed shoreline.

As noted before, recognizing that the first and second methods for estimating Y_2 are too large and too small respectively, it is recommended that an average of the two be used, i.e.

$$Y_2 = \frac{1}{2}\left(Y_{2_a} + Y_{2_b}\right) = \frac{Rb}{\tan\theta}\left[B + \frac{h_* + \frac{3}{5}h'}{2}\right] \qquad (5)$$

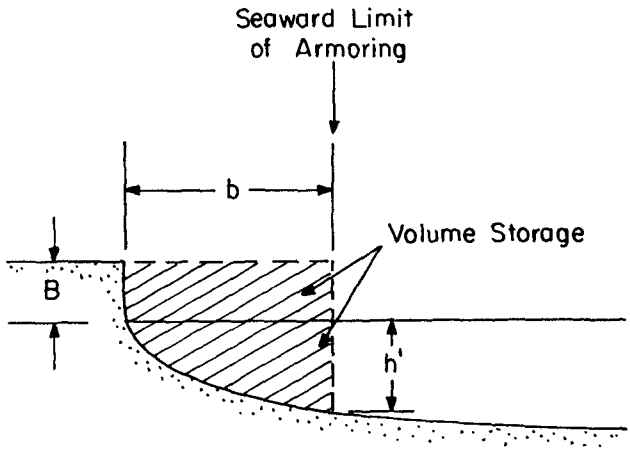

Figure 9. Profile Considerations in Method B.

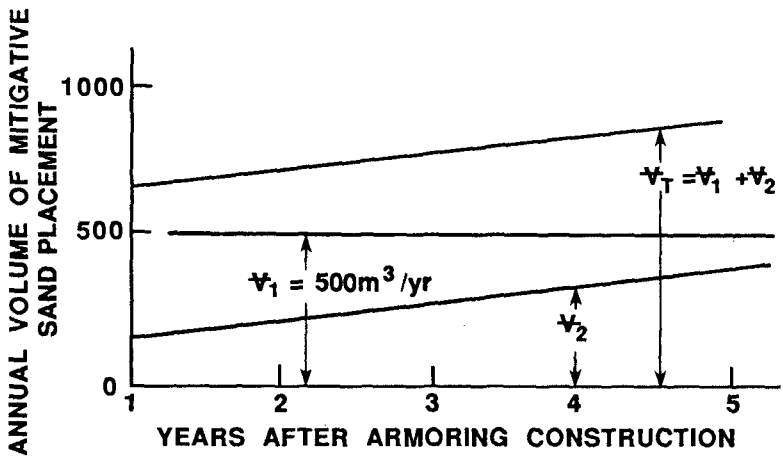

Figure 10. Illustration of Annual Volume of Mitigative Sand Placement for Example Presented in Text.

As an example, suppose that R = 1 m/yr, b_o = 2 m, tanθ = 0.1, B = 2 m, h_* = 7 m and A = 0.1 m $^{1/3}$. The mitigative sand requirement increases with time as presented in Figure 10 where Ψ_1, Ψ_2 and the total annual mitigative sand requirement $\Psi_T = \Psi_1 + \Psi_2$ are presented.

It should be noted that an upper limit to, Ψ_2, should be the net longshore sediment transport and that bypassing around a projecting armoring could be considered as an alternate mitigative strategy.

SUMMARY AND CONCLUSIONS

Uncertainties resulting from a lack of definitive information has led to considerable speculation and claims regarding the adverse effects of coastal armoring on the adjacent shorelines. Employing sound principles and laboratory and field data, an attempt is made to evaluate the potential adverse effects of armoring. It is concluded that:

1. There are no factual data to support claims that armoring causes: profile steepening, increased longshore transport, transport of sand to a substantial distance offshore, or delayed post-storm recovery.

2. The interaction of an armored segment of shoreline with the littoral system is more of a "geometric" or "kinematic" interaction as contrasted to a "dynamic" interaction. The interaction depends on the amount of sand in the system vis-a-vis the equilibrium beach profile for the prevailing tide and wave conditions.

3. Armoring can cause localized additional storm scour, both in front of and at the ends of the armoring. A simple sediment supply-demand argument is proposed to explain the scour.

A methodology is presented to quantify the potential adverse effects of an armoring installation and appropriate periodic sand additions proposed as a means of mitigation to elevate the installation to one of neutral impact on the adjacent shoreline.

CHAPTER 136

Scour About a Single, Cylindrical Pile Due to Combined Random Waves and a Current

Robert W. Eadie, IV* and John B. Herbich,** M.ASCE

Introduction

There have been many studies of scour around piles caused by waves, and some studies of scour by waves and currents combined. However, almost all of the studies were conducted with monochromatic waves. The purpose of this investigation was to study what scouring effects various currents and random waves have on a single, cylindrical pile. These results were then compared with the results from previous studies of scour resulting from currents and monochromatic waves at Texas A&M University (Armbrust, 1982 and Wang, 1983).

Experiments were conducted in a two-dimensional wave tank. The pile used in this study had a diameter of 1.5 inches. Two water depths, four currents, one sediment size and four random wave spectra were utilized. Using data obtained from the experiments, an attempt was made to describe scour in terms of relevant dimensionless parameters.

Scour

The scour phenomenon begins with the incipient motion of sediment particles. Incipient sediment motion is defined to be "an instantaneous condition reached when the resultant of all the active forces on the particle intersects the line connecting the bed particle contact points," (Eagleson and Dean, 1961). There are three types of active forces acting on a sediment particle. Two of these forces, the drag and lift forces, are due to the fluid motion. These forces are in turn balanced by the sediment particle mass.

A thorough understanding of these forces is required in order to comprehend fully the processes of incipient motion, bedload transport and bed form development; all of which depend on the collective response of initially stationary bed particles to fluid forces.

In oscillatory flow generated by waves, the scour hole initiates at the side of the cylinder, and sometimes sediment deposition is found to occur against the upstream and downstream sides of the cylinder. Once fully developed, the scour hole is a radially symmetric frustrum of an inverted cone having side slopes at the angle of repose of the sediment (Palmer, 1969).

The mechanics of scour due to waves and currents are quite complicated and this type of scour occurs in almost all ocean environments. The

**Professor, Civil and Ocean Engineering, Civil Engineering Department, Texas A&M University, College Station, TX 77843-3136.

scale and shape of the scour hole depends on the relative magnitude of the unidirectional velocity and the oscillatory flow velocities.

Experimental Study

Apparatus. Scour experiments were conducted in a 120-foot long (36.6 m), 3-foot deep (0.91 m) and 2-foot (0.61 m) wide, two dimensional, glass-walled wave flume. The test area was located approximately 40 feet (12.2 m) from the wave generator. The entire test area measured 40 feet (12.2 m) in length and was divided into several sections. An 8-foot (2.4 m) long, 5-inch (0.13 m) deep test sediment bed was bordered on each end by an 8-foot long (2.4 m) 10-inch (2.7 m) high false bottom. At the leading edge of the test area, a 16-foot (4.9 m) long ramp was used to gradually bring the wave up to the new depth at the top of the false bottom. A 1.5 inch (0.04 m) diameter aluminum pile was positioned along the centerline of the sediment bed.

Currents were produced using a centrifugal pumping system. The flow rate was monitored using a Fischer and Porter electromagnetic flow meter. The pump discharge entered the wave flume just forward of the wave generator and was diffused using a louvered grate. A Thermo-Systems model 1050 hot film anemometer was used to measure the vertical velocity distribution of the combined waves and currents.

The random wave generator used was a Seasim modular wave making system. This system consisted of a servo control system amplifier, a programmable spectrum random signal generator, an autocompensating wave height gauge and a paddle type sea wave simulation rolling seal modular wave generator.

A capacitance-type wave gauge was used with a Hewlett-Packard model 17403A carrier pre-amplifier to measure wave profile. To determine the significant wave height from the wave profile, a wave digitizer was used.

A wave absorber was positioned in the wave flume at the opposite end of the wave generator to reduce any reflections which might occur.

Scour depth readings were made using a point gauge after each test.

Procedures

A total of 20 experiments were performed. Four runs utilized currents only and the remainder used a combination of waves and currents. All test runs used a 1.5 inch (0.04 m) diameter pile placed in a bed of glass microbeads. The microbeads had a mean diameter (D_{50}) of 0.1 mm and a specific gravity of 2.45. Four different wave spectra were generated: Darbyshire, Pierson-Moskowitz, Jonswap (wave period = 8 secs) and Jonswap (wave period = 10 sec). Two water depths 0.917 ft (0.28 m) and 1.167 ft (0.36 m) and two different currents at each depth were employed, i.e. 0.380 fps (0.116 mps) and 0.650 fps (0.198 mps) at 0.917 ft (0.280 m), and 0.405 fps (0.123 mps) and 0.485 fps (0.148 mps) at 1.167 ft (0.036 m).

At the onset of each test, the sediment bed was leveled to a 5 inch (0.13 m) uniform thickness. After achieving the required water depth, the proper flow rate was established. The desired water level was maintained by regulating a 10-inch discharge valve located at the rear of the tank. The sediment bed was once again leveled as the above variables remained constant. The previously programmed signal generator then started generating the desired wave spectrum. Maximum scour depth was recorded at various intervals throughout each run, the time increment increasing as the test progressed. Each test was completed when equilibrium in the measured maximum scour depth was attained. After draining the tank, the patterns were photographed and sediment elevations, taken in the form of a rectangular grid, were established with the point gauge to determine equilibrium scour depth.

Results

Dimensionless Plots. There are many pertinent variables in a study of scour; the more important are: water depth (h), significant wave height ($H_{1/3}$), acceleration due to gravity (g), combined wave-current velocity (U), pile diameter (D), median sediment diameter (D_{50}), sediment/fluid density difference ($\rho_s - \rho$), density of water (ρ), kinematic viscosity of water (ν), and ultimate scour depth (S_d).

Since random waves were used in the study, and were defined by the significant wave height ($H_{1/3}$), wave period and wave length were omitted from the above list of variables. In the dimensional analysis S_d was chosen as the unit of length, S_d^2/ν as the unit of time and $/S_d^3$ as the unit of mass. The remaining seven variables expressed in these units give the following dimensional numbers:

$$S_d/h,\ S_d/H_{1/3},\ S_d/D,\ S_d/D_{50},\ \rho/(\rho_s-\rho),\ \nu^2/S_d{}^3g,\ \nu/S_d u$$

by rearranging and combining terms:

$$\frac{1}{(S_d/D)(\nu/S_d u)}\ \frac{UD}{\nu} = N_{RP}$$

$$[(S_d/h)(1/(\nu/S_d u)^2)(\nu^2/S_d{}^3g)]^{1/2} = u/\sqrt{gh} = N_F$$

$$[(S_d/D)(1/(\nu/S_d u)^2)(\nu^2/S_d{}^3g)]^{1/2} = u/\sqrt{gD} = N_{FP}$$

$$[(1/2)(\nu 2/S_d{}^3g)(1/(\nu/S_d u)^2)]^{1/2} = u/\sqrt{2S_d g} = N_{ES}$$

$$[(1/(\nu/S_d u)^2)(\nu^2/S_d{}^3g)(S_d/D_{50})(\rho/(\rho_s-\rho))]^{1/2}$$

$$= U/\sqrt{gD_{50}((\rho_s-\rho)/\rho)} = N_S$$

Therefore, the functional relationship for scour is:

$$\frac{S_d}{h} = f(S_d/H_{1/3},\ S_d/D,\ S_d/D_{50},\ N_{RP},\ N_F,\ N_{FP},\ N_{ES},\ N_S).$$

On various dimensionless plots, data from experiments conducted by Armbrust and Wang were used in combination with data obtained from the random wave-current interaction experiments. Regression analysis was performed on the plots in order to construct the appropriate curves. Logarithmic regression analysis was used on the semi-logarithmic plots, and power regression analysis was used on the full logarithmic plots. The "r^2" term adjacent to each curve represents the correlation coefficient for each curve.

It was discovered that a relationship exists between scour depth and sediment number (N_S), (Figures 1 and 2) as well as between scour depth and the pile Reynolds number (N_{RP}), (Figures 3 and 4). However, scour depth is not dependent on N_S, or N_{RP} alone, but is also dependent on pile diameter as well as sediment size.

By plotting the relative scour depth (S_d/h) against the product of the pile Reynolds number and the sediment number (N_{RP})(N_S), all data points collapsed onto a single curve regardless of variance in pile diameter or sediment size (Figure 5). It appears that since all data collapse onto a single curve, the type of wave train used for model studies, either monochromatic or random, is insignificant in the prediction of scour depth about a single cylindrical pile. However, the geometric shape of the scour hole differs with the type of wave train generated. By using a dimensionless plot (Figure 5), it appears as though predictions of scour depth could be made for situations in which the pile diameter or mean sediment size varied without utilizing scaling factors. Before any conclusions can be made, field data are required to evaluate the need, if any, for scale effects.

Scour Patterns. The rate of scour hole development by wave-current interaction was faster than that due to a steady current alone. Scour development is very rapid initially, the scour rate then decreases until the equilibrium scour depth is reached. Figure 6 shows a typical pattern of scour development in its initial stages, approximately the first 2 to 5 minutes of test. Figures 7 and 8 are the typical scour patterns that occur due to wave-current interaction 30 minutes and 2 to 3 hours after test commencement, respectively.

In all cases, the scour hole due to wave-current interaction was similar in shape to the scour hole formed by a steady current. This shape resembles an inverted cone. A typical example of a scour hole formed by a steady current is shown in Figure 9. Figures 10 to 13 depict the scour pattern formed by the same current used in Run 4 (Figure 8), combined with four different random wave spectra. As stated previously, the equilibrium scour hole associated with the wave-current interaction was deeper when compared to the equilibrium scour hole formed by a steady current alone. The size and shape of the equilibrium scour hole associated with wave-current interaction was at times greater than, approximately equal to, or less than the size and shape of the scour hole due to a steady current alone. These results differ from the prediction made by Niedoroda and Dalton in 1982. They stated that the scour hole

size and shape for combined waves and currents should not be as great as that developed by a steady current alone.

The general scour pattern was one of localized scour around the pile. A vortex formed around the pile due to disturbed flow and suspended the sediment. The sediment was carried farther downstream under the combined effects of waves and currents than it was with a steady current alone. Initially, the sediment suspension appeared to become greater as the scour hole developed, possibly due to a strengthening of the vortex system surrounding the pile. Because of the disturbance of flow caused by the pile, trailing ripples formed immediately behind the pile extending in the direction of wave propagation as the test progressed.

In all cases, the maximum scour depth occurred downstream of the pile, approximately 1/4 inch from the pile, and at an angle of approximately 40 degrees to the left or right of an imaginary line drawn through the pile and parallel with the wave flume walls.

Summary

1. Scour development was very rapid initially. The scour rate then decreased until an equilibrium scour depth was reached.

2. Scour development due to current and wave action occurred faster than scour due to a steady current alone.

3. The equilibrium scour depth caused by wave-current interaction is approximately 10 percent greater than the scour depth caused by a steady current alone.

4. The shape of the scour hole due to waves and currents and the shape of the hole due to current alone are similar. The shape resembles an inverted cone.

5. A relationship exists between scour depth and sediment number (N_S). However, scour depth is not dependent on N_S alone, but is also dependent on pile diameter and sediment size.

6. A relationship also exists between scour depth and the pile Reynolds number (N_{RP}). Again, scour depth is not dependent on (N_{RP}) alone, but is also dependent on pile diameter, as well as sediment size.

7. By plotting the relative scour depth (S_d/h) against the product of the pile Reynolds number and sediment number, (N_{RP}) (N_S), all data points collapse onto a single curve regardless of variance in pile diameter or sediment size.

Although the amount of data is limited, due to the fact that all data could be collapsed onto one curve when plotting S_d/h versus (N_{RP})(N_S), (Figure 5), it appears as though the type of wave train used for model studies, either mono-chromatic or random, is insignificant in the

prediction of scour depth about a single, cylindrical pile. However, when attempting to predict the geometry of the scour hole, the irregularity of the wave train becomes very significant. Armbrust stated that the pattern of scour for wave-current interaction is no longer conical in shape, but the pattern is irregular due to the wave particle orbital motion. The data in this study clearly indicate a conical scour pattern for random wave-current interaction. Although these results are different from those of Armbrust, they agree with field data, as well as with the predictions of Niedoroda and Dalton. The fact that the geometric shape of the scour hole differs with the type of wave train used, may become important in the prediction of scour depth around multiple pile cases.

The conclusions resulting from this study were found for a flow in which the steady current was greater than the oscillatory flow produced by the waves. If the magnitude of the two flows in relation to one another change, the flow patterns will also change and the geometry of the scour hole may very likely differ from results found in this study.

CHAPTER 137

PIER PROTECTION SYSTEM FOR THE DUWAMISH SHIP CHANNEL IN SEATTLE

Y. Eisenberg[1]; M. ASCE

ABSTRACT

In 1978 an out-of-control ship hit and severely damaged a bascule bridge across the Duwamish West Waterway in Seattle seriously affecting both ship and highway traffic. The high level West Seattle Bridge was subsequently constructed to handle all through-highway traffic. A swing bridge was also designed to handle local traffic over the ship channel. The function of the pier protection system described in this paper is to protect the pivot piers and swing spans of this new bridge from damage by absorbing the part of the tranverse energy component imparted by a colliding ship, which is not absorbed by deformation of the ship's hull.

1. DESIGN

The Duwamish ship channel in the Port of Seattle, Washington will be widened from 150 to 250 feet (46 to 76 meters) and deepened to 43 feet (13 meters) below mean low low water (MLLW), thereby accommodating ships with displacement of up to 100,000 kips (45,000 tons) and a length of 650 feet (200 meters). The pier protection systm to be placed along the edge of the channel shall provide protection for the pivot piers and the open swing span superstructures from ship impact.

1.1 DESIGN ASSUMPTIONS

1.1.1 Design Vessel

The maximum size of vessel which is expected to use the Duwamish waterway has a displacement of 100,000 kips (45,000 tons) and a length of 650 feet (200 meters).

1.1.2 Design Collision

The pier protection was designed to protect the bridge elements from the impact of the assumed design vessel moving at three knots or 5 ft. (1.5 meters)/sec. at an angle of between 0 and 18 degrees to the centerline of the channel. A transverse impact of the stern of the ship was also considered.

Impacts in the longitudinal (head-on) direction were assumed at each end of the pier protection system only.

[1] Parsons Brinckerhoff Quade & Douglas, Inc.
San Francisco, California, U.S.A.

It was further assumed that transverse impacts may occur anywhere along the pier protection system.

1.1.3 Design Energy

1.1.3.1 Longitudinal

The kinetic energy of the ship in the longitudinal direction was taken as:

$KEL = \frac{1}{2} MV^2$ with M = Mass of the ship and V = Velocity of the ship

$KEL = \frac{1}{2} \times \frac{100,000}{32.2} \times 5^2 = 38,000$ ft.-kips, say 40,000 ft.-kips (5,500 meter-tons)

1.1.3.2 Transverse

The transverse component of the 5 ft. (1.5 m)/sec. velocity at an angle of 18 degrees is 1.55 ft. (0.47 m)/sec.

In addition, in the transverse direction, a factor of about 1.0 must be added to account for the hydrodynamic mass of the water behind the vessel.

Therefore, total $KE = \frac{1}{2} \frac{100,000}{32.2} \times 1.55^2 (1+1) =$ 7,500 ft.-kips (1,040 meter-tons).

A vessel trying to correct course may impact the pier protection with its stern. As there are no reliable data available for this type of impact, the use of a somewhat higher transverse design energy seemed prudent. Therefore, a value of 10,000 ft.-kips (1,400 meter-tons) was finally used.

1.1.4 Transverse Clearance

The height of the pier protection system was selected to restrain the ship deck overhangs of the design vessel from damaging the bridge. For purpose of the design of the pier protection, low water was taken as elev. -12 ft. (-3.66 m) and high water was taken as elev. 0.0. All elevations were based on the City of Seattle datum.

1.2 LOAD RESISTANCE FOR DESIGN IMPACTS

A collision of a fully-loaded design vessel at the design speed and angle has a very low probablility of occurring. The normal design safety factors were, therefore, not applied. The total resistance of the pier protection system was utilized, and

the timber protection was considered expendable for anything other than minor impacts.

1.2.1 Longitudinal Design

At each end of the pier protection system, a concrete topped sheet pile cell will protect the bridge from head-on impact. If the full design energy will have to be dissipated, it was assumed that substantial damage to both the pier protection system and the vessel will occur.

1.2.2 Transverse Design

The pier protection system for transverse impacts consists of timber facing, reinforced concrete distribution beam and rubber fenders. This system will be supported by dolphins on piles.

To absorb the full transverse design energy, the plastic deformation of the pier protection system and of the vessel will take place, resulting in damage requiring repair work to both the pier protection and the vessel.

1.3 OTHER COLLISIONS

1.3.1 Usual Collisions

The usual type of collision to be expected is a glancing blow by a vessel. This will require an energy dissipation of a small percentage of the full design energy. Another probable occurrence is that of a ship which may drift sideways and use the pier protection system as a guideway.

A timber facing consisting of rubbing planks (placed from elev. -12 ft. (-3.66 m) to +2 ft. (+0.61 m) and timber piles shall run the full length and extend at least 30 feet beyond the center of each end cell. At this point, the timber protection shall be turned around a pile cluster toward the bank of the waterway.

This timber protection will limit damage to ships at low energy impacts. Damage which may occur to the timber elements will be relatively easy to repair.

1.3.2 Collision Exceeding Design

An effort has been made to provide a reasonable level of protection for the bridge. It must be recognized, however, that it is possible that the waterway may be used by larger vessels or vessels of unusual configuration. It was not deemed to be economical to try to prevent damage to the bridge for all possible impact conditions. Therefore, some risk factors remain.

1.4 DESIGN COMPONENTS

The pier protection system (see Figures 1, 2 and 3 - Plan, Elevation and Section) consists of the following components:

- o Timber piles (with timber facing) driven to 15 to 20 feet (5 to 6 meters) below channel bottom and end cluster dolphins, one at each corner of the pier protection system. (See Figure 2)
- o Small timber and structural steel wale system for transmitting loads from the timber piles and facing to the reinforced concrete distribution beams. (See Figure 3)
- o Reinforced concrete distribution beams. (See Figure 3)
- o Rubber fendering units transmitting horizontal loads from the distribution beams to the reinforced concrete dolphins. (See Figure 4)
- o Reinforced concrete dolphins vertically supporting the distribution beams and resting on batter piles. (See Figure 3)
- o Supporting struts carrying horizontal loads from the distribution beams to the reaction blocks. (See Figure 3)
- o Reinforced concrete reaction blocks. (See Figure 3)
- o Sheet pile cells, one at each corner of the pier protection system. (See Figure 1)

The various components of the pier protection system are described below:

Timber piles with timber facing and end cluster dolphins

The timber piles will be driven to a depth of 15 to 20 feet (5 to 6 meters) below the channel bottom. They are essentially designed to withstand only minor scraping by passing ships and to protect small craft. A blow of any consequence will surely damage or destroy them, but they can be easily replaced.

Timber and structural steel wale system

The wale system consists of 12 inch x 12 inch (0.30 m x 0.30 m) timber wales and structural steel WT members and its function is to tie the timber pile system to the distribution beams and thereby facilitate the transmission of loads from the piles to the beams.

Reinforced concrete distribution beams

The distribution beams are continuous reinforced concrete beams with spans varying from 115 feet to 132 feet (35 to 40 meters).

They are supported vertically on reinforced concrete dolphins and on intermediate 18-inch (450 mm) diameter pipe piles and are restrained laterally by fendering units.

The pipe piles are provided to assist in resisting an instantaneous vertical component from a ship impact at midspan of the distribution beam. Both dolphins and fenders are discussed further below. The distribution beams, whose main function is to transmit lateral ship loads, are approximtely 4 feet (1.25 meters) high and 12 feet (3.65 meters) wide. They are designed to withstand at yield an equivalent horizontal colliding ship load in excess of 2,000 kips (900 tons). Stainless steel plates are embedded in the concrete dolphin surfaces interfacing with the distribution beams to facilitate lateral sliding. The distribution beams are restrained from moving laterally by energy-absorbing rubber fenders that have lateral displacement capacity of almost 5 feet (1.50 meters).

Fendering Units

The function of the fenders is to absorb the colliding ship's energy as they compress and transmit the lateral loads from the distribution beams to the supporting dolphins. The buckling column type fenders are composed of trapezoidally-shaped rubber manufactured by several producers. The corner fenders (1,500L x 2,500H) are over 8 feet (2.5 meters) thick. The intermediate fenders (1,500L x 2,000H) are over 6 feet (2.0 meters) thick. the corner fenders are sized to absorb up to 3,000 foot-kips (415 meter-tons) of energy with a reaction of 2,000 kips (900 tons) at each dolphin. The intermediate fenders are sized to absorb up to 2,000 foot-kips (280 meter-tons) of energy with a reaction of 1,900 kips (800 tons) at each dolphin.

Reinforced Concrete Dolphins

The reinforced concrete dolphins are supported vertically by two 36-inch (915 mm) diameter batter piles. The piles are battered in the longitudinal direction, i.e., in the direction of ship traffic, and provide some resistance to longitudinal impacting ship forces. The dolphins' main function, however, is to transmit the lateral impacting ship forces through the timber piles, wale system, distribution beams and fender units and on to the supporting struts.

Supporting Struts

The supporting struts, which are about 60 to 100 feet (18 to 30 meters) long, are composed of 48-inch (1,220 mm) diameter steel pipes with a compressive ultimate capacity of 2,500-3,000 kips (1,100 to 1,400 tons). The function of the supporting struts is to carry the lateral loads from the reinforced concrete dolphins to the reaction blocks.

Reinforced Concrete Reaction Blocks

The reaction blocks and supporting struts will be placed in sheeted or bentonite slurry trenches. The reaction blocks, which are 20 feet (6 meters) high and 25 feet (7.6 meters) wide are designed to mobilize sufficient ultimate passive soil pressure, at 550 lbs/ft^3 (8800 kg/m^3) equivalent fluid pressure, behind them to withstand a minimum lateral load of 3000 kips (1400 tons) on any strut. In fact, the supporting struts are designed to buckle or yield at below 3,000 kips (1400 tons) load to forestall backward movement and upward heave of the soil behind the reaction blocks.

Sheet Pile Cells

The sheet pile cells are composed of 45-foot (13.7 meters) diameter interlocking sheet piles driven to elev. -75 feet (-23 meters) or about 20 feet (6 meters) below the channel bottom. They are filled with compacted or densified sand and gravel and are capped with 5 feet (1.5 meters) of reinforced concrete to elev. 0. Their function is to act as crash barriers at the four corners of the pier protection system. They are able to withstand a lateral or longitudinal force of about 2,600 kips (1200 tons) by a ship in the channel with 6-inch (0.15 meters) to one-foot (0.3 meters) displacement, and a force of up to about 3200 kips (1,450 tons) while being permanently displaced by no more than 4 to 5 feet (1.2 to 1.5 meters) in the process. While being thus damaged, the sheet pile cells will, in the process, deflect serious damage from the swing bridge and other components of the pier protection system.

Total Pier Protection System

The energy absorption capacity of the total pier protection system, just prior to its collapse is about 10,000 to 12,000 foot-kips (1400 to 1700 meter-tons).

1.5 DESIGN PROCESS

Since it was assumed that a design level impact will be such an infrequent occurrence, structural yielding was permitted as an energy dissipating device, as mentioned before. The pier protection system elements will yield as follows: the timber fendering will crush; the distribution beam will form plastic hinges; some rubber marine fender will be crushed; some struts will develop plastic hinges; some intermediate supports will develop plastic hinges; the colliding ship's hull will be deformed; and some sheet pile cells will deform plastically.

The distribution beams were modeled to reflect the beam spans, size and support conditions including the nonlinear behavior of large rubber marine fenders. The model was loaded either in spans or at supports with a uniform load of a magnitude

corresponding to a yield stress on the ship's hull. This is a maximum unit force that the ship can impart to the distribution beam. The magnitude of the force can increase only by increasing the area of ship yielding, i.e., the contact length. The ship can contact the distribution beam at one area for a given collision; therefore, only single spans or single supports are loaded. The load length is increased until either the energy requirements are met or the beam undergoes structural yielding. When yielding occurs, a plastic hinge is applied to the model and the load is increased. To install a plastic hinge, a member end is released for rotation and equal and opposite hinge capacity movements are applied to the member ends framing into the joint. The load is then increased until energy requirements are met while checking that secondary hinges do not form elsewhere in the structure.

Energy requirements are met when the sum of energy absorbing components equals or exceeds the design energy. The energy absorbing components considered are the ship's hull deformation caused by the beam reaction, the marine fender deformation, the beam elastic strain energy, the sheet pile cell deformation and the hinge rotation from the development of plastic hinges.

Marine fenders were sized to allow adequate displacement to absorb energy, yet minimize beam moments. A combination of two fender sizes was found adequate to meet these requirements.

The distribution beam plastic hinge capacity was determined by selecting reinforcing bars patterns that provide large moment capacities for the section. Although the reinforcing steel percentage is very high it was accepted because of the anticipated infrequency of the collision design loading.

The dolphin structure was modeled to reflect the three-dimensional nature of both the structure and the loadings. Reactions from the distribution beam analysis, both along the channel and normal to the channel as well as gravity loads, were applied to the dolphins. Batter piles and struts were designed for biaxial bending such that yield may occur under imparted design ship energy.

As mentioned before, the timber fendering was designed so that the timber piles are the "weak link". Timber piles are capable of absorbing a relatively small amount of energy before failure, thus the failure loads were used for design of the timber system.

2. CONSTRUCTION

Construction of the pier protection system will be completed in two phases. The first phase will provide protection to the west pier of the swing bridge and minimal protection to the east pier. The second phase will complete the pier protection system at the east pier of the bridge.

CHAPTER 138

THE DESIGN OF A SLOTTED VERTICAL SCREEN BREAKWATER

J D Gardner*, I H Townend* and C A Fleming**

INTRODUCTION

This paper describes the wave studies, model testing and structural design of a 250 metre long slotted vertical screen breakwater for a marina at Plymouth, England.

The marina is being developed by Plymouth City Council to provide a purpose built facility for hosting the major long distance races that start or finish at Plymouth, in addition to the usual marina facilities for private boat owners.

After examining three alternative locations Plymouth Council selected a site in the north-east corner of Plymouth Sound as shown in Figure 1.

The site is confined on two sides by existing shipping channels and by a rocky shore on the land side. Exposure to wave attack is limited to the south west sector.

Because the existing seabed at the marine site was the responsibility of the Duchy of Cornwall, an Act of Parliament was required before Plymouth Council could commence construction. The Act contains clauses regulating the use of the marina and the permissable changes to the wave conditions in the adjacent shipping channels.

DESIGN CRITERIA

The basic maritime criteria governing the design are:-

(i) Wave heights in the marina should not exceed Hs = 0.3 metres for more than 200 hours per year.

(ii) With the exception of a 10 metre carriageway on the SW face of the breakwater wave heights in the adjacent shipping channels should not be increased, as a consequence of the breakwater, by more than 50% above the conditions existing before construction.

(iii) The breakwater should be designed to withstand the 100 year return period storm occurring at any tide level.

** Director, Sir William Halcrow & Partners Ltd, Burderop Park, UK

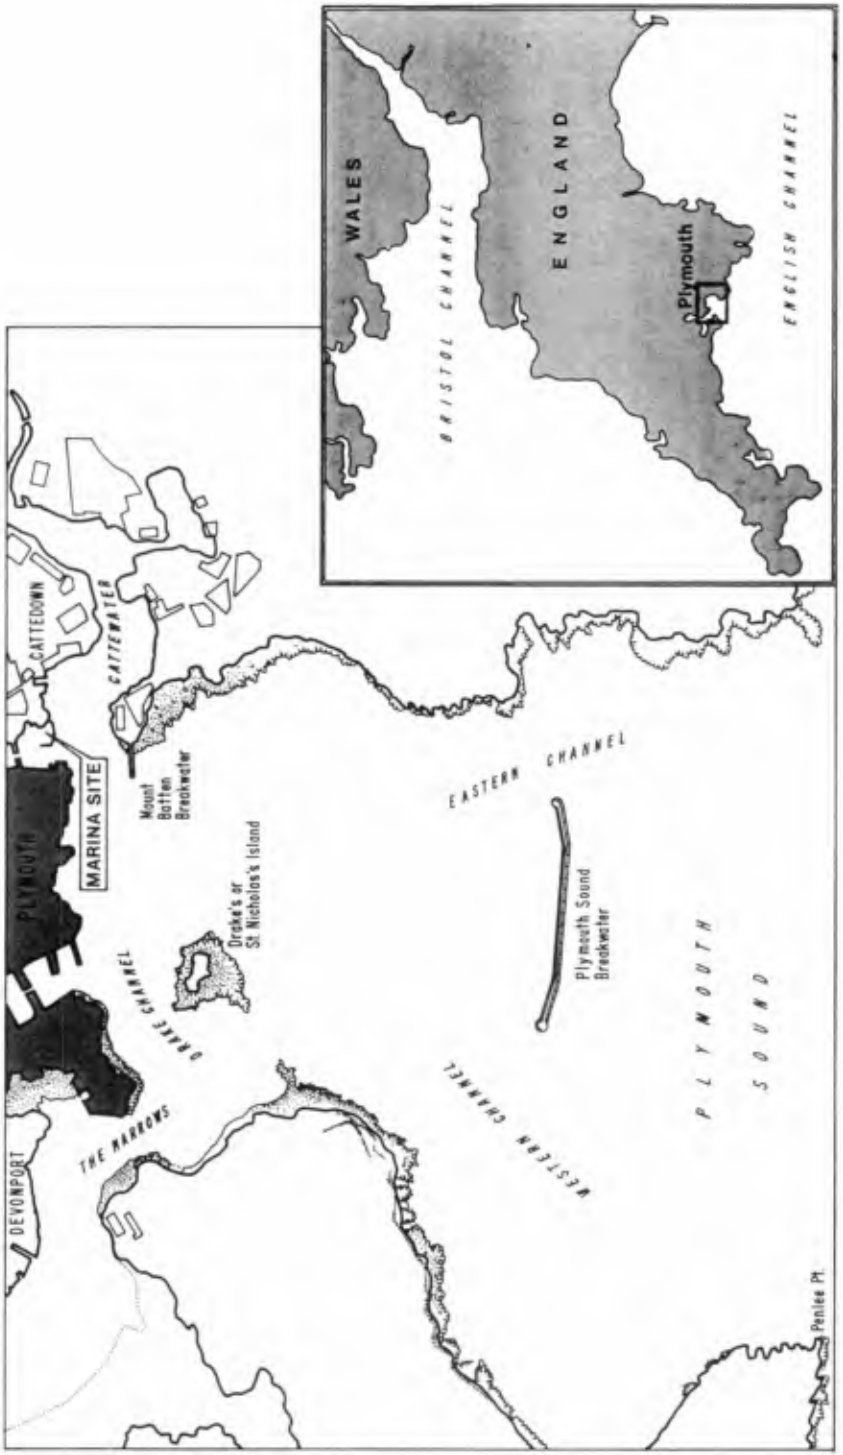

Figure 1: Site Location Plan

The preparation of construction drawings and tender documens was not started until parliamentary approval had been given. This was obtained in April 1985 and Plymouth Council decided that the marina should be ready for hosting the Two Handed Trans Atlantic Race in June 1986. To achieve this programme detailed design, testing and tender documents had to be prepared in the period May to mid-August so that tenders could be received by mid-September to allow construction to commence in November 1985.

EXISTING WAVE CONDITIONS

Deep water swell from the English Channel can only reach the marina area from the south-west. The most severe wave conditions will therefore comprise combined swell waves and locally generated wind waves arriving from this direction.

Data for deep water wave conditions were available from the Institute of Oceanographic Sciences (IOS) in the form of a report on data collected by a Waverider buoy located near the Eddystone Lighthouse. The deepwater wave climate was transferred to the marina site in two stages.

(i) wave refraction backtracking and spectrum transfer from deep water to the Plymouth Sound breakwater.

(ii) diffraction of the resulting wave energy spectrum from the Plymouth Sound breakwater to the marina site.

Wave heights and periods for locally generated waves were calculated using the Carter Equations derived from the Jonswap energy spectrum formulation. Wind speeds calculated from data recorded at Fort Stanford, Plymouth and the equations used for a fetch limited growing sea were:

$$H_s = 0.0163\ X^{0.5}\ U$$
$$T_z = 0.439\ X^{0.3}\ U^{0.4}$$

where X is the effective fetch in kilometres and U is the wind speed in metres per second.

The resulting wave heights at the marina site were as follows:

Return Period	Hs(m) (deepwater)	Hs(m) (local)	Hs(m) (combined)
100	1.5	0.8	1.7
50	1.4	0.75	1.6
10	1.2	0.7	1.4
1	1.1	0.6	1.3

Examination of the Admiralty Charts for Plymouth shows that the approach direction for the swell waves is limited by Penless Point to the west and the Plymouth Sound and Mount Batten Breakwaters to the east. Approach directions for the critical wave condition are therefore limited to the sector between 210° and 220°.

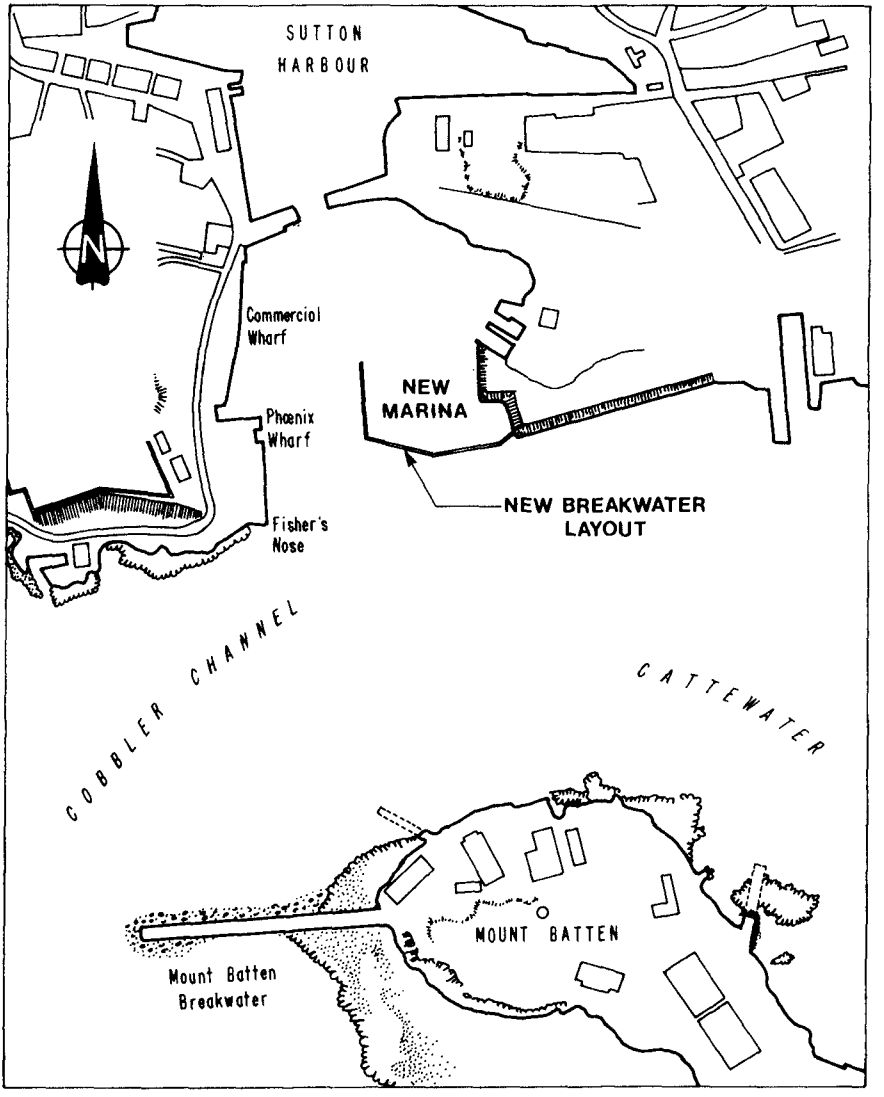

Figure 2: Outline plan for new marina

Under critical wave conditions the wave climate to the west and south of the marina will be influenced by sheltering and diffraction effects caused by the coastline adjacent to Fisher's Nose (see Figure 2).

The treatment of wave diffraction was based on the Sommerfeld solution as presented by Wiegel (1964). A Halcrow computer model was used to evaluate wave height factors at the nodes of a square grid across the area of study. Wave height factors being defined as:

$$\text{wave height factor} = \frac{\text{wave height at node}}{\text{height of incident wave}}$$

The model could be used to evaluate wave conditions in the vicinity of systems of one or two impermeable breakwaters. The breakwaters could also assume any degree of reflection of incident wave energy.

The sheltering effect of Fisher's nose was represented by a breakwater aligned north/south. The resulting wave height factors are given in Figure 3 where the factors are expressed relative to the incident wave height off Fisher's Nose.

WAVE CONDITIONS AFTER CONSTRUCTION OF THE MARINA BREAKWATER

The wave diffraction model was run for each segment of the breakwater and the results were superimposed to provide a composite diffraction solution. Thus a relatively simple program provided a quick and realistic answer. The results for a fully reflecting breakwater are shown in Figure 4.

Comparison of Figure 3 with Figure 4 gives the percentage change in wave height factors resulting from construction of the breakwater. These initial results showed that wave heights would increase to an unacceptable level in the two adjacent shipping channels.

The wave diffraction model was re-run using breakwater reflection coefficients less than unity and it was found that acceptable wave conditions could be achieved with the following reflection coefficients:

Section A - $K_R \leq 0.8$
Section B - $K_R \leq 0.5$
Section C - $K_R = 1$

In this appraisal the consequence of varying the incident wave period was also examined and this was found to alter the area influenced by the reflected waves quite significantly.

CHOICE OF STRUCTURE FOR THE MARINA BREAKWATER

Several types of structure were considered during the feasibility stage of the project. These included: a floating breakwater; a rubble mound breakwater; a blockwork wall and a vertical screen breakwater.

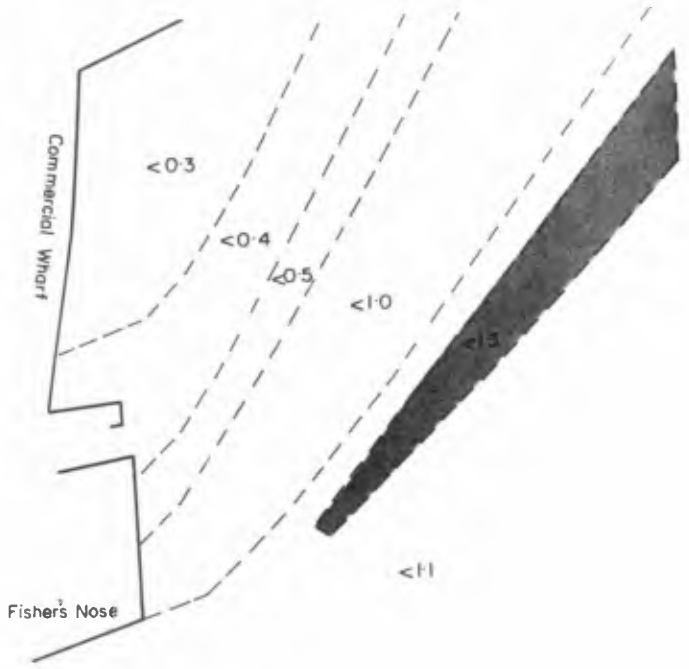

Figure 3: Wave height factors for existing site

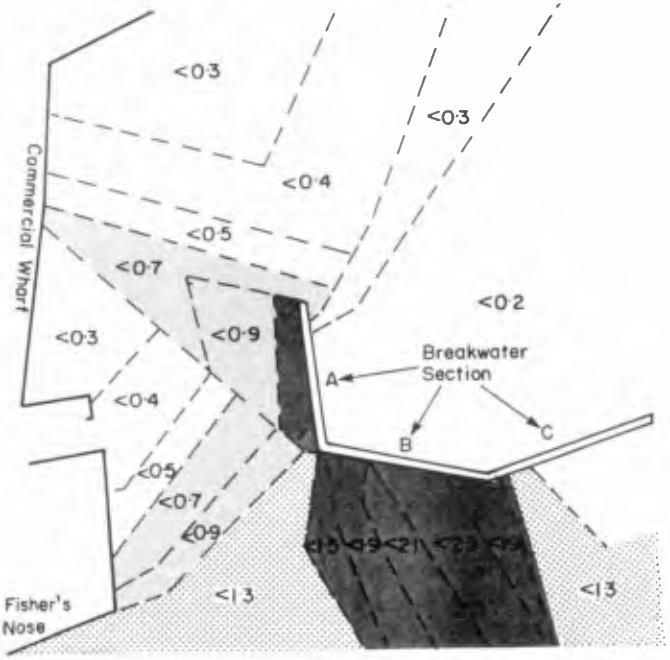

Figure 4: Wave height factors with fully reflecting breakwater

However this site has three major constraints: the seabed consists of soft silt up to 30 metres thick overlying bedrock; the area available for the marina is small; the spring tidal range is 5 metres. A vertical screen supported by piles driven to bedrock was considered to be the most practical and economic solution within these constraints.

Following the initial numerical diffraction and reflection analysis various configurations of perforated screens were examined. Examination of existing literature (refs 1, 3, 4 and 5) indicated that a double screen would be required for Section B whereas a single screen would be sufficient for Section A. The extent of the double screen was a balance between wave reflection, wave transmission into the marina and construction cost.

Although existing case histories were sufficeint to demonstrate that a solution could be found to suit the basic design criteria there was insufficient information to permit detailed design to be carried out. The final configuration of the screens was therefore based on the results of a set of simple flume tests.

MODEL TESTING

To meet the tight design programme, model testing commenced at the start of the detailed design phase. This then enabled the final structural design to take account of the test results.

Model testing was carried out at Hydraulics Research, Wallingford in a 45 metre long wind wave flume. The purpose of the tests was to measure the reflection and transmission coefficients (K_R and K_T) for single and double screens whilst changing the following variables identified during the conceptual design stage:

(i) Wave periods between 3 and 12 seconds
(ii) Screen porosity varying between 8% and 35%
(iii) Space between screens varying between 5 metres and 15 metres
(iv) Slots horizontal or vertical
(v) The gap between the bottom screen and the seabed
(vi) The effect of changing the plank thickness from 300 mm to 150 mm
(vii) Screens tilted or vertical

The model scale was 1:15 and random waves were used. Wave measurements were made using three wave probes and incident and reflected spectra calculated using an analysis program. The method determines the reflection and transmission coefficients for each frequency considered in the incident wave spectrum.

As the model tests progressed some changes were made to the testing sequence taking account of the previous results and the requirements of the structural design, which was proceeding simultaneously, thereby avoiding tests unlikely to yield a useful solution. In all 54 tests were carried out and the results are given by Hydraulics Research Laboratory (1986).

The principal results are summarised in Figures 5, 6 and 7.

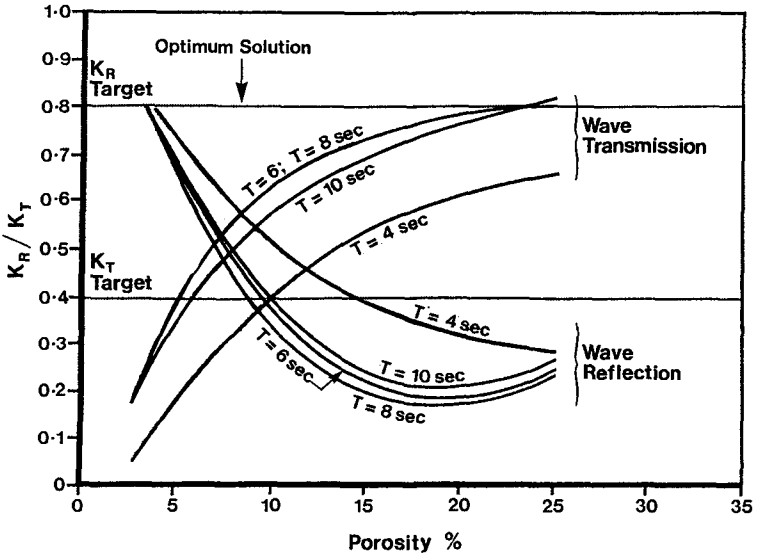

Figure 5: Reflection coefficient (K_R) & Transmission coefficient (K_T) v Porosity for single vertical screen

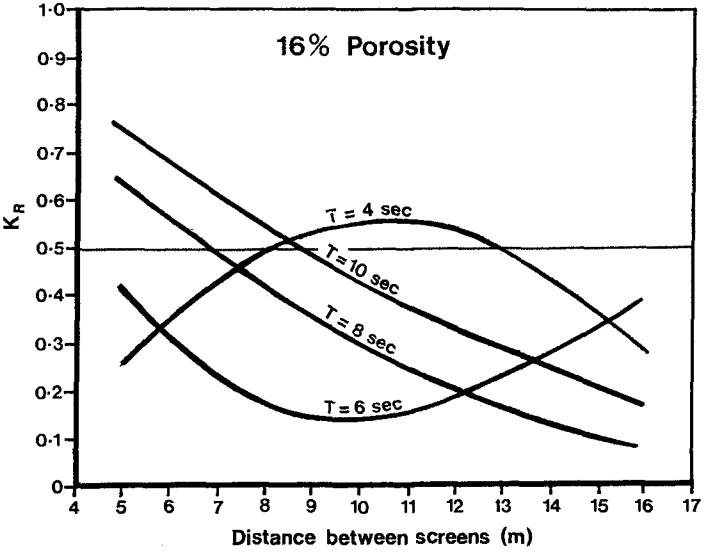

Figure 6: Reflection coefficient v Distance between screens

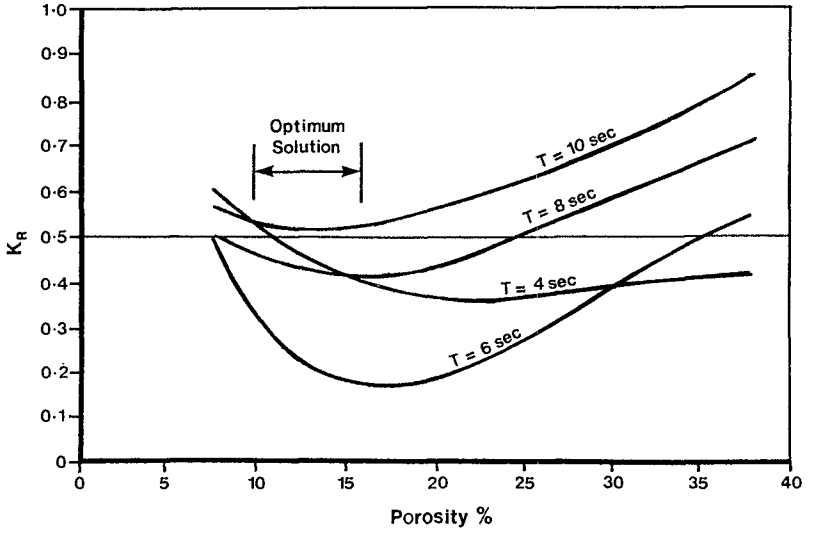

Figure 7: Reflection coefficient v Front screen details for screen spacing of 8m

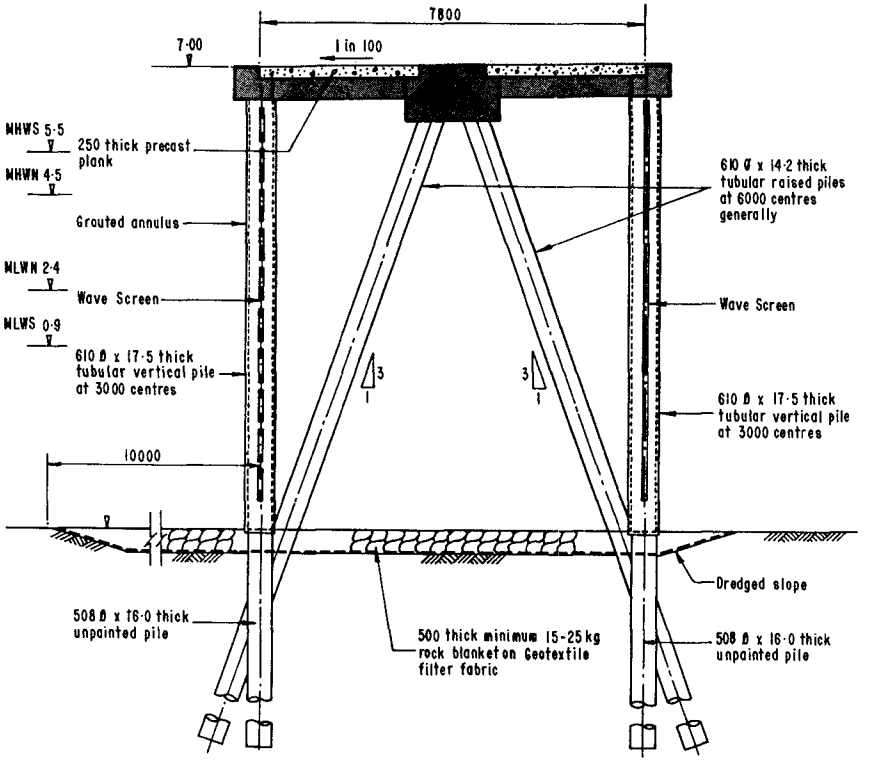

Figure 8: Section through double screen

For the single screen:

(i) a porosity of 8% gave acceptable values of K_R and K_T (see Figure 5)

(ii) the performance of horizontal slots was similar to that of vertical. Horizontal slots were therefore adopted because this orientation suited the proposed construction method

(iii) a 1 metre gap beneath the screen gave unacceptable wave transmission results

(iv) the hydraulic performance of 150 mm planks was similar to that of 300 mm planks.

For the double screen:

(i) a double screen with a front screen with 16% porosity spaced 8 metres from a solid back screen gave suitable reflection coefficients (see Figures 6 and 7)

(ii) the performance of horizontal slots was similar to that of vertical. Horizontal slots were therefore adopted because this orientation suited the proposed construction method

(iii) a 1 metre gap beneath the screens gave unacceptable wave transmission results

(iv) the hydraulic performance of 150 mm planks was similar to that of 300 mm planks

(v) tilting the screens did not show any improvement over vertical screens.

FINAL WAVE STUDIES USING MODEL TEST RESULTS

The numerical diffraction model previously discussed was re-run using the results from the flume test as follows:

Wave Period (secs)	4		6		8	
Breakwater Section	K_R	K_T	K_R	K_T	K_R	K_T
A (single, 8% porosity)	0.6	0.3	0.6	0.4	0.6	0.4
B (double, 16% porosity 8 m space)	0.4	0.0	0.2	0.0	0.4	0.0
C (single, solid)	0.9	0.0	0.9	0.0	0.9	0.0

The results showed that wave heights outside the breakwater were within the required limits except for one small area to the south of the breakwater. It should be noted that the diffraction - reflection - transmission analysis does not take account of wave-wave interaction, wave breaking and the lateral internal diffraction of waves. As these non-linear effects would all lead to a reduction in resultant wave heights it was decided that this small area did not justify any changes in the proposed breakwater.

The results also showed that transmission into the majority of the marina had been retained below the target value of Hs = 0.3 metres. A small area in the south-west corner showing higher contours would be deleted by an additional length of double wave wall.

STRUCTURAL DESIGN

The typical structural details for the double screen are shown in Figure 8. The single screen is similar except that the rear screen and half of the deck is deleted. Typical isometric views of both types of screen are illustrated in Figure 9.

The wave loads on the screen are transmitted to the bedrock by the pairs of raking piles. The maximum compression and tension loads are approximately 2500 kN and 1800 kN respectively. The high compression loads are taken by end bearing on the rock and for this reason the pile toes are plugged with concrete. The tension loads are taken by dead anchors drilled beyond the pile toes and grouted into bed rock.

The vertical pile is a composite pile with the upper section comprising an external sleeve grouted onto the inner pile after the inner pile has been driven to bed rock. The external pile is a prefabricated section with flanges for wave screen plank fixing. The use of the composite pile allowed the inner pile to be designed for the forces below the bed level, with the grouted sleeve above bed level providing the additional stiffness to carry the high moments induced by the wave screen. This arrangement also helped to eliminate alignment problems with the plank fixings.

The screen planking material is greenheart timber and the deck is concrete. Handrails and lights are provided on the deck to provide a public promenade and viewing area.

The cost of the breakwater, excluding pontoons and other marina items, is approximately £1.8 million, of which approximately 65% is the cost of the tubular steel piles.

The Contractor for the project was Dean and Dyball (Western) Ltd from Exeter.

Figure 10 shows the project nearing completion.

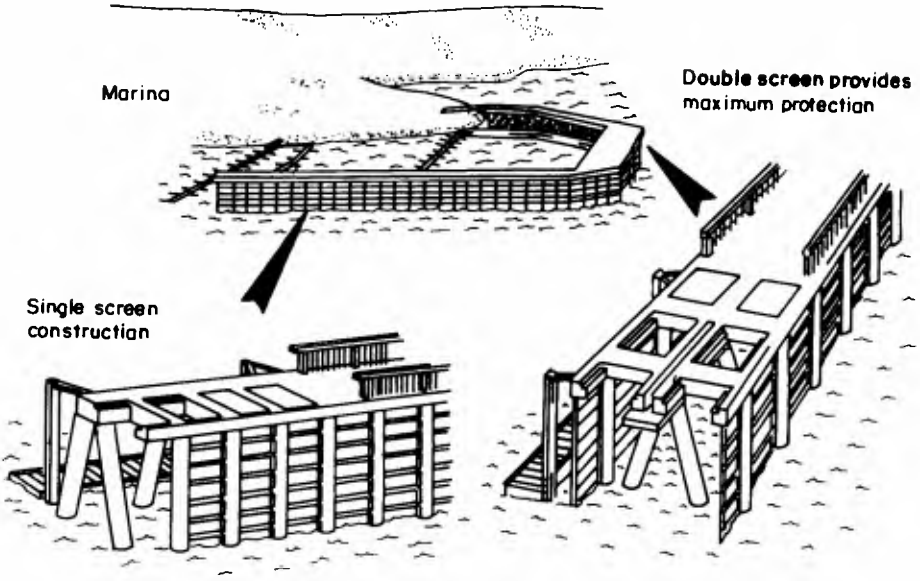

Figure 9: Typical views of single and double screen breakwater

Figure 10: Marina Nearing Completion

CONCLUSION

Based on visual information during the 4 month period since the breakwater was completed wave reflection into the shipping channels appears to be well within the permissible levels.

Without the use of a slotted vertical screen the marina project would not have been allowed to proceed, but using the relatively inexpensive methods of analysis and testing described in this paper a practical and aesthetically acceptable solution has been found.

ACKNOWLEDGEMENT

The authors are indepted to the City Engineer, Plymouth for his permission to publish this paper.

CHAPTER 139

STABILITY ANALYSIS OF OCEAN PIPELINES : A PROBABILISTIC APPROACH

Leon C Geustyn*, Gideon de F Retief**

ABSTRACT

A probabilistic approach to the lateral stability of a pipeline on the sea-bed is considered. The uncertainties involved in the deterministic approach, due to the stochastic nature of variables, inaccuracy of models and statistical error are discussed. Variables representing these uncertainties are identified and their statistical properties investigated. Procedures for computing the probability of stability failure are developed using both analytical and Monte Carlo simulation techniques. Example calculations are presented indicating typical applications. It is concluded that the probabilistic procedure, as presented here, can serve as a valuable tool in the stability analysis of ocean pipelines.

1. INTRODUCTION

An important consideration in the design of pipelines resting on the ocean bottom involves their protection against possible structural instability. Included in the stability design must be a provision for the capacity of the structure to resist forces caused by wave-induced water motion and currents. This is normally achieved through an application of some form of anchorage or weighting down of the pipeline and taking into account the resistance against sliding of the bottom foundation.

Determination of the structural loads and resistances entering the stability design problem is based on theoretical and/or empirical models that consider a variety of influencing factors, such as hydrodynamic forces and soil frictional resistance. Due to uncertainties involved in various aspects of these models (e.g., random variable input parameters, experimentally determined coefficients, etc.), the final design is heavily influenced by the experience and judgement of the designer.

* Engineer, Ocean Engineering, University of Stellenbosch, and Geustyn, Forsyth & Joubert, PO Box 413, Stellenbosch South Africa, 7600

** Professor, Ocean Engineering, University of Stellenbosch Stellenbosch, 7600 South Africa

This has often resulted in conservative attitudes in code directives and design decisions. The latter are commonly based on the concept of a global factor of safety. Recognition of the factor of safety's nonlinear relationship to certain input parameters and inability to distinguish between contributions of parameters separately, have caused designers to propose improvements in the method of expressing safety (Ellinas et al, 1984).

The objectives of the present study are to: (1) identify random variables that are present in the stability analysis; (2) determine their statistical properties and (3) develop a procedure to determine the probability of stability failure. A probabilistic description of the relevant random functions is used. The random variables in the analysis are the wave height and period, force and soil coefficients and variables representing uncertainty in the prediction of wave kinematics. Distribution functions for the variables are either determined from available data or using their commonly accepted representations. Evaluation of the random functions is done through analytical transformation of variables and Monte Carlo simulation.

2. PROBLEM FORMULATION

The case under consideration is that of a straight pipeline situated directly on a flat, rigid, impermeable bottom in the ocean. In terms of structural, lateral stability, the pipeline is considered to be safe if no movement thereof occurs.

For the purpose of this study the demand on the pipeline is considered to be the hydrodynamic forces exerted on it due to it being exposed to wave-induced oscillatory flow and a steady uniform current. The resistance to movement is considered to be provided by either anchorage or frictional resistance of the bottom soil.

The wave and current directions relative to the pipeline, θ_w and θ_c respectively, are assumed to be sufficiently small for the forces along the section of the pipeline which is of interest, to be essentially constant. A unit length of the pipeline is therefore considered to be representative of the section of interest in the design. For the unit length of pipeline the stability criterion requires that the lateral component of the force, F_H, be less than the resisting force, F_R. The stability condition to be investigated can therefore be expressed in terms of a stability parameter, G as

$$G = \frac{F_H}{F_R} < 1 \qquad \text{- - - - (1)}$$

3. DETERMINISTIC ANALYSIS AND IDENTIFICATION OF UNCERTAINTIES

The deterministic (conventional) methods used to evaluate lateral stability of a pipeline can be generally summarised under the following steps:

- Definition of the environmental conditions, with regard to waves and currents, based on specific statistical extreme states.
- Definition of the kinematics at the seabed using appropriate wave theories.
- Definition of the hydrodynamic forces through application of semi-empirical force models.
- Evaluation of the lateral stability using models describing the resistance to movement provided by either anchorage or the bottom soil, for chosen anchorage specifics or pipeline weight.

The specific models normally applied, and uncertainties involved in the procedure, are discussed in the next sections.

3.1 Definition of environmental conditions

The parameters which normally are used to define the environmental conditions are wave height, H, and period, T, and uniform current, U_c. These parameters are, due to their stochastic nature, most often determined in terms of an expected frequency of occurrence, or more practically, in terms of a return period, such as 50 or 100 years. The implication is that for decisions in this respect there has to be relied on extrapolation from statistical models which are based on measured data. The accuracy of results derived through this process depends heavily on the quantity and quality of the basic data. Mol et al (1984) describes inaccuracy in prediction of H due to (1) scatter and inaccuracies of the original data; (2) selection of a probability function and (3) extrapolation outside the observation period, resulting in a coefficient of variation typically in the order or 10% to 15%.

Further uncertainty is also present in the selection of the right design wave height and period combination. Chen et al (1979) e.g., determined distributions for T conditional to H from measurements within a stationary sea state. According to their study the conditional distribution of T is normal with a coefficient of variation which decreases with increasing H from about 18% at H_S to about 8% at H_{max}.

3.2 Definition of the kinematics at the sea-bed

Kinematics at the sea-bed such as horizontal velocity and acceleration are normally determined through use of a wave theory. Although verification of certain wave theories such as the linear, vocoidal and stream function theories, in relation to specific conditions such as water depth, has been done (Swart and Loubser, 1979; Dean and Perlin, 1986), it is only in the average sense.

Results of experimental work, especially such as those obtained by Grace (1976) in real ocean conditions, show large scatter and possible errors in the prediction of the maximum horizontal velocity, u_m, by the linear or stream function theories of up to 60% and 50% respectively. Even larger scatter and possible errors exist in the prediction of the maximum horizontal acceleration, a_m. Substantial uncertainty therefore exists in the prediction of kinematics at the sea-bed by wave theories.

3.3 Definition of the hydrodynamic forces

Application of Morison-type equations to determine the magnitude of hydrodynamic forces on a pipeline, is widely accepted to provide good average values (Karal, 1985; Grace and Zee, 1981).

The maximum hydrodynamic forces per unit length can be expressed as follows (Grace and Zee, 1981):

$$F_{Hm} = 0.5\rho D C_{Hm} u^2_m \quad - - - - \quad (2)$$

and

$$F_{Lm} = 0.5\rho D C_{Lm} u^2_m \quad - - - - \quad (3)$$

where

F_{Lm}, F_{Lm} = maximum horizontal and lift forces in a wave cycle, normal to the pipeline
ρ = water density
D = pipe outside diameter
C_{Hm}, C_{Lm} = maximum force coefficients (horizontal, lift)
u_m, a_m = maximum horizontal particle velocity and acceleration in a wave cycle, normal to the pipeline.

The accuracy of predictions by the above equations relies heavily on the choice of values for the force coefficients used. There is however a substantial degree of uncertainty related to appropriate choices in this respect, due to large scatter in the results of experimental work performed in the laboratory such as reported by Jacobsen and Bryndum (1984), and even more so for results from ocean experiments such as performed by Grace and Zee (1981) and the Hydraulics Research Station (1982).

The type of uncertainty involved in the prediction of the hydrodynamic forces is therefore mainly related to model inaccuracies. A certain degree of measurement error, in the determination of force coefficient values, would however also be present.

3.4 Uncertainties in the evaluation of the lateral stability

If the resistance to movement is provided by the soil frictional resistance the Coulomb friction force model is normally considered appropriate. The resistance force is thus determined as

$$F_R = S(W_S - F_L) \qquad ---- \quad (4)$$

Therefore the stability condition is described by

$$G = \frac{F_H}{S(W_S - F_L)} \qquad ---- \quad (5)$$

where

S = lateral soil resistance coefficient
W_S = submerged weight of the pipeline.

In the application of this model the main source of uncertainty lies in the value of S. Experimental results show considerable scatter in values of S (Anand and Agarwal, 1981) and choices normally has to be made from a range of possible values. Predictions of S, based on experience of soil conditions similar to those occurring in the case under consideration, or theoretical predictions from measurements of soil characteristics, will be subjected to a large degree of uncertainty. Even if this procedure was totally reliable, the possible variation of soil conditions along the pipeline and random results from measurements of values of soil parameters would introduce uncertainty in the prediction of S for a specific pipeline section.

3.5 The effects of uncertainties on the stability design

The effect of having to cope with uncertainties in the stability design of a pipeline, is that of introducing methods which are aimed at producing an overall conservative result. Upper bound values are used for random parameters such as coefficients and environmental parameters, and procedures, such as linear vectorial addition of wave and current kinematics are implemented. In addition to this a safety factor is included in the final analysis.

Although such practices would normally ensure safety, no quantifiable estimate can be made of the real degree of safety since the procedure does not account for the uncertainty related to true parameter values and model predictions. With conservatism being introduced at each step of the design procedure, the cumulative effect of the conservatism is difficult to quantify. Apart from this situation being unsatisfactory from a scientific viewpoint, the risk for unduly conservative design, or even failure in some cases, is present. The effects of over-conservative design could be drastic due to the sensitivity of installation methods to pipeline weight.

4. PROBABILISTIC APPROACH

The objective of the probabilistic approach is to account for the uncertainties involved in an analysis and to provide an improved measure for the reliability of the structure. The procedures followed in this approach are aimed at determining the probability of failure, P_f, for a structure. These procedures can generaly be summarized as:

- Description of the failure function $F = f(x_1,x_2,x_3 \ldots x_n)$ (where $x_1,x_2,x_3 \ldots x_n$ are the n variables in the analysis);
- Identification of the variables representing the uncertainties in the analysis and description of their statistical distributions or properties;
- Determination of the statistical distribution or properties of F and consequently P_f = Probability that $F < 0$, by approximate methods (Level II) or exact methods (Level III).

In the present study the above listed procedures are followed to develop a method through which the probability of stability failure of a pipeline can be determined. The probabilistic modelling is done according to the exact method (Level III) which implies full description of the random variables in terms of their probability density functions. Calculation of P_f is performed by both analytical development of the failure function and Monte Carlo simulation.

4.1 Description of the failure function

Since the stability criterion determines that $G < 1$, as defined in equation (1), it follows that to satisfy this criterion

$$F = F_R - F_H > 0 \qquad \text{- - - -} \quad (6)$$

which is the basic expression for the failure function F.

If maximum forces are considered and the resistance is assumed to be provided by the bottom friction force, equation (6) can be expanded to

$$F = S(W_S - BF_{Lm}) - F_{Hm} \quad ---- \quad (7)$$

where B is a reduction factor on F_{Lm} at the instant when F_{Hm} occurs.

Introducing equations (2) and (3) into (7) gives:

$$F = S(W_S - 0.5\rho DBC_{Lm}u^2_m) - 0,5\rho DC_{Hm}u^2_m \quad --- \quad (8)$$

where u_m is e.g. described by the linear wave theory as

$$u_m = \frac{HgT\cosh[2\pi(z+d)/L]}{2L\cosh(2\pi d/L)} + U_c \quad ---- \quad (9)$$

with
- L = wavelength
- d = waterdepth
- z = - depth below still water level
- U_c = uniform current velocity

4.2 Description of variable statistics

In the description of probability distributions to be used for the variables in the probabilistic analysis, distinction is made between two types of variables. The first type concerns those variables whose distributions will be dependant on the specific conditions of the case under consideration. The variables H, T and S are of this type as their statistical properties will be determined from measured data, only applicable to the relevant conditions. The second type of variable concerns those variables for which distributions can be derived which are generally applicable. It is assumed here that those variables which represent model uncertainty, such as C_{Hm} and C_{Lm} are of this type.

