ABSTRACT

This book contains over 200 papers presented at the 20th International Conference on Coastal Engineering. The book is divided into five parts: theoretical and observed wave characteristics; coastal processes and sediment transport; coastal structures and related problems; coastal, estuarine and environmental problems; and ship motions. Reports include the effects of wind, storms, and currents. Erosion, sedimentation and beach nourishment are covered. The papers approach these topics with theoretical studies, case reports, models, and field studies.

FOREWORD

Only one International Conference on Coastal Engineering has been held in the same city thus far. Moreover no country has been the venue for more than one Conference except the United States. Although repeat venues are not discouraged, the extremely time consuming activities of planning and conducting a major international conference do not encourage a second effort by the same group. Having the venue in different countries allows the participants to learn first hand about coastal problems and solutions around the world. This approach also allows those engineers and coastal scientists who could not travel to foreign countries to meet the international coastal community.

The papers in the Proceedings have been prepared by the authors who made presentations at the 20th International Conference on Coastal Engineering. The authors were asked to make their presentations and submit final papers based on review of the abstracts that were submitted well in advance of the conference. These abstracts were reviewed by a committee of four professionals including representation from the local organizing committee. These papers are eligible for discussion in the Journal of the Waterway, Port, Coastal and Ocean Division. All papers are eligible for ASCE Awards.

Venues for the 21st and 22nd conferences are Torremolinos (Malága), Spain, and Delft, The Netherlands, respectively. Countries desiring to host a future conference should contact the Secretary of the Coastal Engineering Research Council to receive information about submitting a proposal.

Maximum Entropy Spectral Estimation for Wind Waves

Jorge Calderón Alvarez*
Adolfo Marón Loureiro*

Some results are presented on the application of new spectral estimation techniques using AR and ARMA models, also known as Maximum Entropy Methods, to wind wave spectral analysis. The results are compared with those obtained with conventional FFT methods. The application of some mathematical methods for model order selection is included. The relation between the optimum order and different spectral parameters is investigated.

1 INTRODUCTION

In recent years new spectral analysis methods have substituted traditional ones in many fields of science and technology. Among them, one of the most useful ones is based in the use of autorregresive models (AR), moving average models (MA) and mixed autoregressive-moving average models (ARMA). Using these models for spectral analysis is directly related with what is called Maximum Entropy Methods (MEM) for spectral estimation.

Among the possible advantages of these methods found in the literature, we can note the following ones:

1- No assumption is made about how the time series behaves outside the known interval, while FFT methods assume that the series either is zero or repeats itself indefinitely outside such interval.

2- The spectral density can be easily represented by a small number of parameters (the model coefficients).

3- Good spectral estimates can be obtained from a very short sample of the time series.

4- Real time forecasting can be easily performed.

Although wind wave spectra have been lately analysed by means of the Fast Fourier Transform (FFT), some attemps of using ARMA models have come out in publications. However, to the authors knowledge, no systematic applications for wind wave analysis have been reported.

Generally speaking, we can say that ME methods try to model a non-deterministic, discrete and stationary stochastic process $\{x(t)\}$ by an ARMA model of finite orders (m,n), whose mathematical description is as follows:

$$\sum_{k=0}^{m} b_k \, x(t-k) = \sum_{k=0}^{n} a_j \, w(t-j) \quad ; \quad t = 1, 2, 3, \ldots \qquad (1)$$

* Programa de Clima Marítimo y Banco de Datos Oceanográficos. Dirección General de Puertos y Costas. Po. Castellana, no.16, 28046-Madrid, Spain.

Where
m is the order of the autorregresive part,
n is the order of the moving average part,
a_k are the autorregresive coefficients,
b_j are the moving average coefficients and
w(t) is a zero mean white noise with variance σ^2.

The energy spectral density of the process corresponding to this model is given by the following expression:

$$S(f) = \frac{\sigma^2 \cdot A(z) \cdot A(1/z)}{B(z) \cdot B(1/z)} \quad \text{in the Nyquist range} \quad f \in [0, \frac{1}{2T}] \qquad (2)$$

where:

$$A(z) = \sum_{k=0}^{m} a_k \cdot z^k \quad , \; z = \exp(-i2\pi Tf) \; ;$$

$$B(z) = \sum_{j=0}^{n} b_j \cdot z^j \quad \text{and}$$

T is the duration of the time series.

Many different algorithms have been proposed for estimating the coefficients a_k and b_k from the data, most of them dealing with pure autorregresive models. We have selected two of the most used ones for AR models and other two for ARMA models.

First the algorithm due to Burg (1975) which tries to minimize the sample white noise variance in successive steps, beginning with an AR (1) model and increasing the order by one on each step up to a previously selected order. The method, fast and stable, is based on the powerful Levinsons' recurrence.

The second is the least square method which tries to minimize the prediction error by a least square procedure. The equations are solved by an algorithm proposed by Marple (1980). The method is easier in conception than that Burg's one but the stability of the solution is not warranted.

For ARMA models we have tried first the Box-Jenkins (1970) algorithm, but difficulties in the convergence for large series as those of wave records, make it impossible its use in a rutinary basis. Nevertheless some results are presented in this paper. At the present time we are implementing a much stable algorithm known as Yule-Walker modified method (Kay-Marple, 1982), but no results are available for this paper.

One of the main difficulties that appear when applying AR and ARMA models, is the selection of the adequate order. We have chosen for this study three criteria among those found in the literature:

a) "Final Prediction Error"(FPE): Based in the fact that for a stationary process the prediction error (σ^2) should be stationary. It gives the following performance index:

$$(FPE)_m = \frac{N + (m+1)}{N - (m+1)} \sigma_m^2 \qquad (3)$$

where: N is the total number of points in the time series and
σ_m^2 is the white noise variance for order m.

b) "Akaike's information criteria"(AIC): Assumes that data are normally distributed and tries to find the order for which the model distribution better approximates the data distribution. The following index results:

$$(AIC)_m = - N \log (\sigma_m^2) + 2m \qquad (4)$$

c) "AR Transfer function"(CAT). Tries to minimize the difference between the shape of the spectral density corresponding to an AR (m) model and the underlying AR(∞) model. The resulting index is:

$$(CAT)_m = \frac{1}{N} \sum_{j=1}^{m} \frac{N - j}{N\sigma_m^2} - \frac{N - m}{N\sigma_m^2} \qquad (5)$$

These are indexes that tend to lower values as the model fits the data better. They have performed successfully in other scientific fields. We hope that comparison of these indexes with FFT results will give a good idea about their validity.

We have not tried similar criteria for ARMA models.

2 WAVE DATA

The primary objective of the study was to evaluate the behaviour of the different algorithms when applied to real wave data in a rutinary basis. Therefore we choose a set of successive wave buoy records that were representative of the different sea states that are encountered in practice.

The total number of records is 230 and were measured by a waverider buoy moored in deep water at the Bay of Biscay (North of Spain) and covering the period of February and part of March 1984. Is in this time of the year when the worst sea states are more likely ot occur. Each record consists of 2048 sea surface elevation points with a sample rate of 2 Hz measured each three hours.

3 AR ANALYSIS OF WAVE DATA

In order to do a comparative analysis between the AR estimation algorithms and the FFT estimation,we calculated with Burg and Least squares algorithms the estimation of AR models with order varying from 1 to 40 for all the set of records.We made some tests with selected wave records trying to confirm the highest order of the AR model where the main peak of the spectrum was completely developed, finally we chose the 40.

We selected seven spectral parameters in order to characterize each spectrum:

Condition A: Direction: North West
H_s = 4.75 m
T_p = 14.5 sec.
γ = 1.4

Condition B: Direction: North
H_s = 3.50 m
T_p = 14.5 sec
γ = 1.4

The first layout has been considered only under wave condition A.

As a resume, comparisons have been made in these three cases:

Test 1: First layout and Wave Condition A
Test 2: Second layout and Wave Condition A
Test 3: Second layout and Wave Condition B

The comparison carried out with both modelling systems (physical and numerical) is based on relative significant wave height.

An example of the results of the numerical modelling and the results of the physical model can be seen simultaneously in Fig. 2

In Figures 6,7,8 comparisons of the three tests can be seen. In the horizontal axis distance in meters have been represented and in the vertical axis significant wave heights relative to the entrace are shown.

5.2.- TEST 1

The lines along which comparisons have been made can be seen in fig. 3 and the comparisons along these lines are shown in fig. 6

In all the cases the agreement is seen to be excellent.

5.3.- TEST 2

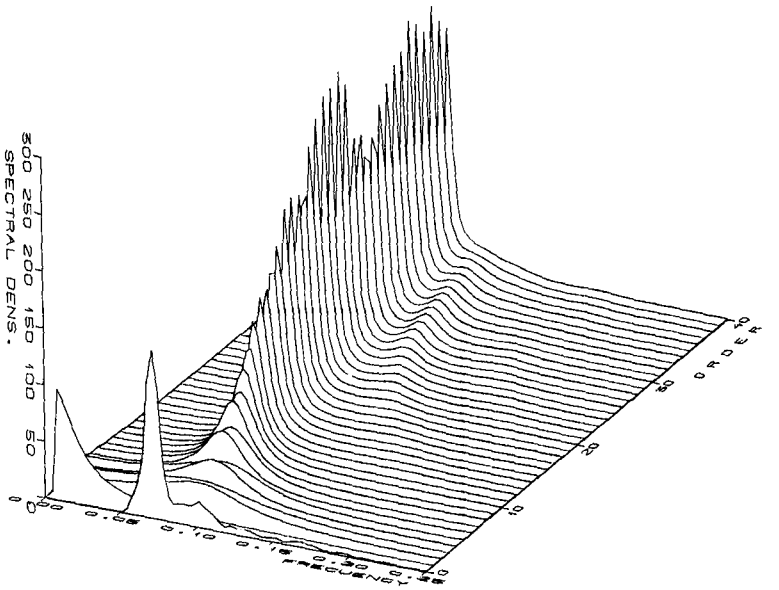
The lines along which comparisons have been made can be seen in fig. 4 and the comparisons along these lines are shown in fig. 7

In all the cases the agreement of the results of the physical and the numerical model is found to be good except for the points in which the influence of the reflection

Therefore the Maximum Entropy spectra (MES) were normalized with FFT spectra, trying to condense all the available information (40 AR models and 7 FFT estimations; raw spectrum and 3 smoothed spectra with two different windows;for each wave record).The mean and variance of normalized parameters were calculated for each possible combination. Then we could represent in graphs the spectral parameters against the order of the AR model for each FFT estimation (Figure 3).

First of all, we analysed the results obtained by both methods (Burg and Least squares),and they were very much the same,though the LS method was more unstable.Sometimes we could find records were the model did not converge and in most cases convergence is very slow compared to Burg method. Therefore the resulting conclusions for one method are valid for the other one.

The same can be said for different degrees of smoothings and smoothing windows with very similar results. Plots of normalized mean an variance can almost be superimposed.



Fiture 2. Dependence of spectral shape with order of AR model. The first spectrum is the corresponding FFT spectrum.

The normalized spectral moments tend very quickly to 1,having a small variance (Figure 3),the other 3 parameters have greater variance and need higher orders to stabilize.Around 20 for Fp and more than this order for the other parameter,Qp and Smax. Obviously,the normalized Qp and

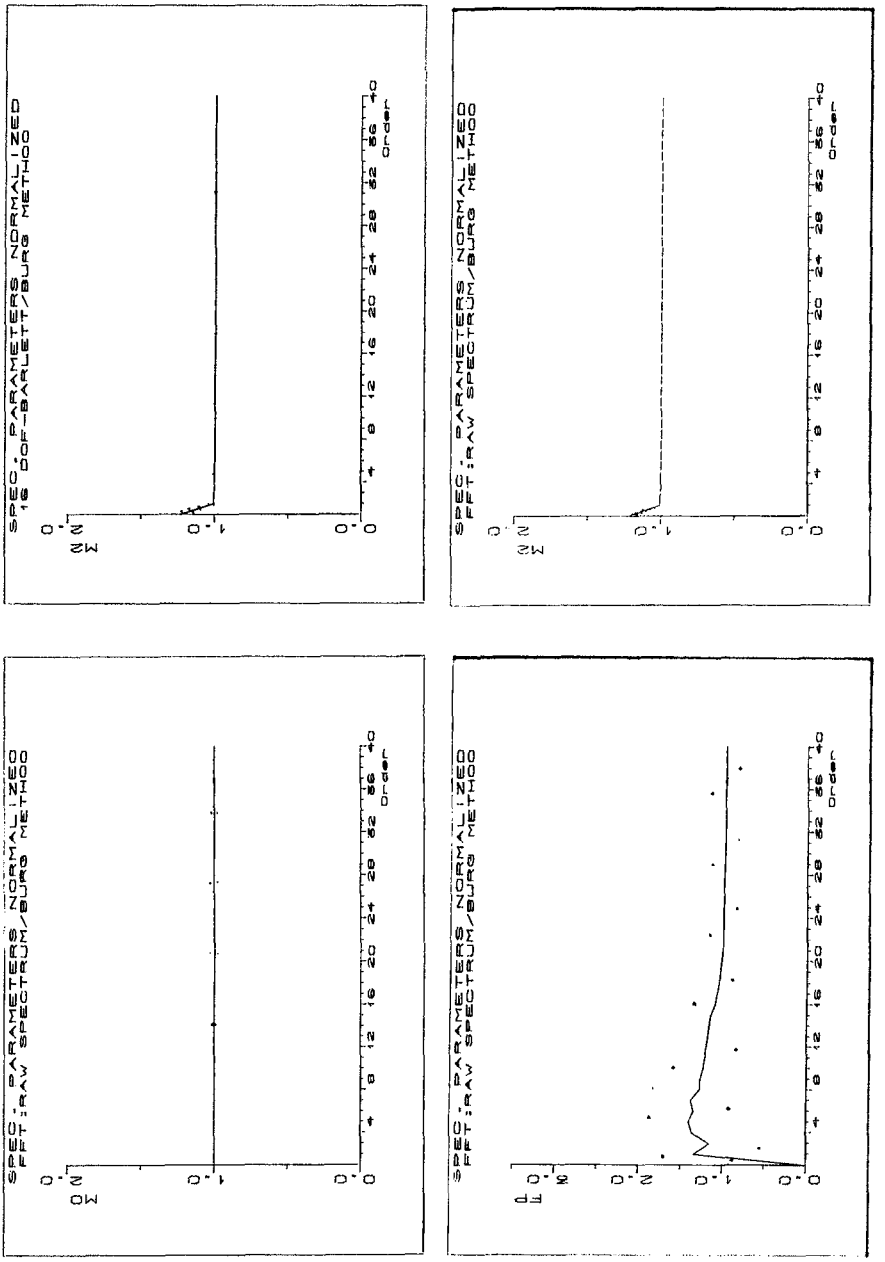


Figure 3. Examples of spectral parameters normalized.Mean (continuous - line) and standard deviation (dotted line) are represented.

Smax do not tend to 1 because their values depend largely of the degree of smoothing and the kind of used window. Though behaviour of Qp is more regular than Smax (Figure 3).

4 DETERMINATION OF THE ORDER OF AR MODELS

In order to be able to apply AR algorithms to wave data in a rutinary basis, some mathematical way of selecting the optimum order for the model should be available for its implementation in the computer. The importance of the selected order in the results is clearly illustrated in figure 2 where it can be seen how the peak frequency is converging very slowly to the true value as the order increases while it is very poorly defined for the low orders. Also some strong oscillation of the spectral value at the peak can be observed. These characteristics are common to most of the studied records.

We tried with the three criteria explained before. These criteria are based in some mathematical indexes which can be easily introduced in the programs. Theoretically, one has to evaluate such indexes for successive orders and select that order which gives the minimum value. We found actually that the indexes are monotonically decreasing when applied to waves for orders up to forty.

Therefore we choose as possible optimum order the one corresponding to the first point in the index variation curve where somo tendency to stabilization seems to happen. As a second candidate we choose the highest point were such an stabilization appears. Obviously, this method is somehow subjective and difficult to model in the computer. Actually we did the selection by hand.

Table I presents the best mean values of the normalized parameters (those nearer 1) and their corresponding standard deviations, as well as the order for which these values are obtained. The normalization is made with FFT spectra of 8 an 32 degrees of freedom. lt can be seen that different parameters need very different orders to reach an optimum.

TABLE II-Results for Burg algorithm. Parameters normalized by FFT results with 8 & 32 dof. (Barlett w.). Order selected by FPE criterion.

the differences are not very significative except for the Qp parameter.

Of the two orders selected for each criteria we decided to deal only with the smaller one because the second one tend to be very high and no important improvement appear in the results when compared with the first one.

The three criteria gave very similar results and only a slight better performance of the FPE criteria can be mentioned.

Finally, we drew plots of the criteria selected order (mean and standard deviation) for groups of records with different values of the spectral parameters in order to see if any correlation could be found between order and spectral parameters. In general no good correlation was observed for the different parameters considered (see fig. 5 for example) and only some correlation seems to exist with the significative wave height Hs (see fig. 6). This last result is in agreement with that found by Houmb (1981) by other means.

5 VARIATION OF THE ORDER OF AR MODEL DEPENDING ON DIFFERENT STATISTICAL PARAMETERS.

We sought a possible correlation between the optimum order of the model with some spectral parameters. We first tried with significant height (Hs) and subsequently with the peak frequency (Fp).

We divided our set of data in different groups of Hs in such way that they were homogeneous, by subtracting randomly some records from those groups having more data. The five groups were divided as follows:

1.- 0. <= Hs < 1.
2.- 1. <= Hs < 2.
3.- 2. <= Hs < 3.
4.- 3. <= Hs < 4.
5.- 4. <= Hs

We repeated again the procedure described in point 3,normalizing the spectral parameters of the 40 estimated orders through Burg algorithm , via FFT estimations with 8, 16 and 32 degrees of freedom and Barlett window. In order to compare the results we represent in the same plot the curves if the mean of the five groups,and also in a separated plot the curves of the absolute value fo the standard deviation (Figure 3).

We can deduce some interesting behaviours.For the normalized spectral moments there is no distinct difference among the various groups,for both the means and the s.d., the latter ranges over a very small interval. Figure 3 shows superimposed curves corresponding to all the groups.

Concerning the Fp we found similar behaviour. The only difference found is that the first group has a turning point around the 16th. order that moves towards 1 faster than the rest of the groups,which fit into a similar shape. The s.d. for the first group is higher than for the rest of the groups but with a shape of the same sort. We cannot blame this difference to the order of the model but rather to the changing Fp, resulting from the FFT spectra for such a small Hs.

The Goda parameter behaves alike in all groups for low orders,and takes higher values for the high orders of the big groups. The s.d. is not so uniform but we did not find differences that would lead us to any conclusive result.

We tried again with the same procedure but dividing the sample in five groups according to the Fp:

1.- $0.05 \leq Fp < 0.07$
2.- $0.07 \leq Fp < 0.09$
3.- $0.09 \leq Fp < 0.11$
4.- $0.11 \leq Fp < 0.15$
5.- $0.15 \leq Fp$

We uniformized the groups not taking into account the fifth group, since it is not statistically significant for having almost no sample (Figure 4).

The means of the normalized moments do not change whichever the FFT estimation used is, but s.d. decrease in the high orders for those groups having a higher Fp. For the normalized Fp those groups with high frequencies tend towards 1 (around order 18) faster than those of low frequencies (group number 2 about order 24 and group 1 more than order 30). The behaviour of s.d. is somewhat more irregular for high orders, but we found it quite similar to that described for the normalized moments.

Finally the Qp, the normalized values of groups with higher Fp tend towards 1 faster than groups with low Fp. For the s.d.the values tend to 0. starting from a particular order but its even faster as higher the group is.

We will talk about the analysis of all these results later on when we come to the conclusions.

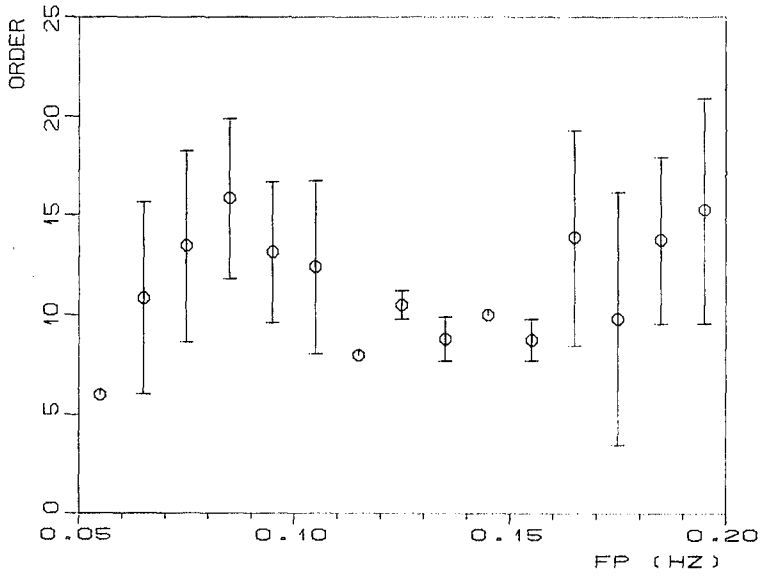

Figure 5.- Dependence of order selected by FPE criteria with peak frequency.

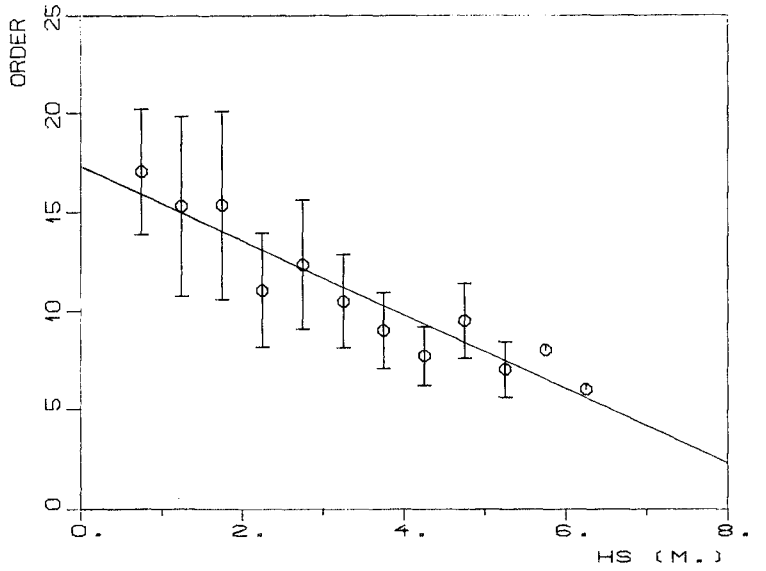

Figure 6.- Dependence of order selected by FPE criteria with significant wave height.

6 APPLICATION OF ARMA MODELS

As a first trial we selected the Box-Jenkins algorithm for ARMA model estimation, being this algorithm one of the most widely used in other fields. But we found that this algorithm performs quite poorly for the large number of data points that constitute the wave records. Computing time is prohibitive and, what is worse, the convergence to a solution is not assured giving rise to frequent running time errors.

Therefore we found it very difficult to apply this algorithm to wave data in a rutinary basis and this made it impossible to carry out a complete comparative analysis as was made for pure AR models.

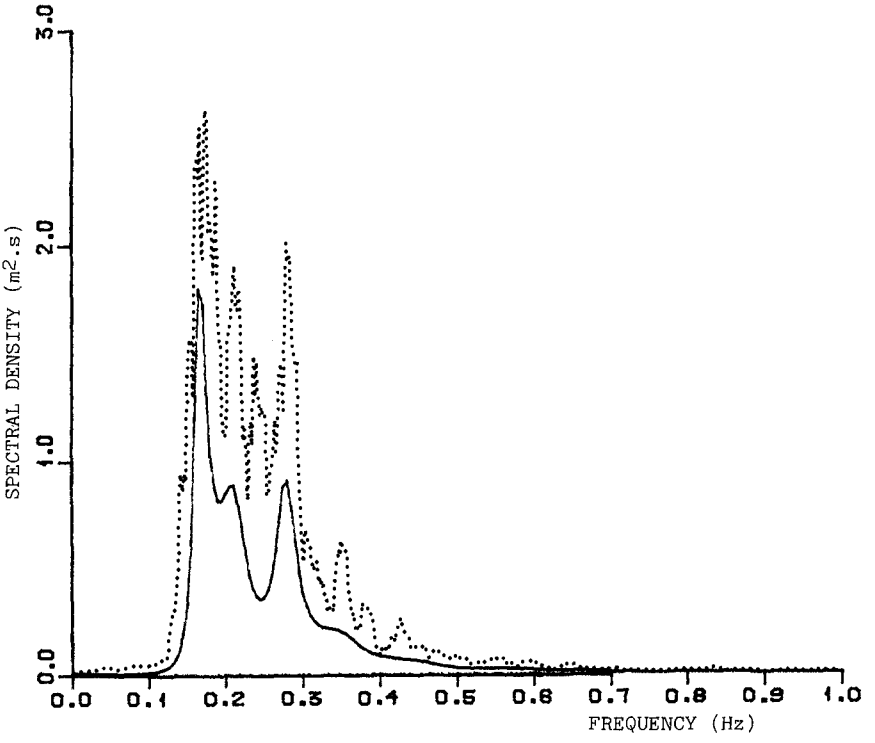

Figure 7. Example of AR spectrum obtained with an ARMA (20, 2) model (continuous line) compared with the corresponding FFT spectrum (dotted line).

We applied the algorithm to just a few cases in order to appreciate if any improvement in the spectral shape was achieved with respect to AR models. Figure 7 is one example of the results obtained using a ARMA (20,2) model to obtain the spectra of a complicated sea state. It can be seen that a very good spectrum is obtained with a very low MA order. The

same was observed for most of the particular cases studied. Specially, it is very interesting to note the way in which the sharp increase in spectral density at the low frequencies is reproduced. This differs from the pure AR models which have difficulties in modelling such part of the spectra (see fig. 1).

At present, we are implementing a new ARMA model estimation algorithm based on the Yule-Walker modified algorithm that we hope will perform much better than the Box-Jenkins one, from the computational point of view.

7 APPLICATION TO SHORT SERIES

One of the main advantages claimed for the ME methods is that they are specially well suite for application to very short time series. This fact could be very helpful in the recovery of spectral information from records where an important part of the signal is lost or distorted.

In order to study if this characteristic could be of interest in the case of wave records, we divided some of the measured records in shorter series of 128 and 256 points and compare the evolution of the estimated spectra for successive short series with that of the complete series. The same was made using FFT techniques.

We observed that AR spectra for short series had a much better resolution than the corresponding FFT spectra and from this point of view the use of AR spectra is recommended. On the other hand, it was also clear that such a small number of points was a sample too short to represent adequately the underlying sea state.

8 CONCLUSIONS

Very shortly we resume the main conclusions obtained during this study:

8.1 - Systematic application of AR models:

- The different AR algorithms used give very similar results. Burg's algorithm being faster and more stable is recommended.
- Visual comparisons between AR and FFT spectra are better made using FFT spectra smoothed to 8 d.o.f. wiht a Barlett window.
- Normalized spectral moments tend to 1 for orders over 5.
- One-peaked spectra are well represented for orders over 12, while two-peaked spectra need orders around 30. Peak frequency is well represented for orders higher than 20.

8.2 - ARMA models:

- Box-Jenkins algorithm for ARMA estimation is inadequate for waves because of long computer time and instability of the solution.
- Anyway, ARMA models seem to better represent wave spectra, mainly in the low frequency range.
- Algorithms better than Box-Jenkins' one can surely be developed.

8.3 - AR order determination:

- FPE criteria seems to behave a little better than AIC and CAT, although differences are relatively small.
- Orders selected using mathematical criteria tend to be much lower than those deduced from comparison with FFT results.
- There is some negative correlation between order selected by mathematical criteria and significative wave height. Nevertheless, the evolution of spectral parameters with order seems to indicate that the correlation should be positive.

8.4 - Relation between order and spectral parameters:

- As stated before, the dependence of model order on significative wave height is not clear. It seems that higher orders are needed to correctly represent the peak frequency for higher wave heights.
- On the other side, there seems to be a high dependence between peak frequency and model order, lower peak frequencies needing higher orders.

8.5 - Application to short series:

- Spectra for short series have higher frequency resolution than the corresponding FFT spectra.
- But, spectra obtained from short series are poor representatives of the underlying sea state.

9 ACKNOWLEDGEMENTS

Dr. Juan Jose Egozcue Rubi, professor at Barcelona University, Spain, implemented the algorithms and introduce the authors to this field. This research is part of the works carried out by the "Programa de Clima Maritimo y Banco de Datos Oceanograficos" of the Spanish Authority of Harbours and Coasts.

CHAPTER 2

A re-analysis of the spectra observed in JONSWAP

J.A. Battjes , T.J. Zitman and L.H. Holthuijsen*

ABSTRACT

The frequency spectra of wind-driven waves observed during JONSWAP are re-analyzed to establish whether the Toba formulation for the high-frequency tail ($\sim f^{-4}$) fits the data better than the Phillips formulation ($\sim f^{-5}$) used originally in the JONSWAP project. The results indicate that the f^{-4}-tail provides a better fit to the observed spectra. The proportionality factor in Toba's spectrum, which is theoretically expected to be a universal constant, is found to be uncorrelated with the growth stage of the waves.

Introduction

In so-called ideal conditions of wave generation (a steady, uniform windfield at right angles to a straight upwind coastline), the spectral distribution of wave energy over the frequencies appears to have a standard shape (see e.g. Hasselmann et al., 1973). In a pioneering paper, Phillips (1958) argued that there should be a range of frequencies where the spectral density $E(\omega)$ is saturated at a level determined exclusively by the local (radian) frequency (ω) and the gravitational acceleration (g). On dimensional grounds this saturation level should obey

$$E(\omega) = \alpha\, g^2\, \omega^{-5} \qquad (1)$$

with α a universal constant. However, Hasselmann et al. (1973) showed that α varied with the growth stage, instead of being a constant, as had been inferred by Phillips.

Another approach to the formulation of the saturation range is due to Toba (1972, 1973). It is based on his so-called three seconds power law for the significant waveheight (H_s) and the significant period (T_s). Stated in spectral terms, this law implies that the integral of the spectral densities, or the variance of the surface elevation (ε), and the peak frequency (f_m) are related according to

$$\varepsilon \sim g u_* f_m^{-3} \qquad (2)$$

in which u_* is the shear velocity of the wind over the water surface.

* Dept. of Civil Engineering, Delft University of Technology, Stevinweg 1, 2628 CN DELFT, The Netherlands

On similarity grounds, Toba (1973) deduced from this that the saturation spectral density should be of the form

$$E(\omega) \cong \beta\ g\ u_* f^{-4} \qquad (3)$$

with β a universal constant.

Toba's formulation (3) and the JONSWAP-spectrum were published in the same year (1973), but the latter found initially much more recognition in the international literature than the former. This has begun to change only recently, with the presentation of further empirical evidence supporting (3) by Mitsuyasu et al. (1980), Kahma (1981), Forristall (1981), and Donelan et al. (1985), and with theoretical work of Kitaigorodskii (1983) and Phillips (1985).

In light of these developments, it was decided to re-analyse the original JONSWAP data set with the purpose of making a comparative investigation of the applicability of the formulations due to Phillips (1958) and Toba (1973). The JONSWAP data were chosen because they are supposed to represent virtually ideal generation conditions, and because the JONSWAP spectrum has widely been accepted in the oceanographic and engineering communities. Moreover, the data set is well documented.

The procedures and results of this study are only briefly described here. A full account will appear elsewhere (Battjes et al., 1986).

Data

The spectra which were analyzed in this study, obtained in the Joint North Sea Wave Project (JONSWAP, see Hasselmann et al., 1973), were kindly made available to the present authors for the purpose of a re-analysis. A total of 108 spectra from the 1969 campaign of JONSWAP was available. Nine double-peaked spectra were removed.

The spectral models

The observed spectra are studied in two frequency ranges: the high-frequency range for which the formulations due to Phillips (1958) and Toba (1973) were intended, and the full frequency range including the spectral peak. Only the results for the high-frequency range analysis are presented here.

For the high-frequency range (defined below), the following expressions are used:

$$\text{Phillips (1958)} : E(f) = \alpha\ g^2 (2\pi)^{-4} f^{-5} \qquad (4)$$

$$\text{Toba (1973)} : E(f) = \beta\ g u_* (2\pi)^{-3} f^{-4} \qquad (5)$$

Analysis procedure

Frequency range

The spectra observed in JONSWAP are given at frequencies between f_{min} = 1/128 Hz and f_{max} = 127/128 Hz, with a sample interval of 1/128 Hz. For the high-frequency range analysis, the lower and upper cut-off frequencies f_1 and f_2 were chosen as $f_1 = 1.5\ f_m$ and $f_2 = f_{max}$. For each observed spectrum, the value of the peak frequency f_m needed to determine f_1 was taken from Mueller (1976) (only for this purpose).

Parameter estimation and goodness-of-fit

The values of α and β were estimated simply as the average level of $(2\pi)^4\ g^{-2} f^5\ E(f)$ and $(2\pi)^3\ (gu_*)^{-1}\ f^4\ E(f)$ respectively, between the frequencies f_1 and f_2.

The best-fit values of α and β obtained for each observed spectrum are considered as a function of growth stage, for which the dimensionless peak frequency ν was chosen:

$$\nu = U_{10}\ f_m/g \tag{6}$$

A linear least-squares method for log scales was used to determine the coefficient r and exponent s of the assumed powerlaw relationship between α or β and ν:

$$\alpha = r\ \nu^s \tag{7}$$

and similarly for β.

To establish quantitatively which of the two models fits the JONSWAP observations best, the values of the integrated squared deviation V between observed spectral density (E') and model spectral density (E) were used:

$$V = \int_{f_1}^{f_2} [\ E'(f) - E(f)]^2\ df \tag{8}$$

However, this value is influenced by both the energy and frequency scales of the spectrum, which are irrelevant for a shape analysis. Therefore, a normalized squared deviation ($\hat{V}$) is considered:

$$\hat{V} = V\ f_m/\varepsilon_{1,2}^2 \tag{9}$$

where $\varepsilon_{1,2}$ is the total energy in the frequency range (f_1, f_2).

Results

Spectral parameters

The mean and standard deviation of the estimated values of α and β and the spectral shape parameters of the best-fit spectra are given in Table I, together with the coefficients and exponents of the power law variations with the dimensionless peak frequency (Eq. 7). A graphical impression of the variation of the scale parameters α and β with ν is given in the figs. 1 and 2.

spectral parameter		mean	standard deviation	r	s
Phillips	α	0.0204	0.0088	0.0563	1.06
Toba	β	0.129	0.0622	0.126	0.233

Table I - Mean and standard deviation of the spectral parameters α and β, and coefficients and exponents of the power law (7).

Goodness-of-fit

The joint variation of the normalized error measures $\hat{V}_P$ and $\hat{V}_T$ is given in fig. 3; the subscripts P and T refer to the Phillips and the Toba formulation, respectively. A histogram of the difference $Q = \hat{V}_P - \hat{V}_T$ is shown in fig. 4.

Discussion

Relative goodness-of-fit

It appears from an inspection of the results concerning $\hat{V}_P$ and $\hat{V}_T$ (fig. 3) and their difference $Q = \hat{V}_P - \hat{V}_T$ (fig. 4) that an f^{-4}-tail fits the observed spectra statistically significant better than an f^{-5}-tail. This is put in quantitative terms as follows. The mean and standard deviation of Q are 0.0948 and 0.0519 respectively, based on 82 observed spectra. With the Student-t test the hypothesis that the expected value of Q is larger than zero is accepted even at a confidence level as high as 99.9% (assuming the sample values of Q to be Gaussian-distributed).

The above quantitative assessment of the goodnes-of-fit of an f^{-4}- or an f^{-5}-tail cannot be compared with similar quantitative tests in the literature since such tests have not been carried out before, at least not to the knowledge of the present authors. Instead, several investigators have used a more graphic approach in which the observed spectra were multiplied with f^4 or with f^5. The functions thus obtained appeared to be more nearly a constant as a function of frequency with the f^4 multiplication than with the f^5 multiplication, e.g. Donelan et al., 1985; Forristall, 1981, Kahma, 1981; Mitsuyasu et al., 1980; Toba, 1973.

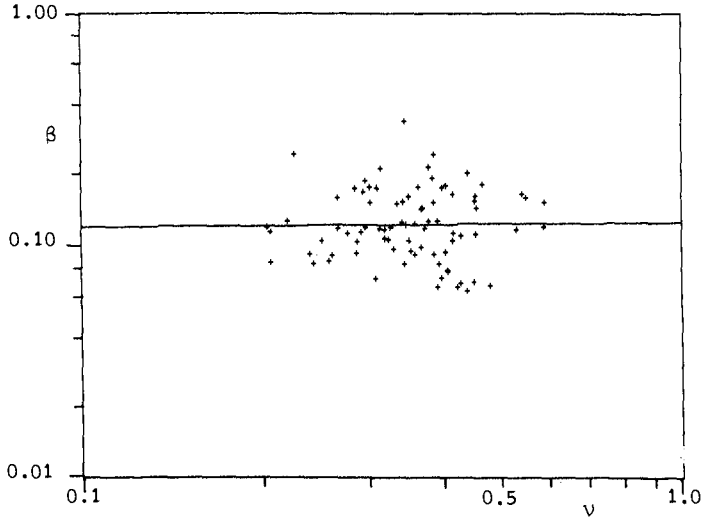

Fig. 2 - Data points: best-fit values of Toba's β vs. dimensionless peak frequency ν. The straight line represents the best-fit power law relationship (7).

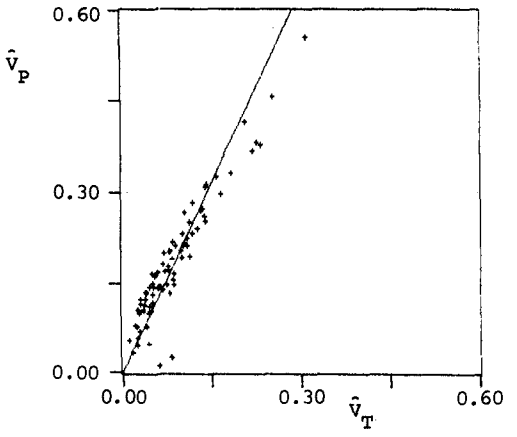

Fig. 3 - Data points: normalized error measures $\hat{V}_P$ (Phillips) and $\hat{V}_T$ (Toba) per observed spectrum. The straight line represents the best-fit proportional relationship.

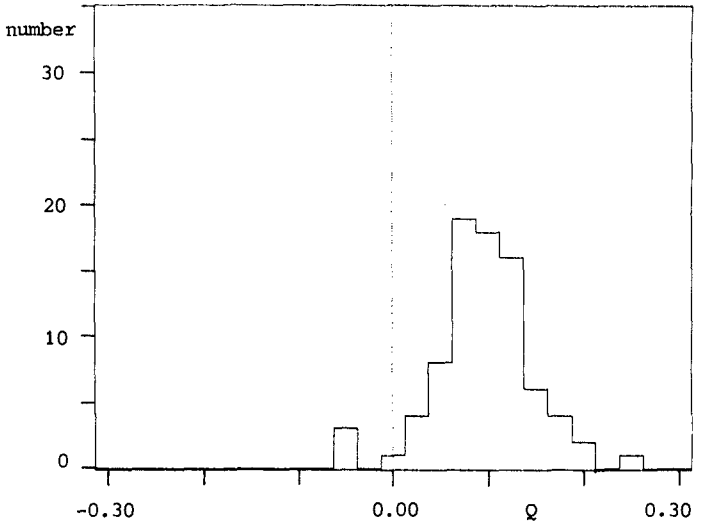

Fig. 4 - Histogram of difference in goodness-of-fit quantified with Q.

Spectral parameters

The discussion of the spectral parameters will focus on the energy scale parameter β and its possible variation with the dimensionless peak frequency ν, compared to the parameter α.

The best fit values of β have been plotted against ν in fig. 2, together with the calculated best-fitting power law relationship between the two. The data show a considerable scatter, but no trend of β with ν is visible. In fact, the hypothesis that the exponent (s) in the power-law relationship between β and ν is zero is accepted at a 99.9% confidence level, using a Student-t test (Draper and Smith, 1981). This observed lack of systematic variation of Toba's β with the growth stage parameter ν contrasts with the variation of Phillips' α (see fig. 1). It supports Toba's original model, insofar as this predicted that β should be a constant. However, in this context the unexplained relatively large scatter in the observed values is disturbing. (It is noted that the unexplained scatter did not decrease by correlating β with ν_*, the peak frequency scaled with g/u_*.)

Among the numerical results concerning Toba's β published previously, only those presented by Donelan et al. (1985) indicate a clear trend with ν. (Although Donelan et al. use a different formulation than the one used here, their results can be transformed into a relation between β and ν; the β-values so obtained have a mean value of about 0.11. Details of this transformation are given in Battjes et al., 1986.) A comparison of these results with those obtained in this paper is given in fig. 5. It is clear that the β-values found by Donelan et al. are correlated with ν, in contrast with those obtained in the present study from the JONSWAP data. The smaller scatter in Donelan et al.'s data suggests that the conditions during the observations of Donelan et al. were more homogeneous (with less unknown variability in geophysical factors) than those during JONSWAP.

The mean values of β from this study are compared in Table II with values reported in the literature. All entries in this table, except those of the present study and those referring to Donelan et al. (1985), have been obtained from Phillips (1985).

A striking outlier in Table II is the value of β from the laboratory data of Toba (1973). It is much lower than those obtained from the field data. Phillips (1985) ascribes this difference to strong wind-drift effects in the laboratory experiments. The values of β obtained from field data (except JONSWAP) vary from 0.06 to 0.11. As pointed out by Phillips (1985), there appears to be a remarkable geographically-based stratification in these results, the Pacific data being considerably lower than the non-Pacific data. The mean value of β from the present study, based on the JONSWAP observations (0.13, with a standard deviation of about 0.06) is somewhat higher than those from the other non-Pacific field data.

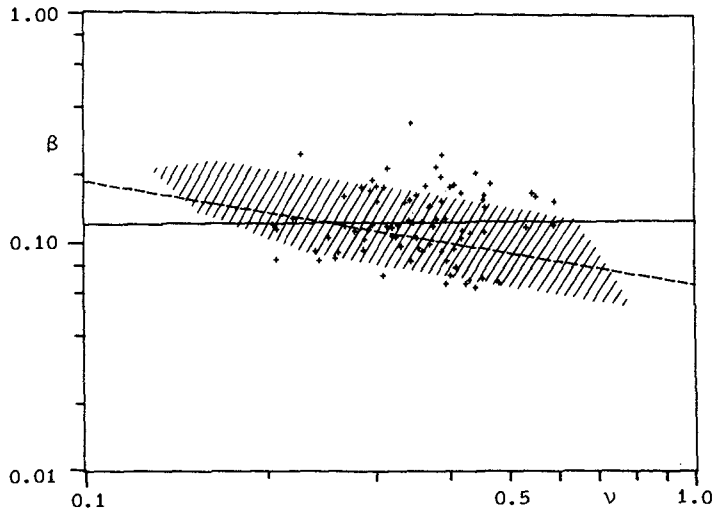

Fig. 5 - Data points and drawn line: see fig. 2. The hatched area and the dashed line represent the range of the transformed results of Donelan et al. (1985) and the corresponding best-fit power law relationship.

author	mean value of β
laboratory	
Toba (1973)	0.02
field	
Kondo et al. (1973)	0.06
Kawai et al. (1977)	0.062
Mitsuyasu et al. (1980)	0.087
Kahma (1981)	0.11
Forristall (1981)	0.11
Donelan (1985)	0.11
this study (JONSWAP)	0.13

Table II - Mean value of the energy scale parameter β from various sources.

CONCLUSIONS

A re-analysis of the original spectra measured in the JONSWAP campaign indicates that the high-frequency part of the wave spectrum can be better approximated with an f^{-4}-tail than with an f^{-5}-tail. The difference in goodness-of-fit is statistically significant at a level of confidence of 99.9%.

The estimated values of the energy scale parameter β in the Toba spectrum are found to be virtually independent of the stage of wave development represented by the dimensionless peak frequency ν. This finding is consistent with Toba's hypothesis that β should be a universal constant. However, it differs from the data of Donelan et al. (1985), whose results indicate a noticeable increase of β with a decrease in ν.

The β-values as determined from the JONSWAP data display a relatively large scatter. Their average value is slightly larger than the mean values reported in the literature.

Acknowledgements

We greatly appreciate the permission of the JONSWAP group to use their original data for a re-analysis.

CHAPTER 3

MATHEMATICAL AND PHYSICAL WAVE DISTURBANCE MODELLING COMPLIMENTARY TOOLS

by

I.Berenguer(1), P.A.Madsen(2), M.Rubjerg(3), A.Kej(4)

ABSTRACT

This paper presents comparisons between physical and numerical model reproductions on the basis of comprehensive wave disturbance studies of a major spanish port.

Mathematical modelling has reached in many cases a degree of reliability comparable to that of a physical model, but it is essential that both types of modelling systems are validated against measurements.

1.- INTRODUCTION

During the past decade, the advancement of digital computers and numerical techniques have made possible a deterministic numerical modelling of wave penetration in coastal areas and ports, i.e. a mathematical reproduction of wave time series resulting from the combined effects of refraction, diffraction and (partial) reflection of irregular waves. Such tools have now reached a degree of reliability comparable to that of a physical model. Even though further developments of the numerical tools are still needed, the coastal and port engineer is already now faced with the question whether to consider physical and numerical models as alternative or as complimentary tools.

(1) Head, Mathematical Modelling Area, Centro de Estudios de Puertos y Costas (Spain)
(2) Senior Hydraulic Engineer, Danish Hydraulic Institute (Denmark)
(3) Senior Hydraulic Engineer, Danish Hydraulic Institute (Denmark)
(4) Head, Computational Hydraulics Centre, Danish Hydraulic Institute (Denmark).

On the background of comprehensive wave disturbance studies of a major Spanish port, this paper analyses strengths and weaknesses of the two tools applied (physical and numerical model), and outline the contribution that the individual tools would make to the decision basis required by the port authority, today and in the future. The analysis contains qualitative and quantitative comparisons between physical and numerical model reproductions of the same port layout and wave conditions.

2.- PHYSICAL MODELLING

2.1.- Introduction

Complete similitude between hydraulic scale models and their prototypes is not possible unless the scale is such that the model is as large as its prototype. Some priorities must be established in order to simulate correctly the most important forces of the system considered.

In Coastal Engineering projects the forces on system elements consist of the kinetic reaction due to the inertia of an element's mass, gravity, viscous shear, surface tension, elastic compression and the pressure forces.

For overall similarity, the ratio of inertia forces, model to prototype, must equal the ratio of the vector sum of the active forces.

If gravitational forces predominate the ratio (Froude Number) model/(Froude Number) prototype, must be equal to 1, where the

$$\text{Froude Number} = \frac{V}{(gL)^{1/2}}$$

If viscous fores predominate the ratio

(Reynolds Number) model /(Reynolds Number) prototype, must be equal to 1, where the Reynolds Number = $\frac{LV}{(\mu/\rho)}$

If Surface Tension effects predominate the ratio

(Weber Number) model /(Weber Number) prototype, must be equal to 1, where the Weber Number =

If Elastic Compression forces predominate the ratio

(Mach Number) model /(Mach Number) prototype, must be equal to 1, where the March Number = $\frac{V}{(\sigma/\rho L)^{1/2}}$

2.2.- Estuary Models

There are many problem areas concerned with tidal model- ling techniques but tidal action provides the major amount of system energy, and as gravitational forces are predominant in tidal flows the Froude Number guides the modelling process.

Due to the large areas that must be simulated the use of distorted scale models is usual but the higher the degree of distortion used in the model, the greater is the roughness which is required in the model.

2.3.- Harbour Wave Action Models

Short period wind waves (T=5-20 sec) are designed in accordance with the Froude model law and are constructed geometrically similar to their prototypes.

When reproducing intermediate and long period waves (T> 20 sec) excessively large scale models are usually required because, otherwise, friction effects may be excessive and it results in excessive bottom friction losses. In such cases distorted linear scales are usually adopted. It also provides easier measurements of wave heights but wave reflection effects are increased.

Similarity of diffraction requires that the linear scales for horizontal distances on the model be equal to the wavelength scale. This ensures a correct simulation of modes of oscillation in the basins for all wave periods and, therefore, the occurrence of resonance at correct wave periods.

For long waves of small amplitude at depths smaller than 0,05 x wavelength distorted scale models reproduce wave refraction, diffraction and resonant periods accurately. For bigger depths the scale distortion has the effect of distorting the wave refraction patterns.

2.4.- Coastal erosion models.

Most of the fluid processes involved are complicated by non-linear fluid behaviour, turbulence and complex boundary conditions. In attempting to develope similitude relations, the idea of reproducing the dominant physical processes may be abandoned and attention turned to an attempt to mantain similitude of the beach profiles and longshore transport rates.

If adequate prototype data ara available and verification procedures in the model are successful we can have confidence in the results of the model although the combination of forces that occur in the prototype cannot always be reproduced exactly in the model.

3.- NUMERICAL MODELLING

3.1.- The "System 21. Mark 8"

The numerical model "System 21 Mark 8" considered here is based on the time-dependent vertically integrated Boussinesq equations of conservation of volume and momentum, assuming constant density. It is able to simulate unsteady two-dimensional flows in vertically homogeneous fluids. The Boussinesq terms account for the deviation from hydrostatic pressures distribution due to vertical accelerations and are of special interest to the short wave simulations because they make possible to consider a large range of water waves without being restricted by linear assumptions. The equations include porosity terms by means of which it is possible to consider partial reflection and wave transmission from and through piers and breakwaters. The model was described in detail by Abbott et al (1978, 1983) and the equations are included in Appendix A.

3.2.- Advantages and drawbacks of numerical modelling.

As mentioned in section 2 a general problem in physical modelling is the distorted scales. In a numerical model this problem does not exist at all and as long as you can describe the phenomena with a set of mathematical equations, prototype simulations can be made no matter how large the model area is. This is a significant advantage considering estuary models.

Often the numerical and the physical models are applied as complimentary tools. The numerical model can be used to establish the current pattern in a large area and to provide boundary conditions for a detailed physical model of a minor area of special interest.

In the numerical as well as in the physical model the accuracy of the solution will depend on the quality of the boundary data. However it is much easier to control the inflow conditions in the numerical model where the required variation of the water level or discharge simply is specified.

Another problem related to wave modelling is to control reflections in the model area. In the physical model it is very difficult to avoid reflections of long waves from the model boundaries and from the paddle generator. This is no problem in a numerical model where the wave energy can be damped out artificially along the closed boundaries or can be allowed to pass through an open boundary without any re--reflection.

Partial reflection from piers and breakwaters can also be simulated in the numerical model. You can either achieve a certain specified reflection coefficient or you can simulate the actual partial reflection from a given vertical rubble mound. Natural breakwater, however, are not always vertical and in this case experimental data is neccessary to estimate the reflection coefficients.

Finally there is the problem of data collection from the model tests. In the physical model you will have to measure for instance the velocity at certain pre-selected locations. If the scale is very distorted this cannot easily be done without affecting the flow you are actually measuring. Furthermore the data collection can only be made in a minor number of pre-selected points. In the numerical model the results will be computed in every single grid point which means that a huge number of information can be stored on a tape for later display by graphics. As an example you can determine significant wave heights in every single grid point leading to a very accurate map of isolines.

On the other hand it should of course be mentioned that the numerical model is limited by the size of the computer and wave simulations longer than 25 minutes real time are seldom made. In some situations this could be a drawback cosidering the statistics made on the results. Therefore you have to make sure that the relative significant wave heights determined do not vary with the length of the simulation.

4.- A CASE STUDY

The extension of the harbour of Bilbao has been subject to intensive studies to obtain its optimum configuration considering social, economical, and technical reasons. The port area considered for the extension covers an area of 6 by 4 km. (See fig. 1)

As part of the complete study, investigations have been carried out at the Danish Hydraulic Institute (DHI) using a mathematical modelling system (System 21 Mark 8) covering the model area with approximately 70.000 computational points.

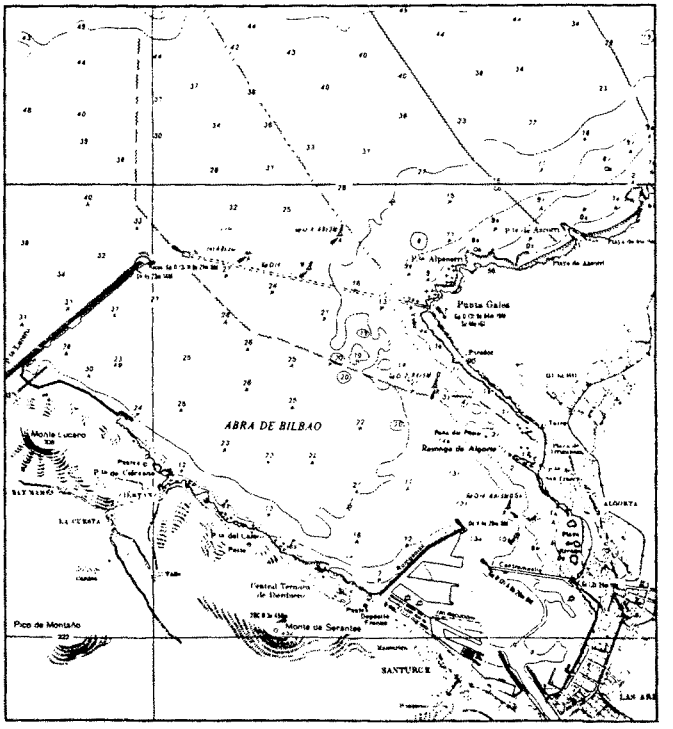

Fig. 1.- Extension Area

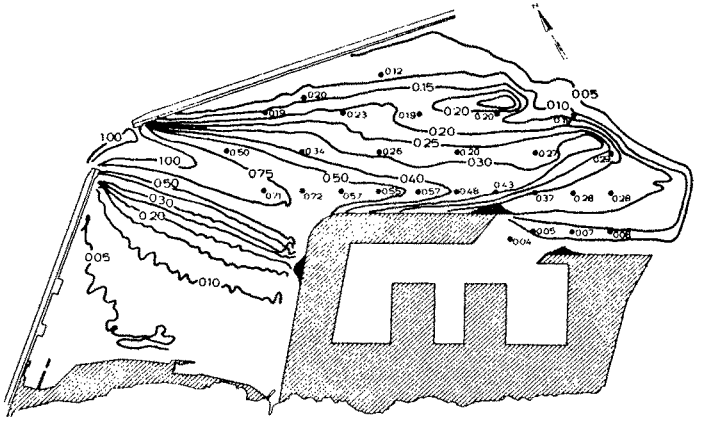

Fig. 2.- Physical and Mathematical Model Results

The grid size used for the present application was 20 m., while the time step was 1.25 seconds. This combination of grid size and time step has been considered a reasonable compromise between high accuracy of the numerical scheme for the type of waves to be simulated and realistic computer requirements.

A simulation period of 20 minutes has been chosen, allowing waves to reach the innermost parts of the harbour and to be reflected an still leave a reasonable amount of data for the following statistical analysis.

Simultaneously, studies using a physical model (scale 1:150) have been carried out at the Centro de Estudios de Puertos y Costas (CEPYC) in Madrid.

It includes the inner harbour and the area covered by the model in the laboratory is 2875 m^2.

Where partial reflection was desired a 0.33 reflection coefficient was chosen and the section obtained in some previous one-dimensional tests was constructed in the model. This section was composed of a concrete slope with stones sticked on it.

Both modelling systems (numerical and physical) have been used to reproduce time series of irregular waves synthesized on the basis of a Jonswap spectrum. A peak period of 19 seconds and a significant wave height of 4.75 m. have been considered.

5.- COMPARISON BETWEEN PHYSICAL AND NUMERICAL MODELLING

5.1.- Introduccion

Two different layouts of the harbour have been considered in this paper.

The first layout is composed of two outer breakwaters and a single operational zone close to the already existing harbour of Bilbao (Fig. 3)

The second layout is composed of the same two outer breakwaters as in the first case, but it also includes a complete development of the western side of the protected area. Additional protection is obtained through the construction of an inner breakwater with a bending of almost 90 degrees (Fig. 4 and Fig. 5)

Two different wave conditions have been considered:

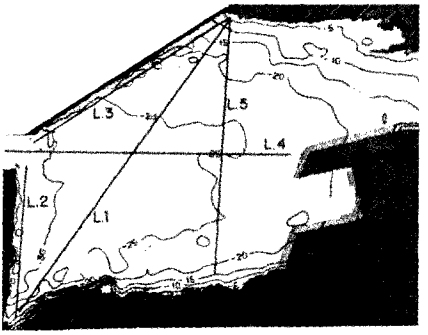

Fig. 3.- Test 1. Bathimetry and comparison lines

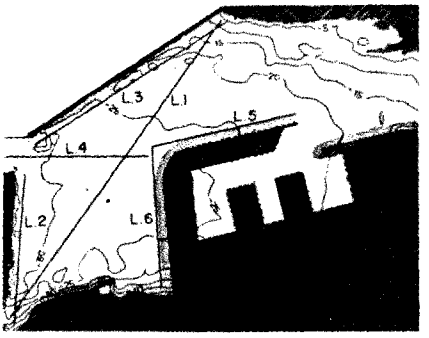

Fig. 4.- Test 2. Bathimetry and comparison lines

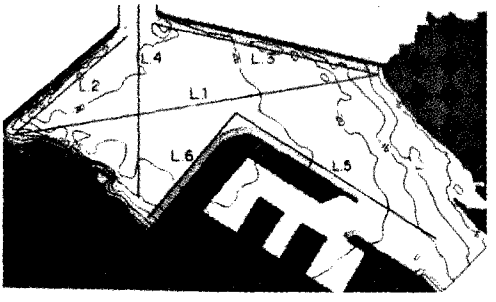

Fig. 5.- Test 3. Bathimetry and comparison lines

- Spectral Moments of order 0, 1, 2 and 4
- Peak frequency (Fp) and Spectral Density at the peak (Smax)
- Peakness Parameter (Qp) as proposed by Goda

We also had to compute the FFT spectra for comparison with the AR algorithm, the spectra computed were: the raw spectrum and smoothed spectra of 8, 16 and 32 degrees of freedom. Two spectral windows, Barlett and Rectangular, were used for each estimation.

The reason behind, this is the dependence of the chosen parameter upon the degree and shape of smoothing. Moreover, in order to get a feeling of the spectral shape, we drew graphs for a few number of wave records with one FFT estimation against the 40 AR calculated spectra, and therefore we could compare the FFT estimation with the 40 orders. Figure 2 shows an example of this kind of graph. An ordinary spectrum was selected and we ould observe some characteristics that come out in all AR estimations:

- A peak appears for high frequencies and slides towards low frequencies for higher orders of the AR model.
- A new peak is born around the 20th. order.
- We notice that we cannot increase indiscriminately the order, since for higher orders both peaks could merge.
- Difficulties in modelling the FFT results for low frequencies of the AR estimations, and reaching the Fp of the FFT for low orders of the models.

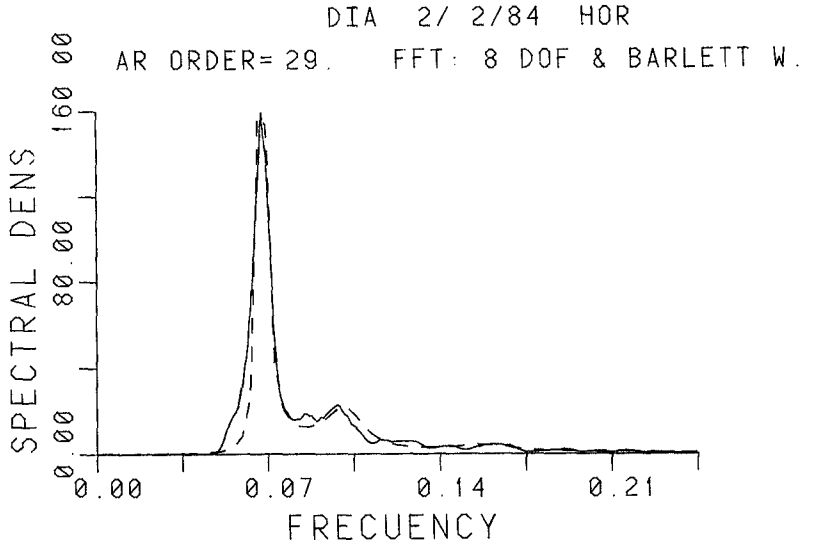

Figure 1. Comparison between FFT spectrum versus Maximum Entropy Spectrum

We could obtain in some cases fittings, as Figure 1 shows, between FFT estimation and an AR model.

of waves is predominant. In these cases the waves heights obtained from the physical model are higuer than those obtained in the numerical model. Hence it can be concluded that the partial reflection from the piers is different in the two systems of modelling.

5.4.- TEST 3

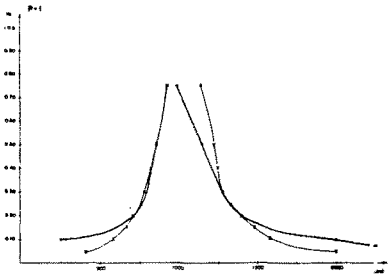
The lines along which comparisons have been made can be inFig. 5 and the comparisons along these lines are shown in fig. 8

As in TEST 2 discrepancies between the numerical and the physical model results appear in the points affected by the partial reflection from the bended inner breakwater in the second layout. Obviously the partial reflection coefficients achieved in the two modelling systems are different. In the physical model some preliminary one-dimensional tests have been carried out using regular waves. A table of reflection coefficients has been established as a function of depth, wave period, wave height, slope and porosity of the structure. Knowing the characteristics of the structure in the prototype some assumtions on the reflection coefficient can be made and modelled in the Laboratory.

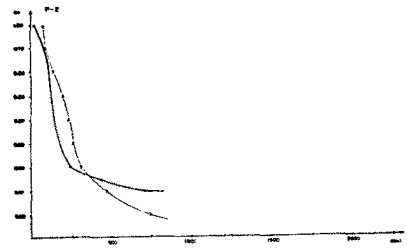
In the numerical model the same assumptions can be applied and one can obtain the desired reflection coefficients through the specifications of the rubble mound. The equations solved by the numerical model include porosity which makes it possible to simulat the flow inside vertical porous structures. As shown by Madsen and Warren (1984), the partial reflection from vertical rubble mouds can be simulated very accurately using this method. The reflection will depend on the porosity, the diameter of stones, the width of the rubble mound, the water depth, the wave height and of the wave period. Natural breakwaters, however, are not always vertical and in this case the reflection will be different. In th numerical model, one can still obtain the reflection desired, just by changing the specifications of the vertical rubble mound, but to actually estimate the reflection for a given type of non-vertical construction, experimental data is reequiered.

On the other hand, scale effects will influence the reflections obtained in the physical model. Hence, it becomen important to validate both modelling systems directly against field measurements.

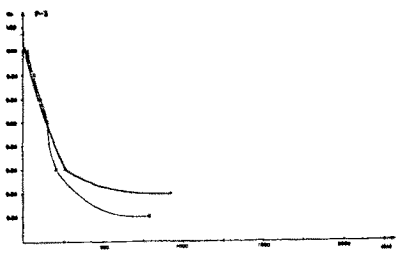
This has not been possible in the present situation and for the time being it can only be concluded that the reflections from the proposed inner breakwater in layout no. 2 are different in the physical and the numerical modelling.



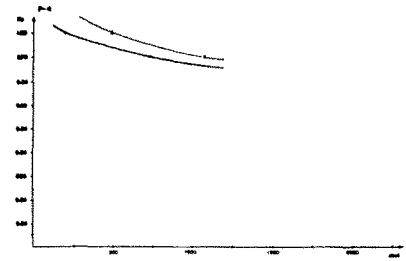
Line 1



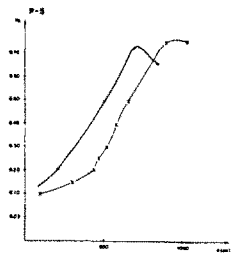
Line 2



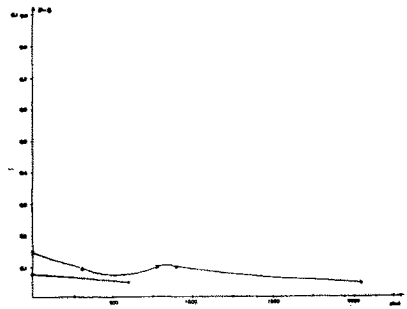
Line 3



Line 4



Line 5



Line 6

Fig. 8.- Test 3. Comparison of results

Finally some other general tendencies can be pointed out on the basis of the three cases studied. The results obtained from the physical model are slightly higher in the more inner points at the lee of the breakwaters and slightly lower in the main direction of wave propagation than the results obtained by the numerical model. The explanation for this discrepancy can be found in the way the wave input has been specified in the two types of modelling. Firstly a one-directional input has been applied in the numerical model leading to a perfectly straight wave front at the entrance to the harbour. Secondly some variation across the entrance was observed to take place in the physical model. The reason for this variation is that part of the outer harbour bathymetry was included in the physical model. Hence along the line where the input to the numerical model was supposed to be one-directional, the wave generated in the physical model actually turned out to be directional.

Sand et al (1983) investigated the effect of directional diffraction of waves in a numerical and a physical model. Both modelling systems showed that right in the opening of the harbour the directional wave heights were smaller than the one-directional wave heights but behind the breakwaters the directional waves were clearly higher. This explains the present discrepancy between the physical and numerical model results.

6.- CONCLUSION

The transmission of waves from the sea into a harbour protected by breakwaters is a process which involves shoaling, refraction, diffraction and partial reflection processes.

This paper presents comparisons between numerical model simulations and physical model tests from a practical case study.

It is proven that engineers can confidently apply such models to the study of development projects for harbours and coastal regions. However, until now, numerical wave disturbance models have been validated primarily against results from physical models where scale effects appear. Bottom Friction, wave transmission through pervious structures, and wave reflection are phenomena that with the geometrical similarity are ill-considered in physical models and should be subject to special consideration. Hence, it is essential that both types of modelling systems (physical and numerical) are validated against field measurements.

8.- APPENDIX A

The equations solved by the numerical model

The numerical model is based on the time-dependent vertically integrated Boussinesq equations conserving mass and momentum. The model is described in detail by Abbott et al. (1983). The equations are given below:

Continuity

$$n\frac{\partial \zeta}{\partial t} + \frac{\partial p}{\partial x} + \frac{\partial q}{\partial y} = 0$$

x-momentum

$$n\frac{\partial p}{\partial t} + \frac{\partial}{\partial x}\left(\frac{p^2}{h}\right) + \frac{\partial}{\partial y}\left(\frac{pq}{h}\right) + n^2 gh\frac{\partial \zeta}{\partial x} + n^2 p\left(\alpha + \beta\sqrt{\frac{p^2}{h^2} + \frac{q^2}{h^2}}\right) - \frac{p^2}{nh}\frac{\partial n}{\partial x} - \frac{pq}{nh}\frac{\partial n}{\partial y} = n\frac{Hh}{3}\left(\frac{\partial^3 p}{\partial x^2 \partial t} + \frac{\partial^3 q}{\partial x \partial y \partial t}\right)$$

y-momentum

$$n\frac{\partial q}{\partial t} + \frac{\partial}{\partial y}\left(\frac{q^2}{h}\right) + \frac{\partial}{\partial x}\left(\frac{pq}{h}\right) + n^2 gh\frac{\partial \zeta}{\partial y} + n^2 q\left(\alpha + \beta\sqrt{\frac{p^2}{h^2} + \frac{q^2}{h^2}}\right) - \frac{q^2}{nh}\frac{\partial n}{\partial y} - \frac{pq}{nh}\frac{\partial n}{\partial x} = n\frac{Hh}{3}\left(\frac{\partial^3 q}{\partial y^2 \partial t} + \frac{\partial^3 p}{\partial x \partial y \partial t}\right)$$

CHAPTER 4

Statistical Modelling of Long-Term Wave Climates

Richard Burrows* and Barham A. Salih**

Abstract

The paper discusses the long-term statistical properties of ocean and coastal wave climates derived from the analysis of instrumental wave data. The aim of the work reported has been to determine the theoretical distributions, from those commonly used in analysis of wave data, which best describe the joint probability of significant wave height, Hs, and mean zero-upcrossing period, Tz. A method of modelling the wave climate in this manner has been developed utilizing parametric means of specification. The data base used in the study covers records from 18 sites around the British Isles.

Introduction

Mathematical models considered previously for this application have been examined as part of the study. Ochi (1978) proposed the use of a bi-variate (2-dimensional) Log-Normal distribution for the joint probability density function (pdf) denoted by p(Hs,Tz). This can be defined in terms of the first and second order statistical moments of the marginal pdfs of both Hs and Tz and a measure of the correlation between these wave properties. Appendix 1 presents a summary of the relevant mathematics for this and other probability distributions discussed herein.

Whilst the fit shown by Ochi for the Log-Normal distribution, applied to various data sets, was good for the bulk of the probability mass the tails, in particular that of Hs, were not well matched beyond a cumulative probability of about 0.99. It is this region which is often of interest in engineering design and a need for improved modelling of extremal (Hs,Tz) sea states has recently been identified by U.K. Department of Energy (1986).

As part of a research programme aimed at wave climate synthesis by the National Maritime Institute (NMI, but now British Maritime Technology), a development of Ochi's modelling was proposed by Fang and Hogben (1982). This involved the inclusion of a measure of the skewness in a term modifying the Log-Normal form of the marginal distribution of Hs.

The joint pdf, p(Hs,Tz), can be expressed as a product of the marginal pdf of Hs and the conditional pdf of Tz (given Hs), i.e.

*Lecturer/**Research Assistant, Department of Civil Engineering, University of Liverpool, PO Box 147, Liverpool L69 3BX, U.K.

$$p(Hs,Tz) = p(Tz/Hs).p(Hs) \quad (1)$$

Houmb and Overvik (1976) utilized the form of this equation for the description of wave climate off the coast of Norway. For both the marginal distribution of Hs and the conditional distribution of Tz, they employed a 2 parameter Weibull distribution (equivalent to the 3 parameter Weibull but with A=0, see Appendix 1). Parameters B and C in p(Tz/Hs) were then specified as functions of Hs, following regression for their sites under study.

More recently Haver (1985) has proposed a similar form of modelling to that of Houmb and Overvik but with the conditional distribution of Tp (the spectral peak period, replacing Tz) fitted to a Log-Normal distribution. The marginal distribution of Hs is described in the lower region by the Log-Normal distribution also but for the upper tail ($Hs > \alpha$, where α is a chosen threshold) a 2 parameter Weibull distribution is employed.

This latter model has not been investigated herein but the other methods described above have been applied together with several modified approaches. These include; (i) an extension of Houmb and Overvik's model by the use of the 3 parameter distribution for both marginal and conditional probability distributions, (ii) use of a mixed Weibull and Log-Normal model with p(Hs) described by the former and p(Tz/Hs) by the latter, (iii) direct specification of p(Hs,Tz) in terms of a 2-dimensional Weibull distribution. For the latter, the derivation given by Kimura (1981) for application to short-term wave climates has been utilized. Relevant equations are contained in Appendix 1.

The study has been conducted in 3 parts. Firstly, the goodness of fit of the different models to the data was investigated, the models being fitted using statistical moments of the various data samples. This provided a shortlist of preferred probability distributions. Secondly, empirical relationships between the significant wave height, Hs, and both the conditional statistics of Tz and the parameters of the different models were investigated. In this way it was hoped to improve the means of description of the Tz domain of the wave climate. By considering the degrees of exposure and wind field statistics of the different sites trends were observed and, ultimately, regression equations linking Tz statistics to the marginal statistics of Hs have been established for 2 groups of sites, loosely termed 'oceanic' and 'coastal'. The third and final part of the study has been to use the regression equations for specification of the parameters of the different models and to again assess their respective merits.

Data

The data base used in the study consisted of scatter diagrams (bi-variate histograms of the 3-hourly observation of Hs and Tz) covering periods of measurement ranging from 1 to 7 years. An example of such a diagram is given in Fig. 1. Locations of the various sites are indicated on the map in Fig. 2.

The data set is far from ideal since for few sites do recordings

exceed one or two years duration. In consequence, the effects of variability in annual wave climate will potentially cloud any 'between site' trends which may be present. Whilst these inadequacies of the data will have an unquantifiable effect on the results developed, this should not be so large as to undermine the value of the study.

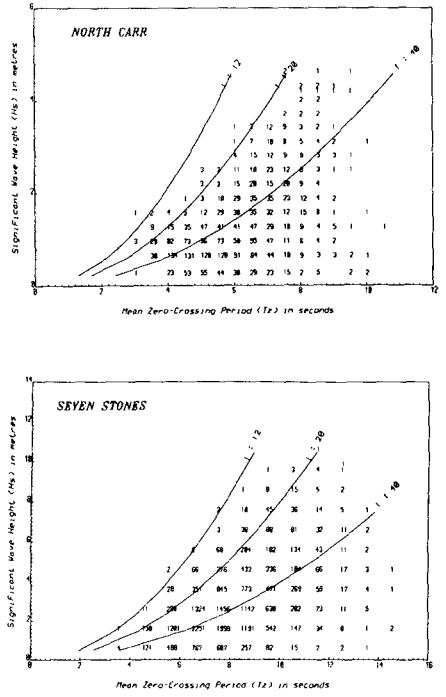

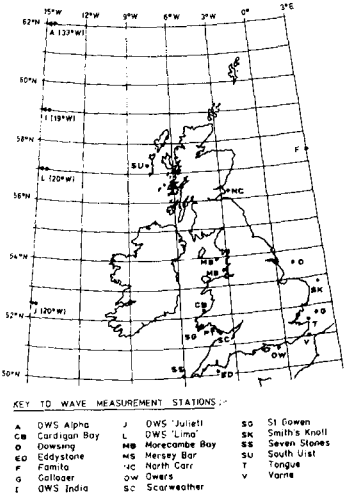

FIGURE 2 LOCATION MAP SHOWING SOURCES OF WAVE DATA

Analysis of Scatter Diagrams Forming the Data Base

The statistical properties of Hs and Tz computed from scatter diagrams for the 18 sites are listed in Table 1. These parameters (mean, standard deviation and skewness of the marginal distributions and the correlation coefficient) can be used to define each of the theoretical probability distributions referred to above (and in Appendix 1). The Weibull distribution is most conveniently expressed in terms of parameters A,B,C, each being related to the statistical moments, and these are also included in Table 1.

Marginal Distribution of Hs: The marginal histograms of Hs from the data sets have been compared against the (3 parameter) Weibull, Log-Normal and Modified Log-Normal (NMI) distributions. Fully objective 'method of moments' fitting has been used in each case. Examples, in Fig. 3, of the observed frequency histograms with theoretical distributions superimposed show each of the above to

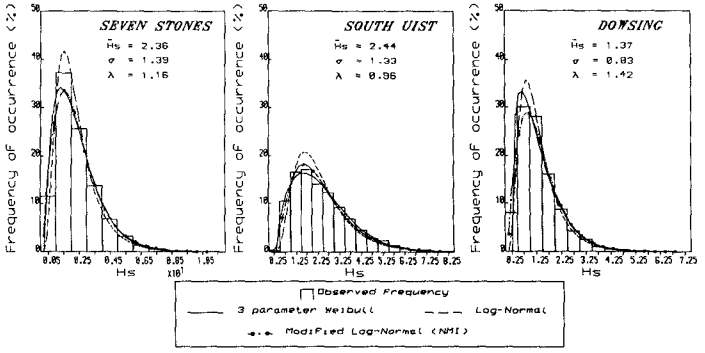
(note: percentage frequency $\equiv p(H_s)\Delta H_s \cdot 100$)



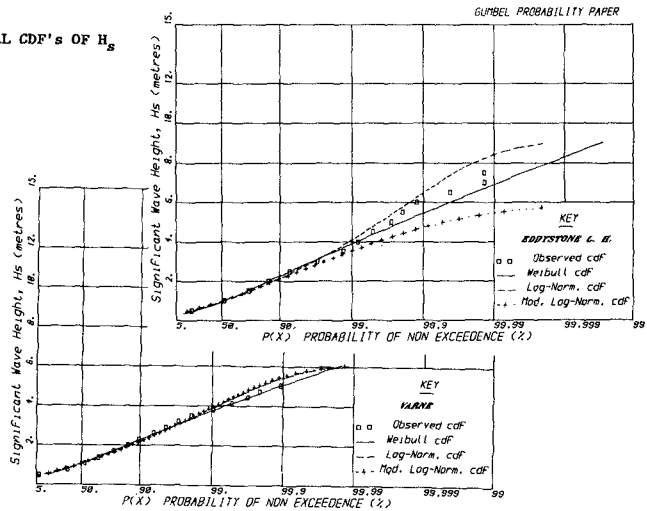
reasonably describe the main probability mass. An indication of relative performance, in terms of 'goodness-of-fit', can be obtained from an application of the χ^2 test. The χ^2 statistic is defined as:

$$\chi^2 = \sum_{i=1}^{k} \frac{(Oi-Ei)^2}{Ei} \qquad (2)$$

where Oi and Ei are the observed and expected frequencies for class (i) of (k) classes. Because, generally, the number of classes did not conform to the requirements of the standard test, for the relevant sample sizes, resulting values of χ^2 cannot be related to appropriate 'levels of significance' in the usual way. Numerical values have, therefore, been used as only qualitative indicators of

goodness-of-fit. Utilizing this approach, and making allowance for the potential departures of the Weibull fit for the lowermost classes arising from the imposition of the location parameter A, this distribution produces the best fit. Indeed, this slight limitation associated with the Weibull distribution is restricted to a region (low Hs) of little practical significance (Salih, 1986).

FIGURE 4 MARCINAL CDF's OF H_s



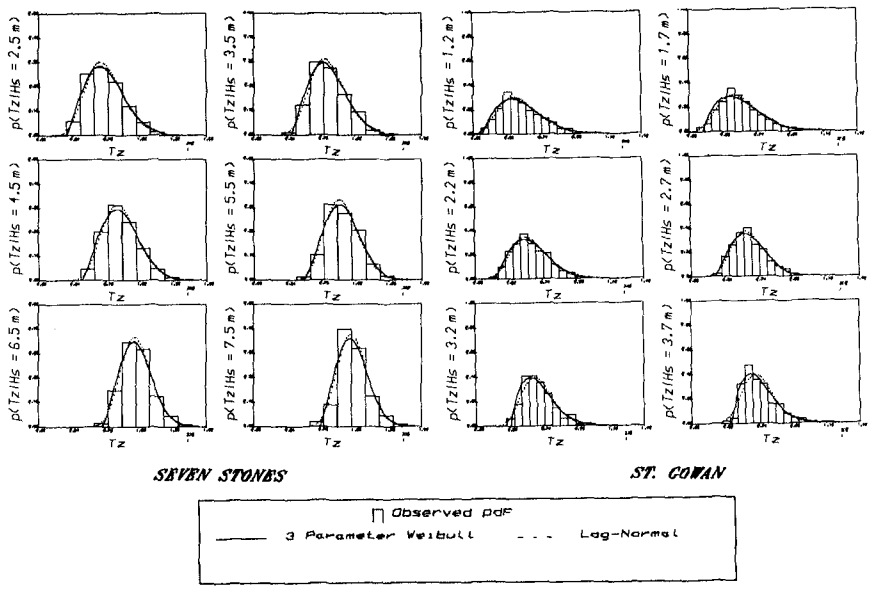
However, directing attention to the cumulative distributions of Hs the Weibull distribution is most clearly superior, as may be seen from Fig. 4. The NMI modification has not been found to improve the basic Log-Normal fit in the tails, a result which was borne out quantitatively from a Kolmogorov-Smirnov statistical test. Again, for the same reasons as those discussed above this goodness-of-fit test could not be applied rigorously. Nevertheless, the Weibull distribution performs most adequately and satisfied the test at a 5% significance level for a number of the data sets.

Marginal Distribution of Tz: The marginal distributions of Tz were treated in a similar way to that described for Hs above. In this case all three distributions showed a good fit to the data over the whole range of periods. Again, the Weibull distribution produced overall the lowest χ^2 values and generally showed the closest fit to the cdf. In view of the satisfactory behaviour of all distributions in the extreme tail the Kolmogorov-Smirnov test was not applied.

Conditional Distribution of Tz: Fig. 5 shows an example of the conditional frequency histograms of Tz for various classes of Hs forming the scatter diagrams. Both Weibull and Log-Normal distributions follow the data closely. In addition, a 2 parameter Weibull distribution and predictions from the fitted 2-dimensional Log-Normal and Weibull distributions have been considered. χ^2 estimates have been made for all conditional distributions at each site and are tabulated in (Salih, 1986). These results showed the 3 parameter Weibull and Log-Normal distributions to provide the best

fits with near equal merit. The 2 parameter Weibull distribution adopted by Houmb and Overvik is unable to locate the central probability mass in many cases and produces large χ^2 errors. Of the two 2-dimensional distributions the Weibull form was found, in this test, to consistently produce the better fit over the Log-Normal.

FIGURE 5 CONDITIONAL FREQUENCY HISTOGRAMS OF T_Z



Joint Distribution of Hs and Tz: On the basis of the above findings contour maps overlaying the scatter diagrams were produced with the joint probability p(Hs,Tz) defined by:

(1) p(Hs)-Weibull, p(Tz/Hs)-Weibull; (W-W)
(2) p(Hs)-Weibull, p(Tz/Hs)-Log-Normal; (W-LN)
(3) p(Hs,Tz)-2-dimensional Log-Normal; (2DLN)
(4) p(Hs,Tz)-NMI modification to (3); (NMI)
(5) p(Hs,Tz)-2 dimensional Weibull; (2DW)

In order to establish the relative goodness-of-fits of these different approaches a 2-dimensional χ^2 computation was made. This was equivalent to the application of Eq. 2 to the conditional frequency histograms of Tz for each class of Hs in the scatter diagram with the resulting values summed to give an overall χ^2 estimate. Table 2 presents these findings which show that approach (1) above is best able to represent the characteristics of the data sets considered. Approach (2) is only marginally inferior. The Weibull distribution (5) again shows substantial improvement over the other 2-dimensional distributions.

Modelling the Joint Distribution of Hs and Tz

Having assessed the relative merits of the different probabilistic descriptors of p(Hs,Tz) it remains to develop means of modelling from the minimal amount of wave climate data that may be available. In this respect attention is focussed on the specification of the Tz domain, since marginal Hs statistics can be adequately established using existing methods. These include the various wave forecasting and hindcasting techniques from wind data, recently reviewed by Holtuijsen (1983) and the semi-empirical approach developed by British Maritime Technology in the U.K. and marketed as 'NMIMET' which uses both windspeed and visual waveheight archives (Andrews et. al., 1983).

A first step in this exercise is to establish empirical relationships to link the various statistical properties of Tz, in both the marginal and conditional domains, to those of Hs. From an initial investigation of this nature it was found that the data could be conveniently categorised into three groups, termed 'oceanic', 'coastal' and 'bays/estuarial' and the placements into these groups are indicated in Table 1. The statistics necessary for specification of the different probability models were then obtained for each group using 'least-squares' regression to the statistics of Hs. Due to the limited nature of the data bases, simple regression equations of the form;

$$Y = a.(\bar{Hs})^b.(\sigma_{(Hs)})^c.(\lambda_{(Hs)})^d \qquad (3)$$

were used where Y is any of the required Tz statistics and (a,b,c,d) are the regression coefficients.

In the event, due to the small size of the 'bays' group this has not been treated by regression until such time that further data sets are incorporated into the data bank. Resulting regression equations are summarised in Appendix 2 but it must be appreciated that these would

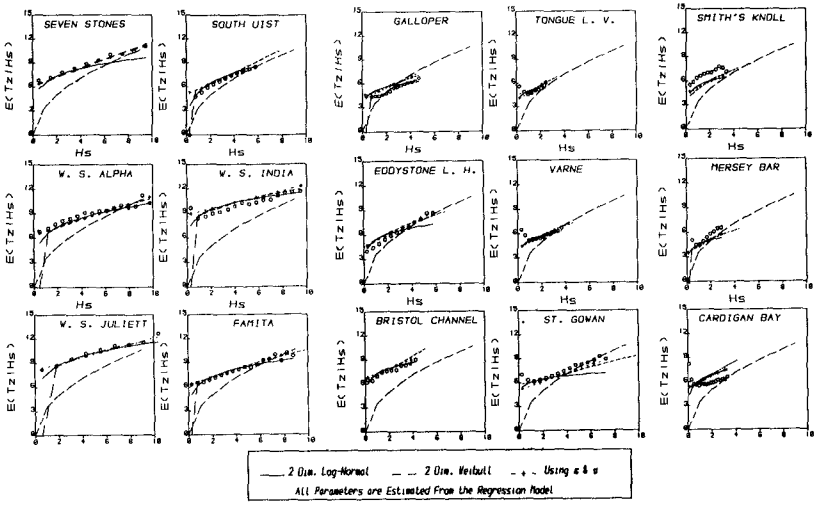
be continuously updated as new data is added. The regression equations produced mean relative errors of about 10% (3.8-17.9%) when compared with the various data sets in each group. The 'oceanic' group produced smaller errors than the 'coastal' group of sites. Dealing with each statistic in turn:-

Conditional Mean E{Tz/Hs}: Conditional mean values for each class of Hs for various sites are plotted in Fig. 6. With increasing Hs it was anticipated that the values of E{Tz/Hs} would become equivalent to the Tz values of the associated wind generated sea states, since the effects of swell would diminish. This was substantiated by the superimposition of such relationships based on the moments of Pierson-Moskowitz spectra onto the plots. In S.I. units this can be expressed as:

$$E\{Tz/Hs\} = 3.55.(Hs)^{0.5} \qquad (4)$$

Departures from this relationship for the lowest classes of Hs, therefore, give an indication of the presence of swell conditions at the different sites. A systematic variation from site to site in this respect is observed where the most exposed locations generally show the greatest departures. To model this behaviour a linear variation of E{Tz/Hs} with Hs has been assumed, defined by an intercept of the period axis κ and slope ν. Regression using the data sets for the two climate categories, as appropriate, produces the fits shown in Fig. 6. Also included here are the relationships output from the use of the relevant regression equations in the 2-dimensional models.

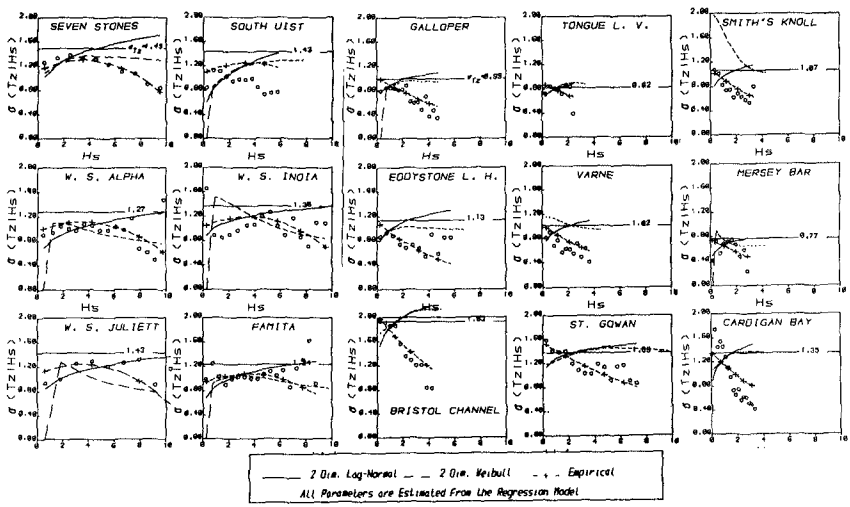
FIGURE 6 RELATIONSHIP BETWEEN CONDITIONAL MEAN VALUE OF T_Z, $E\{T_Z/H_S\}$, AND H_S



Marginal and Conditional Standard Deviations $\sigma_{(Tz)}$ and $\sigma_{(Tz/Hs)}$: Fig. 7 shows plots of the variation of $\sigma_{(Tz/Hs)}$ with Hs for sites from both groups used in the regression exercises. From the general trends

observed a quadratic variation was chosen for the 'oceanic' group and an exponential decay for the 'coastal' group. Regression equations for these are given in Appendix 2 and involve the marginal standard deviation $\sigma_{(Tz)}$ which is itself expressed in terms of a regression relationship. Resulting functions are shown on the graphs. Behaviour of the fitted 2-dimensional probability models are again included and in several instances these show serious divergence from the observed trends. This indicates the inflexibility of these theoretical functions to describe features of the scatter diagrams in close detail.

FIGURE 7 RELATIONSHIP BETWEEN CONDITIONAL STANDARD DEVIATION OF T_Z, $\sigma(T_Z/H_S)$, AND H_S



The various data sets taken individually show, in Fig. 7, significant departure from the regression functions illustrating the approximate nature of the modelling and pointing to a need for further data so that segregation into additional groupings may be made practicable.

Conditional Skewness $\lambda_{(Tz/Hs)}$ and Weibull Parameters $A_{(Tz/Hs)}$ and $A_{(Tz)}$: Definition of the 3 parameter Weibull distribution normally requires sample estimates of the first three statistical moments (see Appendix 1). However, the reliability of these estimates diminishes with the 'order' of the statistic for samples of limited size. In consequence, the computed values of skewness, λ, being a third order statistic, show much greater scatter than that shown by $E\{Tz/Hs\}$ and $\sigma_{(Tz/Hs)}$ which are determined from the first and second order moments respectively. This problem is particularly acute for the highest classes of Hs where the number of observations forming the samples are small. The scatter observed in plots of $\lambda_{(Tz/Hs)}$ against Hs (Salih, 1986) was such that no underlying trend could be detected and they are not presented here.

As an alternative approach to the full specification of the 3 parameter Weibull distribution by 'method of moments', an empirical

method was considered for definition of parameter A. Computation of remaining parameters B and C is then achieved from the first two moment estimates which are also necessary for fitting to the other probability distributions under consideration here.

Parameter $A_{(Tz/Hs)}$ represents a lower limit on the value of wave periods in the scatter diagram. If the notion of a maximum 'sea state steepness', S, is taken to be the ratio of Hs to a deep water wave length expressed in terms of this minimum wave period, it can be expressed as:

$$S = 2\pi.Hs/\{g.(A_{(Tz/Hs)})^2\} \quad (5)$$

Various steepness curves defined in this way were superimposed on the scatter diagrams, see Fig. 1, and a value of 1/12 was found to provide an upper envelope of the observations consistently for the majority of data sets. This empirical relationship has thus been incorporated into the method of modelling for the 3 parameter Weibull distribution.

A similar situation arises when employing the 2-dimensional (3 parameter) Weibull distribution since in this case an estimate of $A_{(Tz)}$, the lower limiting value of Tz from the marginal data, can render unnecessary the estimation of the sample skewnesses. In this case values of 4.0 and 3.0 have been adopted intuitively from observation of the scatter diagrams for the 'oceanic' and 'coastal' groups respectively.

Linear Correlation Coefficients $\rho_{(Hs-Tz)}$ and $\rho_{(\log(Hs)-\log(Tz))}$: These statistics are required in the specification of the 2-dimensional Weibull and Log-Normal distributions respectively. Sample estimates of the former are included in Table 1 and regression equations are given in Appendix 2.

Synthesis of Scatter Diagrams using the Regression Equations:

Test against Original Data Base: Applying the regression equations to each of the probability models provides a means of testing each approach on equal terms. The data input in these circumstances are the relevant statistics of Hs and the site exposure group, which leads to the appropriate regression equations.

Table 3 lists the 2-dimensional χ^2 values per unit observation for all sites with the exception of the 'bays' group. Overall, approach 1 (W-W) produces the minimum departures from the observed data as measured by this test whilst approach 2 (W-LN) produces the best fit in more cases. Both of these 'marginal/conditional distribution' approaches to the joint probability modelling are better than the 2-dimensional theoretical models although the Weibull form is only slightly inferior. However, although the χ^2 values do not show great disparity between any of the models, the 2-dimensional versions are significantly less able to closely represent the distributions of Tz for the higher Hs classes. This can be seen from the frequency histograms in Fig. 8 and the scatter diagrams in Fig. 9. It is immediately apparent that in the predictive mode departures from observed histograms are substantially greater than those associated

with the earlier analysis phase.

Test against Independent Data: Data sets from W.S. Lima, Owers light vessel, and Cardigan Bay (considered earlier but not used in the regression), see Fig. 2, have been compared against those synthesised by the models, Table 4 shows resulting normalised 2-dimensional χ^2 values. With such a small set of test data results cannot be conclusive but, contrary to the above findings, in these tests at least, the 2-dimensional models perform with comparable accuracy to the 'marginal/conditional' models. Further testing is clearly necessary.

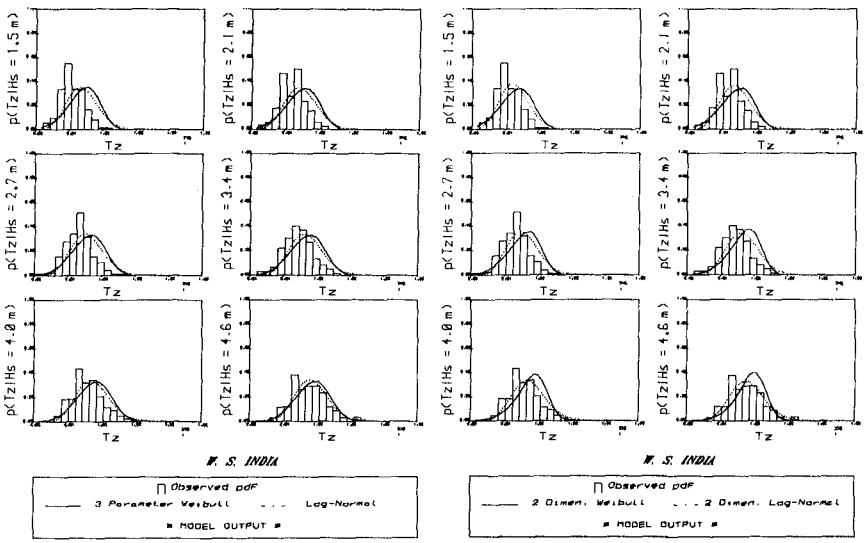

FIGURE 9 CONTOUR PLOTS FROM REGRESSION MODELS SUPERIMPOSED OVER OBSERVED SCATTER DIAGRAMS

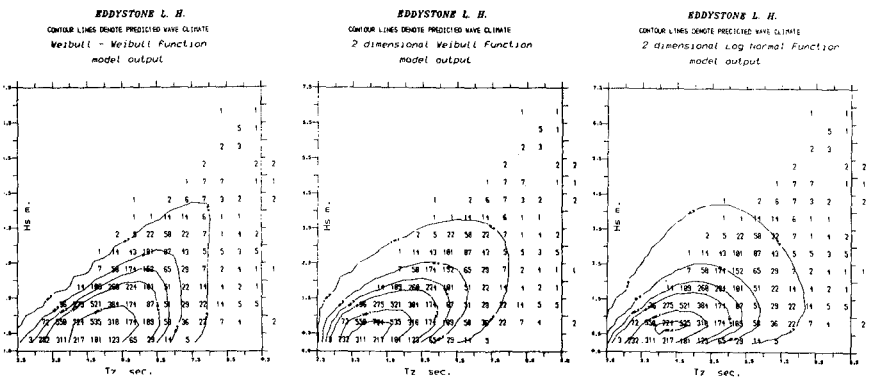

Conclusions

(1) From an analysis of scatter diagrams from 18 sites around the British Isles it has been found that the 3 parameter Weibull distribution provides a better fit than the Log-Normal distribution to the marginal properties of Hs and Tz whilst both functions describe with near equal merit the conditional behaviour of p(Tz/Hs).

(2) Regression equations linking the statistics of the various probability distributions considered to the statistical moments of Hs have been established on the basis of two categories of site exposure, loosely termed 'oceanic' and 'coastal'. Further segregation of site classification is not practicable until the data base is extended.

(3) Links between site category, exposure conditions (such as 'effective fetch' and wind field strengths) and Hs statistics are currently under investigation although preliminary findings have proved inconclusive.

(4) Synthesis of wave climates when tested against the data sets available have shown the relative accuracy of the different approaches to follow the rank order:-

1) p(Hs)-Weibull, p(Tz/Hs)-Weibull
2) p(Hs)-Weibull, p(Tz/Hs)-Log-Normal
3) p(Hs,Tz)-2-dimensional Weibull
4) p(Hs,Tz)-NMI modified 2-dimensional Log-Normal
5) p(Hs,Tz)-2-dimensional Log-Normal

(5) Limited tests of the regression based models to independent data have not clearly substantiated the above and, in consequence, further validification is necessary.

Appendix 1 : Probability Distributions

The probability density function (pdf) of a random variable x is denoted by p(x) and the cumulative distribution function by P(X), where,

$$P(X) = \text{Prob}(x \leqslant X) = \int_{-\infty}^{X} p(x)\, dx \qquad (I.1)$$

The various forms of probability distribution considered herein are as follows:-

(i) Weibull Distribution

$$p(x) = \frac{(x-A)^{C-1}}{B^C} .C.\exp\left\{-\left[\frac{x-A}{B}\right]^C\right\} \qquad (I.2)$$

where A, B and C are constants, representing location, scale and shape parameters of the distribution. These parameters are related to the statistical moments of x as follows:-

$$\text{Mean}, \quad \bar{x} = E\{x\} = A + B\Gamma(1+1/C)$$
$$\text{Variance}, \quad \sigma^2_x = E\{(x-\bar{x})^2\} = B^2[\Gamma(1+2/C) - \Gamma^2(1+1/C)]$$
$$\text{Skewness}, \quad \lambda_x = \frac{[\Gamma(1+3/C) - 3\Gamma(1+2/C)\,\Gamma(1+1/C) + 2\Gamma^3(1+1/C)]}{[\Gamma(1+2/C) - \Gamma^2(1+1/C)]^{3/2}} \qquad (I.3)$$

where Γ is the Gamma function

(ii) Log-Normal Distribution

$$p(x) = \frac{1}{\sqrt{2\pi}\, xb} \cdot \exp\{-\frac{1}{2b^2}(\log(x) - a)^2\} \qquad (I.4)$$

where parameters a and b are the mean and standard deviation of log(x) and are related to the moments of x as follows:-

$$\begin{aligned} \bar{x} &= \exp\{a + b^2/2\} \\ \sigma^2_x &= \exp\{2a + b^2\}[\exp\{b^2\} - 1] \end{aligned} \qquad (I.5)$$

In the context of the paper, x can take the form of either Hs or Tz in the above equations. However, in the remaining 2-dimensional distributions it is convenient to make direct reference to the wave parameters.

(iii) 2-Dimensional Log-Normal Distribution

$$p(Hs,Tz) = \frac{1}{Hs.Tz} \cdot \frac{1}{2\pi\sqrt{1-\rho^2_{ht}}\,\sigma_h\sigma_t} \cdot \exp\{\frac{-R}{2(1-\rho^2_{ht})}\}$$

$$\text{and } R = [\frac{(h-\bar{h})^2}{\sigma_h^2} - 2\rho_{ht}\frac{(h-\bar{h})}{\sigma_h} \cdot \frac{(t-\bar{t})}{\sigma_t} + \frac{(t-\bar{t}^2)}{\sigma_t^2}] \qquad (I.6)$$

where $h = \log(Hs)$; $t = \log(Tz)$; $(\bar{h},\sigma_h)$ and $(\bar{t},\sigma_t)$ are the equivalents of (a,b) in Eq. (I.5), representing the fit parameters for the respective marginal distributions; and ρ_{ht} is the linear correlation coefficient, $\rho_{ht} = E\{(h-\bar{h}).(t-\bar{t})\}/\sigma_h\sigma_t$ (I.7)

(iv) 2-Dimensional Weibull Distribution

$$p(Hs_N,Tz_N) = \frac{m\,n}{4\beta} Hs_N^{m-1}\, Ts_N^{n-1} \exp\{-\frac{1}{2\beta}(\Phi_2 Hs_N^m + \Phi_1 Tz_N^n)\}.I_o(Hs_N^{m/2}.Tz_N^{n/2}.\gamma/\beta) \qquad (I.8)$$

where I_o is the Modified Bessel function of zero order; γ is a correlation parameter linked to the linear correlation coefficient (of the form of Eq. (I.7)) as follows:

$$\rho = \frac{\Gamma(\frac{m+1}{m})\,\Gamma(\frac{n+1}{n})\,[F(-\frac{1}{m}; -\frac{1}{n}; 1; \frac{\gamma^2}{\Phi_1\Phi_2}) - 1]}{\sqrt{[\Gamma(\frac{m+2}{m}) - \Gamma^2(\frac{m+1}{m})]\,[\Gamma(\frac{n+2}{n}) - \Gamma^2(\frac{n+1}{n})]}}\ ;\ \beta = \Phi_1\,\Phi_2 - \gamma^2 \qquad (I.9)$$

F is the Hypergeometric function; $m \equiv C_{Hs}$, $n \equiv C_{Tz}$, $\Phi_1 \equiv \frac{1}{2}(B_{Hs})^m$,

$\Phi_2 \equiv \frac{1}{2}(B_{Tz})^n$, $Hs_N \equiv (Hs - A_{Hs})$ and $Tz_N \equiv (Tz - A_{Tz})$.

Parameters A, B and C are the Weibull parameters from the marginal distributions of Hs and Tz as appropriate.

Appendix 2 : Regression Equations

In the following (O) represents the 'oceanic' group of data sites and (C) represents the 'coastal' group. Using the definition of Eq. (3), most statistics have been expressed in the form,

$$Y = a\ (H_s)^b\ (\sigma_{(Hs)})^c\ (\lambda_{(Hs)})^d$$

Y		a	b	c	d
$\bar{T}_z$	(O)	4.482	0.51	-0.11	0.70
	(C)	8.758	-0.67	0.80	-0.41
$\sigma_{(Tz)}$	(O)	11.453	-3.55	3.69	-1.40
	(C)	2.984	-1.59	1.75	-0.75
$\rho_{(Hs-Tz)}$	(O)	2.329	-2.88	4.23	-2.71
	(C)	0.348	-0.28	0.14	1.26
$\rho_{(logHs-logTz)}$	(O)	3.353	-3.73	5.48	-3.68
	(C)	0.429	-1.20	0.30	1.03
κ	(O)	2.872	0.85	-0.44	1.12
	(C)	6.510	-0.42	0.68	-0.54
ν	(O)	3.484	-2.72	2.24	-1.59
	(C)	0.326	1.05	-1.11	0.82
* μ	(C)	3.0	-1.40	1.70	-0.88
ν	(C)	-0.172	-1.10	0.305	0.531

* for 'coastal' sites: $\sigma_{(Tz/Hs)} = \mu \exp(-\nu H_s)$
  for 'oceanic' sites: $\sigma_{(Tz/Hs)} = (0.75 - 0.01 H_s + 0.07 H_s^2)\ \sigma_{(Tz)}$

CHAPTER 5

Numerical Simulation of 1964 Tsunami Across the Pacific Ocean

Michael H. Chen [1]

A two dimensional numerical longwave model using an appropriate open sea boundary condition has been developed. The use of the open-sea boundary condition makes it possible to simulate longwave propagation using a smaller region without covering the entire ocean. The numerical model is used to predict the arrival time of tsunamis resulting from the 1964 Alaskan earthquake at various stations with reasonable success.

Introduction

Tsunami is a seawave generated by a near shore shallow-water undersea ground movement. It usually causes major damage to the coastal area not only next to the epicenter of the earthquake, but also at a distance away. Due to its nature, studies of the tsunami can be classified into three categories: (1) generation, (2) propagation and dispersion across the ocean and (3) response at the coastal region. A very lengthy summary of references regarding every aspect of tsunami phenomena was presented by Wiegel (1980) in his study of tsunamis in the Philippines.

Most analytical models related to tsunamis are either limited to a one dimensional model or a two dimensional model with a constant water assumption. Mathematical models are also available for water depths which vary in some specific manner.Using an integral transform technique, Carrier (1966) developed a one dimensional analytical model to relate the wave height at the source region to a location far away. The generation of a tsunami in the region adjacent to the earthquake epicenter has been studied extensively by Hammack (1972) in his theoretic and experimental work.

Apart from the theoretic approach, many numerical models have been developed to study the longwave phenomena. Using a space-staggered implicit finite difference method, Leendertse (1967) gave a detailed discussion on the aspects of a numerical model for the longwave equation. Hwang et al. (1973) developed a numerical longwave model in spherical coordinates using methods described by Leendertse to examine the effect of the earth's curvature on the propagation of a seawave. A similiar two dimensional numerical model was also presented by Skovgaard and Jonsson (1980). In their studies, Homma's mathematical model for a longwave over a parabolic island was included.

[1]Member of Technical Staff, TRW Defense System Group, One Space Park, Redondo Beach, CA 90278

In the present study, a numerical longwave model in spherical coordinates has been developed using an alternated direction. explicit finite difference method proposed by Loomis (1973). A suitable open sea boundary condition based on the concept of matched impedance is adapted. Applying this open sea boundary condition, it is possible to investigate wave response at a particular area in the middle of Pacific Ocean without including the entire ocean.

The performance of the numerical model is verified by performing a simulation of a wave impinging upon a circular island over a constant water depth, and a real time tsunami simulation resulting from the 1964 Alaskan earthquake.

Governing Equations

With the assumption that the Coriolis force and convective terms can be neglected and the wave height, η, is small compared to the original water depth, d, the linearized longwave equations in spherical coordinates can be expressed as:

$$\frac{\partial u}{\partial t} = -\frac{g}{R}\frac{\partial \eta}{\partial \theta} \tag{1}$$

$$\frac{\partial v}{\partial t} = -\frac{g}{R sin\theta}\frac{\partial \eta}{\partial \phi} \tag{2}$$

$$\frac{\partial \eta}{\partial t} = -\frac{1}{R sin\theta}\left[\frac{\partial (du sin\theta)}{\partial \theta} + \frac{\partial (dv)}{\partial \phi}\right] \tag{3}$$

where u and v are the velocity components in the x and y direction, respectively; d and η are the original water depth and wave amplitude, respectively; θ and ϕ are the angles related to the local latitude and longitude respectively; R is the radius of the earth and t is for the time.

The above set of equations are then expressed in their finite difference forms to construct the numerical model for investigaing the longwave propagation and its response at the coastal area.

Boundary Treatment

In addition to the stability problem related to the numerical scheme, the specification of the boundary condition at the artificial boundary where the computation terminated is also very important. In his survey articles on acoustic radiation, Shaw (1970) related several physical boundary conditions to their corresponding mathematical forms. The most suitable boundary condition at the open sea is the matched impedance condition where the wave is assumed to be totally transmitted.

Applying linearized wave theory with the assumption of constant depth beyond the computational domain, the matched impedance condition becomes

$$\frac{\partial \eta}{\partial t} = -\frac{c}{R sin\theta}\left[cos\delta \frac{\partial \eta}{\partial \theta} + sin\delta \frac{\partial \eta}{\partial \phi}\right] \tag{4}$$

where c is the wave speed and δ is the angle between the wave direction and the local open boundary.

This is equivalent to the radiation condition given by Sommerfeld (1949) at the far field for the scattered wave. Equation (4) will be used at the open sea boundary where the time derivative of the wave amplitude can be related to its spatial derivative.

In addition to the open-sea condition, a treatment at the solid boundary is also required. This treatment is relatively quite simple and can be achieved by appling the null nomal derivative conditions for all flow quantities. The condition for the wave amplitude at a solid boundary is:

$$\vec{n} \cdot \left[\frac{\partial \eta}{\partial \theta}\hat{i} + \frac{\partial \eta}{\partial \phi}\hat{j}\right] = 0 \tag{5}$$

where $\hat{i}$ and $\hat{j}$ are unit vector in the θ and ϕ direction respectively and $\vec{n}$ is the local outward normal at the shoreline.With these boundary treatments, the numerical longwave model can then be formulated.

Finite Difference Scheme

The numerical model is constructed by using a space and time staggered method. The flow quantities are assigned at a location half a grid space apart. The vector quantities such as u and v are assigned at the edge of the grid element. On the other hand, the scalar quantities, d and η, are assigned in the middle of the grid element. The value at the location where a particular quantity is not computed is approximated by its average value among its four surrounding points.

Using the above arrangement for the flow quantities, the finite difference equations of the linearized longwave equations are:

$$u_{i,j}^{n+1} = u_{i,j}^{n} - \frac{g\Delta t}{R\Delta\theta}\left[\eta_{i,j}^{n+1} - \eta_{i,j-1}^{n+1}\right] \tag{6}$$

$$v_{i,j}^{n+1} = v_{i,j}^{n} - \frac{g\Delta t}{Rsin\theta_j\Delta\phi}\left[\eta_{i,j}^{n+1} - \eta_{i-1,j}^{n+1}\right] \tag{7}$$

$$\begin{aligned}\eta_{i,j}^{n+1} = \eta_{i,j}^{n} - \frac{\Delta t}{2Rsin\theta_j}\Big\{&\left[(d_{i+1,j}^{n} + d_{i,j}^{n})v_{i+1,j}^{n+1} - (d_{i,j}^{n} + d_{i-1,j}^{n})v_{i,j}^{n+1}\right]/\Delta\phi \\ &+ \left[(d_{i,j+1}^{n} + d_{i,j}^{n})u_{i,j+1}^{n+1}sin\theta_{j+1/2} - (d_{i,j}^{n} + d_{i,j-1}^{n})u_{i,j}^{n+1}sin\theta_{j-1/2}\right] \\ &/\Delta\theta\Big\}\end{aligned} \tag{8}$$

Equations (6), (7) and (8) are the basis of the current numerical model. In conjunction with the treatment of solid and open boundary, the propagation of a tsunami over an ocean can then be studied.

The actual integration in time is achieved in two stages. First, the wave amplitude, η, at $(n+1)^{th}$ step is integrated using its value at n^{th} step and the newly calculated velocities, u and v through equation (8). With this newly obtained wave amplitude, $\eta_{i,j}^{n+1}$, the velocities, $u_{i,j}^{n+1}$ and $v_{i,j}^{n+1}$, are then computed using their values at n^{th} step using equations (6) and (7), respectively. This method of integration is not exactly an explicit method but is crucial in the numerical stability. A completely explicit method is usual not stable.

Verification

It is desired to verify the performance of a numerical model by comparing the computed result with either an analytical solution or experimental data. A general solution for the wave height at the shore due to a series of monochromatic waves is given by Morse and Feshback (1953).

Such a solution for a monochromatic wave with an amplitude of one meter and a period of 4 minutes impinging upon a circular island having a radius of 18 km among a uniform depth of 4 km was presented by Vastano and Reid (1966) in their study of tsunami response at an island. A similar simulation has been performed using the present numerical model. The results of three models are shown in Figure 1.

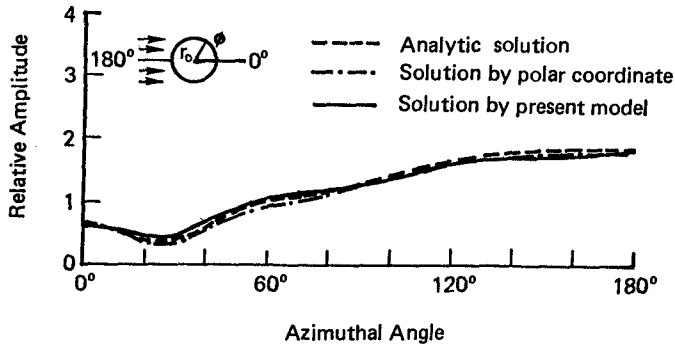

Figure 1. The comparison of maximum wave amplitude at shoreline among three models.

The predicted results by both numerical models agree quite well with the analytic solution. The use of the matched impedance condition at the open boundary transmits the progress wave outward to the open sea successfully. A similiar calculation was also presneted by Skovgaard and Jonsson (1980). In their model, the treatment on the open sea boundary is different. A known solution from the

analytical model was used at the open sea. The open-sea boundary treatment presneted in the current study is not adapted in their model.

Results and Discussions

The current numerical longwave model has been applied to simulate the destructive tsunami resulting from the 1964 Alaskan Earthquake. The original water depth is obtained from the world hydrographic chart prepared by the Scripps Institutes of Oceanography. The initial tsunamis distribution is derived from the work of Hwang and Divoky (1970) which uses the ground displacement data of the 1964 Alaskan earthquake summarized by Plafker (1969) as its data to compute the near field tsunami wave height. The computational basin is 91 $\times$ 63 (Longitude by Latitude) which covers the area from the North American continent to the Ilusian Island and from the Alaska to the equator. The grid size is 1^o by 1^o which is relatively large.

The ground displacement aftershock was illustrated by Plafker (1969). It had a broad crustal warping along a northeast - southwest trend hinge line from Prince William Sound, Alaska to Kodiak, Alaska, USA. He suggested that the axis of seabed uplift was also the axis of the source region for the generated tsunami. This axis determined the direction of the main wave. His assertion was clearly demonstrated by the numerical result. The recorded tide gage at several stations along the Pacific Ocean were presented by Spaeth and Berkman (1967). These valuable records are used to verify how well the numerical model performed.

The reported duration for the completion of ground motion was approximately 150 seconds which is very short. In other words, the initial tsunami spatial distribution could be approximated by the net undersea ground displacement, instantaneously. This assumption was adopted by Hwang and Divoky (1970) in their nearfield tsunami calculation in the earlier stage. The surface elevation at 200 seconds in their report is then converted into a 1^o by 1^o grid in spherical coordinates and is used as the initial condition in the current numerical simulation.

This initial surface height used in the current simulation is given in Table 1.

TABLE 1. THE SIMULATED INITIAL WAVE HEIGHT OF TSUNAMIS DUE TO the 1964 ALASKAN EARTHQUAKE
(unit: meter)

	152°[1]	151°	150°	149°	148°	147°	146°	145°	144°	143°	142°
59°N	⋆[2]	⋆	⋆	⋆	⋆	3.01	1.86	1.43	⋆	⋆	⋆
58°N	⋆	⋆	.402	2.45	5.86[3]	4.61	2.16	1.43	.772	.319	.038
57°N	⋆	-.49	2.68	5.19	2.55	1.09	.765	.151	.025	.001	0.00
56°N	.646	1.80	4.99	1.76	.691	.047	.003	0.00	0.00	0.00	0.00
55°N	.391	1.28	1.12	.243	.025	.000	0.00	0.00	0.00	0.00	0.00

notes:

1. It is the local longitudinal value on the western hemisphere.
2. The symbol, *, represents a zero wave height at the land.
3. The maximum initial wave height is 5.8644 meter.

The computed wave patterns show a strong seiche phenomenon in the Gulf of Alaska, resulting in very strong wave activity for as long as 10 hours after the shock. This agrees very well with the recorded result. As asserted by Plafker, the main wave propagated in a southeast direction toward the North American continent. Therefore, a portion of the wave was reflected and trapped and formed an oscillating pattern within the Gulf of Alaska. Eventually, this seiche phenomenon died out because part of wave energy was radiating outward into the open sea.

After passing through the Gulf of Alaska, the main wave continued its southeast direction and propagated toward the west coast of the North American continent. The current simulated results predict a higher maximum height at the location where there is a higher angle between the incoming wave and the shoreline which agrees with the recorded tide data. According to the tide-gage records resulting from the 1964 Alaskan earthquake, summarized by Spaeth and Berkman (1967), both Crescent City and Hilo experienced a considerably high wave activity.

The predicted wave heights are smaller than the recorded values. For comparison, the predicted and recorded tide marigrams at Crescent City, California are shown in figures (2) and (3). The predicted wave height at this location merely reaches 1 meter which is very small in comparison with the recorded value of 4 meters. This big difference is partly due to the exclusion of the contribution of the astronomical tide in the numerical simulation.

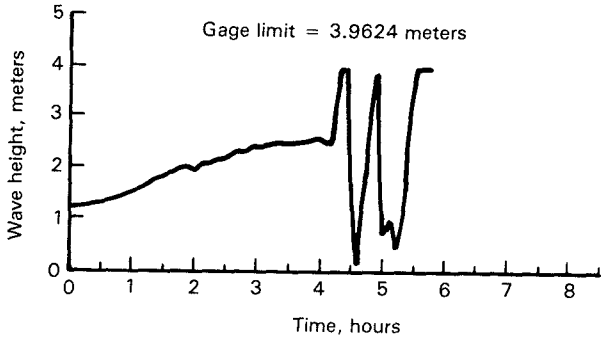

Figure 2. The tide gage record of tsunami at Crescent City, California due to the 1964 Alaskan Earthquake.

From the tide gage record, it indicates the astronomical tide is around 2.6 meters at the moment of the arrival of tsunami. If this value is used as the basis to compute the actual tsunami contribution, the estimated peak tsunami height will not exceed 2 meters. Consequently, the discrepancy between the predicted and record results is reduced considerably.

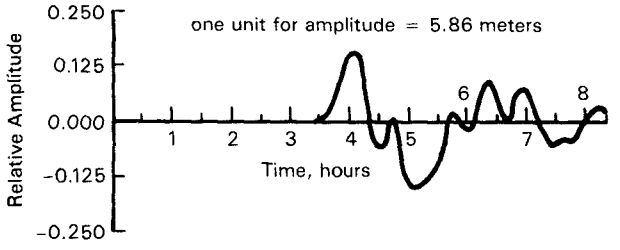

Figure 3. The simulated tsunami time history at Crescent City, California due to the 1964 Alaskan Earthquake.

From the tide marigram, the tsunami arrival time can also be calculated. The arrival time can be determined by the time either when the wave height starts to deviate from its normal state or when the first peak arrives. The former is defined as the first arrival time; the latter is defined as the first peak arrival time. Both arrival times are useful information in the tsunami warning system. The first arrival times at several stations are tabulated in Table 2.

TABLE 2. THE FIRST ARRIVAL TIME OF TSUNAMI RESULTING FROM THE 1964 ALASKAN EARTHQUAKE

Station	Long.° W	Lat.° N	Observed Hr. Min.	Predicted Hr. Min.
Yakutat, Alaska	139	59	1. 24.	0. 20.
Sikta, Alaska	135	57	1. 30.	0. 41.
Crescent City, CA	124	42	4. 03.	3. 28.
San Francisco, CA	122	38	5. 06.	4. 03.
Midway Islands	177	28	4. 51.	4. 21.
Oahu, Hawaii	160	21	5. 09.	4. 40.
Johnston Island	170	17	6. 03.	5. 33.

The difference between the recorded and computed first arrival time is approximately 30 minutes for the island stations and much higher for the stations closer

to the source region. If the arrival of the first peak is compared between the computed and the recorded results, the difference reduces to less than 15 minutes at Crescent City, California. In fact, the difference at the other stations is also reduced considerably.

In spite of a use of relatively large grid spacing, 1° by 1°; and a very rough treatment in the initial tsunami height distribution, the numerical model still predicts results comparable to the recorded data. The performance of the numerical model can be considered very good.

Conclusion and Recommandations

The major objective of the present study is to develop a suitable boundary condition for the open-sea boundary resulting from the partition of a larger area into a smaller region. With the use of this open sea treatment the large-scale propagation of a tsunami across an ocean can be investigated properly. The matched impedance condition in acoustic radiation is adapted to describe the condition at the two-dimensional open-sea boundary. This open sea boundary condition leads to a satisfactory agreement with the analytic steady-state solution for a monochromatic wave impinging upon a circular island of uniform water depth.

Using 1° by 1° spatial grid element and the bathymetry data from the world hydrographic chart, the staggered alternate-direction, explicit scheme of linearized long-wave theory is applied to simulate the 1964 tsunami. In general, the predicted first arrival time is earlier than the recorded values which is due to the difficulty in the treatment of coastal areas, especially at the source region. However, if the arrival of the maximum is used to compared the simulated and recorded data, their differences are much smaller. It indicates the use of the first arrival time as a criterion to determine the performance of the numerical model may not be appropriate. Also, we can conclude that use of a 1° by 1° grid element and linear longwave is sufficient for the prediction of tsunamis arrival time.

As pointed out by Goto and Shuto (1980), in their tsunami runup study, the predicted tsunami runup height by the nonlinear model is about 20% above that by the linear model. Based on their findings and the current result, a much finer and localized investigation should be performed using a higher order longwave equations in order to improve the predictive results at the locations such as Crescent City, California and Hilo, Hawaii where the wave amplification is important.

The conventional procedures for a small scale calculation are performed in two stages. First, a large scale calculation covering a much bigger area is performed. In this stage of calculation, all necessary flow quantities at the boundary of the smaller computational basin are stored. Second, these stored results are used as input boundary conditions in the small scale calculation. In this method, the exact effect to the computed flow quantities due to the reflection from a wall condition at the land area is not known. This uncertainity can be removed if both small and large scale calculation are performed, simultaneously.

Notation

c = the wave speed for a longwave.
d = the original water depth.
g = the acceleration coefficient of the gravitational force.
R = the radius of the earth.
t = the time.
u = the velocity component in the θ direction.
v = the velocity component in the ϕ direction.
η = the water surface elevation.
δ = the angle between wave direction and local open boundary.
ϕ = the angle for its longitude value on earth at each location.
θ = the angle between the north pole and each location.
$\hat{i}$ = the unit vector in the θ direction.
$\hat{j}$ = the unit vector in the ϕ direction.
$\vec{n}$ = the unit outward normal vector at the shoreline.

CHAPTER 6

Tidal Computations for the Yellow Sea

Byung Ho Choi*

Abstract

A two-dimensional numerical model of the Yellow Sea has been used to compute cotidal and coamplitude charts and harmonic constants of tidal currents for the four major tidal constituents M_2, S_2, K_1, O_1 tides in the region with the mesh resolution of 1/5 degree latitude by 1/4 degree longitude finite difference grid system. An additional model incorporating dynamical grid nesting procedurc which employs a one-third grid refinement scheme was also used to reproduce the M_2 tidal regime in more detailed resolution for the part of west coast of Korea where extensive coastal development including potential tidal power and land reclamation scheme is concerned. Comparisons between observations and model result have been carried out based on coastal gauges and moored current meter data. Reasonable agreement was found between obsevations and model results, thus supporting the computed distribution of tides in the region. It was also shown that the dynamically linkaged model particularly well within 5% in amplitude and 5 degrees in phase of observed M_2 tide in the refined mesh region of the west coast of Korea.

Introduction

The tidal phenomena of the Yellow Sea are extremely complex. During the late 1920's and early 1930's extensive studies of this shelf sea area were reported and a considerable number of tidal measurements were made, from which cotidal and corange charts of diurnal and semidiurnal tides were prepared (Ogura, 1933). Russian workers (Boris, 1958; Tsiklauri et al., 1961; Stepanov et al., 1964) reported the first application of two-dimensional mathematical models on the one hand to the Yellow Sea and on the other hand, to the Gulfs of Pohai and Liautung, employing boundary value method which calls for much tidal data at external boundary points along the coast and open boundary. While the latter models were satisfactorily used to reproduce the M_2 and K_1 tides in the Gulfs of Liautung and Pohai where extensive tidal data exists, the Yellow Sea model was only used to test the sensitivity of the tides of that area to changes in the boundary tidal input data, depths along the boundaries and Coriolis parameter. Their results indicated that the computed tides in the Yellow Sea were highly sensitive to even small changes in levelling data and the depths along the boundaries.

During the past few years series of numerical tidal models (An, 1977; Choi, 1980; Shen, 1980; Xia and Wang, 1984) based on initial value method have been reported and it was demonstrated by these models that the tides

*Professor, Dept. of Civil Eng., Sung Kyun Kwan University, Suwon Campus Korea.

can be satisfactorily reproduced, thus providing general information on the tidal dynamics in this sea area. However improvement on the accuracy of the model and verification of computed tidal currents were much limited due to the lack of long-term tidal observations.

In the present paper, an initial attempt is made to provide separate tidal charts of four major M_2, S_2, K_1 and O_1 tides in the Yellow Sea from the numerical model and comparisons between model results and the observations including recently available current meter data were described. Further effort to reproduce the tides in western Yellow Sea in more detailed manner by adopting the mesh-connecting scheme for the purpose of assessing the tidal modification due to coastal development is also included.

Numerical Model

Considering the area covered by the model, the curvature of the earth and the variation with latitude of the Coriolis acceleration are taken into account by adopting spherical coordinates. The equations of motion and continuity as used in this model are (Flather, 1976):

$$\frac{1}{R\cos\phi}\left\{\frac{\partial}{\partial\chi}(Hu)+\frac{\partial}{\partial\phi}(Hv\cos\phi)\right\}+\frac{\partial\xi}{\partial t}=0, \tag{1}$$

$$\frac{\partial u}{\partial t}+\frac{u}{R\cos\phi}\frac{\partial u}{\partial\chi}+\frac{v}{R}\frac{\partial u}{\partial\phi}-\frac{uv\tan\phi}{R}-2\omega\sin\phi v+\frac{k_b u\sqrt{u^2+v^2}}{H}+\frac{g}{R\cos\phi}\frac{\partial\xi}{\partial\chi}$$

$$=0, \tag{2}$$

$$\frac{\partial v}{\partial t}+\frac{u}{R\cos\phi}\frac{\partial v}{\partial\chi}+\frac{v}{R}\frac{\partial v}{\partial\phi}+\frac{u^2\tan\phi}{R}+2\omega\sin\phi u+\frac{k_b v\sqrt{u^2+v^2}}{H}+\frac{g}{R}\frac{\partial\xi}{\partial\phi}$$

$$=0, \tag{3}$$

Eqations (1) - (3) are vertically integrated hydrodynamical equations where the notation is

t	time
χ, ϕ	east-longitude and latitude respectively
ξ	elevation of the sea surface above the undisturbed depth
h	undisturbed depth of water
$H = h + \xi$	total depth of water
R	the radius of the Earth
ω	angular speed of the Earth's rotation
g	acceleration due to gravity
k_b	coefficient of bottom friction
u', v'	components of current in the directions of χ, ϕ respectively at a depth z below the undisturbed sea level
u, v	components of depth-mean current given by $u=\frac{1}{h+\xi}\int_{-h}^{\xi}u'(z)\,dz$, $v=\frac{1}{h+\xi}\int_{-h}^{\xi}v'(z)\,dz$

These equations, formulated with a quadratic law of bottom friction, are integrated on a staggered finite difference grid using the scheme described by Roberts and Weiss (1967) which centers the advective terms in time and space. The method employed for implementing this scheme is described by Flather and Heaps (1975) and Flather (1976).

Initial and boundary condition required for the solution of equations (1) to (3) are as follows:

At $t = 0$: $u(\chi,\phi,t)$, $v(\chi,\phi,t)$ and $\xi(\chi,\phi,t)$

are specified for all positions at which the equations are to be solved. At a land boundary: the component of the flow normal to the boundary is permanently zero:

$$u\cos\theta + v\sin\theta = 0$$

where θ is the angle between the normal to the coast directed out of the sea region and χ axis. Therefore

$u = 0$ is the boundary condition at a ϕ -directed land boundary
$v = 0$ is the boundary condition at a χ -directed land boundary.

Along an open boundary, elevation is specified as a function of time and position along the boundary: $\xi(\chi,\phi,t)$ is supplied.

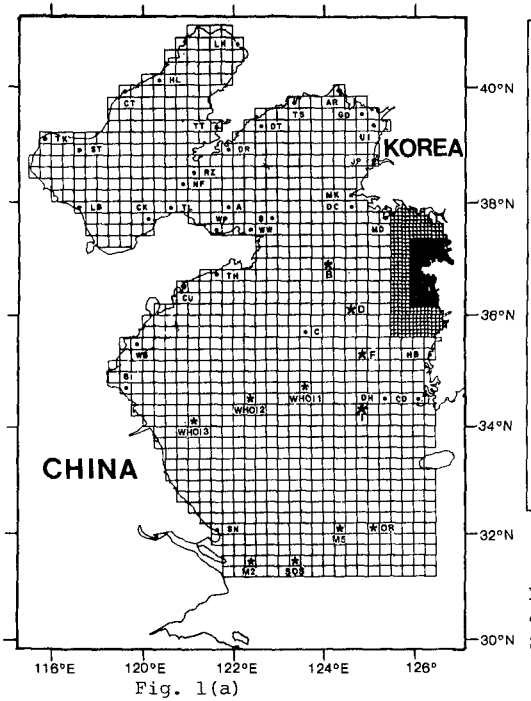

Fig. 1(a)

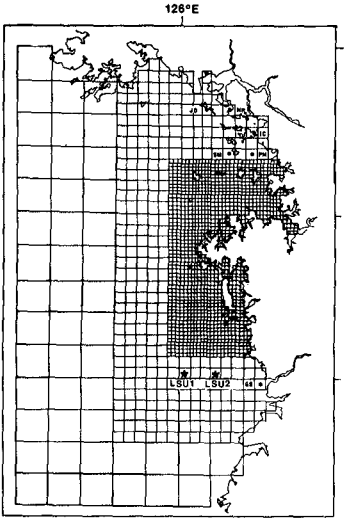

Fig. 1(b)

Fig. 1. Finite difference grid system of the Yellow Sea model.

In shallow sea areas provision is made in the numerical scheme for representing the drying of tidal flats.

The three different grid systems of the model are shown in Fig. 1. The coarse mesh has a grid resolution of 1/5 degree latitude by 1/4 degree longitude and this coarse grid has been used to compute overall tidal distribution in the Yellow Sea. This is the same grid spacing as that used in the two-dimensional shelf model of Choi (1980). The mesh size of intermediate grid system is one-third of this (1/15 degree latitude by 1/12 degree longitude) and a fine mesh system resulting from another refinement to provide a resolution of 1/45 degree latitude by 1/36 degree longitude. The dynamically linkaged model interconnecting three different grid systems has been used to compute the M_2 tidal regime of the west coast of Korea in detailed resolution.

In the model three different values of frictional parameters (0.0025 for the coarse grid and 0.0028, 0.0030 for the intermediate and fine grids) were used to give the best results for the reproduction of the tides. The open boundaries of the modcl border the line of latitude 31.2 degree North from the entrance of Changjiang River and the line of longitude 126.5 degree East. The boundary elevations were specified as a function of position and time. To satisfy explicit stability conditions, a timestep of six minutes was used for the coarse grid model and a timestep of one lunar minute was used for the dynamically linkaged model. Time and phases referred to in this study are referenced to 135 degree east longitude (time zone, -9H).

The numerical scheme employed was described prcviously (Choi, 1980) and the dynamic grid nesting procedure for joining the different grid mesh is similar to those by Owen (1979). When a computation of a variable on the one grid system in the mesh connected area requires a variable on another grid system, a linearly interpolated value is used.

Fig. 2 shows the mesh refinement grid area between two different size of meshes which are connected with an one-third refinement scheme. The finite difference scheme, which advances ξ, u, v over the entire network at time t to obtain their values at time $t + \Delta t$ is explicit and changes its scanning direction for calculation of u, v at alternate timesteps. When calculation of u, v on one grid system in the connected region requires variables ξ, u, v 's on joining grid system, a linearly interpolated values were used.

Referring to Fig. 2(a) showing mesh refinement in u-direction, u-velocities in the fine grid region are calculated as:

$$u_{i+n-1} = \frac{1}{2}\left(u_{i+n} + \frac{1}{3}(2u_{\ell} + u_{\ell m})\right) \tag{4}$$

$$u_{i-1} = \frac{1}{2}(u_{\ell} + u_{i})$$

$$u_{i+n-1} = \frac{1}{2}\left(u_{i+n} + \frac{1}{3}(2u_{\ell} + u_{\ell+m})\right)$$

The calculation of u in the coarse side of the connection requies

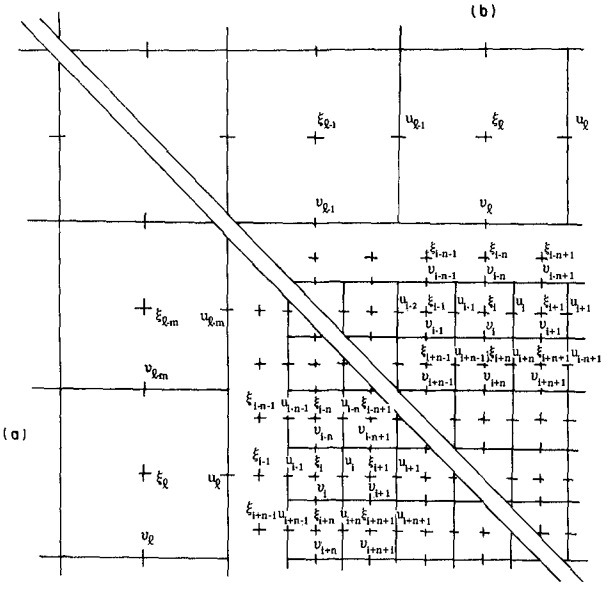

Fig. 2. Combination of two different grid system.

ξ values and v value in the fine mesh side:

$$\tilde{v} = \frac{1}{4}(v_{\ell\text{-}m} + v_{\ell} + v_{i\text{-}2n} + v_{i+n}) \tag{5}$$

$$\xi_{\ell+1} = \xi_i$$

Values of ξ along the connected regions are calculated as:

$$\xi_{i\text{-}n\text{-}1} = \frac{1}{3}\left(\frac{2}{3}\xi_{\ell} + \frac{1}{3}\xi_{\ell\text{-}m}\right) + \frac{2}{3}\xi_{i\text{-}n}$$

$$\xi_{i\text{-}1} = \frac{2}{3}\xi_i + \frac{1}{3}\xi_{\ell} \tag{6}$$

$$\xi_{i+n+1} = \frac{1}{3}\left(\frac{2}{3}\xi_{\ell} + \frac{1}{3}\xi_{\ell+m}\right) + \frac{2}{3}\xi_{i+n}$$

Referring to Fig. 2(b) showing mesh refinement in v-direction, v-velocities in fine grid region are calculated as:

$$v_{i\text{-}n\text{-}1} = \frac{1}{2}\left(v_{i\text{-}1} + \frac{1}{3}(2v_{\ell} + v_{\ell\text{-}1})\right)$$

$$v_{i\text{-}n} = \frac{1}{2}(v_{\ell} + v_i) \tag{7}$$

$$v_{i\text{-}n+1} = \frac{1}{2}\left(v_{i+1} + \frac{1}{3}(2v_{\ell} + v_{\ell+1})\right)$$

The calculation of v in the coarse side of the connection requires u values and ξ value in the fine mesh side:

$$\tilde{u} = \frac{1}{4}(u_{\ell\text{-}1} + u_{\ell} + u_{i\text{-}2} + u_{i+1}) \tag{8}$$

$$\xi_{\ell+m} = \xi_i$$

Values of ξ along the row of the connected region are calculated as:

$$\xi_{i-n-1} = \frac{1}{3}\left(\frac{2}{3}\xi_{\ell} + \frac{1}{3}\xi_{\ell-1}\right) + \frac{2}{3}\xi_{i-1} \tag{9}$$

$$\xi_{i-n} = \frac{2}{3}\xi_{i} + \frac{1}{3}\xi_{\ell}$$

$$\xi_{i-n+1} = \frac{1}{3}\left(\frac{2}{3}\xi_{\ell} + \frac{1}{3}\xi_{\ell+1}\right) + \frac{2}{3}\xi_{i+1}$$

Along the rows and columns of connected region of one grid space, nonlinear advective terms were neglected to avoid excessive interpolations.

Model Results

Tidal Elevations

The dynamically linkaged model of which the grid system is shown in Fig. 1 was run for five tidal cycles to achieve the stable tidal regime. Results of further sixth cycle was then analyzed to yield M_2 tidal harmonic constants. Subsequently the computed amplitude and phase of the M_2 elevation from the model are compared with coastal observations at various places over the Yellow Sea. The model grid points closest to these observation sites are shown in Fig. 1 as closcd circles. Table 1 shows the comparison of observed and calculated amplitude and phase of the M_2 tide for these sites. It should be borne in mind that discrepancies between values from analyses of water levels at coastal stations and values obtained by Fourier analysis of time series from the model elements occur because generally coastal stations and corresponding model points are at slightly different locations, in region where the tidal constituents change considerably over a mesh element, so that a significant error results. In addition to these limitations, the harmonic constants were derived from short period observations of water level except for a few stations. Some variability of amplitude and phase of the M_2 tide for most stations exists.

Within limitations thus imposed, however it is shown that the model generally agrees well with observation to within 10% in amplitude and 10 degrees in phase with some deterioration in Gulf of Liautung and Hangzhou Bay reaching the maximum error of 30cm. Over the coarse grid region, the results were not improved from the previous shelf model (Choi, 1980) but in intermediate and fine grid region, the area of great interest as far as potential tidal power and large land reclamation development schemes are concerned, close agreement was achieved, errors being about 5% in aplitudes and 5 degrees in phases. Fig. 3(a) shows the computed coamplitude and cophase chart of the M_2 tide from the model demonstrating good agreement with existing chart (Ogura, 1933) and previous computation from the shelf model.

The coarse grid Yellow Sea model was run for 17 days to compute S_2, K_1 and O_1 tidal distribution in addtion to previously computed M_2 tide in the Yellow Sea. For this run harmonic constants for open boundary inputs were deduced from existing tidal charts by adopting the mean values of $H_{s_2}/H_{m_2} = 0.4$, $\kappa_{S_2}-\kappa_{m_2} = 38^{\circ}$, and $H_{o_1}/H_{k_1} = 0.7$, $\kappa_{k_1}-\kappa_{o_1} = 30^{\circ}$. Harmonic analyses for each of the grid elements were performed over 15

days of hourly data after discarding the first two days of data containing initial disturbances. Subsequently computed tidal charts of S_2, K_1 and O_1 tides are drawn as shown in Fig. 3(b) - 3(d). Comparison between observations and model results showed that amplitude of S_2 tide overestimated up to 30% and errors in phases of K_1 and O_1 tides were order of 10 degrees. Overall the model gave general qualitative and quantitative agreement with the existing charts and shore-based data when the crudeness of open boundary tidal data is considered.

Tidal Currents

Fig. 4 show an example of computed tidal current fields from the dynamically linkaged model at the time of lunar transit across 135°E. It can be seen from this figure that tidal currents are very strong along the coast of Taean Peninsula and to approach channel to Inchon and Asan. Sets of current vectors also undergo harmonic oscillations of tidal period, - thus the resultant velocity vectors describing the M_2 tidal ellipses are shown in Fig. 5. This chart gives an overall impression of the magnitude and direction of the M_2 tidal current distribution representing the maximum and minimum velocities as major and minor axes respectively. It is worth noting that rotating current pattern in the lower part of the Yellow Sea is in good agreement with Ogura's speculation. In near-coastal areas, elongated major axes indicates current is near-rectilinear.

In Fig. 6 the depth-mean M_2 current ellipses are plotted for the 27 stations over the Kyonggi Bay. The magnitude and time of occurrence of the maximum M_2 tidal currents, at various places are indicated in this plot. Highest currents calculated are of the order of 150 cm/sec in this area. Current observations of comparable quality do not exist over this region, but generally good agreement of the current magnitude can be expected from the fact that the model simulates the M_2 surface elevation over this region with good accuracy.

Computed depth-mean tidal currents from the extended run of coarse grid model were also harmonically analyzed to provide harmonic constants of easterly and northerly components of S_2, K_1 and O_1 tidal currents. This computed result was then compared with current observations from USA - China Marine Sedimentation Dynamics Study (shown as stations M2, M5; refer Larsen et al.,1985), LSU moored current meter data during 1982 experiment and WHOI moored current meter data during November, 1983 and USA - Korea cooperative current observations during 1986 (shown as stations B, D, F, I in Fig. 1).

Fig. 7 and Fig. 8 show comparison between observations and computed currents of M_2, K_1 tides in the form of tidal ellipses which was constructed from harmonic constants. In these figures observed ellipses are shown as solid lines and computed ellipses dotted lines. There is inherent limitation in direct comparison between observed current meter data which was measured at certain depths below sea surface and depth-averaged currents computed from the two-dimensional model, however there is general agreement between the observations and model results.

Conclusion

Some of preliminary results from a non-linear two-dimensional model of the Yellow Sea have been presented in this paper.

The overall tidal regime of major tidal constituents in the Yellow Sea has been computed quite successfully with the coarse grid numerical model employed here. Using this coarser mesh shelf model to provide boundary data for finer mesh models in the western Yellow Sea, the near-shore variations in tides within Kyonggi Bay will be modelled in detail.

A model employing a dynamical grid nesting procedure to give fine resolution on the west coast of Korea could satisfactorily reproduced the M_2 tide in the fine mesh region in detailed manner. By this means tidal modification due to large development schemes can be evaluated.

CHAPTER 7

THE INFLUENCE OF WAVES ON CURRENT PROFILES

by

Felicity C. Coffey* and Peter Nielsen**

ABSTRACT

A simple model is presented for steady current profiles in the presence of waves. The current reduction and apparent roughness increase caused by the waves are shown to depend mainly on one dimensionless parameter $\tilde{u}_*/\bar{u}_*$, i.e. the ratio between the friction velocity amplitude due to the waves and the time averaged friction velocity. The model recognises the need to apply different eddy viscosities to different flow components. Also, the thickness of the wave influenced layer near the bed is comceptually separated from the vertical scale of the wave boundary layer.

INTRODUCTION

The water motion in coastal and estuarine areas is generally a combination of wave motion and currents which can be considered steady compared to the waves. Waves and currents influence each other in mainly two ways. Firstly, variability in current strength will cause wave refraction. Secondly, vigorous wave-induced mixing close to the bed will change the current profile. In the following we shall deal only with the latter type of of interaction.

The problem was studied theoretically by Lundgren (1972), who realised that the waves change the current profile by increasing the eddy viscosity, ν_c, felt by the current in a thin layer near the bed (Figure 1), while outside this thin layer ($z > L$) the waves introduce no mixing. Hence the outer current profile is logarithmic

$$\bar{u}(z) = \frac{\bar{u}_*}{\kappa} \ln (z/z_1) \qquad \text{for } z > L \qquad (1)$$

with the only difference being that the usual zero intercept $z_o = r/30$ has been replaced by the larger z_1; r is the Nikuradse roughness of the bed and $\bar{u}_*$ is the time averaged friction velocity. Thus the wave effect on the outer current profile amounts to a constant shift:

$$\Delta_{\bar{u}} = \frac{\bar{u}_*}{\kappa} \ln (z_o/z_1) \qquad \text{for } z > L \qquad (2)$$

or an apparent increase in bed roughness from $30z_o$ to $30z_1$.

A complete description of the velocity shift or z_1/z_o must contain the three basic, independent variables: $Aw/\bar{u}_*$, A/r, and φ i.e.

$$z_1/z_o = F(Aw/\bar{u}_*, A/r, \varphi) \qquad (3)$$

where A is the horizontal semi-excursion of the wave motion near the bed, ω is the angular frequency $2\pi/T$ and φ is the angle between current and wave propagation. Lundgren evaluated $\ln(z_1/z_o)$ on the basis of wave eddy viscosity measurements by Jonsson and Carlsen (1976) and assuming that the eddy viscosity felt by the current is the one caused by current alone plus the one caused by waves alone, added geometrically.

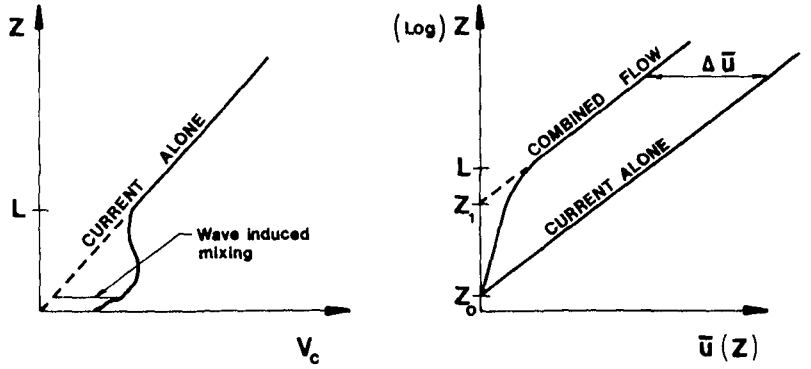

Figure 1 : Waves increase the eddy viscosity ν_c felt by the current inside a thin layer ($z \ll L$) near the bed. The resulting current profile is logarithmic for $z > L$, so the wave induced change to the outer profile amounts to a shift u or in other words, to an apparent roughness increase (from $30z_o$ to $30z_1$).

Lundgren did not consider changes in the wave boundary layer structure due to the current. Such changes were estimated later on theoretical grounds by Grant and Madsen (1979) and Christoffersen (1982). Such changes are however very minor according to empirical data and are probably without practical consequence unless the current is very strong ($\bar{u}_* \gtrsim \hat{u}_*$), see Nielsen (1985).

The models of Grant and Madsen and of Christoffersen both assume that the same eddy viscosity applies to both waves and currents, an assumption which seems altogether reasonable a priori. However, surprisingly it is not valid in general. Laboratory measurements by

van Doorn (1981) show that the eddy viscosities felt by waves and currents at the same point of the same flow can differ by as much as a factor 4, see Coffey and Nielsen (1984). The fact that different eddy viscosities must be applied to different flow components has also been observed by Bakker and van Kesteren (personal communication). In heuristic terms the phenomenon can be explained as follows : The eddy viscosity can be seen as the product of a turbulent velocity and a vertical length scale i.e.

$$\nu_T = V_\nu L_\nu \qquad (4)$$

The turbulent velocity V_ν is probably equally effective with respect to both waves and currents, but that is not the case for the vertical length scale L_ν. The length scale relevant to the current shear stress is known to grow proportionally to the distance from the bed; but the length scale relevant to the oscillatory shear stress cannot grow beyond a certain fraction of the wave boundary layer thickness or the equivalent Stokes length $\sqrt{2\nu_T/\omega}$. Hence the currents feel a larger eddy viscosity than the waves.

The implication of this is that while the eddy viscosity concept is useful as a formal parameter in simplistic flow models, the interpretation into physical terms is not as straight forward as previously imagined.

CHOSING MODEL STRUCTURE

The following section is concerned with choosing the appropriate form of the eddy viscosity felt by the current on the basis of empirical evidence. Obviously, following the remarks above, the same eddy viscosity is not expected to apply to the wave boundary layer structure.

Apart from the fairly complicated, empirical curve suggested by Lundgren (1972), two simple forms have been suggested for the eddy viscosity felt by the current inside the wave dominated layer. Christoffersen (1982) suggested a constant eddy viscosity through the bottom layer while Grant and Madsen (1979) recommended a linearly growing eddy viscosity. Both models will in general result in a discontinuity of ν_c and thus of the current gradient at the top of the wave influenced layer (z = L). See Figure 2.

For both models, it is fairly easy to obtain expressions for z_1/z_o by using the terminology of Figure 2 and the usual assumptions: $\tau/\rho = \bar{u}_*^2$ and $\bar{u}(z_o) = 0$.

For the "Christoffersen type model" (Figure 2A) we have :

$$\nu_c = \begin{cases} K\bar{u}_* z_o F & , \quad z < L \\ K\bar{u}_* z & , \quad z > L \end{cases} \qquad (5)$$

and hence :

$$\frac{d\bar{u}}{dz} = \frac{\bar{\tau}/\rho}{\nu_c} = \begin{cases} \dfrac{\bar{u}_*}{Kz_oF} , & z < L \\ \dfrac{\bar{u}_*}{Kz} , & z > L \end{cases} \qquad (6)$$

which with $\bar{u}(z_o) = 0$ gives :

$$\bar{u}(z) = \begin{cases} \dfrac{\bar{u}_*}{KF}(z/z_o - 1) , & z < L \\ \dfrac{\bar{u}_*}{K}\ln(z/z_1) , & z > L \end{cases} \qquad (7)$$

The value of z_1 is found by matching the two expressions at $z = z_oF$. We find

$$z_1/z_o = \frac{L}{z_o} e^{(1 - L/z_o)/F} \qquad (8)$$

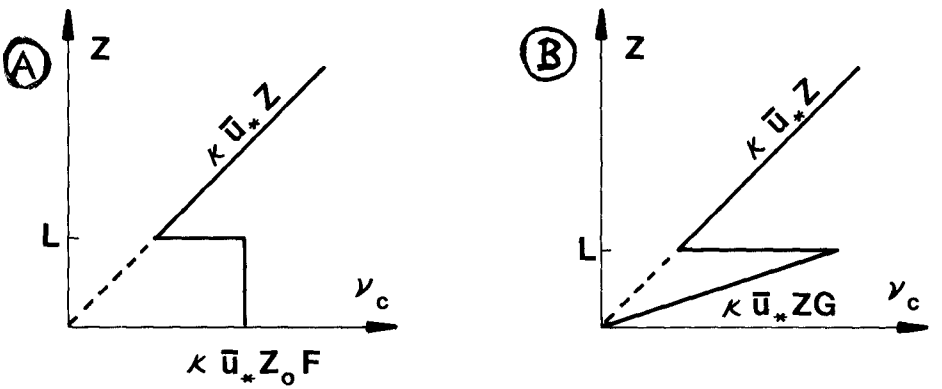

Figure 2 : Two simple previous models for ν_c in combined flows and the resulting apparent roughness change.