The variables which are treated as random variables in this study are:

Wave parameters, H and T
Soil frictional resistance, S
Wave kinematics model uncertainty parameters,

$$E_u = \frac{u_{wm}\ (\text{true})}{u_{wm}\ (\text{theory})} \qquad E_a = \frac{a_{wm}\ (\text{true})}{a_{wm}\ (\text{theory})}$$

with u_{wm}, a_{wm} = maximum horizontal velocity, acceleration due to wave action in a wave cycle.
Wave force coefficients, C_{Hm} and C_{Lm}.

4.2.1 Wave parameters, H and T

As explained above there is no general distribution function which applies for the description of the distribution of e.g. H. Typical distributions used are the Log-Normal and Extremal Type I, II and III. Similarly there is no general distribution for T which applies. Typically it can be taken to be Normal (Chen et al, 1979). The general models developed in this study allow the use of any distribution function for H and T but for specific examples the Log-Normal and Normal distribution are used for H and T respectively. H and T are taken to be uncorrelated.

4.2.2 Soil frictional resistance parameter, S

Although the distribution of S will in practice ideally be obtained from site specific measurements, it could, due to the lack of such measurements, be necessary to assign to it a distribution from previous knowledge pertaining to similar conditions. For this kind of subjective probabilistic treatment a distribution is chosen and parameters for it determined from existing knowledge concerning the value of S, such as its mean or maximum and minimum. Typical distribution functions which can be used in this fashion are the Rectangular, Triangular and Normal distributions. For example calculations in this study the Normal distribution is used for S with chosen mean value, S, and coefficient of variation, CV_S.

4.2.3 Wave kinematics model uncertainty parameters, E_u and E_a

It is assumed that the true value of e.g. u_{wm} is that of u_{wm} predicted by theory multiplied by a random factor, E_u.

The procedure followed to describe the statistical properties of E_u and E_a was as follows:

Using experimental data from which frequency histograms for E_u and E_a could be obtained, best fit general theoretical distribution functions were determined. It was found that the Log-Normal distribution provides the best fit for both E_u and E_a (see Figure 1). Parameters (mean and coefficient of variation) to be used in this distribution, applicable to both the linear and stream function wave theories, were obtained from appropriate available data

sets. A summary of the results obtained is given in Table 1.

TABLE 1: Summary of statistical properties of E_u and E_a.

Variable	Mean	CV	5% value = 95% exceedance according to Log-Normal distribution
E_u (linear theory)	1.10	0.16	1.42
E_u (stream function)	0.96	0.18	1.26
E_a (linear theory)	1.22	0.39	2.10
E_a (stream theory)	1.07	0.36	1.82

Results based on data from: Grace (1976); Swart and Loubser (1979); Dean and Perlin (1986); Grace and Zee (1981).

4.2.4 Force coefficients, C_{Hm} and C_{Lm}

The force coefficients are assumed to represent the model uncertainties in predicting hydrodynamic forces. In the statistical treatment of C_{Hm} and C_{Lm} their distributions conditional to the dimensionless parameter, $P = u_m^2/Da_m$, were obtained. This was done by fitting distributions to available data for P-interval widths equal to 1. The Log-Normal distribution function was found to provide the best fit in general (an example fit is presented in Figure 2). The parameters required in this distribution are the mean and standard deviation. Least squares regression analysis on the means for each interval of P, provided continuous functions of P for $\bar{C}_{Hm}$ and $\bar{C}_{Lm}$. The values of the standard deviations of C_{Hm} and C_{Lm} can be obtained using the "average" coefficient of variation defined from those calculated for each P-interval. Table 2 contains values for the coefficients A, B, C and D obtained from a least squares fit of the equation $C_{Hm}, C_{Lm} = A + B\exp(-CP) + D/P^2$ to the interval means. The latter expression is similar to that used by Grace and Zee (1981).

Values for A, B, C and D resulting from fitting the same equation to the 95% exceedance values obtained for each P-interval, are also shown.

TABLE 2: Statistical properties of C_{Hm} and C_{Lm}.

Variable		$C_{Hm}, C_{Lm} = A + B\exp(-CP) + D/P^2$ for $P > 1$				CV
		A	B	C	D	
C_{Hm}	Mean	1.37	2.45	0.26	4.24	0.21
	5% value	1.89	3.36	0.26	4.47	
C_{Lm}	Mean	1.24	7.66	0.49	-1.47	0.23
	5% value	1.75	10.83	0.49	-2.07	

5% value = 95% exceedance using Log-Normal distribution.
Results based on data from: Grace and Zee (1981); Jacobsen and Bryndum (1984).

4.3 Development of models to calculate P_f

4.3.1 Analytical model

In order to reduce mathematical complexities in the analytical development of P_f, simplification of the failure function is desirable. This proves to be possible as follows:

For the relative narrow range of P values covered in a specific case the ratio between the mean values of C_{Lm} and C_{Hm} can be taken as constant. Also, the analysis is relatively insensitive to variation in the value of B, the reduction factor on the lift force. By assuming B to be constant, the failure function as expressed in equation (7) can now be rewritten as:

$$F = SW_S - F_{Hm}(cS + 1) \qquad ----(10)$$

where $c = BC_{Lm}/C_{Hm}$

If the kinematics model error factor E_u is introduced into equation (10), the final form of the failure function can be written as:

$$F = SW_S - KC_{Hm}(E_u u_{wm} + U_c)^2(cS + 1) \quad -- (11)$$

where $K = 0.5\rho D$

Following the criterion that $P_f = P_r(F < 0)$, the development of (11) in terms of the probability density function of the random variables S, C_{Hm}, E_u and u_{wm} results in:

$$P_f = \int_{F_{min}}^{0}\int\int\int\int \frac{f_S(q)\, f_{C_{Hm}}(t)\, f_{E_u}(w)\, f_{u_{wm}}\left[\sqrt{\frac{qW_S - r}{Kt(cq+1)}} - U_c\right]_{w}}{2Kt(cq+1)\sqrt{\frac{qW_S - r}{Kt(cq+1)}}} dw\, dt\, dq\, dr \quad (12)$$

where $f_X(X)$ is the probability density function of x evaluated at X,
F_{min} and F_{max} are the realistic lower and upper limits respectively of F,
and q, t, w and r are dummy variables in the integration.

The analytical development of $f_{uwm}(u_{wm})$ in terms of $f_H(H)$ and $f_T(T)$ is not possible with existing wave theories. However, if T is assumed constant the linear wave theory allows the development to be performed.

Closed form solutions of the expression in equation (12) is possible only in the most simple cases. A computer program was developed in this study which performs numerical integration to calculate P_f according to equation (12).

4.3.2 Monte Carlo simulation model

Whereas the analytical model prevents development of $f_{uwm}(u_{wm})$ in terms of $f_H(H)$ and $f_T(T)$, the Monte Carlo simulation technique provides a way to include both these variables. A computer program was developed in this study to perform this task using equation (8) and linear wave theory. This entails random generation of a large number of values for each variable according to its specified distribution function, calculation of the failure function for each set of variables and counting of the number of failures. P_f is then calculated as the ratio of the number of failures to the total number of variable sets evaluated.

In both the analytical model and Monte Carlo procedures the distribution function applicable to each variable can be selected by including the appropriate subroutine in the computer programs. The distribution parameters for C_{Hm} and C_{Lm} are determined by establishing the mean value and using the appropriate coefficient of variation in the Log-Normal distribution function. The mean value is calculated in each case through application of the point estimate method, developed by Rosenblueth (1975), to determine moments of the random functions C_{Hm}, $C_{Lm} = f(P) = f(u_m, a_m) = f(H,T,E_u,E_a)$.

5. APPLICATIONS

Calculations for two different cases were performed to serve as examples of the application of the methods described above.

The first example (Case I) comprises a 0.4 m diameter pipeline of which the lateral stability is to be provided by its own weight. The statistical properties assumed for the wave height, period and bottom frictional resistance are given in Table 3.

TABLE 3: Statistical properties of variables in Case I.

Variable	Distribution	Mean	CV	1% Value
H	Log-Normal	6 m	0.13	8 m
T	Normal	12 s	0.08	14 s
S	Normal	0.6	0.08	0.5

1% value = 99% exceedance according to distribution function chosen.

For the statistical properties of E_u, E_a, C_{Hm} and C_{Lm} the values in Tables 1 and 2 are accepted and the value of B was taken as 0.95. The probability of failure, P_f, was calculated at three waterdepths, d = 80 m, 90, m and 100 m for a range of values of pipeline weight, W_S. The results are presented in Figure 3. Also shown are the W_S values obtained in a deterministic analysis with global factor of safety, FS = 1.5, 2.0 and 2.5, for d = 80 m. The analysis was performed using the 1% values in Table 3 for H, T and S, and the 5% values for E_u, E_a, C_{Hm} and C_{Lm} given in Tables 1 and 2.

The second case (Case II) comprises a 0.6 m diameter pipeline of which the stability is to be provided by anchorage. Exactly the same properties for the variables as used in Case I were applied. The calculations of P_f,

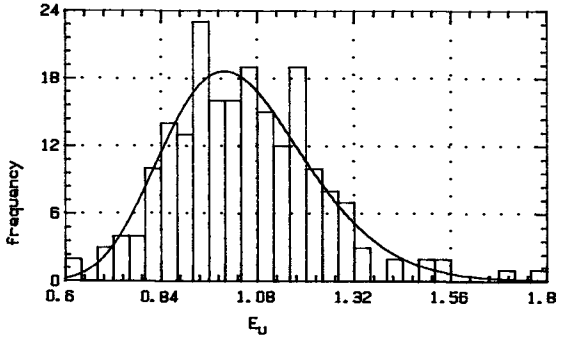

Figure 1: Frequency histogram of E_u with Log-Normal distribution function

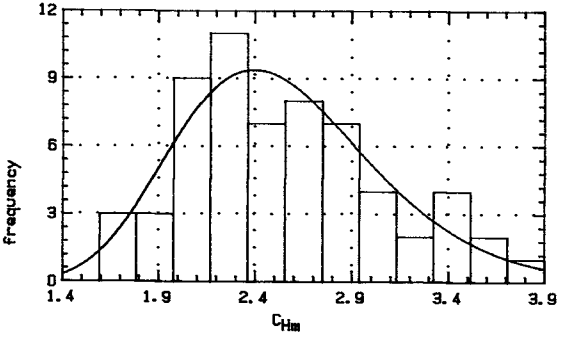

Figure 2: Frequency histogram of C_{Hm} for $3 < P < 4$, with Log Normal distribution function

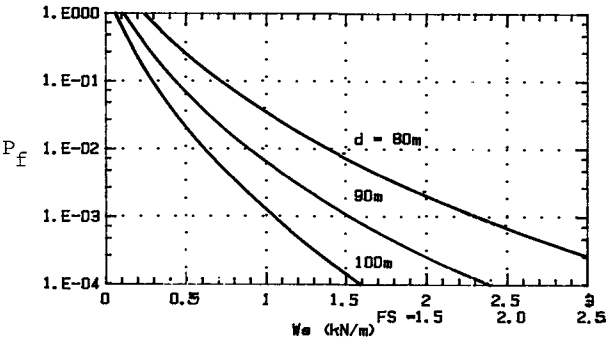

Figure 3: P_f vs W_S for Case I (FS shown for d = 80 m)

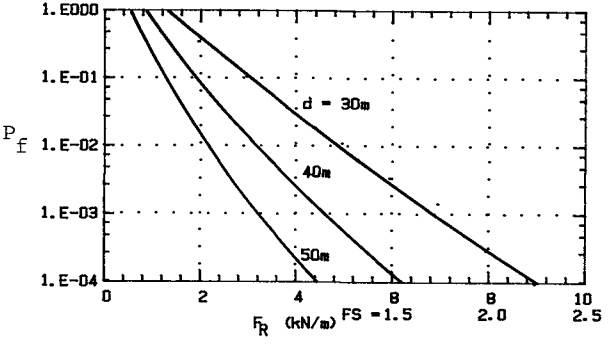

Figure 4: P_f vs F_R for Case II (FS shown for d = 30 m)

for a range of F_R values (F_R = capacity of anchorage), were performed at waterdepth, d = 30 m, 40 m and 50 m. The results are shown in Figure 4. Values for F_R calculated in a deterministic analysis, using the same variable values as in Case I, are also shown for FS = 1.5, 2.0 and 2.5, at d = 30 m.

The almost logarithmic increase in safety, with linear increase in pipeline weight or anchorage capacity, is clearly indicated by the results of the above calculations. In order to utilize these results in the stability design, the important question is that of which P_f value to accept. Meaning can, however, only be attached to such a value in terms of the concept "consequence of failure" incorporated in a risk analysis. Of more immediate practical importance is the evaluation of relative safety between different design options or along a pipeline route, using results such as provided in the examples presented above.

6. CONCLUSIONS

Based on the analyses performed and results obtained in this study the following conclusions can be drawn:

i) The traditional deterministic analysis of ocean pipeline stability involves several uncertainties which are difficult to represent realistically with safety factors alone. It is possible to represent these uncertainties with random variables for which statistical properties can be obtained.

ii) The incorporation of all the random variables representing uncertainties, in terms of their probability density functions, in the probabilistic procedure presented here, provides a more realistic measure of safety than is possible with the application of a safety factor alone.

7. ACKNOWLEDGEMENTS

The authors wish to thank Prof Robert A Grace from the University of Hawaii in Honolulu, and Hydraulics Research in Wallingford, England for making available data from seperate ocean tests on pipelines. Also, valuable advice on the study leading to this paper and comments from Prof Dimitri A Grivas from the Rensselaer Polytechnic Institute in Troy, New York, are sincerely appreciated.

CHAPTER 140

Beachwalls for Beach Erosion Protection

Ralph M. Hayashi, P.E.*
Member, American Society of Civil Engineers

Introduction

Many shoreline property owners, in an effort to protect the beaches from erosion, have constructed sea walls. In many situations, these sea walls have caused an increase in beach erosion forcing, by "domino effect", adjoining properties to construct sea walls to protect their shoreline. The construction of a sea wall often causes erosion on the adjacent property. Unfortunately, more often than not, where beaches once existed, the construction of sea walls in addition to causing beach erosion to adjacent property has caused the disappearance of the beaches.

Because of the concern for the eroding beaches and the proliferation of sea walls, the design of a "beachwall" was proposed over four years ago by the author. Several of these beachwalls have been constructed, and the beaches fronting these structures have thus far been preserved or restored.

The design of a beachwall emulates nature's construction of a typical beach profile terminating with a sand dune or berm (figure 1). The design of the beachwall

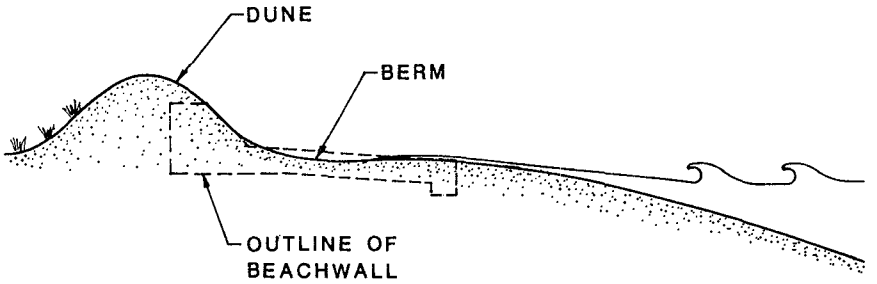

Figure 1. Typical Beach

*Vice-President, M & E (Metcalf & Eddy) Pacific, Inc., 1001 Bishop Street, Suite 500, Honolulu, Hawaii 96813

accommodates the energy forces of waves, minimizes wave rebound and scouring, and allows the deposition of sand, thus encouraging beach build up. The design of the beachwall addresses the problem of erosion at the toe of seawalls.

Protection of Beach Property

In the effort to protect beach property from existing or potential failures, sea walls with vertical or nearly vertical wall faces are often constructed along the property lines. By a "domino effect", property owners adjacent to such sea walls are sometimes forced to construct sea walls for protection of their property. Often, one sea wall causes the construction of another sea wall, which causes the construction of yet another, and so forth.

In many cases, because of the wave energy interaction with sea walls, there is erosion at the toe of the wall ultimately leading to wall failure. Additionally, the wave energy interaction with these walls will not allow beach build up and causes the disappearance of the beach. Thus, although the shoreline and property are saved and preserved by the wall, the beach is lost.

Over four years ago, the author felt a better approach to the then present concept of "protect the shoreline property in spite of losing the beach" would be to "first preserve the beach and in doing so protect the shoreline property". With this in mind, the beachwall design was developed.

Beachwall Design

The design of a beachwall begins with the selection of a design wave and design water level or wave run up as the controlling parameters for the wall design height. Other factors to consider in determining the wall height are the amount of damages that might occur from overtopping of the structure, the littoral drift and amount of sand in suspension in the water, and determination of optimum beachwall slopes, along with seasonal variations of the shoreline and offshore processes.

A practical method for designing the height of a beachwall is to observe wave run up during a high wave action or storm episode. The design high water level may be determined by noting the debris line after the high wave episode. Once the high water level has been determined, a freeboard height is to be selected. The freeboard height is determined to eliminate or minimize overtopping of the structure during extraordinary high wave action, with consideration to property damages that may be suffered by overtopping of the beachwall.

The face of a beachwall (figure 2) is composed of two sections of different slopes. The first section allows for wave run up, and experiences have shown that a slope of twenty percent (20%), 1:5, is satisfactory. The optimum slope for the run up section of the beachwall may be determined by using the slope of the sand existing in the vicinity where the beachwall is to be constructed. The length of the run up section is a function of a) the amount of wave run up (wave energy) to be accommodated by this section of the beachwall, and b) the amount of area available in which the beachwall can be constructed.

The second section is the freeboard portion of the beachwall. Experiences show that this section can have a slope of 1:1 or even steeper as its function, in addition to providing protection, is to eliminate or minimize overtopping. This section must also take care of the wave energy that is not accommodated by the run up section of the beachwall. Experiences show that the wave run up section of the beachwall can be about ten to twelve feet in length. Thus, any wave run up in excess of ten to twelve feet will have to be accommodated by the freeboard section. Of course, the length of the run up section is a function of the wave design height and will vary from one locale to another.

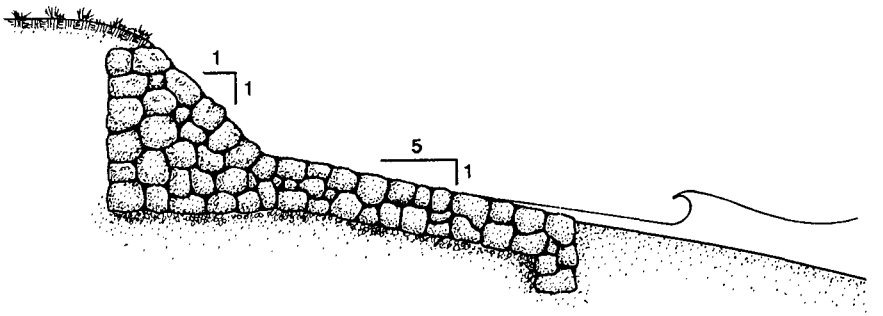

Figure 2. Beachwall

Setting of the beachwall, elevation wise, requires knowing tide levels of the area. Usually historical records of the elevations of high and low tides are available through government sources. In absence of such records, measurements should perhaps be taken through at least one year of seasonal shoreline water level variations. The elevation of the toe of the beachwall is set at or below low water elevation to make certain that

toe erosion will not occur. This elevation, along with the beachwall design accommodating the energy forces of waves, eliminates or minimizes wave rebound and scour thus addressing the problem of toe erosion of the structure.

Wave Energy on Structures

Normally beaches cannot form or reform because of the lack of suspended sand in the water or erosive velocity of the waves. This condition occurs when, following a high wave episode, sand that has been eroded from the beach is, displaced far off shore, trapped behind some reef or seaweed or both, or not allowed to be deposited because of successive high wave episodes. These conditions, especially when successive high wave episodes occur, often lead to the construction of sea walls.

Observations of vertical or nearly vertically faced sea walls and other similar types of structures show that beaches fronting such sea walls often erodes and do not return. The sand beach erodes or cannot form because of the wave forces. This erosion, often noted at the seaward footing of the wall, leads ultimately to wall failure.

When waves approach the shore, most of its energy is in the form of a velocity gradient. If there is sand off shore, the wave may be carrying sand in suspension. When the wave runs up the shore of a beach, its velocity begins to diminish due to slope of the beach and also friction with the shoreline. As the wave's velocity approaches zero, sand held in suspension will drop out because of gravity. This condition causes sandy beaches to form, or in the case of existing beaches, replenishes sand to the beach.

When waves approach a hard structure such as a seawall, it's velocity upon impact with the seawall is directed upward and downward about parallel with the face of the wall. The portion of the wave energy that is directed upward is usually visible as sea spray. The downward portion of the wave energy, often unseen, causes erosion at the base of the seawall. Because of this downward energy force, any sand or loose material at the base of such structures will eventually erode and wash away. This oftentimes leads to structural failure, and also causes the loss of the beach that may have once fronted the structure (figure 3).

Wave Energy on Beachwalls

The design of a beachwall emulates nature's construction of a typical beach profile which is composed of a run up slope section (beach) and terminating with the freeboard section (sand dune). The beachwall by design offers little, if any, wave reflection surfaces and rebound

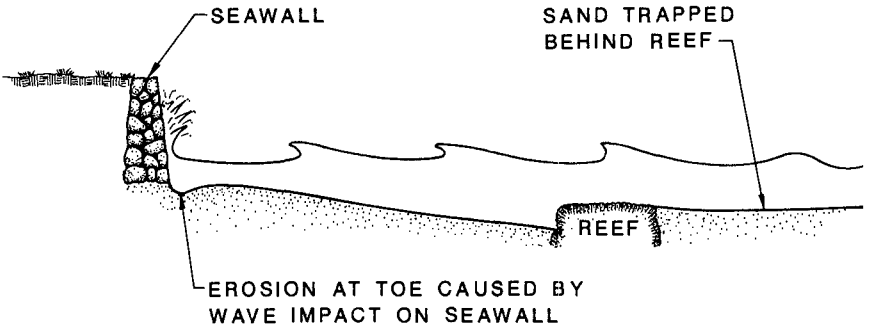

Figure 3. Loss of Beaches

of wave forces. The design effectively emulates a naturally occurring shoreline process. As the approaching wave flows up the run up face of the beachwall, the velocity gradient of the wave diminishes because of friction and slope, similar to the wave run up on a beach. As the velocity gradient approaches zero, sand held in suspension will settle out because of gravity and will be deposited on the beachwall. This action allows sand to accumulate and encourages the build up of a beach in a method similar to that which naturally occurs on sand beaches.

Summary

While it may sometimes be important to protect the shoreline and property from erosion due to wave action, it is equally if not more important to protect the shoreline against the loss of beaches. The task of saving property from erosion is simpler than the task of saving beaches and encouraging the formation of beaches. When the shorelines need to be protected, site conditions both on-shore and off-shore must be assessed before designs and construction of structures are undertaken. Poorly designed and improperly constructed erosion protection devices are oftentimes worse than doing nothing.

There are situations in which erosion control devices such as seawalls, revetments, groins and other hard structural techniques are required. However, erosion control should, whenever possible, begin by considering and utilizing natural shoreline defenses such as encouraging the growth of vegetation. If this is not possible or practical, then softer techniques such as beach fills or perhaps devices such as offshore sandbars should be considered.

Experiences over a three year period have indicated that a beachwall may be considered a soft device. While the beachwall is a "hard" structure, it behaves as a "soft" device by allowing the build up of sand. The beachwall shows promise in preserving and restoring beaches. Keep in mind however, that this beachwall may not necessarily be successful in all applications of preventing beach erosion or encouraging beach restoration.

CHAPTER 141

Studies on fixed rectangular surface barrier against short waves

CHING-HER HWANG* FREDERICK, L.W. TANG**

1. INTRODUCTION

In short waves, the particle motion in deeper region are to be negligible. For rigid vertical breakwaters built in considerable deep water, the lower part of vertical wall does not play the vital role of wave defending. It can be replaced by a frame to support the surface barrier which bears the wave force, and remain vacancy of the lower part of breakwater. Hence the theoretical and experimental characteristics of wave transmission and spectra alternation are investigated respectively here for this kind of the fixed, rigid, rectangular surface barrier in order to obtain an economic section and verify its capable relative depth as the design basis of deep port breakwater.

2. THEORITICAL CONSIDERATIONS

The theoritical considerations in this study are on the basis of the concept of the surface horizontal plate velocity potential theory derived by Dr. IJIMA and extended to this kind of rigid, rectangular surface barrier. Its coordinate scheme is shown as figure 1.

The flow in the fluid region about the breakwater is assumed to be irrotational, the fluid is incompressible and wave of small amplitude. These assumptions imply the existence of a velocity potential $\bar{\Phi}(x,z;t)$

$$\bar{\Phi}(x,z;t) = \phi(x,z) \exp(i\sigma t) \quad \text{.....(1)}$$

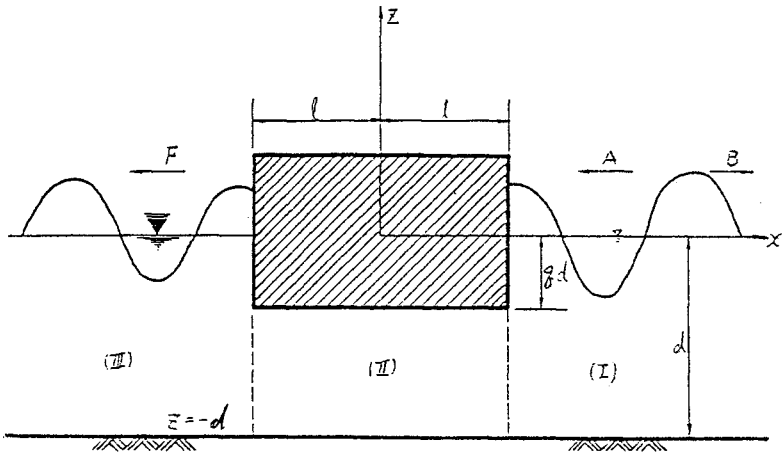

Fig.1 Coordinate system and notation

Table-1 Experimental conditions

	SINUSOIDAL		RANDOM	
RUN	T	H	$T_{1/3}$	$H_{1/3}$
R 1.	0.87	6.00	0.89	5.50
R 2.	1.03	6.24	1.02	5.58
R 3.	1.02	12.40	1.06	9.12
R 4.	1.24	6.19	1.23	6.09
R 5.	1.24	12.36	1.23	12.29
R 6.	1.47	6.38	1.48	6.26
R 7.	1.48	12.81	1.44	12.84
R 8.	1.93	6.63	1.85	5.95
R 9.	1.93	11.75	1.97	11.68

which satisfies the Laplace equation for a scale function $\phi(x,z)$

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial z^2} = 0 \quad \text{.....(2)}$$

In this equation, x is the horizontal coordinate axies, measured positive to the right, z is the vertical coordinate axies,measured positive up from the still water level, and t is the time variable.

A solution is sought for $\phi(x,z)$ which satisfies the fluid equations of motions and the boundary conditions for the fluid and the fixed solid surface breakwater as following
the surface boundary condition

$$\frac{\partial\phi}{\partial z} = \frac{\sigma^2\phi}{g} \quad ; \quad z=0 \quad \text{.....(3)}$$

the rigid body boundary condition at bottom z=-d , -qd

$$\frac{\partial\phi}{\partial z} = 0 \quad ; \quad z = -d\ ,\ -qd \quad \text{.....(4)}$$

In addition to the above boundary conditions, the velocity potential at arbitrary assigned fictitious vertical boundaries on either side of the breakwater must satisfy the radiation conditions, which states that the velocity potential at the boundaries must match the velocity potential for the incident and outgoing waves. Then region I, II and III, the velocity potential are expressed as, respectively

$$\phi_I(x,z)=\left(Ae^{ik(x-\ell)} + Be^{-ik(x-\ell)}\right)\frac{\cosh k(z+d)}{\cosh kd} + \sum_{n=1}^{\infty} C_n e^{-k_n(x-\ell)} \frac{\cos k_n(z+d)}{\cos k_n d} \quad \text{.....(5)}$$

$$\phi_{II}(x,z) = \sum_{r=0}^{\infty} \left(Dr \frac{\cosh \frac{r\pi x}{d-qd}}{\cosh \frac{r\pi\ell}{d-qd}} + Er \frac{\sinh \frac{r\pi x}{d-qd}}{\cosh \frac{r\pi\ell}{d-qd}}\right) \cos \frac{r\pi(z+qd)}{d-qd} \quad \text{...(6)}$$

$$\phi_{III}(x,z) = Fe^{ik(x+\ell)} \frac{\cosh k(z+d)}{\cosh kd} + \sum_{n=1}^{\infty} G_n e^{k_n(x+\ell)} \frac{\cos k_n(z+d)}{\cos k_n d} \quad \text{..... (7)}$$

The coefficients A,B and F are incident, reflective and transmitted wave height respectively. Cn Gn Dr and Er are the unde-

termined coefficients. The symbols k and k_n represent the wave number in which.

$$\frac{\sigma^2 d}{g} = kd \tanh kd = -k_n d \tan k_n d \qquad (n= 1,2,3....)..(8)$$

Then the continuity of mass and energy flux, or similarly the continuation of the velocity and pressure at the fluid-breakwater media interface was considered.

at $x = \ell$

$$\phi_I = \phi_{II}$$

$$\frac{\partial \phi_I}{\partial x} = \frac{\partial \phi_{II}}{\partial x} \quad ; \quad -qd > z > -d \quad .....(9)$$

$$= 0 \quad ; \quad 0 > z > -qd$$

at $x = -\ell$

$$\phi_{II} = \phi_{III}$$

$$\frac{\partial \phi_{II}}{\partial x} = \frac{\partial \phi_{III}}{\partial x} \quad ; \quad -qd > z > -d \quad .....(10)$$

$$= 0 \quad ; \quad 0 > z > -qd$$

we obtain

$$B = \frac{i}{2} \sum_{r=0}^{\infty} \left[I_{or}\, Er + Dr\, I_{or} \tanh \frac{r\pi k\ell}{\bar{\lambda}_o} \right] + A \quad .....(11)$$

$$F = -\frac{i}{2} \sum_{r=0}^{\infty} \left[I_{or}\, Er - Dr\, I_{or} \tanh \frac{r\pi k\ell}{\bar{\lambda}_o} \right] \quad .....(12)$$

$$Cn = -\frac{i}{2} \sum_{r=0}^{\infty} \left[Dr\, I_{nr} \tanh \frac{r\pi k\ell}{\bar{\lambda}_o} + Er\, I_{nr} \right] \quad .....(13)$$

$$Gn = -\frac{i}{2} \sum_{r=0}^{\infty} \left[Dr\, I_{nr} \tanh \frac{r\pi k\ell}{\bar{\lambda}_o} - Er\, I_{nr} \right] \quad .....(14)$$

$$\left.\begin{aligned} Do &= \frac{1}{2} \left[\sum_{n=1}^{\infty} (Cn + Gn)\, R_{nr} + (A+B+F)\, R_{or} \right] \\ Dr &= \sum_{n=1}^{\infty} (Cn + Gn)\, R_{nr} + (A+B+F) R_{or} \end{aligned}\right\} \quad .....(15)$$

$$Er \tanh \frac{r\pi k\ell}{\bar{\lambda}_o} = (A+B-F) R_{or} + \sum_{n=1}^{\infty} (Cn-Gn)\, R_{nr} \quad .....(16)$$

Where

$$R_{nr} = \frac{\sin \bar{\lambda}_n}{\cos \lambda_n} \cdot \frac{1}{\bar{\lambda}_n \left[1-\left(\frac{r\pi}{\bar{\lambda}_n}\right)^2\right]}, \quad \lambda_n = k_n d, \quad \bar{\lambda}_n = k_n(d-qd)$$

$$R_{or} = \frac{\sinh \bar{\lambda}_o}{\cosh \lambda_o} \cdot \frac{1}{\bar{\lambda}_o \left[1+\left(\frac{r\pi}{\bar{\lambda}_o}\right)^2\right]}, \quad \lambda_o = kd, \quad \bar{\lambda}_o = k(d-qd)$$

$$I_{or} = \frac{2\sin\bar{\lambda}_n\cos\lambda_n}{Nn\,\lambda_n} \cdot \frac{r\pi/\bar{\lambda}_n}{[1-(r\pi/\bar{\lambda}_n)^2]}, Nn = \frac{1}{2}\left(1+\frac{\sin 2K_{nd}}{2K_{nd}}\right)$$

$$I_{or} = \frac{2\sinh\bar{\lambda}_o\cosh\lambda_o}{No\,\lambda_o} \cdot \frac{r\pi/\bar{\lambda}_o}{\left[1+\frac{r\pi}{\bar{\lambda}_o}\right]^2}, \quad N_o = \frac{1}{2}\left(1+\frac{\sinh 2kd}{2kd}\right) \ldots(17)$$

After substituting eq (11) ~ eq (14) into eq (15)~(16), we get

$$Dr + \sum_{n=1}^{\infty}\left[\sum_{r=0}^{\infty}\left(Dr\, I_{nr}\tanh\frac{r\pi k\ell}{\bar{\lambda}_o}\right)\right]R_{nr} - i\left[\sum_{r=o}^{\infty}\left(Dr\, I_{or}\tanh\frac{r\pi k\ell}{\lambda_o}\right)\right] R_{or} = 2R_{or} \quad \ldots\ldots(18)$$

$$\left(\tanh\frac{r\pi k\ell}{\bar{\lambda}_o}\right) Er + \sum_{n=1}^{\infty}\left[\sum_{r=0}^{\infty}\left(Er\, I_{nr}\right)\right] R_{nr} - i\left[\sum_{r=0}^{\infty}\left(I_{or}\, Er\right)\right]R_{or} = 2R_{or} \quad \ldots\ldots(19)$$

Then, the water level variations at Region I, the up-lift dynamic pressure distribution of barrier bottom at Region II and the transmitted coefficient at Region III are found respectively

. Water level variations at Region I

$$\eta/A = -\frac{i\sigma}{g}\left\{e^{i[k(x-\ell)+\sigma t]} + (B/A)\, e^{-i[k(x-\ell)-\sigma t]} + \sum_{n=1}^{\infty}(Cn/A)e^{-[K_n(x-\ell)-i\sigma t]}\right\} \quad \ldots\ldots(20)$$

. Up - lift dynamic pressure of barrier bottom at Region II

$$\frac{\rho}{gA} = -\frac{i\sigma}{g}\left\{\sum_{r=o}^{\infty}\left\{\left[(Dr/A)\frac{\cosh\frac{r\pi x}{d-gd}}{\cosh\frac{r\pi\ell}{d-gd}} + (Er/A)\frac{\sinh\frac{r\pi x}{d-gd}}{\cosh\frac{r\pi\ell}{d-gd}}\right]\right.\right.$$

$$\left.\left.\cos\frac{r\pi(z+gd)}{d-gd}\right\}\right\} e^{i\sigma t} \quad \ldots\ldots(21)$$

. Transmitted coefficient of barrier at Region III

$$K_t = |F/A| \quad \ldots\ldots(22)$$

3. EXPERIMENTAL TESTS

Experiments of wave spectra alternation characteristics of this fixed, rigid, rectangular barrier were investigated also in a

$100^m \times 2^m \times 1.5^m$ wind wave flume in Institute of Harbor and Marine Technology. Its arrangement was shown in Figure 2 .

Then, the different immerged depth q ratioes and relative width B/L of barrier were used to investigate its characteristics of the spectra alternation under different relative water depth d/L. Various kind of wave conditions were also carried out in this study as shown in Table 1.

4. RESULTS AND DISCUSSIONS

4-1 Analytical solutions of velocity potential theory

Analytical solution of velocity potential theory were shown in figure 3 to figure 7. Figures 3(a) (b) (c) represent respectively the curves of water level variations before the barrier at region I under relative immerged water depth q=0.3 and different relative width B/L = 0.004 , 0.08 and 0.2 etc. Results indicate the more larger relative water depth d/L and relative width B/L are, the more closed sine curves the water level profiles are. For short waves (ie d/L = 0.5), the minimum η/A ratio value is equal to 1.25 when both q and B/L are equal to 0.3 and 0.2 respectively, and this value is increasing with the relative water depth d/L.

Figure 4~6 show the analytical solutions of the up-lift dynamic pressure distribution at the bottom of barrier at Region II under different relative water depth and relative width. Results indicate that the dynamic pressure distribution has the relationship with B/L , d/L and q etc. respectively. In general, the larger the relative width is, the larger up-lift dynamic pressure difference between both side bottom of the surface barrier is. And its distribution at the bottom of the barrier more uniform if the q value is larger. Moreover, up-lift pressure decreased as the d/L decreased and tend to a horizontal distribution when the relative water depth is equal to 0.2-0.3. For example, as shown in figure 6, the dynamic pressure variations at both sides of the surface barrier bottom are obviously increased with the relative width, comparing with the Figure 4 and 5, under different relative immerged water depth q values. This means that its slope is more

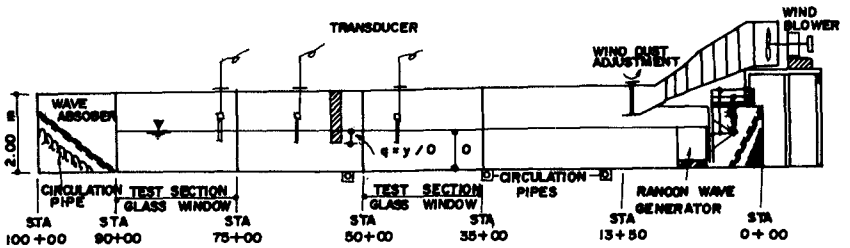

Fig.2 General arrangement

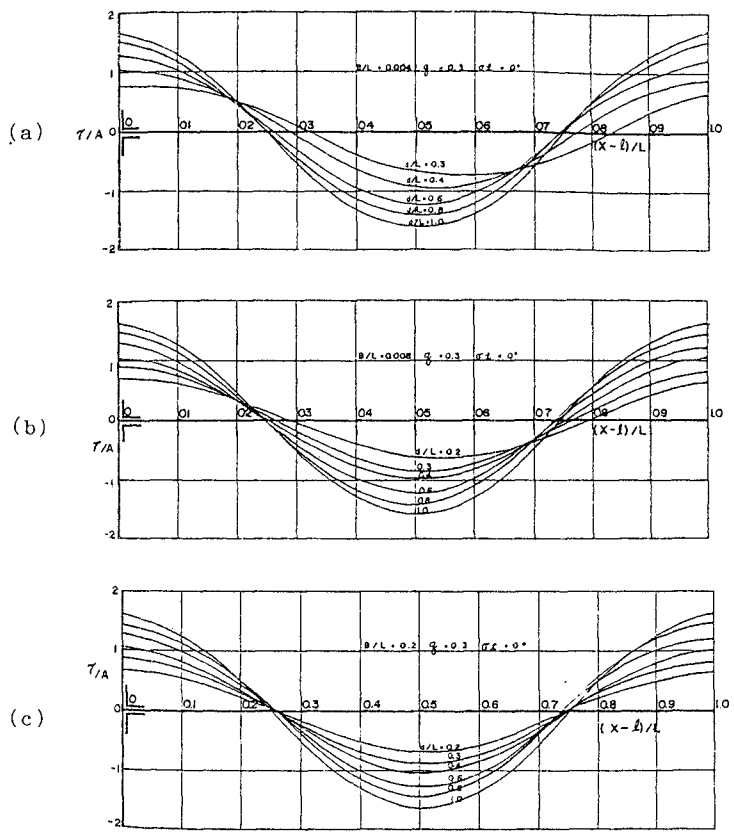

Fig.3 Curves of water level variations before the barrier

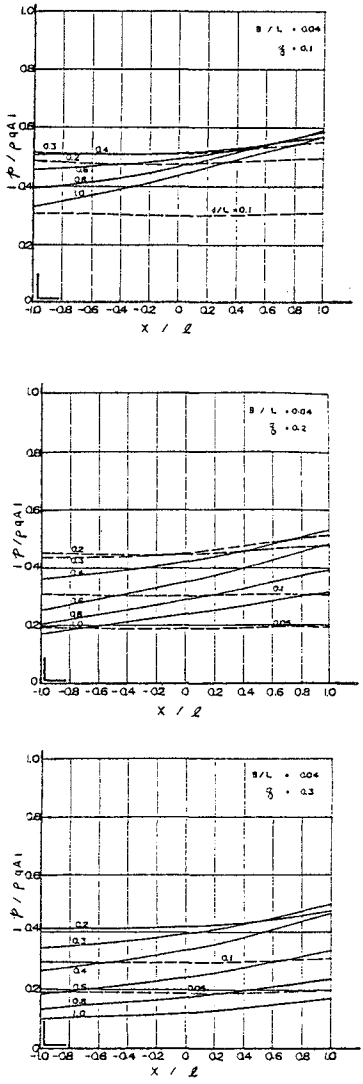

Fig.4 Up-lift dynamic pressure distribution at the bottom of barrier

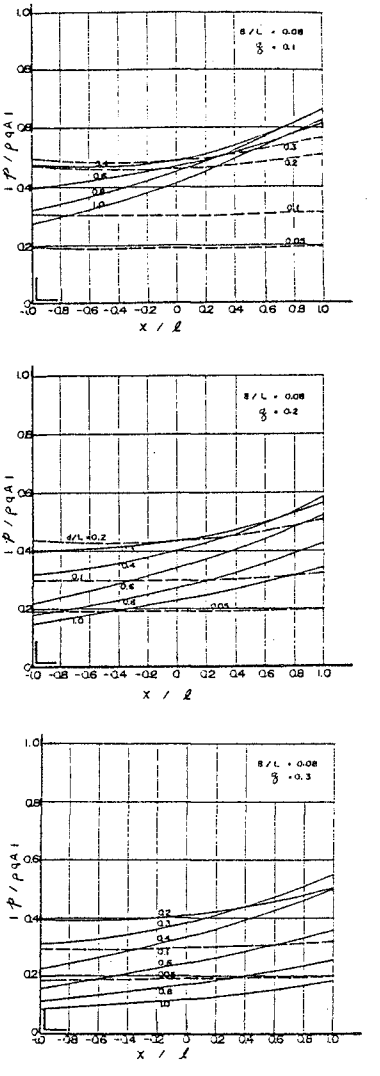

Fig.5 Up-lift dynamic pressure distribution at the bottom of barrier

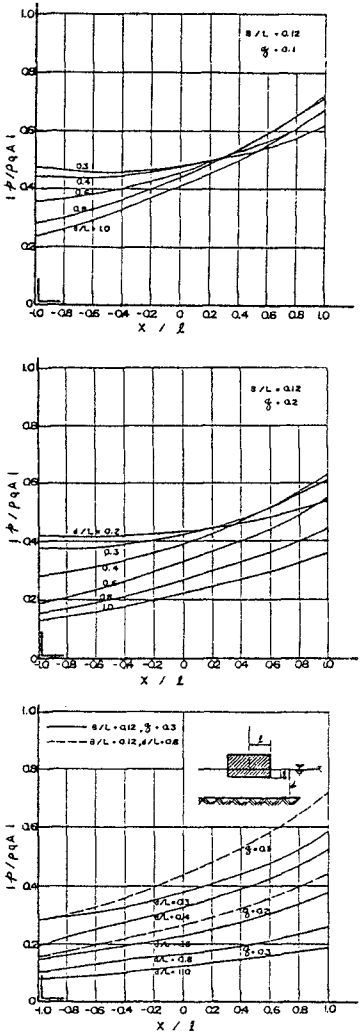

Fig.6 Up-lift dynamic pressure distribution at the bottom of barrier

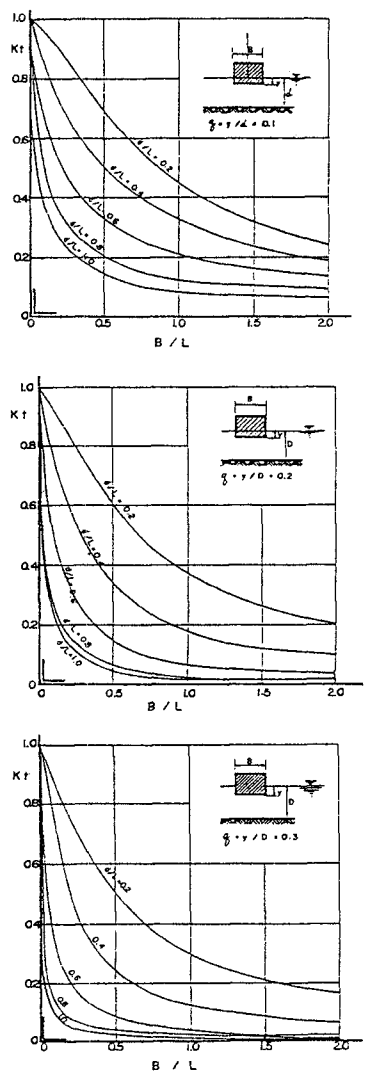

Fig.7 Relationship between K_t and B/L

steepen as the relative width of surface barrier increased.

Figure 7 are results of the analytical relationship between the transmitted coefficient K_t and relative width B/L under various relative water depth d/L at q=0.1,0.2 and 0.3 etc. respectively. Analytical results mean that we can expect to obtain an ideal wave stability behind the barrier when its relative width B/L is equal to 0.2~0.4 and the relative immerged depth q value is equal to 0.3 for the deep water waves i.e. short waves, assume the allowable transmitted coefficient criterion we adopted is equal to 0.2. Therefore, this dimension of barrier is an economic section in theoretical consideration for us to maintain an ideal wave stability at the basin , and can be used as the design section of deep water port breakwater.

4-2 EXPERIMENTAL RESULTS

In order to verify the capability of this type breakwater, laboratory experiments were also carried out under random waves in wind wave flume. Figure 8 and 9 are the results of energy spectrum curves of penestrated wave for various relative width and immerged water depth respectively. Figure 8 (a)~(d) are the experimental results for this breakwater under different immerged water depth q value and various relative water depth d/L. Experimental results show that the energy density peak value decreases above one order if q is equal and greater than 0.3, and relative water depth d/L is greater than 0.5 i.e. for short waves. Figure 9 (a)~(d) are the experimental results for this fixed rectangular surface barrier under different relative water depth d/L relative width B/L at immerged water depth q value is equal to 0.3. Results also indicate that the energy density peak value decreases above one order if relative width B/L is equal to 0.4 at q=0.3 for deep water waves. This means that we can expect again to obtain the same dimension of breakwater used as the section of the deep port breakwater from the experimental viewpoint.

5. CONCLUSIONS AND RECOMMENDATION

Summarize these results mentioned above, we can obtain some conclusions as following :

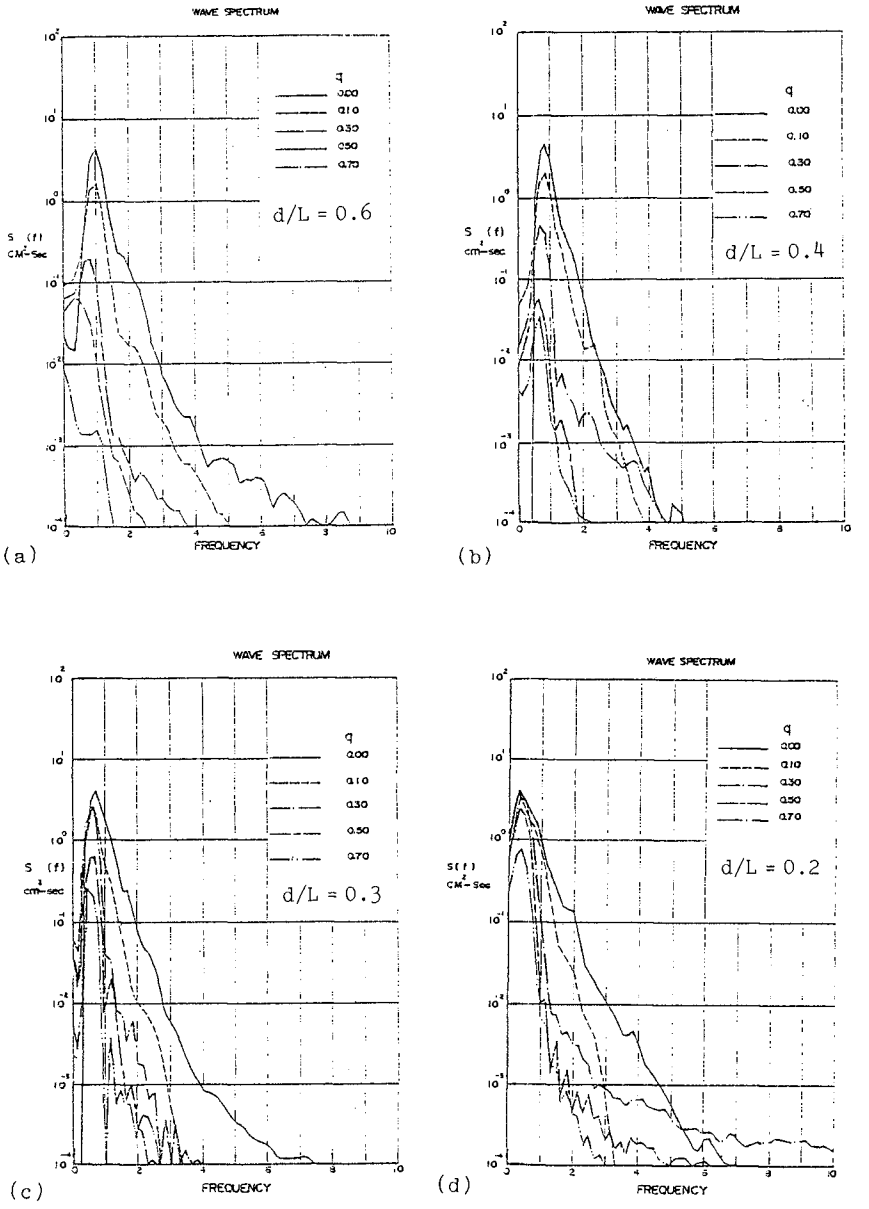

Fig.8 Energy spectrum curves of penetrated wave for various relative width (thin Breakwater)

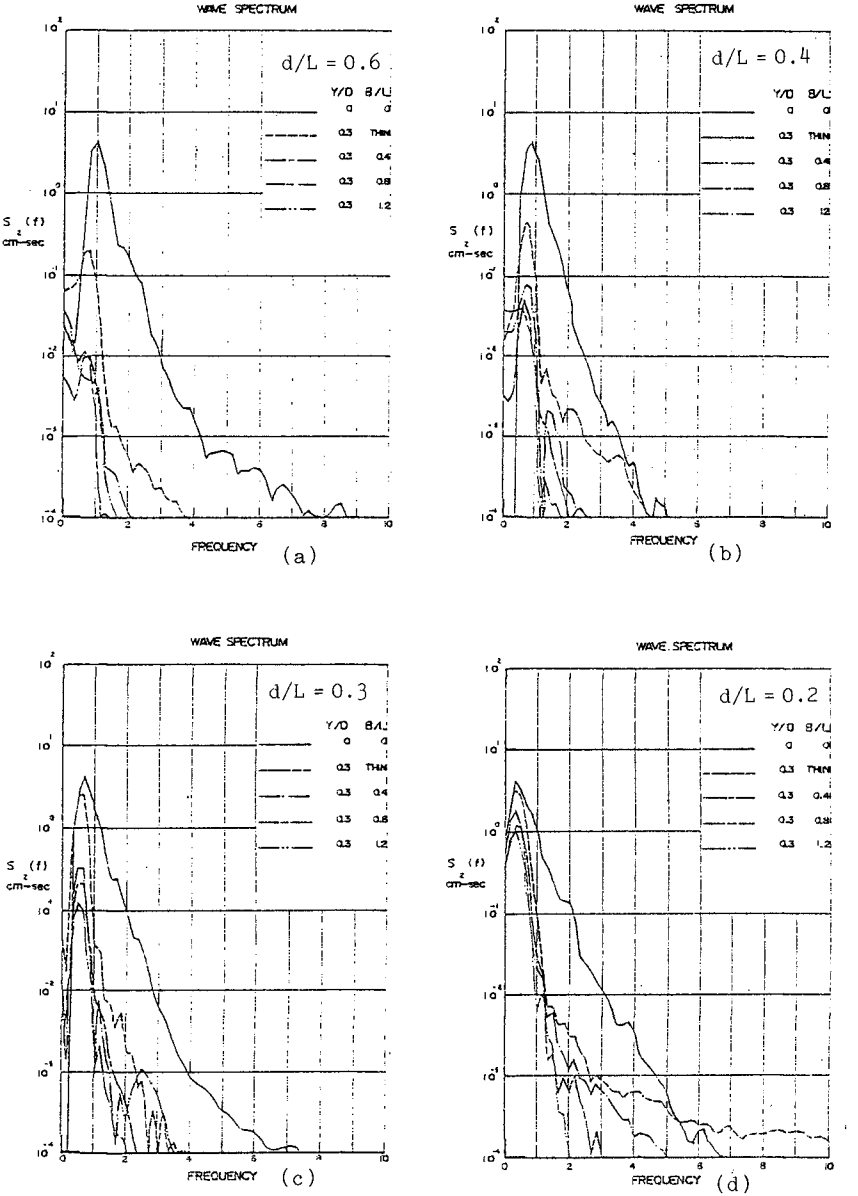

Fig.9 Energy spectrum curves of penetrated wave for various relative width (q = 0.3)

(1) Theoritical results indicate that the up-lift dynamic pressure distribution of barrier has the relationship with B/L, d/L and q etc. respectively. In general, the bigger the relative depth is, the larger the up-lift dynamic pressure difference between both side bottom of the surface barrier is. And its distribution at the bottom of the barrier is more uniform if the q values is larger. Moreover, up-lift pressure decreased as the d/L decreased and tend to a horizontal distribution when the relative depth is equal to 0.2∽0.3.

(2) K_t will decrease as q and d/L decreased for the same B/L value. It verifies that this barrier can defend effectively the short waves when q is equal to 0.3 and B/L is equal to 0.2 ∼ 0.4, and its K_t is less than 0.2.

(3) Energy spectrem curves of penestrated wave for various B/L and q of the surface barrier verify that the peak magnitude of energy spectrum would decrease predominantly above one order and filter many short wave components when the q and B/L of the surface barrier is equal to 0.3 and 0.4 respectively.

(4) This type of breakwater and its economic section mentioned above could be used as the design criterion of the outer breakwater of Yeh-Liu deep port, at the North of TAIWAN, in future if we can solve the engineering problem: "How to fix this kind of surface barrier in deep water region ? ".

6. ACKNOWLEDGEMENTS

The laboratory work in this study was carried out through the sincere cooperation of many people, and authers would like to thank all of them. In particular, I would like to express my appreciation to Mr. C.K. Chang, Deputy Director of IHMT, who affords all possible helps. Authers would also like to thank Miss Joanna Chang to type this manuscript.

CHAPTER 142

WAVE FORCES ON VERTICAL PILES CAUSED BY 2- AND 3-DIMENSIONAL BREAKING WAVES

Søren Peter Kjeldsen [1]
Alf Tørum [2]
Robert G. Dean [3]

ABSTRACT

The present study deals with analysis of results from a new experiment in which local wave forces on a vertical pile penetrating the free surface were measured, both in transient breaking waves and in 2- and 3-dimensional irregular seas, regular waves, and waves and uniform currents superposed. The performance of the entire experimental programme showed that extreme wave load intensities are associated with transient 2- or 3-dimensional breaking waves, of relatively short wave periods, and not with the highest waves in the simulated sea states. The total integrated in-line force and the total overturning moment caused by breaking waves exceeded the values measured in monochromatic regular waves by a factor of 3. Inception of wave breaking was caused by phase superposition, and occurred also for very low values of wave steepness s = 0.05.

1 INTRODUCTION

The study of breaking waves in deep waters was initiated in Norway after a quite large number of capsizings of cargo vessels and fishing trawlers, which had occurred over a few years. Kjeldsen & Myrhaug (1980) analysed field data from 22 gales, and found encounter probabilities for high and steep waves occurring in deep water conditions based on multivariable probability density functions. After this Kjeldsen (1982) developed a non-linear wave generation technique, based on sweep frequency modulation with the ability to produce breaking freak waves with a control of breaker type (spilling, bore, plunging) within a hydrodynamic laboratory. Application of such a technique produces violent plunging breakers at a specified position and time in a wave basin. The plunging breakers occur in deep water and repeat with great accuracy. Further the position of the plunging jet can be shifted horizontally according to rules for non-linear dispersion of transient wave trains. In addition the particle velocities within the crests of these transient plunging breakers in deep waters were measured. This was achieved with a newly developed wave-follower-system, consisting of a carriage with a high-speed cine camera and a current meter that followed one particular wave crest

[1], [2]: MARINTEK, Norwegian Marine Technology Research Institute A/S, P.O. Box 4125, N-7001 Trondheim, Norway.

until it finally became unstable and developed into a plunging jet, see Kjeldsen (1984a). The very large particle velocities measured in the upper part of the crests suggest that local wave forces in breaking waves close to the free surface should be much higher than predictions of wave forces obtained from application of Stokes' higher order wave theories. Wave forces measured on piles in the Mexican Gulf during Hurricane Carla, were analysed by Dean, Dalrymple and Hudspeth (1981), who found quite a reduction in measured wave forces close to the free surface in the crests of the waves. It was then found that theoretical predictions of wave force, based on higher order Stokes' theories, in general overestimate the local wave force in a local area close to the free surface. Therefore, in order to investigate the intensity of local wave forces very close to the free surface in breaking and non-breaking wave crests, an extensive experimental programme was performed in the large new Ocean Simulating Basin at MARINTEK, Trondheim, Norway. The problem we consider is the following: a vertical pile encounters wave crests, which can be 3-dimensional as Fig. 1 shows, or 2-dimensional swell. The wave crests considered here can be either breaking or non-breaking.

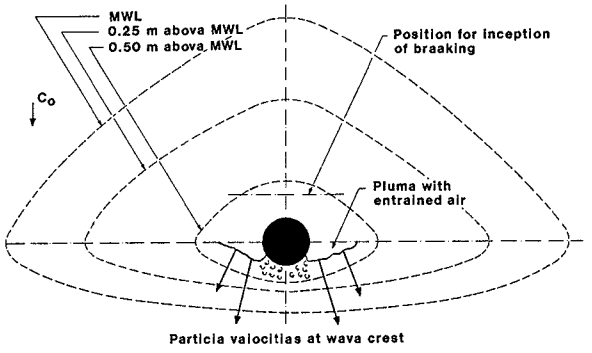

Fig. 1 Definition of problem. Contour lines of a 3-dimensional wave crest near the pile are shown. The wave crest has a very steep front and a less steep rear side. The position for inception of breaking can be controlled. The horizontal particle velocity vectors at the free surface of the upper part of the crest are shown. The ratio between the magnitudes of these vectors and linear phase velocity (shown in upper left corner) is nearly 3.

We focus on force measurements in the upper part of a breaking wave crest. Here the flow is not oscillatory, but it is an accelerating and decellerating flow where the horizontal particle velocity component maintains mainly the same direction. Therefore eddies released behind the pile will not be swept backwards and return in the following wave, as the case is in the fully submerged part of the pile.

Thus the separation points in this upper part of the wave crest will be shifted. In addition air entrainment takes place when the waves break. Thus Morison's equaiton is probably not the best force model to describe such a complicated situation. Emphasis should be given to the 3-dimensional character of the problem. Lift force components of considerable magnitude was found to occur. In the present study in-line forces are defined as force components acting in the main wind direction, which also is assumed to be the main direction for wave propagation in a simulated 3-dimensional sea. These are considered to be mainly drag forces. Lift forces or transverse forces are defined as force components acting perpendicular to the main wave direction.

2 EXPERIMENTAL PROGRAMME

In order to investigate the intensity of local wave forces very close to the free surface in wave crests, an extensive experimental programme was performed in the new Ocean Simulating Basin at MARINTEK, Trondheim, Norway. This basin has the following main dimensions: length - 80 m, width - 50 m. It is equipped with an adjustable bottom that permits water depths in the range 0.1 - 10.0 metres.

Experiments can be carried out with maximum wave heights close to 1.0 m and wave periods in the range 0.5 - 3.6 seconds. It is also possible to superpose waves upon uniform currents with logarithmic profiles. The present experiments were performed with a water depth of 3 metres, corresponding to deep water conditions.

A vertical pile with a diameter of 60 mm (a leg of a steel jacket platform in scale 1 : 25) was installed with 26 shear force transducers mainly located in the zone between the highest wave crest and the lowest wave trough. Each shear force transducer consisted of a 15 mm wide horizontal ring. Force measurements on each ring were obtained by strain gauges. In addition to local measurements of in-line and transverse forces on the pile, sea surface elevations, uniform currents and directional wave spectra were measured. An experimental programme was then performed containing the following test conditions:

SEA SIMULATION	Hydraulic Double Flap Wave Generator	Hydraulic Double Flap Wave Generator with Steady Uniform Current Superposed	Electric Multi Flap Wave Generator with 144 Elements
REGULAR 2-DIMENSIONAL WAVES	20	-	-
2-DIMENSIONAL IRREGULAR SEA WITH PIERSON-MOSKOWITZ SPECTRA	15	-	-
2-DIMENSIONAL TRANSIENT FREAK WAVES, PLUNGING BREAKERS	20	-	-
A UNIFORM CURRENT WITH 2-DIMENSIONAL IRREGULAR SEAS SUPERPOSED (PM-SPECTRA)	-	12	-
3-DIMENSIONAL IRREGULAR SEAS WITH PIERSON-MOSKOWITZ AND JONSWAP SPECTRA	-	-	10
3-DIMENSIONAL SHORT CRESTED BREAKING FREAK WAVES, SPILLING BREAKERS			10
			Total : 87

Fig. 2 shows a vertical section of the pile with the distribution of shear force transducers. The right hand side of this figure shows flow patterns at various horizontal planes behind the pile as functions of Reynolds and Keulegan-Carpenter numbers. In the present investigation Reynolds numbers in a range of 0 - $2.9 \cdot 10^5$ and Keulegan-Carpenter number in a range of 0 - 135 were achieved. Data acquisition took place on 63 channels simultaneously with a sampling frequency of 20 Hz. Data acquisition in the Ocean Basin took place for 5 minutes in each experiment, and for some experiments with irregular seas, data acquisition was extended to 20 minutes.

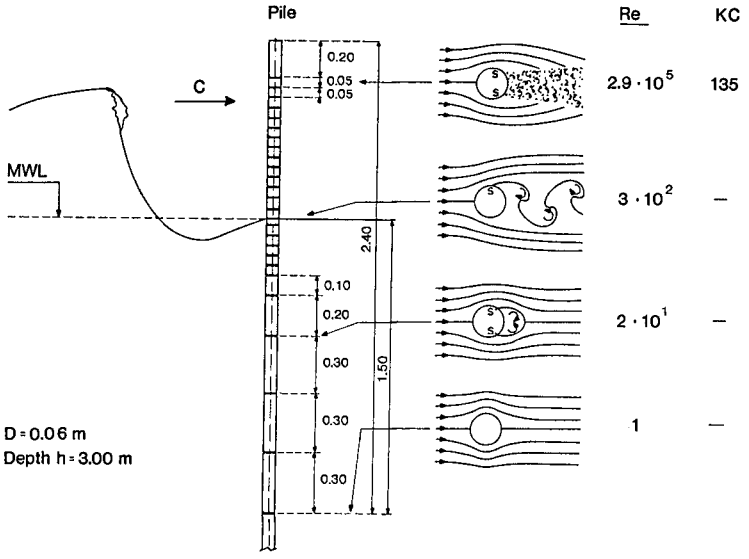

Fig. 2 Left: Experimental arrangement.
Right: Flow patterns and eddy development in horizontal planes behind the pile at various elevations, shown as functions of Reynolds and Keulegan-Carpenter numbers.

3 RESULTS

The main result from the entire programme was that the 2-dimensional breaking waves occurring in deep waters as plunging breakers gave far the largest wave forces. These particular waves were generated as a superposition of 43 frequencies contained in a wave group. By means of a non-linear amplitude-dependent sweep frequency modulation, the breaking waves were obtained right on the structure. Fig. 3 shows an example of the measured surface elevation of such a wave. The wave shown in this particular example had a zero-downcross wave height H_{zd} = 0.504 m, a zero-downcross wave period T_{zd} = 1.385 sec, a horizontal asymmetry factor μ = 0.879 and a crest front steepness ϵ = 0.539. (For definition of μ and ϵ, see Kjeldsen & Myrhaug (1980).)

Fig. 3 also shows the measured in-line and transverse force components in this kind of wave. The lift force component is close to 20 % of the measured drag component and should be taken into consideration in design. The particular shape of the lift force component shown in Fig. 3, indicates that eddy shedding takes place.

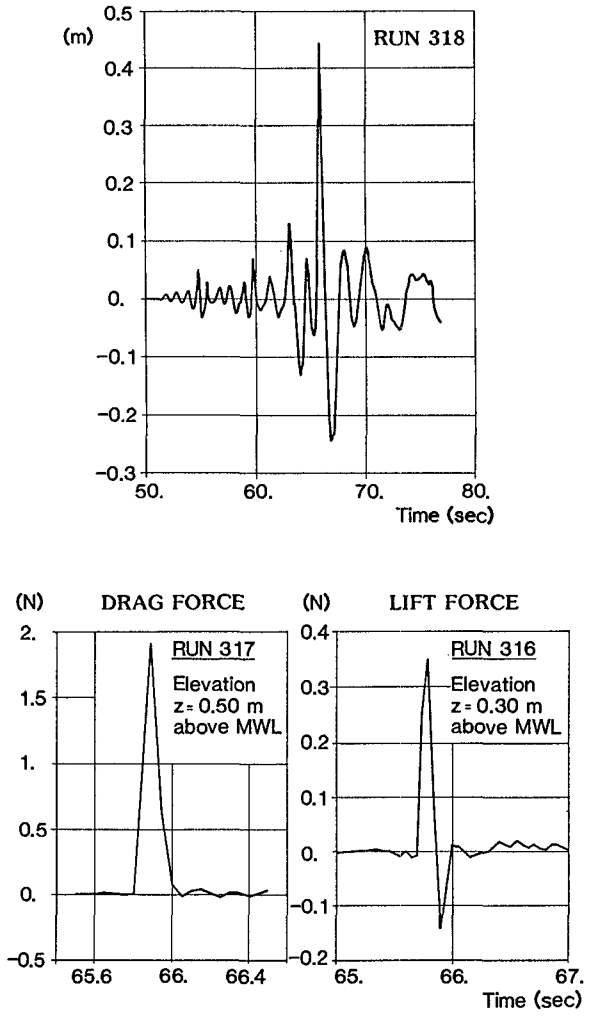

Fig. 3 Above: Surface elevation of a 2-dimensional transient freak wave breaking as a plunging breaker. Below: Drag- and lift force components measured in such waves above mean water level (MWL).

Fig. 4 shows a remarkable result. In this particular example a wave group consisting of 3 waves were obtained at the pile. The upper left corner in Fig. 4 shows the surface elevation of these waves. The first wave is small and unimportant. The second wave A is breaking violently as a plunging breaker. The third wave B is a regular wave very similar in shape to predictions made by Stokes 2-order wave theory. Wave B has a much longer wave period than wave A and we should thus expect that the associated wave kinematics and also the resulting drag force component are higher in wave B than in wave A. However, the measured drag force components shown in Fig. 4 clearly demonstrate that the transient wave A, breaking as a plunging breaker gives rise to much higher drag forces at all levels. This can be explained by the fact that the breaking wave is generated as a phase superposition of many individual waves, and thus contains much more wave energy in the crest, than the higher wave B. This is the case even when wave B has a longer zero-downcross wave period.

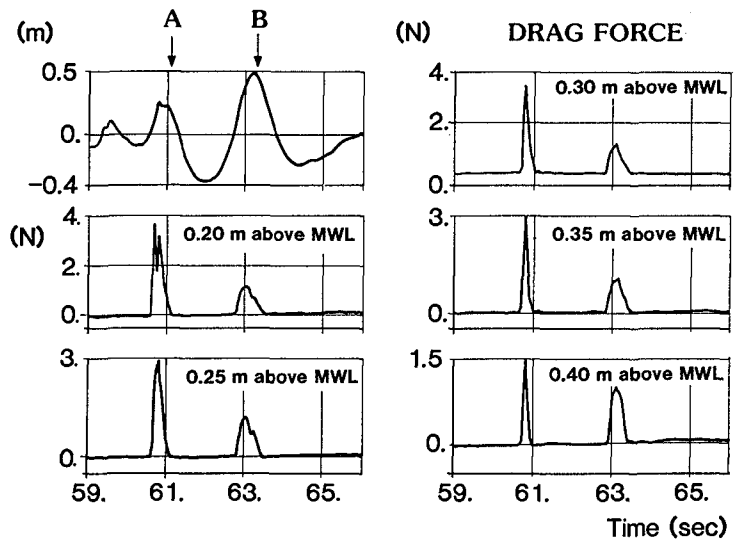

Fig. 4 Upper left: Surface elevation of wave group. Wave A is a plunging breaker. Wave B is a higher more regular wave with a longer wave period. Below and right: Drag force components measured for wave A and wave B above MWL.

Fig. 5 shows a comparison of the vertical profiles of maximum local instantaneous drag forces obtained in a plunging breaker and obtained in a test series with regular monochromatic waves which turned out to have profiles very close to those predicted by Stokes 2. order wave theory. We see in Fig. 5 that the plunging breaker has a maximum local wave force that is close to 5 times larger than the maximum local force obtained in the monochromatic wave.

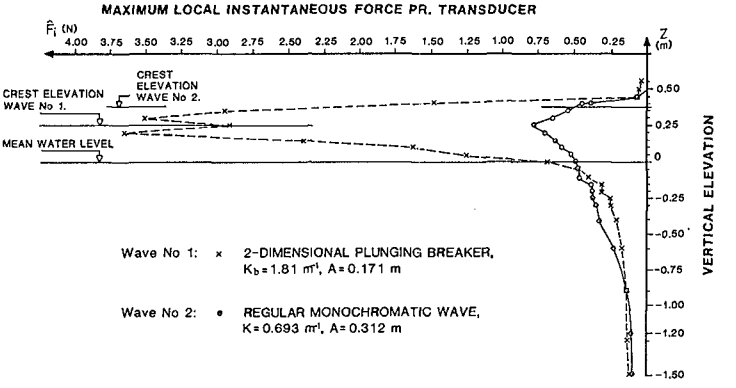

Fig. 5 Comparison between vertical profiles of maximum drag force obtained in plunging breaker and obtained in test series with regular monochromatic waves. (K is the wave number, and A is the wave amplitude H/2.)