The analogous calculations for the model outlined in Figure 2B lead to :

$$z_1/z_o = \left(\frac{L}{z_o}\right)^{1-\frac{1}{G}} \qquad (9)$$

The two results are interestingly similar in that both expressions are assympthotically proportional to L/z_o for large values of the wave-induced eddy viscosity (large F or G). This is very interesting in view of the fact that both Christoffersen and Grant and Madsen hypothesised that L should be closely related to the wave boundary layer thickness δ. If that was true, the formulae (8) and (9) would indicate that z_1/z_o depend mainly on δ/z_o. The available laboratory data do not support this. See Figure 3.

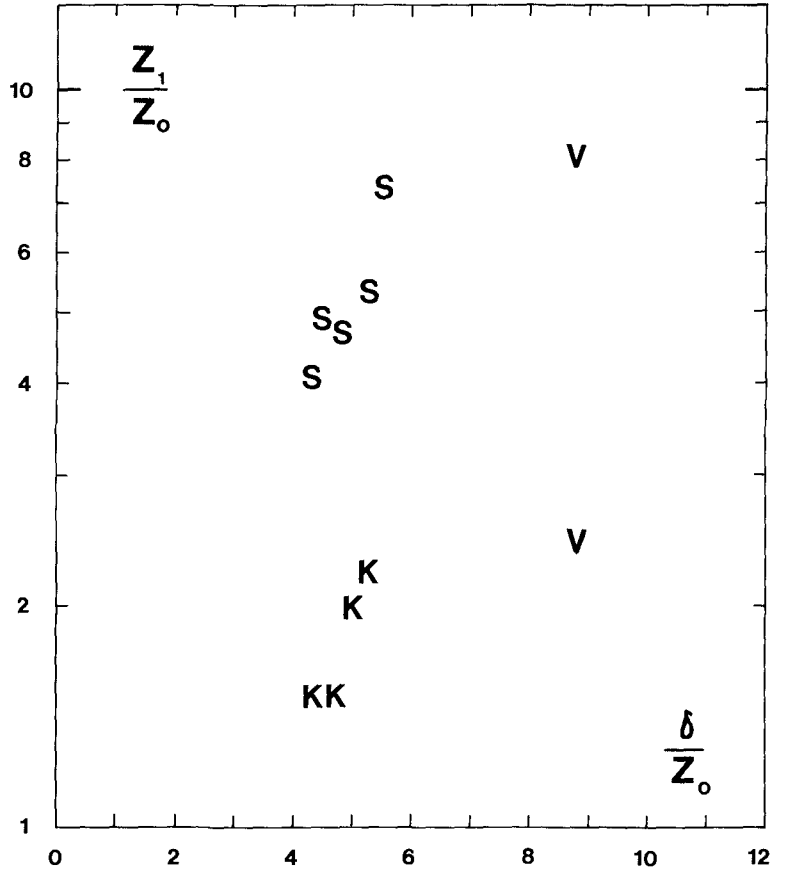

Figure 3 : Apparent roughness increase as function of dimensionless wave boundary layer thickness.

However, as Figure 4 shows, z_1/z_o depends almost exclusively on the friction velocity ratio $\tilde{u}_*/\bar{u}_*$. Such dependence will result if the thickness of the wave influenced layer has the form :

$$L = z_o F(\tilde{u}_*/\bar{u}_*) \qquad (10)$$

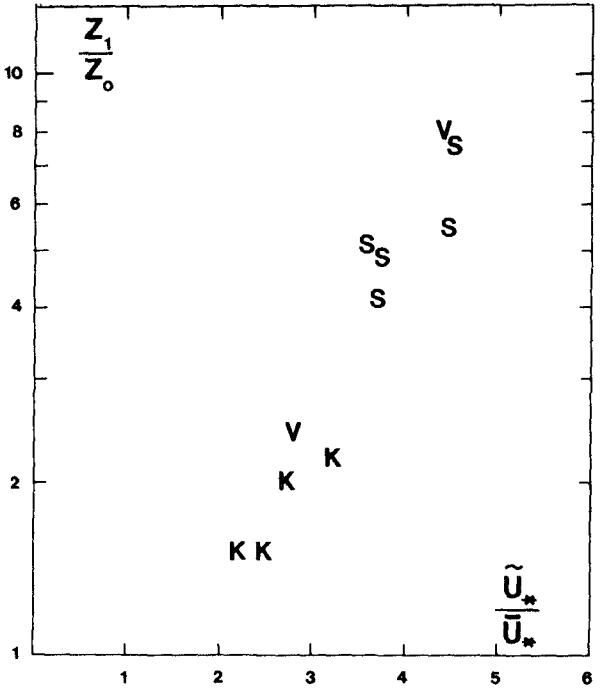

Figure 4 : Apparent roughness increase as function of the friction velocity ratio.

In the following we shall develop a simple model which is in accordance with this empirical observation and in good agreement with the available laboratory data in general. The experimental data used are summarised in Table 1.

AN EMPIRICAL MODEL

The empirical observations above support the eddy viscosity model outlined in Figure 5.

The square toe has been chosen primarily because it allows ν_c and thus the current gradient to be continuous functions of z. But also because there is some evidence (Kemp and Simons, 1982, and van Doorn, 1981, 1982) that it is somewhat more realistic than the triangular one, at least for relative roughnesses (r/A) corresponding to natural sand ripples. (See Figure 6.)

	S	1.0	0.024	0.025	0.014	0.0061

Table 1 : Experimental data

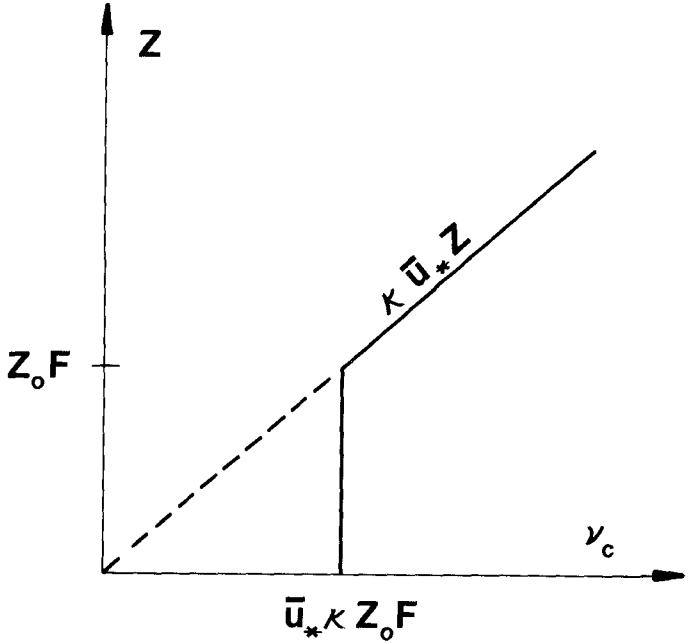

Figure 5 : Proposed distribution of the eddy viscosity felt by a steady current in the presence of waves. F is a function of the friction velocity ratio ($\tilde{u}_*/\bar{u}_*$) and possibly of the angle between current and wave propagation.

The values of ν_c observed in the horizontally homogenous layer ($z > 0.4$ centimetres) show good agreement with the form hypothesised in Figure 5.

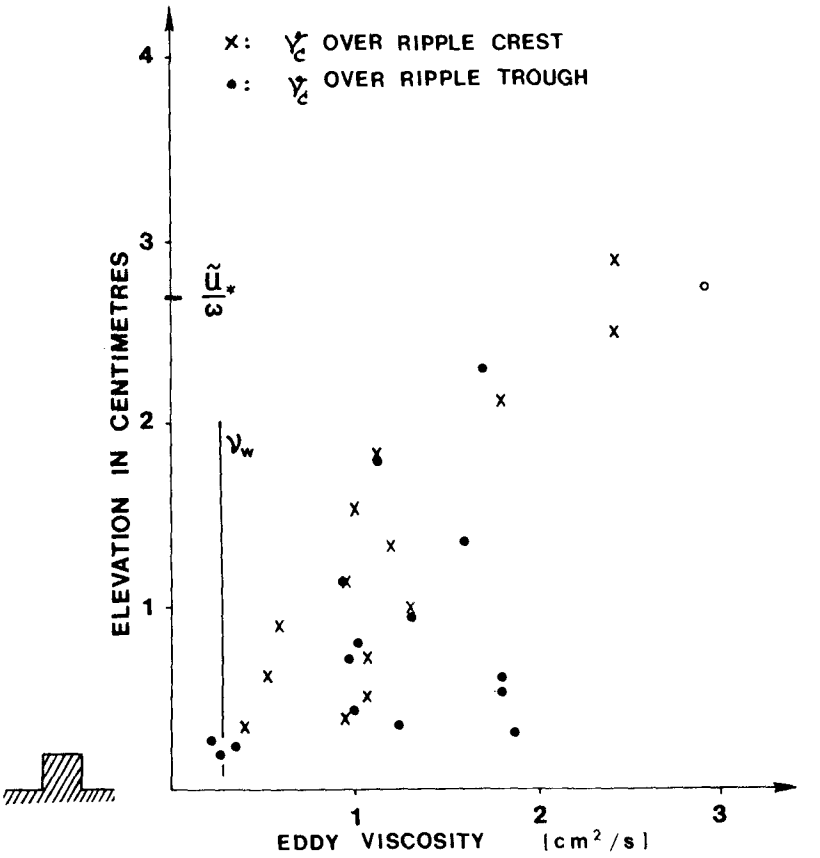

Figure 6 : Observed eddy viscosities from van Doorn (1982), Test S10. The eddy viscosity applicable to the waves (ν_w^+) is derived in accordance with Nielsen (1985) eqs 31-34.

A finite value of the eddy viscosity at the theoretical (or averaged) bed level is appropriate for rough beds. See e.g. Kajiura (1968).

With the eddy viscosity given by :

$$\nu_c^+ = \begin{cases} K\,\tilde{u}_* z_0 F & \text{for} \quad z < z_0 F \\ K\tilde{u}_* z & \text{for} \quad z > z_0 F \end{cases} \qquad (11)$$

and assuming $\overline{\tau} = \overline{u}_*^2$, we get :

$$\frac{du}{dz} = \begin{cases} \overline{u}_*/(Kz_oF) & \text{for} \quad z < z_oF \\ \overline{u}_*/(Kz) & \text{for} \quad z > z_oF \end{cases} \tag{12}$$

and with $\overline{u}(z_o) = 0$, we get :

$$\overline{u}(z) = \begin{cases} \frac{\overline{u}_*}{KF}(z/z_o - 1) & \text{for} \quad z < z_oF \\ \frac{\overline{u}_*}{K}\ln(z/z_1) & \text{for} \quad z > z_oF \end{cases} \tag{13}$$

from which z_1 can be found by matching the two expressions at $z = z_oF$. We find

$$\frac{z_1}{z_o} = F e^{\frac{1}{F}-1} \tag{14}$$

Values of the function $F = F(\tilde{u}_*/\overline{u}_*)$ which must tend towards unity for small $\tilde{u}_*/\overline{u}_*$ have been plotted in Figure 7 and for predictive purposes the curve

$$F = 1 + \frac{1}{6}(\tilde{u}_*/\overline{u}_*)^3 \tag{15}$$

has been fitted to the data.

The form of (15) is rather different from what would result from the hypotheses of Lundgren and Grant and Madsen for combined eddy viscosity, and the underlying mechanics are not understood in detail so applicability outside the experiemental range $\tilde{u}_*/\overline{u}_* < 5$ cannot be guaranteed. Also, future experimental data with different angles between current and wave propagation may call for incorporation of φ-dependence, i.e. $F = F(\tilde{u}_*/\overline{u}_*, \varphi)$.

PRACTICAL APPLICATION

In most practical cases, the problem is to estimate the current profile $\overline{u}(z)$ from knowledge of the bed roughness r and the velocities A_ω and $\overline{u}(z_r)$ at only one reference level z_r, normally one metre above the bed.

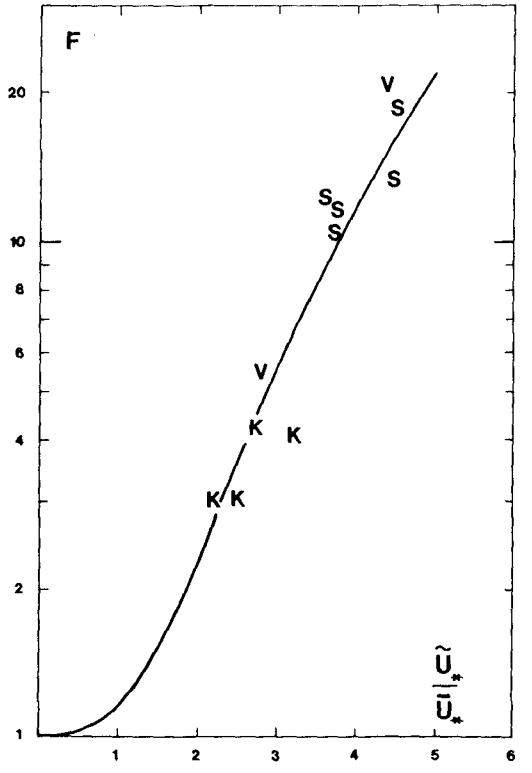

Figure 7 : Observed values of F. The curve corresponds to equation 15.

Thus $\bar{u}_*$ is unknown and must be determined iteratively from :

$$\bar{u}(z_r) = \frac{\bar{u}_*}{K} \ln \frac{z_r}{z_1} \qquad (16)$$

with the use of (14) and (15) or the direct approximation

$$z_1/z_o = 1 + 0.06\ (\tilde{u}_*/\bar{u}_*)^3 \qquad (17)$$

which leads to

$$\bar{u}(z_r) = \frac{\bar{u}_*}{K} \ln \frac{z_r}{z_o\ (1 + 0.06\ (\tilde{u}_*/\bar{u}_*)^3)} \qquad (18)$$

EXAMPLE

As an example, consider the experiment V10 from van Doorn (1981): The Nikuradse bed roughness is r = 0.021m and measurements at z_r = 0.05m give $A\omega$ = 0.257 m/s and u(0.05) = 0.090 m/s. The wave period is 2 seconds so we find A = 0.082m and hence :

$$f_w = 0.37\ (r/A)^{2/3} = 0.149 \qquad (19)$$

(Kajiura 1968) and :

$$\tilde{u}_* = \sqrt{0.5 f}\, A\omega = 0.070 \text{ m/s} \qquad (20)$$

Iterative solution of (18) then gives u_* = 0.0152 m/s, corresponding to $\tilde{u}_*/\bar{u}_*$ = 4.60 and F = 17.2. The apparent roughness increase is

$$z_1/z_o = F \exp\left(\frac{1}{F} - 1\right) = 6.7 \qquad (21)$$

and the shift of the outer velocity profile

$$\Delta\bar{u} = \frac{\bar{u}_*}{K}\ln(z_o/z_1) = -0.07 \text{ m/s} \qquad (22)$$

The velocity profile based on (13) and the above results is shown in Figure 8 together with the measured profile.

DISCUSSION

It has been shown that the apparent roughness increase (z_1/z_o) shown by the logarithmic part of current profiles in the presence of waves is mainly a function of the friction velocity ratio $\tilde{u}_*/\bar{u}_*$.

An empirical model has been established which enables estimation of the lower and the logarithmic part of a current profile from knowledge of the wave conditions, the bed roughness plus either the current friction velocity $\bar{u}_*$ or the current speed at a single evaluation $\bar{u}(z_r)$.

The central idea of the model is the same as used by Lundgren (1972), Grant and Madsen (1979) and Christoffersen (1982), namely that the waves reduce the current gradients near the bed by introducing extra mixing (eddy viscosity) below a certain level L near the bed. The effect of this, relative to a situation without waves is a constant reduction $\Delta\bar{u}$ for $z > L$ which can also be interpreted as an apparent increase of bed roughness, from $30z_o$ to $30z_1$. See Figure 1.

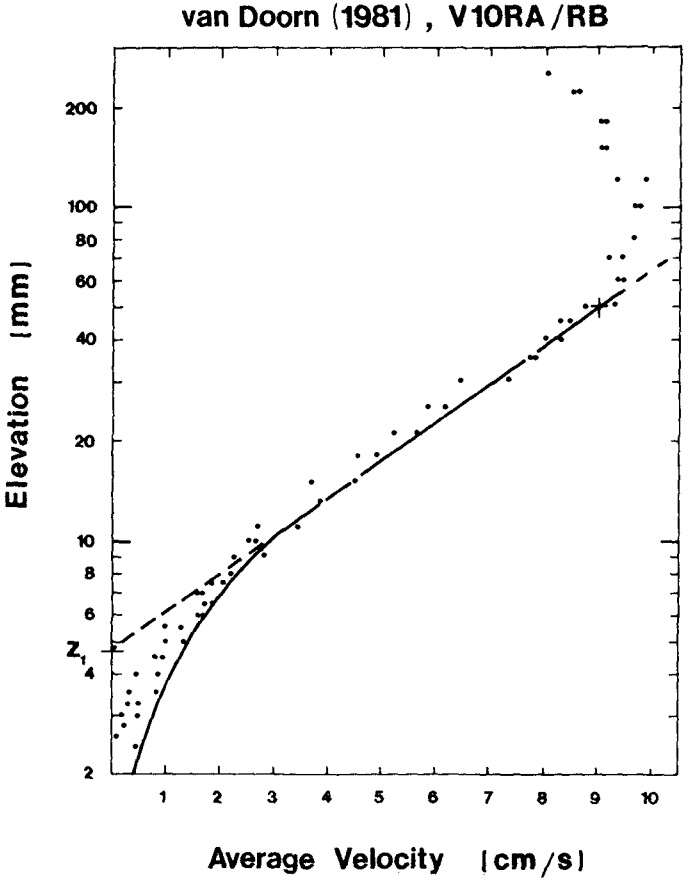

Figure 8 : Current profile predicted from the bed roughness and the velocity at a single point, $\bar{u}(0.05m) = 0.09$ m/s. Measurements by van Doorn (1981). Note that the upper part ($z > 0.07m$) of the velocity distribution is not logarithmic and therefore not covered by the model. The water depth in the experiement was 0.30 metres.

The previous idea of the bottom layer thickness L being proportional to the wave boundary layer thickness (Grant and Madsen 1979 and Christoffersen 1982) has been replaced by :

$$L = z_o \, F(\tilde{u}_*/\bar{u}_*) \qquad (23)$$

a step which is supported by the empirical data as shown in Figures 3 and 4. The conceptual separation of the wave boundary layer thickness as defined by the waves themselves and the thickness of the layer which is felt by the current to be wave influenced is essential. It is related to the fact that the vertical length scales relevant to the corresponding shear stress components are different. The length scale relevant to $\bar{u}$ is Kz, and it can grow to a considerable fraction of the flow depth. On the other hand the length scale relevant to $\tilde{u}$ is restricted to be some fraction of the wave boundary layer thickness.

Dependence of z_1/z_o on the angle between current and wave propagation has not been incorporated because experimental ver ification is not possible at the moment.

Also, the forces driving the boundary layer mass transport under progressive waves have been neglected. These are likely to dominate the profiles of weak currents (for large $\tilde{u}_*/\bar{u}_*$) but the presently available data indicate that they can be ignored for $\tilde{u}_*/\bar{u}_* \lesssim 5$.

The model is suitable for practical use within the experimental range $\tilde{u}_*/\bar{u}_* \lesssim 5$ because it is considerably simpler than previous models and in good agreement with the physical reality.

NOTATION

A	(m)	Water particle semi-excursion.
F	-	Empirical function of u_*/u_{*}, see Figure 5.
f_w	-	Wave friction factor.
L	(m)	Thickness of wave influenced layer.
r	(m)	Nikuradse roughness.
$\tilde{u}$	(m/s)	Wave induced velocity.
$\tilde{u}_*$	(m/s)	Friction velocity for waves alone.
$\bar{u}$	(m/s)	Current velocity
$\bar{u}_*$	(m/s)	Current friction velocity.
$\Delta_{\bar{u}}$	(m/s)	Wave induced current reduction.
z	(m)	Vertical co-ordinate.
z_r	(m)	Reference level.

CHAPTER 8

NEAR-SURFACE ORBITAL VELOCITIES IN IRREGULAR WAVES

K.-F. Daemrich* and A. Götschenberg**

ABSTRACT

The paper deals with measurements of horizontal orbital velocities near the surface of mechanically generated waves in a wave flume.

Due to the characteristics of most velocity probes, it is difficult or impossible to measure with a fixed probe in the area above the lowest trough. As the probe is not submerged continuously, failures or uncertainties in the measurements may occur.

To overcome these limitations, a movable frame for the velocity probe was designed, which can be moved vertically up and down with the surface elevation by a disc rotor servo motor, controlled by a wave gauge. By that continuously velocities up to 3 cm below the surface could be measured.

Theoretical velocities have been calculated for comparison with different simulation methods for irregular waves, based on linear wave theory.

INTRODUCTION

Investigations and measurements of orbital velocities have been conducted for a long time. Whereas the most earlier publications were related to investigations in regular waves to check the various wave theories, the subsequent dealt with the development of simulation methods for the theoretical treatment of irregular waves. Especially the velocities in very steep and breaking waves have always been an important subject of investigations and the research on the influence of the directionality will extend, as adequate test facilities for the generation of directional waves are available now.

Due to the characteristics of most velocity probes, however, in general measurements close to the surface of the waves, especially in the wave crests, are difficult or impossible when the probe is fixed at a certain height above the lowest trough. The sensor is submerged then only a short time (especially in scaled model tests) what might create problems due to the time constants of the instrumentation or disturbing air enclosures.

* 1) Dr.-Ing., Senior Research Engineer
** 2) Dipl.-Ing., Research Engineer
both Franzius-Institut, University of Hannover, FRGermany

Earlier own measurements in irregular waves with inductive type probes had to be restricted to this area, too, and recently in a publication of SVENDSEN (1986) on surf zone turbulence it is summarized that "all investigations have concentrated on the region below trough level where measurements are available".

To overcome these limitations and to be able to perform investigations on velocities in the crest area of irregular waves, a vertical movable frame for the velocity probe was constructed. This frame can be moved up and down with the variation of the water surface by a disc rotor servo motor controlled by the output of a wave gauge. So the velocity probe is always submerged and able to measure velocities very high in the wave crest.

INSTRUMENTATION

The vertical movable frame was designed for measurements in hydraulic models with wave heights up to about 0.50 m, equivalent to the range of the often used wave gauges of the DELFT type.

It consists of a U-profiled aluminium bar sliding between guide rollers and driven via toothed rack and pinion directly connected to the servo motor (120W rated output power). A flat coil spring is used to compensate for the weight of the movable parts and the velocity probe.

Figure 1 gives a principal sketch of the set-up in the wave flume.

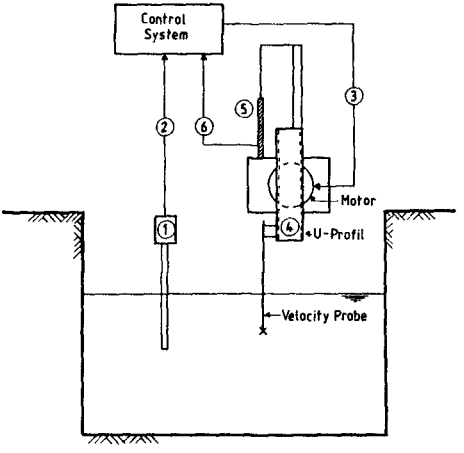

Fig. 1: Principal sketch of set-up of vertical movable frame in the wave flume

The wave gauge (1) measures the actual surface elevation of the water. Its output signal (2) provides the electronic control system which generates the set value (3) for the servo motor. The U-profiled aluminium bar (4) with the velocity probe fixed at the lower

end (and connected to the motor via toothed rack and pinion) is moved up and down by the servo motor following the set value (3). The potentiometer transducer (5) gives the actual position (6) of the U-profile (4) to the control system (actual value) and allows also to compare surface elevation and position of the probe for analysis purpose.

Figure 2 shows the device and the electronic control system, Figure 3 the set-up in the wave flume, fixed to a measuring carriage.

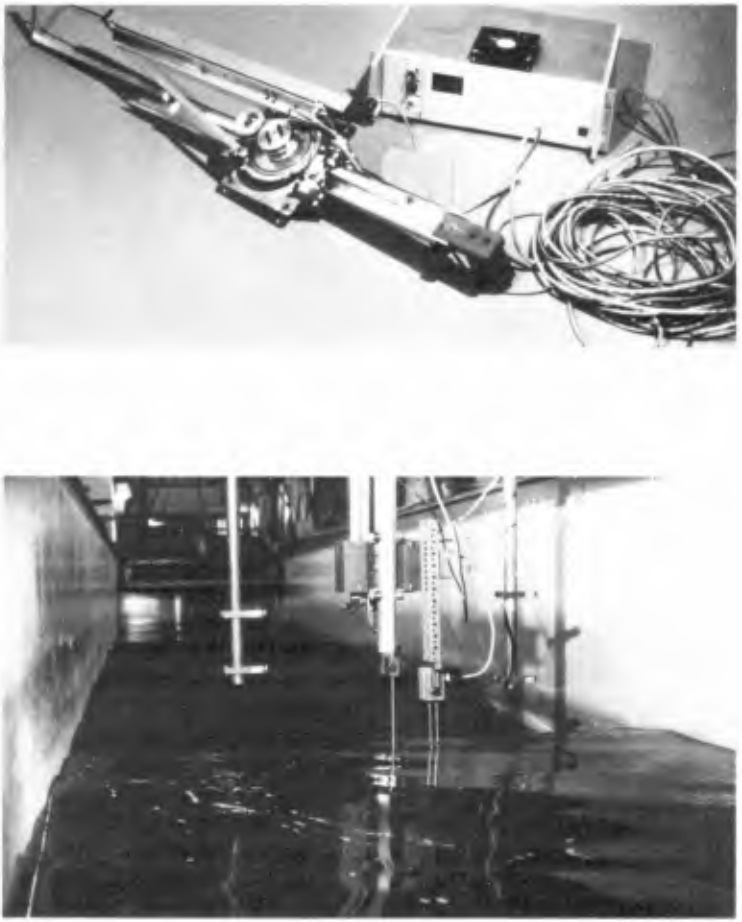

Fig. 3: Set-up of vertical movable frame in the wave flume

For a certain test, the movable frame is mechanically placed in a middle position and the velocity probe is shifted to the pretended submerged depth in still water conditions. After starting the tests the probe is then moved up and down with the surface elevation, measuring in positions approximately parallel to the surface.

Due to the characteristics of the electronic control system, the measured location is not exact constant below the wave surface. However, from the potentiometer transducer, the position of the probe can always be determined and related to the signal from the wave gauge. So the exact position as a function of time is available.

As an example, which demonstrates at the same time the limits of the system, in Figure 4 the time series of water level and probe location, and the difference between both signals, are plotted. The wave train was measured in the area of a 1:30 slope and contained steep and some breaking waves.

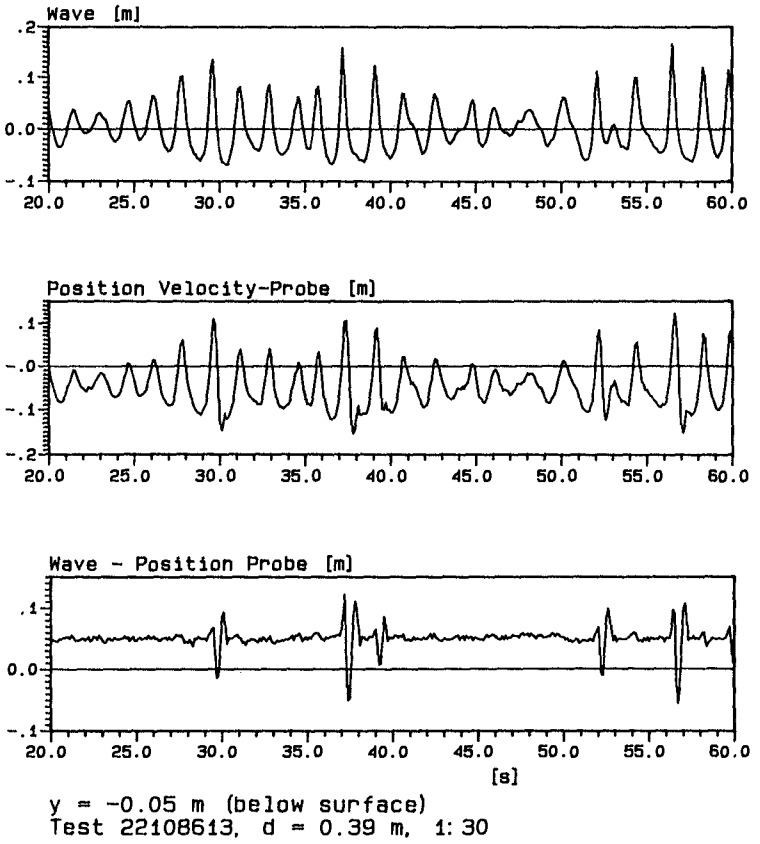

Fig. 4: Comparison of surface elevation and probe location

In the not extreme steep waves the system works with deviations of less than 1 cm. However, in the very steep waves, with the present layout of the motor and the control electronics, the system works not yet satisfying. For further measurements in steep and breaking waves, the system has to be improved by taking a stronger motor and a controller of better quality.

Finally in Figure 5 examplarily maxima (crest) and minima (trough) of the wave time-series and of the time-series of the position of the probe are compared in scatter plots.

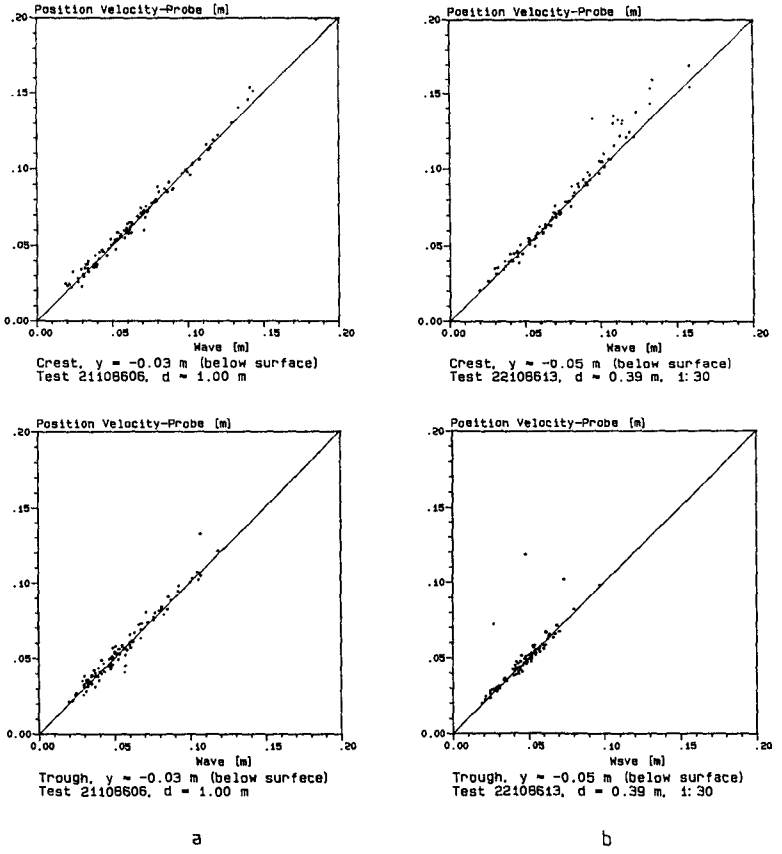

Fig. 5: Comparison of extremal values of wave surface in crest and trough and pertinent position of the probe
a) moderate wave conditions, design condition for equipment
b) very steep and breaking waves

As the motor of the system can be controlled by any external signal, the equipment can also be used for a dynamic calibration of the velocity probes. For the tests discussed in the following, a Delft Propeller Probe was used as a velocity probe. However, also a Minilab SD-12 system was available and included in the test series.

HYDRAULIC BOUNDARY CONDITIONS

The measurements discussed in the following were performed in the wave flume of the FRANZIUS-INSTITUT. The total length is about 120 m, the width 2.20 m. At the end of the flume a 1:30 slope is installed. The water depth during the tests was 1.0 m in the horizontal part.

The results presented here are from a JONSWAP spectrum with

Peak enhancement factor	$\gamma = 3.3$
Spectral peak period	$T_p = 1.8$ s
Significant wave height	$H_{m0} = 0.18$ m

The control signals for the wave machine were calculated according to the random phase spectrum method with a sequence length of 204.8 s for pusher movement of the wave paddle.

Measurements were taken in two sections:
- water depth d = 1.00 m horizontal slope (no breaking waves)
- water depth d = 0.39 m 1:30 slope (some waves breaking)

The submerged depth of the velocity probe was 3, 5, 10, and 15 cm below actual water surface with the moving frame and for comparison, 25 cm and 50 cm below mean water with a fixed height of the probe.

RESULTS OF THE TESTS

During the tests, time-series of waves, horizontal velocities, and probe locations were measured simultaneously. An HP1000/A600+ computer system was used for data acquisition and analysis.

Theoretical results, based on linear wave theory, have been calculated for comparison, with simulation methods described in detail in earlier publications (DAEMRICH, EGGERT, KOHLHASE (1980), DAEMRICH, EGGERT, CORDES (1982)).

In general for the analysis of such tests the transfer function method (or linear filtering method) would be prefered. With this method the theoretical velocity is calculated from the FOURIER coefficients of the wave train, by applying the linear transfer function and getting the time-series by an inverse FOURIER transformation.

For the measurements with the probe location varying with the surface elevation, however, this method leads to a considerable extension of the computer work, and it was decided to use for the present the complementary method, a simulation method in the time domain, which gives results of similar quality, at least in the more pronounced waves. In this method, the maxima of the orbital velocities under crest and trough of a wave were calculated from half-wave parameters. For the horizontal velocities, this half-wave

parameters are the amplitude of a wave crest or a wave trough (zero crossing wave crest height a_C and zero crossing wave trough excursion a_T) and the pertinent half-period (crest period T_C and trough period T_T). The parameter designation is according to the List of Sea State Parameters, IAHR (1986). For further explanations and definition sketches see DAEMRICH et al.(1980), (1982).

As an example, in Figure 6 measured and calculated horizontal velocity maxima for a constant submerged depth of the probe of y = 0.25 m below the mean water level are computed and plotted in scatter diagrams. It is obvious, that there is not to much difference in the tendency.

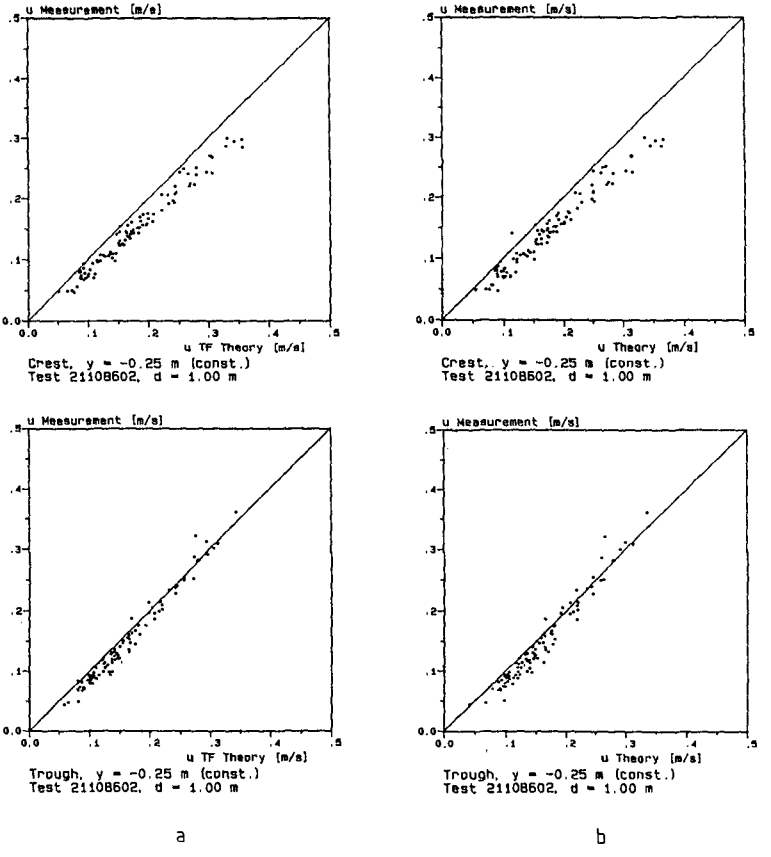

Fig. 6: Comparison of measured and calculated maxima of horizontal orbital velocities in constant submerged depth (y = 0.25 m)
a) Transfer function method b) Complementary method
upper Part: Velocities under the crests
lower Part: Velocities under the troughs

Well known and typically is the tendency of overestimating the velocities under the crests and underestimating the velocities under the troughs, which is somewhat more pronounced in the complementary method. This general deviation in the theoretical results is due to using linear wave theory without any modifications as e.g. stretching of coordinates.

In Figure 7 a part of a measured wave time-series is plotted together with theoretical velocity profiles for crests and troughs of individual waves and measured velocities 3, 5, 10, and 15 cm below the actual surface elevation. For comparison results from measurements in constant submerged depths of 25 and 50 cm below mean water level are inserted.

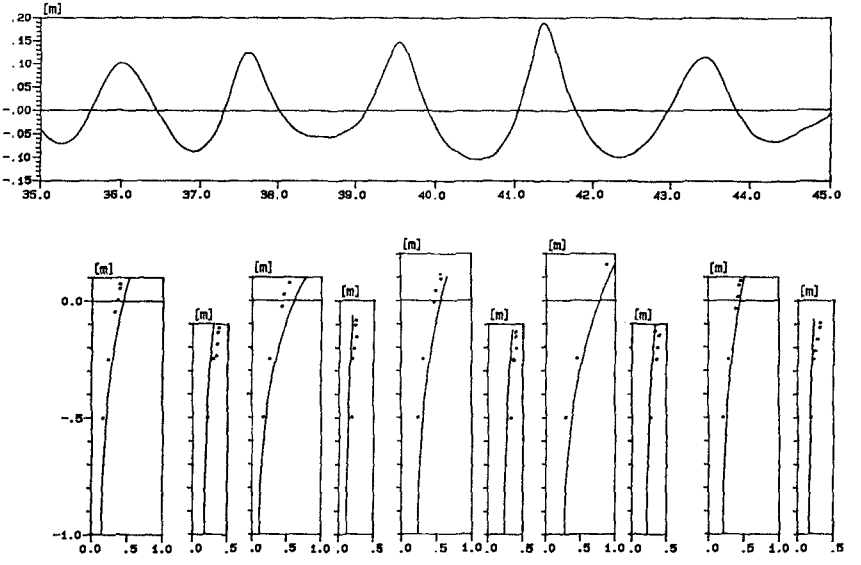

Fig. 7: Velocity profiles in crests and troughs of irregular waves (Theory: Complementary method)

The overestimation of velocities under the crests and the underestimation under the troughs are clearly visibel, however, under these wave conditions there is no change in the general trend closer to the surface.

In Figure 8 and 9 results from the complete time-series are shown as scatter plots. Compared are maxima of measured and theoretically calculated velocities in various submerged depth (upper part: wave crest data, lower part: wave trough data).

Figure 8 gives results measured in the horizontal section of the flume (water depth of 1.0 m), 10, 5, and 3 cm below the surface. The scatter of the data is not too high, also compared to earlier measurements. Overestimation and underestimation are more pronounced closer to the surface.

In Figure 9 similar results are plotted from measurements with the same wave train, but measured in 0.39 m waterdepth in the area of the 1:30 slope. Due to the steeper waves the minimum submerged depth of the velocity probe was 5 cm to avoid surfacing, the maximum submerged depth was 10 cm to avoid bottom contact. To show the trend, results from measurement in a constant submerged depth of 25 cm were added. The scatter of the data measured near the surface has increased due to some very steep or just breaking waves. The highest velocities are measured in a few just breaking waves.

MODIFICATION OF LINEAR WAVE THEORY

To consider the problem of overestimation and underestimation for design purpose the theoretical calculations were conducted exemplarily with a modification of the linear wave theory, similar to the stretching of coordinates (WHEELER (1969)).

Instead of using the actual location of the velocity probe to calculate theoretical values, e.g. 3 cm below surface elevation, we have assumed a constant location of the probe of 3 cm below mean water level for the calculation of the maxima of the near-surface orbital velocities. By this modification, the trend of over- and underestimation is clearly diminished in the complementary method and almost compensated when using the transfer function method as a simulation method.

In Figure 10 scatter diagrams are plotted exemplarily with results of those calculations.

Methods of modification of wave theories, however, have to be tested further for general application. But with the results of several contributions presented at this conference, there seems to be a good chance for simulation methods on the basis of linear wave theories.

ACKNOWLEDGEMENT

The investigation described in this paper was carried out as part of the research programme of the Sonderforschungsbereich 205 at the FRANZIUS-INSTITUT for Hydraulic Research and Coastal Engineering, University of Hannover. The authors gratefully acknowledge the Deutsche Forschungsgemeinschaft for their financial support throughout the investigations.

CHAPTER 9

Transformation of Random Breaking Waves on Surf Beat

by

William R. Dally[1] and Robert G. Dean[2]

ABSTRACT

Based on a previous study by the authors of regular breaking waves in the surf zone, a model for random wave transformation across the nearshore region is developed. The results of a laboratory investigation of the effect of a steady opposing current on the wave decay process are presented and a proposed governing equation verified. Surf beat effects on wave transformation are then included in the model by representing the long wave as a temporally and spatially-varying current and mean water level. The concept of an equivalent water depth, which contains the effect of the current, is introduced and then included in a stochastic form in the random wave model. Surf beat is found to noticeably increase the decay of the root mean square wave height, especially in the inner surf where the beat is strongest. Comparison of the models to two field data sets show very good agreement for Hotta and Mizuguchi (1980), but rather poor for Thornton and Guza (1983). Possible explanations for the unexpected behavior of the second data set, pertaining to filtering, are discussed. Finally, a possible explanation for the dependence of random wave decay on deepwater steepness, noted by Battjes and Stive (1985), is presented.

INTRODUCTION

The major goal of this effort is to predict the transformation of the probability density function (pdf) of wave height as random waves cross the nearshore region and surf zone. Secondary goals include investigation of the interaction of currents with the shoaling and breaking process, as well as the effects of mean wave steepness, beach slope, and surf beat on random wave transformation. Most previous invesigations, e.g. Collins (1970), Kuo and Kuo (1974), Battjes and Janssen (1978), and Thornton and Guza (1983), assume the Rayleigh pdf (or somewhat contrived modifications thereof), is valid in the surf zone. However, this assumption is not supported by laboratory and field data, with the possible exception of the measurements taken

during the Nearshore Sediment Transport Study (NSTS) and analyzed by Thornton and Guza (1983).

The models described herein start with the Rayleigh pdf well outside the surf zone, but then numerically transform the pdf over beach profiles of arbitrary shape using the authors' regular wave model (Dally, Dean, and Dalrymple, 1984,85). A laboratory study of regular breaking waves on opposing currents is briefly reviewed and the resulting governing equation presented. Surf beat is then included in the numerical model by introducing an equivalent water depth approach. Finally, it is shown how some "observed" behavior of laboratory and field data reported in the literature might be a manifestation of 1) the analysis technique used, and/or 2) assuming a Gaussian sea in the surf zone, i.e. assuming $H_{rms} = \sqrt{8m_o}$ where H_{rms} is the root mean square wave height and m_o is the area under the energy spectrum.

RANDOM BREAKING WAVE MODEL

Formulation The basic concept of the random wave model is, starting with a known histogram of wave height at some offshore location, transform each representative wave in the histogram as if it were regular, i.e. assume there is no wave-wave interaction and let each wave shoal, reach incipient breaking, break, reform, etc. independently. Because wave period will be required to determine incipient breaking, the joint distribution of wave height and period for waves in deep water derived by Longuet-Higgins (1983) is adopted as an initial condition. This joint pdf, which yields a marginal pdf for wave height that is nearly Rayleigh in shape, is discretized into a histogram of 3600 bins, each with a representative wave height, period, and probability weight, w. Each representative "wave" is then transformed according to an improved version of the authors' numerical regular wave model.

In this new version, the approximate solution to the dispersion relation for linear waves provided by Nielsen (1984) is utilized to calculate the change in wave height due to shoaling, and the incipient breaking condition is explicitly defined as described in Moore (1982). This empirically based condition is a function of deepwater height, wave period, and local beach slope and is a hybrid of the expressions of Weggel (1972) and Komar and Gaughan (1972). The breaker decay is then calculated using the authors' previous scheme (1984,85) which was calibrated to laboratory data and is applicable on beach profiles of arbitrary shape.

On realistically-shaped bottom profiles, the question arises as to the definition of the effective beach slope, especially when bar/trough systems are present. Based on laboratory tests conducted at the University of Florida, it was observed that the bottom slope just seaward of the break point more directly affected the breaking characteristics in the trough than the local bottom configuration. Consequently, the beach slope used in determining incipient breaking is calculated by averaging the slope over the section just seaward of the point of interest, for a distance of one wave length. The negative slopes occurring on the landward side of a bar are treated as zeros in the averaging process.

Finally, at each location on the profile, the 3600 transformed waves are then ordered according to wave height from smallest to largest using a fast, "heap", sorting routine (Williams (1964)). From this ordered set of heights and associated probability weights, the behavior of any desired statistically representative wave can be calculated and monitored across the surf zone.

The information required to run the model consists of 1) root mean squared wave height and band width parameter, (ν) at the starting location, and 2) the bottom profile. If the spectrum is not available for calculating the moments required to determine the band width parameter (Longuet-Higgins, 1983) a value of ν=0.3 is used for gentle swell conditions and ν=0.6 for "confused" or storm conditions. It should be noted that the concept of addressing random wave transformation in the surf zone by monitoring a set of regular waves was also utilized by Mase and Iwagaki (1982). However, their model was limited to planar beaches, and differs significantly in the details.

Verification The random wave model was tested against the field data sets of Hotta and Mizuguchi (1980) and Thornton and Guza (1983). Hotta and Mizuguchi filmed a series of sixty wave staffs established at 2 to 3 m intervals across the surf zone. The measured bottom profile contained a large bar/trough formation, but unfortunately the cameras documenting the trough area failed during the experiment. Nevertheless, it is still an excellent data set. The bottom profile and transformation of several statistically representative waves (H_{rms}, $H_{1/3}$, $H_{1/10}$) are displayed in Figure 1. The model-predicted results generated using the values for the empirical coefficients as found in the laboratory calibration of the regular wave model (K=0.15, Γ=0.40) are also shown. The agreement is quite satisfactory, except for $H_{1/10}$ and perhaps $H_{1/3}$ in the region just seaward of the surf zone. It is believed this discrepancy is because linear theory underpredicts the rate of shoaling in shallow water, especially for waves of low deepwater steepness. Using a nonlinear theory would increase the peak value of the statistically representative wave and shift its location seaward. Even though a gap in the data in the trough region prevents verification of the wave reformation aspects of the model, the favorable comparison landward of this section lends support to the stable wave assumption of the original regular wave model (1984,85). It is noted that the random wave model predicted that the majority of the waves reformed in the trough, consistent with visual observations made during the experiment.

Figure 2 displays comparison of the transformation of the histogram of wave height as reported by Hotta and Mizuguchi (1980) with results of the model. Wave height has been nondimensionalized by the local average wave height, $\bar{H}$. Note that the Rayleigh distribution represents the actual initial histogram fairly well (station 57) but would not compare well at stations in the inner surf zone. The basic shape of the predicted pdf appears correct, especially for $(H/\bar{H}) > 1.0$. However, in the inner surf zone the model overpredicts the number of waves near $(H/\bar{H}) = 1.0$ and underpredicts for $(H/\bar{H}) < 1.0$.

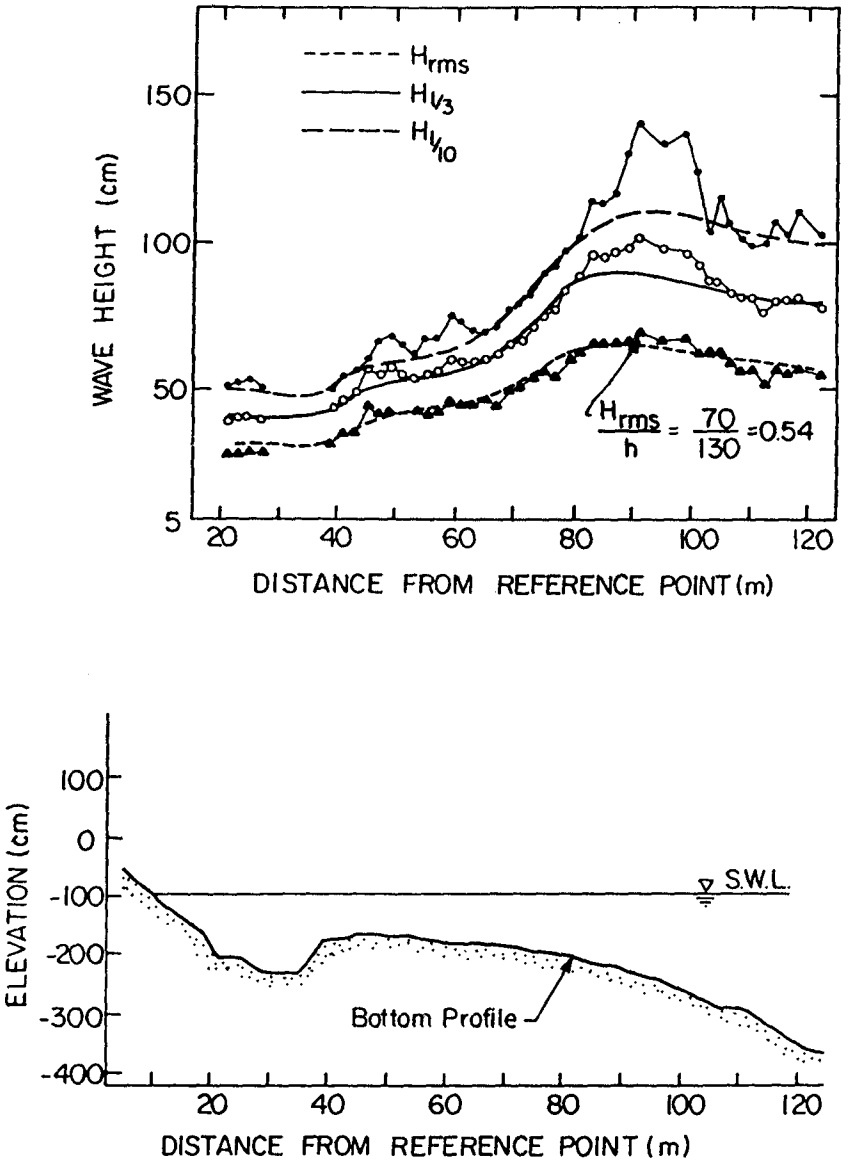

Figure 1. Comparison of transformation of statistically representative waves between model and field data of Hotta and Mizuguchi (1980).

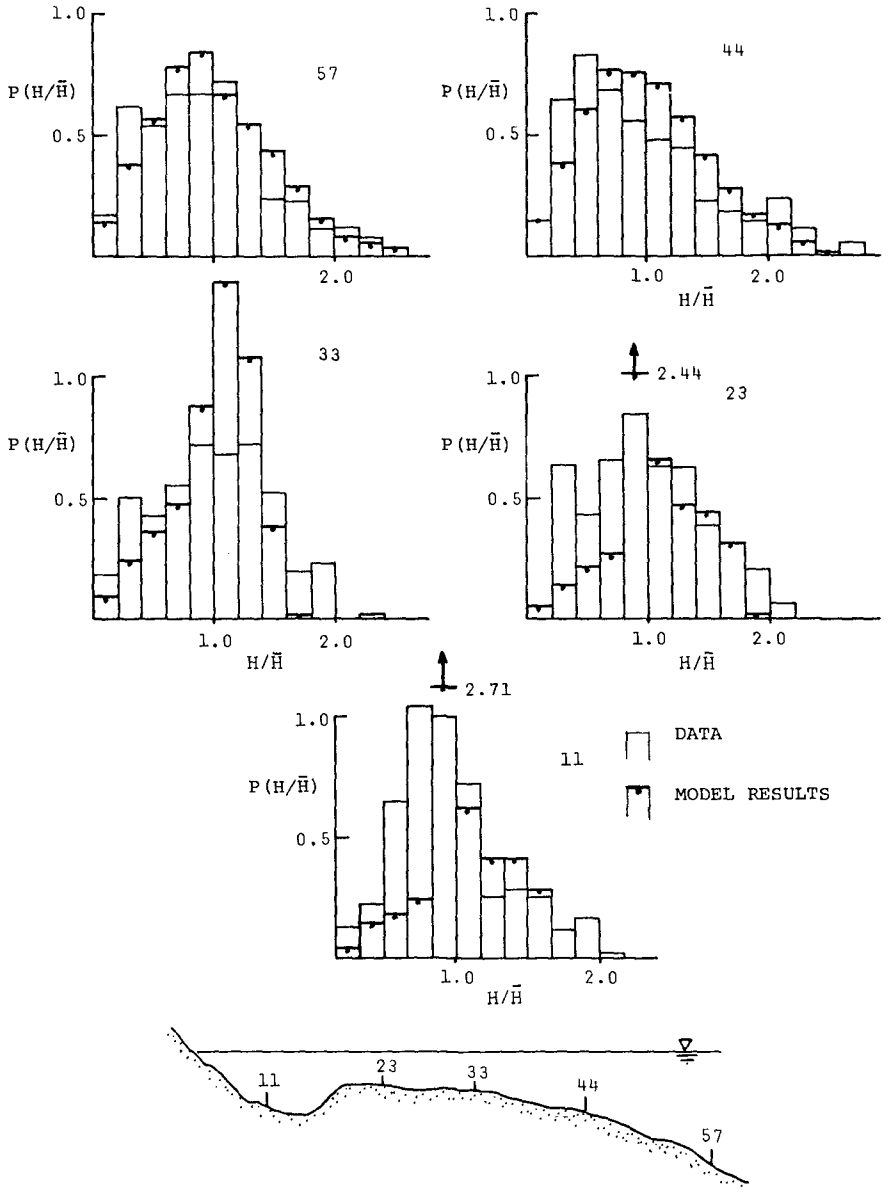

Figure 2. Comparison of transformation of histogram of wave height between model and field data of Hotta and Mizuguchi (1980).

Thornton and Guza (1983) analyzed measurements taken by resistance wire wave staffs, electromagnetic current meters, and pressure sensors during a NSTS field experiment. A typical sample of their results for the transformation of H_{rms} is presented in Figure 3 along with the local beach profile. The model comparison is also displayed, and one can see that it shows a significant discrepancy from the data. It should be pointed out that the point where H_{rms} begins to decay in the data seems to occur much farther seaward than is realistic. The mean water depth at this point was reported as 279 cm and the local ratio of H_{rms} to h was 72/279 = 0.26, which is less than half the value of the Hotta and Mizuguchi data (70/130 = 0.54). Also, it is noted that in histograms of wave height provided by Thornton and Guza, the largest wave never exceeded three times the deepwater H_{rms}, i.e. the largest wave observed anywhere during the test was approximately 168 cm in height. If this wave was just starting to break with an incipient condition H/h of say 0.78, the water depth would be about 215 cm, which is 64 cm shallower than the depth where H_{rms} began to decay.

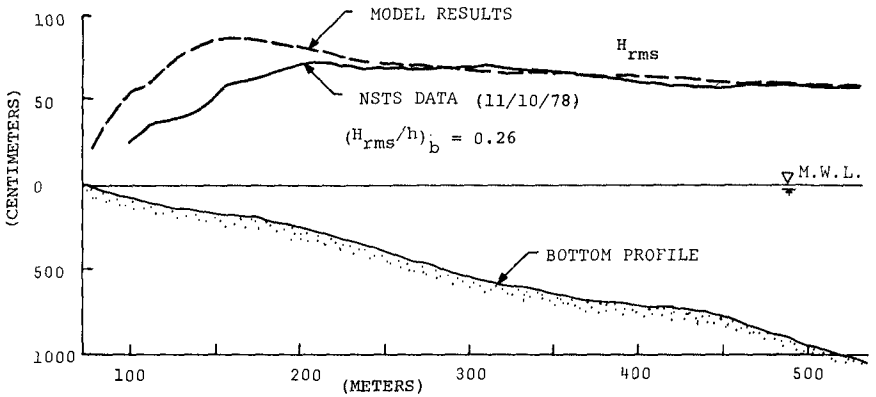

Figure 3. Comparison of transformation of H_{rms} between model and field data of Thornton and Guza (1983).

From the above observations, it is apparent that some phenomenon not included in the model and not present during Hotta and Mizuguchi's experiment was causing wave decay to occur sooner than expected. This phenomenon may be real, or an artifice of the measurement/analysis technique. A real phenomenon to which the majority of the remainder of this paper is devoted, is the interaction of wind waves with long waves such as surf beat. It is hypothesized that during the phase of the beat where the long wave water particle velocity opposes the incident waves and/or the mean water level is depressed, shoaling is accelerated and breaking initiated sooner than would otherwise occur. The opposite phase will tend to stretch the short waves and suppress breaking, but because shoaling is a conservative property while breaking is not, increased decay in average energy density (i.e. H_{rms}) should be expected. The wave conditions during the NSTS experiment

were characterized by long period, very low steepness, groupy swell, and significant long wave energy was documented, at least in the inner surf zone (Guza and Thornton, 1985). During the Hotta and Mizuguchi experiment, the waves were comparable in height to NSTS, but had a peak period less than half. They were not characterized as groupy, and only a small amount of long wave energy was documented.

Another possible source of the unexpected behavior of the NSTS data may lie in the manner the data was filtered during analysis. Although the raw data was taken at a rate of 64 Hz, it was immediately low-pass-filtered to a Nyquist frequency of 1.0 Hz, which may not be sufficient to resolve the wave height for very peaked waves, nor the front face of a broken wave. Hotta and Mizuguchi (1980) recorded on film at 5.0 Hz and did not filter before determining wave height, plus they had waves that were less peaked than NSTS and could therefore better resolve the wave height. These points are discussed further at the end of the paper.

REGULAR WAVES BREAKING ON STEADY CURRENTS

Because surf beat is an order of magnitude longer and an order of magnitude smaller than the wind waves that drive it, we assume that its effect on the short waves can be closely represented as that of a slowly oscillating current and mean water level. The effect of a slowly changing water level (depth) on shoaling and breaking is of course the essence of previous studies, but the effect of a current on a breaking wave has received relatively little attention in the literature. A governing equation for energy dissipation due to breaking on a steady collinear current and changing bottom is therefore proposed, and verified to some extent with a laboratory experiment.

Governing Equation Based on Conservation of Wave Action and linear wave theory, and the intuitive expression for the rate of energy dissipation due to breaking developed by the authors (1984,85), the following governing equation is proposed

$$\frac{\partial\left[H^2(U + Cg)/\sigma\right]}{\partial x} = \frac{-K}{h}\frac{Cg}{\sigma}\left[H^2 - \Gamma^2 h^2\right] \qquad (1)$$

where H is wave height, σ, the intrinsic wave frequency (i.e. relative to the current), U, the current magnitude, Cg, the group velocity relative to the current, h, the water depth, and x, the horizontal coordinate in the direction of wave propagation. K is a decay coefficient (0.15-0.17) and Γ is the stable wave factor (0.4-0.5). The wave number, k, is given by the dispersion relation for linear waves on currents

$$\omega = \sigma + kU = (gk \tanh kh)^{1/2} + kU \qquad (2)$$

where ω is the absolute frequency. If U is zero, these expressions reduce to the original governing equation proposed by the authors.

Verification The validity of (1) was tested by comparing numerical solutions to the results of a laboratory experiment of regular breaking waves on opposing currents. Due to space limitations the experiment will not be fully described here, but Figure 4 shows typical results of wave decay and model comparisons. The proposed governing equation appears valid, especially for mild currents. The results of this investigation are now applied to surf beat.

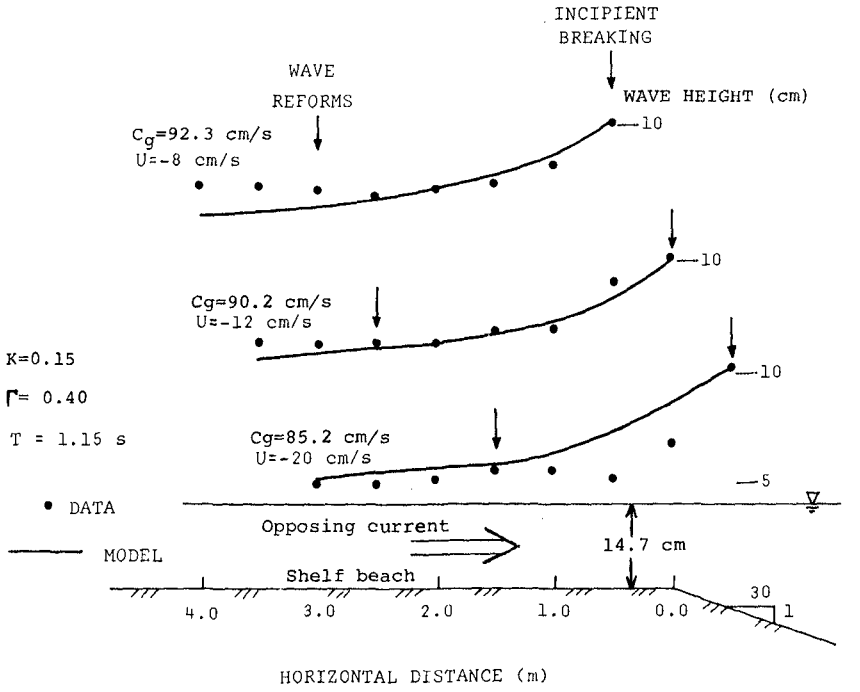

Figure 4. Sample results of wave decay on opposing currents and comparison of model (1).

RANDOM BREAKING WAVES ON SURF BEAT - THE EQUIVALENT DEPTH METHOD

The results of the laboratory investigation tend to indicate that the currents associated with surf beat are of equal or greater importance in the wave breaking process than the mean water level fluctuation. A few previous investigations have attempted to include surf beat in a random breaker model, e.g. Goda (1975) and Mase and Iwagaki (1982), but addressed only water level fluctuations.

To completely explore the problem of a short progressive breaking wave riding a partially-standing long wave, a wave tracking technique based on the method of characteristics would be required. Such a method in turn requires a time series as an initial condition, as well as complete temporal and spatial description of the surf beat.

Initial attempts found such a model numerically time-consuming, and impractical for engineering application due to the extensive input required. Therefore, a method is developed which combines the effects of the current and mean water level fluctuations, and is then included stochastically in the random breaking wave model.

Equivalent Depth The "equivalent water depth" is defined for a wave with absolute frequency ω and wave number k riding on a current as the water depth the wave would have to encounter with no current while still retaining the same wave number, i.e.

$$\omega^2 = [(gk \tanh kh)^{1/2} + kU]^2 = gk \tanh kh_e \tag{3}$$

where h_e is the equivalent water depth. A probability density function (pdf) for h_e in regards to surf beat can be developed. We first assume that the water particle velocity and mean water level associated with the standing long wave are normally distributed and uncorrelated at any location in the surf zone:

$$\text{pdf}(U,h) = \frac{1}{2\pi\sigma_u\sigma_h} \exp\left\{-\frac{1}{2}\left[\left(\frac{U}{\sigma_u}\right)^2 + \left(\frac{h-h'}{\sigma_h}\right)^2\right]\right\} \tag{4}$$

where h' is the mean mean-water level, σ_u and σ_h, are variances of the current and water level respectively.

The conditional pdf of k and h, given ω, is derived by solving the dispersion relation (2) for U and invoking a standard transformation of random variables. The joint conditional pdf of h_e and h given ω (or k_o) is then found in a similar manner by applying an approximate solution to the dispersion relation (3) given by Nielsen (1984):

$$kh_e = \sqrt{k_o h_e}\left[1 + \frac{1}{6} k_o h_e + \frac{11}{360}(k_o h_e)^2\right] \tag{5}$$

where k_o is the deepwater wave number in the absence of currents. This joint pdf is given by:

$$\text{pdf}(h_e, h/k_o) = \frac{1}{2\pi\sigma_u\sigma_h}\left|\sqrt{k_o}\left(-\frac{1}{2} h_e^{-3/2} + \frac{1}{12} k_o h_e^{-1/2} + \frac{11}{240} k_o^2 h_e^{1/2}\right)\right|$$

$$\cdot\left|(gk \tanh kh)^{1/2} - \frac{gk^2 h \operatorname{sech}^2 kh + gk \tanh kh}{2(gk \tanh kh)^{1/2}} - \sqrt{gk_o}\right| \cdot \frac{1}{k^2}$$

$$\cdot \exp\frac{-1}{2}\left[\frac{gk_o + gk \tanh kh - 2\sqrt{gk_o}(gk \tanh kh)^{1/2}}{k^2\sigma_u^2} + \left(\frac{h-h'}{\sigma_h}\right)^2\right] \tag{6}$$

where k is given by (5) as noted. A marginal pdf for h_e is then determined by integrating with respect to h over physically realistic limits (0→2h') and normalizing. In the model this is accomplished numerically using Simpson's Rule. Thus, with estimates of σ_u and σ_h, the pdf (h_e) is determined at any location across the nearshore region. An example is shown in Figure 5, where h_e has been non-dimensionalized by h'.

Stochastic Treatment of Breaking Waves on Surf Beat To include surf beat in the random breaking wave model described previously, the pdf (h_e) can be utilized to generate "equivalent profiles". In the model, the marginal probability density function of equivalent water depth at each location in the surf zone is subdivided into 10 bins of equal area, also shown in Figure 5, and the average equivalent depth of each bin is assigned to a corresponding equivalent profile. Guza and Thornton (1985) provide information from which estimates of the required variances, σ_u and σ_h, can be extracted for the NSTS experiment previously described, and several equivalent profiles are shown in dimensionless form in Figure 6.

Because of the currents, the incipient breaking condition of Moore (1982) is not applicable. A Miche-type wave steepness condition is therefore adopted to determine incipient breaking

$$\frac{H_b}{L} = 0.124 \tanh kh_e \tag{7}$$

where H_b is the wave height at incipient breaking and L the wave length. Note that when kh_e is small, (7) reduces to

$$H_b = 0.78\, h_e \tag{8}$$

In the numerical model, once incipient breaking is attained, a slightly modified form of (1) is invoked to describe wave decay

$$\frac{\partial[H^2(Cg_e/\sigma)]}{\partial x} = \frac{-K}{h'}\frac{Cg}{\sigma}\left[H^2 - \Gamma^2 h'^2\right] \tag{9}$$

where the equivalent water depth is used to calculate Cg_e on the L.H.S., and the average depth (h') used on the R.H.S. If the wave height is less than the local stable wave ($\Gamma h'$) but is greater than the incipient condition (7), the wave is simply "trimmed" to equal H_b.

Each representative wave from the original joint histogram of wave height and period is transformed across its 10 equivalent profiles and the results at each location averaged. Thus an average behavior for each wave from the original offshore histogram is calculated for given surf beat conditions.

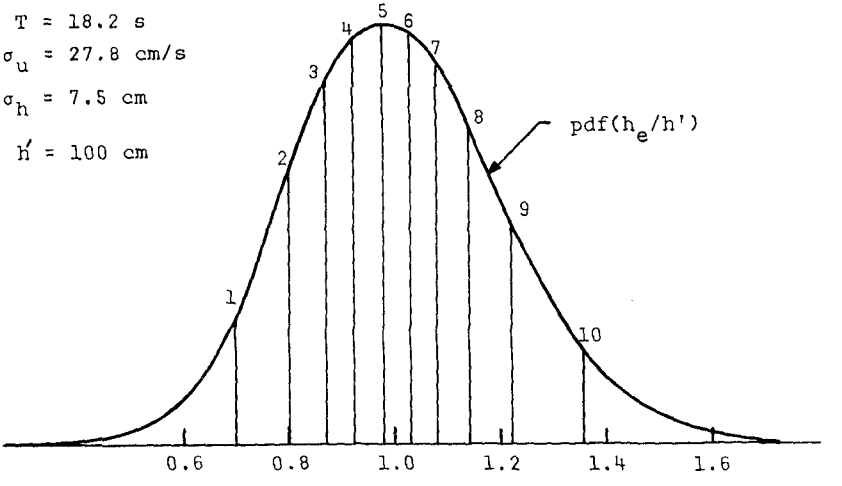

Figure 5. Example of marginal probability density function for equivalent water depth.

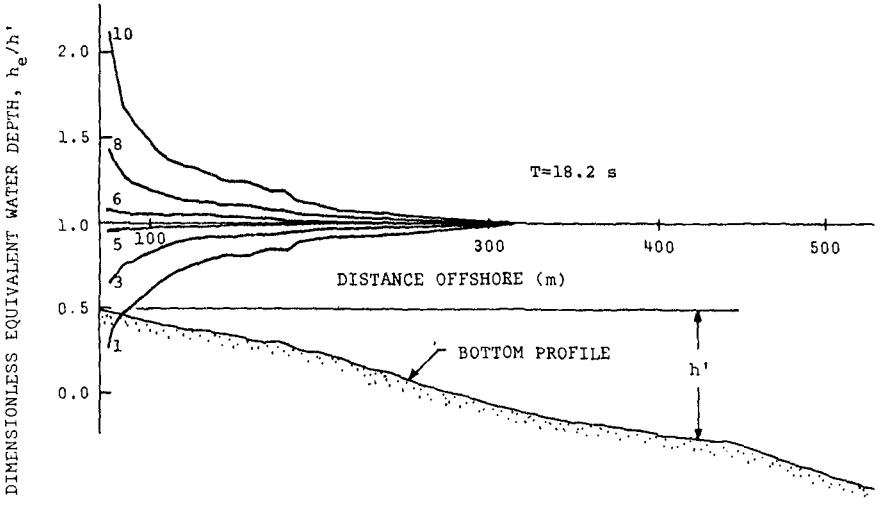

Figure 6. Example set of dimensionless "equivalent depth profiles" for NSTS data (for peak period T = 18.2 s).

Results The model including surf beat effects was run for the NSTS experiment and is compared to the data and the model results without surf beat in Figure 7. Note that surf beat did cause decay in H_{rms} to begin sooner and with greater intensity, but not to the anticipated degree. It appears that only unrealistically energetic surf beat could yield reasonable comparison of the model in its present form to this data set. Although there are some compromises encountered when adapting the decay expression (1) for regular waves on steady currents to random waves on surf beat, it is highly unlikely that they could account for the remaining discrepancy between model and data. We are now left to explore the possibility that the manner in which the data was filtered and analyzed could be responsible for the unexpected behavior.

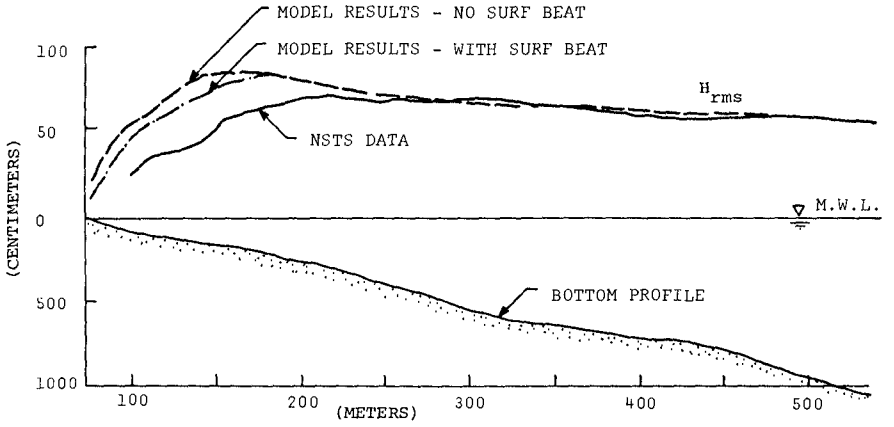

Figure 7. Comparison of H_{rms} transformation between model, with and without surf beat, to field data of Thornton and Guza (1983).

FILTERING-INDUCED "CLIPPING" OF WAVE HEIGHT

Application of the zero-up-crossing technique for analyzing wave records often involves first low-pass filtering the signal to remove higher frequency oscillations from the free surface. This high frequency "noise" increases the number of waves counted in a record by the up-crossing technique, and results in lower calculated values for statistically representative waves, such as H_{rms}. The original data for NSTS-Torrey Pines was taken at 64 Hz, block averaged which reduced the sampling rate to 8 Hz, deglitched, then low-pass-filtered "to substantially reduce energy between 0.5 and 1 Hz", and finally output to tape at 2 Hz (Gable, 1979). Thornton and Guza (1983) treated these time series further by Fourier Transforming the filtered record and zeroing the amplitude coefficients above 0.5 Hz (for gages in shallower water). The time series was then reconstructed and wave heights and periods determined using the up-crossing technique. However, if the original waves are either very peaked (as they are

when approaching the break point) or have sudden discontinuities (as is the case at the front face of a wave at incipient breaking, or the face of a bore), filtering in the above manner can significantly "clip" the wave height. As noted, wave conditions during NSTS were characterized by long-period, low deepwater steepness swell, which become very peaked in shallow water. For the peak frequency of 0.055 Hz, significant deepwater height of 79 cm, and local water depth equal 279 cm (i.e. where the data begin decay), and assuming Stream Function Theory is valid (Dean, 1974), the free surface before and after filtering above 0.5 Hz (the ninth harmonic in this instance) is shown in Figure 8. Note that the wave height was clipped by almost 25%.

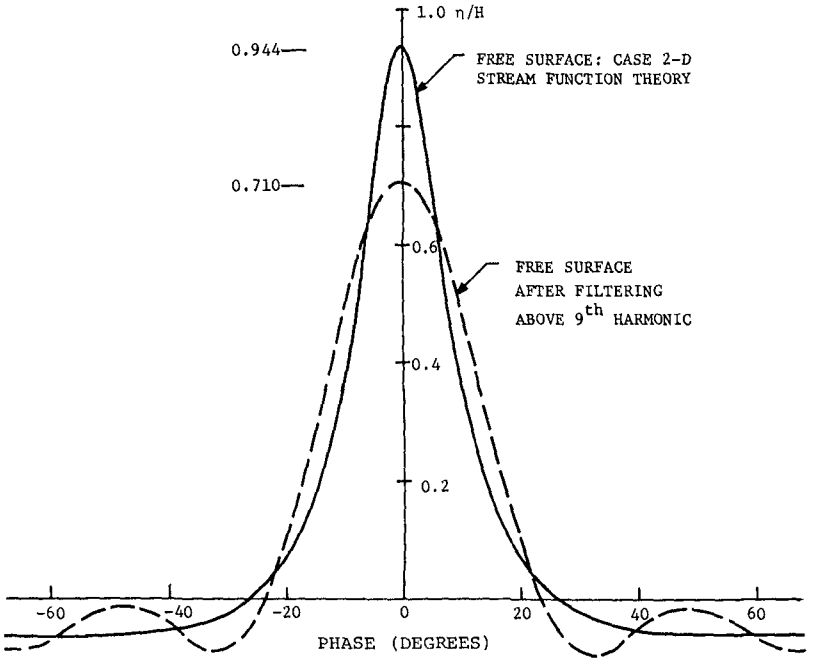

Figure 8. Wave height "clipping" due to low-pass-filtering of peaked waves. Conditions are analogous to NSTS data.

It seems the clipping artifice was induced more by the original filtering of the raw data, as one of these records from the inner surf zone was analyzed with and without the additional filtering of Thornton and Guza, and only a 6% drop in H_{rms} was found (Thornton - personal communication). This artifice is also believed by the authors to be responsible for the apparent agreement between the Rayleigh pdf and histograms of wave height in the surf zone as reported by Thornton and Guza (1983). Filtering the waves makes them appear more sinusoidal and narrow-banded, so assuming a Gaussian sea becomes, artificially, more valid. This would also appear to be why

Thornton and Guza found $H_{rms} = \sqrt{8m_o}$ to be relatively valid in the surf zone.

MEAN WAVE STEEPNESS "EFFECTS" ON RANDOM WAVE TRANSFORMATION

A few previous investigations have noted an apparent dependence of random wave decay on mean wave steepness, e.g. Battjes and Stive (1985). These models increase the decay in wave height for low deepwater steepness waves by varying empirical coefficients. The authors believe this requirement may be an artifice of assuming a Gaussian sea in the surf zone, i.e. that $H_{rms} = \sqrt{8m_o}$. A low steepness wave becomes peaked in shallow water and even though it may have the same actual height as a higher steepness wave, it contains less energy. (Steepness was found by the authors (1984,85) to have little effect on wave height decay after breaking is initiated.) Therefore, if energy is used to calculate H_{rms} rather than the actual free surface displacement between trough and crest, a lower value for wave height is produced. As a result, for the transformation of H_{rms} as defined by $\sqrt{8m_o}$, the heights of the breaking waves in the model must be artificially suppressed to obtain good fit if the measured waves were of low steepness.

CONCLUSIONS AND RECOMMENDATIONS

1) The model for random wave transformation in the nearshore region and surf zone described herein (without surf beat) appears valid in comparison to the field data of Hotta and Mizuguchi (1980), in regards to both statistically representative waves and the probability density function of wave height. However, it does not compare well to the field data of Thornton and Guza (1983). The differences are believed to be due to a "clipping" artifice induced by low-pass-filtering during the original treatment of the raw data.

2) To accurately represent surf beat in any nearshore wave model, depth and current variations should be included.

3) The stochastic model which utilizes an equivalent depth approach to represent surf beat shows that random wave transformation in the surf zone can be noticeably affected by surf beat and is characterized by an increase in breaker decay.

4) In nature, surf beat effects may be significant, but are probably limited to the inner surf zone where the surf beat is strongest.

5) In laboratory experiments, surf beat effects might be unrealistically amplified if long wave energy is trapped in the tank.

6) High frequency filtering can artificially reduce wave height, especially for waves of low deepwater steepness.

7) $H_{rms} = \sqrt{8m_o}$ is not valid in the surf zone. This is believed to be the major reason for the "observed" dependence of decay on wave steepness found in previous studies.

8) It is recommended that in data analysis, low pass filtering be used only to obtain wave periods and that the original record be used to obtain wave heights.

ACKNOWLEDGEMENT

The authors wish to express their gratitude to Dr. Edward B. Thornton, Naval Postgraduate School, for his valuable comments and assistance in the analysis of the NSTS data during this investigation.

CHAPTER 10

A Numerical Solution to Transient Wave Induced Harbor Oscillations Using Boundary Element Technique

Vedat Demirel[1], and Shen Wang[2],

Abstract

A new numerical technique for solution to transient linear long wave induced oscillations is introduced. It is based on the boundary element method, which is well recognized by its numerical efficiency and convenience. Several harbor models are investigated. Advantages of the proposed method as compared to the existing techniques are discussed.

1. INTRODUCTION

Studies concerning harbor oscillations can be classified into two major groups, periodic wave excitations and transient wave excitations. The assumption of periodic incoming waves reduces the problem from a solution of wave equation to one of Helmholtz equation. There are a number of well-established theories available in the literature for the time harmonic case. However, only a few studies have been reported on the transient problem. The traditional approach to the transient problem is to utilize the knowledge of frequency response of the harbor and derive the solutions by means of Fourier synthesis (Carrier and Shaw, 1969). An alternative approach using finite element method (FEM) was introduced by Lepelletier (1980) to solve the problem by a time marching scheme with a time dependent ocean boundary condition.

The present study introduces a boundary element method (BEM) solution for the transient oscillations of arbitrary-shaped, constant depth harbors. Unlike Fourier synthesis approach, this method provides the required information in a natural and direct way. Moreover, this procedure requires neither internal cells nor their associated domain integrals, making the method especially attractive from the computational point of view.

2. THEORETICAL BACKGROUND

Most of the existing numerical harbor models emerge on the validity of the linear wave theory. Indeed, good agreement between the linear theory predictions and experimental results has been reported by various authors, Lee (1969) and Lepelletier (1980), for example. Hence, the problem is formulated within the framework of linear wave theory. The theory assumes irrotational flow of an inviscid, incompressible fluid, and the wave amplitude to be

[1] Graduate Assistant, University of Miami Rosenstiel School of Marine and Atmospheric Science, Division of Applied Marine Physics.
[2] Professor, University of Miami Rosenstiel School of Marine and Atmospheric Science, Division of Applied Marine Physics.

infinitesimally small. In addition, the water depth is assumed to be constant and the wave length is long enough to meet criterion for long wave approximation.

Under these conditions, the governing equation in two horizontal dimensions x and y is given by

$$\frac{\partial^2\phi}{\partial t^2} = c^2 \left(\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2}\right) . \qquad (1)$$

Here ϕ is the unknown velocity potential and c is the speed of propagation. Following the long wave approximation, c is known as $c=(gd)^{1/2}$ with g and d being earth's gravitational acceleration and the water depth, respectively.

The solution of ϕ within the domain sketched in Fig-1 is sought in the present study. The configuration under consideration consists of an interior domain which will be identified as domain II and an exterior domain, domain I. Domain II is an arbitrary-shaped, constant depth harbor with vertical boundaries. It is connected to domain I with a partially or fully open entrance. Domain I represents the open ocean with semi-infinite boundaries. One part of the boundary coincides with the straight coastline extending from $-\infty$ to $+\infty$. The remaining part is a fictitious semi-circle of radius $R=\infty$, connecting both ends of the coastline.

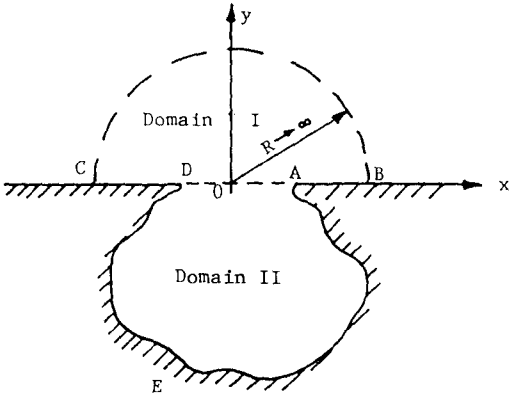

Fig-1. Geometric configuration of an arbitrary-shaped harbor.

Parallel to the time harmonic model of Lee (1969), the problem is formulated in the two regions separately. In domain I, decomposition of the velocity potential ϕ_I into components is conventional in linearized water wave problems:

$$\phi_I = \phi_i + \phi_r + \phi_s \tag{2}$$

where ϕ_i is the incident wave potential, ϕ_r is just its reflection as if the harbor did not exist, and ϕ_s is the scattered potential representing the disturbance introduced by the harbor. Since the incident wave potential is normally known, ϕ_i and ϕ_r are immediately determined. Therefore, only formulation and solution of ϕ_s will be sought in domain I.

The boundary and initial conditions are specified as:

	Domain I	Domain II	
Boundary conditions:			
	$q_s=0$ on the straight coastline	$q_{II}=0$ on DEA	(3)
	$\phi_i+\phi_r+\phi_s=\phi_{II}$	on DA	(4-a)
	$q_s=-q_{II}$	on DA	(4-b)
Initial conditions, at t=0:			
	$\phi_s = \frac{\partial \phi_s}{\partial t} = 0$	$\phi_{II} = \frac{\partial \phi_{II}}{\partial t} = 0$	(5)

Here, q is the normal derivative of ϕ, $q=\vec{n}\cdot\nabla\phi$, and $\vec{n}$ is a unit outward normal vector along the boundary.

Condition (3) assures that boundaries are impermeable by forcing the particle velocities to vanish. Conditions (4-a) and (4-b) are basically necessary to have a continuous surface elevation and fluid velocity across the boundary interface of the two domains. Notice that condition (4-b) is obtained by differentiating (4-a) with $\partial(\phi_i+\phi_r)/\partial n=0$ being understood. The negative sign in (4-b) indicates that the outward normal vectors are directed in opposite directions in I and II on DA. The last constraints are due to the hyperbolic character of the governing equation where one needs two initial conditions. They are chosen to be zero for convenience. It implies that the analysis will be started from a moment when the body of water in the harbor is at rest. However, this is not on approximation but rather a mathematical convenience; as will be seen later, a BEM formulation may include any initial state. It is worth mentioning that the radiation condition of the time harmonic problem is replaced by the causality principle to ensure the mathematical uniqueness. This constraint will be imposed in the determination of the Green's function

of the problem. For a complete derivation of the Green's function and a detailed formulation of the problem, one is referred to Demirel (1986).

3. NUMERICAL ANALYSIS

No analytical solution of the problem described in the previous section exists. On the other hand, a numerical solution is always possible by utilizing one of the solution techniques depicted in Fig. 2.

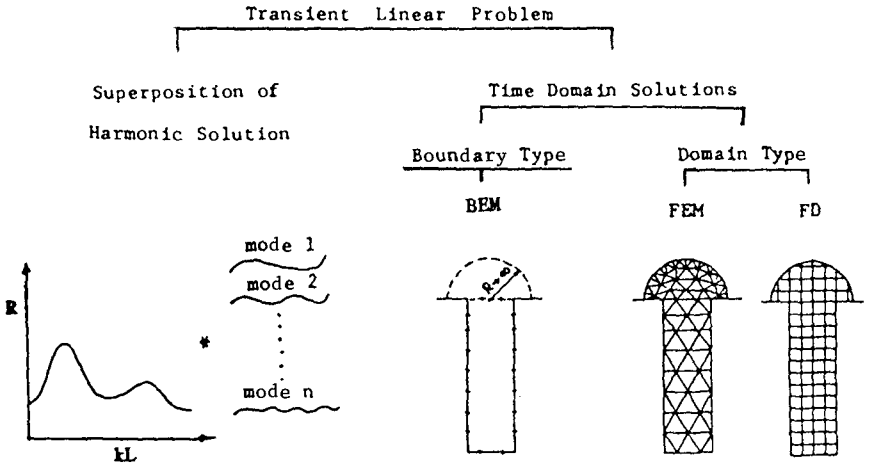

Fig-2. Classification of available solution techniques.

The first method is the traditional Fourier synthesis technique. This is a two-step procedure in which the transfer function of the harbor must be determined first. Afterwards, the transfer function and the Fourier transform of the incident wave system are convolved in the frequency domain followed by an inverse Fourier transform of the product. The second group contains time domain solution techniques. They can be sub-grouped into two categories, domain type solutions and boundary type solutions. Two major differences stand out between these categories as shown in Fig. 2. First of all, in the domain type technique, determination of the potential at any point requires the simultaneous solution of the entire domain. In contrast, in the boundary type solution technique, information of the boundary potential is sufficient to determine the interior potential at any point. Secondly, the open sea region can be extended to infinity in the boundary type method without introducing any approximation. In the domain type technique, however, the exterior domain has to be terminated at a finite distance. Because of these two reasons, BEM is used in this study. An outline of the method is summarized in the following.

The first step is to transfer the governing differential equation

to an integral form. Afterwards, the solution of this integral equation is sought. The resulting integral equation for the wave equation in two dimensions is in the following form (Mansur and Brebbia, 1982):

$$4\pi\lambda\phi(r,t) = \int_o^t \int_\Gamma \frac{\partial R}{\partial n} (\phi B + \frac{v}{c} \phi^*) \, d\Gamma \, d\tau + \int_o^t \int_\Gamma q\phi^* d\Gamma \, d\tau$$

$$+ \frac{1}{c} \int_\Omega \left(\frac{v_o}{c} \phi_o^* - \phi_o B_o + \frac{\partial \phi_o}{\partial R} \phi_o^* + \phi_o \frac{\phi_o^*}{R} \right) d\Omega \qquad (6)$$

where v denotes the time derivative of ϕ, $v = \partial\phi/\partial t$, q is the normal derivative of ϕ and R is the distance between the observation point r and the source point ξ, $R=|r-\xi|$. The parameter λ is equal to 1, 0 or 1/2 for r to be inside, outside or on a smooth part of the Γ boundary, respectively. Definition of the terms ϕ^* and B are given as,

$$\phi^* = \phi^*(r,t/\xi,\tau) = \frac{2c}{[c^2(t-\tau)^2-R^2]^{1/2}} H[c(t-\tau)-R] \qquad (7)$$

$$B = B(r,t/\xi,\tau) = \frac{2c[c(t-\tau)-R]}{[c^2(t-\tau)^2 - R^2]^{3/2}} H[c(t-\tau)-R] \qquad (8)$$

with $H[c(t-\tau)-R] = \begin{cases} 0 & c(t-\tau)<R \\ 1 & c(t-\tau)>R \end{cases}$, a unit step function .

The term ϕ^* is the Green's function for the two-dimensional wave operator, which may be considered as the effect of a source applied impulsively at $t=\tau$ located at $r=\xi$. A subscript o, as appeared in (6), indicates initial time, t = 0. Integrals over Γ are boundary integrals, while over Ω are domain integrals. All integrals are Cauchy principal-value integrals.

In order to evaluate the line integrals in (6), the boundary is discretized into a series of elements and the integrals are computed on each element piecewise. The boundary of the harbor ADE is discretized into N straight segments. In addition, the time dimension is divided into F time steps. Furthermore, functions ϕ and q in equation (6) are assumed to vary within each element and time step according to the space and time interpolation functions such that;

$$\phi(r_j,t_f) = \psi_j^T \gamma^f \phi_j^f \qquad (9)$$

$$q(r_j,t_f) = \mu_j^T \theta^f q_j^f \tag{10}$$

Here ψ_j and μ_j are space interpolation functions, γ^f and θ^f are time interpolation functions, whereas ϕ_j^f and q_j^f are column vectors containing the nodal values of ϕ and q, respectively, within the jth segment. Substituting (9) and (10) into equation (6) and applying a time stepping scheme to initiate the time integration always from the initial time yields the following set of algebraic equations:

$$\sum_{f=1}^{F} [H^{Ff}] \{\phi^f\} = \sum_{f=1}^{F} [G^{Ff}] \{q^f\} . \tag{11}$$

The elements of the matrices $[H^{Ff}]$ and $[G^{Ff}]$ are given by

$$h_{ij}^{Ff} = 4\pi\lambda\delta_{ij}\delta_{fF}\phi_i^F - \int_{\Gamma_j} \frac{\partial R_{ij}}{\partial n} \psi_j^T \int_{t_{f-1}}^{t_f} (\gamma^f B + \frac{\partial \gamma^f}{\partial \tau} \frac{\phi^*}{c}) d\tau d\Gamma$$

$$g_{ij}^{Ff} = \int_{\Gamma_j} \mu_j^T \int_{t_{f-1}}^{t_f} \theta^f \phi^* \, d\tau d\Gamma \quad . \tag{13}$$

Note that all the domain integrals in (6) are dropped out since ϕ and $\partial\phi/\partial t$ are zero in accordance with the initial conditions (5) and the time integrals are evaluated always from the initial time t=0.

Equation (11) is simultaneously applied to both domains. In each domain, the velocity potential ϕ is expressed in terms of the unknown normal derivatives of ϕ at the harbor entrance. These unknowns are determined by satisfying the matching conditions (4) on the entrance. Having obtained the derivatives of the potential along the entrance, the interior potential is calculated by letting the observation point approaching to any interior point desired.

4. NUMERICAL EXAMPLES

In the numerical computations, three model harbors were considered. A rectangular harbor and a circular harbor were taken first. Both harbors have an uniform water depth and are connected to an open-sea. The third is a model of the East and West basins of Long Beach Harbor, California. The interpolation functions ψ_j, μ_j and θ^f were taken as constant whereas γ^f was taken as linear in the computation.

The results given here were computed for two incident wave forms, an exponentially decaying cosine wave and a solitary wave:

$$\eta_i = A\, e^{-\alpha|t|} \cos(\omega_o t) \tag{14}$$

$$\eta_i = A \,\mathrm{sech}\,(mt) \tag{15}$$

where A, α, ω_o and m are the amplitude of the incident wave, a decay factor, the incident wave frequency and a dummy frequency parameter, respectively.

In the following figures, the results of the present BEM model were compared against the Fourier synthesis solutions. In each figure, the incident wave system is plotted in the upper part. The lower part is allocated for the comparison of two different approaches. The solid curve and the circles represent the results of the Fourier synthesis solution and the present theory, respectively. Coordinates of the figures were nondimensionalized by suitable parameters. For instance, values of the surface elevation were nondimensionalized by $(\eta_i)_{max}$ defined as the maximum elevation of the incident wave. Likewise, the elapsed time is nondimensionalized either by the period of the incident wave, as in the case of exponentially decaying cosine waves, or by a representative time scale for the case of a solitary wave. For a solitary wave defined by (15), the representative time scale was taken as $\bar{T}=\bar{\lambda}/(gd)^{1/2}$. Here $\bar{\lambda}$, the so-called effective wave length, is defined as twice the distance between the peak of the sech(mt) and a point at which the amplitude reduces to 0.1% of its maximum.

Case 1: A rectangular harbor

A fully open rectangular harbor with a width to length ratio b/L= 0.5 (b=2.5 feet, L=5.0 feet) and a uniform water depth d=0.5 feet was considered as the first case. The boundary of the harbor was discretized into N=32 constant elements with 6 of them placed on the entrance. The observation point was taken to be located at the back boundary of the harbor.

Fig-3 shows the time history of oscillations due to an exponentially decaying cosine wave having a frequency equal to the first natural frequency of the harbor, kL=1.1. The figure indicates that the maximum amplification for this transient wave is 3.8 and the oscillations last a little longer than 4 times the period of the incident wave system.

In the next figure, harbor response due to a solitary wave of $\bar{\lambda}/L=5.7$ was considered. As Fig-4 shows, the magnitude of the first, peak, which represents the major impact of the solitary wave, is in good agreement although there exist relatively minor discrepancies in the subsequent time steps.

Case 2: A circular harbor

The second harbor considered is a circular model previously used by Lee (1969) with a radius r=0.75 feet, a constant depth d=0.5 feet and a 60 degrees gap. For this harbor, the observation point was taken at the center of the harbor. The boundary of the harbor was discretized to N=30 straight elements with 6 of them located at the entrance.

Fig-5 shows the harbor response due to an exponentially decaying cosine wave of kr=0.5. It is seen that the peak amplitude is slightly lower but in general agrees well with the Fourier synthesis solution. Oscillations last approximately 8 cycles, reaching a maximum amplification of 2.9. The subsequent amplitudes are slightly different and decay faster in the BEM solutions.

The solitary wave induced oscillations in the circular harbor of r=0.75 were plotted in Fig-6 along with the incident wave systems. The upper part of Fig-6 represents the incident wave system with $\bar{\lambda}/2r=12.5$. The computed surface elevation at the center of the

Fig-4. A comparison of time history of oscillations at the back boundary of a rectangular harbor, b/L=0.5, due to a solitary wave of $\bar{\lambda}$/L=5.7.

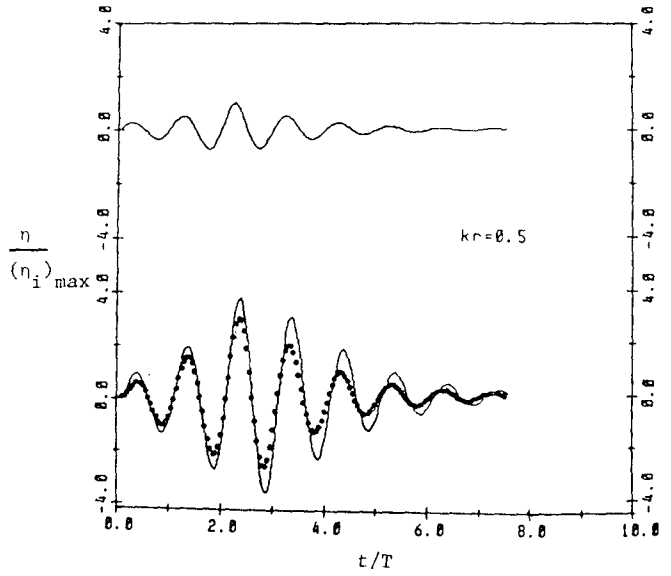

Fig-5. A comparison of time history of oscillations at the center of a circular harbor, r=0.75, due to an exponentially decaying cosine wave of kr=0.5 with a decay factor α=0.3.

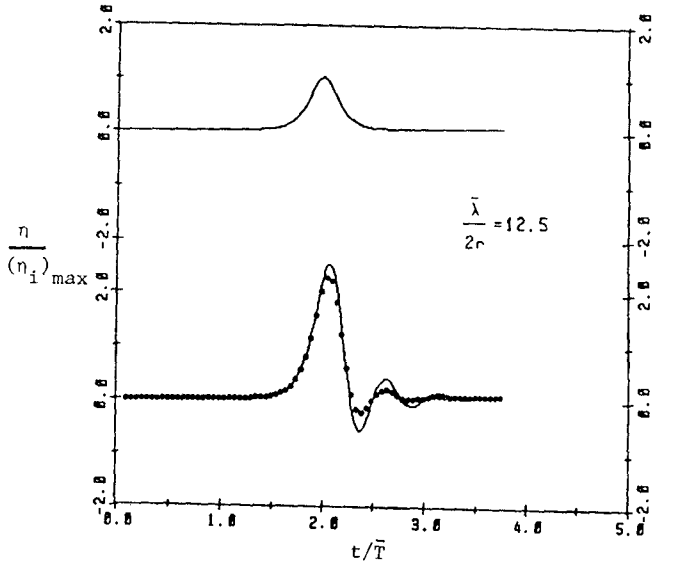

Fig-6. A comparison of time history of oscillations at the center of a circular harbor, r=0.75,due to a solitary wave of $\bar{\lambda}/2r$=12.5.

harbor is placed in the lower part of the same figure. As Fig-6 shows, the maximum amplification is 2.2 and there are few minor oscillations following this peak. This implies that the incident wave is so long that the presence of the harbor practically does not perturb the reflected wave pattern.

Case 3: Long Beach Harbor

A model of the East and West basins of Long Beach Harbor as shown in Fig-7 was considered as the last case. The same model was also used by Lee (1969). The entrance of the harbor is 0.2 feet, the water depth is d=1 feet and the characteristic length is L=1.44 feet. For this harbor, the observation point was chosen at the lower right corner of the harbor, Fig-7. The boundary of the harbor was discretized into N=75 straight elements with two elements located on the entrance.

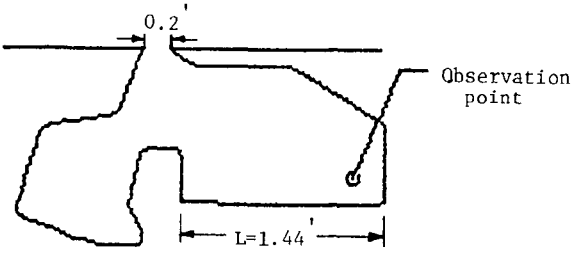

Fig-7. A model of East and West basins of Long Beach Harbor, California.

Fig-8 shows the results of a computation conducted for an exponentially decaying cosine wave input of kL=0.6. The figure indicates that the maximum amplification is 3.2 and the duration of oscillations is approximately 5 times the period of the incident wave system.

The transient response at the designated observation point of the Long Beach harbor due to a solitary wave of $\bar{\lambda}/L = 10.5$ was shown in Fig-9. It is seen that the present prediction matches well with the Fourier synthesis solution especially for the leading wave. According to the figure, the present theory estimates a maximum amplification of 2.5 and the duration of oscillations to be nearly 4 times the effective wave period $\bar{T}$.

5. CONCLUSIONS

A numerical solution to transient linear wave induced harbor oscillations using BEM is introduced. The transient linear long waves are focused in two horizontal dimensions penetrating into a constant depth, arbitrary shaped harbor. Utilizing the fundamental

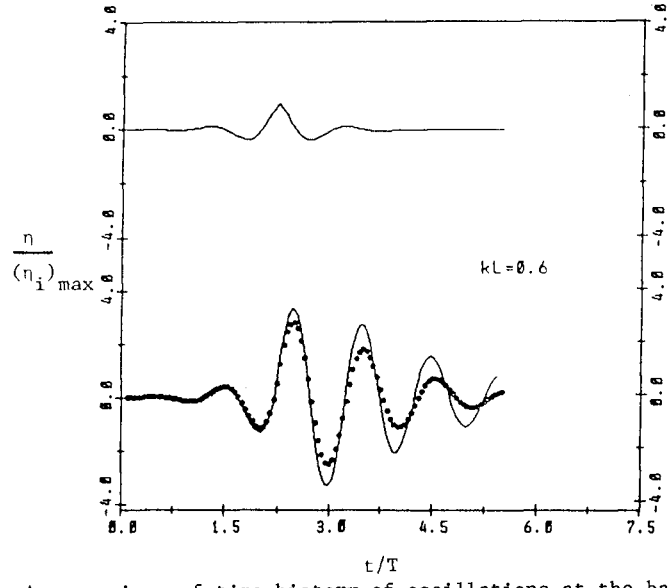

Fig-8. A comparison of time history of oscillations at the back boundary of the Long Beach Harbor model due to an exponentially decaying cosine wave of kL=0.6 with α=0.3.

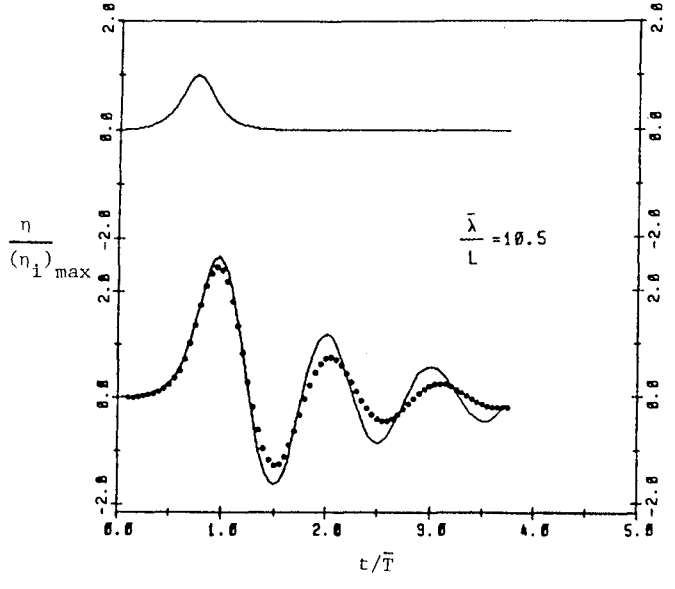

Fig-9. A comparison of time history of oscillations at the back boundary of the Long Beach Harbor model due to a solitary wave of $\bar{\lambda}$/L=10.5.

solution of Green's function for wave equation in two dimensions, only inputs of potential or surface elevation due to transient waves at the harbor entrance is required. The fluid domain is discretized into two regions but a matching technique is used at each time step to evaluate the condition at the entrance. The interior potential or elevation is obtained with only knowledge of the boundary potential.

This method has advantages over frequency domain solution in that it provides in a natural and direct way the time history of oscillations. Moreover, the computation time of the BEM solution is considerably less than that of the Fourier synthesis approach. This is because of the fact that a sufficiently large number of frequency responses are needed to carry out a proper Fourier synthesis solution.

Comparing with the theories based on the domain type techniques, the BEM approach carries forward some widely recognized priorities, such as less data preparation and reducing in the dimensionality of the problem. Also, solution in the exterior domain can be obtained easily without any approximation on the boundary conditions at the infinity. In contrast, in the FEM, a time dependent boundary condition must be specified along a large semi-circle in the open sea to avoid an artificial reflection. The accuracy of the results and the computation time are closely related to the choice of the radius of this circle.

6. ACKNOWLEDGEMENTS

The authors are indebted to Dr. John D. Wang and Dr. Chia-Chi Lu for their collaboration. Dr. Bernard Le Mehaute is also acknowledged for his valuable comments.

CHAPTER 11

EXTREME WAVE PREDICTION USING DIRECTIONAL DATA

M.C. Deo* and R. Burrows**

ABSTRACT

Potential inconsistencies in the predictions of long term wave heights can be experienced as a result of different methods of analysis possible when using directional wave data. This paper attempts to illustrate some of them. It involves analysis of two sets of directional wave data - one from a coastal location in the Irish Sea and another from an offshore location in the North Sea. An attempt is made to eliminate the discrepancies between the long term return-value wave height predictions based upon the conditional height distributions associated with different direction sectors and those derived from the omni-directional data set.

1. INTRODUCTION

The estimation of the long term wave heights is often made by fitting the wave data to a convenient probability distribution and extrapolating it upto the chosen 'return period' probabilities. A graphical technique using a probability paper is often employed.

The estimates made in this way normally do not account explicitly for the directions of the wave or those of winds generating them. It is implied by this procedure that all wave directions are equally likely to occur and that the conditions of wind speed and fetch generating the waves are directionally unbiased. If this is not the case, the method involves implicit extrapolation of sea states in direction sectors with restricted fetch beyond a physical upper limit.

Design engineers are increasingly asking for estimates of the probability of occurrence of extreme wave heights from different points of the compass. It is however observed that such estimates are not always consistent with the omni-directional estimates and it is quite

* Assistant Professor, Department of Civil Engineering, Indian Institute of Technology, Bombay-400 076, India.
** Lecturer, Department of Civil Engineering, University of Liverpool, Liverpool, L69 3BX, U.K.

possible that because of the sample size and fitting errors, the extreme wave height predictions from the worst direction may exceed the corresponding omni directional estimates.

Graham (1981) has suggested the simple factoring of the estimates from the worst direction to make them compatible with the omni-direction estimates to overcome this problem. An alternative approach is proposed here which is based on the convolution of the directional wave height distributions, that can subsequently be correlated against the omni-directional estimates to eliminate all inconsistencies.

2. DATA FOR THE STUDY

Two sets of directional wave data were available for the present studies. One set was the outcome of an earlier wave hindcasting study from seven years (1964-1970) of wind measurement at a nearshore site on the 'Mersey Bar' in the Irish Sea. The wave heights so derived have shown good correlation with observations at the site over a shorter period of one year (Burrows et al., 1985).

Figure 1 shows this site while Table 1 gives fetch length as well as corresponding estimates of significant wave height (Hs) generated from an extreme 'hurricane force' wind speed of 80 knots. It may be noted that the physical upper limit for the wave heights generated along different direction sectors varies from 4.12 to 10.06 m.

The other data set consisting of significant wave heights, average zero cross period (T_z) and wind direction, was from indtrumental recordings over the period 1975-1976 and 1980-1981 at a location in the North Sea (Figure 1). For such an open site, the fetch lengths corresponding to different directions were very large - the minimum value being 97 miles. Consequently, all of the corresponding Hs values at the 80 knots wind speed exceeded 11 m.

3. VARIABILITY IN DIRECTIONAL DISTRIBUTIONS

The data was categorized into different direction sectors and for each sector theoretical probability distributions of Gumbel, Weibull, extreme value Type III-U forms were fitted (expressions for these distributions are given in the Appendix). Estimates of the return value Hs were then abstracted.

Figure 2 shows the directional distributions of Hs values for the Irish Sea location along with selected 100-year return value probabilities. Table 1 gives the estimates of the '100 year' Hs values obtained by moments fitting to the Gumbel distribution in case of the Irish Sea data. The suitability of the Gumbel distribution fit for this

(SCALE – 1mm = 100 SEA STATES)

location was checked (Deo and Burrows, 1985). It is immediately seen that the total number of sea states coming from different directions is not the same and hence the assumption to that effect, made implicitly in the normal extreme wave prediction procedure is not valid.

Figure 3 shows the similar distribution fittings to the North Sea data.

Both sets of data showed that predictions of extreme wave heights from certain worst direction sectors (e g m = 13, 14, 16 in Table 1) exceed the equivalent prediction using the complete data set i.e. the normal omni-directional approach.

This outcome was found to be sensitive neither to the fitted distribution nor to the extrapolation techniques of moments or least squares. This behaviour departs from the outcome of statistical reasoning but can be explained by the different levels of uncertainty associated with the distribution fitting to data sets of different sizes.

One way to account for the above mentioned inconsistency between the directional and omni-directional estimates is to factor the former and make predictions from the worst directions compatible with the omni-directional distributions (Graham 1981) Whilst this satisfies the engineering requirements, it is not statistically correct but is nevertheless conservative. The error in this approach follows because the omni-directional predictions must exceed the worst direction values since there will generally be a finite chance of the extreme conditions (in 100 years, say) arising from other than the worst direction.

Herein, an alternative and statistically consistent technique is followed which is described in the following section.

4. CONVOLUTION OF CONDITIONAL (DIRECTIONAL) WAVE HEIGHT DISTRIBUTIONS

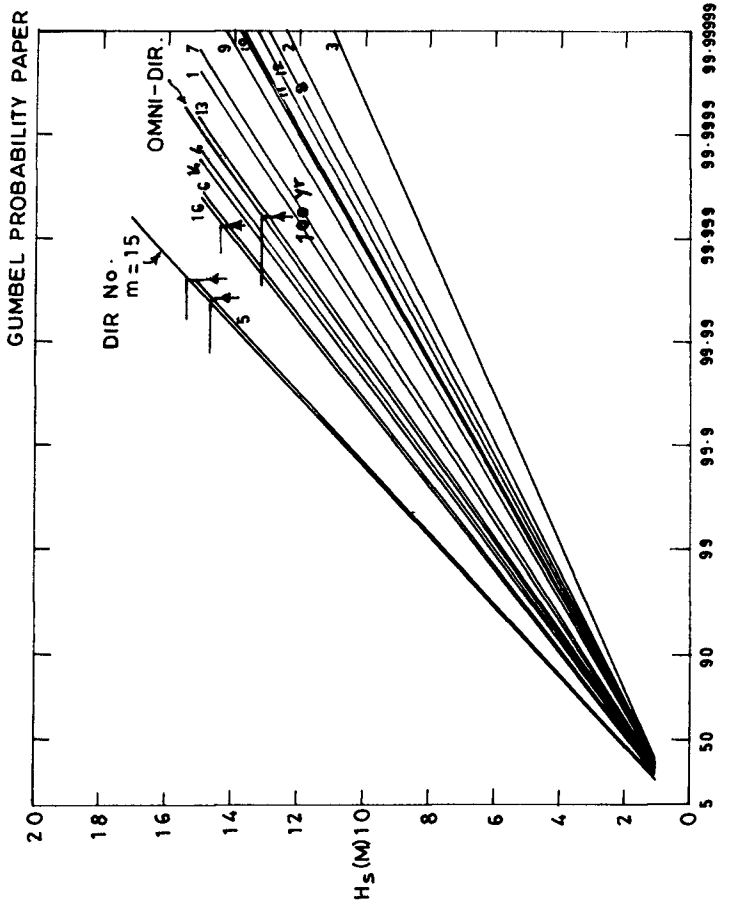
a) Long Term Distribution of Significant Wave Heights

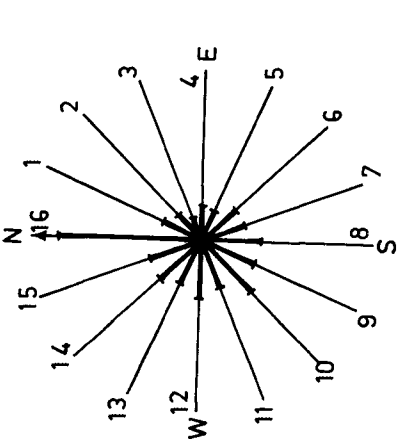
The revised procedure to predict the return value estimates of Hs is as follows:

(i) Categorize the data into different direction sectors

(ii) Obtain the fitted conditional distribution of Hs for each direction

(iii) Introduce appropriate wave height ceilings to each direction sector





ROSE DIAGRAM INDICATING TOTAL NUMBER OF SEA STATES ALONG DIFFERENT DIRECTIONS

(SCALE–1 mm = 50 SEA STATES)

FIG.3 DIRECTIONAL H_s DISTRIBUTION (North Sea Data)

(iv) Convolute the different directional distributions and obtain an equivalent all direction distribution as follows:

$$P(Hs) = \sum_{\text{all } \theta} P(Hs/\theta)\, W(\theta) \qquad \ldots(1)$$

where

$P(Hs)$ = equivalent all direction distribution function of Hs

θ = wave direction

$P(Hs/\theta)$ = conditional distribution function of Hs for given θ

$W(\theta)$ = weighting function representing the proportion of sea states along the direction θ in the entire population.

(v) Make predictions of long term Hs values on the basis of equation (1) or if there is no directional bias in fetch or wind field, divide the all-directional Hs value obtained as the outcome of equation (1) at the appropriate return period and use this as a factor for adjustment of the directional wave height predictions. This then makes them statistically consistent with the omni-directional values which in the situation may be viewed as the most reliable estimation since it is based on fitting and extrapolation of the entire data set.

b) Long Term Distribution of Individual Wave Heights (H)

This can be made by two alternative techniques:

Method 1 : (i) Use the equivalent all direction distribution of Hs values as per equation (1) to calculate the long term distribution P(H) in the normal manner (Battjes 1970; see Appendix) or

Method 2 : (i) Use the following convolution technique to get P(H) :

$$P(H) = \sum_{\text{all } \theta} P(H/\theta)\; W'(\theta) \qquad \ldots (2)$$

where

$P(H)$ = equivalent all-direction long term distribution

$P(H/\theta)$ = conditional long term distribution of H along direction θ

$W'(\theta)$ = weighting function representing proportion of individual waves in the entire population (Deo and Burrows 1985)

(ii) Predict return individual wave heights in a similar manner to step (v) in (a) above relating to significant wave height predictions.

For each data set the equivalent all-direction distribution of Hs was obtained according to equation (1) for each year separately as well as for the total data set. These distributions were then compared with the corresponding omni-directional distributions obtained by following the normal procedure. This was repeated by varying the underlying theoretical probability distribution as well as by varying the fitting technique.

Figure 4 shows a typical outcome of this exercise and it pertains to the case of Gumbel distribution fit to the Irish Sea data using the method of moments.

It was observed that the equivalent all-direction distribution does not follow the same theoretical form as the constituent conditional distributions (Gumbel, in the present case). This result is evident also from theoretical considerations. Further the introduction of appropriate wave height ceilings along different directions, in these cases, had a negligible effect on the resulting equivalent all-direction distribution. This is probably due to the fact that this imposition did not affect any of the worst directions that dictate the extreme tail of the distribution since the most frequent wind directions fall in the sectors of longest fetch.(Refer to limiting Hs values in Table 1). In other geographical circumstances this may not be the case. In the present case the effect of applying wave height limits for each direction is certainly overshadowed by other curve fitting and extrapolation uncertainties.

It was also noted from the above mentioned comparisons that the equivalent distribution resulting from convolution technique lies on the probability paper above the one obtained on the basis of the existing (omni-direction) procedure. This indicated that it would produce conservative estimates of the design wave heights. This outcome remained unchanged in case of the North Sea data as well (Figure 5). It was also not sensitive to the choice of the theoretical distributions and the fitting techniques.

Figure 6 pertains to the equivalent all-direction distribution of individual wave heights obtained by following the methods-1 and 2 as well as by using the normal procedure. This outcome is also in line with the one discussed above in case of Hs distributions.

The values of the 100-year return period wave heights were extracted from these plots and it was found that the equivalent all-direction distribution produced conservative estimates of Hs ranging from about 5 to 20 percent for all cases involved. The corresponding overestimation of individual wave heights by the use of methods-1 and 2 was 9 to 20 percent.

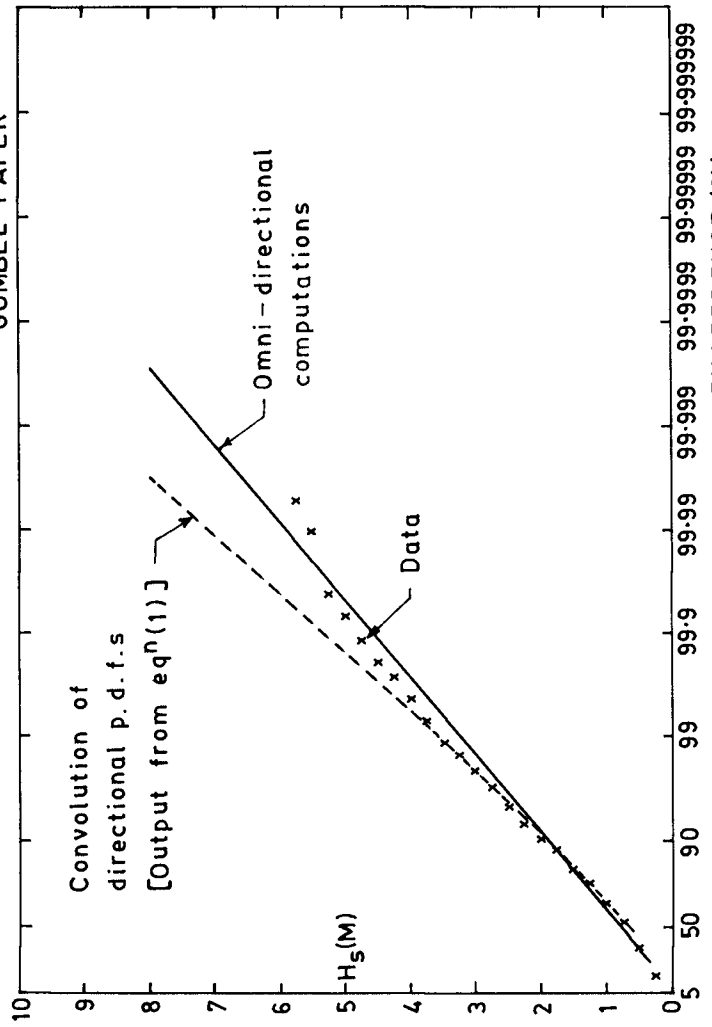


FIG. 4 COMPARISON OF H_s DISTRIBUTIONS (Irish Sea Data)

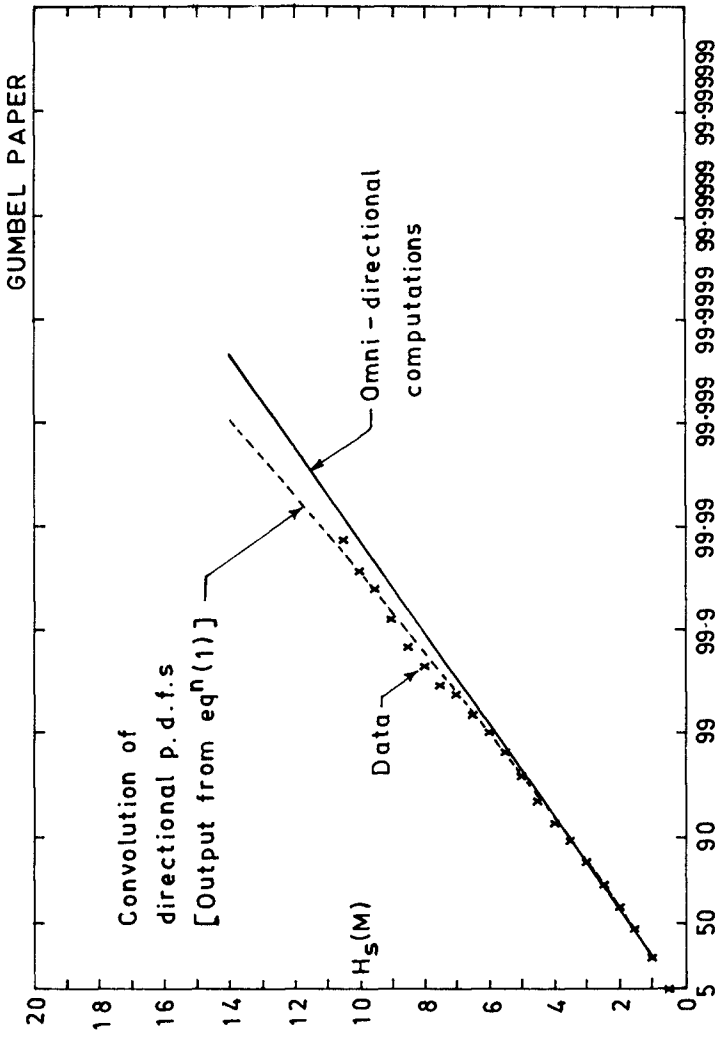

FIG. 5 COMPARISON OF H_s DISTRIBUTIONS (North Sea Data)

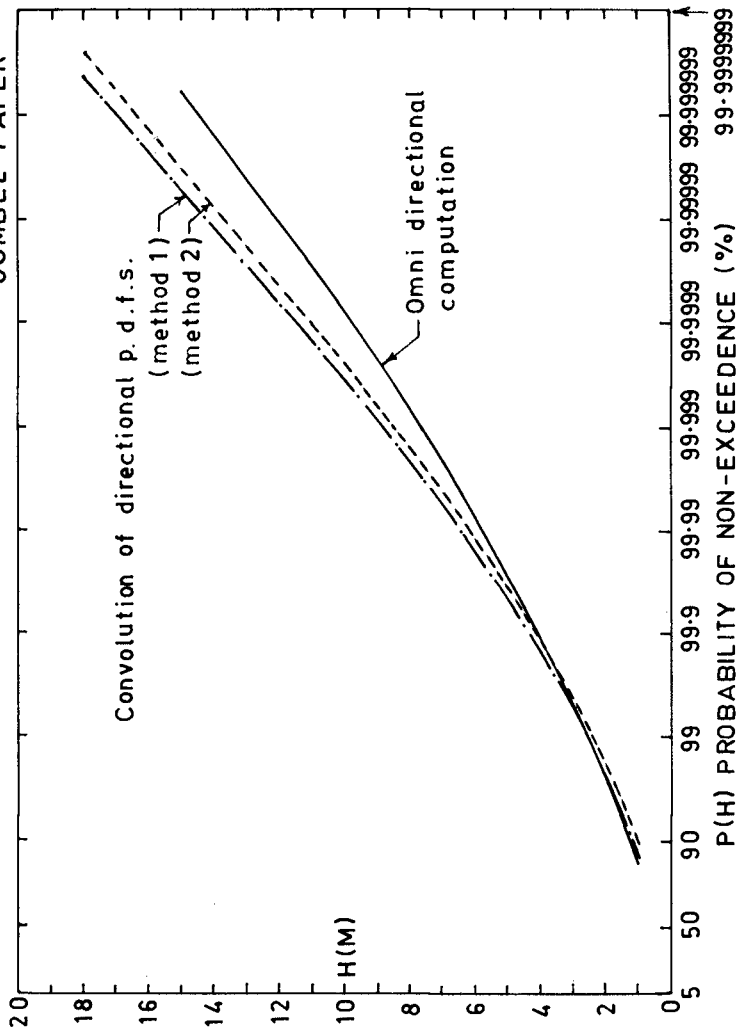

FIG. 6 COMPARISON OF 'H' DISTRIBUTIONS (Irish Sea Data)

5. CONCLUSIONS

(a) A discrepancy in the long term wave height predictions will generally arise if the directionality of the wave data is taken into account.

(b) The normal procedure to predict the long term values of the wave heights implicitly incorporates extrapolation of wave fields in certain direction sectors beyond potential physical limits. It is deficient, therefore, where severe directional bias in the fetch and wind field exists. In these circumstances, the methods presented here are more apporpriate, although they involve higher levels of uncertainties due to the smaller sample sizes considered in curve fitting and extrapolation procedures.

(c) When no such directional bias exists, the methodology enables the computation of a statistically consistent set of directional return-value wave heights which can be factored to bring them into line with the normal omni-direction calculations, having more statistical confidence due to the large sample sizes involved.

(d) Since all the procedures to predict the long term wave heights discussed here are essentially empirical in nature, their theoretical justifications are weak and hence the choice of a particular method should be left to the designer. A need for compatible sets of directional and omni-direction distributions, however, may call for the application of the methods presented herein.

ACKNOWLEDGEMENTS

The work reported herein was conducted whilst the first author was a Visiting Research Fellow at the University of Liverpool, U.K., sponsored by the TCTP scheme of the British Council. The study formed a part of the wider investigation into the probabilistic properties of wave climate supported as project (NW/L/1.5) by the UK Science and Engineering Research Council over the period 1/14-12/85.

CHAPTER 12

SHOALING SURFACE GRAVITY WAVES: A BISPECTRAL ANALYSIS

J.C. Doering* and A.J. Bowen*

Abstract

Nonlinearities (wave–wave interactions) play a vital role in many aspects of nearshore dynamics, such as wave shoaling and breaking, wave forces, wave–current interactions, radiation stress effects, and sediment transport. The importance of nonlinearities in the nearshore region cannot be overemphasized. At present, however, there is no wave theory that adequately accounts for these interactions, and field observations are sparse. Herein, the bispectrum is used to investigate the temporal and spatial variation of wave–wave interactions in cross-shore velocity for shoaling surface gravity waves in several nearshore environments. The implications for sediment movement of the sign of the observed wave–wave interactions for both the real part of the velocity bispectrum (which is related to the skewness of the horizontal asymmetry) and the imaginary part of the velocity bispectrum (which is related to the skewness of the temporal derivative) are discussed. A parameterization is given for the amplitude and phase evolution of the self–self sum interactions within the wind–wave peak for both planar and barred nearshore topography. The results of this paper underline the potential importance of infragravity wave energy in determining nearshore morphology.

1. Introduction

There have been a lot of papers written about the statistics and nonlinearities of sea surface elevation and slope (Srokosz & Longuet-Higgins, 1986; Longuet-Higgins, 1982, and the many references therein). Most of this literature, however, pertains only to deep water where nonlinearities are assumed to be weak in order for the problem to remain reasonably mathematically tractable. Similar theory has not been completed for shallow water as the complexities are formidable. This is particularly true near breaking where nonlinearities are generally not considered to be weak. Until the collection of data by field programs such as the Nearshore Sediment Transport Study (NSTS), and most recently the Canadian Coastal Sediment Study (C^2S^2), observations were sparse.

As waves propagate into shallow water they undergo a dramatic transformation and eventually break. Freilich and Guza (1984) have shown that a nonlinear model including triad interactions across the wind-wave frequency band can accurately predict the Fourier Coefficients (amplitude and phase) of the wave field through the shoaling region. Elgar and Guza (1985) used the bispectrum to examine the nonlinear interactions in the observed pressure field of shoaling surface gravity waves. In addition, Elgar and Guza (1986) used Freilich and Guza's nonlinear equations to model bispectral evolution through the shoaling region. The model results were qualitatively similar to the observations. The bispectral quantities examined by Elgar and Guza (1985, 1986) were plotted against depth. However, it is clear from inspection of Elgar and Guza (1985, 1986), that depth cannot provide a general parameterization of bispectral evolution. Such a parameterization would be useful, especially for modelling sediment transport since the models of Bowen (1980) and Bailard (1981) require the skewness of the velocity field as an input. Guza and Thornton (1985) computed a variety of velocity moments, including skewness, for some NSTS data, which

* Department of Oceanography, Dalhousie University, Halifax, Canada B3H 4J1

they also plotted as functions of depth. There is, however, no obvious relationship between the depth and most of the quantities they considered.

The objectives of this paper are to investigate the following aspects of the cross-shore velocity field:

i) the temporal and spatial evolution of triad interactions through the nearshore region
ii) the sedimentary implications of the observed wave–wave interactions
iii) the parametric dependence of the salient interactions

2. The Bispectrum

To investigate wave–wave interactions, the bispectrum is used. For a stationary random function of time $\zeta(t)$, the auto bispectrum is given by the Fourier Transform of the mean third-order product (Hasselmann *et al.*, 1963).

$$B(\omega_j,\ \omega_k) = \frac{1}{(2\pi)^2} \iint_{-\infty}^{+\infty} S(\tau_j,\ \tau_k) e^{-i(\omega_j \tau_j + \omega_k \tau_k)} d\tau_j d\tau_k \tag{2.1a}$$

$$S(\tau_j,\ \tau_k) = E[\zeta(t)\zeta(t+\tau_j)\zeta(t+\tau_k)] \tag{2.1b}$$

τ is a lag, ω is a radian frequency, and E denotes an expected or average operator. For digital data the (auto) bispectrum is given by Kim and Powers (1979) as

$$B(\omega_j,\ \omega_k) = A_{\omega_j} A_{\omega_k} A^*_{\omega_{j+k}} \tag{2.2}$$

where A_{ω_j} represents the complex Fourier Coefficient of radian frequency ω_j and * denotes the complex conjugate.

The bispectrum can be expressed in a normalized form known as the bicoherence (Kim and Powers, 1979).

$$b^2(\omega_j,\ \omega_k) = \frac{|B(\omega_j,\ \omega_k)|^2}{E[|A_{\omega_j} A_{\omega_k}|^2] E[|A_{\omega_{j+k}}|^2]} \tag{2.3}$$

Note that Cauchy-Schwarz's inequality ensures $b^2 \leq 1$ for (2.3); this is not true for the bicoherence expression given by Haubrich (1965). The variance of bicoherence estimates has been shown to be less than $\frac{2}{d.o.f.}$ (Kim and Powers, 1979).

The 95% level for zero bicoherence is defined by Haubrich (1965).

$$b^2 \simeq \frac{6}{d.o.f.} \tag{2.4}$$

Although the bicoherence indicates the wave–wave interactions that are significant above some chosen level, it does not provide any information regarding the relative contribution of these interactions to the nonlinearity of the record as measured by skewness. This information is, however, provided by the real part of the bispectrum. Integrating the real part of the bispectrum yields an estimate of skewness.

$$E[\zeta^3(t)] = \sum_{\omega_j} \sum_{\omega_k} \mathfrak{Re}\{B(\omega_j,\ \omega_k)\} \tag{2.5}$$

Prior to the work of Masudo and Kuo (1981) no physical interpretation had been attached to the imaginary part of the bispectrum. However, they showed that the imaginary part of the bispectrum is related to the vertical asymmetry of the waves. Moreover, Elgar

and Guza (1985) showed that the imaginary part is related to a measure of the skewness of the temporal derivative of a time series (i.e., the Hilbert transform).

$$E\left[\left(\frac{\partial \zeta}{\partial t}\right)^3\right] = \sum_{\omega_j} \sum_{\omega_k} \omega_j \omega_k \omega_{j+k} \Im m\{B(\omega_j,\ \omega_k)\} \tag{2.6}$$

Lastly, from (2.5) and (2.6) it is clear the bispectrum can be written in terms of an amplitude and phase

$$B(\omega_j,\ \omega_k) = |B(\omega_j,\ \omega_k)| e^{i\theta(\omega_j,\ \omega_k)} \tag{2.7a}$$

where

$$\theta(\omega_j,\ \omega_k) = \tan^{-1}\left\{\frac{\Im m[B(\omega_j,\ \omega_k)]}{\Re e[B(\omega_j,\ \omega_k)]}\right\} \tag{2.7b}$$

3. Data Base

The data for this investigation were collected from four nearshore environments: Pte. Sapin, New Brunswick (C^2S^2), Stanhope Lane, Prince Edward Island (C^2S^2), Queensland, Nova Scotia, and Leadbetter Beach, California (NSTS). These data provide a range of beach slopes (including a barred environment), wave periods, depths, and (significant) wave heights — see table 1 for a summary. Because of space limitations a detailed analysis of only 1 run (run 52 from Pte. Sapin) is presented. Doering and Bowen (submitted) have shown that a bispectral analysis of cross-shore velocity and pressure for the February 2, 1980 data from Leadbetter are very similar. Therefore, the reader is referred to Elgar and Guza (1985) for a detailed analysis of the Feb. 2 Leadbetter data.

The velocity data from these four environments were collected using 2-axis, 4 centimeter diameter, spherical probe, electromagnetic current meters manufactured by Marsh-McBirney Incorporated (model 512/OEM). Corrections were made for the filter characteristics of the current meter electronics where necessary.

4. Observations & Discussion

Figure 1 shows the beach profile and location of the current meters deployed at Pte. Sapin, New Brunswick during C^2S^2. The cross-shore velocity spectra for current meters C26 ($h = 3.2m$, line *a*), C23 ($h = 2.9m$, line *b*), C07 ($h = 2.0m$, line *c*) and C16 ($h = 1.7m$, line *d*) for run 52 at Pte. Sapin are given in Figure 2. Note the sharpening of the spectral peak and the relative increase in both harmonic and infragravity wave energy as the waves shoal (lines $a \rightarrow d$).

The results of a bispectral analysis of these data are plotted as 3-D plots in Figures 3-6. The following notes apply to all the 3-D plots in this paper:

1) For an auto bispectrum only $\frac{1}{8}$ of the $(\omega_j,\ \omega_k)$ frequency plane is unique (Kim and Powers, 1979). However, plotting the entire 1^{st} quadrant allows the backside of some of the peaks to be seen. For this reason, the entire 1^{st} quadrant ($\omega_j,\ \omega_k > 0$) has been plotted.
2) The origin is located at the left corner.
3) The two axes defining the frequency plane show the non-radian frequency, $f_1,\ f_2 = \frac{\omega}{2\pi}$, and both run from 0 to 0.5 Hertz.
4) There is symmetry about a 45° line ($f_1 = f_2$).

To facilitiate visualizing the bicoherence plots, only the bicoherence values above the 95% level for zero bicoherence ((2.4)) are shown. The "slab" thickness indicates the 95% value. The four panels of figure 3 show the bicoherence plots for current meters C26 (panel 1), C23 (panel 2), C07 (panel 3) and C16 (panel 4) for run 52 at Pte. Sapin. In panel 1,

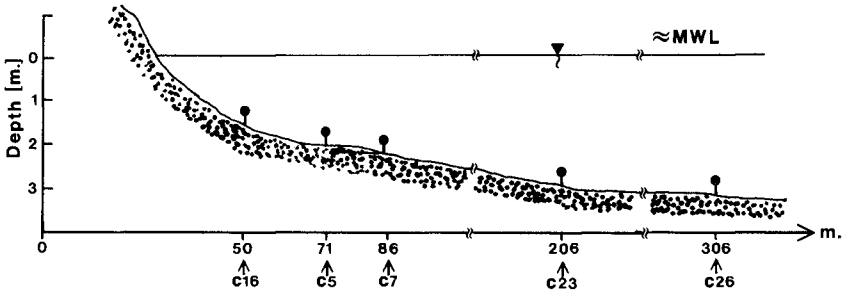

FIGURE 1. Beach profile and location of the current meters deployed at Pte. Sapin, New Brunswick.

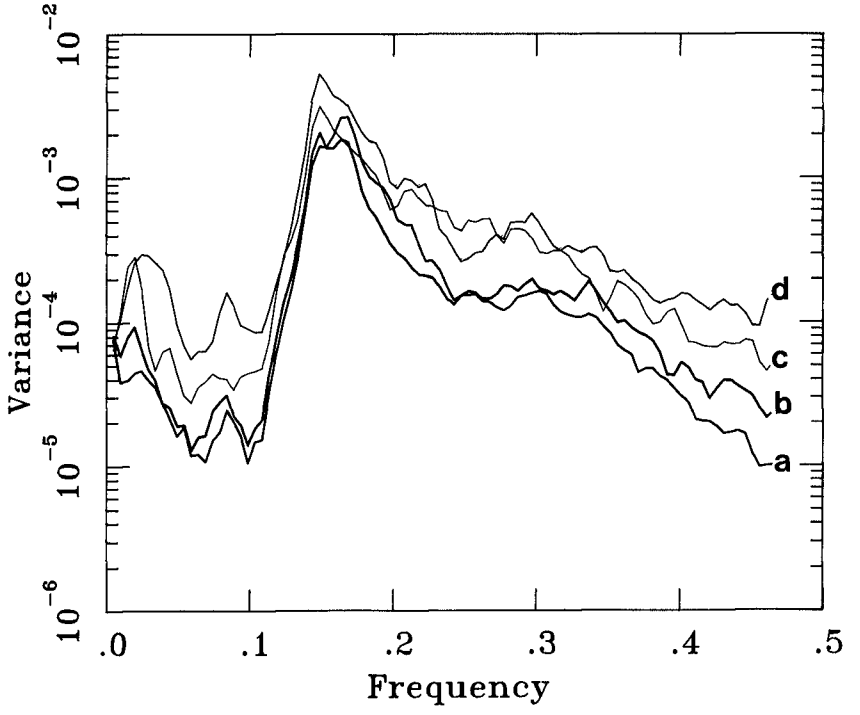

FIGURE 2. Cross-shore velocity spectra for current meters C26 (a), C23 (b), C07 (c) and C16 (d) deployed for run 52 at Pte. Sapin. *d.o.f.* = 100.

two (unique) salient peaks are noted. The peak centered at $(0.15Hz, 0.15Hz)$ indicates nonlinear phase coupling between fundamental and first harmonic frequencies of the incident waves; this interaction is hereinafter denoted (f, f). The peak at $(0.15Hz, 0.02Hz)$ indicates coupling between the fundamental and a long wave. Physically, this peak suggests that neighboring frequencies within the fundamental peak interact to form a beat or wave group, which forces a long wave, at the difference frequency; this interaction is hereinafter denoted $(f, \Delta f)$. After propagating $\sim 100m$ further shoreward, over essentially a flat bottom, panel 2 shows that very little additional coupling occurred. This is also evident from figure 2 (lines *a* and *b*). However, panel 3 indicates that additional coupling did occur after propagating $\sim 120m$ further shoreward over a gently sloping seabed. In particular, the bicoherence of the (f, f) peak increased, and broadened slightly. In addition, a new peak is present at $(f, 2f)$, indicating coupling between the fundamental and the first harmonic. The shallowest station (panel 4), which is $\sim 36m$ shoreward of C07 (panel 3), reveals several new interactions. The peaks at $(2f, 2f), (f, 3f)$ and $(3f, 3f)$ indicate sum interactions between the first harmonic and itself, the fundamental and the second harmonic, and the second harmonic with itself, respectively. Of particular interest though, are the peaks at $(2f, \Delta f)$ and $(3f, \Delta f)$. These peaks suggest that interactions within the (forced) harmonic peaks result in (harmonic) groups, which are coupled to a (forced) long wave beneath the group.

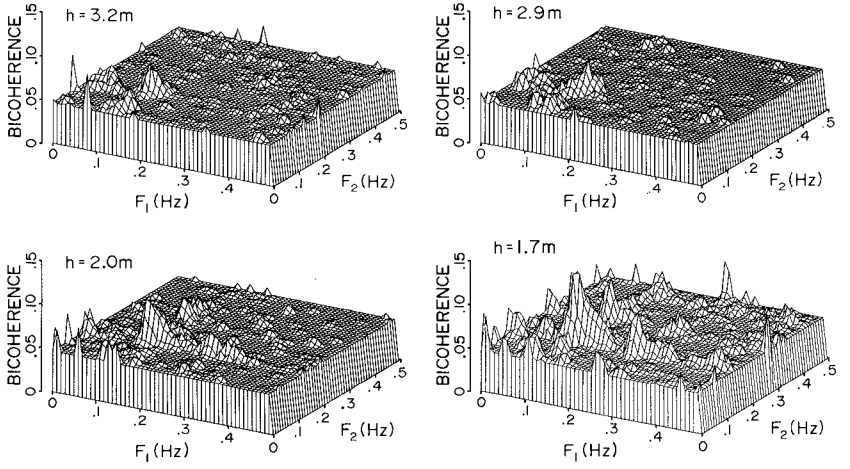

FIGURE 3. Bicoherence for current meters C26 ($h = 3.2m$), C23 ($h = 2.9m$), C07 ($h = 2.0m$) and C16 ($h = 1.7m$) for run 52 at Pte. Sapin. Only values above the 95% level for zero bicoherence (indicated by the thickness of the slab) are shown.

Figure 4 shows the real part of the bispectrum for the same four sensors as figure 3. Inspection of these four panels readily yields several points. First, the observed skewness of these cross-shore velocity time series is essentially due to the (f, f) interaction. Second, the sign of the skewness of the (f, f) interaction is opposite to that of the $(f, \Delta f)$ interaction. These observations of velocity bispectra are consistent with the pressure observations of Hasselmann *et al.* (1963) and Elgar and Guza (1985). For sediment transport this implies that the skewness of the horizontal velocity field arising from the (f, f) interaction pushes sediment in an opposite direction to the skewness arising from the $(f, \Delta f)$ interaction.

The sedimentary significance of these two interactions was noted by Wells (1967), who used Biesel's second-order solution for a discrete number of gravity wave trains to investigate the spatial variation of skewness across a beach. Wells suggested that a neutral line of zero skewness exists separating two regions, one of positive skewness in shallow water (skewed onshore), the other of negative (or seaward) skewness in deep water; he notes that, "sand in deeper water can actually be transported in a seaward direction". This mechanism was recently employed by Shi and Larsen (1983) to explain the seaward transport of fine sand and silt on the continental shelf. It is worth noting the shallow water portion of Wells' results are suspect as he extended his computations into relatively very shallow water where the underlying assumptions of the theory are no longer met.

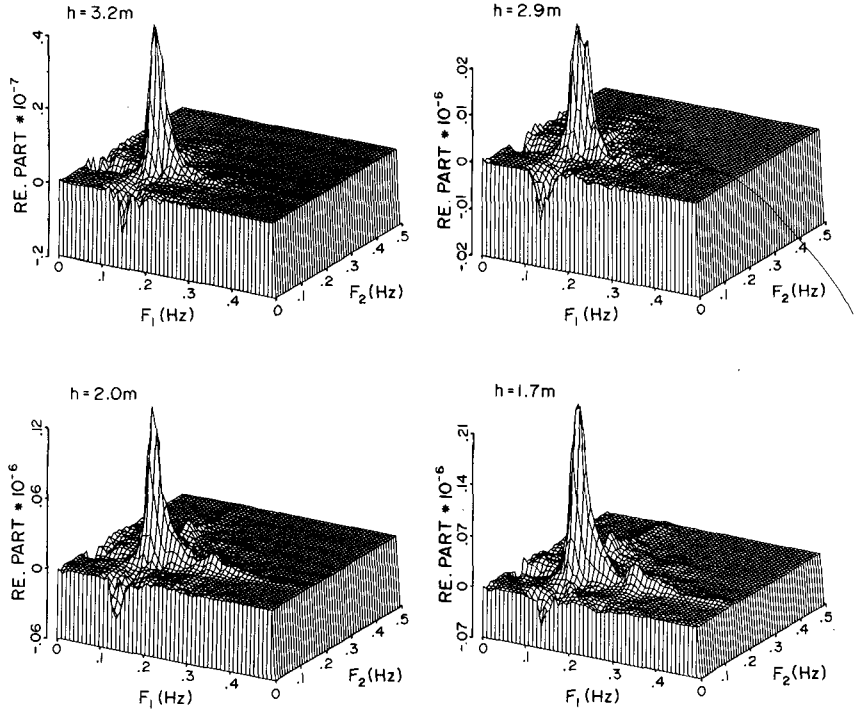

FIGURE 4. Real part of the bispectrum for current meters C26 ($h = 3.2m$), C23 ($h = 2.9m$), C07 ($h = 2.0m$) and C16 ($h = 1.7m$) for run 52 at Pte. Sapin.

Figure 5 shows the imaginary part of the bispectrum for the same four sensors as figures 3 and 4. From (2.6) it is clear that for a velocity time series, figure 5 provides information related to the wave–wave interactions that give rise to the skewness of horizontal acceleration. Note that the relative strength of the wave–wave interactions observed from these plots is biased because each imaginary estimate was not multiplied by the respective triple product of radian frequencies; as a result, the strength of the high(er) frequency interactions is deemphasized. For panel 1 the $(f,\ f)$ interaction is negative, indicating that the horizontal acceleration of this interaction is negatively skewed, therefore suggesting back-

ward tilted waves. This is, of course, not the usual direction that shoaling waves are tilted. As the waves shoaled further (panels 2 to 4) the (f, f) interaction becomes increasingly more positive (i.e., forward tilting). Although partially obscured, the $(f, \Delta f)$ interaction for panels 1 to 3 is negative, indicating that the horizontal acceleration of this interaction is skewed seaward. However, at the shallowest station, panel 4, the $(f, \Delta f)$ interaction is positively skewed. This is not the usual direction that the horizontal acceleration of this interaction is skewed, which suggests that the amplitude and phase of the Δf Fourier coefficients may include a partially reflected component.

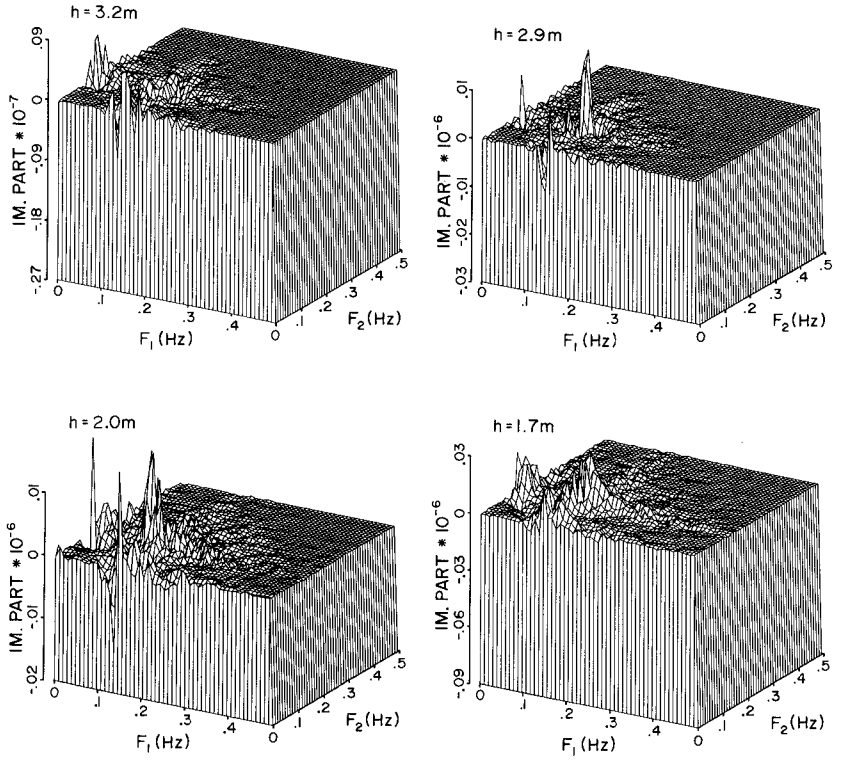

FIGURE 5. Imaginary part of the bispectrum for current meters C26 ($h = 3.2m$), C23 ($h = 2.9m$), C07 ($h = 2.0m$) and C16 ($h = 1.7m$) for run 52 at Pte. Sapin.

For progressive waves, in shallow water, it is known that sea surface elevation and the horizontal velocity in the predominant direction of propagation are strongly coherent for wind–wave frequencies (Guza and Thornton, 1980). Skewness of the horizontal acceleration resulting from vertical asymmetry of the waves, therefore, is related to the skewness of the vertical velocity. Vertical asymmetry of the waves may be an important mechanism for suspended sediment transport, since an upward skewed vertical velocity (under forward tilting waves) could balance gravitational settling, thereby maintaining suspension for advection by the mean flow (e.g., horizontal skewness).

To parameterize bispectral evolution, it is easiest to express the bispectrum as an amplitude and phase. Figure 6 shows the amplitude plots for the four previously considered sensors. Clearly, the (f, f) and $(f, \Delta f)$ interactions dominate these plots. A first-order parameterization of bispectral evolution therefore necessitates parameterizing the amplitude and phase of these interactions through the shoaling region.

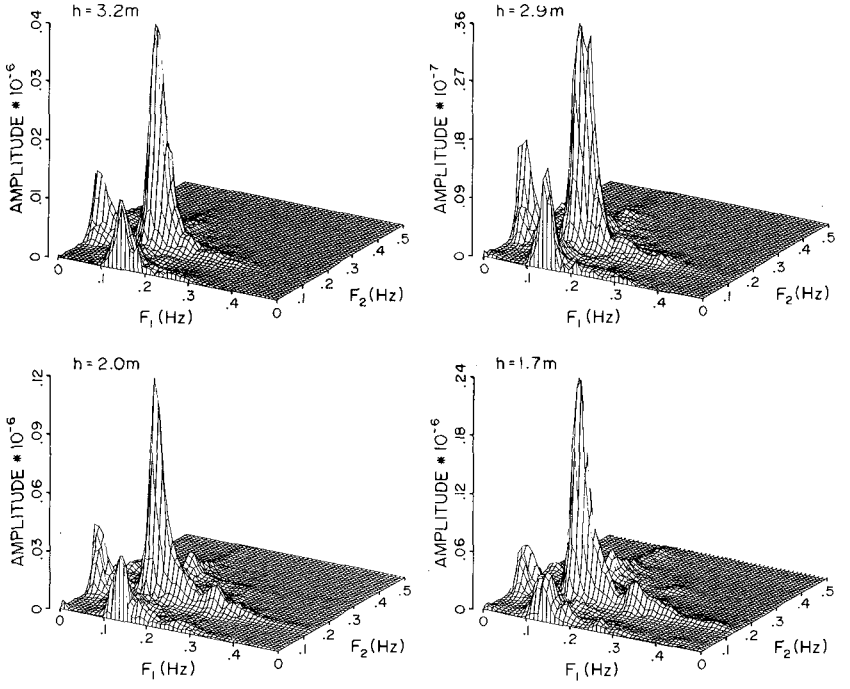

FIGURE 6. Amplitude of the bispectrum for current meters C26 ($h = 3.2m$), C23 ($h = 2.9m$), C07 ($h = 2.0m$) and C16 ($h = 1.7m$) for run 52 at Pte. Sapin.

It can be readily shown that the skewness arising from a second-order Stokes wave (a fundamental and its phase-locked, in phase harmonic) can be parameterized in terms of the Ursell number (Ursell 1953)

$$\lim_{kh \to 0} \frac{\eta^{(2)}}{\eta^{(1)}} \sim \frac{3}{4} \frac{ak}{(kh)^3} = U_r$$

In shallow water the Ursell number can be expressed as

$$U_r = \frac{3}{4} \frac{g}{8\pi^2} \frac{H_s T^2}{h^2}$$

where g is the acceleration due to gravity, H_s is the significant wave height, T is the period, and h is the local depth. Note that taking the same limit for $\frac{u^{(2)}}{u^{(1)}}$ also yields the

Ursell number. The Ursell number would seem to be a logical quantity to choose for the parameterization of the $(f,\ f)$ interaction observed in cross-shore velocity. Figure 7 shows the normalized (i.e., divided by the appropriate band integrated variance to the $\frac{3}{2}$ power) amplitude of the $(f,\ f)$ interaction for run 52, and all the other data listed in table 1, as a function of U_r. Least squares regression yields for this interaction

$$\text{Nrm. Ampl.}(f,\ f) = .48 + .31\log(U_r),\ r^2 = .92 \tag{4.1}$$

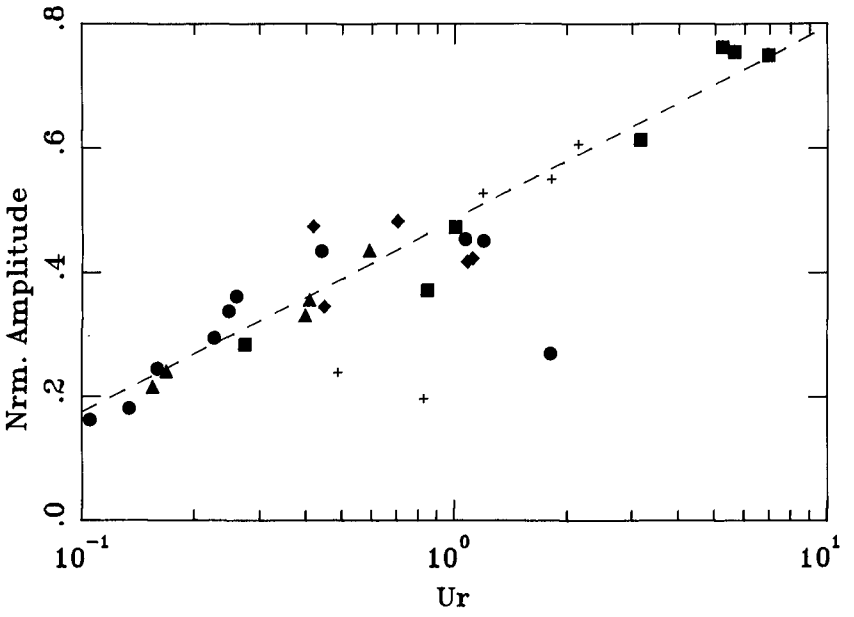

FIGURE 7. Normalized (NRM) amplitude for the self–self sum interaction of the wind-wave peak as a function of the Ursell number (U_r) for Pte. Sapin run 52 ▲, run 62 ◆, Stanhope Lane ●, Leadbetter Beach ■, and Queensland Beach +.

All of the Queensland data, which is strongly dominated by backwash, and the one Stanhope run from breaking wave conditions (circle near lower right of figure 7) were excluded from the regression. The relatively high correlation between these two quantities implies several points. First, the majority of the energy at the first harmonic is forced (ie. free energy would beat down r^2). Second, there is a relative increase in first harmonic energy as the waves shoal. Lastly, the growth of the $(f,\ f)$ interaction is dependent on depth, but apparently not on slope as U_r contains no beach slope information. Figure 7 also suggests that the relatively long period incident waves, which are commonly observed on the Pacific coast, develop much stronger nonlinearities before breaking than the shorter period waves of the Gulf of St. Lawrence or Atlantic coast.

It can be shown for a wave consisting of a fundamental and a phase-locked harmonic that the value of the $(f,\ f)$ biphase represents the phase difference, δ_1, between the fundamental and its first harmonic. Iwagaki and Sakai (1972) give a solution, correct to second-order, for the evolution of the phase shift δ_1. Their expression, which is a function of the

dimensionless quantity $\frac{\beta}{\sqrt{k_\infty h}}$, was found to be poorly correlated with the present data. However, figure 8 shows that the $(f,\ f)$ biphase was found to be well correlated with the relative depth (i.e., local estimate of kh). The two lines suggest, not surprisingly perhaps, that the evolution of the $(f,\ f)$ biphase is different for planar (dashed line) and barred (dotted line) beaches. This was not the case for the evolution of the $(f,\ f)$ normalized amplitude. Least squares regression gives,

$$\text{planar}: \quad \theta(f,\ f) = 64 + 179\log(kh),\ r^2 = .93 \tag{4.2a}$$

$$\text{barred}: \quad \theta(f,\ f) = 35 + 211\log(kh),\ r^2 = .97 \tag{4.2b}$$

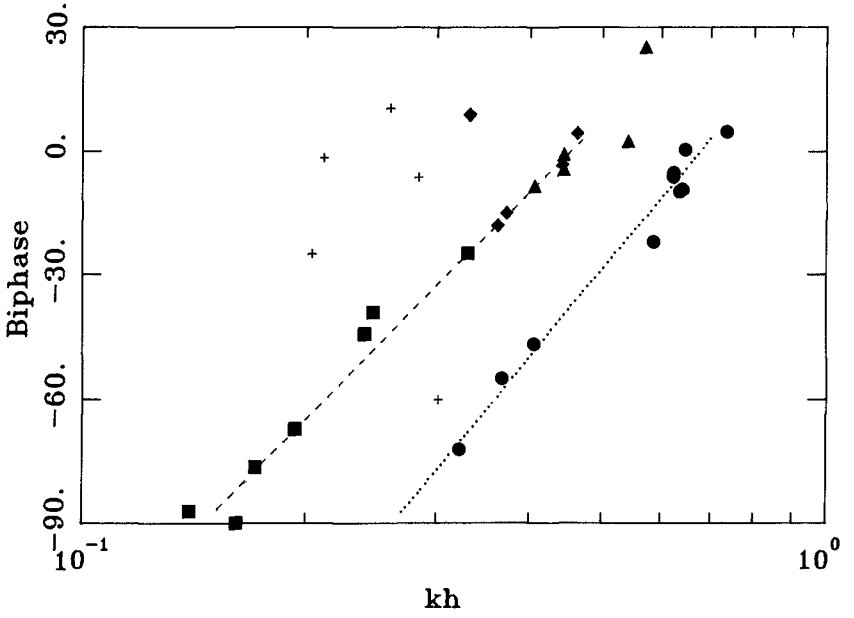

FIGURE 8. Biphase of the self–self sum interaction, $\theta(f,\ f)$, of the wind–wave peak as a function of kh for Pte. Sapin run 52 ▲, run 62 ◆, Stanhope Lane ●, Leadbetter Beach ■, and Queensland Beach +.

The Queensland data was once again excluded from the (planar environments) regression analysis. The strong backwash, noted previously, is evident in the very different biphase evolution. However, the Stanhope data point which was excluded from (4.1) has been included in (4.2*b*). This suggests (rather lightly as it is based on only one point) that $\theta(f,\ f)$ is not affected by wave breaking as strongly as as normalized amplitude was observed to be. The similar evolution of $\theta(f,\ f)$, over the steep Leadbetter Beach and gently Sloping Pte. Sapin beach suggests that $\theta(f,\ f)$ is not strongly dependent on beach slope (β). The work of Flick (1981) indicates that $-90 \leq \delta_1 \leq 0$. Therefore, equations (4.2*a*) and (4.2*b*) should be restricted to this range.

The other peak to be parameterized is the $(f,\ \Delta f)$ interaction. The observed evolution of normalized amplitude and phase suggests that the estimated Fourier Coefficients of the

low frequency (Δf) component of this interaction are complicated by reflection and possibly other sources of low frequency energy. Clearly, the estimates of amplitude and phase from a sensor beneath a partially reflected wave depends on where the sensor is located (ie. node $\rightarrow$ anti-node). Since discerning the composition of the low frequency energy in these data sets is in itself a formidable task, a parameterization of this interaction is not considered here.

5. Conclusions

Current meter data, collected from four nearshore environments, were used as an input to the (auto) bispectrum to investigate wave–wave interactions in the cross-shore velocity field of shoaling surface gravity waves. Bicoherence values indicate that as shoaling begins coupling occurs first within the wind–wave peak, i.e., (f, f) and (f, Δf) interactions. As shoaling progresses coupling occurs between the fundamental-harmonic (f, $2f$), and eventually within and between the harmonic peaks, e.g., ($2f$, $2f$), ($2f$, Δf) and ($2f$, $3f$). The real and imaginary parts of the velocity bispectrum indicate that the skewness and asymmetry, respectively, of the (f, f) interaction is usually of opposite sign to the (f, Δf) interaction.

Bispectrum amplitudes clearly show that the (f, f) interaction, and to a lesser extent the (f, Δf) interaction, are typically much stronger than the other triads. Least squares regression indicates that the normalized amplitude of the (f, f) interaction is well parameterized ($f^2 = .92$) by the Ursell number for planar and barred environments; the data provide no evidence for any strong return of energy to the fundamental frequency (as necessary, for example, for the Fermi-Pasta-Ulam instability) which might lead to wavelike horizontal variability in the (f, f) interaction, one of the suggested mechanisms for bar formation. A suitable parameterization was not obtained for the smaller amplitude (f, Δf) interaction, as the observed amplitudes and phases of this interaction were quite erratic. This suggests that the Fourier Coefficients of the Δf component are contaminated by reflection and possibly other forms of infragravity wave motion. These observations highlight the potential role that low frequency motion may play in determining seabed topography (e.g., the shore parallel bars observed at Stanhope Lane).

The biphase of the (f, f) interaction, $\theta(f, f)$, was observed to evolve differently for planar and barred environments, but for both types of beach profiles was well parameterized ($r^2 \geq .93$) as a function of kh. This implies that, like normalized amplitude, $\theta(f, f)$ does not appear to depend strongly on the beach slope. Observations indicate that the Pacific coast data (NSTS) tend to exhibit not only stronger nonlinearities prior to breaking than the east coast data (C^2S^2), but also $\theta(f, f)$ values that are much closer to $-90°$. This implies that the NSTS data develops stronger (vertical) asymmetry before breaking than the C^2S^2 data, which suggests that wave skewness/asymmetry cannot by itself be used as a breaking criteria. Since skewness/asymmetry depend on a combined functional form of kh and U_r (which is a function of kh and $\frac{a}{h}$) suggests that another or additional parameter is required to determine the inception of breaking; kh and $\frac{a}{h}$ apparently do <u>not</u> provide this information.

CHAPTER 13

Water-wave modulation

J.W. Dold* and D.H. Peregrine†

Abstract

Accurate numerical computations of wave trains with small modulations that grow are described. The range of wave steepness and modulation lengths that give breaking waves are determined. The number of wave crests is reduced for a time at greatest modulation but frequency downshifting is not observed. Near-breaking wave-group structure is always similar, with energy concentrated into one or two wavelengths.

1. Introduction

The ocean surface rarely, if ever, has the form of a uniform periodic travelling wave train. In part, this is due to the instabilities of such waves. The first instability to be found was the Benjamin-Feir (1967) modulational instability. Unlike other instabilities it occurs for wave trains of steepness well below the maximum steepness of steady waves at which crests approach a 120° angle, and so may be especially relevant to the evolution of ocean waves. For more recent theoretical studies of the instability itself see McLean (1982 a,b).

Experiments demonstrate that the instability leads to the formation of strongly modulated wave groups, and further evolution can lead to a recurrence of an approximately uniform wave train. One of the most striking features of experiments is that for sufficiently steep initial waves the recurrence of a uniform wave is accompanied by a decrease in frequency. (Lake et al, 1977, Melville 1982, Su et al 1982). Lake and Yuen (1978) conjecture that this frequency downshifting is related to the decrease in the dominant frequency of wind waves with fetch and duration.

Previous theoretical studies have been made with approximate equations, see Lake et al (1977), Stiassnie and Kroszynski (1982), and Lo and Mei (1985). They show strong modulation and recurrence of uniform waves, but no frequency downshifting. Since these approximations are weakly nonlinear they cannot describe the wave breaking that occurs at strongest modulation.

This work describes numerical computations of the evolution of small amplitude modulations on a uniform wave train. These computations use an efficient program solving for irrotational flow with the exact

*Research Associate and †Reader, School of Mathematics, University of Bristol, University Walk, Bristol BS8 1TW, England.

inviscid boundary conditions. The computations can continue to describe the initial overturning stage of wave breaking, and hence clearly indicate when breaking occurs.

2. Computation

The method of computation is based on a boundary-integral solution of Laplace's equation for the complex velocity $\phi_x - i\phi_y$ in two dimensions. It is based on Cauchy's integral theorem for functions of a complex variable $(x + iy)$. The method is briefly described in Dold and Peregrine (1984, 1985): a more detailed account is in preparation.

Initial conditions are chosen for the surface elevation, ζ, and velocity potential, ϕ, and were made up as follows:

(i) an initial uniform wave train on deep water; $\zeta = a \cos x$ is the relevant first approximation, but an accurate steady wave form and potential were used in units with gravity = 1, wavelength = 2π.

(ii) the computational region contained n waves, where $3 \leq n \leq 10$.

(iii) a perturbation of the form

$$\varepsilon a\left[\cos\left(\frac{n+m}{n}x - \tfrac{1}{4}\pi\right) + \cos\left(\frac{n-m}{n}x - \tfrac{1}{4}\pi\right)\right]$$

was added to ζ together with a corresponding perturbation to ϕ. This gave a modulation length of n/m waves; m was 1 or 2. The phase shift was chosen to be $\frac{1}{4}\pi$ since Stiassnie (private communication) indicated this gave the most rapid growth. The value of ε was usually 0.1 and sometimes 0.05. We did not intend to study the growth of infinitesimal perturbations.

Periodic boundary conditions were imposed on the computational region, and the effect of the above initial conditions is to give a weak periodic modulation on the wave train. The time evolution of this modulation was then followed through its initial growth until either:

(a) the computation failed because the wave crest had become too sharply curved for satisfactory resolution, which is a clear indication of the proximity of breaking. By rearrangement of computational points wave overturning could be modelled.

or (b) a near recurrence of the uniform wave state occurred. In some cases more than one recurrence was computed.

Most previous calculations with this general type of program had been for one or two periods involving no more than two waves. The present examples were for up to 10 waves followed for a hundred or more periods. Accuracy was checked in this case by running the same initial conditions with various numbers of initial points and varying the explicit tolerances for iterations and time-stepping within the computation. We aimed to find the most economical values which gave sufficient accuracy. The high-order approximations used in the method

permitted as little as 8 computational points per wave and time-steps as large as 0.1 period for the gentler waves. Figure 1 shows part of one such computation just after it has lost accuracy, together with a more accurate profile using 12 points per wavelength from the initial time.

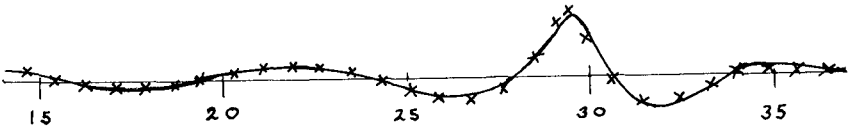

Figure 1. A partial comparison of computations of surface elevation with 8 and 12 points per wave length after 60 linear periods, i.e. $t = 120\pi$. The more accurate profile is shown with a continuous line, the computational discretization is shown for the 8 point profile. The initial steepness is 0.12, and the whole computation includes 2 modulations over 9 wavelengths. The vertical exaggeration in the figure is 5 times. The actual maximum wave slope is 23°.

3. Some examples related to wave breaking

A summary of the calculations is given in figure 2 which indicates whether or not waves grow to breaking. Some of the shorter modulations of $2\frac{1}{2}$ or 3 waves are too short to be unstable. For the instability of just two waves and its evolution see Longuet-Higgins (1978) and Longuet-Higgins and Cokelet (1978).

One important feature of all the computations is that except for a fraction of a wave period before wave breaking the linear-wave concepts of phase velocity and group velocity give a good approximation for any time interval of two or three wave periods. Hence, should anyone wish to compare any of the spatial wave profiles with wave measurements at a fixed point this is possible. The most significant point to be noted is that since for deep water waves group velocity, c_g, is half the phase velocity, c, the number of waves in a modulation on a temporal record is twice the spatial number used here; see figure 6.

Figure 3 is a representative example of cases where the small initial modulation evolved into a steep, short wave group and back to a recurrence of a near uniform wave-train. Slightly more than one modulation length of 5 waves is shown. The wave profiles are given at multiples of 10 or 20 periods since by choosing an interval of $2n$ or $4n$ periods the effects on the wave profile of both phase velocity and linear group velocity lead to a recurrence of the wave and modulation positions.

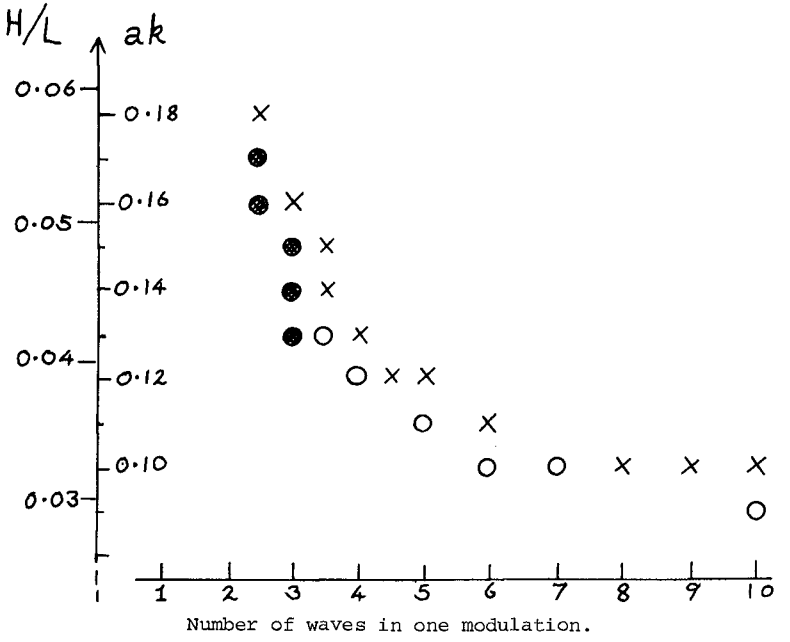

Figure 2. Summary of wave modulation computations. Crosses indicate waves grew to breaking. Open circles indicate modulation grows and uniform waves recur. Filled circles indicate no growth of modulation.

Typical features shown in figure 3 include:

(a) a short group of steep waves at maximum modulation.

(b) waves of close to zero amplitude each side of the steep waves. The modulation does have two precise zeros in the evolution.

(c) a time interval around the time of maximum modulation during which one wave crest disappears.

(d) an advance in the relative position of the peak of the modulation over that predicted by linear group velocity.

(e) a change of relative phase of waves at recurrence, but no lasting frequency downshift which requires the loss of a wave.

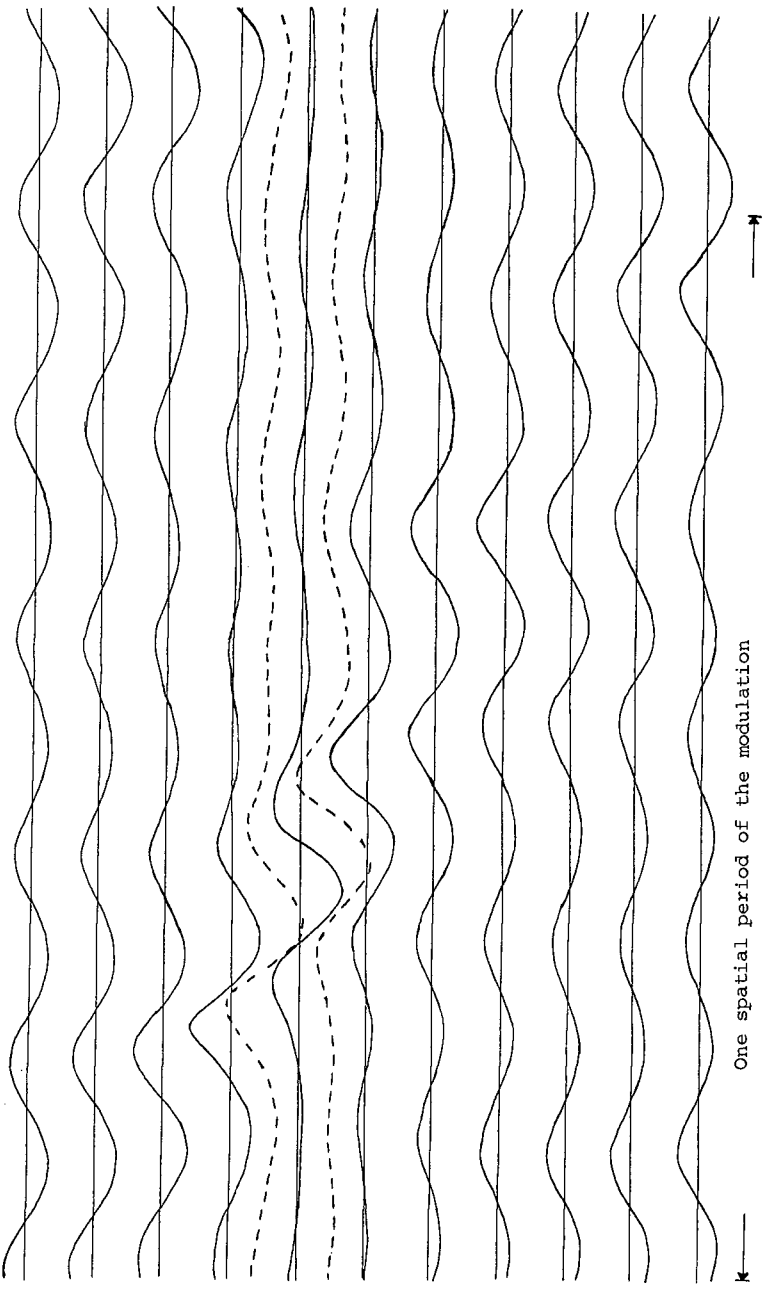

Figure 3. Evolution of the surface profile of a 5 wave modulation shown at intervals of 20 periods with supplementary profiles at 70 and 90 periods. The initial wave steepness is $ak = 0.11$, and the perturbation has $\varepsilon = 0.1$. The vertical exaggeration is 5 times.

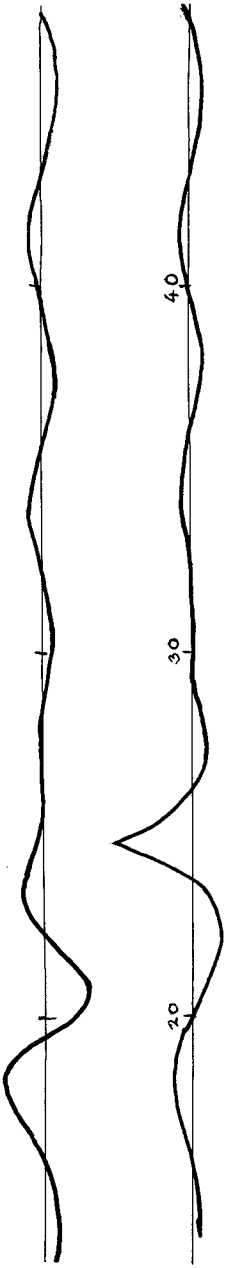

Figure 4. The surface profile of a 5 wave modulation at 60 periods and 61 periods for initial wave steepness ak = 0.12 with perturbation ε = 0.1. The vertical exaggeration is 5 times.

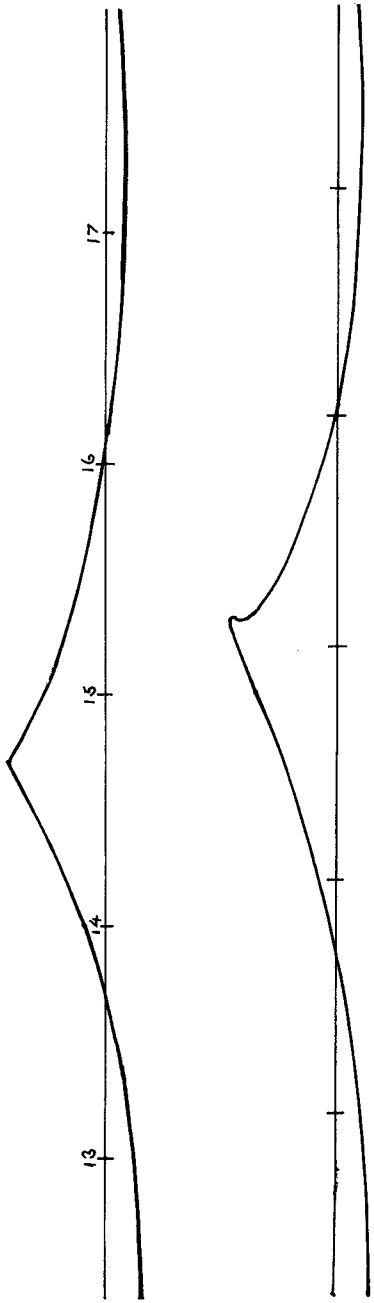

Figure 5. Computed wave profile at "breaking" for a 5 wave modulation with initial steepness ak = 0.12. (a) with initial modulation ε = 0.1 (b) with ε = 0.05. No vertical exaggeration.

Those modulations that break differ little from the first part of figure 3. This is illustrated in figure 4 which shows two profiles for the slightly greater initial wave steepness of $ak = 0.12$, compared with $ak = 0.11$ in figure 3. The first profile, at 60 periods, fits almost precisely on the supplementary profile at 70 periods in figure 3. It is significant that the ratio 70:60 is close to $(0.12)^2:(0.11)^2$ which is the relative scaling one would expect from the nonlinear Schrödinger equation. A wave trough is near the maximum point of the modulation.

The second profile in figure 4 is just one period later: the crest of a wave is now at a point close to the peak of the modulation. A very short time later the computation ceased because the wave crest was too sharp. Improved numerical resolution met the same problem. This wave crest is very close to the form of the limiting travelling wave with a corner of 120° at the crest. The maximum slopes of the waves are close to 30°. This crest is shown without vertical exaggeration in figure 5.

Also in figure 5 is a breaking wave derived from the same wave train but with the initial perturbation $\varepsilon = 0.05$ instead of $\varepsilon = 0.10$. This produced a slightly more energetic breaker at a later time.

Two isometric plots of the later stages of the computation with $\varepsilon = 0.05$ are chosen to show profiles in the time direction cutting a wave group when the peak modulation is in a trough, figure 6(a) and when it is at a crest, figure 6(b). They also show how each successive wave passes through the energy maximum.

The energy of the modulation continues to be focussed near the peak so that there is eventually one wave which either just breaks or breaks more strongly depending on the relationship between the energy focussing and wave phase. In reality each successive wave passing through such a group can break. This is reported from ocean observations by Donelan et al (1982). In a real sea the relationship between energy focussing and wave phase is likely to be even more variable, so this aspect of wave breaking has not been studied further.

The detailed shape and evolution of the short steep wave group that occurs for some periods before breaking, as illustrated in figure 6, is remarkably similar for a range of initial wave steepnesses and modulations. Profiles chosen at comparable times of wave passage through the groups can be superposed with only slight differences detectable.

4. Frequency downshifting

The problem of frequency downshifting has been examined carefully. In these calculations there is no frequency downshift at recurrence. On the other hand, at maximum modulation there is every sign of downshifting. There is normally one wave crest lost for each modulation: see figure 7 where at the end of a computation with 9 waves and two modulations only seven crests are visible. Similarly the spatial Fourier coefficients show a strong spectral shift to the lower perturbation wavenumber: figure 8 shows the time evolution of the coefficients

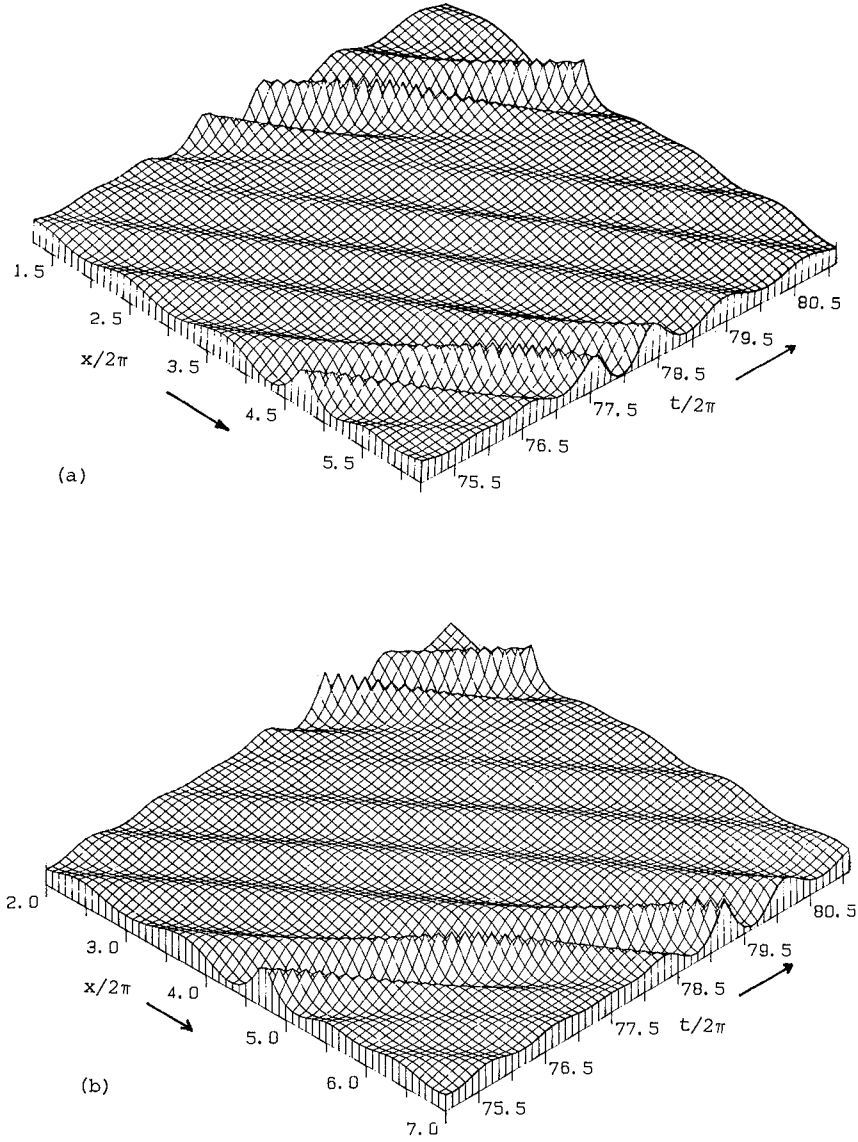

Figure 6. Isometric plots of the last 6 periods before breaking for the 5 wave modulation with initial steepness $ak = 0.12$, and initial modulation $\varepsilon = 0.05$. The "exposed" time profile has a trough at peak modulation in (a), and a crest in (b).

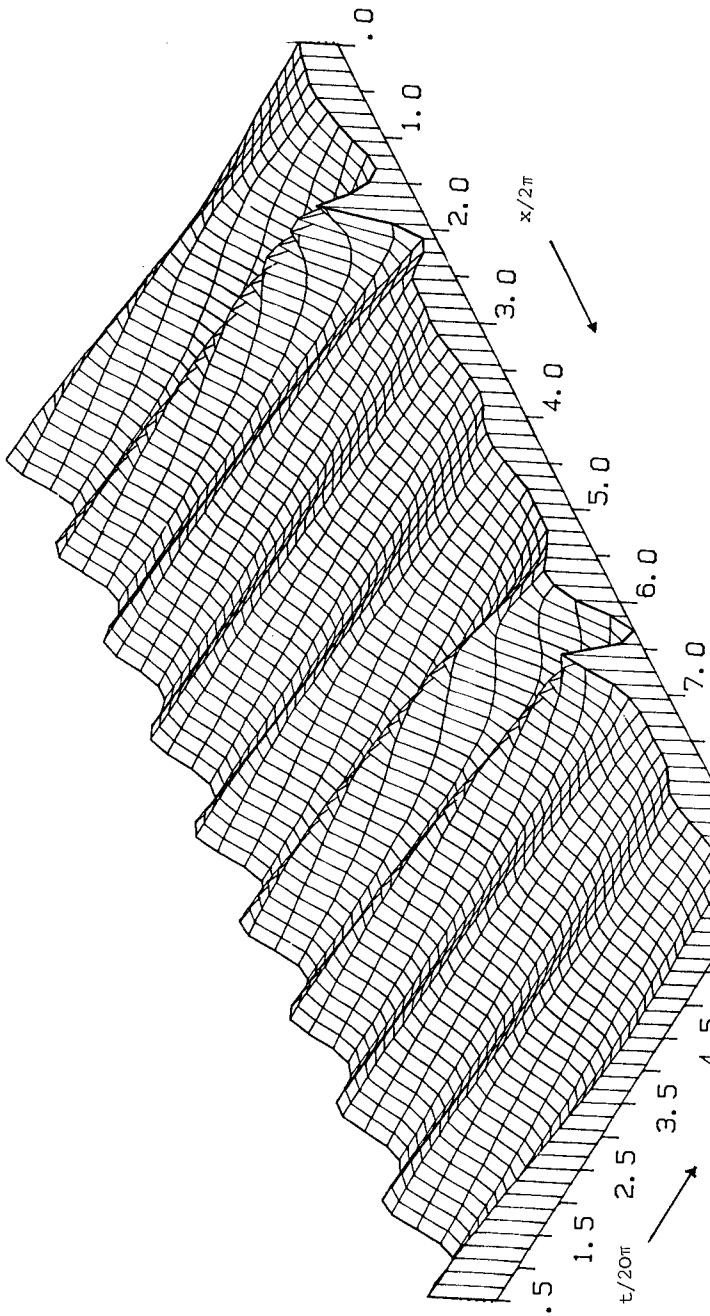

Figure 7. Plot of the time development for 64 periods of two 4½ wave modulations on an initial steepness of ak = 0.12. Phase and group velocity effects are minimised by taking data only every 2 periods. (The apparent roughness of the profiles shown is due to limitations of the plotting routine). Note the transition to 7 crests and 7 troughs.

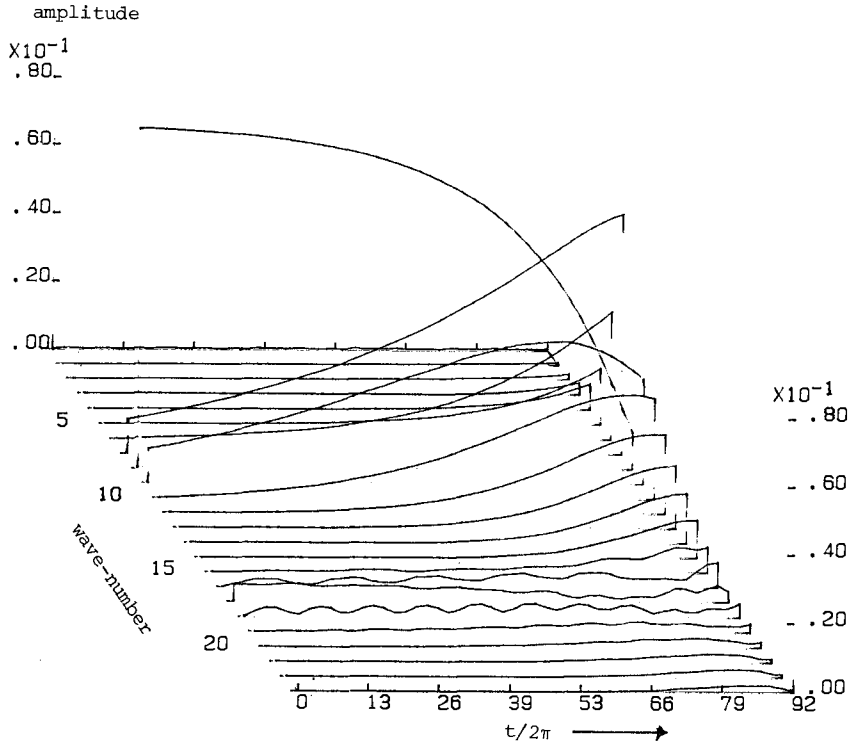

Figure 8. Time evolution of the spatial Fourier coefficients for a 9 wave modulation on waves with initial steepness 0.10. Breaking occurs at 92 periods with most energy in the "8" wave number component.

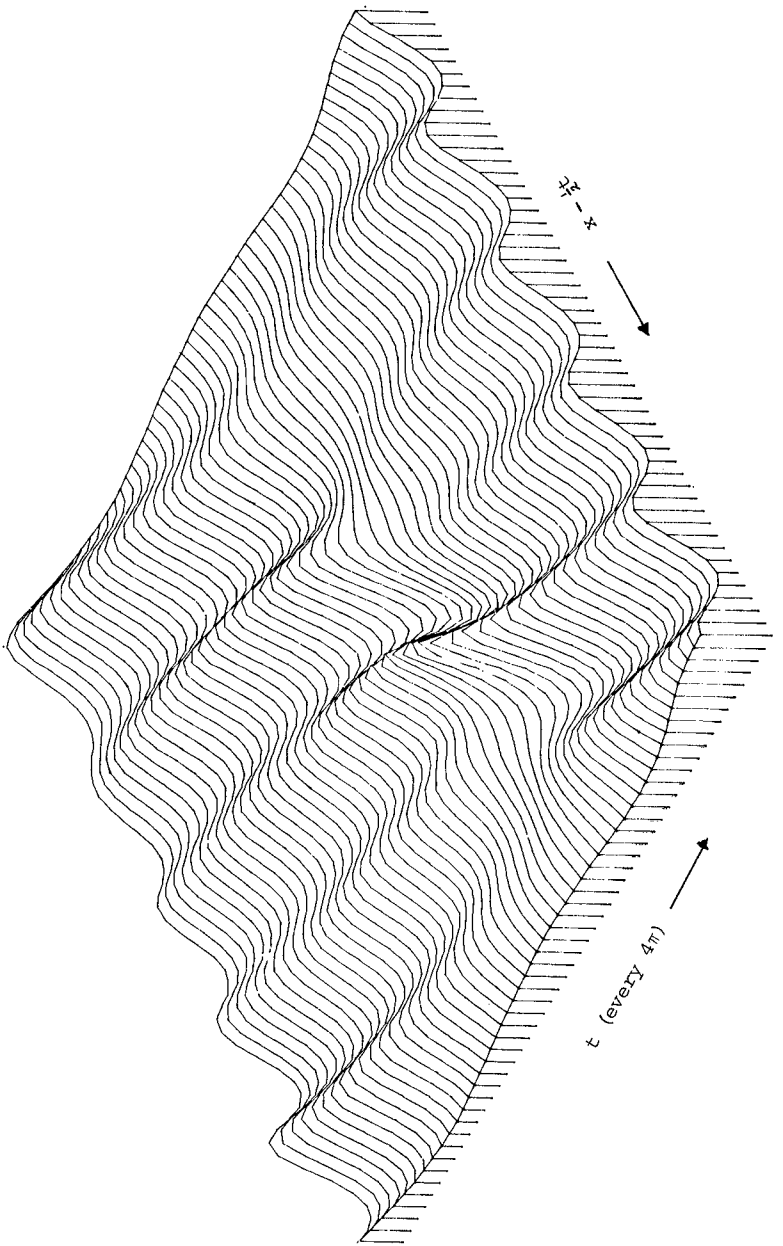

Figure 9. Evolution to recurrence, with linear phase and group velocity effects minimised, of a 5 wave modulation on wave steepness 0.11.

for a single 9-wave modulation. However, when recurrence occurs, as in figures 3 and 9 the original wavelength and period also return.

These computations support the hypothesis that breaking is essential for frequency downshift. This is consistent with experiments. However, waves actually disappear, or reappear, in the vicinity of zeros of wave amplitude. In each case of recurrence two such zeros were found at different times and one less wave can be seen during the time interval between zeros.

5. Conclusions

Computations describe many details of the evolution of weak modulations on a uniform wave train. The boundary of modulations that grow to breaking is outlined in terms of initial wave steepness and modulation length. Wave trains as gentle as $ak = 0.10$, $H/L \doteq 0.03$, can develop into breaking waves. For comparison, the energy density of a wind driven sea is equivalent to a uniform wave train, at the frequency of the spectral peak, of around $ak = 0.13$, and the limiting wave train of maximum steepness has $ak = 0.44$.

The steepest waves all occur in similar short groups a little more than one wavelength long. Such groups endure for around ten or more wave periods.

Although there are indications of frequency downshifting in the computations, the origin of the phenomenon is still obscure.

Comparisons with theory suggest:

(a) for times of a few periods linear theory gives a fair indication of wave behaviour, even for the steepest nonbreaking waves, but wave shape is nonlinear.

(b) for long time intervals, the weakly nonlinear NLS equation gives a qualitatively correct evolution, with quantitative discrepancies which are consistent with Dysthe's (1979) higher order approximation. These comparisons will be reported elsewhere.

CHAPTER 14

APPLICATION OF A NESTED NUMERICAL MODEL TO IDEALISED RECTANGULAR HARBOURS

by

Roger A. Falconer[1] and Lida Mardapitta-Hadjipandeli[2]

Abstract

The paper gives details of a two-dimensional depth averaged nested numerical model and its application to a range of idealised rectangular harbours, having a constant plan cross-sectional area and varying length to breadth ratios. The main aims of the study have been to investigate the problems associated with nested numerical modelling and to apply this modelling approach to assess the influence of the shape of a harbour on its natural tidal flushing efficiency and mixing characteristics.

Introduction

In recent years there has been an increasing awareness of the tidal exchange characteristics and flushing efficiencies of ports, harbours and narrow entranced coastal basins. This incresed awareness can be attributed to a number of factors and, in particular, is partly attributable to the occurrence of poor water quality characteristics within both natural and man-made harbours and coastal basins. The main problems giving rise to poor water quality characteristics in coastal basins include such phenomena as:- low dissolved oxygen, eutrophication and low exchange rates and flushing efficiencies. The greater public concern and awareness of deteriorating water quality characteristics has partly arisen as a result of increased recreation and has led to many countries now establishing guidelines as to acceptable water quality standards within such coastal basins.

In attempting to minimise the occurrence of such phenomena as low dissolved oxygen and low tidal exchange rates, there are insufficient engineering design guidelines available to the coastal engineer faced with the task of designing a new harbour or modifying an existing coastal basin. For example, little knowledge exists in the technical literature as to:- (i) the optimum shape of harbours for maximum flushing efficiency, (ii) the ideal entrance configuration, (iii) the optimum depth for maximum flushing and minimum dredging requirements, and (iv) the effects of longshore currents on the basin's internal flow structure and exchange characteristics. Furthermore, the use of traditional physical model studies to obtain related design guidelines concerning tidal flushing and exchange characteristics for harbours is of limited

1. Lecturer in Civil Engineering, University of Birmingham, Birmingham, England.

2. Formerly Research Student, Department of Civil Engineering, University of Birmingham, England.

value, in view of the scaling problems associated with recirculating free surface flow models, i.e. Reynolds number effects. These scaling problems are particularly prevalent in harbours where the dimensions of the plan-form area, the narrow entrance width and the tidal range are such that tidal eddies occur within the basin on the flood tide.

In view of the growing concern about the water quality characteristics within narrow entranced coastal basins, such as harbours, and the problems associated with related physical model studies, there has also been an increasing use made of mathematical models for such studies e.g. Falconer (1,2). These mathematical model studies have either been undertaken for site specific studies or have been associated with related research programmes, such as:- (i) fluid mechanics and turbulence modelling, (ii) cohesive sediments and mud transport modelling, (iii) aspects of ecological, biological and chemical reaction modelling, e.g. the nitrification cycle, (iv) numerical methods, e.g. discontinuity modelling related to sewage effluent outfalls, and (v) field data acquisition and interpretation.

In earlier work reported by Falconer (1,3), a single grid-size mathematical model study was described wherein the model was specifically developed to predict the two-dimensional tide induced recirculatory velocity fields and solute transport distributions in harbours and narrow entranced coastal basins. Although reasonably encouraging agreement was obtained between the mathematical and physical model velocity and solute transport fields, at the same scale, no counter-rotating gyres - or tidal eddies - were predicted in the numerical model simulations and the dominant tidal eddy was always observed to be distinctly weaker in the numerical model predictions. The main cause of these discrepancies was attributed to the imprecise description of the velocity field at the harbour entrance and hence the main objective of this study was to develop a nested two-dimensional flow and solute transport model, with the aim of describing the velocity distribution across the harbour entrance more accurately. The model, which only required a marginal increase in the computational effort relative to the single grid-size model, was then applied to the rectangular harbours studied in an earlier research programme, by Falconer (1,3). The model was also used to investigate the effects of varying the harbour shape, entrance conditions and tidal range, with a view to establishing some fundamental engineering guidelines relating to the water quality aspects of rectangular harbours. The model included a refined turbulence model incorporating both free shear layer and bed generated turbulence, with simulations being undertaken at both prototype and physical model scales. Further physical model tests were undertaken to extend previous findings by Jiang and Falconer (4,5), and experimentally measured and numerically predicted velocity fields and exchange coefficients were compared for the physical model scale dimensions.

Governing Differential Equations

In determining the velocity and solute transport fields from the mathematical model, the depth averaged velocity components in the horizontal plane and the spatial solute distributions were obtained from the depth integrated equations of continuity, momentum - in both x and y directions in the horizontal plane - and the solute transport or

advective-diffusion equation. The full derivation of these equations is given by Falconer (6), with the equations of mass and momentum conservation being respectively given as:-

$$\frac{\partial \eta}{\partial t} + \frac{\partial UH}{\partial x} + \frac{\partial VH}{\partial y} = 0 \qquad \ldots\ (1)$$

$$\frac{\partial UH}{\partial t} + \beta\left[\frac{\partial U^2H}{\partial x} + \frac{\partial UVH}{\partial y}\right] - fVH + gH\frac{\partial \eta}{\partial x} + \frac{\tau_{bx}}{\rho} - \frac{1}{\rho}\left[\frac{\partial H\sigma_{xx}}{\partial x} + \frac{\partial H\tau_{xy}}{\partial y}\right] = 0 \qquad \ldots\ (2)$$

$$\frac{\partial VH}{\partial t} + \beta\left[\frac{\partial UVH}{\partial x} + \frac{\partial V^2H}{\partial y}\right] + fUH + gH\frac{\partial \eta}{\partial y} + \frac{\tau_{by}}{\rho} - \frac{1}{\rho}\left[\frac{H\tau_{yx}}{\partial x} + \frac{H\sigma_{yy}}{\partial y}\right] = 0 \qquad \ldots\ (3)$$

where η = water surface elevation above datum (e.g. MWL), t = time, U, V = depth mean velocity components in x,y directions, H = total depth of flow, β = momentum correction factor for non-uniform vertical velocity profile, f = Coriolis parameter, g = gravitational acceleration, τ_{bx}, τ_{by} = bed shear stress components in x,y directions, ρ = fluid density and σ_{xx}, τ_{xy}, τ_{yx}, σ_{yy} = Reynolds stress components in x,y directions.

For the bed shear stress components, the traditional quadratic friction law was used, giving (see Dronkers (7)):-

$$\tau_{bx} = \frac{\rho g U\bar{V}}{C^2} \quad \text{and} \quad \tau_{by} = \frac{\rho g V\bar{V}}{C^2} \qquad \ldots\ (4)$$

where $\bar{V}$ = depth mean fluid speed and C = Chezy roughness coefficient - evaluated in the numerical model from the Colebrook-White equation, given as:-

$$C = \frac{\sqrt{8g}}{\sqrt{f}} = -2\sqrt{8g}\,\log_{10}\left[\frac{k_s}{12R} + \frac{2.5}{Re\sqrt{f}}\right] \qquad \ldots\ (5)$$

where f = Darcy friction factor, k_s = length parameter characteristic of bed roughness, R = hydraulic radius, Re = Reynolds number = $4UR\nu^{-1}$ where ν = kinematic viscosity of fluid.

For the Reynolds stresses, the assumption was made that the direct stresses σ_{xx} and σ_{yy}, were generally small in comparison with the lateral shear stress, τ_{xy} and τ_{yx}, see Kuipers and Vreugdenhil(8) and, in the mixing zone, the lateral shear stresses were subdivided into two components. These components included turbulent shear contributions arising from free shear layer and bed generated turbulence and can be

summarised for the x-direction as follows:-

$$\tau_{xy} = \rho \left[\frac{U_1^2}{2\sqrt{2\pi R}} e^{-R/2(y^1/x^1)^2} + \frac{0.16\sqrt{g}\,\bar{V}H}{C} \frac{\partial U}{\partial y} \right] \quad \ldots\ (6)$$

where U^1 = free stream velocity, R = experimental constant and x^1, y^1 = co-ordinate axes for the mixing layer. This empirical shear stress distribution is based on the assumption of a Gaussian lateral velocity distribution in the horizontal plane and a logarithmic velocity distribution in the vertical plane. Full details of the derivation of equation (6) are given by Falconer, Wolanski and Mardapitta-Hadjipandeli (9) and Falconer and Mardapitta-Hadjipandeli (10).

The depth integrated advective-diffusion equation was attached to the hydrodynamic model, thereby enabling the transport of a conservative tracer S to be evaluated accordingly:-

$$\frac{\partial SH}{\partial t} + \left[\frac{\partial SUH}{\partial x} + \frac{\partial SVH}{\partial y} \right] = \frac{\partial}{\partial x} \left[HD_{xx} \frac{\partial s}{\partial x} + HD_{xy} \frac{\partial s}{\partial y} \right]$$

$$+ \frac{\partial}{\partial y} \left[HD_{yx} \frac{\partial s}{\partial x} + HD_{yy} \frac{\partial s}{\partial y} \right] \quad \ldots\ (7)$$

where D_{xx}, D_{xy}, D_{yx}, D_{yy} = depth mean longitudinal dispersion and turbulent diffusion tensor coefficients in x,y direction, as given by Fischer (11).

Mathematical Model Details

In numerically solving equations (1), (2), (3) and (7) an alternating direction implicit finite difference model was used, including a traditional space staggered grid scheme (see Falconer (2,3)). The difference equations were fully centred in time and space and the advective accelerations and diffusion terms were centred by a single iteration procedure (see Mardapitta-Hadjipandeli(12)). The model had no stability constraints, although it was established that the accuracy of the scheme deteriorated when the Courant number exceeded about eight, i.e. for accuracy:-

$$\Delta t \sqrt{gH}\, \Delta x^{-1} \leq 8 \quad \ldots\ (8)$$

where Δt = time step and Δx = grid spacing.

In the model, particular attention was given to the treatment of the advective accelerations, with these terms being expressed in a conservative form in both the differential and difference equations. This conservative representation of these terms allowed a more accurate simulation of the jet type flow field, associated with the flood tide flow past the narrow harbour entrance. In addition, the cross product advective accelerations were expressed in a modified form of the marker and cell technique, see Falconer et al (9), thereby allowing the momentum flux to be evaluated nearer to its position of

origin and the introduction of sufficient artificial diffusion to eliminate grid scale oscillations.

For the treatment of discontinuities, arising as the tracer contaminated fluid was advected into the region of non-contaminated fluid, sufficient artificial diffusion was introduced into the scheme to avoid the occurrence of negative concentration values. However, other than in the immediate vicinity of the discontinuity, the degree of artificial diffusion introduced into the scheme was negligible. This scheme was similar to that first outlined by Leendertse (13) and is described in more detail in Falconer (14).

Model Application

In extending work undertaken previously by Falconer et al (1)-(5), the physical and mathematical model studies were applied to idealised prototype rectangular harbours, having a flat bed, vertical sides and an asymmetric entrance. The idealised prototype harbour was assumed to have a constant plan-form area of $0.16km^2$, a mean depth of 6.0m, an entrance width of 100m, a tidal range of 5.0m and a variable length to breadth ratio - varying from 0.38 to 4.0. Each harbour shape considered was assumed to be initially contaminated uniformly within the basin by a conservative tracer of concentration 10ppm. The range of harbour shapes considered are illustrated schematically in Fig.1, which gives an illustration of the laboratory tidal tank and the harbour configuration.

For the physical model studies, the basin was modelled using a distorted Froude scale model, with horizontal and vertical length scales of 1:500 and 1:50 respectively. The resulting scaled laboratory model harbours had a plan-form area of $0.64m^2$, a mean depth of 120mm and an entrance width of 100mm. Likewise, for dynamic similarity, the corresponding velocity and time scales were 1:7.07 and 1:70.7 respectively, resulting in a model tidal period of 10.52 minutes and a range of 100mm.

In undertaking the laboratory model tests, the model harbour walls were first adjusted to give the required length to breadth ratio, for the constant plan-form area of $0.64m^2$. The overflow weir was set at the low tide level and the tidal tank was filled and the inflow rate adjusted to ensure a continuous flow over the weir for the whole model tide. After any initial circulation engendered within the basin had been dissipated, the harbour entrance was temporarily sealed and 75ml of Rhodamine B, of concentration 7.5mg/ℓ, was thoroughly mixed with the enclosed harbour fluid. The spatially averaged initial concentration was then determined from twelve evenly distributed sampling points. The temporary barrier across the harbour entrance was then removed and the tidal generator was run for three tides, after which time the generator was stopped and the temporary barrier simultaneously replaced. The spatially averaged final concentration was then determined as before and the exchange coefficient was evaluated as defined by the following equation (see Nece and Richey (15)):-

$$E = 1 - (Co/Ci)^{1/i} \quad \ldots\ (9)$$

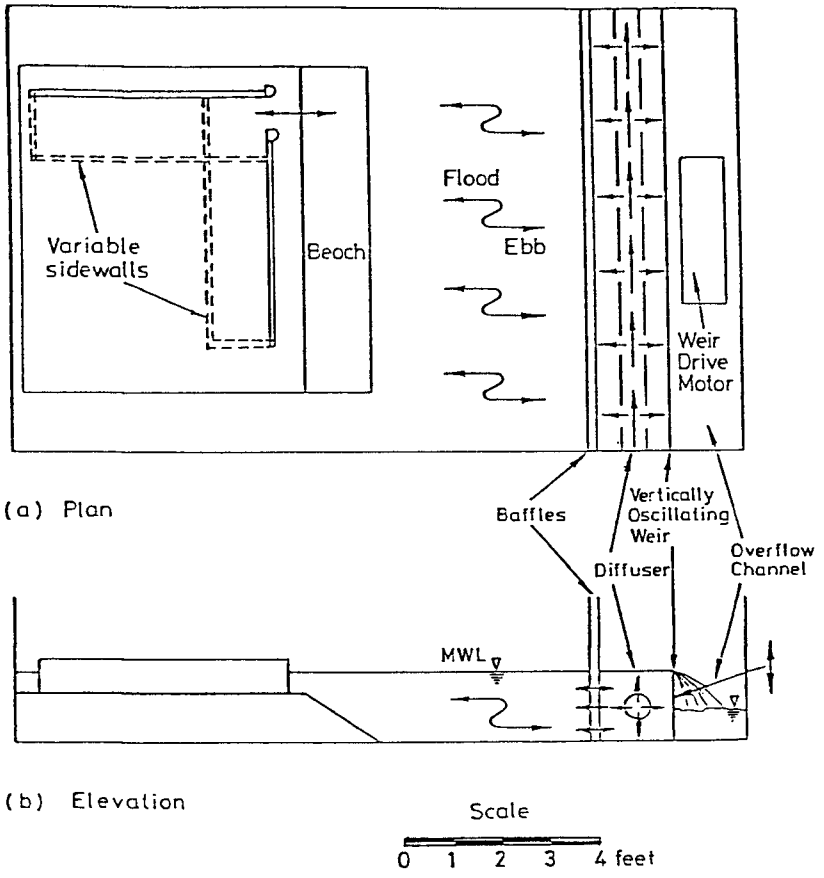

FIG.1 Details of Laboratory Tidal Tank and Harbour Configuration

where E = average per cycle exchange coefficient, Co = initial spatial average concentration, Ci = final spatial average concentration after i tidal cycles.

After the exchange coefficient had been determined, the depth mean velocity field was estimated at mean water level - for both the ebb and flood tide - using weighted drinking straws as drogues. The depth mean velocities were estimated as closely as possible at the intersecting points on a cartesian grid, which coincided with every other grid point of the mathematical model. The complete set of results for the tracer studies and velocity fields are given in Mardapitta-Hadjipandeli (12), with earlier results being given by Falconer et al (1)-(5).

For the mathematical model studies, a one-way interaction nested model was used. One-way interaction models involve the initial computation of the overall coarse-grid model which, in turn, provides the boundary conditions for the independent computation of the small-sized fine-grid model. The alternative two-way interaction models require the simultaneous computation of both grids, thus enabling the regions of different spacings to be dynamically inter-linked. The latter method therefore allows the response of the coarse-grid domain to small-scale processes occurring within the fine grid to be taken into account, giving rise to more coherent results over the computational domain. However, the dynamic coupling of the nested grid requires a more complex computational code. On the contrary, in one-way interaction models it is inherently assumed that the large scale motion of the coarse grid determines the small scale motion in the fine grid, without being affected by small scale processes occurring within the fine grid.

The overall coarse-grid domain for the rectangular harbour model studies was chosen to cover the whole plan-form area of the tidal tank and consisted of 27 x 34 grid points, of uniform grid spacing of 100mm, and with the tidal tank bathymetry being as depicted in Fig.2. At the open boundary, water elevations were presecribed according to a sine wave of the form:-

$$\eta = a \sin(\omega t + \phi) \qquad \ldots\ldots (10)$$

where a = amplitude, ω = tidal frequency and ϕ = phase angle governing the initial conditions. Since the tidal flow entered and exited the tidal tank uniformly across the oscillatory weir and in a direction normal to the open boundary, the advective accelerations were omitted along the open boundary and the tangential velocities were equated to zero. At the closed boundaries the no-slip boundary condition was implemented. A timestep of 0.84s was used in the model, giving rise to a maximum Courant number of about 9.0.

The domain of the fine grid model covered the plan-form area of the model and extended beyond the harbour entrance, as illustrated by the shaded region in Fig.2. The open boundaries of the fine-grid model were located well beyond the harbour entrance, so that small scale inaccuracies at the fine-grid open boundaries did not disturb the internal flow field predictions. The ratio of the grid scales between the coarse and fine grids in such models is arbitrary, although in practice

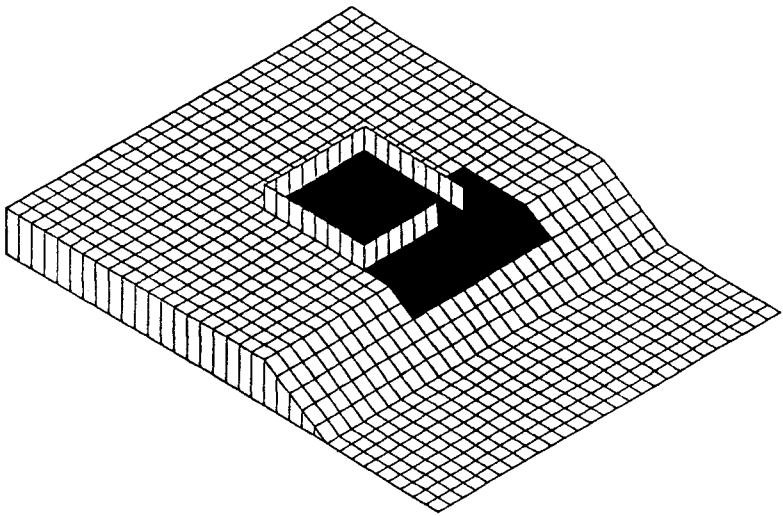

FIG.2 Isoparametric Projection of Tidal Tank Bathymetry Showing Extent of Nested Grid Domain

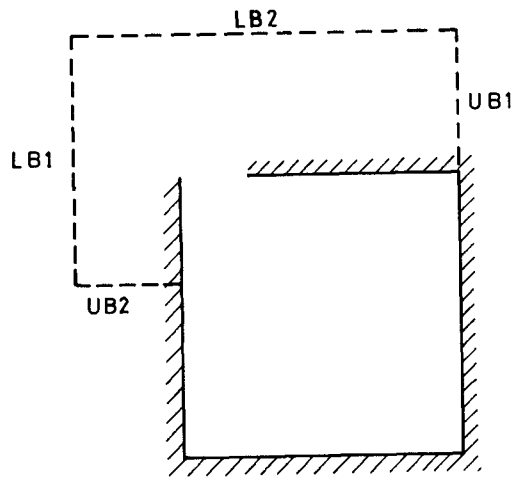

FIG.3 Schematic Illustration of Fine-Grid Open Boundaries

it has been suggested that the ratio should be kept below about 5 (see Thabet et al (16)). In this study the ratio of both the grid and time scales between the two nested grids was chosen to be 3, giving rise to a Courant number of about 9 in both grids. The decrease in the grid size and, as a consequence, in the timestep of the fine-grid model required both the time and space interpolation of the Coarse-grid model predictions in order to provide proper boundary conditions at the appropriate points along the fine-grid model boundaries. In the interpolation process, linear variations were assumed for the velocities and elevations, in both time and space.

Concerning the open boundary conditions of the fine-grid model, no guidelines were available as to the most suitable representation. Tests were therefore undertaken to determine the most appropriate combination of the open boundary conditions for this particular case study. The following combinations of open boundary conditions were tested at the four open boundaries of the fine-grid model (see Fig.3) for the square harbour configuration:-

(a) Water elevations and tangential velocity components along the lower boundaries, LB1 and LB2, and normal and tangential velocity components at the upper boundaries, UB1 and UB2.

(b) Normal and tangential velocity components at the lower boundaries, LB1 and LB2, and water elevations and tangential velocity components at the upper boundaries, UB1 and UB2.

(c) Normal and tangential velocity components at all four open boundaries.

(d) Normal and tangential velocity components along the boundaries LB1, LB2 and UB1, with water elevations being prescribed along UB2.

All four combinations gave similar velocity field predictions within the harbour, with some discrepancies occurring at the open boundaries. Combination (a) yielded the worst flow field predictions at the boundaries, where unrealistic circulation patterns were predicted along the water elevation boundaries, see Mardapitta-Hadjipandeli (12). For combination (b), grid scale oscillations were observed along the boundary UB1 and an obvious poor reproduction of the water elevation field was predicted using combination (c). The best water elevation and velocity field predictions were obtained using combination (d) and hence this inter-connecting boundary combination was used for all of the subsequent numerical model simulations.

Apart from applying the nested model to the idealised rectangular harbours at the laboratory model scale, the model was also applied to the equivalent scaled prototype harbours. The main objective of this exercise was to model directly the physical processes associated with tidal action in such harbours, thus enabling the influence of scaling in the physical model simulations to be considered. The nested model for the prototype harbours was geometrically similar to that for the physical model scale tests. The boundary conditions for the coarse and fine grid models were the same as those deployed in the physical scale model tests, with the exception of the coarse-grid model open boundary, where the

inclusion of the Coriolis term required the inclusion of a water surface slope, see Falconer et al (9). All prototype simulations were commenced from an initial state of rest, at low tide, with a timestep of 60s in the coarse-grid model and 20s in the fine-grid model - again giving rise to a Courant number of 9 in both models. As before, the computations were performed for two complete tidal cycles, with velocity, elevation and concentration fields being reproduced at every quarter of the tidal cycle.

Summary of Results

The complete set of results, for both the mathematical and physical model studies, are described in detail in Mardapitta-Hadjipandeli (12). For the nested numerical model the main finding was that the velocity field within the fine-grid model was best described by transferring only velocity information from the coarse grid model at all but one inter-connecting boundary, and by transferring water elevations at the remaining open boundary. The nested model gave better results than the non-nested model, for a similar computational effort, with the velocity fields predicted by the nested model being in much closer agreement with the physical model results. The coarse and fine grid flow structure was often significantly different between comparable simulations, with the coarse grid model incorrectly predicting a strong eddy at low tide for example. Furthermore the fine grid flow structure within the idealised harbours was not found to be strongly affected by the coarse grid flow structure, with this being best illustrated when the advective accelerations were excluded from the coarse grid model - see Mardapitta-Hadjipandeli (12).

For the laboratory scale model tests, comparisons showed a close agreement between the measured and predicted velocity and concentration distributions, as can be seen for the velocity distributions by comparing Figs. 4 and 6 respectively. An analysis of the results for the free shear and bed generated stress distributions showed that these turbulent stress components were of a similar magnitude at this scale, although from the vorticity field distributions it was confirmed that the effects of bed friction variations were not significant. Comparisons were also undertaken to establish the significance of using free slip and no slip boundary conditions at the closed boundaries, with the results confirming that the flow structure was very different for these two types of boundary condition. The no slip boundary condition gave much closer agreement with the physical model results and it was therefore concluded that this boundary condition was more appropriate in the numerical model, even though the boundary layer thickness was generally a sub-grid scale phenomenon. In terms of the flushing efficiency and exchange characteristics, the numerical and physical model results both indicated that there was a marked reduction in the exchange coefficient for aspect ratios (i.e. L/B ratios) of less than about 0.5 and greater than 2.0. The numerical model results indicated that the peak exchange coefficient occurred for an aspect ratio of unity, i.e. for a square harbour, although this was not clearly confirmed from the physical model results. Finally, for all of the comparisons undertaken at the laboratory model scale, it was evident from both types of modelling procedures that the harbour corners were always observed to be regions of poor local exchange.

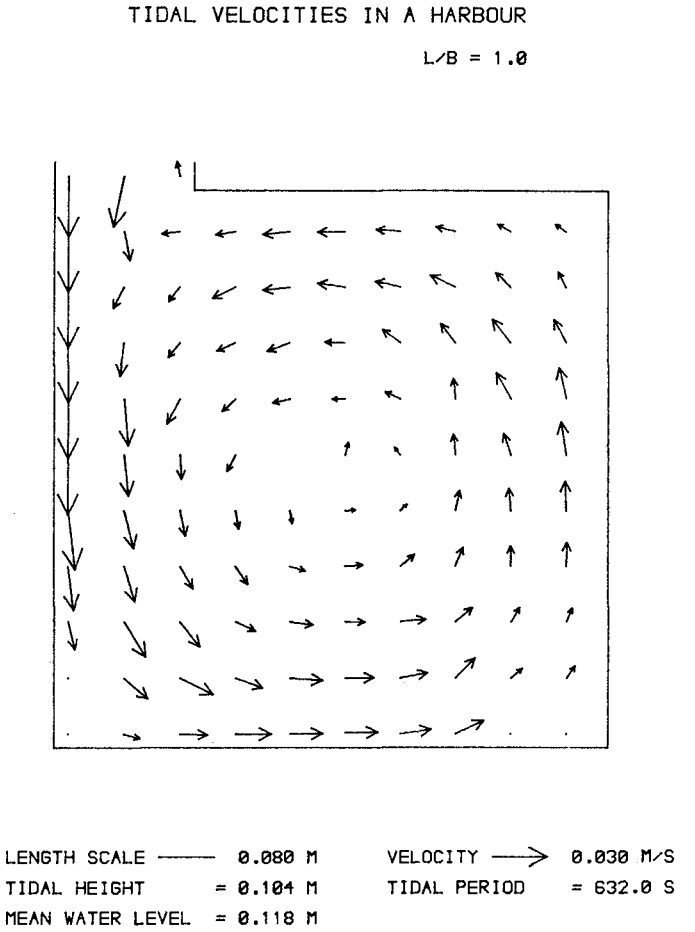

FIG.4 Experimentally Measured Velocities at Mean Water Level Flood Tide for L/B = 1.0

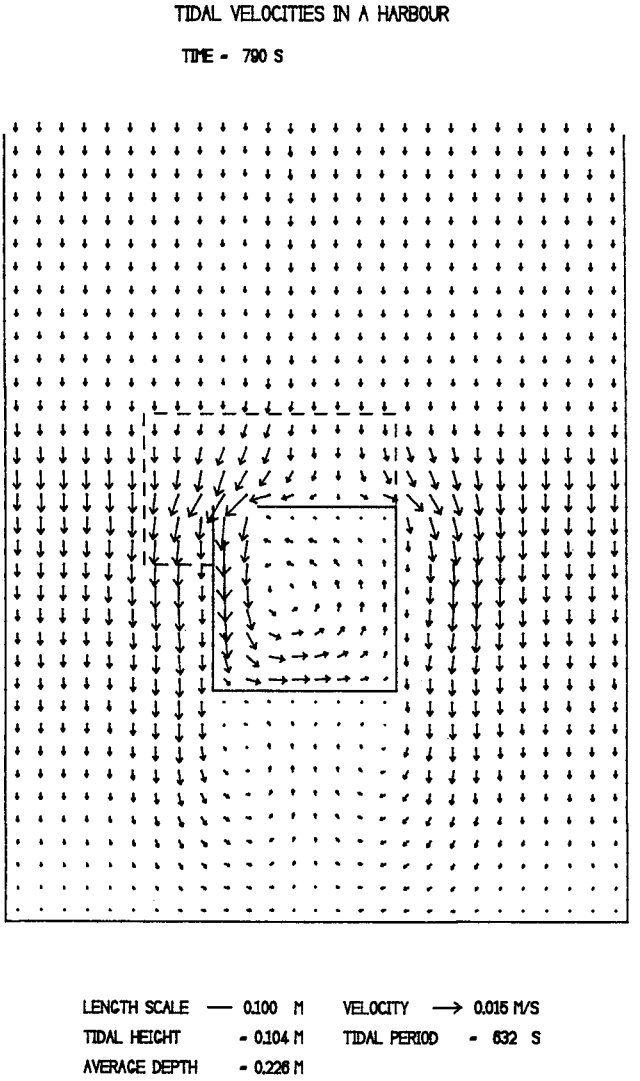

FIG.5 Predicted Coarse-Grid Velocity Field in Model at Mean Water Level Flood Tide for L/B = 1.0

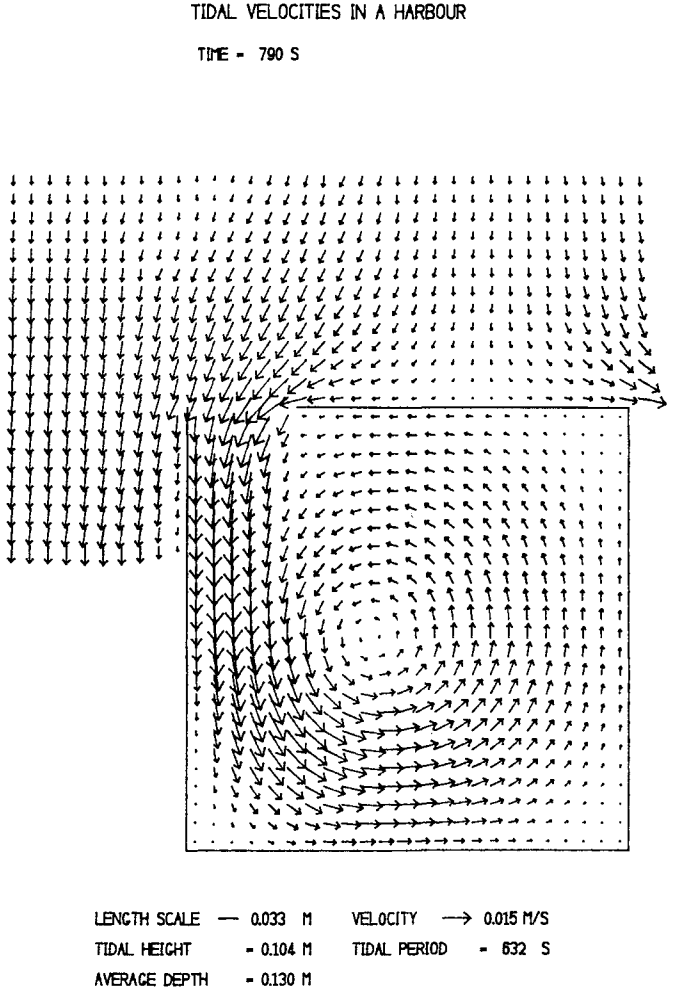

FIG.6 Predicted Fine-Grid Velocity Field in Model at Mean Water level Flood Tide for L/B = 1.0

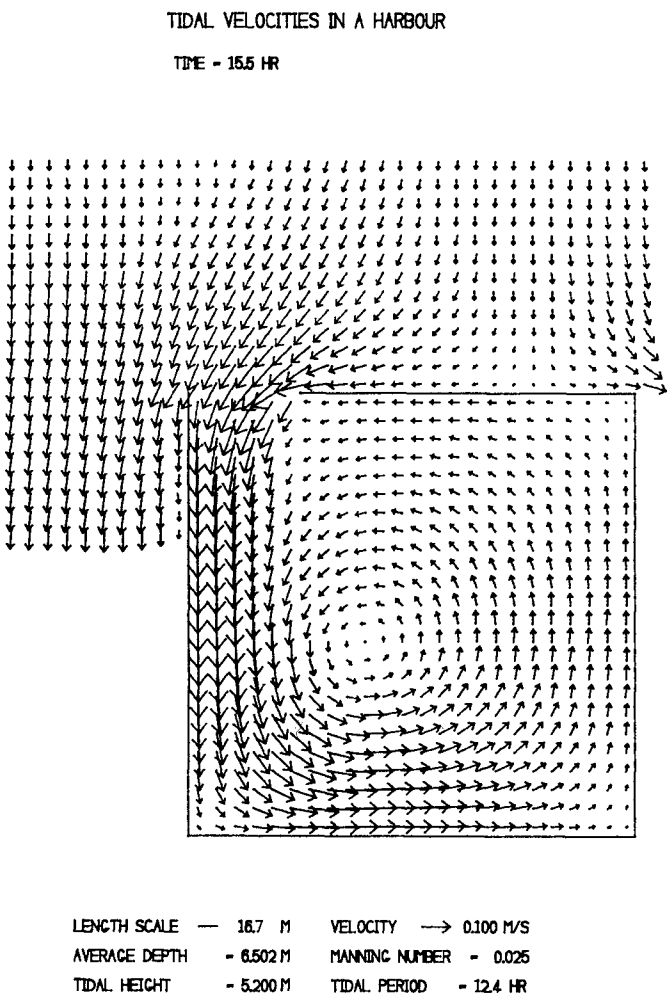

FIG.5 Predicted Fine-Grid Velocity Field in Prototype at Mean Water Level Flood Tide for B/L = 1.0

For the prototype numerical model simulations, comparisons with the laboratory model scale numerical results showed similar agreement for the coarse grid results. However, for the fine grid comparisons the velocity field patterns were often markedly different, see Mardapitta-Hadjipandeli (12). This difference between the prototype and laboratory model scale predictions was particularly pronounced during an ebb tide and was highlighted by the obvious difference in the eddy structure. Such a difference in the numerical model results for the prototype and laboratory model scale harbours has confirmed the problems associated with laboratory model studies of recirculating flows and has raised further questions as to the suitability of distorted laboratory models. As for the laboratory model scale simulations, an analysis was undertaken of the relative magnitudes of the free shear stress and bed generated stress components. The resulting comparisons showed that the free shear stress dominated over the bed generated stress in the mixing zone - unlike the laboratory model scale results - with this conclusion being confirmed by theory (12). Likewise, pronounced changes in the bed roughness coefficient were shown to have a marked effect on the vorticity structure, whereas the effects of dispersion were found to be less significant in the prototype simulations. These results also differed from the laboratory model scale predictions and confirmed the implications of a dimensional analysis study, in that vertical distortion results in an over-estimation of dispersion-diffusion processes and momentum transfer by bed generated turbulence, and an under-estimation of the effects of bed friction. Finally, the numerically predicted prototype scale exchange coefficients and flushing characteristics indicated that the optimum flushing efficiency occurred for an aspect ratio of 2.6, with a distinct reduction occurring in the exchange coefficient for a square harbour. A comparison of the corresponding standard deviation of the concentration distribution within the various shaped harbours, at both prototype and laboratory model scales, also showed that the concentrate was more uniformly mixed in the prototype harbours.

Conclusions

A nested numerical model has been developed and applied to idealised rectangular harbours to predict velocity fields, exchange coefficients and flushing efficiencies for various harbour shapes. Encouraging agreement has been obtained between the numerical model predictions and laboratory model results at the same scale, with similar prototype model simulations and comparisons highlighting the problems associated with scaling effects in distorted laboratory models. The laboratory model scale results showed that the exchange coefficient deteriorated markedly for rectangular harbours when the length to breadth ratio was less than 0.5 or greater than 2.0, whereas for the prototype model simulations the optimum exchange coefficient was obtained when the aspect ratio was about 2.6.

CHAPTER 15

Polynomial approximation and water waves

John D. Fenton*

A different approach to the solution of water wave problems is considered. Instead of using an approximate wave theory combined with highly accurate global spatial approximation methods, as for example in many applications of linear wave theory, a method is developed which uses local polynomial approximation combined with the full nonlinear equations. The method is applied to the problem of inferring wave properties from the record of a pressure transducer, and is found to be capable of high accuracy for waves which are not too short, even for large amplitude waves. The general approach of polynomial approximation is well suited to problems of a rather more general nature, especially where the geometry is at all complicated. It may prove useful in other areas, such as the nonlinear interaction of long waves, shoaling of waves, and in three dimensional problems, such as nonlinear wave refraction and diffraction.

1. Introduction

Conventional linear wave theory, for example, uses a physical approximation which is of a low order of accuracy, neglecting terms which have a magnitude of the order of the square of the wave steepness. In most applications of this theory, however, a global spatial approximation method is used. Often the wave field is approximated by a full spectral representation (Fourier series), so that the spatial approximation is of very high accuracy, and is valid throughout the region of interest. This not only leads to an apparent large discrepancy between the accuracy by which the physical system is modelled and the numerical accuracy used in that model, but also severe limitations as to the boundary geometries which can be considered. In fact, anything other than a flat bed is usually very difficult to treat.

Long wave theory uses approximations based on the limitation that the motion have a large horizontal length scale relative to the water depth, so that the variation of velocities etc. with elevation in the fluid is relatively small. In this case there is a greater degree of harmony between the level of physical and numerical approximation. However, to higher orders of approximation, shallow water (long wave) theory quickly becomes unmanageable as the equations become complicated, and almost invariably higher derivatives occur at each level of approximation. For example, the Boussinesq equations and their relations involve third derivatives at first order, and so on. This

* Professor, Department of Civil Engineering, University of Auckland, Private Bag, Auckland, New Zealand. Work performed while a Senior Lecturer, School of Mathematics, University of New South Wales, Kensington, N.S.W., Australia 2033.

compares with the the full nonlinear equations, where there are no derivatives higher than the first in the boundary conditions. Another feature of long wave theory, as in methods which use wave steepness expansions (Stokes' methods), is that the presence of anything other than a flat bed quickly complicates the method and equations.

This paper is an initial attempt to turn in the direction of conventional numerical methods for the simulation of nonlinear waves, so that the level of physical and numerical approximation is consistent, and that as far as possible routine computational techniques can be used. In particular, local polynomial approximation methods are to be used, which are of a finite order of accuracy, but which are much simpler to use, especially in their incorporation into the full nonlinear boundary conditions. They have a further major advantage, in that they can be used to satisfy other boundary conditions locally, so that irregular boundaries can be treated, including problems of wave interactions with solid boundaries of a possibly abrupt nature, or of a gentle nature such as an irregularly varying bottom.

In this paper, it is attempted to explore where methods of local polynomial approximation might be used, by considering one problem only, that of analyzing the data obtained by a pressure transducer, and inferring other wave properties from that data, for example the surface elevation, the fluid velocity components at other points in the fluid, and possibly spectra of these and other gross quantities associated with the waves.

The information obtained by a pressure transducer is $p(t_n)$, the pressure at a finite number of instants t_n, $n = 1, 2, \ldots, N$. From these pressure readings it is simple to calculate the mean and to infer the mean depth. This can then be used as a length scale for non-dimensionalisation. Throughout the rest of this paper, all quantities are to be taken as having been non-dimensionalised with respect to the mean depth d, gravitational acceleration g, and/or fluid density ρ. (For example, pressure p is "$p/\rho gd$" in dimensional terms, horizontal velocity u is actually "$u/\sqrt{(gd)}$", and so on.) The conventional approach based on linear wave theory would be to take the signal $p(t_n)$, obtain its discrete Fourier transform P_j, for $j = 0, \pm 1, \ldots, \pm N/2$, use linear wave theory to find the corresponding harmonic components, for example U_j and V_j, of the fluid velocity, and then to obtain the actual velocities $u(x,y,t)$ and $v(x,y,t)$, in the horizontal and vertical coordinate directions x and y respectively. A limiting feature of linear theory is that all components of the waves are travelling at the speed corresponding to that phase as given by linear theory, and that there are no nonlinear interactions at all. Particularly in near-shore regions, with the observed tendency of long waves to travel as (nonlinear) waves of translation, where the individual components are bound to the main wave and travel with its speed, this is an unnecessarily limiting assumption.

This is not as critical a problem as the fundamental ill-conditioning of the problem as posed, of inferring fluid motions governed by an elliptic equation (Laplace) from boundary data specified on one level only, that of the pressure transducer. This occurs if the probe is located far below the point at which the velocities are

required or it is desired to find the surface elevations $\eta(t_n)$, from the inferred spectrum Y_j of the free surface elevation. The transfer function connecting Y_j and P_j is proportional to $\cosh k(j)/\cosh k(j)y_p$, where k is the wavenumber given by the linear dispersion relation for the jth harmonic of the signal. For higher frequency components the transfer function varies like $\exp(k(j)(y-y_p))$, and using the short wave approximation for the linear dispersion relation, this varies as $\exp(j^2\omega^2(y-y_p))$, where ω is 2π divided by the total time of the record. It is clear that the transfer function grows remarkably quickly with j, corresponding to higher frequency components. Even for smooth records with spectra P_j which decay quite quickly in j, this exponential growth of the transfer function with j completely destroys any accuracy for harmonic components shorter than the water depth. The method is really only suited to long waves in shallow water. Unfortunately it is for these conditions that linear wave theory is not particularly appropriate, as the waves are likely to be nonlinear and to be long, giving rise to the presence of higher harmonics with their attendant ability to destroy the meaningful part of the signal.

Proceeding in the other direction does not present the same set of problems, as noted above. For example, if the surface elevation is recorded, to give the Y_j, and it is desired to calculate velocities deeper in the fluid, then the transfer function works so as to dramatically reduce the U_j relative to the Y_j for higher frequency components, and the process is well-conditioned. For example, Vis (1980) and Daemrich, Eggert & Kohlhase (1980) used this approach, and found that for waves which were not high the linear theory gave good results for the fluid velocities.

Use of the spectral method outlined above does have some further practical problems. To implement the method it is usually necessary to resort to a number of techniques of data analysis, which degrade the information provided by the original signal. These techniques include trend removal, multiplying by a "window" to remove spurious components due to end discontinuities, filtering and so on.

The method used in this paper, based on local low-degree polynomial approximation does not overcome the fundamental ill-conditioning of the problem, but in water of finite depth the approach is much less susceptible to the problems described above. The application of local approximation for this problem was originated by Nielsen (1986), who used an approach based on local interpolation by trigonometric functions combined with linear theory.

2. Theory

Throughout this work it is assumed that the waves are travelling over an impermeable bed which is locally flat with coordinate origin on that bed, that all motion is two-dimensional, and that the fluid is incompressible and the fluid motion irrotational such that a complex velocity potential w exists, $w = \phi + i\,\psi$, where ϕ is velocity potential and ψ is stream function, which is an analytic function of the complex coordinate $z = x + i\,y$. The coordinate origin is taken to be on the bed, beneath the pressure probe. As the entire discussion is based on

local approximation we can introduce a local time t, which is zero at t_n, the instant at which the pressure reading is taken. The velocity components (u,v) are given by $u - i\,v = dw/dz$. The approximation is made here that the motion locally is propagating without change in the x direction with a speed c, which is as yet unknown. Hence, variation with x and t can be combined in the form x - ct. Locally, this is a reasonable assumption, as the time scale of distortion of the wave as dispersion and nonlinearity take effect is considerably larger than the local time over which the theory is required to be valid.

A principle of local polynomial approximation is adopted, such that in the vicinity of the pressure probe, throughout the depth of fluid, the complex velocity potential w(x,y,t) and the free surface η(x,t) are given by polynomials of degree M:

$$w(x,y,t) = \phi(x-ct,y) + i\,\psi(x-ct,y) = \sum_{j=0}^{M} \frac{a_j}{j+1}(z-ct)^{j+1}, \qquad (2.1)$$

where z = x + iy, and

$$\eta(x,t) = \sum_{j=0}^{M} b_j (x-ct)^j. \qquad (2.2)$$

Expansion (2.1) satisfies the governing equation for irrotational flow of an incompressible fluid (Laplace's equation) identically throughout the flow. The bottom boundary condition v(x,0,t) = 0 is satisfied if the coefficients a_j are real only, as the b_j are. It remains to satisfy the boundary conditions on the free surface, that the pressure is constant and that particles remain on the surface. Here we use the approximation again that motion is steady in a coordinate system (x-ct,y).

The steady kinematic equation that the value of ψ is constant on the surface y = η is

$$\psi(x-ct,\eta(x-ct)) = -Q, \qquad (2.3)$$

where Q is a constant. The steady Bernoulli equation is

$$R = \frac{1}{2}\left|\frac{dw}{d(z-ct)}\right|_s^2 + \eta, \qquad (2.4)$$

where R is a constant, and the subscript s denotes the surface y = η.

Also, in the frame in which motion is steady Bernoulli's equation can be written for the point $(0,y_p)$, where the pressure probe is located. The pressure around that point can be expressed as a Taylor series in x-ct:

$$p(x,y_p,t) = R - \frac{1}{2}\left|\frac{dw}{d(z-ct)}\right|_{y_p}^2 - y_p \qquad (2.5.1)$$

$$= \sum_{j=0}^{M} p_j (x-ct)^j. \qquad (2.5.2)$$

The coefficients p_j can be found from the pressure readings $p(t_n)$. Details of this will be presented further below.

Substitution of the series (2.1) and (2.2) into equations (2.3), (2.4) and (2.5) gives polynomials in x-ct. These polynomials must be valid locally for all values of x-ct, hence the coefficients of each power of x-ct must agree across the equation. This gives a system of nonlinear equations in the unknown coefficients a_0, a_1, a_2, ..., and b_0, b_1, b_2, ... The equations are in terms of the coefficients p_0, p_1, p_2, ..., which are assumed to have been calculated from the pressure readings.

It is feasible to produce the equations by hand calculation for M = 2. However for larger values of M the amount of calculation becomes prohibitive. The symbolic algebra manipulation package MACSYMA was used on the computer in the School of Mathematics at the University of New South Wales to produce solutions for M = 2 and M = 4. MACSYMA has the facility of producing executable code, and the output could be used to evaluate the full set of equations.

3. Equations

The equations can be written in the form

$$K_1 = K_2 = K_3 = K_4 = \ldots = 0, \quad D_1 = D_2 = D_3 = D_4 = \ldots = 0,$$

and

$$P_0 = P_1 = P_2 = P_3 = P_4 = \ldots = 0, \tag{3.1}$$

where the quantities K, D and P come from the kinematic equation (2.3), the dynamic equation (2.4) and the pressure equation (2.5) respectively. The subscripts 0, 1, 2 *etc.* refer to the power of x-ct of which this term is coefficient.

For a quadratic level of approximation, M = 2, the quantities are defined by:

$$K_1 = -b_0^2 b_1 a_2 + a_0 b_1 + b_0 a_1,$$

$$K_2 = -b_0^2 a_2 b_2 + a_0 b_2 - b_0 b_1^2 a_2 + b_0 a_2 + a_1 b_1,$$

$$D_1 = 2b_0^3 b_1 a_2^2 - 2a_0 b_0 b_1 a_2 + b_0^2 a_1 a_2 + b_0 a_1^2 b_1 + b_1 + a_0 a_1,$$

$$D_2 = 2b_0^3 a_2^2 b_2 - 2a_0 b_0 a_2 b_2 + b_0 a_1^2 b_2 + b_2 + 3b_0^2 b_1^2 a_2^2 + b_0^2 a_2^2 - a_0 b_1^2 a_2 + 2b_0 a_1 b_1 a_2 + a_0 a_2 + a_1^2 b_1^2/2 + a_1^2/2,$$

$$P_0 = a_2^2 y_p^4/2 - a_0 a_2 y_p^2 + a_1^2 y_p^2/2 - b_0^4 a_2^2/2 + a_0 b_0^2 a_2 - b_0^2 a_1^2/2 + p_0 - b_0 + y_p,$$

$$p_1 = a_1 a_2 y_p^2 + p_1 + a_0 a_1,$$

$$p_2 = a_2^2 y_p^2 + p_2 + a_0 a_2 + a_1^2/2. \qquad (3.2)$$

This system of equations is overdetermined, in that it contains seven nontrivial equations in the six unknowns a_0, b_0, a_1, b_1, a_2 and b_2.

For the case M = 4, where quartic variation is allowed, a system of 13 equations in 10 unknowns results. The system is similarly overdetermined. In this case, the equations are rather longer and space does not permit their inclusion here.

4. Solution of equations

The problem is, for each of the N values of the $p(t_n)$, take several adjacent values, find the local approximating polynomial by finding the p_j for $j = 0, \ldots, M$, and solve the equations to give the a_j, b_j for $j = 0, \ldots, M$. This enables a complete local solution for the velocity field to be obtained, from the a_j, and the free surface variation from the b_j.

The solution procedure is as follows.

Step 1: Initially, assume that the disturbances everywhere travel at the speed of linear long waves $c = 1$ ($c = \sqrt{g \times \text{mean depth}}$ in physical terms).

Step 2: For successive iterations until the process converges, repeat Steps 3 to 6. (In the calculations described in Section 5, 3 iterations were sufficient for four-figure accuracy).

Step 3: For each of the times t_n, n from 1 to N, perform Steps 4 and 5.

Step 4 Calculation of p_j for $j = 0, \ldots, M$: Consider equation (2.5.2) written for the point at which the pressure probe is located, $x = 0$, $y = y_p$:

$$p(0, y_p, t) = \sum_{j=0}^{M} p_j (-ct)^j. \qquad (4.1)$$

To find the coefficients in this series it would be possible to use simple finite difference methods based on the M+1 pressure readings $p(0, y_p, t_m)$ in the vicinity of t_n, for $m = -N/2, \ldots, 0, \ldots, +N/2$. (Here an ambiguous but convenient notation t_m has been used for discrete values of the local time such that $t_0 = 0$, whereas t_n will continue to be used to refer to instants at which pressure readings have been taken. This use of local time is important in the simplifications which lead to equations (4.2.1) and (4.2.2).) As it is intended that the method be used in practice, where there are likely to be irregularities in the input data, such interpolation of the pressure record is a rather dangerous procedure, as interpolating polynomials fitted to experimental points exhibit wild fluctuations. A better procedure would be to use a least-squares procedure using K points, where K is rather

greater than M+1. It can be shown (see standard numerical analysis textbooks) that the least squares procedure leads to the matrix equation

$$\begin{bmatrix} K & \Sigma t_m & \cdots \\ \Sigma t_m & \Sigma t_m^2 & \cdots \\ \cdots & \cdots & \cdots \end{bmatrix} \begin{bmatrix} p_0 \\ -p_1 c \\ \cdots \end{bmatrix} = \begin{bmatrix} \Sigma p(t_m) \\ \Sigma t_m p(t_m) \\ \cdots \end{bmatrix}.$$

In this expression all the summations are over K values of m. If approximation by a quartic is used, this matrix equation involves five equations in five unknowns, and the solution is complicated. A useful simplification can be made, however. Here and throughout the rest of this work it will be assumed that the points are obtained at equal intervals of time Δ, K is chosen to be an odd number, and points are distributed symmetrically about the point of calculation, such that m varies from $m = -(K-1)/2$ to $m = +(K-1)/2$. Then all the sums over odd powers of t_m become zero, and the system can be written as two separate systems, one of third-order and the other second-order. With a little re-arrangement they can be written:

$$\begin{bmatrix} K & \Sigma m^2 & \Sigma m^4 \\ \Sigma m^2 & \Sigma m^4 & \Sigma m^6 \\ \Sigma m^4 & \Sigma m^6 & \Sigma m^8 \end{bmatrix} \begin{bmatrix} p_0 \\ p_2 c^2 \Delta^2 \\ p_4 c^4 \Delta^4 \end{bmatrix} = \begin{bmatrix} \Sigma p(t_m) \\ \Sigma m^2 p(t_m) \\ \Sigma m^4 p(t_m) \end{bmatrix}, \tag{4.2.1}$$

and

$$\begin{bmatrix} \Sigma m^2 & \Sigma m^4 \\ \Sigma m^4 & \Sigma m^6 \end{bmatrix} \begin{bmatrix} -p_1 c\Delta \\ -p_3 c^3 \Delta^3 \end{bmatrix} = \begin{bmatrix} \Sigma m\ p(t_m) \\ \Sigma m^3 p(t_m) \end{bmatrix}. \tag{4.2.2}$$

If quadratic approximation M = 2 is used, then the last row and column of the matrices are simply deleted.

The coefficients in the square matrices are simply sums over the powers of the integers, from $m = -(K-1)/2$ to $m = +(K-1)/2$, and analytical expressions can be found for them. however the numerical values are easier to obtain by simple summation than by these complicated formulae, particularly as once the level of approximation M and the number of points K in the least squares fit are decided, the coefficients are simple integer constants for all points of all pressure records. In any case, it is easy to write down the inverses of the matrix equations presented here. That is a standard mathematical task, and will not be done here. Of course, they too are constant, once M and K are adopted.

Although the use of interpolation rather than least squares approximation is not recommended, for that case, where the number of

points is such that K = M + 1, all the matrix formulae presented above are still valid, and one is free to use either interpolation or a least-squares fit simply by choosing the value of K.

Having found the coefficients p_j, the equations can now be solved. However, the above formulae are in terms of the speed c with which the local disturbance is travelling. It is not known a priori, and has to be found iteratively, as described in Step 6.

Step 5 Solve for the a_j, b_j, $j = 0, \ldots, M$, using Method 5a or 5b below: This is the most complicated part of the solution process. To obtain the "best" solution of an overdetermined system of equations (which can never be satisfied identically because there are insufficient free variables), one procedure is to find the solution which minimises the sum of the squares of the errors. This "least-squares" procedure for the system of nonlinear equations is mentioned in Step 5b below. For the calculations described in this paper, it was found that a very simple method gave excellent results. This is described below.

5a. Direct iteration solution of the equations

In this case, sufficient of the equations were discarded, one in the case of M = 2, and three for M = 4, to give the same number of unknowns as equations, N say. Newton's method could be used for this system of nonlinear equations, and is known to converge quickly. However, it involves the calculation of a matrix, whose elements are the derivative of every equation with respect to every variable, plus the numerical solution of that matrix equation at each iteration. Fortunately, however, a much simpler method was found to work for the nonlinear system in this work, which gave results which were within 1% of those using the full overdetermined set of equations.

The solution procedure is the nonlinear equivalent of Gauss-Seidel iteration, whereby each equation is written for one unknown, whose influence dominates that equation, and the set of equations evaluated repeatedly until a solution is obtained. As the next value of each variable is calculated, its new value is subsequent equations. In the calculations it was found that the procedure worked well, both for M = 2 and M = 4.

Examining the "P" equations in (3.2) it can be seen that, for example, $P_1 = a_1 a_2 y^- + p_1 + a_0 a_1 = 0$ can be re-arranged to give the equation $a_1 = a_1 - P_1/a_0$. With initial estimates of the coefficients, the right side can be evaluated, and substituted for a_1. Other equations can be similarly rewritten. The scheme which was used in the present work was to recalculate each of the a_j from the pressure equations and each of the b_j from the dynamic equations, for j from 1 to M. In practice it was found that the order in which this was done was not important, but it is recommended that the procedure work from M to 1, so that the coefficients which are smaller in magnitude are iterated first. The P_0 equation was rewritten in terms of b_0.

If the kinematic equations are examined, it is not so obvious that any one term dominates, and it was felt that if any equations were to be deleted it should be these. The procedure adopted was, that if

locally the linear contributions were greatest, then $K_1 = 0$ should be used. At such a point, if it were a point of inflection in the pressure record, p_2 would be zero, as would all the a_2 and b_2 so that $K_2 = 0$ would be satisfied identically. Similarly near a crest or trough, the quantities with subscript 1 would be close to zero, and it would be better to use $K_2 = 0$. The criterion adopted was simply whether $|p_1|$ or $|p_2|$ was greater.

Rewriting the kinematic equations as above would give the scheme for K_1 for example, $a_0 = a_0 - K_1/b_1$. In practice, this was found to give an iteration scheme which was occasionally unstable. Luckily, a simple remedy was found to give very reliable scheme. This was to multiply the previous expression by a_0 and to take the square root to give

$$a_0 = -\sqrt{a_0(a_0 - K_1/b_1)} \text{ or } a_0 = -\sqrt{a_0(a_0 - K_2/b_2)},$$

whether $|p_1|$ or $|p_2|$ respectively was greater. The value of a_0 is negative, and of a similar magnitude to c.

To commence iteration it is desirable to have some estimate of the solution. The following were found to work well in practice:

$$b_0 = p_0 - p_2 p_0^2, \quad a_0 = -\sqrt{b_0}, \text{ and } a_j = b_j = p_j, \quad \text{for } j = 1, \ldots, M.$$

These are exact for no wave motion. In subsequent passes of the iteration terminating in Step 6, the results from the previous pass were used.

The iteration scheme can be summarised:

```
For successive iterations until solution converges
  {
  For j=M to 1 in steps of -1
     {
     a_j = a_j - p_j / a_0
     b_j = b_j - D_j
     }
  If (|p_1| > |p_2|)  a_0 = -sqrt(a_0(a_0 - K_1/b_1))
  Else a_0 = -sqrt(a_0(a_0 - K_2/b_2))
  b_0 = b_0 + P_0
  }
```

In practice it was found that convergence of this scheme was sure and rapid. Four iterations were enough to have the solution converge to four significant figures.

5b. Newtonian iteration for overdetermined systems

A more complicated but theoretically-sounder method than that described in Step 5a is to obtain that solution which minimises the errors of the complete set of equations, rather than identically satisfying some of those equations. The method is much more complicated and

takes more computational time. It was implemented by the author, but was found to give results which were little different from those obtained from the method of Step 5a. Comparisons are not presented here. It is recommended that the simpler method be used in practice.

Step 6 Recalculate the speed c: Having processed all the points n = 1, ..., N, excluding those at the beginning and end of the pressure record which cannot be treated by scheme (4.2), it is now possible to estimate the speed of propagation of the disturbances. Locally, there is no information provided by the act of measuring the pressures, and it is necessary to make rather ad hoc assumptions.

From equation (2.1), it can be easily shown that the horizontal fluid velocity in the frame of the moving disturbance, at x = 0 and t = 0 is $a_0 - a_2y^2 + a_4y^4$, hence the fluid velocity in the frame of reference of a stationary observer is

$$u(0,y,t_n) = c + a_0 - a_2y^2 + a_4y^4. \tag{4.3}$$

This provides us with a means of calculating the speed of propagation c, for if the mean current (fluid velocity) at a point of elevation y is known, denoted by $\bar{u}$, this is the mean of u over all the t_n, n = 1, ..., N. (In the absence of any knowledge of $\bar{u}$, a value of zero would be a reasonable approximation.) Substituting into equation (4.3) we have

$$c = \bar{u} - \overline{a_0} + \overline{a_2}\, y^2 - \overline{a_4}\, y^4, \tag{4.4}$$

where the $\overline{a_i}$ denotes the mean of the a_i averaged over all the n. Clearly the result shows that the value of c obtained depends upon the value of y at which the expression is evaluated. However, as the a_2 and a_4 express fluctuations of velocity about a mean, in general their means will be small and one would expect the deduced value of c to show little variation with y.

In most cases it might be rather more realistic to use the depth-integrated value of the current, denoted by $\bar{U}$. By integrating (4.3) from 0 to b_0, the surface elevation at time t_n, and taking the ensemble mean over all the n, then

$$c = \bar{U} - \overline{a_0} + \frac{\overline{a_2}}{3}\, b_0^2 - \frac{\overline{a_4}}{5}\, b_0^4 \tag{4.5}$$

With the new value of c as obtained in this step, return to Step 2, unless the process has converged. If it has converged, then

Step 7 Solution: The most useful results are the surface elevations, represented by the b_0, and the fluid velocity, given by

$$u = c + a_0 + a_1(x-ct) + a_2((x-ct)^2 - y^2) + a_3((x-ct)^3 - 3(x-ct)y^2) + a_4((x-ct)^4 - 6(x-ct)^2y^2 + y^4),$$

and

$$v = -a_1 y - 2a_2(x-ct)y - a_3(3(x-ct)^2 y - y^3) - a_4(4(x-ct)^3 y - 4(x-ct)y^3).$$

If it were desired, now a Fourier transform of the surface profile could be taken, to obtain the spectral data.

5. Results

Comparisons were made with accurate numerical solutions of steadily-progressing waves in water of constant depth. Solutions were obtained using a Fourier approximation method (Rienecker & Fenton, 1981; Fenton, 1987), giving values of pressure on the sea bed at equally-spaced intervals and the corresponding surface elevations. Using the pressure values the method of Section 4 above was applied. For both quadratic and quartic approximations 7 adjacent points were used to fit the polynomials at each point, that is, K = 7.

The family of steady waves is a two-parameter one. To obtain an idea of the accuracy of the local polynomial approximation method, a traverse through this two-dimensional space was made, considering four waves. The height/depth increased from 0.25, 0.333, 0.5, to 0.667 while the wavelength/depth simultaneously was 3, 5, 10 to 15. It would be expected that the polynomial method would work best for long waves, while for shorter waves the variation with y tends to exponential and it would not be appropriate.

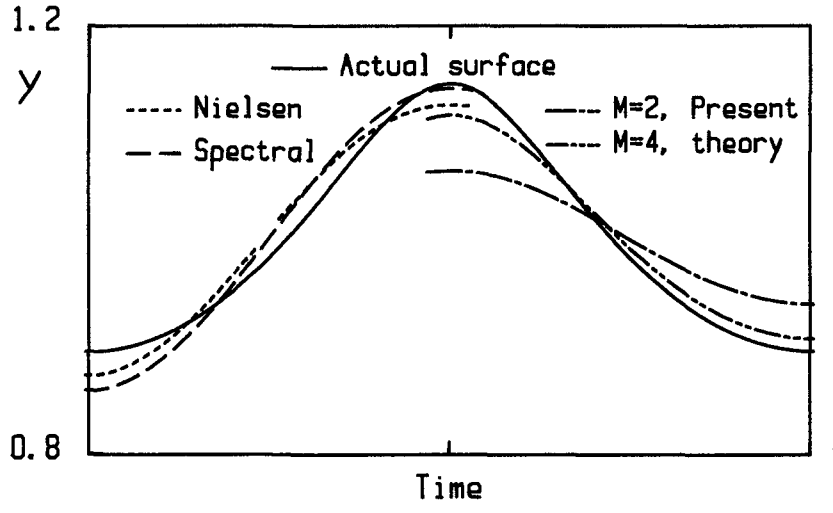

Figure 1. Actual and calculated free surface of a steady wave of height 1/4 of the depth and a length 3 times the depth.

Results are shown in Figures 1 to 4. On each figure the free surface obtained from the numerical solutions is shown as a solid line. There

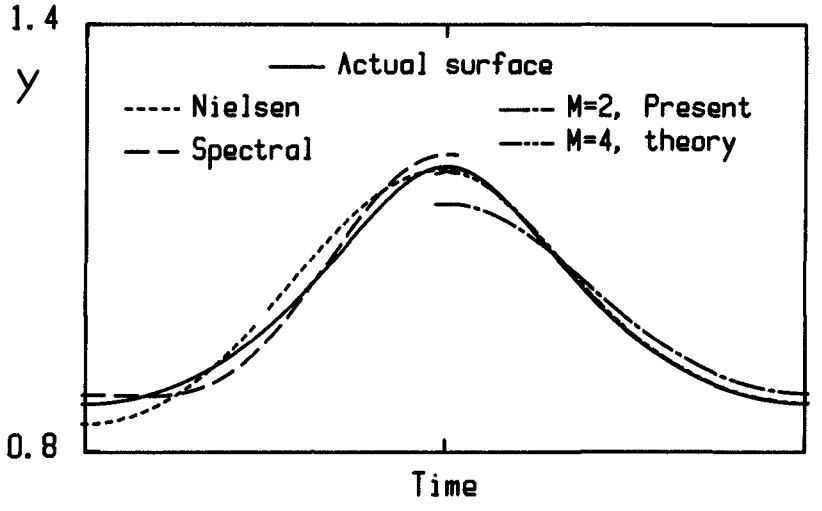

Figure 2. Actual and calculated free surface of a steady wave of height 1/3 of the depth and length 5 times the depth.

are two curves plotted on each half of the wave, plotted according to four methods of inferring the free surface from the pressure results. The actual pressure record is not shown. On the left half of the wave is shown two sets of results from linear theory. The long dashed line shows the results of applying linear wave theory using the full spectral representation. The resulting Fourier series was truncated at the last term where the successive contributions were still decreasing. After that point the results would be meaningless. The short dashed line shows results obtained from the simple empirical approximation of Nielsen (1986), able to be presented in a single formula. On the right half of the wave are shown results from the present theory, for the quadratic (M = 2) and quartic (M = 4) approximations.

It can be seen that the use of linear wave theory and a full spectral representation gives poor results for the longer and higher waves. Nielsen's local approximation method, based on fitting of a trigonometric function to part of the pressure signal is capable of good accuracy near the crest and trough of the waves. In fact, the agreement at the crests is remarkably good, considering the approximations implicit in the method. At the wave crests, the method is usually more accurate than the polynomial approximation method. Over part of the wave, however, near the inflection points, the fitting of a sinusoid breaks down, and the method gives wildly divergent results or none at all.

The results for the polynomial approximation method are shown on the right sides of the figures. For a relatively short wave (3 times the depth) the polynomial approximation is poor (Figure 1), as expected. It would be necessary to include higher order approximation

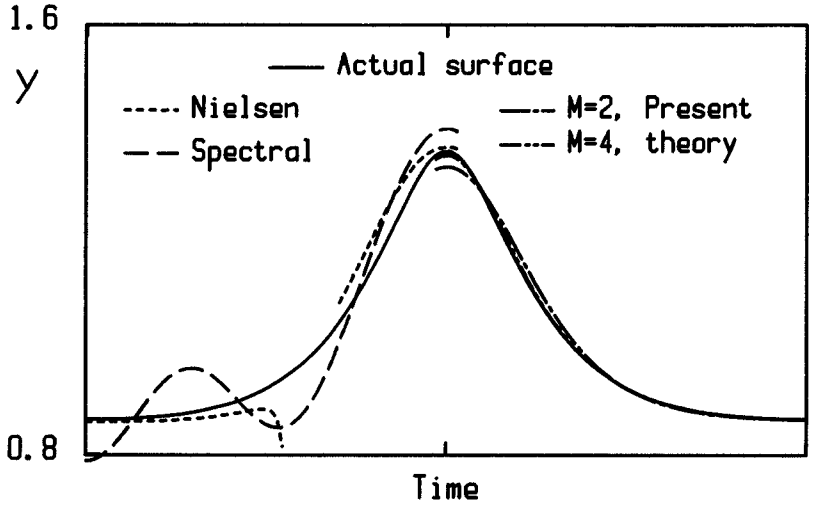

Figure 3. Actual and calculated free surface of a steady wave of height 1/2 of the depth and length 10 times the depth.

for waves this short. The situation changes quickly as longer waves are considered. For a wave which is only 5 times the water depth, Figure 2 shows that the present method is capable of high accuracy, but that it is necessary to use quartic approximation. As longer waves are considered, the quadratic approximation becomes more acceptable. Figure 3 shows a wave 10 times as long as the depth with a height of 0.5 of the depth. It is clear that the quartic approximation is excellent, usually being obscured by the surface on the plot of this scale. Finally, Figure 4 shows a very demanding case, of a wave which is 15 times the water depth in length, and a height of 2/3 of the depth. This is probably close to breaking. Except at the very crest, the M = 4 results are excellent, with the M = 2 results slightly less so. Altogether it seems that the method proposed here, with quartic approximation, is capable of high accuracy for waves up to close to the breaking point, provided that they are no shorter than about 5 times the water depth. This range of accuracy is very much greater than that of conventional wave theories and suggests that the local polynomial method, based on no approximations other than the truncation at finite degree, is capable of accurate description of steady water waves.

Peter Nielsen has kindly made available a set of his experimental results so that an indication of the robustness of the method in practice might be had. Waves were generated in a laboratory flume, and at a station two wave gauges were used to measure the free surface elevations and a pressure probe was located on the bottom. A comparison of the different methods and experimental results is given in Figure 5. The wave is high, about half the mean depth, and has the sharp crest and flat trough associated with long waves. It can be seen that Nielsen's local trigonometric approximation method works rather better

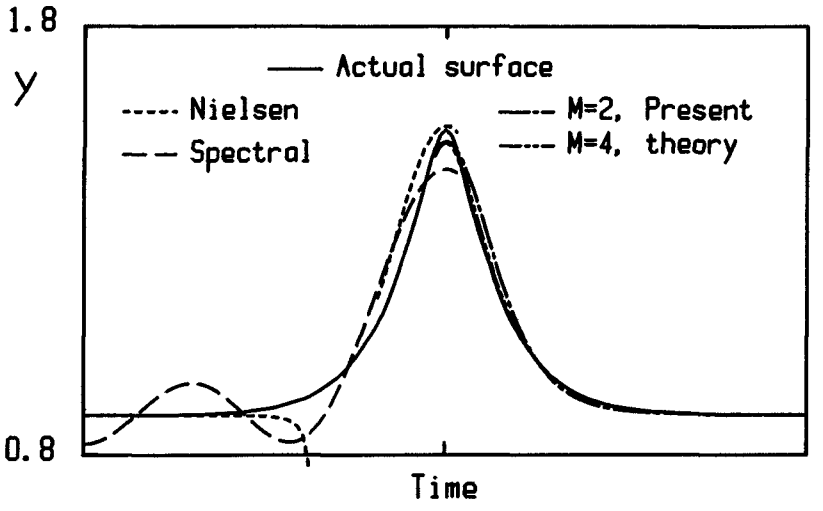

Figure 4. Actual and calculated free surface of a steady wave of height 2/3 of the depth and length 15 times the depth.

than the M = 2 approximation of the polynomial theory near the crest of the wave. However, the M = 4 level of the theory seems to be very accurate indeed. Almost everywhere the double chain-dashed line is obscured by the two lines corresponding to the wave gauge results, even at the crest. In this case, however, as the experimental results showed the expected small irregularities, it was found necessary to use the least-squares method with 13 points. For any fewer points it was found that the irregular data was such that the method of solving the equations did not converge. With 13 or more points, however, it was robust and accurate.

6. Conclusions

It has been shown that relatively low degrees of polynomial approximation can describe waves accurately in water of finite depth. This has the potential of allowing solution of wave problems by polynomial means, which allows the use of the full nonlinear boundary conditions and which may allow the incorporation of other more-general geometries.

For the problem considered here, the method has provided a technique for obtaining free surface data from pressure data, which obviates the need for Fourier transform programs and has important computational advantages over traditional methods based on Fourier analysis.

The examples presented here have not demonstrated the accuracy and robustness of the proposed method over a wide range of waves and under field conditions, however, they do suggest that the method could be used in a variety of applications.

CHAPTER 16

KINEMATICS IN THE CRESTS OF STORM WAVES

George Z. Forristall*

ABSTRACT

Uncertainty about kinematics in the crests of high waves has prevented random wave simulation from being accepted as a reliable method for computing wave forces for platform design. A theoretically defensible method of calculation for wave crest kinematics has been developed recently. The method produces a potential function which fits the kinematic boundary condition specified by second order wave theory and is thus named the Kinematic Boundary Condition Fitting (KBCF) method. KBCF agreed well with measurements of mechanically generated irregular waves made by a laser Doppler current meter in a wave tank. In order to obtain further data during high, short crested storm waves, instruments for the Fulmar Wave Crest Kinematics (FULWACK) experiment were installed in the North Sea early in November 1981. During a storm later in that month, good velocity measurements at heights up to 25 feet above mean water level were obtained in over 30 waves. For comparison with this data, KBCF was extended to three dimensions. Statistics of the velocities thus simulated agreed well with statistics of the measurements. KBCF has thus been verified as a accurate method for simulating the kinematics of natural storm waves.

INTRODUCTION

Monte Carlo simulations are needed to model the dispersive and directionally spread nature of ocean waves. Forristall (1981) showed that such simulations agreed well with velocity measurements made below mean water level in storms at sea. However, heuristically motivated modifications to linear theory are necessary to produce realistic velocities above mean water level, and it is not clear which modification is best.

Forristall (1985) then developed a new method for computing the kinematics of irregular waves based on the numerical calculation of a potential function with a given kinematic free surface boundary condition (KBCF). The boundary condition was specified correct to second order using the intermediate depth interaction equations developed by Sharma and Dean (1979). Measurements made by Bosma and Vugts (1981) using a laser Doppler current meter in the Delft Hydraulics Laboratory wave tank were particularly appropriate for testing KBCF theory. Velocities were measured one standard deviation of wave height above mean water level as well as below mean water level. The waves were mechanically generated and unidirectional. The wave staff record could thus be used to specify the phases of the component wavelets, and only a two-dimensional potential function had to be calculated. The agreement found by Forristall (1985) between measured and simulated velocities was excellent. There was also good agreement between the statistics of measured and simulated velocities when only the spectral density of the waves was specified as input to the simulations.

Since KBCF is derived from the equations of wave motion using defensible assumptions, the extrapolation from laboratory scale to storm waves can be made with some confidence. Still, there is no substitute for verification with measurements made in natural short crested waves with heights comparable to those used in design. In response to this need, the Fulmar Wave Crest Kinematics (FULWACK) experiment was conducted in the central North Sea during the winter of 1981-82. Five electromagnetic current meters were mounted on taut wires stretched outboard of the north face of the Fulmar platform. Two of the meters were below mean water level and gave an estimate of the directional spectrum when used in conjunction with a wave staff. The other three meters were at nominal heights of 6, 16, and 26 feet above mean water level and gave velocity records when they were briefly immersed in the crests of high waves.

Shortly after the instruments became operational in November 1981, a pair of storms produced the most severe conditions observed during the winter. Data from these storms were digitized, and the velocity records from the second storm were used to verify KBCF wave theory. We first calculated directional wave spectra from the records. The velocity data from the wave crests were then compared with Chappelear (1961) regular wave theory and with the empirical modifications of linear theory known as stretching and extrapolation.

KBCF theory was originally developed for two-dimensional waves, and the three-dimensional problems required substantially more computational effort. The code that was developed uses the vector processing

* Shell Development Co., Box 481, Houston, TX 77001

and large storage capabilities of the Cray computer. Statistics of peak velocities simulated by the three-dimensional KBCF compare very well to the statistics of the measured velocities.

KBCF wave theory agrees with both high quality laboratory measurements and measurements made in extreme waves in a natural seaway. In the last section, we consider how the realistic simulations it produces can be used for structural design.

THE FULWACK EXPERIMENT

The Fulmar platform is located in block 31/16 in the central North Sea, within sight of the Auk platform in the same block. The platform is in 270 feet of water approximately 170 miles east of Dundee, Scotland. A Baylor wave staff and five Marsh-McBirney model 524 electromagnetic current meters were mounted just outside the north face of the platform as shown in Figure 1. The current meter support system consists of a wire rope stretched around upper and lower sheaves to form a taut wire loop. Frames for the current meters and their cables were clamped to one side of the loop and lowered to position by rotating the top sheave. The response of the taut wire system was investigated using the finite difference program described by Forristall and Hamilton (1978). Since the taut wires were clamped to the spider deck at the 20 foot level, current meters 3 and 4 were predicted to have the biggest motion: about 3 feet in a 75 foot wave. The natural periods of the taut wire sections above and below the clamps were each close to 0.5 sec.

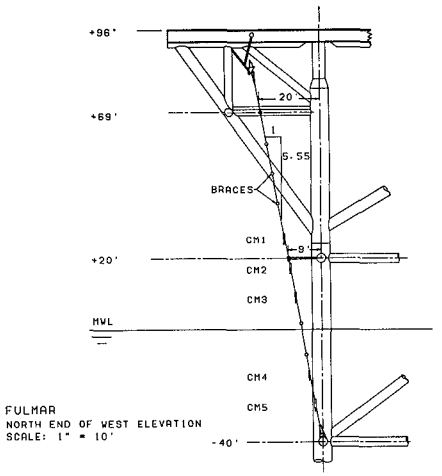

Figure 1.

The nominal locations of current meters 1–5 respectively were 26, 16, and 6 feet above mean water level, and 18 and 28 feet below it. During the data analysis, the water level on the wave staff was used to give the water level relative to the current meters. Float switches were also installed next to the top three current meters to determine the precise times of their immersions. Laboratory test showed that the response time of the switches was approximately 0.2 sec. However, the strong flow during storm waves apparently held the floats down part of the time, and the immersion times were usually determined from the wave staff signal.

The current meter axes were aligned with the platform so that a positive x-axis response indicated flow towards platform east and a positive y-axis response indicated flow toward platform north. Platform north is 18.5° counterclockwise from true north, so positive x-axis response indicated flow toward 71.5° true.

A J-Tec vortex shedding anemometer was mounted above the crown block on the drilling derrick, 345 feet above mean water level. Some possible blockage might be caused by the flare stack located to the south-southeast of the derrick. We intended to mount the anemometer so that the direction reading

would be in degrees from true north, but later comparisons between visual observation of vane position and instrument output indicated that about 15° should be subtracted from the measured directions.

The signal conditioning and recording system was manufactured by Evans-Hamilton Inc. and was housed in an instrument shelter located at the northeast corner of the cellar deck. All signals except those from the immersion switches were passed through 4 pole Butterworth filters with a cutoff frequency of 3.0 Hz. These filters replaced the output filters normally supplied with the Marsh-McBirney current meters. The Butterworth filters give a sharper cutoff as well as producing equal phase lags in the wave staff and current meter signals.

The conditioned signals were recorded on 14 channel Geotech FM analog tape recorders. Two recorders were used to give redundancy in the event of mechanical failure of one of the recorders. The recorders ran continuously at 0.03 inch/sec, and had flat frequency response to above 4 Hz. The system switched from data recording to an automatic calibration mode once each hour. During the two phases of the calibration, which lasted two minutes each, calibration signals were substituted for data and recorded through the same signal conditioning circuits. The wave staff calibration was given by two shorter bars operated by relays. The electromagnetic current meters included an internal calibration feature which fed a portion of the magnet driver excitation voltage through the channel amplifiers.

Data from two storms in November 1981 were digitized for detailed analysis. During the analog to digital conversion, the field recorded tapes were played at 3.75 inch/sec, giving a playback/field speed ratio of 125. The digitization rate was 500 Hz at playback speed, equivalent to 4 Hz at field speed. The A/D circuit had a resolution of 12 bits or one part in 4096. To avoid aliasing, the wind, wave, radar, and current meter 4 and 5 signals were filtered using 4 pole Butterworth filters with a cutoff frequency of 200 Hz at playback speed or 1.6 Hz at field speed. The immersion switch channel and current meters 1–3 were not filtered because of the intermittent nature of the signals.

The digital data were calibrated using the hourly calibration values. For each hour of field data, 6 records containing 2048 time-steps of 14 channels each were written. The effects of both the signal conditioning filters used in the field and the anti-aliasing filters were removed by multiplying the Fourier transforms of the signals by the transfer function

$$T(f) = (\tilde{f} - p_1)(\tilde{f} - \bar{p}_1)(\tilde{f} - p_2)(\tilde{f} - \bar{p}_2) \tag{1}$$

where

$$p_1 = -.3827 + .923872i,$$

$$p_2 = -.923873 + .3827i,$$

and

$$\tilde{f} = f/f_c,$$

f_c is the cutoff frequency for either of the four pole Butterworth filters, and overbars denote complex conjugation. For the filters used in the instrumentation system $f_c = 3.0$ Hz, and for the filters used during digitization $f_c = 1.6$ Hz.

Components above the cutoff frequency were removed. The current meter records were also corrected for the slight nonlinearity and non-cosine response established by tank testing of meters of this type. The calibrated current meter signal was divided by the factor r, given by

$$\begin{aligned} r &= \beta(1 - \alpha\sin 2\theta), \\ \beta &= 0.87 \quad \text{for} \quad Re < 2.51 \times 10^4 \\ &= 1.0612 - 4795/Re \quad \text{for} \quad 2.51 \times 10^4 < Re < 7.84 \times 10^4 \\ &= 1.0 \quad \text{for} \quad Re > 7.84 \times 10^4 \\ \alpha &= 0.083 - 1.5 \times 10^{-6} Re \quad \text{for} \quad Re < 5.52 \times 10^4 \\ &= 0 \quad \text{for} \quad Re > 5.52 \times 10^4. \end{aligned} \tag{2}$$

Re is the Reynolds number of the flow around the spherical sensor (4" in diameter), and θ is the direction of the flow with respect to an electrode.

THE NOVEMBER 1981 STORMS

The FULWACK system operated from November 12, 1981 to April 29, 1982, but two storms in the middle of November 1981 produced the most severe wave conditions during the experiment. The first storm developed from a low which formed east of Newfoundland and expanded as it moved to the North Sea with a minimum pressure of 972 mb. Thirty-six hours later, another low formed and followed the same track. It suddenly deepened, reaching 975 mb near the Faroe Islands (Mariner's Weather Log, 1982). The slow forward motion of the storm was partly responsible for the very high waves observed in the North Sea on November 24.

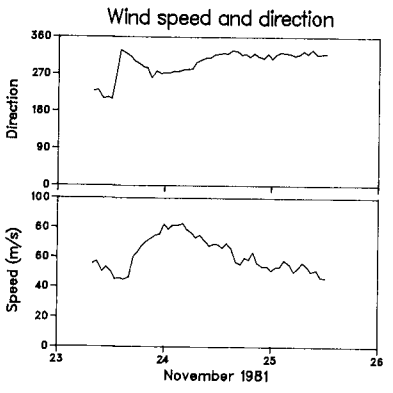

Figure 2.

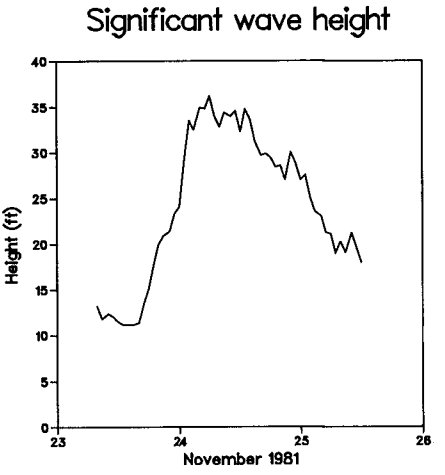

Figure 3.

Figure 2 shows the wind speed and direction measured by FULWACK during the second storm, and Figure 3 shows the significant wave height. The winds are as measured from the location at the top of the derrick. The wind speed and direction were averaged over 6 data records, giving approximately one hour averages. The wind direction has been corrected for the 15° error in instrument alignment discussed above. The wind speed reached a brief peak of 77 miles/hr on the afternoon of November 20. Then on November 24, the wind speed was near its peak of 82 miles/hr for several hours, and the direction was nearly constant.

The significant wave height in Figure 3 was calculated as four times the standard deviation of the wave signal. On November 20, the peak significant wave height was 30 feet, and on November 24 it was 36 feet. Figure 4 is a photograph taken by Mr. Mike Philpot from the Borgland Dolphin accommodations semisubmersible on November 24, illustrating the severity of the conditions. The view is toward the north face of the platform which the wave crest is approaching. The wave crest appears to be considerably higher than the spider deck located at 20 feet above mean sea level.

With two exceptions, the sensors and recording system worked very well during the storms. The y-axis of current meter 3 did not operate in either storm, and a radar wave gage installed as part of another experiment but recorded on the FULWACK system failed during the first storm.

Figure 4. A large wave on November 24

WAVE SPECTRA

We calculated directional spectra for each hour of digitized data using the methods of Forristall *et al* (1978). The information on wave direction available from a wave staff and current meter is equivalent to that from a pitch and roll buoy. It does not provide very sharp directional resolution in the sense of separating two directional peaks at one frequency. However, it can provide very good information on the mean direction of travel and amount of directional spreading for waves in each frequency band.

The co-spectra between the wave staff and current meters 4 and 5 were used to find the best estimates of the parameters in the function

$$S(f,\theta) = S(f)N(s)\cos^{2s}(\theta - \theta_o/2) \tag{3}$$

The mean direction of travel, θ_o and the spreading parameter, s, are both functions of frequency. The function $N(s)$ is included to normalize the integral of the spreading function to unity. The spectral density as a function of frequency alone, $S(f)$, was calculated directly from the wave staff data. We also calculated the rms spread, skewness, and kurtosis of the direction distribution.

With a time step of .25 sec and a record length of 2048 points, the raw spectra from a fast Fourier transform have a frequency resolution of 1/512 Hz. We took averages over 5 frequencies and ensembles of 6 spectra to give spectra with 60 degrees of freedom and a resolution of 0.01 Hz.

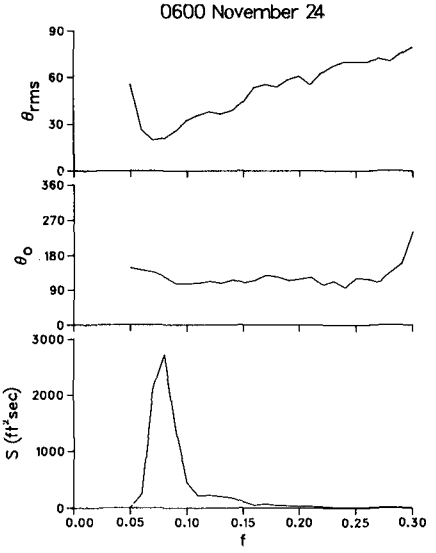

Figure 5. Directional wave spectrum at 0600

Although the energy level of the spectra varied during the storm, their directional characteristics were quite constant. Figure 5 shows the directional spectrum for 0600 on November 24, the time at which the significant wave height reached its maximum of 36.20 feet. The bottom panel of the figure shows the power spectrum, the middle panel shows the mean direction of travel, and the top panel shows the rms directional spread, all as a function of frequency. The power spectrum is unimodal with a peak at 0.08 Hz. The mean direction of travel is nearly constant with frequency, with the waves traveling toward 110° true in the mean. The rms spread is smallest at the peak of the spectrum and increases with frequency. The rms spread is related to the parameter s in equation (3) by

$$s = 2/\theta_{rms}^2 - 1 \tag{4}$$

where θ_{rms} is expressed in radians. The rms spread is a more physically appealing measure of the spreading while equation (3) is useful when a definite form of the spreading function is needed. The qualitative features of the spectrum shown in Figure 5 are typical of those computed throughout the storm.

The calculation of directional spectra from wave staff and current meter data is based on linear wave theory and gives a check on the accuracy of linear theory. The average ratios of measured to linearly predicted velocities were 0.97 for current meter 4 and 0.99 for current meter 5.

CREST VELOCITY MEASUREMENTS

The main purpose of the FULWACK experiment was to obtain velocity measurements at locations high above mean sea level where the current meters would be immersed only briefly. The behavior of the electromagnetic current meters during intermittent immersion is therefore important. Before installing the instruments on Fulmar, we conducted some immersion tests in a recirculating flume. Figure 6 shows the data recorded during one of the tests where the flow was parallel to the y-axis of the meter. Both channels of the meter had a large noise spike immediately after immersion, but then settled to the correct response after 0.6 second. The characteristics of the noise seem related to the output filter used on the current meter, which was the same in the tests and FULWACK.

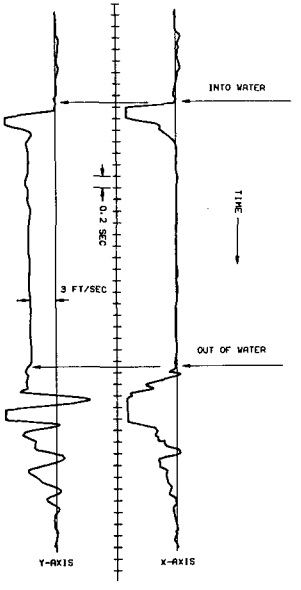

Figure 6. Current meter immersion test

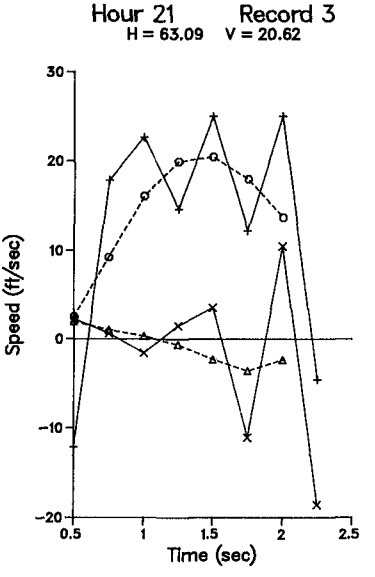

Figure 7. Kinematics of the largest wave

The flume tests indicated that reliable results could be expected only after the meter was immersed at least 0.5 sec. In order to have a few good data points for averaging or curve fitting, we selected only those waves for which a meter was immersed during at least 7 digitized samples. The meter was thus immersed longer than 1.5 sec. Applied to the top current meter, this selection scheme produced 31 waves for study from the November 24 data.

Figure 7 illustrates the quality of the actual data during the highest wave recorded. The solid line marked with + symbols is the output from the x-axis of the top current meter, and the solid line marked with × symbols is the output from the y-axis. All data points during the immersion are shown, and the origin of the time axis is arbitrary. The data has rapid oscillations and spikes with frequencies on the order of 2 Hz. This behavior was not observed in the flume tests and is not expected to be due to wave kinematics, since there is little wave energy at these frequencies. Since the natural frequency of the taut wire system is ncar 2 Hz, it is likely that the oscillations are due to relative motion between the meter and the water. Small amplitude motions can cause large relative velocities at high frequencies. The oscillations were removed by filtering.

After some experimentation with curve fitting and various smoothing schemes, we decided that the

best method for removing the noise would be a simple filter. The velocity components were filtered at $f_c = 0.5$ Hz using a filter with the amplitude response of the four pole Butterworth filter in equation (1), but with zero phase lag. The filter was applied in the frequency domain, so it was simply a real transfer function with amplitude equal to the modulus of the Butterworth transfer function. The result of the filtering is illustrated by the dashed lines in Figure 7. The filtered components seem to give a credible version of the wave velocity while eliminating the physically unrealistic oscillations.

REGULAR WAVE THEORY

The velocity components were combined vectorially and the maximum speed in the crest of each wave found for comparison with wave theories. For the wave in Figure 7, this maximum velocity was 20.62 ft/sec. The maximum speed recorded during the storm at the top meter was 21.47 ft/sec.

We first compared the measurements with the predictions of regular wave theory using the high order numerical solution of Chappelear (1961). This theory gives an excellent fit to the regular wave boundary conditions. For waves of the moderate steepness and water depth encountered by FULWACK, the solution does not differ significantly from that given by Stokes fifth order theory.

For each of the 31 waves, the period and height were computed using the zero downcrossing definition applied to the wave staff record. Figure 8 gives a comparison between the measured maximum speeds at current meter 1 and the speeds calculated by Chappelear theory. The scatter between the measured and theoretical peak speeds is considerable. The theoretical speeds are also biased about 15% to overprediction. These results are consistent with those from previous measurements made below mean water level.

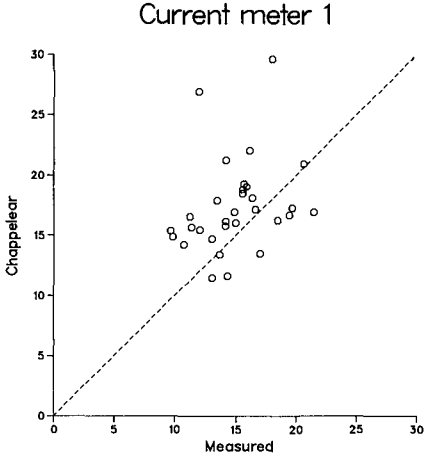

Figure 8. Peak speeds in single waves

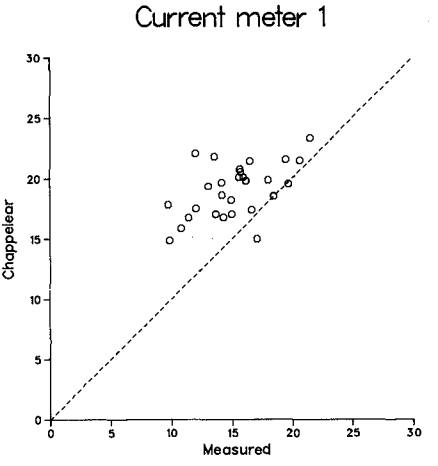

Figure 9. Peak speeds with crest defining wave

Two of the Chappelear velocities in Figure 8 are conspicuously higher than the others. These outlyers are apparently due to short zero crossing periods which do not represent the important frequencies in the wave spectrum. Daemrich and Kohlhase (1980) have suggested another way of selecting the parameters for regular waves which reduced the scatter between theory and their measurements of unidirectional irregular waves in a tank. They defined the wave by the height of the crest and the period of the crest between zero crossings. Since they used linear wave theory, the wave height and period were twice the height and period of the crest. The FULWACK waves were steep enough so that the use of nonlinear theory was advisable, so we modified Chappelear theory to converge to a specified crest height and period rather than the crest to trough height. The wave parameters were selected from the same set of 31 waves as before, and the wave by wave comparison of maximum velocities is shown in Figure 9. The scatter has indeed been reduced somewhat, mostly by the elimination of the two outlyers. The bias remains and is, in fact, larger. The improvement in the comparison is not nearly so much as reported by Daemrich and Kohlhase (1980), presumably because of the complicating effect of directional spreading in the present data.

MODIFIED LINEAR THEORIES

Forristall *et al* (1978) showed that linear simulation of the directional wave spectrum could produce velocity probability distributions which agreed well with measurements below mean water level. However, the linear superposition principle breaks down above mean water level. Empirical modifications such as stretching and extrapolation have thus been necessary to produce reasonable results. Comparisons of these methods with measurements (Forristall, 1981) have not been completely conclusive.

Wave kinematics are stretched by moving the level at which $z = 0$ in the linear wave expansion to the instantaneous free surface. In practice, a coordinate transformation is performed after the linear waves are superposed. Kinematics are extrapolated by taking the linear simulation up to mean water level and then continuing upward using the rate of increase with z calculated just at mean water level.

The simulations were made using a fast Fourier transform technique with random phases selected for each Fourier line. There were 30 directional bands at each frequency. The simulations were based on the directional spectra measured from 0200-2300 GMT. Records having the same length as the measurements were produced, and they were analyzed using the same routine. This single, literal unconditioned simulation of the storm should have the same statistical variability as the measurements. Thus, wave by wave comparisons could not be performed, and, in fact, a slightly different number of simulated waves met the immersion criteria.

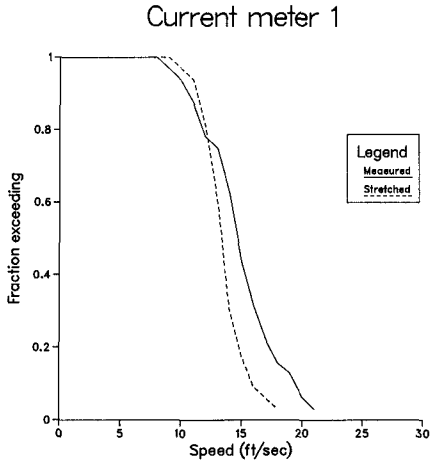

Figure 10. Distributions of measured and stretched speeds

Figure 10 shows the peak speed distribution from the stretched and simulation compared with the measurements at current meter 1. The stretched simulation agrees well with the measurements at lower velocities but is somewhat below the measurements at lower probabilities. The speeds from the extrapolated simulations (not shown) were clearly too high. These results are consistent with those found from a study of MaTS measurements in the Delft Hydraulics Laboratory. However, they disagree with the results of the measurements made at the Exxon Ocean Test Structure (OTS) as discussed by Forristall (1981).

KBCF

The Kinematic Boundary Condition Fitting (KBCF) method was developed to put the calculation of random wave kinematics on a rigorous basis. The kinematic field should be given by a potential function which satisfies Laplace's equation in the interior and the kinematic and dynamic boundary conditions on the free surface. The basic idea of KBCF is that if the shape and time derivative of the surface are known, the kinematic free surface boundary condition alone is enough to completely specify the potential as the solution to a Neumann problem. The solution can be calculated easily enough by numerical iteration. Forristall (1985) found that a specification of the surface correct to second order was sufficient to produce a solution which agreed excellently with the MaTS measurements in the Delft wave tank.

For comparison with the FULWACK measurements and for design use, it is necessary to extend KBCF to three dimensions. The second order wave interactions for infinite water depth were calculated by Longuet-Higgins (1963), and the calculations were extended to intermediate water depth by Sharma and Dean (1979). We reproduce the latter result for completeness. Let the first order water surface be given by

$$\eta = \sum_{n=1}^{N} a_n \cos(\kappa_n x - \sigma_n t + \epsilon_n) \tag{5}$$

where t is time, x is the position vector in the plane, σ_n. ϵ_n and κ_n are, respectively, the radian frequency, phase, and vector wavenumber of wavelet n, and a_n is its amplitude. The frequencies and wavenumbers are related by the linear dispersion equation

$$\sigma_n^2 = g|\kappa_n|\tanh|\kappa_n|d \tag{6}$$

where g is the acceleration of gravity and d is the water depth.

The second order correction to the wave surface given by Sharma and Dean (1979) is then

$$\eta^{(2)} = 1/4 \sum_{i=1}^{N}\sum_{j=1}^{N} a_i a_j \{K^- \cos(\psi_i - \psi_j) + K^+ \cos(\psi_i + \psi_j)\} \tag{7}$$

where

$$K^- = [D_{ij}^- - (\kappa_i \kappa_j + R_i R_j)]\sqrt{R_i R_j} + (R_i + R_j)$$

$$K^+ = [D_{ij}^+ - (\kappa_i \kappa_j - R_i R_j)]\sqrt{R_i R_j} + (R_i + R_j)$$

$$D_{ij}^- = \frac{(\sqrt{R_i} - \sqrt{R_j})\{\sqrt{R_j}(\kappa_i^2 - R_i^2) - \sqrt{R_i}(\kappa_j^2 - R_j^2)\}}{(\sqrt{R_i} - \sqrt{R_j})^2 - \kappa_{ij}^- \tanh \kappa_{ij}^- d} +$$
$$+ \frac{2(\sqrt{R_i} - \sqrt{R_j})^2(\kappa_i \kappa_j + R_i R_j)}{(\sqrt{R_i} - \sqrt{R_j})^2 - \kappa_{ij}^- \tanh \kappa_{ij}^- d}$$

$$D_{ij}^+ = \frac{2(\sqrt{R_i} + \sqrt{R_j})^2(\kappa_i \kappa_j - R_i R_j)}{(\sqrt{R_i} + \sqrt{R_j})^2 - \kappa_{ij}^+ \tanh \kappa_{ij}^+ d} +$$
$$+ \frac{(\sqrt{R_i} + \sqrt{R_j})\{\sqrt{R_i}(\kappa_j^2 - R_j^2) + \sqrt{R_j}(\kappa_i^2 - R_i^2)\}}{(\sqrt{R_i} + \sqrt{R_j})^2 - \kappa_{ij}^+ \tanh \kappa_{ij}^+ d}$$

$$\kappa_{ij}^- = |\kappa_i - \kappa_j|$$

$$\kappa_{ij}^+ = |\kappa_i + \kappa_j|$$

$$R_i = |\kappa_i|\tanh|\kappa_i d| = \sigma_i^2/g$$

$$\psi_i = \kappa_i x - \sigma_i t + \epsilon_i.$$

For infinite water depth, equation (7) reduces to equation (3.7) of Longuet-Higgins (1963) except that the latter equation is missing a factor of $1/2$. The skewness kernel is defined as $(K^- + K^+)/4$ and is a measure of the strength of the second order interaction. It is a function of the frequencies of the two interaction wavelets as well as their angular separation and the water depth. The strength of the interaction is much greater in shallow water, matching the observation that the wave profile is more skewed in shallow water. It is interesting to note that for shallow water the peak of the interaction is not for colinear wavelets, but for wavelets separated by a small angle.

The computations implied by equation (7) can be performed for a spectrum specified either in the frequency or wavenumber domain. The input spectrum is usually specified in the frequency domain, but the numerical iteration which produces the potential function is performed over a spatial grid. It is thus most convenient to transform the directional spectrum to the wavenumber domain at the start of the calculations and then transform to the spatial grid.

The input spectra from FULWACK were given for frequencies in the range $0.050 \leq f \leq 0.340$. The wavenumber grid has a resolution $\Delta\kappa = 0.002ft^{-1}$. The wavenumbers are given by $(K_x\Delta\kappa, K_y\Delta\kappa)$ where $-63 \leq (K_x, K_y) \leq 63$ so that wavenumbers up to $0.1260ft^{-1}$ can be represented. This high wavenumber cutoff corresponds closely to the high frequency cutoff in the input spectrum. Negative wavenumber components must be included since wavelets in the input spectrum can propagate in any direction.

The program begins with a linear random simulation of the type described by Forristall (1981). Linear wavelets are specified at a frequency resolution $\Delta f = 1/512$ Hz and an angular resolution $\Delta\theta = 12^o$. The amplitude of each wavelet is taken from the given directional spectrum, and the phases are taken from a uniform random distribution. The amplitude and phase are then transferred to the proper location in the wavenumber grid.

The interactions of the wavelets are then calculated according to equation (7). If the two interaction wavelets are in close to the same direction and have large wavenumbers, the interaction term at the sum of their wavenumbers will lie outside the wavenumber grid. Wavelets traveling against the main direction of propagation are expected to be small. We thus calculated the interactions only for wavenumbers $-31 \leq (K_x, K_y) \leq 31$. Even then, the calculations are formidable. There are 63 points which satisfy that inequality so approximately 16×10^6 interactions must be calculated. Because of this and the large three-dimensional grid which is used to calculate the potential function, the computations were done on a Cray computer.

The amplitudes and phases of the first and second order wavelets in wavenumber space are transformed to the spatial grid using a fast Fourier transform which was coded to take advantage of the vector processing capabilities of the Cray and is very efficient. Two transforms are taken, first by rows and then by columns. To produce better spatial resolution, we took transforms of length 256 instead of 128. The high wave number terms were set equal to zero. The spatial resolution is then

$$\Delta x = 2\pi/256\Delta\kappa = 12.27\text{ft.} \tag{8}$$

Only the 64×64 grid surrounding $(x, y) = (0, 0)$ is calculated since this gives a large enough area for the solution of the potential function.

The KBCF solution also requires specification of η_x and η_t on the grid. These quantities are easily calculated by differentiation of equations (5) and (7), and transformed in the same way as η. An initial guess for the potential function is given by the potential due to the linear waves, again computed by successive Fourier transforms in space.

A potential function which is consistent with the surface defined correct to second order can now be calculated. Define the potential ϕ such that the velocity components (u, v, w) in the (x, y, z) directions are given by

$$\begin{aligned} u &= -\phi_x \\ v &= -\phi_y \\ w &= -\phi_z \end{aligned} \tag{9}$$

The potential function satisfies Laplace's equation

$$\phi_{xx} + \phi_{yy} + \phi_{zz} = 0 \tag{10}$$

in the interior of the fluid. At the free surface η the kinematic boundary condition is

$$\eta_t + \phi_z - \phi_x\eta_x - \phi_y\eta_y = 0 \tag{11}$$

With η, η_x, η_y, and η_t specified, equations (10) and (11) define a well posed problem which can be solved numerically. However, the wave potential should also satisfy the dynamic boundary condition

$$\eta - \phi_t/g + (\phi_x^2 + \phi_y^2 + \phi_z^2)/2g = const. \tag{12}$$

on the surface. Since the surface is only correct to second order, the numerical solution will not satisfy equation (12) perfectly. KBCF theory based on the second order surface is thus an approximation to the true solution of equations (10)-(12), and its accuracy and usefulness can be verified best through comparisons with measurements.

The potential function can be found through a successive over-relaxation solution. We define a computational grid with spacing Δx in the horizontal directions and Δz in the vertical. The grid indexes are (I, J, K) in the $(x, y, -z)$ directions. Centered difference approximations to the second derivatives are then

$$\Phi_{xx} = \{\Phi(I+1, J, K) + \Phi(I-1, J, K) - 2\Phi(I, J, K)\}/\Delta x^2 \tag{13}$$

$$\Phi_{yy} = \{\Phi(I, J+1, K) + \Phi(I, J-1, K) - 2\Phi(I, J, K)\}/\Delta x^2 \tag{14}$$

$$\Phi_{zz} = \{\Phi(I, J, K-1) + \Phi(I, J, K+1) - 2\Phi(I, J, K)\}/\Delta z^2 \tag{15}$$

At each grid point, there will be a residual given by

$$r = \Phi_{xx} + \Phi_{yy} + \Phi_{zz} \tag{16}$$

At the next step, the approximate potential is replaced by

$$\Phi'(I, J, K) = \Phi(I, J, K) + \omega r/a_{kk} \tag{17}$$

where

$$a_{kk} = 2(2/\Delta x^2 + 1/\Delta z^2) \tag{18}$$

and ω is a constant chosen to speed up convergence. On our $64 \times 64 \times 64$ grid, we used $\omega = 1.87$ and found satisfactory convergence after 100 steps.

The estimates of Φ at the new step are found successively, moving through the grid in a cyclic pattern. To make use of the vector processing capabilities of the Cray, we used what is called a "black-red" ordering. The grid is divided into "black" and "red" points in a three-dimensional checkerboard pattern. The updated potential at all the "black" points is then calculated before that at any of the "red" points. Thus the updated potential is never needed, and the calculations can proceed in parallel.