Not only the local wave force, but also the total integrated drag force was much higher in the breaking wave than the corresponding drag force in the monochromatic wave. A factor of nearly 3 was found. Fig. 6 shows integrated in-line forces for breaking waves and results for monochromatic waves plotted as a function of wave steepness. Also the envelope for the tests with breaking waves is indicated. It is remarkable that plunging breaking waves were found to occur with steepnesses as low as 0.05. Other breaking wave transients occurred with steepnesses as high as 0.191. Thus it is obvious that the theoretical limiting steepness for monochromatic waves s = 0.141 can not be used to predict inception of breaking in transient or random waves. (See also Kjeldsen (1984b) and Dold and Peregrine (1986).)

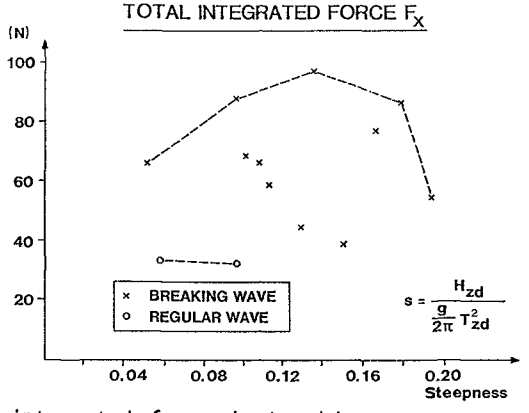

Fig. 6 Total integrated force in breaking waves compared with the total integrated force in regular waves with comparable steepnesses.

Also the total overturning moment was much higher for the breaking waves than for the monochromatic waves. Also here a factor of nearly 3 was found. The contributions from the drag force components near the free surface to the total overturning moment M_y at the seabed become more and more important when structures are developed for deeper waters, see Fig. 7. Results can also be presented in 3-dimensional plots as functions of wave height H_{zd} and wave period T_{zd}.

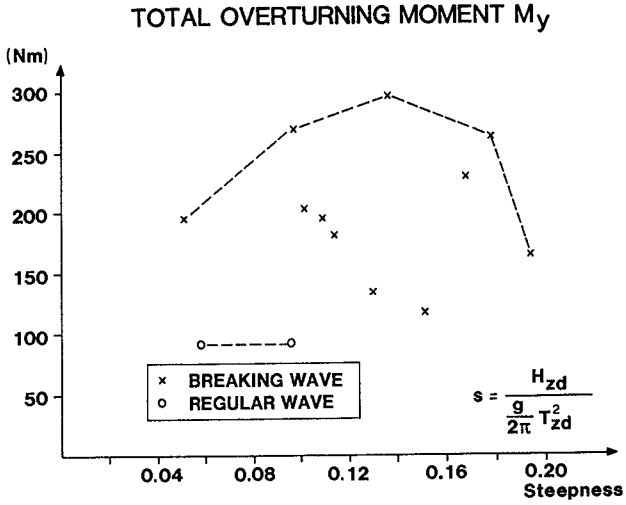

Fig. 7 Total overturning moment in breaking waves compared to total overturning moment in regular waves with comparable steepness.

We now proceed to 3-dimensional short-crested breaking waves occurring in deep water. These waves were focussed over a sector angle nearly 98 degrees. We attempted to model a situation with crossing wave orthogonals in deep water, such as can occur leeward of islands and reefs due to topographic refraction. The short-crested breaking waves were obtained using one frequency and waves approaching from 144 directions towards a focussing point with crossing orthogonals. They were generated with the 144 electrically driven flaps for 3-dimensional sea generation. Fig. 8 shows an example of such a short-crested 3-dimensional breaking wave. (See also Kjeldsen & Åkre (1985).)

Fig. 8 Short-crested 3-dimensional breaking wave with zero-downcross wave height H_{zd} = 0.692 m and zero-downcross wave period T_{zd} = 1.69 sec. The steepness s_{zd} based on these parameters is $2\pi H_{zd}/g \cdot T^2_{zd}$ = 0.155.

Fig. 9 shows an overall non-dimensional comparison of obtained results. Dimensionless local mean pressure Ω is plotted against dimensionless vertical elevation. The mean pressure $\bar{p}_i$ is defined as $\hat{F}_i/D \cdot t'$, where $\hat{F}_i$ is the maximum instantaneous wave force measured in the wave dispersion direction, D is the diameter of the pile, and t' is the width of the shear force transducer.

The wave number K_b at the position where inception of breaking takes place is defined as $K_b = 4\pi^2/g \cdot T^2_{zd}$ where T_{zd} is measured at the position where the wave profile becomes vertical.

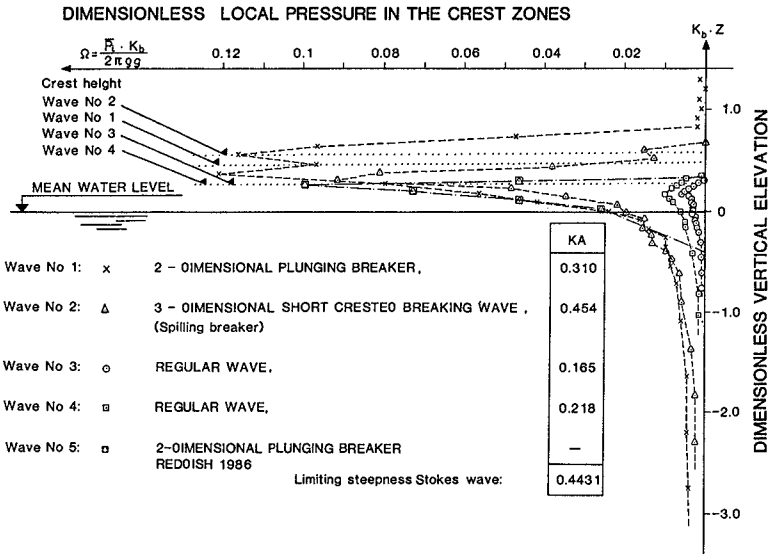

Fig. 9 Comparison between dimensionless local mean pressure in the crest zones measured in 2-dimensional plunging breaker waves, 3-dimensional short crested breaking waves, and 2-dimensional monochromatic waves. (K is wave number, A is wave amplitude H/2.)

The 2-dimensional plunging breakers gave the highest local forces, the highest integrated forces and the highest overturning moments in the entire test programme. The 3-dimensional short-crested breaking waves gave high but somewhat less forces, due to the angular spreading of crest particle velocities. Shown here are also results for a shallow water breaking wave measured by Reddish (1986). Reddish found local wave forces at the same level as the present investigation. However, numerical simulations of kinematics in deep and shallow water waves made by Vinje & Brevig (1981) show that kinematic vectors in breaking wave crests attain larger values in shallow waters than in deep waters. We should therefore expect that also wave forces associated with shallow water breaking waves are higher than the forces associated with deep water breaking waves which are reported here. Tørum (1985) performed an in-depth analysis of measured in-line wave forces associated with regular monochromatic waves. (See also Dean, Tørum, Kjeldsen (1985).)

It is important to be aware of the fact that wave impact or wave slamming is not incorporated in the present investigation. Data was sampled with a frequency 20 Hz. Wave impact forces have durations of the order $1 \cdot 10^{-3}$ sec and that demands much higher sampling frequencies. If wave impact forces occur these forces must be added to the viscous wave forces reported here. A separate investigation of a vertical and tilted plate exposed to impacts from crests of deep water breaking waves was performed by Kjeldsen (1981).

4 WAVE KINEMATICS

The present study is extended to include wave kinematics. Melville (1983) has shown that the Hilbert transform can be used to measure the amplitude, frequency, wave number and phase velocity as continous variables even in a strongly non-linear unsteady wave train. In the present study application of the Hilbert transform is extended to include a continous calculation of the horizontal and vertical particle velocities at the free surface based on measurements of free surface elevation. Fig. 10 presents results of such a calculation. It was found to predict wave kinematics at the free surface, even in very non-linear waves close to inception of breaking. For further details, see Kjeldsen (1986).

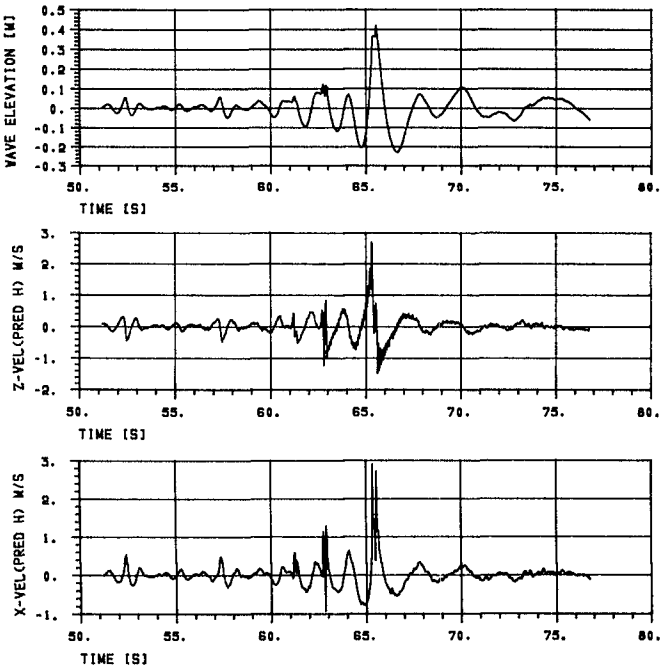

Fig. 10 Surface elevation and predicted horizontal and vertical particle velocities.

5 INSTABILITY OF 3-DIMENSIONAL WAVES

Su, Bergin, Marler and Myrick (1982) found that 3-dimensional subharmonic bifurcation of 2-dimensional wave trains can occur when the wave steepness exceeds $ak \geq 0.25$. As a result 3-dimensional spilling breakers are generated with large crest front steepnesses. During this process, two series of oblique wave groups are formed and radiate symmetrically away from the primary wave direction at a constant angle of about 30 degrees. These spilling breakers are thus examples of a source of directional spreading of wave energy. Such a mechanism can also explain the presence of breaking waves in deep waters. This phenomenon has also been observed in the Ocean Basin.

6 CONCLUSIONS

1) The performance of the entire experimental programme showed that extreme wave load intensities are associated with transient 2- or 3-dimensional breaking waves, of relatively short wave periods, and not with the highest waves in the simulated sea states.

2) Local wave pressures measured close to the free surface in the crests of transient 2-dimensional plunging breakers exceeded local wave pressures in monochromatic regular waves by a factor of 5. The regular waves had surface elevations very close to predictions made from Stokes' second-order wave theory.

3) The total integrated forces and the total overturning moments in breaking waves exceeded those measured in regular monochromatic waves by a factor of 3.

4) Local wave forces measured in 3-dimensional short-crested breaking waves were lower than local wave forces measured in 2-dimensional plunging breakers. This result can be explained by the fact that horizontal crest particle velocities in general are lower in 3-dimensional waves than corresponding horizontal crest particle velocities in 2-dimensional waves.

5) Inception of wave breaking was caused by phase superposition, and occurred also for very low values of wave steepness $s = 0.05$.

6) Our final recommendation is therefore that much more attention should be given to breaking waves, and that experiments of the kind reported here be extended in the future to include breaking waves also in shallow water and breaking waves occurring on beaches.

7 ACKNOWLEDGEMENTS

Acknowledgements are given to the Research Programme for Marine Structures, coordinated by Professor Faltinsen at the Institute of Marine Hydrodynamics, The Norwegian Institute of Technology (NTH). The programme for Marine Structures has the Royal Norwegian Council for Scientific and Industrial Research (NTNF), NORWEGIAN HYDRO and STATOIL as sponsors. The experimental programme on wave forces near the free surface reported here is one of the activities in this research programme. Acknowledgments are also given to Dr. C.T. Stansberg for development of software related to the application of the Hilbert transform.

CHAPTER 143

Flow Computations nearby a Storm Surge Barrier under Construction with Two-Dimensional Numerical Models

H.E. Klatter *

This paper discusses the application of two-dimensional tidal models to the hydraulic research for the storm surge barrier in the Eastern Scheldt in the Netherlands.
At the site of the barrier local energy losses dominate the flow. Three methods are discussed for dealing with these energy losses in a numerical model based on the long wave equations.
The construction of the storm surge barrier provided extensive field data for various phases of the construction of the barrier and these field data are used as a test case for the computation at methods developed. One method is preferred since it gives good agreement between computations and field data. The two-dimensional flow patterns, the discharge and the head-difference agree well.
The results of scale model tests were also available for comparison. This comparison demonstrated that depth-averaged velocities, computed by a two-dimensional numerical model, are as accurate as values obtained from a large physical scale model. Even compicated flow patterns with local energy losses and sharp velocity gradients compared well.

Introduction

As result of the 1953 storm flood disaster the Dutch government initiated a comprehensive construction program called the Delta Plan. Its purpose is to protect the south western part of the Netherlands against storm surges from the North Sea. In accordance with the Plan most Dutch estuaries have been closed by dams. The final, and by far the largest inlet, the Eastern Scheldt (Figure 1) will not be closed, but safety will be ensured by a storm surge barrier. Under normal weather conditions the barrier gates will be open and the tidal move-

Figure 2. Storm Surge Barrier.

The barrier, which was completed in October 1986, has been built in the three main tidal channels. The structure comprises prefabricated piers, rubble sills, concrete sill beams and steel gates (Figure 2). Since the structural elements were to be prefabricated and positioned under open sea conditions, using specially constructed floating derricks, an extensive research program concerning the water motion in the vicinity of the barrier was needed. This research program extended over a period of 10 years, both before and during the barrier construction and was aimed at optimizing the design of the structural elements and derricks and achieving better execution management for the construction works.
At the site of the storm surge barrier the tidal range varies between 2.5 and 3.5 m. The continued reduction of the hydraulic cross-section during the barrier construction, caused increases in current velocities up to 5 m/s through the barrier, under normal tidal conditions.
This paper discusses the use of two dimensional numerical models for the prediction of the depth-averaged tidal motion. These computations provide detailed information of for example:
- overall tidal motion, total discharge
- flow patterns in the mouth of the estuary, used in the prediction of morphological effects
- detailed flow patterns in the vicinity of the barrier for computing, for example, local scour near the barrier.

Main Features of the Numerical Solution

For the two-dimensional (horizontal) simulation of tidal motion the WAQUA program system is used. WAQUA is originally developed by the Rand Corporation, USA. In its further development it has been redesigned by the Data Processing Division of the Netherlands Department of Transport and Public Works and the Delft Hydraulics Laboratory.
WAQUA is based on a numerical solution of the two-dimensional long wave equations. These are derived under the following assumptions:
i) vertical velocities and accelerations are negligible relative to the gravitational acceleration; in other words, hydrostatic pressure distribution is assumed (nearly parallel flow).
ii) the water body is well-mixed vertically.
The resulting equations, containing vertically averaged velocity components, are:

$$\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial x} + V\frac{\partial U}{\partial y} - fV + g\frac{\partial \zeta}{\partial x} - \nu_t\left(\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2}\right) + g\frac{U(U^2+V^2)^{\frac{1}{2}}}{C^2(h+\zeta)} + X = 0 \quad (1)$$

$$\frac{\partial V}{\partial t} + U\frac{\partial V}{\partial x} + V\frac{\partial V}{\partial y} + fU + g\frac{\partial \zeta}{\partial y} - \nu_t\left(\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2}\right) + g\frac{V(U^2+V^2)^{\frac{1}{2}}}{C^2(h+\zeta)} + Y = 0 \quad (2)$$

$$\frac{\partial \zeta}{\partial t} + \frac{\partial((h+\zeta)U)}{\partial x} + \frac{\partial((h+\zeta)V)}{\partial y} = 0 \quad (3)$$

where:

U = depth-averaged velocity in x direction (m/s)

V	=	depth-averaged velocity in y direction	(m/s)
ζ	=	water elevation relative to the reference plane	(m)
h	=	distance from the bottom to the reference plane	(m)
t	=	time	(s)
X,Y	=	external force components per unit mass	(m/s^2)
f	=	Coriolis parameter	(s^{-1})
g	=	acceleration due to gravity	(m/s^2)
ν_t	=	eddy viscosity coefficient	(m^2/s)
C	=	Chézy coefficient for bottom friction	($m^{\frac{1}{2}}/s$)

Equations 1, 2 and 3 are solved at discrete space increments and discrete time intervals by an implicit finite difference method (References 2,3,4). The model area is schematized by a two-dimensional grid composed of equal square cells. In addition, the system possesses a facility to simulate drying and flooding processes of the tidal flats. The eddy viscosity coefficient ν_t is a constant, the corresponding terms taking care of lateral momentum transfer. At the site of the barrier the flow is dominated by energy losses generated by the rapid acceleration and deceleration of the flow. Local vertical velocities and accelerations are then no longer negligible and the depth-averaged equations, equations 1,2 and 3, are no longer valid. A resistance law is applied here, based on an equation of motion derived from the Bernoulli equation (accelerating flow, see Figure 3):

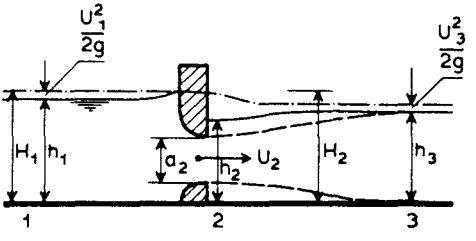

Figure 3. Flow at the Barrier Site.

$$q = a_2\sqrt{2g(H_1 - h_2)} \qquad (4)$$

where:

q	=	discharge per unit length	(m^2/s)
a_2	=	cross section height at Section 2	(m)
g	=	accelaration due to gravity	(m/s^2)
H_1	=	upstream energy level	(m)
h_2	=	waterlevel at Section 2	(m)

In Equation 4, the waterlevel h_2 is replaced by the downstream waterlevel h_3 and a discharge coefficient, μ, is added to compensate

for energy losses caused by the deceleration of the flow. For practical applications the upstream energy level H_1 is replaced by the waterlevel h_1. The inaccuracy of this approximation is small when

$$\frac{U_1^2}{2g} \ll \frac{U_2^2}{2g}$$

U_1 and U_2 are depth-averaged velocities at Section 1 and 2 respectively.

The resulting equation is:

$$q = \mu a_2 \sqrt{2g\,(h_1 - h_3)} \qquad (5)$$

where:

q	= discharge per unit length	(m^2/s)
μ	= discharge coefficient	(-)
a_2	= cross section heigth at section 2	(m)
g	= acceleration due to gravity	(m/s^2)
h_1	= upstream water level	(m)
h_3	= downstream water level	(m)

The discharge coefficient can be obtained from flume tests or from literature. Equation 5 describes a steady state type of flow. For unsteady flow this approach is not precise for the short period around slack water. For most applications this is of minor importance and can be neglected.

Three different methods introducing energy losses at the barrier site into the WAQUA program were applied:

1- Substitution of the long wave eqation by a barrier eqation.
   At the barrier site the long wave equations, Equations 1,2 and 3, are replaced by Equation 5, creating a sort of internal boundary at the barrier site. Both sides of this boundary are coupled by Equation 5.
2- Adapted fixed roughness.
   At the barrier site an adapted fixed value of the Chézy coefficient is calculated by equating the Chézy equation to Equation 5. At the barrier site equations 1, 2 and 3 are solved completely.
3- Dynamically adapted roughness
   This is a mixed version of methods 1 and 2.
   At the barrier site the roughness coefficient is continuously adapted so that the discharge and headloss satisfy Equation 5 for a given value of the discharge coefficient, μ.
   Thus continually a new Chézy value is calculated during the computation.

Methods 1 and 3 make it possible to use different coefficients for different flow directions and different equations for different flow conditions, such as subcritical or supercritical flow.
With Methods 1 and 3 Equation 5 is solved by an explicit method. The solution is found iteratively so that it fits in the results calculated by the implicit WAQUA scheme precisely.

Application of Two-Dimensional Numerical Models to the Storm Surge Barrier in the Eastern Scheldt

In the case of the Eastern Scheldt it is not feasible to use one single model for all purposes. A set of models is therefore used which consists of an overall tidal model and a number of nested detail models (Figure 4).
The main function of the overall model is to provide boundary conditions for the detail models. The overall model covers the entire estuary of the Eastern Scheldt. The model has a length of 65 km and a maximum breadth of 15 km. The grid size is 400 m.
A relatively large detail model describes the mouth of the Eastern Scheldt. This model covers an area 21 km long and 10 km broad. The grid size is 100 m. The model is used to evaluate relatively large scale phenomena such as morphological changes in the tidal channels and on the tidal flats between the main channels (Reference 1).
A set of nested models is used to compute details of the flow pattern in the vicinity of the barrier. This set consists of two models with 90 m grid size and a model area equivalent to 10 x 6 km.One model contains both the northern branches of the estuary, the Hammen and the Schaar, and the other contains the south branch, the Roompot.
Three separate models each with 45 m grid size, are used for the Hammen, the Schaar and the Roompot. The area of these models is equivalent to about 3,5 x 2,5 km. The axis of the 45 m models are orientated so that one axis is parallel to the barrier.
The boundary conditions for the models are a mixture of velocity type and of waterlevel type boundary conditions.

This paper discusses the results of the small detail models, 45 m grid size, in more detail. The parameters used for the calibration of the models are:
v_t, C and μ see Equations 1, 2, 3 and 5. Also the grid size and the timestep are important to the accuracy of the results. The values that were used for these parameters are given below.

- Grid size, $\Delta x = \Delta y$.
  A grid size of 45 m has been selected. 45 m is exactly the distance between the piers of the barrier.
- Time step, Δt
  A time step of 15 s is used to obtain an accurate computed flow pattern.
- Eddy viscosity coefficient, v_t
  For an correct reproduction of the velocity gradients and eddies downstream of the barrier the value of v_t had to be 2 m^2/s has been used. The numercal viscosity is negligible compared with this value of v_t.
- Roughness parameter, C
  A Chézy value is used which corresponds to a fixed value of the Manning coefficient n = 0.0262 $m^{1/3}/s$. The value of the roughness parameters is of minor importance in the small detail models. It determines the overall tidal motion.
- Discharge coefficient, μ
  The discharge coefficients are derived from steady state flume tests

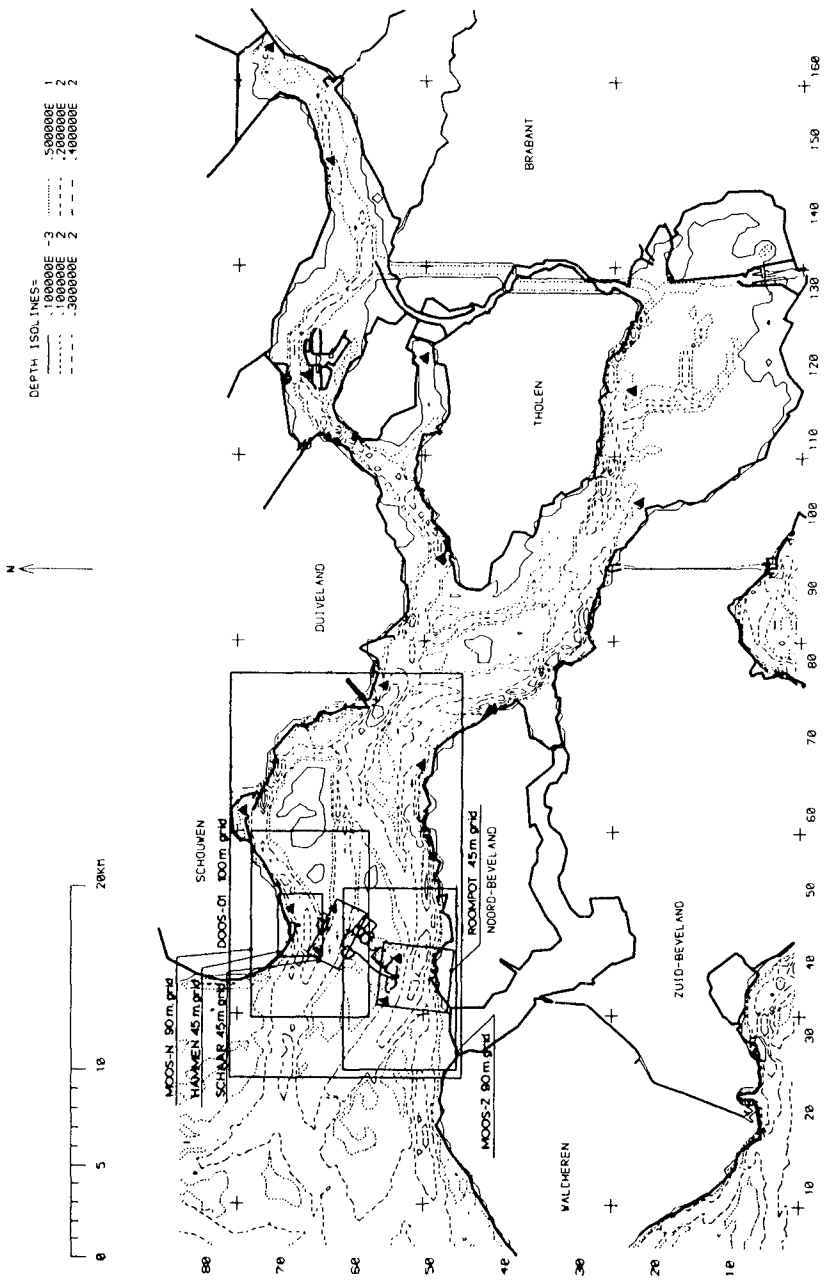

Figure 4. Lay-Out of the Numerical Models

for a 45 m section; 45 m is the distance between the piers.
The coefficients were determined for both flow directions for a number of different construction stages and locations.

Results

The construction of the barrier in the Eastern Scheldt is accompanied by an extensive hydraulic measurement campaign.
The hydraulically most interesting phase is the installation of the sill beams, Figure 2. These beams reduce the flow area between the piers abruptly. This causes an abrupt change of the flow pattern. Installation of the sill beams was a crucial phase for:
- the floating construction equipment
- morphological changes
- the stability of the bed protection near the barrier
- the development of scour holes at the boundaries of the bed protection

For 15 construction stages extensive field data are available. These data consist of waterlevels, head differences, discharges, flow velocities and flow directions upstream, downstream and at the site of the barrier. Special equipment was developed to obtain these field data.
The tidal flow has been computed by the WAQUA system for all these construction stages and was compared with the observed flow.
General conclusions on the three numerical methods used to introduce energy losses at the barrier site are:
- Method 1: Substitution of the long wave equation by a barrier equation.
  The flow pattern downstream the barrier, which is with this method an internal boundary in the model, is disturbed. (compare Figure 11 with Figure 12) The computed total discharge and head difference agree well with observations.
- Method 2: Adapted fixed roughness.
  The downstream flow pattern is correct; the barrier is no longer an internal boundary in the model. A disadvantage is the general approximation of the resistance and, because an averaged roughness is used, it is not possible to account for the influence of different flow directions and different flow conditions. This results in a less accurate reproduction of the discharge and the head difference than Method 1.
- Method 3: Dynamically adapted roughness.
  This proves to be the best solution and the disadvantages of Method 1 as well as of Method 2 are avoided.

For this study the results of a scale model of the mouth of the Eastern Scheldt are available for comparison. This model is an undistorted steady state model with scale 1:80 of approximately the same area as the 45 m grid size numerical detail models.The indications are that the depth-averaged velocities computed with Method 3 agree as well with field data as depth-averaged velocities obtained from the scale model.
The results of the computations are discussed below in more detail for

two situations, see Figure 5:

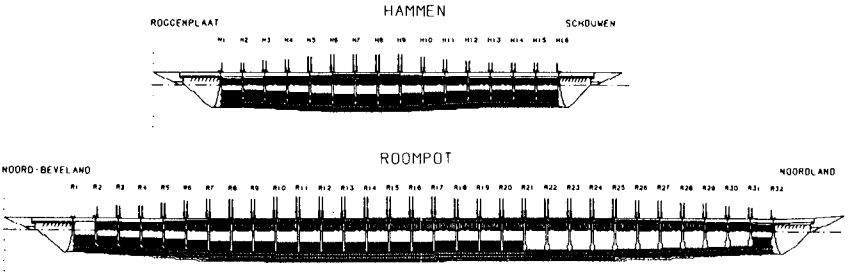

Figure 5. Geometry of the Barrier Under Construction in the Roompot and the Hammen.

- The Roompot: a situation in wchich 21 of the 31 sill beams have been installed. Ebb flow.
- The Hammen: a situation in which all 15 sill beams have been installed. Flood flow.

In these situations the flow is dominated by two-dimensional effects:

- The Roompot: At the transition between the rubble sill and the concrete sill beams there is a sharp discontinuity in the barrier: In the flow opening and in the discharge coefficient. Downstream this discontinuity a mixing zone develops with a sharp velocity gradient.
- The Hammen: Downstream of the barrier a large eddy is formed.

The results presented below have been computed with Method 2: Adapted fixed roughness. Except for one example which shows the effect of Method 1: Substitution of the long wave equation by a barrier equation. On basis of these results it was decided to develop and program Method 3: Dynamically adapted roughness. The initial tests showed that Method 3 is very promising.

The results for both the Roompot and Hammen flow situations are presented in Figures 6 through 13:

- The computed flow pattern in the Roompot has been plotted in Figure 6 for maximum ebb flow.
- In Figure 7 the observed and computed transport rate in the Roompot are given for both ebb flow and flood flow.
- The observed and computed flow velocities and flow directions at 350 m upstream and 630 m downstream of the barrier are presented in Figures 8 and 9 (maximum ebb flow).
  The transport rate per gate opening has also been plotted in Figure 8.
- The transport rate in the Hammen is presented in Figure 10
- In Figure 11 the computed flow pattern in the Hammen during maximum flood flow has been plotted.
- The flow pattern in the Hammen computed with Method 1 (barrier equation substituted) has been plotted in Figure 12; to be compared with Figure 11.

- Figure 13 finally gives the observed and computed velocities at 400 m upstream and 630 m downstream of the barrier and the transport rate per barrier gate (maximum flood flow). Additioned to the field data and computed velocities the observed flow velocities in the scale model are given 630 m downstream of the barrier.

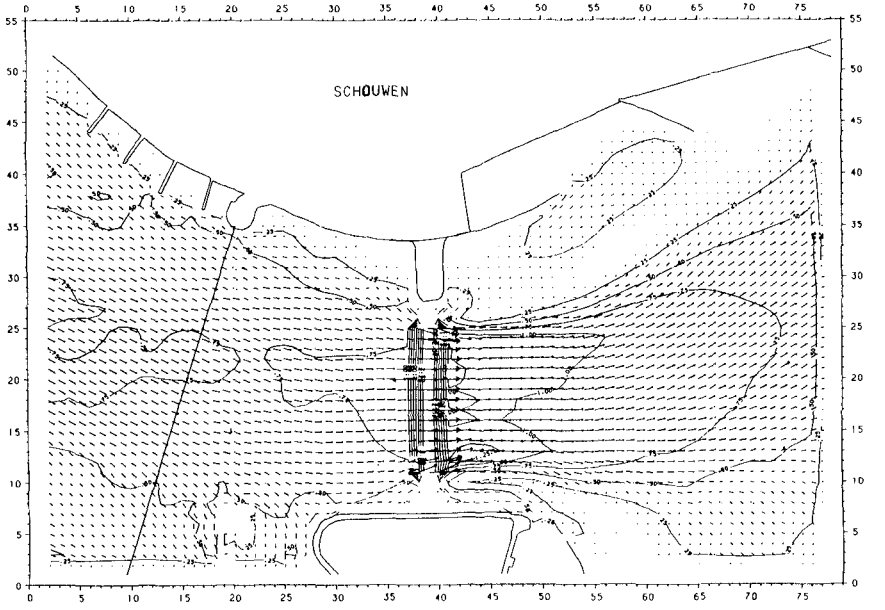

Figure 11. Hammen, Flow Pattern Maximum Flood Flow (Method 2).

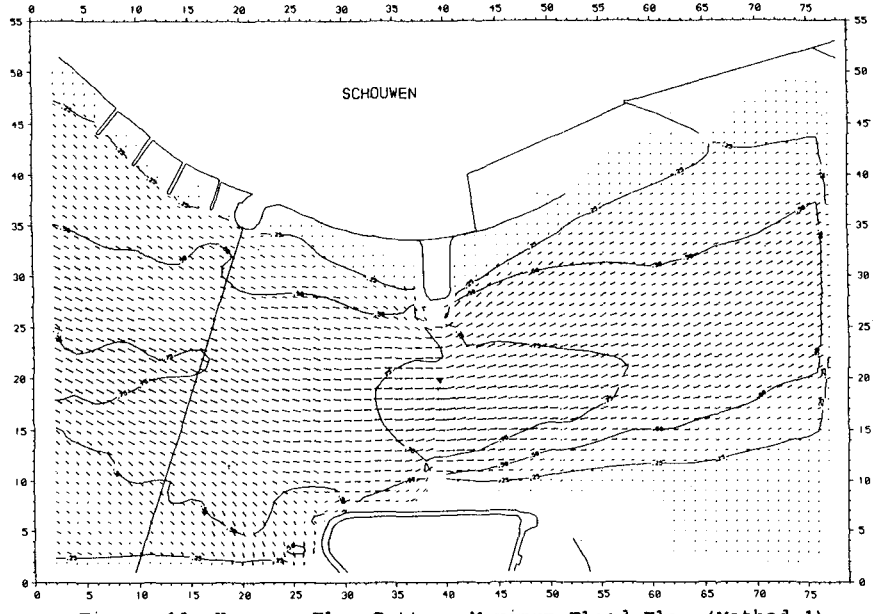

Figure 12. Hammen, Flow Pattern Maximum Flood Flow (Method 1).

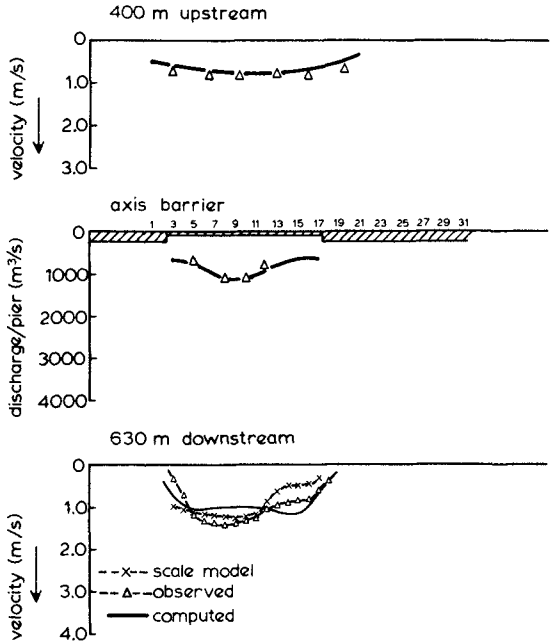

Figure 13. Hammen, Flow Velocities Maximum Flood Flow.

Conclusions

Comparison of the results computed by the WAQUA system with the field data shows that in general the agreement between WAQUA and the field data is good:

- Computed transport rates agree well with field data
- The agreement between the computed flow patterns and the field data is very good upstream of the barrier and at the site of the barrier
- Downstream the barrier the agreement between the computations and field data is acceptable. The computed maximum velocities and the steepness of the velocity gradients are correct. The locations where these occur however are not accurate. For engineering applications, for example calculation of the stability of bed protection or calculations of scour holes, this difference is acceptable.

The quality of the depth-averaged flow pattern computed by WAQUA is as accurate as that obtained from a large physical scale model. The method to deal with the energy losses at the barrier site greatly influenced the quality of the results.
This paper demonstrates that a method based on a local adaptation of the roughness is an accurate way of dealing with these local energy losses.

CHAPTER 144

PREDICTION OF WAVE RUNUP AND RIPRAP STABILITY

By Nobuhisa Kobayashi[1], M.ASCE and Jeffrey H. Greenwald[2], A.M.ASCE

ABSTRACT: A numerical model has been developed to predict the wave motion on a rough impermeable slope and the hydraulic stability and sliding motion of armor units under the action of a specified normally-incident wave train. The developed numerical model has been compared with riprap test results to calibrate and verify the model.

INTRODUCTION

The present design practices of coastal structures protected with armor units such as breakwaters and revetments are based on hydraulic model tests and empirical formulas although our quantitative understanding of the problem has been improving steadily (4,23,26,29,30). Further improvements of the present design practices will require reliable numerical models which can complement hydraulic model tests since large-scale model tests with minimum scale effects are expensive and time-consuming. Furthermore, some of the important quantities such as the spatial variation of the stability of armor units are very difficult to measure in detail.

As a first attempt, Kobayashi and Jacobs (8) developed a simple analytical model to predict the flow characteristics in the downrush of regular waves on a uniform slope and the critical condition for initiation of movement of armor units. This simple model gives a physical insight into the mechanics of armor stability under the action of surging breakers but is not reliable enough to be applied to actual design problems.

In order to improve the analytical model, Kobayashi et al. (12,13, 14) have developed a numerical model to predict the flow characteristics in the uprush and downrush on a rough impermeable slope and the resulting hydraulic stability and sliding motion of armor units under the action of a normally-incident wave train. Comparison with available riprap test data (1,10) has indicated that the numerical model can predict wave runup, rundown and reflection as well as zero-damage wave heights for uniform and composite riprap slopes if some of the input parameters required for the numerical model are calibrated.

In order to calibrate and verify the developed numerical model more

[1]Assoc. Prof., Dept. of Civil Engrg., Univ. of Delaware, Newark, DE 19716.

[2]Grad. Student, Dept. of Civil Engrg., Univ. of Delaware, Newark, DE 19716; presently, Research Staff, Center of Naval Analysis, Alexandria, VA 22302.

extensively, Kobayashi and Greenwald (15) have conducted eight test runs in a wave tank using a 1:3 glued gravel slope with an impermeable base. For each run with the specified incident wave train generated in a burst, measurements have been made of the free surface oscillation at the toe of the slope, the waterline oscillation on the slope, the temporal variations of dynamic pressures on the base of the slope and the displacements of loose gravel units placed on the glued gravel slope. The calibrated numerical model has been shown to be capable of predicting the measured temporal variations of the hydrodynamic quantities and the measured spatial variations of the amount of the riprap movement.

In this paper the mathematical and numerical backgrounds of the numerical model developed by Kobayashi et al. (12,13,14) are critically reviewed to indicate possible future improvements of the numerical model. Then, the riprap experiment conducted for calibrating and verifying the numerical model is described together with the test results which have not been presented by Kobayashi and Greenwald (15). Furthermore, additional experiments required for further calibration and verification of the numerical model are discussed in light of the limitations of the experiment conducted by Kobayashi and Greenwald (15).

WAVE MOTION ON A ROUGH SLOPE

Wave uprush and downrush on the seaward slope of a coastal structure protected with armor units are similar to wave motions in the swash zone on a beach although the structural slope is normally steeper than the beach slope. It is noted that the surf similarity parameter (3) is widely used to describe the gross wave characteristics on the structural and beach slopes. Use may hence be made of the hydrodynamic models developed for breaking waves on beaches which have been investigated more extensively as reviewed by Peregrine (21). The finite-amplitude shallow-water equations including the effects of bottom friction are suited for predicting the movement of the waterline on the rough slope of the coastal structure if the slope is relatively mild and impermeable. The waterline movement on the slope determines wave runup and rundown and affects the hydraulic stability of armor units as shown by the simple analytical model developed by Kobayashi et al. (8,11). However, the finite-amplitude, shallow-water equations based on the assumption of hydrostatic pressure are not capable of describing detailed two-dimensional behavior of overturning waves (17).

Limiting to the case of a normally-incident wave train on the rough impermeable slope shown in Fig. 1, the finite-amplitude, shallow-water equations including the effects of bottom friction may be written as

$$\frac{\partial h'}{\partial t'} + \frac{\partial}{\partial x'}(h'u') = 0 \tag{1}$$

$$\frac{\partial}{\partial t'}(h'u') + \frac{\partial}{\partial x'}(h'u'^2) = -gh'\frac{\partial \eta'}{\partial x'} - \frac{\tau_b'}{\rho} \tag{2}$$

in which t' = time, x' = horizontal coordinate at the still water level (SWL) which is taken to be positive in the landward direction

with $x' = 0$ at the toe of the slope, h' = water depth below the free surface, u' = depth-averaged horizontal velocity, g = gravitational acceleration, η' = vertical displacement of the free surface relative to SWL, τ_b' = bottom shear stress, and ρ = fluid density which is assumed constant neglecting the effects of air entrainment (5). The bottom shear stress may be expressed as

$$\tau_b' = \frac{1}{2} \rho f' |u'| u' \tag{3}$$

where f' = friction factor associated with the rough impermeable slope which is simply assumed constant. It should be noted that f' will depend on h' if Manning formula is used to express τ_b' (18,19). The empirical formula proposed by Madsen and White (16) has been found satisfactory in estimating the constant value of f' for riprap slopes although additional calibration may be required (13,15).

If the permeability of the underlayer below armor units is not negligible, the flow over the rough permeable bottom and the flow in the permeable underlayer are coupled through the mass and momentum fluxes between these two flow regions. Kobayashi (11) formulated this coupled problem and performed an order-of-magnitude analysis to evaluate the degree of the effects of the permeable underlayer. On the other hand, Hannoura et al. (5) analyzed the flow inside a permeable breakwater using the measured pressure on the rough permeable slope as input. Because of the assumption of the impermeable underlayer, the present numerical model is not applicable to permeable breakwaters such as reef type breakwaters (2).

Denoting the characteristic period and height associated with the normally-incident wave train by T' and H', respectively, the following dimensionless variables are introduced

$$t = \frac{t'}{T'} \quad , \quad x = \frac{x'}{T'\sqrt{gH'}} \quad , \quad u = \frac{u'}{\sqrt{gH'}} \tag{4}$$

$$z = \frac{z'}{H'} \quad , \quad h = \frac{h'}{H'} \quad , \quad \eta = \frac{\eta'}{H'} \quad , \quad d_t = \frac{d_t'}{H'} \tag{5}$$

in which z' = vertical coordinate which is taken to be positive upward with $z' = 0$ at SWL as shown in Fig. 1, and d_t' = water depth below SWL where the incident wave train may be specified conveniently. Limiting to the case where the incident wave train is well-behaved without any

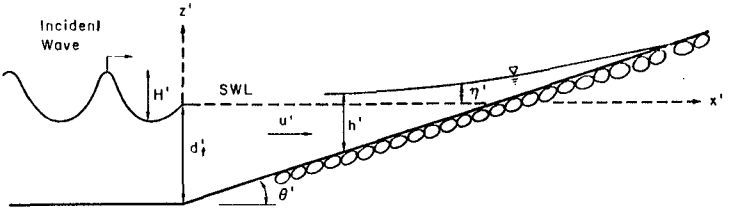

Fig. 1 - Normally-Incident Wave Train on Rough Slope

breaking at the toe of the slope, d'_t is taken to be the water depth below SWL at the toe of the slope as shown in Fig. 1. Substitution of Eqs. 3-5 into Eqs. 1 and 2 yields

$$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x}(hu) = 0 \tag{6}$$

$$\frac{\partial}{\partial t}(hu) + \frac{\partial}{\partial x}\left(hu^2 + \frac{h^2}{2}\right) = -\theta h - f|u|u \tag{7}$$

with

$$f = \frac{1}{2}\sigma f' \quad , \quad \sigma = T'\sqrt{\frac{g}{H'}} \tag{8}$$

$$\theta = \sqrt{2\pi}\,\xi \quad , \quad \xi = \frac{1}{\sqrt{2\pi}}\sigma \tan\theta' \tag{9}$$

in which f = normalized friction factor, σ = dimensionless parameter related to wave steepness, θ = normalized gradient of the slope, and ξ = local surf similarity parameter with θ' = local angle of the slope. For the regular wave incident on a uniform slope of constant θ' as shown in Fig. 1, ξ defined in Eq. 9 reduces to the surf similarity parameter introduced by Battjes (3). The numerical model can easily be applied to examine the effects of the slope geometry on wave runup and armor stability by varying the local slope angle θ' along the slope. Composite slopes approximating the characteristic S-geometry of matured breakwaters have been shown to increase armor stability and reduce wave runup as compared to uniform slopes (4,9,10).

Eqs. 6 and 7 are solved numerically in the time domain to compute h and u as a function of t and x for given θ (i.e., ξ), f, initial and boundary conditions. The initial conditions for h and u are taken such that h = normalized depth below SWL (i.e., η=0) and u=0 at t=0 for the region $x \geq 0$ on the rough slope, corresponding to the conditions before the arrival of the incident wave train at the toe of the slope. In general, the computation in the time domain can incorporate nonlinear effects easily relative to the computation in the frequency domain. However, for the incident regular wave train, the time-domain computation starting from the assumed initial conditions at t=0 needs to be continued until the state of periodicity is reached. For the computation made by Kobayashi et al. (12,13,14) the transient duration has been limited to the relatively short duration $0 \leq t \lesssim 5$ where the normalized period of the incident regular wave train is unity. Furthermore, the time-domain computation will become expensive if the number of individual waves in an incident irregular wave train becomes large.

The landward boundary on the rough slope is located at the moving waterline where the water depth h is essentially zero, assuming that no wave overtopping occurs. However, it is desirable to generalize this boundary condition so as to allow wave overtopping over the specified crest geometry of the structure since some wave overtopping is normally accepted in designing the crest geometry (29). If wave overtopping is to be allowed, it will be necessary to apply a discharge relationship at the point of overflow by assuming the similarity between wave overtopping over the crest of the coastal structure and overflow over

a weir in open channel flow (18).

At the seaward boundary located at x=0 it is normally required for practical applications to specify the incident waves as input and estimate the reflected waves originating from the region x≥0 on the rough slope. This implicitly assumes that the reflected waves will not modify the specified incident waves. In order to derive an appropriate seaward boundary condition, Eqs. 6 and 7 are expressed in the corresponding characteristic forms (13). Then, the equation for the seaward-advancing characteristics originating from the region x≥0 is used to obtain a relationship for the values of u and h at x=0. Since an additional relationship is required to find u and h at x=0, the normalized total water depth at the seaward boundary is expressed as

$$h = d_t + \eta_i(t) + \eta_r(t) \qquad \text{at } x = 0 \tag{10}$$

in which η_i and η_r are the free surface variations normalized by H′ at x=0 due to the incident and reflected waves, respectively. The superposition of η_i and η_r at x=0 implicitly assumes that nonlinear interaction between the incident and reflected waves is negligible in the vicinity of the seaward boundary. The incident wave train at x=0 is specified by prescribing the variation of $\eta_i(t)$ with respect to t≥0. $\eta_r(t)$ may be computed approximately from the value of the seaward advancing characteristic variable at x=0 using the relationship between u and η applicable for linear long waves. This approximation is not crucial as long as wave reflection from the rough slope is small and η_r is negligible in Eq. 10. The practical difficulty associated with the seaward boundary condition is that the design incident waves are normally specified in terms of the wave energy spectrum or the significant wave height and period rather than the temporal variation of the free surface associated with the incident wave train which is directly related to the sequence and group of individual waves in an incident irregular wave train. Furthermore, for the incident regular wave train with given H′ and T′ in the water depth d_t', $\eta_i(t)$ needs to be estimated using an appropriate wave theory. To specify $\eta_i(t)$ at x=0 for given H′, T′ and d_t', Kobayashi et al. (12,13,14) have used cnoidal or Stokes wave theory although these wave theories are not really consistent with the finite-amplitude shallow-water equations. If cnoidal wave theory is applied, it is more consistent to use Boussinesq equations (27). In fact, Pedersen and Gjevik (20) developed a numerical model based on Boussinesq equations for computing runup of a non-breaking solitary wave.

For the specified initial and boundary conditions Eqs. 6 and 7 are solved using an explicit dissipative Lax-Wendroff finite-difference method developed by Peregrine and co-workers (6,7,18,19) for simulating spilling-type breakers and resulting swash oscillations on gentle slopes. In this numerical method, the front of a breaking wave becomes almost vertical without any separate treatment of the wave front but an artificial dissipative term needs to be included to reduce numerical oscillations in the vicinity of the front caused by discretization. Use is made of a finite-difference space and time grid of constant space size Δx and constant time step Δt in which the values of Δx and Δt are determined considering the numerical stability criterion of the

adopted explicit method and the desired spatial and temporal accuracies. Svendsen and Madsen (28) showed that this numerical dissipation would not be required if the effects of turbulence generated by wave breaking were included in the numerical model. Nevertheless, the explicit dissipative Lax-Wendroff finite-difference method has been tested and is relatively easy to apply for simulating the moving waterline on the relatively mild slope where the present computation based on Eqs. 1 and 2 may be appropriate if $(\tan\theta')^2 \ll 1$. The major contribution by Peregrine and co-workers (6,7,18,19) is the development of the predictor-corrector-smoothing procedure dealing with the moving waterline although the details of this procedure are somewhat intuitive and may still be improved (13). As a whole, the adopted numerical method has been found to be very satisfactory although the CPU time for a typical case using 200 nodal points and 2,000 time steps per wave period is approximately 30 sec per wave period (13).

HYDRAULIC STABILITY AND MOVEMENT OF ARMOR UNITS

The finite-difference solution of Eqs. 6 and 7 yields the values of u and h at each of the space grid points along the slope at each time level starting from t=0. In order to compute the normalized horizontal water particle acceleration, du/dt, at each space grid point using the computed values of u and h at given time level, Eq. 7 is rewritten as

$$\frac{du}{dt} = \frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} = -\frac{\partial h}{\partial x} - \theta - \frac{f|u|u}{h} \tag{11}$$

in which use is made of a central-difference approximation of $\partial h/\partial x$. The computed values of u and du/dt at each space grid point at given time level are then used to estimate the hydrodynamic forces acting on an individual armor unit on the rough slope.

The hydraulic stability analysis of stationary armor units performed by Kobayashi et al. (12,14) is similar to the simplified analysis of Kobayashi and Jacobs (8) which was limited to the downrush period only. Fig. 2 shows the forces acting on a stationary armor unit on the 1:cotθ' slope. Limiting to the case of $(\tan\theta')^2 \ll 1$, it is assumed that the drag force F_D and the inertia force F_I act upward or downward parallel to the slope, whereas the lift force F_L acts upward normal to the slope since the flow tends to be parallel to the slope as shown in Fig. 2. On the other hand, the submerged weight W_S acts

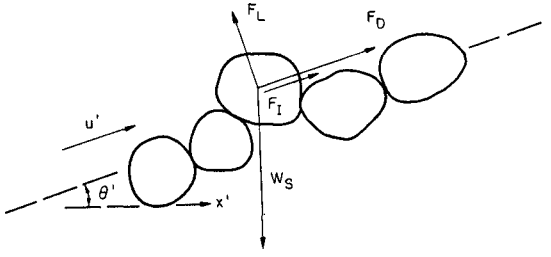

Fig. 2 - Forces Acting on a Stationary Armor Unit

vertically downward. The expressions for F_D, F_I, F_L and W_S are given by Kobayashi and Jacobs (8) except that F_D is proportional to $|u'|u'$ in this analysis for both uprush and downrush periods. The expressions of the hydrodynamic forces F_D, F_I and F_L include the drag, inertia and lift coefficients denoted by C_D, C_M and C_L, respectively. These coefficients need to be determined experimentally on the basis of the simultaneous measurements of the fluid velocity and acceleration and the resulting hydrodynamic forces which will be extremely difficult for an armor unit located on the rough slope under the action of breaking waves. Furthermore, the temporal variations of the hydrodynamic forces can be more complicated than those based on the adopted expressions, judging from the simpler measurements of the lift force on a single sphere near a plane wall in well-behaved oscillatory flow reported by Rosenthal and Sleath (22). Tentatively, Kobayashi et al. (12,14,15) have assumed that for riprap units $C_D \simeq 0.5$, $C_M \simeq 1.5$ and $C_L = 0.18$ -0.4 in which C_L is varied in this range on the basis of available scattered data on C_L summarized by Sleath (25).

The stability condition for a stationary armor unit against downward or upward sliding or rolling are expressed as

$$|F_D + F_I - W_S \sin\theta'| \leq (W_S \cos\theta' - F_L) \tan\phi \tag{12}$$

in which ϕ = frictional angle of the armor units and $\phi \simeq 50°$ for angular riprap units (8,12,14,15). Limiting to the case of $C_D > (C_L \tan\phi)$, Eq. 12 can be rearranged as

$$N_s = \frac{H'}{s-1}\left(\frac{W'}{\rho g s}\right)^{-1/3} \leq N_R\,(t,x) \tag{13}$$

where N_s = stability number, s = specific density of the armor unit, W' = weight of the armor unit, ρ = fluid density, and $N_R(t,x)$ = dimensionless function involving u and du/dt which depends on t and x (12,14). Eq. 11 indicates that du/dt may become very large at the wave front where h decreases rapidly with x. The computed fluid accelerations have been found to be as large as 4g which may not be unrealistic in comparison with the computed accelerations as large as 5g or 6g beneath overturning wave crests obtained by New et al. (17). Nevertheless, it has been found necessary to impose the physical bounds, $a_{min} \leq (du'/dt')/g \leq a_{max}$, which can be rewritten as

$$a_{min}\,\sigma \leq du/dt \leq a_{max}\,\sigma \tag{14}$$

in which the values of the dimensionless parameters a_{min} and a_{max} are chosen such that Eq. 12 is satisfied for u=0 for which $F_D = F_L = 0$. The lower bound in Eq. 14 may not be required since the computed values of du/dt have turned out to be greater than $a_{min}\,\sigma$ in which $a_{min} = -0.8$ has been used (14,15). On the other hand, use has been made of $a_{max} = 1.0$ in the stability computation made by Kobayashi et al. (14,15) on the basis of the experimental results given by Sawaragi et al. (23). This physical upper bound is related to the uncertainty of the computed inertia force using constant C_M at the point of wave breaking as well as to the uncertainty of the response time of an armor unit under the action of the large fluid acceleration of a very short duration.

The stability condition for a stationary armor unit against lifting can be shown to be satisfied as long as Eqs. 13 and 14 are satisfied (14). Consequently, it is sufficient to consider the stability against sliding or rolling for establishing the criterion for initiation of armor movement. For the regular incident wave train specified at x=0, it may be sufficient to consider one wave period after the periodicity of the armor stability is established. The local stability number for initiation of armor movement at given location x along the slope is hence defined as

$$N_{sx}(x) = \min[N_R(t,x) \,|\, t_p \le t \le (t_p + 1)] \qquad (15)$$

in which t_p = normalized time when the periodicity of $N_R(t,x)$ with respect to t is established, and the normalized period of the incident wave is unity. Eq. 15 implies that $N_{sx}(x)$ for given x is the minimum value of $N_R(t,x)$ during one wave period after the establishment of the periodicity. The critical stability number N_{sc} for initiation of armor movement is the minimum value of the local stability number $N_{sx}(x)$ which varies along the slope.

The value of the stability number N_s defined in Eq. 13 can be calculated for specified incident wave and armor unit characteristics. The armor units located in the region of $N_s > N_{sx}(x)$ will slide or roll downwards or upwards along the slope. However, the amount of armor movement needs to be predicted to determine whether a specific moving unit will move in place or be dislodged out of place. Wiberg and Smith (31) developed a detailed theoretical model for saltating sediment particles in uni-directional flow. To simplify the analysis for unsteady flow, moving armor units have been assumed to slide essentially parallel to a rough slope without rolling. The displacement X_a' of a sliding armor unit has then been computed by solving the simplified equation of motion for an individual armor unit identified by its initial location on the slope at time t=0 (14,15). This computation is based on a Lagrangian approach in which each sliding unit of its representative length d' is followed starting from its initial location at t=0 and its subsequent location at each time level is found using the computed normalized displacement $X_a=(X_a'/d')$. As a result, X_a depends on t for each sliding unit identified by its initial location on the slope. The computed normalized displacement may be regarded as a statistical average since the present analysis does not account for the effects of the irregular rough surface on the armor movement explicitly. Moreover, a significant extension of the present analysis will be required to predict the temporal change of the slope profile and the resulting breakwater damage which needs to be considered for the practical design of breakwaters (26). Since the degree of the breakwater damage depends on the wave characteristics during an entire storm such as the number of waves (30), the present numerical model will also need to be simplified to simulate the breakwater behavior during an entire storm.

COMPARISON WITH EXPERIMENTS

Kobayashi et al. (12,13,14) have compared the numerical model with the large-scale riprap tests of Ahrens (1) for uniform slopes with $\cot\theta'$=2.5, 3.5 and 5 in which incident wave trains were generated in a burst and measurements were made of wave runup and zero-damage wave heights. Comparison has also been made with the similar but small-scale riprap tests for composite and 1:3 uniform slopes conducted by Kobayashi and Jacobs (10) who measured wave runup, rundown and zero-damage wave heights. The computed wave runup and rundown using the friction factor f'=0.3 have shown to agree with the visually-measured wave runup and rundown. The numerical model with the adopted seaward boundary condition has also predicted the observed increase of the reflection coefficient with the surf similarity parameter (24). Furthermore, the computed critical stability number for initiation of riprap movement has been shown to be in good agreement with the measured zero-damage stability number if the lift coefficient C_L is calibrated in the range C_L=0.18-0.4 and the upper bound of the computed fluid acceleration is imposed.

Kobayashi and Greenwald (15) have conducted additional riprap tests in a wave tank which is 36 m long, 2.5 m wide and 1.5 m deep. A piston-type wavemaker controlled by a function generator or a computer is used to generate incident regular wave trains in a burst which are measured using resistance wire wave gages with a wave-absorber beach in the tank. The water depth in the tank is kept constant and d'_t=0.4 m in these tests. A 1:3 glued gravel slope with an impermeable base is installed in the tank and exposed to the same incident wave trains. The incident wave conditions considered for eight test runs correspond to plunging, collapsing and surging breakers. For each run with given incident wave train and slope characteristics, measurements are made of the free surface oscillation at the toe of the 1:3 slope, the oscillation of the waterline on the slope, wave pressures on the base of the slope and the displacements of loose gravel units placed on the glued gravel slope. These measured quantities are normalized and compared with the computed normalized quantities for each run. Kobayashi and Greenwald (15) have presented the summary of the comparisons and the detailed results for Runs 2 and 7 which have been selected as typical runs involving plunging and surging breakers, respectively. In the following, the compared results for Run 4 are presented as a typical run for collapsing breakers.

For Run 4 the surf similarity parameter ξ=3.1, the normalized water depth at the toe of the slope d_t=5.6 and the dimensionless parameter related to wave steepness σ=24. Use is made of the friction factor f'=0.1 after comparing the measured oscillation of the waterline with the computed results using f'=0.1 and 0.2. Fig. 3 shows the normalized measured oscillation $\eta_i(t)$ for the incident wave train specified as input for the numerical computation. Fig. 3 also shows the computed oscillation $\eta_r(t)$ at the toe of the slope associated with the normalized reflected wave train. Fig. 4 shows the comparison between the measured and computed free surface oscillation $\eta_t(t)$ at the toe of the 1:3 gravel slope in which the computed oscillation $\eta_t(t)$ is the sum of $\eta_i(t)$ and $\eta_r(t)$ shown in Fig. 3. Fig. 4 indicates

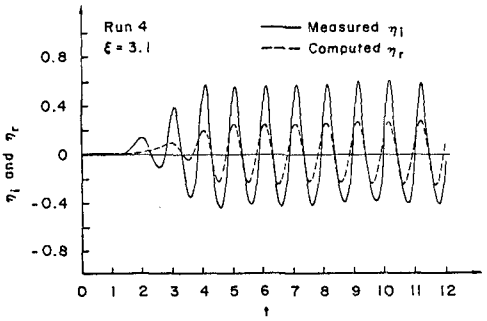

Fig. 3 - Incident and Reflected Wave Trains

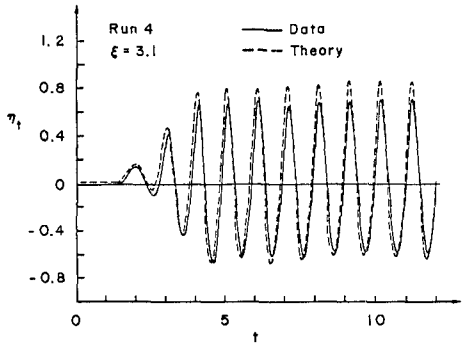

Fig. 4 - Measured and Computed Free Surface Oscillations

appropriateness of the seaward boundary condition used in the numerical model. Fig. 5 shows the comparison of the measured and computed oscillations $z_w(t)$ of the waterline on the 1:3 gravel slope expressed in terms of its vertical elevation relative to SWL normalized by the incident wave height H'. On the other hand, Fig. 6 shows the comparison of the measured and computed dynamic pressure variations at the depth d'=10 cm below SWL expressed in terms of $\eta_p(t) = [p'/(\rho g H')]$ with $p' \approx$ measured dynamic pressure excluding the hydrostatic pressure below SWL. In summary, the agreements between the measured and computed hydrodynamic quantities are similar to those shown in Figs. 4 and 5 but the agreements for η_p are poor for Runs 3 and 4 corresponding to collapsing breakers. The assumption of hydrostatic pressure used in Eq. 2 may not be appropriate at the particular location of the pressure measurement for Runs 3 and 4.

The additional input parameters required for the computation of the hydraulic stability and movement of armor units have been summarized by Kobayashi and Greenwald (15). The lift coefficient C_L alone has been calibrated by trying C_L=0.3 first and then C_L=0.18 or 0.4 if necessary. For Run 4 the lift coefficient C_L=0.3 and the stability number N_s=2.2.

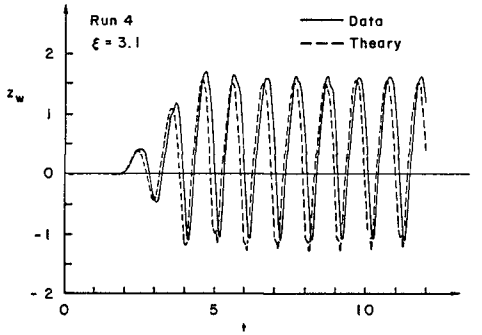

Fig. 5 - Measured and Computed Waterline Oscillations

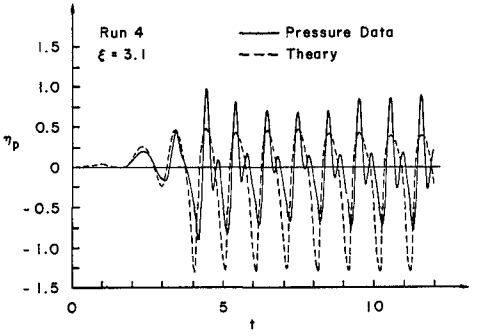

Fig. 6 - Measured and Computed Dynamic Pressure Variations at d'_p = 10 cm

Fig. 7 shows the computed variation of the local stability number N_{sx} defined by Eq. 15 as a function of the normalized vertical location z

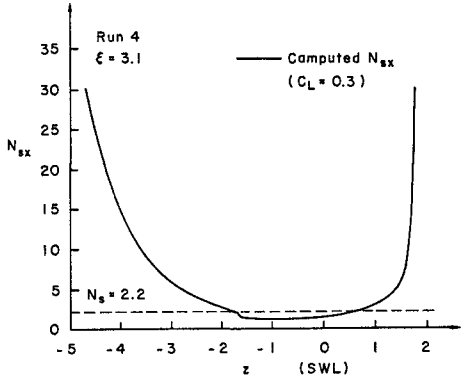

Fig. 7 - Computed Variation of Local Stability Number along 1:3 Slope

relative to SWL along the 1:3 gravel slope. The wave action on the slope is limited in the range $-d_t \leq z \leq R$ where R = computed upper limit reached by the uprushing water above SWL. Loose gravel units placed in the region where $N_s > N_{sx}$ are predicted to move. Fig. 8 shows the comparison between the measured displacements of loose gravel units normalized by the representative length of the units and the computed normalized displacement X_a at the end of the specified incident wave train. The measured and computed values of X_a are plotted as a function of the initial location z on the slope of an individual gravel unit. The negative value of X_a implies the downward movement along the slope. All the measured values of X_a for the eight runs are negative or zero. The data points along the line $X_a=0$ in Fig. 8 correspond to the loose gravel units which are not displaced. On the other hand, the computed points in Fig. 8 include only the displaced units located initially at the finite-difference grid points used for the computation.

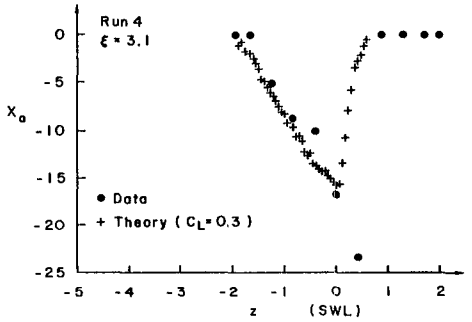

Fig. 8 - Measured and Computed Gravel Unit Displacements

In summary, the agreements between the measured and computed displacements are reasonably good for most of the eight runs.

CONCLUSION

The numerical model developed by Kobayashi et al. (12,13,14) has been show to be capable of predicting the measured quantities related to the wave motion on the riprap slope and the hydraulic stability and movement of riprap units (1,10,15). However, these measurements limited to the quantities which can be measured fairly easily are not sufficient for determining the friction factor f' and the hydrodynamic coefficients C_L, C_D and C_M in a rigorous manner. The fluid velocities and resulting hydrodynamic forces need to be measured so as to better establish these parameters for different armor units. Furthermore, the numerical model needs to be improved and extended to make it as versatile as hydraulic model testing although the present numerical model yields the quantities of practical importance which are difficult to measure.

CHAPTER 145

ON THE SCATTERING OF CONCRETE ARMOUR UNITS OF DETACHED BREAKWATERS DUE TO WAVES

KOHNO, H*., T. UDA** and Y. YABUSAKI***

ABSTRACT

On the Fuji Coast 15 detached breakwaters and 17 wave dissipating breakwaters have been constructed to prevent beach erosion. By virtue of the construction of the breakwaters the retreat rate of the shoreline position has decreased. However a large number of concrete blocks have been scattered due to waves. This study investigates the actual circumstances on the scattering of the concrete armour units of the detached breakwaters through the field observations on the Fuji Coast located in Suruga Bay facing the Pacific Ocean. The change rate of the plane area of the breakwater is examined from the aerial photographs, and the relationships among the parameter, the depth at the offshore foot of the breakwater and the number of the removed concrete armour units are investigated.

I. INTRODUCTION

In recent years beach erosion is severe in Japan. They are caused partly by the construction of dams in rivers, the extraction of sand from rivers, or the influence of the construcion of the harbor structures on the coast. Countermeasure works have been conducted at many locations to improve the condition. The Fuji Coast is one of these coasts, and beach erosion has been caused by the decrease of the fluvial sediment supply from the Fuji River and the interception of longshore sand transport due to the construction of Tagono-ura Port in the middle of the coast. On the coast 15 detached breakwaters and 17 wave dissipating breakwaters, composed of concrete armour units and placed along the shoreline, have been constructed. By virtue of the construction of these breakwaters, the retreat rate of the shoreline position became small. However a large number of concrete blocks have been scattered due to waves, and sometimes fishing nets were damaged by the scattered concrete blocks. The number of the detached breakwaters have been increasing, and hence the stability of the concrete armour units is important for the maintenance of the detached breakwaters or the wave dissipating breakwaters. Nevertheless there are few studies on this kind of problem.

The aim of the study is to investigate the actual circumstances on the scattering of the concrete armour units of the detached breakwaters and the wave dissipating breakwaters by the field investigations on the Fuji Coast. The change rate of the plane area of the breakwater is examined from the aerial photographs, and the relationships

among the parameter, the depth at the offshore foot of the breakwater and the number of the removed concrete armour units are investigated. It is concluded through the study that the change rate of the plane area of the breakwater correlates well with the depth at the offshore foot and it increases with the depth. Furthermore on the detached breakwater the greater the rate of change of the depth at the offshore foot of the breakwater is, the larger the change rate of the plane area becomes. On the wave dissipating breakwater, it is found that the change rate of the plane area correlates well with the total weight of the recovered concrete blocks.

Ⅱ. GEOGRAPHICAL FEATURES OF INVESTIGATED AREA

The Fuji Coast, formed by the fluvial sediment supply of the Fuji River, is located on the bottom of Suruga Bay (Fig. 1). The coast around the river mouth has been eroded since 1960s due to the decrease of the fluvial sediment supply caused by the excavation of sand in the river. Besides, the breakwater of Tagono-ura Port was built between 1959 and 1962, and littoral drift directing eastward was cut due to the presence of the breakwater, so that beach erosion and accretion began on the east and west sides of the breakwater, respectively. On the downdrift coast of the port wave dissipating breakwaters have been placed since 1974 against beach erosion, and detached breakwaters were constructed between the mouth of the Fuji River and the port. By virtue of the construction of the breakwaters, recent retreat rate of the shoreline position became small.

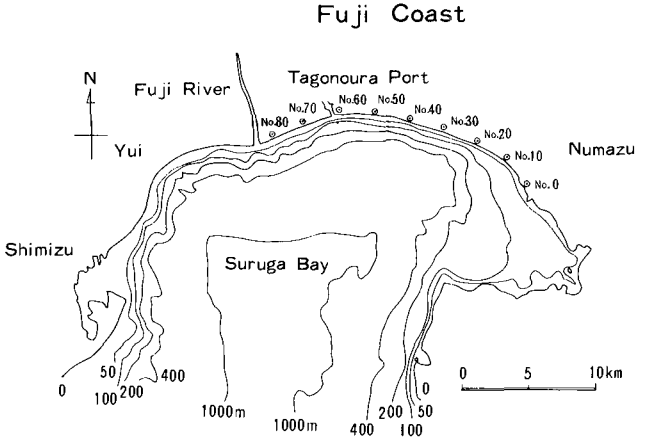

Fig.1 Location of Fuji Coast.