The difference scheme must be modified at the boundaries. Boundary condition (11) can be rewritten as

$$\phi_n = -\eta_t(1 + \eta_x^2 + \eta_y^2)^{-1/2} \tag{19}$$

where ϕ_n is the derivative of the potential in the direction normal to the surface. To form a finite difference estimate of the normal derivative, define

$$\begin{aligned} \epsilon_x &= \eta_x \Delta z/\Delta x \\ and \quad \epsilon_y &= \eta_y \Delta z/\Delta x \end{aligned} \tag{24}$$

Then if ϵ_x and ϵ_y are both positive

$$\Phi_n = \{\Phi(I, J, K) - \Phi_c\}/\Delta z(1 + \eta_x^2 + \eta_y^2)^{1/2} \tag{21}$$

where

$$\Phi_c = (1 - \epsilon_y)\Phi_1 + \epsilon_y\Phi_2$$

$$\Phi_1 = (1-\epsilon_x)\Phi(I,J,K+1) + \epsilon_x\Phi(I+1,J,K+1)$$

and $$\Phi_2 = (1-\epsilon_x)\Phi(I,J+1,K+1) + \epsilon_x\Phi(I+1,J+1,K+1)$$

The residual at the surface node (I,J,K) is then

$$r = \eta_t + \{\Phi(I,J,K) - \Phi_e\}/\Delta z \tag{22}$$

and the new potential is

$$\Phi'(I,J,K) = \Phi(I,J,K) - \omega r \Delta z \tag{23}$$

Equation (21) must be modified in an obvious way for ϵ_x or ϵ_y negative.

The bottom boundary condition is that the normal derivative of the potential is zero. The change in the solution was insignificant when the potential at the bottom was fixed equal to the linear potential. This approximation speeded convergence somewhat, and it would be reasonable to use it at a false bottom for a KBCF solution in very deep water. The potential at the lateral boundaries of the grid was also kept constant at the linear value. Forristall (1985) showed that this condition had little effect on the solution under the wave crest in the center of the grid.

COMPARISONS WITH FULWACK MEASUREMENTS

The starting point for the KBCF calculations was the linear Monte Carlo simulation that formed the basis of the stretched and extrapolated simulations. This is the same procedure that we would be following in using KBCF for design, but it means that the simulated time series is a random realization of the process defined by the directional spectrum, and wave by wave comparisons with the data are not possible. The verification of the method is thus through a comparison of speed probability distributions.

The second order interactions tend to sharpen the crests of the waves and flatten the troughs, producing a skewed sea surface. One check of the theory can thus be made by comparing the skewness of the measured and simulated profiles, where skewness is defined as

$$\alpha_3 = m_3/m_2^{3/2} \tag{24}$$

and m_2 and m_3 are the second and third moments of the wave profile. The comparison is shown in Figure 11. Skewness is not a very stable statistic: the observed value varies significantly from one record to the next. However, there is very little bias between the measured and simulated values. The agreement is in fact somewhat better than Forristall (1985) found for the MaTS wave tank data, perhaps because the finite length of the tank affected the low frequency set down under wave groups given by the subtraction term in equation (5).

The most important result of the calculations is the comparison between the measured and KBCF simulated maximum speeds at current meters 1 and 2. Figure 12 shows the comparison for current meter 1. The simulation is an essentially unbiased predictor of the measurements: the agreement is almost perfect at the 50% level. The median value of the measured maximum speed for the sample of large waves was 14.67 ft/sec at current meter 1 and 13.80 ft/sec at current meter 2. The corresponding KBCF simulations were 15.05 ft/sec at current meter 1 and 13.24 ft/sec at current meter 2, both within 5% of the measurements. The interquartile ranges (.25% to .75% exceedance) at current meter 1 were 3.67 and 3.14 ft/sec for the measurements and 2.10 and 2.17 ft/sec for the simulations. This extra variability in the measurements might be attributed to noise which remained after the filtering process. It should be recalled that the data shown in Figure 12 came only from the 31 highest waves in 12 hours of measurement in a severe storm. All of the distribution shown in the figure thus comes from the tail of the overall speed distribution. The good match of simulated and measured peak velocity statistics constitutes a verification of KBCF theory for high, directionally spread waves.

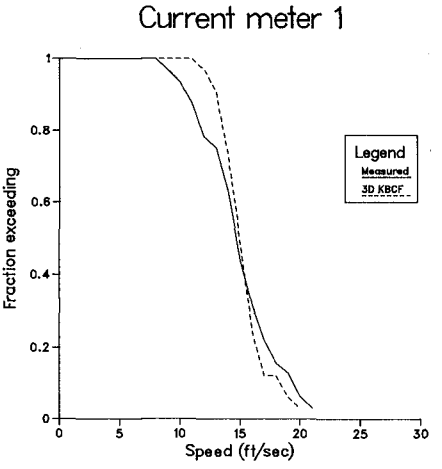

Figure 12. Distribution of measured and KBCF speeds

CONCLUSIONS

KBCF was developed as a rational approximation to the equations of motion for kinematics in the crests of irregular waves. It was compared to high quality measurements of two-dimensional waves made in a MaTS project and gave excellent results. The FULWACK experiment was designed as a full scale verification of the theory, which had to be extended to three dimensions to include the directional spreading of natural waves. Storms during November 1981 produced a good data set which included a number of waves that inundated current meters up to 26 feet above mean water level. The agreement between the velocity statistics simulated by KBCF and those measured was very good. We conclude that KBCF has been verified and is the best method of simulating the kinematic field of a complex natural seaway.

Although KBCF requires the use of a large computer, its cost is not prohibitive for simulations of individual high waves in a sea state. A number of representative waves for a design sea state could be simulated and used for static design of fixed structures. Dynamic design calculations present more of a problem, since many time steps of simulation are likely to be necessary and the cost of the simulations may become important. For these calculations and for routine design calculations on smaller computers, the best use of KBCF may be to calibrate simpler empirical models of kinematics. Rodenbusch and Forristall (1986) have developed a modification to the standard stretching algorithm which matches KBCF well in the crests of large waves.

ACKNOWLEDGEMENTS

The FULWACK project would not have been possible without the help and participation of many parts of the Shell Group. SIPM EP/23 coordinated the various activities involved. Shell Expro was extremely helpful in the design and installation of the instrument mounting system. The work of I. Middlehurst on the design and G. Grice on the installation was particularly appreciated. KSLA (Amsterdam) graciously gave us room in their instrument house, and several times loaned us spare parts from their supplies. R.C. Hamilton and T. Swarthout of Evans–Hamilton performed the instrument installation most efficiently. G. Rodenbusch and R.D. Larrabee gave helpful comments on an earlier version of this report.

CHAPTER 17

Mediterranean Sea Level Changes From Tidal Records

Victor Goldsmith* and Michal Gilboa*

Abstract

Of the more than 90 tide gage records in the Mediterranean, 10 representative gages were analyzed for indications of sea level rise (SLR). No definitive trend of regional sea level rise has been discerned for this area. The lack of SLR may be partially attributed to local effects on sea level such as seasonal water temperature and wind differences, and to local tectonics. The extent of these seasonal changes is in the order of tens of cms/year, and varies greatly from year to year, probably masking the trends of long-term SLR of mm/yr.

Introduction

Recent studies indicating a sea level rise on some coasts (Aubrey and Emery, 1983), together with analyses of the "greenhouse effect", have led to predictions of a future global sea level rise of 60 cm in the next 40 years (summarized in Barth and Titus, 1984). As a result, subsequent efforts have concentrated on rezoning the coasts and re-defining criteria for all coastal constructions, for the expected SLR.

In this study attention is directed at documenting and explaining seasonal sea level changes discerned in Mediterranean tide gages. These analyses are then used to help define SLR.

Tide Data

Tide records for Israel have been obtained from Israel government agencies for the following locations:

Haifa 1956-60, 1965-76
Jaffa 1955-59, 1962-73, 1975-82
Ashdod 1958-83
Eilat 1965-70, 1975-83

The first three are on the Mediterranean coast, and Eilat is on the Red Sea.

Tide records for the following locations were obtained from the Permanent Service for Mean Sea Level (PSMSL) in Liverpool, U.K.: (Fig.1):

Gibralter 1961-83
Alicante Spain (Mediterranean coast) 1960-78
Trieste Yugoslavia 1934-74
Bakar Yugoslavia 1934-74

*Israel National Oceanographic Institute, P.O. Box 8030, Haifa and Haifa University (V.G.)

Dubrovnik Yugoslavia 1956-74
Piraieus Greece 1969-82

Comparisons of concomitant tidal data at the three Israeli Mediterranean locations indicate that they have very similar tidal curves and amplitudes (30-60 cm). The similarities in these tidal curves provided a check on the efficacy of the data and on the common sea level datum (Goldsmith and Gilboa, 1985).

Seasonal Sea Level Changes

With the exception of Trieste, no clear long term sea level trends were discerned from statis tical analyses of the averages of annual sea levels. Further analyses were conducted by computing the monthly mean sea levels. From these results, strong seasonal changes of 15-20 cm were noted, with the seasonality varying around the Mediterranean. Further, the seasonality varied significantly (>5cm) from year to year.

Plots were made of the averages of all the monthly means for each of the 12 months (Fig. 2).

Temperature Effects

Along the Israeli coast there is a strong tidal seasonality with a range of 20 cm. This is approximately equal to the neap tide range, and 1/3 of the spring tide range. Highest sea levels occur at the end of summer and lowest sea levels occur at the end of winter. Heat flow data obtained over many years by the R/V Shikmona in the southeast Mediterranean continental shelf show a similar seasonality (Fig. 3). Moreover, computations of theoretical sea level changes from the measured heat flow data indicate that sea level changes based on the seasonal water temperature changes alone accounts for 2/3 of the seasonal sea level changes measured by the tide gages. This is due to changes in the water volume (i.e., cold water is denser, hence lower sea levels in winter). There appears to be a certain lag effect, with the coldest and warmest temperatures occuring at the ends of winter and summer, respectively.

A similar pattern is found in the western Mediterranean; e.g., Alicante Spain and Gibralter have a seasonality of 15 cm with highest levels in September to November, and lowest levels in February/March (Fig. 4). Here the seasonality is not so regular nor so sharp as in the eastern Mediterranean.

Wind Effects

Another factor in the seasonal sea level changes involves local wind effects, especially in on/offshore winds. In the southeast Mediterranean, very low monthly mean sea levels occur occasionally in the winter months (i.e. 20 cm below MSL). This is attributed to strong offshore easterly winds which may blow continuously for many days. In the western Mediterranean unusually high monthly mean sea levels occur in the summer months. Along the Spanish coast the

dominant winds are onshore from March to April with the highest frequency in July, and offshore from November to February, peaking in February (Sanjaume, 1984, and Figure 4). The measured monthly mean tide heights decrease from December to February at both Alicante and Gibralter, coincident with the dominance of offshore winds. Similarly, the monthy mean tide heights increase from March to October coincident with the dominance of onshore winds.

Thus the seasonal sea level changes appear to be related to a combination of sea temperature and wind effects in the Mediterranean.

Long-term Sea Level Changes From Yearly Averages

At Trieste the long-term trend is a rise in sea level, but between 1955-83 sea level was relatively stable. At Ashdod and Piraeus in the eastern Mediterranean, the annual average sea level was higher in the 1960's, and decreased by 5 cm in 1979-1980, then rose and fell again. At Gibralter and Alicante in the western Mediterranean, sea level was lower in the 1960's; it peaked higher in Gibralter in 1970-1980 and then decreased by 12 cm. (Fig. 1).

Linear regression analyses and r2 values were derived from the annual averages of the 10 tide gages. The computed trends and the r2 values are presented in the top portion of Figure 5. Only Trieste shows a clear SLR (1.3 mm/yr). Due to the many uncertainties in these tide data (including placement of the gages relative to a common datum, continuity of records, and annual variations in local climatological factors) there is some statistical uncertainty in choosing the proper limiting r2 value. Imaginary tide gage records were constructed using a random numbers table, and similar statistical computations made. In every case, r2 values were $<< 0.1$. Thus, computed sea level trends with $r2 > 0.1$ are accepted (Fig. 5). Note that at two locations, Haifa and Alicante, at opposite ends of the Mediterranean, a trend of sea level lowering is indicated.

Long-term Sea Level Changes From Monthly Averages

Because of the large seasonal range observed in the tide gage records, and the large variations from year to year in this seasonality, it appears that a better indicator of long-term changes might be discerned in the analysis of the trend for an individual month, i.e., the monthly means of all the January's for all the years of record. The results of the statistical analyses of the monthly sea level trends and concomitant r2 values are shown in the bottom half of Figure 5. Of the 120 analyses (10 gages X 12 months) only those with r2 values > 0.1 are shown.

A strong trend of rising sea level of 1-2 mm/yr is clearly shown for Trieste (especially in the summer months) and for the neighboring station of Bakar (for June and August). A weak trend of falling sea level is shown for Ashdod (August and September) and Alicante (June).

What is clar, however, is that the best results occur in the

summer months. This appears to be due to more consistant climatological factors in the summer. In the winter the Mediterranean is in the zone of westerlies with storms passing through on an average of every 7-10 days (Goldsmith and Sofer, 1983). In the summer, the subtropical low moves north and winds in the eastern Mediterranean blow every day from the northwest.

Conclusions

SLR trends in the Mediterranean are "masked" by the local processes including seasonal sea level changes from thermal expansion of the sea due to temperature changes, and from seasonal changes in the offshore/onshore winds. These seasonal changes in the sea level of 15-20 cm have large annual variations (> 5cm). Of the 10 gages analyzed only Trieste shows a definite trend of SLR amounting to 1-2 mm/yr. The location of Trieste, at the end of the Alps, suggests the importance of local tectonic effects.

To overcome the "noise" in the data resulting from seasonal effects, sea level trends of individual months, rather than annual averages, were delineated. In some cases the individual months are statistically more significant than the annual averages. The best results occur in the summer months when climatological conditions are more consistent.

The lack of consistent definitive trends in Mediterranean sea level records suggests the importance of local effects. The analyst looking for indications of SLR should be aware of local effects and take these into account before making definitive statements on SLR trends.

CHAPTER 18

EXPERIMENTAL STUDY ON THE VALIDITY RANGE OF VARIOUS WAVE THEORIES

by

Masataro Hattori*

INTRODUCTION

In the design of coastal structures and the study of nearshore dynamics, rational predictions of the wave kinematics are very important but difficult procedures. Although a large number of nonlinear wave theories have been proposed and used for computing the wave kinematics, there are no theories applicable from the deep water to very shallow water. It is, therefore, very important for coastal researchers and engineers to know which of theories describe well a wave field specified by the wave characteristics and water depth, and to select a particular wave theory for a problem of interest.

Many intensive efforts have been made to examine the validity as well as the applicability of various wave theories. However, there are still no well-accepted guidlines for the application range of the wave theories. The validity evaluation of a particular wave theory has been basically made by means of the following two versions: the analytical (mathematical) validity and the experimental (physical) validity. The analytical validity study has been conducted by various researchers (Dean, 1970; Komar, 1976; Horikawa et al., 1977; Swart, 1978) and revealed the degree of mathematical satisification to the governing equations and boundary conditions for each wave theory. The analytical validity study probably tends to show the relative applicability for various wave theories. It does not ensure that the theory describe well laboratory or field phenomena. Based on the analytical validity of various wave theories by Horikawa et al., Isobe (1985) proposed application ranges for the finite amplitude wave theories in terms of the relative water depth and relative wave height.

The experimental validity refers to how well the prediction of various wave theories agrees with actual measurements (Dean & Dalrymple, 1984). As the wave shoals, wave form becomes more asymmetrical, especially under high wave conditions of interest to design. Such nonlinearity influences greatly the wave kinematics and it makes difficult to predict readily the wave kinematics by several theories. From a practical viewpoint, it is , therefore, requested to establish the application ranges of available wave theories for shoaling waves.

In this study, laboratory data of simultaneous measurements of the

* Professor, Department of Civil Engineering, Chuo University, Kasuga 1-13-27, Bunkyo-ku, Tokyo, 112, Japan.

wave surface elevation and water particle velocities of the shoaling wave were compared with the predictions from various wave theories. On basis of degree of the overall agreement between the measured and predicted time-varying quantities, the validity range of the individual wave theory was specified.

The purposes of the present study are: (1) To propose parameters and criteria for the evaluation of wave theory validity, (2) To evaluate the validity limits for various wave theories, and (3) To determine the application ranges of available wave theories for important ranges of wave conditions of practical interest.

The wave theories included in the evaluation are listed in Table 1. The linear wave theory is the best known and widely used theory. From a practical viewpoint, the Stream Function wave theory of Dean (1965) was adopted as a representative numerical wave theory. The prediction of time-varying quantities by the ninth order irregular Stream Function wave theory, SFM9A, was performed using the measured wave profile, whereas that by the other theories was based on symmetrical profiles with the measured wave height and period.

Ninth order of irregular waves	SFM 9A	

EXPERIMENTAL EQUIPMENT AND PROCEDURES

Experiments were performed in a glass-walled wave flume, 0.30 m wide, 0.55 m high and 20 m long. Waves were produced by a flap-type wave generator installed at one end of the flume. A sloping bottom of 1/20 was installed in the flume. Experimental conditions, given by Table 2, covered a wide range of the wave steepness. The last column of Table 2 gives the Ursell parameter, Ur_0, at the wave generator.

Simultaneous measurements of the wave surface elevation and water particle velocities were made at various locations over the slope. Range of the shallow water Ursell parameter, $Ur = gHT^2/h^2$ (H is the wave height, T is the wave period, h is the water depth, and g is the gravitational acceleration), at measuring section was from about 1 to 110. The wave surface elevation, η, was measured by resistance-type wave gages having excellent linearity and stability. The manufacture's stated frequency response of the wave gage is approximately 20 Hz, higher than the harmonic frequency range of experimental waves due to the nonlinearity. Measurements of the horizontal and vertical water particle velocities, u and w, were made using a laser doppler velocimeter of two

components (DISA, Model 55 X) in a vertical plane beneath the wave surface measurement. Outputs of the wave surface elevation and water particle velocities were recorded on a 7-channel analogue recorder over 70 wave periods minimally. The data were digitized by an A-D converter at a sampling frequency of 167 Hz for computer processing. After individual waves were determined from the wave gage records by means of the zero-upcrossing method, the time series data were averaged over 50 waves with respect to the phase.

DETERMINATION OF THE EVALUATION PARAMETERS

In the most previous studies (Swart, 1978), the validity of wave theory has been discussed on basis of visual comparisons between the theoretical prediction and measured values. In order to determine rationally the application range for a particular wave theory, the wave theory validity should be evaluated with appropriate criteria of non-dimensional parameters representing degree of the agreement of the theory with the measured values. We adopted the four following parameters:

(1) Ratio of the maximum values: $M_R^+ = Y_{max}/X_{max}$,

(2) Ratio of the minimum values: $M_R^- = Y_{min}/X_{min}$,

(3) Coherence between the measured and predicted time histories:

$$C_o = \sum_{i=1}^{m} X_i Y_i / \left(\sum_{i=1}^{m} X_i \sum_{i=1}^{m} Y_i \right)^{1/2}, \text{ and}$$

(4) Overall root-mean-square (rms) between the time histories:

$$E = \left[\sum_{i=1}^{m} (X_i - Y_i)^2 / \sum_{i=1}^{m} X_i^2 \right]^{1/2}.$$

X_i and Y_i, as shown in Fig. 1, are the measured and predicted values sampled at various and evenly spaced phases over one wave period of the time history. X_{max} and Y_{max}, and X_{min} and Y_{min} are the maximum and minimum values of X_i and Y_i, respectively.

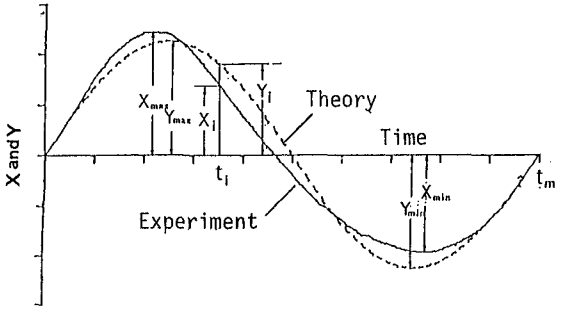

Fig. 1 Definition Sketch for Evaluation Parameters.

From a practical viewpoint, the parameter set of M_R^+ and M_R^- seems to be of a very useful in the validity evaluation. Since the coherence function C_o indicates the degree of similarity in overall profiles of time variations, the parameter set of C_o and M_R^+ is considered as a favorable measure for the validity evaluation. As the overall rms error E indicates the deviation degree of the theory from the experiment throughout the time history of one wave period, E is considered as the principal parameter for the validity evaluation.

EXPERIMENTAL ERRORS AND CRITERIA FOR THE VALIDITY EVALUATION

If experiments could be made under sufficiently well-controlled conditions, measured data are most likely contaminated with a variety kind of errors associated with the experiments. We should determine criterion for evaluation of the wave theory validity with consideration that disagreement between the theory and experiment is at least of the same order as the estimated experimental error, because the experimental validity is based on the comparison between the theory and experiment.

Prior to the determination of the evaluation criterion, it is necessary to discuss potential errors associated with experiments. The experimental errors are attributed to the following causes: experimental equipment and procedures, measuring instruments and techniques, and data processing.

Ursell parameter at the wave generator for each test run, given in the last column of Table 2, is much less than 13, and indicates that experimental waves are completely free from the secondary wave generation (Swart, 1978). Wave reflection from the sloping bottom was

one of the systematic error sources. From measurements of the wave height distribution in a part of uniform water depth, the error due to the reflection was estimated at most ± 5 % under high wave conditions.

In Fig. 2, the experimental results are shown for the variation of wave height for a series of Exps. 1 through 3. The solid line along data plots represents the theory of Shuto (1974), which is the first order Cnoidal wave theory with some second order terms retained in order to take account of the bottom slope effect. For a reference, breaking limits of Yamada and Shiotani (1968) and of Goda (1970), and the isolines of the shallow water Ursell parameter are shown. It is noticed from Fig. 2 that the experiments surprisingly agree well with the theory except for the experiments of low steepness conditions. The small deviation between the measurements and the theory is probably due to capillary effect of the water surface on thin-wire wave gages. The wave measurement error is estimated to be at most ± 2 %.

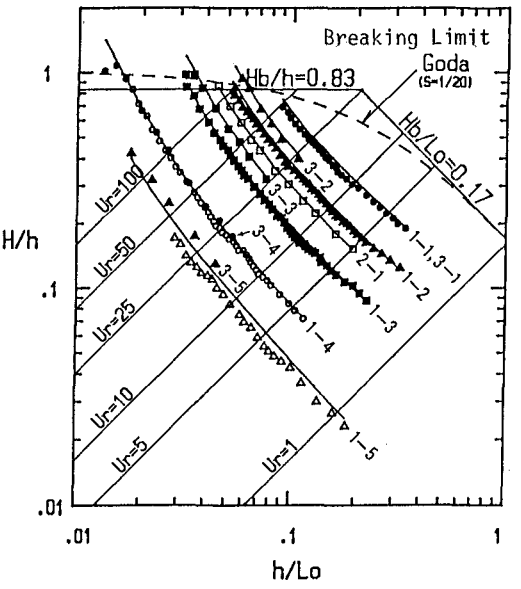

Fig. 2 Wave Height Variation.
———: Theory of Shuto (1974)

The manufacture's stated accuracy of the instruments used was much greater than that required for this class of experiments. Another potential error is due to averaging processes of the measured data, and is estimated ±0.5 % for the wave surface elevation and ± 1 % for the water particle velocity data.

Taking into consideration of the potential errors in the experiment, we determined the overall rms error of $E \leq 0.10$ as the principal criterion of the validity evaluation. Evaluation criteria of the other parameters were determined so as to be equivalent to the principal criterion and were $0.90 \leq M_R^+$ and $M_R^- \leq 1.10$ and $C_o \geq 0.995$. To substantiate the adequancy of the criteria, Fig. 3 presents an example comparison between the measured and predicted time variations of the wave surface elevation and water particle velocities. The theoretical predictions were made by using the measured wave height, wave period, and water depth. E value for the ST 5 theory is equal to the criterion of E = 0.10. Visual comparisons provide fairly well agreements between the experiment and the predictions from the ST 5 theory.

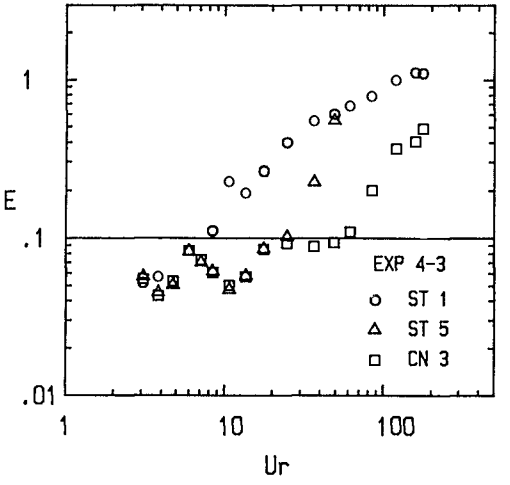

Fig. 4 Validity Limits for Wave Form of ST 1, ST 5 and CN 3 Theories in terms of E and Ur.

VALIDITY EVALUATION FOR THE WAVE SURFACE ELEVATION

Since the prediction by a wave theory is based on the measured wave height and period, the use of M_R^+ and M_R^- is not suitable for the validity evaluation of the wave surface elevation. Thus, validity examinations were performed with respect to the C_o and E parameters.

The validity limits of the ST 1, ST 5, and CN 3 theories for the wave form is shown in Fig. 4, in terms of the overall rms error E and the shallow water Ursell parameter Ur. It was found that the linear theory broke up the validity due to the wave form asymmetry about the mean water level, while the nonlinear wave theory became unable to maintain the validity due to the wave form asymmetry about the wave crest. Nonlinear effects of the shoaling wave on the wave form were discussed with the use of two types of the skewness factor for the wave form (Sekine & Hattori, 1985).

VALIDITY EVALUATION FOR THE WATER PARTICLE VELOCITIES

Since within a region of small Ursell parameter at measuring locations, the wave form is approximately symmetrical, the water particle velocities at the crest and trough phase position are predicted relatively well by either the linear or the Stokes wave theory. As the wave shoals further, the wave form becomes more asymmetrical about the crest as well as the mean water level. Due to such nonlinearity associated with the shoaling, degree of the agreement between the measurement and the prediction of the water particle velocities as well as the wave form depends on the class of wave theory applied to the computation of the wave kinematics.

Figure 5 shows an example comparison of the vertical distributions with depth for the horizontal and vertical water particle velocities under the crest and trough at a section of Ur = 22, where the wave form asymmetry becomes apparent. Under such a circumstance, the nonlinear wave theories, ST 5, CN 3 and SFM 9A, predict fairly well the measured values of the horizontal water particle velocity as seen in Fig. 5. Although the vertical water particle velocity under the crest and trough

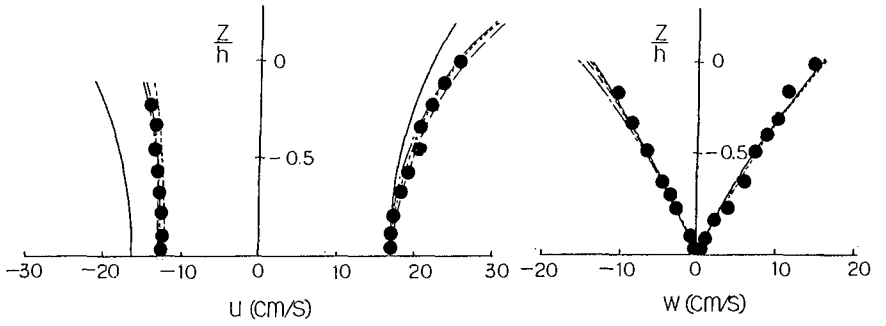

Fig. 5 Vertical Distributions of Water Particle Velocities under Crest and Trough (Exp. 2-1, Ur = 22).
———: ST 1, — — —: ST 5, — — — : CN 3, - - - - - -: SFM 9A

is represented excellently well by every wave theory as in Fig. 5, it is considered that degree of the agreement between the theory and measurements for the horizontal water particle velocity clearly depends upon the theoretical modeling for the nonlinear effect.

Based on comparisons of the vertical distributions between the measured and predicted water particle velocities, we decided to examine the wave theory validity for the water particle velocity through time history data of the horizontal water particle velocity. The validity evaluation was based on spatial distribution of the isoline of each evaluation parameter. Figure 6 is an example showing the validity limit of the ST 1 theory. The top figure is for the E value, the middle figure for the parameter set of M_R^+ and M_R^-, and the bottom figure for the parameter set of M_R^+ and C_o. The validity area is illustrated by the shaded part. The horizontal coordinate is represented by the water depth, instead of the horizontal distance from a reference point. The figure by the sloping bottom is the water depth and that in parentheses is the shallow water Ursell parameter at the measuring section. $_{max}$ and $_{min}$ are the envelop of wave height. B.P. denotes the breaking point.

As waves propagate from the intermediate to very shallow water region, the wave form is gradually translated due to nonlinear effects of the wave motion. As a consequence, the linear wave theory loses the validity for the horizontal water particle velocity as well as for the wave form. An interesting evidence is found that the validity limit for the water particle velocity broadens at the lower portions of the water column, because the bottom boundary restricts the orbital motion of water particles due to waves, especially in the vertical direction. This results degradation of the nonlinearity in the velocity time-variation. From a comparison between the top and middle figures in Fig. 6, we notice that the validity limit determined with the parameter set of M_R^+ and M_R^-, very useful in a practical use, is almost the same as that by E. In contrast, a remarkable disagreement is found between the validity limit determined by E and the parameter set of M_R^+ and C_o. Thus the parameter set of M_R^+ and C_o is not suitable for the validity evaluation. As many previous studies have pointed out, the ST 1 theory provides very good predictions of the wave kinematics even in very shallow water region, up to the breaking point.

Figures 7 and 8 show the validity limit of the nonlinear wave theories, ST 5 and CN 3. The validity limit for the ST 5 theory coincides with the nonconvergence or inapplicability of the wave theory. Although the CN 3 theory is recognized to predict reasonably well the water particle velocity in the very shallow water region, the theory becomes unable to maintain the validity due to the nonlinearity associated with the asymmetry about the maximum velocity under the crest. The CN 3 theory provides a favorable agreement with the measured wave surface elevation in the intermediate region (see Fig. 4). On the other hand, the theory tends to overpredict the horizontal water particle velocity at the crest phase position in the same region. Consequently, another validity limit appears in the intermediate water depth region, and this is expected from the assumption employed in the derivation of the Cnoidal wave theory. According to the validity evaluation for the CN 1 theory, the theory represents very poorly the

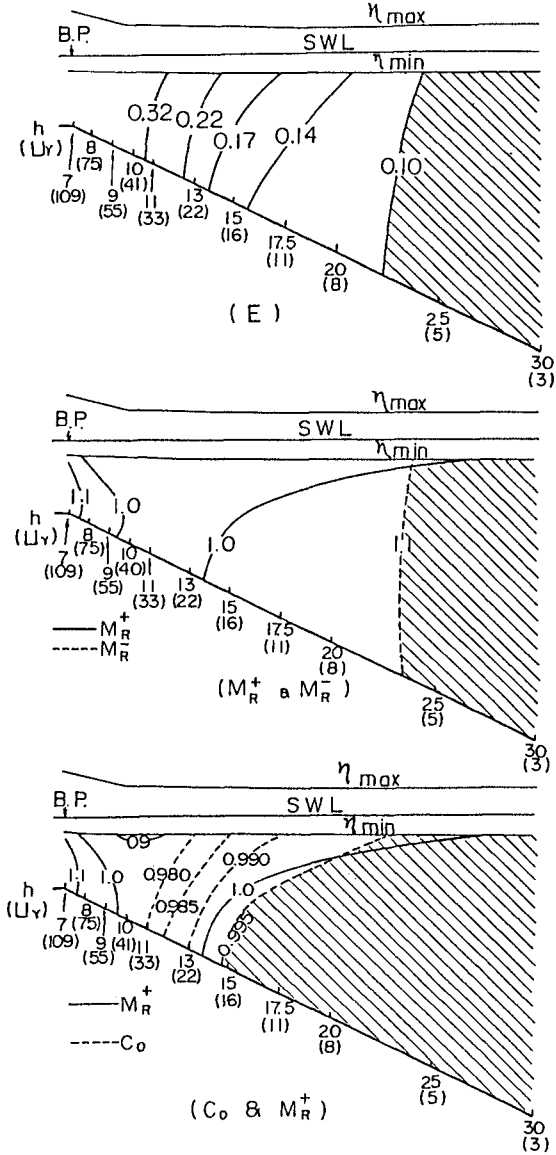

Fig. 6 Validity Limit for Horizontal Velocity of ST 1 Theory (Exp.2-1).

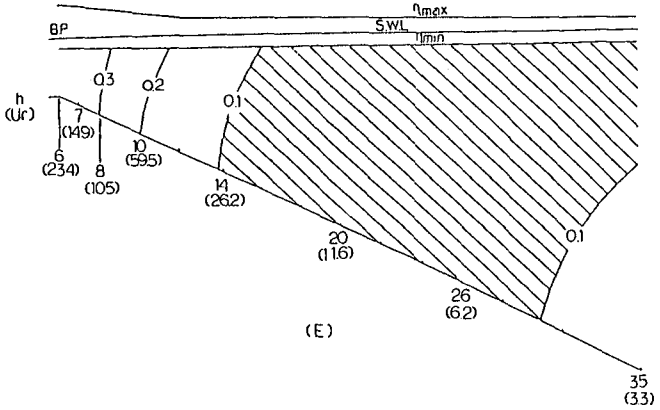

Fig. 8 Validity Limit for Horizontal Velocity of CN 3 Theory (Exp. 4-4).

measures water particle velocity. Thus the rational validity limit of the CN 1 theory could not be determine.

The irregular Stream Function wave theory, SFM 9A, provides the best agreement with the measured water particle velocity over a very wide range from the deep water to very shallow water near the breaking point. This is most probably due to the use of the measured wave surface elevation for the calculation of the SFM 9A theory.

APPLICATION RANGE FOR THE WAVE THEORIES

In the previous sections, we mainly discussed the validity limit for the wave form and the water particle velocity with the aid of the criterion of the overall rms error E = 0.10. The application range of the wave theories can be determined from intercomparisons of the validity limits for the wave form and water particle velocity, in terms of the relative water depth, h/L_0, and relative wave height, H/h, with the auxiliary parameter of the shallow water Ursell parameter, Ur. The results are presented by Figs. 9 through 11.

Application ranges of the ST 1 and ST 5 theories are presented in Fig. 9, in which the broken line is the isoline of the rms error E_T = 0.10 in the free surface boundary conditions for the wave theories, determined from the analytical validity study of Horikawa et al. (Isobe, 1986). Breaking limit by Yamada and Shotani (1968) is also shown. Circle, triangle, and square symbols denote the validity limits for the wave form and the horizontal water particle velocities near the bottom and just below the trough, respectively. According to the validity evaluation results, the validity limit for the wave form coincides with that for the water particle velocities at the upper portions of the water column. Therefore, this determines the application ranges of the ST 1 and ST 5 theories, as shown in Fig. 9.

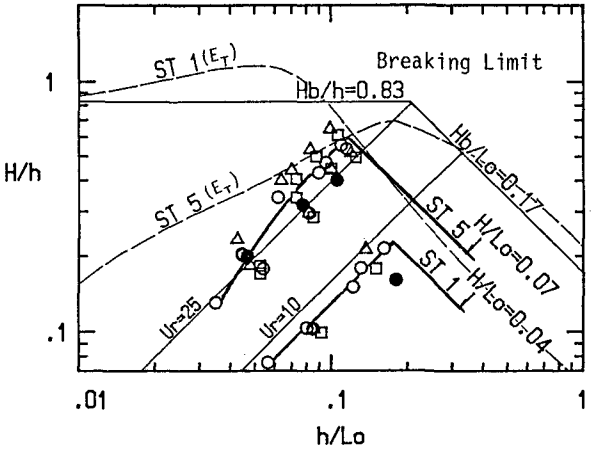

Fig. 9 Application Ranges of ST 1 and ST 5 Theories.
○ ● : the wave surface elevation, △ ▲ : near-bottom horizontal velocity, □ ■ : horizontal velocity below the trough.
—— ——: isoline of E_T = 0.10 by Isobe (1986)

A special feature found in the application range of the CN 3 theory is that the application range is confined within a region bounded by the application limits in very shallow water and in the intermediate water depth region as in Fig. 10, and provides some limitation in application of the Cnoidal wave theory. The CN 3 theory as well as the ST 5 can not represent favorably the measured values in a region of large values of

Ur, in which the asymmetry in the wave form becomes more remarkable (Iwagaki et al., 1972; Flick et al., 1981). Taking into account that there is an application limit of the CN 3 theory of Ur = 6, and that the application range of the ST 5 theory in a region of Ur > 25 is narrow, the isoline of Ur = 25 is considered as a reasonable demarcation between the applications of the ST 5 and CN 3 theories (Le Mehaute, 1976; Isobe, 1985). From Figs. 9 and 10, it is found that the application ranges determined by the experimental validity indicate a similar trend of the isoline of E_T for each wave theory, especially in the intermediate water depth.

Application range of the irregular Stream Function wave theory, SFM 9A, coincides exactly with the validity limit for the water particle velocities (Fig. 11). The SFM 5B theory, assumed the symmetrical wave form can not predict well the wave kinematics in very shallow water region because of the nonlinear effect. From a comparison between Figs. 10 and 11, we find that the application limit of the SFM5B theory is almost the same as that of the CN 3 theory in a region of large values of Ur.

To conclude the discussions in the present study, we propose a diagram representing the application ranges of the wave theories for waves propagating in the shoaling water. Figure 12 presents the application ranges in terms of h/L_0, h/H, and Ur.

CONCLUSIONS

Simultaneous measurements of the wave surface elevation and water particle velocities of shoaling waves have been performed at various locations in a wave flume with a slope of 1/20. The validity of wave theories has been evaluated by comparisons between the measured values

and predictions from the wave theories. The wave theory validity has been discussed using four parameters, representing the degree of the agreement between the measurement and theory. Based on the validity evaluation, the application ranges for the wave theories have been determined in terms of H/h, h/L_0, and Ur.

The main findings of the present study are as follows:

(1) Amongthe non-dimensional parameters for the validity evaluation, the overall rms error E plays a principal role in the determination of the validity limit of various wave theories. In addition, the parameter set of M_R^+ and R_R^- is favorable to the validity evaluation in a practical problem specified by the wave characteristics and water depth.

(2) For wave surface elevation, the validity range of analytical theory for permanent type waves is limited by the nonlinearity attributed to the wave form asymmery about the mean water level for the linear wave theory and about the crest for the nonlinear theory.

(3) The degree of agreement between the measured and predicted horizontal water particle velocity depends on the elevation above the bottom and on the value of Ursell parameter.

(4) Application ranges of the wave theories included in the evaluation are determined by the validity limits for the wave form and horizontal water particle velocity at the upper portions of water column just below the trough. Within the limit of the present study, the application ranges are determined as in Fig. 12 and Table 3.

Table 3 Application Ranges of the Wave Theories.

ST 1	$0.2 \leqq h/L_0 < 0.4$: $H/L_0 \leqq 0.04$ $0.06 < h/L_0 \leqq 0.2$: $U_r \leqq 7$
ST 5	$0.1 \leqq h/L_0 < 0.4$: $H/L_0 \leqq 0.07$ $0.06 \leqq h/L_0 \leqq 0.1$: $U_r \leqq 32$ $0.04 < h/L_0 \leqq 0.06$: $U_r \leqq 25$
CN 3	$0.12 \leqq h/L_0 < 0.4$: $H/L_0 \leqq 0.07$: $6 < U_r \leqq 25$ $0.07 \leqq h/L_0 \leqq 0.12$: $H/h \leqq 0.5$: $6 < U_r \leqq 35$ $0.04 \leqq h/L_0 \leqq 0.07$: $6 < U_r \leqq 35$ $0.02 < h/L_0 \leqq 0.04$: $6 < U_r \leqq 25$
SFM9A	$0.1 \leqq h/L_0 < 0.4$: $H/L_0 < 0.07$ $0.02 < h/L_0 \leqq 0.1$: $H/h \leqq 0.6$

ACKNOWLEDGMENTS

The author would like to express the appreciation to Dr. M. Mizuguchi, Associate Professor of Chuo University and Dr. M. Isobe, Associate Professor of Yokohama National University, for many helpful

suggestions and valuable discussions during the course of this study.

CHAPTER 19

DIRECTIONAL SPECTRA IN CURRENT-DEPTH REFRACTION

F. Hirosue[1] and T. Sakai[2]

ABSTRACT

According to Brink-Kjaer et al.'s discussion(1984), the expression of the wave direction change velocity is modified in our numerical model for the directional wave spectra change due to current-depth refraction (Sakai et al., 1983). The wave reflection and breaking conditions due to current are discussed from a view point of numerical analysis. Effects of the refraction term in the modified wave action equation on the directional spectra change are examined. The relative importance of current and water depth change in the directional spectra change is also examined.

INTRODUCTION

In the design of offshore structures, the wave force is the most predominant force acting on them. At present, it is usual to take into account the frequency spectra of irregular waves in the design. Recently it was pointed out that the frequency spectra were not enough for the design of some kinds of coastal structure. Usually the propagation direction of ocean waves is not uni-directional, but it spreads wide. This directional spreading influences the estimation of wave forces on structures(Battjes, 1982).

The directional spreading of ocean waves is expressed in term of the directional spectra. Several standard forms of directional spectra were already proposed for the deep-water wind waves. However the waves are transformed during propagation, and therefore the directional spectra change. Two main causes of the directional spectra change are the wave refraction due to underwater topography and that due to current. In offshore region, the latter is rather important.

A numerical model was proposed by the authors(Sakai et al., 1983) for the change of directional spectra of irregular waves due to depth-current refraction. Since then, Mathiesen(1984), Brink-Kjaer (1984), Booij et al.(1985) and Yamaguchi et al.(1985) proposed similar numerical models. All models use the following wave action conservation equation as the basic equation for the wave height change of each component composing the irregular waves.

$$\frac{\partial A}{\partial t} + \nabla \cdot \{A(U+c_{gr})\} = 0. \qquad (1)$$

---

2) Dept. of Civil Eng., Kyoto Univ., Sakyo-Ku, 606 Kyoto, Japan

A ($= E/\omega_r$, E is the wave energy of each component, and ω_r is the angular wave frequency relative to the current) is the wave action of each component, t is the time, $\nabla = (\partial/\partial x, \partial/\partial y)$, (x, y) is a horizontal orthogonal coordinate system, $\boldsymbol{U}$ is the vector of the horizontal current velocity, and c_{gr} is the vector of the wave group velocity relative to the current.

In the models of Mathiesen, Brink-Kjaer and Yamaguchi et al., the computation proceeds along the so-called wave ray. On the other hand, in the model of the authors, the basic equations are differentiated directly by a finite difference method. This method has a merit that values can be obtained directly on the grid points, while it is not the case in the ray method.

A steady state is assumed and therefore the local accelaration term $\partial A/\partial t$ can be eliminated in Eq.(1). Instead, a term expressing the spectral density change due to the wave direction change $\partial(A \cdot v_\theta)/\partial\theta$ is added as follows :

$$\frac{\partial}{\partial x}(A \cdot v_x) + \frac{\partial}{\partial y}(A \cdot v_y) + \frac{\partial}{\partial\theta}(A \cdot v_\theta) = 0. \tag{2}$$

This term is added to calculate the changes due to both shoaling and refraction simultaneously, which is called "refraction term" hereafter.

In Eq.(2), v_x and v_y are the x and y components of $\boldsymbol{U} + c_{gr}$ in Eq.(1) and given by

$$v_x = U + c_{gr}\cos\theta, \quad v_y = V + c_{gr}\sin\theta. \tag{3}$$

U and V are the x and y components of $\boldsymbol{U}$, and θ is the angle between the wave direction and the x axis. v_θ is a velocity of wave direction change of each component and given from the irrotational condition of wave number as follows :

$$\begin{aligned} v_\theta = {} & (\partial U/\partial x \cdot \sin\theta - \partial U/\partial y \cdot \cos\theta)\cos\theta + (\partial V/\partial x \cdot \sin\theta - \partial V/\partial y \cdot \cos\theta)\sin\theta \\ & + (\partial c_r/\partial x \cdot \sin\theta - \partial c_r/\partial y \cdot \cos\theta) \\ & + (\partial\theta/\partial x \cdot \cos\theta + \partial\theta/\partial y \cdot \sin\theta)(c_{gr} - c_r), \end{aligned} \tag{4}$$

where, c_r is the wave velocity relative to the current.

In Eq.(4), the spatial derivatives of the wave direction θ are included. The value of these derivatives is not known before the computation. In the authors' model, an approximate method was used to solve such a problem. For this problem, Brink-Kjaer et al.(1984) pointed that the differentiation resulting in Eq.(4) was not complete, and proposed Eq.(5) as a further modified form of Eq.(4).

$$\begin{aligned} v_\theta = {} & \left(\frac{\partial U}{\partial x}\sin\theta - \frac{\partial U}{\partial y}\cos\theta\right)\cos\theta + \left(\frac{\partial V}{\partial x}\sin\theta - \frac{\partial V}{\partial y}\cos\theta\right)\sin\theta \\ & + \omega_r/\sinh(2kh) \cdot \left(\frac{\partial h}{\partial x}\sin\theta - \frac{\partial h}{\partial y}\cos\theta\right), \end{aligned} \tag{5}$$

in which k is the wave number, and h is the water depth. In this equation, the spatial derivatives of wave direction do not appear, so

that the approximate method above mentioned is not necessary.

In this paper, at first, the authors' model(Sakai et. al, 1983) is introduced briefly. Subsequently, a comparison is made between the result of the numerical computation using Eq. (5) and that using Eq.(4). The wave reflection condition and breaking condition due to current are discussed from the view point of numerical model for wave directional spectra change due to depth-current refraction. These conditions are not taken account of in several models above mentioned. The relative contribution of the 1st and 2nd terms(convection terms) and the 3rd term(refraction term) in the left hand side of Eq.(2) to the wave directional spectra change is also examined. Finally, the relative effects of the current and the bottom topography on the wave directional spectra change is examined.

NUMERICAL MODEL FOR DIRECTIONAL WAVE SPECTRA CHANGE DUE TO CURRENT-DEPTH REFRACTION(SAKAI ET AL., 1983)

The basic equations for the wave refraction consist of the kinematic equations for the wave direction and the dynamical equation for the wave height. For the case of wave refraction due to current, they are the equation of condition of irrotationality of wave number and the equation of wave energy conservation in current, respectively.

In regular wave refraction, it is enough to solve these two equations separately. In irregular wave refraction, however, not only the wave height change but also the wave direction change modify the directional spectral distribution. It is , therefore, convenient to solve two equations simultaneously. The basic equation for wave height change is, as already mentioned, the equation of wave action conservation (1).

The differentiation of Eq.(2) for the numerical computation is just similar to the differentiation of Nagai, et al.(1974) for the numerical computation of directional spectra change due to underwater topography only. Fig.1 shows the grid and the definition of the quantities in the numerical computation of Eq.(2) by a finite difference method. Now it is assumed that the x-axis is normal to the shore line and all component waves propagate in the positive x direction.

The differential expression of Eq.(2) is as follows:

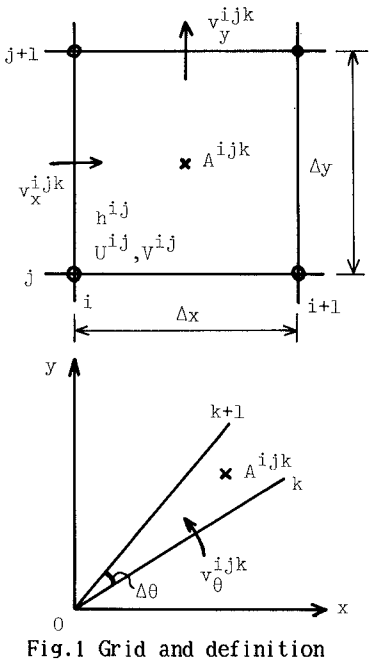

Fig.1 Grid and definition

$$a_1 A^{i\,jk} + a_2 A^{i\,j-1k} + a_3 A^{i\,j+1k} + a_4 A^{i\,jk-1} + a_5 A^{i\,jk+1}$$

$$= b A^{i-1\,jk} = B, \qquad (6)$$

in which $a_1 \sim a_5$ and b are functions of v_x, v_y and v_θ and Δx, Δy and $\Delta\theta$. The quantity $A^{i-1\,jk}$ is known because the computation proceeds in the positive x direction. If the frequency of the component waves and $i(x)$ are fixed, and $j = 1 \sim M$ and $k = 1 \sim N$, then a system of $M \cdot N$ algebraic equations is obtained. By solving this system of equations, the values of wave action A for all wave directions k and the whole range of $y(j)$ are obtained for the given wave frequency and $x(i)$. A similar computation is repeated for $i = i + 1$ until the shoreward boundary of computation is reached. These computations are repeated for each absolute frequency f of the component waves.

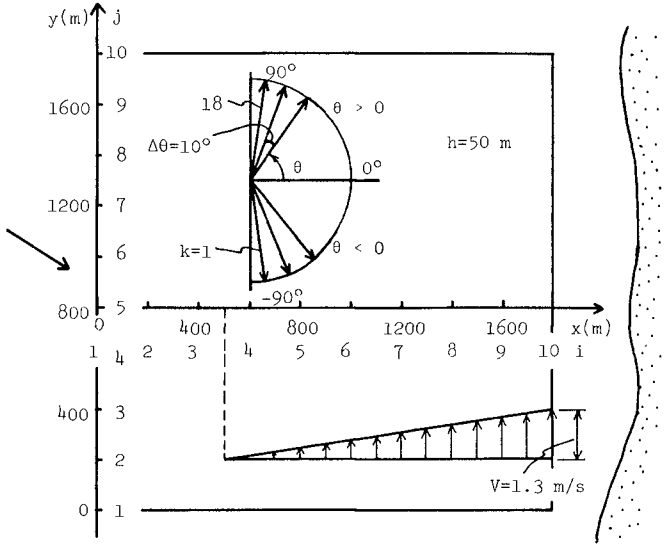

Fig.2 Computation region, water depth, current and division of wave direction

MODIFICATION OF WAVE DIRECTION CHANGE VELOCITY

A numerical computation is done under the same conditions as in the previous paper(Sakai et al., 1983), in order to compare between the computed results by using Eq.(4) with the approximate method and that by using Eq.(5). Fig.2 is the same as Fig.4 in the previous paper, and shows the computation region, the uniform water depth (h = 50m), the profile of current velocity and the division of wave direction.

As in the previous paper, the directional spectrum of Mitsuyasu et

al.(1975) is given as the deep-water directional wave spectrum on the y axis. The significant wave period is 7.0sec, the significant wave height is 3.0m and the value of the parameter S_{max} is 10. The wave frequency range from 0.09Hz to 0.71Hz, where the main part of the wave energy is contained, is divided into 19 segments, so that the logarithm of the frequency is divided with equal intervals. The other conditions are same.

Fig.3, (1) shows the distribution of directional spectral density $D(f, \theta)$ at the offshore boundary in the case of the offshore main wave direction $\theta_{po} = -60°$. In this figure, f is the absolute wave frequency. The figure (2) shows the distribution of the transformed spectral density at $x = 1{,}700$m calculated by using v_θ of Eq.(4) and the approximate method. An abnormal concentration of wave energy is found at a higher frequency region than 0.5Hz, where no energy was located in the offshore spectra(figure (1)). The figure (3) shows the distribution of the transformed spectral density at $x = 1{,}700$m calculated by using the improved wave direction change velocity as pointed by Brink-Kjaer et al.'s discussion(1984)(Eq.(5)). In this case, a slight energy concentration also can be seen in the high frequency region, but the value itself is as small as the value of the marginal part of the original energy distribution.

As seen from Eq.(4) and Eq.(5), the summation of the 3rd and 4th terms in the right hand side of Eq.(4) must be equal to the 3rd term of the right hand side of Eq.(5), which becomes zero when the water depth is constant. The summation of the 3rd and 4th terms in Eq.(4) should also become zero when the water depth is constant. In the computation of Fig.3, the water depth is constant(50m), and therefore no difference should have existed between the results in two figures (2) and (3). The difference between two figures is considered to be due to a wrong estimation of the 3rd and 4th terms in Eq.(4) by using the approximate method(Sakai et al., 1983).

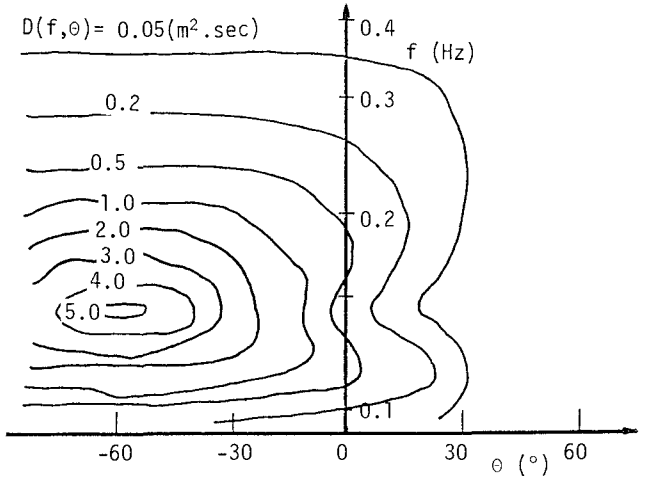

Fig.3,(1) Offshore directional wave spectrum having main wave direction of -60°

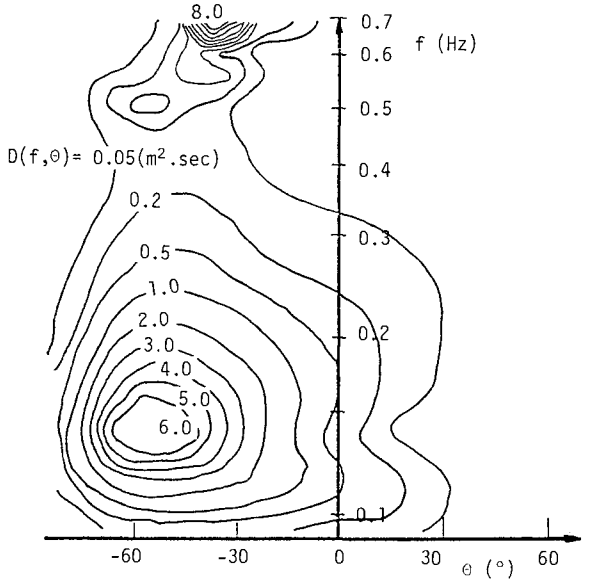

Fig.3,(2) Transformed directional wave spectrum at x = 1,700m calculated by using Eq.(4) and approximate method

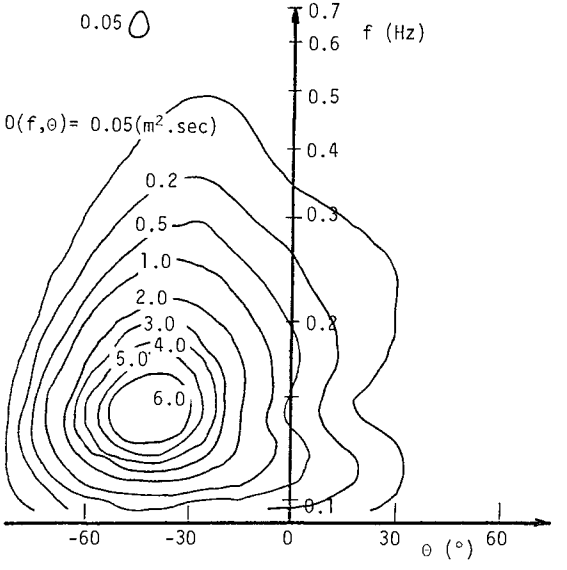

Fig.3,(3) Transformed directional wave spectrum at x = 1,700m calculated by using improved wave direction change velocity(Eq.(5))

In our previous paper, the change of the significant wave height and a representative wave direction was discussed after removing the abnormal energy concentration. Therefore, the change of these two parameters is same between in the case of using Eq.(4) with the approximate method and in the case of using Eq.(5).

REFLECTION AND BREAKING CONDITIONS

Wave reflection due to current

Longuet-Higgins et al.(1961) proposed a maximum velocity of a following current V, beyond which an obliquely incident regular deep-water waves can not penetrate the current. This limit velocity was derived from a condition that an absolute value of sine function does not exceed one in a kinematic equation governing the refraction. In this limiting condition, the wave direction becomes parallel to the current direction. Iwagaki et al.(1977) extended this treatment to a shallow water wave case, and gave the following condition.

$$\frac{V}{c_0} \leqq \frac{1 - (\sin\theta_0 \cdot \tanh\kappa h/\tanh\kappa_0 h_0)^{1/2}}{\sin\theta_0} \tag{7}$$

c is the wave velocity, and the subscript "0" indicates the quantity not in deep-water region but in no-current region. In all numerical models above mentioned, this condition is not taken into account. Tayfun et al.(1976) obtained a similar condition to Eq.(7) in his analytical treatment for the directional spectra change due to a depth and current change in one direction.

As mentioned already, our numerical model(Sakai et al., 1983) differentiates the basic equation (2) directly. The computation does not proceed along the ray of each component. So the condition (7) can not be incorporated directly into this model. In this model, the wave direction is divided as shown in Fig.2. In the computation of Fig.3, the direction of current is parallel to the y axis. This means that, if the reflection corresponds to the fact that the wave direction becomes parallel to the current direction, the wave direction of 90° corresponds to the reflection in this computation. In other words, it is expected that in this model the energy of the component parallel to the current direction at a given point becomes large.

Wave breaking due to current

There exist two kinds of idea as for the breaking of regular waves due to current in the simple theoretical treatment. One is for the case that the wave direction is parallel to the current direction. For this case, Tominaga(1967) derived a condition from a fact that a value of a quantity in a root in an equation giving the wave height change must be positive. In deep water, this condition means that an absolute value of velocity of an opposite current can not exceed the relative wave group velocity.

Another is the case that the the incident waves propagate obliquely into the current. Longuet-Higgins et al. discussed this case. Iwagaki et al. extended their result to a shallow water case. According to Iwagaki

et al., the change of wave direction θ is given by Eq.(8).

$$\frac{\sin\theta}{\sin\theta_0} = \frac{1}{(1-V/c_0 \cdot \sin\theta_0)^2} \frac{\tanh\kappa h}{\tanh\kappa_0 h_0}. \tag{8}$$

The change of wave height is given by Eq.(9).

$$\frac{H}{H_0} = \left(\frac{\sin 2\theta}{\sin 2\theta_0}\right)^{-1/2} \cdot \left(\frac{n}{n_0}\right)^{-1/2} \tag{9}$$

n is the ratio of the relative wave group velocity to the relative wave velocity. One of two cases that the wave height becomes infinite is $\theta = 0$. This case corresponds to $V = -\infty$. This means that the solution exists for any finite value of opposite current velocity. In the obliquely incident wave case, therefore, there exists no breaking condition as in the case that the wave direction is parallel to the current direction.

Tayfun et al.(1976) proposed one condition(Eq.(10)) similar to the breaking condition of regular waves propagating parallel to the current(Tominaga, 1967).

$$U \frac{k}{\kappa} > -c_{gr}. \tag{10}$$

This condition was derived from a fact that the absolute group velocity $\partial\omega/\partial\kappa$ must be positive in an equation(Eq.(11)) which gives the change of energy density of each component along the ray.

$$\Pi(\omega, \theta) = \frac{\kappa\left(\frac{\partial\omega}{\partial\kappa}\right)_0 \left(1 - \frac{U\kappa}{\omega}\right)}{\kappa_0 \left(\frac{\partial\omega}{\partial\kappa}\right)} D(\omega, \theta_0) \tag{11}$$

As seen from above discussion, it can be said that the theoretical wave breaking condition due to current is not yet clearly established. It is also questionable that the breaking condition of regular waves is applicable to each component of irregular waves. Nevertheless it is worthwhile to check the condition (10) of Tayfun et al. in the computation result shown in Fig.3, (3). It is found that component waves which do not satisfy Eq.(10) exist in the region of the slight energy concentration in Fig.3, (3).

CONTRIBUTION OF REFRACTION TERM $\partial(A \cdot v_\theta)/\partial\theta$

From the computation result obtained by using Eq.(5), the relative contribution of the convection terms and refraction term in Eq.(2) is discussed. The conditions are the same as those in Fig.3 except for the offshore main wave direction.

In this case, the water depth is constant, and the phenomena do not change in the y direction. Then Eq.(2) and Eq.(3) become as follow ($U = 0$ considered):

$$\frac{\partial}{\partial x}(A \cdot v_x) + \frac{\partial}{\partial\theta}(A \cdot v_\theta) = 0, \tag{12}$$

$$v_x = c_{gr}\cos\theta, \tag{13}$$

$$v_\theta = \partial V/\partial x \cdot \sin^2\theta. \tag{14}$$

Since c_{gr} is determined from the wave number conservation equation involving the velocity V, v_x contains the effect of the current indirectly. On the contrary, v_θ contains the effect of the current directly.

Fig.4, (1) ~ (3) compares the relative contribution of the convection term $\partial(A \cdot v_x)/\partial x$ and the refraction term $\partial(A \cdot v_\theta)/\partial\theta$ in Eq.(12) to the directional spectra change in the case of offshore main wave direction = -30°. The figure (1) shows the directional spectral density distribution at the offshore boundary. The figure (2) shows the transformed density distribution at x = 1,700m in the case that both terms are taken account of. The figure (3) shows the same density in the case that only the convection term is taken account of.

As seen from the figure (2), in the case that both terms are taken account of, the energy grows near -30° (the offshore main wave direction) where the current is opposite to the component waves. It is seen also that the energy shifts totally in the positive wave direction. On the other hand, in the case that only the convection term is taken account of(figure (3)), an abnormal energy concentration occurs in a high frequency and negative wave direction region. Except in this region, the energy distribution does not change so much from the offshore energy distribution (figure (1)).

From these results, it can be said that, at least for the case treated here, the refraction term has an important effect on the wave directional spectra change. This term explains the energy transfer between the wave components having different wave direction.

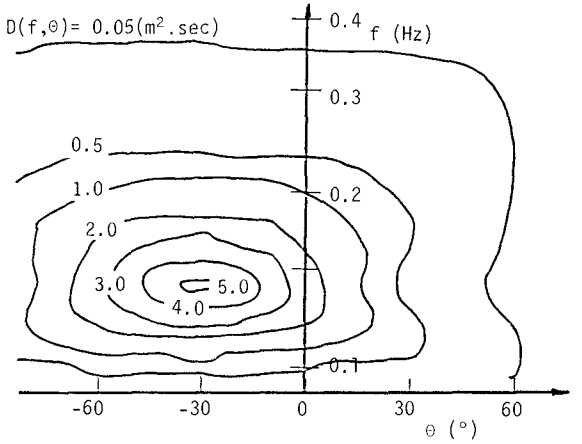

Fig.4,(1) Offshore directional wave spectrum having main wave direction of -30°

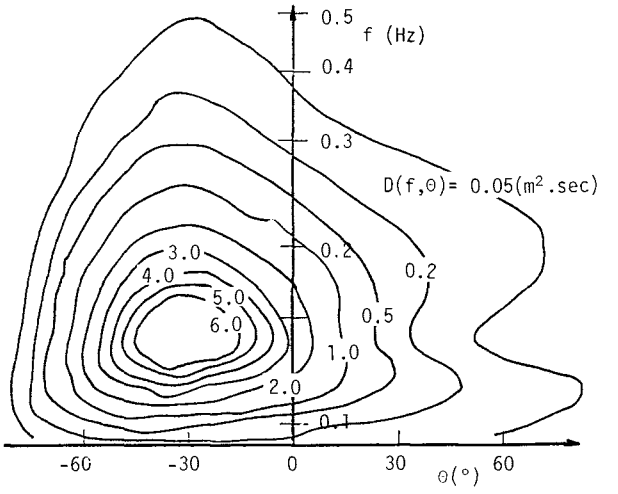

Fig.4,(2) Transformed directional wave spectrum at x = 1,700m in the case that both convection and refraction terms are taken account of

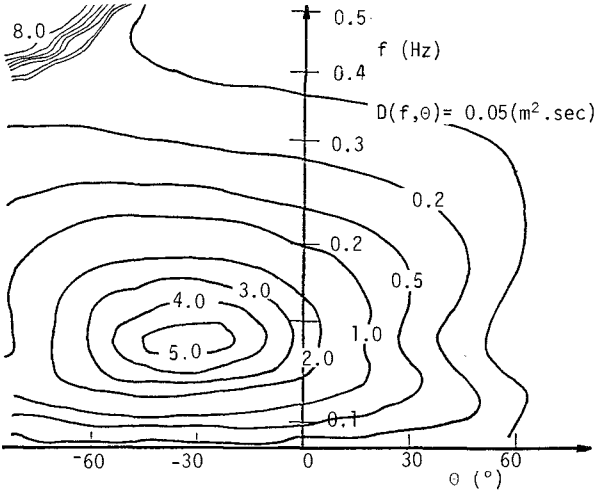

Fig.4,(3) Transformed directional wave spectrum at x = 1,700m in the case that only convection term is taken account of

COMPARISON OF EFFECTS OF CURRENT AND BOTTOM TOPOGRAPHY

Generally speaking, the lower the frequency of a component wave, the earlier the component affected by the bottom topography. It is,

therefore, expected that the effect of bottom topography is predominant for lower frequency components and the effect of current is predominant for higher frequency components. To check this, a case of plane beach of 1/40 slope is discussed in addition to the case of current in Fig.2. The water depth at the offshore boundary is 50m, and it decreases in the x direction.

Numerical computations are done for the following three cases : the current in the constant depth(50m)(Fig.2), the plane beach of 1/40 slope without current, and the same current on the beach of 1/40 slope. The offshore main wave direction is -30°. The change of directional spectra at two values of frequency is compared for these three cases.

Fig.5,(1) shows the directional spectra at a frequency f = 0.11Hz(lower than the peak frequency f_p = 1/7.0Hz = 0.14Hz) at x = 1,700m. The directional spectra in the case of current and depth change(broken line) can be explained roughly by the change in the case of depth change only(chain line). The figure (2) shows the directional spectra at a frequency f = 0.19Hz(higher than the peak frequency) at x = 1,700m. The value of the maximum energy in the case of current and depth change(broken line) can be explained by that in the case of current only(solid line), but the wave direction at which the maximum energy occurs can be explained rather by that in the case of depth change only(chain line).

Above mentioned results depends on the water depth, the beach slope, the current velocity and its profile. Still it can be said that the general trend mentioned at the first part of this section does not always hold.

CONCLUSIONS

The expression of the wave direction change velocity, Eq.(4), in our numerical model for directional wave spectra change due to depth-current refraction(Sakai et al., 1983) was modified according to Brink-Kjaer' et al.'s discussion(1984). The improved expression, Eq.(5), shown by him was used. The wave reflection and breaking conditions due to current were discussed from a view point of numerical analysis. Effects of the refraction term $\partial(A \cdot v_\theta)/\partial\theta$ in the wave action equation, Eq.(2), and the relative importance of current and water depth change in directional spectra change were discussed by using the newly obtained numerical results.

The following conclusions are obtained:

(1) In our previous model where Eq.(4) and an approximate method were used, an abnormal concetration of wave energy occured in a high frequency region. By using Eq.(5) instead of Eq.(4) and the approximate method, this concentration disappears.

(2) The reflection condition of regular waves due to current at first given by Longuet-Higgins and Stewart(1961) can not be incorporated directly into our numerical model. It is expected that the energy density of the component parallel to the local current direction grows rapidly in our model.

(3) There are two theoretical situations for the regular wave breaking on current. One is for waves propagating parallel against the current, where a theoretical breaking condition exists. For waves propagating obliquely into the current, no theoretical limiting condition exists. For irregular waves, Tayfun et al.(1976) showed a similar condition to that for regular waves. In a region where Tayfun et al.'s condition is fulfilled on the frequency direction plane, a slight energy concentration is found in the numerical results.

(4) The refraction term $\partial(A \cdot v_\theta)/\partial\theta$ has a dominant effect on the directional spectra change compared with the convection terms $\partial(A \cdot v_x)/\partial x$ and $\partial(A \cdot v_y)/\partial y$ at least in the example treated here.

(5) Even for a frequency component having a higher frequency than the peak frequency, which is expected to be affected more by the current than by the water depth change, the change of the main wave direction is determined rather by the water depth change, at least in the example treated here.

It is believed that the numerical model proposed here for the directional spectra change of wind waves due to current-depth refraction can be used to predict more accurately the wave condition around offshore structure than the existing wave prediction models. This more accurate prediction of wave conditions will also make the wave force calculation more accurate.

CHAPTER 20

A GRID MODEL FOR SHALLOW WATER WAVES

Leo H. Holthuijsen
and Nico Booij *)

1. INTRODUCTION

Waves in coastal regions can be affected by the bottom, by currents and by the local wind. The traditional approach in numerical modelling of these waves is to compute the wave propagation with so-called wave rays for mono-chromatic waves (one constant period and one deep water direction) and to supplement this with computations of bottom dissipation. This approach has two important disadvantages. Firstly, spectral computations, e.g. to determine a varying mean wave period or varying short-crestedness, would be rather inefficient in this approach. Secondly, interpretation of the results of the refraction computations is usually cumbersome because of crossing wave rays. The model presented here has been designed to correct these shortcomings: the computations are carried out efficiently for a large number of wave components and the effects of currents, bottom friction, local wind and wave breaking are added. This requires the exploitation of the concept of the spectral action balance equation and numerical wave propagation on a grid rather than along wave rays.

The model has been in operation for problems varying from locally generated waves over tidal flats to swell penetration into Norwegian fjords. A comparison with extensive measurements is described for young swell under high wind penetrating the Rhine estuary.

2. THE MODEL

2.1 Introduction

The representation of the wave spectrum in the model is parametric in frequency and discrete spectral in directions, that is, for each spectral direction two prognostic variables are defined: a directional energy density and a mean frequency. The model treats the

*) scientific officers, Delft University of Technology, Stevinweg 1, Delft, the Netherlands.

action balance of the waves for each spectral direction separately (the action balance is used to accommodate current effects). It is therefore a directionally decoupled parametric model.

Propagation of waves in the model is based on the linear theory for bottom and current refraction, while wave generation and dissipation is taken mostly from the literature. The balance equations for the basic wave parameters are integrated with a finite difference method on a regular grid in the study area. This approach avoids the classical problem of crossing rays and caustics frequently occurring in the more conventional wave ray technique. The computations are performed in downwave direction as in the parabolic wave propagation of Radder (1979).

2.2 Equations

Wave hindcasting models are usually based on the energy balance equation of the waves (e.g. Gelci et al., 1956; Hasselmann, 1960). However, in the presence of a mean current it is wave action that is conserved (e.g. Bretherton and Garrett, 1968). Since we wish to include in our model the influence of currents, we base our model on the action balance equation. Wave action in this balance equation is a function of time (t), space (x,y), direction (θ) and frequency (ω). Since in coastal regions a high spatial resolution is required, in view of the scale of the bottom irregularities, some parameterization of the balance equation is necessary to reduce the computer effort. In such a parameterization the directional details of the wave spectrum should be retained since the occurrence of cross-seas is an essential aspect of the wave field in coastal regions. We have therefore parameterized the action balance equation in the frequency domain only, while we retained the discrete spectral direction as independent variable. We have chosen the zero-th and first moment of the action spectrum in the frequency domain as the quantities appearing in the parameterized balance equations. The corresponding two basic wave parameters are the directional action density $A_0(\theta)$ and the mean frequency per direction $\omega_0(\theta)$:

$$A_0(\theta;x,y,t) = \int_0^\infty A(\omega,\theta;x,y,t)d\omega \tag{1}$$

$$\omega_0(\theta;x,y,t) = \frac{1}{A_0}\int_0^\infty \omega A(\omega,\theta;x,y,t)d\omega \tag{2}$$

The conservation equations for the zero-th moment $A_0(\theta)$ and for the first moment $\omega_0(\theta)A_0(\theta)$ are derived essentially by applying the definition operators (1) and (2) to the action balance equation of the waves. With some assumptions added, the results are

(Booij and Holthuijsen, 1987):

$$\frac{\partial A_0}{\partial t} + \frac{\partial}{\partial x}(c_{0x}A_0) + \frac{\partial}{\partial y}(c_{0y}A_0) + \frac{\partial}{\partial \theta}(c_{0\theta}A_0) = \frac{1}{\sigma_0} S_E - \frac{A_0}{\omega_0} S_\omega \qquad (3)$$

$$\frac{\partial}{\partial t}(\omega_0 A_0) + \frac{\partial}{\partial x}(c_{0x}\omega_0 A_0) + \frac{\partial}{\partial y}(c_{0y}\omega_0 A_0) + \frac{\partial}{\partial \theta}(c_{0\theta}\omega_0 A_0) = \frac{\omega_0}{\sigma_0} S_E \qquad (4)$$

in which c_{0x} and c_{0y} are the x- and y-components respectively of the propagation velocity c_0 at frequency ω_0 in direction θ and $c_{0\theta}$ is the rate of directional change of A_0 (i.e. refraction). $S_E(\theta)$ is the rate of change of the directional energy density $E_0(\theta)$ and $S_\omega(\theta)$ is the rate of change of the direction dependent mean wave frequency $\omega_0(\theta)$. $E_0(\theta)$ is taken to be equal to $A_0(\theta)$. $\sigma_0(\theta)$, σ_0 being the average frequency relative to the mean current. The advantage of expressing the developments of $A_0(\theta)$ and $\omega_0(\theta)A_0(\theta)$ in terms of the (direction dependent) source terms $S_E(\theta)$ and $S_\omega(\theta)$ is that these source terms can be estimated, at least to a large extent, from information in the literature.

2.3 Propagation

The conventional approach for computing refractive propagation in shallow water is to use solutions along characteristics (wave rays). However, in such an approach, which is of a Lagrangian nature, the determination of nonlinear wave generation or dissipation would require extensive numerical interactions between different wave rays. This is numerically rather inefficient since a large number of spatial interpolations between the spatially scattered wave rays would be needed. We have therefore chosen for the above Eulerian formulation of propagation i.e. refraction computations on a regular grid (e.g. Karlson, 1969; Sakai et al., 1983). All wave information required for the evaluation of nonlinear source terms is then intrinsically available at each grid point.

For coastal waters and inland waters the travel time of the waves through the area of interest is usually small compared with the time scales of wind and current (e.g. tides). The situation may then be considered as stationary so that the terms with ∂/∂ t vanish from equations (3) and (4).

In the absence of currents the second and third terms on the left-hand side of equation (3) or (4) represent propagation at the group velocity of the waves along straight lines which in varying water depths accounts for the phenomenon of "shoaling". In the presence of currents this propagation is corrected by adding the current velocity to the group velocity:

$$c_{0x} = c_0 \cos\theta + V_x \tag{5}$$

$$c_{0y} = c_0 \sin\theta + V_y \tag{6}$$

in which c_0 is the propagation speed (group velocity) at frequency ω_0 from linear wave theory relative to the mean current (V_x,V_y). The fourth term on the left-hand side of equation (3) represents the change of direction of the action transport, i.e. refraction, induced by bottom- and current variations. From linear wave theory we find the rate of directional change $c_{0\theta}$:

$$c_{0\theta} = -\frac{1}{k_0}\left(\frac{\partial\sigma}{\partial d}\right)_0 \frac{\partial d}{\partial n} - \frac{\underline{k}_0}{k_0} \cdot \frac{\partial \underline{V}}{\partial n} \tag{7}$$

in which n is the coordinate in (x,y)-space normal to the spectral wave direction θ, $\underline{V}$ is the mean current vector (V_x,V_y), $\underline{k}_0$ is the wave number vector corresponding to ω_0 with magnitude k_0 and direction θ and $(\partial\sigma/\partial d)_0$ is the depth derivative of σ for $k=k_0$.

2.4 Generation and dissipation

The generation and dissipation of the waves in the conservation equations (3) and (4) is expressed in terms of the direction dependent source terms $S_E(\theta)$ and $S_\omega(\theta)$. These source terms can be interpreted as the rates of change of $E_0(\theta)$ and $\omega_0(\theta)$ in a homogeneous situation. Each is the sum of the effects of wind wave generation, bottom dissipation, wave breaking and wave blocking on an opposing current. We therefore write the source functions $S_E(\theta)$ and $S_\omega(\theta)$ as the sum of constituent source terms.

The formulation of the source term for wave generation by wind is taken from empirical information in an idealized situation (CERC, 1973). This situation is one in which a homogeneous, stationary wind U blows over deep water perpendicularly off a long and straight coastline. Expressions are available in the literature giving the total energy and the frequency averaged over the whole spectrum as functions of fetch and wind speed. In order to obtain the source terms of wind growth as function of θ, it is assumed that in the above idealized case the energy distribution over θ is of the form $\cos^2(\theta)$, and that the averaged frequency in the idealized situation is independent of direction.

Bottom dissipation in our model is based on the conventional quadratic friction law to represent bottom shear stress. The corresponding energy dissipation for a harmonic wave

with height H and frequency ω (e.g. Putnam and Johnson, 1949) has been extended by Dingemans (1983) to random waves. The form of this expression can be seen as a measure for the orbital velocity multiplied with a measure for the bottom shear stress. The required directional version of this expression is obtained by multiplying a measure for the total orbital velocity with an expression for the shear stress based on the directional energy density and the directional mean frequency. To formulate the source term for the average frequency change due to bottom dissipation we assume a simple spectral shape and a concentration of the dissipation at the lower frequency side of this spectrum. The assumed shape of the spectrum is: zero for frequencies below the peak frequency and a ω^{-m}-tail for frequencies above the peak frequency. The result is an expression relating the source term of the bottom induced frequency change to that of the bottom induced energy change.

The source term for energy dissipation due to wave breaking caused by exceedence of steepness or exceedence of a wave height to depth ratio, is modeled after Battjes and Janssen (1978). Dissipation in this model is based on a bore model. As in the case of bottom friction, only total dissipation is obtained this way. The corresponding directional distribution of dissipation is obtained by assuming that the dissipation per direction is proportional to the energy density at that direction. The frequency change induced by breaking due to steepness is assumed to be zero. For the frequency change due to depth breaking a similar expression is used as described above for bottom friction.

In a situation with a strong opposing current some fraction of the wave energy cannot be transported upstream because the group velocity of the highest frequencies in the spectrum is less than the opposing current velocity. The lowest frequency above which this phenomenon of wave blocking occurs (the critical frequency ω_c) is the maximum frequency for which a solution exists for the wavenumber in the dispersion relationship from linear wave theory (including a mean current). In the model the "blocked" energy is dissipated with a simple relaxation model in which the total wave energy reduces eventually to the "unblocked" energy. The average frequency is similarly reduced to the average frequency of the "unblocked" energy.

3. NUMERICAL BACKGROUND

The prognostic equations for $A_0(\theta)$ and for the product $\omega_0(\theta)A_0(\theta)$, equations (3) and (4), are partial differential equations of first order with the horizontal coordinates x and y and the spectral direction θ as independent variables. Due to the nature of the equation the state in a point in (x,y,θ)-space (e.g. the value of A_0) is determined by the state upwave

from this point (upwave as defined by the propagation speeds c_{0x}, c_{0y} and the directional rate of change $c_{0\theta}$). We have therefore chosen for an upstream finite difference scheme.

The boundary conditions for these partial differential equations are in general that the incoming wave field should be given at the boundaries and that the outgoing wave field is fully absorbed by the boundaries. To fully exploit the stationarity of the wave field in our model we restrict wave directions to a constant directional sector of less than 180° (typically 120°). This seems to be acceptable for most applications of our model since waves propagate from deep water to the coast with directional changes usually less than 90° or the waves are generated by a local wind within a sector of 90° on either side of the wind direction. Since we have restricted wave directions to a sector of less than 180° and since wave information along the lateral boundaries in (x,y)-space is usually not available we assume that wave information is given only along an upwave boundary of the model in (x,y)-space (which may or may not be on land). At the other boundaries in (x,y,θ)-space we assume that no waves enter the model.

4. FIELD AND LABORATORY TESTS

Results of wave propagation in the model have been compared with observations in a large laboratory wave tank simulating swell propagation off San Ciprian (Spain), see Booij et al. (1985), and in an irregular-wave tank containing a submerged bar, see Dingemans et al. (1986). To test the model in geophysical conditions which are more realistic and complicated than in these laboratory tests, the model has been applied in an area of the Rhine estuary. This area was chosen because the model results can be compared with the results of a well documented field campaign of the Ministry of Public Works and Transport in the Netherlands (Dingemans, 1983, 1985). This campaign involved the use of 1 pitch-and-roll buoy, 1 wave gauge and 6 waverider buoys. The situation can be characterized as non-locally generated waves passing from deeper water into shallow water over a shoal with a regeneration by wind behind the shoal. Currents are practically non-existent in the chosen situation.

The bathymetry is given in fig. 1 with the location of the buoys and the wave gauge indicated. This bathymetry can be roughly characterized as a relatively shallow estuary (water depth typically 4 m – 5 m), about 10 km x 10 km in surface area. It is partly protected from the southern North Sea by a shoal of roughly 2 km x 4 km (water depth typically 1 m – 2 m) extending over half of its opening.

The computations have been carried out for a situation which occurred on October 14, 1982 at 22.00 hours (M.E.T.). The waves are locally generated in the southern North Sea with a significant wave height of about 3 m and a mean period of about 7 s at the estuary

entrance. These waves penetrate the area from north-westerly direction. They break over the shoal with a reduction in wave height to about 0.5 m over the shoal. The local wind of 16.5 m/s regenerates the waves to about 0.9 m significant wave height at the wave gauge which is located 5 km behind the shoal (see table 1).

The pitch-and-roll buoy in 16 m water depth (point 1 fig. 1) provided not only the significant wave height and the mean wave period as input at the up-wave boundary of the model (for parameter values see table 1), it also provided the mean wave direction and the directional spreading as input for that boundary. The waverider buoys and the wave gauge located at various locations in the area (points 2 to 7 in fig. 1) provided each a significant wave height and a mean wave period which can be compared with the results of the model. In fig. 2 it is shown that the pattern of the model results is consistent with the pattern of the observations (table 1; Dingemans, 1985; Dingemans, 1983), e.g. the significant wave height which at the up-wave boundary of the model (16 m water depth) is about 3.4 m, reduces gradually to about 2.5 m at 6 m depth and then very rapidly to about 0.6 m over the shoal. South of the shoal the gradual decrease in wave height continues. At the location of the wave gauge (about 5 km behind the shoal) the significant wave height is about 0.9 m. The mean wave period follows roughly the same pattern. A quantitative comparison with the observations is given in table 1.

These results are satisfactory considering that no tuning of the model is used in this complex geophysical situation. Further improvement may be expected from tuning the present model (e.g. high-frequency regeneration of waves behind a shoal should decrease the mean wave period rather than increase it as presently modelled).

Table 1
Observations and model results in the Haringvliet

location	observation		model result	
	H_s (m)	T_{mean}(s)	H_s (m)	T_{mean}(s)
1. pitch-roll buoy	3.38	7.0	3.27	7.0
2. waverider	2.90	6.3	3.19	6.8
3. waverider	2.58	6.3	2.59	6.2
4. waverider	2.68	5.9	2.54	6.1
5. waverider	0.62	2.6	0.60	4.4
6. waverider	1.05	3.7	1.14	4.5
7. waverider	1.60	5.1	1.42	4.7
8. wave gauge	0.95	2.8	0.87	3.8

5 CONCLUSIONS

The model presented here is conceptually different from the traditional approach in shallow water wave models. It is a finite difference approximation of a directionally decoupled action balance equation. Because of the finite difference approximation, classical problems of ray refraction computations are avoided and the effects of wind, currents, bottom dissipation and surf breaking are efficiently computed.

The results of the (untuned) model applied to an observed situation in the Rhine estuary showed an rms-error of about 8.3% in the significant wave height and an rms-error of about 18.7% in the mean wave period.

CHAPTER 21

ROUGH TURBULENT BOUNDARY LAYER IN SHORT-CRESTED WAVES

John R C Hsu *

Abstract

Prior to the investigation of rough turbulent boundary layer in a short-crested wave, the oscillatory laminar boundary layer at the bed is considered. Supported by numerical results of water-particle motions close to the bottom, the general patterns of kinematics in the laminar boundary layer within this wave system are reported in order to promote the understanding of the complex phenomenon. To propose a suitable method for turbulent boundary layer within such a wave system, a two-layer model using time-independent viscosity coefficient is first studied. Potential application of this model to short-crested waves is considered. From numerical results it is found that the time-invariant viscosity model is useful but can not produce velocity profile with flow reversal. It is suggested that a time-varying viscosity model may be more appropriate.

1. Introduction

Unlike progressive waves which propagate in a single direction, and standing waves that fluctuate vertically, the short-crested wave is defined as having a surface elevation which is doubly periodic in two perpendicular directions. Among many other occurrences in nature, oblique wave reflection often results in such a short-crested wave system in front of a long maritime structure. A simple reflection produces a combined progressive wave propagating along the reflecting wall (the x-direction), with a combined celerity C_s, and a standing wave component normal to it, in the y-direction (see figure 1).

Oblique approach of waves to a long rubble-mound breakwater, comprising either large precast concrete armour units or caisson superstructure, can have reflection coefficient as high as 0.8, so forming short-crested systems (Silvester 1986). The wave height of the combined wave system could be double that of the incident wave component, if a near full reflection exists. This doubled wave energy is applied to the bed, and hence can expedite the transmission of sediment along the wall. The occurrence of scour in front of seawalls is well known, and has become a common concern since it could have led to the failure of some maritime structures (Irie & Nadaoka 1984).To estimate the scour and bottom changes in front of a long breakwater, it requires the understanding of the basic mechanisms of waves and currents, particularly that within the bottom boundary layer,within which most of the sediment transport takes place (Hedegaard 1985).

The existence of a thin viscous boundary layer at the bottom in an oscillatory fluid has been extensively studied since Longuet-Higgins (1953), for both laminar and turbulent layers, particularly for two-dimensional progressive and standing waves. The term oscillatory implies that fluid velocities vary over time, so does the thickness of boundary layer. Traditionally, the description of these kinds of boundary layer in waves has been

* Department of Civil Engineering, University of Western Australia, Nedlands, Western Australia 6009, AUSTRALIA.

based upon a direct solution to momentum equations subjected to boundary conditions. This process is often laborious. Similar to the time-invariant viscosity proposed for steady turbulent flow, earlier studies of wave-induced oscillatory turbulent layer have been primarily aimed at determining the bottom shear stress and energy dissipation.

Amongst many laboratory data available for wave boundary layer, Jonsson (1963, 1966) and Jonsson & Carlsen (1976) have published experimental work which has played a significant role in the study of turbulent boundary-layer theory. Their experimental data have since been used by all workers in this area.

Kajiura (1968) developed a three-layer analytical model using the concept of time-invariant effective viscosity. This approach was followed by Noda (1971) and others to examine the turbulent boundary layer in progressive and standing waves. Employing Jonsson's (1980) new approach of velocity defect law, Brevik (1981) presented a two-layer model, which proved to be mathematically simple and yet fairly accurate compared to the three-layer model (Kajiura 1968). More recently, a time-variant effective viscosity model was suggested by Trowbridge & Madsen (1984), for fluid velocity up to second-order.

Although the turbulent boundary layer in two-dimensional waves have been studied extensively, the case for three-dimensional waves has received very little attention. For such short-crested waves, produced by full oblique reflection, the first-order Eulerian water-particle velocities and mass transport have been reported by Mei et al (1972) and Tanaka et al (1972), for a laminar boundary layer on a smooth bed. Hsu et al (1980) have derived the Eulerian water-particle velocities to second-order also for a laminar layer, and have reported experimental data available. However, the investigation of a turbulent layer has not been made previously for this wave system.

Because the wave-induced bottom layer is generally turbulent in relatively shallow water where the ocean bed is rippled and hydrodynamically rough, it is necessary to examine the rough turbulent layer in short-crested wave system, since it differs substantially from the laminar case.

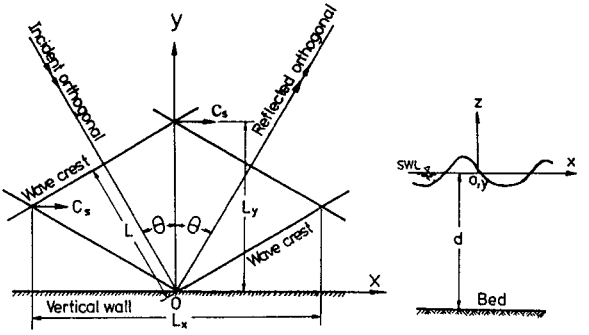

Figure 1. Definition sketch of short-crested wave system, showing co-ordinates, incident and reflected orthogonals, approaching angle θ, wavelengths L and L_x, crest length L_y, and combined wave celerity C_s.

In the present paper, Brevik's (1981) two-layer model is thoroughly studied numerically, especially the effect of varying the thickness of the lower layer (i.e. the overlapping layer of Brevik). From the results of numerical calculations, it was found that the relative velocity curves u_d/u_f and u/u_f may become discontinous upon using some improper values of the thickness of the lower layer. Minor drawback of this model is discussed. To apply the two-layer model to the short-crested waves, necessary adjustment in formulations and procedures are then proposed.

2. Laminar boundary layer at the bottom

Short-crested waves produced from 100% reflection of oblique waves can be equated to two progressive waves of the same amplitude propagating at an angle to each other. The resultant water-particle motions are very complex, varying spatially both in the vertical and horizontal directions (in the x-y plane). Water-particle motions for this simple case of two wave trains of equal height and period is shown schematically in figure 2, where it is seen that rectilinear and elliptical orbits exist along certain alignments. Along that of the combined-crest propagations (i.e. at $y/L_y = 0,1/2,1,...$) water-particle orbits are in a vertical plane. Half-way between, rectilinear horizontal oscillations occur (i.e. at $y/L_y = 1/4,3/4,...$); again half-way between (i.e. at $y/L_y = 1/8,3/8,5/8,...$), the orbits are ellipses at an angle to the vertical which depend upon their depth, being in a horizontal plane at the bed.

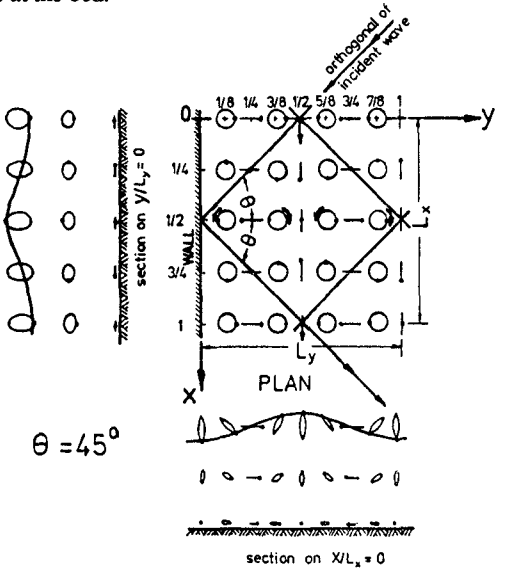

Figure 2. Patterns of water-particle motions along various y/L_y alignments in a short-crested wave system, relative to the reflecting wall.

Hsu et al (1979) have derived a third-order approximatioin of wave theory to short-crested waves by a perturbation method, for the case of full oblique reflection from a vertical wall. Irrotational motion was assumed, the fluid inviscid, incompressible and uniform depth of water. Working with non-dimensional quantities, final expressions for velocity potentials (ϕ), surface elevations (η), angular frequency (ω), and Eulerian water-particle velocities (u,v,w) in each order of approximation were derived in dimensionless form.

In studying the viscous boundary layer at the bed, Eulerian water-particle velocities at the outer edge of the bottom layer (U,V,W) are required, for both laminar and turbulent cases. These velocities are represented by the velocities on the bed from the inviscid wave theory for z = -d. The expressions of free-stream velocity (U,V,W) in the x,y and z-directions respectively are given in dimensional form as follows:

$$U = \varepsilon\phi_x \Big|_{z=-d} = \varepsilon \sqrt{(k/g)}\,(m\omega_o/\sinh kd)\cos(nky)\ \cos(mkx-\sigma t) + \varepsilon^2 \sqrt{(k/g)}\,[2m\beta_2 \cos 2(nky) + 2m\beta_3]\cos 2(mkx-\sigma t) = U_1 + U_2 + O(\varepsilon^3) \quad (1)$$

$$V = \varepsilon\phi_y \Big|_{z=-d} = -\varepsilon \sqrt{(k/g)}\,(n\omega_o/\sinh kd)\sin(nky)\ \sin(mkx-\sigma t) - \varepsilon^2 \sqrt{(k/g)}\,[2n\beta_2\ \sin 2(nky)]\ \sin 2(mkx-\sigma t) = V_1 + V_2 + O(\varepsilon^3) \quad (2)$$

$$W = \varepsilon\phi_z \Big|_{z=-d} = 0, \text{ more practically at the real bed.} \quad (3)$$

in which ε is the small perturbation parameter "ka", where "a" is the amplitude of the short-crested wave to the first-order, and "k" is the wave number $2\pi/L$, L being the wavelength of the incident or reflected wave component, σ is the angular frequency of the incident and reflected waves (i.e. $2\pi/T$, where T is the wave period in seconds), "g" is the acceleration of the gravity, "d" is the water depth in meters, "m" and "n" are the components of wave number "k" in the x and y-directions respectively as shown in figure 1, "ω_o" is the leading term of dimensionless angular frequency (i.e. $\sigma/\sqrt{(gk)}$). The full expressions to β_2 and β_3 have been presented by Hsu et al (1980). U_1 and V_1 are free-stream velocity components to the first-order, and U_2 and V_2 to the second-order.

Based upon the third-order approximation to short-crested waves, the Eulerian water-particle velocities within the laminar bottom boundary layer for a smooth and horizontal bed have been derived (Hsu et al 1980), also by a perturbation method. The procedure used was to solve the governing Navier-Stokes equations in dimensionless form subjected to various boundary conditions at the bed and at the outer edge of the boundary layer. An additional change of non-dimensional variable of kz within the bottom layer was introduced, $\zeta = (\omega_o/2)^{1/2}\,kz$. Inserting the perturbed series of fluid velocities within the boundary layer (u,v,w) and free-stream velocities (U,V,W) into the governing equations, and collecting terms of each order in ε yielded the necessary equations to each order of approximation. The solutions to Eulerian water-particle velocities to the first-order (u_1,v_1,w_1) and to the second-order (u_2,v_2,w_2) have been derived. The algebraic procedures of solving these equations were complex.

The resultant Eulerian water-particle velocities (u_1,v_1,w_1) to the first-order are given in dimensional form as

$$u_1 = \varepsilon \sqrt{(g/k)}\,(m\,\omega_o/\sinh kd)\cos(nky)\ [\cos(mkx-\sigma t) - e^{-\zeta}\cos(mkx-\sigma t+\zeta)], \quad (4)$$

$$v_1 = -\varepsilon \sqrt{(g/k)}\,(n\,\omega_o/\sinh kd)\sin(nky)\ [\sin(mkx-\sigma t) - e^{-\zeta}\sin(mkx-\sigma t+\zeta)], \quad (5)$$

$$w_1 = \varepsilon\,[(\nu\omega_o)^{1/2}\,(gk)^{1/4}/\sinh kd]\cos(nky)\ [\sqrt{2}\,\zeta\sin(mkx-\sigma t) - \sin(mkx-\sigma t+\pi/4) + e^{-\zeta}\sin(mkx-\sigma t+\zeta+\pi/4)]. \quad (6)$$

The non-dimensional variable ζ in equations (4)-(6) regulates the dimensionless distance kz within the bottom laminar layer. In dimensional form, $\zeta = z/\sqrt{(\nu T/\pi)}$, as a relative measure of vertical distance from the bed, where $\sqrt{(\nu T/\pi)} = \sqrt{(2\nu/\sigma)}$ is the usual boundary parameter. It is worth noting that the value of $\zeta = 2\pi$ corresponds to the distance at the outer edge of the laminar boundary layer, because its thickness is usually calculated by $\delta = 2\pi\sqrt{(2\nu/\sigma)} = 2(\pi\nu T)^{1/2}$.

The working procedures leading to the final expressions of the second-order Eulerian velocities (u_2,v_2,w_2) are rather lengthy and complicated. In general, they consisted of time-dependent (periodic) and time-independent (steady) terms. These were reported by Hsu et al (1980). The vertical distributions of velocity profiles vary as functions of position y/L_y (i.e. in the direction normal to the reflecting wall) and the relative time step t/T. It is useful to compare the relative magnitudes of velocity components to the first and second-order, for various y/L_y and t/T in the laminar layer within a short-crested wave. From these comparisons, it will help in obtaining an overall picture of water-particle motions within the turbulent boundary layer.

It is now desirable to show a test case of short-crested wave system produced by incident wave of period T=1 sec and 76 mm in height, with approaching angle at $\theta = 45°$ to a reflecting wall in 300 mm of water.A maximum u≈190mm/s occurs at the combined-crest alignments. Figure 3 depicts the vectorial sums of Eulerian fluid velocities (u_1,v_1,u_2,v_2),up to second-order, for specific y/L_y at various t/T. The maximum values of u and v occur at different y/L_y and t/T, for example, maximum u appears at $y/L_y = 0,1/2,1$ at t/T= 0,1/2,1; while v becomes maximum along alignments $y/L_y = 1/4$ and 3/4 at t/T=1/4 and 3/4. From figure 3, it can be observed, among various t/T, that along the alignments of combined-crest (i. e. $y/L_y = 0, 1/2,1$) water-particle motions are predominantly in the x-direction, and that along $y/L_y = 1/4$ they are mainly transverse. In the vicinity of y/L_y

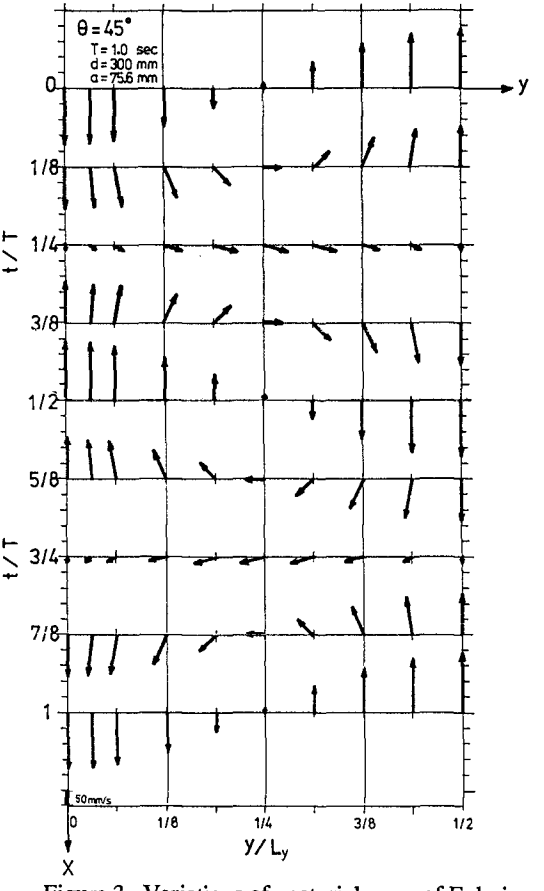

Figure 3. Variations of vectorial sums of Eulerian fluid velocities to second-order, in magnitude and direction, as functions of y/L_y and t/T, in a laminar layer.

= 1/8ths water-particle orbits rotate in ellipses. It can be observed that the orbit rotates anti-clockwise at $y/L_y = 1/8$ while it becomes clockwise at $y/L_y = 3/8$, thus reaffirming the water-particle motions sketched in figure 2.

Knowing that u and v reach their maxima at different y/L_y and t/T as noted, it is beneficial to display the vertical distribution of velocity profiles within the laminar layer as a function of time t/T for the alignments where the velocity is at its maximum as illustrated in figure 3. From figure 4, it can be seen that flow reversal exists in the lower portion of the bottom layer at certain combinations of y/L_y and t/T, even when fluid velocities to the first-order are considered. The relative ordering can be realised from the following example. The maximum ratio of u_1 and u_2 (first-order to second-order velocity) can be obtained from figures 4 and 5, where $u_1 \approx 10u_2$. Figure 5 shows the maximum magnitudes of the second-order velocities, $u_2 \approx 4v_2$, and $u_2 \approx 4w_1$, for the same wave conditions (T=1.0 sec, H=76 mm, d=300mm); in other words, $u_1 \approx 40v_2$ and $u_1 \approx 40w_1$. Further calculation shows that the maximum ratio of $w_1/w_2 \approx 10$, therefore, $u_1 \approx 400\ w_2$.

From the above example, it is clear that the vertical velocity components, w_1 and w_2, are negligibly small, particularly w_2. One may doubt the pragmatic value in which tremendous efforts have been devoted into the laborious process from which lengthy expressions are derived analytically.

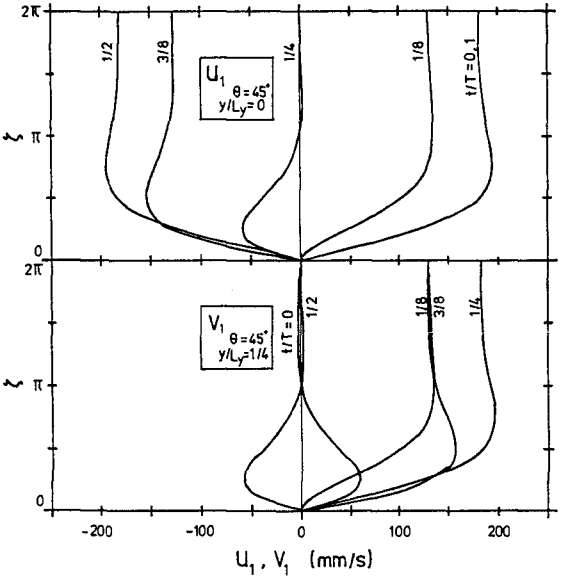

Figure 4. Profiles of Eulerian water-particle velocities u_1 and v_1, through laminar boundary layer at various time steps. waves T=1 sec, incident height H=76mm and θ=45°.

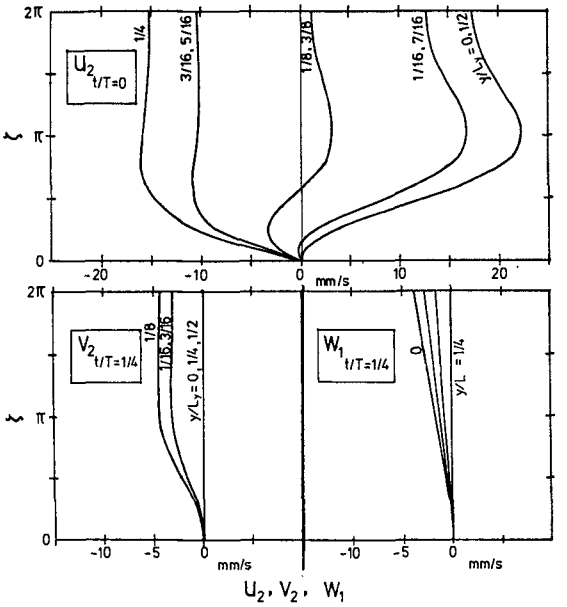

Figure 5. Profiles of Eulerian fluid velocities u_2, v_2 and w_1 through the laminar layer at various y/L_y locations and time steps t/T.

The effect of wave obliquity on the magnitude of fluid velocities is given in figure 6. From this figure, it is found that $u_1 \approx 10\,u_2$ for the case of $\theta = 60°$, and u_2 remains seemingly unchanged for all the three θ cases presented, based upon the same incident wave conditions (T=1.0 sec, H=76 mm, d=300mm) except the approaching angles. The value of u_1 decreases as θ decreases (see figure 1 for the definition of θ).

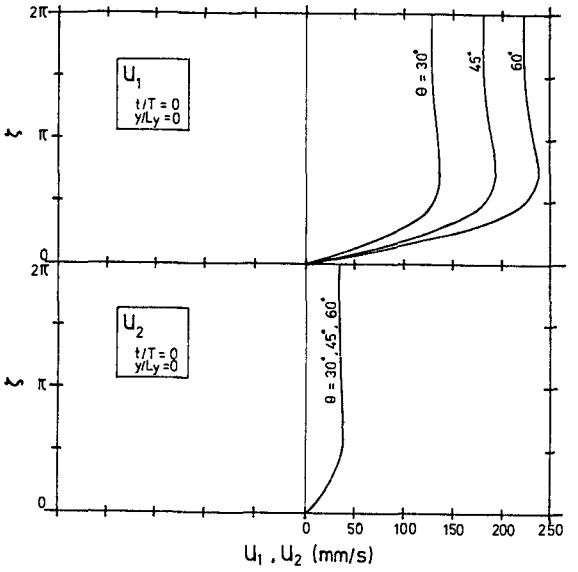

Figure 6. Profiles of the maximum fluid velocities u_1 and u_2 for the same wave conditions as in figure 4, but for various incident angles.

For the cases investigated above, the mass transport velocities (U_{M2} and V_{M2}) in dimensional value are depicted in figure 7. The forward mass transport velocity U_{M2} reaches its maximum along the combined-crest alignments, and is minimal along 1/4-ths of y/L_y, where at this latter alignment V_{M2} is zero. Therefore, all water-particles within the short-crested wave system have a net movement forward irrespective of their position along y/L_y. In the vicinity of 1/8th of y/L_y, the resultant mass-transport velocity vector is inclined towards its neighbouring alignment of combined crest.

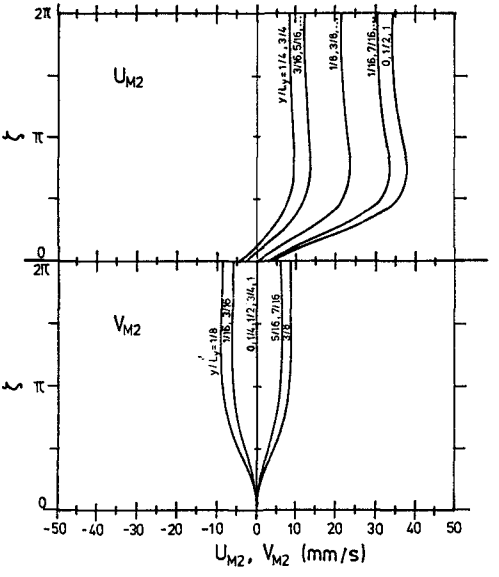

Figure 7. Dimensional mass transport velocities U_{M2} and V_{M2} through a laminar boundary layer within a short-crested wave system.

Within the laminar bottom boundary layer, the bottom shear stress τ_{bx} is defined as

$$\tau_{bx} / \rho = \nu \, (\partial u/\partial z)\big|_{z=0} \quad \text{dimensionally.} \tag{7}$$

The shear stress component in the y-direction τ_{by} can be established in a similar manner.

To the first-order approximation, substituting u_1 and v_1 into equation (7), it yields the expressions of τ_{bx} and τ_{by} as follows

$$\tau_{bx} / \rho(U_{om})^2 R_e^{-1} = \sqrt{2} \cos(\pi ky) \cos(mkx - \sigma t - \pi/4), \tag{8}$$

$$\tau_{by} / \rho(V_{om})^2 R_e^{-1} = -\sqrt{2} \sin(\pi ky) \cos(mkx - \sigma t + \pi/4), \tag{9}$$

where U_{om} and V_{om} are the maximum water-particle velocity at the bed calculated from the wave theory, R_e is the boundary Reynolds number (being $U_{om}\delta_1/\nu$), in which δ_1 is the boundary-layer parameter, $\sqrt{(2\nu/\sigma)}$. Equations (8) and (9) show a phase shift of $\pi/4$ compared to U_{om} and V_{om}. Velocity expressions up to second-order can also be used for u and v in equation (7) to derive the shear stress at the bottom.

3. Turbulent boundary layer at the bottom

Traditionally, the descriptions of an oscillatory turbulent boundary layer in waves have been based upon a direct solution to momentum equations. This process, often laborious algebraically, yields Eulerian water-particle velocities and mass transport directly (for example, Johns 1970, and many others). These approaches considered the overall bottom layer as a whole. Kajiura (1968) has given a most detailed mathematical treatment in which the whole boundary layer is subdivided into three sublayers. Each sublayer had its own characteristic mean turbulent viscosity, assumed time-invariant but as a function of vertical distance within each sublayer. Kajiura's solution agreed with experimental data available, but its mathematical expression was very complicated.

Jonnson (1980) has suggested a new approach, in which a universal law of velocities near the wall was used. After obtaining the defect velocity within the boundary layer, the fluid velocity was then calculated. This new approach was supported by velocity measurements available (Jonsson 1963, 1966; Jonsson & Carlsen 1976). Therefore, there is no need to derive the fluid velocities within a turbulent boundary layer directly from momentum equations. Brevik (1981) has applied this new approach to a two-dimensional wave case, working with dimensional quantities directly from the leading terms in the governing equation.

In this section Brevik's two-layer model is examined for the application to short-crested waves, and the differences between the laminar and turbulent cases described.

3.1 Comparison of laminar and turbulent layers

The main differences between the laminar and turbulent boundary layers are in the thickness of the boundary layer, the velocity profiles, and the mechanism of producing sediment suspension.

Jonsson (1980) suggested expressions for calculating boundary-layer thickness δ and shear friction factor f_w, for the laminar layer on a smooth wall and turbulent layer on a rough bed. He also gave ranges of Reynolds number, based on boundary-layer thickness, for these cases. A useful expression for estimating the thickness of a rough turbulent boundary layer, δ, is given by

$$(\delta/ z_o)\ \log(\delta/z_o) = 0.04\ a_{1m}/z_o\,, \qquad (10)$$

where z_o is the theoretical bed level related to bottom roughness as used by Jonsson (1980) and Brevik (1981), and a_{1m} is the maximum amplitude of the orbital motion calculated from free-stream velocity U_{1m} ($= U_{1m}/\sigma$, where σ being the angular frequency of wave, i.e. $2\pi/T$). Therefore, in a rough turbulent boundary-layer, its thickness is affected by the roughness of the bottom (from the theoretical bed level z_o) and the free-stream velocity which is governed by waves propagating above it.

In the model of time-independent viscosity coefficient, Johns (1970) reported that the overall velocity profiles within a turbulent and laminar cases are very similar, except the boundary-layer thickness of the former is about 10 times of the latter; in which for the laminar case, the boundary-layer thickness was suggested to be about $5(2\nu/\sigma)^{1/2}$. He also gave remarks on the distribution of suspended sediment within these layers. From knowledge available in boundary layer, it is therefore suggested that, for the present investigation, the thickness of a rough turbulent boundary layer at the bottom of a short-crested wave system be taken as 10 times that of the laminar case.

3.2 Two-layer model of Brevik (1981)

By employing Jonnson's approach of velocity defect law and time-invariant viscosity coefficient $\nu_t(z)$, Brevik (1981) successfully developed a two-layer model for a two-dimensional wave case. Considering only the leading terms, the governing momentum equation reduced to

$$\partial u/\partial t = \partial U/\partial t + \partial(\tau_{bx}/\rho)/\partial z, \tag{11}$$

where u(z,t) is the fluid velocity, U(t) is the free-stream velocity at the outer edge of the layer, and $\tau_{bx}(z,t)$ is the shear stress at the bed ($= \rho\nu_t \partial u/\partial z$), and the z-axis is vertically upwards from the bed. Upon assuming harmonic variations to all velocities (u, U, and defect velocity $u_d = u - U$) and bottom shear stress, in terms of $e^{i\sigma t}$, where σ is the angular frequency ($= 2\pi/T$), it yielded

$$\partial u_d/\partial t = \partial(\nu_t\, \partial u_d/\partial z)/\partial z, \tag{12}$$

or finally

$$\partial(\nu_t\, \partial u_d/\partial z)/\partial z - i\sigma u_d = 0, \tag{13}$$

where the mean turbulent viscosity $\nu_t(z)$ was assumed time independent within the boundary layer. It was also assumed that $\nu_t(z)$ is to be proportional to the distance from the theoretical bed level at $z = z_o$ within the lower layer, and became a constant in the outer layer from $z \geq \Delta$ (see figure 8, or figure 1 of Brevik 1981). The theoretical bed level at $z = z_o$ from the real bed was determined by fitting the observed velocity profile above the bed to a logarithmic distribution. Brevik (1981) proposed two different values for Δ, the first value of Δ equal to half of its boundary thickness, and the second Δ as a function of amplitude of water-particle motion close to the bed and shear friction factor f_w. It is worth noting at this stage that an improper choice of Δ will produce discontinuity to velocity profiles of u/u_f and u_d/u_f on a semi-log scale plot.

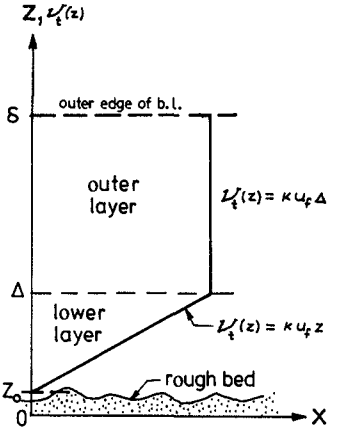

Figure 8. Assumption of the time-invariant turbulent viscosity coefficient ν_t as a function of vertical distance, in the two-layer model of Brevik (1981).

The basic equation was in dimensional form. A dimensionless variable $\xi = (4\sigma z/\kappa u_f)^{1/2}$ was then introduced into equation (13), which transformed the vertical distance z within the boundary layer, where κ is the von Karman's constant (= 0.4), and u_f is the maximum shear velocity at bed. The resultant governing equation,

$$\xi\, \partial^2 u_d/\partial \xi^2 + 2\, \partial u_d/\partial \xi - i\xi u_d = 0, \tag{14}$$

was the standard differential equation for the Kelvin functions of zero-th order, with ξ as independent variable. The solution to defect velocity u_d was related to Kelvin functions of the first and second kinds, (ber, bei, ker, kei at the specific levels of $z = z_o$ and $z = \Delta$ respectively), and generally in complex variable form. Integration constants were determined subject to boundary conditions required. After establishing the defect velocity, water-particle velocity u was found from $u(z,t) = u_d(z,t) - U(t)$, then phases calculated. The new analytical solutions to u and u_d and their phases (Brevik 1981) fit well with data of Test no.1 of Danish measurements (Jonsson 1980, Jonsson & Carlsen 1976), hence confirming the usefulness of the proposed two-layer theory. For detailed derivations and final expressions of $u_d(z,t)$ and $u(z,t)$ in each layer, see the original paper of Brevik (1981).

For calculating u_d, u and their phases numerically, it is necessary to establish a computer program which can reproduce the results of Brevik (1981). A program in PASCAL language was written with graphic ability run on a micro-computer. Expressions of Kelvin functions are obtained from Abramowitz & Stegun (1964). This program reproduced the results of u_d, u and their phases as reported by Brevik (1981) in his figures 2 to 5, using data of Test no.1 of the Danish measurements (Jonnson 1980; Jonnson & Carlsen 1976). An example of u_d/u_f and u/u_f calculated from the present program is given in figure 9 (for wave and boundary-layer conditions: T=8.39 sec, free-stream velocity U = 2110 mm/sec, max shear velocity u_f = 207 mm/sec, thickness of the turbulent layer δ = 60 mm, z_o= 0.77 mm, and $\Delta = 0.5\delta$ = 30 mm).

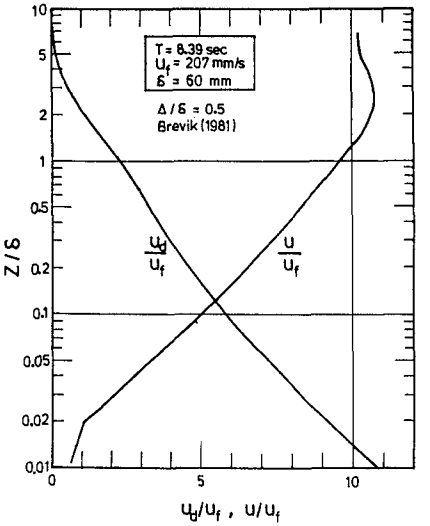

Figure 9. Profiles of relative velocities u_d/u_f and u/u_f, reproduced using data of Test no.1 of Danish measurements (Jonsson 1980, Jonsson & Carlsen 1976).

Figure 10 shows the fluid velocity u and defect velocity u_d obtained from the said conditions, previously presented in figure 9, after being converted to a normal scale plot. Because the thickness of the turbulent layer is about 10 times that of the laminar case, it can be seen that most of the changes in velocity u in the vertical direction above the bed are within the lower 25% of its overall thickness. This region is equivalent to about twice of the thickness of the laminar layer, under the same wave conditions. The remaining 75% of the thickness has rather uniform velocity profile.

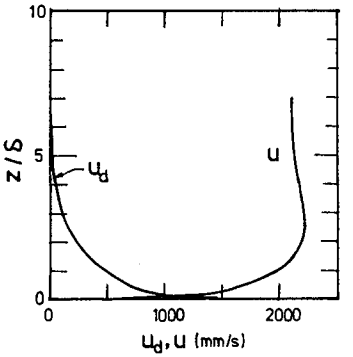

Figure 10. Converted fluid velocity u and defect velocity u_d profiles obtained from conditions specified for Test no.1 of Danish measurements (Jonsson & Carlsen 1976).

In applying Brevik's two-layer model, it is critical in able to choose a suitable thickness for the lower-layer, as can be demonstrated in figure 11. The wave and boundary-layer conditions are the same as that produced figures 9 and 10, but with variable Δ, these being Δ=1/8,1/4,1/2 and 3/4 of the turbulent boundary-layer thickness. Profound discontinuity is obvious for Δ less than half of its boundary-layer thickness. Values of Δ/δ greater than 0.5 (the case presented in figure 9) had negligible effect on the continuity just discussed, even when Δ/δ reached 0.75. The practical problem is how to select the most appropriate value of Δ/δ for each application.

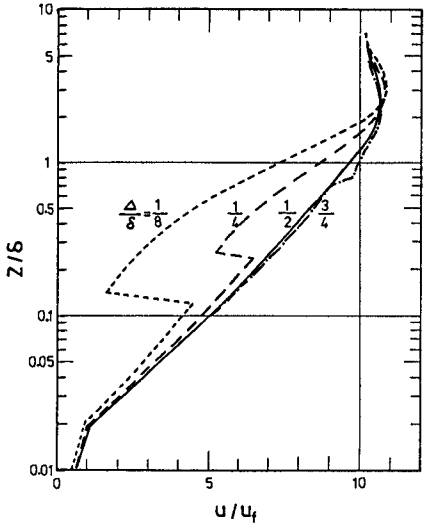

Figure 11. Discontinuity in velocity profile u/u_f on a semi-log plot, resulting from improper choices of Δ/δ, in the two-layer model (Brevik 1981).

Further study showed that the choices of the theoretical bed level z_o from bottom roughness is not critical, though affecting the boundary-layer thickness in the turbulent condition (see equation 10). Hence, this model can be applied to wave cases with reasonably rough bed. Once a proper ratio of Δ (the upper limit of the lower layer) relative to the boundary-layer thickness δ is selected, say Δ/δ = 0.5, the turning point located near the bottom of u/u_f curve in figure 9 may be shifted away from the present value of z/δ = 0.02. Given a bottom roughness 5 times the value as used by Brevik

(1981), the said turning point will be shifted to $z/\delta \approx 0.1$, modifying the slope of velocity profiles u/u_f and u_d/u_f only slightly in the region $z/\delta < 0.1$.

3.3 Application to short-crested waves

Brevik's two-layer model (1981) was derived for the case of two-dimensional progressive waves. In a three-dimensional case, the flow field is much more complex, even to the simplest case of short-crested wave system produced by full oblique reflection from a long vertical wall . Preliminary examination using only leading terms in the governing equations renders

$$\partial u/\partial t = \partial U/\partial t + \partial(\tau_{bx}/\rho)/\partial z, \tag{15}$$

$$\partial v/\partial t = \partial V/\partial t + \partial(\tau_{by}/\rho)/\partial z, \tag{16}$$

and

$$\partial u/\partial x + \partial v/\partial y + \partial w/\partial z = 0, \tag{17}$$

where (u,v,w) are the fluid velocities, (U,V) are the free-stream velocity components, τ_{bx} and τ_{by} are shear stresses at the bed in the x and y-directions respectively.

To apply the two-layer model to this short-crested wave system, dimensional expressions of free-stream velocities are required, at each order of approximation. These can be obtained from equations (1)-(3). The free-stream velocity components U and V contain trigonometric functions such as cos(mkx-σt) and sin(mkx-σt) etc. Expressing the real part of "cos(σt)" and "sin(σt)" in exponential form, such that

$$\cos(mkx-\sigma t) = \cos(mkx)\, e^{i\sigma t} - i \sin(mkx)\, e^{i\sigma t}, \tag{18}$$

and

$$\sin(mkx-\sigma t) = \sin(mkx)\, e^{i\sigma t} + i \cos(mkx)\, e^{i\sigma t}, \tag{19}$$

where $i = \sqrt{-1}$ representing the imaginary part of a complex variable. Unlike U_1 which was a constant $U_1(t)$ in a two-dimensional case, the leading term in equation (1), $U_1(x,y,t)$, is now in complex variable form. $U_1(x,y,t)$ may be split into two terms, one containing $\cos(mkx)e^{i\sigma t}$, and the other in $\sin(mkx)e^{i\sigma t}$, for example

$$\begin{aligned} U_1 &= \varepsilon \sqrt{(g/k)}\, (m\omega_o/\sinh kd) \cos(nky)\, [\cos(mkx) - i \sin(mkx)]\, e^{i\sigma t} \\ &= (\, U_{1c} + i\, U_{1s}\,)\, e^{i\sigma t}, \end{aligned} \tag{20}$$

where $U_{1c}(x,y,z)$ and $U_{1d}(x,y,z)$ relate to the time-independent velocity expressions containing "cos(mkx)" and "sin(mkx)" respectively in equation (20). Similarly, V_1 in equation (2) becomes

$$\begin{aligned} V_1 &= -\varepsilon \sqrt{(k/g)}\, (n\omega_o/\sinh kd) \sin(nky)\, [\sin(mkx) + i \cos(mkx)]\, e^{i\sigma t}, \\ &= (\, V_{1c} + i\, V_{1s}\,)\, e^{i\sigma t}. \end{aligned} \tag{21}$$

The second-order terms U_2 and V_2 in equations (1) and (2) may receive similar treatment, if higher order terms are required.

To calculate $u_{d1}(x,y,z,t)$, which is the defect velocity u_d to the first-order, at a required location (x,y,z) within the short-crested wave system, equation (15) has to be utilised twice, rendering

$$\partial(\nu_t \partial u_{d1c}/\partial z)/\partial z - i\sigma u_{d1c} = 0, \tag{22}$$

and

$$\partial(\nu_t \partial u_{d1s}/\partial z)/\partial z - i\sigma u_{d1s} = 0, \tag{23}$$

in which u_{d1c} and u_{d1s} are related to the free-stream velocity components of U_{1c} and U_{1s} in equation (20) respectively. The magnitude (or modulus) and phase of u_{d1} can be calculated for each sublayer,

$$u_{d1} = u_{d1c} + i\, u_{d1s}, \tag{24}$$

finally leading to the magnitude and phase of u_1. Adopting similar procedure, the first-order defect velocity $v_{d1}(x,y,z,t)$, in complex variable form, is given as

$$v_{d1} = v_{d1c} + i\, v_{d1s}, \tag{25}$$

and fluid velocity v_1 can be calculated after establishing v_{d1}.

Based upon the linear theory above, the flow field at a specific position within a rough bottom layer of the short-crested waves can be determined analytically and numerically. Along the combined-crests, $y/L_y = 0, 1/2, 1, \ldots$, U_{1c} and U_{1s} only are required because $V_1 = 0$; on the other hand, it needs only V_{1c} and V_{1s} along alignments $y/L_y = 1/4, 3/4, \ldots$, since $U_1 = 0$. Along other alignments, all U_{1c}, U_{1s}, V_{1c} and V_{1s} are required in calculations because U_1 and V_1 coexist.

4. Discussions

From theory and experiments available, it has been shown that the water-particle motions in the bottom layer within a short-crested wave system are quite complex, even for the simplest case produced by complete oblique reflection. The resultant wave system is most severe in its erosive capacity. To investigate the rough turbulent boundary layer at the bed, Brevik's (1981) two-layer model using time-invariant viscosity coefficient was here examined.

As revealed from the numerical calculations, Brevik's (1981) two-layer model is a valuable tool in producing a normal velocity distribution through a rough turbulent bottom layer within the short-crested wave system. But this model of assuming time-invariant viscosity coefficient $\nu_t(z)$ to each sublayer can only produce a velocity profile of u similar to that presented in figure 10. Therefore, Brevik's approach is incapable of reproducing a flow reversal in the lower portion of the boundary layer (as in figure 4).

Viewed from the time-varying velocity profiles shown in figure 4 for velocity components at the same location (x,y,z) in a short-crested wave system, a time-dependent viscosity coefficient $\nu_t(z)$ is warranted. An ideal time-dependent viscosity model will ensure the time-varying nature of the velocity profiles as demonstrated in the case of laminar layer, in both magnitude and flow reversibility. This has recently been pointed out by Trowbridge & Madsen (1984). It is suggested that a model using time-variant viscosity coefficient should be considered before a higher order theory is used for the rough boundary layer.

Although it has commonly been envisaged that a turbulent boundary layer can produce a stronger vertical velocity component, w, there is no convincing evidence, from

numerical calculation of the said model, that its magnitude is significant. It is therefore suspected other mechanisms may also be responsible for the suspension of sediments.

CHAPTER 22

Determination of Wind Stress (Drag) Coefficient for Coastal Waters Under Variable Meteorological and Oceanographic Conditions

S. A. Hsu*

Abstract

On the basis of a parametric model of wind stress (drag) coefficient over water surfaces and related experiments, objective procedures to obtain this coefficient under variable wind and wave conditions are outlined and recommended for oceanographic applications and air-sea interaction studies. Methods for both fully and non-fully developed sea conditions are given.

1 Introduction

Wind stress, τ, is one of the most important parameters for air-sea interaction studies see, e.g., Roll, 1965, for momentum flux; Bishop, 1984, for upwelling (current) computation . In order to obtain the magnitude of the wind stress, the drag coefficient is commonly used, i.e.,

$$\tau = \rho U_*^2 = \rho C_D U_z^2 \quad (1)$$

where ρ is the air density, U_* is the shear (or friction) velocity, and C_D is the drag coefficient, which corresponds to the wind speed, U_z, at height z above the water surface.

Variation of C_D with wind speed has been the subject of many investigations (see, e.g., a list given Blanc, 1985). An illustration is provided in Figure 1. In order to explain the increase of C_D with wind speed, Hsu (1986a) has proposed a mechanism that incorporates contributions by both wind and waves. These parameters are modeled into an aerodynamic roughness equation that has proven to be applicable in both coastal waters and open-ocean conditions.

It is the purpose of this paper to outline the procedures necessary for objective computation of the drag coefficient over coastal waters, where meteorological and oceanographic conditions are constantly changing because of variable fetch, duration, and speed of the wind, which in turn produces different characteristics of the wind waves.

2 Procedures

In order to compute C_D, the following objective procedures are recommended:

*Professor, Coastal Studies Institute, School of Geoscience, Louisiana State University, Baton Rouge, LA 70803.

(1) Obtain existing wind records, U_{Land}, from a nearby Weather Service station at a local airport in the coastal plain. Transpose U_{land} to the offshore region by an equation (shown in Fig. 2) provided by Hsu (1986b), i.e.,

$$U_{sea} = 1.62 + 1.17\ U_{land} \tag{2}$$

where the units of U_{sea} and U_{land} are in meters per second.

(2) If the anemometer at the official airport is not located at the conventional height of 10 m above the surface, correct by first using Eq. (2) and then applying the following equation:

$$\frac{U_{10}}{U_{sea}} = \left(\frac{10}{z}\right)^{0.1} \tag{3}$$

Note that if one applies Eq. (2) to the inland region the exponent should be changed. However, owing to complicated geomorphological features onshore, the value of the exponent is less certain than that of the offshore region, as shown in Eq. (2), which was verified by an experiment with tethered balloon soundings in the atmospheric boundary over the Mediterranean Sea, as shown in Figure 3 (Hsu, 1986c).

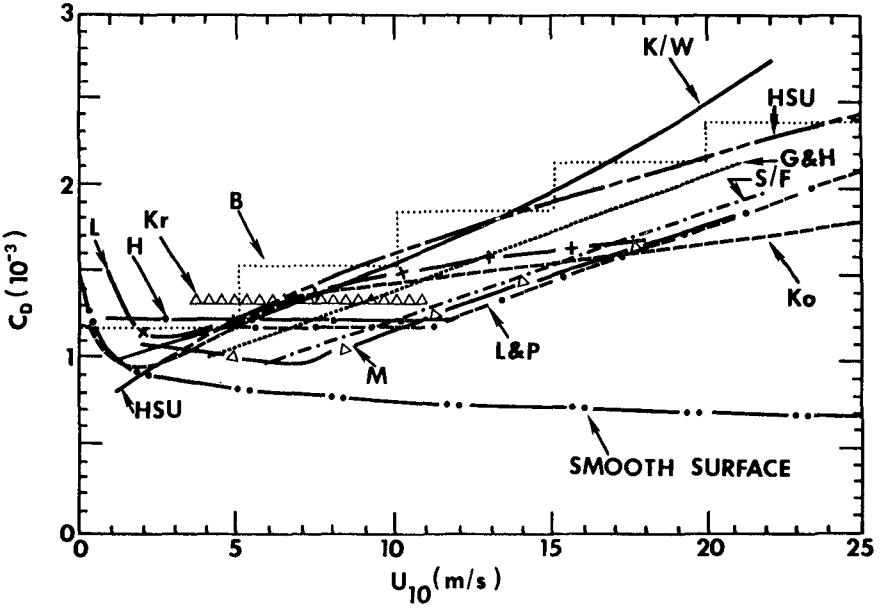

Fig. 1. Variation of the drag coefficient, C_D, with wind speed at 10 m above the sea surface from Blanc, 1985, except the curve labeled "Hsu, this study," which is based on Eq. (4) .

(3) For engineering applications, assume first that the sea is fully developed. According to Hsu (1986a, Eq. 35), we have

$$C_{10} = \left[\frac{\kappa}{14.56 - 2 \ln U_{10}}\right]^2 \tag{4}$$

where κ is the von Karman constant (= 0.4 $\pm$ 0.01; see Hogstrom, 1985).

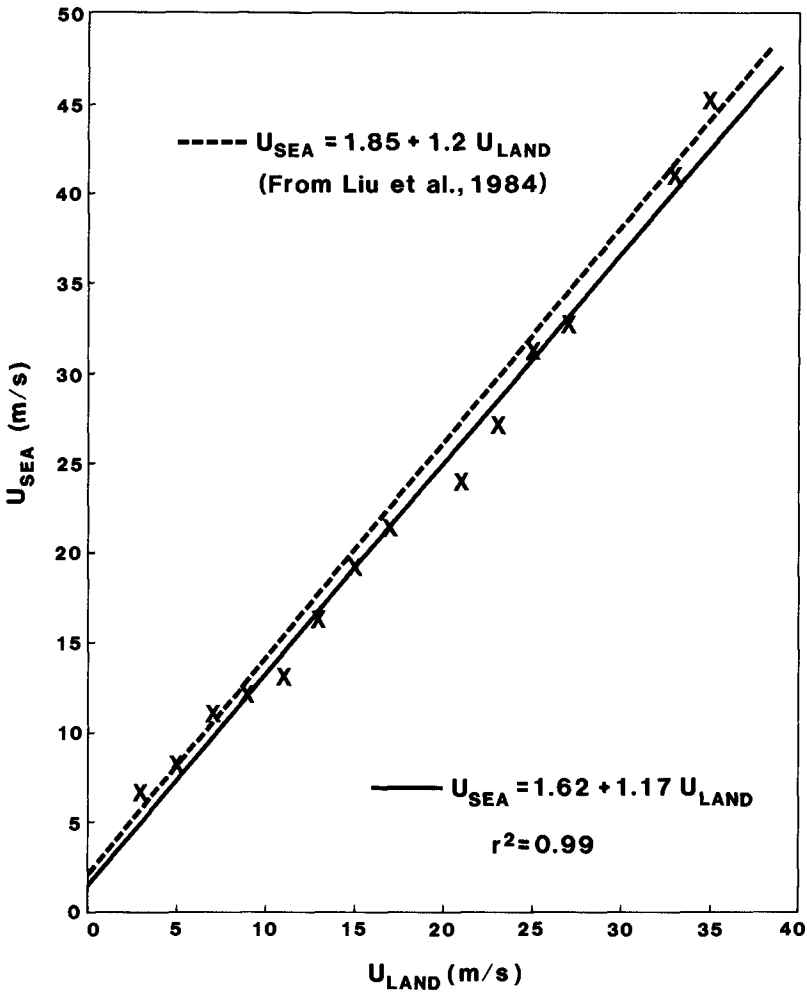

Fig. 2. Variation of U_{sea} as a function of U_{land} (from Hsu, 1986b).

This equation is shown as the curve labeled "HSU" in Figure 1, which is obtained from wind and wave parameterization and is consistent with measurements. Additional verification of Eq. (4) is given in Figure 4 as well as in Hsu (1986a).

(4) If the sea is not fully developed and detailed wind-stress estimates are needed to compute the currents, e.g., during oil spill conditions, the following procedures may be applied. From forecasted weather maps, the fetch, duration, direction, and speed of the wind near the sea surface can be obtained (see, e.g., procedures outlined in U.S. Army Corps of Engineers, 1984). On the basis of these data, wave celerity, C, and significant

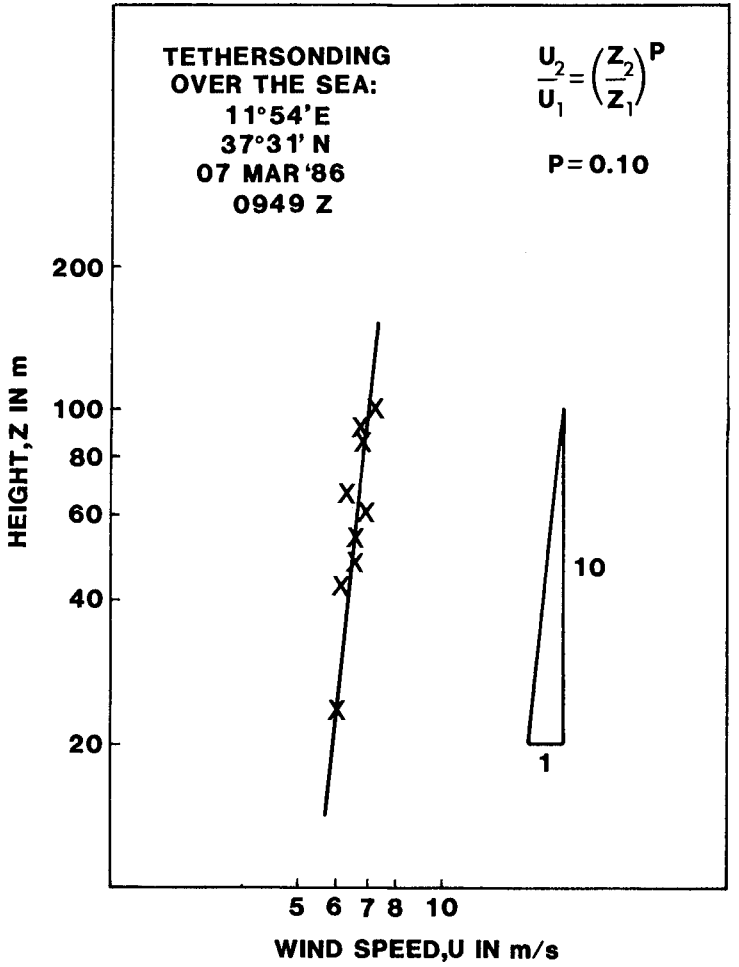

Fig. 3. A log-log plot of U versus Z over the ocean (from Hsu, 1986c).

wave height, $H_{1/3}$, can be computed. A quick way is to use the nomogram provided in U.S. Army Corps of Engineers (1984).

With wind and wave parameters, U_* can be estimated from the nomogram provided in Figure 5 (Hsu, 1976). Then, applying the following formula from Eq. (1):

$$C_D = (U_*/U_z)^2 \tag{5}$$

Note that the effect of atmospheric stability has already been incorporated in the wave characteristics (see Hsu, 1976; Janssen and Komen, 1985).

3 CONCLUSIONS

On the basis of a parametric model of wind stress (drag) coefficient and related experiments, objective procedures to obtain C_D are outlined and recommended for oceanographic applications. These procedures should be useful for coastal engineers.

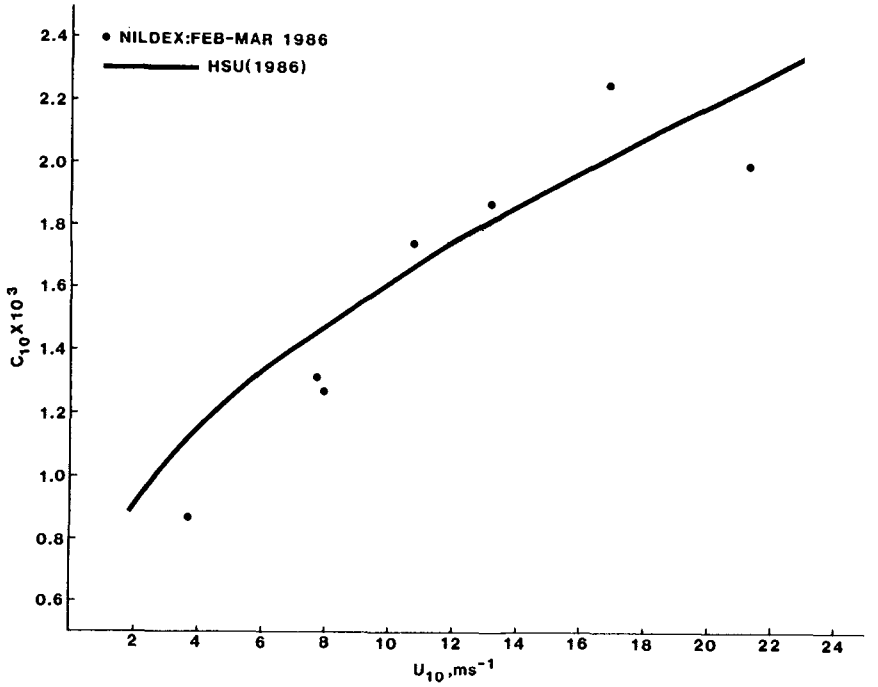

Fig. 4. Variations of C_{10} versus U_{10} as obtained from the Mediterranean Sea (see Hsu, 1986c). The solid line is based on Eq. (4).

4 ACKNOWLEDGEMENT

The 1986 Mediterranean experiment used in this study was sponsored in part by the U.S. Naval Environmental Prediction Research Facility. Additional support from the Marine Meteorology Program of the U.S. Office of Naval Research is appreciated. Travel funds to present the paper were made available by the Department of Geology and Geophysics, Louisiana State University.

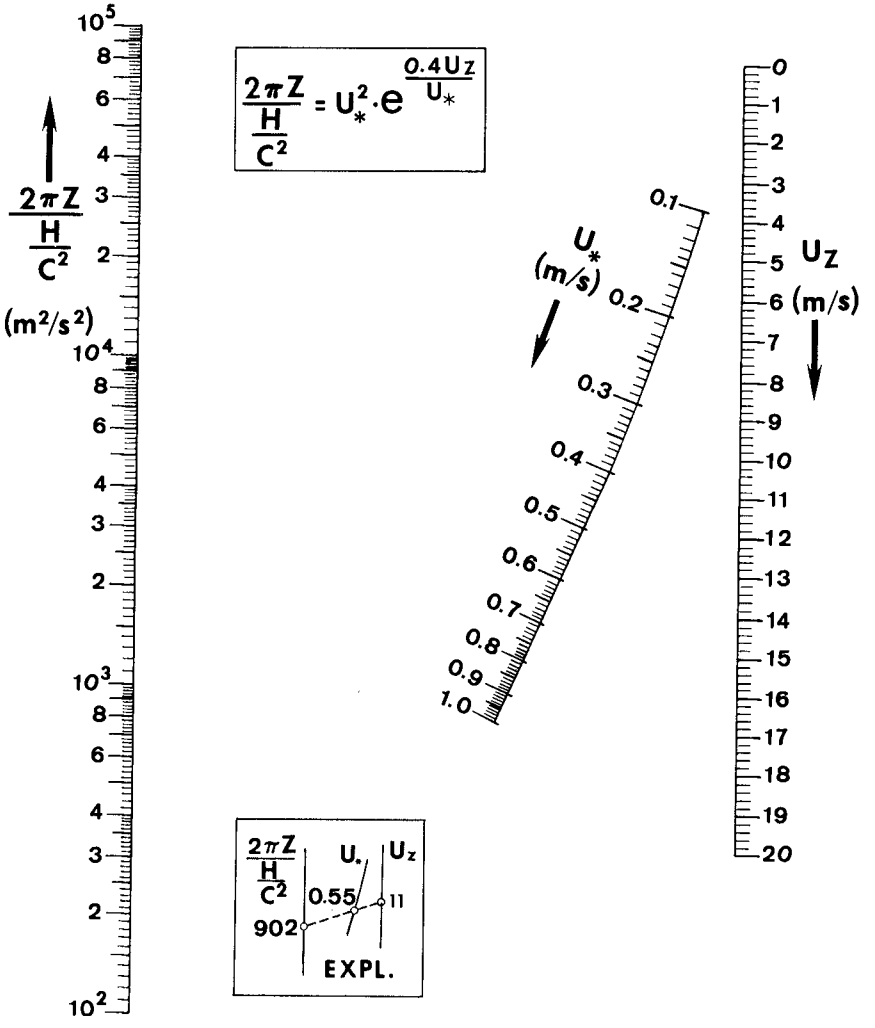

Fig. 5. A nomograph for computing U_* from wind and wave parameters for both fully and non-fully developed sea conditions. The figure gives an example of the use of commonly available wind (U_z) and wave (H and C) parameters to obtain U_* (Hsu, 1976).

CHAPTER 23

Studies on the Correlation of Tidal Elevation Changes Along the Western Coastline of Taiwan

By

Dr. H.H. Hwung[1] C.L. Tsai[2] C.C. Wu[3]

Abstract

In order to understand the characteristics of tidal elevation changes along the western coastaline of Taiwan, the authors collected the tidal records at the same duration from eleven stations and made an elaborate analysis in this paper.

First step, the main tidal constituents were picked out from spectrum analysis, and the amplitudes and phase angles of these tidal constituents would be obtained by harmonic analysis. Then the variations of amplitude and phase lag of the main constituents and the variations of mean high water level and mean low water level along the coastline would be presented in the figures respectively. Finally, based on the results of harmonic analysis, the energy density of tide for every station could be calculated separately, and the location of the maximum energy density would be determined by cubic spline method.

1. Professor of Hydraulic and Ocean Engineering Department and Director of Tainan Hydraulic Laboratory, National Cheng Kung University, Tainan,Taiwan, R.O.C.
2. Assistant Researcher of Tainan Hydraulic Laboratory, National Cheng Kung University, Tainan, Taiwan, R.O.C.
3. Graduate students of Hydraulic and Oecan Engineering Graduate School , National Cheng Kung University, Tainan, Taiwan, R.O.C.

1. Introduction

Taiwan is a narrow island in the western Pacific Ocean, between the East and South-China sea. It is separated from the mainland of China by Taiwan Strait, about 130Km at the nearest part. Under this particular geographical boundary conditions, every time as the tide flooding, sea water flows into the strait from the southern and northern entrance simultaneously, and the flooding water concentrate gradually at one point of the strait until the maximum water level reaches. Then the tide ebbing, water flows back from the strait along the same route to the Pacific Ocean. Through this particular tidal movements, the amplitude of tide varies along the coastline which is only about 0.64m at the southest of Taiwan, and about 0.90m at the northest. But around Tai-Chiung coastal area which closes to the middle point of the coastline, the tidal range reaches 5.85m approximately. In order to understand the characteristics of tidal elevation changes along the western coastline of Taiwan, the authors collected the tidal records of the same duration of 11 stations from Kee-Lung, Tan-Hsui, Chu-Wei, Yung-An, Tai-Chiung, Fang-Yuan, Tai-Hsi, Wen-Kang, Chiang-Chun, Kao-Hsiung and Hsun-Kuan-Tsui shown in Fig-1.

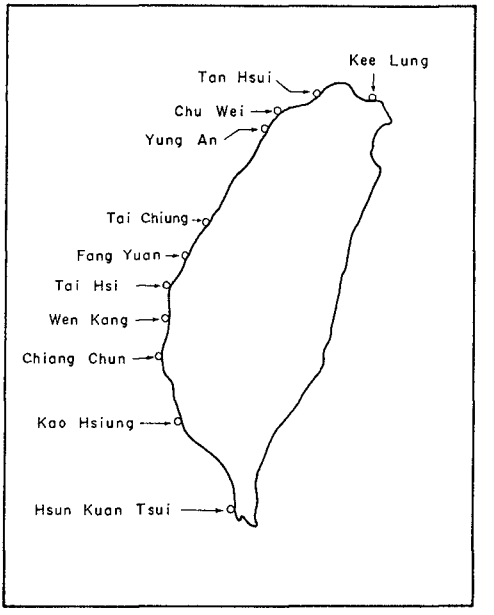

Fig-1

Based on these collected records, the main tidal constituents would be obtained from power spectrum analysis. Then the amplitudes and phase angles of these constituents were also obtained by harmonic analysis. Furthermore, the characteristics of tidal constituents along the western coastaline of Taiwan are presented in this paper.

2. Data Collection and Analysis

In order to inspect the tidal records, firstly, all the collected data for every station would be plotted as a continuous curve shown from Fig-2(a) through Fig-2(k) separately. Since the tidal records may include meteorological tide or storm surge as typhoon passing through around Taiwan island, that the abnormal tide has to be filtered from the records before all of the analysis are made.

Afterwards, the main tidal constituents can be picked out from the spectrum analysis, that 8,192 tidal records ($\Delta f=0.04394^0$/hr) were taken to do the analysis for every station. And the results were presented from Fig-3(a) through Fig-3(k) respectively.

Then based on these main tidal constituents picked out from spectrum analysis, the harmonic constants (amplitudes and phase angles) would be obtained from harmonic analysis by least square method. And after the arguement and correction coefficient of these tidal constituents were determined that the tide function could be established for every station.

3. Results and Discussions

According to the above results of spectrum analysis from Fig-2 (a) through Fig-2(k), it is well to see that the variations of water elevation along the western coast of Taiwan are dominated by semi-diurnal and diurnal tide simultaneously. And it is found that the energy of semi-diurnal tide is the highest at Tan-Hsui, Chu-Wei, Yung-An, Tai-Chiung, Fang-Yuan, Tai-Hsi, Wen-Kang and Chiang-Chun stations. But beyond the above stations, it is said, that Kee-Lung, Kao-Hsiung and Hsun-Kuang-Tsui stations are dominated both by semi-diurnal and diurnal tides.

Then, based on the spectrum analysis, we picked out twenty-five tidal constituents which the summation of energy has occupied over 90% of the tide for every station. Accordingly, the harmonic analysis by least square method was carried out for every station separately. And the results were tabulated in Table-1(a)~Table-1(k).

In general, the type of tide can be classified from the ratio ,R, between the summation amplitude of diurnal tides (K_1,O_1) and semi-diurnal tides (M_2,S_2). As $R\leq 0.25$, the tide is a semi-diurnal type, $0.25\leq R\leq 1.50$, is a mixed-type and $1.50<R$ that it is a diurnal type. Thus, from the results of harmonic analysis, the ratio,R, could be calculated for every station and listed in Table-2 respectively. And it is obviously to see that the tide between the water area of Tan-Hsui and Tai-Hsi is a semi-diurnal type, but out of this region is a mixed-type.

And the variations of amplitude and phase lag of the main constituents along the latitude of western coast from the south to the north of Taiwan island were presented in Fig-4 and Fig-5 respectively. It is obviously to see that all the amplitude of tidal constituents increas with the latitude increasing, and reach a maximum value around Tai-Chiung station, then the amplitude decreas with the latitude increasing. As for the phase lag, we can see that the tendency of variations of phase lag are the same as amplitude does along the latitude, but the larger the angular frequency of tidal constituent is, the larger the phase lag has. Likewise, the variation of the mean high water level, MHW, and mean low water level, MLW, along the latitude are shown in Fig-6.

Fig-7 The distribation of energy density along the western coast of Taiwan

the location is 24° 26′, it is said that 20.9km north of Tai—Chiung station

Finally, based on the main tidal constituents obtained from harmonic analysis, the energy density of tide for every station could be calculated and the result was shown in Fig-7. Then the maximum energy density could be determined by cubic spline method, that is to say, the maximum tidal range is located 20.9Km north of Tai-Chiung station.

4. Conclusions

According to the above results, some of the remarkable conclusions would be made in this paper. They are:

(1). Along the western coast of Taiwan island, twenty-five tidal constituents picked out from the spectrum analysis are enough for engineering uses, because of the summation of energy density of these tidal constituents has occupied over 90% of the tide.

(2). The tide between Tan-Hsui and Tai-Hsi station is a semi-diurnal type which is especially dominated by M_2 constituent. However, out of this region, the tide is a mixed type which is dominated by diurnal and semi-diurnal tides simultaneously.

(3). Although the tidal records of eleven stations along the western coast of Taiwan were collected as possible as in this paper. Accordingly, the location of the maximum tidal range is determined about 20.9Km north from Tai-Chiung station. However, the more tidal stations will be provided for analysis, the more accuracy will be obtained.

CHAPTER 24

A PARABOLIC REFRACTION-DIFFRACTION EQUATION IN THE RAY-FRONT COORDINATE SYSTEM

Masahiko Isobe*

ABSTRACT

The parabolic equation method has been extensively used for combined refraction and diffraction problems of water waves. However, a parabolic equation is valid only when the direction of wave propagation nearly coincides with that of a coordinate; therefore, the validity ranges of the parabolic equations developed so far are restricted.

In order to achieve a wide range of validity, a parabolic equation is derived in this paper by employing a curvilinear coordinate system which has a pattern similar to that of wave rays and fronts. A computer program which is applicable to an arbitrary arrangement of coastal structures is then developed.

Results of numerical calculations are compared with available analytical solutions and laboratory data. It is proved that the present parabolic equation has a high accuracy for a wide range of incident wave direction and structure arrangement.

1. INTRODUCTION

In order to analyze the wave transformation due to combined refraction and diffraction, the mild-slope equation was derived by Berkhoff (1972). The mild-slope equation is an elliptic-type partial differential equation; hence the numerical calculation needs much computing time. Therefore, Radder (1979) and Tsay and Liu (1982) derived parabolic approximation equations which save a great amount of computing time and storage. Recently, the parabolic equation method has been modified in order to include the effects of wave nonlinearity (Kirby and Dalrymple, 1983; Liu and Tsay, 1984) and energy dissipation (Dalrymple et al., 1984; Liu and Tsay, 1985). However, the validity ranges of the parabolic equations are restricted due to the assumption that the direction of a coordinate nearly coincides with that of wave propagation.

The primary objective of this study is to derive a parabolic equation which is applicable even if the incident wave angle relative to the onshore direction and the longitudinal direction of a structure

* Associate Professor, Department of Civil Engineering, Yokohama National University, 156 Tokiwadai, Hodogaya-ku, Yokohama, 240 Japan

is large. This is done by employing a curvilinear coordinate system which has a pattern similar to that of wave rays and fronts. A computer program which can be applied to an arbitrary bottom profile and structure arrangement is developed. Results of numerical calculations are compared with available analytic solutions and laboratory data.

2. DERIVATION OF PARABOLIC EQUATION

2.1 Basic Concept

When Radder (1979) first derived a parabolic equation, Cartesian coordinates were employed. Therefore, if the incident wave angle is large, the direction of the coordinate significantly differs from that of wave propagation. In Tsay and Liu (1982), curvilinear coordinates following Snell's law were employed, which implies that the change in wave propagation direction due to refraction is taken into account. However, since the coordinates are determined independently of structures, a significant difference between the directions of the wave propagation and the coordinate occurs in the shadow region.

Waves are observed to propagate following Huygens' principle. If we define a coordinate system following this principle, the resulting coordinates must coincide with the wave ray and front pattern. We call this coordinate system a "ray-front coordinate system." Figure 1 shows an example of ray-front coordinate system. Rays 7 to 11 are incident wave rays, refracted by the change of water depth. Rays 1 to 5, and 12 and 13 are radiated from the tips of breakwaters and then refracted.

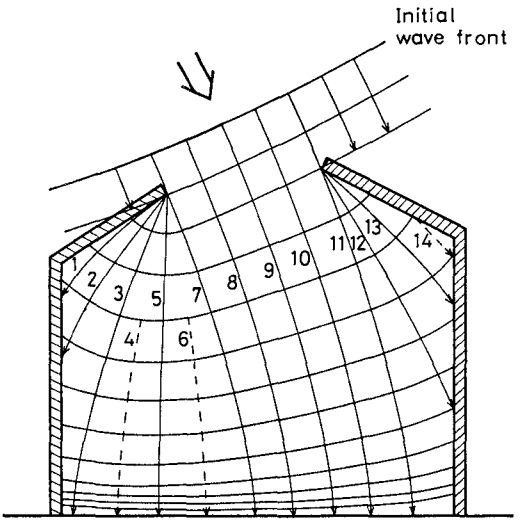

Fig. 1 Example of ray-front coordinate system.

Thus we can define a ray coordinate, and then a front coordinate from the orthogonality condition. By this definition, the direction of wave propagation almost coincides with that of the ray coordinate; therefore, the parabolic equation in this coordinate system is expected to be valid for a wide range of incident wave condition and structure arrangement.

2.2 Ray-front Coordinates

Consider curvilinear coordinates (ξ, η) as shown in Fig. 2. The directions of ξ and η respectively represent those of wave rays and fronts following Huygens' principle; thus the direction, α, of the ξ-coordinate can be determined by the following ray equation in the refraction problem:

$$\frac{1}{h_\xi}\frac{\partial \alpha}{\partial \xi} = \frac{1}{K}\frac{1}{h_\eta}\frac{\partial K}{\partial \eta} \tag{1}$$

where h_ξ and h_η are the scale factors of the curvilinear coordinates; hence $h_\xi d\xi$ and $h_\eta d\eta$ represent the lengths of short line elements. The quantity K is the wave number and usually can be calculated from the given local water depth by the dispersion relation. However, wave rays often intersects with each other for complicated bottom topographies; thus K is calculated from a slightly-modified water depth. The modified bottom topography may be taken as that with straight and parallel bottom contours, since a slight difference between the directions of the coordinate and wave propagation is allowed in the derivation of a parabolic equation. By this modification, the intersection of wave rays does not occur. The scales of axes are arbitrary; hence, we can take $h_\xi = h_\eta = 1/K$ without loss of generality, with which the values of the coordinates have the dimension of phase angle.

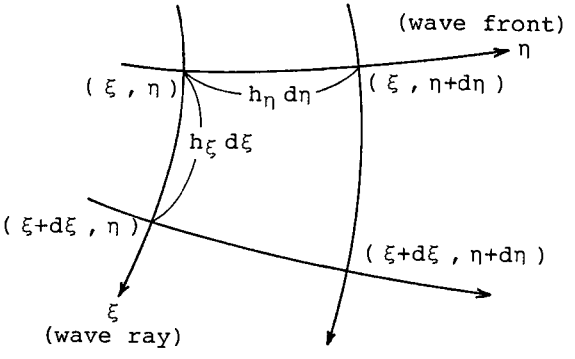

Fig. 2 Curvilinear coordinates

Once α is determined by Eq. (1), the position (x, y) along the ξ-coordinate can be calculated by

$$\frac{1}{h_\xi}\frac{d}{d\xi}(x, y)=(\cos\alpha, \sin\alpha) \tag{2}$$

If the position of a point on a front line is given, the position of the point advanced along a ray to the next shoreward front line can be determined by numerically integrating Eqs. (1) and (2) by the Runge-Kutta-Gill method. Then the η-axis can be determined as the line of ξ = const.

2.3 Parabolic Approximation

Berkhoff (1972) derived the mild-slope equation which governs the combined refraction and diffraction of periodic small-amplitude surface gravity waves over a seabed of a mild slope:

$$\nabla(G\nabla\phi)+k^2G\phi=0 \tag{3}$$

where G = cc_g (c: wave celerity, c_g: group velocity), k is the wave number calculated from the given local water depth by dispersion relation, and ∇ is the differential operator in the horizontal directions. The quantity ϕ represents the complex amplitude of the water surface fluctuation. From ϕ, the water surface fluctuation, ζ, and the velocity potential, Φ, are expressed as

$$\zeta=\phi e^{-i\omega t} \tag{4}$$

$$\Phi=\frac{g}{i\omega}\frac{\cosh k(d+z)}{\cosh kd}\phi e^{-i\omega t} \tag{5}$$

where ω is the angular frequency, g the gravitational acceleration, d the given local water depth, z the vertical coordinate measured upward from the still water level, and t the time.

Equation (3) can be reexpressed in the curvilinear coordinates (ξ, η) as

$$\frac{1}{h_\xi h_\eta}\left\{\frac{\partial}{\partial\xi}\left(G\frac{h_\eta}{h_\xi}\frac{\partial\phi}{\partial\xi}\right)+\frac{\partial}{\partial\eta}\left(G\frac{h_\xi}{h_\eta}\frac{\partial\phi}{\partial\eta}\right)\right\}+k^2G\phi=0 \tag{6}$$

which is an elliptic-type partial differential equation. In the following, we approximate the mild-slope equation (6) to a parabolic equation following Radder (1979).

Equation (6) can be rewritten as

$$\frac{1}{h_\xi}\frac{\partial}{\partial\xi}\left(\frac{1}{h_\xi}\frac{\partial\phi}{\partial\xi}\right)=-\frac{1}{Gh_\eta}\frac{1}{h_\xi}\frac{\partial(Gh_\eta)}{\partial\xi}\frac{1}{h_\xi}\frac{\partial\phi}{\partial\xi}-\left\{\frac{1}{Gh_\xi}\frac{1}{h_\eta}\frac{\partial}{\partial\eta}\left(G\frac{h_\xi}{h_\eta}\frac{\partial}{\partial\eta}\right)+k^2\right\}\phi \tag{7}$$

Here, we assume that ϕ can be splitted into two parts: the complex amplitudes ϕ^+ and ϕ^- due to incident and reflected waves, respectively, i.e.,

$$\phi=\phi^{+}+\phi^{-} \tag{8}$$

$$\phi^{\pm}\sim a^{\pm}\exp\left(\pm i\int kh_{\xi}d\xi\right) \tag{9}$$

From Eqs. (8) and (9), we have

$$\frac{1}{h_{\xi}}\frac{\partial\phi}{\partial\xi}=ik\phi^{+}-ik\phi^{-} \tag{10}$$

Then, we can eliminate ϕ^{-} from Eqs. (8) and (10):

$$\phi^{+}=\frac{1}{2}\phi+\frac{1}{2ik}\frac{1}{h_{\xi}}\frac{\partial\phi}{\partial\xi} \tag{11}$$

By taking the gradient of Eq. (11) in the direction of ξ and substituting Eq. (7), we obtain

$$\frac{1}{h_{\xi}}\frac{\partial\phi^{+}}{\partial\xi}=-\frac{1}{2ik}\left\{\frac{1}{Gh_{\xi}}\frac{1}{h_{\eta}}\frac{\partial}{\partial\eta}\left(G\frac{h_{\xi}}{h_{\eta}}\frac{\partial}{\partial\eta}\right)+k^{2}\right\}\phi$$
$$+\left\{\frac{1}{2}-\frac{1}{2ik^{2}}\frac{1}{h_{\xi}}\frac{\partial k}{\partial\xi}-\frac{1}{2ik}\frac{1}{Gh_{\eta}}\frac{1}{h_{\xi}}\frac{\partial(Gh_{\eta})}{\partial\xi}\right\}\frac{1}{h_{\xi}}\frac{\partial\phi}{\partial\xi} \tag{12}$$

On substituting Eqs. (8) and (10), we have a differential equation which contains ϕ^{+} and ϕ^{-}. Here, we further assume that $|\phi^{+}|>>|\phi^{-}|$, i.e., $\phi^{+}\fallingdotseq\phi$ and $\phi^{-}\fallingdotseq 0$. Thus we finally obtain the following parabolic equation for ϕ:

$$\frac{1}{Gh_{\xi}}\frac{1}{h_{\eta}}\frac{\partial}{\partial\eta}\left(G\frac{h_{\xi}}{h_{\eta}}\frac{\partial\phi}{\partial\eta}\right)+2ik\frac{1}{h_{\xi}}\frac{\partial\phi}{\partial\xi}+\left\{\frac{i}{Gh_{\eta}}\frac{1}{h_{\xi}}\frac{\partial}{\partial\xi}(kGh_{\eta})+2k^{2}\right\}\phi=0 \tag{13}$$

In order to make the change of ϕ slower, we transform the unknown variable from ϕ to ψ as

$$\phi=\psi\exp\left(i\int Kh_{\xi}d\xi\right) \tag{14}$$

Since K is the approximate local wave number, the exponential term in the above equation roughly represents the phase of ϕ; hence, the spatial change of ψ is expected to become slow. On substituting Eq. (14) into Eq. (13), we obtain the following parabolic equation for ψ:

$$\frac{1}{Gh_{\xi}}\frac{1}{h_{\eta}}\frac{\partial}{\partial\eta}\left(G\frac{h_{\xi}}{h_{\eta}}\frac{\partial\psi}{\partial\eta}\right)+2ik\frac{1}{h_{\xi}}\frac{\partial\psi}{\partial\xi}+\left\{\frac{i}{Gh_{\eta}}\frac{1}{h_{\xi}}\frac{\partial}{\partial\xi}(kGh_{\eta})+2k(k-K)\right\}\psi=0 \tag{15}$$

Equation (15) is parabolic; therefore, we can numerically solve it step by step from offshore to onshore if adequate boundary conditions are given. It should be noted that Eqs. (13) and (15) agree with those of Radder (1979) when they are described in Cartesian coordinates.

In deriving parabolic equations, we can adopt slightly different assumptions, obtaining different equations in high-order terms. However, the result of numerical calculation showed that the present parabolic equation has the highest accuracy among several possible equations.

2.4 Physical Interpretation of Parabolic Equation

Following Berkhoff et al. (1982), we separate the amplitude and phase of ϕ as

$$\phi = a e^{i\varepsilon} \tag{16}$$

On substituting Eq. (16) into Eq. (15), we have

$$\frac{1}{h_\xi}\frac{\partial \varepsilon}{\partial \xi} = k - K - \frac{1}{2k}\left(\frac{1}{h_\eta}\frac{\partial \varepsilon}{\partial \eta}\right)^2 + \frac{1}{2akGh_\xi}\frac{1}{h_\eta}\frac{\partial}{\partial \eta}\left(G\frac{h_\xi}{h_\eta}\frac{\partial a}{\partial \eta}\right) \tag{17}$$

$$\frac{1}{h_\xi h_\eta}\left[\frac{\partial}{\partial \xi}(a^2 k G h_\eta) + \frac{\partial}{\partial \eta}\left(a^2 \frac{1}{h_\eta}\frac{\partial \varepsilon}{\partial \eta} G h_\xi\right)\right] = 0 \tag{18}$$

from real and imaginary parts, respectively. Equation (17) can be rewritten as

$$\left(K + \frac{1}{h_\xi}\frac{\partial \varepsilon}{\partial \xi}\right)^2 + \left(\frac{1}{h_\eta}\frac{\partial \varepsilon}{\partial \eta}\right)^2 = k^2 + \left\{k - \left(K + \frac{1}{h_\xi}\frac{\partial \varepsilon}{\partial \xi}\right)\right\}^2 + \frac{1}{aGh_\xi}\frac{1}{h_\eta}\frac{\partial}{\partial \eta}\left(G\frac{h_\xi}{h_\eta}\frac{\partial a}{\partial \eta}\right) \tag{19}$$

Equation (19) corresponds to the eikonal equation in refraction problems but includes the effect of diffraction in the η-direction as seen from the last term on the right hand side.

Since $G \approx \omega c_g/k$, Eq. (18) represents the conservation of wave energy. In the first parentheses, however, the ξ-component of the wave number should appear instead of k itself. Therefore, if the direction cosine in the ξ-direction is significantly less than unity, i.e., the direction of wave propagation is significantly different from the ξ-direction, the error of the present parabolic equation will become large. Usually this does not occur, since the coordinates are determined following Huygens' principle.

2.5 Boundary Condition

The condition of complete reflection is imposed on fixed boundaries; thus the derivative of ϕ in the normal direction of the boundaries becomes zero. This can be expressed in terms of ϕ as

$$\frac{1}{h_\eta}\frac{\partial \phi}{\partial \eta} - \left(\frac{1}{h_\xi}\frac{\partial \phi}{\partial \xi} + iK\phi\right)\tan\delta = 0 \tag{20}$$

where δ denotes the direction angle of the boundary measured from the ξ-direction toward the η-direction.

The first term in the parentheses of Eq. (20) is usually small compared to the second term; therefore, it can be neglected as

$$\frac{1}{h_\eta}\frac{\partial \phi}{\partial \eta} - iK\phi\tan\delta = 0 \tag{21}$$

The accuracy of numerical caculation was higher when Eq. (21) was adopted as the boundary condition than when Eq. (20) was adopted. The reason of this result is not clear, but the error of Eqs. (18) and (21)

may cancel with each other. Hereafter, Eq. (21) will be used for boundary conditions.

For open boundaries, Eq. (21) with $\delta = 0$ was used. This means that the waves propagate in the ξ-direction just by refraction and the gradient in the η-direction is zero. If the open boundaries are located far from structures, they give no influence on the wave field around structures. However, once the disturbance from structures reaches the open boundary, the present condition induces the reflection of the disturbance.

3. PROCEDURE OF NUMERICAL CALCULATION

In order to determine the ray-front coordinates, Eqs. (1) and (2) were integrated by the Runge-Kutta-Gill method. The Crank-Nicholson scheme in which the weights for the old and new front lines are equal was applied to solve the parabolic equation (15). The weights for the two lines in the boundary condition were also taken equal.

The procedure of numerical calculation is summarized as follows:

1) Determine the position of an initial front line and the values of ϕ on the line from Snell's law.

2) Determine the position of the front line at the next step by Eqs. (1) and (2). From the tip of a structure, new wave rays are added as rays 1,2,3 and 5, or 12 and 13 in Fig. 1. If the distance between two adjacent rays exceeds a given value, new rays are also added by interpolation as rays 4,6, and 14 in Fig. 1.

3) Solve the parabolic equation (15) in order to determine the value of ϕ on the new front line.

4) Repeat 2) and 3) until the domain of calculation is covered with the ray-front coordinates.

A FORTRAN program which can be applied to an arbitrary incident wave condition, boundary condition, and bottom topography was developed.

4. RESULTS

4.1 Comparison with Analytical Solutions

In Fig. 3, circles show calculated wave height changes due to refraction. Waves are incident obliquely to a plane sloping beach with a slope of 1/10. In the figure, θ_o denotes the wave angle in deep water, d/L_o the ratio of local water depth to deep-water wavelength, and H/H_o the ratio of local wave height to deep-water wave height. In the numerical calculation shown in this figure, the grid size to wavelength ratio, Δ/L, is 1/20, which was proved to be sufficiently small by numerical experiment. Solid lines indicate wave height

changes obtained by Snell's law. The agreement is good even if the incident wave angle is large.

Next, the diffraction coefficient due to semi-infinite breakwater is examined. Figure 4 shows the diffraction coefficient along the line from A to B and from B to C. Various symbols indicate the results of the present numerical calculations with various grid sizes. The analytical solution by Penny and Price (1952) is shown by a curve. Though the small oscillation from A to B is not accurately reproduced, the agreement is good on the whole. Figure 5 compares the numerical and analytical diffraction coefficients behind a semi-infinite breakwater for various incident wave directions. The agreement is good for a wide range of incident wave direction.

Figure 6 compares the wave height distribution in front of the breakwater. Since the ray-front coordinates are defined from the direction of the incident waves, the ξ-direction can be significantly different from the propagation direction of the reflected waves. Therefore, as seen from the open triangles in Fig. 6(b), the calculated oscillation of wave height differs significantly from the analytical solution. A mirror image technique was employed to improve the accuracy of calculation in the reflective region: 1) the semi-infinite breakwater is first removed, 2) a numerical solution is obtained for a semi-infinite breakwater with θ_0=-90° (this value does not change the result significantly), and 3) the solution is folded along the given semi-infinite breakwater and superimposed. Closed symbols indicate the results; the agreement between the numerical and analytical results become much better.

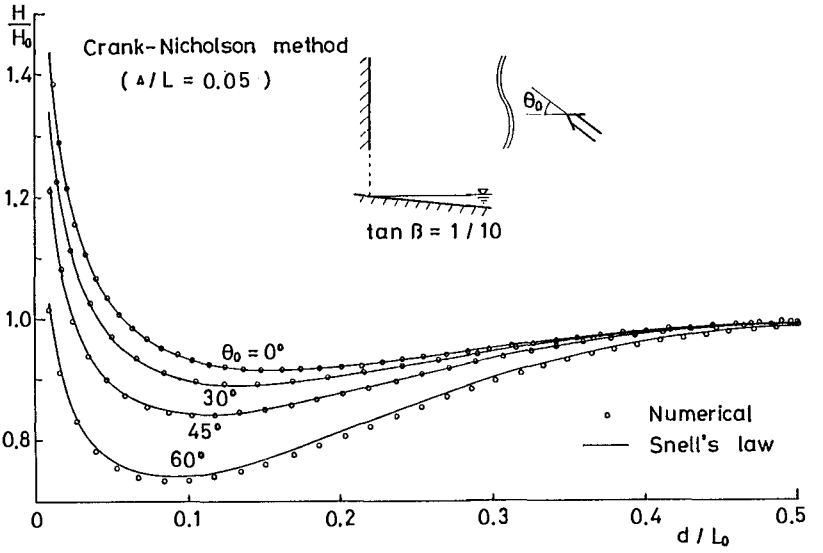

Fig. 3 Comparison of numerical and analytical wave height changes due to refraction.

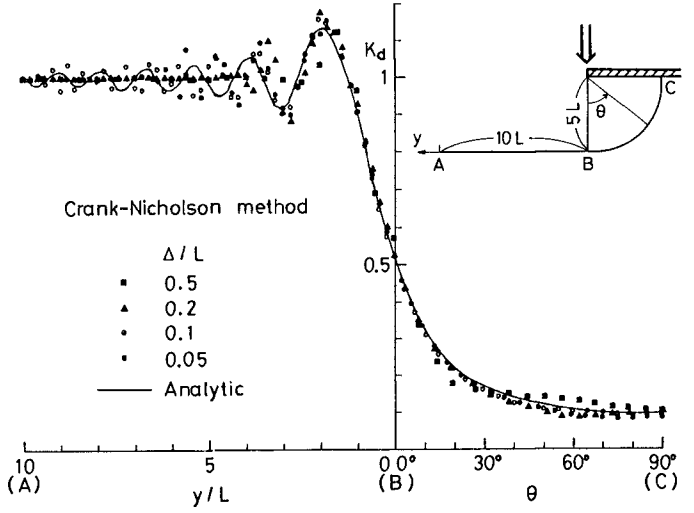

Fig. 4 Effect of grid size on the diffraction coefficient around a semi-infinite breakwater.

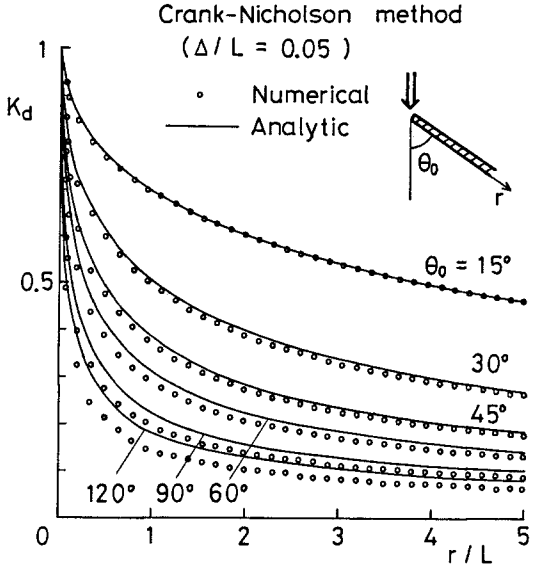

Fig. 5 Comparison of numerical and analytical diffraction coefficients just behind a semi-infinite breakwater.

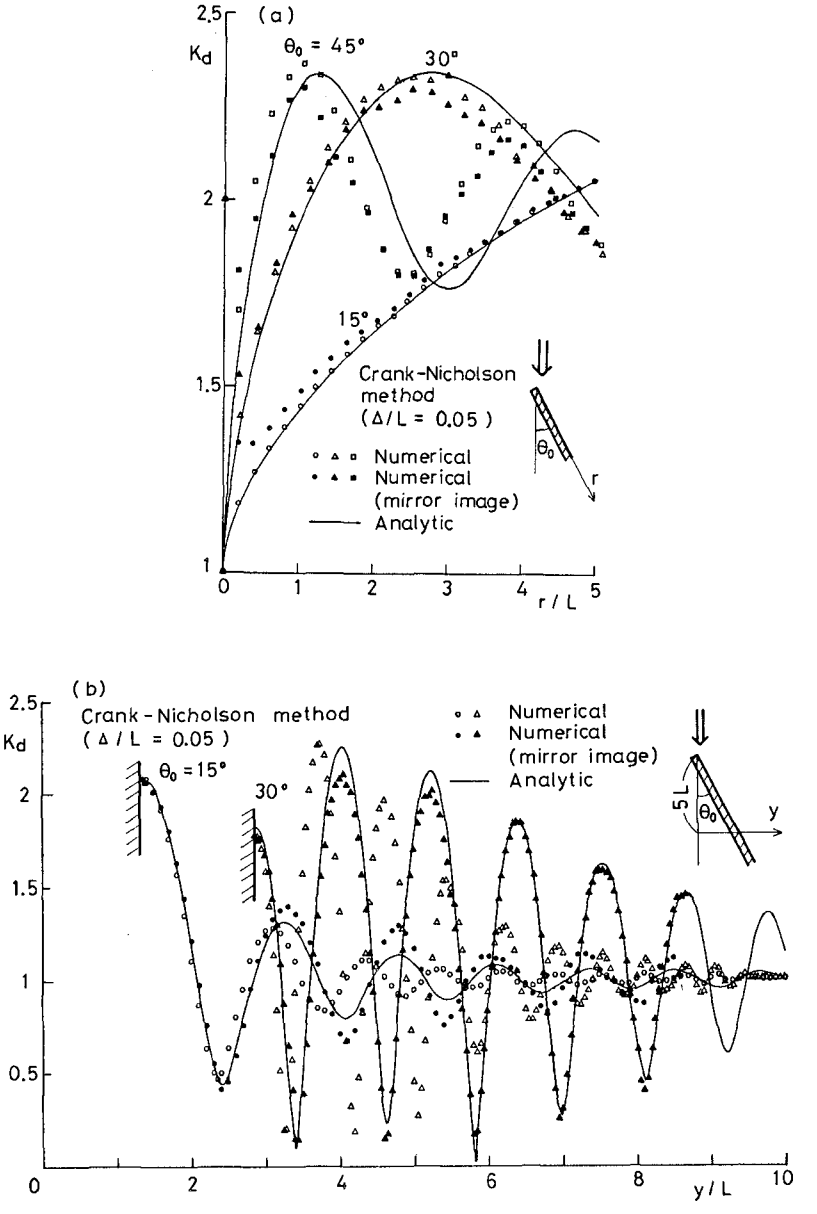

Fig. 6 Comparison of numerical and analytical wave height distributions in front of a semi-infinite breakwater.

4.2 Comparison with Experimental Data

Figure 7 shows the present experimental apparatus. A wave basin which is 9m wide and 9m long was used. As seen in the figure, a plane beach with a slope of 1/15 was attached and breakwaters were arranged on the beach. A flap-type wave maker was set obliquely to the wave basin. Capacitance wave gages were used to measure the water surface fluctuation. The incident wave height, period, and angle were 9.1cm, 0.83s, and 18°, respectively.

Figure 8 compares the calculated and measured wave height distributions from A to A' and from B to B'. The agreement is fairly good. In shallower region, time history of water surface fluctuation becomes asymmetrical due to nonlinear effect; hence comparison was not made.

5. CONCLUSION

Curvilinear coordinates which follow Huygens' principle and are named ray-front coordinates were introduced. In the coordinates, a parabolic equation for combined refraction and diffraction of water waves was derived. Numerical calculation was carried out and the results were compared with available analytical solutions and experimental data.

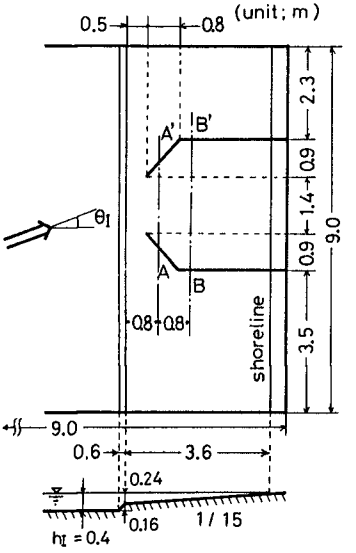

Fig. 7 Experimental apparatus.

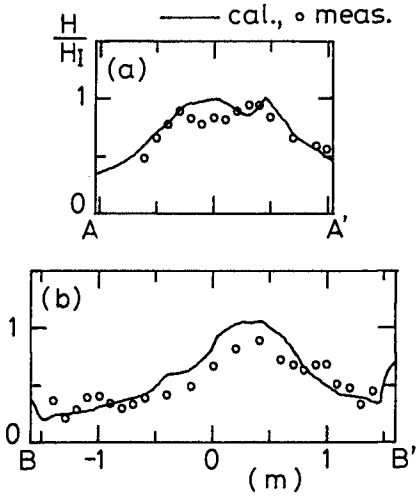

Fig.8 Comparison ofcalculated and measured wave height distributions.

The present method was proved to have a high accuracy for refraction and diffraction of linear water waves. However, in the reflective region, direct application of the parabolic equation yields a significant error because incident and reflected waves exist in the region. The accuracy of the numerical calculation was improved by employing a mirror image technique.

CHAPTER 25

BREAKING CRITERION ON NON-UNIFORMLY SLOPING BEACH

Takashi Izumiya* and Masahiko Isobe**

ABSTRACT

This paper deals with the breaker height on non-uniformly sloping beaches. A large number of experiments were carried out to obtain a breaking criterion on bar and step-type beaches. Based on the experimental data, a relationship among the breaker height, water depth, and wave period is investigated for various bottom configurations. As a result, the breaker height on non-uniformly sloping beaches is found to be well predicted by substituting an equivalent bottom slope in Goda's breaker index which has been obtained for uniformly sloping beaches. The equivalent bottom slope is defined as the mean slope in the distance of $5h_B$ offshoreward from a breaking point, where h_B denotes the water depth at the breaking point. The method for calculating the breaker height on natural beaches is also presented.

INTRODUCTION

The determination of the breaking point and breaker height is indispensable for planning and designing coastal structures. Theoretical investigations on the limiting wave condition of permanent waves on a horizontal bottom have been extensively done, for example, by Miche (1944), Hamada (1951), Yamada and Shiotani (1968), Schwartz (1974), and Cokelet (1977). However, there seems to be no theoretical treatment for the breaking height on sloping beaches.

Goda (1970) re-analyzed various laboratory data on the breaker height obtained by several researcheres, and proposed a breaker index. For bottom slopes less than 1/50, the index was determined to be coincident with the limiting wave condition presented by Yamada and Shiotani (1968). Since a large number of data were carefully re-analyzed, the breaker index is considered to be sufficiently reliable. However, in applying the index to the waves on non-uniformly sloping beaches such as natural beaches, it is not clear how to determine the representative value of the beach slope. This problem must be solved on the basis of empirical data because no theory adequately describes the breaking condition for such complicated bottom profiles.

** Associate Professor, Ditto

Therefore, we conducted a large number of experiments on the breaker height over non-uniformly sloping beaches. The aims of the experiments are

(1) To investigate the effect of change in bottom slope on breaker height.

(2) To propose a method to evaluate an equivalent bottom slope in order to apply Goda's breaker index to the waves breaking on non-uniformly sloping beaches.

First, the validity of Goda's breaker index is verified for uniformly sloping beaches. It is confirmed that in spite of some scatter in the data, the breaker index agrees well with experimental results. Next, from the measured values of breaker height, water depth and wave period, the apparent values of bottom slope which satisfy the equation of Goda's breaker index are evaluated. Then, the equivalent bottom slopes are approximated by a simple linear equation. The breaker height is estimated by using the equivalent bottom slope in Goda's breaker index, and compared with the experimental data.

EXPERIMENTAL SETUP AND PROCEDURE

The experiments were carried out by using a wave flume of 17m long, 0.6m wide, and 0.55m deep. Various bottom configurations were built in the wave flume by connecting steel segments, each of 1m long. The bottom profile can be changed by adjusting the lengths of columns of steel segments. For each bottom profile, regular waves with period of 0.7s to 1.6s were generated. The total number of cases amount to 670. Wave height was measured by two capacitance wave gages. The breaker point was determined as the point where the wave height was maximum.

EXPERIMENTAL RESULTS

Figure 1 compares Goda's breaker index with the experimental results for uniformly sloping beaches. In the figure, H_B denotes the breaker height, h_B the water depth at the breaking point, Lo ($=gT^2/2\pi$, g: gravitational acceleration, T: wave period) the wavelength of small amplitude waves in deep water, and S the bottom slope. The vertical axis is the breaker height to water depth ratio, H_B/h_B, and the horizontal axis is the relative water depth , h_B/Lo. The solid lines show Goda's breaker index for the bottom slopes of 1/10, 1/20, and 1/30. The open, semiclosed and closed circles denote the experimental data for the slopes of 1/10, 1/20, and 1/30, respectively. Although the experimental data for the slope of 1/10, having some scatter, show smaller values than those of Goda's breaker index, Fig. 1 shows, in general, a good agreement between the breaker index and the experimental data.

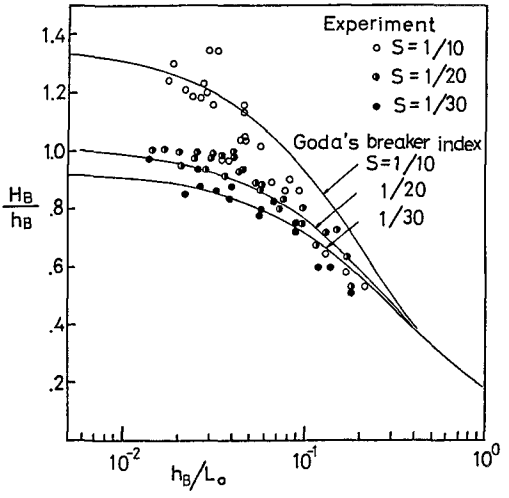

Fig. 1 Breaker index for uniformly sloping beaches.

In case of a step type beach as shown in Fig. 2, Goda's breaker index can not be applied without modification. If the incident wave height is large, the waves may break on the offshore slope S_1. As the incident wave height becomes smaller, the waves tend to break on the onshore slope S_2. In the latter case, the breaker height may be significantly influenced by the offshore slope S_1.

Figure 3 shows the relationship between the breaker height to water depth ratio and the relative water depth for bilinear bottom profiles (offshore slope S_1=1/20, onshore slope S_2=0 for Fig. 3-(a), and S_1=1/20, S_2=1/10 for Fig. 3-(b)). The curves represent Goda's breaker index for the bottom slopes, $S=S_1$ and S_2. The semiclosed circles and triangles in Fig. 3-(a) respectively denote the data for waves breaking on the slopes S_1=1/20 and S_2=0. The semiclosed squares and circles in Fig. 3-(b) respectively show the data for waves breaking on the slopes S1=1/10 and S2=1/20. In spite of some scatter in the data, most of the data lie between the two curves. This implies that the breaker height on the onshore slope is affected by the offshore slope.

In order to estimate the effect of the offshore slope on the breaker height, an equivalent bottom slope was defined and compared with the real slope. The equivalent slope, S^*, is defined as the slope which satisfies Goda's breaker index, which is approximately expressed as (Goda,1975)

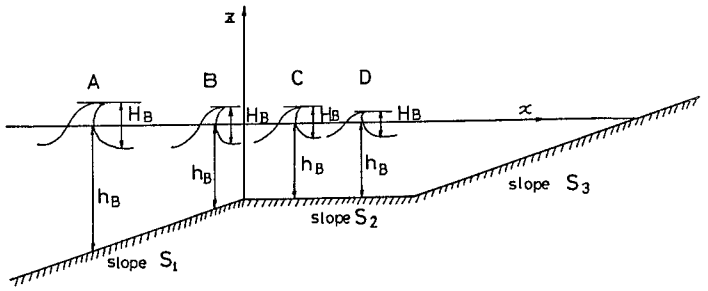

Fig. 2 Wave breaking on a step-type beach.

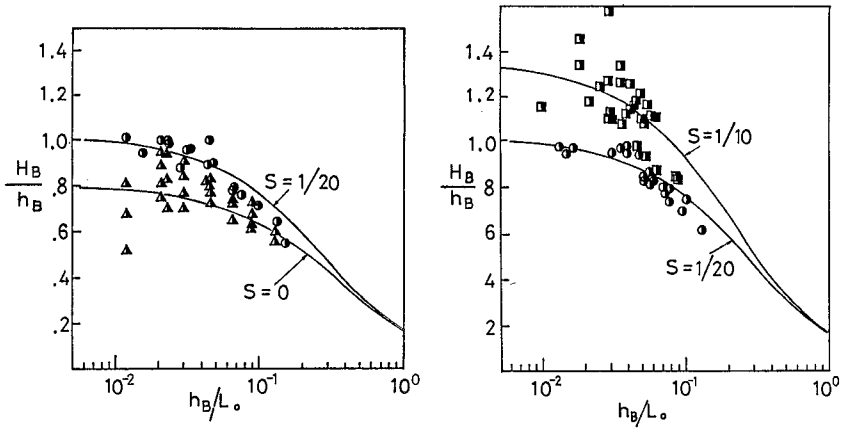

Fig. 3 Breaker index for step-type bottom profiles.

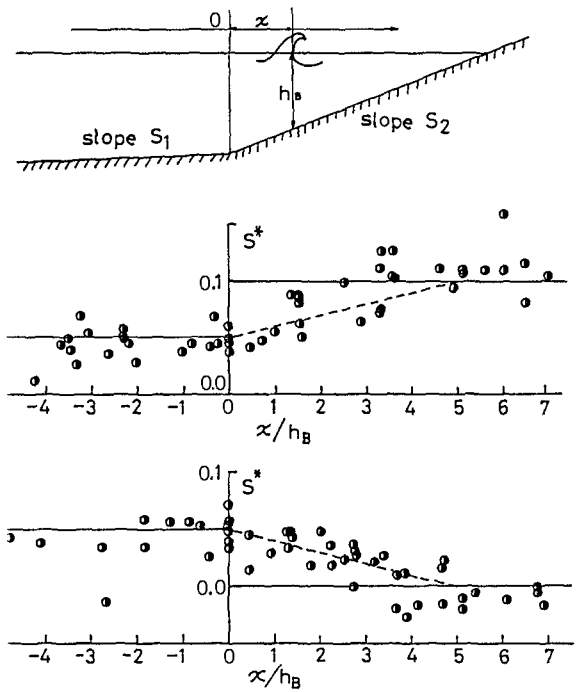

Fig. 4 On-offshore distributions of the equivalent bottom slope.

$$\frac{H_B}{h_B} = A\left\{1-\exp\left[-1.5\frac{\pi h_B}{L_o}(1+15S^{4/3})\right]\right\}\Big/\left(\frac{h_B}{L_o}\right) \qquad (1)$$

where A takes the value of 0.17 for regular waves. From Eq. (1), the equivalent bottom slope, S^*, is expressed by

$$S^* = \left\{-\frac{1}{15}\left[\frac{\ell n\left(1-\frac{1}{A}\frac{H_B}{h_B}\frac{h_B}{L_o}\right)}{1.5\pi(h_B/L_o)}+1\right]\right\}^{3/4} \qquad (2)$$

If we substitute the measured values of H_B, h_B and T into Eq. (2), we obtain a value of the equivalent bottom slope. Fig. 4 shows the on-offshore distribution of the equivalent bottom slope. The axis of the abscissa is normalized by the water depth h_B. A point x=0 is the point where the bottom slope changes. The middle figure is for the slopes of S_1=1/20 and S_2=1/10. The lower figure is for the slopes of S_1=1/20 and S_2=0. For waves breaking on the offshore slope, the values of the

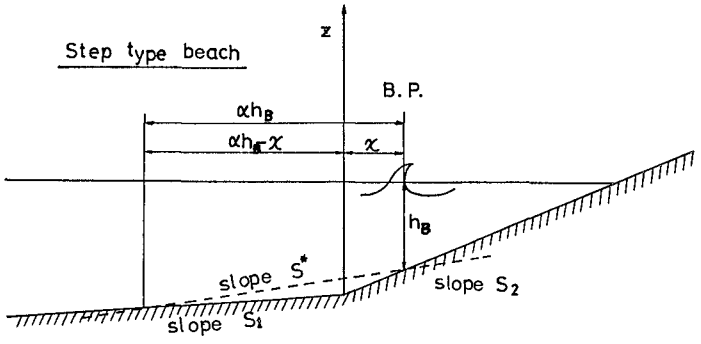
equivalent bottom slope are about 0.05 as an average relation, although there is a some scatter in the data. For waves breaking on the slope S_2 , the values of S^* changes almost linearly with the increase of non-dimensional distance. It is also found that the values of S^* tend to approach the values of actual slope S_2 in the vicinity of the point $x/h_B=5$. This means that for waves breaking onshoreward of the point of $x/h_B=5$, the breaker heights are no longer affected by the offshore slope S_1. In the transition zone, the value of the equivalent bottom slope can be approximated by the linear relationship:

$$S^*=S_1+(S_2-S_1)*x/5h_B \qquad (3)$$

The equivalent bottom slope expressed by Eq. (3) is illustrated by a broken line in Fig. 5. For a bar type beach, if waves break in the trough, the breaker height must be more influenced by the water depth at the top of the bar, h_{min}, than by the breaking water depth. Therefore, h_{min} was used to define the equivalent slope:

$$S^*=\left\{-\frac{1}{15}\left[\frac{\ell n\left(1-\frac{1}{A}\frac{H_B}{h_{min}}\frac{h_{min}}{L_o}\right)}{1.5\pi(h_{min}/L_o)}+1\right]\right\}^{3/4} \qquad (4)$$

If the quantity in the curly brackets in Eq. (4) is negative, the value of S^* should take the opposite sign. It is found that Eq. (1) is nearly satisfied by substituting the equivalent bottom slope even for bar-type beaches. The equivalent bottom slope for a bar-type beach is illustrated by the broken line in Fig. 6.



$$S^*=\frac{(\alpha h_B-x)S_1+xS_2}{\alpha h_B}=\frac{(\alpha-X)S_1+XS_2}{\alpha}$$

$$X=x/h_B \qquad \alpha=5$$

Fig. 5 Definition sketch of the equivalent bottom slope for a step-type beach.

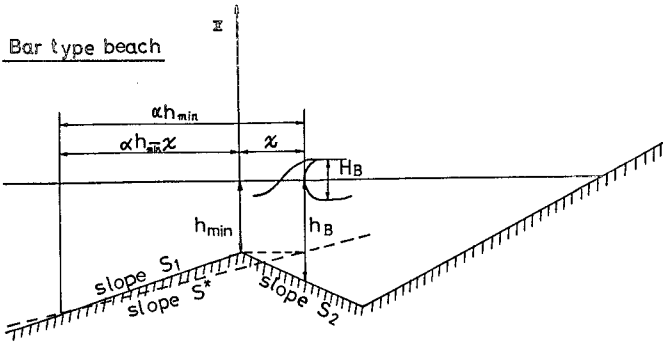


Fig. 6 Definition sketch of the equivalent bottom slope for a bar-type beach.

METHOD FOR CALCULATING BREAKER HEIGHT

On the basis of the above discussion, the method for calculating breaker height is summarized as follows:

(1) For a given site, calculate the mean slope in the range of $5h_B$ distant from that point.

(2) Calculate the breaker height, H_B, using Eq. (1) with use of the water depth, h_B, deepwater wavelength, Lo, and equivalent bottom slope S^*. For a bar-type beach, use the minimum water depth, h_{min} in stead of h_B.

Fig. 7 shows a comparison between the measured and calculated values of the breaker height for step-type beaches. The agreement between them is fairly good. For bar-type beaches, the comparison between them is shown in Fig. 8. The closed circles are for waves breaking on the offshore slope of a bar and the open circles are for waves breaking on the anti-slope of a bar. These figures show that the breaker height is well predicted by the present model.

For a natural beach, the procedure for calculating the breaker height is essentially the same as the procedure stated above. The schematic illustration is shown in Fig. 9.

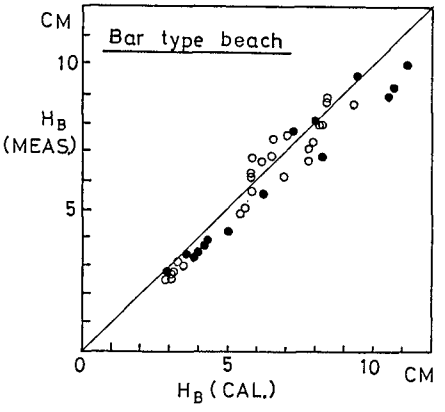

Fig. 8 Comparison between the measured and calculated values of breaker height for bar-type beaches.

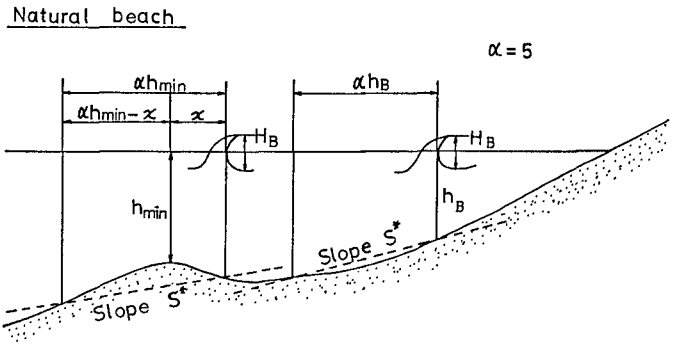

Fig. 9 Definition sketch of the equivalent bottom slope for a natural beach

CONCLUDING REMARKS

A large number of experiments were carried out in order to obtain a breaking criterion on non-uniformly sloping beaches. From the measured breaker height, water depth, and wave period, the equivalent bottom slope was evaluated by using Goda's breaker index. The spatial change of the equivalent bottom slope was examined; then it was found that the equivalent bottom slope can be determined as the mean slope in the distance of five times the water depth from a breaking point. Therefore, the breaker height on a non-uniformly sloping beach, can be predicted by substituting the equivalent bottom slope in Goda's breaker index. However, the applicability of the present model is limited because all of the data were obtained from laboratory experiments with monochromatic waves. Therefore, additional verification is necessary for irregular waves breaking on a natural beach.

ACKNOWLEDGEMENT

The authors would like to express their thanks to Mr. H. Saotome (Penta Ocean Co. Ltd.) and Mr. K. Tachibana(Pasuko Co. Ltd.) for the assistance in the laboratory experiments.

CHAPTER 26

Applications on Non-linear Wave Combination

J.T. Juang*

Due to the special bathymetry in Taiwan Strait, the waves off the western coast of Taiwan are considered to be composed of two-source wave system. One propagates from the central part of the Strait named main wave, and the other is generated by the local wind known as local wave which occurs along the shore. After the combination and the transformation procedure from these two-nonlinear-source wave system, the wave height distribution in Taiwan Strait should be modified. A comparison of the wave height distributions based on the present proposed method with the field data indicates that the present method yields a better result than other theorems. Furthermore, the result of application of two non-linear wave theorem to wave prediction are also presented.

Introduction

In a previous paper[11], the author proposed a theoretical expression for the wave height distribution, which was combined by using two linear source-wave system. At about the same time, Chen et.al.[1] investigated the effect of nonlinearity on the distributions of surface elevation and wave heights of random sea. In that study, it was found that the wave height distribution is effected by wave steepness and the tendencies biased toward the left and peaked toward the middle from Rayleigh distribution ($\delta_r=0$) as the value of nonlinear factor δ_r increases. Longuet-Higgins[7] also proposed a wave height distribution which was based on the joint distribution of wave periods and amplitudes in a random wave field. His wave height distribution was affected by the well-known spectral width parameter. Both of their approaches are based on single non-linear wave theorem. However, for the case where the sea wave is composed of different source-wave system, its wave height distribution should be changed. Therefore, following the same procedures as described in[11] , a two non-linear wave combination theorem was proposed.

Non-linear waves combination

According to the single non-linear wave theorem [1], the wave height distribution can be calculated by the following formula:

*Asso. Prof., Dept. of Civil Engineering, National Central University, Chung-li City, Taiwan, Rep. of China.

$$P(H)=\frac{\pi}{2}D_0^2\cdot H\cdot\left[1+\frac{D_2}{4}\cdot H^2+\left(\frac{3}{64}D_4+\frac{D_2^2}{128}\right)H^4+\frac{1}{512}D_2D_4\cdot H^6\right.$$

$$\left.+\frac{3}{32768}D_4^2\cdot H^8\right]\cdot\exp\left(-\frac{H^2}{8\overline{\zeta^2}}\right) \qquad \cdots\cdots(1)$$

In the above formula, the values of the coefficients D_i, which are functions of the root-mean-sguare of the wave steepness δ_r, are:

$$D_0=\frac{1}{\sqrt{2\pi\overline{\zeta^2}}}\left[\frac{5}{8}+\frac{1}{8}\cdot\frac{3+8(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\right]^2}{\left\{1+(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\right]^2\right\}^2}\right] \qquad \cdots\cdots(2)$$

$$D_1=-\frac{6\sqrt{2\pi}}{(\overline{\zeta^2})^{1/2}}\cdot\frac{\frac{3}{8}(\pi\delta_r)\left[1-(\pi\delta_r)^2\right]+\frac{1}{4}(\pi\delta_r)^3\left[1-(\pi\delta_r)^2\right]^3}{5+\frac{3+8(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\right]^2}{\left\{1+(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\right]^2\right\}^2}}$$

$$\cdot\frac{1}{\left\{1+(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\left[1-\pi\delta_r)^2\right]^2\right\}^{3/2}} \qquad \cdots\cdots(3)$$

$$D_2=-\frac{2}{\overline{\zeta^2}}\cdot(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\right]^2\left\{2-3(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\right]^2\right\}$$

$$/\left[5+\frac{3+8(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\right]^2}{\left\{1+(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\right]^2\right\}^2}\right]\cdot\left\{1+(\pi\delta_r)^2\left[1-(\pi\delta_r)^2\right]^2\right\}^2 \cdots(4)$$

$$D_3=-\frac{D_1}{3\overline{\zeta^2}} \qquad \cdots\cdots(5)$$

$$D_4=\frac{D_2}{6\overline{\zeta^2}} \qquad \cdots\cdots(6)$$

From the above eguation, it can be found that as soon as δ_r approaches to zero, the distribution of the wave height will become Rayleigh's.

However, when the combination of two non-linear waves are considered, the above equation can be modified as

$$P(H)=u_{1,i}\cdot H\cdot\exp\left(-\frac{H^2}{u_{6,i}}\right)+u_{2,i}\cdot H^3\cdot\exp\left(-\frac{H^2}{u_{6,i}}\right)$$

$$+u_{3,i}\cdot H^5\cdot\exp\left(-\frac{H^2}{u_{6,i}}\right)+u_{4,i}\cdot H^7\cdot\exp\left(-\frac{H^2}{u_{6,i}}\right)$$

$$+u_{5,i}\cdot H^9\cdot\exp\left(-\frac{H^2}{u_{6,i}}\right) \qquad \cdots\cdots(7)$$

$$u_{1,i} = \frac{\pi}{2} D_{0,i}^2 \qquad \cdots\cdots(8)$$

$$u_{2,i} = \frac{1}{4} D_{2,i}^2 \cdot u_{1,i} \qquad \cdots\cdots(9)$$

$$u_{3,i} = \left(\frac{3}{64} D_{4,i} + \frac{D_{2,i}^2}{128}\right) \cdot u_{1,i} \qquad \cdots\cdots(10)$$

$$u_{4,i} = \frac{1}{512} D_{2,i} \cdot D_{4,i} \cdot u_{1,i} \qquad \cdots\cdots(11)$$

$$u_{5,i} = \frac{3}{32768} D_{4,i}^2 \cdot u_{1,i} \qquad \cdots\cdots(12)$$

$$u_{6,i} = 8\overline{\zeta_i^2} \qquad \cdots\cdots(13)$$

In the above formulas, $U_{1,i}, U_{2,i}, \ldots, U_{5,i}$ are the coefficients and $U_{6,i}$ are the wave energy of these two-sour-ce waves where i=1 stands for the refracted wave and i=2 represents the local wave.

Since the wave energy is proportional to the square of the wave height, we have

$$y = H^2 \quad , \quad dy = 2HdH \quad , \quad \frac{dH}{dy} = \frac{1}{2H}$$

After transformation from eq.(7), the distribution of wave energy becomes

$$P(y) = \frac{dH}{dy} P(H) = \frac{1}{2\sqrt{y}} \cdot P(H)$$

$$= \frac{u_1}{2} \exp\left(-\frac{y}{u_6}\right) + \frac{u_2}{2} y \cdot \exp\left(-\frac{y}{u_6}\right) + \frac{u_3}{2} \cdot y^2$$

$$\cdot \exp\left(-\frac{y}{u_6}\right) + \frac{u_4}{2} \cdot y^3 \cdot \exp\left(-\frac{y}{u_6}\right) + \frac{u_5}{2} \cdot y^4 \cdot \exp\left(-\frac{y}{u_6}\right) \cdots\cdots(14)$$

Under the assumption that the total energy of the combined wave is the sum of the energy of the wave associated with each source, that is,

$$z = y_1 + y_2 \qquad y_2 = z - y_1$$

the Jacobian of this transformation is

$$|J| = \begin{vmatrix} \frac{\partial y_2}{\partial z} & \frac{\partial y_2}{\partial y_1} \\ \frac{\partial y_1}{\partial z} & \frac{\partial y_1}{\partial y_1} \end{vmatrix} = \begin{vmatrix} 1 & -1 \\ 0 & 1 \end{vmatrix} = 1$$

The energy distribution for the refracted and the local wave can then be found, respectively, as

$$P(y_1) = \left[\frac{u_{1,1}}{2} + \frac{u_{2,1}}{2} y_1 + \frac{u_{3,1}}{2} \cdot y_1^2 + \frac{u_{4,1}}{2} \cdot y_1^3 + \frac{u_{5,1}}{2} \cdot y_1^4\right] \cdot \exp\left(-\frac{y_1}{u_{6,1}}\right) \cdots (15)$$

$$P(y_2) = \left[\frac{u_{1,2}}{2} + \frac{u_{2,2}}{2} \cdot y_2 + \frac{u_{3,2}}{2} \cdot y_2^2 + \frac{u_{4,2}}{2} \cdot y_2^3 + \frac{u_{5,2}}{2} \cdot y_2^4\right] \cdot \exp\left(-\frac{y_2}{u_{6,2}}\right) \cdots (16)$$

Since both distributions are mutually independent, we can obtain

$$P(z, y_1) = P(y_1, y_2) \cdot |J| = P(y_1) \cdot P(y_2) = P(y_1) \cdot P(z - y_1)$$

$$P(z) = \int_0^z P(z, y_1)\, dy_1 = \int_0^z P(y_1) \cdot P(z - y_1) \cdot dy_1 \quad \cdots (17)$$

Substituting equs.(15) and (16) into eq.(17), we have

$$P(z) = \int_0^z \left[\frac{u_{1,1}}{2} + \frac{u_{2,1}}{2} \cdot y_1 + \frac{u_{3,1}}{2} \cdot y_1^2 + \frac{u_{4,1}}{2} \cdot y_1^3 + \frac{u_{5,1}}{2} \cdot y_1^4\right]$$

$$\cdot \left[\frac{u_{1,2}}{2} + \frac{u_{2,2}}{2} \cdot y_2 + \frac{u_{3,2}}{2} \cdot y_2^2 + \frac{u_{4,2}}{2} \cdot y_2^3 + \frac{u_{5,2}}{2} \cdot y_2^4\right]$$

$$\cdot \exp\left[-\frac{y_1}{u_{6,1}} - \frac{y_2}{u_{6,2}}\right] \cdot dy_1$$

$$= \int_0^z A_1 \cdot A_2 \cdot \exp\left(-\frac{z}{u_{6,2}}\right) \cdot \exp(u \cdot y_1) \cdot dy_1 \quad \cdots (18)$$

$$A_1 = \frac{u_{1,1}}{2} + \frac{u_{2,1}}{2} \cdot y_1 + \frac{u_{3,1}}{2} \cdot y_1^2 + \frac{u_{4,1}}{2} \cdot y_1^3 + \frac{u_{5,1}}{2} \cdot y_1^4 \quad \cdots (19)$$

$$A_2 = B_1 - B_2 \cdot y_1 + B_3 \cdot y_1^2 - B_4 \cdot y_1^3 + B_5 \cdot y_1^4 \quad \cdots (20)$$

$$u = \frac{u_{6,1} - u_{6,2}}{u_{6,1} \cdot u_{6,2}} \quad \cdots (21)$$

$$B_1 = \frac{1}{2}(u_{1,2} + u_{2,2} \cdot z + u_{3,2} \cdot z^2 + u_{4,2} \cdot z^3 + u_{5,2} \cdot z^4) \quad \cdots (22)$$

$$B_2 = \frac{1}{2}\left(u_{2,2} + 2u_{3,2} \cdot z + 3u_{4,2} \cdot z^2 + 4u_{5,2} \cdot z^3 \right) \quad \cdots\cdots(22)$$

$$B_3 = \frac{1}{2}\left(u_{3,2} + 3u_{4,2} \cdot z + 6u_{5,2} \cdot z^2 \right) \quad \cdots\cdots(24)$$

$$B_4 = \frac{1}{2}\left(u_{4,2} + 4u_{5,2} \cdot z \right) \quad \cdots\cdots(25)$$

$$B_5 = \frac{1}{2} u_{5,2} \quad \cdots\cdots(26)$$

$$\begin{aligned} A_1 \cdot A_2 = & \frac{1}{2}\left[u_{1,1} + u_{2,1} \cdot y_1 + u_{3,1} \cdot y_1^2 + u_{4,1} \cdot y_1^3 + u_{5,1} \cdot y_1^4 \right] \\ & \cdot \left[B_1 - B_2 \cdot y_1 + B_3 \cdot y_1^2 - B_4 \cdot y_1^3 + B_5 \cdot y_1^4 \right] \\ = & c_1 + c_2 \cdot y_1 + c_3 \cdot y_1^2 + c_4 \cdot y_1^3 + c_5 \cdot y_1^4 + c_6 \cdot y_1^5 \\ & + c_7 \cdot y_1^6 + c_8 \cdot y_1^7 + c_9 \cdot y_1^8 \end{aligned} \quad \cdots\cdots(27)$$

$$c_1 = \frac{1}{2}\left(u_{1,1} \cdot B_1 \right)$$

$$c_2 = \frac{1}{2}\left(u_{2,1} \cdot B_1 - u_{1,1} \cdot B_2 \right)$$

$$c_3 = \frac{1}{2}\left(u_{3,1} \cdot B_1 - u_{2,1} \cdot B_2 + u_{1,1} \cdot B_3 \right)$$

$$c_4 = \frac{1}{2}\left(u_{4,1} \cdot B_1 - u_{3,1} \cdot B_2 + u_{2,1} \cdot B_3 - u_{1,1} \cdot B_4 \right)$$

$$c_5 = \frac{1}{2}\left(u_{5,1} \cdot B_1 - u_{4,1} \cdot B_2 + u_{3,1} \cdot B_3 - u_{2,1} \cdot B_4 + u_{1,1} \cdot B_5 \right)$$

$$c_6 = -\frac{1}{2}\left(u_{5,1} \cdot B_2 - u_{4,1} \cdot B_3 + u_{3,1} \cdot B_4 - u_{2,1} \cdot B_5 \right)$$

$$c_7 = \frac{1}{2}\left(u_{5,1} \cdot B_3 - u_{4,1} \cdot B_4 + u_{3,1} \cdot B_5 \right)$$

$$c_8 = -\frac{1}{2}\left(u_{5,1} \cdot B_4 - u_{4,1} \cdot B_5 \right)$$

$$c_9 = \frac{1}{2}\left(u_{5,1} \cdot B_5 \right) \quad \cdots\cdots(28)$$

Substituting eq.(27) into eq.(18), we have

$$\begin{aligned} P(z) = e^{\left(-\sqrt{u_{6,2}}\right)\cdot} \{ & c_1 \int_0^z e^{(u \cdot y_1)}\, dy_1 + c_2 \int_0^z y_1 \cdot e^{(u \cdot y_1)} \cdot dy_1 \\ & + c_3 \int_0^z y_1^2 \cdot e^{(u \cdot y_1)} \cdot dy_1 + c_4 \int_0^z y_1^3 \cdot e^{(u \cdot y_1)} \cdot dy_1 \end{aligned}$$

$$+c_5\int_0^z y_1^4\cdot e^{(u\cdot y_1)}\cdot dy_1+c_6\int_0^z y_1^5\cdot e^{(u\cdot y_1)}\cdot dy_1+c_7\int_0^z y_1^6\cdot e^{(u\cdot y_1)}\cdot dy_1$$

$$+c_8\int_0^z y_1^7\cdot e^{(u\cdot y_1)}\cdot dy_1+c_9\int_0^z y_1^8\cdot e^{(u\cdot y_1)}\cdot dy_1\} \qquad \cdots\cdots\cdots\cdots(29)$$

$$\int_0^z e^{(u\cdot y_1)}dy_1=\frac{e^{uz}}{u}-\frac{1}{u}$$

$$\int_0^z y_1\cdot e^{(u\cdot y_1)}dy_1=\frac{e^{uz}}{u^2}(uz-1)+\frac{1}{u^2}$$

$$\int_0^z y_1^2\cdot e^{(u\cdot y_1)}\cdot dy_1=\frac{e^{uz}}{u^3}(u^2z^2-2uz+2)-\frac{2}{u^3}$$

$$\int_0^z y_1^3\cdot e^{(u\cdot y_1)}\cdot dy_1=\frac{e^{uz}}{u^4}(u^3z^3-3u^2\cdot z^2+6uz-6)+\frac{6}{u^4}$$

$$\int_0^z y_1^4\cdot e^{(u\cdot y_1)}\cdot dy_1=\frac{e^{uz}}{u^5}(u^4\cdot z^4-4u^3\cdot z^3+12u^2\cdot z^2-24u\cdot z+24)-\frac{24}{u^5}$$

$$\int_0^z y_1^5\cdot e^{(u\cdot y_1)}\cdot dy_1=\frac{e^{uz}}{u^6}(u^5\cdot z^5-5u^4\cdot z^4+20u^3z^3-60u^2\cdot z^2+120uz-120)+\frac{120}{u^6}$$

$$\int_0^z y_1^6\cdot e^{(u\cdot y_1)}\cdot dy_1=\frac{e^{uz}}{u^7}(u^6\cdot z^6-6u^5\cdot z^5+30u^4\cdot z^4-120u^3\cdot z^3+360u^2\cdot z^2$$

$$-720uz+720)-\frac{720}{u^7}$$

$$\int_0^z y_1^7\cdot e^{(u\cdot y_1)}\cdot dy_1=\frac{e^{uz}}{u^8}(u^7\cdot z^7-7u^6z^6+42u^5z^5-210u^4\cdot z^4+840u^3\cdot z^3$$

$$E_4=u_{5,1}\cdot u_{1,2}+\frac{1}{u}(u_{5,1}\cdot u_{2,2})+\frac{2}{u^2}(u_{5,1}\cdot u_{3,2})-\frac{54}{u^3}(u_{5,1}\cdot u_{4,2})$$

$$-\frac{1656}{u^4}(u_{5,1}\cdot u_{5,2})+\frac{1680}{u^7}(u_{5,1}\cdot u_{5,2}) \quad \cdots\cdots(39)$$

$$F_4=u_{1,1}\cdot u_{5,2}-\frac{1}{u}(u_{2,1}\cdot u_{5,2})+\frac{2}{u^2}(u_{3,1}\cdot u_{5,2})-\frac{6}{u^3}(u_{4,1}\cdot u_{5,2})$$

$$+\frac{24}{u^4}(u_{5,1}\cdot u_{5,2}) \quad \cdots\cdots(40)$$

$$E_5=\frac{336}{u^3}\cdot u_{5,1}\cdot u_{5,2}-\frac{336}{u^7}u_{5,1}\cdot u_{5,2} \quad \cdots\cdots(41)$$

$$E_6=-\frac{56}{u^2}u_{5,1}\cdot u_{5,2}+\frac{56}{u^7}u_{5,1}\cdot u_{5,2} \quad \cdots\cdots(42)$$

$$E_7=\frac{8}{u}u_{5,1}\cdot u_{5,2}-\frac{8}{u^7}u_{5,1}\cdot u_{5,2} \quad \cdots\cdots(43)$$

$$E_8=-u_{5,1}\cdot u_{5,2}+\frac{1}{u^7}u_{5,1}\cdot u_{5,2} \quad \cdots\cdots(44)$$

Since $Z=H^2$ and $dZ=2HdH$, the combined wave height distribution is proposed as

$$P(H)=\frac{dz}{dH}P(z)$$

$$= \frac{H}{2u} \{ (E_0 + E_1 \cdot H^2 + E_2 \cdot H^4 + E_3 \cdot H^6 + E_4 \cdot H^8 + E_5 \cdot H^{10} + E_6 \cdot H^{12} + E_7 \cdot H^{14} + E_8 \cdot H^{16}) \cdot e^{(-H^2/u_{6,1})} - (E_0 + F_1 \cdot H^2 + F_2 \cdot H^4 + F_3 \cdot H^6 + F_4 \cdot H^8) \cdot e^{(-H^2/u_{6,2})} \} \quad \cdots\cdots (45)$$

Comparison with the measured data and the other theorems

In a study of non-linear wave height distribution, Longuet-Higgins [7] proposed a probability density function from the joint distribution of wave periods and amplitudes in a random wave field as

$$P(x) = 2x \cdot \exp(-x^2) \cdot N(\nu) \cdot F(x/\nu) \quad \cdots\cdots (46)$$

$$F(x/\nu) = \frac{1}{\sqrt{\pi}} \int_{-\infty}^{x/\nu} \exp(-\beta^2)\, d\beta \qquad (\text{error function}) \quad \cdots\cdots (47)$$

Where $x = H/H_r$, ν is a spectral width parameter; $N(\nu)$ is a normalization factor.

In a similar study, Chen et. al.[1] applied non-linear effect wave theory to obtain a dimensionless wave height distribution.

Comparison between the wave height distributions computed from the above-mentioned formulas and the field data is shown in Fig.1. It indicates that the present proposed method yields a better result.

Application

In order to apply the non-linear wave combination theorem to the prediction of wave in Taiwan Strait, the weather forecasting data, such as the weather chart, wind velocity and its direction must be available. Then, the prediction of wave can be completed using the following steps.

1. Waves from the East China Sea and Taiwan Strait are evaluated by Liang's [4] element wave prediction model.
2. The local wave height is computed by Tang's[9] shallow water wave prediction formula.
3. Since the wave steepness of two-source wave system can be calculated independently, the distribution of wave height of the combined wave using two non-linear wave combination theorem could be obtained.

The preliminary result of this prediction model is shown in Fig.2. It can be found that the results obtained by the non-linear two-source wave system are in agreement with those obtained by the two-linear source-wave system

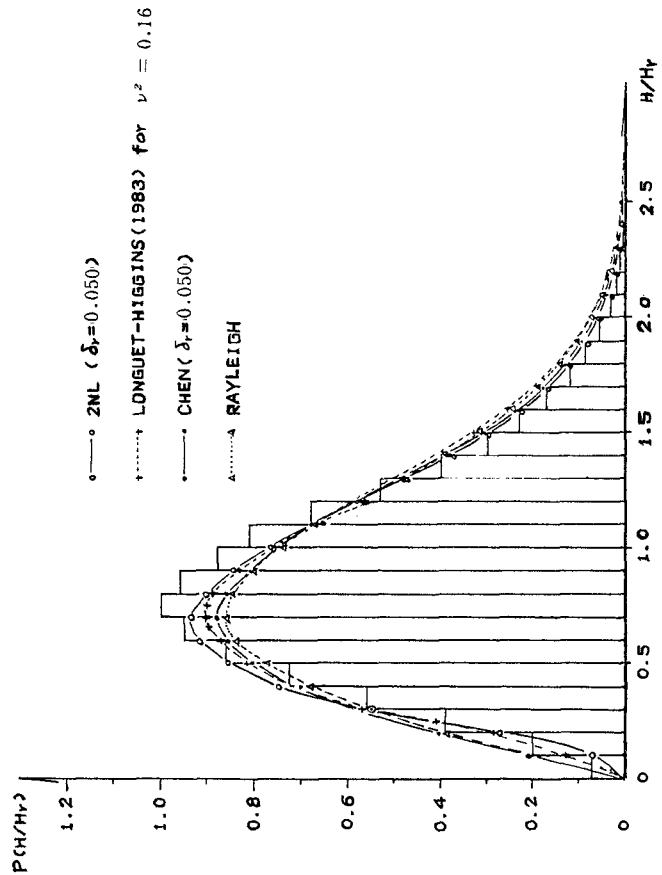

Fig.1 Comparison of the wave height distributions

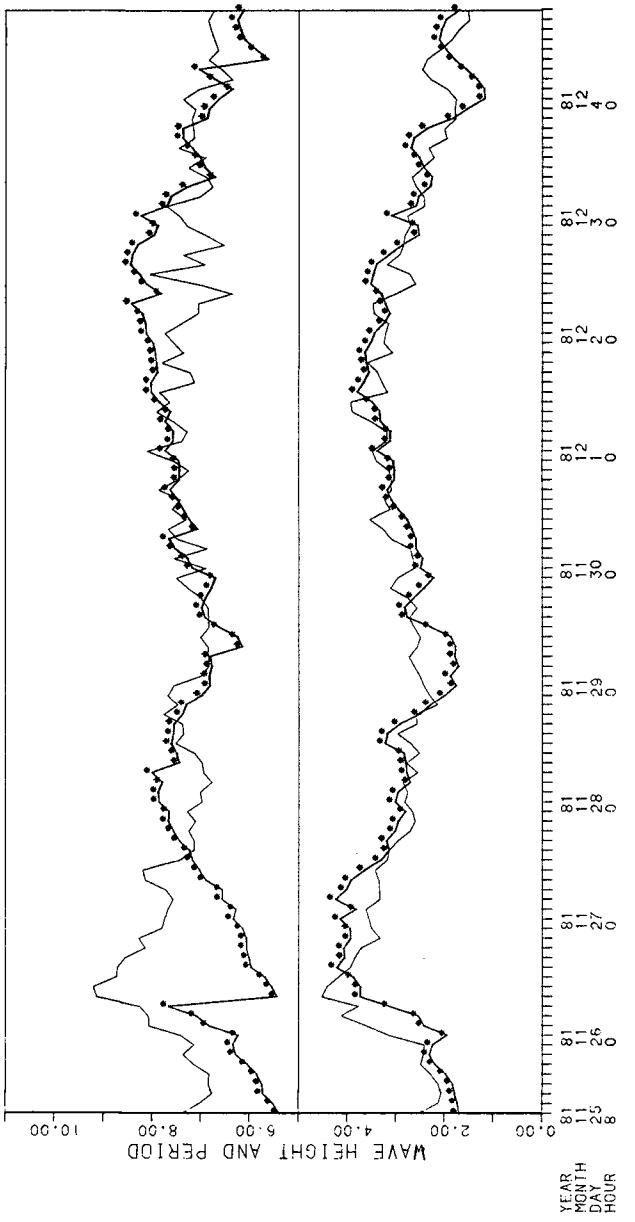

Fig.2 Results of wave prediction

including the energy loss effect. This implies that the higher-order terms in the non-linear two-source wave system are related to the energy loss.

Conclusion

In this study, the distribution of wave-height for two nonlinear source wave system is proposed, which yields the same result as those of two linear source-wave system as the wave steepness approaches zero.

From the field data, it was found that due to wave-wave interaction, some of the short-period wave will disappear which causes the mean wave height to increase and the maximum wave height to decrease. The proposed distribution can describe such a phenomenum.

Finally, it should be pointed out that although the proposed model is slightly complicated, as compared with that proposed by Chen et. al., the model is still simple to use and the computational effort does not increase significantly.

CHAPTER 27

Measurements from a fast-moving air-cushion platform

P. Kerckaert *
A. Grobben **
P. De Candt ***

Abstract

In 1976 the Belgian Government decided to enlarge the harbour of Zeebrugge and to execute an artificial beach renourishment on the beaches at Knokke-Heist. A comprehensive survey program along the 24 km coastline was conceived using remote sensing techniques. This enabled correct momentary recordings of the beach areas, the production of differential charts and calculations of dune and beach volumes. However, the observations of the nearshore and offshore areas from ordinary survey vessels take too long so that no accurate momentary recordings of the seabottom topography can be achieved. On these grounds, in 1983, the Belgian Authorities have instructed the Eurosense Belfotop Company to develop an effective measuring method based on the use of a hovercraft.

This hovercraft platform, named "BEASAC" and designed for hydrographic surveys, is now used for monitoring the coastal morphology and the dredging activities in the access channels to the major Belgian seaports. On the basis of the "Beasac"-soundings of the nearshore area and the aerial remote sensing data of the beach, charts and differential charts of the combined beach and nearshore area are produced.

The results of this technique are very promising and will be incorporated in the further survey programs ordered by the Belgian Authorities as a substitute for the classic bathymetric vessel soundings.

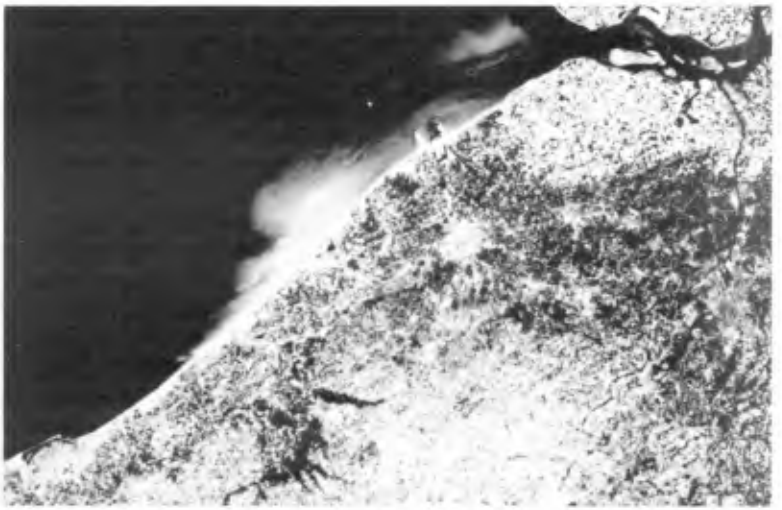
1. Introduction

As already reported in former conferences and technical papers, the Belgian authorities have always paid special attention to efficient shore protection of the Belgian East Coast (ref. 1,2). Picture 1 shows a Landsat-satellite picture of the Belgian Coast and the seaward side of the Westerscheldt estuary in 1984. Significant sediment movements are clearly visible around the harbour extension of the port of Zeebrugge. The Belgian East Coast is situated in the area between Blankenberge (4 km west of Zeebrugge) and the Belgian-Dutch border (10 km east of Zeebrugge).



Picture 1 : satellite picture of the Belgian Coast and the Western Scheldt Estuary

The reason for the coastal protection of the Belgian East Coast is obvious : for several decades the alarming regression of the shoreline on those beaches has offered a real threat to the important tourist and residential resorts of the city of Knokke-Heist and the nature reserve "Het Zwin".

Two phenomena are the main causes for this evolution (see figure 1). First of all in front of the beaches at Knokke-Heist a gully called the "Appelzak" with a depth of about 8 m under low water level developed to within a distance of 500 m of the seawall causing important beach erosion via offshore transport. Moreover the port of Zeebrugge - built at the turn of the century - intersected the easterly flow of longshore drift so that the incoming sediment was not sufficient for natural beach replenishment.

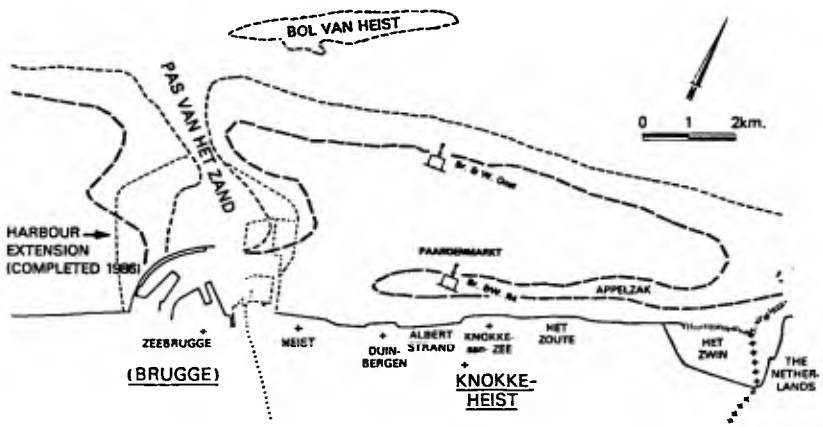


Fig. 1. : The Belgian East Coast : General Situation in 1976.

As a result, a strip of beach of only 50 to 100 m remained available in front of the seawall at low tide and the beaches disappeared nearly completely at high tide. Storms damaged the seawall on several occasions so that coastal protection works became very urgent. Picture 2 illustrates very clearly the precarious situation before 1976 when during storms, waves could overtop the existing sea-dike.

Picture 2 : During storms, waves overtop the existing sea-dike (winter 1975)

2. Coastal protection works

In 1976 the Belgian Government decided to enlarge the harbour at Zeebrugge. This included the construction of new breakwaters extending approximately 3,5 km into the sea from the existing seawall. Picture 3 gives an overall view of the harbour extension; behind them : the East Coast beaches. From the start the new expansion works of the outer Zeebrugge harbour were considered as a possible supplementary threat to the East Coast beaches. Therefore, and after a comprehensive study of the problem, it was decided to execute preventative coastal protection works on the beaches at Knokke-Heist starting at the same time with the harbour extension.

Picture 3 : The new outer harbour at Zeebrugge (1986)

In 1977 the decision was taken to execute an artificial beach renourishment of about 8,4 millions m^3 of coarse dredged sea sand. This work was completed between December 1977 and March 1979. As a result a new beach with the width of about 100 m at high tide was created. Picture 4 shows clearly the newly created beaches at Knokke-Heist. In comparison with the previous situation in 1976, the positive result is spectacular. In order to observe the evolution of the restored beaches, a comprehensive survey program along the 24 km coastline was conceived and started in june 1979. This was particularly important with regard to the influence on the beaches of the harbour extension works.

Picture 4 : Beaches at Knokke-Heist after beach renourishment

3. Coastal survey techniques

The aim of this paper is to give more details upon an important new development in the survey technique which was invented and applied to the considered coastal area. First of all it is important to know that an important contribution to the survey program was given by remote sensing techniques. This means the use of a specially conceived aeroplane, equipped with the most sophisticated cameras and multispectral scanners. These instruments are necessary in order to collect all the necessary data and to treat them by means of stereoscopic techniques. The results are then stored and ranged by specially developed computer software. The advantages of this method are obvious : speed and accuracy of measurement, the ability to provide easily assimilated results (i.e. differential charts and calculations of beach surfaces and volumes) and last but not least a correct momentary recording of a large area of observation.

In this way differential charts of the east coast beaches resulting from two aerial observations were made giving erosion and/or acretion areas.

So far, aerial remote sensing techniques in coastal engineering have been mostly limited to surface observations above the low water level especially in muddy or silty seawater areas. Sedimentological processes are however not solely restricted to the beach area itself. Important morphological phenomena occur offshore and cannot be reached by aerial remote sensing techniques. These offshore areas are even of a larger extend than the beach area and need other solutions in order to detect e.g. longshore and tidal transport.

Until now, the observation of the seabottom morphology was performed from classic bathymetric vessels. However, these vessels possess two essential disadvantages. In many cases the bathymetric soundings cannot be performed close enough to the beach so that the link with aerial remote sensing data of the beach is difficult to achieve or even impossible. Moreover, in practice, the observations from an ordinary survey vessel take too long - sometimes several months for one area - so that no accurate momentary recording of the seabottom topography can be achieved as the beginning and the end of the observations are difficult to compare.

This can result into mistakes; especially in coastal areas with rapidly changing morphological conditions. Only the use of a fast moving survey platform , capable of reaching the most shallow waters can provide an effective solution.

On these grounds, in 1983, the Belgian Authorities have instructed the Eurosense Belfotop Company to develop an effective measuring method based on the use of a hovercraft.

4. The "BEASAC"-platform

Picture 5 gives a general view of the new hydrographic measuring system, named "BEASAC".
"BEASAC" is the acronym for "Belfotop Eurosense Acoustic Sounding Air Cushion" platform.

Picture 5 : The BEASAC-platform

Although the idea to use a hovercraft for hydrographic purposes is not new, earlier attemps encountered numerous difficulties. Nevertheless the demand for hovercraft in surveying is likely to increase significantly. A first problem to be solved is the realisation of an accurate positioning system, not only with regard to the horizontal coordinates but also for the vertical location with respect to a fixed datum. Furthermore the speed of the craft leads to registration and treatment of a great amount of data, which is only feasable using special computer techniques. Finally, the craft had to be equipped as a reliable, fast and manoeuvrable high speed survey vessel.

An extended test program was set up and realised. The accuracy of the depth measurements in shallow water was checked by the terrestrial surveying of control points in the tidal zone between high and low water. The deviations between both methods were, on average, less than 10 centimers and consequently acceptable.

5. Combined charts of beach and nearshore area

On the basis of the aerial remote sensing data of beach topography and the BEASAC-platform soundings of the nearshore area a chart showing the combined beach and nearshore area was realised. Differential recordings of this total area, above and beneath the low water level line are easy to produce and give a much better insight into the morphological changes of the coastal area.

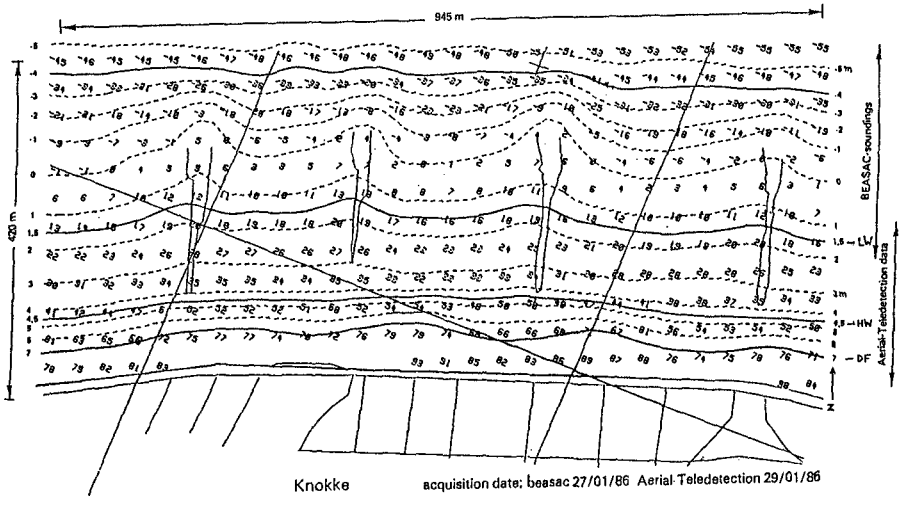

Fig. 2. : Combined chart of remote sensing and BEASAC data

Figure 2 shows the very first combined relief map realised with both aerial remote sensing techniques and Beasac soundings. The difference in data between the two methods in the overlap zone is only 10 centimeters on average.

In this way, charts of the total area east of the Zeebrugge harbour were made by a combination of remote sensing and Beasac data. While this area was normally covered by classic bathymetric vessels over a period of two to three months, it is now done by the BEASAC-platform in four to six days. Such a map can be produced on regular basis and accurate differential charts become also possible now.

After the execution of the test program, the newly developed sounding platform was accepted by the Belgian Authorities. It is now used to observe the beaches and nearshore areas of the Belgian Coast.

6. Control and monitoring surveys

The advantages of a fast moving survey platform are also obvious in other applications such as : the control and monitoring of dredging activities, and the monitoring and charting of large remote oceanographic territories. The accuracy of the measurements effected at high speeds of up to 50 km/h, in large areas such as open sea channels or sand bank configurations, was checked by classic bathymetric soundings from an hydrographic vessel. Under normal conditions the difference between both methods is less than 20 centimeters.

In this manner the Beasac platform is successfully employed for monitoring the evolution of the access channels to the major Belgian seaports, and for supervising the extensive dredging operations at these locations. The major advantages of the Beasac-system - namely the fast moving and accurate soundings - have proved to be important assets in observing and controlling sedimentological and dredging processes. More frequent charting allows evaluation of the need for, and the effectiveness of, dredging operations.

Figure 3 shows a nautical chart with absolute depth values realised with the BEASAC-platform. The represented zone is the entrance channel to the new outer harbour of Zeebrugge.

Differential depth charts of the the same area between two Beasac observation campaigns are also produced. These charts are very useful to monitor dredging operations.

The newly developed air cushion platform can indeed be considered as an important contribution towards more accurate and economical observations of morphological processes both natural and/or artificial.

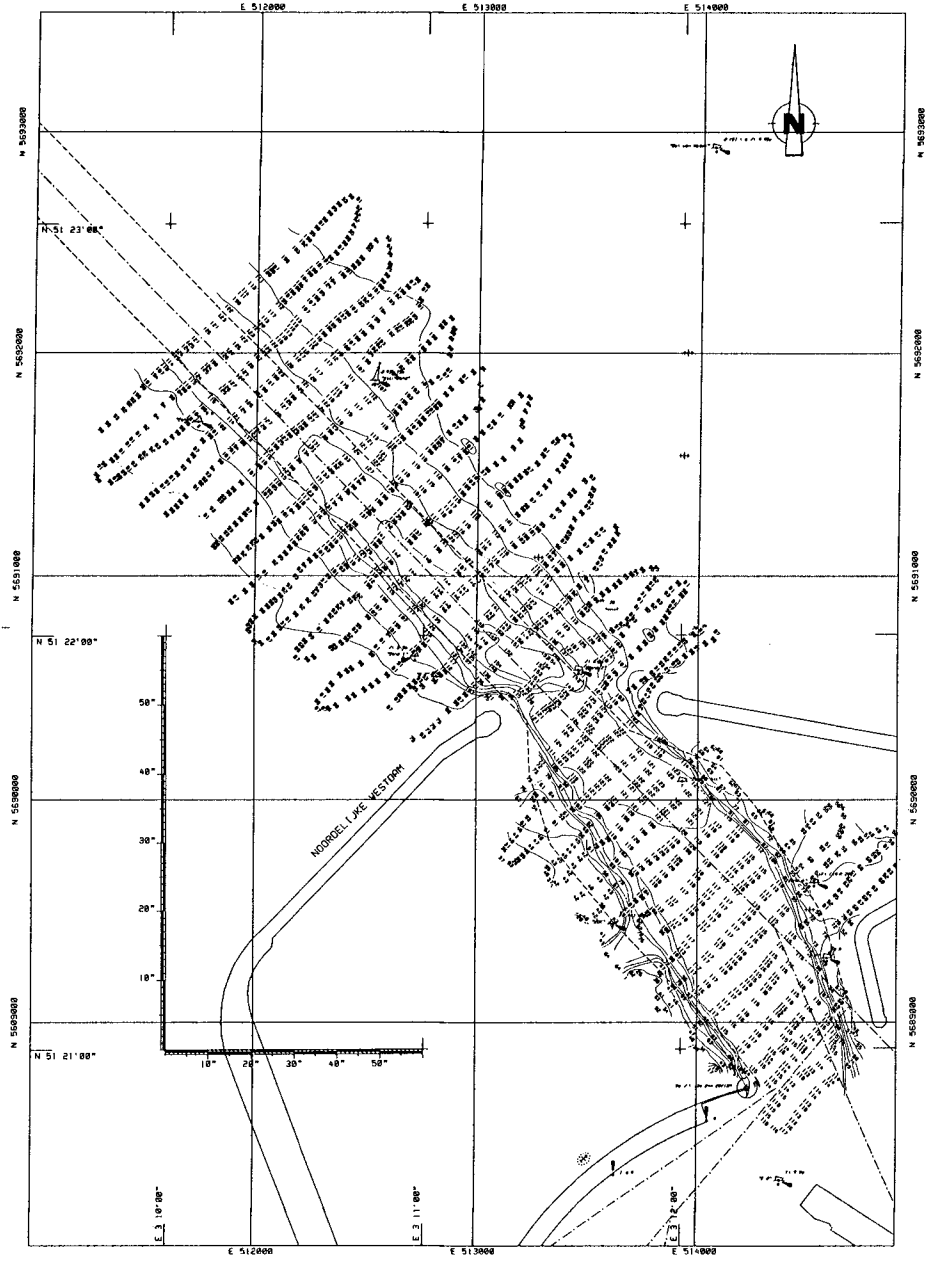

Fig. 3. : Nautical chart of the entrance channel to the port of Zeebrugge made by BEASAC

7. Survey equipment

Picture 6 shows the main cabin with the survey equipment : two Atlas Deso 20 - with 33 and 210 Khz transducers - and system control terminals are installed.

In front of the pilot, a navigation screen is mounted near the instrument panel on which the predefined tracks, the position of the hovercraft, its speed and the distance off-track are displayed.

Studies about the subject of dynamic positioning at sea resulted in the development of a very accurate and reliable positioning and navigation system, combining the use of a hyperbolic (Toran) and a circular (Trisponder) system.

Picture 6 : The main cabin with the survey equipment

On both sides of the hovercraft an acoustic transducer is installed in a stainless steel fish (see picture 7). The streamlined profile of the fish is designed for a survey speed of 27 knots, although higher speeds are possible.

The fish can be brought in or out of the water by manual or computer control. A mechanical weak link construction prevents damage to the sword or the craft in case of collision with floating objects. When approaching the shoreline the fish are retracted automatically.

Picture 7 : Stainless steel, sword and fish

In the hangar, a modern jacking system with eight jacks can lift the craft for periodic skirt inspections.

Picture 8 shows the Beasac-platform in operation near the beach. During these surveys a mobile shore beacon mounted on a jeep helps to optimise the dynamic positioning of the craft.

After each survey mission the data is transferred to the host computer system of the data center in Zeebrugge. Immediately several routine procedures are started which result in graphical and numerical reviews of the raw data. The tide-corrected data can then be plotted on a hydrographic chart.

Picture 8 : BEASAC-platform in operation near the beach

8. Conclusions

- The morphological research campaign started in 1979 on the Belgian East Coast, and, supported by aerial remote sensing techniques, it can be considered as very successful. On the basis of this campaign the decision was taken to execute a new beach renourishment of about 1 million m^3 of sand in the period March-April 1986 on locations resulting from the observations of the past survey program.

- At the same time, an important and fundamental contribution was made to more accurate observation of the nearshore and seabed area by means of a fast moving hydrographic-survey hovercraft : Beasac. The results of this new technique are very promising and will be incorporated in the further survey programs ordered by the Belgian Authorities as a substitute for the classic bathymetric vessel soundings.

CHAPTER 28

Wind Specification for Spectral Ocean-Wave Models

M.L. Khandekar* and B.M. Eid**

Abstract

This paper investigates the utility of winds obtainable from a numerical weather prediction model for driving a spectral ocean-wave model in an operational mode. Wind inputs for two operational spectral wave models were analyzed with respect to observed winds at three locations in the Canadian east coast offshore. Also, significant wave heights obtainable from the two spectral models were evaluated against measured wave data at these locations. Based on this analysis, the importance of appropriate wind specification for operational wave analysis and forecasting is demonstrated.

Introduction

Spectral ocean-wave models based on the energy balance equation are used operationally in many areas of the world oceans at present. The spectral models are capable of providing a detailed description of the sea-state in terms of a two-dimensional (frequency-direction) wave spectrum at a given location. For real-time operations, a spectral wave model utilizes winds which are generally extracted from an operational weather prediction model.

In this study, two operational spectral wave models are chosen for which wind inputs were analyzed with respect to observed winds at three selected locations in the Canadian Atlantic ocean; also, wave products from these models were evaluated against the observed wave data at these locations. Two sets of observed wind and wave data were utilized to evaluate the model products. Based on this evaluation, the importance of appropriate wind specification for operational wave analysis and forecasting is demonstrated.

Details of Models

The two wave models used in this study are the SOWM (Spectral Ocean Wave Model) of the U.S. Navy (see Pierson, 1982) and the ODGP (Ocean Data Gathering Program) model developed by Cardone et al (1974). The SOWM is a hemispheric model which provides operational wave forecasts for the three ocean basins of the northern hemisphere; the SOWM grid is designed on a gnomonic icosahedral projection with 325 grid points in each equilateral triangle and about 1575 ocean points over the

* Research Scientist, Atmospheric Environment Service, Downsview, Ontario, Canada.
** Senior Oceanographer, MacLaren Plansearch Ltd., Halifax, Nova Scotia, Canada.

northern hemisphere. The ODGP model has a nested grid (see Figure 1) and operates over the western north Atlantic ocean with a finer grid spacing than the SOWM in deep water and half of that spacing over the continental shelf region. The ODGP model uses 24 direction bands (as against 12 used in the SOWM) while both the models use 15 frequency bands. The governing equation for both models can be expressed as

$$\frac{\partial}{\partial t} E\ (f,\ \theta,\ \bar{x},\ t) + C_g . \nabla E = (A+BE)\ (1-E/E_{PM}) \qquad (1)$$

Here E is the energy density of the wave field described as a function of frequency f, direction θ, position $\bar{x}$ and time t; C_g is the group velocity of the wave in deep water, A and B are the linear and the exponential growth terms and E_{PM} is the Pierson-Moskowitz (1964) spectrum for a fully developed sea at a given wind speed. The Pierson-Moskowitz spectrum plays an important part in modelling the transition from a growing sea to a fully developed sea. Both the models use an empirically developed dissipation term which attenuates those frequency components travelling against the winds while the nonlinear wave-wave interaction term is neglected in both the models.

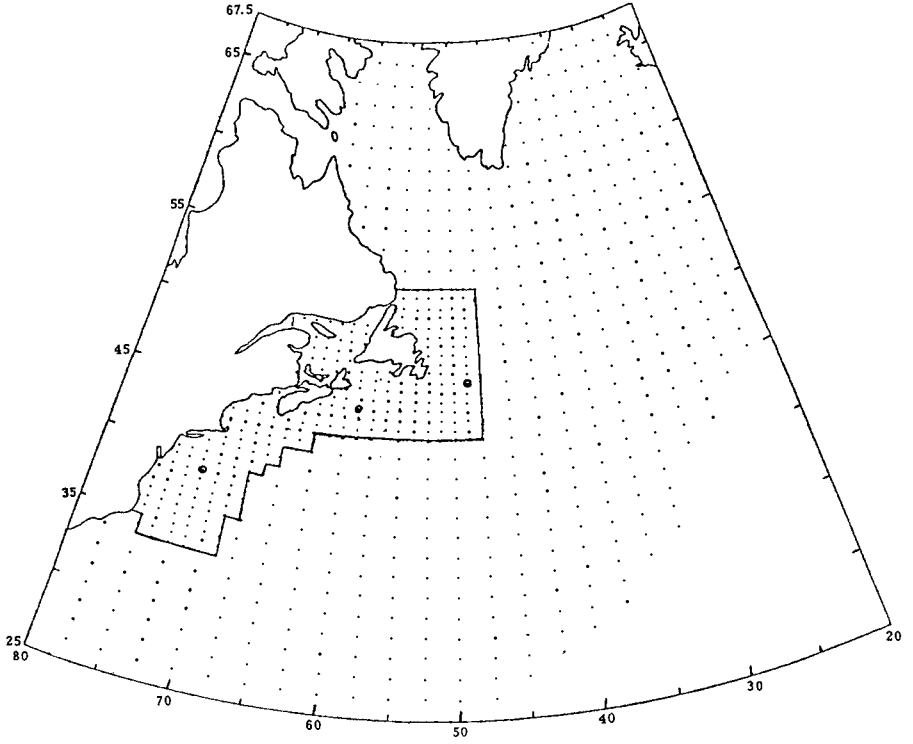

Figure 1: The operational ODGP model grid. The coarse grid has a spacing of 1.25° latitude by 2.50° longitude. The nested fine grid has half the spacing. Three circled grid points are the locations for wave model evaluation.

In SOWM, the terms A and B are modeled following the studies of Phillips (1957) and Miles (1957). The ODGP model uses an improved formulation of the term, A, following the studies of Inoye (1967) and Snyder and Cox (1966). Further, in the ODGP model, the growth algorithm was modified to allow for rapidly turning winds and the dissipation of bands travelling crosswinds was suppressed, so that at any time step no angular band is eligible for both growth and dissipation. Thus, the ODGP model has better spatial and spectral resolution and uses an improved growth algorithm than the SOWM.

Wind Input

The SOWM uses winds generated by the U.S. Navy's operational weather prediction model at Monterey, California. This operational weather prediction model is a global multi-level model which has a coupled boundary layer model where the influence of atmospheric stability is incorporated. The model generates analysis and forecast winds at 19.5m level which are then utilized to drive the SOWM; more details of the U.S. Navy's weather prediction model can be found in Mihok and Kaitala (1976).

For the ODGP model, the analysis winds are derived from the six-hourly north Atlantic surface charts prepared at the National Meteorological Centre (NMC) in Washington, D.C. (U.S.A.); these charts are reanalyzed based on latest ship weather reports and then digitized. A boundary layer model developed by Cardone (1969, 1978) is applied to generate effective neutral winds at 20m level above the ocean surface. According to Cardone (1969), a 20m-level wind speed of 24 knots under stable atmospheric conditions (air temperature warmer than water temperature) has the same effective wave generating ability as that of a 19-knot wind in neutral conditions and that of a 17-knot wind in unstable conditions (air temperature cooler than water temperature). Cardone's boundary layer model takes into account the (air-water) temperature difference at a given location and generates effective neutral winds at 20m level for driving the ODGP model. The forecast winds for the ODGP model are based on subjectively adjusted surface prognostic charts from the LFM (Limited-area Fine Mesh) model at NMC Washington; this 'man-machine mix' appears to provide an improved wind specification for the ODGP model.

Data

Two sets of wind and wave data measured at selected locations in the Canadian east coast offshore were used to evaluate the model products. The first set of data consisted of four storm events ranging from 3 to 5 days and selected from the historical weather charts dated 1 October 1983 to 31 March 1984. The movement of these storms off the Canadian coast is shown by the storm tracks in Figure 2. Each track shows the movement of the storm centre over the 2-day period which is marked on the tracks. Figure 2 also shows the three sites at which the model products were evaluated. Site 1 is near the NOAA buoy 44004 which is operated by the National Oceanic and Atmospheric Administration (NOAA), Washington. Sites 2 and 3 are near some of the oil rigs (Glooscap, Alma, Terra Nova) operated by various

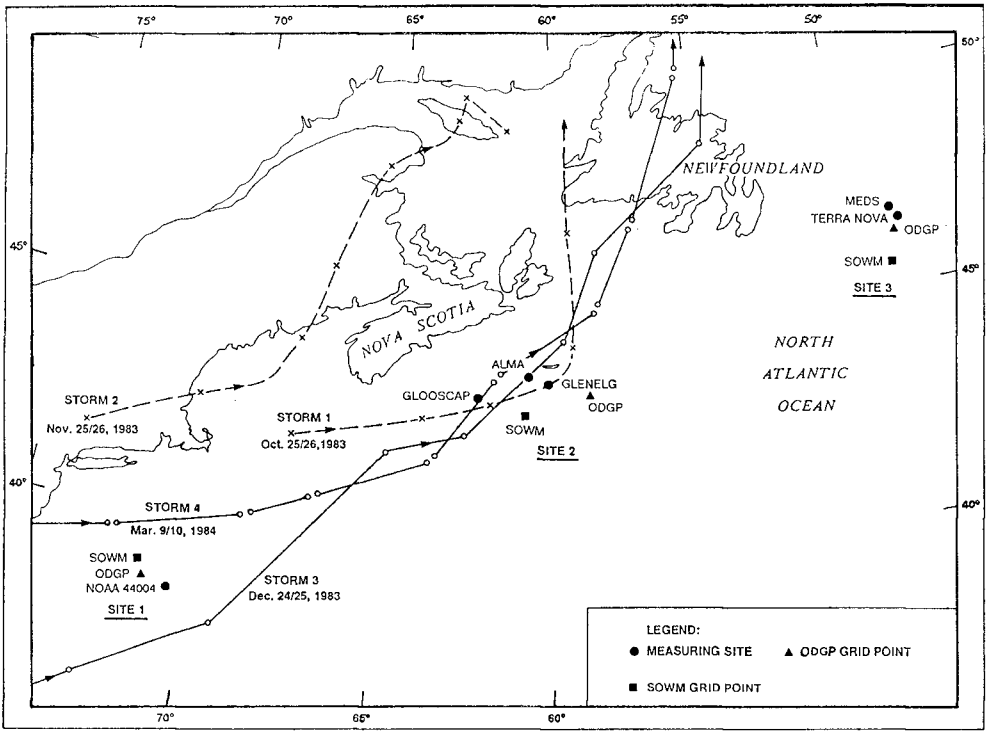

Figure 2: Locations of three sites and tracks of four storms selected for model evaluation.

oil companies. The wind and wave products generated by the two models (the SOWM and the ODGP) were evaluated for the four storm events.

The second set of data covered a two-month period from 15 January to 15 March, 1986; this was the period of a field project for the Canadian Atlantic Storms Program (CASP) during which a large amount of meteorological and oceanographic data was collected to study the evolution of winter storms that affect the Canadian Atlantic provinces. During the CASP field project, the ODGP model was run in an operational mode using two different wind inputs. One wind input was the operational wind field based on the man-machine mix as described above. The second wind input was provided by the weather prediction model of the Canadian Meteorological Centre (CMC) in Montreal. The CMC winds were extracted at the 0.998 sigma-level which corresponds to about 17m above the ocean surface in a standard atmosphere. The CMC winds were interpolated at the ODGP grid and were used without any modification, to drive the ODGP model. The CMC weather prediction model incorporates a surface turbulent flux formulation (Delage, 1985) so as to include the effect of atmospheric stability on wind variation in the vertical.

Results and Discussion

The results of the model evaluation using the first set of data are presented in Figure 3 and Table 1. Figure 3 shows a sample wind and wave plot for storm 2 covering a period November 25-30, 1983. At site 1 (in Figure 3), the maximum wind speed of 38 knots was recorded at about 18GMT, 25 November, whereas the maximum significant wave height of 9m was recorded 12 hours later at about 06GMT, 26 November. At site 2 (on the Scotian Shelf), the storm produced maximum wind and wave heights during 26 and 27 November. As the storm moved northeastward, it produced a maximum wind speed of 48 knots at site 3 (off Newfoundland) on 29 November (00GMT) and a maximum wave height of 8.5m about six hours later. An examination of the model plots shows that both the SOWM and the ODGP models produce similar wind speeds during the storm period; however, the ODGP model produces wave heights which agree more closely with observed wave heights than to SOWM wave heights. For a quantitative evaluation of the model products, a statistical analysis of the errors (model value-observed value) at all

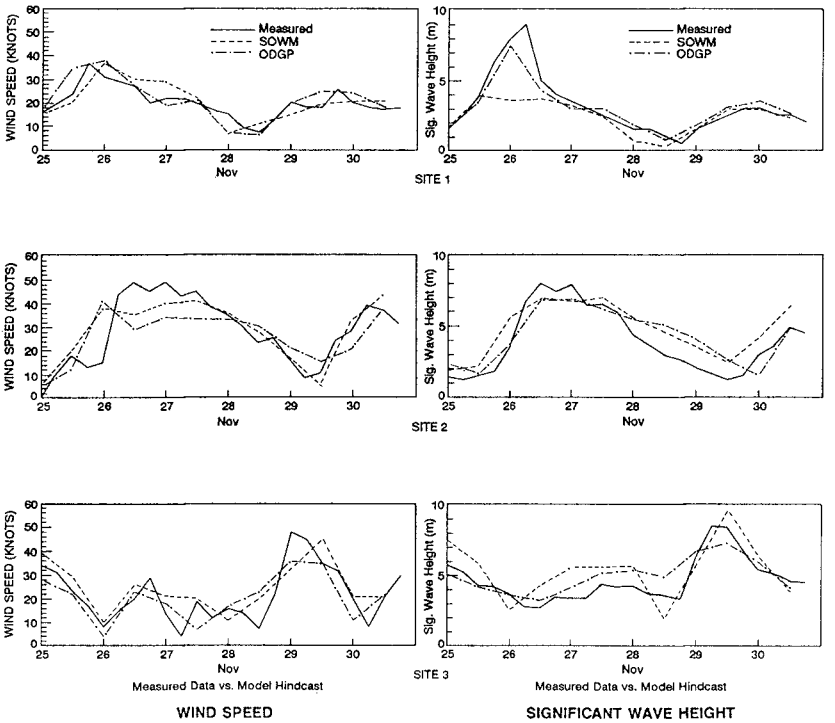

Figure 3: A sample plot showing variation of wind speed and significant wave height at three sites during the storm period November 25-30, 1983.

sites and for all 4 storm periods was made and Table 1 shows the Root Mean Square Error (RMSE) and the Mean Error (ME) together with values of the Scatter Index (SI) and the linear correlation coefficient (r) between model and observed values. The error statistics are prepared for hindcast (zero-hour forecast) products as well as for 24- and 48-hour forecast products. The results of this Table strongly suggest that the ODGP model performs better than the SOWM in a hindcast as well as in a forecast mode.

The results of the model evaluation using the CASP data set are presented in Figures 4 and 5 and in Table 2. The ODGP model was run in an operational mode during the CASP field project using the CMC winds as well as the 'man-machine mix' operational winds and the two products were designated as ODGP-CMC and ODGP-OPR respectively. In

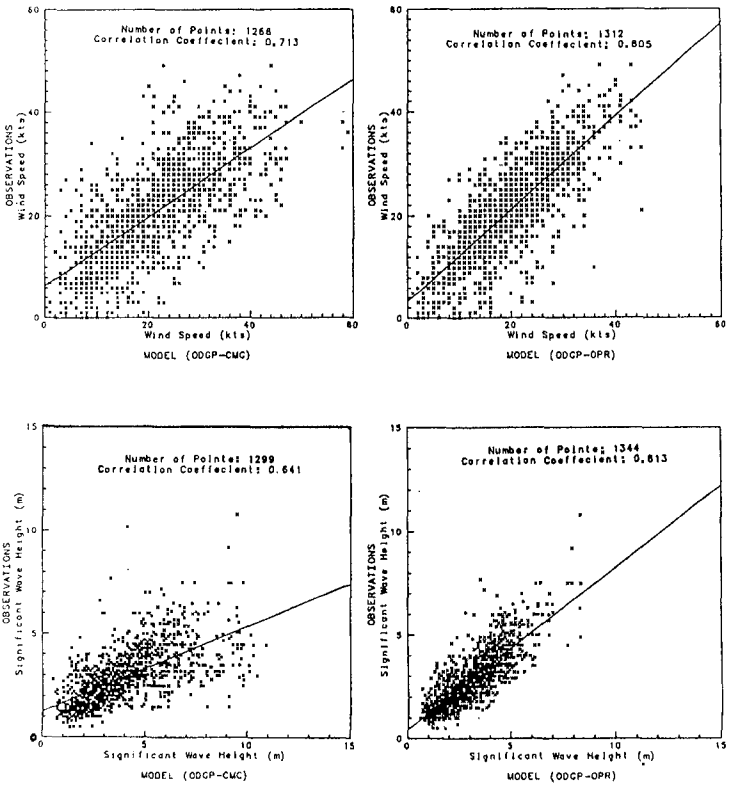

Figure 4: Scatter diagrams between observed versus model wind speed and significant wave height at all sites during the CASP field project 15 January - 15 March, 1986. The regression lines between observed and model values are also shown.

Figure 4 are shown scatter diagrams between model and observed values of wind speed and significant wave heights at analysis time (zero-hour forecasts). The data set covered the two-month period (15 January - 15 March, 1986) of the CASP field project and all three sites were included with two locations assigned to each site. The wind and wave

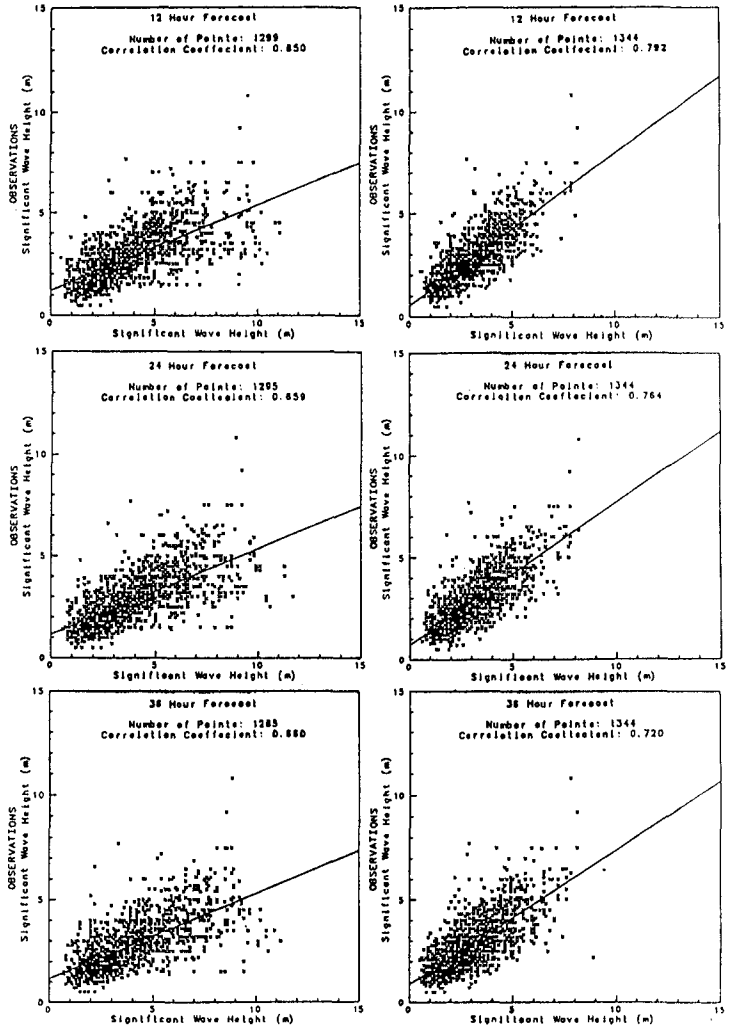

Figure 5: Scatter diagrams between observed versus model significant wave height, at 12-, 24- and 36-hour forecast times. Left: wave heights from model ODGP-CMC; Right: wave heights from model ODGP-OPR.

data were evaluated at four standard meteorological times (00, 06, 12 and 18GMT) during each day of the CASP field project; this provided a sample of 1300 or more data points (excluding missing values) for model validation. The scatter diagrams of Figure 4 suggest that at analysis time, the man-machine mix or the 'OPR' winds provide a slightly better diagnosis of winds when compared with observations at the three sites; this is also indicated by a higher value of the linear correlation coefficient between model and observed wind speeds. The scatter diagrams for significant wave height at analysis time shows that the ODCP-OPR provides significantly better values than those provided by ODGP-CMC. Figure 5 shows the scatter diagrams between model and forecast wave heights at 12-, 24- and 36-hour forecast times. In general, wave heights obtained using OPR winds provide less scatter and higher correlation coefficients with corresponding observed values than those generated using CMC winds. For a quantitative evaluation of the wind and wave products, various error statistics were calculated and these are presented in Table 2. An examination of the wind speed statistics shows that the Mean Error (ME) of the OPR winds has been significantly reduced, most certainly due to the man-machine mix procedure; this, in turn produces smaller RMSE (Root Mean Square Error) for the wind speed and consequently smaller RMSE for the wave height in analysis as well as in forecasting mode.

These error statistics, however, do not provide any information about the spatial differences in the wind fields generated by two different wind models. In order to get an appreciation of these differences, Figures 6 and 7 are presented which show a comparison of wind fields generated by the CMC and the OPR (man-machine mix) models for 16 February 1986. Both the wind fields (in Figures 6A and 6B) refer to the 00GMT analysis time while in Figure 7 are shown differences in the two wind fields obtained by subtracting the OPR wind field from the CMC wind field. The vector at each point in Figure 7 represents the difference in the wind direction while the number at the end of the vector represents the difference in wind speed. A vector parallel to the latitude lines indicates no difference in wind direction between the two wind fields. A positive number indicates that the CMC wind speed is greater than the corresponding OPR wind speed. These three Figures (namely six, seven and eight) show clearly the spatial differences in the two wind fields, particularly in the vicinity of the low pressure centre southwest of Newfoundland where the differences in wind speed and wind direction can be as large as 20 knots and 45 degrees respectively. Furthermore, it can be seen that the CMC weather prediction model in general produces surface marine winds with a definite positive bias when compared against the corresponding ODCP winds; this positive bias appears to produce larger Root Mean Square Error and Scatter Index for ODCP-CMC wave heights as shown in Table 2.

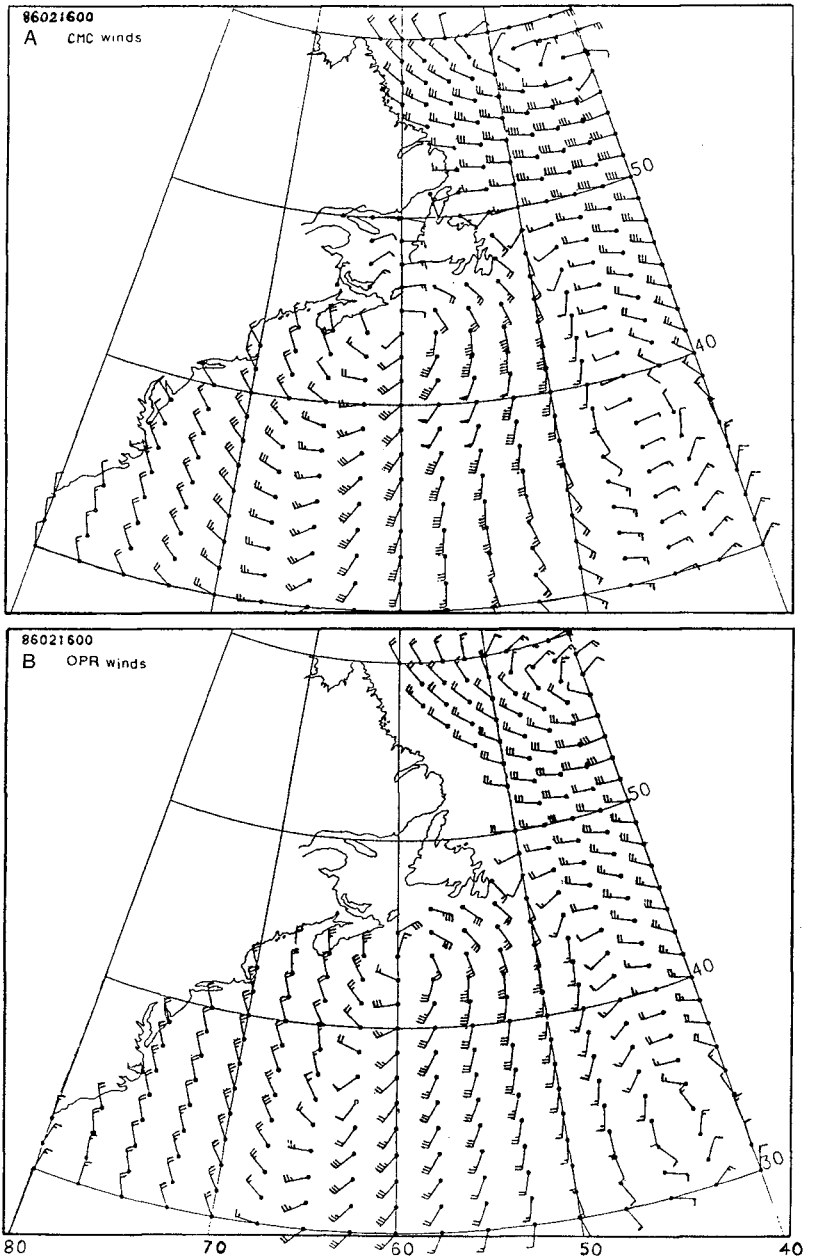

Figure 6: North Atlantic surface wind field, 16 February 1986, 00GMT. A: CMC Model; B: OPR 'Man-Machine Mix' model.

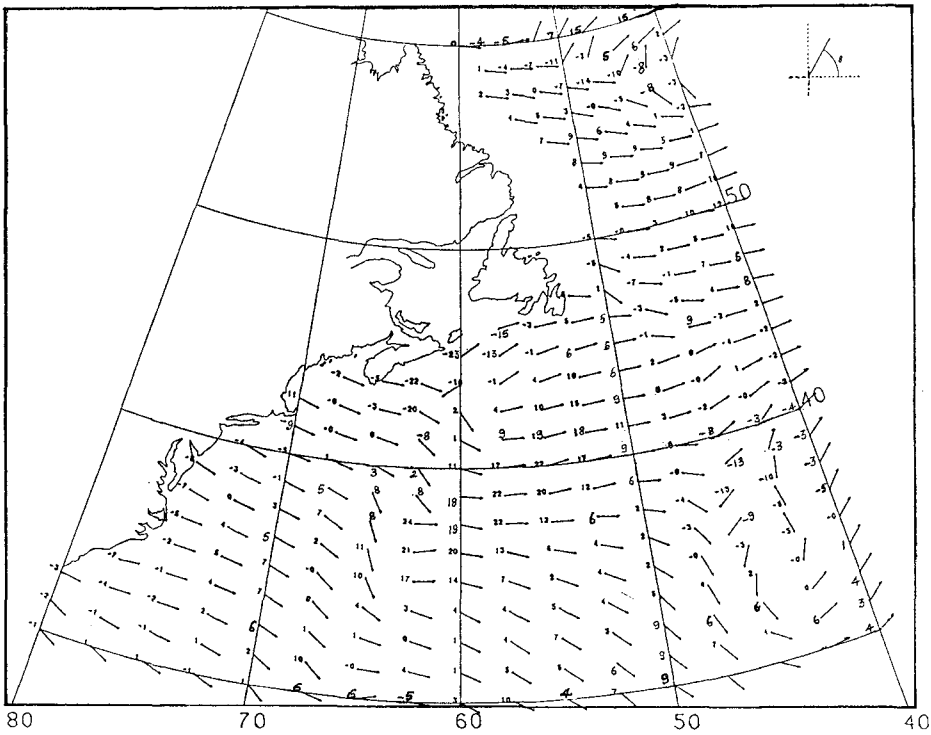

Figure 7: Scalar and vector differences between CMC and OPR wind fields. The vector represents the difference in wind direction (see inset), while the number indicates the difference in wind speed between the two wind fields.

Concluding remarks

The results presented here demonstrate the usefulness of accurate wind specification for driving an operational wave model. The man-machine mix procedure used in the operational running of the ODGP model generates winds which are superior to those produced either by the U.S. Navy's wind model or by the CMC wind model. Furthermore, the study demonstrates the need to adjust the CMC winds for application to a spectral ocean-wave model.

Acknowledgements

The evaluation of the SOWM and the ODGP was done by the MacLaren Plansearch Ltd., Halifax, on contract from the Meteorological Services Research Branch of the Atmospheric Environment Service, Downsview, Ontario. CHAPTER 29

LATERAL MIXING AND WAVE DIRECTION IN THE WAVE-CURRENT INTERACTION REGION

Kyoung Ho Kim [1], Sawaragi Toru [2], Deguchi Ichiro [3]

ABSTRACT

The lateral mixing coefficient, in which the wave energy dissipation by wave breaking is taken account and the assumption of Richardson's 4/3 power law is involved, is derived for the surf zone and the diffusion of tracers injected in the wave-current interaction region is discussed experimentally to investigate the proposed lateral mixing coefficient. Furthermore measurements of velocity field on the three dimensional sloping beach of plane wave flume have been made by a bidirectional electromagnetic current meter. The results were used to investigate the characteristics of the structure of on-offshore and alongshore mean currents and the techniques for the determination of wave angle in the surf zone

1. INTRODUCTION

There are many problems which have to be solved in analyzing the nearshore currents system in the surf zone, such as the expressions for the bottom shear stress, lateral mixing, wave direction, and radiation stress and so on. Of them, especially, the lateral mixing and wave direction problems have not been clarified sufficiently.

The studies of oceanic and estuarine mixing have been performed a lot experimentally and theoretically, however, for the lateral mixing which designates the turbulent exchange of momentum few detailed studies have been made because the turbulence generated due to breaking waves is not universally defined. Wave directions have been computed on the basis of the law of conservation of waves together with the irrotationality of wave number. In laboratory, in general, by taking the angle between the shoreline and the wave crest line wave angles are determined, however, this has many problems in the surf zone because of the difficulties in the de-

1. Assistant professor, Dept. of Civil Engineering, Chungbuk National University, Cheongju, Korea
2. Professor, Dept. of Civil Engineering, Osaka University, Suita, Osaka, Japan
3. Assistant professor, Dept. of Civil Engineering, Osaka, University, Suita, Osaka, Japan

termination of the wave crest line .

In this paper, the equation for the lateral mixing coefficient in which the wave energy dissipation is taken account is proposed. Using the experimental results for longshore currents and diffusion of tracers injected in the wave-current interaction region, the validity of proposed lateral mixing coefficient is verified. The methods of the determination of wave directions are also examined by using the horizontal velocity components and the results are compared with the values obtained from other methods.

2. LATERAL MIXING

The lateral mixing term corresponding to the horizontal turbulent momentum exchange in the wave-current interaction region is an important parameter for determining the spatial distribution of longshore current with distance to the shoreline and it has been said to be dependent on the local gradient of mean currents.

In the paper, lateral mixing coefficient is derived by using the wave energy dissipation rate due to wave breaking. The dependence of the lateral mixing coefficient on the wave steepness and bottom slope are discussed. The principle assumptions are used herein as follows.

(1) Lateral mixing in the surf zone can be expressed by Richardson's 4/3 power law.
(2) The mean dissipation rate of turbulence energy is in balance to that of wave energy due to wave breaking(Battjes, 1975)
(3) The mixing scale is the same in order as mean water depth(see Iwata and Sawaragi, 1982).

From the assumption (1), lateral mixing coefficient K becomes following expression.

$$K \sim \varepsilon^{1/3}(\sqrt{\overline{Y}^2})^{4/3} \tag{1}$$

where ε is the mean rate of turbulent energy dissipation and $\sqrt{\overline{Y}^2}$ is the mixing scale. The mean dissipation rate of turbulent energy and the mixing scale are expressed from the assumptions (2)and (3)

$$\varepsilon \sim D/\rho d \tag{2}$$

$$\sqrt{\overline{Y}^2} \sim d \tag{3}$$

where D is the mean rate of wave energy dissipation, which by hypothesis equals the rate of prodection of turbulent energy. ρ is the water density and d is the mean water depth.

Sawaragi et. al.(1984) already reported that the mean dissipation rate of wave energy D can be expressed as Eq.(3) using the experimental results for the breaking waves on the sloping beach.

$$D = cF\rho^{-1/2}d^{-3/2}E^{3/2} \tag{4}$$

where c is the dimensionless constant, E is the wave energy density and F is the wave decay coefficient, which is expressed by surf similarity parameter ξ_o and the bottom slpoe S .

$$F = \begin{cases} 5.30 - 3.30\xi_o - 0.07S^{-1}, & \text{in the surf zone} \\ 0 & \text{, outside the surf zone} \end{cases} \tag{5}$$

Substituting Eqs. (2)- (4) into Eq. (1), we obtain the follwing relation

$$K = \begin{cases} AF^{1/3}\sqrt{gd}\ H, & \text{, in the surf zone} \\ 0 & \text{, outside the surf zone} \end{cases} \tag{6}$$

where A is the dimensionless constant and H is the wave height. Considering the variation of mean water level and using the coefficient γ, which is the empirical proportionality factor between the wave height and the mean water depth, Eq. (6) is transformed into Eq.(7).

$$K = \begin{cases} AF^{1/3}\gamma S^{*}x'\sqrt{gd}, & \text{in the surf zone} \\ 0 & \text{, outside the surf zone} \end{cases} \tag{7}$$

where S^* is the modified bottom slope and x' is the distance from the mean shoreline.

Perhaps the most well-known and frequently used expression for K was given by Longuet-Higgins(1970b). He suggested Eq.(8) for K by using Prandtl's mixing length theory.

$$K = N\,x\sqrt{gd} \tag{8}$$

where N is the constant which has the range of $0 < N < 0.016$. On the other hand, Battjes(1975) proposed Eq.(9) for K assuming the turbulent energy generated due to breaking waves.

$$K = (5/16\gamma^2)^{1/3}S^{4/3}M\sqrt{gd} \tag{9}$$

where M is the constant which is similar to N of Eq.(8).

Comparing Eq.(7) with Eqs.(8) and (9), we find that K in Eq.(7) comprises the wave steepness H_o/L_o, wave height-water depth ratio γ and the bottom slope S which represent

the wave characteristics. Accordingly it is thought that the constant A in Eq.(7) is more universal than the constants M and N.

To examine how K in Eq.(7) depends on wave steepness and the bottom slope, the relationship between $S*F^{1/3}$ and H_o/L_o is shown in Fig. 1. The values of $S*F^{1/3}$ are almost the function of S only and are not directly related with the wave steepnesses. Eq.(7) is similar to Eq.(9) proposed by Battjes.

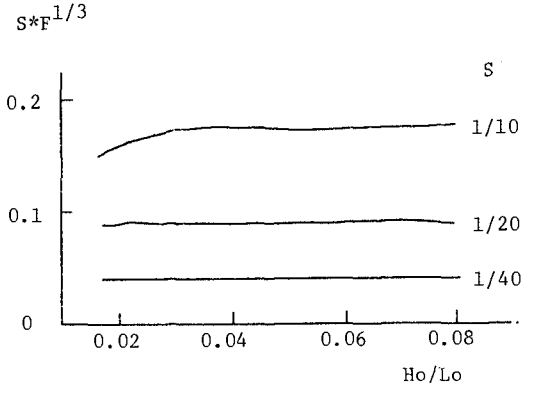

Fig. 1. Value of $S^*F^{1/3}$ versus Ho/Lo.

3. WAVE DIRECTION

Wave angle just prior to wave breaking may be the most important parameter in the surf zone for the determination of longshore currents and sediment transport. According to Longuet-Higgins(1970 a,b) good estimates of wave angle are critical for the calculation of the alongshore component of radiation stresses, particularly when the angle of incident wave is small. Sherman et. al. (1986) reported that when the wave angle is 5°, a 1° error in the angle estimate results in a 20% error in the radiation stress computation.

In the numerical calculation of nearshore current, the wave angle is computed by the law of conservation of waves together with the irrotationality of wave number. On the other hand, in the field or laboratory wave directions have been determined by using either the horizontal velocity components measured with a current meter or the angle between wave crest line and shoreline. In laboratory, in general, the latter has been used, however, this has many problems because of the difficulties in the determination of obvious

wave crest line in the surf zone. Thus the validity of the above-mentioned methods has been performed not by the comparison of the computed results with the measured results but by how the calculated currents can revive the real currents.

In the present paper, the horizontal velocity components were measured by a bidirectional electromagnetic current meter in the fixed bed of plane flume and the problems in the measurements and the calculation of wave angle are examined by comparing the results from the above-mentioned methods. The wave angle is defined by the angle relative to the shore-normal as shown in Fig. 2.

If u and v are the onshore(x) and alongshore(y) components of velocity, respectively, two methods for determining the wave angle are derived as follows.

$$\theta_p = \tan^{-1}[2\overline{(u-U_o)(v-V_o)}/\{\overline{(u-U_o)^2} - \overline{(v-V_o)^2}\}]/2 \qquad (10)$$

$$\theta_t = \tan^{-1}(v_w/u_w) \qquad (11)$$

where "$\overline{\quad}$" represents the time mean values and the subscripts o is corresponding to the time mean currents and w corresponding to the components of fluctuation.

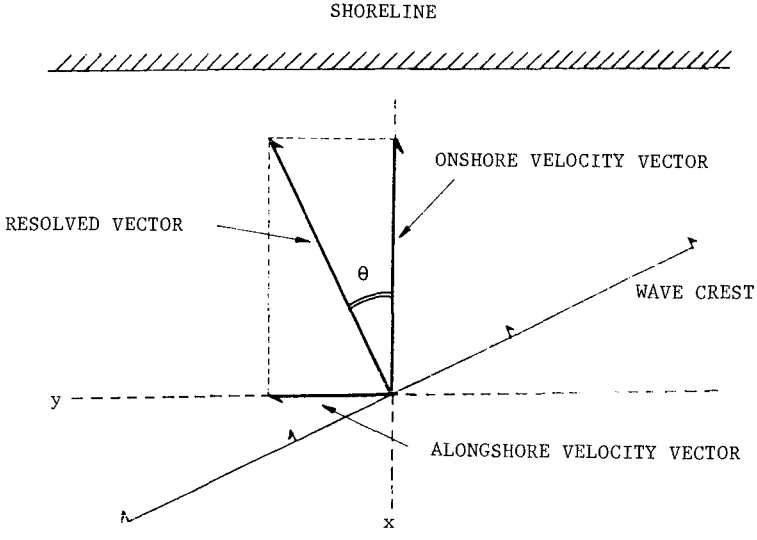

Fig. 2 Coordinate system for the wave angle.

4. EXPERIMENTS AND RESULTS

4.1 Experimental set-up and procedures

The wave facility at Osaka university was used to conduct the experiments. The plane flume is 20m long, 10m wide and 50cm deep. The waves broke on the bottom slope 1/10 (Fig. 3) and the shoreline was made in order to form the angle of 30° against the wave generating board. The wave conditons are shown in Table. 1.

Table. 1 Wave conditions

bottom slope S	wave period T(sec)	wave steepness H_o/L_o	wave height H_o(cm)	incident wave angle θ(degree)
1/10	0.91	0.052	6.70	30
	1.15	0.033	6.68	30
	1.44	0.015	6.70	30

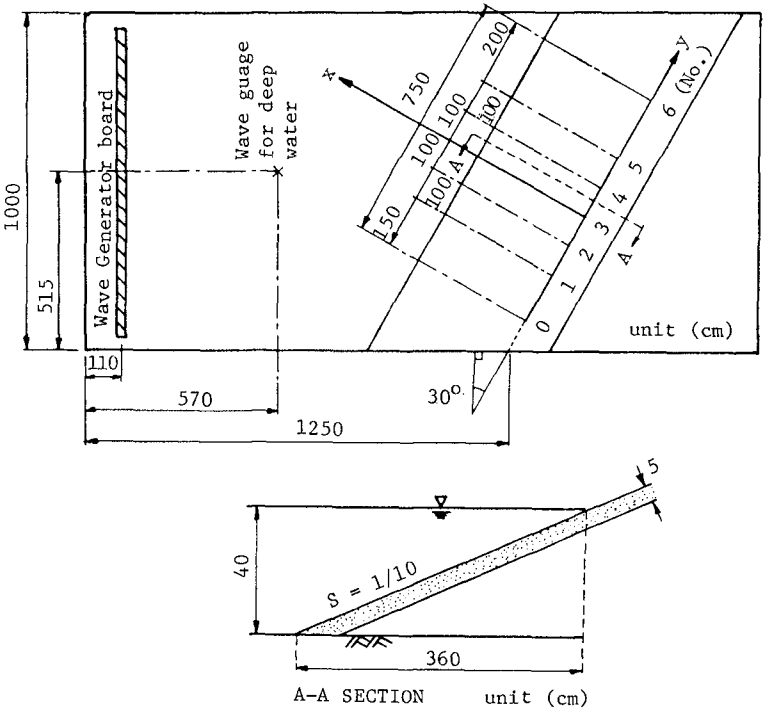

Fig. 3 Experimental set-up.

Wave profiles were measured over the surf zone at positions with an interval of 10cm or 20cm to the onshore direction(x) by means of the capacity type wave gauges. velocities were measured at 1-3 points of the vertical directions with the same measuring points of wave profiles by a bidirectional electromagnetic current meter. Simultaneously the wave crest and the diffusion of tracers injected in the flume were took photograps by a 16mm cine-camera to determine the wave direction and the coefficient of diffusion of tracer (L).

The wave profiles and the velocities were recorded as electric signals with a data recorder and they were destised at 100 hz by computer over 40 or 50 waves per each measueing point and the computer techniques were utilized to obtan the ensemble mean values. In Fig. 4-6, the example of the experimental results are shown. The upper figure shows the distributions of wave height H and the variation of mean water level $\overline{\eta}$ and the lower is the distribution of longshore current with the distance to the shoreline together with the computed values of them.

(Ho/Lo = 0.052)

4.2 Time mean on-offshore and longshore current

Fig. 7 shows the vertical distributions of time mean on- offshore(U_o) and longshore current(V_o) measured in the case in which the wave steepness H_o/L_o= 0.015. As shown in Fig. 7(a) the longshore current is almost uniform vertically at least under the wave trough. The values of longshore currents in Fig. 4-6 are the mean values of these ones.

On the other hand, the on-offshore current U_o in Fig. 7 (b) is facing the offshore directions and the magnitude of them is larger in the upper zone and smaller in the lower zone. Whether this offshore current is a kind of rip current or a compensating one for the mass transport is not clear yet. In two-dimensional sloping beach, however, Nadaoka et. al.(1982) and Svendsen(1984) already reported that steady flows compensating for the mass transport exist. The values of U_o increse as they go towards the shoreline and the maximum value of it appears within the surf zone.

Fig. 8 shows the comparisons of the offshore mean current U_o in the present experiments which is measured on the

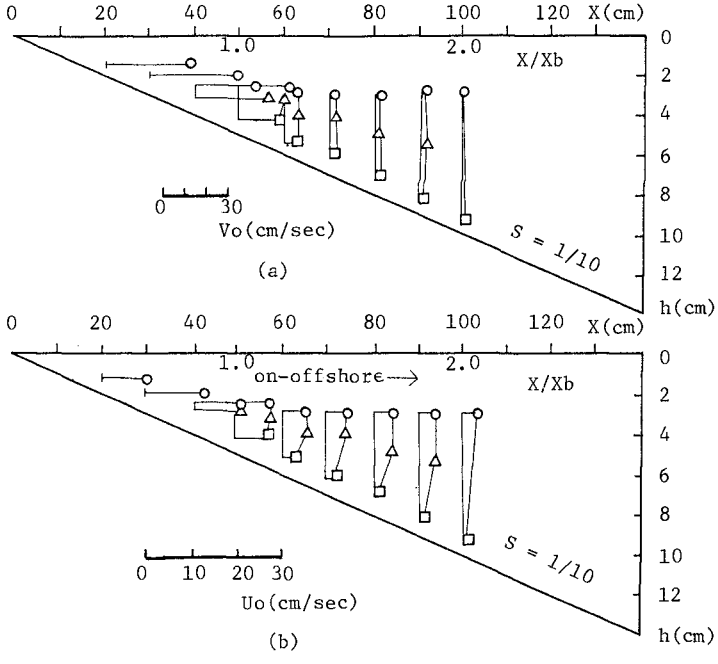

Fig. 7 Vertical distribution of on-offshore and longshore currents.

three-dimensional sloping beach with those measured on the two-dimensional sloping beach by Nadaoka et. al.(1984). The normalized values of U_o by $\sqrt{gh_b}$ (h_b is the water depth corresponding to the breaking point) are plotted with the distance to the shoreline. The results are favourably good in magnitude and direction except for the neighbourhood of the shoreline. This mean current was also measured for the cases of H_o/L_o= 0.033 and 0.052, and its maximum value is nearly $U_o/\sqrt{gh_b} \cong 0.2$ regardless of wave steepnesses. This makes us to guess that compensating flow for the mass transport exists even in the three-dimensional flow field where longshore currents occur.

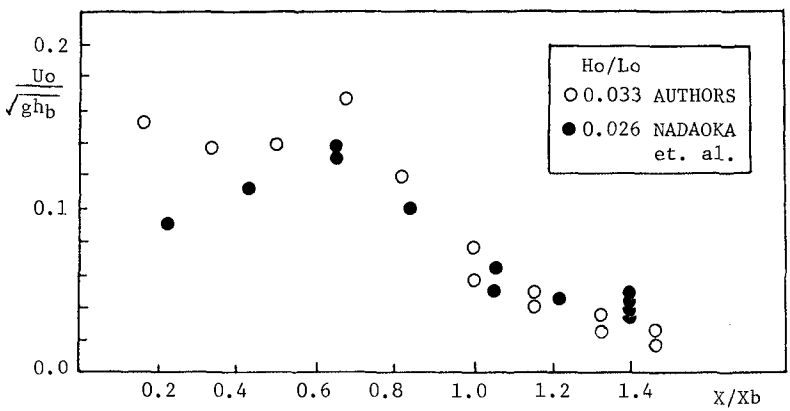

Fig. 8 Comparison of offshore current.

4.3 Diffusion coefficient

The diffusion coefficient(L) is shown in Fig. 9, which is obtained from the time variation of tracers continuously injected at positions x/x_b=1/3, 2/3, 1 and 3/2, when the longshore currents occur(x_b is the distance to the breaking point). The diffusion coefficient somewhat decreases as the wave steepnesses increase, however, the variation is small and it is in proportion to the power of 3/2 of the distance from the shoreline. it is almost zero outside the surf zone.

It was already shown that the present model for the lateral mixing in sectin 2 is in proportion to the bottom slope S, wave height-depth ratio γ, and the distance from the shoreline x. In the present experiments the value of γ, has the range of 0.8~1.2 except for the vicinity of the shoreline and the breaking point. Its local variation is larger rather than that due to wave steepnesses, that is, the diffusion coefficient may not have the obvious dependency on the wave steepness. since it is thought that the

mechanisms of the lateral mixing can be assumed to be the same, the present model for the lateral mixing, Eq.(7) is reasonable. To conform this fact, the numerical calculation for the distributions of longshore currents with the distance to the shoreline and wave deformation was performed by using the conservation equations of mass, momentum and energy together with Eq.(4) for wave energy dissipation rate and Eq.(7) for the lateral mixing coefficient.The calculated results are illustrated in Fig.4- 6 together with the experimental results. In the calculation, radiation streses, which are computed by the small amplitude wave theory for long waves , were multiplied by the reduction coefficient of 0.6-0.7 according to Stive and Wind (1984). In the figures the computed profiles of longshore currents using Eq.(8) for the lateral mixing coefficient proposed by Longuet-Higgins are also shown for comparisons. In the calculation of them the effect of wave-current interaction was considered. The computed longshore currents with Eq.(7) is in good accordance with the experimental results, particularly, outside the surf zone.

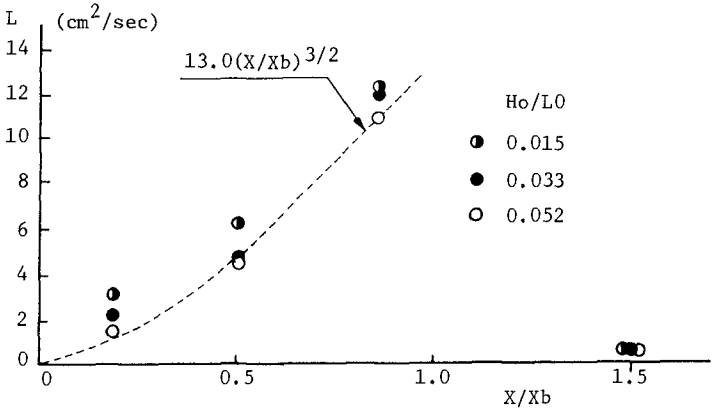

Fig. 9 Diffusion coefficient.

4.4 Wave direction

Fig. 10 shows the comparisons of wave angles obtained by using the methods mentioned in section 3. θ_m is the angle obtained by taking between the shoreline and the wave crest line taken photographsby 16mm cine-camera. θ_p is the one computed by Eq.(10). The computed values obtained by the numerical analysis are also shown for comparisons. From Fig. 10, it is found that θ_p shows a good accordance with the calculated values by the law of conservation of waves outside the surf zone. Within the surf zone the values of θ_p largely varies, however, on the average they are nearly in accordance with the calculated values considering the effect of wave-current interaction. The wave angles obtained from

the wave crest line are generally overestimated.

In Fig. 11 and 12, the phase mean velocity components of wave fluctuation u_w and v_w are vectorally plotted for the regions of $x/x_b=0.6$ in the surf zone and of $x/x_b=2.2$ outside the surf zone, respectively. In the figure(a) of each the vector(u_w, v_w) and the wave angles θ_p and θ_t are shown. Figure (b) shows the profiles of the phase mean values of the displacement of water level η_w and those of water particle velocities due to fluctuation(u_w, v_w). In the surf zone the phases of η_w, u_w and v_w do not accord well one another. Though the values of v_w were taken over thirty waves, the turbulence of it is very large. Thus the wave direction θ_t determined by the vector(u_w, v_w) greatly varies according to the phases with the range of about ±80°. On the other hand, outside the surf zone the phases of η_w, u_w and v_w show a good accordance one another, especially, the accordance of the phases between u_w and v_w is so good. Accordingly, the change of θ_t is small and it varies within the range of about ±15° . The values of θ_p is almost the same as those of θ_t in the phase in which η_w is less than zero.

From these results we see that outside the surf zone where longshore current and turbulence are not predominant, the wave direction can be determined by θ_p and θ_t, however, in the surf zone where the turbulence due to breaking and longshore current are predominant, it can not be always determined by them. The large variation of θ_p in the surf zone is thought to be caused by the turbulence of v_w and the interaction between the water particle velocities due to fluctuation and the mean currents.

5. DISCUSSION

In this paper, the lateral mixing coefficient, wave direction and the characteristics of on-offshore(U_O) and longshore current(V_O) are discussed. Firstly the lateral mixing coefficient is derived for the three-dimensional sloping beach where longshore current occurs. Secondly experiments are carried out to examine the wave direction, the structure of mean current in the surf zone and the diffusion of tracers injected.

The lateral mixing coefficient on the basis of wave energy dissipation is shown to be applicable for the surf zone. Wave angle θ_p caculated by the horizontal velocity compcnents and the mean currents show good estimates outside the surf zone. Within the surf zone the variation of θ_p is large, however, on the average its values are nearly in accordance with those by traditional refraction analysis of deep water waves considering the effect of wave-current interaction. Wave angles obtained by the photographic interpretation of wave crest are generally overestimated. Furthermore it is found that even on the three-dimensional sloping beach where longshore current occurs the compensating flow may exist.

CHAPTER 30

CIRCULATION KINEMATICS IN NONLINEAR LABORATORY WAVES

Tae-In Kim,[1] Robert T. Hudspeth,[2] and W. Sulisz[3]

ABSTRACT

A weakly nonlinear solution is presented for the two-dimensional wave kinematics forced by a generic wavemaker of variable-draft. The solution is valid for both piston and hinged wavemakers of variable-draft that may be double articulated. The second-order propagating waves generated by a planar wave board are composed of two components; viz., a Stokes second-order wave and a second-harmonic wave forced by the wavemaker which travels at a different speed. A previously neglected time-independent solution that is required to satisfy a kinematic boundary condition on the wavemaker as well as a mixed boundary condition on the free surface is included for the first time. A component of the time-independent solution is found to accurately estimate the mean return current (correct to second-order) in a closed wave flume. This mean return current is usually estimated from kinematic considerations by a conservation of mass principle

INTRODUCTION

Flick and Guza (1980) investigated the motion of a hinged wavemaker that is hinged either on or below the channel bottom using a Stokes expansion. They studied the relationship between the second-harmonic (secondary) waves forced by the wavemaker and the Stokes waves by computing the coefficients for the propagating eigenmode numerically. Their solution, like that of Daugaard (1972), neglects the interactions of the first-order evanescent eigenmodes at the free-surface boundary near the wavemaker because these evanescent eigenmodes do not contribute to the propagating waves. Furthermore, their solution as well as that of Madsen (1971) and Daugaard (1972) is not exact because they neglect the time-independent, second-order solutions which are required to satisfy exactly the boundary conditions at the wavemaker and at the free surface.

Massel (1981) attempted to extend the work of Flick and Guza (1980) by including a time-independent solution but only for the kinematic boundary condition at the wavemaker.

A closed-form solution is presented that is correct to second-order (except for the singularities at the irregular points) for the fluid motion forced by a sinusoidally moving generic wavemaker of variable draft. The generic wavemaker motion is doubly articulated and includes both piston and hinged wavemakers. The previously

neglected time-independent solutions required to satisfy both the nonlinear free surface and wavemaker boundary conditions are compared with the Eulerian mean horizontal momentum per unit area. The mean return current required to satisfy conservation of mass in closed wave flumes is estimated reasonably well by the time-independent, second-order solution for a broad class of planar wavemakers.

NONLINEAR WAVEMAKER THEORY

For convenience, all physical variables (denoted by superscript asterisks, *) will be made dimensionless by the following: $(x,z,h,d,b,\Delta,L) = k^*(x^*,z^*,h^*,d^*,b^*,\Delta^*,L^*)$; $(t,T) = \sqrt{g^*k^*}\,(t^*,T^*)$; $(H,\eta,S,\xi,\chi) = (H^*,\eta^*,S^*,\xi^*,\chi^*)/a^*$; $(u,w) = (u^*,w^*)/(a^*\sqrt{g^*k^*})$; $\Phi = \Phi^*/(a^*\sqrt{g^*/k^*})$; $B = B^*/(a^*g^*)$; and $p = p^*/(\rho^*a^*g^*)$ where a^* = amplitude of the first-harmonic wave component; $k^*(= 2\pi/L^*)$ = the wave number; L^* = wave length; g^* = gravitational constant; ρ^* = fluid mass density; and T^* = wave period = the period of the wavemaker oscillation.

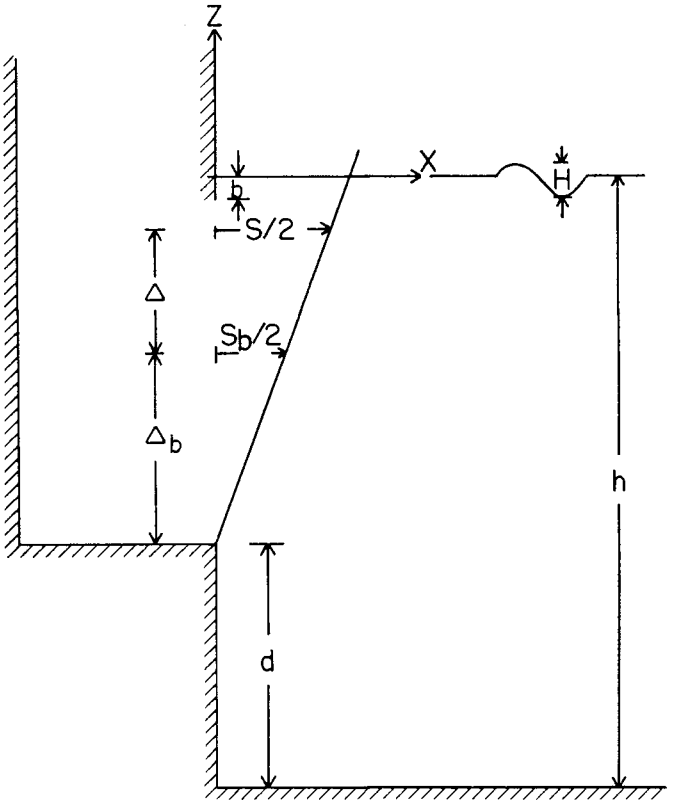

Fig. 1. Definition sketch for generic wavemaker

A generic wavemaker is shown in Fig. 1 which generates two-dimensional, irrotational motion of an inviscid, incompressible fluid in a semi-infinite channel of constant, still water depth, h. The fluid motion may be obtained from a scalar velocity potential $\Phi(x,z,t)$ by

$$[u,w] = -\vec{\nabla}\Phi \tag{1}$$

in which the two-dimensional gradient operator is $\vec{\nabla}(\cdot) = [\partial/\partial x, \partial/\partial z]$.