The locations of the detached breakwaters and the wave dissipating breakwaters on the Fuji Coast are shown in Fig. 2. Figure 2 (a) is the arrangement of the detached breakwaters in Fuji region, where is adjacent to the mouth of the Fuji River on the west side and ends by the breakwater of Tagono-ura Port on the east side. The direction of littoral drift in the region is eastward[1),2)], so that the sediment supply

from the Fuji River is carried eastward. The construction of 17 detached breakwaters had been done by using 50-ton concrete armour units (tetrapod) by the order of the number shown in the figure during 1978 through 1984. Similarly Fig. 2 (b) is the arrangement of the wave dissipating breakwaters in Yoshiwara region located on the east side of Tagono－ura Port. On the west side of the region the breakwater of the port was constructed during 1959 through 1962, and littoral transport directing east was obstructed, so that severe beach erosion occurred on the downdrift coast. In order to prevent the shoreline retreat, 17 wave dissipating breakwaters had been constructed by the order of the number shown in Fig. 2 (b) from west to east during 1974 through 1979. These breakwaters were useful for the preservation of the shoreline position, but the scattering of the concrete blocks is severe in recent years. Because of the severity of the scattering of the blocks, the weight of the concrete armour units composing the wave dissipating breakwaters have been increased year by year. At first, 25-ton concrete armour units were used for No. 1 through No. 4 breakwaters built in earlier years. For No. 5 and No. 6 breakwaters, 40-ton concrete armour units were used at offshore part of the breakwater to strengthen the breakwater and to prevent the subsidence of the concrete armour units. Regarding No. 7 through No.17 breakwaters, 25-ton and 40-ton blocks are mixed, and both sides of the breakwaters are strengthened by 50-ton blocks to prevent further scattering of the blocks.

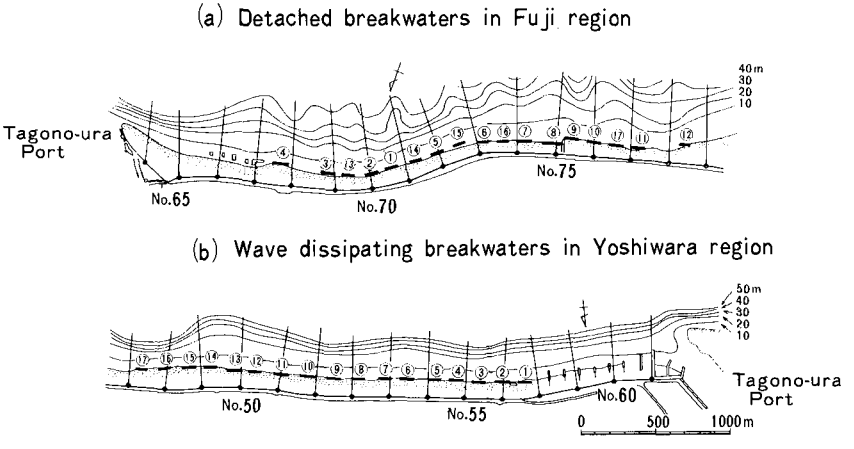

Fig.2 Locations of detached breakwaters and wave dissipating breakwaters on Fuji Coast.

The concrete armour units of the detached breakwaters are set on the sea bed directly without the rock mound in a shallower region than about 6 m, because of the difficulty of the construction of the rock mound on the steep slope beach. Similarly the armour units of the wave dissipating breakwaters are set on the shoreline without the rock mound.

Figure 3 shows the cross section of the beach passing through the center line of No.17 detached breakwater, which is useful to understand the relative location between the coastal dike and the detached breakwater. The distance between the coastal dike and the detached breakwater is around 100m in length, and there are foot protection works and wave breaking works between two structures. Since the beach slope of the Fuji Coast is very steep like as 1/3−1/10, and Suruga Bay, where the Fuji Coast is located, is facing the Pacific Ocean, the incident wave height in the typhoon season becomes so large. For the planned wave condition, significant wave height and wave period are equal to 17m and 20 sec, respectively. Because of frequent attack of high waves, the crown height of the coastal dike is high enough to attain to 17m above the mean sea level. In the sectional view of the beach shown in Fig. 3, the recent beach profiles are also shown. It is found that the sea bed off the detached breakwater was eroded between June, 1985 and February, 1986, and the maximum change of the bed reached to 1.7 m.

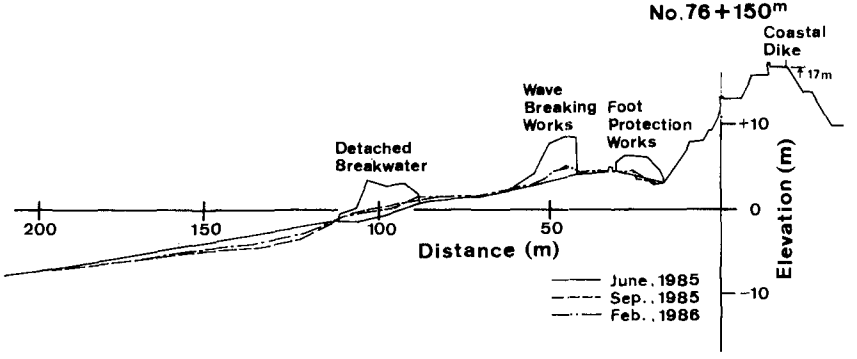

Fig.3 Cross section of the beach passing through the center line of No.17 detached breakwater.

Ⅲ. SCATTERING OF CONCRETE ARMOUR UNITS OF DETACHED BREAKWATERS

For the investigation on the scattering of concrete armour units, the change of the plane area of the breakwater was examined first. The plane shape of the breakwater was traced from the aerial photographs, whose scale is 1/2500, and the change of the shape was determined by the subsequent photographs. Furthermore, the shoreline positions around the breakwaters were also examined, and the relation between the shoreline change and the scattering of the blocks were investigated. The results of the investigation are summarized in Fig. 4. The change of the shape of the detached breakwaters is expressed in an order from east to west. Each breakwater was constructed on the date shown in the figure. Tidal levels in the subsequent photographs differ from each other, but the correction of the shoreline change due to the change of the tide level was not considered, because the beach slope around the

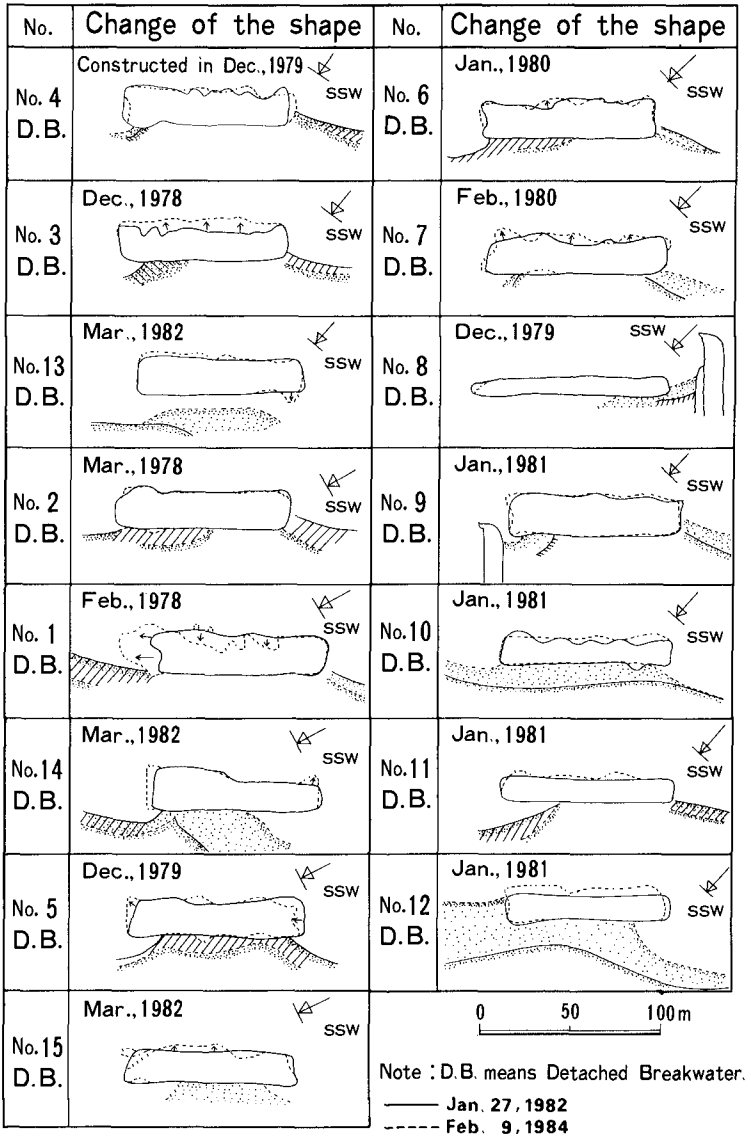

Fig.4 Traces of shapes of detached breakwaters in February, 1982 and February, 1984. Each breakwater was constructed on the dates shown in the figure.

breakwaters is very steep.

During the examination period of change of the form of the detached breakwaters between February, 1982 and February, 1984, high waves of Hmax= 9.85m and H 1/3=7.26m attacked the coast in September, 1982. Large change of the form are observed in No. 3, No. 1, No. 5, No. 15, No. 7 and No. 12 detached breakwaters during the period, and particularly the change of No. 1 breakwater is large. Regarding the general features of the form change of the detached breakwaters, large changes are observed at the offshore side and the east end of the breakwaters. Three causes are considered. First, wave force is large at the offshore side of the breakwater, so that the blocks are apt to be scattered by strong wave force. Second, the east end of the breakwater may be scoured, since the predominant direction of littoral transport is eastward. Thirdly, wave force acts on the blocks obliquely, because wave incidence prevails between S and SSW in storm wave condition on the coast and this wave incidence makes a considerably large angle with the longshore direction of the breakwaters.

The direction of the detached breakwater, θ, measured counterclockwise from South, the offshore distance from the shoreline to some contour lines, ℓ, and the total number, M, and the total weight of recovered concrete blocks, W_T, are expressed in Fig. 5 as well as the arrangement of the detached breakwaters. The abscissa is the number of the survey lines of 250m intervals. The directions of the breakwaters, defined by the angle between the normal of the breakwater and South, at No. 2 through No.15 detached breakwaters differ from those at the other breakwaters over 20 degrees, since the directions of coastline themselves change to a great extent as shown in Fig. 2. The offshore distances from the shoreline to 10, 20 and 30m deep contour lines have such a distinctive feature that they are short between No. 2 through No.15 detached breakwaters. In other words, the bottom slope of the detached breakwater is steep at locations between No. 2 and No.15 breakwaters compared with the other locations. Under such a condition the incident waves are considered to attack the breakwaters without large attenuation of wave energy, so that the scattering of the blocks should be severe at these locations.

On the Fuji Coast the recovery works of the scattered concrete blocks, obstructing the local fishery, have been conducted at offshore zone up to about 10m deep off the detached breakwaters and the wave dissipating breakwaters since 1981. The total number and the total weight of the recovered blocks in Fig. 5 are the summation during the period from October, 1982 to February, 1984. The location where many scattered blocks were recovered agrees well with the one where the normal to the detached breakwater makes a large angle with South, the offshore distances to some contour lines are short, and hence the beach slope is very steep.

Next, the change rate of the plane area of the breakwater (Y), the depth at the offshore foot of the breakwater (h), and the change of the depth ($\triangle$h) from February 1982 to February, 1984 are expressed in Fig. 6. Y is equal to the change of the plane area during the period divided by the area measured in February, 1982. h is obtained in the central section of the breakwater, and in addition $\triangle$h is positive when the water depth increases. In the calculation of the plane area of the breakwaters there are two cases in which the change of the shape of the breakwater protrudes

against the original form and it is depressed to the original one. Here, the change of the plane area is defined by the addition of both changes. The change rate of the plane area of the breakwater, Y, has a fairly large variations alongshore, and its maximum is 0.34 at No. 1 breakwater. It is found that Y is in good correlation with the depth at the offshore foot, h in February, 1984 except the data at No. 12 breakwater, where is close to the river mouth of the Fuji River. Generally the change rate of the plane area, Y increases with the depth at the offshore foot of the breakwaters. To the contrary, it is not in good correlation with h in February, 1982.

On the changes of the depth, $\triangle$h, from February 1982 to February 1984 shown in Fig. 6, the changes are considerably large, that is, maximum increase and decrease of the water depth attain to 2.2m at No. 3 breakwater and −2.2m at No.12 breakwater, respectively. There is a tendency that the depth at the offshore foot of the breakwater having larger number than No. 8, expressing the later construction than No. 8 breakwater, decreases and the depth increases at the older breakwaters than No. 8. This means that sand accumulate not only behind the breakwater, forming a tombolo, but also in the offshore zone of the newly constructed breakwaters,

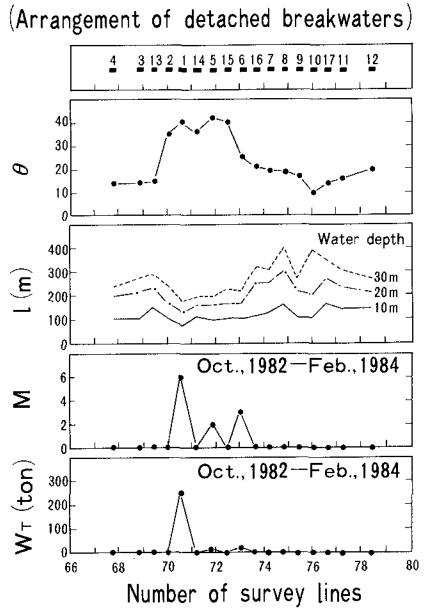

Fig.5 Spatial changes of the direction of the detached breakwater, θ, the offshore distance from the shoreline to some contour lines, ℓ, and the total number, M, and the total weight of recovered concrete blocks, W_T.

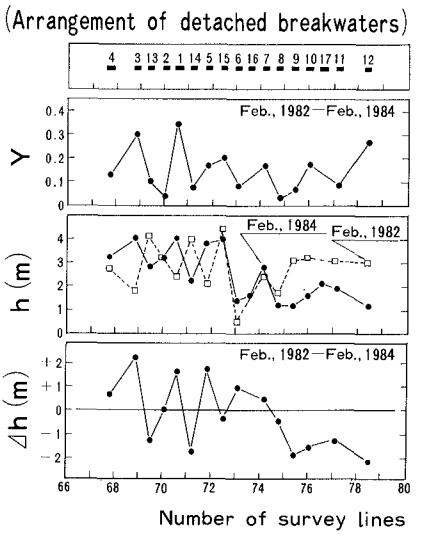

Fig.6 Spatial changes of the change rate of the plane area of the breakwater, Y, the depth at the offshore foot of the breakwater, h, and the change of the depth, $\triangle$h, from February, 1982 to February, 1984.

although the cause is not clearly understood.

Regarding the relation between the change of the depth at the offshore foot of the breakwater, $\triangle h$, and the change rate of the plane area, Y, fairly good correlation can be found. In other words, the change rate tends to increase with the positive change of the depth except No.12 breakwater located close to the river mouth.

The relations among the change rate of the plane area, the depth at the offshore foot and the change of the depth are investigated directly. Figure 7 expresses the relationship between Y and h. The relation is given by the equation

$$Y = 0.019h^2 \qquad (1)$$

where Y is a dimensionless variable and h is the depth in meter unit. The change rate of the plane area increases with the square of the depth at the offshore foot of the breakwater. The relation is considered to be obtained because wave height depends on the water depth strongly near the surf zone where the detached breakwaters are located, and in addition wave force acting on the concrete armour units depends on the wave height at that depth.

The relation between Y and $\triangle h$ is shown in Fig. 8. Two broken lines in the figure are drawn in order to confine almost the lower and upper limits of the data except that at No. 12 breakwater. It is known from the relation that Y also increases as $\triangle h$ becomes large. Namely, this means that the scattering of the concrete blocks becomes severe with the increase of the depth at the offshore foot of the breakwater.

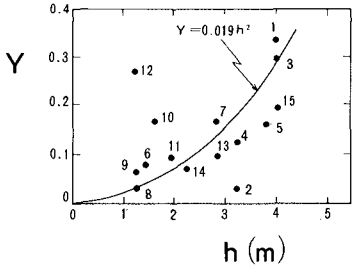

Fig.7 Relationship between the change rate of the plane area of the breakwater, Y, and the depth at the offshore foot of the breakwater, h.

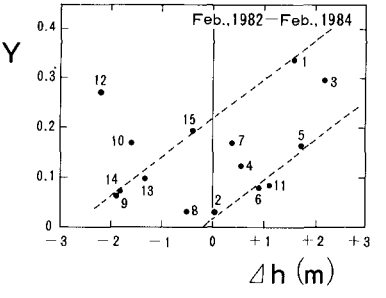

Fig.8 Relationship between the change rate of the plane area of the breakwater, Y, and the change of the depth at the offshore foot, $\triangle h$.

Finally, pictures taken to know the setting condition of the concrete armour units at the offshore foot of the breakwater are shown in Pictures 1 and 2, where No.17 detached breakwater is selected as an example. These underwater photographs were taken at the east end of the breakwater as shown by the circle sign in Fig. 9 on February 20, 1984. The water depth is around 4 m deep. There does not exist the local scouring hole, and bed materials mainly consist of gravels in the vicinity of the

breakwater. Far from the location there extends sandy bed and sand ripples develop. For the reference length for the decision of the ripple scale and diameters of gravels, it can be used that the radius of tip of the leg of 50-ton concrete armour units is equal to 0.455m and in addition the length of the leg is about 1.8 m long. Comparing these scales with the gravels, it is found that the maximum scale of the bed materials are around 10-20 cm.

Picture 1 Underwater picture taken at the offshore foot of No.17 detached breakwater (1).

Picture 2 Underwater picture taken at the offshore foot of No.17 detached breakwater (2).

Owing to the grain size test of the bed materials on the Fuji Coast, generally coarse materials having the median diameter of 10-20 mm are found at the foreshore, and then the diameter of the materials decreases with the water depth. The median diameter in the offshore zone deeper than 6 m becomes less than 1 mm. These features of the grain size distribution of the bed materials agree considerably well with the ones observed in Pictures 1 and 2.

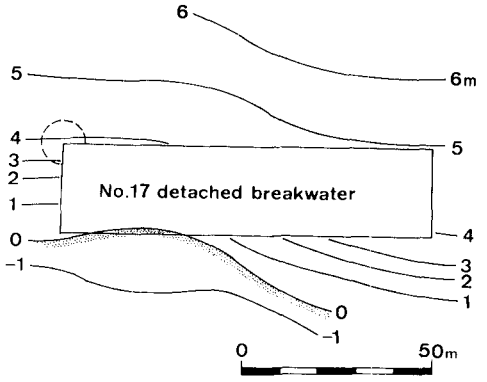

Fig.9 Bottom contours around No.17 detached breakwater measured on February 20, 1984.

V. SCATTERING OF CONCRETE ARMOUR UNITS OF WAVE DISSIPATING BREAKWATERS

Regarding the wave dissipating breakwaters, the same kind of the investigation was carried out as the detached breakwaters by using the aerial photographs. The arrangement of the wave dissipating breakwaters, the direction of the normal to the breakwater, θ, the offshore distance to some contour lines from the shoreline, ℓ, the change rate of the plane area, Y and the depth at the offshore foot of the breakwater, h are expressed in Fig. 10. The total number and the total weight of the concrete blocks recovered between October, 1981 through February, 1984 are also shown. The abscissa is the number of the survey lines of 250 m intervals. The direction of the coastline where the wave dissipating breakwaters were placed is almost uniform as shown in Fig. 2. The direction of the normal to the breakwater, measured counterclockwise from South, does not vary so much alongshore, since the breakwaters are set along the straight shoreline. According to the offshore distances to 10-30m deep contour lines, the bottom slope is steep in the zone deeper than 20m, because the interval of the distances is relatively narrow. The change rate of the plane area, Y, was calculated from the photographs obtained in December, 1979 and February, 1982. The maximum wave height in the period is Hmax=8.6 m, H1/3= 3.5m measured in October, 1981. It is found that Y correlates well with h measured in December, 1979, although its correspondence with the depth in February, 1982 is

not dominant. The depth at the offshore foot, h, was particularly large at four locations of No. 6 , No. 7, No. 10 and No. 11 breakwaters in 1979, but then increased as a whole in February, 1982 because of beach erosion.

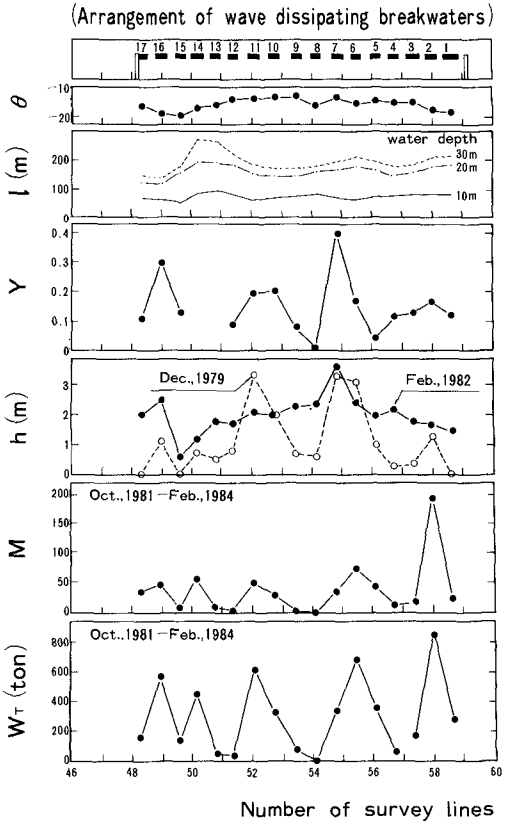

Fig.10 Spatial changes of the direction of the normal to the breakwater, θ, the offshore distance to some contour lines from the shoreline, ℓ, the change rate of the plane area, Y, the depth at the offshore foot of the breakwater, h, the total number, M, and the total weight of the scattered concrete blocks, W_T.

Next, the total number and the total weight of the scattered concrete blocks shown in Fig. 10 are studied. It is understood that there is a good correlation among Y, M and W_T. The total number and the total weight of the scattered blocks increase with Y. The change rate of the plane area of the wave dissipating breakwater determined from the aerial photographs becomes a good parameter for judging the extent of the scattering of the concrete blocks.

Since the longshore distributions of the depth at the offshore foot and the actual

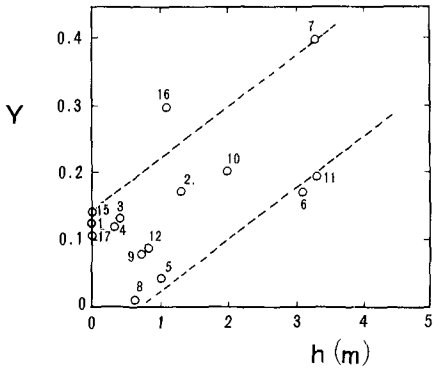

Fig.11 Relationship between the change rate of the plane area of the breakwater,Y, and the depth at the offshore foot of the breakwater,h.

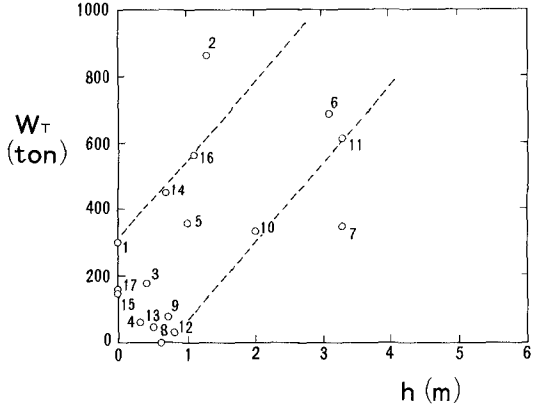

Fig.12 Relation between the total weight of the concrete blocks, W_T, and the depth at the offshore foot, h.

conditions of scattering of the concrete blocks have already been known, the relations among the parameters are studied. The relation between the rate of change of the plane area of the wave dissipating breakwaters, Y, and the depth at the offshore foot of the breakwater, h, measured in December, 1979 is expressed in Fig. 11. There are considerably large scatter in the relation, so that lower and upper limits, enveloping the almost whole data, are shown by the broken lines to decide the mean relation. It is found that a relation stands between the rate of change of the plane area, Y, and the depth at the offshore foot, h, except No.16 wave dissipating breakwater.

$$0.077h - 0.052 < Y < 0.077h + 0.143 \qquad (2)$$

where Y is dimensionless parameter and h is the depth in meter unit. On an average, the change rate of the plane area of the wave dissipating breakwater, Y, is proportional to the depth at the offshore foot of the breakwater, h. Similarly, Figure 12 expresses the relationship between the total weight of the recoverd concrete blocks, W_T, and the depth at the offshore foot of the breakwater, h. There are some scatters in the relation, but almost all data can be confined within two broken lines except No. 2 and No. 7 breakwaters. It should be noted that the total weight of the scattered concrete blocks increases with the greater foot depth.

Finally the weight and the number of the recovered concrete blocks by the sweeping operation of the sea bed are counted at 0.5m deep intervals as shown in Fig.13. In the figure the recovered weight of the detached breakwaters and the wave dissipating breakwaters are shown differently by open and solid circles, respectively. Solid line represents the summed number of the recovered concrete blocks at every 1 m deep interval. It can be concluded from the figure that almost all scattered concrete blocks concentrate on the depths between 6 and 8 m deep. The reason is due to the abrupt change of the beach slope. Taking survey line No.75 for an example, beach slope between the foreshore and 5 m deep contour is steep enough as 1/9, and on the other hand between 5 and 10 m deep contours the slope becomes relatively mild like as 1/25. It may be concluded that it is difficult for the scattered concrete blocks to stop on the steep slope between the foreshore and 5 m deep contour, and that scattered blocks are apt to gather on the bed of relatively mild slope.

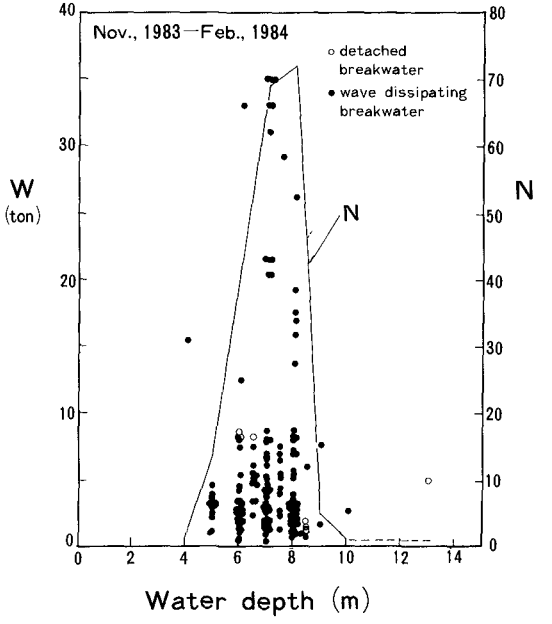

Fig.13 Vertical distributions of the weight and the number of the recovered concrete blocks.

V. SUMMARY OF SCATTERING OF CONCRETE BLOCKS

The relation between the scattering of the concrete blocks and wave conditions is studied based upon the actual results of the recovery of the concrete armour units. Table 1 summarizes the results. The recovery works were carried out during October through February in each fiscal year, and in this study the data from October, 1981 to February, 1983 are summarized. The items of the data summary are the number of the scattered blocks, the total weight of the blocks, the average weight of a scattered block, the maximum weight of the blocks and the average distance of the scattering. Wave conditions observed at Tagono-ura Port or Hara Observatory on the Fuji Coast are also summarized. ΣHmax・t and ΣH1/3・t are the summations of the maximum wave height larger than 5 m and the significant wave height larger than 3 m, respectively, multiplied by the observation period (t= 2 hr) in place of the duration of the waves.

Table 1 Summary of scattering of concrete blocks.

		Oct.1981 −Feb. 1982	Oct. 1982 −Feb. 1983	Nov. 1983 −Feb. 1984
D. B.	M	0	7	4
	Wt (t)	−	254.7	30.7
	$\overline{W}$ (t)	−	36.3	7.7
	Wmax(t)	−	45.1	8.6
	$\overline{X}$ (m)	−	31.6	31.3
	$\overline{W}\cdot\overline{X}$	−	1147	241
W. D. B.	M	43	360	215
	Wt (t)	318.6	3640	1040
	$\overline{W}$ (t)	7.4	10.3	5.1
	Wmax(t)	24.5	46.0	35.0
	$\overline{X}$ (m)	26.1	39.9	41.7
	$\overline{W}\cdot\overline{X}$	193	409	211
	Hmax (m)	6.59	9.85	6.94
	ΣHmax・t	25.5	305.6	78.7
	H⅓ (m)	3.57	7.26	5.0
	ΣH⅓・t	20.3	223.9	46.1

D.B. : Detached breakwater, W.D.B. : Wave dissipating breakwater, M : Number of the scattered blocks, Wt : Total weight of the scattered blocks, $\overline{W}$: Average weight, Wmax : Maximum weight, $\overline{X}$: Average distance of the scattering.

The number of the scattered blocks are less than 10 on the detached breakwater, but on the wave dissipating breakwaters they reach 360 at maximun. The fact that a large number of the concrete armour units are scattered is due to the causes that the beach slope is steep and the beach has been eroded year by year at the sites where the

wave dissipating breakwaters are located, and that the weight of the concrete armour units of the wave dissipating breakwaters is lighter than that of the detached breakwaters. $\overline{W}_B \cdot \overline{X}$, expressing the work done by wave force, is large on the detached breakwaters rather than on the wave dissipating breakwaters. This implies that the wave force acting the blocks of the detached breakwaters is greater than that in a case of the wave dissipating breakwaters. Regarding the comparison of the period, many blocks were scattered from October, 1982 to February, 1983, because maximum significant wave height of about 10 m attacked the breakwater. The average weight of the scattered blocks is less than 10 tons except the data obtained from October, 1982 to February, 1983 on the detached breakwater, although 50-ton blocks are used for the detached breakwaters, and 25, 40 and 50-ton blocks for the wave dissipating breakwaters. It should be noted that almost all scattered concrete blocks are broken ones. Two causes of the damage of the concrete blocks are considered. First, the blocks are damaged directly due to the wave force. Second, the engagement of the blocks is worsen and it is damaged by both dead load of the blocks itself and the wave force.

Ⅵ. CONCLUSIONS

The conclusions obtained through the study are summarized as follows.

(1) The change rate of the plane area of the breakwater calculated by the aerial photographs becomes a good parameter in order to analyse the scattering condition of the concrete armour units of the breakwaters.

(2) There exists a correlation between the change rate of the plane area of the breakwater, Y, and the depth at the offshore foot of the breakwater, h. A relation $Y = 0.019\ h^2$ stands.

(3) Y also becomes large when the rate of increase of the depth h is large.

(4) Concrete armour units of the detached breakwaters were scattered severely at locations where the depth off the breakwater is deeper compared with the average depth and the direction normal to the shoreline makes a large angle with the direction of the incident wave, because of large longshore sand transport.

(5) The change rate of the plane area of the wave dissipating breakwater correlates well with the total weight of the recovered concrete blocks. Due to the actual results of the recovery of the concrete armour units, the average weight of the scattered blocks is less than 10 tons. It is concluded that almost all scattered blocks are broken ones, judging that the initial weight of the blocks is greater than 25 tons.

CHAPTER 146

MEASUREMENT OF REFLECTION COEFFICIENT OF SEAWALL IN OMURA BAY

by

Kosuke Kondo*, Masayuki Akama** and Masahiko Isobe***

ABSTRACT

Field investigations were performed in order to establish the reflecting characteristics of a steel sheet-piling type seawall and two vertical wave-dissipating type seawalls through directional wave measurements of wave reflection systems. A pre-designed line array of several capacitance-type wave gauges was used to measure the wave field just in front of the seawall, and the MMLM (Modified Maximum Likelifood Method) was applied for the calculation of the directional wave spectrum and the reflection coefficient. The estimated directional spectra demonstrated that the MMLM has high resolution power and can sufficiently separate the incident and the reflected wave energies. As a result , it was found that the reflection coefficient of the vertical steel sheet-piling seawall is about 0.9 and is independent of the incident wave conditions, whereas those of the vertical wave-dissipating type seawalls show considerable change in correlation to the incident wave period or the mean water level.

1. INTRODUCTION

Many types of wave-dissipating vertical seawall structures have recently been constructed in Japan in order to reduce the effect of reflected waves from these structures. In designing and constructing them, it is necessary to estimate the reflective characteristics of these structures.

Laboratory flume tests are often performed using a scale model of a seawall. Actual reflection coefficients are, however, expected to be different from those obtained in laboratory flumes because actual sea waves are directionally spread and so measuring the reflection coefficient of seawalls in the field is of great importance.

The following methods have been examined in the field to know the reflection coefficient of prototype structures(Goda,1985):

1) simultaneous measurement of the wave height Hs in front of a structure (at a distance more than one wave length from the structure) and the incident wave height Hi at a location free from the effect of reflected waves;
2) measurement of the directional wave spectrum sufficiently far from the reflective structure where the effect of phase-locking of incident and reflected waves becomes negligible; and
3) application of the method for resolving the incident and reflected wave spectra in a wave flume by using the autocorrelation function (Kajima, 1969) or the fast Fourier transform technique (Goda and Suzuki,1976).

These methods have, however, the following problems. By the method 1, the reflection coefficient is affected too much by a slight change of wave height ratio Hs/Hi. For example, 10% error of Hs/Hi changes the reflection coefficient between 0.1 and 0.7 when the actual reflection coefficient is 0.5. In using the method 2, the dispersion of waves reflected from a finite length of reflective structure has to be considered. The method 3 is only applicable when waves incident to a structure with narrow directional spreading and the mean direction is almost perpendicular to the structure.

Recently, Isobe and Kondo (1984) presented a theory named MMLM (Modified Maximum Likelihood Method) to measure the directional wave spectrum in a wave reflection system and to determine the reflection coefficient of a structure in a directional sea. The object of this study is to confirm the applicability of the MMLM to the field data and to establish the reflecting characteristics of three different types of seawalls through directional wave measurements of wave reflection systems in the field.

2. FIELD INVESTIGATIONS

2.1 Site Description

The field investigations were performed on the eastern shore of Omura Bay, Nagasaki Prefecture, Kyushu, Japan in March, 1982 and in January, 1984. A location map of the investigation site is showen in figure 1. Omura Bay is almost entirely separated from the open sea by the surrounding topography. The scale of the bay is about 20 km north to south and about 10 km east to west. The wave climate is very mild throughout most of the year. The exception is winter when the northwest monsoon sometimes blows and wind waves develop.

During the first investigation in 1982, data for a vertical steel sheet-piling type seawall was collected. After this investigation, two vertical wave-dissipating type seawalls (Type A and Type B) were constructed. In 1984, about half a year after the seawalls were constructed, the second investigation were carried out in order to collect the data for the newly constructed seawalls.

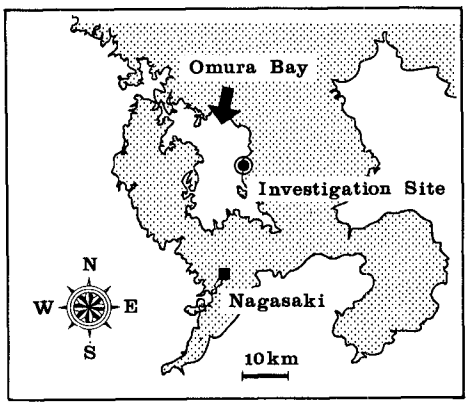

Fig. 1 Location map of the investigation site.

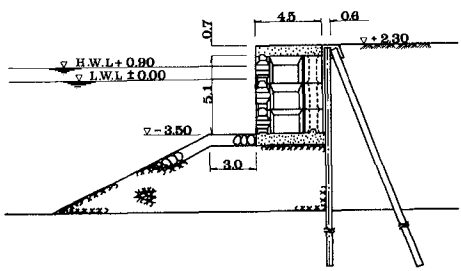

Fig. 2 Schematic profile of the Type A wave-dissipating seawall.

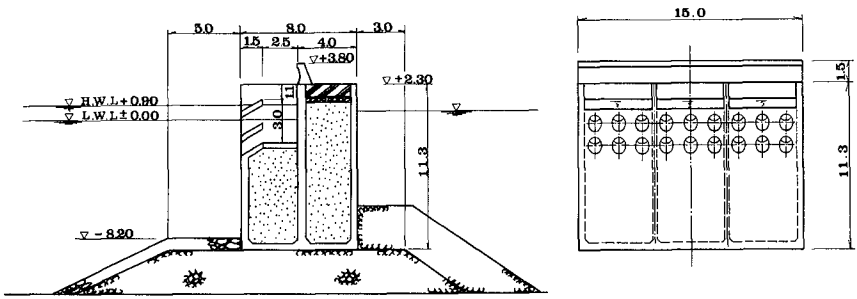

(a) Side view (b) Front view

Fig. 3 Schematic profile of the Type B wave-dissipating seawall.

Schematic profiles of these vertical wave-dissipating type seawalls are given in figures 2 and 3. Type A is a block type. Three concrete blocks with wave chambers are piled up just in front of the steel sheet-piling wall. Type B is a caisson type. As seen in the front view, this type has many sloping holes in its front wall.

2.2 Field Investigation Program

The field investigation program consisted of these three items:

1) measurements of incident and reflected waves in front of the seawall by a line array using three to five capacitance-type wave gauges arranged perpendicular to the wall;
2) measurements of incident waves in the location free from the effect of reflected waves by a line array using two to four capacitance-type wave gauges arranged nearly perpendicular to the wind direction; and
3) measurements of wave height distribution within 1 km of the seawalls using a floating buoy with a twice electronically integrated accelerometer or ultrasonic wave gauges.

In the first investigation, three capacitance-type wave gauges were installed with the distances of 10.0 m, 11.2 m and 13.6 m away from the steel sheet-piling wall respectively, and two capacitance-type wave gauges with an interval of 1.2 m each other were placed about 2 km north of the seawall. The location and arrangement of the wave gauges in the second investigation is explained in figure 4. Five capacitance-type wave gauges were installed just in front of each vertical wave-dissipating type seawall. The incident wave measuring point was located about 2 km north of the seawalls as was in the first investigation, and four capacitance-type wave gauges were arranged with intervals of 2.4 m, 3.6 m and 1.2 m.

A truck-crane was used at the seawalls to support the beam from which wave gauges hung. Several red and white poles were placed at regular intervals between the wave gauges to determine the details of wave height distribution within one wave length of the seawall. This was filmed with a 16 m/m memo-motion camera. At the incident wave measuring point, a small self-elevating platform was used. The wind speed and direction were measured at the level of 10 m over the ground surface at the north cornor of the reclaimed area.

The arrangement of wave gauges just in front of the seawalls in the second investigation was decided by numerical simulation so as to achieve a high resolution power of the directional wave spectrum and high accuracy in estimating the reflection coefficient. Details about the procedure for this numerical simulation will be explained later.

Every analogue record of approximately 5 minutes length was converted to disital record with a sampling interval of 0.1 second. All data were analyzed statistically, including the calculation of significant wave height and period by the zero-up-crossing method. The frequency spectra were computed using the fast Fourier transform technique on records of 2048 samplings with an interval of 0.1 second after the correction of mean water level. The effective number of degree of freedom was about 23.

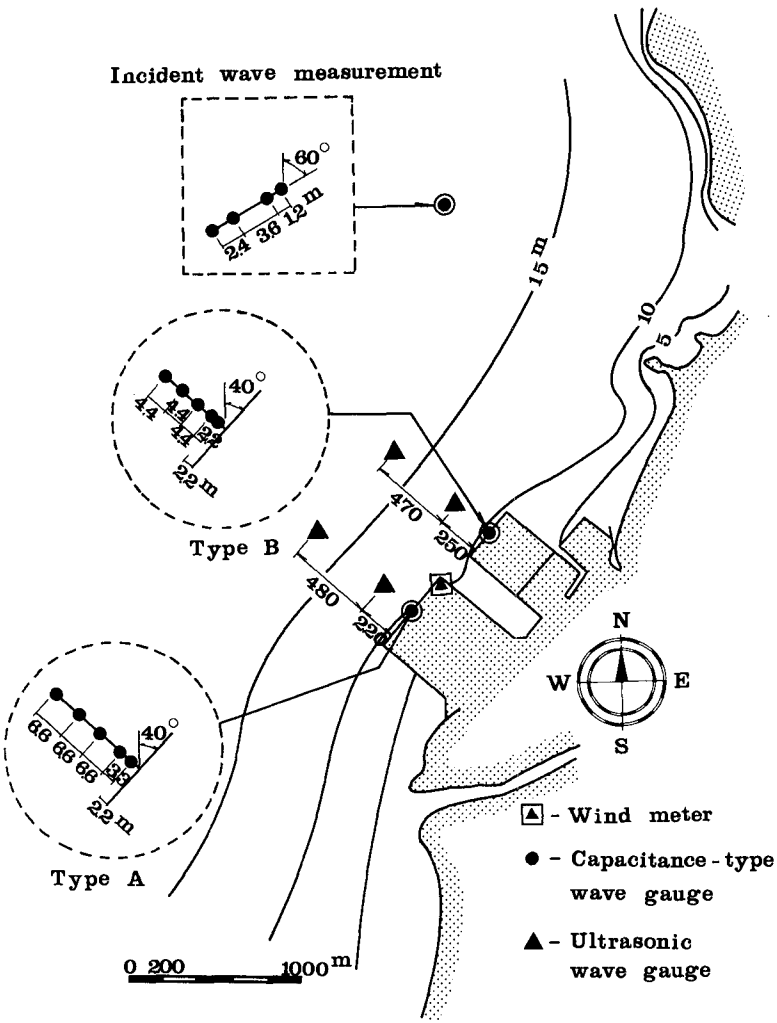

Fig.4 Location and arrangement of the wave gauges in the 2nd investigation.

2.3 Wind and Wave Conditions

The wind and wave conditions during the observation periods are shown in figure 5. From the upper side, wind speed, wind direction, wave height, wave period, wave direction and tidal level are presented. Significant wave height reached 0.5 m to 0.8 m in each observation. Significant wave period was 2.5 seconds to 3 seconds. Most of the observed frequency spectra had the shape that indicated greater part of the energy concentrated around the peak frequency. Wave direction was almost equal to the wind direction, that was north-west, and was nearly perpendicular to the seawalls. The wind conditions in the first investigation changed markedly, whereas in the second investigation rather steady wind conditions prevailed.

Figure 6 compares the height of incident waves and that of waves in front of the seawalls. The incident wave height is indicated by the broken line, and that of waves in front of the seawalls is shown by the black or white circle. The wave height near the seawall is an averaged value of those measured by two or three wave gauges located more than one wave length away from the reflecting surface. In the first investigation, the wave height near the seawall was unexpectedly found to be lower than the incident wave height. This may have been due to the unsteadiness of the wind conditions during the first investigation. Such phenomena were very rare in the second investigation. Comparing the two wave heights in front of the Type A and Type B vertical wave-dissipating seawalls, that of Type A is generally greater, which implys that the reflection coefficient of Type B is smaller than that of Type A.

3. DIRECTIONAL WAVE SPECTRUM

3.1 Basic Formura for Estimating the Directional Spectrum

In the analysis of the directional spectrum with no reflected waves, all the component waves are assumed to be independent, with random and uniformly distributed phase angles. In analyzing the directional wave spectrum in the wave reflection system, however, the fixed phase relation of each pair of incident and reflected wave components should be considered. Therefore, the Modified Maximum Likelihood Method or MMLM was applied for the calculation of the directional wave spectrum and the reflection coefficient. This method is based on the relationship between the directional spectrum and the cross-power spectrum, with extra terms so called phase interaction terms. A directional wave spectrum and a reflection coefficient can be estimated by these two equations.

$$\frac{\alpha}{\hat{S}(\boldsymbol{k},\sigma)} = \sum_m \sum_n \Phi^{-1}_{mn} \exp\{i\boldsymbol{k}(\boldsymbol{x}_n - \boldsymbol{x}_m)\} - \frac{[\sum_m \sum_n \Phi^{-1}_{mn}[\exp\{i\boldsymbol{k}(\boldsymbol{x}_n - \boldsymbol{x}_{mr})\} + \exp\{i\boldsymbol{k}(\boldsymbol{x}_{nr} - \boldsymbol{x}_m)\}]]^2}{4\sum_m \sum_n \Phi^{-1}_{mn} \exp\{i\boldsymbol{k}(\boldsymbol{x}_{nr} - \boldsymbol{x}_{mr})\}} \quad (1)$$

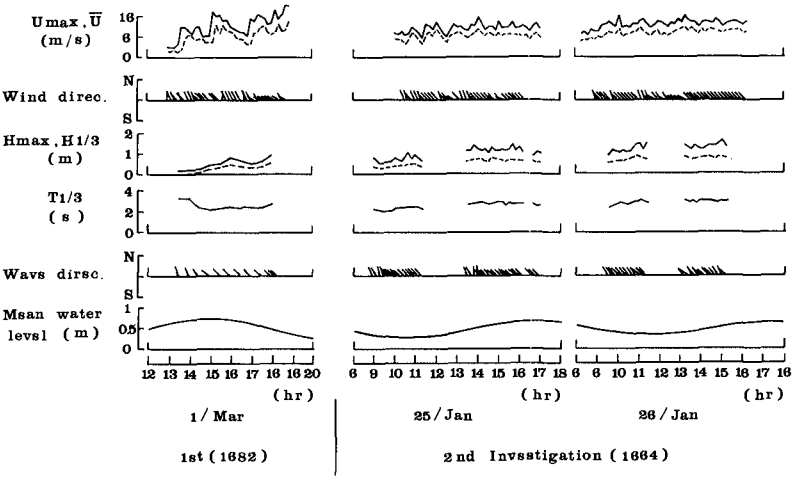

Fig. 5 Wind and wave conditions during the observation period.

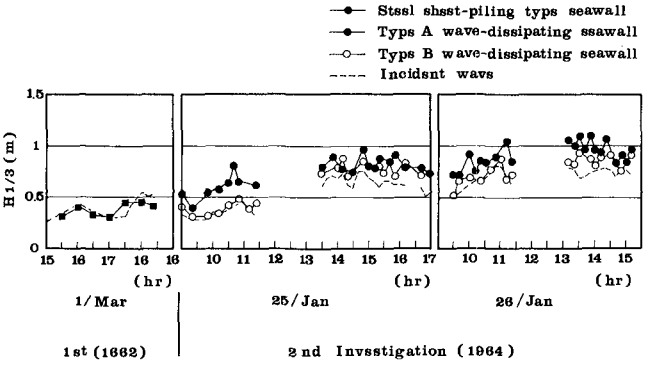

Fig. 6 Comparison between the height of incident waves and that of waves in front of the seawalls.

$$r=-\frac{\sum_m \sum_n \Phi^{-1}_{mn}[\exp\{i\boldsymbol{k}(\boldsymbol{x}_n-\boldsymbol{x}_{mr})\}+\exp\{i\boldsymbol{k}(\boldsymbol{x}_{nr}-\boldsymbol{x}_m)\}]}{2\sum_m \sum_n \Phi^{-1}_{mn}\exp\{i\boldsymbol{k}(\boldsymbol{x}_{nr}-\boldsymbol{x}_{mr})\}} \tag{2}$$

Where $\hat{S}(\boldsymbol{k},\sigma)$ means the estimated wavenumber-frequency spectrum. r denotes the reflection coefficients. $\Phi_{mn}(\sigma)$ is the cross-power spectrum of the water surface variations at point $\boldsymbol{x}_m$ and point $\boldsymbol{x}_n$. And α is a propotionality constant to adjust the power of the spectrum. Without the second term in the right-hand side of equation (1), it completely coincides with that for the standard MLM.

3.2 Design of Wave Gauge Array

The resolution power of a directional wave spectrum of the MMLM depends on the number and the arrangement of wave gauges. Therefore, the design of wave gauge array is one of the most important procedure in planning the measurement of the directional wave spectrum and the reflection coefficient. Numerical simulation was performed prior to the second investigation in order to study adequate arrangements of wave gauges. The procedure for the numerical simulation is as follows:

1) Specify a form for the directional energy distribution $S(\boldsymbol{k},\sigma)$ and the reflection coefficient. Here, the Mitsuyasu-type directional distribution expressed by equation (3) was used. The constant reflection coefficient was assumed for every directional component of waves.

$$S(\boldsymbol{k},\sigma)=\cos^{2s}\{(\theta-\theta_0)/2\} \tag{3}$$

where θ_0 is a principal wave direction and s is a parameter representing the degree of directional energy concentration.

2) Calculate $\Phi_{mn}(\sigma)$ for a given wave gauge array using the relationship between the cross-power spectrum and the directional wave spectrum in an incident and reflected wave field, which is expressed by equation (4).

$$\begin{aligned}\Phi_{mn}(\sigma)=\int_{\boldsymbol{k}} & S(\boldsymbol{k},\sigma)\\ & \times\{\exp(i\boldsymbol{k}\boldsymbol{x}_m)+r\exp(i\boldsymbol{k}\boldsymbol{x}_{mr})\}\\ & \times\{\exp(-i\boldsymbol{k}\boldsymbol{x}_n)+r\exp(-i\boldsymbol{k}\boldsymbol{x}_{nr})\}\,d\boldsymbol{k}\end{aligned} \tag{4}$$

3) Estimate the directional energy distribution from equation (1) and compare to the given one.

A line array with four wave gauges which has a pattern described in figure 7 was analyzed by the numerical simulation, using the values of the parameter s of 5 and 50. In figure 7, Δx is the distance between the first wave gauge and the reflective wall and D is the basic distance between the first and the second wave gauges. The third is located at 2D away from the second and the last is at 4D from the third.

The results indicated that the arrangement, in which Δx is less than 0.5L and D is between 0.2L and 0.3L, is effective for wide range of wave length. In the investigation, one more wave gauge was placed at the middle of the third and the last wave gauges.

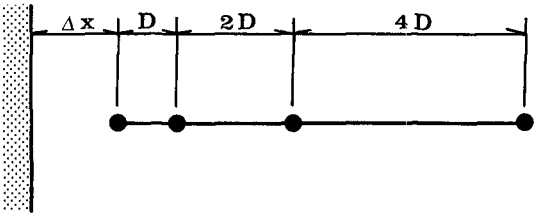

Fig. 7 Definition sketch of wave gauge array

3.3 Analysis of Field Data

Figure 8 shows some examples of the directional wave spectrum estimated from field data with MMLM. These are derived by integrating the wavenumber-frequency spectrum with respect to the frequency. The energy level is normalized by the total wave energy. The directional wave spectra for the incident waves, for the waves in front of the Type A and for the waves in front of the Type B seawall are compared. 0° and 180° are parallel with the line array of wave gauges. These directions are simultaneously perpendicular to the seawall line in figures 8(b) and 8(c).

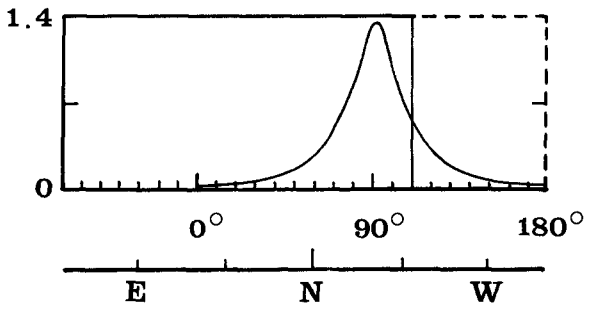
At the incident wave measuring point, the wave direction is nearly perpendicular to the line array and most of the energy concentrates around the peak direction. The estimated directional wave spectrum in front of a seawall has two peaks in the symmetrical positions of 90°, corresponding to the incident and the reflected waves. The directional peaks of the incident and the reflected waves are sufficiently separated.

An example of the normalized directional energy distribution for each frequency is shown in figure 9. The graphs are arranged from bottom to top and from left to right, as the frequency increases. The peak frequency of wave energy is around 0.32 Hz. The separation of the incident waves and the reflected waves is good enough for each frequency.

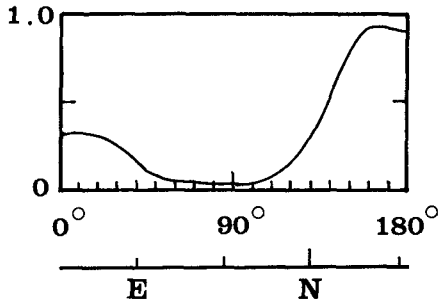
4. REFLECTION COEFFICIENT

4.1 Definition of Reflection Coefficient

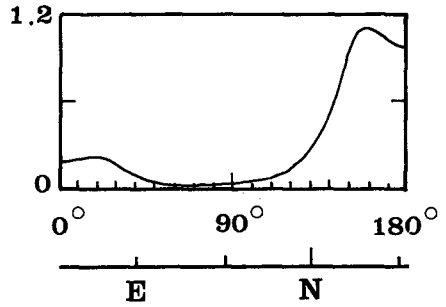
In estimating the reflection coefficient, the following two methods were compared. Equation (2) gives an estimation of the reflection coefficient for each frequency and for each direction. The first method is to adopt this one at the peak frequency and the peak direction. This reflection coefficient is denoted by r_p. The second



(a) Incident waves



(b) Incident and reflected waves in front of the Type A seawall.



(c) Incident and reflected waves in front of the Type B seawall.

Fig. 8 Examples of estimated directional wave spectrum (1984/1/26, 13:30).

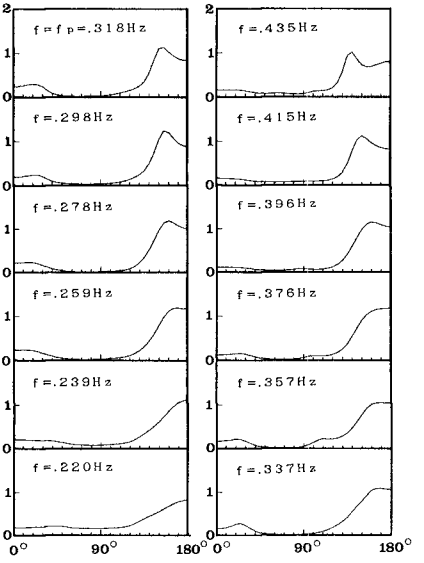


Fig. 9 An example of directional energy distribution for each frequency.

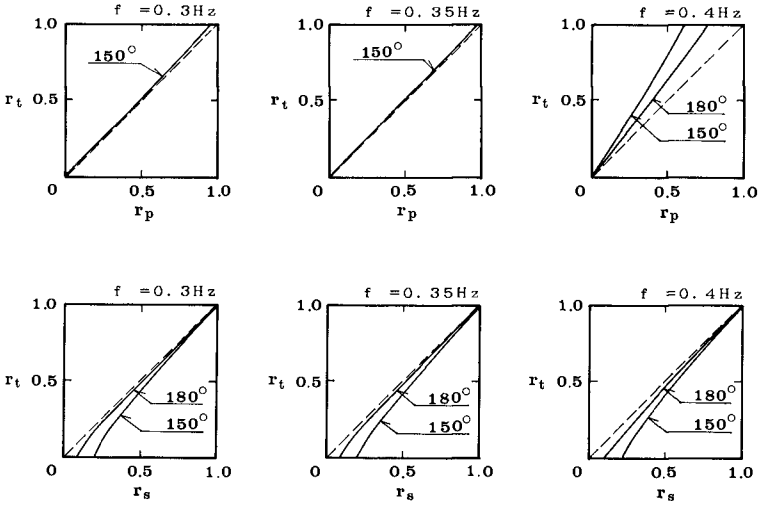

Fig. 10 Comparison between estimated and true reflection coefficients.

method is to adopt the square root of the ratio between the integrated reflected and incident wave energy. This reflection coefficient is denoted by r_s. The correspondence between the true reflection coefficient and the estimated one was analyzed by numerical simulation.

The results are presented in figure 10. In each graph the horizontal axis is an estimated reflection coefficient r_p or r_s and the vertical axis is a true reflection coefficient r_t. Three different frequency cases are shown for both r_p and r_s. The arrangement of wave gauges was assumed as that adopted in front of the Type B seawall. It can be found that r_p gives a fairly accurate value for the full range of the reflection coefficient when the peak frequency is between 0.3 and 0.35. Should the peak frequency be 0.4, r_p tends to underestimate in the high reflection range. When the true reflection coefficient is larger than 0.5, r_s gives a fairly good value for all frequencies.

4.2 Reflecting Characteristics of Seawalls

Tabel 1 shows the reflection coefficients of the vertical steel sheet-piling seawall estimated for twelve occasions of measurement. The incident wave direction, defined as an angle from the normal direction of the seawall line, varied between -20° and 30°. The peak frequency of the incident wave was between 0.34 and 0.44. The reflection coefficient is independent of the direction and the peak frequency of the incident wave and shows rather stable values between 0.85 and 1.0 with a mean value of 0.92.

Figure 11 shows the relationship between the relative width of wave chamber to wave length (l/L) and the reflection coefficient of the Type A wave-dissipating seawall. The wave length was calculated for the peak frequency of the incident wave. The reflection coefficient shows the minimum value of 0.3 at $l/L = 0.25$ and the maximum value of 0.9 at $l/L \approx 0.5$. This is the same tendency as was obtained by Tanimoto and Yoshimoto (1982) in the wave flume experiment for a vertical slit caisson (figure 12).

The reflection coefficient of the Type B wave-dissipating seawall was also plotted against l/L, but there seems to be poor correlation (figure 13). Figure 14 shows the relationship between the mean water level and the reflection coefficient. The reflection coefficient of the Type B doesn't depend on l/L, but has a good correlation to the mean water level. This is considered to be caused by the relative position of the holes through the front wall of the caisson and the water surface level under the condition of rather low wave height compared to the size of the holes.

The tendencies of the reflection coefficient changes stated above was also confirmed by the results of the wave height distribution measurements carried out simultaneously in the front area of the seawalls.

5. CONCLUSIONS

The MMLM was applied to the field data in order to estimate the reflection coefficients of three different types of seawalls. The estimated directional wave spectra demonstrated that the MMLM has high resolusion power and can sufficiently separate the incident and the reflected wave energies.

As a result , it was found that the reflection coefficient of the vertical steel sheet-piling seawall is about 0.9 and is independent of the direction and the period of the incident wave, whereas those of the vertical wave-dissipating seawalls show considerable change in correlation to the incident wave period or the mean water level.

The design of wave gauge array is one of the most important procedure in planning the measurement of the directional wave spectrum and the reflection coefficient. It was possible in this study to determine the arrangement of wave gauges by numerical simulation so as to achieve a high accuracy in estimating the directional spectrum and the reflection coefficient since the dominant wave period and direction at the study area had been known before the investigation. Much more analysis by numerical simulation and understanding of the applicable limit of a wave gauge array used may be necessary in the measurement in an open sea, where the wave condition changes in a wide range of wave period and direction.

ACKNOWLEDGEMENTS

The authors express their appreciation to Mr. R. Kajima of the Central Research Institute of Electric Power Industry for his valuable consultation and advice. We would also like to thank Mr. K. Kaneko and Mr. T. Oku of the Kyushu Electric Power Co., Ltd. for their support to this study and for their permission to publish this paper.

CHAPTER 147

WAVE ENERGY DISSIPATION IN ARBITRARILY SHAPED HARBOURS OF VARIABLE DEPTH

J.K. Kostense*, K.L. Meijer*, M.W. Dingemans*,
A.E. Mynett* and P. van den Bosch*

ABSTRACT

A finite element model for combined refraction-diffraction problems of linear water waves has been extended to include the effect of various dissipative mechanisms on wave excitation response in harbours of arbitrary shape and variable depth. Especially, the effects of bottom friction, partial absorption along the harbour contours, and transmission through permeable breakwaters have been considered. Although, within the mild slope approximation, the model is valid for arbitrary wave lengths, in this paper its effectiveness for harbour design applications is demonstrated for long wave induced resonance phenomena. For this purpose a realistic harbour geometry has been selected. A hydraulic scale-model of this harbour enabled experimental verification of the computational results.

1. INTRODUCTION

The propagation of linear time-harmonic waves in areas of variable depth can be described by the mild-slope equation, as derived by Berkhoff (1972). He solved the equation using a hybrid finite element method, representing the solution in the exterior by a continuous distribution of sources along the radiating boundary. A more elegant approach, resulting in symmetric matrices, was formulated by Chen and Mei (1974). They used a series expansion in terms of Hankel functions for the radiating waves and included the unknown expansion coefficients in a variational formulation.

After the introduction of a partially reflective boundary condition, Berkhoff (1976) could use his model to compute the wave disturbance in harbours with arbitrary reflective properties. As all absorbing conditions for numerical models, this condition cannot maintain the rate of energy dissipation for waves of different angles of incidence. Behrendt (1985) showed how to approximate the perfect boundary condition to higher order.

Booij (1981) suggested a modification of the mild-slope equation to account for the effect of bottom friction by adding a dissipative term. Dingemans (1985) considered the effect of bottom dissipation for shallow water conditions and shows the analogy between the obtained equations and the modified mild-slope equation. Dalrymple et al. (1984) have given several forms of the extra dissipation term for different energy dissipation mechanisms. Liu et al. (1986) showed that the extra term even can

* Delft Hydraulics, the Netherlands

be used to estimate the effects of reflective and transmissive breakwaters in numerical models based on the parabolic approximation of the mild-slope equation. On the other hand, Behrendt (1985) included the effect of bottom friction in the original mild-slope equation by formulating the energy loss as a flux of complex energy through the bottom.

Especially for very long waves the energy loss at the harbour entrance due to flow separation may be important. The modelling of a quadratic flow separation term can be incorporated in a numerical model by amending the matching conditions for pressure and normal velocity at the harbour entrance, see e.g. Berger (1986), who considered diffraction only.

Dissipation mechanisms may have a considerable influence on the wave disturbance in harbours, either for short period wind waves and swell, or for long period waves (tsunamis etc.), or both. For long waves resulting in harbour resonances the peak amplitudes at resonance are influenced by a number of mechanisms, see e.g. Mei (1983):

- radiation damping, i.e. energy escaping seaward from the harbour entrance,
- partial absorption along harbour boundaries due to wave breaking and frictional losses, including internal losses in permeable breakwaters,
- bottom friction,
- flow separation near the harbour entrance,
- finite-amplitude effects of energy transfer into higher harmonics.

Apart from the finite-amplitude effects, all these mechanisms can be accounted for in a newly developed numerical model solving the mild-slope equation. When finite-amplitude effects are expected to be the dominant mechanism, a model based on the Boussinesq equations for shallow water conditions could be applied, see e.g. Abbott et al. (1978).

The newly developed model solves the modified mild-slope equation accounting for bottom friction, and is equipped with a variety of options for appropriate boundary conditions, including one for combined reflection and transmission. To illustrate the effectiveness of the model for harbour design, a series of long wave computations is discussed for one specific realistic harbour geometry (see Fig. 1). Part of these computations have been compared with hydraulic scale-model experiments.

2. MODIFIED MILD SLOPE EQUATION

The mild-slope equation as derived by Berkhoff (1972, 1976) is a two-dimensional depth-integrated elliptic wave equation governing the propagation of linear time-harmonic waves in areas of moderate slope. The modified equation including the dissipation term as suggested by Booij (1981) reads

$$\nabla.(cc_g\nabla\phi) + cc_g(k^2 + ik\gamma)\phi = 0, \tag{1}$$

where $\phi(x,y)$ denotes the two-dimensional velocity potential in the horizontal plane, related to the total potential $\Phi(x,y,z,t)$ according to

$$\Phi(x,y,z,t) = \phi(x,y)\,\frac{\cosh k(h+z)}{\cosh kh}\,e^{-i\omega t}. \tag{2}$$

In Eq. 1, c, c_g and k represent the phase velocity, the group velocity and the wave number, respectively, which can be evaluated from the linear dispersion relation. The funtion γ is defined as W/c_g, where W is the rate of energy dissipation per unit wave energy intensity.

In order to derive Eq. 1, including the effect of energy dissipation due to bottom friction, the principle of virtual work may be employed. Notice in this respect that the original mild-slope equation was obtained by application of a variational principle, and that variational principles are especially suited for conservative systems. However, this approach would be rather intricate and will not be followed here. Instead, Eq. 1 will be made plausible by showing the analogy to the result for shallow water waves. For the case of shallow water, the vertically integrated continuity equation and the horizontal momentum equation read in linearized form

$$\frac{\partial\eta}{\partial t} + \nabla.(\vec{hu}) = 0 \quad , \quad \frac{\partial\vec{u}}{\partial t} + g\nabla\eta + \frac{\vec{\tau}}{\rho h} = 0 \ , \tag{3}$$

where $\vec{\tau}$ is the bottom shear stress vector, for which the friction law

$$\vec{\tau} = \frac{1}{2}\,f_w\,\rho|\vec{u}_b|\vec{u}_b \tag{4}$$

is taken, where $\vec{u}_b$ is the wave velocity just outside the bottom boundary layer. With $\vec{u}_b = \vec{u}/\cosh kh$, according to linear theory, the term $\vec{\tau}/\rho h$ is linearized as $W\vec{u}$, so as to obtain the same amount of dissipation over one wave period. This results in

$$W = \frac{4f_w}{3\pi h}\,\frac{1}{(\cosh kh)^2}\,u_e, \tag{5}$$

where f_w is the wave friction coefficient, and u_e represents the effective amplitude of the horizontal velocity

$$u_e = \frac{3\pi}{8}\int_0^T(\vec{u}.\vec{u})^{3/2}dt \;/\; \int_0^T(\vec{u}.\vec{u})dt \ . \tag{6}$$

The product $(\vec{u}.\vec{u})$ can be written as

$$\vec{u}.\vec{u} = p + q\cos(2\omega t - \alpha), \tag{7}$$

where p and q are functions of the derivatives of the real and imaginary parts of the velocity potential $\phi(x,y)$ with respect to x and y. Substituting Eq. 7 into Eq. 6, one obtains after some algebraic manipulation

$$u_e = \sqrt{p+q}\ \{E(m) - \frac{1}{4}(1 - \frac{q}{p})K(m)\}, \qquad m = \frac{2q}{p+q}\ , \tag{8}$$

in which K(m) and E(m) denote the complete elliptic integrals of the first and second kind, respectively, and m is the elliptic parameter. Notice that for p=q the horizontal velocity components are in phase, and the effective velocity amplitude equals the amplitude of the unidirectional velocity $\hat{u}$. Upon combination of the continuity and the momentum equation, and introducing the velocity potential, one obtains for time-harmonic motion

$$\nabla.(gh\nabla\phi) + gh(k^2 + \frac{ikW}{\sqrt{gh}})\phi = 0\ . \tag{9}$$

Because of the close resemblance between this equation and the unmodified mild-slope equation for shallow water, where $c = c_g = \sqrt{gh}$, it seems reasonable to model wave dissipation in the mild-slope equation according to Eq. 1.

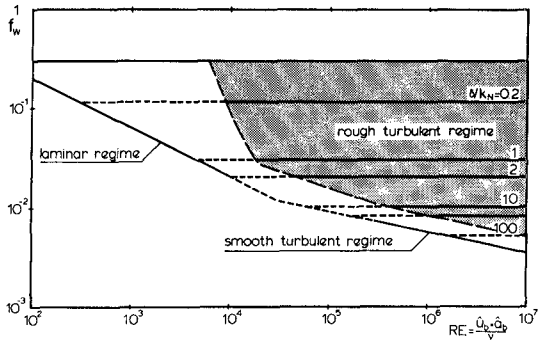

Figure 3 Wave friction coefficient f_w for different boundary layer regimes, see Jonsson (1978)

To determine the wave friction coefficient f_w, as defined in Eq. 4, the relations derived by Jonsson (e.g. 1978) have been used. Jonsson distinguishes three relations for the different types of boundary layers (see Fig. 3):

- laminar regime: $f_{w,l} = 2\ (RE)^{-0.5}$ (10)
- smooth-turbulent regime: $f_{w,s} = 0.09\ (RE)^{-0.2}$ (11)
- rough-turbulent regime: $f_{w,t} = 0.0605/(\log \frac{27\delta}{k_N})^2$. (12)

Moreover, the friction coefficient has a maximum value:

$$f_w \leq 0.30\ . \tag{13}$$

In these relations the amplitude Reynolds number is defined as

$$RE \equiv \frac{\hat{u}_b\ \hat{a}_b}{\nu}\ , \tag{14}$$

where ν denotes the kinematic viscosity, and $\hat{a}_b$ represents the amplitude of the particle excursion at the bed. The thickness of the rough-turbulent boundary layer, δ, can be determined from

$$\delta = 0.072 \, (\hat{a}_b k_N)^{0.25}, \tag{15}$$

where k_N is the well-known Nikuradse roughness parameter. Although the above equations have been derived for unidirectional oscillating flow conditons, $\hat{u}_b$ can be approximated by $u_e/\cosh(kh)$ and $u_e/[\omega\cosh(kh)]$, respectively (see Eq. 6). In nature the boundary layer will always be rough-turbulent. However, as all regimes have been implemented in the numerical model, small-scale hydraulic model conditions can be handled too. This is especially useful for verification studies.

Eq. 1 is solved by means of standard finite element techniques, using triangular elements with linear interpolation functions. The non-linearity, as introduced by the dissipation term, is treated in a straightforward iterative way. If the bottom friction is a predominant dissipation factor, which can be the case for harbour resonance problems, an average number of 3 to 5 iterations appears to be adequate to obtain reliable results. However, if the bottom friction is only a secondary dissipative effect, as for most problems where short wind waves are involved, 2 iterations are already sufficient in most cases.

3. BOUNDARY CONDITIONS

Different types of boundary conditions have been implemented in the finite element model, viz.

- radiation conditions,
- a wave-maker condition,
- a condition for partial reflection, and
- a condition for combined partial reflection and transmission.