The velocity potential is a solution to

$$\nabla^2\Phi = 0 \qquad ; \; x > \varepsilon\chi(z,t) \; , \; -h < z < \varepsilon\eta(x,t) \tag{2a}$$

with boundary conditions (Phillips, 1977)

$$\partial\Phi/\partial z = 0 \qquad ; \; x > \varepsilon\chi(-h,t) \; , \; z = -h \tag{2b}$$

$$\frac{\partial^2\Phi}{\partial t^2} + \frac{\partial\Phi}{\partial z} - [\varepsilon\frac{\partial}{\partial t} - \frac{1}{2}\varepsilon^2\vec{\nabla}\Phi\cdot\vec{\nabla}]\left|\vec{\nabla}\Phi\right|^2 + \frac{dB}{dt} = 0; x>\varepsilon\chi(\eta,t), z=\varepsilon\eta(x,t) \tag{2c}$$

$$\partial\Phi/\partial x + \partial\chi/\partial t - \varepsilon\partial\Phi/\partial z \; \partial\chi/\partial z = 0 \quad ; \; x = \varepsilon\chi(z,t) \; ; \; -h < z < \varepsilon\eta(t) \tag{2d}$$

where $B(t)$ = the Bernoulli constant and the parameter $\varepsilon = a^*k^* << 1$. In addition, a radiation condition is required at infinity as $x \to +\infty$ in order to insure that propagating waves be only right progressing or that evanescent eigenmodes be bounded. The instantaneous wavemaker displacement from its mean position, $\chi(z,t)$, is given by

$$\chi(z,t) = \xi(z)[U(z+h-d)-U(z+b)]\sin\omega_o t = \xi(z)\Delta U \sin\omega_o t \tag{3}$$

where $U(\cdot)$ = the Heaviside step function. The amplitude of the wavemaker displacement, $\xi(z)$, for a double-articulated piston or hinged wavemaker of variable draft is given by the following equation for a straight line:

$$\xi(z) = [(S/2)/(\Delta/h)][M(1+z/h)+B'] \tag{4}$$

where $M = (1-S_b/S)$; and $B' = [\Delta/h - M(d/h+\Delta_b/h+\Delta/h)]$; in which $S/2$ = the dimensionless wavemaker stroke measured at an arbitrary elevation above the wave flume bottom at $z = -h+d+\Delta_b+\Delta$. A piston wavemaker is represented by $S_b = S$; and a wavemaker of full-depth draft is represented by $b = d = 0$ and $\Delta = h$. The dimensionless free-surface $\eta(x,t)$ and total pressure $p(x,z,t)$ are

$$\eta(x,t) = \partial\Phi/\partial t - \frac{1}{2}\varepsilon\left|\vec{\nabla}\Phi\right|^2 + B(t) \quad ; \; x > \varepsilon\chi(\eta,t) \quad , \; z = \varepsilon\eta(x,t) \tag{5}$$

$$p(x,z,t) = \partial\Phi/\partial t - \frac{1}{2}\varepsilon\left|\vec{\nabla}\Phi\right|^2 - z/\varepsilon + B(t) \; ; \; x>\varepsilon\chi(z,t) \; , \; -h<z<\varepsilon\eta(x,t) \tag{6}$$

Equations (2c & d) & (5) may be expanded in a Maclauren series by

$$\sum_{n=0}^{\infty}\frac{(\varepsilon\eta)^n}{n!}\frac{\partial^n}{\partial z^n}[\frac{\partial^2\Phi}{\partial t^2} + \frac{\partial\Phi}{\partial z} - (\varepsilon\frac{\partial}{\partial t} - \frac{1}{2}\varepsilon^2\vec{\nabla}\Phi\cdot\vec{\nabla})\left|\vec{\nabla}\Phi\right|^2 + \frac{dB}{dt}] = 0 \; ; x>0 \; , z=0 \tag{7a}$$

$$\eta - \sum_{n=0}^{\infty}\frac{(\varepsilon\eta)^n}{n!}\frac{\partial^n}{\partial z^n}[\frac{\partial\Phi}{\partial t} - \frac{1}{2}\varepsilon\left|\vec{\nabla}\Phi\right|^2 + B] = 0 \quad ; \; x > 0 \; , \; z = 0 \tag{7b}$$

$$\sum_{n=0}^{\infty} \frac{(\varepsilon\chi)^n}{n!} \frac{\partial^n}{\partial x^n} \left[\frac{\partial \Phi}{\partial x} + \frac{\partial \chi}{\partial t} - \varepsilon \frac{\partial \Phi}{\partial z} \frac{\partial \chi}{\partial z}\right] = 0 \quad ; \; x = 0 \; ; \; -h \leq z \leq 0 \tag{7c}$$

In addition, the functions Φ, η, B, p, and ω may also be expanded in the small parameter, ε, by the following:

$$\Phi(x,z,t) = \sum_{n=0}^{\infty} \varepsilon^n \, {}_{n+1}\Phi(x,z,t) \tag{8a}$$

$$\eta(x,t) = \sum_{n=0}^{\infty} \varepsilon^n \, {}_{n+1}\eta(x,t) \tag{8b}$$

$$B(t) = \sum_{n=0}^{\infty} \varepsilon^n \, {}_{n+1}B(t) \tag{8c}$$

$$p(x,z,t) = p_s(z) + \sum_{n=0}^{\infty} \varepsilon^n \, {}_{n+1}P(x,z,t) \tag{8d}$$

$$\omega t = \tau = \left(\sum_{n=0}^{\infty} \varepsilon^n \, \omega_n\right) t \tag{8e}$$

in which $p_s(z) = z/\varepsilon$ = the dimensionless hydrostatic pressure.

Substituting Eqs. (7) & (8) into Eqs. (2)-(6) and collecting terms of the same order in ε results in a set of linear boundary value problems which may be solved in successive order.

Linear Solution

The linear boundary value problem for first-order (ε^o) is

$$\nabla^2 \, {}_1\Phi = 0 \quad ; \; x \geq 0 \; , \; -h \leq z \leq 0 \tag{9a}$$

$$\partial \, {}_1\Phi/\partial z = 0 \quad ; \; x \geq 0 \; , \; z = -h \tag{9b}$$

$$\mathcal{L}\{{}_1\Phi\} + \omega_o \, \partial \, {}_1B/\partial\tau = 0 \quad ; \; x \geq 0 \; , \; z = 0 \tag{9c}$$

$$\partial \, {}_1\Phi/\partial x = -\omega_o \partial\chi/\partial\tau \quad ; \; x = 0 \; , \; -h \leq z \leq 0 \tag{9d}$$

in which the linear, free-surface operator, $\mathcal{L}\{\cdot\}$, is defined by

$$\mathcal{L}\{\cdot\} = (\omega_o^2 \, \partial^2/\partial\tau^2 + \partial/\partial z)\{\cdot\} \tag{10}$$

The solution to Eqs. (9) must also satisfy a radiation condition at infinity as $x \to +\infty$ that will admit only right progressing waves or bounded evanescent eigenmodes.

The first-order, free-surface elevation, ${}_1\eta(x,\tau)$, and the dynamic pressure ${}_1P(x,z,\tau)$ may be determined from

$${}_1\eta(x,\tau) = \omega_o \, \partial \, {}_1\Phi/\partial\tau \quad ; \; x \geq 0 \; , \; z = 0 \tag{11}$$

$${}_1P(x,z,\tau) = \omega_o \, \partial \, {}_1\Phi/\partial\tau \quad ; \; x \geq 0 \; , \; -h \leq z < 0 \tag{12}$$

A simple-harmonic solution to the linear problem requires that ${}_1B$ be identically zero in Eq. (9c). The linear solution which satisfies the radiation condition as $x \to +\infty$ is well-known and may be expressed

by the following eigenfunction expansion (Hudspeth and Chen, 1981):

$$ {}_1\Phi(x,z,\tau) = -a_1\phi_1(z)\sin(x-\tau) - \cos\tau \sum_{m=2} a_m\phi_m(z)\exp(-\alpha_m x) \qquad (13) $$

in which the orthonormal eigenfunctions, $\phi_m(z)$ in the interval of orthogonality $[-h\leq z\leq 0]$ are given by $\phi_m(z) = \cos[\alpha_m(z+h)]/n_m$; where the normalizing constants, n_m, are computed from $n_m^2 = [2\alpha_m h+\sin 2\alpha_m h]/4\alpha_m$; provided that $\omega_o^2 h+\alpha_m h \tan \alpha_m h = 0$ where $\alpha_1 = +i$.

The dimensionless coefficients, a_m, in Eq. (13) are given by

$$ a_1 = \frac{\omega_o(S/2\Delta)}{n_1} D_1(h) \; ; \; a_m = \frac{\omega_o(S/2\Delta)\, D_m(\alpha_m h)}{\alpha_m^3 n_m} \; ; \; m \geq 2 \qquad (14) $$

$$ D_1(h) = h[M(1-b/h)+B']\sinh[h(1-b/h)]-h[M(d/h)+B']\sinh[h(d/h)\cdot U(d/h)] $$

$$ - M\{\cosh[h(1-b/h)]-\cosh[h(d/h)\cdot U(d/h)]\} \qquad (15a) $$

$$ D_m(\alpha_m h) = -(\alpha_m h)[M(1-b/h)+B']\sin[(\alpha_m h)(1-b/h)] $$

$$ +(\alpha_m h)[M(d/h)+B']\sin[(\alpha_m h)(d/h)\cdot U(d/h)]-M\{\cos[(\alpha_m h)(1-b/h)] $$

$$ -\cos[(\alpha_m h)(d/h)\cdot U(d/h)]\} \; ; \quad m \geq 2 \qquad (15b) $$

where M and B' are defined by Eqs. (4) and $U(\cdot)$ = Heaviside step function which is required for negative-draft wavemakers ($d < 0$).

Second-Order Solution

The boundary value problem for second-order (ε^1) is

$$ \nabla_2^2\Phi = 0 \qquad ; \; x \geq 0 \; , \; -h \leq z \leq 0 \qquad (16a) $$

$$ \partial_2\Phi/\partial z = 0 \qquad ; \; x \geq 0 \; , \; z = -h \qquad (16b) $$

$$ \mathcal{L}\{{}_2\Phi\} + \omega_o \, \partial_2 B/\partial\tau = -2\omega_o\omega_1 \, \partial^2{}_1\Phi/\partial\tau^2 + \omega_o \frac{\partial}{\partial\tau} \left|\vec{\nabla}_1\Phi\right|^2 $$

$$ - {}_1\eta \frac{\partial}{\partial z}(\omega_o^2 \, \partial^2{}_1\Phi/\partial\tau^2 + \partial_1\Phi/\partial z) \qquad ; \; x \geq 0 \; , \; z = 0 \qquad (16c) $$

$$ \partial_2\Phi/\partial x = -\omega_1\partial\chi/\partial\tau+\partial_1\Phi/\partial z \; \partial\chi/\partial z-(\partial^2{}_1\Phi/\partial x^2)\chi \; ; \; x=0 \; , -h\leq z\leq 0 \qquad (16d) $$

The solution to Eqs. (16) must also satisfy a radiation condition at infinity as $x\to+\infty$ that will admit only right progressing waves or bounded eigenmodes. Because Eq. (16d) is an inhomogeneous Neumann condition, any constant times x may also be used for any time-independent solution.

The Bernoulli constant is ${}_2B = (a_1/2n_1)^2$ and $\partial_2 B/\partial\tau = 0$ in Eq. (16c). The first term in the right hand side of Eq. (16c) must vanish since $\partial^2{}_1\Phi/\partial\tau^2$ is a homogeneous solution of the linear operator on the left hand side of Eq. (16c) so that $\omega_1 = 0$.

It is customary in boundary value problems with inhomogeneous boundary conditions on orthogonal boundaries such as those given by Eqs. (16c & d) to linearly decompose the solution into complementary

homogeneous and inhomogeneous solutions. Accordingly, the solution to Eqs. (16) may be expressed as the linear sum of four scalar velocity potentials given by $_2\Phi = {}_2\Phi^s + {}_2\Phi^e + {}_2\Phi^f + \Psi$ in which $_2\Phi^s$ is a second-order Stokes wave potential; $_2\Phi^e$ is a near-field evanescent interaction potential; $_2\Phi^f$ is a wavemaker-forced potential; and Ψ is a time-independent potential needed to satisfy Eqs. (16c & d) exactly. This linear decomposition of $_2\Phi$ reduces Eqs. (16c & d) to

$$\begin{aligned}
&\mathcal{L}\{{}_2\Phi^s+{}_2\Phi^e+{}_2\Phi^f+\Psi\} = a_1^2 f_1(\phi_1)\sin 2(x-\tau) \\
&- a_1 \sin(x-2\tau)\sum_{m=2} a_m \exp(-\alpha_m x) f_2(\phi_1,\phi_m) \\
&+ a_1 \cos(x-2\tau)\sum_{m=2} a_m \exp(-\alpha_m x) f_3(\phi_1,\phi_m) \\
&- \sin 2\tau \sum_{m=2}\sum_{n=2} a_m a_n \exp[-(\alpha_m+\alpha_n)x] f_4(\phi_m,\phi_n) \\
&- a_1 \cos x \sum_{m=2} a_m \exp(-\alpha_m x) f_5(\phi_1,\phi_m) \quad ; \; x\geq 0 \; , \; z=0
\end{aligned} \tag{17a}$$

$$\begin{aligned}
\frac{\partial}{\partial x}\{{}_2\Phi^s+{}_2\Phi^e+{}_2\Phi^f+\Psi\} &= +\frac{a_1}{2} W_1(\phi_1,\xi,z)[1-\cos 2\tau] \\
&+ \frac{\sin 2\tau}{2}\sum_{m=2} a_m \alpha_m W_2(\phi_m,\xi,z) \quad ; \; x=0, \; -h\leq z\leq 0
\end{aligned} \tag{17b}$$

in which the nonlinear, free surface interaction terms f_1, f_2, f_3, f_4, and f_5, and the nonlinear, wavemaker interaction terms W_1 and W_2 represent nonlinear interactions involving first-order quantities that are defined in Appendix I.

The second-order Stokes wave potential, $_2\Phi^s$, must satisfy exactly Eqs. (16a & b); a radiation condition at infinity as $x \to +\infty$ requiring only right progressing waves, as well as the inhomogeneous part of the nonlinear free-surface condition in Eq. (17a) given by

$$\mathcal{L}\{{}_2\Phi^s\} - a_1^2 f_1(\phi_1)\sin 2(x-\tau) = 0 \qquad ; \; x \geq 0 \; , \; z = 0 \tag{18}$$

The well-known Stokes (1847) wave potential is simply $_2\Phi^s = -(3\omega_o/8)\operatorname{cosech}^4 h \cosh 2(z+h) \sin 2(x-\tau)$.

The near-field evanescent wave potential, $_2\Phi^e$, must satisfy Eqs. (16a & b), a radiation condition at infinity as $x \to +\infty$ requiring only bounded evanescent eigenmodes, as well as that part of the inhomogeneous free-surface boundary condition given by

$$\begin{aligned}
&\mathcal{L}\{{}_2\Phi^e\} + a_1 \sin(x-2\tau)\sum_{m=2} a_m \exp(-\alpha_m x) f_2(\phi_1,\phi_m) \\
&- a_1 \cos(x-2\tau)\sum_{m=2} a_m \exp(-\alpha_m x) f_3(\phi_1,\phi_m) \\
&+ \sin 2\tau \sum_{m=2}\sum_{n=2} a_m a_n \exp[-(\alpha_m+\alpha_n)x] f_4(\phi_m,\phi_n) = 0 \; ; \; x \geq 0 \; , \; z = 0
\end{aligned} \tag{19}$$

A solution for the near-field evanescent potential that satisfies a radiation condition as $x \to +\infty$ is assumed to be given by

$$
\begin{aligned}
{}_2\Phi^e(x,z,\tau) = a_1 \cos(x-2\tau) \sum_{m=2} a_m \exp(-\alpha_m x)[A_m \phi_1(z)\phi_m(z) + B_m \phi_1'(z)\phi_m'(z)] \\
- a_1 \sin(x-2\tau) \sum_{m=2} a_m \exp(-\alpha_m x)[A_m \phi_1'(z)\phi_m'(z) - B_m \phi_1(z)\phi_m(z)] \\
- \sin 2\tau \sum_{m=2} \sum_{n=2} a_m a_n \exp[-(\alpha_m+\alpha_n)x] C_{mn}[\phi_m(z)\phi_n(z) - \phi_m'(z)\phi_n'(z)]
\end{aligned}
\tag{20a}
$$

where

$$
\phi_1'(z) = \sinh(z+h)/n_1; \qquad \phi_m'(z) = \sin[\alpha_m(z+h)]/n_m; \qquad m \geq 2 \tag{20b}
$$

Substituting Eqs. (20) into Eq. (19) and equating coefficients of like functions gives

$$
A_m = \frac{\alpha_m^2 \omega_o^3 \{12 + 2(\alpha_m^2-1)/\omega_o^4 + \operatorname{cosec}^2\alpha_m h - \operatorname{cosech}^2 h\}}{[4\omega_o^4 + \alpha_m^2 - 1]^2 + (2\alpha_m)^2} \tag{21a}
$$

$$
B_m = \frac{\alpha_m \omega_o^3}{2} \frac{\{[4\omega_o^4 + \alpha_m^2 - 1][\operatorname{cosech}^2 h - \operatorname{cosec}^2\alpha_m h - 4] + 8(\alpha_m/\omega_o^2)^2\}}{[4\omega_o^4 + \alpha_m^2 - 1]^2 + (2\alpha_m)^2} \tag{21b}
$$

$$
C_{mn} = \alpha_m \alpha_n \omega_o^3 \frac{[1 + (\alpha_n \alpha_m/\omega_o^4) + \frac{1}{4}(\operatorname{cosec}^2\alpha_m h + \operatorname{cosec}^2\alpha_n h)]}{(2\omega_o^2)^2 + (\alpha_m - \alpha_n)^2} \tag{21c}
$$

The wavemaker-forced potential, ${}_2\Phi^f$, must satisfy Eqs. (16a & b); a homogeneous form of the linear, free-surface operator defined by Eq. (10); a radiation condition at infinity as $x \to +\infty$ requiring only right progressing waves and bounded eigenmodes; as well as that part of the inhomogeneous wavemaker boundary condition given by

$$
\begin{aligned}
\frac{\partial}{\partial x}\{{}_2\Phi^f\} + \frac{\partial}{\partial x}\{{}_2\Phi^s + {}_2\Phi^e\} + \frac{a_1}{2}\cos 2\tau \; W_1(\phi_1,\xi,z) \\
- \frac{\sin 2\tau}{2} \sum_{m=2} a_m \alpha_m W_2(\phi_m,\xi,z) = 0 \; ; \; x = 0, \; -h < z < 0
\end{aligned}
\tag{22}
$$

A solution for the wavemaker-forced potential that satisfies a radiation condition at $x \to +\infty$ is assumed to be given by

$$
\begin{aligned}
{}_2\Phi^f(x,z,\tau) = \{E_1 \cos(\beta_1 x - 2\tau) + F_1 \sin(\beta_1 x - 2\tau)\} Q_1(z) \\
- \sum_{j=2} \exp(-\beta_j x)\{E_j \sin 2\tau + F_j \cos 2\tau\} Q_j(z)
\end{aligned}
\tag{23}
$$

in which the orthonormal eigenfunctions, $Q_j(z)$, in the interval of orthogonality $[-h \leq z \leq 0]$ are $Q_j(z) = \cos\beta_j(z+h)/N_j$; where the normalizing constants are $N_j^2 = (2\beta_j h + \sin 2\beta_j h)/(4\beta_j)$; provided that $4\omega_o^2 h + \beta_j h \tan \beta_j h = 0$ and that $\beta_1 = i\beta_1$.

The coefficients E_j and F_j are

$$E_j = -\beta_j^{-1}\{\sum_{m=2} a_m[a_1(A_m+\alpha_m B_m)\langle\phi_1\phi_m,Q_j\rangle_z + \sum_{n=2} a_n(\alpha_m+\alpha_n)C_{mn}\langle\phi_m\phi_n,Q_j\rangle_z]$$

$$+ \sum_{m=2} a_m[a_1(B_m-\alpha_m A_m)\langle\phi_1'\phi_m',Q_j\rangle_z - \sum_{n=2} a_n(\alpha_m+\alpha_n)C_{mn}\langle\phi_m'\phi_n',Q_j\rangle_z]$$

$$- \sum_{m=2} \frac{a_m\alpha_m}{2}\langle W_2,Q_j\rangle_z\} \quad ; j \geq 1 \tag{24a}$$

$$F_j = \beta_j^{-1}\{\frac{3\omega_o}{4\sinh^4 h}\langle\cosh 2(z+h),Q_j\rangle_z + a_1\sum_{m=2} a_m[(A_m\alpha_m-B_m)\langle\phi_1\phi_m,Q_j\rangle_z +$$

$$+ (A_m+\alpha_m B_m)\langle\phi_1'\phi_m',Q_j\rangle_z] - \frac{a_1}{2}\langle W_1,Q_j\rangle_z\} \quad ; j \geq 1 \tag{24b}$$

where the inner product terms $\langle\cdot,\cdot\rangle_z$ in Eqs. (24) are summarized in Appendix II.

An interesting feature of the second-order problem which has not previously been given much detailed attention is the time-independent potential, $\Psi(x,z)$, which must satisfy the following:

$$\nabla^2\Psi = 0 \quad ; x \geq 0\ ,\ -h \leq z \leq 0 \tag{25a}$$

$$\mathcal{L}\{\Psi\} = \frac{\partial\Psi}{\partial z} = -a_1 \cos x \sum_{m=2} a_m\exp(-\alpha_m x)f_5(\phi_1,\phi_m) \quad ; x \geq 0\ ;\ z = 0 \tag{25b}$$

$$\frac{\partial\Psi}{\partial z} = 0 \quad ; x \geq 0\ ;\ z = -h \tag{25c}$$

$$\frac{\partial\Psi}{\partial x} = \frac{a_1}{2} W_1(\phi_1,\xi,z) \quad ; x = 0\ ;\ -h \leq z \leq 0 \tag{25d}$$

Because the time-independent solution is not a progressive wave, the radiation condition at infinity as $x \to +\infty$ is relaxed to admit bounded, time-independent velocities.

Similarly, Ψ may be decomposed into two linearly independent potentials according to $\Psi = \Psi^{fs} + \Psi^{wm}$.

The free surface potential, Ψ^{fs}, must satisfy Eqs. (25a & c); a boundedness condition as $x \to +\infty$; in addition to the inhomogeneous free surface boundary condition given by Eq. (25b). A solution which is bounded is given by

$$\Psi^{fs}(x,z) = a_1 \cos x \sum_{m=2} a_m\exp(-\alpha_m x)[b_m\phi_1(z)\phi_m(z) + c_m\phi_1'(z)\phi_m'(z)]$$

$$- a_1 \sin x \sum_{m=2} a_m\exp(-\alpha_m x)[b_m\phi_1'(z)\phi_m'(z) - c_m\phi_1(z)\phi_m(z)] \tag{26a}$$

where

$$b_m = - \frac{\omega_o^3 \alpha_m^2 \, [\mathrm{cosech}^2 h + \mathrm{cosec}^2 \alpha_m h]}{(\alpha_m^2 + 1)^2} \tag{26b}$$

$$c_m = - \frac{\omega_o^3 \alpha_m (\alpha_m^2 - 1)[\mathrm{cosech}^2 h + \mathrm{cosec}^2 \alpha_m h]}{2(\alpha_m^2 + 1)^2} \tag{26c}$$

The wavemaker potential, Ψ^{wm}, must satisfy Eqs. (25a & c); a boundedness condition on the velocity as $x \to +\infty$; in addition to a homogeneous free surface boundary condition given by

$$\mathcal{L}\{\Psi^{wm}\} = \frac{\partial \Psi^{wm}}{\partial z} = 0 \qquad ; \; x \geq 0 \; ; \; z = 0 \tag{27}$$

and an inhomogeneous wavemaker boundary condition given by

$$\frac{\partial \Psi^{wm}}{\partial x} - \frac{a_1}{2} W_1(\phi_1, \xi, z) + \frac{\partial \Psi^{fs}}{\partial x} = 0 \qquad ; \; x = 0 \; ; \; -h \leq z \leq 0 \tag{28}$$

A solution for Ψ^{wm} is given by the following eigenfunction expansion:

$$\Psi^{wm}(x,z) = \sum_{j=0} d_j \psi_j(z) [\exp(-\mu_j x) + \delta_{jo}(x-1)] \tag{29}$$

where the orthonormal eigenfunctions, $\psi_j(z)$, in the interval of orthogonality $[-h \leq z \leq 0]$ are given by

$$\psi_j(z) = \cos \mu_j (z+h) / [h/(2-\delta_{jo})]^{1/2} \qquad ; \; j \geq 0 \tag{30}$$

provided that the eigenvalues, μ_j, are given by $\mu_j = j\pi/h$.

The coefficients d_j are

$$d_j = - (\mu_j - \delta_{jo})^{-1} a_1 \{ \tfrac{1}{2} \langle W_1, \psi_j \rangle_z + \sum_{m=2} a_m [b_m (\alpha_m \langle \phi_1 \phi_m, \psi_j \rangle_z + \langle \phi_1' \phi_m' , \psi_j \rangle_z)$$

$$+ c_m \, (\alpha_m \langle \phi_1' \phi_m', \psi_j \rangle_z - \langle \phi_1 \phi_m, \psi_j \rangle_z)] \} \qquad ; \; j \geq 0 \tag{31}$$

where the inner product terms $\langle \cdot, \cdot \rangle_z$ are summarized in Appendix II.

CIRCULATION KINEMATICS

It is of interest to compare the second-order (ε), time-independent solution forced by the weakly nonlinear boundary conditions at both the free surface and the wavemaker boundaries given by Eqs. (17) with the mean horizontal momentum per unit area. The time- and depth-averaged dimensionless mean horizontal momentum per unit area is defined by (Phillips, 1977)

$$M_E = \left\langle \int_{-h}^{\eta} U_E \, dz \right\rangle_{2\pi} \tag{32}$$

where the temporal averaging operator $\langle\cdot\rangle_{2\pi} = (2\pi)^{-1}\int_0^{2\pi}(\cdot)d\tau$ and U_E is an Eulerian horizontal velocity component.

The horizontal component of the dimensionless Eulerian velocity may be determined approximately from

$$M_E = U_\Psi + U_\Phi + O(\varepsilon^2) \tag{33}$$

The dimensionless horizontal component, U_Ψ, that is forced by f_5 and W_1 in Eqs. (17) may be estimated from the time-independent velocity potential according to $U_\Psi = U_{\Psi,\infty}(d_o) + U_{\Psi,e}(a_m)$ where

$$U_{\Psi,\infty}(d_o) = -\varepsilon(2\omega_o)^{-1}\left\{\frac{n_1}{D_1(h)\phi_1'(o)}\right\}\{h[M(1-b/h)+B']\cosh b(\omega_o^2-\tanh b)$$
$$-h[M(d/h)+B']\sinh d\ \mathrm{sech}\ h$$
$$+\omega_o^6\sum_{m=2}\frac{\phi_m(o)D_m(\alpha_m h)}{n_m\alpha_m^2(\alpha_m^2+1)}[\mathrm{cosech}^2 h+\mathrm{cosech}^2\alpha_m h]\} \tag{34a}$$

$$U_{\Psi,e}(a_m) = \varepsilon\frac{\omega_o^5 n_1}{D_1(h)\phi_1'(o)}\cos x\sum_{m=2}\frac{\phi_m(o)D_m(\alpha_m h)}{n_m\alpha_m^3(\alpha_m^2+1)}\exp-\alpha_m x$$
$$[\mathrm{cosech}^2 h+\mathrm{cosech}^2\alpha_m h][\alpha_m-\tan x] \tag{34b}$$

Similarly, the dimensionless horizontal component, U_Φ, may be estimated from the first-order eigenmodes by a Maclauren series expansion about the still water level according to

$$U_\Phi = -\varepsilon\omega_o\langle(\partial_1\Phi/\partial x)(\partial_1\Phi/\partial\tau)\rangle_{2\pi} = U_{\Phi,\infty}(\omega_o)+U_{\Phi,e}(a_m)\ ;\ z=0 \tag{35a}$$

The dimensionless, far-field component, $U_{\Phi,\infty}(\omega_o)$, is given by

$$U_{\Phi,\infty}(\omega_o) = \varepsilon(2\omega_o)^{-1} \tag{35b}$$

which is the well-known Eulerian description of the dimensionless Stokes drift (Longuet-Higgins, 1953). The dimensionless evanescent component, $U_{\Phi,e}(a_m)$, is given by

$$U_{\Phi,e}(a_m) = -(\varepsilon/2)\cos x\sum_{m=2}a_m\phi_m(o)\exp-\alpha_m x\ [\alpha_m-\tan x] \tag{35c}$$

In the far-field ($x > 3h$, say), the evanescent components of the mean horizontal momentum per unit area, $U_{\Psi,e}(a_m) + U_{\Phi,e}(a_m)$, are negligible. This implies that far away from the local wavemaker effects, the mean horizontal momentum per unit area is approximately

$$M_E \sim \varepsilon(2\omega_o)^{-1}\{1-[\frac{n_1}{D_1(h)\phi_1'(o)}][h(M(1-b/h)+B')\cosh b(\omega_o^2-\tanh b)$$
$$-h(M(d/h)+B')\sinh d\ \mathrm{sech}\ h$$
$$+\omega_o^6\sum_{m=2}\frac{\phi_m(o)D_m(\alpha_m h)}{n_m\alpha_m^2(\alpha_m^2+1)}(\mathrm{cosech}^2 h+\mathrm{cosech}^2\alpha_m h)]\} \tag{36}$$

which implies that for wavemakers intersecting the free surface (i.e., b=o), the leading-order coefficient, d_o, approximately estimates the uniform return current required to insure a zero net mass flux in a closed wave flume. This may be observed by plotting the dimensionless, time-independent Eulerian velocities.

The dimensionless horizontal component of the second-order (ε), time-independent fluid motion is

$$U_\psi(x,z) = -\varepsilon \frac{\partial \psi^{wm}}{\partial x} - \varepsilon \frac{\partial \psi^{fs}}{\partial x}$$

$$= \varepsilon \sum_{j=0} d_j(\mu_j \psi_j(z) \exp -\mu_j x - \delta_{jo})$$

$$- \varepsilon \frac{\omega_o^3}{4} \frac{n_1}{D_1(h)} [1+2h \text{ cosech } 2h] \cos x \sum_{m=2} \frac{D_m(\alpha_m h)}{n_m} \frac{\exp -\alpha_m x}{\alpha_m^2(\alpha_m^2+1)}$$

$$[\text{cosech}^2 h + \text{cosec}^2 \alpha_m h][\phi_1(z)\phi_m(z)(1+\alpha_m \tan x)$$

$$+ \phi_1'(z)\phi_m'(z)(\alpha_m - \tan x)] \qquad (37a)$$

and the dimensionless vertical component is

$$V_\psi(x,z) = -\varepsilon \frac{\partial \psi^{wm}}{\partial z} - \varepsilon \frac{\partial \psi^{fs}}{\partial z}$$

$$= \varepsilon \sum_{j=1} d_j \mu_j \psi_j'(z) \exp -\mu_j x$$

$$- \varepsilon \frac{\omega_o^3}{4} \frac{n_1}{D_1(h)} [1+2h \text{ cosech } 2h] \cos x \sum_{m=2} \frac{D_m(\alpha_m h)}{n_m} \frac{\exp -\alpha_m x}{\alpha_m^2(\alpha_m^2+1)}$$

$$[\text{cosech}^2 h + \text{cosec}^2 \alpha_m h][\phi_1(z)\phi_m'(z)(1+\alpha_m \tan x)$$

$$- \phi_1'(z)\phi_m(z)(\alpha_m - \tan x)] \qquad (37b)$$

where $\psi_j'(z) = \sin \mu_j(z+h)/\sqrt{h}$.

The magnitude of the velocity $[U_\psi^2(x,z) + V_\psi^2(x,z)]^{1/2}$ is illustrated in Figs. 2 & 3 for both a piston and hinged wavemaker. Figures 2 & 3 demonstrate that the mean return current is estimated reasonably well by the leading coefficient, d_o.

ACKNOWLEDGEMENTS

Support has been provided to RTH by the Office of Naval Research under the University Research Inititative (URI) Contract No. N00014-86-K-0687; to WS (in part) by the United States-Spain Joint Committee for Scientific and Technological Cooperation under Contract No. CCA8510095; and to T-IK by the Office of Overseas Education of the Korean Army. The support of each of these agencies is gratefully

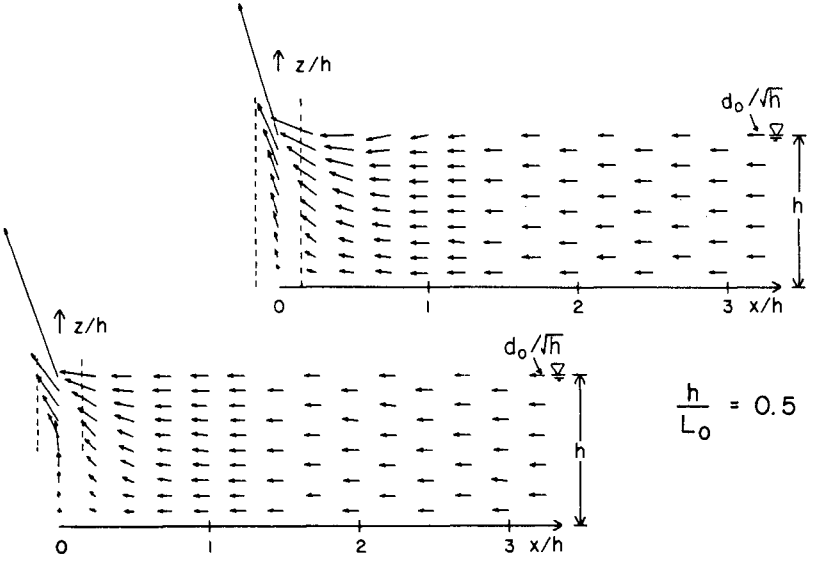

Fig. 2. Magnitude of dimensionless time-independent velocity (piston)

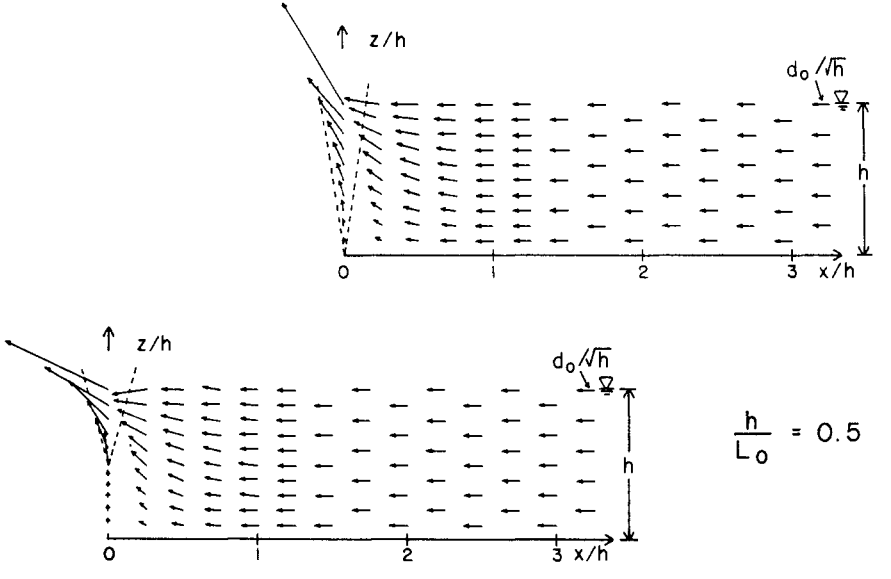

Fig. 3. Magnitude of dimensionless time-independent velocity (hinged)

appreciated. We are deeply indebted to R.B. Guenther and A.N. Williams for illuminating a number of obscure and subtle features of weakly nonlinear boundary value problems.

APPENDIX I: NONLINEAR INTERACTION COEFFICIENTS

The nonlinear, inhomogeneous free surface interaction terms in Eq. (17a) are defined from first-order quantities by the following:

$$f_1(\phi_1) = 3\omega_o n_1^{-2}/2 \tag{I.1}$$

$$f_2(\phi_1,\phi_m) = 2\alpha_m\omega_o\phi_1(0)\phi_m(0) \tag{I.2}$$

$$f_3(\phi_1,\phi_m) = \frac{\omega_o^5}{2}\,\phi_1(0)\,\phi_m(0)[\operatorname{cosech}^2 h - \operatorname{cosec}^2\alpha_m h - 4] \tag{I.3}$$

$$f_4(\phi_m,\phi_n) = \omega_o^5\,\phi_n(0)\,\phi_m(0)\,[\alpha_n\alpha_m/\omega_o^4+1+\tfrac{1}{4}\,(\operatorname{cosec}^2\alpha_m h+\operatorname{cosec}^2\alpha_n h)] \tag{I.4}$$

$$f_5(\phi_1,\phi_m) = (\omega_o^5/2)\phi_1(0)\,\phi_m(0)[\operatorname{cosech}^2 h + \operatorname{cosec}^2\alpha_m h] \tag{I.5}$$

The nonlinear, inhomogeneous wavemaker interaction terms in Eq. (17b) are defined by the following:

$$W_1(\phi_1,\xi,z) = [\phi_1'(z)\partial\xi/\partial z+\phi_1(z)\xi]\cdot[U(z+h-d)-U(z+b)] \tag{I.6}$$

$$W_2(\phi_m,\xi,z) = [\phi_m'(z)\partial\xi/\partial z+\alpha_m\phi_m(z)\xi]\cdot[U(z+h-d)-U(z+b)] \tag{I.7}$$

where $\xi(z)$ is defined in Eq. (4); ϕ_m' are defined in Eq. (20b); and

$$\partial\xi/\partial z = M(S/2\Delta) \tag{I.8}$$

APPENDIX II: INNER PRODUCTS $\langle\cdot,\cdot\rangle_z$

The inner product terms used to compute the coefficients of the second-order potential are determined from

$$\langle\cdot,\cdot\rangle_z = \int_{-h}^{o}\{\cdot,\cdot\}dz \tag{II.1}$$

These inner products are:

$$\langle\phi_m\phi_n,\Lambda_j\rangle_z = \phi_m(o)\phi_n(o)\Lambda_j(o)\left\{\frac{2(\omega_o\lambda_j)^2+\Omega_j[2\omega_o^4+\alpha_m^2+\alpha_n^2-\lambda_j^2]}{(\alpha_m^2+\alpha_n^2-\lambda_j^2)^2-(2\alpha_m\alpha_n)^2}\right\} \tag{II.2}$$

$$\langle\phi_m'\phi_n',\Lambda_j\rangle_z = \phi_m(o)\phi_n(o)\Lambda_j(o)\left|\alpha_m\right|\left|\alpha_n\right|$$

$$\left\{\frac{\omega_o^2[\alpha_m^4+\alpha_n^4-\lambda_j^2(\alpha_m^2+\alpha_n^2)+\omega_o^2\Omega_j(\alpha_m^2+\alpha_n^2-\lambda_j^2)]-2(\alpha_m\alpha_n)^2[\omega_o^2-\Omega_j]}{\alpha_m^2\alpha_n^2[(\alpha_m^2+\alpha_n^2-\lambda_j^2)^2-(2\alpha_m\alpha_n)^2]}\right\} \tag{II.3}$$

$$\langle \cosh 2(z+h), Q_j \rangle_z = \frac{4\omega_o^6 \, Q_j(0)}{(\omega_o^4 - 1)(4 + \beta_j^2)} \tag{II.4}$$

$$\langle W_1, \Lambda_j \rangle_z = \frac{S}{2\Delta} M \langle \phi_1' \Delta U, \Lambda_j \rangle_z + \langle \phi_1 \xi \Delta U, \Lambda_j \rangle_z \tag{II.5}$$

$$\langle W_2, \Lambda_j \rangle_z = \frac{S}{2\Delta} M \langle \phi_m' \Delta U, \Lambda_j \rangle_z + \alpha_m \langle \phi_m \xi \Delta U, \Lambda_j \rangle_z \tag{II.6}$$

$$\langle \phi_m' \Delta U, \Lambda_j \rangle_z = \frac{|\alpha_m|}{\alpha_m^2} [\lambda_j^2 - \alpha_m^2]^{-1} \{ \phi_m(0) \Lambda_j(0) \cos \alpha_m b \cos \lambda_j b \tag{II.7}$$

$$[(\omega_o^2 + \alpha_m \tan \alpha_m b)(\Omega_j + \lambda_j \tan \lambda_j b) + \alpha_m^2 (1 + \tan \alpha_m h \tan \alpha_m b)(1 + \tan \lambda_j h \tan \lambda_j b)]$$

$$- \phi_m [d \cdot U(d) - h] \Lambda_j (d \cdot U(d) - h) \alpha_m^2 [1 + (\lambda_j / \alpha_m) \tan(\lambda_j d \cdot U(d)) \tan(\alpha_m d \cdot U(d))] \}$$

$$\langle \phi_m \xi \Delta U, \Lambda_j \rangle_z = \frac{S}{2\Delta} M (\alpha_m^2 - \lambda_j^2)^{-2} \{ \phi_m(0) \Lambda_j(0) \cos \alpha_m b \cos \lambda_j b$$

CHAPTER 31

DECOMPOSITION OF NONLINEARLY REFLECTED IRREGULAR WAVES BY THE WAVE BREAKING AND DEFORMATION

by A. KIMURA*

ABSTRACT

This paper deals with a new method to decompose incident and reflected waves from the measured data of irregular standing waves. The theory by Goda et al. is extended to cope with the reflection from such a coastal structure that has a sloping surface and brings about different reflection coefficient for each incident waves. Irregular standing waves are decomposed into incident and reflected irregular waves by the short-term wave spectrum analysis method. And the reflection coefficient of the approximated zero-up-cross waves are defined as the ratio between envelopes of these irregular wave profiles. The calculated reflection coefficients can be discussed in terms of the incident zero-up-cross wave parameters such as a wave steepness, Ursell parameter, etc. An effective wave gauge system to measure irregular standing waves which have a wide band spectrum is also discussed and a method to compose the system is proposed.

1. INTRODUCTION

The theories by Kajima[1], Thornton et al.[2] and Goda et al.[3] have been commonly used to decompose incident and reflected waves from irregular standing waves formed in the vicinity of a model of off-shore structure. With these theories, irregular wave data measured at two or more different points[1] in a wave tank are firstly analyzed by the Fourier transform method and then decomposed into incident and reflected waves. The reflection coefficient is calculated for every frequency component of a spectrum. By these methods reliable reflection coefficients are calculated from an experiment of irregular waves when incident and reflected waves η_I and η_R can be written in the form

* Associate Prof. Faculty of Engg. Tottori University, Koyama Minami 4-101, Torrori, 680, Japan

$$\eta_I(t) = \sum_{n=1}^{\infty} a_{In}\cos(2\pi f_n t - \phi_{In}) \quad (1)$$

and

$$\eta_R(t) = \sum_{n=1}^{\infty} a_{Rn}\cos(2\pi f_n t - \phi_{Rn}) \quad (2)$$

in which f_n is the frequency of the n-th component. a_{In}, a_{Rn} are the amplitudes, ϕ_{In}, ϕ_{Rn} are the phases of incident and reflected waves, respectively.

In case of a breakwater made of stones or blocks, which has a sloped surface, however, the reflection characteristics of the irregular waves change almost wave by wave which are defined by the zero-up-cross method. A wave with a large steepness, for example, tends to break on a slope and loses significant part of its energy. Therefore, the resultant reflection coefficient is presumably very small for this wave. On the contrary, a wave with a small steepness is reflected with a large reflection coefficient, since it may not break on the slope. Since reflection coefficients differ wave by wave for this type of breakwater, amplitudes and phases in eq.(2) may change occasionally. There has been no established method to calculate the amplitude and phase of each wave from those reflected irregular waves. The amplitudes and phases of component waves decomposed by the ordinary Fourier transform method are, therefore, apparent ones in the analysis of reflection for this type of breakwaters. A large portion of existing offshore structures, however, somehow exhibit this type of reflection. This study aims to develop a method which facilitates the calculation of the reflection coefficient of irregular waves reflected from this type of breakwater.

2. DECOMPOSITION OF IRREGULAR STANDING WAVES INTO INCIDENT AND REFLECTED COMPONENT WAVES

For simplicity, the reflection of uni-directional irregular waves from a breakwater is treated in this study (see Fig.1). The coordinate system is shown in the same figure. Wave gauges with the interval $\Delta\ell$ are installed at a distance D from the breakwater. This breakwater is assumed to be of such a type that changes reflection characteristics according to the individual incident wave properties (e.g. steepness). Amplitudes and phases of reflected component waves in eq.(2), therefore, may be assumed constant only within a zero-up-cross interval of the wave profile. The Fourier transform method requires the constant amplitudes

and phases of component waves. However, since they are disturbed locally, data are analyzed with a data window in this study.

$$\gamma(u)=(\sqrt{2}/T')\exp[-\pi(t-u)^2/T'^2] \tag{3}$$

This window is the so called Gaussian window and has finite values only around t=u and has negligibly small values outside $t=u\pm T'/2$. Executing the convolution with wave profiles $\eta_1(t)$ and $\eta_2(t)$ measured at $x=x_1$ and $x=x_2$ in the wave tank respectively and the data window, amplitude of composed (i.e., incident and reflected) component wave is given as

$$A_{jn}(u)+iB_{jn}(u)=\frac{2}{T}\int_{-T/2}^{T/2}\eta_j(t)\gamma(u)\exp(-i2\pi f_n t)dt \tag{4}$$

in which $i=\sqrt{-1}$, $T>>T'$, $f_n=n/T$ $(n=1,2,\ldots)$ and $A_{jn}(u)$ and $B_{jn}(u)$ are

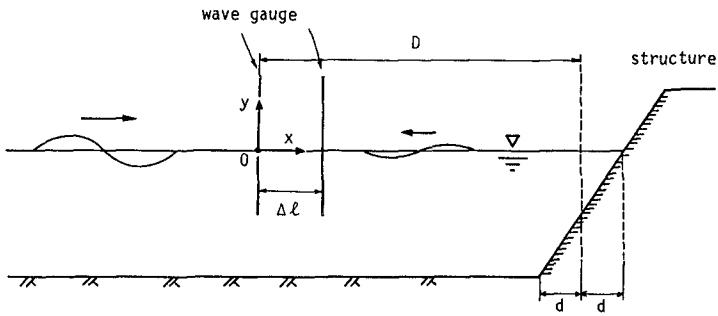

Fig.1 Illustration of wave gauges and a structure and the coordinate system.

real and imaginary parts of the n-th Fourier component of a spectrum. Subscript j indicates that those are the calculated values from the wave profiles $\eta_j(u)$ $(j=1,2)$. Substituting these components into the following equations, amplitudes and phases of incident and reflected component waves are obtained[3]:

$$a_{In}(u)=\frac{1}{2|\sin(k_n\Delta\ell)|}\{[A_{2n}(u)-A_{1n}(u)\cos(k_n\Delta\ell)-B_{1n}(u)\sin(k_n\Delta\ell)]^2$$
$$+[B_{2n}(u)+A_{1n}(u)\sin(k_n\Delta\ell)-B_{1n}(u)\cos(k_n\Delta\ell)]^2\}^{1/2}$$

$$a_{Rn}(u)=\frac{1}{2|\sin(k_n\Delta\ell)|}\{[A_{2n}(u)-A_{1n}(u)\cos(k_n\Delta\ell)+B_{1n}(u)\sin(k_n\Delta\ell)]^2$$
$$+[B_{2n}(u)-A_{1n}(u)\sin(k_n\Delta\ell)-B_{1n}(u)\cos(k_n\Delta\ell)]^2\}^{1/2}$$

$$\phi_{In}(u)= \tan^{-1}\left[\frac{-A_{2n}(u)+A_{1n}(u)\cos(k_n\Delta\ell)+B_{1n}(u)\sin(k_n\Delta\ell)}{B_{2n}(u)+A_{1n}(u)\sin(k_n\Delta\ell)-B_{1n}(u)\cos(k_n\Delta\ell)}\right] - k_n x_1$$

$$\phi_{Rn}(u)= \tan^{-1}\left[\frac{-A_{2n}(u)+A_{1n}(u)\cos(k_n\Delta\ell)-B_{1n}(u)\sin(k_n\Delta\ell)}{-B_{2n}(u)+A_{1n}(u)\sin(k_n\Delta\ell)+B_{1n}(u)\cos(k_n\Delta\ell)}\right] - k_n x_1 \qquad (6)$$

in which $a_{In}(u)$ and $a_{Rn}(u)$ are amplitudes and $\phi_{In}(u)$ and $\phi_{Rn}(u)$ are phases of incident and reflected component waves. Wave number k_n has the following relation with f_n:

$$(2\pi f_n)^2 = gk_n\tanh(k_n h) \qquad (7)$$

in which h is a water depth and g is the acceleration of gravity. Figure 2 shows an example of decomposed incident and reflected irregular wave components $a_{In}(u)$ (above) and $a_{Rn}(u)$ (below). Analyzed irregular waves are numerically simulated for the spectrum given by eq.8.

$$S(f)=2^{1/4}\exp[-\pi(f-f_p)^2\tau^2] \qquad (8)$$

In which the peak frequency f_p and the width parameter τ are 1.0Hz and 5s respectively. One hundred component waves from f=0.84Hz to 1.16Hz are composed in the simulation. The reflection coefficient of the breakwater is set to be 0.5 and no phase shift is assumed at the breakwater for all the component waves. Other parameters such as h=10cm, $\Delta\ell$ =23cm (1/4 wave length of the dominant component, f_n=1.0Hz), D=(2+0.23)m and T'=5s (eq.3) are used in the calculation. Plotted are the amplitudes of dominant frequency (f_n=1.0Hz).

Gradual changes of the incident and reflected wave amplitudes are

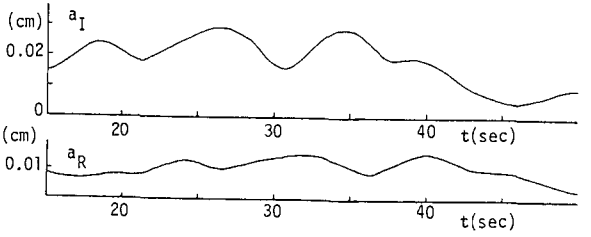

Fig.2 Gradual change in decomposed amplitudes of incident and reflected waves (f_n=1.0Hz).

observed in Fig.2. Only a time-independent single couple of incident and reflected amplitudes for individual component waves are obtained from the ordinary theories. The gradual changes in the present method are due to the leakage of a data window. The data window works not only for the emphasis of local property of data but also for the reduction of a resolution power by the Fourier transform method. If $\cos(2\pi f_0 t)$, for example, is analyzed instead of $\eta_j(t)$ in eq.(4), the calculated Fourier spectrum is not a single spike spectrum but has a spreading of spectrum values around $f=f_0$ as shown in Fig.3. This broad nature of the calculated spectrum is so called the leakage of a spectrum. The neighboring frequency components bring about this gradual change in the amplitudes (Fig.2). These changes in a_{In} and a_{Rn} are not the independent and random ones but seem to be coherent with each other since the prominent peaks in a_{In} reappear in a_{Rn} with some time interval. Although amplitude of reflected peaks reduce somehow. The averaged interval between these corresponding peaks is about 5.5s and this is the time required to go back and forth over the distance D (see Fig.1), with a group velocity of the dominant component wave (f_n=1.0Hz). The ratios between the time shifted amplitude $a_{Rn}(u-5.5)$ and the incident amplitude $a_{In}(u)$ are approximately 0.5 at any time irrespective of u. The gradual changes in the calculated wave amplitudes due to leakage, therefore, may be considered as an advantage of this method for the study of local correspondences of incident and reflected waves inspection.

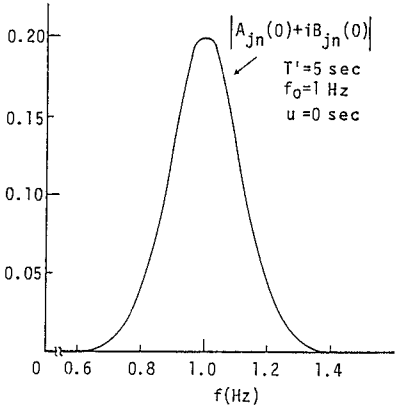

Fig.3 Leakage of a calculated spectrum.

3. THE METHOD OF EVALUATING THE LOCAL REFLECTION COEFFICIENT FROM THE ENVELOPES

Incident wave profile $\eta_I(u)$ and its envelope $E_I(u)$ are given in terms of $a_{In}(u)$ and $\phi_{In}(u)$ as

$$\eta_I(u)=\sum_{n=1}^{\infty} a_{In}(u)\cos[-2\pi f_n u+\phi_{In}(u)] \tag{9}$$

and

$$E_I(u)=[\eta_{Ic}^2(u)+\eta_{Is}^2(u)]^{1/2} \tag{10}$$

where

$$\eta_{Ic}(u)=\sum_{n=1}^{\infty} a_{In}(u)\cos[-2\pi(f_n-f_p)u+\phi_{In}(u)]$$

$$\eta_{Is}(u)=\sum_{n=1}^{\infty} a_{In}(u)\sin[-2\pi(f_n-f_p)u+\phi_{In}(u)] \tag{11}$$

Reflected wave profile $\eta_R(u)$ and its envelope E_R are also expressed in terms of $a_{Rn}(u)$ and $\phi_{Rn}(u)$ in the same way as

$$\eta_R(u)=\sum_{n=1}^{\infty} a_{Rn}(u)\cos[-2\pi f_n u+\phi_{Rn}(u)] \tag{12}$$

and

$$E_R(u)=[\eta_{Rc}^2(u)+\eta_{Rs}^2(u)]^{1/2} \tag{13}$$

where

$$\eta_{Rc}(u)=\sum_{n=1}^{\infty} a_{Rn}(u)\cos[-2\pi(f_n-f_p)u+\phi_{Rn}(u)]$$

$$\eta_{Rs}(u)=\sum_{n=1}^{\infty} a_{Rn}(u)\sin[-2\pi(f_n-f_p)u+\phi_{Rn}(u)] \tag{14}$$

Solid lines in Fig.4 show $\eta_I(u)$ (above) and $\eta_R(u)$ (below). Dotted lines are envelopes $E_I(u)$ and $E_R(u)$. Analyzed irregular waves are the same as those used in the calculation of Fig.2.

Numerically simulated incident waves and their calculated reflection waves are composed first and then decomposed into incident and reflected wave profiles again by use of equations from eqs.(4) to (6) and eqs.(9) to (14). Calculated decomposed wave profiles of incident and reflected waves show good agreements with those originally simulated ones.

Figure 5 shows the Lissajous' figure of E_I and E_R although E_R is shifted by 5.5s to adjust a time correspondence with E_I. The solid line shows the relation of $E_R=0.5E_I$. Since the reflection coefficient is set to be 0.5, this is approximately the theoretical relation in this case. Except small deviations in the small part, the agreement is found fairy good. The present method is extended to evaluate the reflection coefficient of individual waves defined by the zero-up-cross method in terms of their properties (e.g. steepness) as follows. Since E_I and E_R approximately pass the crests and troughs of waves as seen in Fig.4 and from the

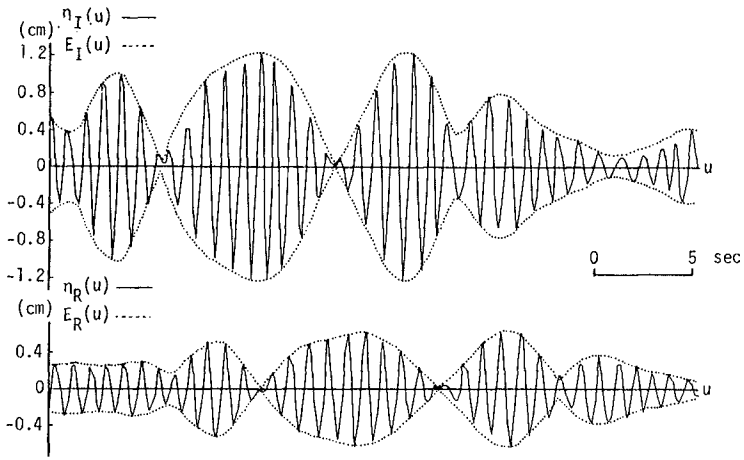

Fig.4 Decomposed wave profiles (solid lines) and their envelopes (dotted lines) for narrow-band spectrum case.

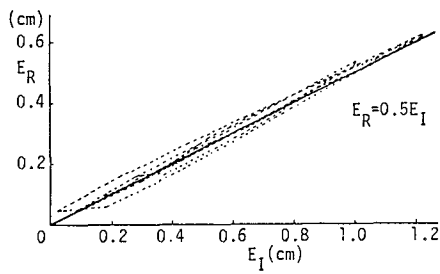

Fig.5 Lissajous' figure of E_I and E_R.

definition that an envelope is symmetrical about the u-axis, wave envelope may presumably have an instance u_i, within a zero-up-cross interval, when the twice of the envelope is equal to the zero-up-cross wave height determined in the same interval. Incident and reflected wave heights $H_I(u_i)$ and $H_R(u_i)$ are, therefore, approximated by equations

$$H_I(u_i) \simeq 2E_I(u_i), \qquad H_R(u_i) \simeq 2E_R(u_i) \tag{15}$$

The wave period of individual waves are approximated as follows. Equation 4 gives the short-term wave spectrum[4] in terms of u. The squared sum of amplitudes $| A_{jn}^2 + B_{jn}^2 |$ then changes from time to time according to the local properties of waves. The occasional zero-up-cross wave period can be approximated with $1/f_p(u_i)$ in which $f_p(u_i)$ is the peak frequency of the above squared spectrum at the instance u_i when the wave height is determined by eq.(15). The wave length is approximated by the small amplitude wave theory with this $1/f_p(u_i)$[5]. The wave steepness, for example, is determined as

$$H_I/L_I\big|_{t=u_i} \simeq 2E_I(u_i)/L_I[f_p(u_i)] \tag{16}$$

where $L_I\ [\ f_p(u_i)\ ]$ is the wave length given by

$$L_I[f_p(u_i)] = \frac{g}{2\pi f_p^2(u_i)} \tanh \frac{2\pi h}{L_I[f_p(u_i)]} \tag{17}$$

The reflection coefficient at the instance is therefore given as

$$r(u_i) = 2E_R\{u_i - 2D/C_g[f_p(u_i)]\}/2E_I(u_i) \tag{18}$$

in which $C_g\ [\ f_p(u_i)]$ is the group velocity of a frequency $f_p(u_i)$. As explained so far, the present theory uses wave envelopes instead of wave heights to calculate the reflection coefficients. Because the reflection coefficients calculated from the corresponding wave profiles may inevitably include errors to a certain degree due to a dispersive nature of irregular wave profiles. The change in the envelope, on the other hand, is rather gradual and small in comparison with the irregular wave profile itself unless the distance is large.[6] So the present method may have an advantage in the calculation of reflection coefficients. However a clear definition of the instance u_i to determine wave height and frequency (period) in eqs.(15) - (18) still has not been developed.

4. ARRANGEMENT OF WAVE GAUGES FOR THE MEASUREMENT OF IRREGULAR WAVES OF A WIDE BAND SPECTRUM

The fundamental concept of the present theory is exemplified for a irregular waves of narrow band spectrum in the former chapter. The theory is verified for irregular waves of a wide band spectrum in this chapter. In case of a wide band spectrum, there are component waves which make $\sin(k_n\Delta\ell)$ equal or nearly equal to 0 in the denominator of eqs.(5) and (6). Calculated reflection coefficients for these component waves are extremely inaccurate. The theory by Goda et al.[3] recommended an interval from $0.1\pi/k_n$ to $0.9\pi/k_n$ as an effective frequency or wave number range where reliable reflection coefficients can be calculated with eqs.(5) and (6). In this connection, a little narrower range from $0.3\pi/k_n$ to $0.7\pi/k_n$, for example, should be employed to improve the resolution. The narrower the effective frequency range becomes, however, the wider the incalculable frequency range becomes in the spectrum. To avoid this situation, the multi-wave gauge system is adopted in this study. Wave gauges are arrayed irregularly so that there is at least one suitable wave gauge pair that guarantees an effective frequency range for all the component waves in the spectrum. Intervals of wave gauges are determined as follows, if the same effective frequency range as above mentioned is adopted. The largest wave gauge interval $\Delta\ell_1$ is calculated in terms of the given low frequency bound f_d to be analyzed in the spectrum as

$$\Delta\ell_1 = \frac{0.3}{2} L(f_d) \tag{19}$$

in which $L(f_d)$ is the corresponding wave length of f_d. An upper bound of the effective frequency range f_1 for this pair of wave gauges is determined implicitly by

$$\Delta\ell_1 = \frac{0.7}{2} L(f_1) \tag{20}$$

The second largest wave gauge interval $\Delta\ell_2$ is given as

$$\Delta\ell_2 = \frac{0.3}{2} L(f_1) \tag{21}$$

since f_1 should be the lower bound of the effective frequency range for the second interval, if no overlapping of effective frequency ranges is permitted. Repeating the same procedures from eq.(19) to eq.(21) until the upper frequency bound for the i-th wave gauge interval f_i (i=1,2,...) exceeds the high frequency bound f_u to be analyzed in the

spectrum, whole intervals of the system ($\Delta\ell_i$) (i=1,2,...) can be determined. Intervals of a sample wave gauge system is listed in Table-1. Pierson-Moskowitz spectrum whose peak frequency f_p equals to 1.0Hz is used in a calculation of these intervals. High and low frequency bounds of the spectrum are set to be 0.5Hz and 3.5Hz, respectively, effective frequency interval is set to be $0.3\pi \leqq k_n < 0.7\pi$ and water depth h is set to be 10cm.

Four pairs of wave gauges are necessary to cover the entire frequency range in this case. Example arrangements of wave gauges in this case are schematically shown in Fig.6 (a), (b) and (c). The direction of incident wave is from left to right. Centers of all pairs of wave gauges coincide with each other in the system (a), one wave gauge is commonly used as a partner of the individual pairs in the system (b) and some wave gauges are commonly used twice as a partner in two wave gauge pairs in the system (c). A total number of wave gauges can be reduced in the system

Table-1 Sample of the wave gauge intervals and their effective frequency range.

f(Hz)	0.50-1.09	1.09-2.02	2.02-3.18	3.18-3.50
$\Delta\ell$(cm)	29.2	12.5	5.4	2.3

(b) and (c). Judging from the numerical simulation, the resolution by the system (c) is preferable to (b). The origin of x-axis in the system (c) is preferable to set on the offshore-side a wave gauge pair which is used to analyze the dominant component. And the system is preferable to apply as close as possible to the structure.

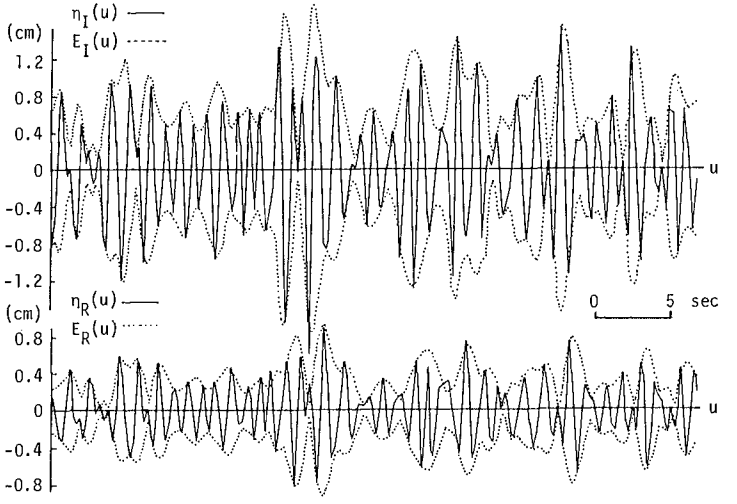

Fig.7 Decomposed wave profiles (solid lines) and their envelopes (dotted lines) for wide-band spectrum case.

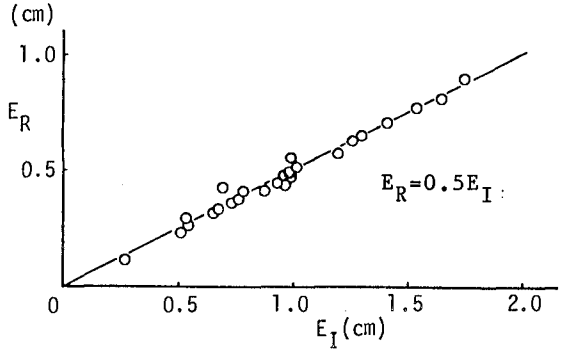

Fig.8 Relation of the values at the prominent summits in the wave envelopes for incident and reflected wave profiles.

Figure 7 shows the calculated result of incident and reflected wave profiles and their envelopes by the system (c). The distance from W-1 to the breakwater is set to be 0.3m. The reflection coefficient is set to be 0.5 and no phase is shifted for all the component waves. Notations and lines are the same as those used in Fig.4. Local disagreements between wave profiles and envelopes are a little prominent in comparison with the narrow band spectrum case. This comes from the asymmetric nature of the wave profile with the zero-level line, which irregular waves with a wide band spectrum usually have. With the ordinary method which dispenses with a data window[7], however, calculated results are almost the same as those by the present method. It can be distinguished from this figure and has been sometimes reported in the field measurements that irregular waves tend to form groups in a few waves which are enveloped by a single prominence of an envelope. Despite of the remarkable changes between incident and reflected wave profiles, the wave envelope maintains its form even after the reflection and transition. And every calculated time interval between the corresponding summits in the envelopes is almost equal to that required to go back and forth over the distance D with the group velocity of the wave around the summit. Every wave group presumably behaves as a single wave "packet[8]" in the process of reflection and transition. At the trough of an envelope, the side foot of the neighboring packets cross each other. Then the Lissajous' figure of E_R and E_I shows inevitably fluctuations around their troughs. To minimize this error, reflection coefficients are calculated only at the summit of individual prominences in E_R and E_I in

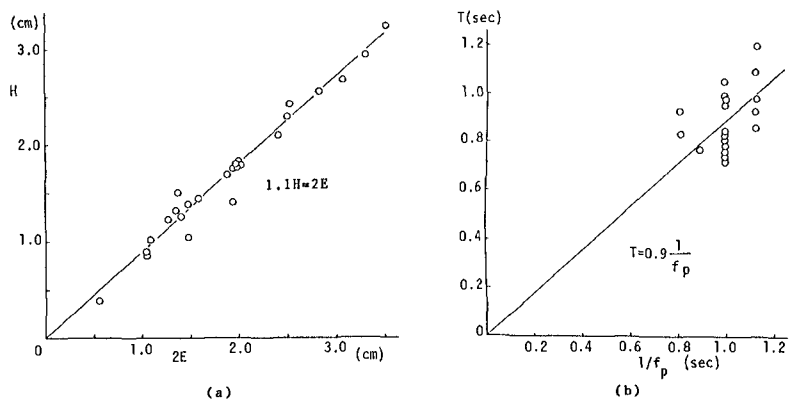

Fig.9 Comparison of (a) wave height, (b) wave period between those by the zero-up-cross method and the present definition.

this study. The relations of corresponding summits in E_I and E_R in Fig.7 are plotted in Fig.8. The solid line shows the relation of $E_R=0.5E_I$. The reliable reflection coefficient can be evaluated for those values. Wave height and period (frequency) in eqs.(15) - (17) are, then, determined at the prominent summit of the envelope. The calculated wave heights and periods, however, tend to be a little larger in this theory than those determined by the zero-up-cross method.

Figure 9 (a) shows the relation between the wave height determined by eq.(15) at the prominent summit of the envelopes and that by the zero-up-cross method just around the same instance. The solid line shows the relation $1.1H_I=2E_I$ or $1.1H_R=2E_R$. Figure (b) shows a relation of the zero-up-cross wave period to $1/f_p(u_i)$ at the prominent summit of an envelope. The solid line shows the relation of $T=0.9/f_p(u_i)$. Although the data show a little scattering, the zero-up-cross wave height and period can be approximated with the small modifications for calculated wave height and period. The calculated reflection coefficient from the present theory, therefore, can be discussed in terms of local properties of incident waves such as the steepness, Ursell number, etc. The numerically calculated constants for modifications, i.e., 1.1 and 0.9 in Fig.9 (a) and (b) respectively, are almost the same as those for wide band spectra such as Pierson-Moskowitz, Neumann and JONSWAP spectrum.

5. DISCUSSION

Since we assumed that an amplitude and a phase of a reflected wave may be constant only within a zero-up-cross interval, the width parameter of the data window in eq.(3) is desirable to be of the same order as that for a period of the dominant wave. The smaller this value becomes, however, the more uneven characteristics of the wave envelope prevail and the wider the calculated reflection coefficients fluctuate on the average. On the contrary, the larger this value becomes, the more locally the occasional nature of wave properties are averaged. Since the single wave group consists of 2-5 waves with similar properties (i.e., wave height, wave period) on the average, reflection characteristics of waves around the summit of an envelope may be assumed mutually equal. Two to five times of the dominant wave period is recommended for this value.

CHAPTER 32

Large-angle Parabolic Equation Methods

James T. Kirby*

Large-angle parabolic equation methods for the propagation of surface water waves are discussed. The methods described here are limited to forms which are solvable by the Crank-Nicolson method, but are successful in opening the allowed range of propagation directions to ~ 50° with respect to normal incidence.

Introduction

The application of the parabolic equation method (PEM) to any relevant wave propagation problem implies that a principal propagation direction may be identified in the {x,y} plane of propagation. Then, an aperture, or window of directions with respect to the principal direction, is associated with any particular approximation, and limits the range of propagation directions which may be adequately represented by the approximation (Figure 1). The borders of a given aperture are defined only loosely and depend mainly on the amount of error the modeller is willing to allow in the wave prediction. This error may be evaluated for any given approximation by examining the approximation in terms of the related expansion of the wavenumber vector. Errors in predicted wavelengths and propagation directions may then be evaluated directly.

The purpose of this paper is to examine two methods of extending the basic parabolic equation method to include large-angle effects. The first scheme is based on the Padé approximant extension of the lowest-order scheme, following the work of Booij (1981) and Dingemans (1983). The second scheme is based on a minimax principle, and has been applied previously by Green (1984) to the problem of underwater sound propagation.

Parabolic Equations and Padé Approximants

The lowest-order parabolic equation for forward scattering of time-harmonic linear waves in the x (principal) direction in water of constant depth may be derived by substituting

$$\eta(x,y) = A(x,y)e^{i(kx-\omega t)} \tag{1}$$

into the governing Helmholtz equation to obtain

$$2ikA_x + A_{yy} = 0 + \text{higher order terms} \tag{2}$$

*Assistant Professor, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611

where we have assumed that $|A_x| << O(k|A|)$. This approximation may be examined in light of the plane wave of permanent form

$$\eta = ae^{i(\ell x + my - \omega t)} \quad ; \quad \ell^2 + m^2 = k^2 \tag{3}$$

A(x,y) in eq. (1) is then given by

$$A(x,y) = ae^{i[(\ell-k)x + my]} \tag{4}$$

which gives

$$\frac{\ell}{k} = 1 - \frac{1}{2}\left(\frac{m}{k}\right)^2 \tag{5}$$

after substitution in eq. (2). Equation (5) in turn is the lowest order binomial expansion of

$$\frac{\ell}{k} = \left\{1 - \left(\frac{m}{k}\right)^2\right\}^{1/2} \tag{6}$$

for fixed $m/k = \sin\theta << 1$, θ being the propagation direction. The accuracy of any approximation over the range of propagation directions $0 \leq \theta \leq \theta_a$, where θ_a is the aperture width, may be evaluated by comparing predicted ℓ/k to exact $\ell/k = \cos\theta$ over the range in question. This comparison is given in Figure 2 for eq. (5). Equation (5) forms the basis of the so-called lowest-order approximation.

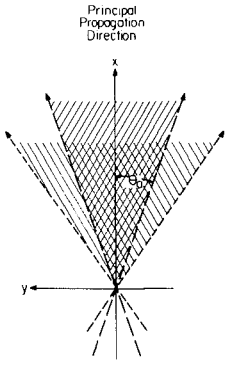

Fig. 1: Definition of aperture for parabolic approximations
//// allowed aperture: lower-order approximation
\\\\ allowed aperture: higher-order approximation (reprinted with permission of Elsevier Press)

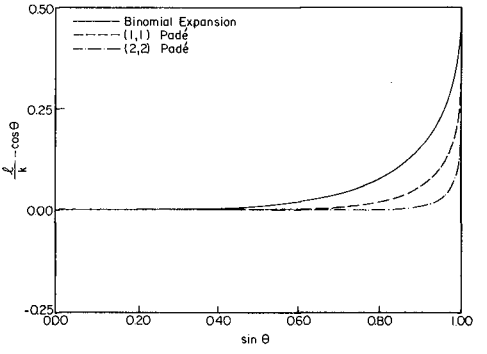

Fig. 2: Absolute errors $(\ell/k) - \cos\theta$ for several expansions of $(\ell/k) = (1 - (m/k)^2)^{1/2}$ about $(m/k) \to 0$ (reprinted with permission of Elsevier Press)

One of the simplest ways of extending the accuracy of a polynomial expansion is to construct a rational approximation consisting of the ratio of two polynomial expressions. Of the possible choices, the Padé approximant serves as the logical starting point (Baker, 1975). For eq. (6), the appropriate (1,1) Padé approximant is given by

$$\left(\frac{\ell}{k}\right) = \frac{1 - \frac{3}{4}\left(\frac{m}{k}\right)^2}{1 - \frac{1}{4}\left(\frac{m}{k}\right)^2} \tag{7}$$

The Padé approximant has the property of predicting the proper value and slope of the approximated function ℓ/k as m/k (or θ) becomes small. The approximation thus maintains the accuracy of the lowest-order approximation at small θ, and at the same time extends the accuracy of the approximation as θ increases, as shown in Figure 2. Using eq. (7) and retracing the steps of eqs. (2-5) in reverse order then gives

$$2ikA_x + A_{yy} + \frac{i}{2k} A_{xyy} = 0 \tag{8}$$

Dingemans (1983) has shown that the no-current, constant depth form of Booij's (1981) parabolic approximation is essentially equivalent to eq. (8), and proposed the Padé approximant as the relevant analysis of the splitting method employed by Booij to obtain his PEM approximation.

Padé Approximant: Computational Example

As a test of the higher-order parabolic model, we study the wave field in the vicinity of the shore-attached breakwater described in Figure 3. An extensive set of data for the wave field in the shadow zone downwave of the breakwater has been given by Hales (1980) for a number of wave periods, amplitudes, and angles of incidence. A closed form asymptotic solution in the linear, mild-slope approximation has been provided by Liu et al (1979) and has been compared to the experimental data by Liu (1982), who found qualitative agreement between the linear theory and experimental results.

The parabolic equation for the general case of uneven topography was developed according to the approximation of the previous section and is given in Kirby (1986).

For this case, we restrict our attention to the linearized theory in order to compare parabolic model results to the asympototic theory of Liu et al. The experimental results are complicated by the presence of a wave-induced current system due to the surf zone in close proximity to the measurement transects, and it is likely that neglected wave-current interaction effects have as much influence on the data as the neglected nonlinearity.

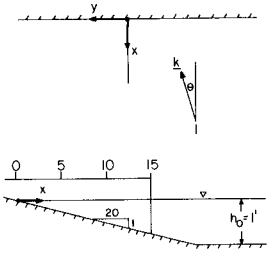

Fig. 3: Geometry of shore-attached breakwater (reprinted with permission of AGU)

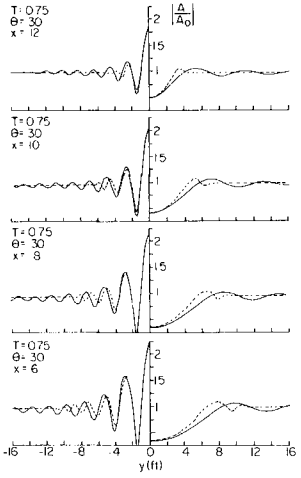

Fig. 4a: Shore-attached breakwater: comparison of lowest-order approximation and asymptotic theory of Liu et al (1979). Dashed line, lowest-order approximation; solid line, asymptotic theory; T = 0.75 s, θ = 30°. (reprinted with permission of AGU)

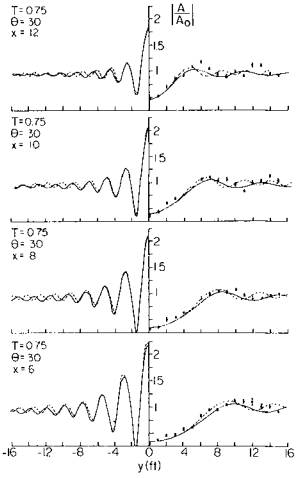

Fig. 4b: Shore-attached breakwater: comparison of higher-order approximation, asymptotic theory of Liu et al (1979), and data of Hales (1980). Dashed line, higher-order approximation; solid line, asymptotic theory, Φ experimental data; T = 0.75 s, θ = 30°. (reprinted with permission of AGU)

The geometry corresponding to the experimental arrangement consists of a plane beach with slope 1:20, extending out to a depth of 1 ft (.3048 m), beyond which the bottom is flat. The x coordinate is oriented offshore from the shoreline. The breakwater extends to x = 15 ft (4.572 m), and measured wave data in the shadow zone of the breakwater are available for the transects x = 6, 8, 10, and 12 ft (1.829, 2.438, 3.048, and 3.658 m) (Hales, 1980). Values for incident wave data are with reference to the offshore region with h = 1 ft (.3048 m).

In Figures 4a and 5a we show comparisons of the predictions of the lowest-order approximation with the asymptotic theory of Liu et al for the extremes of the test conditions T = 0.75 s, θ = 30° and T = 1.5 s, θ = 20°, respectively. In both cases it is apparent that the diffracted wave disturbance spreads laterally at a much slower rate in the lower-order approximation than in the analytic theory, which encompasses an unapproximated mild-slope equation. Both the height of the reflected wave on the upwave side of the breakwater and the wave height in the shadow zone adjacent to the downwave side of the breakwater are well predicted. However, most of the diffracted wave information is lost farther from the breakwater, well before significant amplitude modulations in the asympototic wave field die out. These results indicate that the group velocity for lateral motion of diffracted waves is too small in the lower-order approximation.

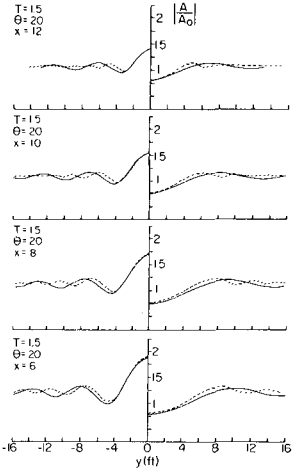

Fig. 5a: As in Figure 4a; T = 1.5 s, θ = 20°. (reprinted with permission of AGU)

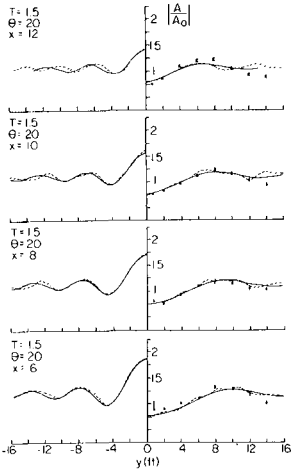

Fig. 5b: As in Figure 4b; T = 1.5 s, θ = 20°. (reprinted with permission of AGU)

For the Padé approximation, plots of results for the two test conditions are given in Figures 4b and 5b. Data in the shadow and downwave regions for these cases correspond to the lowest-amplitude runs from Hales (1980), which would be expected to correspond more

closely to the assumption of linearity. The plots indicate that the diffracted wave field is able to spread laterally in the higher-order approximation to a much greater degree than in the lower-order approximation. A comparison of the parabolic model results to the asymptotic theory indicates that the parabolic model is initially contaminated by components with large transverse wavenumber, which cause the computed amplitude modulations transverse to the breakwater to undulate more rapidly than the corresponding asymptotic results. These rapid undulations may be successfully damped using any one of several types of dissipative filters.

Minimax Approximation

Greene (1984) has suggested that improvements may be achieved while staying within the scheme of eq. (7) by relaxing the exact connection between eq. (7) and eq. (6) as $(m/k)\to 0$ in favor of adopting an approximation which minimizes the maximum error $(\ell/k - \cos\theta)$ over a prespecified aperture $0 \leq \theta \leq \theta_a$. These so-called minimax approximations may be written in the present context as

$$\left(\frac{\ell}{k}\right) = \frac{a_0 + a_1 \left(\frac{m}{k}\right)^2}{1 + b_1 \left(\frac{m}{k}\right)^2} \quad , \tag{9}$$

The coefficients of the minimax approximation are chosen so as to minimize the error

$$e = \mathrm{MAX}\left|\ell/k(\theta) - \cos\theta\right| \quad ; \quad 0 \leq \theta \leq \theta_a \quad , \quad \theta_a \text{ given} \tag{10}$$

where ℓ/k is predicted by eq. (12) and $\cos\theta = \ell/k$ is given by eq. (6). The procedure for obtaining minimax approximations is too extensive to summarize here; the reader is referred, for example, to Chapter 6 of Morris (1983). A list of values of a_0, a_1 and b_1 are given in Table 1 for aperture widths ranging from 10° to 90° in increments of 10°. The coefficient values are seen to be asymptotic to the (1,1) Padé approximant at $\theta_a \to 0$. Figure 6 gives plots of the absolute error in predicted (ℓ/k) for values of θ_a = 40°, 60° and 80°. A plot of the (1,1) Padé approximant is included for comparison. For values of $\theta_a < 60°$, the correspondence between the minimax and (1,1) Padé approximant remains close at $\theta=0$, the deviation for θ_a = 60° being $(1 - a_0) \times 100$ = 0.2%. Deviations for $\theta_a > 60°$ at $\theta\approx 0$ increase rapidly due to the difficulty in approximating eq. (7) as $m/k\to 1$. However, the advantages of the θ_a = 60° approximation over the (1,1) Padé approximant, when considered over the entire range $0 \leq m/k < 1$, are apparent. A comparison of Figures 2 and 6 indicates that the θ_a = 60° approximation attains about the same level of accuracy as $m/k\to 1$ as the (2,2) Padé approximant, with only a slight decrease in accuracy at small values of θ.

Equation (12) may be used to derive the corresponding parabolic approximation

TABLE 1. COEFFICIENTS OF THE RATIONAL APPROXIMATION DETERMINED BY VARYING APERTURE WIDTH.

$$2ikA_x + 2k^2(a_0 - 1)A + 2(b_1 - a_1)A_{yy} - \frac{2ib_1}{k} A_{xyy} = 0 \qquad (11)$$

which reduces to eq. (10) as $\theta_a \to 0$.

Tests of the Minimax Approximation at Large Angles of Incidence

The minimax approximation of the previous section has been used to develop a corresponding refraction-diffraction model including the effects of weak nonlinearity and wave current interaction: details are given in Kirby (1987). In order to test the large-angle capabilities of the model, we choose a shoal geometry given by

$$h(x,y) = \begin{cases} h_0 = 0.336 \text{ m} & ; \quad r > R \\ h_0 + 0.3 - 0.5\{1 - [(\frac{x}{5})^2 + (\frac{y}{5})^2]\}^{1/2} & ; \quad r \leq R \end{cases}$$

where R = 4 m and $r = (x^2 + y^2)^{1/2}$. The symmetry of the shoal allows the incident wave field to be rotated to any angle to the x-axis; a "correct" model will be one that causes no distortion to the resulting focusing pattern resulting from changes in θ_0, the incidence angle.

We take a rectangular grid with $\Delta x' = \Delta y' = 0.25$ m and overall dimensions $0 \leq x'y' \leq 24.75$ m. We use the incident wave period and amplitude conditions of Berkhoff et al (1982). Two incident wave directions are studied; $\theta_0 = 0°$, with the shoal centered at (x',y') = (5,10), and $\theta_0 = 45°$, with the shoal centered at (x',y') = (5,5).

For the first series of tests, we use the (1,1) Padé model to study the two incident wave angles. Figure 7 shows the wave patterns for the two incidence angles in the form of contours of surface elevation in increments of $0.5\ A_0$. The asymmetrical distortion to the focusing pattern at the 45° angle of incidence is apparent, as is a tendency for the focus to be shifted off the picture diagonal in the +x direction, or downwave in the computational sense. The distortion to the wave pattern due to the 45° angle of incidence is illustrated clearly by the superposition of wave amplitude contours in Figure 8. The superposition was obtained by rotating the wave field of Figure 7b about the center of the shoal by 36.5° in a counterclockwise sense, or 45° minus an 8.5° distortion which represents the angle between the diagonal and the line joining the shoal center to the point of maximum wave height in the focus. This 8.5° distortion accounts for the shift of the diffraction pattern in the downwave sense on the computation grid. Figure 8 shows clearly that the focus is elongated and shifted further from the shoal center than in the normal incidence case, with corresponding distortion in the diffraction fringes. Contour values in Figure 8 (and 10) are relative to incident wave amplitude.

Figure 9 shows the wave field for the 45° angle of incidence, using the $\theta_a = 70°$ minimax approximation. There is still some apparent asymmetric distortion and a shift of the focus off the diagonal in the +x direction; however, these effects are much less accentuated

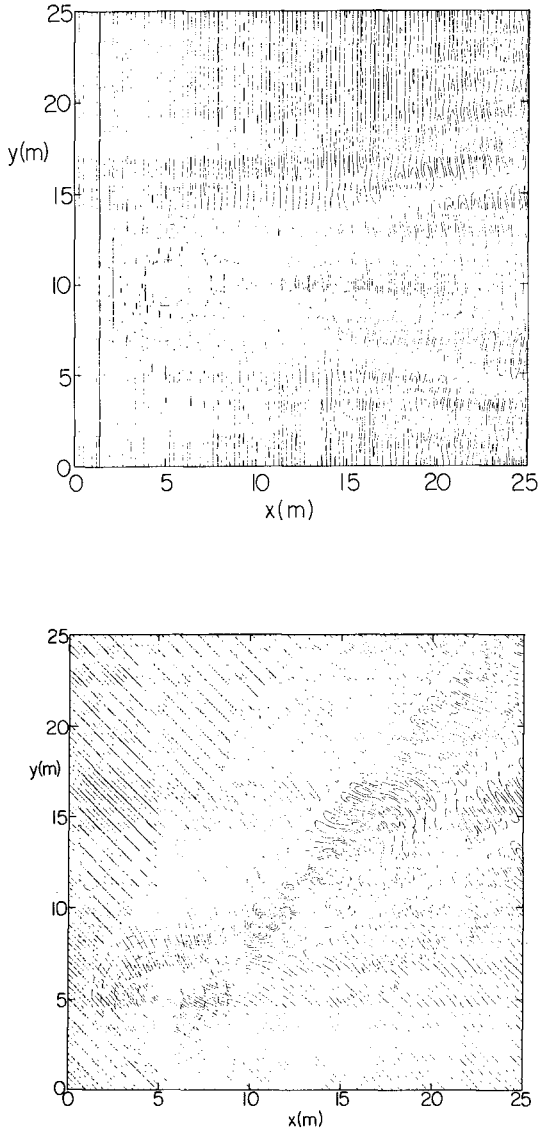

Fig. 7: Wave fields calculated using the (1,1) Padé model. Contours are in increments of 0.5 A_0 for instantaneous $\eta(x,y)$. a) $\theta_0 = 0$, normal incidence. b) $\theta_0 = 45°$. (reprinted with permission of Elsevier Press)

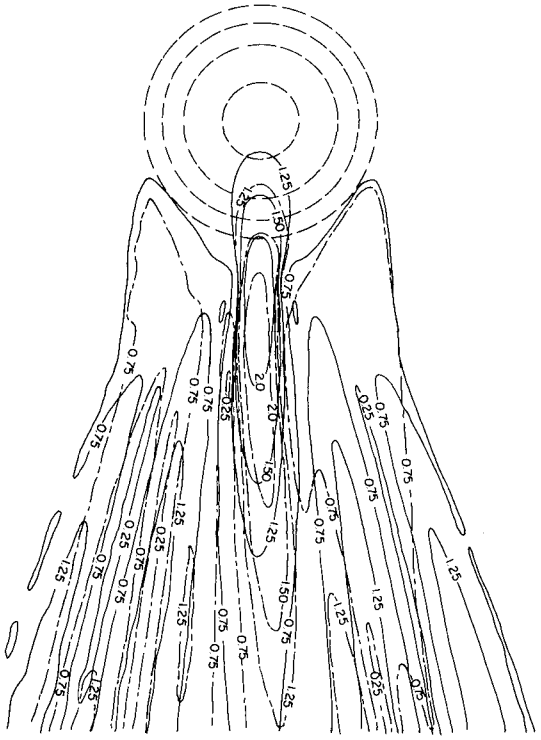

Fig. 8: Amplitude contours and topography for circular shoal. Amplitude contours $|A/A_0|$ as labelled; (1,1) Padé approximant. —— θ_0 = 0°; —•—•— θ_0 = 45°; — — depth contours. (reprinted with permission of Elsevier Press)

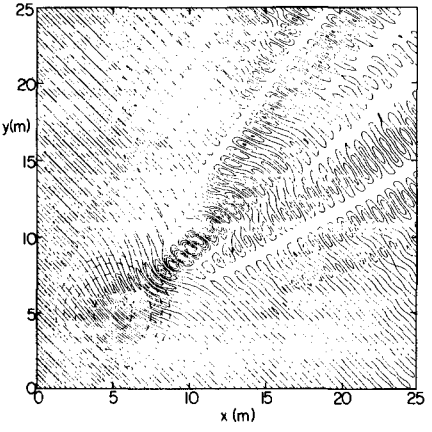

Fig. 9: Wave field calculated using θ_a = 70° model; θ_0 = 45°. Contours as in Figure 7. (reprinted with permission of Elsevier Press)

than in the Padé model. Amplitude contours for the normal and 45° incidence in the 70° approximation are superposed in Figure 10. Here the counterclockwise rotation of the 45° case is 39.75°, with a distortion of 5.25°. The two results agree reasonably well in terms of the area and extent of contours in the focus, and in the distance of the focus from the shoal center. The overall diffraction pattern is maintained reasonably well out to two maxima of the diffraction fringe away from the central focus.

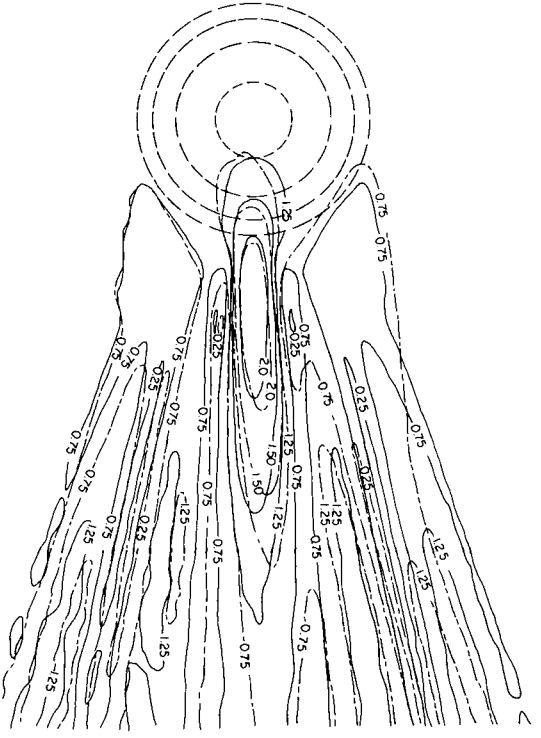

Fig. 10: Amplitude contours and topography for circular shoal, θ_a = 70° approximation. —— θ_0 = 0°; —•—•— θ_0 = 45°; --- depth contours. (reprinted with permission of Elsevier Press)

The θ_a = 70° minimax approximation clearly provides a better model for large-angle propagation than does the Padé approximant model. Further tests were conducted using the 80° approximation. This model exhibited marginally better agreement between θ_0 = 0° and 45° than did the 70° model, but caused a significant distortion to the overall extent of the focus in comparison to the Padé and 70° models.

Refraction Effects in Parabolic Approximations

For the special case of topographies varying as h(x) only, and for angles of incidence θ_0 at reference depth h_0, each of the parabolic approximations may be solved to yield an estimate of the leading-order, slowly varying wave field undergoing shoaling and refraction. Solutions for the full refraction approximation and for each of three parabolic methods follow:

Exact Refraction Solution

$$\eta = A_0\left(\frac{C_{g_0}}{C_g}\right)^{1/2}\left(\frac{\cos\theta_0}{\cos\theta}\right)^{1/2} e^{i\int k\cos\theta\, dx - my)} \tag{12}$$

Small-Angle Equation Solution

$$\eta = A_0\left(\frac{C_{g_0}}{C_g}\right)^{1/2} e^{i\int k\left(\frac{\ell}{k}\right)dx - my}\ ;\ \frac{\ell}{k} = 1 - \frac{1}{2}\left(\frac{m}{k}\right)^2 \tag{13}$$

(1,1) Padé Approximation

$$\eta = A_0\left(\frac{C_{g_0}}{C_g}\right)^{1/2}\frac{\left(1 - \frac{1}{4}\sin^2\theta_0\right)}{\left(1 - \frac{1}{4}\sin^2\theta\right)} e^{i\int k\left(\frac{\ell}{k}\right)dx - my}\ ;\ \frac{\ell}{k}\frac{1 - \frac{3}{4}\left(\frac{m}{k}\right)^2}{1 - \frac{1}{4}\left(\frac{m}{k}\right)^2} \tag{14}$$

Minimax Approximation

$$\eta = A_0\left(\frac{C_{g_0}}{C_g}\right)^{1/2}\frac{\left(1 + b_1\sin^2\theta_0\right)}{\left(1 + b_1\sin^2\theta\right)} e^{i\int k\left(\frac{\ell}{k}\right)dx - my}\ ;\ \frac{\ell}{k} = \frac{a_0 + a_1\left(\frac{m}{k}\right)^2}{1 + b_1\left(\frac{m}{k}\right)^2} \tag{15}$$

It is apparent that, with each increase in level of approximation, that the phase function of the shoaled wave becomes better approximated. Also apparent are large variations in each model's ability to reproduce the refraction coefficient $(\cos\theta_0/\cos\theta)^{1/2}$ of the "exact"solution; in particular, it is not modelled at all in the lowest-order case and is only apparent starting with the (1,1) Padé approximant method. Figure 11 gives results for computed refraction coefficients for four angles of incidence 20°, 40°, 60°, and 80° with respect to shore-normal. The minimax values are based on a chosen

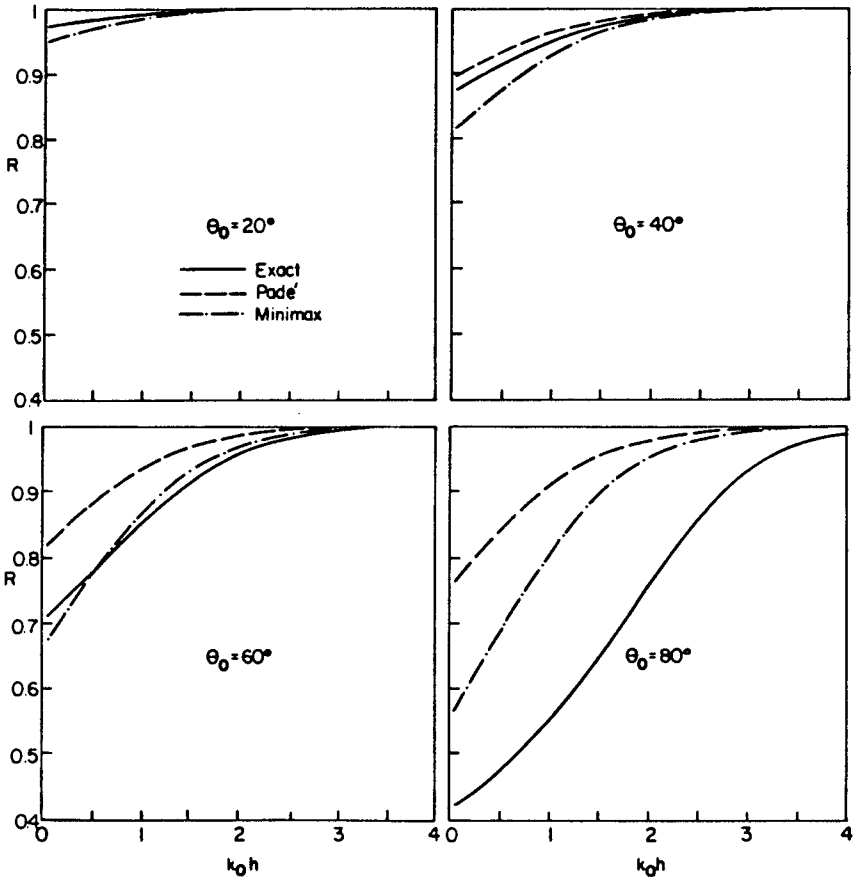

Fig. 11: Variation in refraction coefficient with deepwater angle of incidence θ_0 and water depth.

width $\theta_a = 70°$. For small angles of incidence, the (1,1) Padé approximant method exhibits favorable behavior in comparison to the minimax approximation, due to its enhanced level of accuracy as local $\theta(x) \to 0$. However, for $\theta_0 = 60°$, the minimax approximation performs quite well, while the (1,1) Padé approximant is clearly over-extended. For $\theta_0 = 80°$, the propagation angle is outside the range of both higher-order models, and each perform poorly. In each of the cases above, θ_0 is taken to be the deepwater value.

Conclusions

It has been shown that the range of wave angles which is allowable within the limitations of the parabolic approximation may be significantly increased by relaxing the local accuracy of approximations based on Padé approximants at normal wave incidence in favor of minimax approximations, which minimize the maximum error occurring over a prespecified range of wave directions. We have shown that the minimax approximations provide quantitatively accurate results for a focussing pattern developing in a wave propagating at 45° to the principal direction. This range of quantitative accuracy is seen to be well beyond the limitations of the (1,1) Padé approximant model given above. Results for wave refraction calculations suggest that it would be desirable to limit the aperture width θ_a in the minimax approximation to a value consistent with the largest expected local propagation direction, since the Padé approximant model is somewhat better at predicting the refraction coefficient at small angles of incidence.

CHAPTER 33

ESTIMATION OF WATER PARTICLE VELOCITIES OF SHALLOW WATER WAVES BY A MODIFIED TRANSFER FUNCTION METHOD

Hirofumi KOYAMA* and Koichiro IWATA**

ABSTRACT

This paper is intended to propose a simple, yet highly reliable approximate method which uses a modified transfer function in order to evaluate the water particle velocity of finite amplitude waves at shallow water depth in regular and irregular wave environments. Using Dean's stream function theory,the linear function is modified so as to include the nonlinear effect of finite amplitude wave. The approximate method proposed here employs the modified transfer function. Laboratory experiments have been carried out to examine the validity of the proposed method. The approximate method is shown to estimate well the experimental values, as accurately as Dean's stream function method, although its calculation procedure is much simpler than that of Dean's method.

1. INTRODUCTION

The water surface profile of shallow water waves sharpens at the crest and flattens at the trough, and generally becomes asymmetric due to shoaling on a sloping beach. The asymmetry of the water surface profile gives rise to the unsymmetrical field of the wave kinematics[1]. So far, no exact theory for asymmetrical waves has been proposed. This has prevented depicting precise characteristics of the kinematics of asymmetric regular and irregular waves. The previous investigations[2)-4)] have pointed out that the Dean's stream function method[5)] (hereafter referred to as DSFM), among several methods, predicts most accurately the water particle velocity of asymmetrical steep and near-breaking waves. However, DSFM requires a complicated iterative calculation as well as a full record of the water surface profile in order to obtain only a maximum water particle velocity. The accurate estimation of the maximum velocity is an important coastal engineering problem. Therefore, DSFM is not necessarily so useful for field engineers to estimate the kinematics of the design wave.

First of all, the difference of the water particle velocity estimated by the transfer function method using the linear wave theory (LTFM) and

---

** Dr. Eng., Professor, Dept. of Civil Eng., Nagoya Univ., Nagoya, Aichi, Japan.

DSFM is investigated. The linear transfer function is then modified by introducing the nonlinear effect of finite amplitude waves with the help of Dean's stream function table[6]. The modified transfer function method (MTFM) which employs the modified transfer function is proposed as a simple yet highly reliable approximate method. The calculation procedure is much simpler than that of DSFM. Lastly, laboratory experiments are carried out to examine the validity of MTFM. The experiments show that MTFM is a highly reliable approximate method to calculate the wave kinematics.

2. MODIFIED TRANSFER FUNCTION

2.1 Modified transfer function for horizontal velocity of water particle

The present authors[7] showed that a time history of the horizontal velocity u(t) is closely correlated to that of the water surface profile and that the transfer function method is an useful one to estimate the horizontal component of the water particle velocity. The transfer function $H_u(h,T,s)$ for the horizontal particle velocity is defined by

$$u(t) = H_u(h,T,s)\eta(t) . \qquad (1)$$

Equation (1) shows that the horizontal velocity is predicted from the water surface profile through a filter of the transfer function. In this paper, the water surface profile is not decomposed into Fourier component waves, whether the waves are regular or irregular; the actual water surface profile is employed as $\eta(t)$.

The transfer function $H_u(h,T,s)$ and the horizontal velocity u(t) in case of the linear wave theory are described as follows;

$$H_u(h,T,s) = \frac{2\pi}{T}\frac{\cosh ks}{\sinh kh} , \qquad (2)$$

$$u(t) = \frac{2\pi}{T}\frac{\cosh ks}{\sinh kh}\eta(t) . \qquad (3)$$

One example of comparison between the laboratory experiments and the estimation with Eq.(3) is shown in Fig.1. This figure indicates that the peak value obtained by the experiment agrees comparatively well with Eq.(3) for $\eta<0$. However, in the range of $\eta>0$, the calculated peak value is generally higher than the experimental value. This is a general tendency recognized for many data. The experimental fact implies that the nonlinear effect of finite amplitude waves which is not included in Eq.(3) should be considered in estimating the horizontal velocity, especially for the range of $\eta>0$. Then we will attempt to modify Eq.(2) so as to include the nonlinear effect.

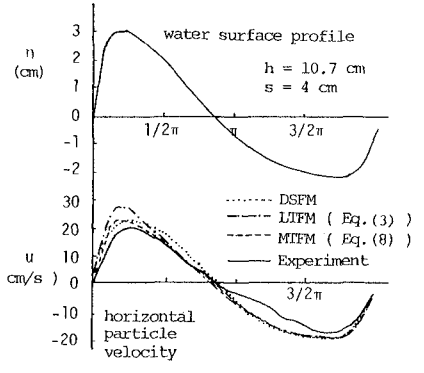

Fig.1 Comparison between measurement and calculations(Regular wave; experimental and DSFM's values are from Nadaoka et al.[4]).

We modify Eq.(2) for $\eta>0$, introducing a correction function f as expressed by

$$\left.\begin{aligned} H_u(h,T,s) &= \left(\frac{2\pi}{T}\frac{\cosh ks}{\sinh kfh}\right); \quad \eta > 0 \\ u(t) &\doteq \left(\frac{2\pi}{T}\frac{\cosh ks}{\sinh kfh}\right)\eta(t); \quad \eta > 0 \end{aligned}\right\} \text{--- (4)}$$

In Eq.(4), fh is used in place of h. The accuracy of u(t) thus evaluated for the finite amplitude waves depends largely upon how accurately f is determined.

The correction function f is formulated by using Dean's stream function table for symmetrical regular waves under various conditions. The nonlinear effect of finite amplitude waves is supposed to be predominant at the phase of wave crest. Therefore, first, the correction function f at the two locations $s=h+\eta^+$(water surface) and s=0(bottom) are determined. That is, the maximum horizontal velocities u^+ at the two locations s=0 and $s=h+\eta^+$ are first read from Dean's stream function table, where η^+ is the wave crest height. Using the second equation of Eq.(4), the values of the correction function f for various combinations of u^+ and η^+ at the locations $s=h+\eta^+$ and s=0 are calculated. The values thus calculated are given in Figs. 2 and 3 in relation to η^+/h with auxiliary parameters h/Lo and H/Lo.

According to Figs.2 and 3, the correction function f can be approximated by Eq.(5) in the range of $h/Lo \leq 0.2$.

$$\left.\begin{aligned} f &= 1+\eta^+ \quad ; \text{ for } s = 0 \\ f &= 1 \quad ; \text{ for } s = h+\eta^+ \end{aligned}\right\} \text{ for } \eta=\eta^+ . \text{ ---------- (5)}$$

Further, two assumptions are made here to formulate f for any value of s in the range of $\eta>0$;

(1) Equation (5) is extended to all positive values of η. In other words, we can substitute η (>0) for η^+.

(2) The correction function f at any depth s is expressed by a linear interporation between the values at $s=h+\eta^+$ and s = 0.

Using these assumptions, the correction function f for $\eta>0$ is formulated as

$$f = 1 + \frac{\eta^+}{h}\left(1 - \frac{s}{(h+\eta)}\right). \text{ ---------- (6)}$$

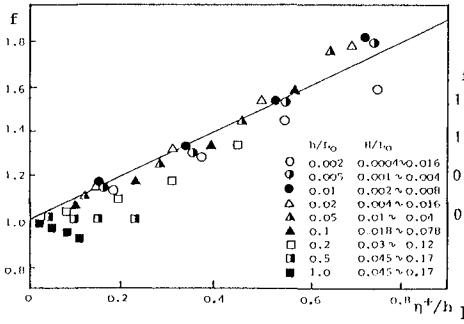

Fig.2 Value of correction function f at s = 0.

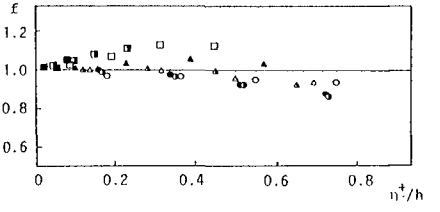

Fig.3 Value of correction function f at $s = h + \eta^+$ (symbols of calculated values are the same as those in Fig.3).

Now, let us discuss the correction function f for $\eta \leqq 0$. As already stated, Eq.(3) predicts comparatively well the experimental values for $\eta \leqq 0$. The same thing has been pointed out by Nadaoka et al. Eq.(2) is, therefore, used as the transfer function for $\eta \leqq 0$ without modification. Based on the above mentioned, the modified transfer function f proposed is given by

$$\left.\begin{aligned} H_u(h,T,s) &= \frac{2\pi}{T}\frac{\cosh ks}{\sinh(h+\eta(1-s/(h+\eta)))} ; \eta > 0 \\ &= \frac{2\pi}{T}\frac{\cosh ks}{\sinh kh} ; \eta \leqq 0 \end{aligned}\right\} \text{-------} \quad (7)$$

Using Eqs.(1) and (7), the horizontal velocity u(t) is evaluated by

$$\left.\begin{aligned} u(t) &= \frac{2\pi}{T}\frac{\cosh ks}{\sinh k(h+\eta(1-s/(h+\eta)))}\eta(t) ; \eta > 0 \\ &= \frac{2\pi}{T}\frac{\cosh ks}{\sinh kh}\eta(t) ; \eta \leqq 0 \end{aligned}\right\} \text{------} \quad (8)$$

As seen in Figs.1 and 4, the estimation with the modified transfer function method (MTFM) is in better agreement with DSFM. Then, it can be said that MTFM is much better than the linear transfer function method (LTFM).

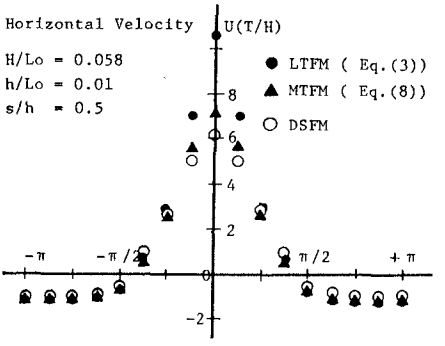

Fig.4 Comparison among DSFM, MTFM and linear transfer function method (LTFM).

2.2 Modified transfer function for vertical velocity of water particle

Judging from the conservation law of mass flux and u(t) given by Eq.(8), it can be supposed that the transfer function for w(t) should include the term $\partial\eta/\partial x$, where x is the horizontal distance. It is not desirable, however, that the transfer function involves the term of $\partial\eta/\partial x$ to avoid a complicated calculation which is not convenient to field engineers. Hence, we try to deduce a simple transfer function for w(t) as follow.

The present authors[7] have already shown that the time profile of the vertical velocity of water particle resembles that of the water surface with a certain time lag, Δt. In addition, the water surface profile can be transferred to the horizontal velocity profile of water particle by use of Eq.(8). Then, w(t) can be expressed by

$$\left.\begin{aligned} w(t) &= H_w(h,T,s)\eta(t+\Delta t) \\ &= H_{u-w}(h,T,s)u(t+\Delta t) \end{aligned}\right\} \text{----------} \quad (9)$$

where, $H_w(h,T,s)$ is a transfer function between w(t) and $\eta(t+\Delta t)$, $H_{u-w}(h,T,s)$ a transfer function between w(t) and $u(t+\Delta t)$ and Δt a time lag from a zero-upcrossing point to the next coming wave crest. The time lag Δt in Eq.(9) can be determined from a record of water surface profile.

In case of the linear wave theory, the transfer function H_{u-w} and Eq.(9) are expressed as Eq.(10) and Eq.(11), respectively.

$$H_{u-w}(h,T,s) = \tanh ks \qquad \text{---------- (11)}$$

$$w(t) = \tanh ks \times u(t + \Delta t) . \qquad \text{---------- (11)}$$

One example of comparison between the estimation with Eq.(10) and the values of DSFM is shown in Fig.5. The figure shows that the negative peak value is underestimated by Eq.(10). And, in some another cases, the positive peak value is also apart from the value of DSFM.

Therefore, we try to introduce a correction function g as expressed by

$$\left.\begin{aligned} H_u(h,T,s) &= (g \tanh ks) \\ w(t) &= (g \tanh ks) \times u(t + \Delta t) \end{aligned}\right\} . \qquad \text{---------- (12)}$$

The correction function g is formulated by Dean's stream function table, the procedure of which is the same as that of the correction function f for the horizontal velocity. Figs. 6 and 7 show the calculations of the correction functions g for positive and negative peak values in relation to the parameter of $\eta Lo/h^2$, respectively. In the figures, the correction function g calculated at s/h=0.5 is only shown. The correction functions g at other locations from the bottom up to the water surface were almost equal to that of s/h=0.5.

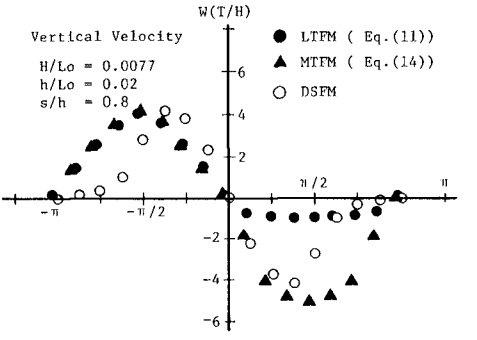

Fig.5 Comparison of vertical velocity of water particle among DSFM, LTFM and MTFM.

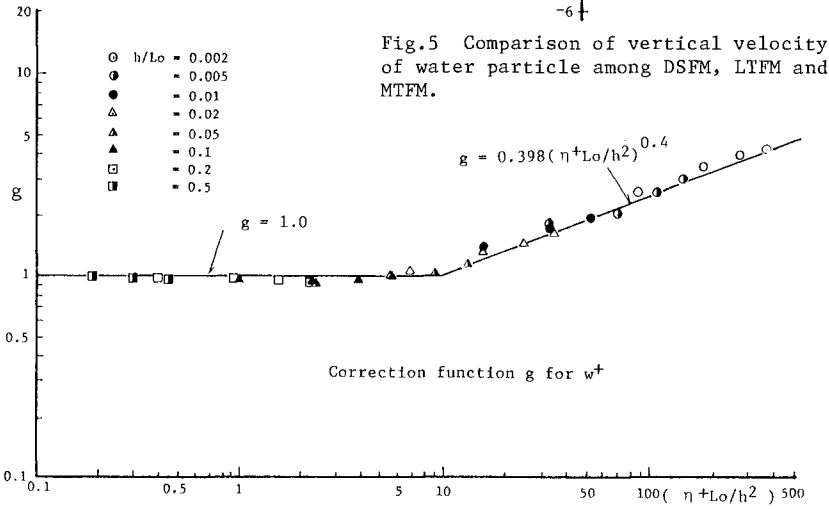

Fig. 6 Value of correction function g for w^+.

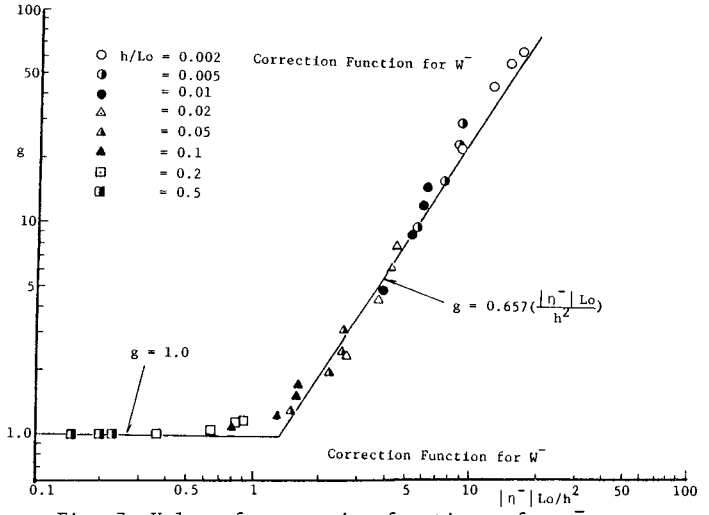

Fig. 7 Value of correction function g for w^-

According to Figs. 6 and 7, the correction function g can be approximated by

$$\left.\begin{aligned} g &= 0.398\left(\frac{\eta Lo}{h^2}\right)^{0.4} ; && \eta Lo/h^2 > 10 \\ &= 1 ; && -1.3 \leqq \eta Lo/h^2 \leqq 10 \\ &= 0.657\left(\frac{|\eta| Lo}{h^2}\right)^{1.6} ; && -1.3 > \eta Lo/h^2 \end{aligned}\right\} \quad \text{----- (13)}$$

Using this correction function, the vertical velocity of the modified transfer function method is evaluated by

$$\left.\begin{aligned} w(t) &= 0.398\left(\frac{\eta Lo}{h^2}\right)^{0.4} \times \tanh ks \times u(t+\Delta t) ; && \eta Lo/h^2 > 10 \\ &= \tanh ks \times u(t+\Delta t) ; && -1.3 \leqq \eta Lo/h^2 \leqq 10 \\ &= 0.657\left(\frac{|\eta| Lo}{h^2}\right)^{1.6} \times \tanh ks \times u(t+\Delta t) ; && \eta Lo/h^2 < -1.3 \end{aligned}\right\} \quad (14)$$

Figure 5 shows one example of comparison among DSFM, LTFM and MTFM by Eq.(14). The estimation of MTFM correspods well to that by DSFM , although there is a discrepancy between their time profiles.

Summarizing the above stated, it can be pointed out that MTFM which uses Eqs.(8) and (14) is a highly reliable approximate method to evaluate the wave kinematics.

3. LABORATORY EXPERIMENT

In the experiment, an indoor wave tank of 0.7m in width, 0.95m in depth and 25m in length at Nagoya University was used. At one end of the

wave tank, was installed a flap-type wave generator controlled by an oil-pressure servo system. At the other end of the wave tank, beach slope of 1/15 and 1/8 and a horizontal step having a slope of 1/15 at the leading edge were set, as shown in Fig.8. Experimental conditions are given in Table 1.

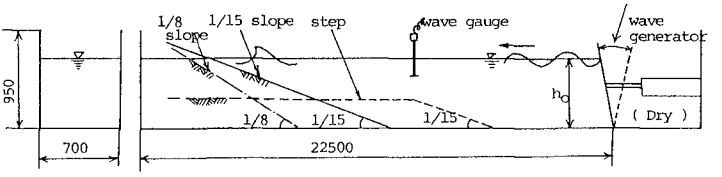

Fig.8 Schematic view of experimental set-up

Table 1 Experimental conditions

run	bottom slope i	wave period T, T1/3(s)	wave height H,H1/3(cm)	stillwater depth h(cm)	breaker depth h_b(cm)	breaker height H_b(cm)	wave

4 - 2	"	1.32	10.3	"	-	-	"

($H_{1/3}$ anf $T_{1/3}$ are significant wave height and period, respectively)

Wave profiles were measured by capacitance-type wave gauges. The water particle velocity was measured by a cantilever type velocimeter newly devised by the present authors[8]. The water particle velocities were measured at many locations from s=0 up to nearly $s=h+\eta^+$ in the vertical direction and from h= 60cm up to h= 1cm in the horizontal direction. Time profiles of water surface and particle velocities were recorded on a magnetic tape over a period of 1 min.

4. RESULTS AND DISCUSSION

In this section, the validity of MTFM is discussed by comparing with DSFM, LTFM and the experimental values. In the calculation of DSFM, the water surface profile was divided into 20 discrete values for one wave cycle. Following Dean's method, with use of the 20 discrete values, the iterative calculation was performed 4 or 5 times until the relative error between the measured and the predicted water surface profiles becomes less than 5%.

4.1 Regular wave

(1) Time profile of water particle velocity

Figure 9 shows time profiles of the water particle velocity estimated by MTFM and DSFM, and experimental values. Figures 9(a), (b) and (c) are

the typical examples of the horizontal and vertical velocities for the waves before breaking, just at breaking point and after breaking, respectively. In case of the non-breaking wave, as in Fig.9(a), the water particle velocity predicted by MTFM is very close to that by DSFM, and both estimations are generally in good agreement with experiments. On the other hand, in case of waves just at breaking point and after breaking (see Fig.9(b) and (c)), the horizontal velocity u(t) estimated by MTFM corresponds well to that by DSFM, and the agreement of both calculations with experimantal values is very good. Concerning the vertical velocity w(t), however, a little difference between the two calculations was generally observed. In Figs.9(b) and (c), w(t) estimated by MTFM has a better agreement with experimetal values than that by DSFM.

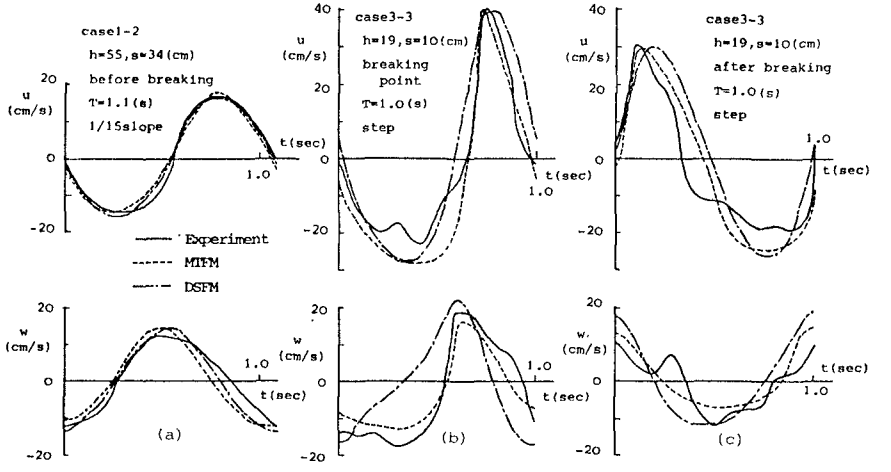

Fig.9 Comparison of time profiles of water particle velocities between calculations and experiments (for regular waves)

(2) Vertical distribution of maximum water particle velocity

Figure 10 shows some examples of the vertical distribution of the maximum horizontal and vertical velocities, where the positive and negative values of $u/\sqrt{gh}$ are, respectively, the non-dimensional onshore and offshore horizontal velocities, and the positive and negative values of $w/\sqrt{gh}$ are the non-dimensional upward and downward vertical velocities, respectively. In Fig.10, the calculated values of DSFM, MTFM and LTFM are drawn to be compared with experimental values. Using Eqs.(8) and (14), the maximum values of $u^+(s)$, $u^-(s)$, $w^+(s)$ and $w^-(s)$ by MTFM are given by

$$\left.\begin{aligned} u^+(s) &= \frac{2\pi}{T}\frac{\cosh ks}{\sinh k(h+\eta^+(1-s/(h+\eta^+)))}\eta^+ \quad (\text{for onshore velocity}) \\ u^-(s) &= \frac{2\pi}{T}\frac{\cosh ks}{\sinh kh}\eta^- \quad (\text{for offshore velocity}) \\ w^+(s) &= \frac{2\pi}{T}\frac{\sinh ks}{\sinh k(h+\eta^+(1-s/(h+\eta^+)))}\eta^+ \quad (\text{for upward velocity}) \\ w^-(s) &= \frac{2\pi}{T}\frac{\sinh ks}{\sinh kh}\eta^- \quad (\text{for downward velocity}) \end{aligned}\right\}. \tag{15}$$

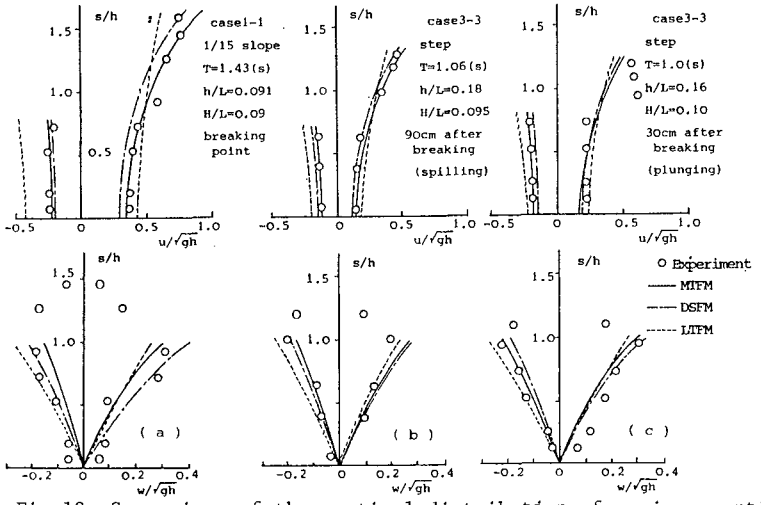

Fig.10 Comparison of the vertical distribution of maximum particle velocity between measurements and calculations (for regular waves).

In Eq.(15), η^+ and η^- are the wave crest and trough elevations, respectively, and it should be stressed that $w^+(s)$ and $w^-(s)$ are derived for $-1.3 \leqq \eta Lo/h^2 \leqq 10$.. Therefore, although they cover a wide range of wave conditions,different expressions of $w^+(s)$ and $w^-(s)$ should be used in place of Eq.(15) for the range of $\eta Lo/h^2 \geqq 10$ and $\eta Lo/h^2 \leqq -1.3$.

According to Fig.10, it can be pointed out that the vertical distributions of maximum horizontal and vertical velocities predicted by MTFM and DSFM are in good agreement with the experiments except near the free surface of the plunging breaker and the bottom. The plunging breaker has usually a bore-like character with entrainment of air bubbles. Any of the three methods does not consider the entrainment of air bubbles. This may have caused the discrepancy between the calculations and experiment for the plunging breaker. Figure 10 also shows that $w^+/\sqrt{gh}$ and $w^-/\sqrt{gh}$ near the bottom tend to be underestimated by the three methods. The reason is, as pointed out by Nadaoka et al., that the three theories assume a horizontal bottom and then they cannot exactly express the vertical component of wave motion along the bottom slope.

In Fig.10, calculated values above the stillwater level ($s/h \geqq 1$) are not indicated. The experimental values show that $w^+/\sqrt{gh}$ and $w^-/\sqrt{gh}$ decrease linearly with s/h toward the wave crest. Judging from the comparisons between the calculations and experiments including those in Fig. 10, LTFM seems to be inferior to MTFM and DSFM in predicting the maximum values, $u^+/\sqrt{gh}$, $u^-/\sqrt{gh}$, $w^+/\sqrt{gh}$, and $w^-/\sqrt{gh}$ as well as time profiles of the water particle velocity, u(t) and w(t).

4.2 Irregular wave

In evaluating the velocities of water particle u(t) and w(t), the irregular wave is not decomposed into Fourier component waves, but is treated by the wave-by-wave analysis which uses the zero-downcrossing

method. Equations (8) and (14) are applied to the individual waves in a random wave train. In calculating w(t), Δt was given by an average value of time intervals between a zero-upcrossing point and the next-coming wave crest of the wave train.

Figures 11 shows one comparison between the measurements and calculations by means of DSFM and MTFM. First, let us discuss on u(t). As seen in Fig.11, the time profiles estimated by MTFM as well as DSFM correspond well, in general, to the experimental values. However, in Fig.11, DSFM underestimates the positive peak value of u(t) for the particular waves with symbole * for which the mean water level is higher than the still-water level. On this point, MTFM can be said to be superior to DSFM. Concerning the vertical velocity w(t), both theories (DSFM and MTFM) do not predict well the experimental values. One reason of this is attributed to the method of wave definition employed, i.e. the wave-by-wave analysis like the zero-downcrossing method. The zero-downcrossing method divides the water surface profile into two parts at the zero-downcrossing point. Since the water surface profile near the stillwater level governs sensitively a peak value of w(t), the use of the zero-downcrossing method yields errors in evaluating the peak value. The same thing can be said for the zero-upcrossing method. Therefore, as pointed out by Daemrich at al.[9], the crest-to-crest method may be recommended in order to estimate the vertical velocity.

Lastly, peak values of the horizontal particle velocity u^+ at 2cm above the stillwater level are discussed. Table 2 gives peak values u^+ for successive ten waves in a random wave train, and schematic water surface profiles are shown in the second row for convenience of discussion. Comparing the calculated values with DSFM and MTFM with experimental ones, MTFM can be said to predict the experimental values much better than DSFM in general. However, it should be noted that MTFM as well as DSFM tend to underestimate u^+ of the waves which have two peaks on the water surface above the stillwater level such as No.1, No.4, No.8 and No.9.

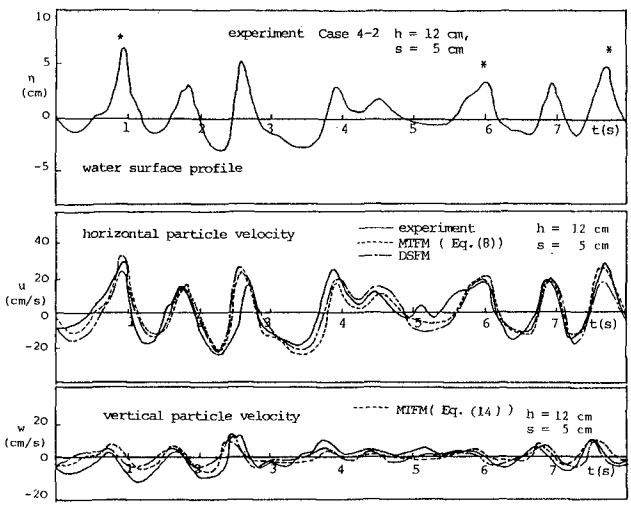

Fig.11 Time profile of water particle velocities for irregular wave (Case 4-2, h=12cm and s=5cm).

Table 2 Comparison between experimental and calculated values of horizontal particle velocity for irregular wave (Case 4-2, h = 21cm and s = 23cm).

Wave No.	1	2	3	4	5	6	7	8	9	10
water surface profile η(t) (cm)										
period T (sec)	1.52	1.39	0.97	1.61	0.97	0.94	0.90	1.68	1.61	1.13
wave height H(cm)	6.4	10.7	8.8	7.5	3.5	7.6	9.2	5.5	9.1	8.7
u^+(Experiment)	40.0	56.1	50.9	46.2	26.8	48.4	46.5	44.7	46.5	43.2
u^+(DSFM)	22.7	51.7	41.3	25.0	18.7	31.0	34.5	21.9	31.0	34.4
u^+(MTFM(Eq.(8))	29.4	62.0	53.4	31.8	25.3	50.5	40.8	31.2	31.4	46.7

u^+(Experiment), u^+(DSFM) and u^+(MTFM(Eq.(8)); unit (cm/s)

Two peaks on the free surface profile will imply the existence at least two different waves. Then, it seems difficult for DSFM and MTFM proposed for a monocromatic wave to evaluate well the particle velocities for such composite waves.

As stated above, the water particle velocity estimated by MTFM is in good agreement with the experimental value of the so-called "quasi-regular waves" in a random wave train. Comparing the modified transfer function method with Dean's stream function method, it can be said that MTFM is never inferior to DSFM in evaluating accurately the water particle velocity of finite amplitude regular or irregular waves. Since the calculation procedure of MTFM is much simpler than that of DSFM, the modified transfer function method proposed in this paper is useful and highly reliable for evaluating the wave kinematics.

5. CONCLUDING REMARKS

The approximate method which uses the modified transfer function has been presented to evaluate the water particle velocity of finite amplitude waves, for engineering purposes. The approximate method (modified transfer function method) is never inferior to Dean's stream function method in evaluating the wave kinematics of asymmetrical or symmetrical finite amplitude waves in regular and irregular wave environments, although its calculation procedure is much simpler than that of Dean's stream function method. In particular, the use of the approximate method is recommended to estimate the maximum water particle velocity of finite amplitude waves in shallow water depth. However, it is found that the predominant large velocity of water particle near the free surface in the surf-zone cannot be estimated accurately by any existing method.

CHAPTER 34

Nonlinear Theory on Particle Velocity and Pressure of Random Waves

Yi-Yu Kuo* and Hwar-Ming Wang**

ABSTRACT

In this paper, to the third approximation, we used the Fourier-stieltjes integral rather than Fourier coefficient to develop a weakly nonlinear theory. From the theory, the nonlinear spectral components for water particle velocity and wave pressure can be calculated diretly from the directional spectrum of water surface displacement. Computed results based on the nonlinear theory were compared with that of experiment made by Anastasiou (1982). Furthermore, in accordance with the different characteristics of wave properties, such as wave steepness, water depth and so on, the nonlinear effects on wave kinematic and pressure properties were extensively investigated by using some standard power spectra.

1. INTRODUCTION

To the first approximation, ocean waves can be described as a superposition of statistically independent free waves which have random phases and satisfy the linear wave theory. More recently, however, it has been found by many investigators that these spectral components of ocean waves do not necessarily follow the linear wave theory, especailly in the shallow water areas. Several nonlinear random wave theories were developed by, such as Phillip (1960), Hasselmann (1962), Weber (1977) and Masuda(1979) et al. But their description were mostly confined to the spectrum of water surface displacement.

The studies on random and nonlinear characteristics with respect to the wave kinematics and pressures are seldom discussed. Hudspeth (1975) developed a simulation method to determine the uni-directional second-order sea surface characteristics; however, in his report the water particle kinematics are computed by the digital linear filter technique. Following the nonlinear wave theory developed by Longuet-Higgings (1963), Sharma (1979) proposed a second order directional wave theory by using discrete frequency component to predict the wave kinematic and dynamic property. In the present study, for similar work but to the theird order approximation, we used the Fourier-stieltjes integral rather than Fourier coefficient to develop a weakly nonlinear theory for wave kinematics and wave pressures.

2. FORMULATION

For irrotational motion of an incompressible fluid, there is a velocity potential $\Phi(x,z,t)$ governed by

$$\nabla^2\Phi(\vec{x},z,t)=0 \tag{1}$$

Here $x=(\vec{x},y)$ is the horizontal co-ordinates, z is the vertical one and t

* Professor, Department of Civil Engineering, National Chiao-Tung University, Hsinchu, Taiwan, R.O.C.

** Graduate Research Asistant, Department of Civil Engineering, National Chiao-Tung University, Hsinchu, Taiwan, R.O.C.

is the time. The solution of (1) with the condition that Φ vanishes as z=-h is given by

$$\Phi(\vec{x},z,t)=\int_K \frac{\cosh|k|(h+z)}{\cosh|k|h} e^{i\chi} dA(K) \tag{2}$$

where K denotes (ω,k). ω is angular frequency, k is wave number vector, the increment dA(K) is a random variable and $\chi=k\vec{x}-\omega t$ is the phase. The integration is over the entire ω and k space. In the same way the surface displacement η can be expressed as

$$\eta(\vec{x},t)=\int_K e^{i\chi} dB(K) \tag{3}$$

Substituting with equation (2) and (3) in the kinematic boundary condition at water surface, and using the series expasion

$$\frac{\cosh\{|k|(h+z)\}}{\cosh|k|h}=1+|k|z\tanh|k|h+\frac{1}{2}|k|^2z^2+\ldots \tag{4}$$

we can find the relationship between dA(K) and dB(K) to the third order as

$$\begin{aligned} dA(K)=&\frac{-i\omega}{|k|\tanh|k|h} dB(K) \\ &+\int_{K_1} \frac{i\omega_1\cdot k\ k_1}{|k||k_1|\tanh\{|k|h\}\tanh\{|k_1|h\}}\cdot dB(K_1)dB(K-K_1) \\ &+\int_{K_1}\int_{K_2} \frac{i\omega_1}{|k|\tanh\{|k|h\}}\{\frac{1}{2}|k_1|^2+k_1\cdot k_2 \\ &-\frac{k\cdot(k_1+k_2)k_1\cdot(k_1+k_2)}{|k||k_1+k_2|\tanh\{|k_1|h\}\tanh\{|k_1+k_2|h\}} \\ &dB(K_1)dB(K_2)dB(K-K_1-K_2) \end{aligned} \tag{5}$$

2.1 water particle velocity

The increment of water particle velocity is also defined by

$$\vec{Q}=\int_K dq e^{i\chi} \tag{6}$$

However, the particle velocity vector $\vec{Q}$ can be obtained by taking the gradient of velocity potential Φ. Therefore, from the equations (2) and (6), we have

$$dq^H(K,Z)=\frac{i|k|\cosh\{|k|(h+z)\}}{\cosh|k|h} dA(K) \tag{7}$$

where dq^H is the increment of horizontal water particle velocity. Substituting equation (5) into equation (7), we obtain

$$\begin{aligned} dq^H(K,z)=&f_1(K,z)dB(K)+\int_{K_1} f_2(K,K_1,z)dB(K_1)dB(K-K_1) \\ &+\int_{K_1}\int_{K_2} f_3(K,K_1,K_2,z)dB(K_1)dB(K_2)dB(K,K_1,K_2) \end{aligned} \tag{8}$$

where
$$f_1(K,z)=\frac{\omega k\cosh\{|k|(h+z)\}}{|k|\sinh|k|h}$$
$$f_2(K,K_1,z)=-\frac{1}{2}\left\{\frac{\omega_1 k<k,k_1>}{\tanh|k_1|h}+\frac{(\omega-\omega_1)k<k,k-k_1>}{\tanh\{|k-k_1|h\}}\right\}\frac{\cosh\{|k|(h+z)\}}{\sinh|k|h}$$
$$f_3(K,K_1,K_2,z)=\frac{\omega_1 k\cosh\{|k|(h+z)\}}{\sinh|k|h}\left\{\frac{1}{2}|k_1|^2+|k_1||k_2|<k_1,k_2>\right.$$
$$\left.-\frac{|k||k_1+k_2|<k_1,k_1+k_2><k,k_1+k_2>}{\tanh|k_1|h\,\tanh\{|k_1+k_2|h\}}\right\} \qquad (9)$$

Here $<k,k'>\equiv k.k'/|k||k'|$ denotes the cosine of the angle formed by this vectors k and k'. For further development, let the increment dB(K) is represented as the sum of primary component $dB_1(K)$, second component $dB_2(K)$ and so on. However, following a previous study (Masuda et al 1979), $dB_2(K)$ and $dB_3(K)$ can also be expressed in terms of $dB_1(K)$. Taking the mean square value of the increment dq^H and using the definition of power spectrum

$$\frac{\overline{dq^H(K)\,dq^H(K')}}{dK\,dK'}=\phi_H^q(K)\,\delta(K+K') \qquad (10)$$

we finally obtained the horizontal water particle velocity spectrum ϕ_H^q as

$$\phi_H^q(K,z)=f_1(K,z)f_1(-K,z)\phi_1(K)$$
$$+2\int_{K_1}\frac{f_1(K,z)f_1(-k,z)}{W(K)W(-K)}\{fv_2(K,K_1)\}^2\phi_1(K_1)\phi_1(K-K_1)dK_1$$
$$+4\int_{K_1}\frac{f_1(-k,z)}{W(k)}f_2(k,k_1,z)\{fv_2(k,k_1)\}\,\phi_1(k_1)\phi_1(k-k_1)dK_1$$
$$+2\int_{K_1}f_2(k,k_1,z)f_2(-k_1,-k_1,z)\phi_1(k_1)\phi_1(k-k_1)dK_1$$
$$+4\int_{K_1}\frac{f_1(-k,z)}{W(k-k_1)}f_2(k,k_1,z)\{fv_2(k-k_1,-k_1)$$
$$+fv_2(k-k_1,k)\}\phi_1(k)\phi_1(k_1)dK_1$$
$$+2\int_{K_1}f_1(-k,z)\{f_3(k,k_1,-k_1,z)+f_3(k,k_1k,z)$$
$$+f_3(k,k,k_1,z)\}\phi_1(k)\phi_1(k_1)dK_1$$
$$+2\int_{K_1}\frac{f_1(k,z)f_1(-k,z)}{W(k)}\left\{2\frac{fv_2(k,k_1)}{W(k-k_1)}+fv_3(k,k_1,-k_1)\right.$$
$$\left.+fv_3(k,k_1,k)+fv_3(k,k,k_1)\right\}\phi_1(k)\phi_1(k_1)dK_1 \qquad (11)$$

where

$$W(K)=g-\frac{\omega^2}{|k|\tanh|k|h} \tag{12}$$

$$fv_2(K,K_1)=\frac{1}{2}\{\omega^2-\omega\omega_1+\omega_1^2-\omega\omega\frac{<k,k_1>}{\tanh\{|k|h\}\tanh\{|k_1|h\}}$$
$$-\omega(\omega-\omega_1)\frac{<k,k-k_1>}{\tanh|k|h\ \tanh\{|k-k_1|h\}}$$
$$-\omega_1(\omega-\omega_1)\frac{<k_1,k-k_1>}{\tanh|k_1|h\ \tanh\{|k-k_1|h\}} \tag{13}$$

$$fv_3(K,K_1,K_2)=\frac{1}{4}\{\frac{\omega_1^2|k_1|}{\tanh|k_1|h}+\frac{\omega_2^2|k_2|}{\tanh|k_2|h}\}$$
$$+\frac{1}{2}\omega_1\omega_2\{\frac{|k_1|}{\tanh|k_1|h}+\frac{|k_2|}{\tanh|k_2|h}\}$$
$$+\frac{1}{4}\frac{\omega}{|k|\tanh|k|h}\{\omega_1|k_1|^2+\omega_2|k_2|^2\}$$
$$-\frac{1}{2}(\omega_1+\omega_2)|k_1+k_2|\{\frac{\omega_1<k_1,k_1+k_2>}{\tanh|k_1|h}+\frac{\omega_2<k_2,k_1+k_2>}{tnah|k_2|h}\}$$
$$-\frac{1}{2}\omega(\omega_1+\omega_2)\frac{|k_1||k_2|<k_1,k_2>}{|k|\quad\tanh|k|h}$$
$$+\frac{\omega}{2}|k_1+k_2|\frac{<k,k_1+k_2>}{\tanh|k_1|h\ \tanh\{|k_1+k_2|h\}}$$
$$\{\frac{\omega_1<k_1,k_1+k_2>}{\tanh|k_1|h}-\frac{\omega_2<k_2,k_1+k_2>}{\tanh|k_2|h}\}$$
$$-\frac{1}{2}\omega_1\omega_2|k|\{\frac{<k,k_1>}{\tanh|k_1|h}+\frac{<k,k_2>}{\tanh|k_2|h}\}$$
$$+\frac{1}{2}\frac{\omega_1\omega_2}{\tanh|k_1|h\ \tanh|k_2|h}\{\frac{|k-k_1|}{\tanh\{|k-k_1|h\}}<k_1,k-k_1><k_2,k-k_1>$$
$$+\frac{|k-k_2|}{\tanh\{|k+k_2|h\}}<k_1,k-k_2><k_2,k-k_2>\} \tag{14}$$

In equation (11), the first term on right is the linear component and the others are nonlinear components. $\phi_1(K)$ is the first order spectrum. Although usually difficult to obtain, the first order spectrum can often be replaced by the total power spectrum to compute the nonlinear components approximately (Masuda at al 1979). It is clear that, based on equation (11), the nonlinear spectral component of horizontal particle velocity can be calculated directly from the directional spectrum of water surface displacement.

On the other hand, from the equation (2) and (6) for vertical velocity component, we have

$$dq^V(k,z)=\frac{i|k|\sinh\{|k|(h+z)\}}{\cosh|k|h}dA(K) \tag{15}$$

where dq^V is the increment of vertical water particle velocity. Similarily, using the same procedure described above, we can obtain a formula to calculate the nonlinear spectral component of vertical water particle velocity. This formula is just as same as the equation (11) except that the functions f_1, f_2 and f_3 are completely different from equation (9). The functions for vertical velocity spectrum are shown as follows

$$f_1(K,z)=\frac{i\omega\ \sinh\{|k|(h+z)\}}{\sinh|k|h}$$

$$f_2(K,K_1,z)=-\frac{i}{2}\{\frac{\omega_1|k|<k,k_1>}{\tanh|k_1|h}$$

$$+\frac{(\omega-\omega_1)|k|<k,k-k_1>}{\tanh\{|k-k_1|h\}}\}\frac{\sinh\{|k|(h+z)\}}{\sinh|k|h}$$

$$f_3(K,K_1,K_2,z)=-i\frac{\omega\ \sinh\{|k|(h+z)\}}{\sinh|k|h}$$

$$\{\frac{1}{2}|k_1|^2+|k_1||k_2|<k_1,k_2>$$

$$-\frac{|k||k_1+k_2|<k_1,k_1+k_2><k,k_1+k_2>}{\tanh|k_1|h\ \tanh\{|k_1+k_2|h\}} \tag{16}$$

2.2 wave pressure

Neglecting the Bernoulli's constant, we have the Bernoulli's equation as

$$\frac{p}{\rho}+\frac{1}{2}(\nabla\Phi)^2+\frac{\partial\Phi}{\partial t}=0 \tag{17}$$

Here the increment of wave pressure dC(K) is defined by

$$\frac{p}{\rho}=\int_K dC(k,z)e^{i\chi} \tag{18}$$

(where p is the dynamic wave pressure, and ρ is the water density). Substituting the equation (2) into equation (17), we can obtain

$$dC(k,z)=f_1^p(k,z)dB(k)+\int_{K_1}f_2^p(k,k_1,z)dB(k)dB(k-k_1)$$

$$+\int_{K_1}\int_{K_2}f_3^p(k,k_1,k_2,z)dB(k_1)dB(k_2)dB(k-k_1-k_2) \tag{19}$$

where

$$f_1^p(K,z)=\frac{\omega^2}{|k|\sinh|k|h}\cosh\{|k|(h+z)\}$$

$$f_2^p(K,K_1,z)=-\frac{1}{2}\{\frac{\omega\omega_1<k,k_1>}{\tanh|k_1|h}+\frac{\omega(\omega-\omega_1)<k,k-k_1>}{\tanh\{|k-k_1|h}\}\frac{\cosh\{|k|(h+z)\}}{\sinh|k|h}$$

$$+\frac{1}{2}\omega_1(\omega-\omega_1)(1-\frac{<k_1,k-k_1>}{\tanh|k_1|h\ \tanh\{|k-k_1|h\}})$$

$$\frac{\sinh\{|k-k_1|(h+z)\}}{\sinh\{|k-k_1|h\}}\ \frac{\sinh\{|k_1|(h+z)\}}{\sinh|k_1|h}$$

$$f_3^p(K,K_1,K_2,z)=-\frac{\omega\omega_1\cosh\{|k|(h+z)\}}{|k|\sinh\{|k|h\}}\{\frac{1}{2}|k_1|^2+|k_1||k_2|<k_2,k_2>$$

$$-\frac{|k||k_1+k_2|<k,k_1+k_2><k_1,k_1+k_2>}{\tanh|k_1|h\ \tanh\{|k_1+k_2|h\}}-\frac{\omega_1\omega_2}{|k_2|}$$

$$(1-\frac{<k,k-k_1>}{\tanh\{|k_1|(h+z)\}\tanh\{|k-k_1|(h+z)\}})\frac{|k-k_1|k_2}{\tanh|k_2|h}$$

$$\frac{\sinh\{|k-k_1|(h+z)\}}{\sinh\{|k-k_1|h\}}\ \frac{\sinh\{|k_1|(h+z)\}}{\sinh|k_1|h} \tag{20}$$

In the same way, by using of perturbation expasion of dB(K) and the definition of power spectrum, the formula for calculating the nonlinear spectral component of wave pressure can be obtained. This formula is also as same as equation (11) except that the functions f_1, f_2 and f_3 must be replaced by functions f_1^p, f_2^p, and f_3^p (equation (20)).

3. COMPARISON WITH EXPERIMENTAL RESULTS

An experimental result concerning water particle velocities is used to verify the above nonlinear theory. The measurement was made by Anastasiou (1981) in laboratory random waves by using Laser Doppler anemometry. The random waves were simulated by using the spectral form of Pierson-Moskowitz type

$$S(\omega)=\frac{0.081}{\omega^2}\exp(\frac{-0.74\omega^4}{\omega^4}) \tag{21}$$

and generated by an irregular wave maker.

Figure 1 shows the comparison of partical velocity spectrum between the theoretically computed results and the experimental results with a water depth of 0.7m, wave steepness of 0.0478 and measurement elevation of 0.1m under water surface, where "I" denotes the measured spectrum including 95% confidence limits. From the comparison, we can find that the measured data are better consistent with the nonlinear theory than the linear theory. But in this case, the nonlinear phenomenum is not obvious because of the experimental wave conditions. In future, we will try to

make the comparison with more suitable data.

4. DISCUSSION

After normalizing the formula (11) with total energy and the peak frequency of power spectrum, we use some standard form of power spectrum in place of linear spectrum $\phi_i(k)$ in equation (11) to investigate some nonlinear characteristics of water particle velocity and wave pressure.

First, based on Pierson-Moskowitz spectrum, the influence of wave steepness on the nonlinear effect is investigated. The computational results with relative water depth (h/Lm) of 0.15, and relative measured elevation (Z/Lm) of -0.08 (measured from water surface) are shown in Figure 2. In the figures, the significant wave steepness δ is defined by significant wave height ($H_{1/3}$) and wave length (Lm), while the latter is correoponding to the peak frequency fm. The results calculated by linear theory are also shown in these figures. From the fact that the nonlinear component appear in higher and lower frequency ranges, we can learn from figure 2 that the nonlinear effect increases as the wave steepness increases.

Figure 3 shows the influence of surface displacement spectral form on the nonlinear effect for horizontal water particle velocity. Figure 3(a) and 3(b) show the results computed by using Pierson-Moskowitz spectrum and JONSWAP spectrum respectively. From the comparison between these two figures, it is found that the sharp form like JONSWAP spectrum produces clearer nonlinear effect than the milder form like Pierson-Moskowitz spectrum.