Radiation damping can be treated in two ways. Both methods match the finite element region and the outer region, where constant depth is assumed by requiring the continuity of pressure and normal velocity. The first method, applied by Berkhoff (1972, 1976), is to represent the solution in the outer region by a continuous distribution of sources along the open boundary:

$$\phi_s = \int_A u(M) \, \frac{1}{2i} \, H_0^1(kr) \, ds \, , \tag{16}$$

where ϕ_s is the velocity potential of the scattered waves, A is the open boundary, and $H_0^1(kr)$ denotes the Hankel function of the first kind and zero'th order. The unknown source strength $\mu(M)$ at point M must be solved along with the inner region by requiring the two matching conditions. Chen and Mei (1974) succeeded to incorparate the matching conditions as natural boundary conditions in a variational principle by representing the velocity potential of the scattered waves as a series expansion of Hankel functions,

$$\phi_s = \sum_{n=0}^{\infty} H_n^1(kr) \, (\alpha_n \cos n\Theta + \beta_n \sin n\Theta) \, , \tag{17}$$

where r and Θ are polar co-ordinates. Again, the coefficients α_n and β_n are determined by matching with the solution in the inner region. Both methods have been implemented in the numerical model. In general, the second method is to be recommended, as it results in a symmetric matrix. However, as the region to be modelled will generally be larger for this method, sometimes the source method may be preferable, especially for harbours and bays with wide openings.

To be able to compare with hydraulic model experiments, a wave-maker condition is very useful. The implemented condition reads

$$\frac{\partial \phi}{\partial n} + ik\tilde{\phi} = 0 \ , \tag{18}$$

where $\tilde{\phi}$ is the velocity potential of the generated waves, and n is the direction normal to the wave paddle. As can be simply derived, Eq. 18 implies a 100% reflective paddle.

Partially reflective harbour contours are modelled with the well-known equation (see e.g. Berkhoff, 1976)

$$\frac{\partial \phi}{\partial n} - ik(1-r)\phi = 0 \ . \tag{19}$$

This condition will work for all kinds of incident wave systems in regions of variable depth, and for curved boundaries. However, to relate the actual reflection coefficient R to the complex coefficient r, a long-crested wave incident on a straight boundary in constant water depth is assumed, i.e.

$$\phi = \phi_i e^{i(kx\cos\alpha - ky\sin\alpha)} + R\phi_i e^{i(kx\cos\alpha + ky\sin\alpha + \rho)} , \tag{20}$$

where ρ denotes the phase shift at the boundary. Subsitution in Eq. 19 yields

$$Re^{i\rho} = \frac{\sin\alpha - 1 + r}{\sin\alpha + 1 - r} , \tag{21}$$

showing the dependence of R on the angle of incidence α.

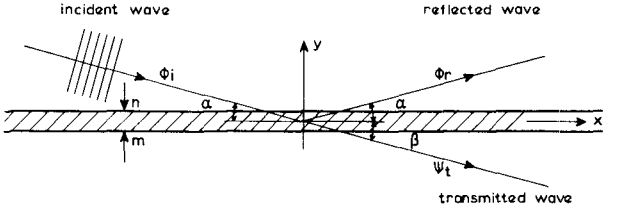

Figure 4 Definition sketch for a transmitting boundary

Analogously to Eq. 19 a boundary condition for combined reflection and transmission has been developed, assuming equal reflection and transmission characteristics in both directions, i.e. symmetrical constructions. The velocity potentials on either side of the transmitting boundary are denoted as ϕ and ψ, where

$$\phi = \phi_o + \phi_t \quad , \quad \psi = \psi_o + \psi_t . \tag{22,23}$$

The subscript t refers to that part of the local potential which originates from transmission, see Fig. 4 for a reference sketch. The general form of the boundary condition consists of the following set of four equations

$$\psi_t = s\phi_o \quad , \qquad \phi_t = s\psi_o \tag{24,25}$$

$$\frac{\partial\phi_t}{\partial m} = -t\frac{\partial\phi_o}{\partial n} \quad , \qquad \frac{\partial\phi_t}{\partial n} = -t\frac{\partial\psi_o}{\partial m} \quad , \tag{26,27}$$

where s and t are complex coefficients. Eq. 19 for ϕ_o and a similar one for ψ_o, Eqs. 22, 23 and similar ones for the normal derivatives of the potential, and Eqs. 24 to 27 constitute a set of 10 equations for 12 unknowns. Elimination yields the following two equations in terms of the potentials ϕ and ψ, and their respective normal derivatives:

$$(1-s^2)\frac{\partial\phi}{\partial n} - ik(1-r)\{(1+st)\phi - (s+t)\psi\} = 0 \tag{28}$$

$$(1-s^2)\frac{\partial\psi}{\partial m} - ik(1-r)\{(1+st)\psi - (s+t)\phi\} = 0 \ . \tag{29}$$

Across the boundary the velocity potential jumps discontinuously, which can be numerically treated by means of line elements with double nodes. To achieve full reflection for r = 1, as well as non-transmission for t = 0, the coefficient s has been taken to be

$$s = (1-r)t \ . \tag{30}$$

Again assuming long-crested waves in constant water depth, the velocity potential on either side of the boundary may be described by Eq. 20 along with

$$\psi = T\phi_i e^{i(kx\cos\beta - ky\sin\beta + \tau)} , \tag{31}$$

where τ denotes the phase shift of the transmitted wave over the barrier, see also Fig. 4 for the reference system. For $\beta = \alpha$, substitution of Eqs. 20 and 31 in Eqs. 28 to 30 yields

$$Re^{i\rho} = \frac{-t^2(1-r)^2(1-\sin\alpha)(1+\sin\alpha) + (1-r+\sin\alpha)(1-r-\sin\alpha)}{+t^2(1-r)^2(1-\sin\alpha)^2 - (1-r+\sin\alpha)^2} \quad \text{and} \tag{32}$$

$$Te^{i\tau} = \frac{-2t(1-r)(2-r)\sin\alpha}{+t^2(1-r)^2(1-\sin\alpha)^2 - (1-r+\sin\alpha)^2} \ . \tag{33}$$

As an example, for t = 1 and $\rho = \tau = 0$ these equations result in

$$R + T = 1 \ , \tag{34}$$

which implies a rate of energy dissipation

$$D = 1 - R^2 - T^2 . \tag{35}$$

Eq. 34 has been derived by Madsen and White (1975) for a permeable breakwater and long waves. Fig. 5 shows the dependency of R and T on the angle of incidence, also for t = 1 and $\rho = \tau = 0$. For normally incident waves Eqs. 32 and 33 reduce to

$$Re^{i\rho} = \frac{r}{2-r} \qquad \text{and} \qquad Te^{i\tau} = \frac{2t(1-r)}{2-r} \ . \tag{36,37}$$

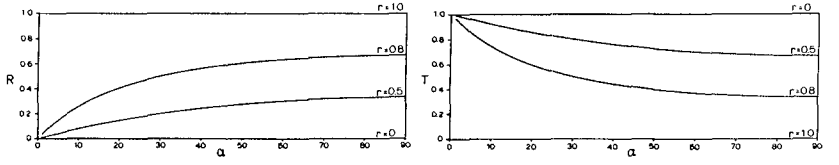

Figure 5 Reflection (R) and transmission (T) coefficients as functions of the angle of incidence (α); $t = 1$, $\rho = \tau \approx 0$

Apart from transmission through permeable breakwaters, the transmission conditions might be also applied to approximate the effect of energy loss due to flow separation at the harbour entrance, and at protruding structures within the harbour. The usual formulation for the energy loss at the harbour entrance is

$$\eta^- - \eta^+ = \frac{f_e}{2g} u|u|, \tag{38}$$

where η^- and η^+ denote the free-surface displacements on either side of the constriction, and u is the velocity component normal to the entrance. In the equation the apparent inertia term has been neglected, which is acceptable for long waves. Unfortunately, direct empirical knowledge of the friction coefficient f_e is hardly available, but generally f_e is assumed to be ≤ 1.5.

4. SOME APPLICATIONS FOR A COMPLEX HARBOUR GEOMETRY

The model has been satisfactorily verified for a variety of simple configurations, permitting a comparison with analytical solutions. The verification programme included the classical Homma island surrounded by a parabolic shoal, a rectangular harbour with constant depth, and obliquely incident waves over a linearly sloping bottom with constant depth at both sides. After these verifications the model has been used in normal laboratory advice practice, mostly to study harbour responses due to wind waves and swell. The model has recently been implemented on a CRAY-XMP supercomputer. Taking full advantage of the vector-processor, the sytem of equations is solved quite efficiently. Until now, the largest system which has been solved, referred to a grid of 37,000 nodal points for a 10 second wave computation without bottom dissipation in an area of about 10 km^2. The CPU time to execute this computation was about 2 minutes.

Hereafter, some results of further research will be shown to illustrate the effectiveness of the numerical model to solve harbour resonance problems. It is well known that harbour oscillations induced by long waves may result in considerable hazards for e.g. moored ships. Although a variety of forcings can be responsible for these oscillations, the most studied forcing is due to incident free long waves (tsumamis etc.). Until now, most numerical models mainly predict the natural frequencies of the harbour and the corresponding oscillation modes. However, there is an increasing need for realistic peak amplitudes at resonance, especially for numerical methods to determine the dynamic behaviour of moored vessels inside a harbour, see e.g. Mynett et al. (1985). To examine whether this model could fulfil this need, a series of computations was

performed for a realistic harbour geometry (see Fig. 1). The choice of this specific lay-out enables the comparison with experiments in a physical model having a length scale of 1:80. The harbour area of about 1 km^2 is divided into two parts by an inner breakwater. The main part has been dredged to -9.0 m; the shallow part accomodates fishing-boats etc. All computations and experiments have been carried out for a water level of Chart Datum + 1.25 m. For the computations three different finite element grids have been used, viz.

- grid no. 1, including the harbour area only, and having scale-model dimensions (see Fig. 2),
- grid no. 2, reproducing the scale-model (see Fig. 9), and
- grid no. 3, reproducing the harbour and surroundings at natural scale (see Fig. 13).

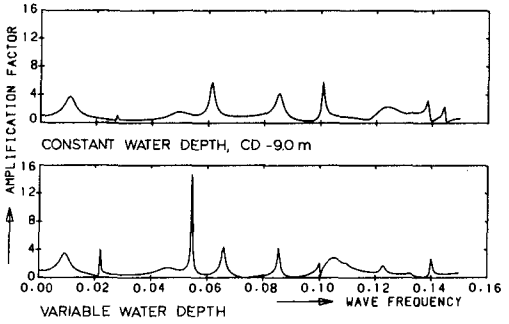

Figure 6 Harbour response at position B for constant and variable depth; radiation damping only, grid no.1

Grid no. 1 was used for some first computations on the effects of the variable depth and the (laminar) bottom friction. The direction of the incident waves was 30° from North (see Fig. 1) and the harbour contours were 100% reflective. Fig. 6 shows for position B (see Fig. 1), that, even for a harbour with constant water depth in its main part, a combined refraction-diffraction model is essential to predict natural frequencies. For the same position, Fig. 7 illustrates the effect of bottom friction, using a Nikuradse roughness of k_N = 0.5 mm, which represents the cemented bottom of a scale model. Even for a very moderate height of the incident waves, H = 1.5 mm, the reduction due to bottom friction can be quite considerable, especially for sharp resonance peaks. For example, the peak at 0.055 Hz, representing a mode with half a wave length between the inner breakwater and the eastern one, is reduced to less than 20% at point B.

A sketch of the lay-out of the physical model is shown in Fig. 8. The long wave experiments have been performed for one wave direction, for which situation the position of the wave generator and two guiding walls have been indicated. Monochromatic waves with a wave height of 3 mm were generated for a series of wave periods between 10 and 40 seconds, excluding the occurrence of wave breaking. Ten wave height gauges were used, including one in the harbour mouth. The measured signals have been Fourier analysed to obtain the wave amplitude in the fundamental frequency. All breakwaters had a 1:2 slope of rough stones and were fully

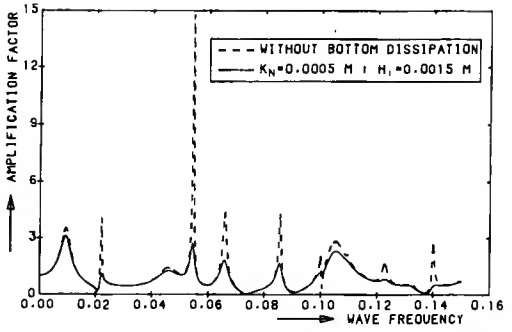

Figure 7 The effect of frictional damping on the harbour response at position B, grid no. 1

impermeable. The boundaries at the south end of the harbour were vertical quays. The finite element grid for the verification study is shown in Fig. 9. The main reason to reproduce the area around the access channel was to be certain of correct wave directions at the harbour mouth. As Fig. 9 shows, the regions behind the guiding walls have not been reproduced. The boundaries at the end of the guiding walls have been supposed to be fully absorbing; all other boundaries were 100% reflective. Earlier computations had revealed that only a marginal absorption rate in the order of 5% can reduce the harbour response at resonance by more than 25%, see also Behrendt (1985). However, such small reductions are hardly measurable in a complex harbour model. Another main reason to expect lower responses in the scale model beforehand, is that the wave generators are not fully reflective, which was assumed in the numerical model, see Eq. 18.

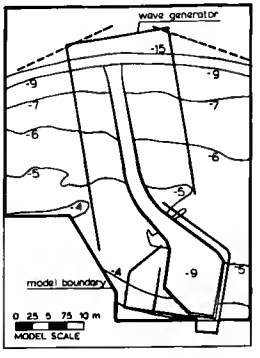

Figure 8 Lay-out of 1:80 scale model

Figure 9 Finite-element grid no. 2

Fig. 10 shows representative examples of the comparison between measurements and computations for two stations. Position A refers to a corner in the shallow basin and position C is situated in the harbour entrance, see Fig. 1. The lowest graph shows the amplification between both stations. Looking at the upper graphs, it is obvious that in general the

computed responses indeed exceed the measured ones. However, especially for two frequencies considerable discrepancies occur, i.e. for f=0.039 Hz and f=0.066 Hz. As shown in Figs. 11 and 12, these specific frequencies induce resonance in the outer area, between the wave generator and the breakwaters. This distance equals one wave length for f = 0.039 Hz and 2.5 wave lengths for f = 0.066 Hz. The discrepancies at these frequencies may be explained by the fact that the wave generator did not reflect the incident wave energy completely, as was assumed in the numerical model. Nevertheless, this hardly explains the large amplification between stations A and C for 0.066 Hz (see Fig. 10). A more thorough examination of this frequency revealed that the amplification was very sensitive for the position of the antinodal line at the harbour entrance. A minor change of this position, due to a slightly different grid in the sharp corner between the western breakwater and the outer boundary, reduced the amplification between stations A and C considerably. Apart from the discussed frequencies, the agreement between measurements and computations is quite satisfactory, especially when considering the amplification between the harbour entrance and positions within the harbour. In general, the computations result in higher responses at resonance frequencies. This may be attributed to the following reasons: minor absorptions along the boundaries, the energy loss due to flow separation at the breakwater ends, and finite-amplitude effects resulting in energy transfer to higher harmonics. The small shifts in the peak frequencies are ascribed to non-linear effects.

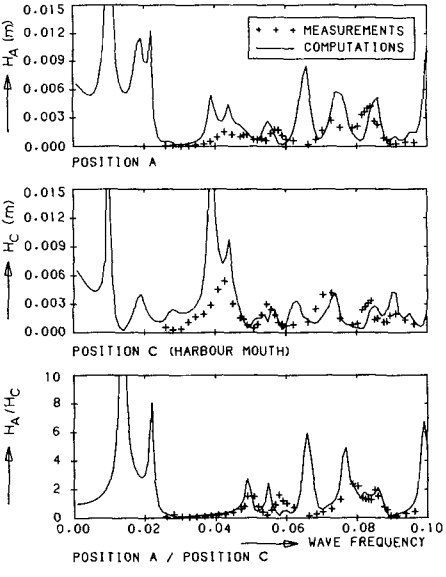

Fig. 10 Comparison between measured and computed harbour response at positions A and C; H_I = 0.003 m, k_N = 0.0005 m

The third set of computations refers to prototype scale, implying turbulent boundary layers. The bathymetry in the grid area is shown in Fig. 13. A constant value of the Nikuradse roughness, k_N = 0.04 m, has been taken for the entire area. Although less dominant than for the laminar case the effect of bottom friction can still be considerable; results will be reported elsewhere. The effects of partial reflection and transmission have been studied for monochromatic waves incident from a direction perpendicular to the main breakwater (70 °), with an incident wave height H = 0.25 m and wave frequencies up to 0.01 Hz. The boundary conditions 28 and 29 have been used for all three breakwaters, whereas the southern boundaries of the harbour have been assumed to be fully reflective for all computations. As an example of the results, the harbour response at position A is compared in Fig. 14 for the following three breakwater characteristics:

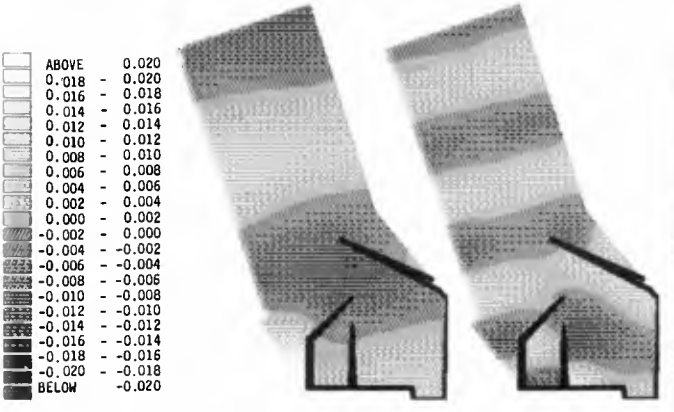

Fig. 11 Free surface contours at the moment of maximum elevation for $f = 0.039$ Hz; $H_I = 0.003$ m, $k_N = 0.0005$ m

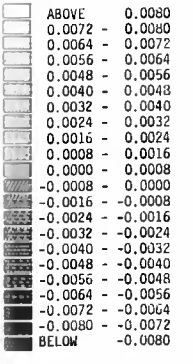

Fig. 12 Free surface contours at the moment of maximum elevation for $f = 0.066$ Hz; $H_I = 0.003$ m; $k_N = 0.0005$ m

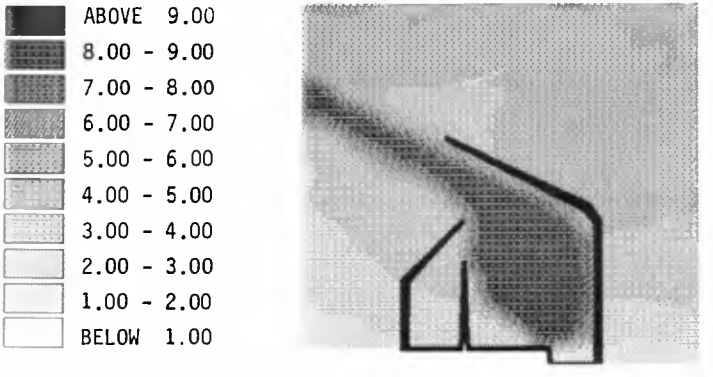

Figure 13 Bathymetry in computational area (grid no.3)

a) full reflection: $R = 1.0$, $T = 0.0$
b) partial reflection: $R = 0.9$, $T = 0.0$ and
c) partial reflection and transmission: $R = 0.9$, $T = 0.1$.

The constants in Eqs. 28 and 29 have been determined from the relations 36 and 37 under condition of no phase shift, i.e. $\rho = \tau = 0$.

A comparison of conditions a) and b), see Fig. 14, shows that a small reduction of R results in a considerable reduction of the amplifications at resonance. The maximum amplification is seen to be about 2, which also holds for other positions within this specific harbour. Although, for impermeable breakwaters a reflection coefficient of $R = 1.0$ is quite

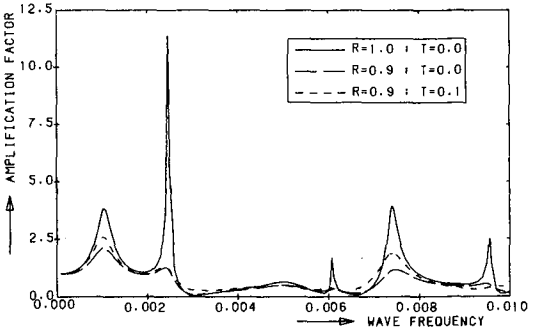

Figure 14 The effect of partial reflection and transmission on the harbour response at position A, grid no. 3

realistic for relatively long waves, condition c) is more appropriate for permeable breakwaters of the rubble mound type, for which T = 0.1 is even a rather low value. As Eq. 35 shows, conditions b) and c) result in almost the same energy loss at the boundaries. However, due to transmission there is an extra inflow of energy through the breakwaters, here primarily through the main breakwater. A comparison of conditions b) and c) in Fig. 14 shows a small increase in amplification due to transmission for all frequencies. It is noted that for other positions the amplifications of c) can also be less than those of b) for parts of the frequency range. The above results suggest that for permeable breakwaters the energy dissipation within the breakwater is of paramount influence on the response characteristics, whille the extra inflow of energy is much less important.

In Fig. 14 the response peak at 0.0246 Hz refers to the Helmholtz mode of the inner shallow basin. The small peak at 0.00608 Hz represents an oscillation mode of the main basin. This mode is shown in Fig 15 for four different conditions, and illustrates again that partially absorbing boundaries may have an enormous effect on peak responses.

5. CONCLUSIONS

A finite element model solving the modified mild-slope equation for waves with arbitrary wave length has been applied to study dissipative effects on harbour resonance phenomena. The effects of bottom friction, partially absorbing boundaries, and also transmission have been considered. To model the effect of combined reflection and transmission, a new boundary condition has been proposed. The following conclusions have been obtained:

- In harbour design studies, it is essential to include the effect of variable depth in the mathematical model to obtain a good prediction of the resonance frequencies.
- Bottom dissipation may be of considerable influence on the harbour response at resonance, both for laminar and turbulent flow regimes.
- Usually, harbour response studies are performed for fully reflective harbour contours. It has been shown that a small reduction of reflection coefficients may result in a drastic decrease of the harbour response at resonance. Such reductions occur in case of permeable rubble mound breakwaters. The effect of the additional inflow of wave

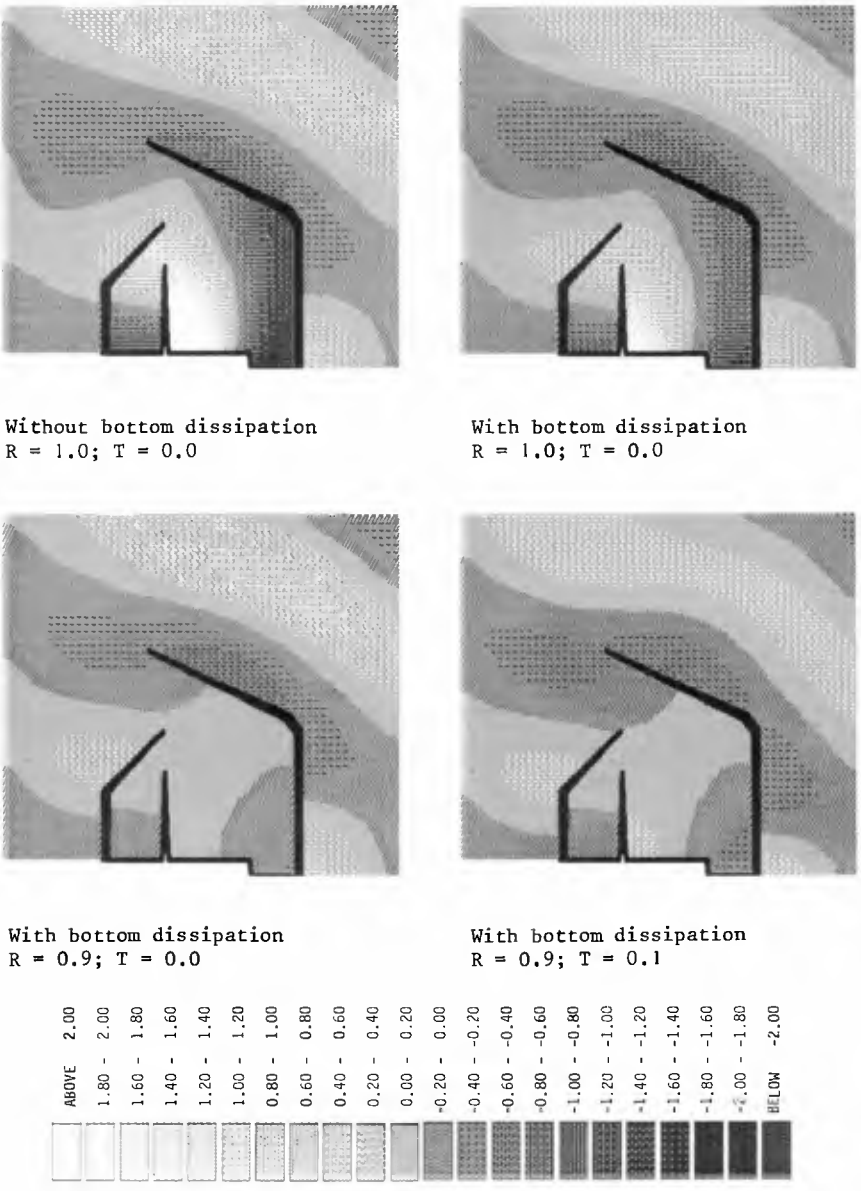

Figure 15 Free surface contours at the moment of maximum elevation for f = 0.00608 Hz; H_I = 0.25 m, k_N = 0.04 m

energy through these breakwaters is found to be less important than the effect of energy dissipation within the breakwater.

- Comparison between measurements in a hydraulic scale model and numerical computations shows a satisfactory agreement in harbour responses. This confirms that, also for long waves, the numerical model is an useful tool for engineering design purposes. The agreement might be even further improved by inclusion of the effect of flow separation in the model. However, for applications it is most essential to represent the appropriate boundary conditions correctly.

CHAPTER 148

On the floating breakwater - a new arrangement

C.H. LEE* and S.W. TWU**

Abstract

A new type of floating breakwater composed of net-tubes and buoy-balls is presented in this paper. A series of model studies have been carried out for several arrangements of this structure. As wave damping effect is concerned, a case that the structure being set vertically is shown to be better than the one being set horizontally, while more than two rows of the structures are set vertically and separately, a case which being connected with ropes between adjoining rows is proved to be better than the case without connecting ropes.

1 INTRODUCTION

Breakwaters have been developed into many practical patterns. Most of them are made of rubble or/and caissions which are effective but expensive. It is known that most wave energy distributes over the upper portion of water depth. Hence it is economical to attenuate wave energy in the vicinity of free surface.

With booming of economics and a rise in population, Republic of China is in urgency searching any available resources to meet the demand of continuous development. Fortunately, Taiwan is situated on the continental shelf where is fit for aquaculture, knowever, the wave conditions make it difficult to run. Consequently a special device of floating breakwater may be the alternative.

In general, most floating breakwaters are designed to be laid over the water surface "horizontally". It is interesting to note what the effect is if a floating breakwater is set "vertically". A structure composed of net-tubes and buoy-balls has been developed by the authors as shown in photo 1, also named wave-fence for convience. This type of floating breakwater may meet the requirements of water-circulation and wave-dissipation effectively as well as economically if designed properly.

2. ANALYSIS OF WAVE DISSIPATION BY THE NEW ARRANGEMENT

It is reasonable that multiple rows of wave-fences will be more effective than single one. If each of them is linked by ropes, the water body within those rows can be regarded as a part of the damping system and the effect of wave damping will be better.

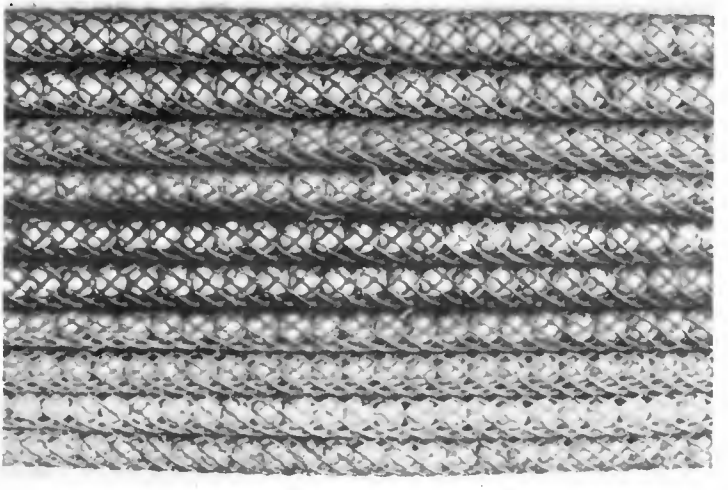
* Engineer, Planning Dept., BES Engineering Corporation, P.O. Box 335, Taipei Taiwan Republic of China.
** Professor Hydraulics & Ocean Engg. Dept., Cheng-Kung University, Tainan, Taiwan, Republic of China.

According to the small amplitude wave theory, it is known that the water particles in the crest and the trough of a wave move in the same magnitude but opposite direction respectively. With this idea, we may set the interval of two rows to be half length of the incident wave and connect them with ropes simultaneously. When the crest and the trough are exactly on the two rows respectively, each of which will incur wave forces in the same magnitude but opposite direction. Then the two rows will stand still like a fixed system for a while and the exerting wave forces will be eliminated each other through such a system.

In fact the waves on the open sea cover a wide range of period. We may pick up some dominant waves, i.e. design waves, of different periods which are to be disposed, say N waves. The required number of wave-fences, M, is related with N by the formula

$$\frac{M(M-1)}{2} = N \qquad \text{where } M > 2$$

For example, when M=4, there are 3 spacing, say S1, S2, S3 in sequence, among these four rows of wave fences. Then the system has six effective intervals, i.e. N=6, they are S1, S2, S3, S1+S2, S2+S3, S1+S2+S3 respectively. If each effective interval coincides half length of a design wave, and the fences are linked with ropes, the damping system will work all the time.



3. EXPERIMENTAL STUDIES

The wave periods ranged from 0.8 sec to 2.0 sec were carried out for the model test. The wave heights varied between 2 cm and 23 cm. The specific gravity of buoy-ball, γ_b, used in the experiments is 0.3.

First, the comparison of damping effect was made between the horizontally moored style, as Fig 1, and the vertically moored style, as Fig 2, of the same floating breakwater. The experimental results are shown in Fig 4-7, where the transmission coefficient K is the ratio of the average wave height behind the floating breakwater to the average incident wave height, and q is the immersing ratio of the draft of wave-fence h to water depth D. The cross-points and the solid lines represent the results of horizontal style, and the dot-points and the dash lines represent the data of vertical style. It is evident that the solid lines are always higher than the dash lines. It goes without saying that the wave-fence will be more effective if moored vertically.

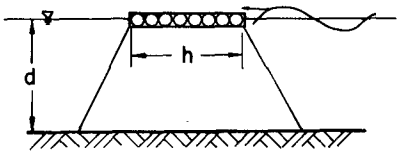


Fig 1. Horizontally moored style of wave-fence

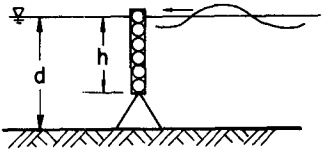

Fig 2. Vertically moored style of wave-fence

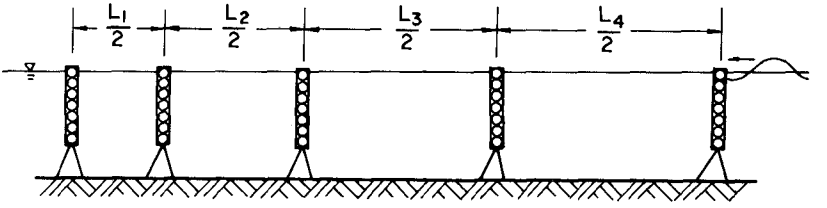

Fig 3. Five rows of wave-fences without/with connection which intervals correspond to half of designed wavelengths respectively

Since the wave-fence is flexible and swinging with the waves that diminishing the function of dissipation. The multiple wave-fences were then arranged to be tested. With the idea stated in previous section. if two rows of wave-fences which interval is equal to half of wave length of a certain wave period, the linking-effect would function only for that kind of waves. Therefore, for practical purpose, a system of more than two wave-fences is needed and set

in to be tested in the wave channel. A system of this structure of five rows with four spacings is chosen for the model test, Four perids of 0.8 sec, 1.2 sec, 1.6 sec, 1.8 sec were chosen as the basic spacings for the experiments. For convenience, five rows of wave-fences were arranged with appropriate intervals matching each half wavelength. A series of model tests with wave periods ranging from 0.8 sec to 2.0 sec were performed. The results are plotted in Fig. 8 The solid line and dash line represent linked and unlinked conditions respectively, which indicates that the former is much better than the latter.

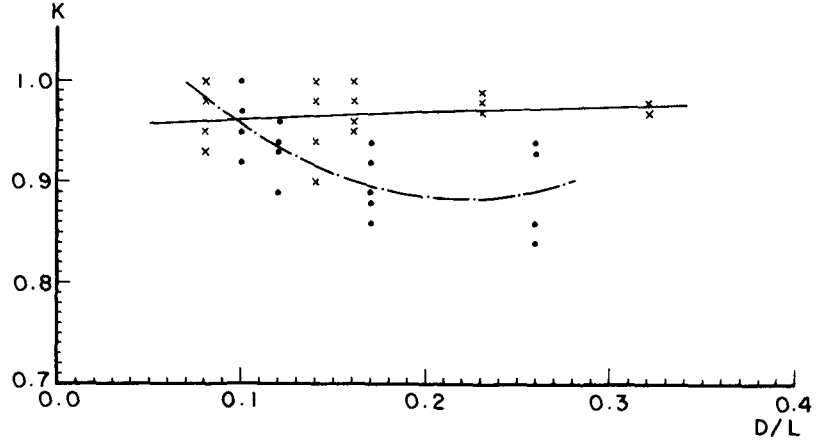

Fig 4. Transmission coefficient VS. relative depth for q=0.3,γ_b=0.3

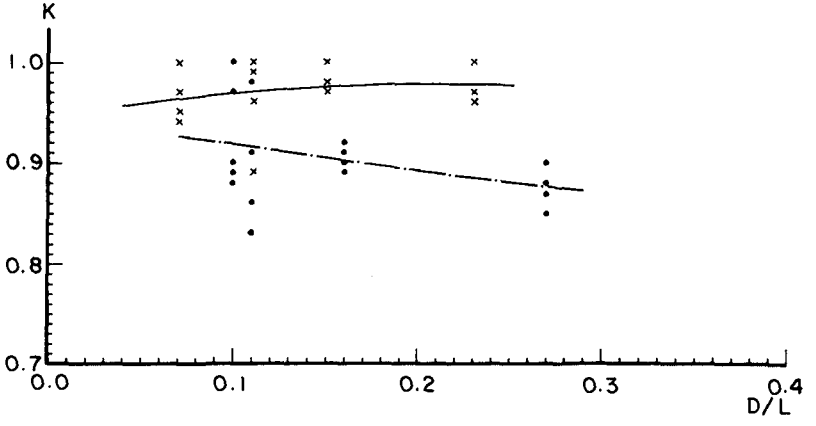

Fig 5. Transmission coefficient VS. relative depth for q=0.4,γ_b=0.3

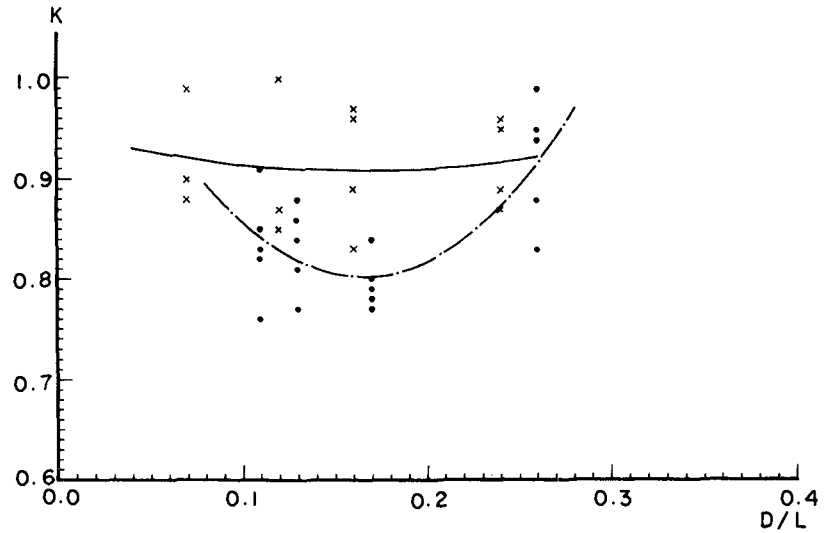

Fig 6. Transmission coefficient VS. relative depth for q=0.5, γ_b=0.3

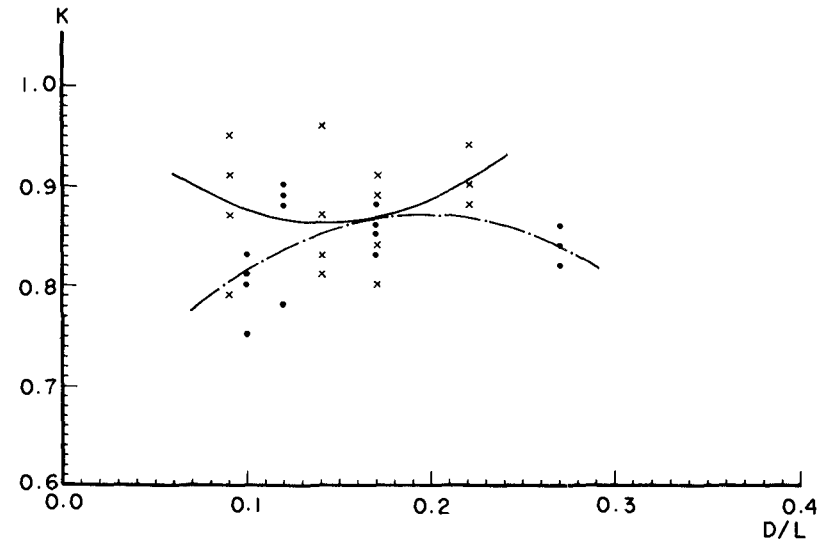

Fig 7. Transmission coefficient VS. relative depth for q=0.6, γ_b=0.3

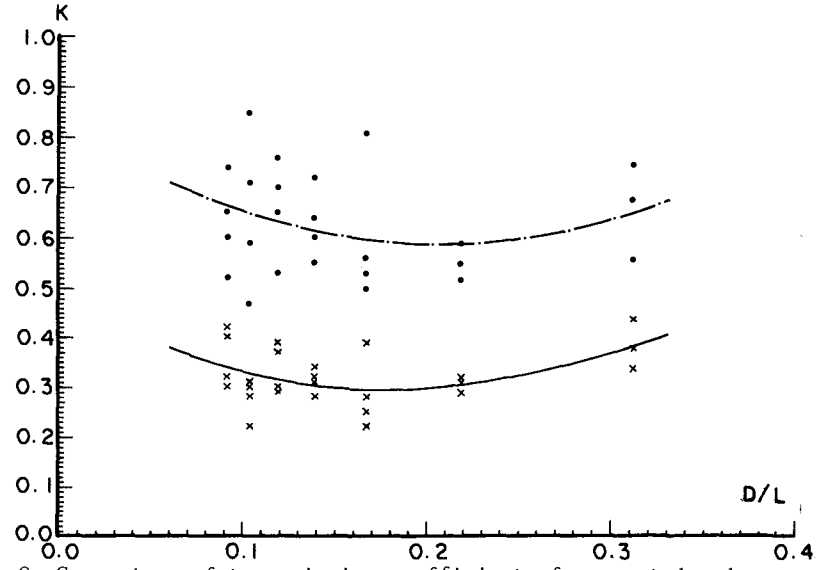

Fig 8. Comparison of transmission coefficient of connected and unconnected conditions for five-row wave-fences

4. CONCLUSION

(1) As wave dissipation is concerned, it is better to lay the wave-fence vertically than horizontally.
(2) The system of more than two rows of wave-fences being connected with ropes is always more effective than that without connection.
(3) If each "effective interval" of the system corresponds to each half length of a number of design waves, and the adjoining rows are linked with ropes, this system will serve as a good wave-fence.

Wave Uplift on Platforms or Docks in Variable Depth

Jiin-Jen Lee* and C.P. Lai**

ABSTRACT

Wave uplift forces on two dimensional platforms or docks in a variable depth medium has been studied theoretically and numerically. The incident waves are non-linear waves with maximum amplitude greater than the clearance between the still water surface and the underside of the platforms or docks.

The flow is assumed to be inviscid, irrotational without ambient current. Thus, the theoretical model solves the Laplace equation along with full non-linear free surface conditions. In order to conveniently handle the moving free surface in an irregular bottom topography with the presence of platform or dock an isoparametric mapping technique was used to transfer the fluid domain and its boundaries into a regular geometry. A Galerkin finite element model is developed to model the transformed fluid region. The resulting discrete equations are solved iteratively by using adaptive Line SOR (Successive-Over-Relaxation) technique. Artificial viscosity is included in both the dynamic and kinematic free surface equations to damp out the free surface oscillations in the front region of the platform or dock. The Runge-Kutta method is employed to integrate the time variation in the nonlinear free surface equations.

Results obtained by the numerical method were compared to the available experimental data obtained by others in order to demonstrate the workability of the proposed algorithm.

1. INTRODUCTION

In a storm or in the present of unusual wave activities, marine structures, such as platforms or docks, may be subjected to significant uplift forces even if they are built above the still-water level. These forces occur when large incident wave propagate beneath the structure and make contact with it. If these uplift forces are not properly accounted for in the design, they can ultimately destroy the structure.

When waves approach the coastal region, they are continously modified by the bottom topography and the coastline configuration. The decrease in water depth contributes to the increase in the effect of nonlinearity of the wave. Due to the importance of nonlinearity effect in sloping bottom, finite amplitude wave theories has to be applied. Furthermore, if a platform or dock which is built above the still-water level is present then the problem will be more complex. The problem to be encountered is a combination of nonlinear free surface conditions, upper and bottom rigid boundaries, and shoreward edge rigid boundary (if dock problem is considered). A suitable numerical model must be applied to handle this complex problem.

The major objective of this paper is to present a convenient numerical model to investigate aspects of wave uplift forces on platforms and/or docks either in horizontal or a sloping bottom.

2. MATHEMATICAL AND NUMERICAL FORMULATION

To develop the mathematical model, the flow is assumed to be inviscid, irrotational and without ambient current. The entire physical problem can be illustrated in Fig. 1 and the governing equations for the velocity potential are:

$$\nabla^2\phi = 0$$

$$\phi_y = h_t + \phi_x h_x \tag{1}$$

$$\phi_t + \frac{1}{2}(\phi_x^2 + \phi_y^2) + gh = 0 \qquad on \quad y = h(x,t)$$

Due to the nonlinearity of free surface equations, irregular bottom topography, and the presence of platform or dock, the original physical problem is difficult to solve by ordinary finite element method. To overcome this difficulty, a transformation technique is applied to map the complex physical domain into a regular computational domain.

Two steps are needed to transfer the physical domain into a regular computational domain by using isoparametric mapping. The first step is to transfer the irregular free surface and the bottom boundary into straight line segments by using six-node isoparametric elements. In this stage, the flow field has been transfered into several rectangular cells. The second step is to consider each rectangular cell as being separately mapped by a local bilinear isoparametric mapping to a new isoparametric plane.

The transformed governing differential equations take the following form:

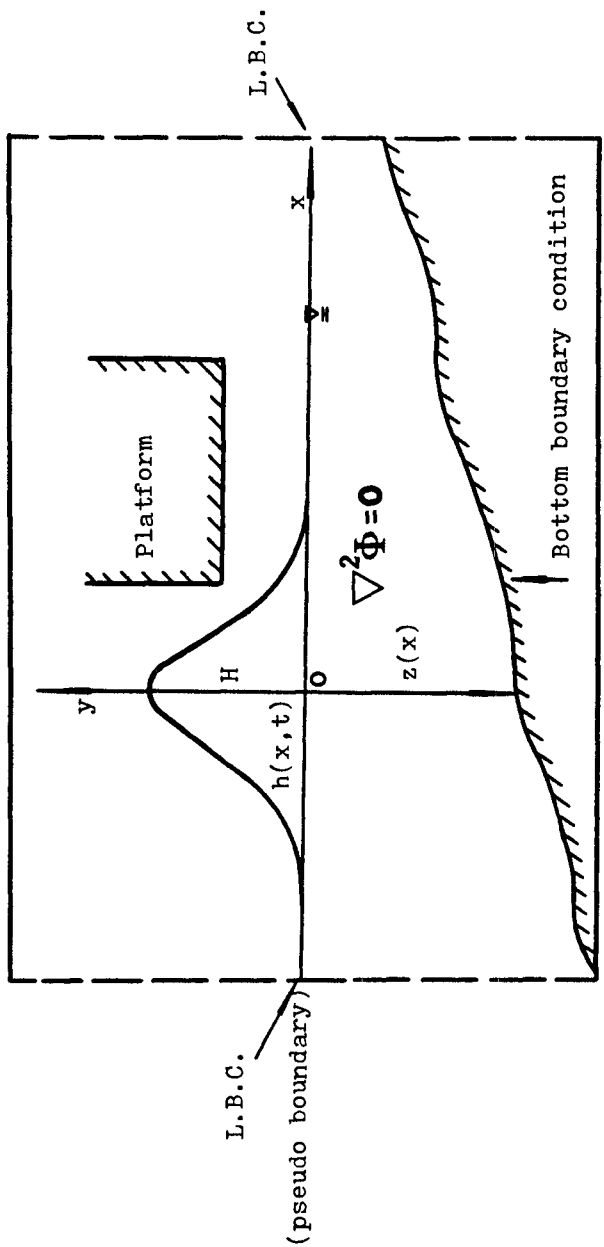

Fig. 1 Conceptual model of a solitary wave hitting a platform or a dock.

$$A_{KM}\phi_{\overline{\xi}\xi} + B_{KM}\phi_{\overline{\eta}\eta} + C_{KM}\phi_{\overline{\xi}\overline{\eta}} + D_{KM}\phi_{\overline{\eta}} = 0$$

$$\phi_t + \frac{1}{2}A_{KM}\phi_{\overline{\xi}}^2 + \frac{1}{2}B_{KM}\phi_{\overline{\eta}}^2 + \frac{1}{2}C_{KM}\phi_{\overline{\xi}}\phi_{\overline{\eta}} + gh = 0 \qquad (2)$$

$$h_t + A_{KM}h_{\overline{\xi}}\phi_{\overline{\xi}} + H_{KM}\phi_{\overline{\eta}}h_{\overline{\xi}} - G_{KM}\phi_{\overline{\eta}} = 0$$

where the following various coefficients are defined

$$A_{KM} = \xi_x^2 \qquad D_{KM} = \eta_{xx}Q$$

$$B_{KM} = (\eta_x^2 + \eta_y^2)Q^2 \qquad G_{KM} = \eta_y Q$$

$$C_{KM} = 2\xi_x\eta_x Q \qquad H_{KM} = \eta_x\xi_x Q$$

$$\text{where } Q = \overline{\eta}_\eta = \frac{2}{\Delta\overline{h}}$$

In the analysis, the approximate solutions of the transformed equations are sought by using the Galerkin's finite element method. The finite element model is advanced in time by integrating the free surface dynamic and kinematic equations. The Runge-Kutta method is employed with mass lumping. A major difficulty in numerical integration of the free surface equations is the nonlinear computational instability. To avoid the instability of numerical integration, artificial viscosity is included in both dynamic and kinematic free surface equations. An adaptive line SOR algorithm is developed and used to speed the repeated solution of linear algebraic equations resulting from finite element discretization of the transformed Laplace equation. It was found the adapted line SOR algorithm could effectively reduce the error norm by several orders of magnitude for the similar number of iteration.

3. NUMERICAL RESULTS

When ocean waves approach the coastal region, the wave shape and the propagation direction would change because of changes in coastal topography. A solitary wave traveling in a uniform depth region would not change its unique shape, however, it will break into a number of solitons when it propagates into a shallower continental shelf. Such "fission" phenomena have been found by many investigators (for example, see Madsen and Mei (1969) and Kim (1977)).

Fig. 2 presents the numerical solution of the development of an initial solitary wave over a shelf of 1:20 slope using the numerical model developed in the present study. The initial wave amplitude is 0.36 in., the water depth at the upstream of the shelf is assumed to be 3 in.; downstream of the shelf is chosen to be 1.5 in.. This bottom configuration has been used by Madsen and

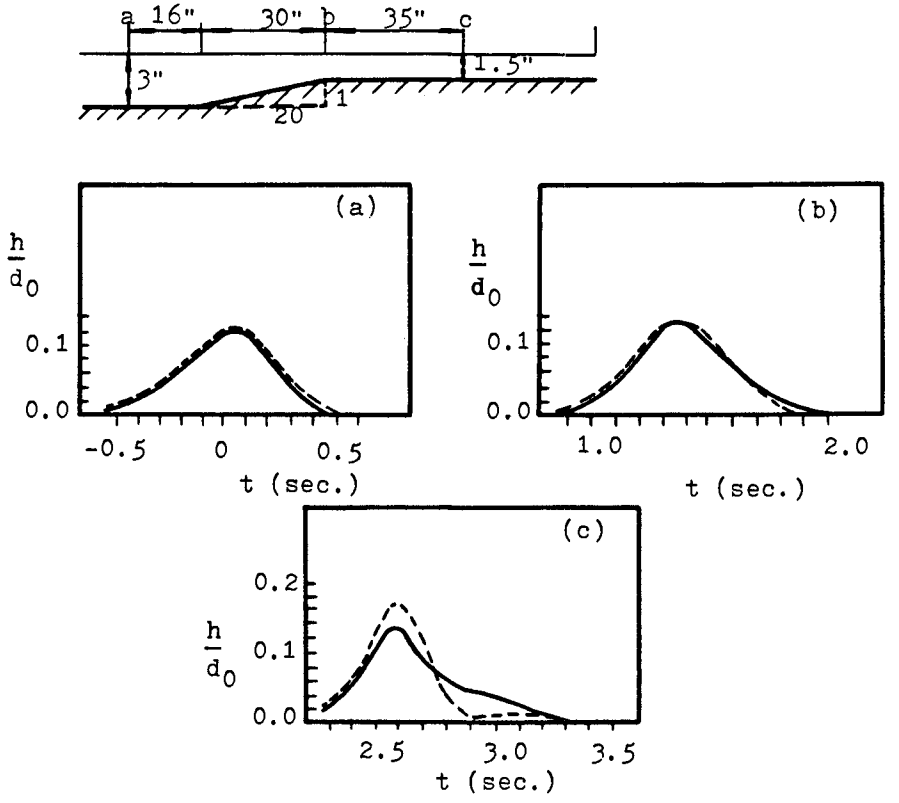

Fig.2 The propagation of solitary wave over an uneven bottom. Comparison of numerical results and experiments. ($H/d_0=0.12, d_0=3.0"$)

Mei (1969) in their numerical and experimental analysis. In our computational model, the time increment is taken to be 0.01 sec., and spatial interval is chosen to be 1.0 in.. The computational time for this case requires about 1 hour and 5 minutes (on VAX-11/780 machine).

The numerical results of wave profile at locations (a) and (b) in Fig.2 agree well with the experimental data obtained by Madsen and Mei (1969). However, by observing the wave profile at location (c) in Fig.2, there is disagreement between numerical and experimental values of wave profile. The maximum amplitude of computed wave profile is higher than that of experimental wave profile. A small hump in the tail of computed wave profile can be seen. This hump in the wave tail will be separated from the leading wave when the wave is propagated further downstream. This result have been found by Madsen and Mei (1969) and Kim (1977) using the same geometrical data and fluid parameters. This example demonstrates that the present numerical model is acceptable for sloping bottom.

Fig.3 shows the hydrodynamic uplift force on a horizontal platform resulting from a solitary wave travelling in a constant water depth. The ratio of the crest amplitude to the water depth is 0.24 which is 20% larger than the platform clearance. The ordinate is the ratio of the total hydrodynamic uplift forces (integrated from the computed uplift pressure over the entire platform) divided by the total hydrostatic force. The total hydrostatic force (Fs) is taken as the integrated weight of the water above the elevation of the platform which is denoted as the shaded area in the inserted sketch. The computed force based on the present numerical procedure is plotted as a function of the normalized time history. The experimental data was obtained by French (1969). The present numerical results are also compared with Iradjpanah's results (1983). It is seen from Fig.3 that the present numerical results agree reasonably well with the experimental data. It shows that when the solitary wave strikes the platform the platform experiences an uplift force followed by a negative force which is substantially larger than the positive uplift.

Fig.4 presents the time-history of normalized total force for a relative amplitude $H/d=0.32$ of wave propagating over a shelf. The platform is situated at the location which is 40 in. away from the beginning point of the slope. The horizontal dimension of the sloping bottom is 200 in.

It can be seen from Fig.4 that the effect of sloping bottom on the normalized total hydrodynamic force is very significant and the normalized total force increases in the sloping bottom. However, the total hydrodynamic force of the steep slope is slightly smaller than that of the mild slope.

If the platform is moved further away from the beginning point of the slope

(H/d=0.24,s/d=0.2,L/d=4,d=15")

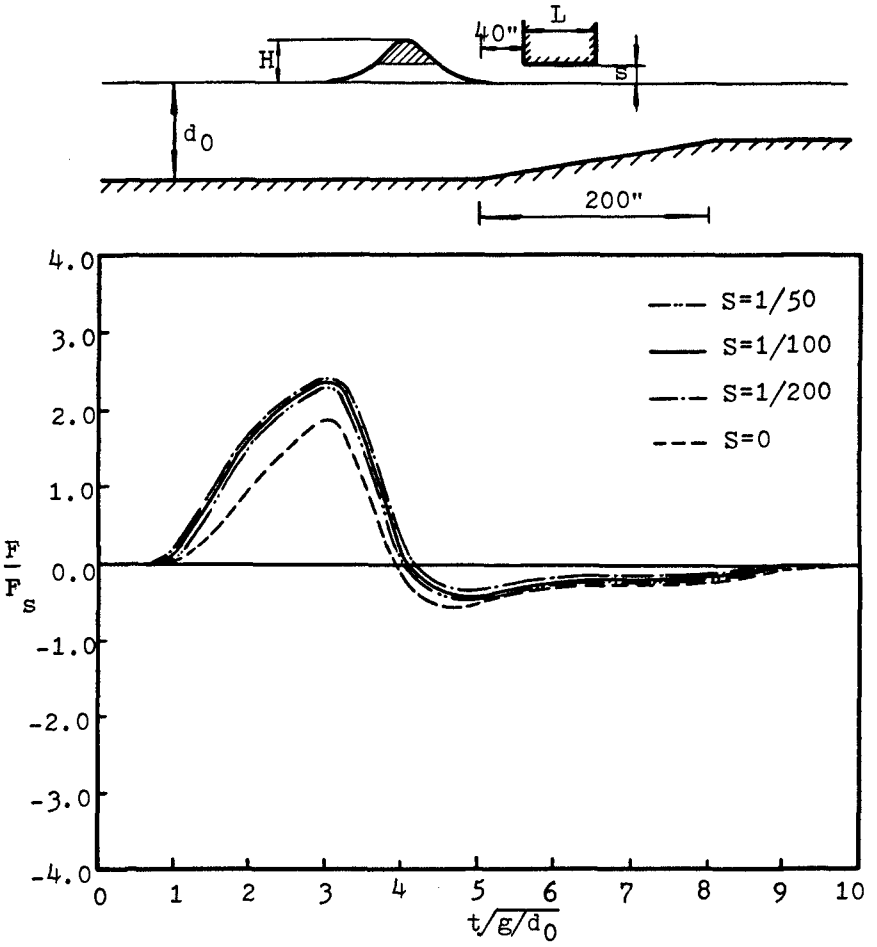

Fig. 4 Normalized total hydrodynamic force per unit width.
(H/d_0=0.32, s/d_0=0.2, L/d_0=4, d_0=15")

as shown in Fig.5, the nonlinearity and reflection effects of sloping bottom are more remarkable than that in Fig.4. The increase in the effect of nonlinearity increases the maximum amplitude of the wave, hence the total hydrodynamic force. This phenomenon is more significant for the mild slope than for the steep slope. A possible reason for this phenomenon is that the reflection effect reduces more nonlinearity effect for the steep slope than for the mild slope such that the amount of the increase of the total hydrodynamic force or the maximum amplitude is not proportionally increased.

Fig.6 shows the resulting uplift force when a reflecting boundary is introduced and the water depth is allowed to vary. This would represent a dock located near a reflecting wall. The ordinate and the abscissa are normalized as that shown in Fig.3. The incident wave height however is 60% greater than the platform clearance. By comparing the general feature of Fig.3 and 6, it is seen that the effects of the sloping bottom and the reflecting boundary significantly increase the positive uplift forces.

4. CONCLUSIONS

The numerical results computed from various incident wave heights in different bottom profile striking platforms and/or docks of varying nature show a consistent picture that the present numerical model works well. The platform experiences a positive uplift followed by a negative uplift force when a wave stikes the platform. The magnitude of this uplift force can be computed using the developed model but can not be generalized by a simple formula because of the complexity of the problem. For a dock problem (reflecting wall placed at the end of the dock) the positive uplift appeared to be significantly increased while the negative uplift is reduced.

CHAPTER 150

NEARSHORE CIRCULATIONS DUE TO WAVE INDUCED CURRENTS BY OFFSHORE BREAKWATER IN FINITE ELEMENTS

Shinn-Chung Liang *

1. INTRODUCTION

The objective of the present study is concerned with the numerical prediction of wave patterns and wave induced currents adjacent to a breakwater. The wave theory used is that of Berkhoff's (1972) mild slope wave equation with effects of diffraction, refraction and reflection described as Bettess, Liang and Bettess (1984). A finite element model is applied with appropriate boundary conditions. The singularity in the velocity at the tip of the breakwater is modelled effectively using the technique of Henshell and Shaw (1975), originally developed for elasticity. In the case of waves induced currents a potential representation of velocity in the fluid has been used to derive a set of radiation stress expressions based on the theory of Longuet-Higgins (1964, 1970a,b), which are for an arbitrary wave pattern and the bottom variation. These expressions used account for the mean sea level and satisfy Mei's (1973) static balance of momentum flux.

The radiation stress is applied to obtain forcing terms for use in a shallow water equation in conjunction with limiting ratio wave breaking where wave height, wave period, wave steepness and beach slope may be considered. Finally, an offshore breakwater on a beach for shore protection has been applied in a complete finite element model to predict both wave pattern and nearshore currents. Two angles of wave incidence are chosen. A series result has been produced.

2. THEORIES

2.1. WAVES

The wave equation of Berkhoff (1972,1975) is used as

$$\nabla.(cc_g \nabla\phi_o) + \frac{\omega^2 c}{c} g\phi_o = 0 \qquad (1)$$

with ω : angular frequency,
c : wave celerity and $c = \omega/k$, k is a wave number,
c_g : group velocity by $c_g = nc$ and $n = \frac{1}{2}(1+2kh/\sinh 2kh)$
ϕ_o : velocity potential in deep water.

For shallow water due to kh is small and tanh kh = kh Eq. (1) becomes

$$\nabla.(h\nabla\phi_o) + \frac{\omega^2}{g} \phi_o = 0 \qquad (2)$$

For deep water, kh is large and so tanh kh = 1, this leads to $c = g/\omega$ and n = 1/2, so that

*Visiting Aso. Professor, Department of Hydraulics and Ocean Engineering National Cheng Kung University, Taiwan. Formerly: Department of Civil Engineering, Imperial College, U. K.

$$\nabla^2 \phi_o + \frac{\omega^4}{g^2} \phi_o = 0 \qquad (3)$$

The boundary conditions of Eq. (1) must be satisfied and specified. On a solid boundary the velocity must be zero and hence $\partial\phi / \partial n = 0$, with n : outward normal to the surface. This implies a total reflection of a wave. In a real problem the reflection will be partial as energy absorption will occur on a beach due to wave breaking, or/on a real breakwater where the porous nature of the boundary does not result in a zero boundary velocity. For such a boundary the condition can be written as

$$\frac{\partial \bar{\phi}}{\partial n} = \frac{\alpha}{c} \frac{\partial \bar{\phi}}{\partial t} \qquad (4)$$

where $\bar{\phi}$: velocity potential for periodic wave, and

$\bar{\phi}(x,y,z,t) = \phi(x,y,z) \exp(i\, t)$

: a real dimensionless damping coefficient, as

$\alpha = 0$: total reflection

$\alpha = 1$: total absorption

$0 \leq \alpha \leq 1$: any partial reflection.

Where the energy absorption is due largely to inertia terms, such as occur in wave breaking, α could be given a complex value.

2.2. WAVE BREAKING

Waves break in different ways depending on wave height, wave period, steepness and beach slope. The determination of the initial line of breaking is a purely empirical matter. Breaking criteria are based on three important aspects of the breaking theories which are solidary wave, Airy wave theories and similarity parameter introduced by McCowan (1891) etc., Komar and Gauphan (1972) and Iribarren and Nogales (1949) respectively.

Lacking direct empirical data for waves with varying amplitude, a plausible criterion to waves with longshore modulation is extended as

$$\phi(x,y,t) = -\frac{ig}{\omega} \eta'(x,y,t) \qquad (5)$$

where $\bar{\eta}$ is the local wave amplitude. Approximating for shallow water and invoking along with breakerline

$$\eta'(x,y) = \gamma(\bar{\eta} + h) \qquad (6)$$

with γ is an empirical breaking criterion, obtain from previous ideas.

Inside the surfzone wave energy is dissipated due to the generation of turbulence in wave breaking and bottom friction. The local wave amplitude decreases towards the shore and becomes negligible along the mean shoreline. Using three different breaking criteria to find the waves inside the surfzone, the variations of radiation stresses are obtained in two channel meshes of slope = 1/10 and 1/50, as shown in Figs. (1) and (2). There are no significant differences among three criteria in mild slope case but for the steeper of slope = 1/10, we would prefer to use one of the criteria of Iribarren and Nogales or Komar and Gauphan, which considers more factors, such as bottom slope and wave steepness.

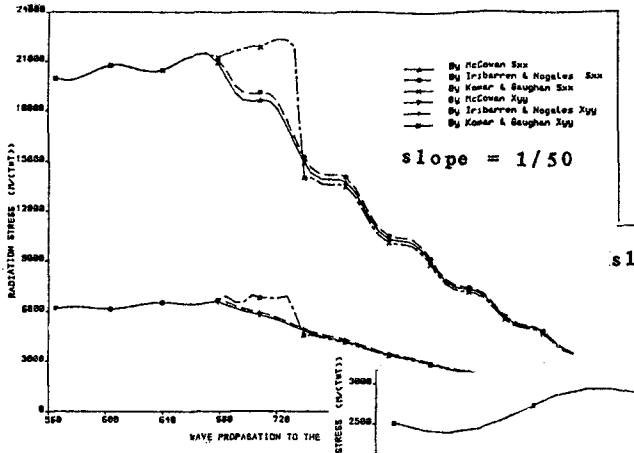

Figure 1.

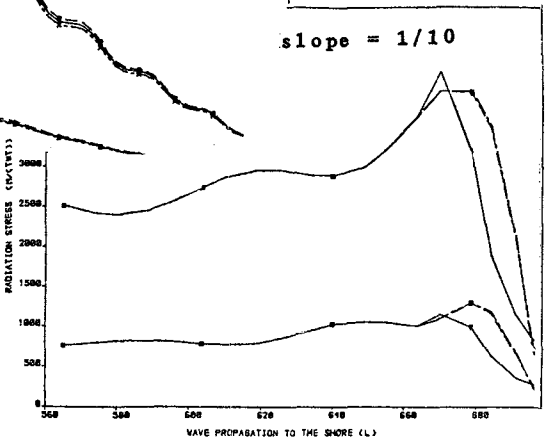

Figure 2.

2.3. RADIATION STRESSES

Based upon Longuet-Higgins and Stewart (1964) and Mei (1973), a finite element model of radiation stress has been developed by Liang (1983) to generalize the radiation stress for arbitrary wave patterns and bottom variations. Mei (1973) mentioned that the equation of a static balance of momemtum is given as

$$\bar{P}_h \frac{\partial h}{\partial x_\alpha} - \rho g h \frac{\partial \bar{\eta}}{\partial x_\alpha} - \frac{\partial S_{\alpha\beta}}{\partial x_\beta} = 0(ka)^3 \tag{8}$$

For constant depth (h = constant) the equation becomes

$$-\rho g h \frac{\partial \bar{\eta}}{\partial x_\alpha} - \frac{\partial S_{\alpha\beta}}{\partial x_\beta} = 0 \tag{9}$$

where $\alpha, \beta = 1,2$, $S_{\alpha\beta}$ is the radiation stress tensor and $\bar{\eta}$ is the time average of mean sea level. For slowly varying depth, due to higher derivatives of h are small comparing with other two terms, therefore the first term is usually insignificant. The static balance is also as Eq. (9) shown.

The next step is to determine the expressions of $S_{\alpha\beta}$ and $\bar{\eta}$ in Eq. (9). The radiation stress tensor is defined as

$$S_{\alpha\beta} = S^{(1)}_{\alpha\beta} + \delta_{\alpha\beta} S^{(2)} \tag{10}$$

where $\delta_{\alpha\beta}$ being the kronecker delta and to the second order of the approximation these expressions are equivalent to

$$S^{(1)}_{\alpha\beta} = \rho\int_{-h}^{\bar{\eta}} \overline{u_\alpha u_\beta}\, dz + O[(ka)^3] \tag{11}$$

$$S^{(2)} = \int_{\bar{\eta}}^{\eta} \bar{p}\,dz + \int_{-h}^{\bar{\eta}} \bar{p}\,dz - \frac{1}{2}\rho g(\bar{\eta}+h)^2 + O[(ka)^3] \tag{12}$$

In the first term of Eq. (12), the pressure is taken as hydrostatic

$$p = \rho g(\eta - z), \qquad 0 < z < \eta(x,y,t). \tag{13}$$

In the second term of the equation, P can be obtained from the time averaged as

$$\bar{p} = \rho g(\bar{\eta} - z) + \rho\int_{-h}^{\bar{\eta}} \frac{\partial}{\partial x_i}(\overline{u_i w})\,dz - \rho(\bar{w})^2 \tag{14}$$

with $x_i = x, y$ and $u_i = u, v$. Therefore components of radiation stress tensor can be written as:

$$S_{xx} = \int_{-h}^{\bar{\eta}} \rho(\overline{u^2} - \bar{w}^2)\,dz + \frac{\partial}{\partial x}\int_{-h}^{\bar{\eta}}\int_{z'}^{\bar{\eta}} \rho\,\overline{uw}\,dz'dz + \frac{\partial}{\partial y}\int_{-h}^{\bar{\eta}}\int_{z'}^{\bar{\eta}} \rho\,\overline{vw}\,dz'dz + \rho g h\bar{\eta} + \int_{\bar{\eta}}^{\eta} \bar{p}\,dz \tag{15}$$

$$S_{xy} = \int_{-h}^{\eta} \rho\,\overline{uv}\,dz \tag{16}$$

S_{yy} and S_{yx} can be found by interchanging x and y everywhere in Eqs. (13) and (14).

The mean sea level of Eq. (9) is derived from Longuet-Higgins (1967) and Mei (1973) as

$$\bar{\eta} = -\frac{1}{g}\overline{\frac{\partial \phi}{\partial t}} - \frac{1}{2g}\overline{\left[\left(\frac{\partial \phi}{\partial x}\right)^2 + \left(\frac{\partial \phi}{\partial y}\right)^2 - \left(\frac{\partial \phi}{\partial z}\right)^2\right]} \qquad z = 0 \tag{17}$$

or

$$\bar{\eta} = -\frac{1}{g}\overline{\frac{\partial \phi}{\partial t}} - \frac{1}{2g}\left[\overline{u^2} + \overline{v^2} - \overline{w^2}\right] \qquad z = 0 \tag{18}$$

If set

$$\phi(x,y) = A(x,y) + iB(x,y) \tag{19}$$

and

$$\phi = \mathrm{Re}\,[\phi(x,y)\cosh k(z+h)\exp(-i\omega t)] \tag{20}$$

Where A and B are real and $i = \sqrt{-1}$, then the velocities, such as u, v and w and their square or time-averaged values etc., are easy to derive in terms of A and B. That means if we can find the values of A and B and their higher order derivatives through velocity potential of wave in the technology of finite element simulations, we can find the tensor straightwards.

The major interest for us is to find the tractive forces which induce currents and set-up. These are

$$\tau_x = -\left(\frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y}\right) \tag{21}$$

$$\tau_y = -\left(\frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y}\right) \tag{22}$$

The gradients can be found in terms of A and B as

$$\begin{aligned}\frac{\partial S_{xx}}{\partial x} = {} & \frac{\rho}{8}\left[\left[2\left(\frac{\partial A}{\partial x}\frac{\partial^2 A}{\partial x^2} + \frac{\partial B}{\partial x}\frac{\partial^2 B}{\partial x^2}\right) - \frac{1}{2}\frac{\partial F}{\partial x}\right]\left(\frac{\sinh 2kh + 2kh}{k}\right)\right. \\ & \left. + \left[\left(\frac{\partial A}{\partial x}\right)^2 + \left(\frac{\partial B}{\partial x}\right)^2 - \frac{F}{2}\right]\frac{\partial}{\partial x}\left(\frac{\sinh 2kh + 2kh}{k}\right)\right] \\ & + \frac{\rho}{4}\left[\frac{\partial F}{\partial x} h \cosh^2 kh + F\frac{\partial h}{\partial x}\cosh^2 kh + Fh\frac{\partial}{\partial x}(\cosh^2 kh)\right. \\ & \left. + (A^2 + B^2)\frac{\partial}{\partial x}(k^2 h) + 2k^2 h\left(A\frac{\partial A}{\partial x} + B\frac{\partial B}{\partial x}\right)\right] \\ & + \frac{\rho}{8g}\left[\left[\left(\frac{\partial A}{\partial x}\right)^2 + \left(\frac{\partial B}{\partial x}\right)^2 + \left(\frac{\partial A}{\partial y}\right)^2 + \left(\frac{\partial B}{\partial y}\right)^2\right]\cosh^2 kh\right. \\ & \left. - k^2(A^2 + B^2)\sinh^2 kh\right]\left[\left[\left(\frac{\partial A}{\partial x}\right)^2 + \left(\frac{\partial B}{\partial x}\right)^2 + \left(\frac{\partial A}{\partial y}\right)^2\right.\right. \\ & \left.\left. + \left(\frac{\partial B}{\partial y}\right)^2 - k^2(A^2 + B^2)\right]\cosh kh \sinh kh \frac{\partial(kh)}{\partial x}\right. \\ & \left. + \left[\left(\frac{\partial A}{\partial x}\frac{\partial^2 A}{\partial x^2} + \frac{\partial B}{\partial x}\frac{\partial^2 B}{\partial x^2}\right) + \left(\frac{\partial A}{\partial y}\frac{\partial^2 A}{\partial x\partial y} + \frac{\partial B}{\partial y}\frac{\partial^2 B}{\partial x\partial y}\right)\right]\cosh^2 kh\right. \\ & \left. - k\left[k\left(A\frac{\partial A}{\partial x} + B\frac{\partial B}{\partial x}\right) + \frac{\partial k}{\partial x}(A^2 + B^2)\right]\sinh^2 kh\right]\end{aligned} \tag{23}$$

$$\begin{aligned}\frac{\partial S_{xy}}{\partial x} = {} & \frac{\rho}{8}\left[\left(\frac{\partial A}{\partial x}\frac{\partial A}{\partial y} + \frac{\partial B}{\partial x}\frac{\partial B}{\partial y}\right)\frac{\partial}{\partial x}\left(\frac{\sinh 2kh + 2kh}{k}\right)\right. \\ & \left. + \left(\frac{\sinh 2kh + 2kh}{k}\right)\left(\frac{\partial A}{\partial x}\frac{\partial^2 A}{\partial x\partial y} + \frac{\partial B}{\partial x}\frac{\partial^2 B}{\partial x\partial y} + \frac{\partial A}{\partial y}\frac{\partial^2 A}{\partial x^2} + \frac{\partial B}{\partial y}\frac{\partial^2 B}{\partial x^2}\right)\right]\end{aligned} \tag{24}$$

$$\begin{aligned}\frac{\partial S_{xy}}{\partial y} = {} & \frac{\rho}{8}\left[\left(\frac{\partial A}{\partial y}\frac{\partial A}{\partial x} + \frac{\partial B}{\partial y}\frac{\partial B}{\partial x}\right)\frac{\partial}{\partial y}\left(\frac{\sinh 2kh + 2kh}{k}\right)\right. \\ & \left. + \left(\frac{\sinh 2kh + 2kh}{k}\right)\left(\frac{\partial A}{\partial y}\frac{\partial^2 A}{\partial x\partial y} + \frac{\partial B}{\partial y}\frac{\partial^2 B}{\partial x\partial y} + \frac{\partial A}{\partial x}\frac{\partial^2 A}{\partial y^2} + \frac{\partial B}{\partial x}\frac{\partial^2 B}{\partial y^2}\right)\right]\end{aligned} \tag{25}$$

where

$$F = -\frac{1}{h}\left[\frac{\partial h}{\partial x}\left(A\frac{\partial A}{\partial x} + B\frac{\partial B}{\partial x}\right) + \frac{\partial h}{\partial y}\left(A\frac{\partial A}{\partial y} + B\frac{\partial B}{\partial y}\right) + (A^2 + B^2)\, k \tanh kh\right]$$

$$+ \left(\frac{\partial A}{\partial x}\right)^2 + \left(\frac{\partial A}{\partial y}\right)^2 + \left(\frac{\partial B}{\partial x}\right)^2 + \left(\frac{\partial B}{\partial y}\right)^2 \tag{26}$$

$$\frac{\partial F}{\partial x} = -\left[\frac{\partial}{\partial x}\left(\frac{A}{h}\frac{\partial h}{\partial x}\frac{\partial A}{\partial x}\right) + \frac{\partial}{\partial x}\left(\frac{B}{h}\frac{\partial h}{\partial x}\frac{\partial B}{\partial x}\right) + \frac{\partial}{\partial x}\left(\frac{A}{h}\frac{\partial h}{\partial y}\frac{\partial A}{\partial y}\right)\right.$$

$$\left. + \frac{\partial}{\partial x}\left(\frac{B}{h}\frac{\partial h}{\partial y}\frac{\partial B}{\partial y}\right) + \frac{\partial}{\partial x}\left(\frac{A^2 k}{h}\tanh kh\right) + \frac{\partial}{\partial x}\left(\frac{B^2 k}{h}\tanh kh\right)\right]$$

$$+ \frac{\partial}{\partial x}\left[\left(\frac{\partial A}{\partial x}\right)^2 + \left(\frac{\partial A}{\partial y}\right)^2 + \left(\frac{\partial B}{\partial x}\right)^2 + \left(\frac{\partial B}{\partial y}\right)^2\right] \tag{27}$$

The expression for $\frac{\partial S_{yy}}{\partial y}$ is analogous to that $\frac{\partial S_{xx}}{\partial x}$ just change x to y everywhere in Eqs. (22) and (26).

2.4. NEARSHORE CURRENTS

The finite element program to be used to calculate currents in the whole nearshore system is based upon the penalty form of shallow water equations of Zienkiewicz (1978) for a steady state which are similar in form to the Navier - Stokes equations for turbulent flow. These are

$$\frac{\partial}{\partial x}(h\bar{u}) + \frac{\partial}{\partial y}(h\bar{v}) = \frac{\eta}{\lambda} \tag{28}$$

$$\rho\left[\bar{u}\frac{\partial \bar{u}}{\partial x} + \bar{v}\frac{\partial \bar{v}}{\partial y} - f\bar{v}\right] - \rho g\lambda\frac{\partial}{\partial x}\left[\frac{\partial}{\partial x}(h\bar{u}) + \frac{\partial}{\partial y}(h\bar{v})\right]$$

$$= 2\frac{\partial}{\partial x}\left[\mu_h\frac{\partial \bar{u}}{\partial x}\right] + \mu_h\frac{\partial}{\partial y}\left(\frac{\partial \bar{u}}{\partial y} + \frac{\partial \bar{v}}{\partial x}\right) + \frac{\tau_x}{h} - \frac{C\bar{u}}{h} \tag{29}$$

$$\rho\left[\bar{u}\frac{\partial \bar{v}}{\partial x} + \bar{v}\frac{\partial \bar{v}}{\partial y} + f\bar{u}\right] - \rho g\lambda\frac{\partial}{\partial y}\left[\frac{\partial}{\partial y}(h\bar{u}) + \frac{\partial}{\partial x}(h\bar{v})\right]$$

$$= 2\frac{\partial}{\partial y}\left[\mu_h\frac{\partial \bar{v}}{\partial y}\right] + \mu_h\frac{\partial}{\partial x}\left(\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{v}}{\partial y}\right) + \frac{\tau_y}{h} - \frac{C\bar{v}}{h}. \tag{30}$$

Where μ_h is a horizontal mixing length (eddy) viscosity coefficient and f is an angular rotation of coriolis acceleration and c is a friction coefficient. λ is a very large number called penalty parameter. τ_x and τ_y are wave tractive forces. u and v are represented the mean transport velocity component.

The equations are discretized using the method of weighted residuals. The choice of a penalty parameter, λ is fairly critical although empirical. If it is too large machine error will dominate the results, while if it is too small the condition is not enforced. A value of λ in the order of 10^6 was suggested for this shallow water problems.

Longuet-Higgins (1970a,b) reasoned that the eddy viscosity effects should tend to zero at the shoreline and suggested

$$\mu_h = N\rho |x| (gh)^{1/2} \tag{31}$$

N is a dimensionless constant. μ_h is horizontal viscosity. From studies of the effects of littoral friction on the velocity profile using field data, the range of N was found to be between 0.0024 and 0.0096. Many authors also had introduced their expressions for eddy viscosity. James (1974) summarized some available values of N were between 0.009 and 0.064. N = 0.01 is used in this computation.

Longuet-Higgins assumed a similar quadratic law which similar to standard quadratic law for turbulent river for bottom stress, would apply to the oscillatory flows encountered under waves in the surfzone. He suggested that if there were longshore currents bottom friction under a wave would be given by

$$\tau_b = F_{LH} |u_{orb}| u_{orb} \tag{32}$$

where u_{orb} was the orbital velocity and F_{LH} was the Longuet-Higgins friction coefficient. The coefficient is given as

$$F_{LH} = \frac{g}{C_z^2} \tag{33}$$

where C_z is Chezy's coefficient. If there is a range of Chezy's coefficients of 60 - 100, there is a range of Longuet-Higgins' coefficients of 0.003 - 0.001. Longuet-Higgins' suggested value for F_{LH} = 0.01. Liu and Mei (1976a,b) adopted two values of 0.01 and 0.09 in their nearshore current computations.

Longuet-Higgins etc. supposed that the radiation stress was a crucial driving force in the nearshore current. Inside the surfzone the wave energy decreases shoreward, leading to a decrease in the radiation stress. Outside the surfzone because of no wave energy dissipation the longshore gradient of the radiation stress is always zero, and the flow is therefore driven only inside the surfzone. The radiation stress terms τ_x and τ_y are given as Eqs. (21) and (22).

2.5. LONGSHORE BOUNDARY CONDITIONS

When waves and currents are predicting numerically in a region adjacent to a long coastline, there are four boundaries enclosing the region of interest: the coastline, two roughly normal to the coast and a seaward boundary. When waves are incident from deep water upon the coastline at some angle, θ , due to shoaling effects they refract and diminish the angle of incidence as they travel into the shallow water. In the region, the problem can be complicated by wave reflections leading to partial standing waves, diffraction resonance effects. Incorrect treatment of these artificial boundaries of the model will induce chaos in the problem. some damper and repeatibility boundaries are introduced in the present model.

Shoreline - A finite depth and smoothing the depth profile near shoreline is given to prevent infinite number of elements in the mesh

due to wave number k tending to infinity. Then we apply boundary damper by Sommerfeld's (1896) radiation condition to absorb the incident wave.

Boundary parallel to the shoreline - The model is simply terminated at this boundary.

Boundaries normal to the shoreline - Dampers and Snell's law have been used. The dampers absorb and generate the longshore component of the incoming wave.

In the case of current model it is assumed the flow profile at one artificial boundary is the same as the flow profile at the second boundary and a repeatability condition is applied as

$$u(x,0) = u(x,L)$$
$$v(x,0) = v(x,L) \qquad (34)$$

The condition is restrictive in that the beach slope and water depth need to be identical at each end of the model.

3. GEOMETRY, DATA AND RESULTS

3.1 GEOMETRY

The geometry chosen here is that of an offshore breakwater at Santa Monica, California which has been described by Liu and Mei (1976a,b). These are as Fig. (3) shown,

breakwater
- length : 700 m
- thickness : 0 m
- wall : vertical and perfectly reflective
- position : 350 m from shoreline
- domain : x = 350 m, 350 m $\leq$ y $\leq$ 1050 m parallel to the shore
- depth : 7 m

beach profile
- uniform slope : slope = 1/50 for all y.

3.2 DATA

In order to model the wave accurately four elements per wavelength rule is maintained. Wider spacing is used in y direction, except at the tips of the breakwater where singularities occur. Restricted by the computation time for the fact that the numbers of the element will become enormous for covering all the describing region after the mesh is finer, a little bit longer wave period will be set to match the rule instead of subdividing the mesh in this computation. The wave climates are as

periods	: T = 10 sec and 20 sec
incident wave amplitute	: a = 0.5 m
angular frequency	: ω = 0.62832 and 0.31416 (1/sec)
gravity	: g = 9.81 m/sec^2
mass density of water	: ρ = 1000 kg/m^3
incident angles	: θ = 0 and 10 degrees.

Empirical data are

breaking criterion	: McCowan's value γ = 0.8
eddy viscosity	: μ_h = 10.0 kgf.s/m
friction coefficient	: F_{LH} = 0.0015, 0.01 and 0.09
penalty parameter	: P = 100000 and 1000000
coriolis coefficient	: f = 0.

3.3 RESULTS

3.3.1 DIFFRACTION AND REFRACTION

In Fig. (4) contours of absolute values of wave elevation around offshore breakwater in the case of normal wave incidence of T = 10 sec are shown. It is could be seen that a strong reflection effects has resulted in standing waves in front of the breakwater. The peak of the wave elevation was at 1.2 m, compared with an incident wave amplitude of 0.5 m. Meanwhile some diffracted waves had intruded into the sheltered area of the breakwater. Similar situation is shown in Fig. (5) of T = 20 sec but wave penetrations are more profoundly because of longer wavelength. Fig. (6) is shown an oblique incident wave of 10 degrees attacks on the breakwater. A standing waves were form obliquely in front of the breakwater and more intruded waves In the upstream part.

3.3.2 NEARSHORE CURRENTS

As shown in Figs. (7), (9) and (11) which are in normal wave incidence of T = 10 sec there are two symmetrical counter - rotating cells found behind the breakwater in the case of friction coefficients, F_{LH} = 0.0015, 0.01 and 0.09 respectively. The variations of alongshore mean velocity component, V, through the centres of the circulation cell of constant y are shown in Figs. (8), (10) and (12) respectively. Two features can be seen immediately. First, the values of the velocity are decreasing as friction increasing. The maximum mean alongshore velocity component decrease from 1.911 m/sec, 1.310 m/sec to 0.568 m/sec. Second, the centres of the circulation cells shift outward about 50 m in each case apparently. This show the velocity is strongly affected by the friction which is a very difficult quantity to ascertain in the field. The two cells theoretically should be symmetrical but because of different distances from the boundaries chosen the unsymmetrical are found.

In the cases of a normal wave incidence of T = 20 sec, two more compact circulation cells are induced as shown in Figs. (13). The maximum alongshore mean velocity components, V, is 0.831 m/sec as Fig. (14) shown. In a 10 degree wave incidence of T = 20 sec because the wave force acts obliquely a strong circulation cell is found on the upstream of the surfzone. However on the other end, downstream, it is much weak comparatively. The maximum mean alongshore velocity is 0.845 m/sec on the upstream and much weak on the downstream. These are as Figs. (15) and (16) shown.

3.3.3 COMPARISONS

Because of the restriction of the available values of longshore current in the field or laboratory, only two references can be used for comparison. Firstly, Sauvage etc. (1955) has carried out a laboratory studies with sandy bottoms for an offshore breakwater and current directions. The observed trend of current and particle movement is sketched in Fig. (17). It is consistent with the present results above. Secondly, Liu and Mei (1976a,b) have developed a finite different model based on ray theory and ignoring that of convective inertia and viscosity. The comparisons between Liu and Mei and present results have been made in Fig. (18) and describe as:

Normal wave incidence, F_{LH} = 0.01

1. Position of the circulation centres
   y - direction
   Liu and Mei : y = 1125
   present : y = 1200
   x - direction
   Liu and Mei : x = 60
   present : x = 135
2. Max. mean alongshore velocity components, V
   Liu and Mei : 0.48 m/sec
   present : 1.365 m/sec

The above comparisons show good agreement in the general form of the circulation pattern, although there are some differences of detail.

4. CONCLUSIONS

An offshore breakwater on a beach for shore protection has been considered in the complete finite element model to study the wave variations due to diffraction, refraction and reflection, and nearshore current due to breaking wave inside or near surfzone with the considerations of convective inertia, eddy viscosity and bottom friction. A quite pleased result has been produced in this research.

CHAPTER 151

Effects of Short-crested Waves on the Scouring Around the Breakwater

Ming-Chung Lin* Chi-Tung Wu**
Yen-Chi Lu*** Nai-Kuang Liang****

The aim of this research is to investigate qualitatively the influence of short-crested waves on the scouring around the breakwater through mainly some laboratory studies. At first, we succeed to observe clearly in laboratory some sedimentary bed forms such as troughs, holes, triangle bars and longitudinal bars under short-crested wave actions. Then we elucidate the associstion of their formation mechanism with theory of short-crested waves, also indicate its effect on scouring at the toe of breakwaters. In addition, it is shown that the breaking wave height of short-crested waves is certainly higher than that of two-dimensional standing waves. Finally we demonstrate some facts of failure of breakwater caused by short-crested wave breaking basing on some field results.

1. Introduction

As the breakwater is built in the sand bed region the incident waves and their reflected waves are combined into Short-crested waves system. The vortex motion and maxro-tubulence structure under the wave system can scour deep holes and result in subsidence of the breakwater. This phenomen is well known to the practicing engineers.

A theorietical solution presented by Fuchs (1952), based upon linear theory, had been applied to short-crested wave system. Later, the extensive work by Chappelear (1961) had improved the accurocy of Fuch's approximation, but with the difficulty of immediate application due to very length formulation. A more sophisticated second order theory had been proposed by Hamada (1965) by means of the secondary interactions. A third order approximation to the short-crested waves was derived by Hsu (1978). In addition, that breaking wave height of short-crested waves is certainly higher than that of two dimensional progressive waves was shown by Halliwell and Machen (1981). The breaking wave height obtained from the third approximation of Hsu & Siloverster (1982) matchs well with that result by Halliwall (1981). The aim of this paper is to investigate qualtatively influence of short-crested waves on the scoaning around the breakwater through mainly the movable model tests studies.

2. Summary of short-crested wave theory

2.1 Basic properities of short-crested waves

When waves approach and are reflected from vertical breakwater, they creat a surface undulation of a diamond pattern, known as short-crested waves, as shown in Fig. 1. With a coordinate system of x being in the direction of advancing the combined crest, Y tranversally to the celerity vector of the combined wave and Z positive upward from the still water surface, Fuchs (1952) derived the frist order approximation as:

$$\phi = \frac{ag}{m C_s} \frac{\cosh r(d+y)}{\cosh(rd)} \cos m(X - C_s t) \cos nZ \quad \text{(2-1)}$$

$$m = \frac{2\pi}{L} \qquad n = \frac{2\pi}{L'} \qquad r^2 = m^2 + n^2$$

$$Y_s = -\left[\frac{1}{g}\frac{\partial \phi}{\partial t}\right]_{y=0} = a \sin m(X - C_s t) \cos nZ \quad \text{(2-2)}$$

$$C_s^2 = \frac{gr}{m^2} \tanh(r \cdot d)$$

$$= \frac{gL}{2\pi}\sqrt{1 + \left(\frac{L}{L'}\right)^2} \tanh\left[\frac{2\pi d}{L}\sqrt{1 + \left(\frac{L}{L'}\right)^2}\right] \quad \text{(2-3)}$$

where ϕ, Y_s and C_s are velocity potential, surface profile and wave velocity repectively.

$$C_s = \frac{gT}{2\pi}\sqrt{1 + \left(\frac{L}{L'}\right)^2} \tanh\left[\left(\frac{2\pi d}{L}\right)\sqrt{1 + \left(\frac{L}{L'}\right)^2}\right] \quad \text{(2-4)}$$

because $\sqrt{1 + \left(\frac{L}{L'}\right)} \geq 1$ then

$$C_s \geq \left(\frac{gT}{2}\right) \tanh \frac{2\pi d}{L} \quad \text{(2-5)}$$

Eq.(2-5) Show that the combined celerity of short-crested wave is larger than wave celerity of incident waves.

The water partical velocities in X,Y and Z direction under the short-crested waves are as follows:

$$u = \frac{\partial \phi}{\partial X} = \frac{ga}{C_s} \frac{\cosh[r(Y+d)]}{\cosh(rd)} \sin m(X - C_s t) \cos nZ$$

$$v = \frac{\partial \phi}{\partial Y} = -\frac{gar}{mC_s} \frac{\sinh[r(Y+d)]}{\cosh(rd)} \cos m(X - C_s t) \cos nZ$$

$$w = \frac{\partial \phi}{\partial Z} = \frac{gan}{mC_s} \frac{\cosh[r(Y+d)]}{\cosh(rd)} \cos m(X - C_s t) \sin nZ \quad \text{(2-6)}$$

The orbital of water partical is :

$$X = \left(\frac{H}{2}\right) \frac{\cos\left(\frac{2\pi}{L}\right)(Y+d)\sqrt{1+\left(\frac{L}{L'}\right)^2}}{\sqrt{1+\left(\frac{L}{L'}\right)^2}\sinh\left(\frac{2\pi d}{L}\right)\sqrt{1+\left(\frac{L}{L'}\right)^2}} \left[\cos\left(\frac{2\pi Z}{L'}\right)\sin\left(\frac{2\pi X}{L}\right)\right]$$

$$Y = \left(\frac{H}{2}\right) \frac{\sinh\left(\frac{2\pi}{L}\right)(Y+d)\sqrt{1+\left(\frac{L}{L'}\right)^2}}{\sinh\left(\frac{2\pi}{L}\right)\sqrt{1+\left(\frac{L}{L'}\right)^2}} \left[\cos\left(\frac{2\pi Z}{L'}\right)\cos\left(\frac{2\pi X}{L}\right)\right]$$

$$Z = \left(\frac{H}{2}\right)\left(\frac{L}{L'}\right) \frac{\cosh\left(\frac{2\pi}{L}\right)(Y+d)\sqrt{1+\left(\frac{L}{L'}\right)}}{\sqrt{1+\left(\frac{L}{L'}\right)^2}\sinh\left(\frac{2\pi d}{L}\right)\sqrt{1+\left(\frac{L}{L'}\right)^2}} \left[\sin\left(\frac{2\pi Z}{L'}\right)\cos\left(\frac{2\pi X}{L}\right)\right] \quad \ldots(2\text{-}7)$$

The water particles follow elliptical paths which are angled to the horizontal.

$$\tan\beta = \frac{n \tan(nZ)}{r \tanh r(Y+d)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (2\text{-}8)$$

Furthermore, also derived the free surface profile to the second-order approximetion as follow:

$$\phi = A \cosh r(d+Y) \cos m(X - C_s t) \cos n Z + B \cosh 2r(d+Y) \cdot \sin 2m(X-C_s t) \cos 2nZ + D \cosh 2m(d+Y) \sin 2m(X-C_s t)$$

$$A = \frac{am}{r} \frac{\cosh r(d+Y)}{\sinh r d} \cos n Z$$

$$B = -\frac{3}{16} \frac{A^2 r^2}{C_s m \sinh^2 r d}$$

$$D = \frac{A}{8 m C_s} \frac{4 n^2 \cosh^2 rd - 3r^2}{2 \cosh 2md - (m \sinh 2md/r \tanh rd)} \quad \ldots\ldots\ldots \quad (2\text{-}9)$$

$$Y_s = a \sin m(X-C_s t) \cdot \cos nZ + \frac{a^2 r^2}{4 \sinh 2rd}(2 \sinh^2 rd - 1 + \frac{3 \cosh 2rd}{\sinh^2 rd}) \cdot \cos 2m(X-C_s t) \cdot \cos 2nZ + \frac{a^2(m^2-n^2 \cosh 2rd)}{4r \sinh 2rd} \cdot \cos 2nZ + \frac{a^2}{4r \sinh 2rd} \left[\frac{(3r^2-4n^2\cosh^2 rd)\cosh 2md}{\cosh 2md - (m \sinh 2md/2r \tanh rd)} - m^2 \cosh^2 rd + 3r^2 \sinh^2 rd + n^2 \cosh^2 rd\right] \cdot \cos 2m(X-C_s t) \quad \ldots\ldots\ldots \quad (2\text{-}10)$$

2.2 Water partical motions under the short-crested waves system.

Basing on the Fuths theory, Silvester (1974) sketched the schematic diagram of water particle path under short-crested wave action, as Fig. 2. From this figure, the water particle motions can be described as

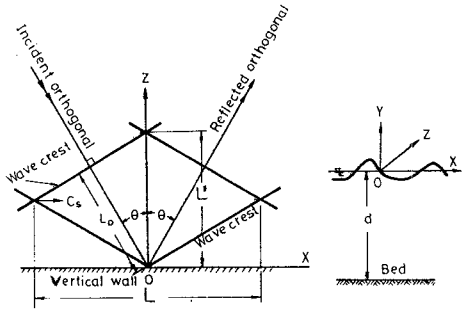

Fig. 1 Short-crested wave formed in front of a vertical wall.

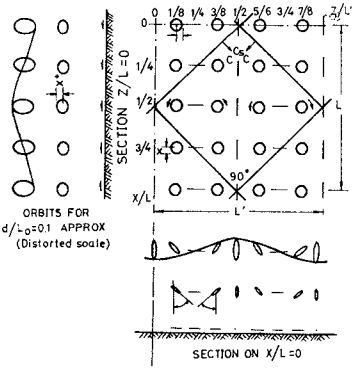

Fig. 2 Water particle orbits and mass transport under the short-crested wave. (Silverster, 1974)

follows.

(1) The wave profile along the centreline of the crests, at Z/L' = o, 1/2 , 1. etc., is more likely to be that of a solitary wave.
(2) Half-way between these crest alignment, at Z/L'=1/4, 3/4, etc., the orbital motion are rectilinear and are transverse to wave propagation.
(3) Between these again, at Z/L' = 1/8, 3/8, 5/8 , etc., the water particles follow elliptical paths which are angled to the horizontal.

The influence of these complex water motions on a sedimentary bed have been examined by. Tanalca and ozasa (1972), and Silvester (1974).

2.3 The breaking wave height wave height of short-crested wave.

There are two different theorm on the breaking wave height of short-crested wave so far. One is solitery wave theorm, another is progressive wave theorm.

(A) Solitary wave theorm:
Halliwell and Machen (1981), basing upon work of Milies (1977) , derived the breaking wave height of short-crested as follows:
when

$$C_S/C_1 \doteqdot \text{Sec } \theta_1$$

$$C = \sqrt{g(\eta+d)} \quad \text{.....(2-11)}$$

$$\frac{d+\eta_3}{d+\eta_1} = \text{Sec } \theta_1 \quad \text{.....(2-12)}$$

$$\frac{\eta_3}{\eta_1} = \left(\frac{d}{\eta_1}+1\right)\sec^2\theta_1 - \frac{d}{\eta_1} \quad \text{..... (2-13)}$$

$$\therefore \ \eta_3 \geq \eta_1 \quad \text{..... (2-14)}$$

Let the breaking wave condition be $U_{max}/C_S = 1$, since $C_S > C$, there are greater Umax than that of incideut progressive wave with celectiy C. That is why the breaking wave height of short-crested wave is higher than that of progressive wave.

(B) The interaction of progressiv wave theorem.
Hsu & Silverster (1982), basing the third order approximation and taking the $U_{max}/C_S=1$ as a condition of breaking wave, got the breaking wave height which is larger than that of progressive wave and depend on the angle of interaction of two progressive wave.

3. Laboratory experiments

In order to investegate the effects of short-crested wave on the scouring around the breakwater, the movable bed model expeniments were performed in a wave basin with 60 m length, 43 m width and 1 m depth. A vertical breakwater was built in wave basin for producing a reflected wave train . The scouring at the toe of the breakweter has been since before one of the serious problems confronting the Taichung engineers. The laboratory studies are therefore based on the model test of Taichung Harbour located in Mid-western Taiwan. Fig. 3 depictes a schematic sketch of the experimental hydraulic model employed.

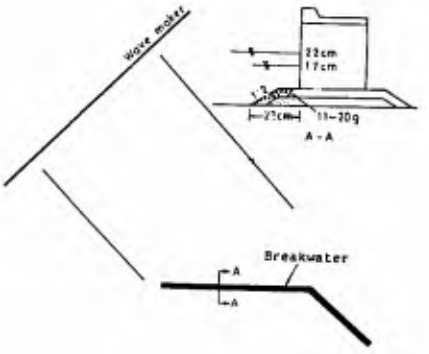

Fig. 3 Schematic diagram of the experimental model.

Fig. 4 Short-crested wave formed in front of the breakwater.

The ratios of model employed were that the breakwater , wave period, wave velocity., and wave pressure were 1/64 and the rock weight was $1/64^3$. The sand used for movable bed was directly taken from the natural beach in the vicinity of Taichung Harbour and its mean median diameter D_{50} was 0.22 mm.

It takes about one hour of time to complete a run of experiaments. Measurements performed were mainly included wave height distribution, breaking wave height and overall bed form. The bed forms were simultaneously obtained by photographing and level measuring. In order to investigete the scouring, when performing the experiments, we paid particularly attention to the situation as the short-crested waves are breaking.

4. Results and discussions

The runs of model test, the results of laboratory studies and the field data survey are shown in Table 1, 2 and 3. The short-crested wave formed in front of the breakwater was shown in Fig. 4 and Fig. 5. A typical result of bed forms under the action of short-crested waves are depicted in Fig 6 and 7. It can be clearly seen from this figure that the sedimentary bed is scoured by the breaking short-crested waves. As shown in Fig. 8 and Fig. 9, concerning the bed form in detail near the breakwater, deep holes and triangle bar are generally formed at the place of wave breaking. In Fig. 10 the sand ripples appear in the front of the breakwater and in Fig 11, the longitudinal bar and trough appear around the corner of the breakwater. If the breaking short-crested wave height is even greater, the impinging wave breaking will produce a large scouring hole just at the toe of the breakwater, as shown in Fig. 12.

(1) The brearking wave height resulting from the short-crested wave is greater than that of incident wave and this result matchs that of Hsu & Silvester. (1982), as shown in Fig. 13 and 14.

(2) The scouring in front of breakwater under the short-crested wave is strong and serious. The characteristics of the scouring as follows.
   (a) at Z/L'=0,1/2 , 1..., the sand hed were scoured and the sediments were transported in the X dinection.
   (b) at Z/L'=1/4, 3/4, ... there are the back and forth motion of water particles along the Z direction. There are no sediment transported in the X direction
   (c) at Z/L'=1/8, 3/8, 5/8, 7/8...etc., the swirling motion of water particles have much contribution in expediting the sediment movement. The moving sediments are transported into the adjoining regions.

(3) The mechanism of various sedimentary bed forms may be explained as follws:
   (a) at Z/L'= 0, 1/2, 1, etc, the sediments are transportad along the short-crested wave progessing. The greater the wave height is, the more the transportation is. Then, in this condition, the trough is formed along these lines (Z/L'=0, 1/2, 1 etc), as shown in fig. 1.
   (b) at Z/L'=0, 1/4, 1, .. only a few sediments are transported along transverive and longitadinal direction. In this characteristic, the longitudinal bar was formed.
   (c) When the breaking waves take place, the sand bed is formed

into deep hole under the breaking waves, and the sand bed, by the deep hole, was formed triangle bar.

(d) Furthermore, for comparision, the sea bottom contours around the corner of the breakwater obtaned from the field data survey is depicted in Fig. 15, revealing the same tendancy as that of leboratory.

5. Conclusions and Remarks

From the laboratory experiments and field observation, the scouring effect, resulted from the short-crested wave system, on the foundation of breakwater can be drawn:

(1) Oblique incident waves and their reflected waves are formed into short-crested waves system in front of the breakwater. This short-crested waves progress along the breakwater and gradually swell up. Swelling up along the breakwater is greater than that of breaking wave height limit, the short-crested wave are broken. The breaking short-crested wave height is larger than that of progressive wave, and belong to plunging breaking wave. This breaking waves result in serious scouring around the breakwater.

(2) The characteristics of water particle motions under the short-crested wave system enforced the sediment transport and form into special bed forms such as troughs, holes, triangle bars and longitadinal bars.

(3) While the breaking waves happen, the vortex motions penetrate to the bed in the vicinity of the breakwater scour the foundation of the breakwater, and result in subsidence of the breakwater.

(4) It's suggested that when the breakwater is designed or built, the influence of short-crested wave should be considered.

(5) However, in this paper, only the qualitative results were reported.

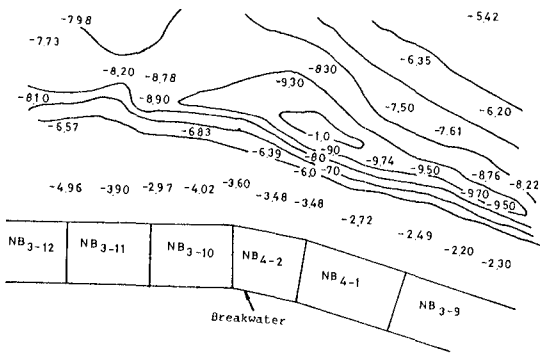

Fig. 15 Bottom contours around the corner of the breakwater for field case.

CHAPTER 152

THE STRUCTURAL RESPONSES OF DOLOS ARMOR UNITS UNDER THE DYNAMIC LOADING

Wei-Ming Lin*, Cheng Rau**, Rea-Lon Su**

ABSTRACT

The "Dolos" is now used widely for harbor and shore protection works in various ports of Taiwan (R.O.C.) and some damage has been noted. The purpose of this research is to understand the major factors which influence dolos breakage. The factors studied include plain or reinforced concrete, rebar arrangement, chamfered or enlarged fillet corner and the fracture behavior by pendulum and drop test.

Site observations and laboratory dynamic tests are included in this paper. The site observation investigated the behavior of the broken dolos at each habor. In the laboratory dynamic tests 42 specimens of 1.5 tons dolos were used for drop tests; frontal and transverse pendulum tests (Fig.1).

The results show that the fracture behavior in the laboratory tests agree with those of site observation, i.e. cracking due to frontal impact is more severe than that of transverse impact. The arrangement of rebar also influences the strength of the dolos. Therefore, it is suggested that the dynamic tests are necessary for dolos tesing.

INTRODUCTION

The sequence of breakwater failures in the late seventies and early eighties raised questions whether there were deficiencies in the design or construction of rubble mound breakwaters. Conclusions from some of the damage investigations were [1]:

- Damage to dolos of more than 15 tons can occur due to rocking, and hydraulic damage criteria are no longer applicable.
- More basic research and full scale monitoring is required to establish proper design guidelines.

A successful desing must ensure both the hydraulic and structural stability of the units. Consequently, problems related to the structural strength of dolos have been discussed. Lillevang[2] used 3D

* Head of Harbor Engineering Material Division, Institute of Harbor & Marine Technology, WuChi, Taichung District, Taiwan, R.O.C.

** Assistant Researcher of Harbor Engineering Material Div. Institute of Harbor & Marine Technology, Taichung, Taiwan, R.O.C.

photoelastic stress analysis to examine the stress distribution of dolos models with various shapes of stem-fluke corner under static loads. Burcharth[3] did drop and pendulum tests using 1.5 tons and 5.4 tons dolos, and proposed a method for a dynamic test, and Terao[4] also carried out drop and static load tests using 0.04 tons, 0.4 tons and 4 tons units.

Dolos have been used in various ports of Taiwan, R.O.C. The dolos have suffered impact loading resulting from rocking/rolling of units and missiles of broken units.

SITE OBSERVATIONS

Fig.2 is key map of the site obscration of dolos destruction in Taiwan and Table 1 shows a summary of detailed information of these dolos projects in Taiwan. The most severe storm damage which occurred at the east breakwater of Hua-Lien Harbor during typhoon Andy was up to 70%. The probable reason was the limited ability for placing 40 tons Dolos, hence the units were unstable on the steep armor slope. Damage of 20% occurred at the west breakwater of Hua-Lien Harbor, while still under construction and before the crown wall had been constructed. Hua-Lien Harbor faces the Pacific ocean and the units suffered from severe wave impact loade. Typical dolos destruction in Taiwan, R.O.C. is shown in Fig. 3.

THEORETICAL CONSIDERATIONS FOR ANALYSIS OF DYNANMIC TESTS

The dynamic testing of dolos to destruction is to simulate the impace force when the units are rocking or struck by broken units. Burcharth[3] derived formulae for the maximum tensile stress in a dolos exposed to impace load in a drop test and a pendulum test (Fig.4) by using impulse moment equations and dimensional analysis as follows:

$$\text{drop test : } \frac{\sigma}{MghC^{-3}} = C_1 \frac{1+r}{r^2}\sqrt{\frac{E}{\rho gh}} \quad , \quad 0.3 \leq 4 \leq 0.4 \quad \ldots\ldots\ldots\ldots \quad (1)$$

$$\text{pendulum test (1) : } \frac{\sigma}{mghC^{-3}} = C_2 \frac{1}{r^3}\sqrt{\frac{E}{\rho gh}} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (2)$$

where σ = maximu tensile stress
$M(m)$ = dolos (pendulum) mass
h = fall height of pendulum (or dolos center of gravity)
C = dolos height
g = gravitational acceleration
E = elastic modulus
ρ : mass density of pendulum and dolos
r : waist ratio (0.319 in this test for 1.5 tons dolos)
C_1 and C_2: constant factors to be determined by tests

Since thest formulae were developed for specific test set-ups involving bending and shear stress in the most exposed cross seciton, we developed another test set-up for a transverse pendulum test which creates mainly torque in the stem. A formula were developed similar to the frontal pendulum test as follows:

pendulum test (2) : $$\frac{\tau}{mghC^{-3}} = C_3 \frac{1}{r^3}\sqrt{\frac{E}{\rho gh}} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (3)$$

where τ = torsion
C_3= constant to be determined by tests.

TEST PROGRAMME

Test Specimens

A total of 42 units of 1.5 tons dolos were used in the tests and classified into seven types. Six units of each type were used for drop tests, frontal and transverse pendulum tests. The geometry and specifications of the units are shown in Fig. 5 and Table 2 respectively.

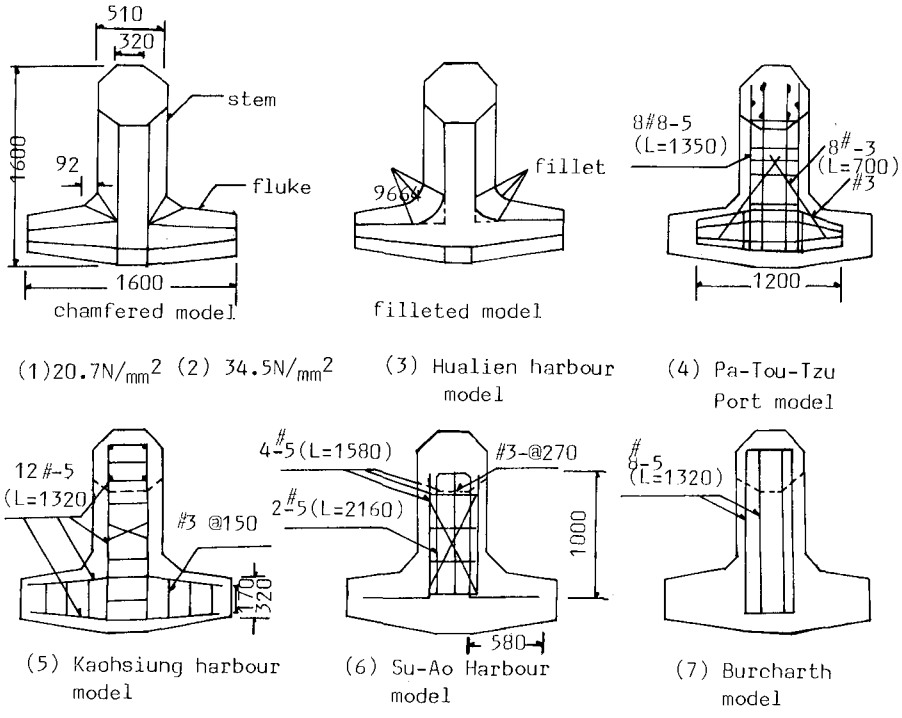

Fig 5. GEOMETRY OF DOLOS UNITS

Fig. 6 shows the preparation of dolos specimens. For quality control, two control specimen (15 cm x 30 cm) for each dolos unit were manufactured and tested by 100 tons universival material testing machine (Fig.7). They were also taken nondestructive tests by using test hammer (Fig.8) and ultra-sonic pulse measuring units (Fig.9). These data were compared to the compressive strength of control specimen's results.

Experimental Method and Equipment

Three different types of test were used (Fig. 4). The drop test simulates the wave induced rocking of the units. The pendulum tests (1) and (2) simulate the frontal and transverse impact from pieces of broken units that are thrown around by the waves.

The experiment was carried out on a test platform. In the drop test, one end of the dolos is lifted to a predetermined height and then dropped by means of a quick release hook (Fig. 10 & 11). In the pendulum tests (1) and (2), the pendulum is pulled back a certain distance and then released.

The pendulum is a steel cylinder mould with wall thickness of 10 mm, filled with the same type of concrete as used in the dolos. Its weight is 1/5 of the dolos weight. The pendulum is suspended on two wires hanging on a steel gantry.

Before dynamic testing the dolos specimen were tested by using test hammer and ultronic-sonic pulse measuring unit (Fig.12) to be sure of good quality.

In the drop tests, we measured the fall height (the vertical distance from the base to the center of the fluke end); the initial drop of 100mm was gradually increased in increments of 20mm. In the pendulum tests, we measured the draw back distance (the shortest distance between the surface of the pendulum and the impact point on the dolos); and it was gradually increased from 300mm in the first strike, in increments of 20mm.

Because of the rebound, the dolos was jerked back against the steel packing block after each pendulum blow.

The concrete surface was carefully examined after each strike and the width and extent of the cracks were recorded.

With the purpose of examining the fracture, the loading on the plain concrete was continued until the unit broke into two pieces. Failure of the reinforced units was taken as occurring when the crack width exceeded o.15mm which examined by a crack detection microscope (Fig.13).

TEST RESULTS

Maximum Fall Height

The average maximum fall height of the pendulum (or the dolos center of gravity) was defined as the point at which the plain concrete dolos broke into two pieces and the crack width of reinforced units exceeded 0.15mm.

The test results of average maximum fall height of dolos destruction for the seven types used are shown on Fig.14. It is quite obvious that the Pa-Tou-Tzu fishery port model is the best one. For chamfered corner dolos made of plain concrete, a strength of 34.5 N/mm² (5000 psi) is better than that of 20.7 N/mm² (3000 psi), and for the same strength of 34.5 N/mm² (5000 psi), the chamfered corner type is better than the enlarged fillet corner type.

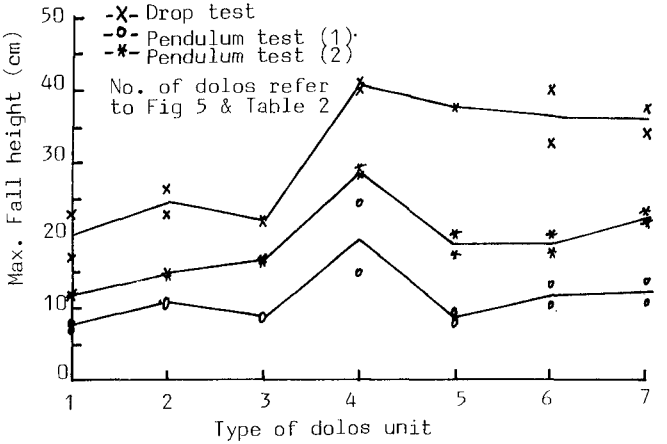

Fig 14 Max. Fall Height of Dolos Destruction

Fracture Types

The fracture types of dolos destruction are shown on Fig.15 and Fig.16 and described as follows:

Drop test: There were two fracture types. In the first type, cracks started at the top of the stem-fluke corner and spread to the bottom of the stem. In the second type, the fractures not only developed in the stem-fluke corner but also in the middle part of the bottom of stem, and spread to the top of the stem.

Pendulum test (1) : In one type, cracks started at the bottom of the stem-fluke corner and spread to the top of the stem. In another, cracks started at the top of stem-fluke corner and spread to the fluke.

Fig 16. Typical cracks and fractures under dynamic tests

Pendulum test (2) : The cracks either started in the middle part of the top of the stem and spread to the bottom of the stem, or started at the top of the stem-fluke corner and spread to the fluke. For reinforced units, the crack spread is fast in the fluke and very slow in the stem.

Maximum Stress vs Fall Height

Test data for the three kinds of plain concrete units were input into eq.(1), eq.(2) and eq(3). The constant factors were determined by test results and are shown in Table 3. The maximum tensile stress on the dolos is proportional to the square root of the average maximum fall height of the pendulum. This relationship is shown in Fig.17. Therefore by comparing with the plain concrete cylinder splitting test data, the mean static tensile strength of each type of dolos model can be obtained and is shown in Table 4.

TABEL 3. FACTORS IN EQ.(1)-(3) DETERMINED BY TEST RESULTS

Test type	Factor	34.5N/mm² Chamfered	34.5N/mm² Filleted	20.7N/mm² Chamfered

Pendulum(2)	4.595	4.132	4.155	4,540

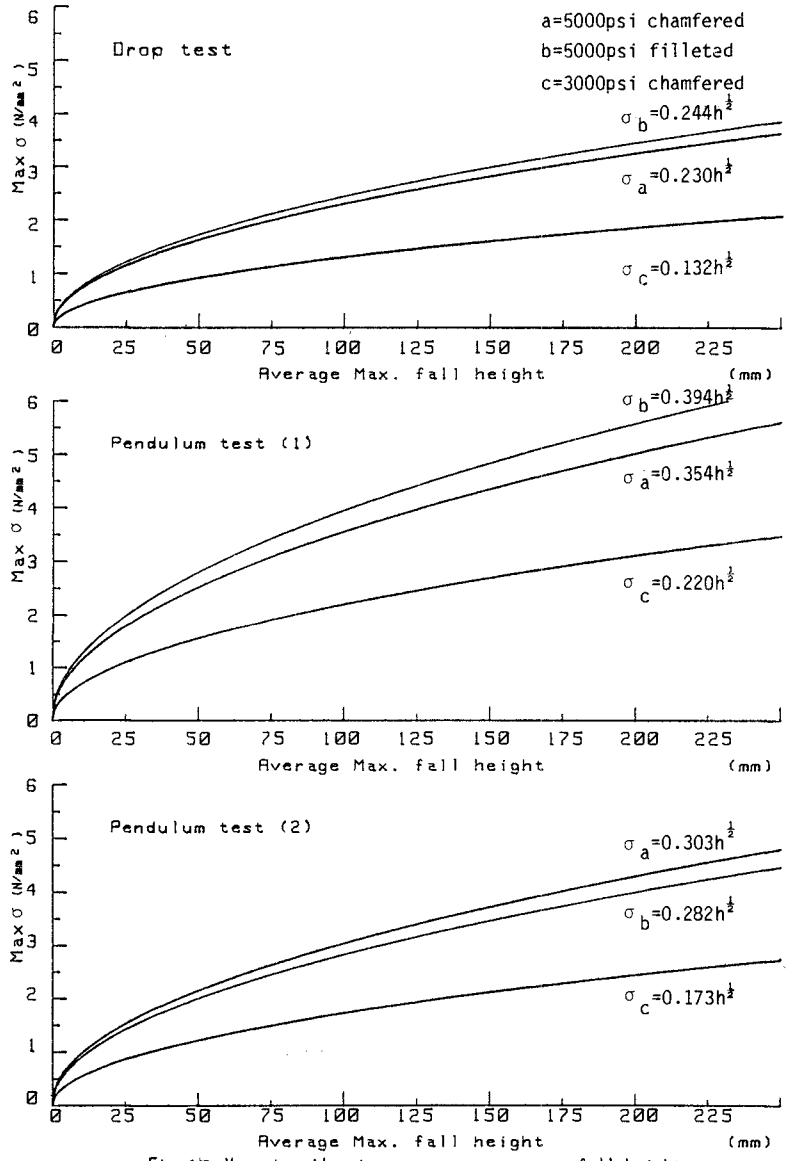

Fig 17 Max. tensile stress vs average max. fall height

DISCUSSION

1. Fig.14 shows that the dynamic strength of reinforced concrete units is better than that of plain concrete, therefore putting suitable rebar into the tension zone will reinforce the tensile strength of dolos.

2. Wave forces are random, therefore the rebar should be distributed throughout the stem and fluke of the dolos. In the Su-Ao Harbor model, the rebar in the fluke deflected to one side, and the dynamic strength was low. In the Kaoshiung harbor model, the quantities of rebar in the stem were inadequate. There is no rebar in the fluke of the Burcharth model, so it is easy to break the fluke. The rebar design in the Pa-Tou-Tzu fishery port model is better, and therefore it shows the best performance in the dynamic tests.

CONCLUSIONS

1. The cracking behavior in dynamic tests coincided with those of site observation. In the design of dolos, the design criteria should consider both the hydraulic and mechanical instability.

2. Comparing the results for units of both reinforced and plain concrete, it is clear that reinforcement of the unit could reduce the magnitude of the stress concentration, but a suitable rebar arrangement must be made to ensure durable behavior, otherwise corrosion of rebar may occur.

3. From the dynamic tests, it was found that cracks start at the corner between the stem and fluke. If the cross section of this corner is increased, then the free length of fluke will be shortened and the probability of dolos fracture will be decreased.

4. Fracture by frontal impact is more severe than that of transverse impact which in turn is more severe than that of the drop test.

CHAPTER 153

PROTOTYPE EXPERIENCE WITH RUBBLE MOUND BREAKWATERS

K.J. MacIntosh* and W.F. Baird*

ABSTRACT

At the 19th ICE Conference in Houston in 1984 an alternative concept for the design of rubble mound breakwaters was introduced. This concept has the objective of providing a least-cost structure by optimizing the use of locally available materials and utilizing simple construction procedures. Contractors' bids demonstrated that significant cost savings could be achieved, when compared to the cost of traditional designs.

Considerable prototype experience has now been obtained with this concept of breakwaters. Breakwaters have been built using the concept in Canada, the United States, and Iceland since 1984 and have been subjected to storms and ice action.

Prototype observations have supported the performance predicted during the design process. In this paper surveys of a breakwater taken after construction and after storm action are presented. In addition to wave action, this breakwater has also been subjected to extensive ice action. The response of the breakwater has been monitored and observed and is discussed.

INTRODUCTION

In 1984, Baird and Hall described an alternative procedure for designing a rubble mound breakwater. The objective of the design procedure is to maximize the use of local materials and to give consideration to construction procedures with the intent of minimizing cost.

It is useful to consider that successful rubble mound breakwater designs, providing protection from extreme storms, may extend from the use of one layer of large stones to sand beaches. Considering this "family" of breakwaters there is, of course, a point where there occurs extensive movement of the "stones" or sand grains that must be considered in the design process. However, stones at least one-fifth the weight of conventional armor stones (placed in two layers) can be used without any continuing movement of stones occurring, even at the head of the breakwater.

* W.F. Baird & Associates Coastal Engineers Ltd., 38 Antares Drive, Suite 150, Ottawa, Canada, K2E 7V2

Baird and Hall (1984) describe breakwater designs where continuing movement of stones does not occur. The designs specify armor stones significantly smaller than armor stones required for two layer conventional armor designs. Stability is achieved by increasing the width of the armor layer and through interlocking of the armor stones at the surface of the breakwater.

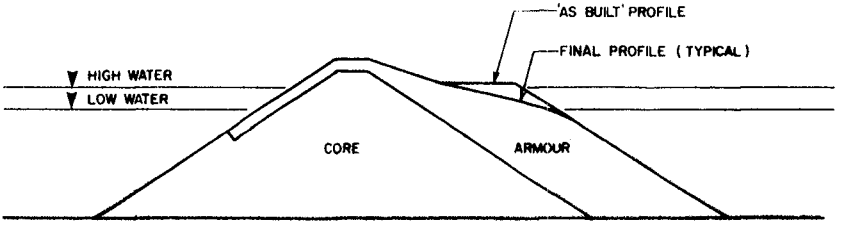
This alternate design using smaller armor stones is based on the observation that if the armor layer is built to significantly greater thickness than that of two stones, much smaller stones are required to provide stable protection against wave action. Therefore, the thickness of the armor layer for a specific breakwater is determined based on the gradation of the available armor stones and the incident wave climate.

The relatively high porosity of the mass of armor stones allows the waves to propagate amongst the stones and dissipate their energy over a large area within the wide armor layer. In a conventional two stone armor layer, the flow produced by the incident wave is restricted by the relatively impermeable filter and core and, consequently, there are large velocities produced by the wave uprushing or downrushing within the narrow armor layer. In the berm the flow has a larger area into which it can move and as a result localized velocities are greatly reduced thereby decreasing the external hydrodynamic forces applied to the stones. A considerable increase in stability is achieved as a consequence of this dissipation of wave energy within the permeable mass of armor stones.

The mass of armor stones also increases its stability as a result of wave action. Wave action causes consolidation and a resulting increase in shear strength of the mass of stones. Motion of some stones at the surface results in "nesting" of the surface stones. This nesting process also results in an increase in the frictional restraint on individual stones. Depending on the size of stones available and the design wave conditions, movement of stones on the outer surface may occur to varying degrees during the early stages of exposure to wave action. The stones eventually find a geometrically similar space in the berm surface into which they nest. The result of this process is a natural armoring of the outer layer of the stones.

These designs have allowed the engineer to use the most appropriate stones for the selected location. This has allowed complete utilization of local quarries at some locations, and has allowed the use of material produced as a by-product of an existing quarry operation at another.

The basic design consists of a core, which may consist of the lower fraction of the quarry yield, and the armor, which may consist of the upper fraction of the quarry yield, as shown in Figure 1.



EXAMPLE OF BREAKWATER WITH WIDE ARMOUR LAYER(BERM)

Figure 1

Breakwaters based on this design concept have been built at a number of locations. They are summarized below.

Codroy, Newfoundland.

The breakwater was designed to use the yield of a local quarry with stones ranging from 0.5 to 4.0 tonnes. The depth limited design wave height was 6 m. Construction was completed in the fall of 1984. Although no recorded wave data exists, it is expected that the design wave conditions have occurred on more than one occasion since construction.

Iceland

Seven breakwaters have been designed using this concept, by the Icelandic Harbour Authority, since 1983.

Helguvik Bay, Iceland

The breakwater was designed to use the yield of a local quarry which provided 1.7 to 7 tonne stone. The design significant wave height was 6 m, with depths renging from 25 to 30 m. Construction began in the spring of 1986 and is expected to be completed by the fall of 1987.

Racine, Wisconsin

The breakwater was designed to use the yield of a local limestone quarry. Stone sizes ranged from 0.14 to 2.7 tonnes. The design significant wave height was 4.4 m, with depths ranging up to 7.5 m. Construction was completed in November 1986.

North Bay, Ontario

A stockpile of waste stone from a previous construction project was used as the source of material for the North Bay breakwater. Stones weighing between 4 and 250 kg (the maximum weight available) were used to construct the breakwater. The

structure is located in depths up to 5 m, with a design significant wave height of 1.5 m. Construction was completed in November 1984.

The experience gained by the authors with their involvement with the design, construction and monitoring of these breakwaters is described below.

TRANSPORTATION

Restrictions and cost premiums associated with transportation of armor stones have been found to be important considerations in the design of a breakwater. Trucks and procedures for transportation also vary from location to location depending on the local construction requirements.

In Ontario, Canada, for example, highway trucks will carry stones below a certain size range (approximately 500 kg) without charging a premium. For stones larger than 1 ton, flat-beds are generally used. It is found that 2 to 5 tonne stones represent an ideal weight range where full loads can be obtained. A premium is charged for other sizes.

In Racine, highway trucks with special rock boxes were used that could carry any sized stone up to 2.7 tonnes. In North Bay it was possible to use highway trucks with regular boxes because of the smaller stone size. At other locations such as Helguvik Bay, it was possible to use off road trucks for construction of the breakwater and no restrictions or problems were encountered.

QUARRY OPERATIONS

Generally, there are two situations to consider in the design process. Either a quarry is to be operated specifically for the breakwater construction, or a product of an existing quarry operation will be used.

In either case, the weight gradation of the quarry or available quarried material is estimated and the breakwater is designed to optimize the use of these materials. Each design provides for the simple division of the quarry yield into two fractions, the armor stone and the core material.

During construction, the essential requirement is to verify that the actual gradation being obtained is similar to that assumed in the design process. Monitoring of the gradation of the armor is required with the procedure used depending on the stone weight. For relatively small stones, satisfactory results have been obtained by taking representative samples and establishing the gradation of the sample. For large stones (for example, greater than one tonne), in addition to establishing the gradation of representative samples, it is also useful to count the number of stones in selected trucks and compare this to the total weight of the load (which is measured by a weigh scale).

There will be a unique number of stones to weight ratio for any defined gradation.

Quarry operations are simple because a particular size of stone is not being selected. The armor stones may be produced by a screening process or by removal of all stones above a specified weight. Both processes have been successfully used in prototype situations as discussed below.

The North Bay breakwater design consisted of using all the stones available above 4 kg. The removal of the material less than 4 kg, completed with a grizzly operation, was required to provide sufficient voids for wave energy dissipation in the armor layer. Some difficulties occurred in developing an efficient grizzly operation; however, the problems associated with the removal of the small stones were eventually resolved. Because of the size of the breakwater and amount of stone available it was not necessary to build a core. It was more economical to build the entire breakwater cross-section of one stone gradation.

In Helguvik Bay, a quarry operation was set up on the rock bluff directly adjacent to where the breakwater is under construction. The rock was blasted and then sorted using hydraulic excavators. Then, depending on the stage of construction, the stone was trucked to an armor stock pile or trucked directly to the breakwater for placement. This efficient operation is shown in Figures 2 and 3.

PLACEMENT

Experience with armor placement has been obtained with the use of bulldozers in an essentially "dump-and-push" operation, and with cranes.

Both have been successfully used, although there is a limit to the stone weight that can be effectively moved by a bulldozer during breakwater construction. Bulldozers were used at Codroy, Racine, and North Bay for moving armor stone. With larger armor stones, such as at Helguvik, a crane operation can proceed very quickly because there is no requirement to carefully locate and place each stone in the armor layer. Contractors have found that a crane operation can easily keep up with the truck supply. If a crane operation is implemented then it is important that a well designed grab be used, appropriate for the size of stones to be handled.

Figure 2 Quarry Operation Adjacent to Breakwater Construction

Figure 3 Breakwater Construction

ARMOUR SPECIFICATIONS

The essential specifications for the armor are as follows:

1) The stones must be durable, or the durability must be known and accounted for in the design process,

2) The gradation of stone weights must be the same as that specified,

3) The voids must not be contaminated with undersized material since it is essential that the permeability of the armor be maintained.

The propagation of waves and the dissipation of their energy within the mass of armor stones is very evident and an important test of the correct construction of the armor. The propagation of waves up to the core can be seen and heard provided that the voids have not become filled with undersized material.

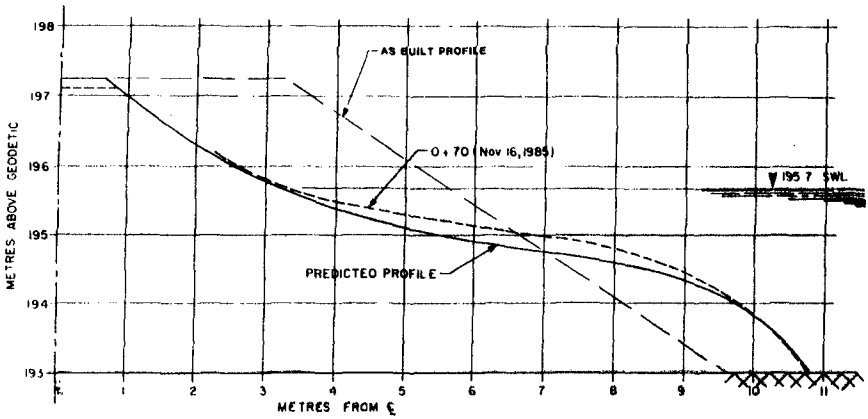
CORE SPECIFICATIONS

The core has been specified to contain any material not required for the armor. Filter layers have not been specified. In all of the very extensive model tests that have been completed (with geometric scales varying from 1:25 to 1:50), leaching of core material into the armor was not observed. However, a specification for a maximum percentage of fines, for example the percentage by weight of material less than 1kg, should be developed.

It is proposed that an appropriate percentage of allowable fines would be in the order of 30 per cent, as opposed to the 5 or 10 per cent specified for conventional breakwaters.

MONITORING

As noted in Baird and Hall, 1984, consolidation and change in the profile of the armor will occur when subjected to wave action. Prototype results from the North Bay breakwater reveal an accurate prediction of the expected profile by comparing it to the prototype profile measured after the breakwater was subjected to numerous storms. An example of the cross-section surveyed on the breakwater at North Bay, the as-built profile and the profile predicted from model test results are shown in Figure 4.



COMPARISON OF PREDICTED & MEASURED PROFILES

Figure 4

ICE

A field monitoring program of ice interaction with the North Bay breakwater was undertaken during the winter of 1984-85.

Because of the small armor stone size on the North Bay breakwater, there was concern about the effects of ice interaction with the structure. Therefore, a detailed field investigation was undertaken during the structure's first winter in service.

The objectives of this study were to:

1) Gather data on ice-breakwater interaction using surveying techniques, photography, and other general observations.

2) Determine the structure and origin of the various ice types present around the breakwater and relate the results to the meteorological data for the site.

3) Study the formation of ice and temperature profiles within the breakwater, by designing and installing an array of thermocouples (temperature sensors) to assess the extent of ice growth within the structure.

4) Analyze the collected data and develop relationships between the various parameters.

5) Provide an assessment of the ability of the breakwater to withstand interaction with ice.

The study program consisted of several measurement and observation techniques including: temperature measurements throughout the horizontal and vertical profile of the breakwater; surveys of the external profile of the breakwater structure and of the surrounding shore and ice profiles; determination of the properties and characteristics of the ice adjacent to the breakwater using crystallographic techniques; and measurement of water column temperature profiles.

In addition to the measurements noted above, visual observations were made of the modes of failure of ice on the breakwater and the relationship of water level changes to failure modes. The visual observations of ice-structure interaction were documented using field notes, photography and video recorders, as presented in MacIntosh (1985).

The investigation provided several interesting results concerning the response of the breakwater to ice action.

1) No significant ice inclusions formed within the berm due to the combination of heat provided by the lake water and insulation from the snow and ice, overlying the breakwater. Consequently, the voids within the breakwater were never filled with ice.

2) Failure and deterioration of the ice surrounding the breakwater occurred in such a manner that the ice did not move any stones from the breakwater either by plucking or by pushing. The buildup of spray ice on the surface of the breakwater was not sufficient to create any substantial loads or influence the stability of the breakwater slope.

3) The profile developed by wave action on this breakwater was advantageous in protecting the breakwater against damage from ice.

Overall, it appears that the berm type breakwater is not significantly affected by the interaction of fresh water ice with the structure. However, additional monitoring of the performance of the berm design under ice loadings, especially at other locations, is recommended. Extreme ice conditions not covered in the North Bay study may occur in the future although the ice conditions of 1984-85 were considered to be above average severity.

CONCLUSIONS

Prototype experience with rubblemound berm breakwaters has supported the performance predicted during the design process and led to the development of more efficient, cost effective construction techniques. Each berm design construction project, completed to date, has had a unique set of construction procedures. Variations in the quarry operations, transportation

methods, placement of armor and core materials, and monitoring of gradations have provided a better understanding of what methods are the most beneficial in each situation. Although each breakwater construction project completed in the future will also be unique, the experience gained during the construction of the breakwaters described in this paper is extremely valuable. The application of this knowledge to both the design and construction aspects of future projects will translate into more efficient and lower cost breakwater construction projects.

CHAPTER 154

Verification of the Analytical Model for Ocean Wave-Soil-Caisson Interaction

William G. McDougal[1], Yau-Tang Tsai[2], and Charles K. Sollitt[1]

Abstract

An analytical model for wave-soil-caisson interaction is verified by comparison with a finite element model and large scale experimental results. The analytical and finite element model estimates of the stresses and surface displacements of an elastic layer of finite thickness are in good agreement. The physical model experiments were conducted at the O.H. Hinsdale Wave Research Facility at Oregon State University. A 10-ft high, 8-ft long caisson was constructed on a bedding layer overlying 1 to 3 ft of soil. The caisson was exposed to waves with heights of 0.68 to 4.4 ft with periods of 1.77 to 8.80 sec. Experimental and analytical comparisons for porewater pressure were in agreement but the displacements were quite scattered.

1. Introduction

Caissons on permeable bases have been designed and constructed for a variety of needs in coastal and offshore engineering. An evaluation of the adequacy of the foundation beneath the structure is required for an economic and safe design. Recently, an analytical solution (Tsai et al., 1986) has been developed to model the wave-induced displacements, stresses, and porewater pressure under caissons. Before this solution can be used in engineering practice, it must be verified. Therefore, both a finite element model and a physical model are used to verify this analytical model.

2. Finite Element Model

The finite element model developed by Milovic et al. (1970) predicts the stresses and displacements in an elastic soil of finite thickness. The applied load is inclined and eccentric over a rigid strip. This configuration is shown in Fig. 1, in which F is the applied load, e is the eccentricity, θ is the inclined angle of the load, 2c is the width of the strip, and d is the thickness of the elastic layer. The strip foundation is perfectly rigid and has a rough base. The soil is assumed to be an isotropic, homogeneous, linearly elastic layer bounded by a plane horizontal boundary above and by a rigid base below. This numerical model corresponds to the radiation problem in the analytical model.

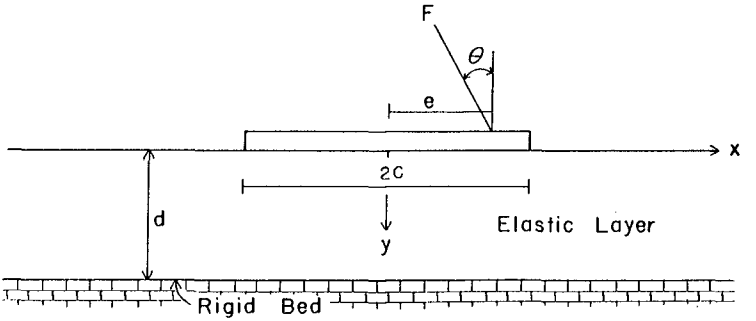

Figure 1. Definition sketch for a loaded infinite long rigid strip overlying an elastic layer

In this comparison the stresses are scaled by the averaged load per unit area and the displacements and thickness of the elastic layer are scaled by the block half-width. The comparison of contact stresses is presented in Fig. 2. The agreement between these two methods is reasonable for dimensionless soil depths of D = 2.0 and D = 6.0. Figure 3 shows the comparison of the vertical stress profiles along the center line of the strip for D = 2.0 and D = 6.0, respectively. Again, the analytical model and numerical model are in good agreement. The comparison of surface displacements in Fig. 4 shows that the analytical model predictions are slightly less than the finite elment model values for all three degrees of freedom. These comparisons also indicate that the soil responses are not particularly sensitive to the thin soil assumption in the development of the analytical model.

In the development of the analytical model, the solution for a contact problem was modified to provide the displacement boundary condition along the entire mudline for the outer region problem. The contact solution is developed under the assumption of a thin elastic layer so that the solution satisfies negligibly small shear stress and vertical normal stress conditions along the exposed upper surface for the radiation problem. The influence of the soil depth on these stresses is examined for various soil depths and locations along the exposed mudline. For this examination, the conditions in Table 1 are assumed.

Figure 5 reveals that at a dimensionless distance of 0.1 from the toe, the normal stress is less than one percent of the peak stress at the caisson toe, even though the dimensionless soil depth is up to 6. At a distance of 0.001, the stress ratio is small (0.15%) only for dimensionless soil depths less than 0.25. A similar result is also obtained for shear stress.

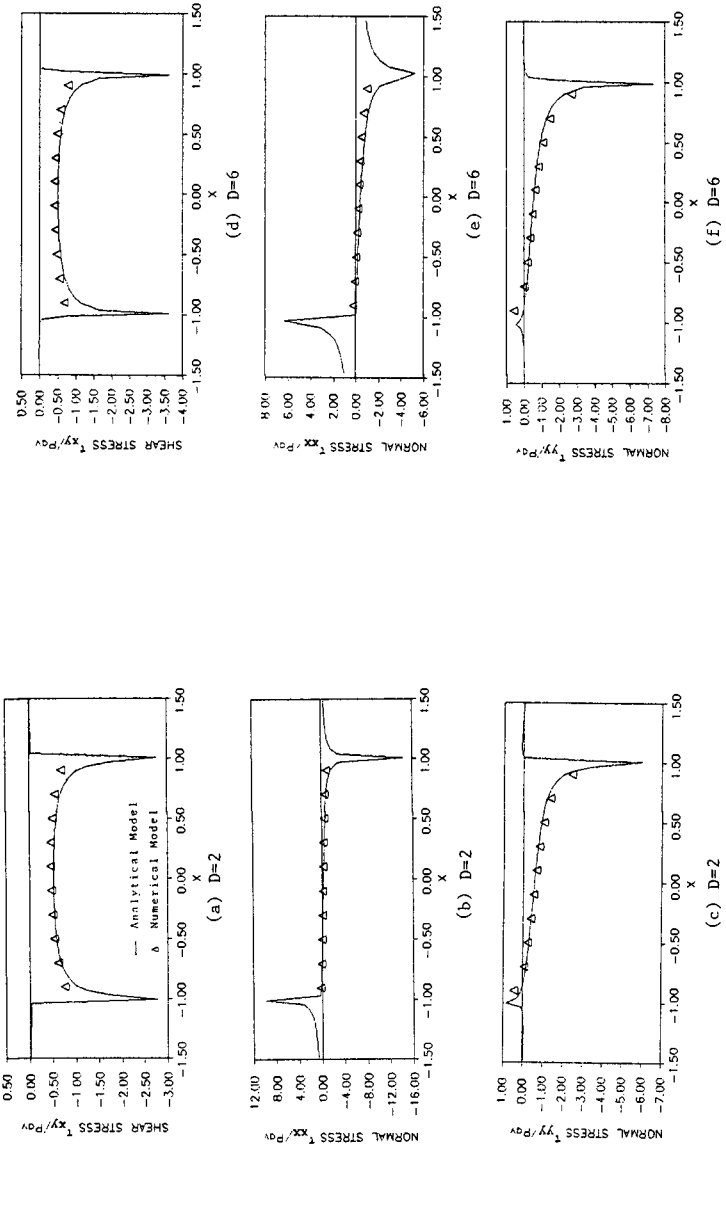

Figure 2. Comparison of the analytical and finite element models for the contact stresses on an elastic layer for Poisson's ratio = 0.3 and eccentricity = 0.5

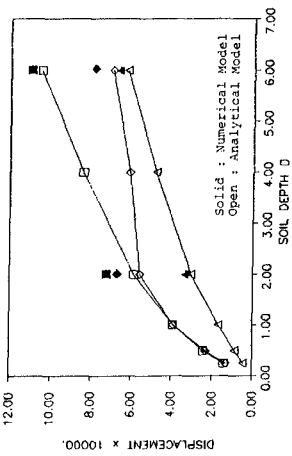

Figure 4. Comparison of the analytical model and finite element model for the surface displacements

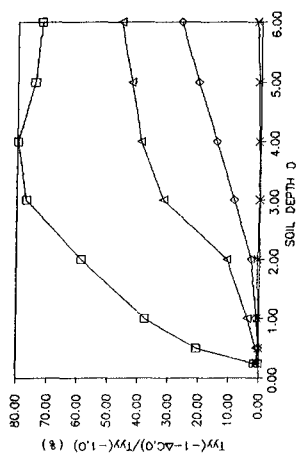

Figure 5. Vertical normal stress ratio along the exposed mudline as a function of soil depth

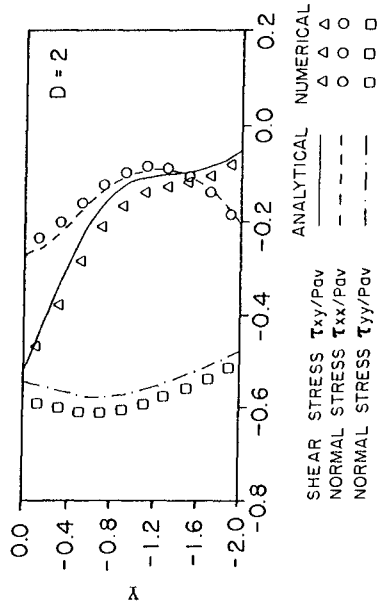

Figure 3. Comparison of the analytical model and finite element model for the vertical stress profiles at the strip center for Poisson's ratio = 0.3 and eccentricity = 0.5

Table 1. Conditions used in the examination of the thin layer assumption

Wave Period	= 4 sec
Wave Height	= 4 ft
Water Depth	= 8 ft
Thickness of the Rubble Bedding Layer	= 1 ft
Caisson Half-Width	= 4 ft
Mass of the Caisson	= 83 slugs
Mass Moment of Inertia of the Caisson	= 3,660 slugs-ft^2
Poisson's Ratio	= 0.3
Shear Modulus	= 80,000 psf

From the above and comparison with the numerical model, the influence of the thin layer assumption on the analytical model may be summarized as:

a) For the soil regions under the caisson and under the exposed mudline greater than 0.1c from the caisson, the analytical model is applicable for all soil depths.

b) For the response in the region (0~0.1)c from the caisson, the model is applicable only for soil depths d/c < 0.25.