Figure 4 shows the influence of water depth on the nonlinear effect. In the figures, A_N/A_L denotes the relative magnitude of nonlinear total energy to linear total energy. The results are computed by using Pierson-Moskowitz spectrum. The breaking limit drawing with dash line in these figures is calculated from Hamada's wave breaking formula (Hamada 1951). It is shown that the horizontal velocity, vertical velocity and wave pressure all exhibite the same properties. From the figures, it is found that the nonlinear effect increases as relative water depth h/Lm decreases when the h/Lm in the range between 0.1 and 0.3. However when h/Lm is larger than 0.3, the nonlinear quantity is independent of the relative water depth. On the other hand, when relative water depth approaches 0.1, the nonlinear components approach to infinitive. In fact, in this water depth or shallower area, this formula can no longer be used because the formula is derived based on the weakly nonlinearity assumption.

Figure 5 shows the influence of measured elevation on the nonlinear effect. Z denotes the measured elevation from mean water surface. The results are computed by using Pierson-Moskowitz spectrum and with relative water depth of 0.15. For particle velocities, horizontal component and vertical component exhibite the same properties. From the figure (a), it is found that the measured elevation tends not to bear influence on the nonlinear effect. But as to the wave pressure (Figure(b)), it is found that the nonlinear effect increase as the elevation decreases.

In the above description, all simulate computational results only concern one-dimensional spectrum. In figure 6, the influence of direction-

al dispersion on the nonlinear effect is investigated with relative depth of 0.15, relative measured elevation of -0.04 and wave steepness of 0.06. The nonlinear spectral components calculated by the directional wave spectrum is compared with that of calculated by uni-directional wave spectrum. For convenience, the form of $\cos^2\theta$ was used as the wave directional distribution to calculate the nonlinear spectral components. In the computations, we found that it has to take a long computing time to integrate the directional distribution to obtain the ordinary power spectra of particle velocity or wave pressure. In Figure 6, from the comparison, it is found that the wave directional dispersion diminishes the nonlinear effect.

5. CONCLUSION

This paper is composed of two parts. First, a weakly nonlinear random wave theory in finite water depth was developed. The nonlinear spectral components for water particle velocity and wave pressure can be calculated directly from the directional spectrum of water surface displacement. The theoretical computed results were verified by experiment. Next, a simulate computation was performed. In accordance with the different characteristics of wave properties, such as wave steepness, water depth and so on, the nonlinear effects on wave kinematic and pressure properties were extensively investigated by using some standard power spectrum. From the investigation, we found some important conclusions as follows. First, the important characteristics of nonlinear effect for water particle velocity and wave pressure are similar to that for water surface displacement spectrum. Second, it takes much more computing time for directional spectrum than that for one-dimensional spectrum. Third, this theory can not be used in shallow water area when relative water depth is below 0.1.

CHAPTER 35

EFFECTS OF THE GULF STREAM ON NEARSHORE WAVE CLIMATE

R.J. Lai and S.L. Bales*

ABSTRACT

Large scale ocean currents, such as the Gulf Stream, Kuroshio, Peru Current, Agulhaus Current, etc., strongly modify the surrounding wave characteristics. As the Gulf Stream moves along the Continental Shelf of the southeast coast of the United States, the local ocean environment is divided into three wave climatic regimes. They are the offshore, the Gulf Stream, and the nearshore regimes. The nearshore zone is bounded by the land to the west and the Gulf Stream to the east. The distance between land and the Gulf Stream varies from 10 to 60 miles. Most of the waves in this regime are generated offshore and cross the Gulf Stream. The correlation of local wind and waves in the nearshore regime is poor except in the presence of a persistent onshore storm.

A semi-empirical approach has been developed to compute the nearshore wave climate. The hindcast/forecast directional waves from the Spectral Ocean Wave Model (SOWM) of the Navy Fleet Numerical Oceanography Center have been used as the source of the initial offshore wave conditions. After crossing the Gulf Stream, which is assumed to be a uniform current with a velocity of 2 m/s, the waves are either refracted to the nearshore regime or reflected to the offshore regime following ray theory. The onshore waves in the nearshore zone are confined to the sector from 30 to 150 degrees. The computed results are then compared with measured data with good agreement.

In summary, the Gulf Stream acts as a barrier to damp long waves and to regroup short waves. The refraction of long waves can be predicted by using ray theory. Further field experiments are needed to quantify the variation of the Gulf Stream and to investigate the interaction with approaching long waves and local wind generated short waves.

1. INTRODUCTION

The development of wave climate of a region provides the general prevailing wave conditions throughout the year. This is considered important to the design of offshore structures and for the planning of ship operations. The rapid development and large increase of population along the coastal zone makes the nearshore wave climate an urgent task for all phases of engineering works. These nearshore activities include safe ship navigation to avoid collision and

*David W. Taylor Naval Ship Research and Development Center, Bethesda, Maryland 20084-5000, U.S.A.

grounding, pollution transport, nearshore structure, beach erosion abatement, etc.

The complexity of the boundary conditions and changing dynamic parameters from the interaction of air-sea-land at the nearshore zone make the generalization of wave dynamics in coastal zones a difficult task. Furthermore, large scale ocean currents moving along major continental shelves strongly modify the approaching waves from the offshore to the nearshore. One of these regions is located at the southeast coast of the United States. The nearshore regime is bounded by the land to the west and the Gulf Stream to the east. The distance between land and the Gulf Stream varies from 10 to 60 miles (see Figure 1). The local ocean environment of this area is divided into three wave climatic regimes. They are the offshore, the Gulf Stream, and the nearshore regimes. Most of the waves in this regime are generated offshore and approach the nearshore regime by crossing the Gulf Stream. The effects of the Gulf Stream play an important role in the formation of nearshore wave climate which will be presented here.

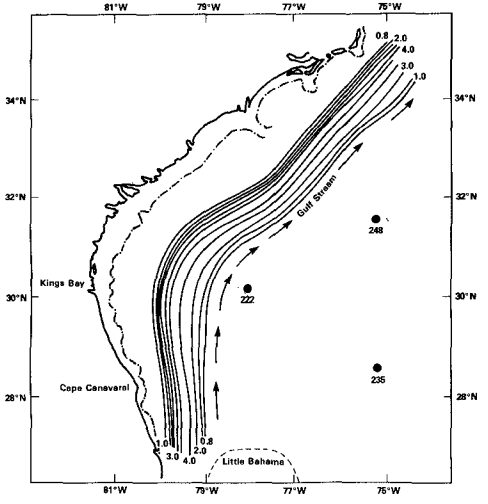

Figure 1. Map showing the Gulf Stream and SOWM grid points used at St. Marys (Kings Bay) and Cape Canaveral

2. LOCAL WAVE CHARACTERISTICS

A field measuring program has been ongoing to investigate the wave characteristics of this region since 1984. The results have been used to calibrate the Shallow Water Wave Model (Lai and Silver, 1986a) and to develop the local wave climate. The measured results of 1984 and 1985 have been published recently (Lai and Foley, 1986b). In short, submersible field stations measured directional waves four times a day at Cape Canaveral, Florida and St. Marys Inlet, Georgia. Although the data recovery rate is about 60 percent during the

measuring period, the measured data reveal many interesting local wave characteristics. These can be briefly summarized as follows:

a. Correlation of Local Wind and Wave

Strong winds imply high seas in deep water. In the nearshore zone, however, winds come from all directions and waves are limited to onshore directions; therefore, the correlation of local wind and waves becomes a difficult task. Measurements at St. Marys Inlet, Georgia provide both amplitudes and directions of wind and waves. Based on these data, wind and wave roses for the winter season of 1984 have been developed and are given in Figures 2a and 2b. Although most of the winds of the nearby shore station at the Mayport Air Station are from west, north, and northeast directions, the approaching wave directions are confined by geography to northeast, east, and southeast directions. Similar data for the summer are shown in Figures 3a and 3b for 1984. There is some correlation between the wind and wave data; however, a precise local correlation is almost impossible to establish. This has been illustrated in Figure 4 in which both daily variations of offshore and nearshore wind are compared with measured directional waves. It is clearly shown that offshore wind has better correlation with nearshore waves. This points out the fact that the wave climate in the nearshore zone is dominated by the storm and wind patterns offshore and propagates to the shore with some local wind input unless the onshore storm persists for more than 24 hours. At that time, the local wind and wave direction coincide.

b. Directional Wave Spectra

A series of measured directional wave spectra have been evaluated. The direction of long waves tends to be from the 50 to 120 degrees band while the directions of short waves are scattered. Although the same offshore storms pass through the southeast coast of Florida, the measured directional wave data at Cape Canaveral and St. Marys Inlet show different characteristics (see Figures 5 and 6). The major differences of these nearshore zones are the local topography and the heading of the Gulf Stream north (Cape Canaveral) versus northeast (St. Marys Inlet). Some of these characteristics at these two sites resulted from the effects of the Gulf Stream, which will be discussed further in the following section. While the data of Figures 5 and 6 were collected for different storms, their general characteristics are representative of each site.

3. APPROACH

The measured field data reveal the characteristics of the local waves and the poor correlation of local wind and waves. However, the data can only provide short-term wave statistics which are not enough to establish nearshore wave climatology. Therefore, hindcasting techniques have been applied here to develop the nearshore wave climate.

The U.S. Navy Fleet Numerical Oceanography Center (FNOC) has operated a Northern Hemispheric wave forecast/hindcast model, called the Spectral Ocean Wave Model (SOWM) (Lazanoff and Stevenson, 1975)

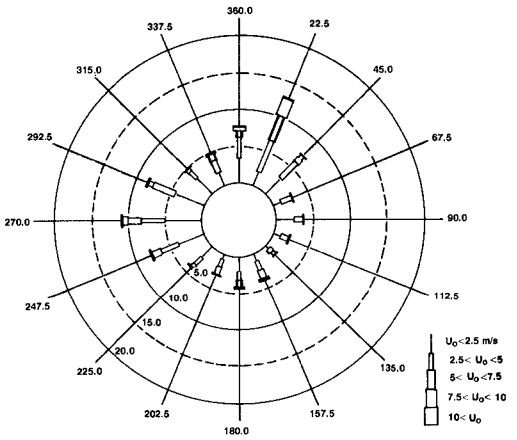

Figure 2a. Wind rose for Mayport Naval Air Base near St. Marys for winter 1984

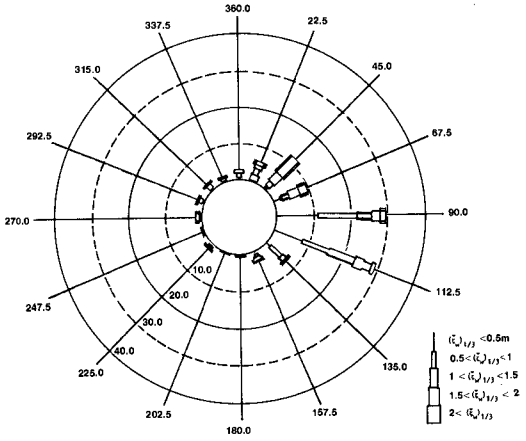

Figure 2b. Wave rose for St. Mary entrance Station 5 offshore for winter 1984

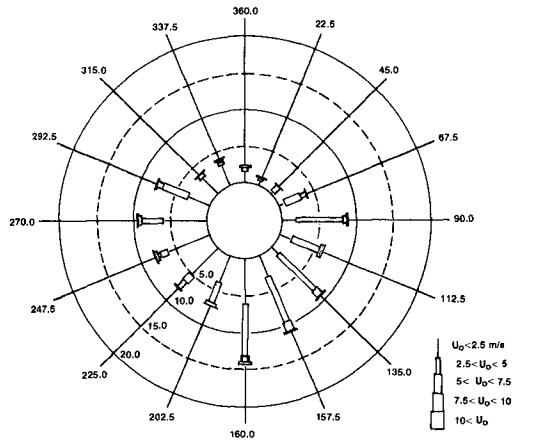

Figure 3a. Wind rose for Mayport Naval Air Base near St. Marys for summer 1984

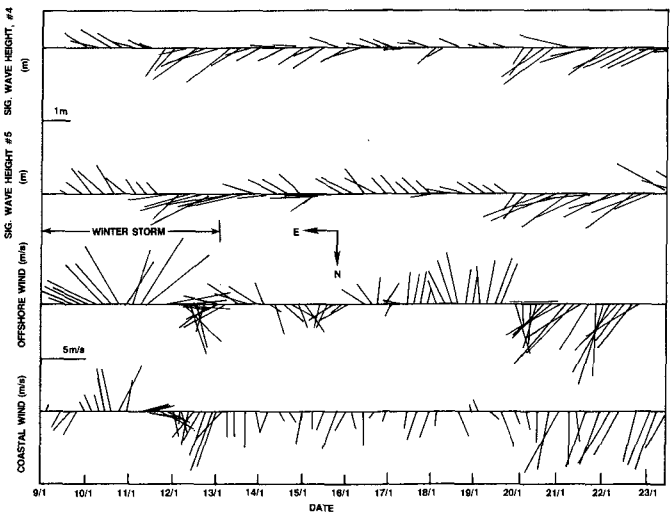

Figure 4. Measured waves at Stations 4 and 5 and winds at offshore buoy (Uo) and coastal station (Un)

from 1975 to 1985.* The deep water wave statistics derived from SOWM have been widely used at the David Taylor Naval Ship Research and Development Center (DTNSRDC), other Navy and government centers, NATO countries, and in the private sector (Bales, et al., 1982). The approach here was to transform the corresponding offshore data from the SOWM hindcast climatology to the nearshore zone to establish wave statistics over a period of 15 years.

The process of transforming waves from deep water to shallow water requires three wave parameters deirved from SOWM: significant wave height, $(\tilde{\zeta}_w)_{1/3}$; primary incident wave direction, θ_o; and incident modal wave period, T_o. Since the distance between deep and shallow water in this case is less than 120 kilometers and the uncertainty of predicting wave frequency, the shift of wave period for long waves (with $T_o \geq 6$ sec) has not been considered. Therefore, the shallow water wave periods are assumed to be the same as the hindcast ones from SOWM. The other two parameters are interrelated and are treated separately.

The correlations of significant wave height between deep (hindcast/forecast) and shallow water (measured) were developed using the given forecast wave direction and normalized by the significant wave height of the SOWM at the deep water grid points. The average of three grid points located along the central Florida east coast are used to provide the hindcast/forecast wave spectrum for both Cape Canaveral and St. Marys Inlet. These are grid points 221, 222, and

*The SOWM has now been replaced by a global model called GSOWM.

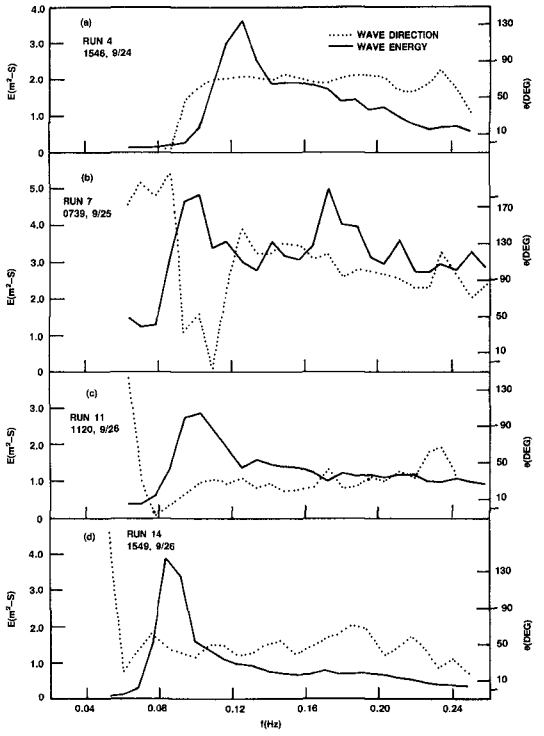

Figure 5. Measured wave spectra with mean directions at Station 2 of Cape Canaveral during the passage of the storm of 1983

235 which are located at (31.8° N, 75.1° W), (30.4° N, 77.9° W), and (28.8° N, 75.2° W), respectively, see Figure 1. The averaged spectral values of these grid points provides the overall wave forecast by the SOWM at the offshore region (Lai, et al., 1984).

The changes of approaching wave direction from deep to shallow water are complex on the Florida east coast due to the existence of the Gulf Stream, see Figure 1. Therefore, the process of transforming the forecast wave direction of SOWM into shallow water has been divided into two steps. The first step was to calculate the change in SOWM wave direction from deep water into intermediate depth by crossing the Gulf Stream. Then, by using the Shallow Water Wave Model (SWWM), the waves at the intermediate depths were transformed to the shallow water zone.

A simplified analytical solution and numerical model have been used to transform the offshore wave direction to the nearshore zone. The Gulf Stream along the Florida east coast heads northward running almost parallel to the coast line and turns to northeast direction

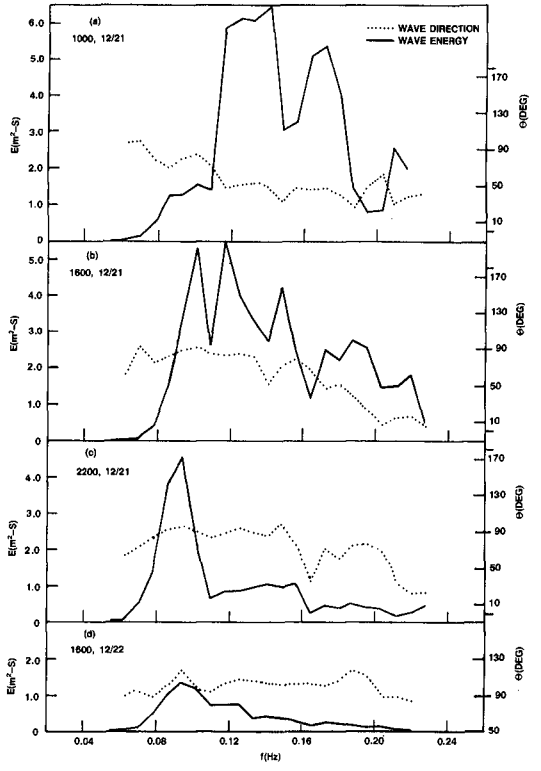

Figure 6. Measured wave spectra with mean directions at Station 5 of St. Marys during the passage of the storm of 1984

near Jacksonville, Florida. Here, it is assumed that the Gulf Stream is a uniform current, with a mean velocity of 2.0 m/s. The changes of wave direction are calculated from the following analytical solution

$$\cos\ \theta_1 = \cos\ \theta_0 / \left[1 - \frac{U_1 - U_0}{C_0} \cos\ \theta_0\right]^2 \qquad (1)$$

where θ_0 and θ_1 are the primary incident and refracted wave directions before and after crossing the Gulf Stream, respectively (Kenyon, 1971; Phillips, 1981). U_0 and U_1 are the mean currents of the deep water offshore section and the Gulf Stream, and C_0 is the original wave phase velocity. The value of U_0 was assumed to be zero in this computation.

The relationship between the parameters defined in Equation (1) are shown in Figure 7. The wave direction after refraction by the Gulf Stream is a function of the incident modal wave period, T_0, and incident direction, θ_0. The relationship between θ_0, θ_1, and T_0, with

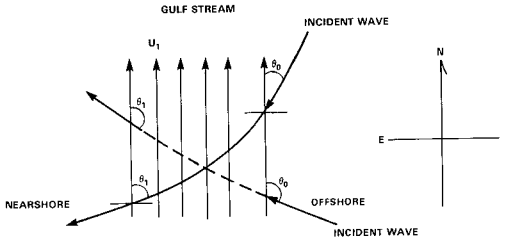

Figure 7. Change of Wave direction by the Gulf Stream where θ_0 is incident wave direction and θ_1 is predicted wave direction after crossing

assumed values of U_0 and U_1, are shown in Figures 8 and 9. In the Cape Canaveral area, as shown in Figure 8, when the waves approach from the southeast with large wave periods, the waves may reflect back to the deep water zone as shown in the upper section of the figure. This phenomenon has been discussed by Hayes (1980) and others (Chao, 1970). Furthermore, the incident waves from the north and northeast are refracted to the wave direction greater than 30 degrees. This implies that the direction of most waves (except the local wind waves in the intermediate water zone) are refracted and arrive in the nearshore zone range from the northeast, the east, and the southeast directions after crossing the Gulf Stream. In the St. Marys Inlet area, due to the change of flow direction of the Gulf Stream and the bottom bathymetry, the results are different from those of the Cape, as shown in Figure 9. Here the shoreline turns to the northeast direction near the St. Marys area, as does the Gulf Stream. The incident wave directions of the offshore zone are then confined to the 40 to 180-degree range. The changes of wave directions after crossing the Gulf Stream around St. Marys are shown in Figure 9. The offshore wave directions are limited from 40 to 160 degrees range. The nearshore wave directions range then from 70 to 165 degrees according to Equation (1).

The changes of wave directions after crossing the Gulf Stream have been computed using SWWM (Lai, et al., 1984), and will not be discussed in detail here.

4. RESULTS AND DISCUSSIONS

The wave statistics from the transformed SOWM data over a period of 15 years have been developed and published in other reports (Lai, Silver and Bales, 1984). In general, the characteristics of these wave statistics are dependent on the site chosen around the nearshore zone. Two of them are located near the field measuring sites. Thus, the measuring wave data can be used to develop short term statistics and to verify the transformation method. Two sets of short terms wave

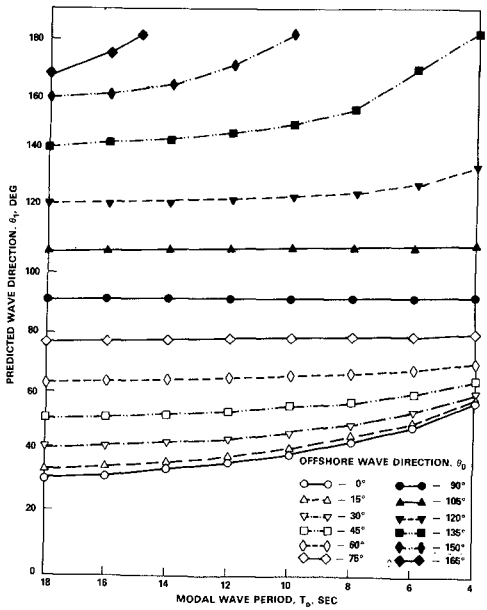

Figure 8. Predicted wave direction (θ_1) after crossing the Gulf Stream at Cape Canaveral

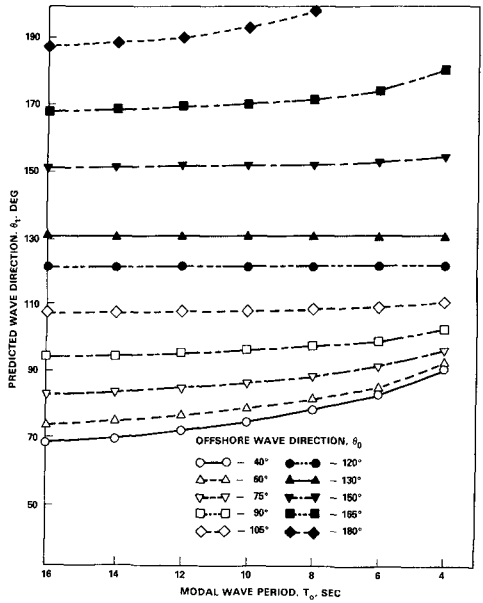

Figure 9. Predicted wave direction (θ_1) after crossing the Gulf Stream at St. Marys

statistics are presented. One is from measured field data, and the other is from the corresponding transformed SOWM data. Comparisons are made to evaluate the transformation method and to discuss the effects of the Gulf Stream on wave climate.

The wave statistics are grouped according to seasons, i.e., Winter (December to February), Spring (March to May), Summer (June to August), and Fall (September to November). Since the recovery rate of field data is around 60 percent during 1984 and 1985, it is difficult to compute wave statistics for all four seasons. The available measured and hindcast data of the rougher seasons (i.e., Winter and Fall) were chosen for comparison.

Comparison of measured and hindcast wave direction statistics are shown in Figures 10, 11, and 12. The solid lines represent the offshore hindcast data from SOWM. The dashed lines represent the nearshore transformed hindcast data, and the dotted lines represent the measured field data at the same period of time. Each figure is divided into parts (a) and (b). The data in part (b) consist of all waves. The results of part (b) show that the transformation method which takes into account the effects of the Gulf Stream and the local shoaling zone is credible. The waves from north, northeast, and east directions refract to east, normal to the shore, as predicted from the ray theory. However, the waves from south and southeast directions reflect to the offshore which is difficult to assess in the transformation process. Furthermore, when offshore waves cross the Gulf Stream, longer waves tend to follow the ray theory, and short waves are affected by the currents and local wind force. These local energy inputs interact dynamically with short waves and cause the waves to break or reorganize. This has been clearly indicated from the measured data. The analyzed results of long waves without confused sea of short waves are shown in part (a). Overall improvement for the long waves is evident especially for the waves from the north, northeast, and east directions. Here, the long waves are defined as waves with periods larger than 6.7 sec (or frequencies less than 0.15 Hz). There is only a moderate improvement on the waves from the south and southeast directions due to the complex phenomenon of wave reflection and due to less accuracy for predicting waves generated from the south near Little Bahama Basin by the SOWM (see also Figure 1).

Comparison of measured and hindcast wave period statistics is shown in Figure 13. The solid lines are from the hindcast data of SOWM and the dashed lines are from the field measured data. The wave periods from SOWM are taken from offshore region and applied to nearshore region directly. The assumption of this direct application has been discussed in a previous publication (Lai et al., 1984). The results show the direct comparison of three sets of data as referred to (a), (b), and (c) in Figure 13. The data of Figure 13(a), (b) and (c) are identical to the data of Figures 10, 11, and 12. The agreement is encouraging if one separates the long and short waves again. The overall wave period of long waves between two data sets agrees well although the distribution is not very consistent. Further research is needed to take into account the local wind force on wave evolution during the process of crossing the Gulf Stream.

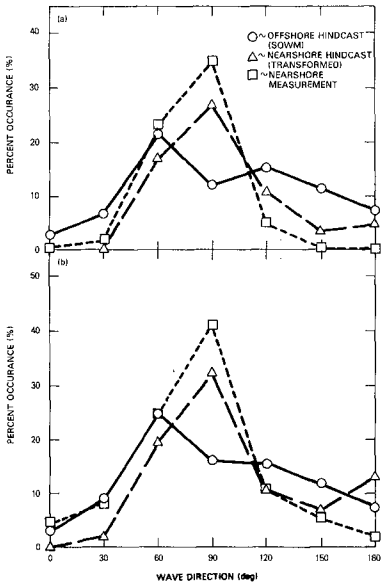

Figure 12. Comparison of measured and hindcast wave direction statistics of winter 1985 at Cape Canaveral, (a) long waves only, (b) all waves

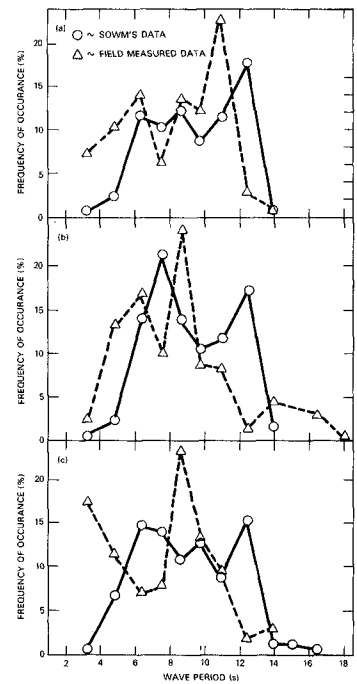

Figure 13. Comparison of measured and hindcast wave period statistics, where (a) winter of 1984 at St. Marys, (b) fall of 1984 at St. Marys, (c) winter of 1985 at Cape Canaveral

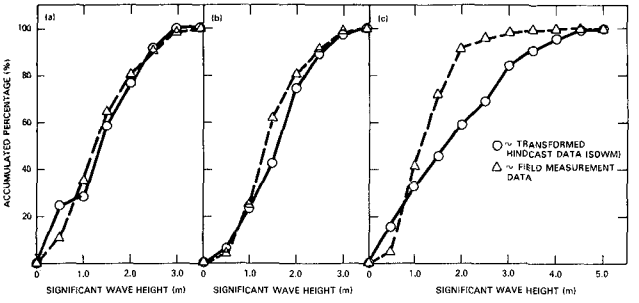

Figure 14. Comparison of measured and hindcast wave height statistics, where (a) winter of 1984 at St. Marys, (b) Fall of 1984 at St. Marys, (c) winter of 1985 at Cape Canaveral

Comparison of measured and hindcast significant wave height statistics is shown in Figure 14. The agreement between transformed hindcast data from SOWM and field measured data in the St. Marys area is very good but not so in the Cape Canaveral area. The reason for this poor agreement is not clear. However, after re-examining the data of Cape Canaveral, it was found that some stormy data during the winter of 1985 are from the south and southeast directions which may be attributed to this poor agreement. The hindcast storm data from the south and southeast directions by SOWM had been hampered by the existence of Bahama Bank to cause such discrepancy, as pointed out previously.

5. CONCLUSION

Developing nearshore wave climates require complex procedures. Shoreline structure, bottom topography, offshore wind and wave conditions and surrounding ocean current must be considered. A wave climate for the southeast coast of the United States has been developed. The offshore hindcast data from SOWM has been transformed to the nearshore zone. The transformation method takes into account the effects of the Gulf Stream and shallow water shoaling. The results have been compared with the field measured data with generally good agreement. The effect of the Gulf Stream on crossing waves should be divided into two categories, i.e., long waves and local wind waves. The refraction of long waves can be predicted by using ray theory. However, to clarify the generation and reflection of waves from the south and southwest directions further research work or field data is needed. Strong currents cause local generated wind waves (i.e., short waves) to stop, break, and reorganize. Further field experiments and research are needed in this area to predict the process of wave evolution in the ocean environment which present strong currents.

CHAPTER 36

Empirical Prediction of Wave Spectrum for Wind-Generated Gravity Waves

Jung-Tai Lin*

In the energy-containing range, an empirical frequency spectrum representing a general sea state was derived,

$$\frac{n_o^3 \phi(n)}{u_* C_o} = A_1 r \left(\frac{n}{n_o}\right)^{-r} \exp\left[-\frac{r}{r-1}\left(\frac{n}{n_o}\right)^{-r+1}\right] .$$

Experimental data were used to verify this empirical frequency spectrum. The value of A_1 was approximated to be 0.044 and the value of r is related to $n_o u_*/g$ by

$$r = 9.1 \left(\frac{n_o u_*}{g}\right)^{1/4} .$$

In the equilibrium range, the saturated frequency spectrum was approximated by

$$\frac{n_o^3 \phi(n)}{u_* C_o} = 0.08 \left(\frac{n_o u_*}{g}\right)^{-1/4} \left(\frac{n}{n_o}\right)^{-5} .$$

Experimental data were used to test whether the Phillips spectrum, $\phi(n) = \beta g^2 n^{-5}$ would serve as a better approximation of the wave spectrum than the Toba spectrum, $\phi(n) = \alpha u_* g n^{-4}$. Measurements of both the wave slope spectrum and the mean square wave slope favor the Phillips spectrum.

Introduction

Wind-Generated gravity wave has been of great interest to researchers and engineers in the field of coastal engineering because it is one of the important considerations in the engineering studies and designs for ship navigation, coastal and off-shore structures, shore protection, oil pollution control, and wave energy conversion. An accurate prediction of the wave height, wave frequency, and wave spectrum is critical to the success of these engineering studies and designs.

Based on dimensional reasoning, Phillips (20) hypothesized that in the equilibrium range, the wave frequency spectrum of wind-generated gravity waves, $\phi(n)$ is saturated and can be approximated by

*ASCE member; President, United Industries Corp., 12835 Bell-Red Rd. #120, Bellevue, WA., U.S.A. 98005

$$\phi(n) = \beta g^2 n^{-5} \quad \text{for } n_o << n << n_\gamma \tag{1}$$

where g is the gravitational acceleration, n is the angular wave frequency, n_o is the wave frequency of the dominant wave, n_γ is defined as $(4g^3/\gamma)^{\frac{1}{4}}$, γ is the surface tension per unit density and β is a non-dimensional numerical coefficient. To approximate the frequency spectrum in both the equilibrium range and the energy-containing range for fully developed wind waves in the open ocean, Pierson and Moskowitz (23) proposed the PM continuous frequency spectrum

$$\phi(n) = \beta g^2 n^{-5} \exp\left[-\frac{5}{4}\left(\frac{n}{n_o}\right)^{-4}\right] . \tag{2}$$

For a growing sea that the wind wave field has not yet reached the fully-developed stage, Hasselmann, et al, (6) proposed the JONSWAP continuous frequency spectrum

$$\phi(n) = \beta g^2 n^{-5} \exp\left[-\frac{5}{4}\left(\frac{n}{n_o}\right)^{-4}\right] \delta^\Gamma \tag{3}$$

Equation (3) was derived by multiplying the peak-enhancement function, δ^Γ, to the PM spectrum expressed in Equation (2). Here δ is the ratio of the spectral maximum to the spectral maximum derived from the PM spectrum, Γ is defined by $\Gamma = \exp\left[-(n - n_o)^2/2\sigma^2 n_o^2\right]$, and $\sigma = \sigma_a$ for $n \leq n_o$ and $\sigma = \sigma_b$ for $n \geq n_o$.

Huang, et al. (8) proposed the unified two-parameter WALLOPS frequency spectrum to approximate the frequency spectrum in the energy-containing range for a general sea state

$$\phi(n) = \frac{\beta g^2}{n^m n_o^{5-m}} \exp\left[-\frac{m}{4}\left(\frac{n_o}{n}\right)^4\right] \tag{4}$$

When the value of m is equal to 5, Equation (4) is identical to the Pierson-Moskowitz spectrum.

Based on the three-second power law (Toba, 29a) and the concept of the similarity wave spectrum, Toba (29) proposed that in the equilibrium range,

$$\phi(n) = \alpha g u_* n^{-4} \quad \text{for } n_o << n << n_\gamma \tag{5}$$

$$\phi(n_o) = \alpha_o g u_* n_o^{-4} \tag{5a}$$

where u_* is the frictional velocity of the wind, and α and α_o are non-dimensional numerical coefficients. A theoretical support for the n^{-4} equilibrium range was provided by Zakharov and Filonenko (32).

In analogy to the JONSWAP Spectrum, Donelan, et. al (4a) proposed a continuous wave spectrum which yields to the n^{-4} spectrum in the equilibrium range,

$$\phi(n) = \alpha_d g^2 n^{-4} n_o^{-1} \exp\left[- \left(\frac{n_o}{n}\right)^4 \right] \delta^r \qquad (6)$$

where α_d is a non-dimensional numerical coefficient. In a recent paper, Battjes, et. al (1a) reanalyzed the JONSWAP data and concluded that the n^{-4} spectrum may fit the data as well as or even better than the n^{-5} spectrum.

For the present study, the wave spectrum is examined by using similarity analysis. An empirical equation was provided to approximate the wave spectrum in the energy-containing range. The wave spectrum behavior in the equlibrium range was analyzed and the slope measurements were used to determine which of the n^{-5} or n^{-4} spectrum is preferrable.

Similarity Wave Spectrum

By definition, the integration of the wave frequency spectrum, $\phi(n)$, over the whole frequency range between zero and ∞ should be equal to $\overline{\eta^2}$, i.e.,

$$\int_0^\infty \phi(n)\, dn = \overline{\eta^2}. \qquad (7)$$

where $\overline{\eta^2}$ is the mean square of the vertical displacement from the mean water surface. Rewriting Equation (7) in a non-dimensional form

$$\int_0^\infty \frac{n_o \phi(n)}{\overline{\eta^2}}\, d\left(\frac{n}{n_o}\right) = 1 \qquad (8)$$

would provide an integral constraint on the function of $\phi(n)\, n_o/\overline{\eta^2}$. Mitsuyasu (14) presented similarity frequency spectra by plotting $\phi(n)\, n_o/\overline{\eta^2}$ vs. n/n_o and showed that his laboratory data had different shape of similarity spectrum from his Hakata Bay data.

Equation (7) may be rewritten in another non-dimensional form

$$\int_0^\infty \frac{\phi(n)}{\phi(n_o)}\, d\left(\frac{n}{n_o}\right) = \frac{\overline{\eta^2}}{n_o\, \phi(n_o)} \qquad (9)$$

As shown by Burling (1) and Mitsuyasu (14), the nondimensional parameter $\overline{\eta^2}/n_o\, \phi(n_o)$ can be approximated by a numerical constant, and, thus, plots of $\phi(n)/\phi(n_o)$ vs. n/n_o would present another form of similarity frequency spectrum. Donelan, et. al (1985) presented both their laboratory and field data by plotting $\phi(n)/\phi(n_o)$ vs. n/n_o, but the data cannot be collapsed into a single similarity shape.

These two forms of similarity frequency spectrum presented above have the scaling factors, including the wave characteristics, such as ϕ (n_o), n_o, and $\overline{\eta^2}$, while the wind speed, which is responsible for generating wind waves, is not explicitly included. From the point of view of predicting wave spectrum, these similarity spectrum forms may not be readily applicable. It is therefore the intention of this paper to obtain a similarity frequency spectrum that will be readily applicable in predicting wave spectrum.

In a recent paper to analyze the wind wave momentum equation

$$\rho_w g \frac{d}{dt} \left(\frac{\overline{\eta^2}}{C_o}\right) = \tau_w \tag{10}$$

Lin (11) proposed a closure approximation for the wind-wave momentum:

> The wind-wave momentum per unit area per unit weight of water, $\overline{\eta^2}/C_o$, is characterized by the wind frictional velocity u_*, and the dominant wave frequency n_o.

Here, τ_w is the effective wind wave drag and ρ_w is the density of the water. By virtue of dimensional reasoning, he derived an empirical equation

$$\frac{\overline{\eta^2}}{C_o} = A_1 \frac{u_*}{n_o^2} \tag{11}$$

where A_1 is a nondimensional coefficient, C_o is the phase speed of the dominant wave, u_* is the frictional velocity of the wind defined as $u_* = \sqrt{C_d}\ U_{10}$, C_d is the drag coefficient, U_{10} in m/sec is the wind speed at 10m above the water surface. For calculation of C_d, the empirical equations by Wu (30) were used,

$$C_d = 0.0026 \text{ for } U_{10} > 15 \text{ m/sec}$$

$$C_d = 0.0005\sqrt{U_{10}} \text{ for } 1 < U_{10} < 15 \text{ m/sec}. \tag{12}$$

Because of the importance of Equation (11) in supporting the present paper, experimental data used to verify Equation (11) are reproduced in Figure 1. These experimental data were obtained under a wide range of wind and wave conditions and in different seas around the world. The nondimensional coefficient A_1 was determined to be 0.044 for wind waves in deep waters. It is expected that the numerical value of A_1 could vary with the water depth and the current, and that it would depend on whether the wind wave field is in the growing or decaying stage. Equation (11) with $A_1 = 0.044$ may be converted to

$$\varepsilon = 1.8 \times 10^{-4} \sqrt{C_d}\ \nu^{-3} \tag{11a}$$

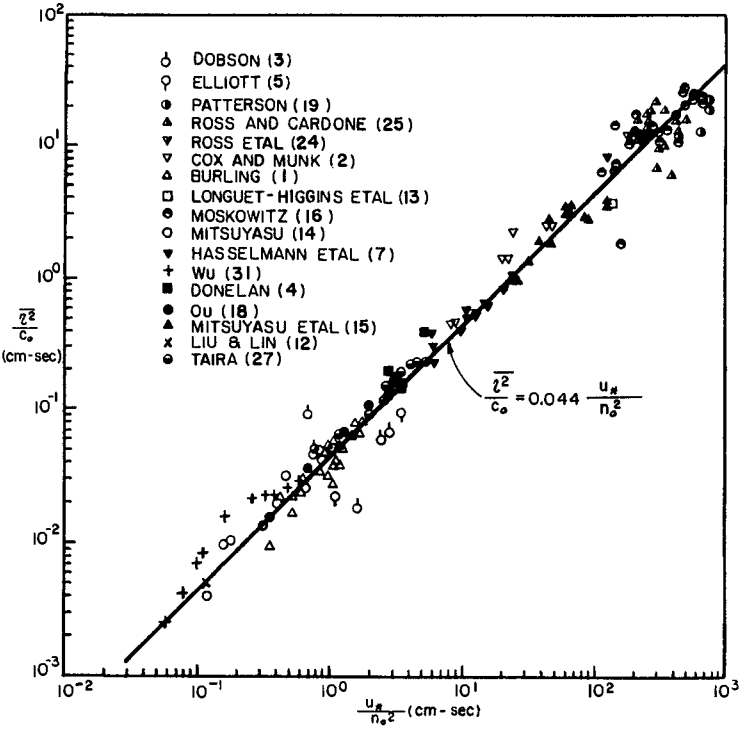

FIGURE 1 Wind - Wave Momentum Per Unit Area Per Unit Weight, $\overline{\zeta^2}/c_o$ Vs u_*/n_o^2

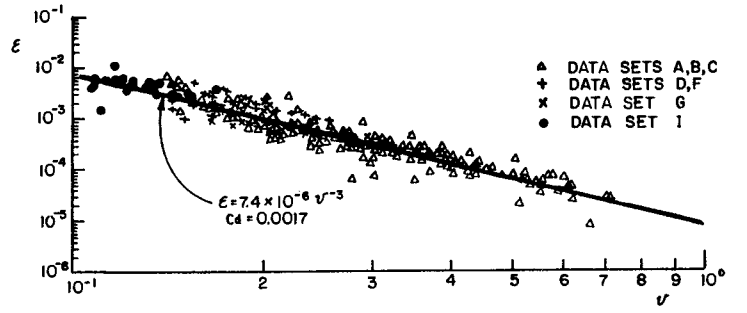

FIGURE 2 Variation of ε With ν for Wind Waves. Data Available From Hasselmann, Etal (7) and Van Müller (17)

where $\varepsilon = g^2 \overline{\eta^2}/U_{10}^4$ and $\nu = n_o U_{10}/(2\pi g)$. In Figure 2, data available from Hasselmann, et al. (7) and Von Müller (17) are replotted. A solid line representing Equation (11a) with $C_d = 0.0017$ for $U_{10} = 12$ m/sec fit the data very well.

Using Equation (11), Equation (7) is rewritten as

$$\int_0^\infty \frac{n_o^3 \phi(n)}{u_* C_o} \, d\left(\frac{n}{n_o}\right) = \frac{\overline{\eta^2}\, n_o^2}{u_* C_o} = A_1 \tag{13}$$

For wind waves in deep waters, the scaling factor of the frequency spectrum expressed in Equation (13) becomes $u_* g/n_o^4$ which is consistent with that used by Toba (29).

In Figure 3, we plot $n_o^3 \phi(n)/u_* C_o$ vs. n/n_o for wind wave data obtained in the laboratory wind-wave tanks by Mitsuyasu (14), by Toba (29), by Ou (18), and by Liu and Lin (12), and in the field by Burling (1) and Mitsuyasu (14). In Figure 4, several spectral measurements of the fully developed wind waves in open ocean conducted by Pierson (22), by Longuet-Higgins, et al. (13), by Ross and Cardone (25), and by Mitsuyasu, et al (15) are also presented in non-dimensional form as $n_o^3 \phi(n)/u_* C_o$ vs. n/n_o.

Energy-Containing Range

The energy-containing range may be defined as the frequency range in which the energy contained would represent the majority, say 95 percent, of the total wave energy. As shown in Figures 3 and 4, the slope of the rear face of the wave spectrum in the energy containing range, expressed as r in the power law: $\phi(n) \sim n^{-r}$, has a value as high as 10 for the laboratory data and it decreases as $n_o u_*/g$ decreases. To obtain the variation of the r values with $n_o u_*/g$, the experimental data plotted in Figures 3 and 4 together with additional spectral data available from Burling (1) and Mitsuyas (14) were used. The data points shown in Figure 5 may be fitted approximately by a power law,

$$r = 9.1 \left(\frac{n_o u_*}{g}\right)^{1/4} \quad \text{for } 0.017 < \frac{n_o u_*}{g} < 2.1 \tag{14}$$

The decrease of the rear face slope of the spectrum with the sea state may be attributed to the enhancement of the wave breaking process as the value of $n_o u_*/g$ decreases.

To reflect the change of the spectral shape with the sea state, an empirical wave spectrum was derived as

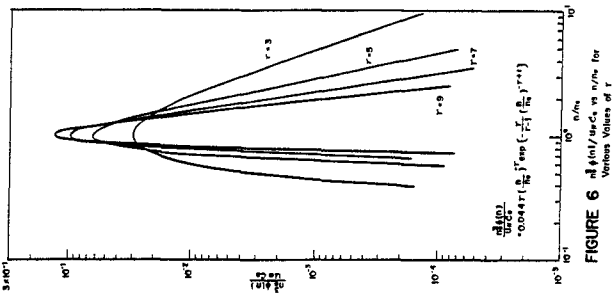

FIGURE 6 $n^3\phi(n)/u_*c_o$ vs n/n_o for Various Values of γ

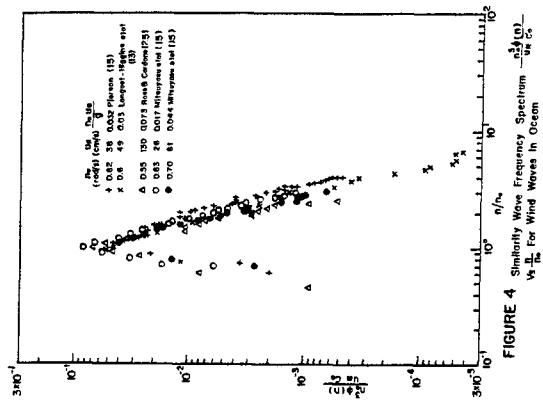

FIGURE 4 Similarity Wave Frequency Spectrum $\frac{n^3\phi(n)}{u_* c_o}$ vs $\frac{n}{n_o}$ For Wind Waves In Ocean

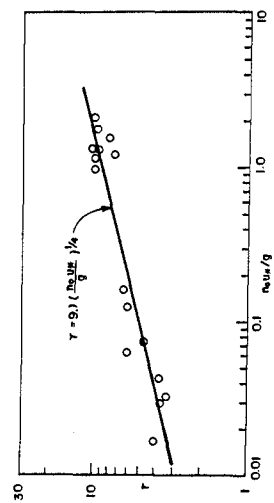

FIGURE 5 The Slope of the Rear Face of the Frequency Spectrum, γ vs $n_o u_*/g$

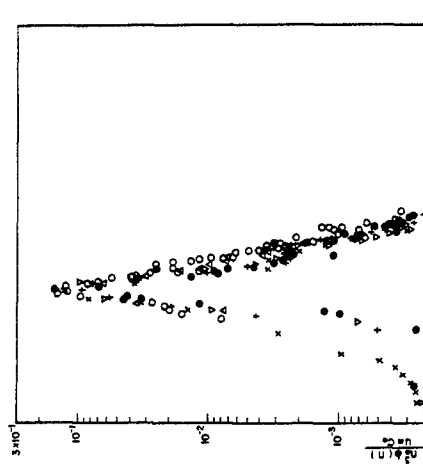

FIGURE 3 Similarity Wave Frequency Spectrum $\frac{n^3\phi(n)}{u_* c_o}$ vs $\frac{n}{n_o}$ For Fetch-Limited Wind Waves

$$\frac{n_o^3 \phi(n)}{u_* C_o} = A_1 \, r\left(\frac{n}{n_o}\right)^{-r} \exp\left[-\frac{r}{r-1}\left(\frac{n}{n_o}\right)^{-r+1}\right] \tag{15}$$

Equation (15) can readily be integrated to satisfy Equation (13), and it also satisfies the condition that the spectrum peaks at $n = n_o$. The Pierson-Moskowitz spectrum is a special case of Equation (15) when $r = 5$. Another important feature of Equation (15) is that when the value of r increases with $n_o u_*/g$ according to Equation (14), the spectral peak increases. This feature is apparently consistent with the experimental data presented in Figures 3 and 4.

To illustrate the variation of the spectral shape with r, Equation (15) is presented in Figure 6 with $A_1 = 0.044$. Also we plot $\phi(n)/\phi(n_o)$ vs n/n_o in Figure 7 as

$$\frac{\phi(n)}{\phi(n_o)} = \left(\frac{n}{n_o}\right)^{-r} \exp\left\{-\frac{r}{r-1}\left[\left(\frac{n}{n_o}\right)^{-r+1} - 1\right]\right\}. \tag{16}$$

The normalization of $\phi(n)$ with respect to $\phi(n_o)$ further accentuates the sharpening of the spectral shape when the value of r increases. In Figure 8, the analytical solutions expressed in Equation (15) for r = 10, 5 and 4 are presented for comparison with the experimental data obtained in the laboratory and in the field. The comparison is fairly well.

Equilibrium Range

In the equilibrium range, the wave frequency spectrum, according to Phillip's concept, is saturated and governed by the gravitational acceleration. By fitting the experimental data presented in Figures 3 and 4 with the n^{-5} spectrum, one may find out that the value of ß in Equation (1) is not a universal constant. On the other hand, one may also estimate the value of α as expressed in Equation (5) by fitting the experimental data with the n^{-4} spectrum. In Figure 9, the values of $ß(n_o u_*/g)^{-1}$ and α are plotted against $n_o u_*/g$. Two solid lines are drawn to approximate the experimental data as

$$ß = 0.08 \left(\frac{n_o u_*}{g}\right)^{3/4} \tag{17}$$

$$\alpha = 0.027 \left(\frac{n_o u_*}{g}\right)^{-1/3} \tag{18}$$

Since the spectral measurements of wave variances could not accurately settle the difference between n^{-4} and n^{-5} in the equilibrium range, research effort was directed to analyzing the spectral

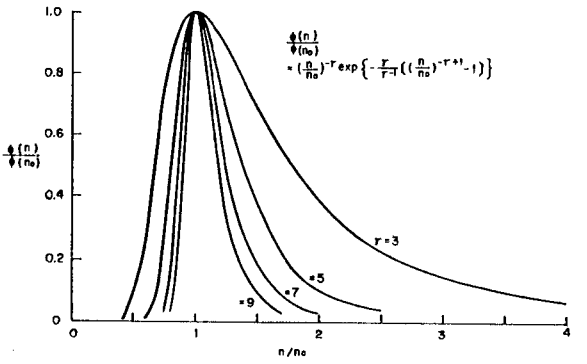

FIGURE 7 $\phi(n)/\phi(n_o)$ vs n/n_o for Various Values of r

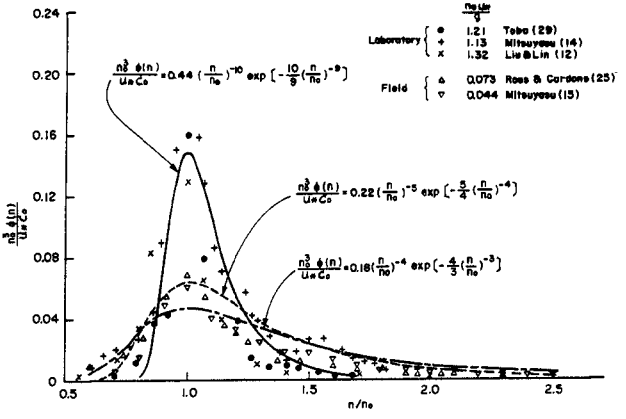

FIGURE 8 Comparsion of Analytical Solution Expressed in Equation (15) for r = 10, 5, and 4, and Experimental Data

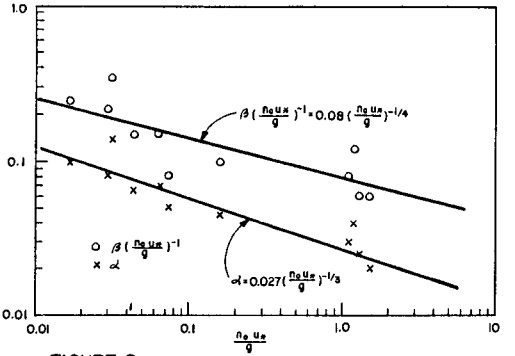

FIGURE 9 Variation of β and α With $n_o u_\pi/g$

measurements of wave slopes. Using the dispersion relation $n^2 = gk$ for gravity waves and $\phi(n)dn = \chi(k)kdk$, the wave-number spectrum $\chi(k)$ corresponding to Equations (1) and (5) are derived respectively as follows:

a) Phillips spectrum

$$\chi(k) = \frac{\beta}{2}k^{-4} \tag{19}$$

b) Toba spectrum

$$\chi(k) = \frac{\alpha}{2} u_* g^{-1/2} k^{-7/2} . \tag{20}$$

Hence, the wave slope frequency spectrum $\phi_s(n)$ in correspondence to Equations (19) and (20) are derived below:

a) Phillips spectrum

$$\phi_s(n) = \beta n^{-1} \tag{21}$$

b) Toba spectrum

$$\phi_s(n) = \alpha\frac{u_*}{g} . \tag{22}$$

Equation (22) suggests that, in the equilibrium range, the Toba spectrum would have a constant value, but this result is not supported by the limited data of wave slope spectra measured by Cox (2a) and by Long and Huang (12a).

Further testing may be made by comparing the mean square wave slope measurements and the analytical results based on Equations (19) and (20). According to Phillips (21) the mean square wave slope $\overline{s^2}$ of wind waves may be approximated by

$$\overline{s^2} = \int_{k_o}^{k_\nu} k^2 \chi(k)\, kdk \tag{23}$$

Here k_ν is the cut-off wave number, representing highest wave number of the gravity wave that could be excited by the wind. Hence, the mean square wave slope may be approximated by

$$\overline{s^2} = \frac{\beta}{2} \ln \frac{k_\nu}{k_o} \tag{24}$$

if Equations (19) and (23) are used, or by

$$\overline{s^2} = \alpha \frac{n_o u_*}{g} \left(\sqrt{\frac{k_\nu}{k_o}} - 1\right) \tag{25}$$

if Equations (20) and (23) are used.

Cox and Munk (2) conducted wave slope measurements of the sea surface covered with an artificial slick, and thus, the wave slope measurements were contributed from the gravity waves but not from the capillary waves. Since the measurements showed that wave components shorter than 30 cm were almost entirely absent (Phillips, (21)) k_ν may be approximated by $2\pi/30$ cm^{-1}. Longuet-Higgins, et al. (13) measured the wave slopes of wind waves in the open ocean. Since their measurements were filtered at 4 rad/sec, the cut-off wave number may be estimated using the dispersion relation as $k_\nu = 4^2/g$. In Figure 10, both sets of wave slope measurements are presented and compared with Equation (24) having ß approximated by Equation (17). These data are replotted in Figure 11 and compared with Equation (25) having α approximated by Equation (18). The limited wave slope measurements apparently favor Equation (24) or Phillips spectrum expressed in Equation (1) rather than Equation (25) or Toba spectrum expressed in Equation (5).

The fair agreement between the wave slope measurements and the prediction of the wave slope as expressed in Equation (24) may suggest that the remote sensing $\overline{s^2}$ could lead to estimating the wind field, u_* provided that the dominant wave frequency n_o were measured independently.

Prediction of Wave Spectrum

We have derived a general wave spectrum for the energy-containing range as expressed in Equation (15), in which the spectral density, $\phi(n)$, is scaled by $u_* C_o/n_o^3$, the wave frequency, n by n_o, and the non-dimensional coefficient r is related to $n_o u_*/g$ by Equation (14). We also determined that in the equilibrium range, the non-dimensional coefficient ß expressed in the Phillips spectrum is indeed a function of $n_o u_*/g$. Thus, the prediction of wave spectrum becomes a task of predicting $n_o u_*/g$. Because of interest in predicting $n_o u_*/g$ for fetch-limited wind waves, Lin's paper (15) is further extended for fetch-limited wind waves generated by a non-uniform wind flow.

At limited fetches, the effective wind wave drag, τ_w may be approximated by

$$\tau_w = A_2 \rho_a u_*^2 \tag{26}$$

where A_2 is a non-dimensional numerical coefficient, ρ_a is the density of the air. For a non-uniform wind flow depending on the fetch, F, or the duration, t, according to the power laws

$$u_* = u_{*o} \left(\frac{gF}{u_{*o}^2}\right)^p \tag{27}$$

$$u_* = u_{*o} \left(\frac{gt}{u_{*o}}\right)^q \tag{28}$$

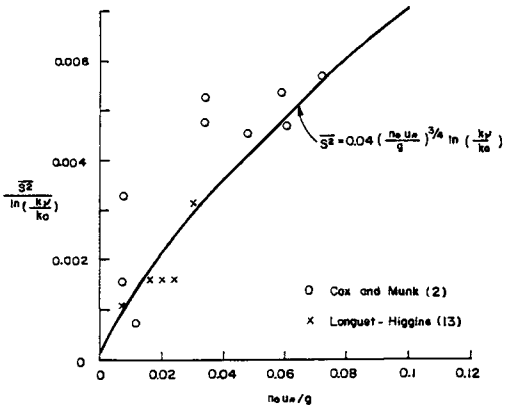

FIGURE 10 Comparsion Between the Analytical Solution Expressed in Equation (24) and Experimental Data

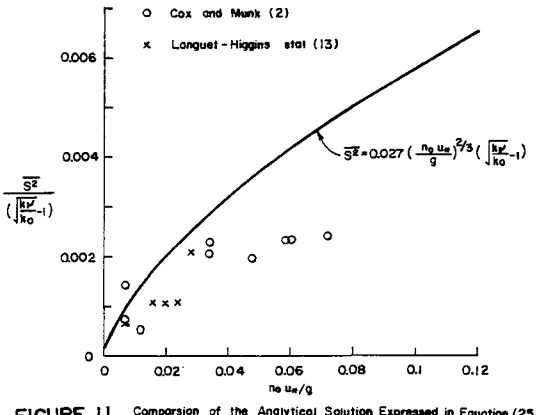

FIGURE 11 Comparsion of the Analytical Solution Expressed in Equation (25) and Experimental Data

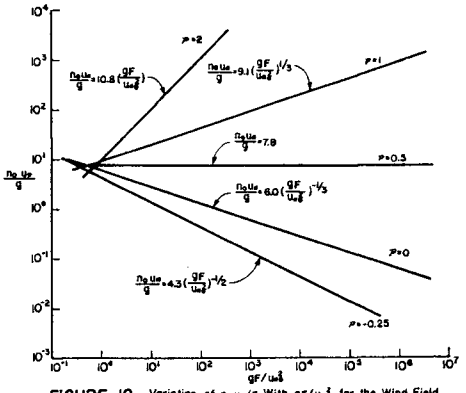

FIGURE 12 Variation of $n_0 u_0/g$ With gF/u_*^3 for the Wind Field $u_* = u_{e0}\,(gF/u_*^2)^{\frac{1}{2}}$

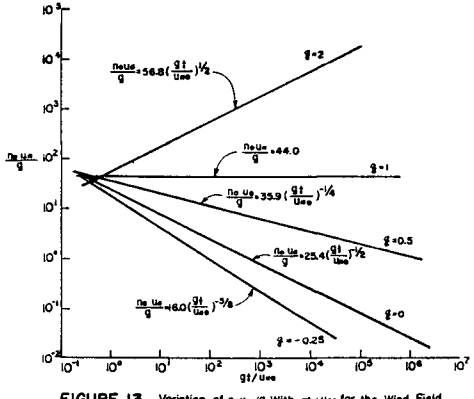

FIGURE 13 Variation of $n_0 u_0/g$ With gt/u_{e0} for the Wind Field $u_* = u_{e0}(gt/u_{e0})^{\beta}$

where u_{*o} is a reference wind speed, Equations (10) and (26) can be solved analytically and have the special solutions,

$$\frac{n_o u_*}{g} = \left[\frac{6\,\rho_a A_2}{(2+5p)\rho_w A_1}\right]^{-1/3} \left(\frac{gF}{u_{*o}^2}\right)^{-(1-2p)/3} \tag{29}$$

$$\frac{n_o u_*}{g} = \left[\frac{\rho_a A_2}{(1+2q)\rho_w A_1}\right]^{-1/2} \left(\frac{gt}{u_{*o}^2}\right)^{-(1-q)/2} \tag{30}$$

for $p > -2/5$ and $q > -1/2$. When $p \leq -2/5$ or $q \leq -1/2$, the wind wave solution is not meaningful as $n_o u_*/g$ becomes zero or imaginary. Figures 12 and 13 present $n_o u_*/g$ vs. gF/u_{*o}^2 and gt/u_{*o} respectively for a family of the parameters p and q when $A_1 = 0.044$, $A_2 = 0.057$ and $\rho_a/\rho_w = 0.0012$.

Conclusions and Recommendations

An empirical wave spectrum in the energy-containing range for a general sea state was derived as expressed in Equation (15). The Pierson and Moskowitz spectrum, as presented in Equation (2), is a special case of Equation (15). The scaling factor of the wave frequency spectrum is $u_* C_o/n_o^3$, while the scaling factor of the wave frequency n is the dominant wave frequency n_o. The non-dimensional numerical coefficient r is the only free parameter in the empirical equation and it can be estimated from the slope of the rear face of spectrum and approximated by the empirical formula expressed in Equation (14) for $n_o u_*/g$ ranging from 0.017 to 2.1.

In the equilibrium range, the saturated wave frequency spectrum is better approximated by the Phillips spectrum expressed in Equation (1) rather than the Toba spectrum expressed in Equation (5). One must point out that the wave slope data used to test the Phillips spectrum and the Toba spectrum are available from only three sources, namely Cox (2a), Cox and Munk (2), and Longuet-Higgins, et al (13). In order to establish the statistical significance of the present conclusion, additional data are required. It is recommended to perform spectral measurements of both wave variances and wave slope simultaneously at the same physical location. The wave slope can readily be measured using remote sensing technique, while the laser displacement gauge (LDG) developed by Liu and Lin (12) may be modified to measure the wave height remotely in the field.

CHAPTER 37

WAVE TRANSFORMATION AND MEAN SEA LEVEL VARIATION

SHI-CHUAN LIN* JENG-SHIN HWANG*

ABSTRACT

For the practical application in coastal engineering, the universal model of water wave, momentum conservation and energy conservation equation with considering of energy loss due to bottom friction and wave breaking is adopted in this paper to evaluate the wave transformation on general slope, which including wave shoaling, breaking and attenuation after breaking as well as wave set-up and set-down during the waves advancing toward the coast.

In comparison with the results of theoretical approaches as well as experimental data accomplished by the traditional method, very good coincidence is obtained besides the mean sea level variation.

INTRODUCTION

The wave transformation and the mean sea level variation for waves propagating from deep sea toward the shore are interesting topics for coastal engineering. Conventionally, the process is divided into three parts: (1) the shoaling of the wave from deep sea till near breaking point, (2) the breaking index and (3) the wave decay and the wave set-up/set-down inside the surf zone. These problems have to be treated separately and different wave theories are to be applied in each zones because of the validity of wave theories in various water depth.

---

* Lecturer, Department of Hydraulic and Ocean Engineering, National Cheng Kung University, Tainan, Taiwan 70101, Republic of China

In the present paper, the so-called universal model of water wave derived by Chen et al. (1982) is adopted and further developed. Coupling with conservation equations of momentum and energy flux and taking bottom friction and energy dissipation due to wave breaking into consideration, the propagation characteristics of a perpendicular incident wave train on a general slope has been investigated continuously from deep sea till the shoreline. This includes the shoaling process, wave breaking, wave decay inside the surf zone and the mean sea level variation, i.e. the forementioned problems can be solved in one model.

In the model, the experimental results of the bottom friction coefficient on smooth bottom by Riedel et al. (1972) is used. The energy dissipation rate in breaking process is estimated from that in a bore of corresponding height. The limiting height of breaking from Goda (1970) is adopted for the breaker control to determine the breaking index. The results are compared with both experimental data and analytical values from other authors.

THEORETICAL ANALYSIS

1. UNIVERSAL MODEL OF WATER WAVE

For the mathematical model of water wave in uniform depth, Chen et al. (1982) proposed a new model derived from stream function, its first order exact solution in steady state are

$$\psi(x,y) = -cy + c\eta_c \frac{\sinh k(d+y)}{\sinh k(d+\eta_c)} \cos kx \qquad \cdots\cdots(1)$$

$$\eta(x) = \eta_c \frac{\sinh k(d+\eta)}{\sinh k(d+\eta_c)} \cos kx \qquad \cdots\cdots(2)$$

$$c^2 = \frac{g}{k} \tanh kd \Big/ \left[1 - k^2 \eta_c^2 \frac{\sinh^2 kd}{\sinh^2 k(d+\eta_c)} \right] \qquad \cdots\cdots(3)$$

$$H = \eta_c \left[1 + \cosh kH - \coth k(d+\eta_c) \sinh kH \right] \qquad \cdots\cdots(4)$$

where ψ is stream function, c wave celerity, $k=2\pi/L$ wave number, d water depth, η wave elevation, η_c elevation of

wave crest, H wave height.

The model is proved mathematically to be used in any case of d/L, which withdraw the restriction of application between other theories, it is to be nominated "universal model", and it is to be adopted in the paper for the wave transmission evaluation.

Dynamic properties in the wave field are definitively derived as

(1) mean kinetic energy

$$K=\frac{1}{2}\rho\overline{\int_{-d}^{\eta}\{(u+c)^2+v^2\}dy}$$

$$=\frac{1}{2}\frac{\rho c^2\eta_c^2 k}{\sinh^2 k(d+\eta_c)}\left\{\frac{\sinh 2kd}{4}+\frac{A}{B}\left\{\left(\frac{1}{B^2k^2}+\frac{1}{2}\right)\right.\right.$$

$$\left.\left.\cdot(\cosh 2kd-1)\right)\left(\frac{1}{\sqrt{1-B^2k^2}}-1\right)-\frac{1}{2}\right\}\right\} \quad \cdots\cdots(5)$$

(2) mean potential energy

$$P=\frac{1}{2}\rho g\overline{\int_{o}^{L}(\eta-\overline{\eta})^2dx}=\frac{1}{2}\rho g(\overline{\eta^2}-\overline{\eta}^2)$$

$$=\frac{1}{2}\rho g\frac{A^2}{B^2k^2}\left(\frac{B^2k^2}{(1-B^2k^2)^{3/2}}-\frac{1}{1-B^2k^2}+\frac{1}{\sqrt{1-B^2k^2}}\right) \quad \cdots\cdots(6)$$

(3) mean momentum

$$I=\rho\overline{\int_{-d}^{\eta}(u+c)dy}$$

$$=\frac{\rho cA}{Bk}\left(\frac{1}{\sqrt{1-B^2k^2}}-1\right) \quad \cdots\cdots(7)$$

(4) mean energy flux

$$F=\overline{\int_{-d}^{\eta}\left\{p+\frac{\rho}{2}\{(u+c)^2+v^2\}+\rho gy\right\}(u+c)dy}$$

$$=(3K-2P)c+\frac{1}{2}\overline{(u_b+c)^2}\{I+\rho(d+\overline{\eta})c\}+g\overline{\eta}I \quad \cdots\cdots(8)$$

(5) radiation stress

$$S_{xx} = \overline{\int_{-d}^{\eta} \{ p + \rho (u + c)^2 \} dy} - \int_{-d}^{\overline{\eta}} p_0 dy$$
$$= 4K - 3P + \rho \overline{(u_b + c)^2} (d + \overline{\eta}) \quad \cdots\cdots(9)$$

In above equations, "-" represents average over one wave length, $u_b' = u_b + c$ horizontal velocity at bottom, and

$$A = \eta_c \frac{\sinh kd}{\sinh k (d + \eta_c)} \qquad B = \eta_c \frac{\cosh kd}{\sinh k (d + \eta_c)}$$

$$\overline{(u_b + c)^2} = \frac{c^2 \eta_c^2 k^2}{2 \sinh^2 k (d + \eta_c)} \quad , \quad \overline{\eta} = \frac{A}{Bk} \left(\frac{1}{\sqrt{1 - B^2 k^2}} - 1 \right)$$

2. CONSERVATIVE EQUATIONS OF MOMENTUM AND OF ENERGY

By omitting the rate of change in time, effects of wind at surface and currents, conservative equations of momentum and of energy in two dimension show respectively

$$\frac{dS_{xx}}{dx} = -\rho g (d + \overline{\zeta}) \frac{d\overline{\zeta}}{dx} \quad \cdots\cdots(10)$$

$$\frac{dF}{dx} = \overline{P_f} + \overline{P_b} \quad \cdots\cdots(11)$$

where S_{xx} is radiation stress, $\overline{\zeta}$ set-up/down of mean water level, F energy flux, $\overline{P_f}$ energy dissipation rate due to bottom friction per unit area, $\overline{P_b}$ energy dissipation rate due to wave breaking per unit area.

3. ENERGY DISSIPATION

In non-breaking zone, the energy dissipation are dominated by bottom friction. However, mixing of air and inducing turbulence become dominant factor for energy dissipation within breaking zone of some distance. After some distance of breaking, the more shallow the depth is, the more impor-

tant is the bottom friction to energy dissipation.

P_f shows energy dissipation due to bottom friction per unit area per unit time presented by

$$P_f = \tau_{bx} \cdot u_b'$$

and $\tau_{bx}=\frac{1}{2}\rho f_w u_b' | u_b' |$ is shear stress at bottom, f_w bottom friction coefficient.

Averaging over one wave length for P_f , we get

$$\overline{P_f} = \frac{1}{L}\int_o^L \frac{1}{2}\rho f_w u_b'^2 \cdot | u_b' | dx$$

$$= \frac{2\rho f_w c^3 \eta_c^3 k^3}{3\pi \sinh^3 k(d+\eta_c)} \qquad \cdots\cdots(12)$$

For the bottom friction coefficient f_w , regression formula are worked out from the experimental data of Riedel et al. (1972) for smooth bottom. The functional form are

$$\left.\begin{aligned} f_w &= 1.993196\,(Re)^{-0.600099} && 10^2 \le Re \le 10^4 \\ \ell n\, f_w &= 74.8895 - 29.6769\,(\ell nRe) + 4.33474\,(\ell nRe)^2 \\ &\quad - 0.287814\,(\ell nRe)^3 + 0.00718364\,(\ell nRe)^4 \\ &&& 10^4 < Re \le 3.393\times 10^5 \\ \ell n\, f_w &= -3005.95 + 842.946\,(\ell nRe) - 88.6773\,(\ell nRe)^2 \\ &\quad + 4.14089\,(\ell nRe)^3 - 0.0724355\,(\ell nRe)^4 \\ &&& 3.393\times 10^5 < Re \le 3.501\times 10^6 \end{aligned}\right\} \cdots\cdots(13)$$

where R_e is Reynolds number.

For spilling breaker, its structure and energy dissipation are similar to bore, which has a strong turbulence mixed with air only near crest. Le Méhauté (1962) suggested that the energy dissipation in spilling breaker can be estimated by a bore of the same height. The average energy dissipation of breakers of unit area in unit time, $\overline{P}_b$, shows

$$\overline{P_b} = \frac{1}{4}\rho g \frac{(h_2 - h_1)^3}{h_1 h_2} Q \simeq \frac{1}{4}\rho g \frac{(\alpha H)^3}{d^2} Q \quad \cdots\cdots (14)$$

where h_1, h_2 are depths before and after the bore respectively, α breaker coefficient, Q discharge in bore per unit area.

Hwang and Divoky (1970) suggested that Q in water wave can be calculated by linear periodic bore Q=cd/L, and we can get

$$\overline{P_b} = \frac{\rho g c (\alpha H)^3}{4 L d} \quad \cdots\cdots (15)$$

NUMERICAL MODEL

In Fig.1, waves propagate from section I to section II with constant wave period T. For L=cT, we get

$$\frac{L_1}{c_1} = \frac{L_2}{c_2} \quad \cdots\cdots (16)$$

Conservative equations of momentum and of energy in finite difference form are

$$\overline{\zeta_2} = \overline{\zeta_1} - \frac{1}{\rho g (d_1 + \overline{\zeta_1})} [(S_{xx})_2 - (S_{xx})_1] \quad \cdots\cdots (17)$$

$$F_2 = F_1 - (\overline{P_f})_1 \Delta x - (\overline{P_b})_1 \Delta x \quad \cdots\cdots (18)$$

and P_b=0 for waves before breaking.

If H_1, L_1, d_1 are known in section I, we can calculate and c_1 from equation (3) and (4), and calculate F_1, $(S_{xx})_1$, $(\overline{P_f})_1$ and $(\overline{P_b})_1$ by solving equations (5)-(9), (12) and (15). Then we can get c_2, η_{c2}, L_2, H_2, $\overline{\zeta_2}$ on section II of given depth d_2 by solving equations (3), (4) and (16)-(18). Newton interaction is applied in implicit function calculation.

Critical condition for limiting waves is controlled by Goda's formula (1970), shows as follow

RESULT

The present results are discussed in four parts, i.e. shoaling process, breaking index, wave decay within the surf zone and the mean sea level variation.

1. SHOALING

The change of wave height from deep sea to breaking point for five wave period T=4,6,8,10 and 12 sec. on five various bottom slope S=1/20,1/50,1/80,1/200 and 1/600 are examined by calculation. Fig.2 shows one of the shoaling diagram.

Table 1 and 2 show the shoaling coefficient $K_s=H/H_o$ between various bottom slope and between various wave period, T. K_s decreases as the bottom slope decreases. However, the differences in K_s for various bottom slope are small and it increases as the relative water depth d/L_o decreases. For given bottom slope, the differences in K_s for various wave periods are under 0.5% and can be neglected in the case of considering the effect of bottom friction.

The comparison of the present results to the experimental data from Hwung (1975) is presented in Fig. 3, it shows the present results are more close to the experimental data.

2. BREAKING INDEX

In calculating of the breaking index, H_b/H_o, d_b/H_o and H_b/L_b, the breaking criterion defined by Goda is adopted. Fig.4 - Fig.8 show the comparison of the present results to the experimental data from other authors. The tendency is well acceptable.

For a given deep water steepness H_o/L_o, the breaking index H_b/H_o and H_b/L_b decreases as the bottom slope decreases, whereas the tendency of d_b/H_o reverses. For a given bottom slope, the difference in breaking index between different

wave periods do not exceed 3.5%, that means the influence of wave period to breaking index is considerable small.

3. WAVE DECAY IN SURF ZONE

Fig.9 and Fig.10 show the comparison of the computational results of the relative wave height H/H_b in surf zone to the experimental data from Horikawa & Kuo (1966) and from Bowen (1968). It can be seen in the Fig.9 that there exists a residual wave height at the stillwater shoreline ($d/d_b=0$) from the computational curve. This is due to the feature of the present model, that the wave set-up can be determined simultaneously by calculating the wave height.

4. MEAN SEA LEVEL VARIATION

Fig.11 and Fig.12 show the comparison of the computational wave set-up/set-down to the experimental results from Bowen (1968) and from Sasaki & Saeki (1974). Seaward of the breaker, the experimental wave set-down can be good approached by present model, but shoreward of the breaker, there exists some difference between measured data and predicted value. However, the tendency of the predicted water level in surf zone coincides with the measured data.

CONCLUSIONS

1. The influences of bottom slope and wave period on the shoaling coefficient are small.

2. The breaking index H_b/H_o and H_b/L_b are positive related to bottom slope, but d_b/H_o is negative related. The comparison of the numerical results to the experimental data from other authors is well acceptable.

3. By proper choice of breaking coefficient α, the numerical results for wave decay in surf zone is good agreement with experimental data.

4. For the mean sea level variation, the tendency of the numerical results agrees with that from experimental data except for that near breaking point.

CHAPTER 38

WAVE GROUPINESS AS A SOURCE OF NEARSHORE LONG WAVES

Jeffrey H. List

Virginia Institute of Marine Science
Gloucester Point, Virginia 23062

Abstract

Data from a low energy swell-dominated surf zone are examined for indications that observed low frequency motions are simply group-forced bounded long waves. Time series of wave amplitude are compared to filtered long wave records through cross-spectral and cross-correlation analysis. These methods are found to have limited usefulness until long waves are separated into seaward and shoreward components. Then a clear picture of a rapidly shoaling bounded long wave emerges, with a minimum of nearly one fourth of the long wave amplitude being explainable by this type of motion close to shore. Through the zone in which waves were breaking, and incident wave amplitude variability decreased by 50%, the contribution from the bounded long wave continued to increase at a rate much greater than a simple shoaling effect. Also present are clear signs that this amplified bounded long wave is reflected from a position close to the shoreline, and is thus released from wave groups as a free, offshore-progressive wave.

Introduction

Numerous recent observations have shown that waves with periods much longer than the more visually apparent wind waves often dominate the spectrum in the inner surf zone, especially during storms. However, much less clear are the origins of these infragravity motions, though a number of theories and few observations exist. Most relate in some wave to the groupiness of the incident waves. Gallagher (1971) developed a theoretical model in which edge waves could be resonantly generated by obliquely incident wave groups; Bowen and Guza (1978) substantiated this concept in a laboratory experiment. Field observations of Huntley et al. (1981) showed that low mode edge waves can dominate the low frequency motion in the longshore currents and recently Oltman-Shay and Guza (1986) have shown that in some cases as much as 50% of the shoreline runup variance is due to low mode edge waves, the size of which can be predicted from offshore measurements of the wind wave variance and wavenumber-frequency distribution.

Still, much if not most of the cross-shore current variance in the low frequency band cannot be explained in this way and appears to be either high mode edge waves or simply leaky mode standing waves. Symonds et al. (1982) provide a model by which oscillations of this

sort could be generated by long wave forcing at a time-varying breakpoint (produced by wave groupiness). However, as of yet there is no conclusive field evidence to support this model; most conspicuous is the absence of a separate standing wave zone landward of the breakpoint and a frequency dependent offshore progressive wave zone seaward of the breakpoint. Laboratory observations exist but seem conflicting. Kostense (1985) conducted a study in which changes in the wave group characteristics (wave difference frequencies, amplitude ratios, etc.) produced outgoing free waves with varying amplitudes qualitatively in accordance with the model of Symonds et al. However, in the experiment of Mansard and Barthel (1985) there seems to be a complete absence of an outgoing free wave generated at a time-varying breakpoint, although experimental conditions are largely the same except for the use of a Jonswap spectrum instead of bichromatic waves.

An alternate explanation of cross-shore surf beat motion is the direct forcing of long waves by radiation stress gradients in groupy waves. Longuet-Higgins and Stewart (1962,1964) showed that the mean water level, $\overline{\eta}$, is related to the component of radiation stress normal to wave crests, S_{xx}, by

$$\overline{\eta} = - \frac{Sxx}{\rho(gh-Cg^2)} + \text{const.} \qquad (1)$$

where h is the mean water depth, ρ is the density, and C_g is the group velocity. The negative sign indicates, for example, that a group of large waves with high S_{xx} would produce a depression of the mean (averaged over several incident wave periods) sea level. Thus the correlation between wave amplitude and long wave time series should be negative, while the corresponding cross-spectrum should show a 180^0 phase difference. Unfortunately, both the shallow water approximation of equation (1) and the spectral approach of Ottesen Hansen (1978) predict unreasonably large values of $\overline{\eta}$ in very shallow water-exactly where the size of this bounded long wave (BLW) must be known to access its contribution to surf beat motion. Nevertheless, Longuet-Higgins and Stewart found support for their theory in Tucker's (1950) observation of a time-lagged negative correlation between wave groups and long waves at an offshore station. They speculated that group bound long waves are released as free waves when incident waves break, and then are radiated offshore after reflection. A substantial shallow water BLW amplification (landward of the measurement location) could explain Tucker's observation that groups are correlated with long waves only after a time sufficient for round-trip travel to the shoreline, and not with an incoming BLW at zero lag. However, in addition to inadequate theory for the shallow water BLW size, no mechanism has been proposed by which this forced response could be released from wave groups as a free wave.

Following the work of several previous Conference authors (Huntley and Kim, 1985, Guza et al., 1985) this study examines field data in an attempt to provide some guidelines for future theoretical investigations.

Data Collection

An experiment conducted in September, 1985 at the U.S. Army Corps of Engineers Field Research Facility in Duck, North Carolina provided the data for this study. (Please see acknowledgements.) Figure 1d shows the nearshore profile and measurement locations. The morphology was fairly 2-dimensional, although some irregularities existed. All bathymetric observations were collected by the Corps using the CRAB profiling system (see Mason et al., 1985 for description). At each of the 9 measurement locations pressure and bi-axial horizontal currents were sampled synchronously for 40 minutes at 2 Hz. Pressure sensors were of the diaphragm type and flows were measured by Marsh Mcbirney electromagnetic current meters.

Waves consisted of highly grouped swell with a fairly narrow spectral peak near T=12 seconds. The angle of incidence was nearly shore-normal, although wave crests and wave groups were not very continuous alongshore.

Processing

Cross-shore currents are defined as positive onshore in order that long waves in the flows and sea-surface show the same relation with wave groups. Fourier transforms of pressure records were converted to the sea-surface by applying linear theory to each coefficient and then back-transforming to the time domain. Time series of long waves in both the sea-surface (η_L) and cross-shore currents (u_L) were found by bandpassing the data using two low-pass least squares filters (Bloomfield, 1976). An incident/long wave band cutoff was chosen at 0.06 Hz based on offshore spectra, in which it was clear that the incident band energy was confined to higher frequencies. (Changes in the η and u cross-spectrum at this frequency also substantiate this cutoff.) Additionally, energy at very low frequencies (below 0.007 Hz) was removed because certain records contained red "wall climber" type energy that was uncorrelated with other records and tended to lower the association with wave groups. Thus the low frequency time series used here contain energy from 0.007 to 0.06 Hz.

Time series of wave amplitude, A_t, were found by low-pass filtering the modulus of the high-passed, incident band sea-surface time series. In order that this series truly follow the wave amplitude, each point was then divided by $\pi/2$ to compensate for the asymmetry of a sine wave modulus. As the size of the BLW is predicted by equation (1) to be proportional to the square of the incident wave height, an additional amplitude function was calculated as the lowpass-filtered square of the incident band waves.

A groupiness factor was found from the amplitude time series as

$$GF = \frac{\sqrt{2}\sigma_{A_t}}{\bar{A}_t} \qquad (2)$$

where σA_t and A_t are the standard deviation and mean of A_t respectively. This groupiness factor has the advantage of being strictly confined between 0 (pure sine wave) and 1.0 (two beating sine waves), as opposed to factors using an amplitude function derived from the square of the incident wave (for example, see Sand, 1982).

All spectra and Cross-spectra presented here were smoothed to give 34 degrees of freedom, resulting in a 95% CI on zero coherence of approximately 0.41. Correlations between A_t and long waves were found at time lags separated by the sampling interval of 0.5 seconds to give a smooth cross-correlation function. As adjacent point in a wave time series are by no means independent, the 95% CI on zero coherence was found using a reduced number of points, N^*, given by Garret and Toulany (1981) as

$$N^{*-1} = N^{-1} + 2N^{-2} \sum_{j=1}^{N'} (N-j)\, R_{xy}(j) \qquad (3)$$

where N is the original number of points, $R_{xy}(j)$ is the lagged auto-correlation of the product of the two series to be correlated, and N' is the number of lags until R_{xy} experiences a zero-crossing. Cross-correlations presented here generally have a 95% CI on r=0 below 0.15.

Some pressure channels showed a high energy, narrow band peak in the spectra that was judged to be some sort of electronic contamination. Gaps in the results presented below represent data that was not analyzed because of this problem.

Cross-shore Statistics

Figure 1 shows the cross-shore variations in significant wave height, H_s, standard deviation of the amplitude time series, σA_t, and groupiness factor, GF. While H_s does not decrease until station 2, it is evident from σA_t and GF that initial breaking of the largest waves must begin inshore of station 6. The waves groupiness in both the current and sea-surface incident band decreases from around 0.65 offshore, a fairly high value for natural waves, to 0.45 by station 1. More importantly, the wave height variability as measured by the standard deviation in A_t, decreases by a factor of 2 across the instrument array. If the size of the bounded long wave is proportional to variations in the wave height squared, as implied by equation (1), then the BLW size might be expected to be proportional to the square of σA_t, implying a four-fold decrease from station 6 to station 1. As it turns out, this does not seem to be the case.

Cross-spectra

The cross-spectra between A_t and η_L were found as a first step in assessing the degree to which long waves in the nearshore are directly forced by wave groups. Figure 2 shows the most coherent cross-spectrum of any calculated between co-located A_t and η_L. As seen in previous

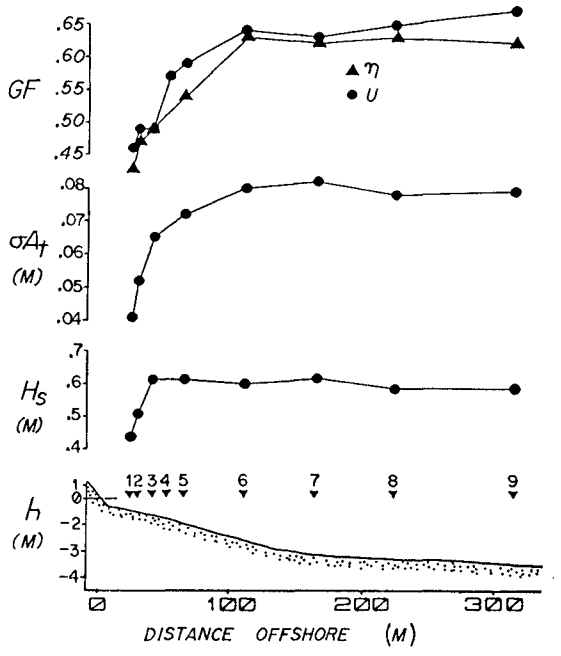

Figure 1 From top: Groupiness factor, standard deviation of amplitude time series, significant wave height (from incident band variance), nearshore profile with instrument stations.

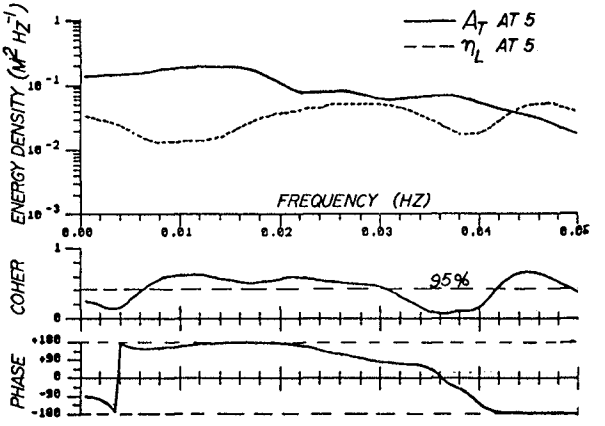

Figure 2 Cross-spectrum between amplitude time series and sea-surface long waves co-located at station 5.

studies (Huntley and Kim, 1985 and others) there is no significant frequency selection in the wave groupiness, precluding the possibility of identifying a groupiness-forced peak in the long waves. While there are some signs of the forced response (phase near 180^0 in bands of significant coherence) the relation is certainly less consistent and strong than presented by Huntley and Kim (1985). Since in addition to the incoming BLW, the nearshore long wave field may well consist of reflected long waves, waves generated at a time-varying breakpoint, and edge waves, it is not surprising Fig. 2 shows an unclear BLW signature. The Huntley and Kim measurements were taken very close to shore on a steep beach where the incoming and reflected waves would be virtually coexisting and other modes of long wave generation (other than the subharmonic) would likely be suppressed. The data presented here seems more representative of an open coast situation with waves breaking offshore and dissipating over a shallow surf zone.

Cross-correlations

In order to differentiate between group-related long wave components traveling shoreward and those either reflected or generated in the surf zone and traveling seaward, cross-correlations were calculated similar to those first presented by Tucker (1950). Figure 3a shows the cross-correlations between co-located A_t and longwaves (in both current and sea-surface) at 8 stations. The bounded long wave response is seen as a negative correlation near zero lag, which is marginally significant at station 9, strengthens to a maximum at station 3 and then decreases and disappears by station 1. That the group structure is forcing longwaves and not visa-versa is supported by a significant degree of correlation between the group structure offshore and inshore up to station 5--in other words the wave groupiness to a large extent is an original feature of the offshore waves through this zone, and is not being created by an interaction of short waves with long wave depth or current modulations. The disappearance of the zero-lag negative correlation landward of station 3 could be due to a decrease in the size of the BLW, but could also be due to this short wave/long wave effect (as has been observed by Abdelrahman and Thornton, 1985) causing a modification in the group structure and masking the ability of the cross-correlation to identify a forced response. To test this idea, the cross-correlations between the amplitude series at station 8 and long waves at 7 stations closer to shore were calculated and are shown in Figure 3b. The forced wave response, now at progressively greater time lags, appears to strengthen all the way to station 1. Solid dots in Figure 3b show the measured group travel time (from A_t cross-correlations), indicating that after waves begin breaking, the forced response tends to lag the wave groups by up to 10 seconds. The question of whether this group-correlated long wave component is still a bounded long wave or now a free wave will be addressed below.

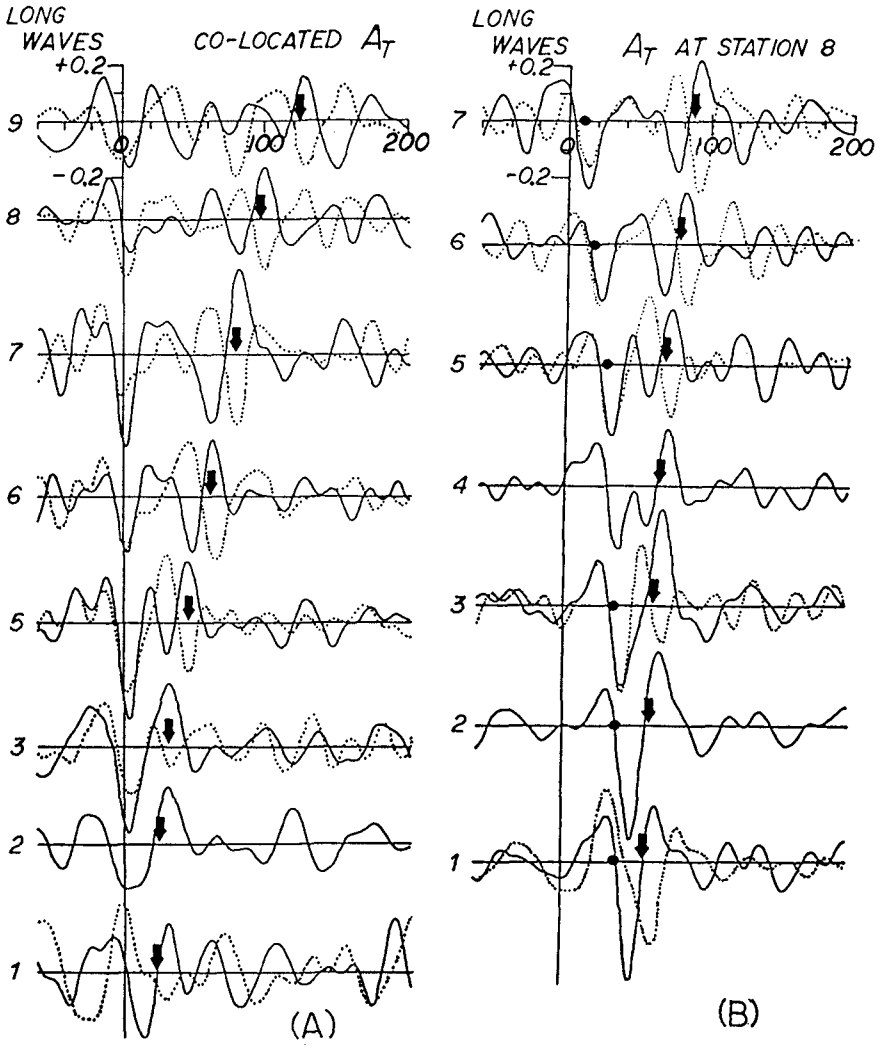

Figure 3 Cross-correlations between long wave (····· sea-surface, —— cross-shore current) and amplitude time series. Horizontal scale is the time lag in seconds, vertical scale is the correlation coefficient. Positive lags indicate a leading group structure. 95% CI on zero correlation is a maximum of 0.15. (A): cross-correlations between co-located amplitude and long waves, (B): cross-correlations between amplitude at station 8 and long waves at 7 stations closer to shore.

Another interesting feature of both Figure 3a and 3b is a series of significant peaks occurring at lags nearly matching the long wave travel time given by

$$T = \int \frac{dx}{\sqrt{gh}} \tag{4}$$

from the point of A_t measurement, to the shore, and back to the point of long wave measurement (marked by solid arrows). The signs of the η_L and u_L correlations are opposite, confirming that this signal represents outgoing wave energy. Since the correlation is negative with η_L and positive with u_L, this signal satisfies the notion that the incoming BLW is released and simply reflected as a free wave, as suggested by Longuet-Higgins and Stewart (1962,1964).

Another sometimes significant signal, appearing mostly beyond the surf zone and having the opposite sign, occurs approximately 20 seconds earlier, corresponding to a point of origin near the outer limit of the breaker zone. (A similar feature is seen in Guza et al., 1985) As it is difficult to predict exactly how a wave generated by a breakpoint forcing model might affect the cross-correlations as calculated here (see Huntley and Kim, 1984), it can only be speculated that correlations at this time lag relate to this model. In a simplistic sense, however, it would seem that since larger waves are predicted to be associated with a higher setup, long waves generated by the model of Symonds et al. (1982) should have a sign of correlation with the wave groupiness structure opposite to that of the BLW (or a recently released long wave of BLW origin). The fact that most of the significant correlations in Figure 3 fit the idea of an incident, released and reflected BLW may indicate that the breakpoint forced waves were of lesser importance during this experiment.

Since the square of the correlation coefficient gives the percent of the variability in one channel that can be predicted by another, the correlations associated with the incoming BLW in Figure 3b could ideally be used to determine the fraction of long wave height attributable to group forcing at each station, resulting in a picture of the cross-shore changes in BLW size. Unfortunately, as shown by Sallenger and Holman (1984), the infragravity variance in η or u can be dependent on the sampling location's position relative to a standing wave structure, as seems to be the case in Figure 4a. Similarly, the correlations at lags for incoming and outgoing waves may merge close to shore, distorting the values in an unpredictable manner. A method of separating the landward and seaward long wave components (Guza et al., 1985) was used to circumvent these problems.

Onshore/Offshore Long Wave Components

After Guza et al. (1985), landward and seaward progressive

long wave components in units of sea surface elevation were found as

$$\eta_L ON = \frac{\eta_L + \sqrt{h/g}\, u_L}{2}$$
$$\eta_L OFF = \frac{\eta_L - \sqrt{h/g}\, u_L}{2} \qquad (5)$$

where η_L and u_L represent each point in the η and u long wave time series and h is the average water depth. The components in units of velocity could be found similarly, but provide no additional information.

Equation (5) cannot be used with many data sets because of a number of restrictions. As noted by Guza et al., long waves must be shore normally oriented. An obliquely angled incident long wave would contaminate the offshore component and an angled outgoing long wave would contaminate the onshore component. Edge wave motions would put spurious energy into both η_L ON and η_L OFF, though probably to equal degrees. Also, long waves are assumed to follow the shallow water, linear dispersion relation, excluding bounded long waves associated with groups not in shallow water or long waves affected by steep bottom slopes.

Test showed that this data set must have largely met these conditions. For example, cross-spectra between two ON components at different stations (Figure 5a) show high coherence and the phase relations of an incoming progressive wave while cross-spectra between two OFF components (Figure 5b) show the reverse. Also, cross-correlations between separate components and A_t show a clear isolation of the incoming and outgoing long wave signals related to wave groupiness. Finally, that the ON/OFF separation has resolved problems with determining long wave heights in standing waves is evident in Figure 4b in which the H_s of ON and OFF components does not reflect the structure in the H_s of the total η_L (Figure 4a).

Cross-correlations: revisited

Correlations are now found between A_t and separate ON and OFF long wave components. The question of interest here is: how much of the long wave height at each station can be explained by a BLW type association? Thus the search is for the A_t series that can predict the most long wave variation at each station. For the onshore component stations 5,6,7,8, and 9 show the highest BLW correlations with co-located A_t; for stations 1 and 3 the highest correlations are with A_t at stations 5. For the offshore component the best correlations were always with the group structure near the maximum limit of wave breaking at station 5. Table 1 summarizes these relationships. The results differ from those presented by Guza et al. (1985) in that the maximum correlations remain negative to the most landward stations in both the ON and OFF components.

Correlations in Table 1a are squared and multiplied by the H_s of the corresponding onshore component (Figure 4b) to give estimates of

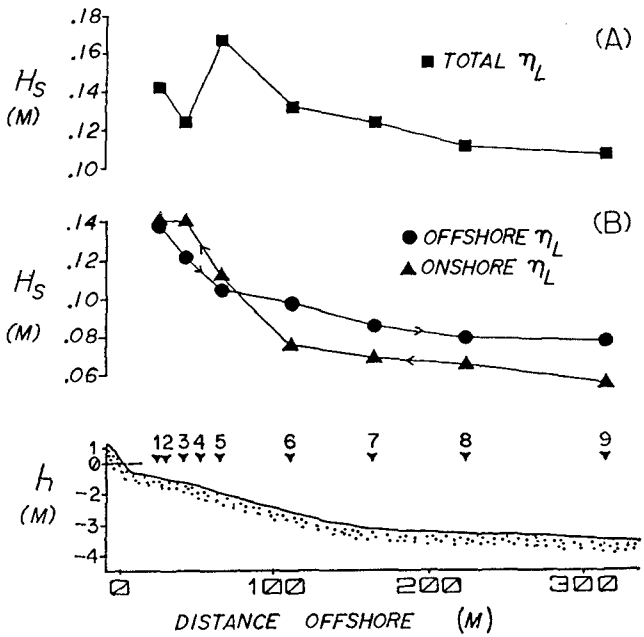

Figure 4 (A) Significant wave height from variance in sea-surface long wave band, (B) significant wave height from variance of separated onshore and offshore progressive long wave components.

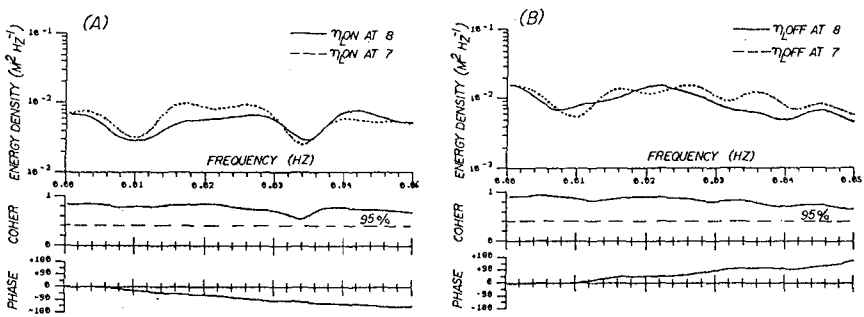

Figure 5 (A) Cross-spectrum between onshore progressive components at stations 8 and 7, (B) Cross-spectrum between offshore progressive components at stations 8 and 7.

BLW height at each station, shown in Figure 6. Values for BLW H_s found through use of the squared amplitude function are also plotted, and indicate that this method results in only a slight improvement in the analysis.

The values of BLW H_s in Figure 6 are extremely low, and probably not far from the limit of the instrument's measuring ability. However, every point is based on a correlation that is significantly different than zero at the 95% confidence level, and in most cases far better. In addition, cross-spectra calculated between the A_t and η_LON pairs in Table 1a show coherent relationships above the 95% CI. For example, Figure 7 shows that approximately 30% of the variance in η_LON at station 5 can be explained by the wave group structure. Thus it seems that the correlation values used in creating Figure 6 may underestimate the actual size of the BLW, since significant correlations seem to be predicting nearly insignificant wave heights.

Assuming that at least the relative changes in Figure 6 are real, it appears that the BLW undergoes rapid shoaling into shallow water, even through a zone in which waves are breaking. Specifically, between stations 6 and 1 the amplitude variability, σA_t, decreases by a factor of 2 (Figure 1), while at the same time the size of the estimated BLW increases four-fold. (The corresponding increase in A_t versus η_LON correlation is significant to the α=0.003 level.) Some investigators have implied that as incident waves break, the BLW also decays or is released to shoal toward shore as a free wave. However, the group-related long waves as observed here increase much more rapidly than predicted by a $(h_1/h_2)^{1/4}$ long wave shoaling, the rate being closer to $(h_1/h_2)^{5/2}$, the shallow water BLW shoaling predicted by Ottesen Hansen et al. (1981). Toward shore this group-correlated component is thus becoming a progressively larger piece of a progressively larger pie, which would not be the case for a free long wave progressing shoreward. This apparent increase in group forced long waves after incident waves have begun to break was also found by Mansard and Barthel (1985), who observed laboratory long waves increasing in size even through a constant depth zone.

The correlations with offshore components in Table 1b show that the outgoing long waves also contain a significant component related to wave groups. Close to shore these correlations are somewhat less than those for the incoming wave. This could indicate that to some degree the BLW is decreased in size before release and reflection, but could also simply be due to the greater spatial separation between the group structure and outgoing long waves. Not shown in Table 1b are positive correlations that were sometimes significant, and occurred at smaller lags than expected for a shoreline long wave reflection. While these correlations appear to be similar to those observed by Guza et al. (1985), they were never greater than the negative correlations, and were not present in the correlations with the onshore component.

A rapid shallow water increase in the forced response may explain the differences between the size of the incoming and outgoing components (Figure 4b) in the following manner. The onshore component increases rapidly past station 6 as the BLW shoals. At some point close to shore this forced wave is released and reflected as a free

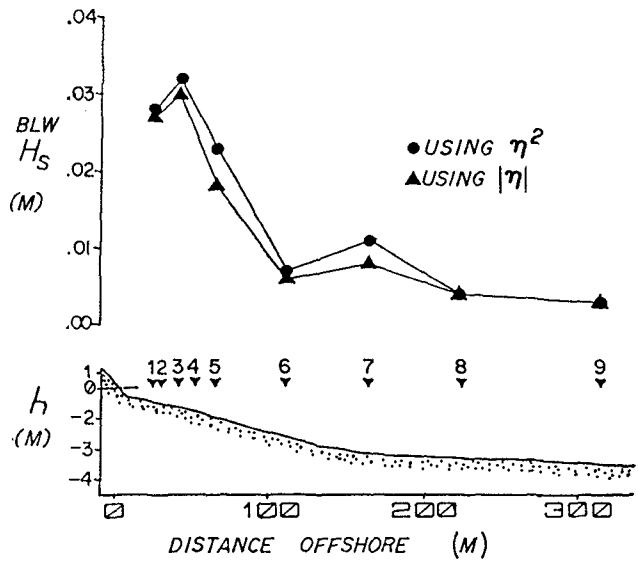

Figure 6 Significant wave height of bounded long wave inferred from correlations between amplitude time series and long waves (Table 1a). ●amplitude time series from square of incident waves, ▲ amplitude time series from modulus of incident waves.

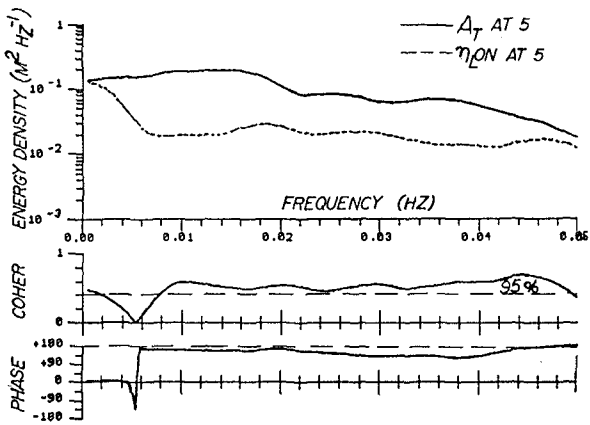

Figure 7 Cross-spectrum between amplitude time series and the onshore component of sea-surface long waves co-located at station 5. (Compare to Figure 2.)

wave which decreases in amplitude offshore at a smaller rate closer to $(h_1/h_2)^{1/4}$. Thus in deep water the offshore component is larger than the onshore component, which would explain why Tucker (1950) observed a forced response only after a large time lag. However, at the most landward stations the onshore component here is larger, implying that at least some of the incoming long wave energy decays in very shallow water with wave groups. Again the results here are different than those given by Guza et al. (1985), in which the onshore component was at all positions larger than the offshore component.

Discussion

Other studies of the BLW in the nearshore have exhibited a varying degree of evidence for the forced wave response. Guza et al. (1985) show that the incoming and outgoing long waves are clearly correlated to wave groups, but interestingly the negative sign of the BLW is overshadowed by positive correlations within the surf zone. Kim (1985) shows evidence of an incoming forced response, but little sign that outgoing long waves are correlated to wave groups. Huntley and Kim (1985) show nearshore long waves almost entirely forced by wave groups in a steep, reflective beach in which a separate outgoing wave cannot be distinguished. The results presented here are therefore not necessarily typical, but may represent an end member in the degree to which the BLW is clearly present in the incoming waves, and seems to be the source for at least part of the outgoing waves.

Evidence for long wave generation at a time-varying breakpoint may also exist to varying degrees throughout these studies of group-forced waves. However, it is still uncertain exactly what kind of relation these waves should show in cross-correlations or cross-spectra with wave groups. The laboratory study of Kostense (1985) showed frequency-dependent outgoing waves (never observed in the field), but this could also be an indication that the degree to which the BLW is released and reflected (instead of decayed with wave groups) is also dependent on the wave characteristics.

Certainly more theoretical work is needed to explain why the forced response seems so variable, and under what conditions the BLW becomes energetic in the nearshore, or could be released and reflected as a free wave. The observation of a BLW increase through a zone of wave breaking may find an explanation in a resonant interaction with residual wave groupiness. Long waves may be released from wave groups if the BLW satisfies the free long wave dispersion relation before incident waves break. The Model of Symonds et al. (1982) must also be

re-examined, with emphasis on possible interactions with group-bound waves, and on new methods of evaluating field data for this effect.

Conclusions

The following applies only to this study:

1. The bounded long wave, as measured by correlation coefficients with a squared wave group function, accounts for one-fourth of the incoming long wave height. This is probably a conservative estimate.

2. The bounded long wave increases in size even through a zone of wave breaking.

3. The outgoing long waves have a component correlated to wave groups with a sign and lag suggesting release and reflection of the BLW.

Acknowledgements

Many thanks to everyone at the U.S. Army Corps of Engineers Field Research Facility in Duck, North Carolina for providing an outstanding environment for field research, and for their generous data exchange policy without which this study would have been impossible. Thanks also to J. Hubertz of the U.S. Army Corps of Engineers, R.A. Holman of Oregon State University, and R.W. Sternberg of the University of Washington for allowing the use of data collected by their instruments in their field work at Duck.

CHAPTER 39

Estimating Long-Term Wave Statistics From Long-Term Wind Statistics[†]

Paul C. Liu[‡]

The Wave Climate Synthesis method, which derives long-term wave statistics from long-term wind statistics directly, is tested with four years of wind and wave measurements recorded from eight NOMAD buoys in the Great Lakes during 1981-1984. The results show that it is an excellent method for estimating long-term wave statistics and design wave height. While the method is by no means intended to replace wave hindcasting procedures, it is shown to be a useful additional tool for the coastal engineer.

Introduction

One of the first considerations when solving a coastal engineering problem is the determination of a design wave height. The usual procedure of determining a design wave height where actual wave measurements are not available consists of gathering pertinent long-term wind data, making wave hindcasts from the wind data, and subsequently performing statistical analysis on the hindcast wave data to estimate design waves. Although this conventional approach does provide useful information, it can be time consuming. In this paper we examine an alternative approach called Wave Climate Synthesis (e.g., Andrews et al., 1983) which derives long-term wave statistics directly from long-term wind statistics, bypassing wave hindcasting. This approach simplifies the process of estimating a design wave height. The validity and usefulness of this approach are demonstrated with four years of wind and wave measurements recorded from eight NOMAD buoys in the Great Lakes during 1981-1984.

Approach

The Wave Climate Synthesis method, pioneered by Hogben and collaborators (Andrews, et al., 1983, Hogben, 1987, and Hogben and Dacunha, 1985) at British Maritime Technology (formerly National Maritime Institute), is based on the concept of relating long-term marginal probabilities of significant wave height $P(H_s)$ and wind

---

[†]GLERL Contribution No. 539.

[‡]Oceanographer, NOAA/Great Lakes Environmental Research Laboratory, 2300 Washtenaw Avenue, Ann Arbor, MI 48104.

speed $P(W_r)$ by means of a parametric model of the conditional probability $P(H_s|W_r)$ as

$$P(H_s) = \Sigma P(H_s|W_r)P(W_r). \quad (1)$$

$P(H_s|W_r)$ is assumed to be represented by the Gamma distribution,

$$P(H_s|W_r) = [q^{p+1}/\Gamma(p+1)]H_s{}^p \exp(-qH_s), \quad (2)$$

where $\Gamma(.)$ is the Gamma function. The parameters p and q are given in terms of the averages and standard deviations of the wave height in each wind speed interval, H_r and v_r, respectively as

$$p = H_r{}^2/v_r{}^2 - 1, \quad (3)$$

and

$$q = H_r/v_r{}^2. \quad (4)$$

H_r and v_r, measured in m, are empirical functions of wind speed W_r, in m/s, given by

$$H_r = [(aW_r{}^n)^2 + h_2{}^2]^{1/2}, \quad (5)$$

and

$$v_r = h_2(b + cW_r + dW_r{}^2). \quad (6)$$

In the above formulations the parameters a, b, c, d, h_2, and n are all empirically obtainable from known distributions $P(W_r)$ and $P(H_s)$. From extensive oceanic studies Andrews et al. (1983), using the linear form of (6), developed recommended values of coefficients for open ocean and limited fetch conditions as listed in Table 1. One can make use of the recommended values when actual data are not available

Location	h_2	a	n	b	c
Open Ocean	2.000	0.033	1.480	0.500	0.0125
Limited Fetch	0.500	0.023	1.380	0.750	0.0188

Table 1 Recommended values of coefficients in Equations (5) and (6) according to Andrews et al. (1983)

or derive appropriate values by fitting Equations (5) and (6) to available data. In either case, once these parameters are determined

and a long-term wind speed distribution $P(W_r)$ is given, a corresponding long-term wave height distribution $P(H_s)$ can be readily determined.

Data

To test the applicability of formulations (1) - (6) we use the long-term wind and wave data recorded from NOMAD buoys in the Great Lakes. There have been eight NOMAD buoys moored in the Great Lakes (Figure 1) since 1981 in water depths ranging from 15 m to 250 m. These buoys are boat-shaped, 6 m in length, with an electronic payload for measuring wind speed, wind direction, barometric pressure, air temperature, sea surface temperature, and surface wave spectral data. Most of the meteorological sensors are located 5 m above the water surface. Wind speed and direction, as well as air and surface water temperatures, are measured at 1-s intervals, averaged over 8.5 minutes and reported hourly. The waves are measured with an accelerometer using an on-board Wave Data Analyzer system (Steele and Johnson, 1977) that transmits acceleration spectral data via the UHF GOES satellite to a shore station. Wave frequency spectra with 48 degrees of freedom are calculated from 20 min of measurements each hour. Significant wave heights, H_s, are obtained as four times the square root of the total energy integrated over the calculated wave frequency spectrum.

The data recorded from all eight buoys during 1981 through 1984 were used in this study. The total number of data points available from each buoy ranges from 11,606 for the buoy at Lake Superior E. to 19,737 for the buoy at Lake Erie W., as shown in Table 2.

Applications

An example of applying the Wave Climate Synthesis method as formulated in Equations (1) - (6) to the Great Lakes wind and wave data is shown in Figure 2 for buoy 45004 at Lake Superior E. In Figure 2 there are four sections. The top section is the histogram for wind speed distribution, which is the required input for this method. The second section, obtained from recorded data, presents the joint distribution of wind speed and significant wave height, H_s, with the corresponding histogram for the distribution of H_s shown to the right of the joint distribution. The third section shows, in each wind speed interval, the averages and standard deviations of the wave height, defined as H_r and v_r in Equations (3) -(6), as the circles and dashed lines respectively. Equations (5) and (6) can be fitted, by the least-squares method, to yield the appropriate coefficients; and the corresponding Gamma distributions $P[H_s|H_r(W_r),v_r(W_r)]$ are also plotted. Finally, from the information derived from the above three sections, a joint distribution of wave height and wind speed and a wave height distribution, similar to the second section, can be estimated as shown in the bottom section. In general, only the histogram in the top section and a set of empirical parameters are needed to produce the estimation shown in the bottom section.

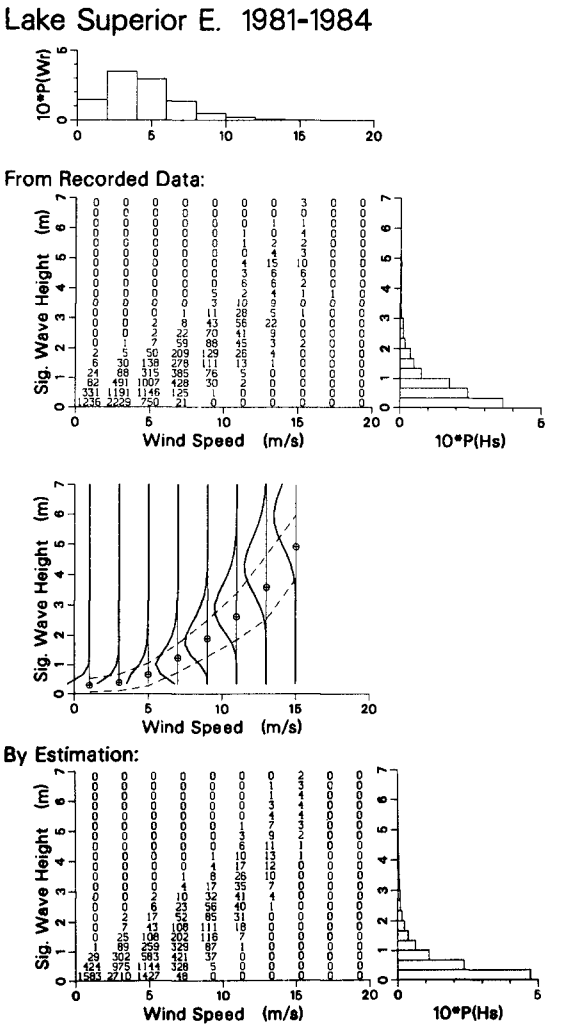

Figure 2 Long-term wind and wave histograms and joint distribution from recorded data and by estimation.

Following this approach, we derived the coefficients in Equations (5) and (6) for the eight buoy locations listed in Table 3. In the oceanic studies, h_2, in m, generally signifies the average swell activity. In the Great Lakes, however, swell is usually less significant, so in this study we simply set h_2 to the average significant wave height corresponding to the lowest wind speed interval (i.e., 0 - 2 m/s). Comparing the results given in Table 3 with the oceanic results in Table 1 indicates that for this study the values of h_2 and coefficient a are smaller while the exponent, n, is larger than those recommended by Andrews et al. (1983) for the oceanic studies. The differences are not significant since they are of the same order of magnitude as the limited fetch cases. A comparison of the fitted curves using the coefficients in Table 3 with recorded data

Gage	h_2	a	n	b	c	d

Table 3 Derived coefficients for Equations (5) and (6) for all eight buoys.

for all eight buoys is shown in Figure 3. Here the model equations (5) and (6) are shown in solid lines with recorded data in dots. Although the degree of goodness of fit varies among the buoys, the model equations can be considered as providing reasonable representations for the recorded data.

Discussions

In Figure 2 the resemblance between the results from measurement and estimation, as shown in the second and bottom sections, appears to be reasonably close. A further and perhaps more effective comparison can be made by plotting the cumulative significant wave height distribution on a Weibull probability scale. This is shown in Figure 4 for all eight buoys. In this figure the recorded data are given in dots, and estimations based on coefficients in Table 3 are represented by the solid lines. The close comparison between recorded data and estimations over the higher wave heights shows that the Wave Climate Synthesis method is a viable approach for estimating long-term wave height statistics from long-term wind statistics.

45007					0.099
45008					0.150

Table 4 Modified coefficients for Equations (5) and (6) for all eight buoys.

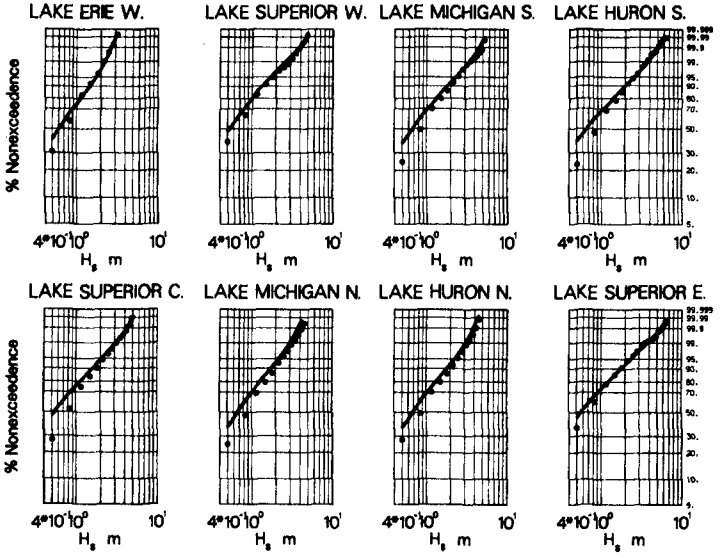

Figure 5 Cumulative distribution of significant wave heights plotted on Weibull probability paper for all eight buoys. Estimation based on Table 4 coefficients appear as solid lines, with recorded data shown as dots.

Closer examination of Figure 4 shows that sometimes the Wave Climate Synthesis method clearly overestimates the recorded data, as in the case of Lake Huron S. Sometimes, as in the cases of Lake Superior C. and Lake Superior E., the method tends to underestimate the recorded data at the high wave height end. The underestimation is especially unacceptable from a design engineer's point of view.

In an effort to rectify these unsettled cases as well as to simplify the use of different coefficients for different buoy locations, we first notice that in Table 3 the values of h_2, a and n for Equation (5) are not significantly different among the different buoys. In addition when we set d = 0 and use only the linear form of representation for the $v_r(W_r)$ function, we found that the coefficients b and c in Equation (6) vary from 0.326 to 1.138 and from 0.013 to 0.225 respectively. Assuming that the variations in b are also not significant, we then choose to use the same average values of h_2, a, n, and b for all eight buoy locations. Thus as shown in Table 4 we allow c to be the only coefficient that is different for different buoy locations. The values of c in the table are determined by trial and error.

Figure 5 presents the resulting cumulative distribution of wave height plots based on the new set of coefficients given in Table 4. This simplified version of coefficients effectively rectifies the excessive overestimation and underestimation and provides satisfactory results for practical applications. Using Table 4, for any given location in the Great Lakes where only wind statistics are available, one needs only to choose an appropriate value of the coefficient c and can then readily proceed to estimate design wave heights with justifiable accuracy.

Concluding Remarks

In this paper we examined applications of the Wave Climate Synthesis method for estimating long-term wave height statistics from given long-term wind statistics. Based on four years of data from each of eight NOMAD buoys in the Great Lakes we found that this method provides reasonably accurate and useful estimations. Many of the results presented here are preliminary in nature. The values of coefficient c in Table 4, for instance, are deduced by trial and error. More detailed analysis and data fitting as well as error analysis will be applied in subsequent studies. The model equations and coefficients will be further examined when additional longer-term data become available. While this method will not replace comprehensive wave hindcasting, it has been shown to be a useful additional tool for estimating design wave heights for coastal engineers.

CHAPTER 40

EVALUATION OF A MODIFIED STRETCHED LINEAR WAVE THEORY

by

Jen-Men Lo[1] and R. G. Dean[2]

Introduction

Many experimental investigations of the drag and inertia force coefficients have relied on the determination of water particle kinematics from measured wave forms. Since the pioneering work of Airy (1845), Stokes (1847, 1880) and others, a number of wave theories have been developed for predicting water particle kinematics. Clearly, the use of a certain wave theory will lead to corresponding force coefficients. Therefore, a wave theory that provides more accurate water particle kinematics is very important.

Reid (1958) developed the simple superposition method for predicting water particle kinematics from a measured sea surface that could be either random or periodic. The method is based upon linear long-crested wave theory. Borgman (1965, 1967, 1969a, 1969b) introduced the linearized spectral density of wave force on a pile due to a random Gaussian sea. The drag force component has been approximated in the simplest form by a linear relation. This method, however, cannot calculate properties of the wave field and wave force above the mean water level.

Wheeler (1969) applied simple superposition with a stretching factor in the vertical coordinate position for hurricane-generated wave data during Wave Project II. With this method it was possible to evaluate the wave force above the mean water level.

Hudspeth, et al. (1974) compared the wave forces computed by simple superposition and irregular stream function methods. By using the simple superposition and a stretched vertical coordinate to calculate water particle kinematics, the comparison between measured and calculated forces indicates the stream function method was generally better than the linear wave theory method. The magnitudes of the difference between the theories, however, is not consistent. For maximum forces, the differences are not great. They noted that the linear

[1]Associate Research Scientist, Environmental and Earth Sciences Division, Kuwait Institute for Scientific Research, P.O. Box 24885, 13109 - Safat - Kuwait

wave theory provides greater facility in carrying out certain mathematical operations than is possible using nonlinear wave theories.

The advantage of using the simple superposition method is that the entire measured sea surface data can be analyzed without the need to consider only one extreme wave using a nonlinear symmetric wave theory or irregular stream function theory. This paper will introduce a new mathematical stretching factor similar to the stretching factor used by Wheeler (1969). For several wave conditions, the symmetrical stream function wave theory, the stretched linear wave theory, and the new approach will be compared.

Simple Superposition

To simplify the problem, only two-dimensional wave motion will be considered. A long, irregular sequence of linear waves can be represented as an infinite sum of simple harmonic waves with closely spaced frequencies and random phase angles, i.e.,

$$\eta(x,t) = \sum_n a_n \cos (k_n x - \sigma_n t + \alpha_n) \tag{1}$$

where η is the water surface displacement; $a_n = \sqrt{2P_\eta(\sigma_n)\Delta\sigma}$; $P_\eta(\sigma_n)$ is the (one-sided) energy density spectrum of the irregular sea, varying with angular frequency σ_n; k_n is the wave number for the nth wave component ($k_n = 2\pi/L_n$); L_n is the wave length of the nth wave component; x is distance and α_n is the phase angle for the nth wave component.

When the small amplitude wave theory is used to estimate the flow regime in a wave system from the surface profile (Eq. 1), the velocity potential may be expressed by

$$\phi(x,z,t) = \sum_n \frac{a_n g}{\sigma_n} \frac{\cosh k_n(h+z)}{\cosh k_n h} \sin (k_n x - \sigma_n t + \alpha_n) \tag{2}$$

where z is referenced to the mean water surface and is positive upwards. The dispersion relationship is given by

$$\sigma_n^2 = g k_n \tanh k_n h \tag{3}$$

The horizontal water particle velocity component is given by

$$u(x,z,t) = -\frac{\partial\phi}{\partial x} = \sum_n \frac{a_n k_n g}{\sigma_n} \frac{\cosh k_n(h+z)}{\cosh k_n h} \cos(k_n x - \sigma_n t + \alpha_n) \tag{4}$$

From Eq. 4, the horizontal water particle kinematics at any given time or any given position can be found very easily. But when the position is close to the free surface, the results are not in agreement with laboratory or field data. Mathematically, Eqs. 2 and 3 are determined individually, component by component, using the small amplitude wave theory approach assuming that all wave components are independent of

each other. Fig. 1 shows a high-frequency wave component superimposed upon a low frequency wave component. Evaluating Eq. 4 at a time when both components are maximum, the vertical surface coordinate is z = $a_1 + a_2$, and it is found that the contribution of the high-frequency component to the kinematics is exaggerated by the vertical displacement due to the large low-frequency wave.

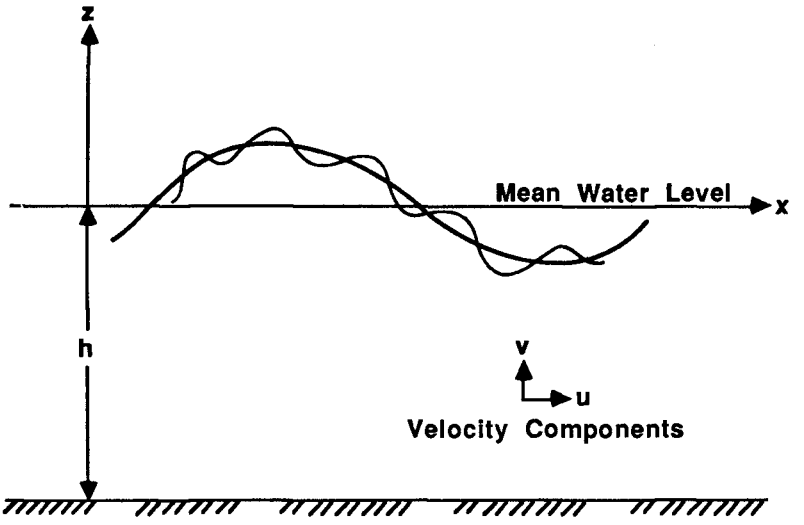

Fig. 1. Superposition of a high frequency wave on a low frequency wave.

Stretched Linear Wave Theory (SLWT)

The simple superposition technique was first developed by Reid in 1958. Wheeler applied the technique to hurricane-generated wave data in 1969. The simple superposition technique, however, predicts unreasonably large wave kinematics when it applies to locations that are above the mean water level. Therefore, Wheeler introduced an intuitive stretching factor to predict the wave kinematics by using the simple superposition method. If kinematic predictions are desired at elevation S = h + z above the bottom (where h is the mean water depth), then the stretching results in calculations being carried out at elevation S' above the bottom, where

$$S'(x,z,t) = \alpha(x,t)S \tag{5}$$

and

$$\alpha(x,t) = \frac{h}{h+\eta(x,t)} \tag{6}$$

Here $\eta(x,t)$ is the instantaneous water surface displacement measured from the mean water level. This vertical stretching is particularly significant near the free surface. It is of interest to note that the velocity potential that is stretched in this manner no longer exactly satisfies the Laplace equation.

By using the stretched linear wave theory, the kinematics (and other quantities) calculated at the actual free surface are the same as those evaluated at the mean water level in an unstretched system, thus eliminating the exaggeration of the high frequency component described previously.

Stream Function Wave Theory (SFWT)

The stream function wave theory, as described by Dean (1965), can be used to represent both theoretical symmetrical and irregular waves. In application, the theory is used to generate a symmetric wave with given parameters, such as wave height, period, and water depth. It is this symmetric form of the stream function wave theory that will be used in the comparison.

Taking a frame of reference moving with wave celerity C, the problem is reduced to a steady form. Then the kinematic free surface boundary condition becomes

$$v = \frac{\partial \Psi}{\partial x} = (u - C)\frac{\partial \eta}{\partial x} = -\frac{\partial \Psi}{\partial y}\frac{\partial \eta}{\partial x} \text{ on } z = \eta(x) \tag{7}$$

where v is the vertical velocity component and Ψ is the stream function. Eq. 7 is satisfied exactly by the equation for the stream function:

$$\Psi(x,z) = \frac{L}{T} z + \sum_{n=1}^{NN} A(n) \sinh\left[\frac{2n\pi}{L}(h+z)\right] \cos\left(\frac{2n\pi}{L} x\right) \tag{8}$$

Evaluating this expression on the free surface, i.e., setting $z = \eta$, the free surface is

$$\eta = \frac{T}{L}\Psi_n - \frac{T}{L}\sum_{n=1}^{NN} A(n) \sinh\left[\frac{2n\pi}{L}(h+\eta)\right] \cos\left(\frac{2n\pi}{L} x\right) \tag{9}$$

Since the coordinate system is moving with the wave celerity, and the pressure is zero on the free surface, the dynamic free surface boundary condition is

$$\frac{1}{2g}\left((u-C)^2 + v^2\right) + \eta = Q \text{ on } z = \eta(x) \tag{10}$$

where Q is the total head or "Bernoulli constant" on the free surface.

The numerical problem of establishing the wave theory is thus one of determining values of A(1), A(2),...., A(NN), L, Ψ_η, such that the dynamic free surface boundary condition is satisfied as closely as possible. These coefficients are determined iteratively employing a nonlinear least-squares procedure.

Modified Stretched Linear Wave Theory (MSLWT)

The SLWT was reported to be based on wave tank studies; Lo (1979) introduced a new stretching factor by using the free surface boundary conditions. Assuming that the pressure is zero on the free surface, the dynamic free surface boundary condition is

$$\frac{1}{2g}(u^2 + v^2) + z - \frac{1}{g}\frac{\partial \phi}{\partial t} = C(t) \quad , \quad z = \eta \tag{11}$$

The kinematic free surface boundary condition is

$$\frac{\partial \eta}{\partial t} + u\frac{\partial \eta}{\partial x} = v \quad , \quad z = \eta \tag{12}$$

Eqs. 11 and 12 are nonlinear partial differential equations, and the nonlinearities come from two major sources. One is the product terms in the equations, i.e., u^2, v^2 and $u\ \partial\eta/\partial x$; the other is that the equation applies to the actual free surface, $z = \eta$. The most popular technique for solving these equations is by using the Taylor series expansion to expand the value of the condition from $z = 0$ to $z = \eta$ (mean water level, a known location), then by using the perturbation procedure to solve the equations order by order. For example, the small amplitude wave theory is the solution of the first order, and the Stokes theories of various orders are extensions of the approach.

The MSLWT will be solved to the first order by using Eqs. 11 and 12 only on the free surface $z = \eta$. The solution is:

$$\eta(x,t) = a\cos(kx - \sigma t) \tag{13}$$

$$\phi_m(x,y,t) = -\frac{ag}{\sigma}\frac{\cosh k\,(h+z)}{\cosh k\,(h+\eta)}\sin(kx - \sigma t) \tag{14}$$

$$\sigma^2 = gk\tanh k(h+\eta) \tag{15}$$

Eqs. 13, 14 and 15 satisfy the boundary conditions (without the product terms in Eqs. 11 and 12) exactly. But, like the solution of the stretched linear wave theory, they no longer satisfy the Laplace equation. The effective wave number k now depends on water surface displacement. Comparing the solution for small amplitude wave theory with that for the modified stretched linear wave theory, the new stretching factor found for the modified stretched linear wave theory is given by

$$\text{Stretching Factor} = \frac{\cosh kh}{\cosh k\ (h+\eta)} \tag{16}$$

This stretching factor was established by using the boundary conditions of the wave system. For a given time, position and mean water depth, this factor will be a constant through the vertical coordinate. But under the same conditions, the stretching factor for the stretched linear wave theory (Equations 5 and 6) is a function of depth, and it has a maximum value at the free surface, a minimum value at the bottom.

To describe the statistical properties of a random water surface, it is convenient to decompose the variable of interest into Fourier components. The Fourier series representation of the water surface displacement is given by the simple superposition method as Eq. 1.

When the MSLWT is used to estimate the flow regime in a wave system from the surface profile, the velocity potential may be expressed by

$$\phi_m(x,z,t) = -\sum_n \frac{a_n g}{\sigma_n} \frac{\cosh k_n(h+z)}{\cosh k_n(h+\eta)} \sin\ (k_n x - \sigma_n t + \alpha_n) \tag{17}$$

where the dispersion relationship is given by

$$\sigma_n^2 = g\ k_n \tanh k_n(h+\eta) \tag{18}$$

and the first order horizontal and vertical water particle velocities are derived from Eqs. 17 and 18, as follows:

$$u_m(x,z,t) = \sum_n a_n\ \sigma_n \frac{\cosh k_n(h+z)}{\sinh k_n(h+\eta)} \cos(k_n x - \sigma_n t + \alpha_n) \tag{19}$$

and

$$v_m(x,z,t) = \sum_n a_n\ \sigma_n \frac{\sinh k_n(h+z)}{\sinh k_n(h+\eta)} \sin\ (k_n x - \sigma_n t + \alpha_n) \tag{20}$$

Comparison Between SLWT and MSLWT

Ohmart and Gratz (1978) presented a comparison of measured and predicted ocean wave kinematics. They found by comparing linear wave theory, Stokes Fifth Order Wave Theory and the Irregular Stream Function Wave Theory (IRSF) that IRSF yields better results. The field data were measured from the test structure (the CAGC Eugene Island 266F platform), located in the Gulf of Mexico. Mean water depth was 177 feet. A wave staff was mounted on one corner of the structure. The current meters were mounted at elevations of 5 and 20 feet below mean water level.

A 34 minute block of data was recorded each two hours or four hours depending upon the severity of the storm. The data sampling rate was at 0.5 second intervals.

Two sets of Ohmart and Gratz's data were selected for comparison with IRSF, the MSLWT, and the SLWT. Both sets were measured during storm Delia in September 1973 and in the deep water region. Figs. 2-5 present a representative comparison of the horizontal water particle velocities among the data, the IRSF theory, the MSLWT and the SLWT. The comparison shows that both the MSLWT and SLWT agree reasonably well with the data. The SLWT yields a better result (4% closer to the data) than that of the MSLWT near the crest phase angle.

Stream function wave theory (SFWT) results are known to provide a reasonably good fit with laboratory and field data. Therefore, a comparison between the SLWT, MSLWT and SFWT was also studied.

The SFWT is a nonlinear wave theory, thus the wave components given by Eq. 1 for the SLWT and MSLWT cannot be regarded as independent linear components. Rather these components are nonlinear harmonics of the fundamental. Therefore, the wave number k cannot be solved component by component using the dispersion relationship (Eq. 3) for the SLWT and Eq. 15 for the MSLWT for this condition. Only the first component can be solved for the wave number based on Eqs. 3 and 15; in general, the wave number of the nth component is nk.

Six sets of dimensionless wave conditions were selected for tabulation and evaluation from Dean's stream function tabulations (1974). Each case is characterized by values of h/L_o and H/L_o. In the present study, three values of the parameter h/L_o ranging from 0.002 to 2.0 were selected and include the relative depth range of shallow, intermediate, and deep water. The parameter H/L_o includes wave steepness ratios: 0.25 and 1.0 of the breaking wave steepness for each of the 3 h/L_o values. Fig. 6 shows the dimensionless wave conditions selected for evaluation and also indicates the referencing notation for the cases. Tables I and II present the horizontal water particle velocity comparison between the MSLWT and SFWT, and SLWT and SFWT for wave case No. 2. The wave steepness (H/L_o) for wave case 2 is 0.001564, and the relative depth (h/L_o) is 0.002 (Note: This wave is at breaking).

The percent values listed in the tables are the differences between the SFWT and the MSLWT (or the SLWT), defined as

$$\text{Percent} = \frac{\text{MSLWT (or SLWT)} - \text{SFWT}}{\text{SFWT}} \times 100 \qquad (21)$$

The main body of the table lists the dimensionless horizontal water particle velocities of the MSLWT (or SLWT). The row labelled "surface" represents the dimensionless velocities evaluated at the free surface; the percentage differences for velocities are calculated as defined above (Eq. 21). The remaining part of the table represents the dimensionless velocities and percentage differences evaluated on a grid of (Θ, S/h). The lack of entries for the higher S/h and larger Θ values (right side of page) result from the fact that the wave profile

in the trough region is lower than in the crest region (left side of page). If asterisks appear, it means that the percentage differences are very large and cannot be covered by the computer output. This avoided the tabulation of very large percentages that would have been the result of division by a small number. Generally, although the asterisks indicate a large percentage error, they occur at locations where the denominator in Eq. 21 is near zero and are associated with small absolute differences. Finally, it is noted that the small percentage differences in relative water surface displacement are due to the stream function profile being used to develop a truncated Fourier series representation as an input water surface profile to both of the stretched wave theories. Figs. 7 and 8 present a comparison of the horizontal water particle kinematics between the SFWT, SLWT, and MSLWT under the crest. From this comparison, the MSLWT provides a better fit to the SFWT than for the SLWT.

Summary and Conclusions

A new stretching factor was developed based on the first order free surface boundary conditions. The simple superposition method and the modified stretched linear wave theory, provide reasonable agreement with the water particle kinematics from the Stream Function Tables. This technique is useful and convenient for the following reasons:

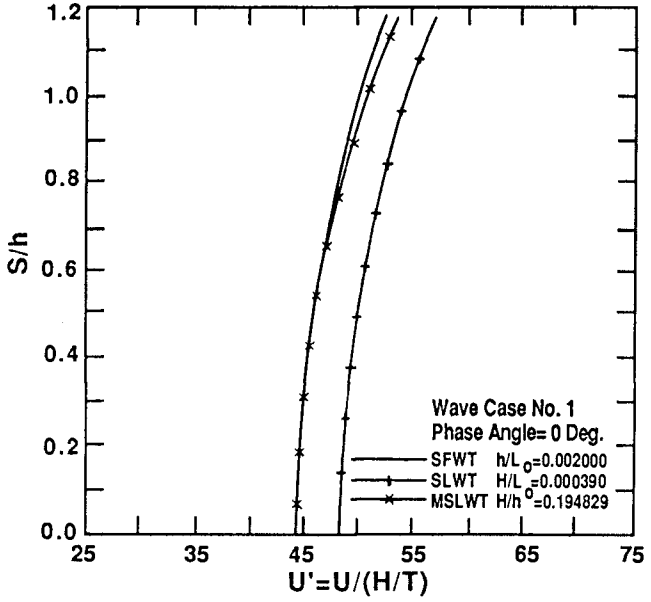

Fig. 7. Dimensionless horizontal water particle velocity distribution over depth (under the crest).

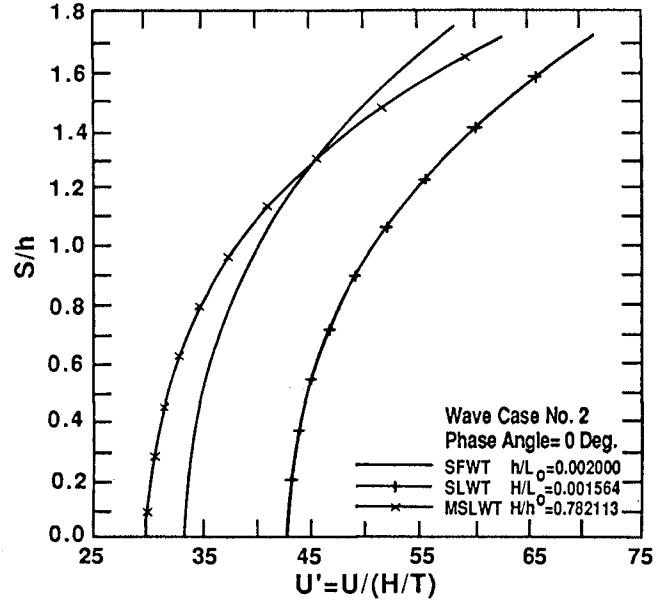

Fig. 8. Dimensionless horizontal water particle velocity distribution over depth (under the crest).

1. The simple superposition method and the MSLWT can be used to analyze any length of irregular wave records for design and dynamic studies of offshore structures. Through the superposition method, a given wave record (usually available as a function of time only) can be represented as an infinite sum of simple harmonic waves with closely spaced frequencies and appropriate phase angles.

   When the MSLWT is used to estimate the flow regime in a wave system from the surface profile, Eqs. 16, 18, 19 and 20 allow the calculation of the potential function and the kinematics.

   This method is convenient for the analysis of long and irregular wave profiles which can be characterized by power spectra and thus related to statistical wave prediction techniques that relate wave spectra to weather history for a given location.

2. Most nonlinear wave theories require a periodic wave profile, but by using the simple superposition method and the MSLWT, aperiodic wave profiles can be analyzed.

3. Based on the MSLWT, the spectral and probabilistic approaches to wave force prediction can be extended to include calculations from the sea floor to the free surface without neglecting the contribution from the mean water surface to the free surface.

4. In laboratory studies of nonlinear waves, the simple superposition method and the MSLWT will yield reasonable kinematic predictions.

5. A more extensive comparison between field data and the result of using the simple superposition method and the MSLWT is desirable and will be pursured when additional data are available. It is planned to extend the MSLWT to account for nonlinear terms included in the complete free surface boundary conditions.

CHAPTER 41

LIMIT WAVES ON HORIZONTAL SEA FLOOR

Chia-Chi Lu[1], John D. Wang[2], M. ASCE and Bernard Le Mehaute[3] M. ASCE

ABSTRACT

A numerical solution to periodic nonlinear irrotational surface gravity waves on a horizontal sea floor is developed using an iterative Boundary Integral Equation Method (BIEM). This solution technique is subsequently applied to determine the characteristics of limit waves for which the wave crest theoretically ceases to be rounded and become angled with an included angle of 120 degrees.

INTRODUCTION

Analytic wave theories (1,2,3) have shown that for large waves, nonlinear effects become important and wave theories that account for some of these effects give more accurate results. Most of these wave theories are based on the solutions to the irrotational monochromatic wave problem on a horizontal bottom. Application of the numerical results provided by Dean's stream function solution (4), which is of this type, is presently being recommended in the Shore Protection Manual (5) to determine forces on piles, although high order Stokes solutions have also been used. The Dean's stream function and similar solutions (4,6,7,8), are based on truncated Fourier expansions for which the accuracy of the solution decreases as the wave height approaches limit wave conditions. A limit wave has a stagnation point at the crest and, as shown by Stokes (9), the wave crest is sharp and includes an angle of 120 degrees.

A solution to limit waves based on the transformed (complex potential) plane and including terms to specifically account for the crest flow has been given by Williams (10). His solution consists of combinations of periodic motion modes and the mentioned crest terms. Since the solution is performed in the transform plane all but the dynamic surface condition are satisfied. A collocation technique satisfying the dynamic condition at discrete nodal points is used to determine the mode amplitudes. The number of modes required for accurate results and convergence depends on wave steepness and depth and was determined through empirical trial and error. Although the mode amplitudes have been calculated for a number of different wave conditions the application of the results is somewhat cumbersome and interpolation does not seem straightforward.

The numerical solution described here offers an attractive alternative method for determining limit wave parameters. The method is convergent and explicitly accounts for wave set-down.

The Boundary Integral Equation Method (BIEM), (11) solves a govern-

[2,3] Professors,Div. Applied Marine Physics, Rosenstiel School of Marine and Atmospheric Science, 4600 Rickenbacker Cswy. Miami, FL. 33149

ing differential equation (e.g. Laplace equation) by evaluating the two principal dependent variables on a given physical boundary. The basic concept employed stems from the application of Green's theorem and the resulting boundary method is now firmly established as an important alternative technique to the prevailing numerical methods of analysis in continuum mechanics. The efficiency of the BIEM is attributed primarily to the fact that in non-linear problems with an unknown free surface which must be determined through interaction, it is much easier to move a few nodes on the surface for each iteration than it is to update an entire spatial grid.

In this study, a numerical solution for limit waves by means of the BIEM technique is developed. It is obtained in a coordinate system translating at wave phase speed and in which the wave motion consequently is steady. The limit waves considered here are monochromatic and periodic. They are assumed to be irrotational and symmetric around a wave crest plane. The limit wave under these conditions is taken as the wave with crest particle velocity equal to the celerity, according to Stokes criterion (9). Although Benjamin and Feir (12) have questioned the stability of a periodic solution, this study does not intend to elaborate on this aspect of the problem, but accepts it as a valuable working assumption.

THEORETICAL FORMULATIONS

Two-dimensional periodic surface gravity waves at the non-breaking limit are considered as shown in Figure 1. With horizontal coordinate x' and vertical coordinate z', the origin is on the bed and moves with the same speed as the waves so that in this moving frame all motion is steady. When the assumption of an incompressible fluid and irrotation-

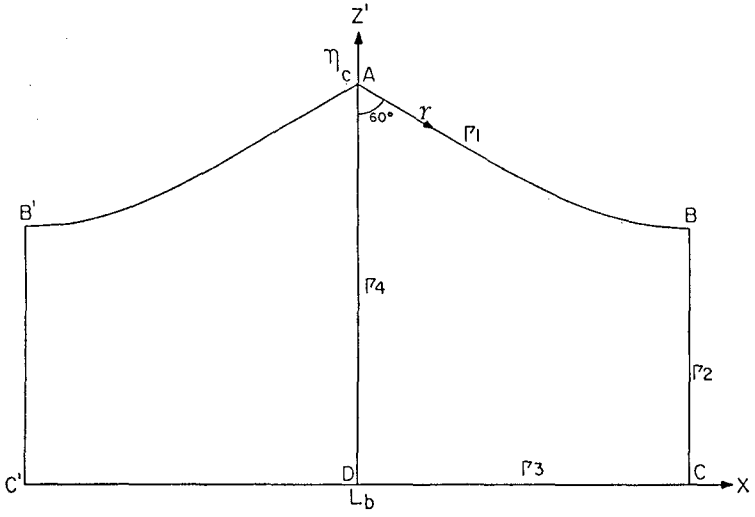

Fig. 1 Definition sketch.

al motion are incorporated, the steady-state solution is represented by a velocity potential function satisfying the Laplace equation, i.e.

$$\nabla^2\phi' = 0 \tag{1}$$

The velocity potential (ϕ') is defined in terms of velocity components u' and w' in the moving frame as

$$-\frac{\partial\phi'}{\partial x'} = u' = u - C_b \tag{2}$$

$$-\frac{\partial\phi'}{\partial z'} = w' = w \tag{3}$$

in which C_b is the speed of the limit wave and u, w are the velocity components in the corresponding fixed frame (here and in the following we use ' to designate variables measured in the translating coordinate system). The kinematic boundary condition applies to both the free surface and the bottom, i.e.

$$w' = 0 \qquad z' = 0 \tag{4}$$

$$\frac{\partial\eta}{\partial x'} = \frac{w'}{u'} \qquad z' = \eta(x') \tag{5}$$

where η is the free surface displacement.

The dynamic boundary condition on the free surface is given as

$$\eta + \frac{1}{2g}[u'^2 + w'^2] = B \qquad z' = \eta(x') \tag{6}$$

in which B is the Bernoulli constant and g is the gravitational constant.

In this study, we are specifically searching for limit wave solutions and therefore impose a further condition that the particle velocity at the crest equals the wave phase speed. This yields the well-known result that the crest has an included angle of 120 degrees and the fluid in the vicinity of the crest is characterized by a 120 degree corner flow (9), i.e.

$$\left.\frac{\partial\eta}{\partial x'}\right|_{x'=0} = -\tan^{-1}\frac{\pi}{6} \tag{7}$$

It is noted that solution of regular non-limit waves can be obtained in a very similar manner to the one described here by eliminating eq. (7) and specifying a value for B, see Lu (13).

The celerity C_b is obtained from the second definition of wave

celerity by Stokes (1), i.e.

$$C_b = -\frac{1}{d}\int_0^{\eta} u'\, dz' \ . \tag{8}$$

where d denotes the water depth.

There exists a close relationship between the celerity and the overall volume transport. If Q' is defined as the total volume rate of flow underneath the steady wave per unit width, it and the wave celerity C_b are related by

$$Q' = -d(C_b - C_s) \tag{9}$$

in which C_s is the average mass transport velocity. If pure wave motion is assumed to cause no overall volume transport of fluid (i.e., C_s=0), then $C_b = -Q'/d$.

The water depth, d*, is determined so that the crest area equals the trough area, or

$$\int_0^{L_b} \eta(x')\, dx' = d^* \tag{10}$$

in which L_b denotes the limit wave length.

Based upon the assumption of irrotationality and periodicity, the mean water level is always depressed due to existence of waves (14). The mean water level obtained by eq. (10) is lower than the undisturbed water level. The difference Δd is defined as set-down. The set-down can be determined by (see Lu (13))

$$\Delta d = \frac{1}{2g}\left[-C_b^2 + \overline{\left(\frac{\partial \phi'}{\partial x'}\right)^2 + \left(\frac{\partial \phi'}{\partial z'}\right)^2}\ \right]_{z=\eta(x')} \tag{11}$$

where overbar denotes the spatial average over a wave length along the free surface.