These limits on thin layer assumption are illustrated in Fig. 6.

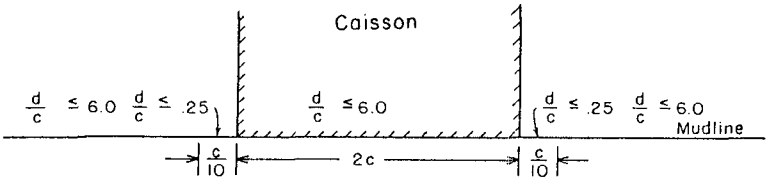

Figure 6. Limits on "thin layer" assumption

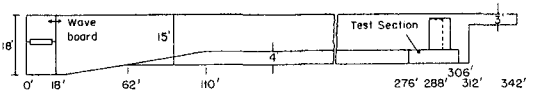
3. Physical Model

Two series of experiments of wave-soil-caisson interaction were conducted at the O.H. Hinsdale Wave Research Facility at Oregon State University during the springs of 1984 and 1985. A variety of wave conditions were examined. Incident waves, reflected waves, and transmitted waves were measured. Porewater pressure was monitored in the soil under the caisson. Three degrees of caisson motion, surge, heave, and pitch were measured with sonic transducers. Wave pressures also measured along the front face and bottom of the caisson and along the upstream portion of the mudline.

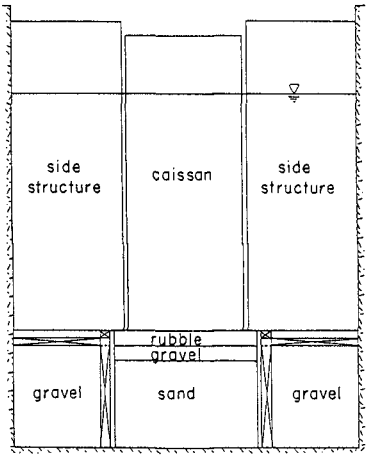
Experimental Conditions

Wave Tank - The OSU wave flume is 342 ft long, 12 ft wide, and 15 ft deep. The hinged-flap-type wave generator is able to produce solitary, periodic, and random waves. Simple periodic waves up to 8 sec in period and 5 ft in height can be generated. A polyurethane seal around the edges of the wave board confines the water to one side of the board. Precast concrete panels are available to form a false bottom with the desired water depth and slope.

Test Section - A test section, 30 ft long, 5 ft wide, and 4 ft deep, was constructed at the downstream end of the wave flume. A false channel bottom was installed to match the test section elevation. The sides and ends of the test section were fabricated with reinforced plyboard. The entire test section was bolted to the channel bottom and side walls. Figure 7 shows the test section. The side chambers of the test section were filled with highly permeable gravel to provide the extra strength and prevent side wall deflection during



(a) Elevation



(b) Cross section

Figure 7. Test section

the test. A perforated pipe was laid on the bottom of the channel to facilitate drainage during dewatering. In the middle chamber, a 3-ft layer for sand was used for the 1984 test. In the 1985 test, a 6-inch thick reinforced concrete slab was constructed as an impermeable hard-bed 1.5 ft above the bottom to provide a 1-ft deep sand layer above the concrete slab. These sand beds were fluidized and then reconsolidated back to a homogeneous condition. The fluidization was accomplished by using an inverted T-shaped manifold to inject a high-pressure water jet into the sand (Nath et al., 1977). This procedure prepared a uniform soil layer to ensure the repeatability of the experiments. Soil conditions are given in Table 2. The reconsolidation was induced through an over-burden of 6 to 12 inches of pea gravel separated from the sand by a geotextile. Rubble then was placed over the lift of the pea gravel to form a rubble bedding layer of approximately 1 ft thickness. The rubble had a mean diameter of 4 inches. The test caisson was then placed on the rubblemound foundation. Toe and heel protection were added.

Table 2. Soil properties for the tests

Year	1984	1985
Poisson's Ratio	0.3	0.28
Porosity	0.49	0.5
Shear Modulus	140,000 psf	110,000 psf
Permeability Coefficient	0.00033 ft/sec	0.00040 ft/sec

To provide a continuous caisson face across the width of the flume, fixed dummy side structures were constructed along each side of the caisson. These dummy sections were rigidly attached to the side walls of the wave flume. To allow caisson motion, a 1-inch gap was left between the caisson and side structures. The front of the gap was covered with a rubber strip to provide a watertight seal. The side structures were 3.9 ft wide, 12.3 ft long, and 10.5 ft high. They were constructed of heavily reinforced plyboard and rigidly bolted to the bottom and sides of the wave flume.

Test Caisson - The test caisson was 10 ft high, 8 ft long, and 4 ft wide. It was also made of heavily reinforced plyboard. To obtain the desired mass, the caisson was filled with concrete cylinders and sand bags. For the 1984 test, only the weight of the cylinders and bags was measured. For the 1985 test, the locations of cylinders and bags were also measured. The weight of the empty caisson in air was 1470 pounds. The total weight of the caisson including the ballast was 5640 pounds in the 1984 test. For the 1985 test, three different weights of the caisson in water were tested, as shown in Table 3.

Instrumentation - The wave profiles and caisson motions were measured with sonic transducers. The dynamic pressures were measured with pressure transducers (Druck model PDCR10). Carborundum filter stones covered the transducer housings to prevent soil from clogging the pressure transducers. A small amount of air in the stone may sig-

Table 3. Weight, mass, and mass moment of inertia of the caisson in water for the 1985 tests

Weight (pounds)	Mass (slugs)	Mass Moment of Inertia (slugs-ft^2)
5,280	164	2,765
7,150	222	5,630
10,690	332	14,631

nificantly affect the dynamic response of the transducers. Therefore, the stones were first boiled to remove air and then always kept underwater. The transducers were calibrated by raising and lowering the still water level in the channel before and after each sequence of runs. The instrument locations for the 1984 and 1985 tests are shown Figs. 8 and 9, respectively.

Wave Conditions - The tests were run at a water depth of 8 ft. The periods and heights of the simple periodic waves were selected to span deep to shallow water conditions based on Dean's stream function wave theory (Dean, 1974). The wave case, height, and period employed in the tests are shown in Table 4. In the 1985 experiments, the wave periods were slightly adjusted to provide pure standing waves in the flume.

5B	5.59	3.07
4A	8.84	1.56

Experimental Results

One of the sonic profilers used to measure the caisson motion malfunctioned in the 1984 experiment. Several of the pressure transducers in the 1985 experiment did not calibrate well. Therefore, only the pore pressure measurements of the 1984 tests and the caisson motion measurements of the 1985 tests were analyzed.

Typical records of pore pressure and displacement are shown in Fig. 10. Significant noise was observed in the displacement measurements. To remove this noise, an eleven-point moving box car (i.e., Δt = 0.076–0.381 sec) was used. This poor signal-to-noise ratio and heavy filtering reduces the confidence in the displacement data.

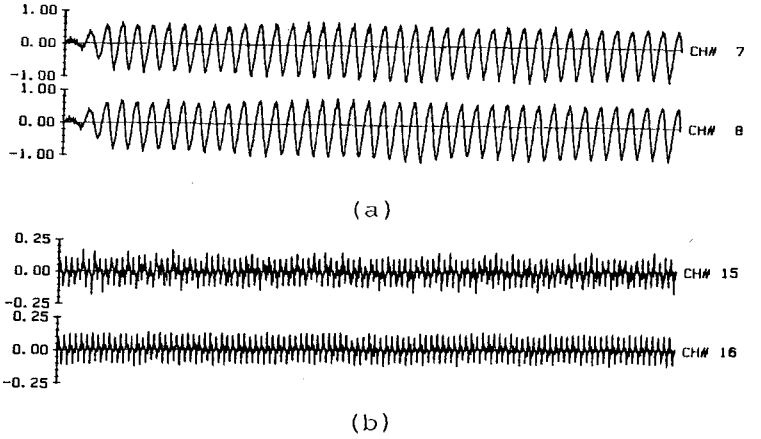

Figure 10. Measurement samples: (a) pore pressure and (b) caisson motion

The dimensionless pore pressure amplitudes are shown as a function of wave period in Fig. 11. The pressure amplitudes were scaled by S2; the pressure on the caisson front face measured one foot above the mudline. A smooth line has been drawn through the data to help iden-

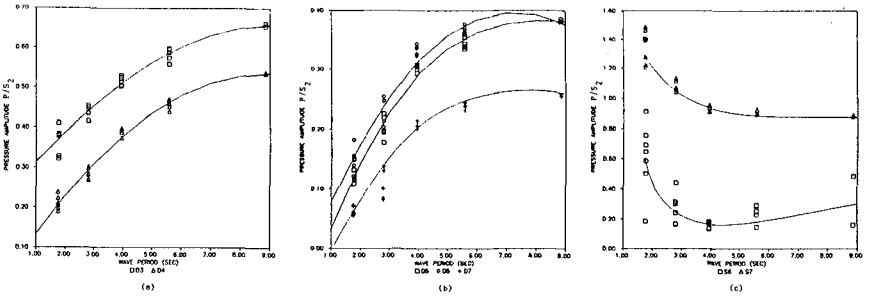

Figure 11. Pore pressure ampltitude of measurements: (a) gages D3 and D4, (b) gages D5, D6, and D7, and (c) gages S6 and S7 as a function of wave period

tify trends. The caisson motion had the least influence on gages D3 and D4 since they were not underneath the caisson. The pressure at these locations decayed with the soil depth. The two pairs, D5-D6 and S6-S7, were obviously affected by the caisson motion because the pore pressure increased with the soil depth. For gages D3, D4, D5, D6, and D7 the dimensionless pressure amplitudes increase with increasing wave period. For gages S6 and S7 the opposite is observed.

The dimensionless mudline displacements are plotted against H/h (wave height to water depth) for various values of h/Lo (depth to deep water wave length) in Fig. 12. Generally, the displacement increases with an increase in water height or wave period. This result is anticipated because the wave force on the caisson is proportional to the wave height and wave period. However, the vertical and rotational displacements are somewhat scattered.

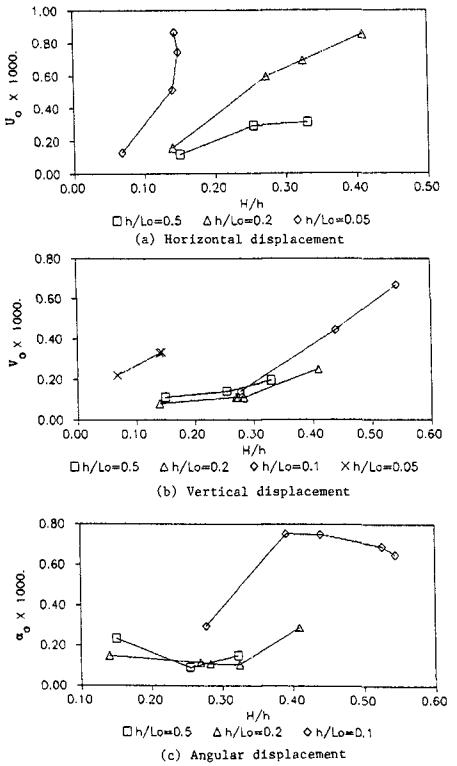

Figure 12. Dimensionless mudline displacements of measurements as a function of wave height for different water depths

Comparison of Theory and Measurements

The measurements of D5, D6, D7, S6, and S7 (cf. Fig. 8) were compared with the analytical model. Figure 13 shows the calculated pressure versus the measured pore pressure. Although the trend is predicted, there is considerable scatter. Figure 14 shows the computed contours of pore pressure and measurements. Again, the trend is in general agreement but there is considerable scatter. The deviation of the predicted porewater pressure from the measured may result from the assumption of a linear wave pressure distribution underneath the caisson. A more accurate pressure model being developed by Ward (1986) may be employed to obtain a more realistic pressure boundary condition. Unfortunately, this model was not completed in time to be used in the present study.

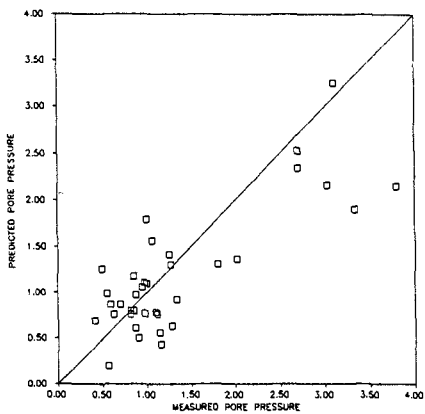

Figure 13. Comparison of theory and measurements for pore pressure

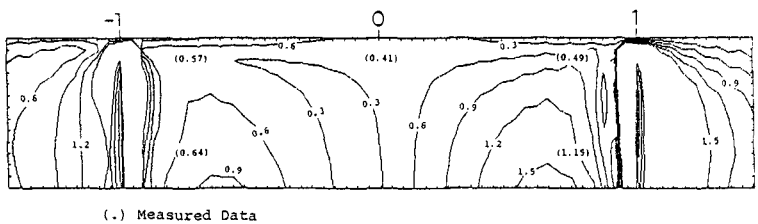

Figure 14. Comparison of the predicted pressure contours and the measured data (T = 5.6 sec and H = 3.2 ft)

The measured and the predicted displacements are shown in Fig. 15. The dimensionless displacements were plotted to the dimensionless calculated horizontal wave force in the caisson F_1/wh^2. The wave force, F_1, was calculated by the method recommended in the Shore Protection Manual (1984). The measured displacements are rather scattered. The horizontal and the vertical displacement data are larger than the predicted. However, the measured rotational displacement data are in reasonably good agreement with the predicted. The predicted angular displacement is in better agreement with the laboratory results than both the horizontal and vertical displacements because the angular motion is the largest among the three degrees of the caisson motion. Thus, the noise effects on the measured angular displacement are less than on the horizontal and vertical displacement measurements.

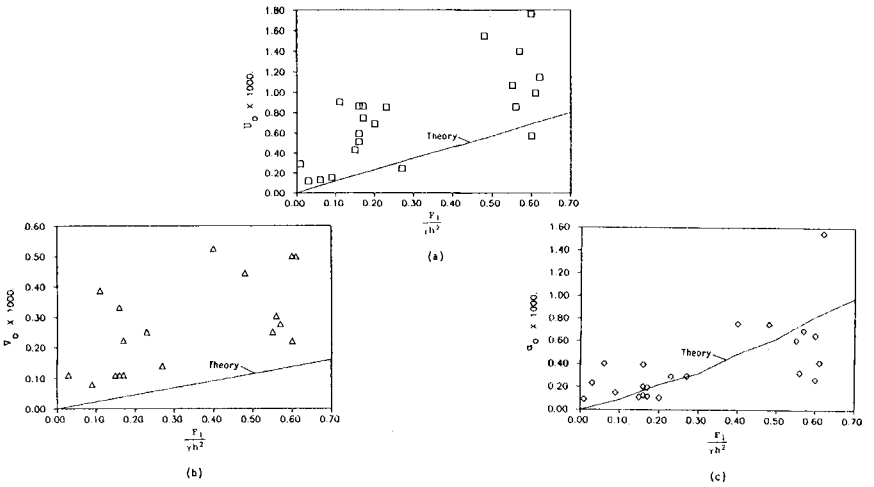

Figure 15. Comparison of the predicted and measured displacements: (a) horizontal, (b) vertical, and (c) angular

4. Conclusions

1. The analytical model agrees well with finite element model for all soils depths examined. This implies that the analytical model is not particularly sensitive to the thin layer assumption for the soil.

2. Under the caisson, the porewater pressure in the soil increases with the depth because of the confining of the impermeable rigid bed below. This is observed in both the analytical and physical models.

3. The predicted porewater pressure is in reasonable agreement with the measured data.

4. Displacement data are unreliable due to the very poor signal-to-noise ratio. Thus, the following modifications to the experimental procedure are recommended:
   a) Using an LVDT for displacement measurements.

   b) Occupying entire wave channel width for caisson to avoid the effects on the measurements from both the side channels and dummy structures.

   c) Making a stiffer caisson, e.g., using concrete.

5. For comparison with data, more accurate methods to estimate the wave pressure on the mudline and forces on the caisson would be useful.

5. Acknowledgment

CHAPTER 155

Analysis of Permeable Breakwaters

Hitoshi MURAKAMI*, Yoshihiko HOSOI** and Yoshitaka GODA***

Abstract

This paper discusses the characteristics of hydraulic and water exchange due to the wave action against vertical slit-type breakwaters. The theoretical solution of the reflection and the transmission coefficients for the breakwater models is compared with the experimental results. Furthermore, the water exchange discharge and the water concentration change through the gap of the permeable breakwater are examined experimentally. Finally the most effective geometry of the cross section is suggested for the breakwaters used here.

1. Introduction

With increasing pressure to conserve in a clean way the water quality in a harbor, a new breakwater should be devised. That means an effective breakwater for not only the reduction of the reflection and transmission of wave energy but also the increase of the water exchange discharge through a permeable wall.

Since Jarlan(1961) proposed the perforated vertical wall breakwater, many different kinds of permeable wall breakwaters have been designed(Kondoh et al.,1983). The hydraulic characteristics of these breakwaters have been examined experimentally for the most part. The theoretical solutions for the reflection and the transmission coefficients have been obtained only for the breakwaters with a comparatively simple cross section geometry.

Furthermore, the water exchange characteristics due to the wave action through a permeable wall has not been discussed sufficiently.

This study deals with both hydraulic and water exchange characteristics of the vertical slit-type breakwaters with some devised horizontal cross section geometries in a chamber of the breakwater, though they are very simple as shown in Fig.1. The purpose of this study is to obtain the necessary data to make a breakwater with a horizontal cross section geometry effective from those viewpoints mentioned above.

From here on, we shall call the models by their abbreviations S.P, G.C, G.E and so on.

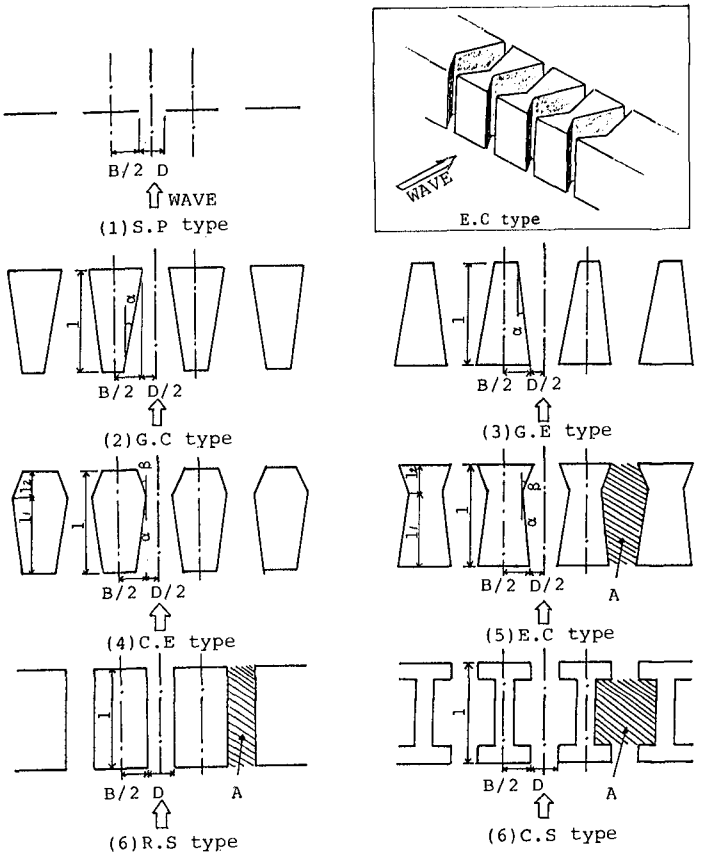

Fig.1 Horizontal cross sections of vertical slit-type breakwaters

2. Theoretical Solution of Reflection and Transmission Coefficients

Let us show as an example how to obtain the result of the reflection and the transmission coefficients for the C.E type breakwater in Fig.1-(4).

Fig.2 shows a coordinate system and a definition of the notation. For analysis, we consider a limited width of the breakwater (D+B) and divide the region into four parts. Then, we assume a small amplitude long wave coming perpendicular to the breakwater, the wave height along the breakwater not varying and the water depth being constant in all the regions.

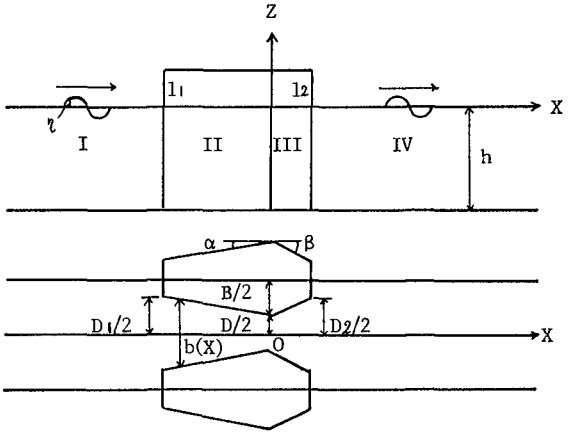

Fig.2 Coordinate system and definition of notations

A momentum and a mass equation at Regions II and III are expressed by eqs (1) and (2), respectively.

$$\partial u/\partial t + g\partial \eta/\partial x = 0 \qquad (1)$$

$$\partial \eta/\partial t + (h/b)\partial(bu)/\partial x = 0 \qquad (2)$$

$$b = D - 2x \tan\alpha , \qquad -l_1 \leq x \leq 0 \qquad (3)$$

$$b = D + 2x \tan\beta , \qquad 0 \leq x \leq l_2 \qquad (4)$$

where, η ,u and g are water elevation from still water, horizontal water particle velocity and gravity acceleration,respectively; b represents the gradually changing width between the wedges.
A mass equation at Regions I and IV are as follow:

$$\partial \eta/\partial t + h(\partial u/\partial x) = 0 \qquad (5)$$

The boundary conditions for each region which are energy and mass conservation laws are represented by eqs (6)-(11).

$$\eta_1 - \eta_2 = (C_A/g)\{(D + B)/D_1 - 1\}u_1|u_1| , \qquad x = -l_1 \qquad (6)$$

$$(D + B)u_1 = D_1 u_2, \qquad x = -l_1 \qquad (7)$$

$$\eta_2 = \eta_3, \qquad x = 0 \qquad (8)$$

$$u_2 = u_3, \qquad x = 0 \qquad (9)$$

$$\eta_3 - \eta_4 = (C_B/g)\{1 - (D + B)/D_2\}u_4|u_4| , \qquad x = l_2 \qquad (10)$$

$$D_2 u_3 = (D + B)u_4, \qquad x = l_2 \qquad (11)$$

In eqs (6) and (10), the energy loss coefficients are given as C_A and C_B, respectively.

By solving the above equations to satisfy the boundary conditions, we can obtain the result of the reflection and the transmission coefficients as eqs (12) and (13), respectively.

$$r_R = \frac{\sqrt{\{-1 + Eo - Gn + (\psi g/c)\}^2 + (Ep + Gm)^2}}{|1 + (\psi g/C)|} \qquad (12)$$

$$r_T = \frac{\sqrt{(E's - G'r)^2 + (E't + G'q')^2}}{|1 + (\phi g/C)|} \qquad (13)$$

where,

$$o = h'm - jn$$

$$p = jm + h'n$$

$$q' = \frac{(Ao - Fn)A'a + (Ap + Fm)(A'b' + F')}{A'^2a^2 + (A'b' + F')^2}$$

$$r = \frac{(Ap + Fm)A'a - (Ao - Fn)(A'b' + F')}{A'^2a^2 + (A'b' + F')^2}$$

$$s = aq - b'r$$

$$t = b'q + ar \qquad (14)$$

$$h' = (fd + eg')/(d^2 + e^2)$$

$$j = (dg' - ef)/(d^2 + e^2)$$

$$m = -2\underline{k}/(\underline{k}^2 + \underline{l}^2)$$

$$n = 2\underline{l}/(\underline{k}^2 + \underline{l}^2)$$

$$\underline{k} = \{1 + (\psi g/C)\}(D_1Ij + D_1M)/p - Eh'$$

$$\underline{l} = -\{1 + (\psi g/C)\}D_1Ih'/p - Ej - G$$

$$d = -H'b'A - L'A - A'b'H - F'H$$

$$e = H'aA + A'aH$$

$$f = H'aF + A'a\underline{L}$$

$$g' = H'b'F + L'F + A'b'\underline{L} + F'\underline{L}$$

$$a = \frac{\{1 + (\phi g/C)\}(D_2 E'M'/p - D_2 G'I'/p)}{\{1 + (\phi g/C)\}^2 D_2^2 I'^2/p^2 + E'^2}$$

$$b' = \frac{-\{1 + (\phi g/C)\}^2 D_2^2 M'I'/p^2 - E'G'}{\{1 + (\phi g/C)\}^2 D_2^2 I'^2/p^2 + E'^2}$$

$$\psi = C_A\{(D + B)/D_1 - 1\}|u_1|/g$$

$$\phi = C_B\{1 - (D + B)/D_2\}|u_4|/g$$

$$C = \sqrt{gh}$$

where,

$$A = J_0[kD/\gamma], \qquad A' = J_0[kD/\gamma']$$

$$E = J_0[k(l_1 + D/\gamma)], \qquad E' = J_0[k(l_2 + D/\gamma')]$$

$$F = N_0[kD/\gamma], \qquad F' = N_0[kD/\gamma']$$

$$G = N_0[k(l_1 + D/\gamma)], \qquad G' = N_0[k(l_2 + D/\gamma')]$$

$$H = J_1[kD/\gamma], \qquad H' = J_1[kD/\gamma'] \qquad (15)$$

$$I = J_1[k(l_1 + D/\gamma)], \qquad I' = J_1[k(l_2 + D/\gamma')]$$

$$L = N_1[kD/\gamma], \qquad L' = N_1[kD/\gamma']$$

$$M = N_1[k(l_1 + D/\gamma)], \qquad M' = N_1[k(l_2 + D/\gamma')]$$

$$\gamma = 2\tan\alpha, \quad \gamma' = 2\tan\beta, \quad k = 2\pi/L$$

where, J_i and N_i are the Bessel and the Neumann functions of i-th order, respectively. L is a wave length.

The energy dissipation factor ε is expressed as follows:

$$\varepsilon = 1 - r_R^2 - r_T^2 \qquad (16)$$

We can obtain the solution for any other breakwater by the same procedure (Murakami (1984,1985,1986)).

3. Experiments for Hydraulic Characteristics

The wave tank with a flap-type wave generator at an end, which is 15 cm long, 20 cm wide and 30 cm deep was used for measuring an incident, reflection and the transmission wave. The models were placed at a distance of 10 cm from the wave generator.

The water depth h and the wave period T were kept 15 cm and 0.75 sec, respectively. Incident wave steepnesses H/L were in the range of 0.01 to 0.05.

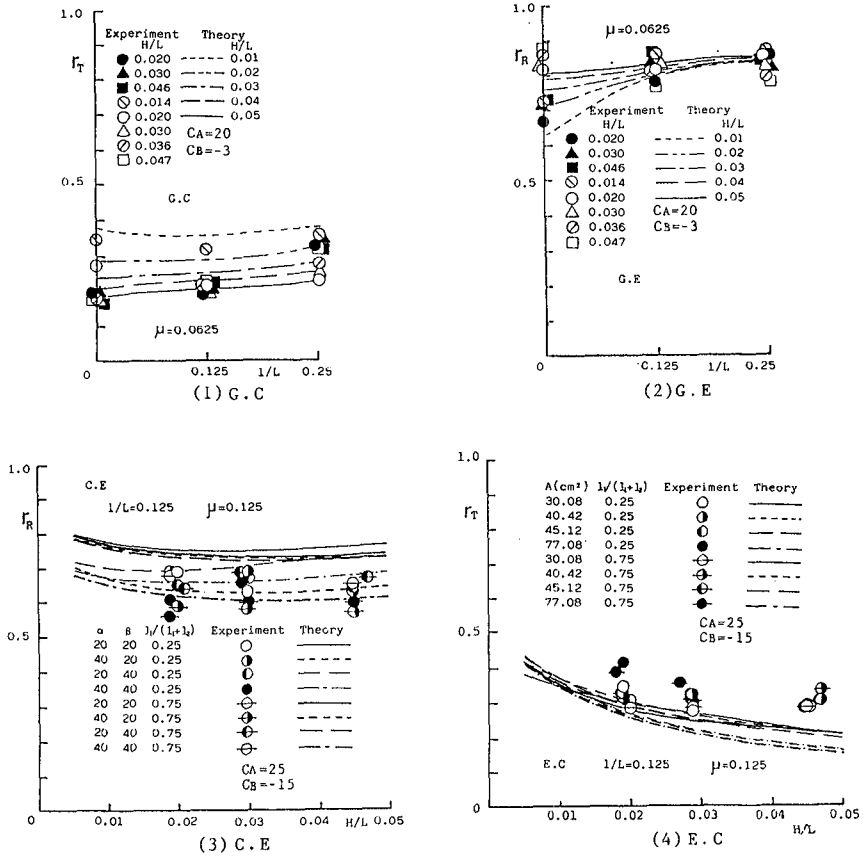

Fig.3 Comparison of theoretical results with experimental data

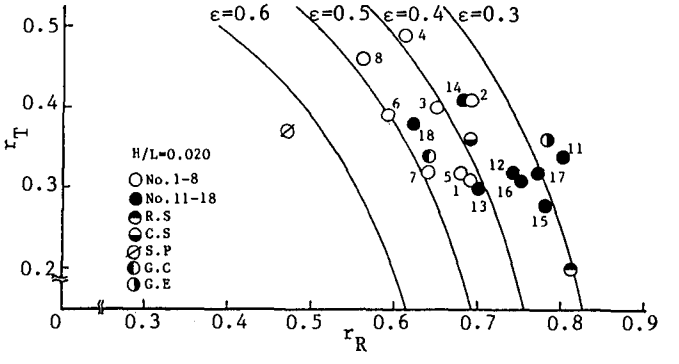
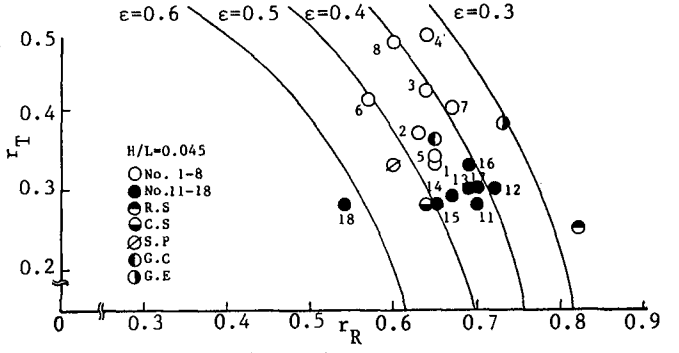
Fig.3 shows some examples of the transmission and the reflection coefficients comparing theoretical results with experimental data. In figures, μ is the opening ratio D/D+B. It is found that the theoretical results coincide comparatively well with the experimental data, if appropriate values are assumed for the energy loss coefficients C_A and C_B.



(1) H/L=0.020



(2) H/L=0.045

Fig.4 Relation between reflection coefficients and transmission coefficients for each breakwater

Fig.4 illustrates, on the basis of the experimental results, the relation among the reflection coefficient r_R, the transmission coefficient r_T and the energy dissipation factor ε.

These experimental data are plotted for the relative breakwater width 1/L = 0.125 and the opening ratio μ = D/D+B = 0.125. In the G.C type, the wedge angle α equals 19 degree. The experimental conditions of other types are shown in Table 1.

Table-1 Experimental Conditions

T=0.75sec, h=15cm, h/L=0.20, H/L=0.01~0.05

7					20	40	
8					40	40	
11	E.C	0.125	9.4	0.25	20	7	30.08
12					40	16	40.42
13					46	20	45.12
14					68	40	77.08
15				0.75	7	20	30.08
16					16	40	40.42
17					20	46	45.12
18					40	68	77.08
20	R.S	0.125	9.4				21.62
30	C.S	0.125	9.4				77.08

First, let us compare the values of three simpler types, S.P, G.C and G.E. The transmission coefficients of the three are almost the same, while the reflection coefficient becomes progressively larger from S.P through G.C to G.E.

For the R.S type, the reflection coefficient is largest in all the data, though the transmission coefficient is smallest.

The group of white circles is concerned with the C.E types. When we note the pairs of No.1 and No.2, No.3 and No.4 , No.5 and No.6 in order to discuss the effect of the wedge angle, the transmission coefficient has a larger value for the bigger number of the pair. On the other hand , the reflection coefficient does not change remarkably. This means that it is effective to make the wedge angle small for the breakwater in consideration of the hydraulic aspect. In the C.E type, the wedge angles α and β , the relative wedge length l_1/l_1+l_2 affect mainly the transmission coefficient.

The group of black circles is concerned with the E.C type. They have a chamber in each breakwater. The bigger the number, the larger the chamber area is. It is found that chamber area A and the relative wedge length l_1/l_1+l_2 do not remarkably affect the transmission coefficient, though an exception can be observed in the case of H/L = 0.02. Generally speaking, the transmission coefficients for the E.C type are much smaller than those for the C.E type. On the other hand, the reflection coefficients for the E.C type are nearly equal or a little bit larger than those for the C.E type.

The C.S type in this study has the same chamber area as those for the No.14 and No.18 of the E.C type. The transmission coefficients of both types are almost equal to each other for H/L = 0.045 and they are a little bit smaller in the C.S type for H/L = 0.02.

4. Experiments for Water Exchange Characteristics

4.1 Water exchange discharge

The horizontal water particle velocity at the smallest gap of a breakwater was measured by the propeller type current meter at the point of 7 cm from the water surface. The water exchange discharge per unit breakwater length through a gap caused by the wave action is expressed as follow:

$$q = \frac{4}{T}\int_0^{T/4} \frac{Dh}{D+B} V_{max} \cos\frac{2\pi}{T}t = \frac{2Dh}{\pi(D+B)} V_{max} \qquad (17)$$

where, V_{max} is the average value of maximum water particle velocities of two opposite directional flows at a gap.

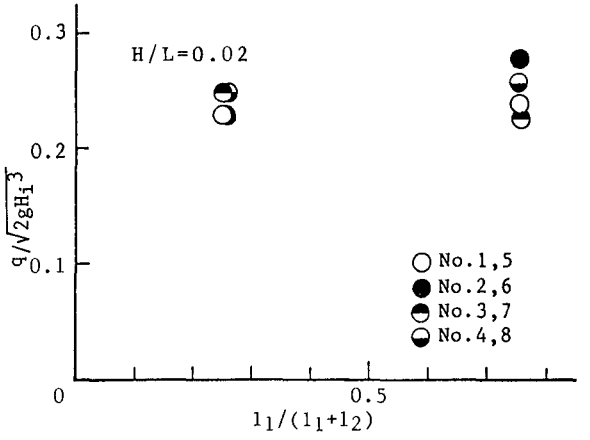

Fig.5 Relation between $q/\sqrt{2gH_i^3}$ and l_1/l_1+l_2

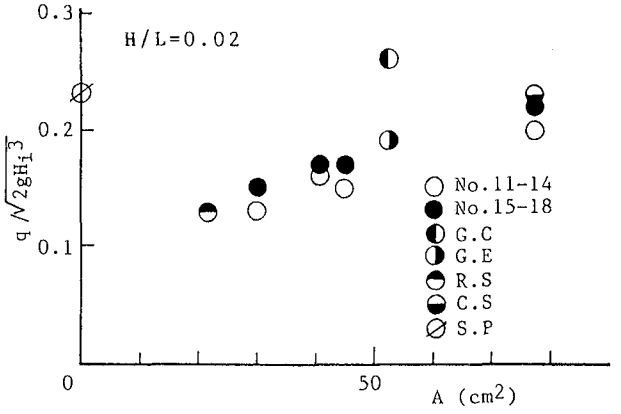
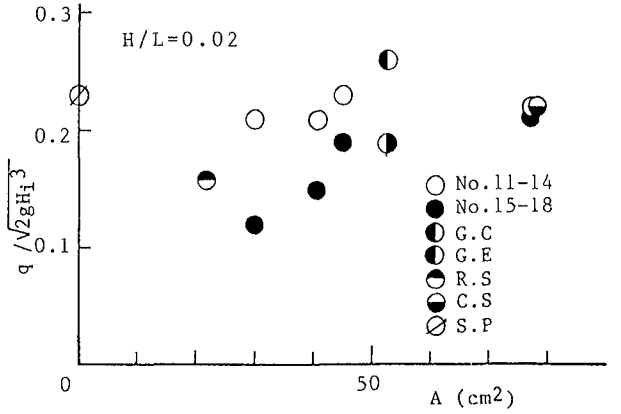
Fig.5 shows the relation between a nondimensional water exchange discharge and the relative wedge length for the C.E type. H_i in the vertical axis expresses an incident wave height. In this type, the water exchange discharge increases slightly with the increase of the relative wedge length l_1/l_1+l_2. However, such a relative wedge length and the wedge angles α and β do not remarkably affect the water exchange discharge.

To cite for reference, the values of $q/\sqrt{2gH_i^3}$ for the S.P, G.C and the G.E types are 0.23, 0.26 and 0.19, respectively. The water exchange discharge for the C.E type is nearly equal or bigger than those for the S.P and G.C types.



(1) front side



(2) rear side

Fig.6 Relation between $q/\sqrt{2gH_i^3}$ and A

Fig.6 is concerned with the E.C type. This type of breakwater has two gaps at the front and the rear. The abscissa of the figure represents a chamber area as shown by the shadow zone in Fig.1.

The exchange discharge increases slightly with the increase of chamber area A. The discharge at the rear side gap is large when l_1/l_1+l_2 is small, though the tendency is opposite at the front side gap. It seems that both values of discharge for the C.E and C.S types are almost equal, when the two chamber areas are equal. The R.S type breakwater is not effective for water exchange.

As a result of considering the water exchange discharge, we can say that the C.E type breakwater has the most effective cross section in these experiments.

4.2 Diffusion characteristics

Fig.7 shows the experimental equipment. The wave tank was sheltered by two sheets of thin plates from the rear of the breakwater to a distance of about 2 m in front. Salt water with a constant concentration was in this basin. Other regions of the wave tank were filled with fresh water. The sheltering plates were pulled up before an incident wave had just reached the posision of the front side plate. Then concentration changes at the three points of 1 cm, 2.5 cm and 4 cm from the bottom at a distance of 15 cm behind the breakwater were measured by the concentration meters for about 4 minutes.

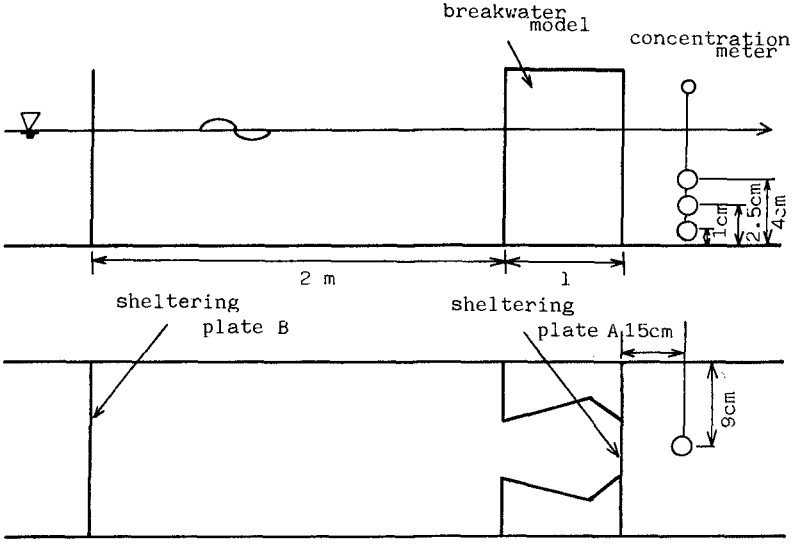


Fig.7 Experimental equipment for water concentration change through gap of breakwater

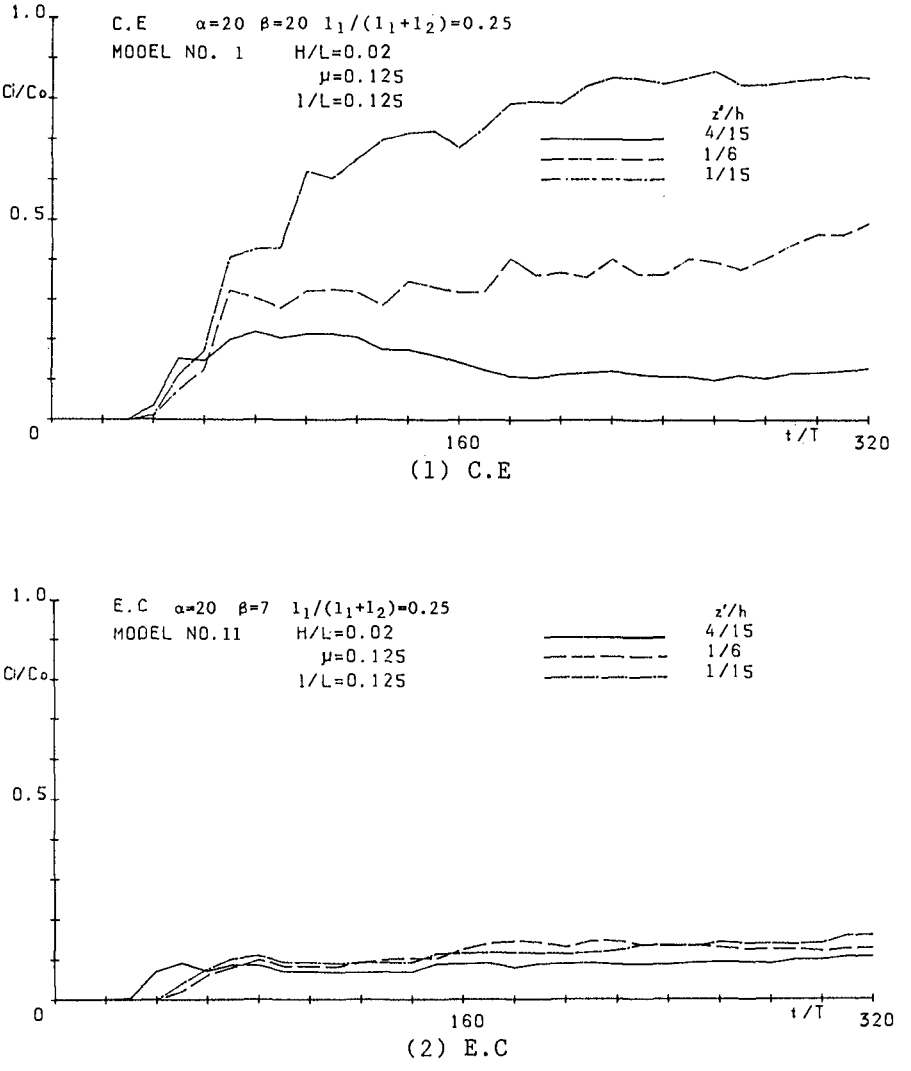

Fig.8 Nondimensional concentration change with time

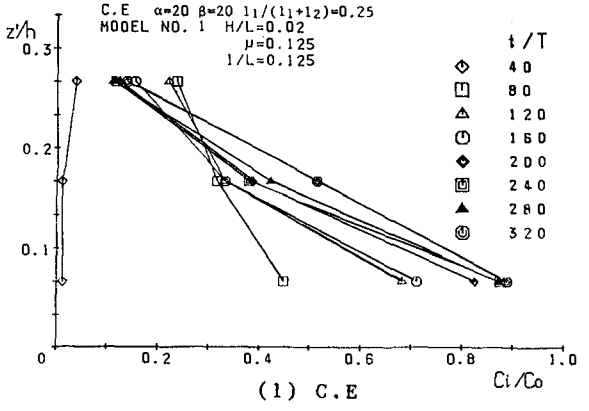
Fig.8 shows two typical examples of nondimensional concentration changes with time t. C_0 is an initial concentration. T is a wave period. The concentration changes at the measuring points were remarkable for the G.E and R.S types as well as for the C.E type. On the other hand, the concentration did not change at the three points for the S.P, G.C and the C.S types, which are similar to the E.C type.



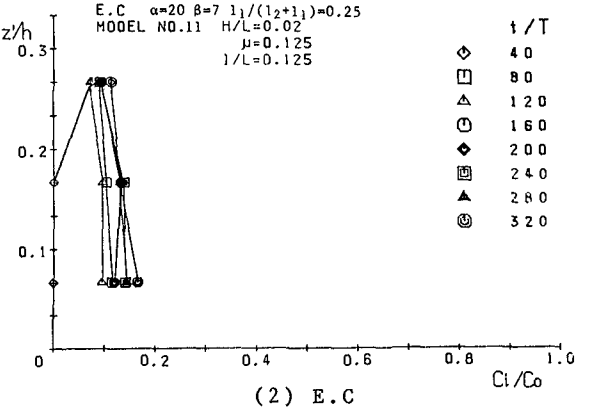


Fig.9 Vertical concentration distribution at regular time intervals

Fig.9 shows the vertical concentration distribution at regular time intervals for the C.E and E.C types. The ordinate z'/h is the nondimensional distance measured from the tank bottom. The parameter t/T represents the number of waves which penetrated through the slit after sheltering plates were pulled out. In the case of the C.E type, the concentration changes at the lower measuring points are more remarkable than at the upper point. The concentration near the bottom becomes almost the same as in the open sea after the 320th wave. In contrast, the vertical concentration distributions do not vary with time. Furthermore, all values of the concentration at each point are smaller than those for the C.E type.

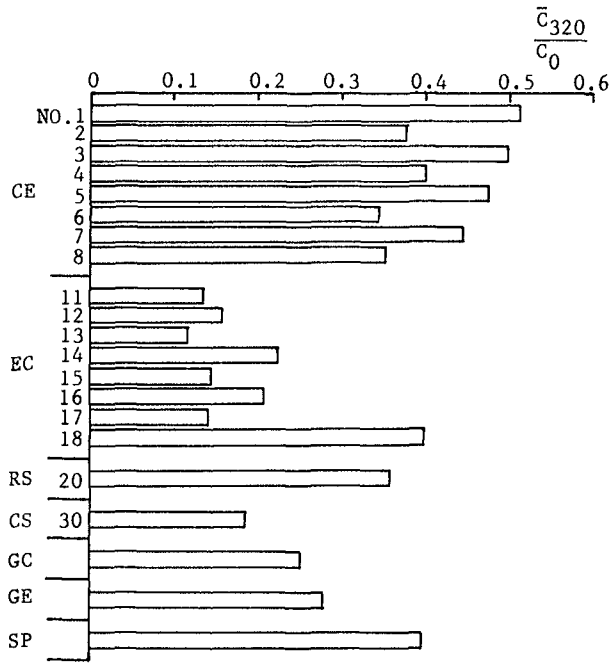

Fig.10 Comparison of average concentration after 320th wave for each breakwater

Fig.10 shows the comparison of the average concentration after the 320th wave for each breakwater. The values of concentration for the C.E type breakwaters are comparatively bigger than those for all other cases. Especially, in comparison of No.1 with No.2 or No.1 with No.5, the water mixes actively between the inside of the breakwater and the outside, when both the wedge angle α and the relative wedge length $1_1/1_1+1_2$ are small.

The nondimensional concentration for the E.C type is smallest in all experiments except the No.18. The value for the R.S type is much bigger, though the water exchange discharge was not bigger, than those for other cases. This means the characteristics of diffusion due to the setting up of the breakwater is not the same as those of the water exchange discharge due to the wave action.

5. Conclusion

The characteristics of the hydraulic and the water exchange due to the wave action against vertical slit-type breakwaters were discussed. Results are summarized as follows.

(1) We can estimate analytically the reflection and the transmission coefficients of the permeable breakwater with composition of the wedge shape parts for the horizontal cross section.

(2) We can find in this study that the C.E type breakwater is most effective as to both the hydraulic and the water exchange characteristics.

CHAPTER 156

ON STRESS IN TETRAPODS UNDER WAVE ACTION

Wakiro Nishigori*
Taiji Endo**
Atsuyuki Shimada***

ABSTRACT

Recently, as well as hydraulic stability, structural strength of armor blocks has emerged as a major problem in breakwaters. This problem is studied by research organizations in many countries. In Nippon Tetrapod Co., Ltd., a series of hydraulic model tests was conducted to measure the surface strain on Tetrapods under wave action.

In this paper, the results of the hydraulic model test are described. Prior to the hydraulic test, a similitude relation on impact stress and strain between the prototype and model was derived and a drop test was performed to investigate the scale effect on impact strain on Tetrapods. The hydraulic test was conducted to measure the surface strain on 50kg model Tetrapods using strain gages. In addition, impact strain on 50t Tetrapods under wave action was estimated applying the similitude relation.

The strain on Tetrapods under wave action was clarified through this study.

1. INTRODUCTION

In recent years very large armor blocks have been used for many coastal structures especially in rubble mound breakwaters in deep areas. Wave forces hitting structures in these areas are very large. Blocks in an armor layer receive extreme wave forces and some of them are subject to breakage. In one such incident, the breakwater in Sines, Portugal received serious damage.

Armor layers are usually designed by means of Hudson's formula or hydraulic experiments on their stability. Structural damage to individual blocks is not considered, so there is a possibility that the armor blocks are hydraulically stable but structurally unstable

* Research Engineer, Hydraulic Laboratory, Nippon Tetrapod Co., Ltd. , 2-7 Higashi-Nakanuki, Tsuchiura, Ibaraki, 300 Japan.
** Dr. Sc., Director, Hydraulic Laboratory, Nippon Tetrapod Co., Ltd. , 2-7 Higashi-Nakanuki, Tsuchiura, Ibaraki, 300 Japan.
*** Senior Research Engineer, Central Research Institute of Electric Power Industry. , 1646 Abiko, Abiko-shi, Chiba, 270-11 Japan.

as a result of such design methods. Structural damage to individual blocks can escalate into hydraulic damage to the whole armor layer. It is necessary to design coastal structures that take into consideration not only block hydraulic stability but also block structural strength.

In order to study stress occurring in blocks, Terao et al (1982) and Burcharth (1981) carried out drop tests using prototype Dolosse while Delft Hydraulics Laboratory (1983) and Hall et al (1984) measured bending moment in model Tetrapods and stress in model Dolosse respectively, both made of new materials, under wave action using new measuring techniques.

Stress in blocks is not well known under wave action. If the stress in blocks could be monitored and clarified, the results could contribute to the design of better armor layers.

From this view point, a hydraulic model test was conducted to measure the surface strain on blocks under wave action. The block utilized was Tetrapod because it is commonly used for coastal structures in Japan. In the test section, 50kg Tetrapods were placed in two standard layers and surface strain on two instrumented Tetrapods in the vicinity of each other just above the still water level was measured using strain gages.

The behavior of Tetrapods under wave action can be distinguished as follows, (1) Tetrapods rocking slightly, (2) Tetrapods rocking easily and repeatedly and (3) Tetrapods falling down. The test was conducted to examine the strain on Tetrapods for each category of behavior due to waves.

2. LAW OF SIMILITUDE

In the case of block collisions, the impulse induced by the impact force is assumed to be equal to the change in momentum, so the following equation is validated.

$$\int_0^\tau Pd\, dt = m\,(v' - v) \tag{1}$$

where Pd; impact force
v,v'; velocity of the block just before and after collision respectively
m; mass
τ; duration of impulse

From eq. (1),

$$Pd \propto \frac{m v (1+e)}{\tau} \tag{2}$$

where e; coefficient of restitution

is derived. The time it takes for a longitudinal shock wave to travel from the point of impact to a free edge and back again equals

the duration of an impulse, as shown by Burcharth (1981) and Aoyagi (1972). As concrete was used for the model material , the modulus of elasticity, density, coefficient of restitution and the speed of a longitudinal wave in concrete are the same as those of the prototype. Therefore, the impact force is proportional to the speed of collision, and inversely proportional to the distance between the impact point and a free edge of the block.

In this test, the armor blocks are assumed to be moving according to Froude's law,

$$v_m / v_p = \lambda^{1/2} \tag{3}$$

where λ is a linear scale of a model Tetrapod and the subscripts m and p refer to the model and prototype respectively.

From the consideration above, the similitude ratios of the impact and elastic forces are obtained as follows.

$$Pd_m / Pd_p = \lambda^{5/2} \tag{4}$$

$$Pe_m / Pe_p = (\sigma_m / \sigma_p)\lambda^2 = (\varepsilon_m / \varepsilon_p)\lambda^2 \tag{5}$$

where Pe; elastic force
σ; stress
ε; strain

The similitude relations of the stress and strain between the model and prototype under wave action are represented by eq. (6), as eq. (4) is equal to eq. (5).

$$\sigma_m / \sigma_p = \varepsilon_m / \varepsilon_p = \lambda^{1/2} \tag{6}$$

3.TEST EQUIPMENT AND TEST METHOD

3.1.Model of Tetrapod

The following equation should be valid in order for the similitude relation to hold true.

$$\varepsilon = \alpha v \tag{7}$$

where ε; impact strain
v; collision speed
α; a constant factor

The value of α in the model is the same as that in the prototype. A drop test was performed beforehand to confirm the validity of eq. (7) using from 736g to 4t Tetrapods. Fig. 1 shows α values calculated by eq. (7) utilizing measured values of maximum impact compressive strain generated at the top of a leg (on the compressive side) with a linear scale factor based on 40kg Tetrapods. This figure indicates that α became constant when Tetrapods heavier than 40kg were utilized. So if 50kg Tetrapods were used in the test,

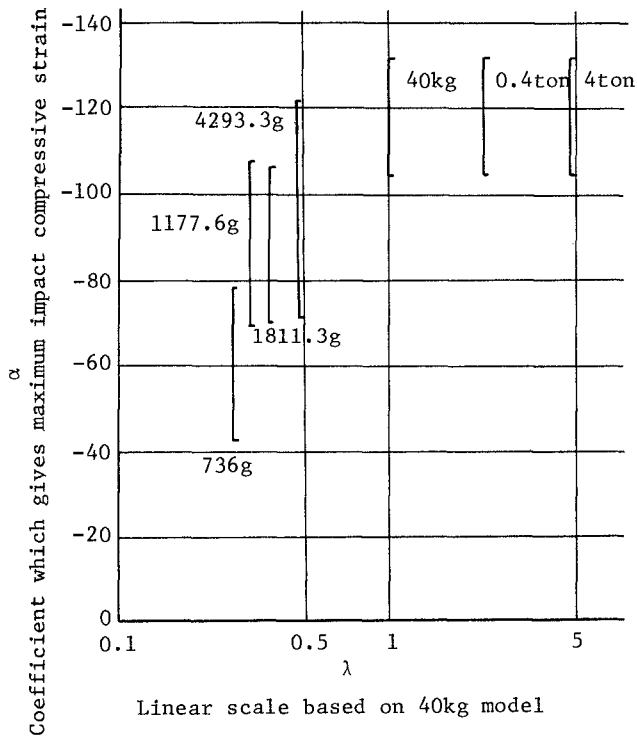

Fig. 1 Scale Effect Concerning Impact Strain on Tetrapod

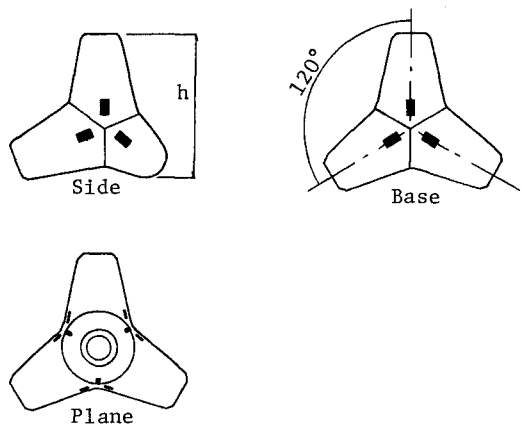

Fig. 2 Locations for Strain Measurement

eq. (6) could be applied. Therefore in the hydraulic experiment, 50kg Tetrapods were used.

Four instrumented Tetrapods of 50kg were made of concrete using gravel of size 25mm. Strain was measured at three locations 120 degrees to each other on the top center of each leg. Totally 12 points per one Tetrapod were examined as shown in Fig. 2. Strain gages (length=10mm) on the surface of the instrumented Tetrapods were covered with waterproofing cement. Photos 1 and 2 show a Tetrapod model completed. Characteristics of the test Tetrapods were measured and tabulated in Table 1. These values were close to standard concrete.

Photo 1 Strain Gages on the Surface of the Test Tetrapod

Photo 2 50kg Tetrapod Model

Table 1 Characteristics of the Test Tetrapods

Characteristics of the test Tetrapods	Moist condition	Air-dried condition
Unit weight (kgf)	50.6	49.7
Specific weight (gf cm^{-3})	2.36	2.31
Static modulus of elasticity (kgf cm^{-2})	3.08x10^5	2.45x10^5
Dynamic modulus of elasticity (kgf cm^{-2})	3.60x10^5	3.68x10^5

3.2.Test Equipment

A large wave channel, 205m long, 3.4m wide and 6.0m deep, at the Central Research Institute of Electric Power Industry was used in order to generate large waves for the 50kg Tetrapods utilized. Fig. 3 shows the diagram of the test section.

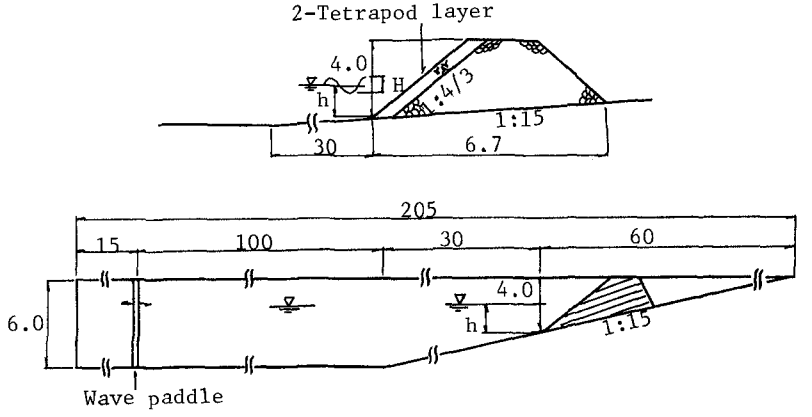

Fig. 3 Sketch of Test Section (unit ; m)

The apparatus for measurement used in the experiment is listed below.

*Dynamic strain amplifier ; This was used for amplifying electric current from strain gages.
*Data recorder ; This was used in order to record analog data through the dynamic strain amplifiers.
*Multi-channel oscillograph ; Strain was reproduced on a multi-channel oscillograph chart.
*Video system ; This was used to record Tetrapod motion.

3.3.Test Method

A test section was constructed at a distance of 130m from the wave paddle in the flume. In the test section, 50kg Tetrapods were set up in two standard layers. The two instrumented Tetrapods were placed in the vicinity of each other just above the still water level so that they received the maximum impact wave force. Photo 3 shows the condition during placement.

Strain was recorded by the data recorder and reproduced on a strip chart at a speed ratio of 1 : 32 that of the recording speed for the duration of the impact strain itself, which was in the order of one millisecond to obtain a clearer result. Strain on the chart was measured by a scale.

Photo 3 The Condition during Placement

3.4.Test Cases

Test cases are summarized in Table 2. In the table,

*h (m) ; water depth at a toe of the Tetrapod slope
*T (sec) ; wave period
*Lo (m) ; wave length in deep water
*Ho' (m) ; equivalent deep water wave height
*H (m) ; wave height at the toe of the Tetrapod slope with the structure not in place
*Ns ; stability number
*Tetrapod Number ; T.P.No.1-4 are the instrumented Tetrapod number.

Experiments were conducted to study the strain on Tetrapods for each category of behavior of Tetrapods due to waves (as mentioned in the introduction).

Table 2 Test Cases

Case No.	h (m)	T (sec)	Lo (m)	Ho' (m)	H (m)	Ns^3	Tetrapod Number
1-1 ~ 1-11	1.7	4.0	24.96	0.96 ~ 1.51	1.04 ~ 1.51	23.6 ~ 72.1	T.P. No.1,4
2-1 ~ 2-9	1.4	6.0	56.15	0.87 ~ 1.17	1.55	78.0	T.P. No.2,3
3-1 ~ 3-8	1.5	6.0	56.15	1.09 ~ 1.31	1.60	85.8	T.P. No.2,3
4-1 ~ 4-4	1.5	4.0	24.96	0.90 ~ 1.33	0.97 ~ 1.35	19.1 ~ 51.5	T.P. No.3,4
5	Drop Test						T.P.No.3

In cases 1-3, tests were carried out after standard placement to measure the impact strain for Tetrapods rocking slightly. In case 4, one of the two instrumented Tetrapods was placed so that it rocked easily and repeatedly, while the other was placed so that it would fall down easily. Waves were generated for 100sec in cases 1 and 4, and 60sec in cases 2 and 3. This was decided after taking effect of re-reflected waves from the wave paddle in the wave tank into consideration. In case 5, one instrumented Tetrapod was pushed down manually from the crown of the dike in the still water condition. Photo 4 shows waves hitting Tetrapods in case 1.

Photo 4 Waves Hitting Tetrapods

4.TEST RESULTS

Test results are classified into three categories according to the behavior of Tetrapods due to waves.

4.1.Category No.1 ; Tetrapods Rocking Slightly

In this category, Tetrapods were placed with sufficient interlocking. Actual motion of test Tetrapods was not visible under wave action in the flume, but was observed by a comparison of the position of Tetrapods just before and after waves hit.

Measured impact strain is tabulated in Table 3. ε tmax and ε cmax are used for the maximum values measured on tensile and compressive side respectively when collisions occurred. Behavior of Tetrapods due to wave attack is shown in Fig. 4.

In case 1, Tetrapods moved gradually according to wave action and Tetrapod No.1 fell down in case 1-11. The impact strain was not measured on Tetrapod No.4, but was measured in case 1-10-3 (during the third wave generation) on Tetrapod No.1. In cases 1-1 - 1-9, impact strain was not measured.

In case 2, a number of waves, of which the wave heights measured 1.55m, hit the Tetrapods. Because both instrumented Tetrapods moved only slightly, the impact strain on them was not measured.

In case 3, impact strain was not measured in cases 3-1 - 3-4, but was measured and found to be $3\text{-}26\text{X}10^{-6}$ on Tetrapod No.2 in cases 3-5 - 3-7-1. Tetrapod No.2 fell down in case 3-7-2, because a number of large waves, of which $Ns^3 = 85.8$ hit them continuously. In this case, impact strain on Tetrapod No.3 was measured after the fall of Tetrapod No.2. When impact tensile strain had just exceeded $25\text{X}10^{-6}$, it decreased gradually even though waves were continuously generated.

4.2.Category No.2 ; Tetrapods Rocking Easily and Repeatedly

In this category, the movements of the instrumented Tetrapod are noted in Fig. 5. Its reactions to waves were as follows ; leg 1 crashed into Tetrapod A due to the waves and returned to its previous location due to gravity. Leg 2 collided with Tetrapod B. The distance which leg 1 moved was approximately 20cm. The measured impact strain is summarized in Table 4.

4.3.Category No.3 ; Tetrapods Falling Down

In this category, the measured values of impact strain are summarized in Table 5.

In cases 1-11 and 3-7-2, Tetrapods rolled down toward the toe of the Tetrapod slope. In these cases, tests were conducted after standard placement with sufficient interlocking. In cases 4-1, 4-2

and 4-3, each instrumented Tetrapod moved down a distance equal to approximately 1/2-1 of the block height. In case 4-4, the instrumented Tetrapod moved down a distance of 1/2 the block height, and continued to roll down toward the toe of the slope. In these cases, tests were performed after each instrumented Tetrapod was placed so that it would fall down easily.

Table 3(a) Measured Impact Strain for Tetrapods Rocking Slightly

Case No.	T (sec)	H (m)	Ns^3	The maximum impact strain ($\times 10^{-6}$)			
				Tetrapod No.1		Tetrapod No.4

5. DISCUSSION

5.1. Impact Strain and Wave Properties

Because impact strain was significantly influenced by Tetrapod placement, correlations between impact strain and wave properties could not be clarified. After waves began to hit the test Tetrapods placed in standard layers, even when wave heights were large, corresponding to $Ns^3 = 70 - 85$, the impact tensile strain was found to be $3 - 12 \times 10^{-6}$ because interlocking was sufficient. However in the three test cases, impact tensile strain was measured to be approximately 25×10^{-6} prior to the instrumented Tetrapod falling or after adjacent Tetrapods fell down. It can be seen that this value was

almost the same as that obtained in the case where the instrumented Tetrapod was placed without sufficient interlocking. When such strain occurred, the instrumented Tetrapod was not in a condition of interlocking. Therefore, such strain was classified into category No.2. When impact tensile strain had just exceeded 25×10^{-6}, one of two things occurred : i.e. the instrumented Tetrapod fell down or the impact strain decreased gradually again even though waves were continuously generated. The latter indicates that Tetrapods are inclined to move from unstable positions to more stable ones under wave action.

In the case where the instrumented Tetrapod was placed without interlocking, behavior of the Tetrapod followed the wave action repeatedly. The measured impact strain when leg 1 crashed into Tetrapod A was larger than that when leg 2 collided with Tetrapod B (as mentioned in 4.2.). It can be deduced that when incident waves hit the test Tetrapod the block accelerated, and when it returned, its behavior depended mainly on gravity.

The maximum impact strain on one instrumented Tetrapod pushed down manually from the crown of the dike into still water was not so large as that generated by the wave down rush even though the falling distance was long. It was observed that when Tetrapods fell down under wave action, their fall accelerated due to wave run-down. Their collision speed also increased.

5.2.Estimation of Impact Strain on 50t Tetrapods

From the test results, the impact strain in 50t Tetrapods under wave action was estimated applying eq. (6) as follows.

$$\varepsilon_{50t} = 3.12\, \varepsilon_{50kg} \tag{8}$$

where ε_{50t}; impact strain in 50t Tetrapods
ε_{50kg}; impact strain in 50kg Tetrapods

The maximum values of impact tensile strain on 50t Tetrapods $\varepsilon_{50t\,tmax}$ were calculated and tabulated in Table 6.

Table 6 Estimated Maximum Impact Strain on 50t Tetrapods

Behavior of Tetrapods	$\varepsilon_{50ttmax}$
Rocking slightly	37×10^{-6}
Rocking easily	94×10^{-6}
Falling down the distance equal to 1/2-1 their size	181×10^{-6}
Falling down toward the toe of the slope	287×10^{-6}
Falling down in the still water condition	112×10^{-6}

When the maximum impact tensile strain on a 50kg model Tetrapod was found to be 92×10^{-6} as in case 3-7-2, cracks or breakage did not occur. On the other hand, Terao et al (1982) carried out drop tests using prototype Dolosse and showed that the maximum impact tensile strain measured without breakage was larger than 250×10^{-6}. However it could not be verified whether breakage of Tetrapods would occur or not under wave action from only the information mentioned above. It must be considered that occurrence of breakage would be influenced by not only the magnitude of strain but also the distribution of strain. Therefore, it was necessary to perform a series of drop tests using the model and prototype Tetrapods in order to examine in more detail the critical impact tensile strain when Tetrapods break.

6. CONCLUSIONS

The following conclusions were derived through the experiment.

(1) When 50kg Tetrapods are used, the similitude relations on impact stress and strain between the model and prototype are satisfied even under wave action.
(2) In cases where Tetrapods fall down under wave action, impact strain generated is larger than that in the still water condition.
(3) It is necessary to examine in more detail the critical impact tensile strain when Tetrapods break.

CHAPTER 157

On the Behavior of Armour Unit in the Coverlayer

Hans Werner Partenscky[1], John Rutte[2] and Reinold Schmidt[3]

1 INTRODUCTION

As a result of the large-scale failure of the rubblemound breakwater at SINES, Portugal in 1978 a number of research programs were begun. At present, however, very little information is available from technical publications regarding new design criteria, recommendations, or test procedures for model tests of rubblemound breakwaters. The need still exists, therefore, for economically practical model tests and standardized test procedures so that more tests can be conducted and reproducible results from different institutions can be compared.

At the same time, a number of factors related to the stability of rubblemound surface elements, and the interrelationships between those factors, have not been adequately examined or explained. Apparently without extensive model tests, for example, it has been suggested that greater stability can be obtained by using elements with greater unit weights (comparing elements of the same absolute weight), either by adding scrap metal or denser materials, such as granite, to the concrete.

Furthermore, susceptibility to breakage is of major importance to the long-term stability of armour layer units, particularly for dolos and similar less massive element types. This aspect has been generally neglected in laboratory tests, however, and attempts to simulate the lower ultimate strength of elements in reduced-scale model tests appear extremely difficult, as well as costly in terms of time and materials.

Several other factors which can significantly affect the stability of an armour layer include the surface roughness of the individual elements, as well as boundary conditions such as the beach slope.

An attempt will be made in this paper to discuss the various factors mentioned above on the basis of extensive testing of rubblemound breakwaters recently conducted at the Franzius Institute for Hydraulics and Coastal Engineering at the University of Hannover. Standardized procedures, which are independent of the type of element, are introduced for conducting model tests as well as for systematically evaluating and quantifying the results. Results will be presented from tests using both concrete and aluminum dolos with different unit weights, in addition to concrete cubes and tetrapods. K_D-values are proposed for these different element types. The

characteristic distribution of wave-induced damage over the face of the breakwater and the reasons for this distribution are given. The complex interrelationships between the beach slope, wave period, and water depth, and their influence on the extent and location of damage are also discussed.

2 TEST PROGRAM AND EQUIPMENT

Model tests were carried out in the wave channel at the Franzius Institute (length = 90 m, width = 2.2 m, max. wave height = 0.50 m) with government funding provided by the Federal Republic of Germany. A computer-controlled hydraulic wave generator was used which is capable of generating all types of spectra and third order regular waves.

Tests of rubblemound breakwaters were conducted using three types of armour layer elements (dolos, cubes and tetrapods), all of which are similar in terms of hydraulic stability. Particular emphasis was placed on the investigation of dolos elements.

A model scale as large as practical was chosen in order to minimize scale effects. The wave heights used ranged from about H_s = 10 cm (settlement phase) to H_s = 30 cm. Reynolds Number values varied from $Re = 3.5 * 10^3$ to $Re = 1.1 * 10^5$.

The weights of the various element types used were chosen so as to conform to the equipment and facilities available, with a range of 0.183 - 1.005 kg. The unit weight of the concrete used for all three element types was 2.24 g/cm^3, while the unit weight of the aluminum dolos was 2.7 g/cm^3. The aluminum dolos were purchased from the Waterloopkundig lab in Delft, Holland.

Individual surface elements were not marked with paint so that the test results would not be distorted by the change in surface roughness. Painted elements generally have a smooth surface which can significantly alter test results.

Due to the action of electrolytic corrosion, which attacked the aluminum within a short period of time following its exposure to water, the surface roughness of the aluminum dolos was considered to be comparable to that of the concrete elements.

Breakwaters were built on bed slopes of 1:15 and 1:30 in order to simulate conditions as close to natural as possible. The generated waves broke either on or directly in front of the breakwater. The water depth at the toe of the breakwater varied from 0.05 m to 0.40 m for overall waterdepths of up to 1.20 m in front of the wave generator.

During the construction of the breakwater an attempt was made to closely simulate actual construction practices. As such, elements were randomly placed according to a grid pattern and were allowed to fall into position after initial contact with the surface of the breakwater.

Each test series was begun at 75% of the maximum wave height which the breakwater could theoretically withstand, calculated using the HUDSON equation of C.E.R.C. (1984). This simulates the normal settlement or consolidation phase which normally follows initial

construction. Wave heights were increased in stages until failure in order to monitor damage progression. Each test with a particular wave height was interrupted twice so that photos could be made in order to differentiate between further consolidation and progressive damage.

The wave spectra used included Pierson-Moskowitsch and Jonswap, as well as order regular waves.

3 DEFINITION OF DAMAGE FOR RUBBLEMOUND BREAKWATERS

The following four different methods were used to observe and evaluate the movement of armour layer elements and the extent of damage to the breakwater:

a) direct observations verbally recorded by test personnel equipted with tape recorders;
b) continuous recordings with a high quality video system, also used to support the direct observations of (a);
c) single frame pictures taken using a Super-8 movie camera whenever the receding wave would leave the surface of the breakwater momentarily exposed;
d) positive-negative overlays of photos taken between test runs, with the water drained away.

An addition procedure for defining damage for breakwaters composed of natural stones or rubble was introduced by VAN DER MEER and PILARCZYK (1984). They suggest using the change in the surface profile of the breakwater following a wave attack as a measure of damage to the breakwater. This method is less suitable for breakwaters with concrete armour layers because the comparatively large displacements in the cover layer would lead to breakage of the concrete armour units.

Close analysis of the test results showed that the overlay method of evaluating surface layer movements is considerably better than a system of direct observations supported by video recordings. Even simple movements are easily recognizable in the overlays and at no time were rocking motions observed or recorded which did not also result in some degree of noticeable displacement in the overlays. The theoretical disadvantages that rocking motions and damage progression cannot be recorded with the overlay method therefore appear to be unfounded, particularly when each test is subdivided into three parts so that the damage development sequence associated with a specific wave height can be monitored. Positive-negative overlays therefore still represent the best method - short of installing accelerometers on every element - of recording and evaluating movements in the armour layer.

Each movement visible in the overlay photos was classified as one of 35 different combinations of rotation (7 classes) and displacement (5 classes) in order to establish a distribution diagram (histogram) of all the elements' movements. The system used for dolos to classify a movement in terms of rotation and displacement is shown in Fig. I. The determination of the extent of movement for a single element begins by considering its rotation. The angle (degree) of rotation is estimated after first establishing the point about which an individual element rotates. The second step is then to determine the translation of this point of rotation. Analogous systems were used for the tetrapod and cube elements.

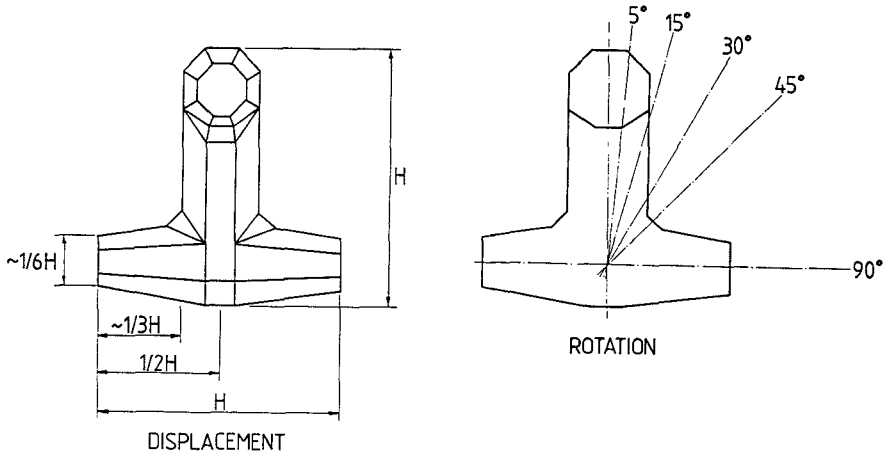

FIGURE I

Classification of Displacement and Rotation for a Dolos Element

A computer was then used to examine various possible groupings of these 35 classes. A meaningful and harmonious distribution was achieved using 6 classes, with the following combinations of rotation : displacement as upper limits:

Class No.	Maximum Rotation	Maximum Displacement	
1	5°	very small	
2	15°	H/6	H = height
3	30°	H/3	of the
4	45°	H/2	element
5	90°	≤ H	
6	90°	roll	

If the rotation and displacement of an element fall into two different classes, only the higher of the two classes is considered. This system is an extension of the method of class division presented by PAUL and BAIRD (1971).

The tests conducted at the Franzius Institut have shown that the damage distributions over large areas were very similar when these 6 general classes were used and the curves normalized, as shown in Fig. II.

This was true for all three types of elements tested, dolos, tetrapod and cube. Likewise, the distribution over a range of loading conditions, from the settlement phase up to the beginning of failure, is almost identical. The number of normalized damage events only first began to increase significantly in classes 4 to 6, with a corresponding decrease in classes 1 to 3, with wave heights which cause greater more progressive damage to the breakwater. This behaviors, which is indicative of unacceptably large damage to the breakwater, was observable in all tests.

A maximum allowable percentage of damage was determined for each of the 6 classes which reflect the susceptibility to breakage of the element type in question. Since the danger of breakage is different for the relatively slender dolos, the more sturdy tetrapods and the rather massive cube elements, these allowable damage limits for each of the 6 classes vary with the type of element. Tests conducted by BURCHARTH (1981) showed that dolos are extremely suspectible to breakage. As such, dolos movements greater than 15° : H/6 should be very strictly limited.

No published information could be found regarding the susceptibility to breakage of cubes or tetrapods. It is known, however, that a relatively high percentage of broken elements have been found in tetrapod breakwaters. The danger of breakage exists even in the case of large concrete cube or block elements as the result of shrinkage cracks caused by temperature changes during curing.

Taking the differing susceptibilities to breakage into consideration, limits on the allowable movements for each of the three types of surface layer elements were set, as shown in Fig. III. As a recommendation, damage curves which exceed these limits in any of the 6 classes should not be considered allowable.

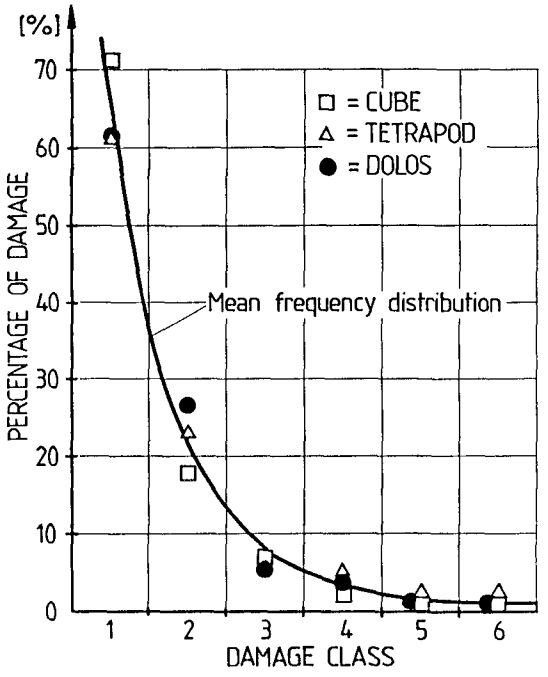

FIGURE II

Normalized Damage Distribution for Dolos, Cube and Tetrapod

(Mean Value)

The percentage of surface layer elements whose movements fall within each of the 6 classes previously described are calculated with reference to the total number of elements within a range extending $1.25 * H_{1/3}$ above and below the still water level (SWL). This is the

region in which almost all of the damage occurs. The percentage of elements experiencing a certain class of movement should always be calculated with reference to the total number of elements within this specified range, not the overall total for the breakwater. Although movements of elements outside of this range were found to be rare, they should also be considered, while still using the same total number of elements as the basis of reference. Only when the breakwater dimensions are smaller than this given range should the total number of surface elements be used.

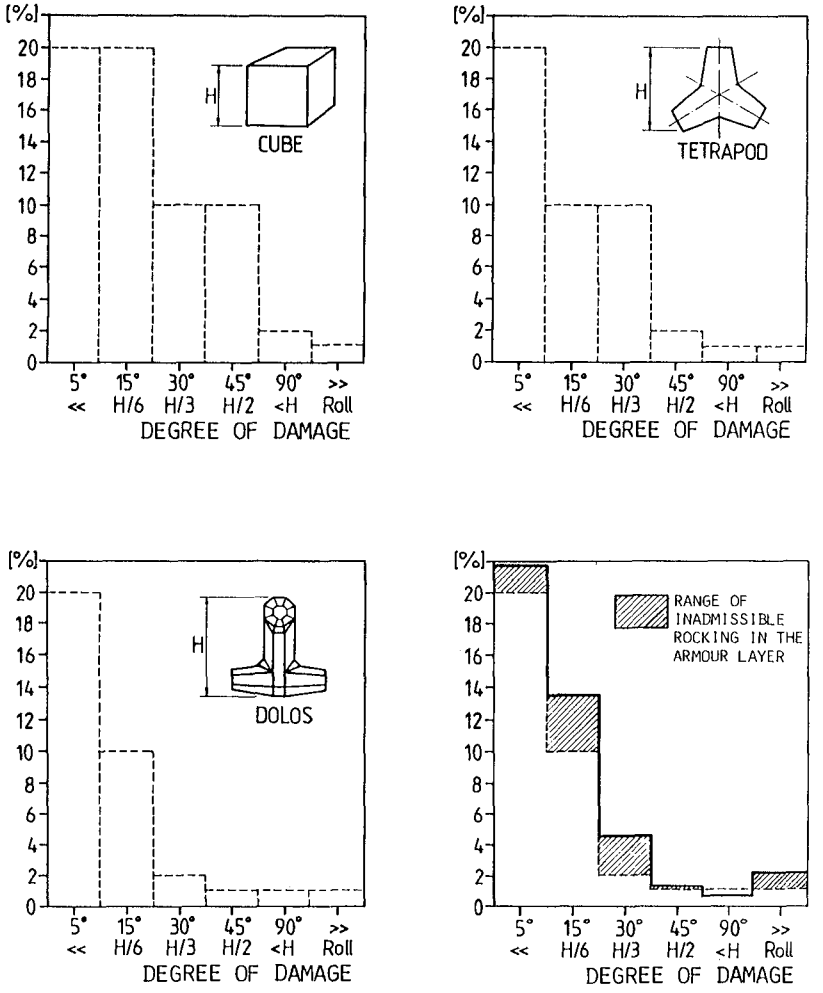

FIGURE III

Allowable Rocking for Individual Damage Classes for Cubes, Tetrapods and Dolos Elements

4 RESULTS

As part of a program of basic research sponsored by the German government's Special Research Department (SFB), extensive model tests of rubblemound breakwaters were conducted using dolos, cube and tetrapod surface layer elements.

Each test was begun using a moderate wave height in order to allow initial consolidation to take place. Following this settlement phase, wave heights were gradually increased until the breakwater failed or a state of progressive damage signaled eminent failure.

Each test at a particular wave height was interrupted twice (ie. subdivided into three parts) so that photographs could be taken. Positive-negative overlays were made from these photos, which were then evaluated using the system previously described. Video recordings of every test were used to confirm the accuracy of the overlays.

The K_D-values determined from these evaluations showed considerable variation in some cases. The influences of the wave period and the offshore slope can be offered as two of the probable reasons for these wide fluctuations.

4.1 INFLUENCE OF THE WAVE PERIOD

Assertions by various authors that wave periods become increasingly critical for breakwaters as they either increase or decrease, depending on the author, were not substantiated. Greater damage was most often associated with a wave period of intermediate length, with the extent of damage decreasing for wave periods both shorter and longer than this critical, intermediate length.

The height of a short (period) wave is limited by its maximum steepness, or breaking limit. Longer waves, on the other hand, roll more slowly over the breakwater. The resulting forces from the up- and downrush of water therefore remain small and the breakwater is not so heavily stressed.

This tendency for more intermediate length wave periods to be more critical was clearly borne out by every series of tests, with all conditions remaining constant except the length of wave period. The actual numerical values of these critical periods varied depending on the type of armour layer element and the form of the foreshore.

4.2 INFLUENCE OF THE SLOPE OF THE FORESHORE

It is obvious that the slope of the foreshore greatly influences the extent of damage. The slope largely controls the form of the wave as well as the interplay between the water rushing up and down the face of the breakwater. The breaking point of a wave, for example, is affected by the extent of the water cushion in front of the breakwater.

At the same time, the dolos elements proved to be extremely sensitive to changes in the foreshore slope and form. The results of different model tests could be characterized as varying from stable to total destruction for a prototype storm duration of 3 hours or less. The wave heights generated and the type of spectra used were identical for these tests, with the only variable being the form of the

foreshore. Statements regarding the reasons for this phenomenon and the various interrelated factors involved, however, would be premature at this point in our continuing study.

The influences of the wave period and foreshore slope were considerably smaller in the case of tetrapods and were hardly noticeable for cube elements, on the basis of these tests.

4.3 INFLUENCE OF THE UNIT WEIGHTS

Test conparisons between two dolos types of different unit weights with the same total block weight, aluminium with 2.7 g/cm^3 (169 lbs/ft^3) and concrete with 2.24 g/cm^3 (140 lbs/ft^3), came out clearly in favor of the less dense (larger) concrete elements. The denser (smaller) elements were similar in terms of stability only in those model tests in which the wave heights were limited by shallow water depths directly in front of the breakwater. The reasons for this can be attributed to the larger stresses exerted on the surface layer when water rushes back down and, at the same time, out of the breakwater; the wave having already broken and lost most of its energy. In such a case a denser element becomes more effective.

On the basis of the model tests, however, the absolute size of the individual elements appears to be the more important factor in those cases where the approaching and breaking waves (plunging and collapsing breakers) exert the principle stresses on the breakwater.

Exactly where the optimum unit weight lies is not yet known. The K_D-values for aluminium dolos determined from these tests were considerably lower than those of the cement elements.

4.4 K_D - VALUES

K_D-values were determined according to the HUDSON formula for the different element types used, as summarized in Table I. These values are valid for the breakerwater trunk and were determined for slopes of between cot = 1.5 - 1.8 (also cot = 1.33 for tetrapods).

Elements Tested	K_D-Values Measured Range	Medium	K_D-Value Recommended
Dolos (aluminum)	5.8 - 10.0	7.9	10.0
Dolos (concrete)	7.6 - 23.1	11.8	
Tetrapod (concrete)	5.9 - 10.6	7.5	7.2
Cube (concrete)	9.5 - 22.0	12.5	7.0

TABLE I

K_D-Values Determined from Tests at the Franzius Institute

In all tests the simple cube showed itself to be surprisingly stable. To be safe, however, the authors hesitate to recommend a drastic increase in the K_D-value for cubes. On the other hand, the K_D-values determined for dolos were so low that hydraulic model tests are strongly recommended as a design check for all larger-scale construction projects involving dolos elements. At the same time, it is very important to incorporate the underwater topography in front of the breakwater to a sufficient extent into the model.

FIGURE IV

Cube Protection at Bari / Italy

5 CONCLUSIONS AND RECOMMENDATIONS

For 25 years now the HUDSON equation has been the principle tool used in the design of rubblemound breakwaters. This despite the fact that the equation is widely known to be less than fully reliable. In his paper "State of the Art" I.W. STICKLAND (1983) determined that considerable damage has occured to 40 rubblemound breakwaters out of a worldwide survey of 148 breakwaters conducted by the P.I.A.N.C. .

This fact is underlined by the recently published book by PER BRUNN, "Design and Construction of Mounds for Breakwaters and Coastal Protection" (1985), in which a great many cases of failure are presented. Despite these serious problems and the obvious shortcomings of the HUDSON equation, research on rubblemound breakwaters has often not gone beyond recommending simple changes in the K_D-values used in the equation.

Completely new breakwater design criteria are not likely to be developed in the foreseeable future. On the contrary, it is more likely that it will become increasingly difficult to make general recommendations as more of the numerous complex factors related to the stability of such structures become better known.

Research conducted on behalf of the Special Research Program of the F.R.G. provided the opportunity to take up and more closly investigate some of these complex factors in hydraulic model tests. Federal support made it possible to conduct this study completely free of constraints on the scope and direction of the research, which are often elements of privately funded work. While these test results are not sufficient to develop a completely new method of designing rubblemound breakwaters, they nevertheless shed new light on several of the more important factors involved.

From the tests conducted thusfar it is clear that the individual components of the design sea state cannot be considered as isolated elements. Rather, the wave height, wave period, and the underwater beach profile, as well as the water depth in front of the structure and the type of surface element used are all closely interrelated factors which determine the effectiveness of the breakwater design. The entire structure can become surprisingly stable or instable as a result of a change in any one of these parameters. As an example, dolos elements are particularly unstable for steep underwater beach profiles with shallow water depths directly in front of the breakwater, while the same conditions have no great negative effect on tetrapods.

A standardized system for evaluating and interpreting test results is urgently needed so that all future work in this field can be better coordinated and compared. The evaluation method presented in the paper, employing positive-negative overlays, is meant to serve as a step in this direction. This method is sufficiently accurate and considerably less costly than installing accellerometers on each and every surface layer element or the use of armour elements of scale-reduced strenght. Furthermore, it is important that additional boundary conditions be made known, such as the actual wave heights used during the test, the water depth at the toe of the breakwater, as well as the inclination and length of the foreslope.

It is the authors' hope that in the near future the present uncertainties surrounding the design of rubblemound breakwaters can be sufficiently clarified so that the need for expensive model tests can be eliminated. For the time being, however, it is highly recommended that design plans be verified by hydraulic model tests. Although such tests can be rather costly, they can protect considerably larger investments in breakwater structures against extremely unpleasant surprises.

CHAPTER 158

DEVELOPMENT OF DESIGN CRITERIA FOR SEGMENTED BREAKWATERS

Joan Pope*
Julie L. Dean**

ABSTRACT

This paper will discuss experience and approaches to the use of segmented breakwaters for beach erosion control in the United States. Several prototype cases are examined and generalizations drawn concerning the resultant beach response. This experience is further evaluated in order to develop a preliminary approach for developing design criteria.

INTRODUCTION

A shore parallel breakwater separated into segments is a viable and proven approach for protecting the shore. Such segmented breakwater projects have been constructed in various areas of the world (Bishop, 1982; Silvester and Ho, 1972; Toyoshima, 1972; Lesnick, 1979). Beach erosion control breakwaters have been designed and constructed as both single and segmented structures. In both cases the breakwater is built approximately parallel to shore with the intent of causing beach accretion. Breakwaters can range from structures that are very close to shore with sufficent elevation to prohibit overtopping, resulting in artifical headlands or tombolos, to those which are offshore submerged structures which cause bulges in the shoreline.

Whereas a single breakwater is usually built to protect a short, local section of beach, a segmented breakwater system has gaps in between and functions as a system to protect large portions of the shore. The purpose of this paper is to discuss the more complex, segmented system. A segmented breakwater system may promote the beach to accrete to the structure resulting in the formation of tombolos. In other situations, a series of sinuous bulges develop in the beach planform, called "salients." A particular system may form both salients and tombolos or evolve back and forth from one form to the other as local wave and water level conditions vary.

BEACH EROSION CONTROL IN THE UNITED STATES

United States shores include eroding sandy beaches, shores which may be innundated by coastal storms, heavily structured shores, eroding cohesive bluffs, and migrating beach forms such as barrier islands. Each beach which has erosion or flooding problems may be worthy of a

* Supervisory Physical Scientist, U.S. Army Engineers, Coastal Engineering Research Center, Waterways Experiment Station, P.O. Box 631, Vicksburg, MS 39180-0631
** Hydraulic Engineer

different solution. Segmented breakwaters are not applicable in all situations. Beach erosion control plans or devices which work well in one place may not work elsewhere. The design intent of a segmented breakwater system may vary. For example, the purpose of the breakwater and the resultant beach response may be to preserve a recreational beach, halt erosion of the backbeach, or reduce storm surge induced flood damages.

Much of the United States shore is developed for recreational, residential, or commerical use. Public interest and shoreline use often dictate the need to design the erosion control solution to minimize downdrift impacts. Expected benefits to the shore to be protected have to be weighed against potential damages to neighboring shores. Beach fill placement is an important means of mitigating these damages, but its behavior is difficult to predict. When designing segmented breakwaters an accurate prediction of the beach response is necessary in selecting the structure configuration. A review of previously constructed segmented breakwater projects provides insite into developing this ability.

SEGMENTED BREAKWATER PROJECTS IN THE UNITED STATES

Experience in the United States with segmented breakwaters has been limited to littoral sediment-poor shores which are characterized by a local fetch-dominated wave climate. Thus these projects typically experience short period, steep waves which tend to approach the shore with only limited refraction, and therefore tend break at a steep angle to the shore. These projects also tend to be in areas which are prone to storm surges and erratic water level fluctuations, particularly the Great Lakes projects.

Table 1 is a summary of the seven breakwater projects in the United States which were assessed in this study. Figure 1 displays the geographic location of each of these projects. Four of these projects are on Lake Erie in the Great Lakes. This does not necessarily mean that these projects are located in "protected waters," as both Presque Isle and Lakeview Park have experienced significant storms accompanied by storm surges in excess of 1 meter. The two projects in the Atlantic coastal area are in relatively protected areas. Only the Holly Beach project can be considered as on the "open" ocean coast.

Most of these projects have been monitored and reported on elsewhere in the literature (Pope and Rowen, 1983; Pope, 1985; Gorecki, 1985; Bender, 1985; Dean, Pope, and Fulford, 1986; Nakashima, et al., 1987). Only the East Harbor and Winthrop Beach projects have not been monitored. The typical monitoring program consists of the acquisition of beach response and some process information for a period of 2 to 5 or more years after initial construction. Full evaluation of the monitoring data is still continuing for most of these projects. However, in all cases, including those projects which have not been subjected to a formal monitoring program, the development of a characteristic equilibrium beach planform and the general impact on the littoral regime can be determined. The brief review which follows on each project will describe the project parameters and beach response.

* Datum used is local average water depth at structure location during the period of post-construction monitoring (unless otherwise stated).
** Beach response is coded as follows:
1 - permanent tombolos
2 - periodic tombolos
3 - well developed salients
4 - subdued salients
5 - no sinuosity

Local conditions make each project unique and the design nontransferable to another site. However, by reviewing the structure configuation and planform response, a pattern of project effectiveness has been identified which can be used to develop some general design guidance. A more detailed summary of most of these projects appears in Dally and Pope, 1986.

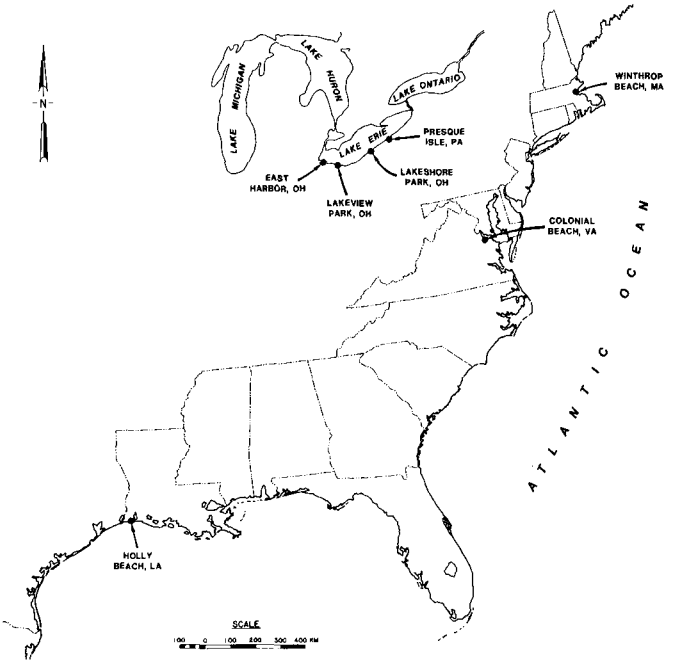

Figure 1. Location Map for United States Segmented Breakwater Projects

Winthrop Beach

The Winthrop Beach project was built in 1935. It consists of five breakwater segments separated by very small gaps. It was built 305 m off of the backbeach seawall and is in an area which experiences an approximately 2.7-m tide range. No beach fill was placed (Magoon, 1976). During high tide the five segments behave as one breakwater, resulting in a single, well developed salient. However, during low tide, individual tombolos are exposed behind several of the segments resulting in low tide headlands (Dally and Pope, 1986). This project has effectively trapped material out of the littoral regime resulting in a stable salient and tombolos along a shore which otherwise lacks a subaerial beach.

Lakeview Park

The Lakeview Park project consists of three breakwater segments, two terminal groins, and a placed beach fill (Walker, Clark, and Pope, 1981). It was constructed in 1977 and formally monitored for 5 years. The monitoring program consisted of semi-annual bathymetric and topographic surveys, three sets of aerial photography each year, annual sediment sampling, Littoral Environment Observations (LEO) made daily by a local volunteer to document the nearshore wave and current conditions, periodic project inspections, and a limited current measurement study and wave gage data collection. The structures have successfully established a stable beach headland along an otherwise sandless coast (Pope and Rowen, 1983). Once the project had established an equilibrium beach planform in response to the structure configuration, the range of wave and water level conditions only caused minor variations in the shoreline. The beach planform at Lakeview Park remained fairly stable within a limited envelope (Figure 2). There is some minor response to seasonal conditions. In particular, during the low water of the fall, the beach tends to exhibit three discernable, although subdued salients. During the high water of the spring, the beach typically will have only two subdued salients and a slight "hip" behind the western-most breakwater. As there is a strong asymmetry to the local wave climate with most of the wave energy out of the west, the west end of the beach retreated. Active transport of the native littoral material continues from west to east, through the project. However, the overall quantity of sand in the lee of the breakwaters has gradually increased through time. Over the five years of monitoring, the project gained approximately 3000 cubic meters of material per year (Pope and Rowen, 1983).

Presque Isle

The Presque Isle segmented breakwater project was built in 1978 as a prototype experiment to determine if breakwaters could be used to retard the erosion of a very large (approximately 10-km long) recurved sand spit which has been the target of various attempts at beach erosion control for over 150 years (Pope and Gorecki, 1978). Three segments were constructed and beach fill was placed. The beach exhibits some seasonal variablity resulting in two characteristic planforms, primarily responding to changes in the water level and the resultant degree of structure overtopping during storm events. During low water levels and low wave energy conditions, a tombolo sometimes forms behind the western-most (updrift) segment with two downdrift salients behind the other segments. However, during high water levels or after significant storms the tombolo is severed from the segment, resulting in three distinctive salients (Figure 3). The amount of sediment behind the breakwaters has remained fairly stable, despite an evolutionary trend toward offshore deepening (Gorecki, 1985).

Colonial Beach

Two segmented breakwater projects were built at Colonial Beach, Virginia on the Potomac River estuary in an attempt to build recreational beaches and protect a public highway which had frequently been

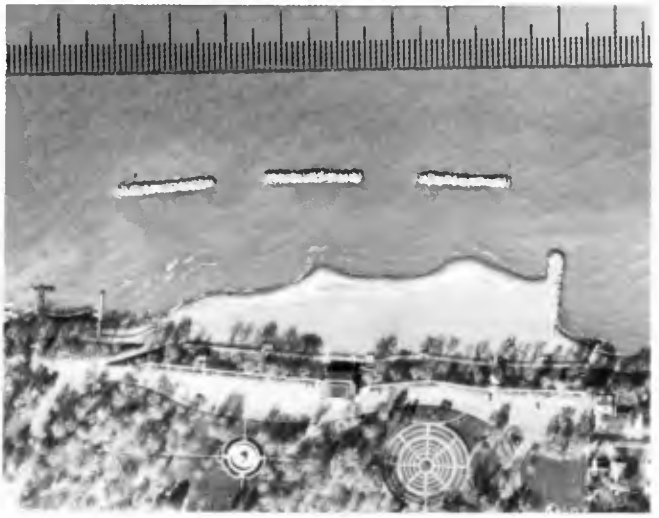

Figure 2 . Aerial Photograph of Subdued Salients at Lakeview Park, Lorain, Ohio

Figure 3. Aerial Photograph of Well-Developed Salients at Presqu Isle, Erie, Pennsylvania During Higher Water Levels

damaged by erosion (Dean, Pope, and Fulford, 1986). Central Beach consists of four segments and Castlewood Park consists of three segments plus a downdrift terminal groin. Beach fill was placed at both locations. The breakwaters in both projects were built fairly close to shore with small gap to segment length ratios (Table 1). Thus the breakwaters functioned as efficient traps which gained material from the littoral system (approximately 2000 cubic meter per year per project). The beach at Castlewood Park has been relatively inactive. Tombolos quickly formed and have remained as stable features. Central Beach is slightly more dynamic with an apparently stable tombolo behind the second segment from the updrift end and well-developed salients behind the other three segments (Figure 4). Between the salients and the breakwater segments there are very narrow channels of open water. The breakwater crest elevation is low enough that moderate storms will cause overtopping of the structure. Dye studies conducted at Central Beach suggest that even this very narrow section of open water behind the segments is important in allowing alongshore transport within the project and in releasing any hydraulic head which may otherwise be created within the compartment during a storm surge.

Lakeshore Park

The Lakeshore Park project is a three-segment structure built in 1982 at Ashtabula, Ohio on Lake Erie (Bender, 1985). Within a very short period of time after construction the placed beach fill shoreline began to retreat. The beach has continued to erode as material is lost alongshore. There is very little suggestion of sinuosity in the beach planform (Figure 5). The tendency for erosion may be partially due to the fine grain size of the beach fill, but the lack of morphological response in the shoreline suggests that the structures are too far offshore to significantly reduce the inshore wave climate and prevent erosion.

East Harbor

Four segments were constructed at East Harbor, Ohio in 1983 to protect and restore a recreational beach. No beach fill was placed and, as this is an area of low sediment supply, the project will mature slowly. High lake levels, poor sediment supply, and a structure location approximately 180 m offshore, have combined to result in the beach planform which is fairly unresponsive to the structures.

Holly Beach

In late 1985, a six-segment breakwater system was built along the erosion and hurricane prone Louisiana coast of the Gulf of Mexico to protect a highway which has frequently been damaged. One segment is rubblemound and the other five segments are built out of various geometries of timber-pile rows with tires stacked over the piles (Nakashima et al., 1987). The tire-and-pile breakwaters tend to have a higher coefficient of wave transmission than the rubblemound structures which have been used at the other project sites reviewed during this study. Salient formation occurred rapidly even though no fill

Figure 4. Aerial Photograph of Periodic Tombolo Formation at Central Beach Colonial Beach, Virginia

Figure 5. Oblique Photograph of Non-sinuous Beach response at Lakeshore Park, Ashtabula, Ohio

had been placed. Initial salient formation occurred at the two ends of the project as sediment was driven into the protected section of shore from either direction. The rubblemound breakwater has created a low-tide tombolo but the tire-and-pile breakwaters exhibit various salient morphologies in response to the wave transmission characteristics of each segment. The higher transmission segments tend to cause more subdued and blunted salients. The lower transmission segments (including the rubblemound) are backed by better defined, more peaked salients.

CLASSIFICATION SCHEME FOR BREAKWATER PROJECTS

In order to develop design criteria for segmented breakwaters, the desired beach response must first be identified (Dally and Pope, 1986). There are specific implications to beach use, degree of protection and effect on the littoral regime associated with tombolo formation. Salient formation may result in a more aesthetic and naturally behaving recreation beach with fewer adverse impacts on the littoral regime, but salients are usually not as stable and therefore tend to be less effective in providing permanent, reliable protection to the backbeach. The amplitude of the salient sinuosity (i.e., well-developed verses subdued) has important implications on the shoreline retreat behind the gaps. In general, the more sinuous the shoreline, the more stable it will be during times of increased wave action.

Beach response characteristics which need to be considered in developing the design are: the resultant beach width and planform (the presence of tombolos or salients); the amount and rate of sediment trapping from the littoral regime including regional impacts; the sinuosity of the beach planform; the beach profile slope and uniformity along the length of the project beach; and stability of the beach despite seasonal changes in wave activity, water level, and storms.

Beach response is a direct result of the amount of wave energy reaching the lee of the breakwater segments. A classification scheme has been developed based on the beach planforms which have been observed in the described projects (Figure 6). The subject projects are ranked relative to a classification scheme where the lowest wave energy in the lee of a breakwater projects results in tombolo formation. Projects in which high wave energy reachs the shore tend to have little or no sinuosity. The five beach response planforms used in this classification scheme follow:

(a) PERMANENT TOMBOLOS - In this case, very little wave energy reaches the shore and the protected beach is stable. There is very little transport along the shore. Littoral transport maybe displaced into deeper water, seaward of the structures. Castlewood Park at Colonial Beach exhibits this planform.

(b) PERIODIC TOMBOLOS - One or more segments are periodically backed by tombolos. This is primarily due to variablity in the wave energy reaching the lee of the individual segments. In the classification scheme developed here, periodic tombolos may be either unstable or stable through time, or the planform maybe variable through the

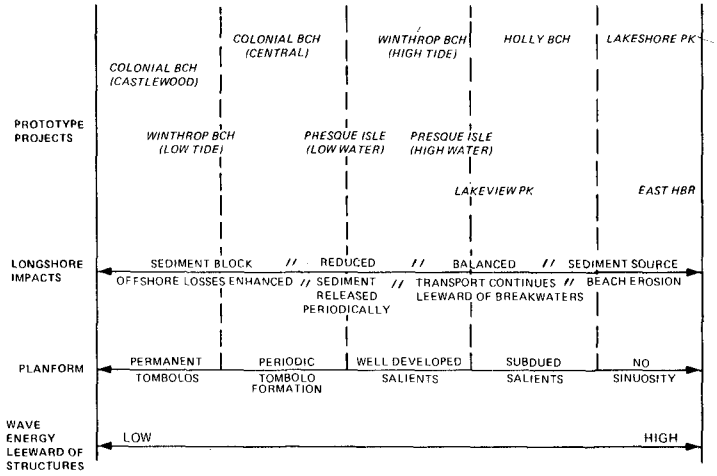

Figure 6. Proposed Classification Scheme for Segmented Breakwaters Based on Beach Response

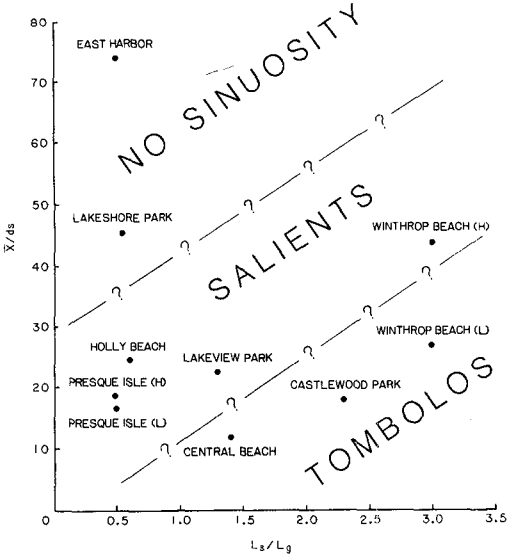

Figure 7. Dimensionless Plot of United States Segmented Breakwater Projects Relative to Structure Configuration.

project length. During high wave energy, tombolo(s) may be severed from the structure resulting in a salients. During low wave energy periods sediment accretes and the tombolo returns. The longshore effect of this type of planform may be periodic trapping of littoral material followed by a release of a "slug" of sediment. Even in a relatively stable project, only some segments may be backed by tombolos, due to alongshore variablity in the amount of energy behind the breakwater system. Presque Isle, during low water, provides an example of periodic tombolos which are unstable. Central Beach at Colonial Beach is an example of periodic tombolos which are stable (Figure 4).

(c) WELL-DEVELOPED SALIENTS - The well-developed salient beach planform occurs when higher wave energy reaches the lee of the structure and is characterized by a balanced sediment budget. Well-developed salients are not apparent until sufficient time has passed for the project shore to stablize relative to the structure configuration. Longshore moving material enters and leaves the project at approximately the same rate. In addition, rip current development within the gaps is unusual and very little material is lost into the offshore. Presque Isle, during high water, exhibits the characteristics of this planform (Figure 3).

(d) SUBDUED SALIENTS - In this case, the shoreline sinuosity is not as obvious, and amplitude of the salient is of lower relief. The project beach may periodically store and release sediment. Although the quantity of material retained in the project may remain generally balanced through time, there will be periods of increased loss or gain and the uniformity of the beach planform is not as assured. Holly Beach and Lakeview Park are examples of this classification (Figure 2).

(e) NO SINUOSITY - If high wave energy reaches the beach, including the area directly behind the segments, the beach planform may not mirror the presence of the segments. Placed beach fill may actually serve as a source of material for downdrift beaches. Although there may be some minor trapping of material from neighboring shores, the characteristic shoreline morphology is missing. Lakeshore Park is an example of a nourished beach and East Harbor is an example of an unnourished beach which illustrate this classification (Figure 5).

PARAMETERS EFFECTING BEACH RESPONSE

The forementioned classification scheme subdivides the observed beach responses into a morphological hierarchy which reflects the level of wave energy which reaches the lee of the structure. The wave energy reaching the lee of the structure (E) may be considered to be a function of the incident wave energy at the structure (W*), the structure configuration or planform (S*), and the wave transmission characteristics of the structure cross section (T*) or;

$$E = f\ (W^*,\ S^*,\ T^*).$$

Incident wave energy, is the wave climate at the structure and the result of transformation of the deepwater wave climate (height, period, and angle) over the nearshore bathymetry. Variability of the wave climate will have a significant effect on stablity of the beach planform. As most segmented breakwater projects are built in shallow water, incident wave energy is frequently directly controlled by the local water depth (ds) and its variablity. The wave climate which drives the characteristic condition of the beach is the "average" wave condition rather than the extreme. A severe storm may erase the beach planform but a structure configuration which is designed for this event will probably not display the desired beach planform on a daily basis.

Structure configuration is the density of protection provided by the structure plan and is defined through several parameters: the segment length (Ls), gap length (Lg), project length (Lp), number of segments, and the distance offshore. The offshore distance is a parameter for which there are several possible definitions. The distance offshore may be described either as the distance off the original pre-project shore or as the distance between the placed beach fill shore and the structures. Neither definition is really a true indicator of the amount of open water over which the transmitted wave energy must be distributed within the lee of the structures. The averaged distance of the structure from the effective shoreline ($\overline{X}$) may be somewhat different due to the artificial advance of the shore by the addition of groins or beachfill.

Transmitted wave characteristics are a result of the amount of incident wave energy which is transmitted into the project lee either through or over the structure crossection. The structure crest elevation controls the amount of overtopping wave energy. The permeablity of the structure cross-section controls the efficiency of the structure in absorbing incident wave energy.

Although a basic assumption of this paper is that wave energy in the lee of the structure controls beach planform, sediment characteristics of the natural littoral regime and the placed fill are also significant in influencing the eventual beach response. The quantity of material available and grain size of the sediment is important in influencing the rate at which the project reaches maturity and the eventual profile slope. Theoretically there is also a relationship between the grain size of the littoral material and the stablity of that material when exposed to various levels of wave energy. However, stablity of various grain sizes under a particular longshore transport potential is here considered as a second-order design factor.

APPROACH FOR DEVELOPING DESIGN CRITERIA

Prototype experience with the described breakwater projects and the relationship between beach response and wave energy in the lee of the structures is used to develop an approach for designing segmented breakwaters. These criteria are based on both experience and an appraisal of coastal processes.

In order to relate the beach response classification scheme to a single measure of the project wave energy, E, each factor which controls E was explored. Although E is a function of three basic parameters, only structure configuration, S*, could be tested using prototype data. The number of prototype projects available to test any approach are very limited as was the data available on each project, particularly regarding incident wave energy, W*. However, a review of the projects suggested that although incident wave climate, W*, was different from project to project, all were located in low to moderate wave environments dominated by steep, local wind fetch generated waves. In each case, the wave transmission characteristics of the structure crossection, T*, did influence the variablity of the shoreline envelope around an average beach planform. However, only the pile-and-tire breakwaters of the Holly Beach project allowed enough wave transmission during non-storm periods, to modify the beach planform from segment to segment.

A number of dimensionless parameters were evaluated in order to test the influence of S* on the beach response characteristics. Figure 7 displays the relationship between all prototype projects relative to two dimensionless parameters. The ratio of segment length to gap length, Ls/Lg, was found to be an excellent parameter for defining the capability of the structure plan to block incident wave energy. The ratio of the average distance of the structures from the effective shoreline to the average water depth at the structures, $\overline{X}/ds$, represents the influence of the structure location in effecting shoaling and diffraction of the incident wave energy. Water depth at the structures, ds, limits the amount of wave energy which can enter through the gaps (i.e., controls the breaking wave height. The distance between the effective shoreline and the structures, $\overline{X}$, implies where the shoreline intersects the diffracted wave pattern.

The projects plotted in Figure 7 display a grouping which may illustrate fields of a predictable beach planform response for low to moderate wave climates. Figure 7 displays, in effect, the inverse of the average post-project slope relative to the segment-to-gap ratio. This is an exploratory effort which may be of interest to the coastal scientist who is selecting a breakwater plan. This is not, however, a final result and much testing of this premise is needed.

FUTURE WORK

Verification and testing of the classification scheme, the relationships discussed, and the fields suggested by Figure 7 are planned. Although additional prototype data will be sought, such data are difficult to attain and are often complicated by site specific parameters. A generalized shoreline response numerical simulation model (Hansen and Kraus, in preparation) will be used to extend the prototype data presently available. Individual prototype cases will be modelled. The dimensionless relationships suggested by Figure 7 and other parameters will be varied to explore the sensitivity of the beach planform to those parameters which affect wave energy in the lee of structures.

SUMMARY

A classification scheme was developed to summarize the stablized, or average, beach planform observed for eight segmented breakwater projects in the United States. Data and monitoring results are presented for each of these projects. An assessment of these projects suggests that beach response is directly related to the wave energy which reaches the lee of the structures. Wave energy in the lee of the structures is a function of the incident wave energy, the structure plan or configuration, and the wave transmission characteristics of the structure crossection. Prototype data is displayed relative to dimensionless parameters which suggest a correlation between the beach slope, segment plan, and beach planform.

This paper attempts to simplify the complexities associated with segmented breakwater design into some generalized design criteria. However, individual projects present a number of site specific limitations which restrict the application of generalized "rules of thumb." The summary presented here is an attempt to translate prototype experience into a form which may help in project planning. The use of physical and numerical models which have been adapted for the specific conditions of the project site are recommended for detailed design.

ACKNOWLEDGEMENTS

Through the various projects and monitoring programs many have contributed to this study. In particular, the work of the United States Army Engineers Districts at Buffalo and Baltimore, the state of Ohio Department of Natural Resources, and the state of Louisiana Geological Survey are recognized for their initiative, not only for using segmented breakwater systems, but also for establishing monitoring programs to learn from these installations. Mr. Clifford L. Truitt, Mr. Thomas W. Richardson, and Dr. Nicholas C. Kraus contributed through helpful discussions during the development of this paper. This study was conducted under the work unit "Evaluation of Navigation and Shore Protection Structures" of the Coastal Structures, Evaluation, and Design Research Program of the United States Army Engineers. Permission was granted by the Chief of Engineers to publish this information.

CHAPTER 159

WAVE FORCE AND MOVEMENT CALCULATIONS FOR A FLEXIBLE OCEAN OUTFALL PIPELINE

J D POS[1], K S RUSSELL[2] and J A ZWAMBORN[3]

ABSTRACT

The design process for the calculation of wave forces and movements for a flexible (plastic) ocean outfall is described. The design procedure is illustrated using a case study of the design of two High Density Polyethylene (HDPE) pipelines of 0,9 m and 1,0 m OD (4 290 m and 5 450 m long) constructed at Richards Bay, South Africa, to dispose of dense and buoyant effluent respectively.

The pipeline anchor weights are based on the 1 in 1 year wave forces on the pipeline, implying that the pipeline is allowed to move during its design life. Special star anchor weights are used which keep the pipe clear of the bed while maintaining the stability of the pipeline.

Friction tests were undertaken with a section of pipeline and two star weights, above water on concrete and sand and below water on sand, to determine realistic friction coefficients for the pipeline design. The results of these tests are summarised in this paper. It was found that the mean friction coefficient for submerged star weights on sand was 0,75.

The movements of sections of the 0,9 m OD pipeline were calculated using a finite difference computer programme developed by Prof I Larsen and the results are summarised in the paper. It was found that movements of 1 to 2 m could occur under design wave conditions (50 to 100 year waves) and these were considered acceptable provided that the pipeline was not obstructed by rock outcrops.

1. INTRODUCTION

Two High Density Polyethylene (HDPE) pipelines of 0,9 m and 1,0 m OD have been constructed at Richards Bay, South Africa, (160 km North of Durban) to dispose of dense and buoyant effluent respectively. The dense and buoyant effluent pipelines are 4 290 m and 5 450 m long (measured from the pump station) and discharge at depths of 24 m and 29 m respectively. The dense effluent consists primarily of waste gypsum from a fertiliser plant while the waste from a large paper pulp mill accounts for the bulk of the buoyant effluent.

1 Research Engineer, Maritime Structures Division, National Research Institute for Oceanology, CSIR, Stellenbosch, South Africa.

2 Deputy Director, National Research Institute for Oceanology, CSIR, Stellenbosch, South Africa

3 Head, Maritime Structures Division, National Research Institute for Oceanology, CSIR, Stellenbosch, South Africa.

During the initial design phase NRIO was involved with the site investigations and the effluent dilution calculations. When the contract went out to tender, flexible HDPE pipelines were proposed and subsequently constructed. These pipelines were originally designed using the Scandinavian Design Procedure (SDP) for flexible pipelines which was based on a large amount of experience with flexible pipelines in the Scandinavian countries. Since previous pipeline experience in South Africa was with rigid concrete or steel pipelines, NRIO reviewed the flexible pipeline design procedure. NRIO was then commissioned to check the "as built" design of the Richards Bay outfall marine pipelines. To do so, the design wave conditions, wave forces and consequently the required weighting along the pipelines were calculated. Friction tests were carried out to determine realistic friction coefficients and the expected movements of various sections of the pipelines were determined.

2. WAVE FORCE CALCULATIONS

2.1 The Scandinavian Design Procedure (SDP)

The forces on the pipelines and the weights of the anchor blocks were calculated in accordance with the SDP. Firstly, it should be noted that there is no "design code" for flexible pipelines. Present design is based on experience gained in Scandinavia over the past 20 years (Janson, 1974, 1978; Janson and Larsen, 1979; Björkland, 1983).

The "design procedure" should include the following steps:

i) The choice of HDPE or PP (Polypropylene) material type is dependant on the effluent temperature.

ii) Pipe wall thickness is determined to ensure that stresses due to internal pressure do not exceed a given value which depends on material, temperature and service life as well as adequate safety against buckling due to external and internal loads.

iii) **Assuming** a friction factor f = 1 stability against sliding requires:

$$f(W - F_L) \geq F_H \qquad (1)$$

where: W = submerged anchor weights

F_L = lift force

F_H = horizontal force (maximum combined).

Thus for $F_L = 0$ (pipe well clear of the bed) it follows:

$$W \geq F_H$$

or the anchor weight is equal to (or greater than) the horizontal force. If f = 1 and square or star-shaped anchor blocks are used the safety against overturning of loose anchor blocks is the same as the safety against sliding.

iv) It is accepted that the pipe may move once or twice a year. This means that, say, the once-a-year occurring **maximum** wave heights must be used to determine the forces on the pipe, that is,

$H_{max} \simeq 2\ H_{mo}$, where H_{mo} is the characteristic wave height based on six-hourly records with an occurrence of once a year.

v) In determining the wave forces it is assumed that the pipe will always be clear of the bottom (resting on the anchor blocks which protrude usually more than D/4 from the pipe, where D is the pipe diameter). If the anchor blocks were to sink into the sea bottom because of local scour, a lift force would develop which would increase at smaller pipe clearances. If the lift force exceeded the anchor weight, the pipe would become buoyant and would lift off the bottom until the vertical forces found a new equilibrium, re-establishing a clearance. Deposition of sand beneath the pipe is unlikely because of increased water velocity and extra turbulence in the area. If it did happen the same lifting process would occur. If the sea bottom were to be raised in the area by general accretion, the pipe would be buried and the wave forces reduced accordingly.

vi) Pipe force calculations may be based on the simplified formulae and refraction graphs contained in Janson (1974) if more detailed information is not available. However, more reliable results can be obtained by using a higher-order wave theory in the shallower water and local wave conditions or wave conditions converted by actual refraction diagrams to the site, taking into account depth-limiting conditions. This information is then fed into the basic Morison equation.

For the SDP the horizontal (parallel to the bed) wave forces on a pipeline are calculated using the Morison equation. Based on the assumption of minimum (D/4) clearance before horizontal motion can take place, the following force coefficients are used:

$C_M = 2$ (inertial/added mass coefficient)

$C_D = 0,7$ ($C_D = 0,33$ is the original SDP value which has been in use for almost 20 years. In view of the new rules of Norske Veritas for oil and gas pipelines, which may be somewhat conservative, and the tests of Sarpkaya, a value of 0,7 was used in these studies; Larsen, 1984)

$C_L = 0$ (lift coefficient).

vii) Knowing the anchor blocks and the pipe characteristics, it must be ensured that the spacing between the blocks will be such that the permissible bending will not be exceeded (Europlast, 1984). It should then be determined whether, for the design life of the pipe, for example 50 years, the total movement and resulting maximum bending moments and strains will be acceptable, that is, movement should preferably not exceed a few metres, short-term strain should not exceed **1,5 per cent** and long-term deformation after 50 years must not exceed 6 per cent (Janson and Larsen, 1979 and Europlast, 1984). Recent data (private communication Prof Larsen) indicates that short-term strains $\leq$ 2,5 per cent would be acceptable. Further details of the SDP are given by Pos (1986).

For the Richards Bay pipelines star-shaped anchor weights were used. It was hypothesised that these weights would provide greater

resistance against sliding than the more conventional square anchor weights. Figure 1 shows typical star weights as installed on a section of the Richards Bay pipelines.

Figure 1: Typical star weights, Richards Bay HDPE pipeline

2.2 Calculation of Anchor Block Weights

The SDP states that the weighting required at a particular location along a pipeline is equivalent to the maximum horizontal 1:1 year wave force expected to occur at that position. The maximum horizontal wave forces along the 0,9 m and 1,0 m marine pipelines, for 1:1 year design waves were calculated using the programe "PIPE" installed on the CSIR's CDC computer. The above programme uses the Vocoidal wave theory (Swart and Laubser, 1978) to calculate the horizontal velocities and accelerations and the Morison equation to calculate the maximum combined horizontal wave forces on the marine pipelines.

The 1:1 year maximum horizontal wave loadings along the 0,9 m OD Richards Bay outfall marine pipeline are given in Table 1 as a sample of the results*. For each chainage position the following data are given in Table 1:

(a) The water depth, wave height, angle of incidence, maximum crest bottom velocity, maximum trough bottom velocity, maximum absolute bottom acceleration (12 s period waves were used throughout).

(b) The maximum drag and inertial and combined drag and inertial (incorporating phase effects) horizontal force (kN/m).

(c) The above horizontal force expressed as a percentage of the weight of water (per m length) displaced by the pipe.

*Details regarding the design wave conditions used for the force calculations are given in CSIR (1985).

(d) The installed weighting.

Comparison of the last two columns in Table 1 shows that except for the first section of the pipeline, the installed weights are larger than those calculated using the SDP, which requires that the submerged anchor weight be equal to the maximum horizontal force for the 1:1 year wave condition (if it is assumed that for a pipe mounted D/4 above the bed inertial, drag and lift coefficients of 2, 0,7 and 0 respectively apply and a friction coefficient of 1,0 was used for these calculations). In a subsequent study Pos (1986) has suggested that based on the work of Sarpkaya (1977) and DNV (1981) inertial, drag and lift coefficients of 2, 0,8 and 0,4 would be more appropriate. The lift force (in phase with the drag force) particularly will have an effect on the pipeline stability in those regions where the drag and inertial forces are of similar magnitude, such as the diffuser sections.

Table 1: 1:1 Year maximum horizontal wave loading along the 0,9 m OD pipeline

Chainages along the pipe	Water depth (m)	Wave height (m)	Angle of incidence (degrees)	Maximum crest bottom velocity (m/s)	Maximum through bottom velocity (m/s)	Maximum absolute bottom accel. C_m = 2,0
C_D = 0,7
C_L = 0,0

3. FRICTION TESTS

3.1 Introduction

In order to check the SDP assumption that the friction factor f = 1, it was decided to carry out tests, using a section of the pipeline with associated star weights, to determine realistic friction coefficients for a range of test conditions.

These tests were carried out at Richards Bay on 23 and 24 April 1985 to establish the friction factors associated with the sliding of the concrete star anchor weights, **out of water** over concrete and sand, and **under water** over sand. The above-water friction tests simulated underwater conditions and enabled a range of surfaces from smooth concrete to dry sand to be monitored visually and photographically. Full details regarding the test configurations, procedures and results are given in CSIR (1985), while the main findings are summarised below.

3.2 Test Configurations

The test configuration used for the above-water concrete and sand friction tests is shown in Figure 2. The test rig consisted of a 3 m section of 900 mm OD (40 mm wall thickness) High Density Polyethylene (HDPE) pipe to which was attached two half star weights spaced 1 m apart symmetrical about the centre of the length of pipe. The two half star weights were clamped to the pipe using two steel clamps. The reason for using the half star weight test rig for all the above-water friction tests is that its weight above water is approximately equal to the submerged weight of the whole star weight rig. It was thus proposed that this test arrangement could be used to simulate, above water, the submerged sliding behaviour of a section of the pipeline.

The test configuration used for the underwater friction tests was the same as that used for the above-water tests except that now full star weights were used. For both configurations the pulling force was applied at the level of the pipe axis.

Figure 2: Above-water friction test configuration

3.3 Test Procedures

The above-water friction test procedures both for the concrete and sand friction tests were virtually identical. The ends of the half loop of chain was shackled to the steel clamps of the test configuration as shown in Figure 2. This was then connected to the pulling cable of a mobile crane via a load shackle. A continuous load (in the form of milli-volts from the strain gauges) versus time plot was obtained for each test via a pen recorder interfaced with the load shackle amplifier. The milli-volt versus time plots were converted into load (in kN) versus time plots using a predetermined calibration curve.

To determine the displacement of the star weights with time two survey staffs were placed on the ground, parallel to the pulling cable, with the beginning of each staff adjacent to the toe of a star weight. For

the tests on concrete the staffs were aligned with the front toes (closest to the crane) of the weights (see Figure 2), while for the above-water sand tests the staffs were aligned with the back toes of the weights. A stop-watch was started at the beginning of the test and the time noted at 0,1 m displacement increments as each weight displaced relative to its staff.

For the tests on concrete, consecutive tests were merely started with the test rig in the position corresponding to the end of the previous test. For the tests on sand, however, after each test, the test rig was lifted and positioned on a section of undisturbed sand before the next test was started.

The underwater friction tests were performed in a large flooded pit with a sand bed using the test configuration described previously. The crane cable was connected to the pulling cable of the test configuration via the load shackle. As for the above-water tests, a continuous load versus time plot was obtained for each test via the load shackle and its peripherals. After each test the test rig was lifted and repositioned in an undisturbed section of the basin.

To determine the displacement of the test rig with time a survey staff was placed on the ground, parallel to the pulling cable, with the beginning of the staff adjacent to a chalk mark on the load shackle. A stop-watch was started at the beginning of the test and the time noted at 0,1 m displacement increments, as the load shackle displaced relative to the staff. A note was also made of the time at which the star weights had stopped displacing laterally and were only tilting.

3.4 Friction Coefficient Calculation Procedure

The friction coefficients were calculated using Equation 1. Setting the lift force F_L to zero and assuming that the pipe is on the point of motion, Equation 1 reduces to:

$$Wf = F_H \tag{2}$$

and thus

$$f = \frac{F_H}{W} \tag{3}$$

where, in this case,

F_H = horizontal pulling force

W = weight of test rig

f = friction coefficient

3.5 Above Water Friction Test Results

The friction test results for smooth (surface roughness $\pm$ 1 mm) and rough (surface roughness $\pm$ 5 mm) concrete are summarised in Tables 2 and 3 respectively. The movement of the anchor weights across the concrete consisted of a number of individual sliding events. Each event consisted of a load build-up phase during which the star weights

tilted over slightly and a sliding phase in which the load was released. The mean peak pulling force (associated with the initiation of sliding) of individual sliding events and the corresponding friction coefficients (calculated by means of Equation 3) for these tests are summarized in Tables 2 and 3. The test mean friction coefficients are 0,82 and 0,76 for the smooth and the rough concrete tests respectively.

Table 2: Friction Coefficients for Smooth Concrete

Test No.	Mean peak pulling force of individual sliding events (kN)	Mean friction coefficient
2-1	20,2	0,83
2-2	20,6	0,84
2-3	19,1	0,78
Test mean	20,0	0,82

Table 3: Friction Coefficients for Rough Concrete

Test No.	Mean peak pulling force of individual sliding events (kN)	Mean friction coefficient
3-1	17,9	0,73
3-2	18,8	0,77
3-3	18,7	0,76
Test mean	18,5	0,76

The above-water wet and dry sand friction test results are summarised in Tables 4 and 5 respectively. In each table the mean friction coefficients for initial movement (F_{init}), for the displacement range 0 - 0,2 m ($f_{0-0,2}$), 0,2 - 0,4 m ($f_{0,2-0,4}$), 0,4 - 0,6 m ($f_{0,4-0,6}$), >0,6 m, ($f_{>0,6}$), and for the pure tilting phase (f_{tilt}) are given. It is evident that there are three distinct phases during the movement of the anchor weights across the sand, namely:

(i) an initial pure sliding phase;

(ii) a sliding and tilting phase in which the weights progressively slide less and tilt more;

(iii) a pure tilting phase in which the weights tilt over with little or no further forward displacement.

Table 4: Friction Coefficients for Wet Sand

Test No.	f_{init}	$f_{0-0,2}$	$f_{0,2-0,4}$	$f_{0,4-0,6}$	$f_{>0,6}$	f_{tilt}
4-3	0,24	0,31	0,58	0,71	-	0,84
4-4	0,30	0,45	0,66	0,73	-	0,85
4-5	0,34	0,50	0,70	0,82	-	0,93
Test mean	0,29	0,42	0,65	0,75	-	0,87

Table 5: Friction Coefficients for Dry Sand

Test No.	f_{init}	$f_{0-0,2}$	$f_{0,2-0,4}$	$f_{0,4-0,6}$	$f_{>0,6}$	f_{tilt}
5-1	0,13	0,32	0,59	0,75	0,81	0,86
5-2	0,13	0,34	0,60	0,74	-	0,91
5-3	0,11	0,41	0,68	0,84	0,89	0,94
Test mean	0,12	0,36	0,62	0,78	0,85	0,90

3.6 Underwater friction test results

The underwater friction test results are summarised in Table 6. As for the above water tests on sand, the initial movement and the mean friction coefficients for the previously described displacement ranges are given in this table. A sample force and displacement plot is shown in Figure 3. From this plot it is evident that, as for the above water friction tests on sand, the displacement of the submerged anchor weights over the sand bed again incorporate the three movement phases of pure sliding, combined sliding and tilting and pure tilting.

Table 6: Friction Coefficients for Underwater Tests

Test No.	f_{init}	$f_{0-0,2}$	$f_{0,2-0,4}$	$f_{0,4-0,6}$	$f_{>0,6}$	f_{tilt}
6-1	0,45	0,56	0,72	0,86	0,94	0,87
6-2	0,50	0,51	0,65	0,71	0,76	0,70
6-3	0,37	0,51	0,69	0,79	-	0,80
Test mean	0,44	0,53	0,69	0,79	0,85	0,79

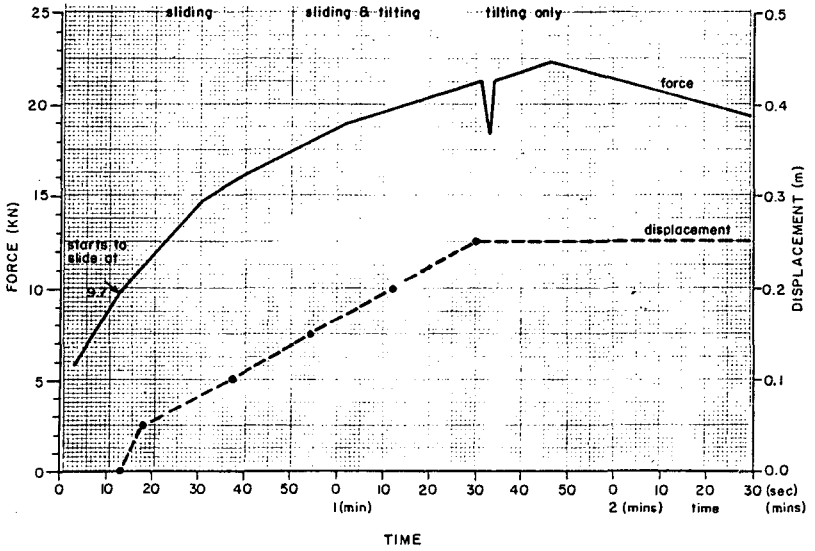

Figure 3: Force and displacement-versus-time plot for underwater friction test No 6-3

3.7 Conclusions

For the smooth and rough concrete tests the mean friction coefficients were 0,82 and 0,76 respectively. The rough concrete friction coefficient of 0,76 would seem the most appropriate for the case for example, of star weights resting on a flat rock reef. This coefficient is significantly less than the SDP assumed friction coefficient of 1. The movement of the anchor weights over such a rock surface will probably consist of a series of sliding events.

The wet sand tests, the dry sand tests and the underwater tests all showed that the movement of the star weights across sand consisted of an initial pure sliding phase, followed by a combined sliding and tilting phase and ended with a pure tilting phase.

Since the pure sliding phase was associated with the digging in of the legs of the star weights, it is thought that the most realistic values to adopt are the $f_{0,2-0,4}$ and $f_{0,4-0,6}$ values. The $f_{>0,6}$ and f_{tilt} values are not thought to be realistic as, due to the high torsional resistance of the pipeline, it is likely that the weights will rotate on the pipe rather than tilt (through any appreciable angle) monolithically with the pipe.

For the above-water tests on sand the wet sand $f_{0,2-0,4}$ and $f_{0,4-0,6}$ values of 0,65 and 0,75 (see Table 4) are thought to be the most representative. For the underwater tests the $f_{0,2-0,4}$ and $f_{0,4-0,6}$ values of 0,69 and 0,79 (Table 6) are thought to be the most appropriate for design purposes.

Based on these data it is suggested that for a sandy sea bottom a value of 0,75 be used, which is significantly lower than the value of 1,0 used when designing the pipeline according to the SDP. It is interesting to note that Lambrakos (1985) also obtained an average maximum friction coefficient of 0,75 for the lateral sliding of a 0,61 m OD steel pipe (with no anchor weights) on a sandy sea bed.

4. PIPELINE MOVEMENT CALCULATIONS

Because the friction tests had shown that friction coefficients could be less than 1, the expected (design wave) movements of the pipelines were calculated for the most critical sections, using a pipeline movement program developed by Prof Larsen (Abbott, Larsen and Verwey, 1977) and modified to incorporate the Vocoidal wave theory (Swart and Laubser, 1978).

For each wave-loading condition investigated a 380 m section of the 0,9 m OD pipeline was modelled using the program. The pipe section was modelled using 39 nodes, that is, with a 10 m spacing between nodes. The time step used throughout was 0,2 s. The relevant design wave data and the results are summarized in Table 7. For each chainage position listed the following data are given:

1. The return period of the design wave conditions used;

2. The MSL water depth, the maximum wave height and the mean angle of incidence of the waves relative to the pipeline axis (12 s period waves were used for all the conditions tested).

3. The pipe OD; for the transition between the pipe and the diffuser runs were done using both 0,9 m and 0,61 m OD pipes;

4. The friction coefficient used (0,5; 0,75 or 1);

5. The installed anchor weighting per metre, expressed as a percentage of the displaced weight;

6. The maximum transient excursion and the maximum residual displacement for one wave cycle (measured in the central 140 m portion of the pipeline). As an example the displacement plot for chainage 4290 for a 1:50 year wave and a relatively low friction factor of 0,5 is shown in Figure 4.

For a friction coefficient of 1 the results showed expected lateral movements of 0,07 to 0,19 m for the 1:1; 0,26 to 0,55 m for the 1:10; 0,65 to 1,09 m for the 1:50 and 0,87 to 1,34 m for the 1:100 year design wave. For a more realistic friction coefficient of 0,75, these movements were approximately double. The total expected movements for design storms can be obtained by accumulating the movements for individual wave heights.

Table 7: Lateral displacements along sections of the 0,9 m OD pipeline

Chainage	Return period (yesrs)	MSL depth (m)	Maximum wave height (m)	Mean angle of incidence (degrees)	Pipe OD (m)	Friction coeffi-cient	Installed weighting expressed as a % of displaced weight	Absolute Displacement

5. CONCLUSIONS

For a proper pipeline design reliable wave height, period and direction data are needed. For the design of the Richards Bay pipelines a detailed wave refraction analysis was combined with nearshore (Waverider) wave height measurements to determine the design wave conditions along the pipeline route. The choice of the design wave conditions for calculations of the anchor weights depends on the acceptable pipeline movements. For flexible pipelines designed according to the SDP the anchor weighting is based on a 1 in 1 year maximum wave height.

To determine the weighting, the bed kinematics must be calculated using a suitable higher order wave theory and the forces on the pipeline must be calculated using a suitable wave force theory. For the Richards Bay pipelines the bed kinematics were calculated using the Vocoidal wave theory and the wave forces were calculated using the Morison equation.

Pipeline movements should be estimated for the design life of the pipeline using a numerical model. The movements will depend largely on the actual weighting and the resistance of the pipeline with anchors to movement (friction). For the Richards Bay pipelines the movements were calculated using a finite difference model developed by Prof Larsen (Abbot, Larsen and Verwey).

Since no data was available on the friction factors for the Richards Bay pipelines with the star weights and because the assumption of $f = 1$ appeared optimistic, full scale friction tests were done to determine the friction factor for star weights on both hard surfaces ("rock") and on sand. The results showed that the friction factors fell predominantly in the range $f = 0,7$ to $0,8$ and that a value of $f = 0,75$ would seem generally applicable. However, initial friction factors (small movements) on sand can be as low as $f_{0-0,2} = 0,4$ to $0,5$.

Using the Vocoidal wave theory, $f = 0,75$ and the actual weighting, movements were found to range from 1,3 to 1,9 m for 1 in 50 year maximum waves. This movement was considered acceptable except for two rocky reef areas where additional weighting was added to those sections of the pipelines passing throught these reef areas.

It became clear from these studies that if movement of the pipeline has to be limited to small values, eg. 0,1 to 0,2 m, as in the case where an HDPE pipeline traverses rocky areas with pinacles, the required weighting may become so large that the pipeline with the anchor weights attached cannot be floated out during laying, thereby loosing much of the advantages of using HDPE piping. It must therefore be concluded that the flexible pipeline concept, which allows acceptable movements of the pipeline under design wave conditions, is particularly suitable for locations where the sea bed consists predominantly of sand.

ACKNOWLEDGEMENT

We would like to thank the Mhlatuze Water Board and consulting engineers Campbell, Bernstein and Irving for their permission to publish this paper. We would also like to thank Mr J D P Scholtz for his help with the friction tests.