BOUNDARY INTEGRAL EQUATION METHOD (BIEM)

The boundary value problem defined through eq. (1) to eq. (7) can be transformed into an integral equation on the boundary only as delineated by Brebbia and Wrobel (15). Thus, the potential at a point p is given by

$$c\phi(p) = \int_\Gamma \frac{\partial \phi}{\partial n}\, \phi^* d\Gamma - \int_\Gamma \phi\, \frac{\partial \phi^*}{\partial n}\, d\Gamma \tag{12}$$

where $\partial\phi/\partial n$ and ϕ are the unknown independent variables, (normal derivative and velocity potential, respectively) and principal value of integrals is implied. The value of c is: c=1 for an internal point, c=0 for an external point, and c=0.5 for a boundary point on a smooth boundary. When the surface is not smooth at the point p, c can be

computed from eq. (12) by setting ϕ = constant over the whole domain Γ is the boundary domain, ϕ^* is the fundamental solution (Green's function) of a concentrated potential at a source point q as determined from the equation $\nabla^2\phi^* + \delta(q) = 0$ ($\delta(q)$ is the dirac delta function). For a two dimensional plane problem, the fundamental solution is $\phi = \ln(1/r)/(2\pi)$, where r is the distance from the source point to the integration point on the boundary. It is noted here that ϕ and $\partial\phi/\partial n$ are two independent variables on the boundary domain since $\partial\phi/\partial n$ cannot be determined from ϕ on the boundary only and vice versa.

For a well posed problem it is sufficient that one of the variables, ϕ or $\partial\phi/\partial n$ be prescribed along every boundary segment. In a numerical solution, the boundary is divided into a number of elements and the independent variables are described by discrete values at element nodes. Consequently a matrix form in terms of ϕ and $\partial\phi/\partial n$ can be written and solved by applying eq. (12) at each node. Once, both nodal velocity potential and normal derivative, ϕ and $(\partial\phi/\partial n)$ are known everywhere on the boundary, the velocity potential and velocity components can be calculated at any interior point as described by Ligget and Liu (16).

NUMERICAL FORMULATION AND SOLUTION

The numerical solution is obtained in the translating coordinate system in which the wave is staionary and symmetric around the wave crest plane. Thus, the model domain need only be half of the wave (i.e. ABCD) as shown in Figure 1.

In the mathematical problem the location of the surface, $\eta(x')$, is not known a priori, but must be determined as part of the solution through the use of conditions (5) and (6). In the present numerical solution an initial location of the free surface is guessed, the dynamic surface condition is imposed and an iterative technique is developed to change the position of the surface until the kinematic condition is also satisfied.

Because only wave length and wave crest elevation can be chosen independently, the problem geometry can be characterized by only a single dimensionless parameter, ξ = ratio between the limit wave crest elevation and limit wave length, making it easier to numerically cover the full range of possible conditions.

Boundary Conditions

Because the wave crest is a stagnation point, the Bernoulli constant $B = \eta_c$, where η_c is the crest elevation. The dynamic free surface condition then becomes

$$V_s = [2g(\eta_c - \eta)]^{1/2} \tag{13}$$

where V_s is the tangential velocity along the free surface. Eq. (13) can therefore be used to determine the velocity potential along a given free surface by performing a line integration along contour AB with the curvilinear coordinate γ.

$$\phi'_s(\gamma) = \int_A^{\gamma} V_s \, d\Gamma + \phi'_s\Big|_A \tag{14}$$

Taking ϕ' in the crest plane equal to 0 and noting $\gamma = \gamma(x')$

a Dirichlet condition is obtained,

$$\phi' = \phi'_S(x') \qquad \text{on } \Gamma_1 \tag{15}$$

A Neumann condition at the bottom is defined by the kinematic bottom boundary condition

$$w' = \frac{\partial \phi'}{\partial n} = 0 \qquad \text{on } \Gamma_3 \tag{16}$$

The assumption that waves are propagating without changing form implies that in the crest and trough planes vertical velocity components are zero, hence, ϕ' is constant

$$\phi' = 0 \qquad \text{on } \Gamma_4 \tag{17}$$

$$\phi' = \phi_T \qquad \text{on } \Gamma_2 \tag{18}$$

where ϕ_T obtained by eq. (14) is the velocity potential at the trough.

Initial Estimate of Surface

A cubic polynomial conforming to the known slopes at both ends (-30 degrees at the crest and 0 degrees at the trough) and passing through the crest and an arbitrarily chosen trough is used as the initial surface. Subsequently, the surface is discretized into a number of elements.

Numerical Schematization

For best possible fit a number of quadratic isoparametric elements are used along the free surface, while normal quadratic elements are used on the rest of the boundary. The nodes are located at the ends and the middle of these elements and have values of ϕ_j and $\partial\phi_j/\partial n$ associated with them, where j=1,2,3...n and n denotes the total number of nodal points.

Because the gradients are expected to be greater near the crest a variable element length is used with elements smallest at that location. Extensive testing showed that a total of 96 boundary elements provided a reasonable compromise between cost of computation and accuracy. The same grid was used for all computations regardless of the value of ξ.

Surface Iteration Technique

Based on the initial surface the BIEM can be executed. The results will in general not satisfy the kinematic boundary condition, but can be made to do so by changing the surface.

A convergent iteration technique based on "influence" solutions and a Newton-Raphson method is developed to perform the surface updating automatically. The technique first computes the change in the kinematic condition residual for unit changes in the elevation of each surface node and organizes the influence solutions in a Jacobian matrix. Based on the current residuals the Jacobian is then used in conjunction with a Newton-Raphson method to determine the optimal change to the elevation of each surface node. Because of the nonlinear nature of the problem, the Jacobian should in theory be computed every time the

surface is changed, however, we have found that in practice the Jacobian does not change much after the first few updates and need not be recomputed.

The iteration technique is continued until an error measure in the kinematic boundary condition defined as

$$\varepsilon_2(\theta) = \frac{\partial \eta}{\partial x'} - \frac{w'}{u'} \tag{19}$$

is below a threshold value. We have chosen this threshold value to be on the order of the round off errors of the method on the 36 bit UNIVAC machine employed for the computations. A flow chart of the solution method is shown in Fig. 2.

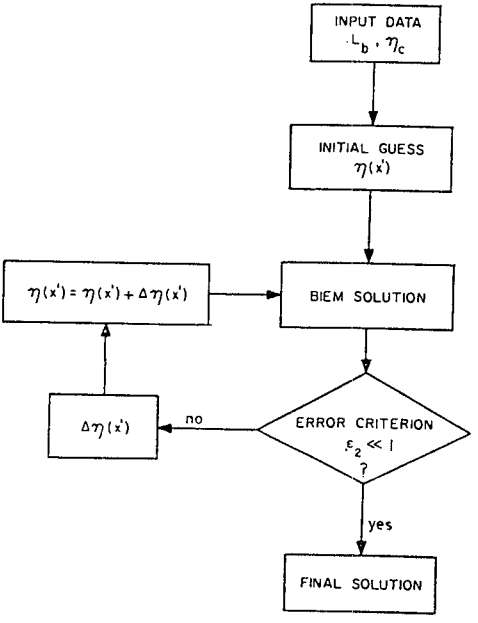

Fig. 2 Flow chart of the BIEM technique.

RESULTS

A unique limit wave is obtained with the BIEM for each discrete value of ξ. (The uniqueness is confirmed by choosing two different initial guesses of surface and obtaining an identical final solution.) However, in practical applications the crest height and wave length necessary to determine ξ are usually not known. The known or more easily obtained parameters are undisturbed water depth (d) and wave period (T). Our results can be made more amenable to practical applications by determining a relationship between ξ and the single dimensionless parameter, d/L_o, with $L_o = gT^2/2\pi$. In addition, it will be

very useful to establish relationships for L_b/L_o, H_b/L_o and η_c/L_o as functions of d/L_o to make possible direct calculation of limit wave length, wave crest elevation and wave height. Due to the assumption of limit waves unique relations can be written as

$$L_b/L_o = f_1(d/L_o) \tag{20}$$

$$\eta_c/L_o = f_2(d/L_o) \tag{21}$$

$$H_b/L_o = f_3(d/L_o) \tag{22}$$

and

$$\xi/L_o = f_4(d/L_o) \tag{23}$$

The functions f_1, f_2, f_3 and f_4 are determined numerically from our results as described in the following.

Based on the BIEM solutions and for each doublet (η_c, L_b) the limit wave height H_b can be calculated by $H_b = \eta_c - \eta_t$, where η_t is the surface elevation at the trough. Furthermore, the undisturbed water depth can be calculated from

$$d = \frac{2}{L_b}\int_0^{L_b/2} \eta(x')\,dx' + \frac{1}{2g}\left[-C_b^2 + \left(\frac{\partial\phi'}{\partial x'}\right)^2 + \left(\frac{\partial\phi'}{\partial z'}\right)^2\right] \tag{24}$$

in which the first term is the mean water level with waves and the second term is the correction for wave set-down.

Invoking the second definition of phase velocity (zero transport), the phase velocity is determined by

$$C_b = -Q'/d \tag{25}$$

in which Q' is the volume flux in the moving frame. Then, the wave period is determined by $T = L_b/C_b$. Consequently, four dimensionless doublets (L_b/L_o, d/L_o), (η_c/L_o, d/L_o), (H_b/L_o, d/L_o), and (ξ, d/L_o) are obtained for each BIEM solution. The relationship among these dimensionless parameters is plotted as shown in Figs. 3, 4, 5, and 6. Thus, for each given wave period and undisturbed water depth the input data, ξ, for the BIEM and the resulting limit wave length, wave height and crest elevation can be determined immediately.

A measure of the error committed in the kinematic boundary condition used by Dean (4) is defined by

$$E_2 = \left[\sum_{j=1}^{N} \varepsilon_2(\theta)^2\right]^{1/2} \tag{26}$$

in which N is the number of sampling points along the wave profile and $\varepsilon_2(\theta)$ is the error at each sampling point. Comparison of E_2 between the BIEM solution with 96 discretized boundary elements and those computed by Dean (4) for other existing wave theories is shown in Fig. 7.

It should be noted that the present solution satisfies the dynamic surface condition "exactly" while the other solutions have errors in

the dynamic condition. Except for very shallow water the BIEM using 96 boundary element provides results with an order of magnitude smaller error. This error could of course be made arbitrarily small by using more elements and a computer with higher precision. Direct comparison with Dean's stream function solution is not possible because it satisfies the kinematic condition exactly while containing errors in the dynamic condition, however, due to the previously mentioned convergence problems significantly better results should be expected from the BIEM solution.

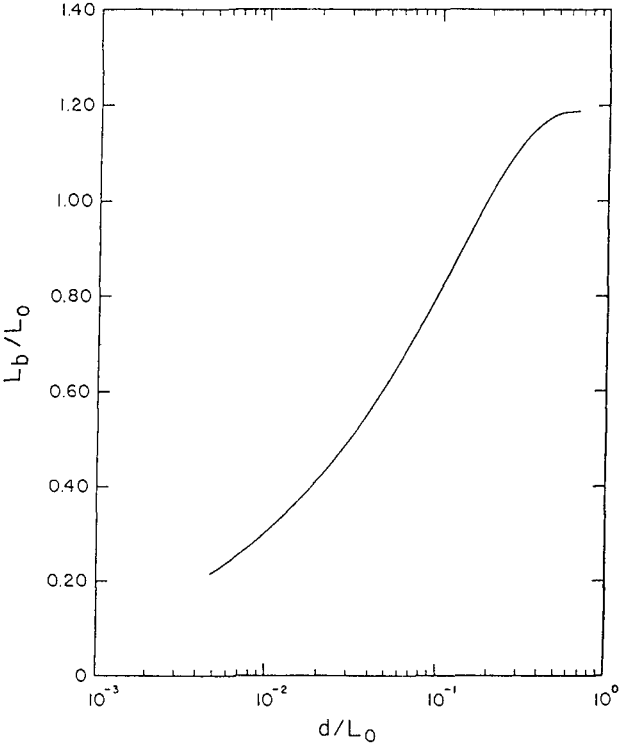

Fig. 3 L_b/L_o versus d/L_o.

The results obtained for H_b/L_o as function of d/L_o (figure 6) may be compared with the theoretical value derived by Michell (17) and Miche (18) who found $H_b/L = 0.142$ in deep water and $H_b/L = .140 \tanh (d/L)$ in intermediate depth water respectively. Due to numerical limitations that the theoretical limit of infinitely deep water cannot be calculated with BIEM approach. The deepest case calculated in this study corresponds to $d/L_o = 0.7$ and the corresponding $H_b/L_b = 0.140$. Note that these expressions use the nonlinear wave-length which is greater than L_o. An earlier study has indicated a ratio between deep water limit wave length and linear wave length of 1.2, (4), while our results yield a value of 1.186 for $d/L_o = 0.7$. As a further verification of our BIEM solutions comparison is also made with the results by

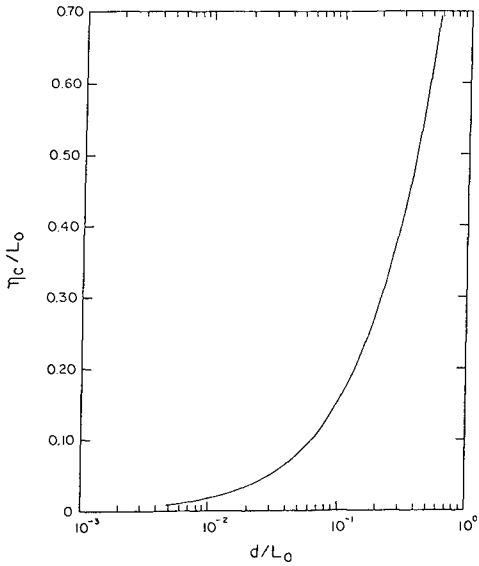

Fig. 4 η_c/L_o versus d/L_o.

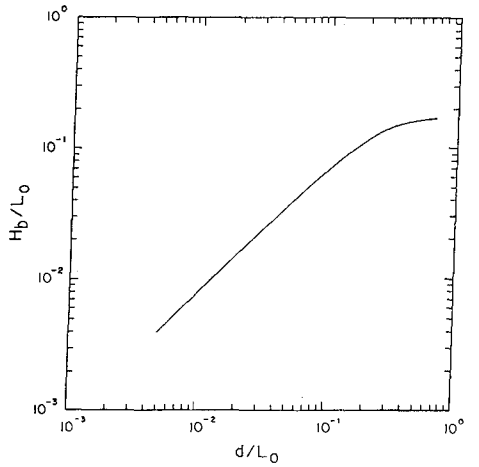

Fig. 5 H_b/L_o versus d/L_o.

Table 1: Comparison of limit wave height for various water depths.

CONCLUSION

A numerical solution for periodic nonlinear irrotational surface gravity limit waves is developed by means of the Boundary Integral Equation Method (BIEM). The formulation for limit waves employs Stokes limit criterion.

The BIEM solution theoretically satisfies exactly the Laplace equation, the dynamic surface boundary condition, and Stokes limit criterion, although any numerical solution will contain finite discretization errors. Solution compliance with the kinematic surface condition is forced by iterating the surface until any error is made arbitrarily small. The final surface is taken as the true limit wave. The wave properties including the dimensionless maximum wave height can be determined as functions of a given water depth and wave period. For the cases considered involving 96 boundary elements and iterating to an error $E_2 < 10^{-3}$ one solution requires approximately 45 minutes of CPU time on a UNIVAC 1100/81 system.

CHAPTER 42

AN EFFICIENT STATISTICAL METHOD OF ESTIMATION OF EXTREME MARITIME EVENTS USING TWO SETS OF RELATED INFORMATION

by

B. MANOHA, J. BERNIER and M. GRAFF *

ABSTRACT

The construction of marine works necessitates a good knowledge of the extreme events which can affect it, such as the storm waves or the water levels. A statistical method of estimation of these extreme events has been developped at L.N.H. The principle of this method, based on the theory of renewal processes, is presented hereafter, as well as the results that it can provide. Some applications of the method are described in the paper ; in particular the application to a site where the available data are insufficient, and where the method enables to precise the results by using complementary numerous data on a neighbouring site, is presented.

1. INTRODUCTION

The important nuclear program developped by Electricité de France since many years, has necessitated, for reasons of safety and reliability, to develop efficient statistical methods enabling to estimate, on the basis of necessarily limited information, extreme natural phenomena such as :

- extreme storm surges (coastal plants) or extreme river flows (river plants), as to fix the highest possible water levels and consequently the corresponding platform levels, thus preventing from flood problems

- extreme low water levels in order to secure a continuous feeding of the intake pumping stations

- extreme waves as to define correct protections of the breakwaters.

The extreme events need to satisfy safety criteria related to return periods associated to these events : for coastal nuclear plants, these return periods are usually 100 years for waves and water level setdowns, 1000 years for water level setups and for river floods (river plants).

* Laboratoire National d'Hydraulique, Electricité de France, Chatou, FRANCE

The method presented hereafter is based on statistical methods previously developped at L.N.H. for problems of floods in rivers ; these methods, derived from the theory of renewal processes, have been adapted to the study of extreme waves, setups and setdowns. It enables a large variety of developments by comparison with the classical method of annual maxima ; in particular this method enables to precise the results by taking into account the complementary information available on a neighbouring site.

We shall only present here examples concerning extreme waves. After a short recall of the notion of return period and of the main other method used, we shall describe the principle of the "partial duration series" method, its practical use, its particular application to the use of two sets of related information, and we shall end with some examples of other applications which can prove useful.

2. THE NOTION OF RETURN PERIOD

It is certainly not useless to recall the important notion of return period and its practical meaning :

The return period T associated with the value H_T of a random variable H (wave height) is defined as the average number of years between two successive occurrencies of the event : $H > H_T$. This definition implicitly assumes a given time unit, the year, at which scale the variable H is defined, for example :

. annual maximum wave height

. significant wave height, for 20 minutes recordings, over-topped every year during 1 day, 2 days, ...

This definition does not imply any regularity of the occurrencies $H > H_T$. The basic assumptions concerning the annual successive occurrencies are :

a/ their independance

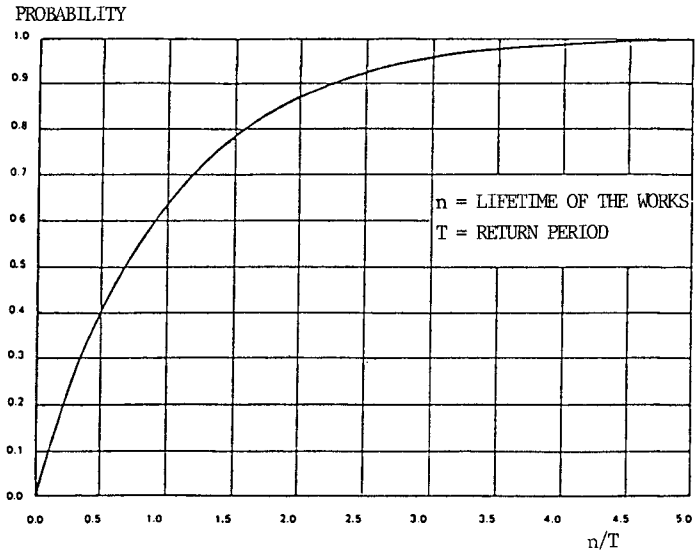
b/ the stationarity : invariance of their probabilities of occurrency during the time.

The number of years N separating two successive occurrencies of the studied event is a random variable such as :

$$\text{Prob}\left[N \leqslant n\right] = 1 - (1 - \frac{1}{T})^n \simeq 1 - e^{-\frac{n}{T}}$$

(valid for T big enough)

In practice, this formula gives, for a project whose lifetime is n, the probability of occurrence of an event whose return period is T (figure 1) :



- Figure 1 -

For example, a plant whose lifetime is 50 years (n = 50) has approximately 10% chances to see, at least once in its life, an event associated with a return period of 500 years (T = 500) ; this occurrency reaches 40% for T = 100 years, and 63% for T = 50 years, which is far from negligible.

This emphasizes the point that the return period of a given project must be chosen equal to several times the lifetime of the works in order to limit the risk of damages to an acceptable level.

3. THE STATISTICAL METHODS

The classical method of estimation of the risks associated to extreme geophysical events uses the notion of annual random variable : maximum annual wave height, maximum annual rainfalls or floods, ... : it is known as the method of annual maximas.

Considering that the risk is based on an annual time scale, it seems logical to base the estimation on series of annual maximum values derived from complete sets of data.

This method, widely used in many geophysical problems, can be applied only if the number of years of available data is sufficiant to make a reasonnable extrapolation to extreme events.

In fact, very often, the available data for marine phenomena are related to short periods of measurements, and this method of annual maxima gives information which can lead to a very important uncertainty.

Another approach enables to use a more complete information : not necessarily the complete set of basic data, which would lead to a too complex probabilistic structure, but the most "significant" information constituted of the maximum values of each storm (for sea states), these values being chosen higher than a given threshold Ho as to eliminate small and non significant values.

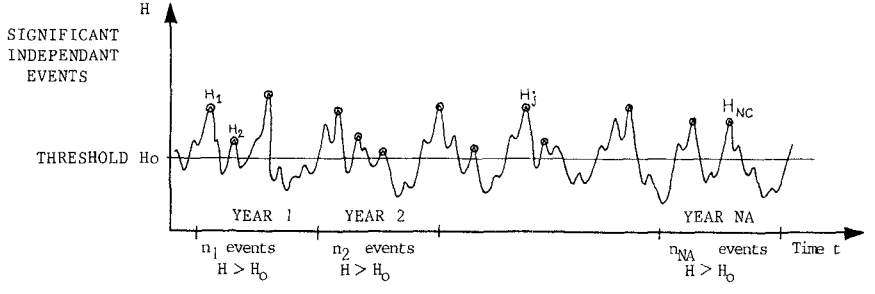
This approach, based on the theory of renewal processes (by analogy with probabilistic models used in problems of reliability of components in plants), is called the "partial duration series" method.

As we shall see hereafter, this method, compared to other classical methods, enables to use a more complete set of information (bigger than a given threshold), and is then much more efficient in the very frequent case of short periods of available data. Moreover, the method enables to provide a "confidence interval" giving the range of reliability of the obtained results.

4. THE PARTIAL DURATION SERIES METHOD

4.1. Principle of the method

Given a chronological series of wave height data (figure 2), one can define significant independant events Hj higher than a given threshold Ho as follows :



- Figure 2 - Chronology of waves

The notion of significant events, related to the threshold Ho, means that the small values corresponding to weak storms do not need to be considered in this kind of problems where we are in fact only interested in strong storms and their associated probabilistic laws enabling to extrapolate to extreme events.

The other notion of independant storms is very important and corresponds to an assumption of the method. Various definitions can be used : the simplest one consists in considering that two successive storms, characterized by their maximum wave heights Hj, are independant if the wave height between those two storms comes lower than the threshold Ho (figure 2) ; other more sophisticated, and more adapted, definitions use different thresholds (one H_1 for defining significant storms, another lower one Ho, related to H_1 as a percentage of it, defining the end of the storm), or integrate the notion of duration of calm (H < Ho) between two successive storms. In fact this notion of independance is rather difficult to appreciate automatically and must be considered very carefully and cautiously.

From this chronology of significant independant events measured during NA years, one can then define two series :

- Series $\{ n_i \}$ i = 1, NA

  where n_i is the number of events H > Ho during year i

  and P (k) is the associated probability of trespassing k times Ho during year i

- Series $\{ H_j \}$ j = 1, NC

  series of independant wave heights H_j > Ho (NC values)

  with F^k (H) associated probability that H > height > Ho during the year.

The selected storms are then interpreted as the combination of two stochastic processes : one of occurrencies (n_i , P (k)), the other of distribution of selected wave heights (H_j , F^k (H)).

For annual risks, the two processes must be combined to obtain the distribution of the annual maximum wave (same kind of procedure for decennial, centennial or other return periods) :

$$\text{Prob } (H_{max} > H) = 1 - \sum_{k=o}^{\infty} P(k).F^k(H)$$

4.2. Statistical laws

. Series of occurrencies $\{ n_i \}$:

In practice, when the selection of independant storms has been correctly made and the threshold Ho chosen high enough, the series of occurrencies most of the time follows a Poisson process of intensity

$$P(k) = e^{-\lambda}\frac{\lambda^k}{k!}$$

Generally, one assumes that the storm phenomenon is stationary, i.e. its statistical characteristics are independant of the season, which means λ = constant.

However it happens sometimes that this Poisson law does not appear realistic ; the computer program developped at LNH enables then to use also the binomial negative law for the series of occurrencies :

$$P(k) = \frac{\Gamma(\gamma + k)}{k!\,\Gamma(k)}\, p^{\gamma}(1+p)^{k}$$

$$\text{with } \Gamma(\alpha) = \int_0^{\infty} e^{-x}\, x^{\alpha-1}\, dx$$

. Series of wave heights $\{H_j\}$:

The series of wave heights can follow various statistical laws which have also to be adjusted in the method. The computer program tests automatically 4 different laws which, from experience, proved generally to be the best fitted with the wave data :

- Exponential : $\text{Prob}(h < H) = 1 - e^{-\varphi(H-Ho)}$
- Weibull : $\text{Prob}(h < H) = 1 - e^{-\varphi(H-Ho)^p}$
- Log-exponential : $\text{Prob}(h < H) = 1 - e^{-\varphi(\text{Log } H - \text{Log } Ho)}$
- Squares : $\text{Prob}(h < H) = 1 - e^{-\varphi(H^2-Ho^2)}$

In practice, for estimate of extreme wave heights, the Weibull law proved, on the french coasts, to be generally the best fitting law. It has to be noted that the exponential law is a particular application of Weibull law with p = 1.

4.3. Adjustment of the statistical laws :

For all the statistical laws tested for the series of occurrencies and heights, the various parameters characterizing the theoretical expressions (λ, φ, p in particular) are estimated through the classical statistical method of Maximum Likelihood, except for the binomial negative law (series $\{n_i\}$) where the Momentum method is used.

4.4. Validation tests

The validation of the assumptions of the model and of the adjusted distribution laws (occurrencies and wave heights series) is performed through statistical tests which are systematically applied for various thresholds Ho. These tests are :

- Serial independance test of the successive selected maximum wave

heights higher than a given threshold Ho. This test uses the classical transformation $T = \frac{\sqrt{V}\,R}{1-R^2}$, approximatively distributed according to a Student law with V degrees of freddom, where R is the autocorrelation coefficient and V the number minus 2 of couples of storms used for the calculation of R. The calculated value T is then compared with the threshold of probabilistic significance equal to 0.95.

- Classical X^2 test. The determination of the K classes necessary to the calculation of :

$$X^2 = \sum_{i=1}^{K} \frac{(n_i - v_i)^2}{v_i}$$

is made so that the theoritical absolute frequencies v_i, to be compared with the observed frequencies n_i, are equal to the constant value n/K (n is the size of the studied sample).

4.5. Confidence intervals

On the contrary of semi-empirical methods, the partial duration series method, which uses a rigorous modelisation of the probabilistic properties of the wave heights process, enables to calculate confidence intervals associated to wave heights H_T corresponding to a given return period T.

The confidence interval, associated to a confidence threshold $1-\alpha$ (70%, 90%, ...), covers the real, but unknown, value of the extreme wave height H_T with a probability equal to $1-\alpha$.

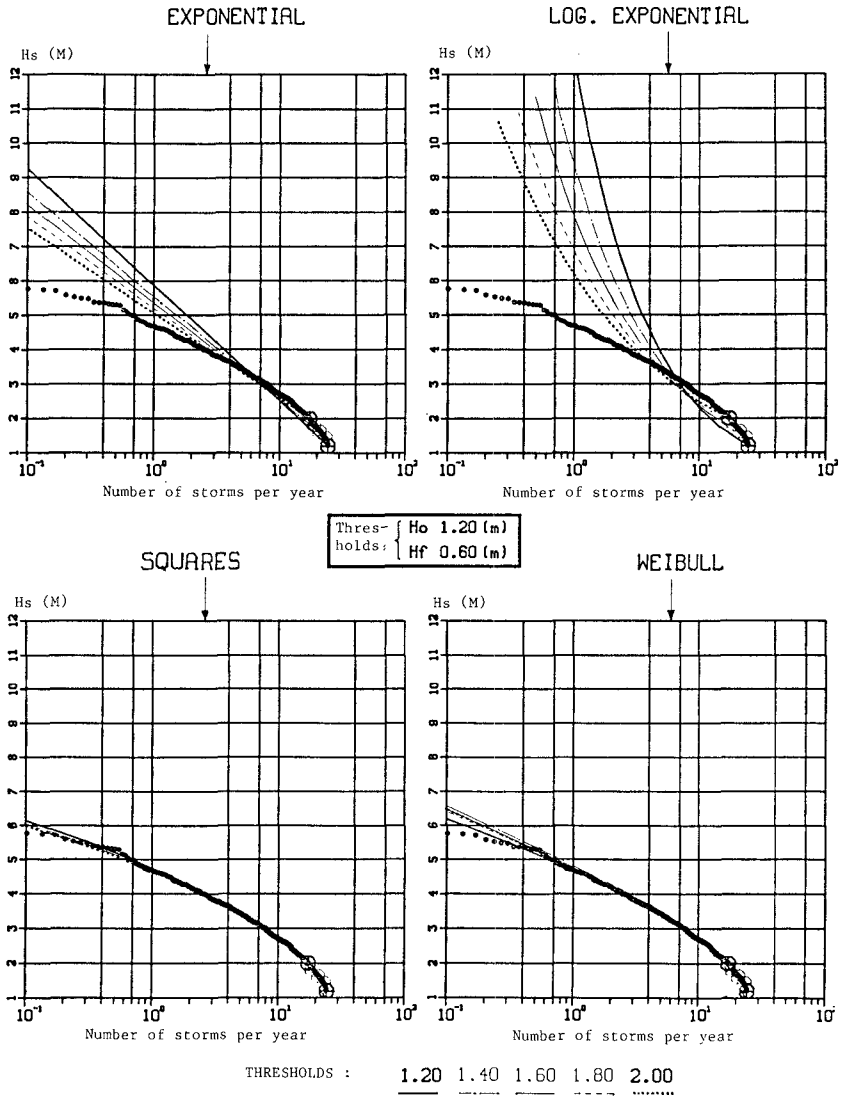
The amplitude of this confidence interval enables to measure the uncertainties on H_T related to the sampling. It is of course all the bigger as the size of the sample is smaller. The interval is calculated for each fixed statistical law, and then it does not take into account the uncertainty related to the choice of the law, this choice being made through the validation tests previously described (cf. 4.4), and through graphical adjustments (see hereafter).

The method of calculation of these confidence intervals, automatically integrated to the computer program which calculates the 70% confidence interval, uses the approximate properties of the estimations of the maximum likelikoods.

5. PRACTICAL USE OF THE METHOD

Given a sample of wave heights during a certain period of recordings, the use of the method implies different steps before leading to the final result, i.e. decennial, centennial, ... wave height with its corresponding confidence interval :

- Choice of the series of independant significant storms whose maximum wave heights H are bigger than a given threshold Ho.



- Figure 3 - Adjustment to the different laws

These wave heights can correspond to mean, or significant H 1/3, or maximum Hmax wave heights derived from the recordings, depending on the problem which is considered. As mentionned previously, different definitions of "independant" events can be chosen.

- From this sample H>Ho, the adjustments to the 4 statistical laws are tested automatically : exponential, Weibull, Log-exponential and squares law (see example of results on figure 3).

- For each statistical law, different thresholds H'o over a basic threshold Ho are tested. As a matter of fact, the threshold which will be finally chosen will have to be :

  . not too low as to represent sufficiently well the impact of the extreme observed events (we are interested here in extreme events corresponding to big return periods)

  . not too high in order to keep a sufficiently large number of events as to be able to make correct statistics on a big enough sample.

- The final choice (statistical law and threshold to be finally considered) will then be made on the basis of the three main following criteria (example of final result on figure 4) :

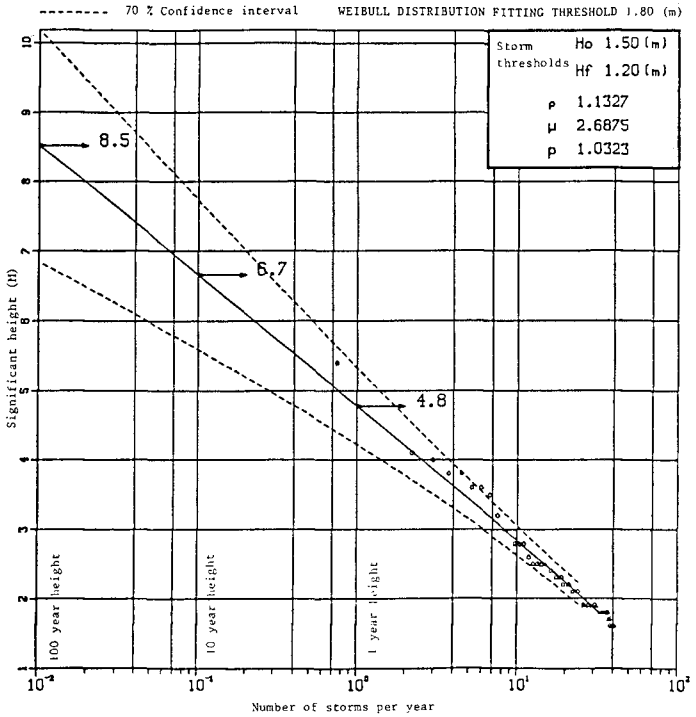


Fig.4 - Annual, decennial and centennial significant waves at BIARRITZ

. graphic adjustment : for each law and threshold, one can see visually if the theoretical adjustment fits or not with the observed values : for the example on figure 3 one can see that the squares law gives the best adjustment with the observations

. X^2 statistical tests : the method provides automatically the X^2 value for each law and threshold and gives an advice, based on statistical criteria, on wheter the adjustment should be accepted or not.

. stability with the threshold : usually, if the adjustment is good, the results on the extreme events do not depend very much on the choice of the threshold H'o.

On the basis of these criteria, one can then make his choice, which is not always very easy, especially for short periods of measurements. An example of final choice is given on figure 4 : on the site of Biarritz, south of France, where some measurements where available from may 1972 to february 1977, the Weibull law was finally chosen with a threshold H'o = 1.80 m (basic threshold Ho = 1.50 m for the definition of independant storms) ; the centennial significant H1/3 wave height (return period of 100 years) was found to be 8.5 m with a 70% confidence interval between 6.8 m and 10.2 m, showing that in this case the uncertainty on the results remains rather large (many holes in the period of measurements).

The method has been used systematically up to now, for 10 sites on the French coast (about 20 more applications are currently under progress), and shows in particular that we need, if we want to get sufficiently reliable results on a site for return periods of at least 10 years, an average period of wave measurements of about 4 years minimum, taking into account the fact that, for many reasons, on average only half of this period (about 2 complete cumulated years) will really provide reliable and useful data.

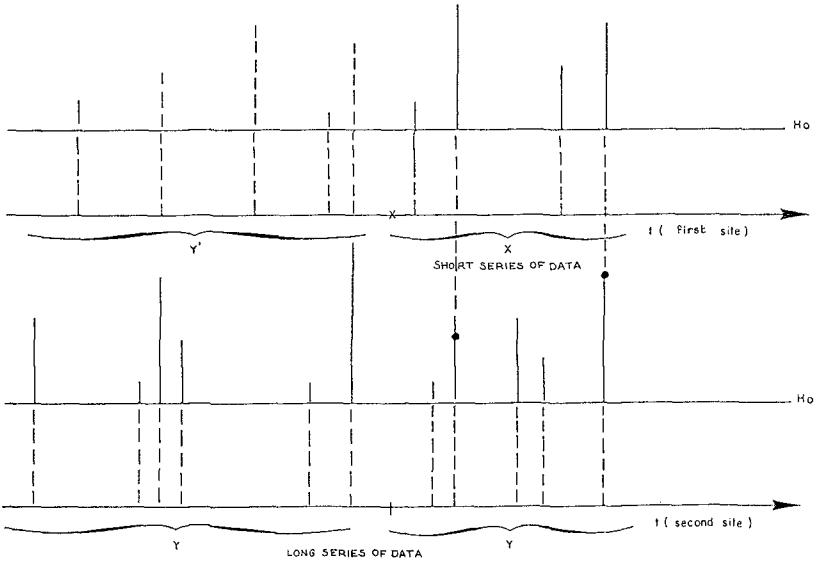
6. USE OF TWO SETS OF RELATED DATA

6.1. Principle

One of the interests of the method is that it is easy to take into account complementary information (punctual historical data, or information on a neighbouring site) in order to precise the results.

A fresent case concerning the wave recordings is that of a site where only a short series of data X is available, which can lead to a big uncertainty on the estimation of extreme events.

If there exists, on a neighbouring site, a longer series of available data Y, this complementary information can be used to precise the results on site X if there exists a good correlation between the data recorded during the concomitant period (figure 5) :



- Figure 5 - Example of concomitant and non concomitant data on the two sites

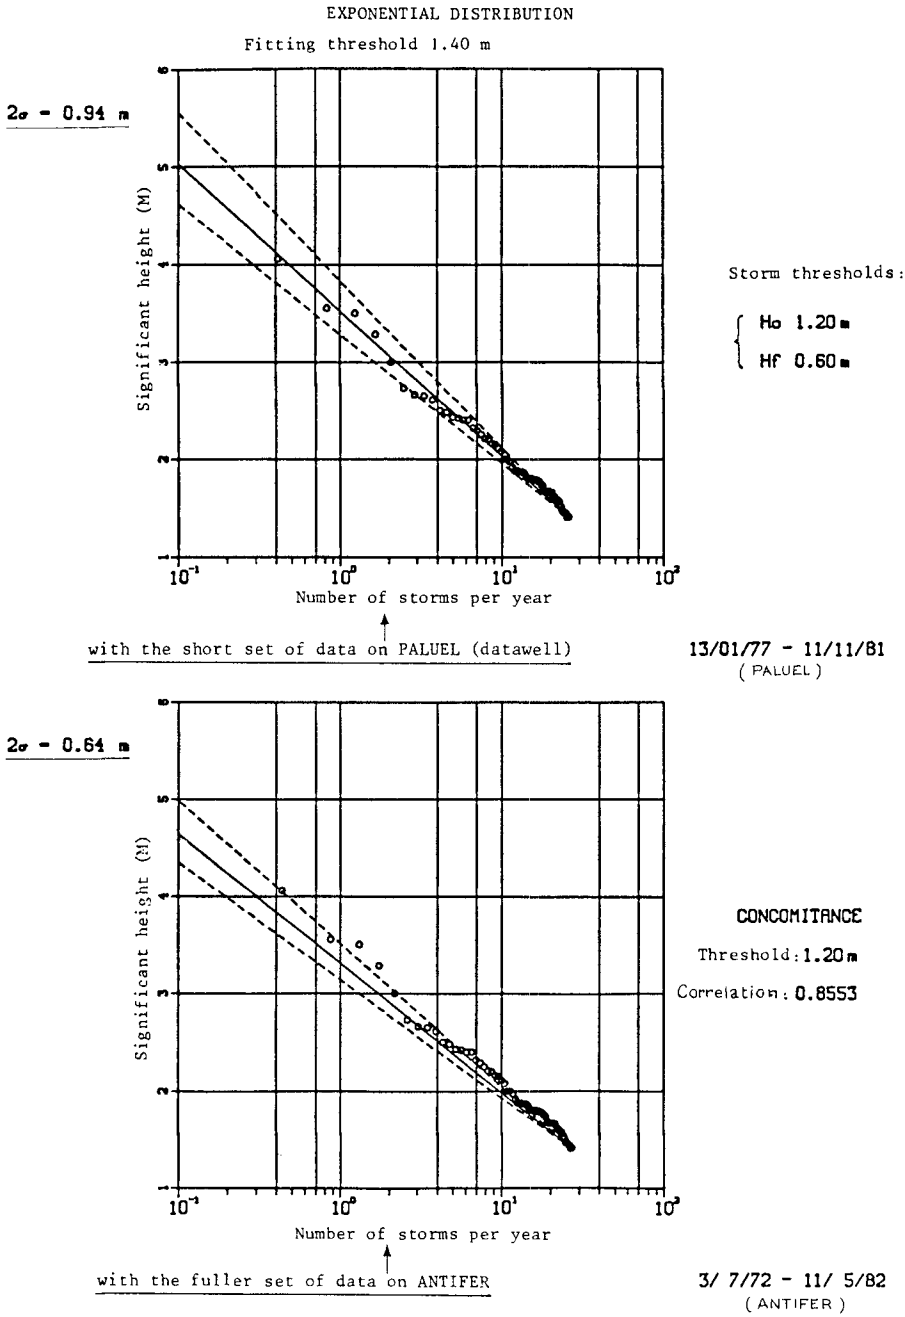
The idea is then, in this case, to complete the existing information X, Y on the two sites by a fictive information Y' corresponding to missing data on the first site.

The problem is now to estimate this missing information Y' $(Y,\lambda,\varphi, p, r)$; as a matter of fact this estimation depends, not only on the complementary existing information Y, but also on the parameters of the partial duration series (λ,φ, p), and on the correlation parameter r between the two sites.

The calibration of the model will then consist in estimating the parameters λ,φ, p and r on the basis of the real observations X completed by the rebuilt complementary fictive data Y' $(Y,\lambda,\varphi, p, r)$, which necessitates a certain preliminary knowledge of these parameters : this approach is then necessarily based on an iterative process. The E.M. algorithm (E : expectation, M : maximization) developped by Dempster and al-1977 was adopted to solve the problem.

6.2 Example

An example of application of this method is presented on figure 6 on the case of Paluel, where 5 years are available, completed by the 10 years of available data on the neighbouring site of Antifer. It shows the estimation, at Paluel, of annual, decennial and centennial significant wave heights obtained without and with the complementary Antifer information. One can see that with the exponential law chosen as the best adjustment, the decennial wave height changes from 5 m to



- Figure 6 - Estimation of the design wave at PALUEL

4.6 m with this complementary information, the confidence interval being moreover reduced from 0.94 m to 0.64 m. In this case the correlation coefficient corresponding to the concomitant data was 0.86.

6.3. Further developments

The general problems to be thought about now are to try to determine which is the minimum duration of the short series, and wich is the minimum value of the correlation in order to be sure to obtain good results.

These problems are linked and depend very much on the quality and homogeneity of the data, and on the proximity of the site where the complementary data are available, considering that we are only interested here in extreme events corresponding to strong storms which, if the neighbouring site is not too far, should reasonnably occur rather similarily on both sites.

Up to now, only the application to Paluel - Antifer has been made and no general rule (if any can be found...) can be deduced from the results. Moreoever the method was applied with various lengths of the measuring period at Paluel (6, 9, 12, 21 and 24 months), showing that, in this case, at least 21 months of cumulated available data were necessary, the correlation coefficient varying from 0.61 (with 6 months) to 0.84 (21 months).

Some applications to other sites are planned and should provide interesting information on these particular points. It seems nevertheless that the degree of correlation between the two sites should be at least 0.8 as to be able to get reliable results on the first site.

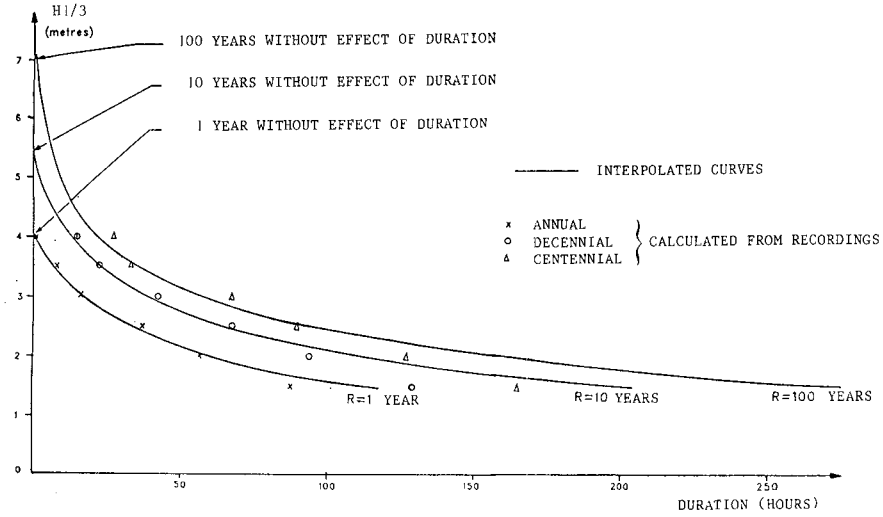
7. OTHER POSSIBLE APPLICATIONS

Without going into detail in the various applications which have been made with the partial duration series method, we can mention some of them and some further developments associated with the method :

- Integration of historical data : the same kind of methodology as described for two sets of related data can be used in the case where punctual historical data are available. This is often the case for setups or river floods, and can also, but less often, happen for waves ; this complementary information can be introduced in the data in order to precise the results concerning extreme events.

- Duration of the storms : for a given sample of wave recordings H>Ho, one can associate a complementary third series of data $\{ Dj \}$ corresponding to the durations of the storms. Then a statistical analysis of these durations, being made for various increasing thresholds H'o through the partial duration series method, can be

performed in order to associate to a given return period, a series of wave heights with their corresponding durations ; this gives then a much more complete information than only the classical extreme wave height associated to a "zero" duration. This has been made for different sites on the french coast and gives very interesting results which can be used for many purposes (example of height - duration diagram at Antifer on figure 7).



- Figure 7 - Height - duration diagram at ANTIFER

- Effect of the sampling interval : very often wave measurements are made every 2 or 3 hours, sometimes rather continuously (every 20 or 40 minutes for example). Then a study has been made to see the effect of the chosen sampling interval on the results ; this study is in fact very connected with the previous one on the durations of storms.

- Effect of the definition of independant storms : different definitions, more or less sophisticated, have also been tested and gave some interested information which, as for the other applications hereabove mentionned, cannot unfortunately be described here in detail.

8. CONCLUSIONS

The partial duration series method has been systematically applied to extreme wave heights on a certain number of sites on the french coast, through an automatic procedure developped in a computer program. Similar versions applied to setups, setdowns and river floods have been used for the setting of nuclear platforms along the coast or rivers. The basic philosophy of elaboration of the method

was to develop practical tools enabling a complete calculation of extreme waves, from the preparation of data, the determination of analysed events, the statistical validation of the assumptions, the adjustments of the laws, to the final presentation (graphic in particular) of the results.

The need of promoting methods adapted to the most common applications encountered in practice led to develop also procedures and methods enabling in particular the treatment of various types of incomplete information.

Further useful developments can be envisaged concerning in particular the adjustment of a non-stationnary model (effect of the seasons in particular) and of a model of treatment of the missing data.

CHAPTER 43

WAVE GROUP PROPERTY OF WIND WAVES FROM MODULATIONAL INSTABILITY

Hajime Mase* and Yuichi Iwagaki, M.ASCE**

ABSTRACT

This paper discusses wave grouping of wind waves from the physical viewpoint of wave modulational instability. Amplitude modulation periods obtained from the smoothed instantaneous wave energy history (SIWEH) of the observed data are compared with the predicted values by the modulational instability theory using the Zakharov equation for a finite constant water depth derived by Stiassnie and Shemer(1984). The modulation period normalized by the typical wave period corresponds to the length of total run. It is shown that the amplitude modulation periods of the observed data agree satisfactorily with the predicted values. Thus we conclude that the modulational instability is a hydrodynamical cause of grouping of high waves.

INTRODUCTION

In recent years wave grouping has been recognized by coastal engineers as an important factor for the stability of rubble mound breakwaters, the fluctuation of wave overtopping quantity of seawalls, the slow drift oscillation of moored vessels and floating structures, the surf beat and so on. Johnson, Mansard and Ploeg(1978) have found by laboratory experiments that even if power spectra of random waves are the same, the degree of damage of a rubble mound breakwater is not the same but depends on the degree of wave grouping; that is, grouped waves cause more severe damage of the breakwater than non-grouped waves.

There are three kinds of theoretical approaches to the statistical properties of run length and total run length of wave heights. One is the theory by Goda(1970) for waves of which successive wave heights are independent, the second is the wave envelope theory by Nolte and Hsu(1973) and Ewing(1973) for waves with narrow-banded spectra, and the third is the Markov process theory by Kimura(1980) for waves of which successive wave heights are mutually correlated with the property of the Markov chain. Elgar, Guza and Seymour(1984)

* Research Associate, ** Professor, Department of Civil Engineering, Kyoto University, Kyoto, 606, Japan

reviewed these existing theories and showed that the theories have internal inconsistencies in their assumptions and treatments.

Studies on statistical properties of wave groups of ocean waves have been carried out by Wilson and Baird(1972), Rye(1974), Chakrabarti and Snider(1974), Goda(1976), Burcharth(1980), Goda(1983), Elgar et al.(1984), Mase and Iwagaki(1984) and Battjes and van Vledder(1984). In these studies, observations of wave group statistics have been compared with the theoretical predictions or with the numerical simulation data. It seems from these studies that among the theories of run length Kimura's theory is most applicable to waves with not only narrow-banded but also wide-banded spectra if the correlation parameter which appears in the two-dimensional Rayleigh distribution and is related to the correlation coefficient of successive wave heights is chosen adequately. However, when the correlation coefficient is larger than 0.4, the mean length predicted by the theory of Kimura is always shorter than the observed one (Mase and Iwagaki, 1984).

Most of the studies concerning wave groups including theories are based on a statistical viewpoint. The existing theories are not based on hydrodynamics of wave motion but consider only statistical wave properties, such as the wave energy spectrum or the wave height distribution. Wave groups are also significant in coastal engineering from a viewpoint of hydrodynamics. One is the modulational instability and the evolution of finite amplitude surface waves. The other is a new model of wind waves such as the envelope soliton model proposed by Mollo-Christensen and Ramamonjiarisoa(1978) (wind wave fields are not composed of linear component waves but composed of envelope solitons which are formed by Stokes waves) and the modulated nonlinear wave model shown by Lake and Yuen(1978) (wind wave fields are considered as a modulated nonlinear wave train with a single carrier wave).

The grouping of high waves can be explained by two different viewpoints. One is the statistical viewpoint in which wave group statistics are discussed in a framework that wave fields are thought to be the superposition of independent linear component waves. The other is the hydrodynamical viewpoint such as the modulational instability. Benjamin and Feir(1967) have made it clear that a uniform wave train in deep water is unstable and that it evolves into a modulated wave train. Lake and Yuen(1978) compared the theoretical modulation frequency by Benjamin and Feir(1967) with the observed one of laboratory wind waves. It was found that both agree qualitatively.

Even if a parameter representing wave groups is a statistical quantity, the characteristic dominated by hydrodynamics is probably contained in the statistical quantity. The objective of this paper is to discuss the wave group property of natural wind waves from the hydrodynamical viewpoint. Concretely, we compare the observed amplitude modulation periods (or repetition periods of groups of high waves) with the predicted ones from the modulational instability theory using the Zakharov equation. The modulation periods normalized by the typical wave period correspond to the lengths of total runs.

ANALYZED WAVE DATA

Wave data used in this paper were collected at Hikone-Aisei of

Lake Biwa in Shiga Prefecture, Japan, where eleven wave gauges of capacitance type were installed. Wave observations at Hikone-Aisei Wave Observatory and Nagahama Wave Observatory were started by Iwagaki et al.(1976) in March, 1975, for the duration of a year to examine properties of fetch-limited wind waves.

Wave data analyzed for amplitude modulation periods are four continuous records of storm waves for five hours from 11:27, 18:00, and 23:00 on October 5, and from 18:30 on December 16, 1975, recorded by the wave gauge N-9 installed in water depth of 4m. The first two have been analyzed in the previous paper (Mase and Iwagaki, 1984) from the statistical viewpoint. The predominant wave direction was NW when the waves analyzed here were recorded, which was nearly perpendicular to the shoreline. The slope of the beach was nearly uniform and approximately 1/50.

The records were digitized at a sampling interval of 0.04 s and recorded on a magnetic tape. These continuous wave records were divided into fourteen segments of twenty minutes long. Fig.1 shows the time series of the significant wave height, $H_{1/3}$, the significant wave period, $T_{1/3}$, the mean wave height, $\overline{H}$, and the mean wave period, $\overline{T}$. The numbers of individual waves contained in each wave record were about 300 to 600.

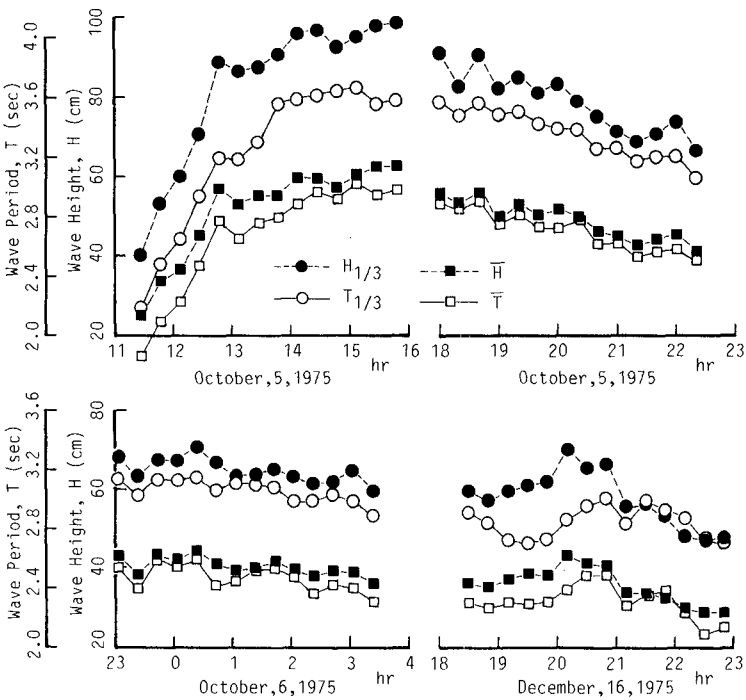

Fig.1. Time series of significant wave height, significant wave period, mean wave height and mean wave period.

AMPLITUDE MODULATION PERIOD BY MODULATIONAL INSTABILITY THEORY

As for the analysis of modulational instability of waves, it has been shown by Crawford, Lake, Saffman and Yuen(1981) that the Zakharov equation first derived by Zakharov(1968) is a useful equation which can consider the effect of finite amplitude. In this section, we describe the theory of modulational instability using the Zakharov equation according to Crawford et al.(1981) and Stiassnie and Shemer(1984), and later we compare the amplitude modulation period predicted by the theory with the observed one. Crawford et al.(1981) used the third order Zakharov equation for infinite deep water, and Stiassnie and Shemer(1984) derived the Zakharov equation to the fourth order for constant (finite or infinite) water depth and investigated the Class I and Class II instabilities by using the modified Zakharov equation. In this study, we use the Zakharov equation up to the third order for finite water depth derived by Stiassnie and Shemer(1984).

Let $B(\boldsymbol{k},t)$ be a kind of amplitude spectrum. The Zakharov equation to the third order is expressed as follows (Crawford et al. and Stiassnie et al.):

$$i\frac{\partial B(\boldsymbol{k},t)}{\partial t} = \iiint_{-\infty}^{\infty} T(\boldsymbol{k},\boldsymbol{k}_1,\boldsymbol{k}_2,\boldsymbol{k}_3)B^*(\boldsymbol{k}_1,t)B(\boldsymbol{k}_2,t)B(\boldsymbol{k}_3,t) \times \delta(\boldsymbol{k}+\boldsymbol{k}_1-\boldsymbol{k}_2-\boldsymbol{k}_3)\exp\{i\{\omega(\boldsymbol{k})+\omega(\boldsymbol{k}_1)-\omega(\boldsymbol{k}_2) - \omega(\boldsymbol{k}_3)\}t\}\,d\boldsymbol{k}_1 d\boldsymbol{k}_2 d\boldsymbol{k}_3, \quad (1)$$

where $*$ denotes the complex conjugate, $\boldsymbol{k}=(k_x,k_y)$ is the wavenumber vector, ω is the angular frequency related to the wavenumber as $\omega(\boldsymbol{k})=(g|\boldsymbol{k}|\tanh|\boldsymbol{k}|h)^{1/2}$, and δ denotes the delta function. Eq.(1) represents the interaction of amplitude spectra or the slow evolution of the dominant components of waves. The kernel $T(\boldsymbol{k},\boldsymbol{k}_1,\boldsymbol{k}_2,\boldsymbol{k}_3)$ (abbreviated as $T_{0,1,2,3}$ hereafter) is shown in the paper of Stiassnie and Shemer(1984). Since there are some misprints in the expression of the kernel, we used the correct expression informed directly by Dr. Stiassnie. The kernel $T_{0,1,2,3}$ is seen in Mase and Iwagaki(1986).

In the case of a uniform wave train with the wavenumber vector $\boldsymbol{k}_0=(k_0,0)$, the solution of Eq.(1) is

$$B_0(\boldsymbol{k}_0,t) = b_0\exp(-iT_{0,0,0,0}b_0^2 t), \quad (2)$$

where $T_{0,0,0,0}b_0^2$ is the Stokes corrected frequency due to the nonlinearity and b_0 is related to the actual amplitude a_0 as follows:

$$b_0 = \pi\left(\frac{2g}{\omega_0}\right)^{1/2}a_0. \quad (3)$$

When disturbances with the wavenumber vectors $\boldsymbol{k}_1=\boldsymbol{k}_0-\boldsymbol{K}$ and $\boldsymbol{k}_2=\boldsymbol{k}_0+\boldsymbol{K}$ with the amplitudes $B_1(\boldsymbol{k}_1,t)$ and $B_2(\boldsymbol{k}_2,t)$ ($|B_1|, |B_2| \ll |B_0|$) are imposed on the uniform wave train, the time evolutions of B_1 and B_2 are

written from Eq.(1) neglecting the squares of small quantities by

$$i\frac{dB_1}{dt} = 2\,T_{1,0,1,0}b_0^2B_1 + T_{1,2,0,0}B_2\,b_0^2\exp(-i\tilde{\omega}t), \tag{4}$$

$$i\frac{dB_2}{dt} = 2\,T_{2,0,2,0}b_0^2B_2 + T_{2,1,0,0}B_1\,b_0^2\exp(-i\tilde{\omega}t), \tag{5}$$

here, $\tilde{\omega} = (2\,\omega_0 - \omega_1 - \omega_2) + 2\,T_{0,0,0,0}b_0^2$. Assuming a solution of the form

$$B_1 = b_1\exp\{-i(0.5\,\tilde{\omega} - \Omega)t\}, \tag{6}$$

$$B_2 = b_2\exp\{-i(0.5\,\tilde{\omega} + \Omega)t\}, \tag{7}$$

the following equation is obtained using the condition that the non-trivial solutions of b_1 and b_2 exist:

$$\Omega = (T_{2,0,2,0} - T_{1,0,1,0})b_0^2 \pm\sqrt{\{0.5\,\tilde{\omega} - (T_{1,0,1,0} + T_{2,0,2,0})b_0^2\}^2 - T_{1,2,0,0}T_{2,1,0,0}b_0^4}. \tag{8}$$

When Ω is not real, disturbances grow exponentially with time and amplitude modulations occur, which means the instability of waves.

For the two-dimensional case such as $K=(K_x,0)$, the non-dimensional perturbation wavenumber κ is defined by K_x/k_0. Fig.2 shows the non-dimensional growth rate $\mathrm{Im}(\Omega)/(\omega_0k_0^2a_0^2/2)$ as a function of $\kappa/2k_0a_0$ for various values of k_0a_0 and for five values of k_0h. Fig.2(a) is the same result as given by Crawford et al.(1981). In experiments with deep water waves by Lake, Yuen, Rungaldier and Ferguson(1977), it was found that even if a uniform wave train is generated by a wave-making paddle the wave train modulates with increase in the propagation distance due to the growth of the most unstable mode which corresponds to the peak of each curve in Fig.2. For example, when waves are generated for which $k_0a_0=0.1$, disturbances with $\kappa/2k_0a_0=0.87$ grow in the case of deep water, see Fig.2(a). It is seen from Fig.2 that the domain of the non-dimensional wavenumber $\kappa/2k_0a_0$ becomes narrow and the non-dimensional growth rate of disturbances $\mathrm{Im}(\Omega)/(\omega_0k_0^2a_0^2/2)$ decreases with decrease in k_0h for the same value of k_0a_0, when $k_0a_0\leqq0.3$. The modulational instability cannot occur if the non-dimensional water depth k_0h is smaller than 1.36.

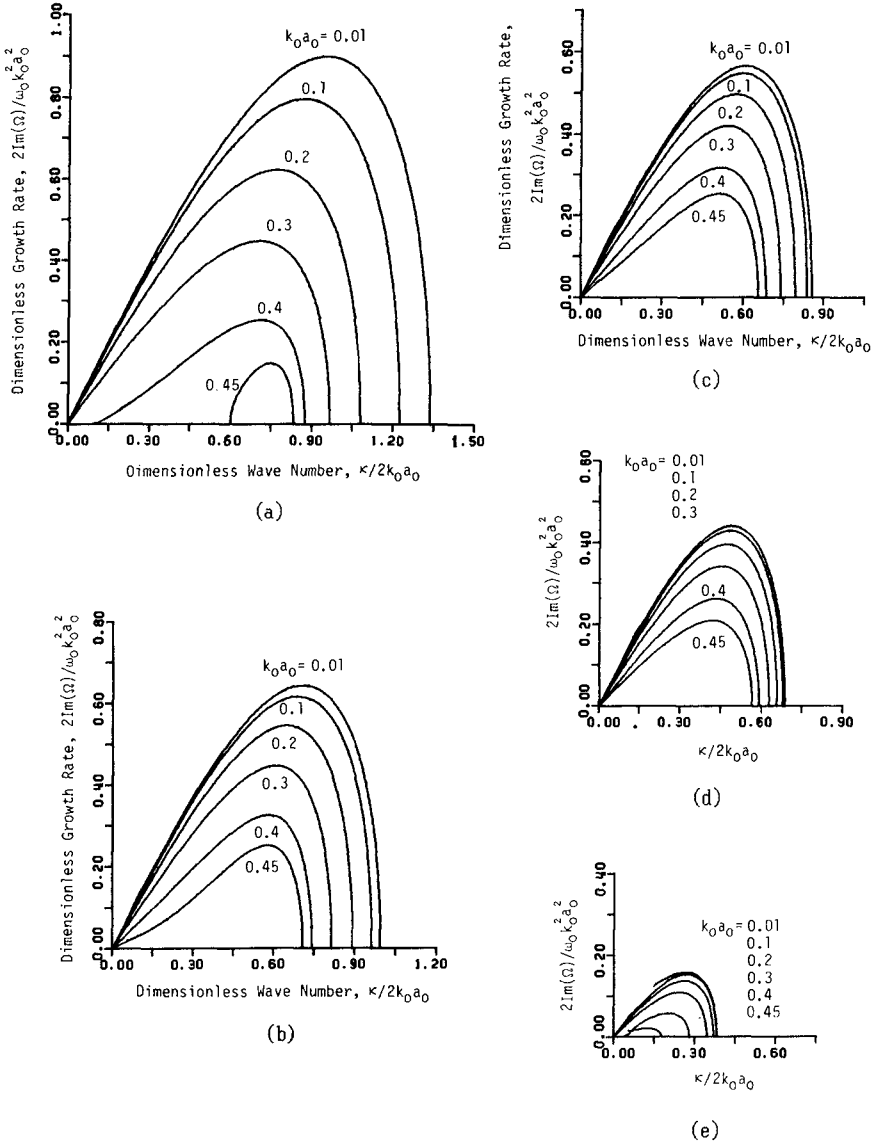

Fig.2. Wave instability diagram. (a) k_0h=10.0; (b) 3.0; (c) 2.5; (d) 2.0; (e) 1.5.

The amplitude modulation period to be compared with the observed modulation period is calculated as follows. For given values of k_0a_0 and k_0h, the value of κ corresponding to the most unstable mode is found. The frequencies of disturbances are given as function of κ by

$$\omega_1' = \omega_1 + 0.5\,\tilde{\omega} - \mathrm{Re}(\Omega), \tag{9}$$

$$\omega_2' = \omega_2 + 0.5\,\tilde{\omega} + \mathrm{Re}(\Omega), \tag{10}$$

where $\mathrm{Re}(\Omega)$ denotes the real part of Ω. The frequency of the dominant wave including the Stokes correction is

$$\omega = \omega_0 + T_{0,0,0,0}b_0^2. \tag{11}$$

The non-dimensional difference between frequencies of the dominant wave and disturbances becomes

$$\Delta = (\omega - \omega_1')/\omega = (\omega_2' - \omega)/\omega$$

$$= \{0.5(\omega_2 - \omega_1) + \mathrm{Re}(\Omega)\}/\omega. \tag{12}$$

Finally, the amplitude modulation period is given by

$$T_g = 2\pi/\Delta\omega. \tag{13}$$

Until now we have used the wavenumber k_0 and the amplitude a_0 of a carrier wave. Wave characteristics obtained by experiments and field observations are not a_0 and k_0, but the wave height H and the wave period T. Therefore, we have to estimate a_0 and k_0 by using H and T. In the estimation of a_0 and k_0 from H, T and the water depth h, we can use the third order Stokes wave theory. Since, however, waves observed in fields are not uniform, and it is not known what quantity we should use as the carrier wave. Lake and Yuen(1978) used the average wave steepness in comparing the experimental results of modulation frequencies with the theoretical values of Benjamin and Feir(1967). In this study, we adopt the significant waves or the mean waves as the carrier waves for the time being, and use $H/2$ as a_0 and the wavenumber determined from T and h by the small amplitude wave theory as k_0.

Fig.3 shows the time series of values of ka and kh obtained from the significant wave (designated with subscript '1/3') and from the mean wave (designated with subscript 'm').

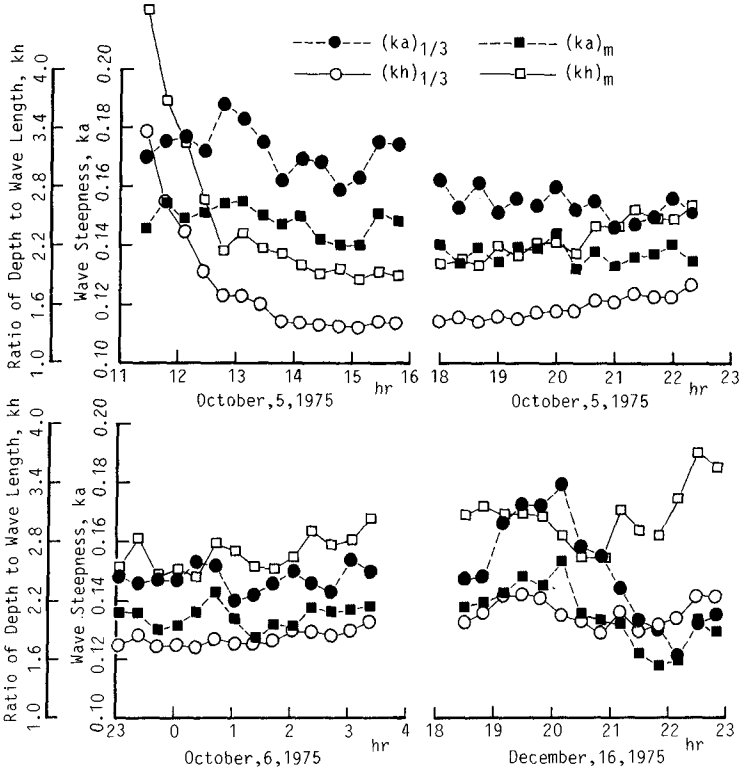

Fig.3. Time series of wave steepness ka and dimensionless water depth kh.

COMPARISON OF OBSERVED AMPLITUDE MODULATION PERIOD WITH PREDICTED ONE BY MODULATION INSTABILITY THEORY

We use the smoothed instantaneous wave energy history (SIWEH) proposed by Funke and Mansard(1979) to calculate the amplitude modulation period of field data. The SIWEH, $E(t)$, is described by

$$E(t) = \frac{1}{T_p} \int_{-\infty}^{\infty} \eta^2(t+\tau) Q(\tau) d\tau, \tag{14}$$

$$Q(\tau) = \begin{cases} 1 - |\tau| / T_p & |\tau| < T_p \\ 0 & |\tau| \geqq T_p \end{cases}, \tag{15}$$

where T_p is the peak period of an energy spectrum, $\eta(t)$ the water surface variation, and τ the time lag.

The amplitude modulation period can be estimated from the SIWEH by various methods. One is to use the peak period of the energy spectrum of SIWEH, $(T_g)_{MP}$. The other is to use the mean value of the zero-up-crossing times of $\{E(t)-\bar{E}\}$, $(T_g)_{MF}$, in which the SIWEH is modified so that the component waves of which frequencies are lower than $0.5/(T_g)_{MP}$ and higher than $1.5/(T_g)_{MP}$ are removed by using the Fast Fourier Transform technique. The amplitude modulation periods $(T_g)_{MP}$ and $(T_g)_{MF}$ almost agree, see Mase and Iwagaki(1986).

Fig.4 shows the comparison of the observed modulation periods $(T_g)_{MP}$ and $(T_g)_{MF}$ with the predicted ones $(T_g)_{CS}$ and $(T_g)_{CM}$ where $(T_g)_{CS}$ is calculated from the significant wave and $(T_g)_{CM}$ from the mean wave by Eq.(13). The predicted values larger than 40.0 s are plotted at 40.5 s in the figure. The values of $(T_g)_{CS}$ are large compared with the observed values except from 11:30 to 12:10 on

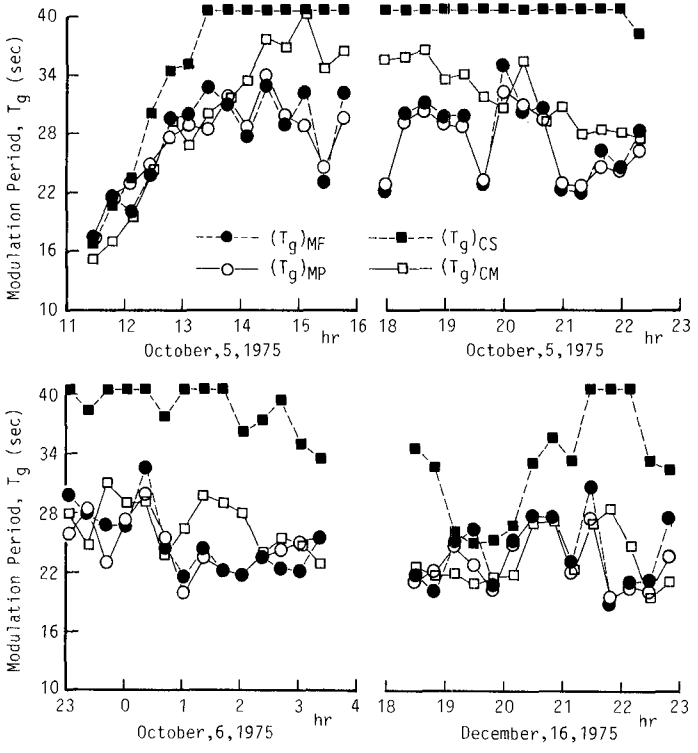

Fig.4. Time series of observed and predicted amplitude modulation periods.

October 5 and from 19:10 to 20:10 on December 16 where the value of $(kh)_{1/3}$ is larger than 2.0. On the other hand, the values of $(T_g)_{CM}$ agree fairly well with the observed data in a wide range. It is seen from the figure that we should better use the mean wave as the carrier wave than the significant wave. However, the values of $(T_g)_{CM}$ are always larger than the observed ones when the value of $(kh)_m$ is smaller than 2.1 (14:30 to 19:30 on October 5).

Fig.5 shows the comparison of $(T_g)_{MF}$ and $(T_g)_{CM}$ in a different form. This figure indicates that the agreement between both values is satisfactory as far as the mean values are concerned. When the non-dimensional water depth $(kh)_m$ is small, the difference between the predicted values and observed ones becomes large the reason is explained in the following discussion.

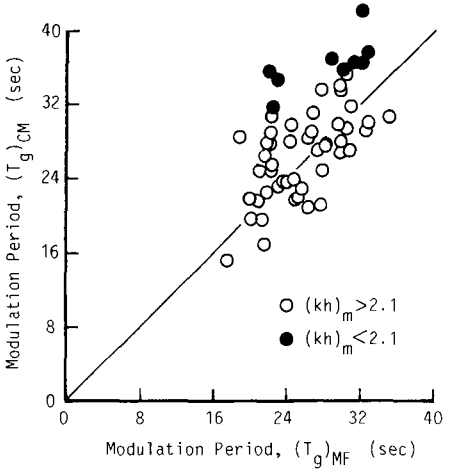

Fig.5. Comparison of observed amplitude modulation period with predicted one.

DISCUSSION

The Zakharov equation derived by Stiassnie and Shemer(1984) was applied to the present study. In spite of the sloping beach of 1/50, the modulational instability theory by the Zakharov equation can predict the amplitude modulation periods of wind waves sufficiently when the non-dimensional water depth is large ($(kh)_m$>2.1 according to the present study). However, there are slight differences between the observed and predicted values of amplitude modulation periods in the case when the water depth is relatively shallow. As shown in Fig.2, the growth rate of disturbances becomes small and the difference between frequencies of the dominant wave and the disturbances becomes

small with decrease in the water depth. Thus, for waves propagating from deep water into a region with small water depth (as $(kh)_m<2.1$), it is considered that amplitude modulations to be formed do not take place sufficiently due to the small growth rate of sideband modes, and that the deep-water amplitude modulation period remains dominant at the shallow-water observation point.

In the experiments of evolutions with the fetch or with the propagation distance of laboratory wind waves by Hatori(1984) and of mechanically generated random waves by Mase, Furumuro and Iwagaki(1984), it was found that there are several significant spikes, or sideband modes around the spectral maximum. The existence of sideband modes indicates that a phenomenon of wave modulational instability occurs in wave fields. Furthermore, Fig.5 in this paper and Fig.13 in the paper of Lake and Yuen(1978) both show that the modulational instability is an important factor in grouping of high waves.

At present, random waves used in experiments are simulated so that their energy spectrum matches a certain target spectrum. However, the sequence of waves, or wave groups, must be considered to simulate the more realistic sea waves. Funke and Mansard(1979) proposed a new technique of random wave simulation which simulates waves to match a target spectrum and a target SIWEH. Mase, Kita and Iwagaki(1983) used the same technique to simulate random waves. From the present study, it is found that the agreement between the amplitude modulation periods obtained from SIWEH of field data and predicted ones by the modulational instability theory is fairly good. This implies that the mean value of repetition periods or the peak period of the target SIWEH used in the random wave simulation must coincide with the theoretical modulation period determined from the wave height and the wave period.

CONCLUSIONS

The grouping of high waves can be explained by two different viewpoints, the statistical and physical viewpoints. Most studies concerning wave groups including run theories depend on the statistical viewpoint. In this paper, we discussed the wave group property of wind waves from the physical viewpoint of wave modulational instability. We chose the amplitude modulation period as a representative factor of the wave group property. The modulation period was calculated from the smoothed instantaneous wave energy history. The theoretical modulation period was calculated by the modulational instability theory using the Zakharov equation.

A comparison of the observed and theoretical modulation periods showed acceptable agreement if the mean wave was chosen as the carrier wave. In particular, when the non-dimensional water depth is as large as $(kh)_m>2.1$, both periods agree well. However, there was a slight difference between both values in the case of shallow water depth, which is attributed to the small growth rate of sideband modes and the effect of the remaining modulation period dominant in the deeper water depth. Thus we conclude that the modulational instability is a hydrodynamical cause of grouping of high waves.

ACKNOWLEDGMENT

We would like to thank Dr. M.Stiassnie, Department of Civil Engineering of Technion (Israel), for his kind suggestion to the Zakharov equation.

CHAPTER 44

ON THE GROWTH OF WATER WAVES BY TURBULENT WIND

H. Mitsuyasu[1)] and T. Kusaba[1)]
Professor Research Associate

Abstract

The growth of water waves by turbulent wind is studied on the basis of typical results of recent studies. It is shown that the energy input from wind to a spectral component is not much affected by the existence of the other spectral components, and the dimensionless growth rate β/f is uniquely determined by u_*/c if the friction velocity u_* measured over the water surface is used for the analysis. It is also shown that steep monochromatic waves without wind action show very complicated spectrum, but, under the wind action, they tend to be a continuous spectrum which has a spectral peak near the frequency of the lower side band and satisfy the 3/2 power law.

1. Introduction

Since the very famous studies of Miles (1957) and Phillips (1957), great many studies have been made on the growth of water waves by turbulent wind. Particularly many reliable results of field and laboratory measurements have been reported on the growth rate of water waves by turbulent wind (Snyder et al. 1981, Plant 1982, Hsiao & Shemdin 1983).

However, there still remains several fundamental problems that are not fully understood. For example, the following questions are still difficult to answer; Is the growth of dominant wave affected by high frequency waves overlapping on the dominant wave ? Is the energy transfer from wind to a certain spectral component affected by the existence of the other spectral components ? What is the role of wave breaking in the process of wave growth ?

In order to answer these questions and to clarify the fundamental process of wind-induced growth of water waves, discussions are made on the basis of typical results of our recent studies. Although individual studies have been published elsewhere (Mitsuyasu & Honda 1982, Kusaba & Mitsuyasu 1984, Kusaba & Mitsuyasu 1986), important results are combined and discussed in the present paper.

2. Experiments

The following three laboratory experiments have been conducted;

Experiment 1; The wind-induced growth of mechanically-generated monochromatic waves with relatively small steepness has been measured in a wind wave flume both for ordinary tap water and for water containing a surfactant (Mitsuyasu & Honda 1982). In the former water, wind waves are generated and overlap on the mechanically-generated waves, while in the latter water, no wind waves develop on the surface of the mechanically-generated waves. Thus we can measure the wind-induced growth of monochromatic waves with or without the effects of wind waves overlapping on the monochromatic waves. Thirty different waves were used in the experiment; their periods were in a range 0.6 sec $\sim$1.3 sec and their steepness without wind action were in a range 0.01$\sim$0.06. The wind speed was changed successively as 5, 7.5, 10, 12.5 (m/s).

Experiment 2; Similar measurements have been made for mechanically-generated composite waves which have two different frequency components to clarify the effects of other spectral components on the energy transfer from wind to a certain spectral component (Kusaba & Mitsuyasu 1984). As shown in Table-1 two kinds of composite waves were used for the experiment. One has two component waves with much different period, i.e., T =0.6 sec and T =1.2 sec. Another one has two component waves with similar periods, i.e., T =0.6 sec and T =0.7 sec.

Experiment 3; The wind-induced growth of unstable monochromatic waves with relatively large steepness has been measured in the same wind-wave flume for ordinary tap water to clarify the effect of nonlinear instability on the wind-induced growth of water waves (Kusaba & Mitsuyasu 1986). The properties of the waves without wind action are shown in Table-1. The wave (7)(T =0.5 sec, H =1.7 sec, H/L=0.044) is a stable one which is used for the comparison, e.g., to verify the empirical relation derived from the results of the Experiment 1, or to compare its growth properties with those of the unstable waves (8) and (9).

All of the measurements have been done in a wind-wave flume 0.8 m high, 0.6 m wide and with a usual test-section length of 15 m (Fig.1). Waves were measured with resistance type wave gauges at eleven stations (eitht stations for Experiment 3) of 1 m interval. Experimental conditions are summerized in Table-1, where Ur is a reference wind speed measured at the inlet of the test section. Power spectra of every waves were obtained through a FFT method and the spectral energy of the fundamental component was analyzed in the studies. The friction velocity of the wind was

determined from the vertical wind profiles measured above the water surface in the test section. More detailed descriptions of the experiment are referred to the individual papers (Mitsuyasu & Honda 1982, Kusaba & Mitsuyasu 1984, Kusaba & Mitsuyasu 1986).

3. RESULTS AND DISCUSSIONS

3.1 Wind-induced growth of monochromatic waves with or without overlapping short waves.

Monochromatic waves superimposed by high frequency wind waves grow exponentially with fetch. Their exponential growth rates, β show a quadratic relation to the friction velocity of the wind, u_*,

$$\beta / f = 0.34 \, (u_*/c)^2, \qquad (1)$$

where f is the frequency of the waves and c is the corresponding phase velocity. Almost the same relation holds for the monochromatic waves with smooth surface, i.e., without overlapping wind waves, if the measured friction velocity of the wind is used for the relation (Fig.2).

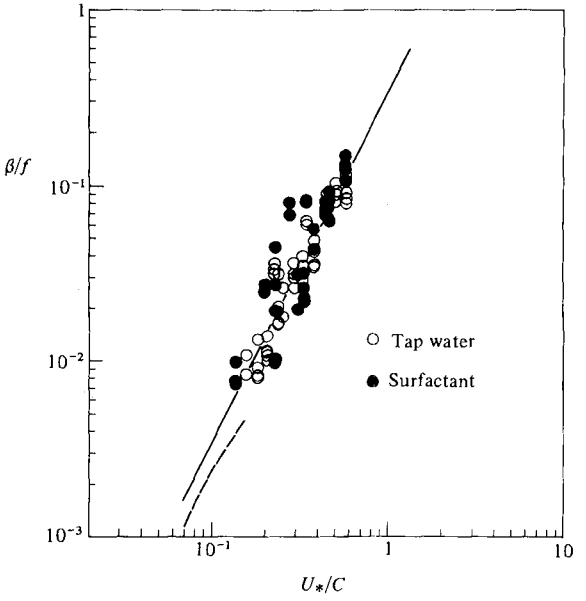

Fig.2 Comparison of β/f for tap water with that for water containing surfactant. The solid line is (1) and the broken line is (2).

For the latter case, the measured growth rate is smaller than that for the former case, but the friction velocity of the wind is also small, and the same relation between β/f

and u_*/c holds for the both cases. A kind of u_*/c similarity is satisfied for the growth of water waves by turbulent wind. We can say, from these results, that the effect of steep short waves overlapping on longer waves are to increase the growth rate of the longer waves through the increase of the downward momentum flux of the wind.

In Fig.2 the broken line corresponds to the empirical relation from Snyder et al. (1981):

$$\beta / f = 0.04 u_*/c - 1.7 \times 10^{-3}, \qquad (2)$$

which is obtained from their original form for the growth-rate parameter $Im\gamma$, $Im\gamma = (0.2 \sim 0.3)(U_5/c-1)$, using the relation $\beta/f = 2\pi(\rho a/\rho w)\, Im\gamma$ and assuming $\rho a/\rho w = 1.2 \times 10^{-3}$ and $U_5 = 23 u_*$. Figure 2 shows that the empirical relation (1) gives slightly larger growth rate than that given by (2) of Snyder et al. (1981) in a region near $u_*/c = 0.1$.

3.2 Wind-induced growth of composite waves.

Figure 3 shows the growth rates of the composite waves, where the growth rates of each component waves alone are also shown with the same symbol. It can be seen that the

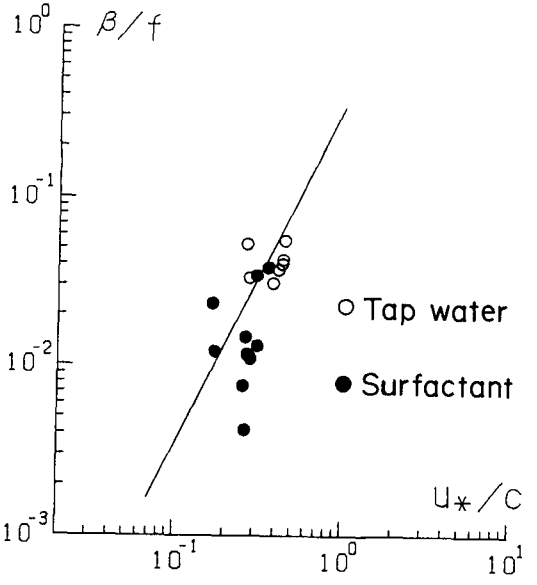

Fig.3 Growth rate of component waves of composite waves which have two frequency components.

growth rates of component waves of the composite waves follow approximately to the empirical relation (1). It should be noted, however, that one of the data for the surfactant water deviate greatly from the empirical relation (1). This data correspond to the wave (5)(T=0.7 sec) co-existing with the wave (4)(T=0.6 sec) for the water containing surfactant*). For this composite wave , since the periods of the component waves are fairly close, the waves show beat structures and their amplitude increase at the loop. Therefore, wave instability or small scale breaking might have happened, which has decreased greatly the growth rate.

Although further studies are needed to clarify the deviation of some data, we can say that the energy transfer from the wind to a certain spectral component is not much affected by the other spectral components if the wave steepness is not large. This is a reason why the empirical relation (1) for monochromatic waves is similar to the relation of Plant (1982), that has been obtained by using various wave data including the waves with contineous spectrum.

3.3 Wind-induced growth of unstable waves

Steep monochromatic waves become gradually unstable even without wind action. Since Benjamine & Fair (1967) made a pioneering study on the nonlinear instability of the Stokes waves, great many studies have been done on this problem; Comprehensive review has been given by Yuen & Lake (1982). However, many of the previous studies are concerned with the instability of steep waves without wind action.

In Fig.4, the left band figure shows the evolution of the spectra of steep unstable waves without wind action and the right hand side shows that of steep unstable waves under wind action. The thin smooth curves in the figure correspond to the wind wave spectra measured independently at each fetch. From the top to the bottom, fetches are 2.51, 4.51, 6.51, 8.61, 10.51 (m) respectively.

The spectra of the steep unstable waves without wind action show many spikes which are attributed to the fundamental frequency component, higher harmonics, and their side bands generated by the wave instability. Under the wind action, however, the higher harmonics and their side band are masked with wind wave spectrum, even the side bands of the fundamental frequency component are obscured, and the wave spectrum tends to be a continuous spectrum which has a

---

*) The similar deviation also happened for the same composite waves on a tap water. This data is out of this figure.

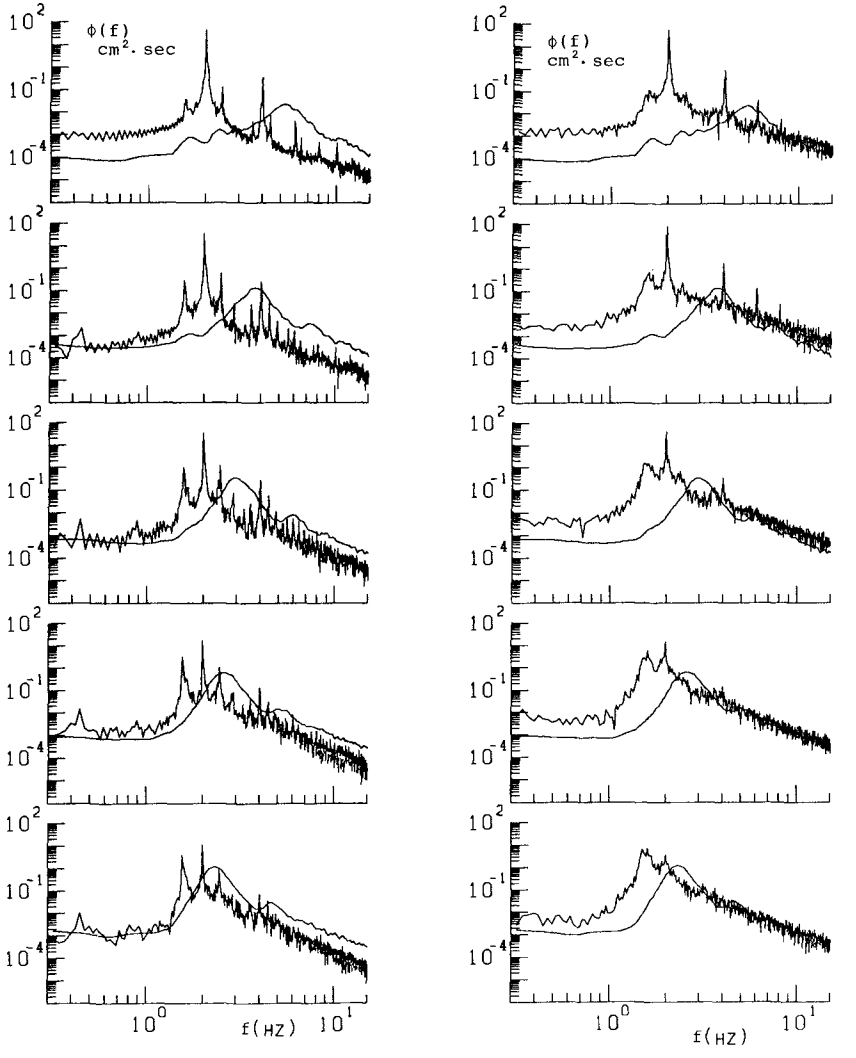

Fig.4 Evolutions of power spectra of steep unstable waves with (right figures) or without (left figures) wind action. Thin smooth curves correspond to the spectra of pure wind waves at each fetch.

spectral peak near the lower side band of the fundamental frequency component. Further development of the wave spectrum is almost the same to that of pure wind waves. These process of the transition to the continuous spectrum are considered to be largely attributed to the effect of wave breaking.

In order to clarify the change of the spectral energy, the wave spectrum was divided into five frequency rigions as shown in Fig. 5, and the spectral energy in each region is studied.

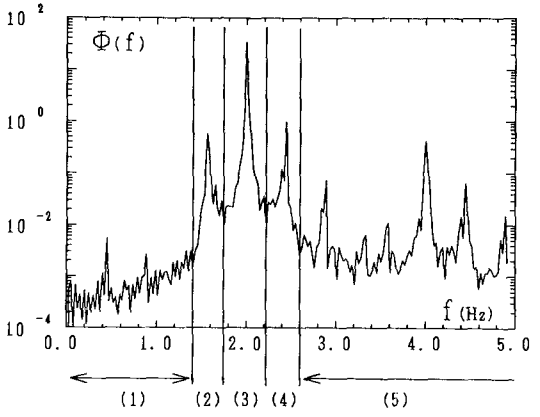

Fig.5 A schematic figure for the characteristic frequency region of the power spectrum of unstable waves.

In Fig. 5, E_1 is the energy in the low frequency region, E_2 the energy of the lower side band, E_3 the energy of the fundamental frequency component, E_4 the energy of the higher side band, and E_5 the energy in the high frequency region.

The change of the spectral energy in each frequency region is shown in Fig. 6. It can be seen that the energy of the fundamental frequency component E_2 decreases gradually with the increase of fetch even under the wind action, while the total wave energy E shows a nearly constant value. At short fetch, E_2 and E_4 are almost the same and increase samely with the fetch. With the increase of fetch, however, E_4 reaches to a saturated value, while E_2 continues to increase with the fetch. The wave energy at the high frequency region, E_5, shows a constant value independent of fetches reflecting a saturation of the high frequency wave spectrum for a fixed wind.

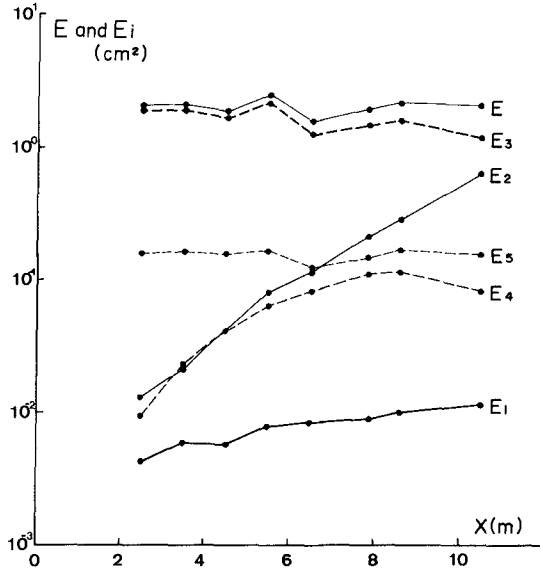

Fig.6 The change of the energy in the characteristic frequency regions of wave spectra under wind action for wave (9), H/L=0.105.

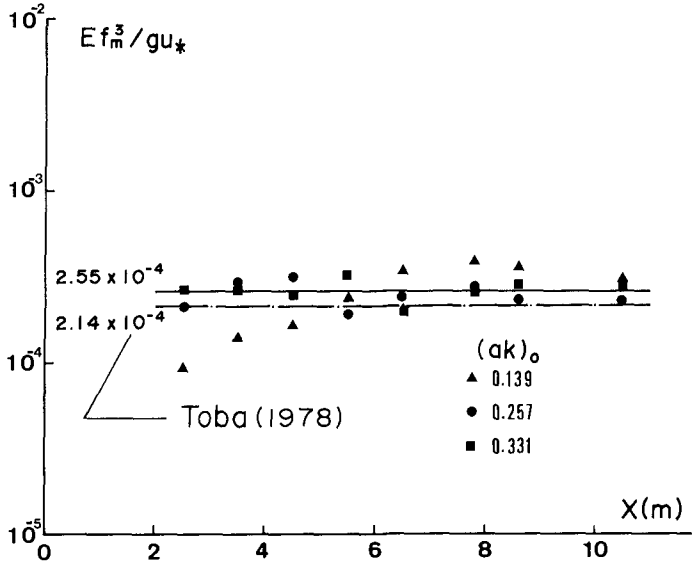

Fig.7 The change of the normalized wave energy.

It is interesting that the total wave energy E shows roughly a constant value within the fetch of the present study. However, it should be noted that this study is concerned with transitional phenomena from monochromatic waves to random waves, which are caused by the wave instability and the wind action. After the transition to the random waves, the waves will develop in the same way as wind waves. Thus, the total wave energy E should increase with fetch, while the dimensionless wave energy Ef^3/gu_* is expected to be constant.

In fact, Fig. 7 shows the saturation of the values of Ef^3/gu_*, and the asymptotic value $Ef^3/gu_* = 2.55\times10^{-4}$ is very close to the value 2.14×10^{-4} which has been obtained by Toba (1978) as the 3/2 power law for developping wind waves.

4. Conclusions

The following conclusions can be drown from the present study;

(i) The growth rate of stable monochromatic waves are given by (1) irrespective of the existence of the high frequency waves, if the measured friction velocity u_* is used in the relation. This is because the high frequency waves overlapping on the monochromatic waves increase both the friction velocity of the wind and the growth rate of the monochromatic waves.

(ii) The growth rate of a component wave of the composite waves is not much different from that of monochromatic waves with the same frequency, if the wave steepness is not large.

(iii) A fundamental frequency component of steep unstable waves decreases with the increase of the fetch even under the wind action, which is considered to be attributed to the wave breaking. However, the lower and higher side bands of the fundamental frequency component increase with the fetch, though the latter tends to be saturated at some fetch.

These properties are quite similar to those of steep unstable waves without wind action. In later stage, however, the spectrum of steep unstable waves under wind action tend to be contineous spectrum which is quite similar to the wind-wave spectrum.

Aknowledgement

The authors are grateful to Mr. K. Marubayashi and Mr. M. Ishibashi for their patient supports during the experiments, and to Miss. M. Hojo for her assistance in preparing the manuscript. This study is a part of Oceanographic Research Project entitled "Measurements and Simulation of Ocean Environment" and supported by the Ministry of Education.

CHAPTER 45

Experimental study on kinematics and dynamics of wave breaking

Masaru MIZUGUCHI*

1 Introduction

Wave breaking on a slope is one of the most important problems for the coastal engineers to be investigated. However wave breaking is a complex phenomenon which is not yet fully understood, in spite of the fact that many researches have been devoted to that subject. It is well known that waves break in different forms: spilling, plunging and surging. Untill now no theoretical explanation is given for the classification of the breaking pattern. Recently numerical simulation of wave breaking with full nonlinear governing equations based on the irrotational assumption have been developed (Longuet-Higgins & Cokelet, 1976 and so on). The simulation results show that the spilling breaker exhibit a small scale plunging jet as Miller (1976) observed in a laboratory experiment.

Most of the research works on the wave breaking are based on the laboratory experiments, in particular visual observation. Basco(1985) is the latest one on this line. Description of wave breaking based on visual observations provide limited information. Hedge & Kirkgöz(1981) report an experimental work in which the photographic approach was supplemented by the velocity measurement by Laser- Doppler Velocimeter. They found that the water particle velocity at the crest is smaller than the wave crest propagation velocity especially on steep slope beaches, and suggest that the plunging jet is not necessary formed at the crest. It is normally accepted that the flow field is irrotational before waves break. Therefore generation of vorticity as well as turbulence can be considered as eminent features of the wave breaking. Few studies are reported where velocity are measured in a fine grid of points so that the vorticity can be evaluated (Okayasu et al., 1986). There are several papers which pay an attention mainly on the structure of turbulence induced by wave breaking (Peregrine & Svendsen, 1978, Stive, 1980 and so on.)

Our aims are to provide a set of experimental data of a wave breaking of plunging type on a slope, in which the velocity field is measured in detail with high accuracy, and to discuss the kinematics and dynamics based on the data set, especially from the inception of breaking through the plunging process. In view of the initiation of wave breaking, forming of the plunging jet or overturning may be essential. Peregrine (1983) gives a comprehensive study of the fluid dynamics of the wave breaking, in which some possiblities of the plunging process are discussed.

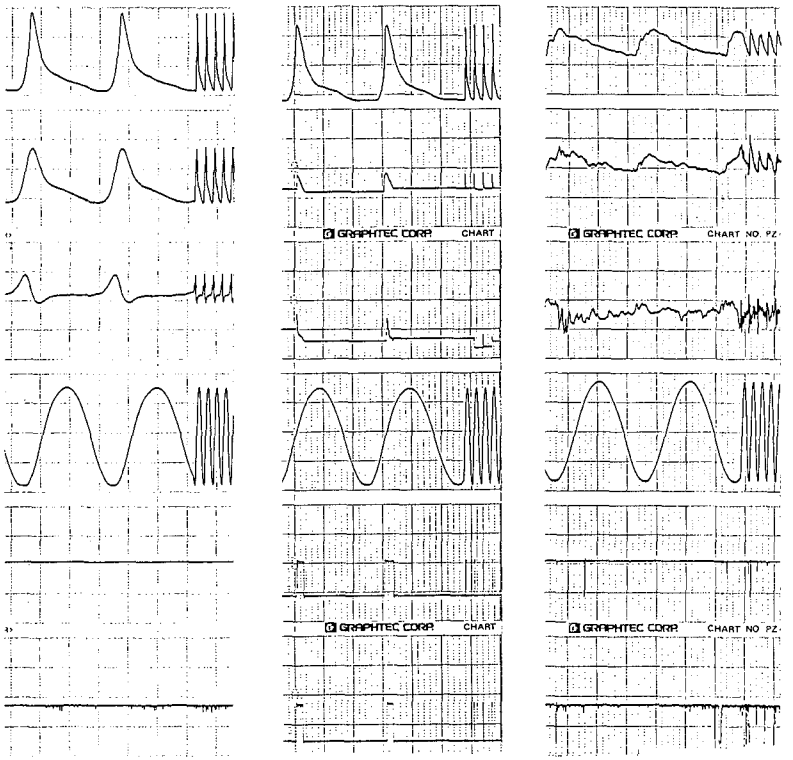
2 Experiment

The experiment was conducted in a laboratory wave flume of width 30 cm and of length 20 m. A wave of period 1.22 s and of wave height 4.4 cm at the uniform depth area of 28.2 cm deep was chosen, as it produced a stable plunging breaker of height 6.1 cm at the depth of 6.5 cm on a

*Assoc. Prof., Dept. Civil Eng., Chuo Univ., Bunkyou-ku Tokyo 113 JAPAN

slope of 1/20. The slope is made of painted steel plate.

Wave profiles were measured by a capacitance-type wave gauge at offshore and by a specially designed resistance-type wire gauge (Masatoyo Kogaku) in the breaker zone. The latter gauge detects the top boundary between the air and the water. The wave gauge has higher frequency response (≅50 Hz for the amplitude of 25cm) and is better to detect the rapid change of the breaking wave profiles. First cross-shore (horizontal) and vertical velocities were measured at 126 points by using two-colour Laser-Doppler Velocimeter (DANTEC). Back scattering method was employed. Later second experiment was carried out, adding 132 measuring points mainly in the shallower and the deeper region. Unfortunately the incident waves were a little (4.5 cm of wave height) larger in the second run. The measuring area covers 112 cm horizontally, extending d=2.7 cm to d=8.3 cm, where d denotes the water depth. It covers the area vertically from the near-bottom to the wave crest level. The measuring section was located about 6 cm apart from the nearer



(a) d=7.5cm, z=-2.0cm (b) d=6.6cm, z=2.0cm (c) d=2.7cm, z=-0.8cm

Fig.1 Examples of raw data. Top, surface elevation by the wire gauge, Second, onshore velocity, u, by LDV, third, upward velocity, v, by LDV, fourth, surface elevation by CWG in uniform depth area, fifth, drop-out signal for u, bottom, drop-out signal for v. Vertical axis is not scaled. LDV signals hold the previous values while they drop out.

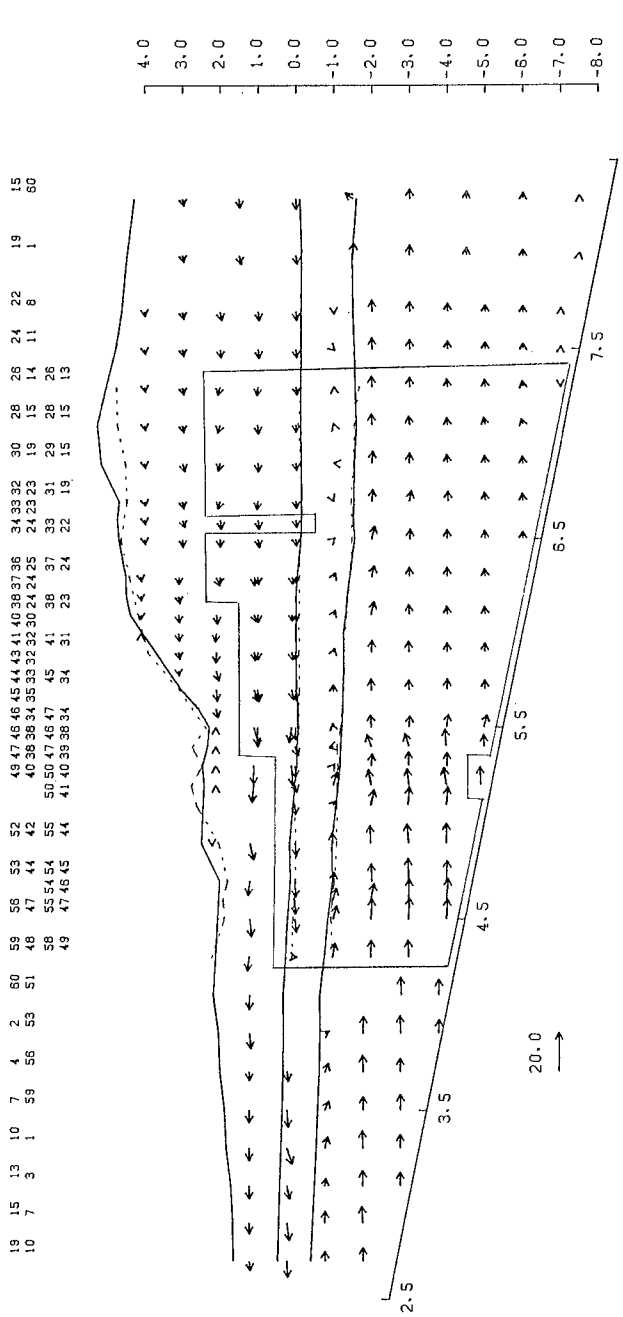


Fig. 2 Measuring points, mean velocities, wave crest level, mean water level and wave trough level. The measuring points within the solid line are for the first run. Some points above the still water level (z=0) were measured in both runs. The number at the top indicate the time by sequence number when the wave crest and trough pass the point. The number of the top two lines are for the second run. The dotted line for wave crest, mean water level and wave trough level are from the first run. The number below the bottom slope indicate the local water depth. Vertical axis is taken upward from the still water level. c.g.s. unit is used throughout the paper.

sidewall, which is made of glass. To prevent the drop-out of LDV signal, it is better to have the section nearer to the wall, although the sidewall effects must be avoided. The experimental data were recorded on a magnetic tape and later digitized with a sampling frequency of 50 Hz.

In Fig. 1 (a)-(c), examples of raw data at various locations are shown. Figure 2 shows the location of measuring points. The mean velocity, mean water level, wave crest level and wave trough level are also plotted in Fig.2. Mean water level, wave crest level and trough level are obtained from the averaged wave profile of those at the points in the same vertical section. It is seen that the total mass flux across a vertical plane may not be zero and directed offshoreward. It is because the LDV signals drop out giving zero velocities when the points, above the trough level, just come into and out of the water as typically shown in Fig. 1-(b). The Eulerian return flow, which compensate the wave mass flux above the wave trough, exhibits uniform vertical distribution after the plunging point. This uniform distribution is attributed to the momentum transfer due to the strong turbulence in that region as shown below. Outside the breaking point the vertical distribution of the return flow show a clear decrease toward the bottom.

Representative temporal profiles of both surface elevation and velocities for one period at each location were obtained by taking the phase average values over the forty waves. In the aerated area and the near-surface area, the signals of LDV drop out frequently as shown in Fig.1-(c). When the signals obtained for no more than ten wave cycles among the forty, the data points for that phase were discarded. Then

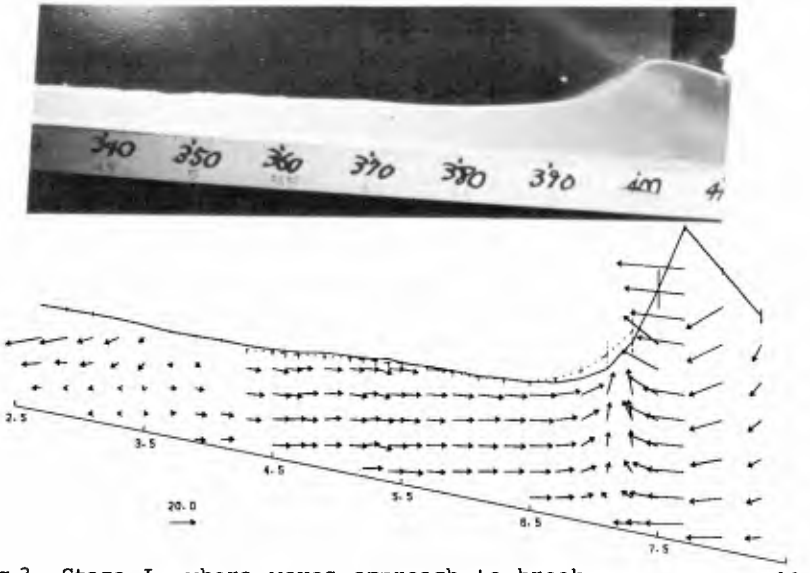

Fig.3 Stage I, where waves approach to break. Photo and (phase averaged) velocity field. (T_i=22) The length of vertical bars on the surface profile denote the standards error of the wave profiles over the points on the same vertical section. It indicates the degree of fluctuation of the waves themselves.

the spatial distribution of the phase-averaged wave profile and velocities are produced by synthesizing the data of all measuring points. The synchronization was done by using the zero crossing point of the wave profiles measured at a fixed point of uniform depth area. Here the error of the order of a sampling time was inevitable. However larger error may occur when the data obtained in a second run and the data in the second run are brought together. These errors may be significant when the spatial derivatives are estimated as done below.

3 Analysis

From the set of spatial distribution of phase averaged velocity, $\underline{u}$, the divergence, $\underline{\nabla}.\underline{u}$ and the rotation, $\underline{\nabla}\times\underline{u}$ of the velocity vector field are calculated. The spatial derivatives of velocities are estimated by fitting a linear plane to the data of the points within an ellipse with a least square error. The ellipse has the horizontal radius $4r_0$ and vertical radius r_0. The value of r_0 is taken to be 1.6 cm. Theoretically the value should be infinitely small. The grid size in our experiments, however, requires a certain finite value. The values of 1.1, 1.3, and 2.1 cm were also tried. Only the results for the values of 2.1 cm produce considerably different distributions of derivatives. The water

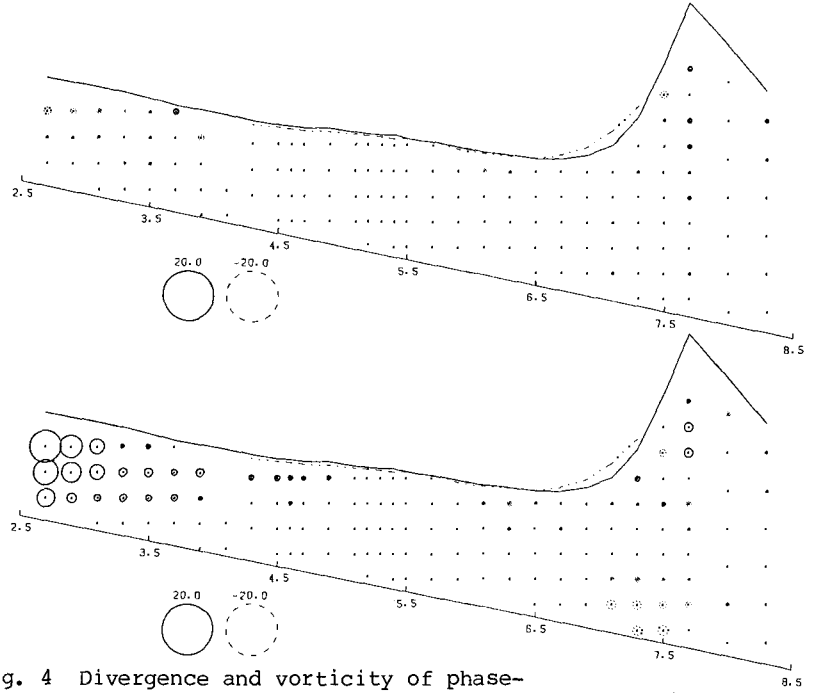

Fig. 4 Divergence and vorticity of phase-averaged velocity field. (T_i=22) The diameters of the circles denote the magnitude. The solid circles indicate positive values while dotted ones do negative values. The positive divergence gives negative gradient of longshore velocity. The positive values of vorticity means anti-clockwise rotation of the water particles.

particle acceleration, $D\bar{u}/Dt$ is evaluated by using the relation $D\bar{u}/Dt = \partial\bar{u}/\partial t+u\partial\bar{u}/\partial x+w\partial\bar{u}/\partial z$. The partial differentiation with respect to time, t, is obtained numerically. Turbulence intensity, $\sqrt{(\bar{u}')^2}$, is also calculated. The turbulence is defined as the difference between the instantaneous velocity and the phase averaged velocity. Thus obtained turbulence include the fluctuation of wave motion and may give overestimation as shown later. From the given spatial distribution of Eulerian velocity field, particle trajectories are traced numerically. Simple forward difference scheme is employed.

4 Results and discussion

Sixty one sequential diagrams of synthesized (phase averaged) velocity field with surface profile are carefully examined. With help of pictures taken during the experiments as well as the quantities $\bar{v}.\bar{u}$, $\bar{v}x\bar{u}$, $D\bar{u}/Dt$ and $\sqrt{(\bar{u}')^2}$, it was revealed that there exist six typical stages in wave breaking, which are qualitatively described as follows.

I) Sharp crested wave, which a little inclines forward, advances in a uniform return flow. This is typically shown in Fig. 3, for the time sequence T_i=22. The initial phase T_i=1 is chosen arbitrary. The uniform return flow under the preceding trough is remarkable. The

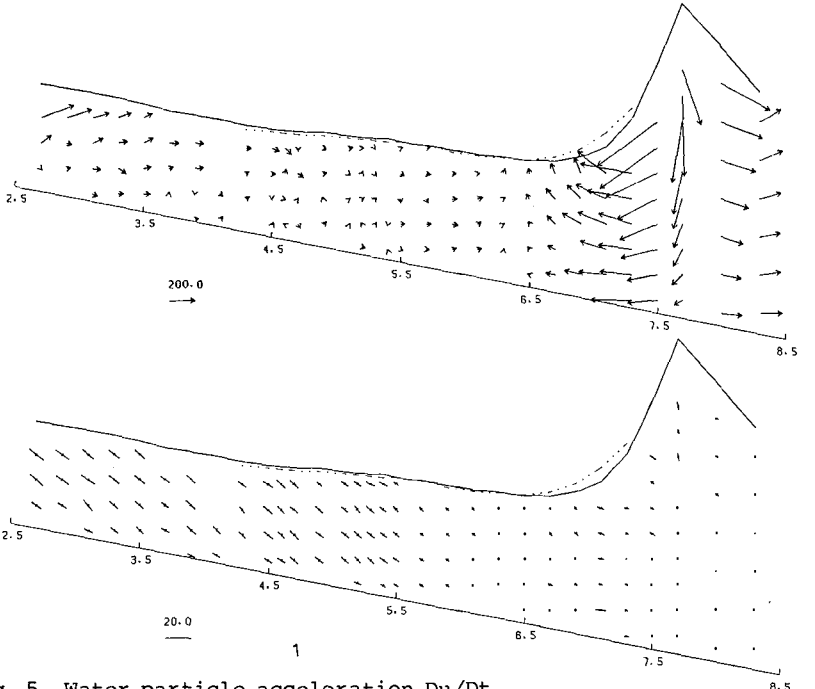

Fig. 5 Water particle acceleration $D\bar{u}/Dt$ and turbulence intensity $\sqrt{(\bar{u}')^2}$. (T_i=22) $D\bar{u}/Dt$ is plotted as a vector. Turbulence intensity is plotted such that the length of the bars has the absolute value of turbulence $\sqrt{(\bar{u}')^2+(\bar{w}')^2}$ and the angle with the onshore horizontal line has the angle $\tan^{-1}(\sqrt{(\bar{w}')^2}/\sqrt{(\bar{u}')^2})$. If the turbulence is isotropic, the angle is 45 deg.

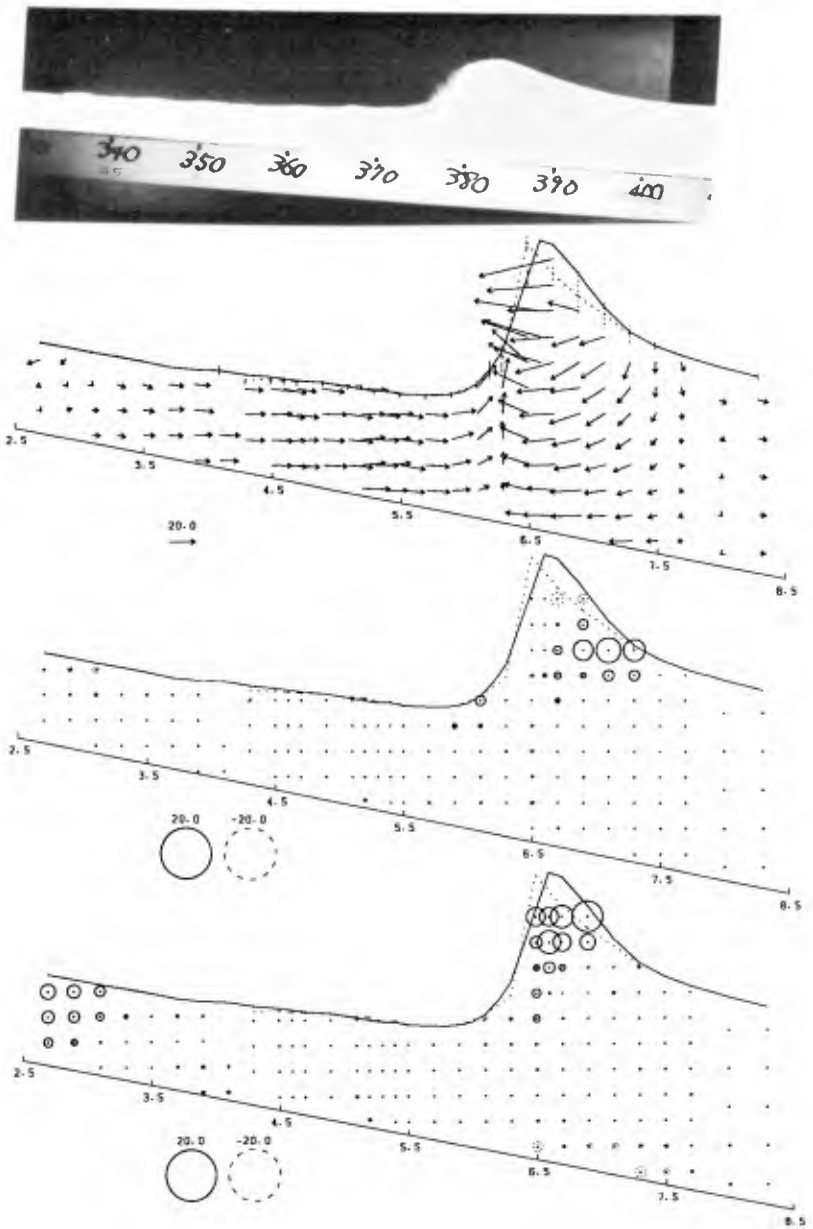

Fig. 6 Stage II, where the wave breaks. (T_i=33) Photo, velocity field, its divergence and vorticity.

foregoing wave has disappeared to the left. In Fig.4, the divergence and rotation are shown for this phase T_i=22. The divergence is nearly zero throughout the measuring area, assuring that the phase averaged flow field is two-dimensional. This may guarantee the reliability of the experiment. The non-zero vorticity, found far left, are the remains of the vorticity generated by the plunging of the foregoing wave. Whether the values of the divergence is negligibly small or not depends on what to compare with. Here the values are compared against the significant values of the vorticity ($\cong 30\ s^{-1}$) observed in this wave breaking process. The vorticity is twice the angular velocity of the rotational motion of a water particle. The indicated values of 20 s^{-1}

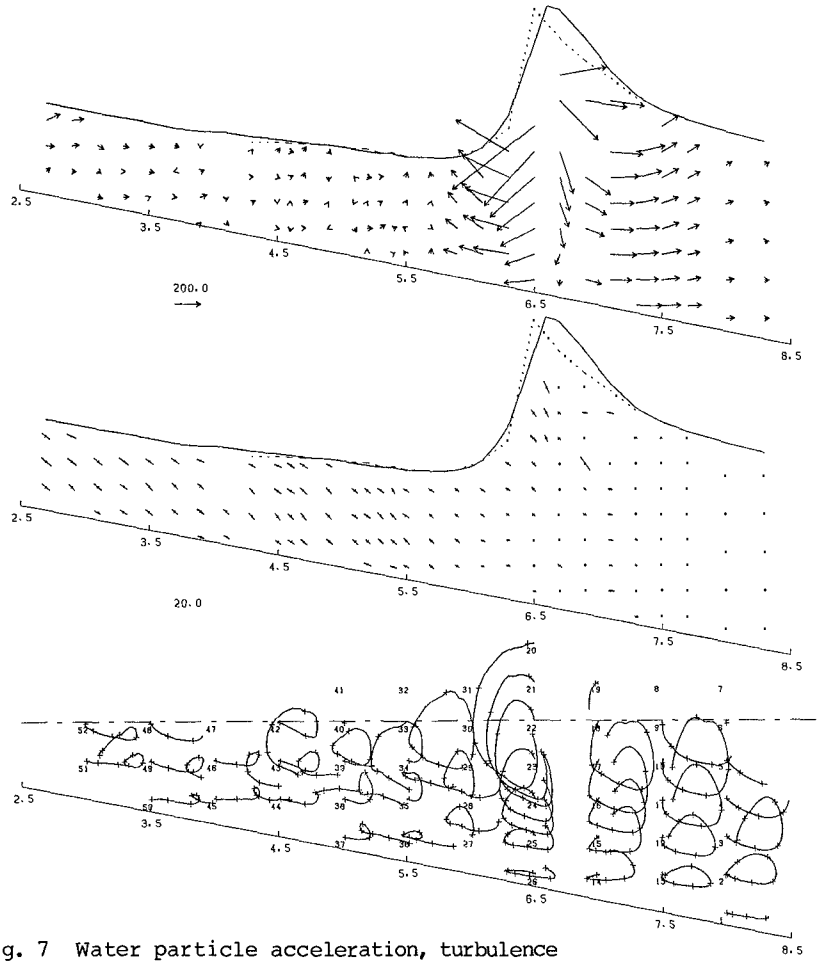

Fig. 7 Water particle acceleration, turbulence intensity and water particle trajectories. (T_i=33) The trajectories are followed for one wave period. The points near the number are the stating positions at this instant.

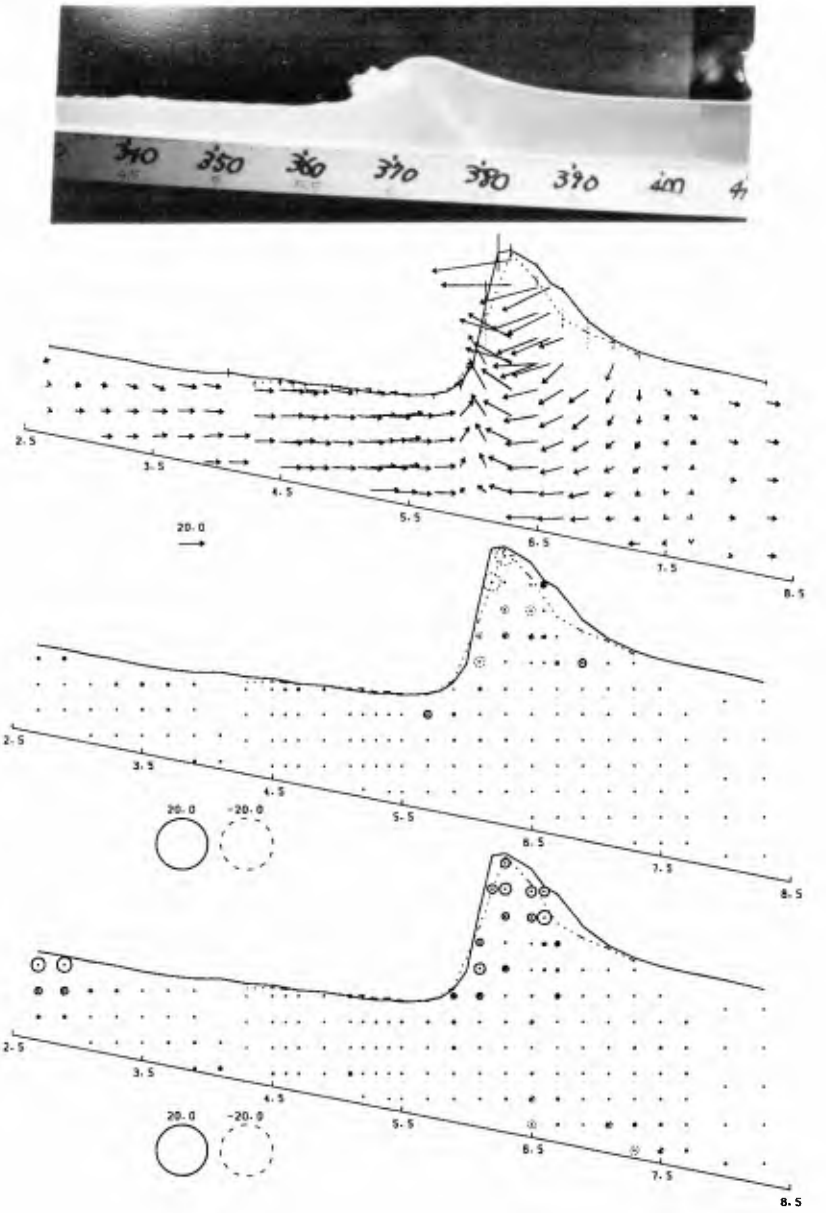

Fig. 8 Stage III, where the breaking (overturning) wave travels. (T_i=36) Photo, velocity field, its divergence and vorticity. The plunging jet does not yet touch down.

in Fig. 4 means that the water particles rotate with the angular velocity 10 s^{-1}. Figure 5 shows the water particle velocity and turbulence intensity for T_i=22. The water particle acceleration shows a reasonable behaviour that particles are accelerated only when the wave crest passes. The dynamics of the breaking wave appears to be quite similar to that of a solitary wave. With respect to the turbulence shown in Fig. 5, significant values are found only after the plunging point. The large values under wave crest are due to the fluctuation of wave motion as is indicated by the vertical bar on the surface profiles in Fig. 3. This stage covers the period of time sequence number (15-32).

II) The crest continues to become sharper and some part of its front face finally becomes vertical. At this breaking moment, horizontally converging and vertically upwelling flow beneath the vertical front face is very remarkable as shown in Fig. 6. Stagnation point is observed at the bottom of the upwelling flow. The maximum value of the velocity measured, which is nearly horizontal, is 67 cm/s. This value is likely to be underestimated as it is the maximum of the phase-averaged ones. From the number plotted in Fig. 2, we have 83 cm/s for wave crest propagation velocity, v_c, near this breaking point. Considering that the point of maximum velocity lies within the fluid, one can imagine that the real maximum velocity is nearly equal to v_c. It is also shown in Fig. 6 that divergence and vorticity take non-zero values around the top of the wave crest. The positive divergence behind the crest results from the fact that the velocity vectors around there do not show a smooth variation. Experimental errors due to very fast

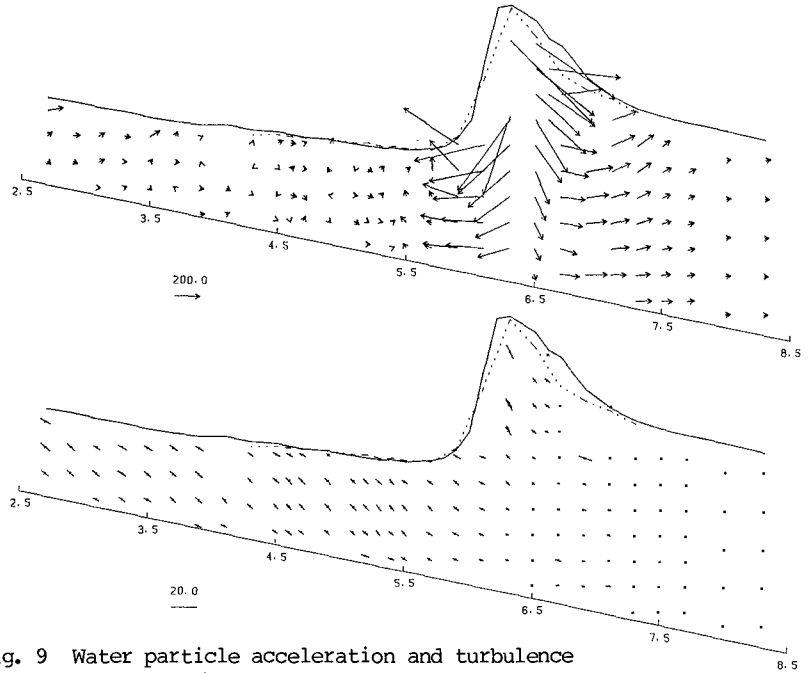

Fig. 9 Water particle acceleration and turbulence intensity for T_i=36.

movement of the breaking wave crest could be responsible for this false (?) three dimensional feature. The positive vorticity at the top of the wave crest is due to the higher nearly-horizontal velocities at the points nearer to the surface. This generation of small vorticity is a token of the breaking inception. Rotational motion at the top of a nearly-breaking wave is also observed for a spilling-type breaker by VanDorn & Pazan(1975). Vorticity far left still remain, decaying. In Fig.7, the observed maximum vertical acceleration is 490 cm/s^2 in the downward direction at the highest point measured beneath the crest. Extaporation up to the surface may give the value of g=980 cm/s^2.

III) The plunging jet is formed from a part of the sharp crest, although the remaining part of the wave continues to propagate independently. As shown in Figs. 8 and 9, the observed features are the same for those of stage II in Figs. 6 to 7, except that the height of wave crest is decreasing. (33-43)

IV) The jet is plunging into the front face of the original wave, hitting the surface as shown in Figs. 10 and 11. In this stage the wave motion still holds its characteristic feature under the plunging jet. This plunging moment is most clearly characterized by the beginning of

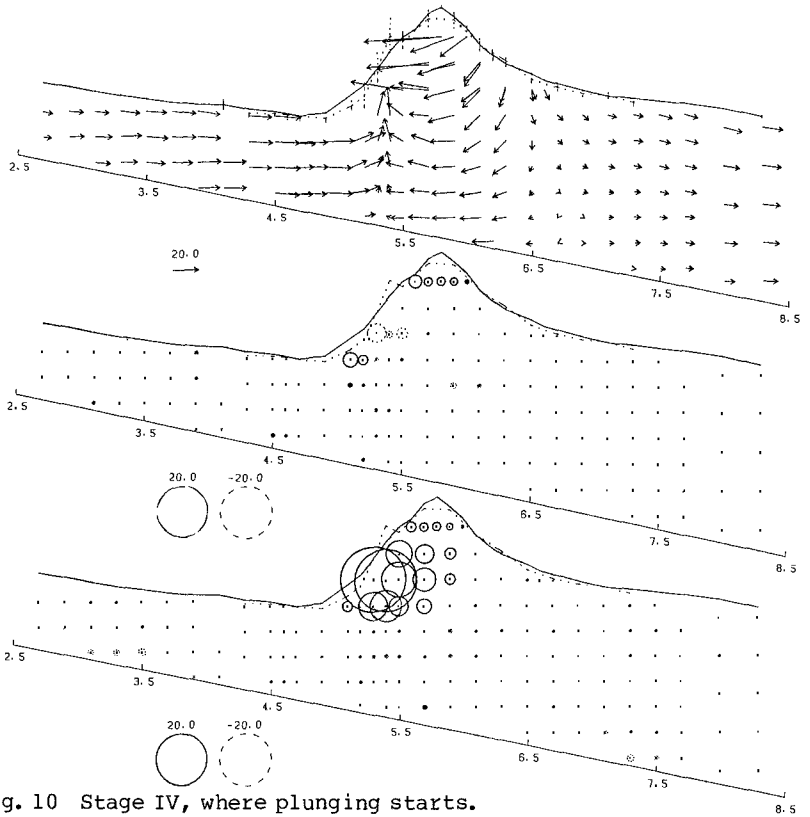

Fig. 10 Stage IV, where plunging starts.
(T_i=44) Velocity field, its divergence and vorticity.

the generation of large vorticity and turbulence near the surface at the plunging point. The vorticity is generated by the strong shear near the surface due to the plunging jet, which appears to flow over the surface. At this stage the vorticity far left produced by the foregoing wave disappears. In Fig. 11 particle trajectories show that the surface particles do not penetrate into water deeply, indicating that the surface generated vorticity and turbulence do not easily reach the bottom. It is noted that the vorticity exists almost only above the wave trough level. On the other hand, the fluctuation of pressure may produce turbulence even near the bottom. (44-50)

V) Then the plunging jet produces a dead water region beneath the plunging point but neither so-called horizontal roller nor offshoreward propagating wave. In Figs. 12 and 13 it appears that the plunging jet bounce up over the dead water region. This process is described by as a jet-splash motion Jannsen(1986) based on visual technique. It is interesting to investigate how this bouncing process changes as the breaking pattern differs. As shown in Fig. 13 and others, turbulence near the surface is likely to be isotropic, but very near the bottom, turbulence in vertical velocity is naturally small. (50-61)

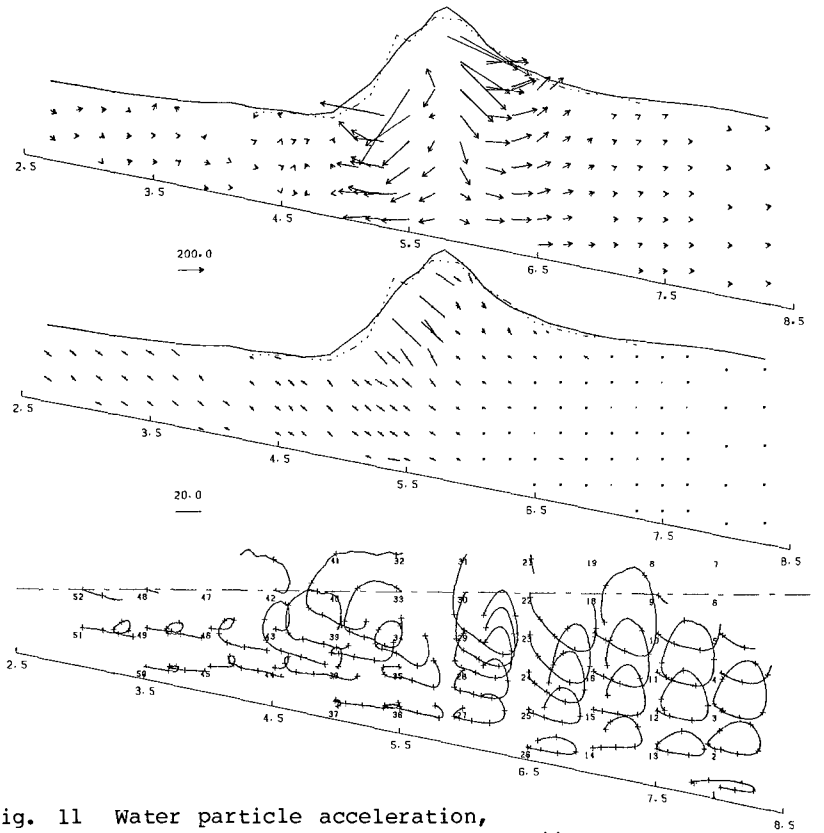

Fig. 11 Water particle acceleration, turbulence intensity, and trajectories for T_i=44.

VI) As shown in Fig. 14, bore-like motion is formed. The flow field at the wave front is similar to that in Stage I as shown in Fig.3. However the vorticity within and behind the bore-like wave exist together with the turbulence. The rotational motion as well as the turbulence is left behind as the crest propagates away. (1-14)

5 Conclusions

It is concluded that wave breaking is a phenomenon in which irreversible motion of the jet-forming with small vorticity stands for its inception and the plunging of the jet into the original wave causes partial destruction of the original wave, resulting with the bore-like motion. However the plunging jet may not penetrate into the interior of water but bounce up over a dead water region and does not form either the roller directly nor the outward-going waves. It also brings about the turbulence together with the rotational motion with vorticity.

Acnowledgements

I would like to give my special thanks to Mr. K. Sakata for his assistance throughout every phase of this study.

CHAPTER 46

FERRY WAVE MEASUREMENTS IN DEEP WATER

Ronald E. Nece, F. ASCE, Michael R. McCaslin,
Derald R. Christensen, and Harry H. Yeh, M. ASCE

ABSTRACT

Data are presented for ship waves generated and measured in deep water. Results show the variation of maximum vessel waves with both vessel speed and distance from the vessel sailing line. Three automobile ferries of different configurations were tested. Field test procedures, limitations, and problems are described.

Introduction

Concerns have been expressed about possible increases in shoreline erosion which might be attributed to waves generated by specific classes of automobile ferries operating fairly close to shore on regular routes in the partially sheltered waters of Puget Sound, Washington, a deep-water estuary on the northern Pacific Coast of the U.S.A. A logical first step in investigating these concerns was to determine whether or not there were indeed significant differences among waves generated by ferries of various vessel classes.

The interest of coastal engineers in ship waves in the past has generally focused on problems associated with operation of ships in confined channels (e.g. Herbich and Schiller, 1984), on shore-mounted or pile-mounted wave gage measurements of waves generated by relatively smaller vessels (e.g., Sorensen, 1967) or on operation of vessels in water of finite depth (exemplified by early laboratory studies such as those reported by Johnson, 1958). The latter concerns arise when the depth Froude number $F_d = V_s / \sqrt{gd}$ (where V_s = vessel speed and d = water depth) becomes greater than about 0.6; the operating conditions for the Puget Sound tests yielded much smaller Froude numbers. Towing tank data were not available on waves generated by the ferries tested. Also, the combination of low Froude numbers and hull configurations placed the ferries out of the range of predictive formulae for wave heights (e.g., Weggel and Sorensen, 1986). Direct field measurements therefore were selected as the best approach. This paper describes the relatively low-cost, single-purpose tests and presents their results.

Department of Civil Engineering, University of Washington, Seattle, Washington, U.S.A.

Objectives

The specific objective was to determine maximum wave heights at various distances from the sailing line for each of three classes of ferries operating over their respective speed ranges in deep water. One representative ferry was tested for each vessel class. The three vessels tested were all double-ended ferries with diesel or diesel-electric propulsion. Characteristics of the vessels at their respective test conditions are listed in Table 1; English units are used.

Table 1
Characteristics of Ferries Tested

Vessel	Displacement[a]	Length[b]	Draft[c]	C_P[d]	C_B[e]
Sealth	2475	314	14.08	0.549	0.345
Yakima	2780	375	17.17	0.528	0.291
Klahowya	1650	301	13.5	0.618	0.310

Notes: a) Long tons, salt water
b) At water line, feet
c) Feet
d) C_P = Prismatic Coefficient = $\frac{\text{Displacement Volume}}{\text{Length x Midship Area}}$
e) C_B = Block Coefficient = $\frac{\text{Displacement Volume}}{\text{Length x Beam x Draft}}$

Test requirements dictated a straight course over which the vessel could be run at a constant speed so the wave pattern was established and non-varying relative to the ship, and so that repetive runs could be made past stationary wave gages. Necessary measurements were of wave height, distance of gage from sailing line, and vessel speed. A calm sea state with minimal tidal currents was desired. The degree to which these requirements were satisfied is discussed for each of the series of tests conducted.

Methodology

Waves were measured by three resistance-type spar buoy staff gages. The three-gage array was deployed in a direction essentially normal to the vessel sailing line along a single mooring line fixed to a permanent buoy at one end and kept in tension and position by being attached to a 9-m sailboat which served as a workboat operating under power at the other end (Figure 1). All electronics are located in the 3.6-m high 75-mm diameter staff portion of the buoys; the 150-mm diameter bottom section provides buoyancy, and the staffs receive their power from a generator on the workboat via a cable attached to the mooring line. The damper plate at the bottom of the spar buoy produces natural periods in heave and roll of 18 and 12 seconds, respectively, both much greater than periods of wind or ship waves at the test sites. Details of the gages have been provided previously (Nelson et al., 1983). The wave staffs were calibrated separately for each series of field experiments.

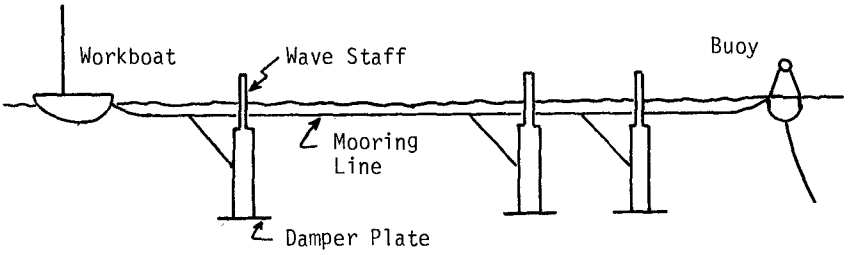

Figure 1. Schematic of wave staff deployment.

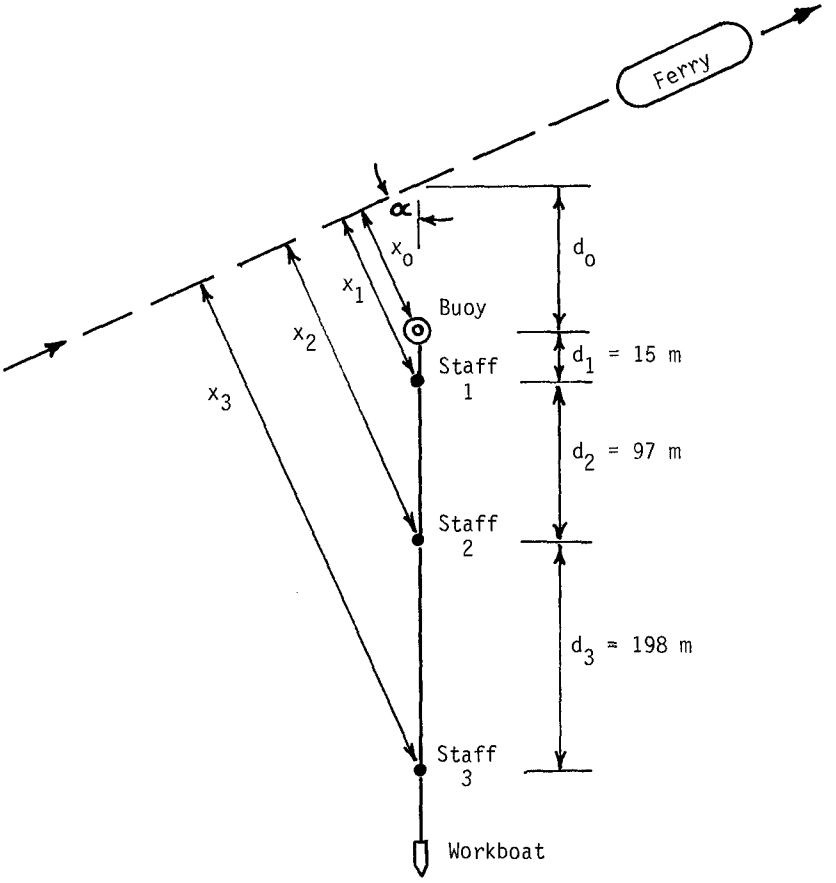

Figure 2. Schematic showing wave staff deployment in relation to ferry sailing line (not to scale).

Four analog recorder channels and one single-channel digital data requisition system were available; the latter could be switched from the output from one wave gage to another so that digital records of the highest ferry waves could be recorded as those diverging waves passed by each staff in turn.

Maximum wave heights were determined by two methods. The unfiltered value presented for each data set listed in Table 2 was obtained by direct visual inspection of the analog trace, using the maximum crest-to-trough reading within the wave train record. Vessel waves had frequencies between 0.25 and 0.5 Hz (2.5 to 4.0-second periods) with maximum wave heights ranging between 0.1 and 0.5 meters. Some coarse filtering was performed on the digital records, using the Fast Fourier Transform technique and a software package described earlier (Christensen, 1984). The filter selected rejected components with frequencies above 1 Hz and below 0.08 Hz. These frequencies are those of typical wind waves on the test dates and of the roll period of the wave staffs; the latter was selected to eliminate any effects of long period motions of the wave staffs caused by tension changes in the mooring line. The filtered data were plotted and the same visual procedure used to determine maximum wave heights. Where gaps occur in the 'filtered' results in Table 2, digital data were not available because of operator error or because the angle between the crests of the ferry-generated waves and the staff array was so small that the ferry waves passed through the array too quickly for more than one channel of digital data to be recorded.

The original project work plan called for both distances and vessel speeds to be obtained via aerial photography. The aerial work was restricted due to bad weather and/or the limitations on the altitudes at which aircraft were allowed to operate; the test sites were within the terminal control area of the Seattle-Tacoma International Airport.

The method used for determining distances for each data set is listed in Table 2. Those particular distances sought were x_1, x_2, and x_3, as identified on Figure 2. Distances d_1, d_2, and d_3 were 'unstretched' mooring line measurements. The six methods are described below:

(1) A photograph was used; the scale was determined by the known length of the ferry. The distance from the buoy to the workboat was measured. This was usually not equal to 310 m, because the mooring line would stretch under tension. Actual values of d_1, d_2, and d_3 were obtained by linear interpolation. The angle α was measured from the photo, also d_0. The "x" distances were determined by trigonometry, with the sailing line determined by extending a straight line back of the ferry. Due to aircraft elevation and/or lighting conditions, the individual wave staffs were not visible in the aerial photos.

(2) Same as (1), except that the distance x_0 was estimated by an observer on the ferry because neither x_0 nor d_0 were obtainable from the photo.

(3) No photographs were available. The distance x_0 was assumed to be 76 m (250 ft), the 'target' value specified to the ferry pilot, α was assumed to be 90 degrees, and wave staff locations were assumed to be the same as determined from photos for adjoining runs.

(4) A photograph was used; the ferry again provided the scale. The same interpolation scheme was used to get distances between staffs. Because of the low 730 m (2400 ft) aircraft elevation, the larger photograph scale allowed measurements to be taken directly off the photo.

(5) A photograph was used, and the distance x_0 measured directly. As not all of the staff array was included in the photograph, the other distances were assumed and were based on those determined in (4) above for an adjoining (in time) run.

(6) No photographs were available. The distance x_0 and angle α were estimated by an observer on the ferry; wave staff positions were determined by assuming a ten percent stretch of mooring line and using trigonometry.

Although distances in Table 2 are listed to within 5 meters, actual accuracy was not that good. It is believed that the greatest source of error was in the distance x_0. The work boat was too small and too close to the ferry to allow use of the ferry's radar, and sextant readings from the workboat were not feasible. An estimate of the actual distance resolution is 15 meters; consequences are discussed later. All distances and wave heights were initially evaluated in foot units.

Aerial photographs were used to estimate the speed of the Klahowya, as speed pairs of photographs incorporating fixed points on land were obtained for the three engine speeds at which the ferry was operated. These speeds are not considered to be extremely accurate because the time intervals between successive photos and the resolution (± 1 second) of the camera clock visible in the photograph could produce errors as large as ten percent. Consequently, data obtained in previous special sea trials of the Sealth and Yakima were used to determine the speeds of these vessels. These prior data, in the form of propeller shaft rotation rate vs. vessel speed, had been taken very accurately through the use of shore-based radar. Their use was considered acceptable because the vessel drafts on the dates of the present tests were almost identical to those in effect during the sea trials. (At neither time was there a load of automobiles and/or passengers on board).

Field Tests - September 1984

The field tests were initially scheduled for the period 17-19 September, 1984. These dates followed immediately after cessation of the summer schedule for the ferry system so that three vessels could be withdrawn for one day each from regular routes in order to participate in the test program, and were scheduled to maximize daylight hours. Also, predicted tide ranges were small (1.5 m maximum) during daylight hours. The site selected was in deep water (depths in excess of 100 fathoms over most of the vessel path) in central Puget Sound about 15

km north of Seattle. The test ferry was to travel back and forth on the basically east-west path shown in Figure 3, past the wave staff array secured at the southerly end of the string to a permanent navigation buoy dividing the northbound and southbound traffic lanes. The wave staff array was aligned with the direction of current motion. Weather conditions were good and the light, southerly wind did not generate any significant wind waves so that the wave gage signals were uncluttered. There was considerable wave activity at the site which could be attributed to passing vessels. Since these waves has frequencies comparable to those which were to be measured it would be difficult to filter them out of the records obtained. Consequently, ferry runs were delayed until visible waves from larger vessels had cleared the area.

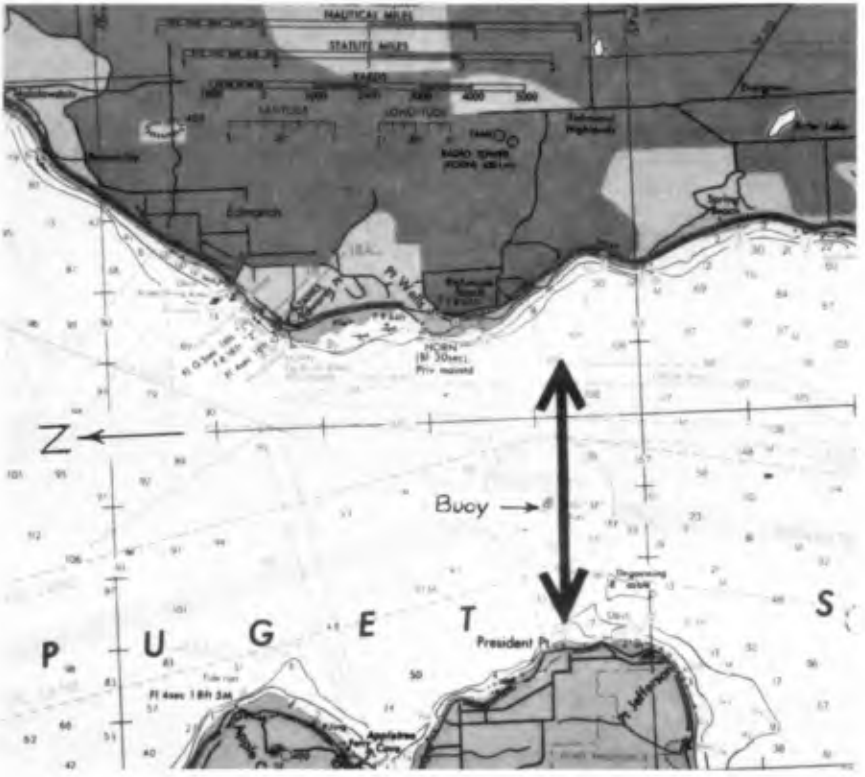

Figure 3. Central Puget Sound site, 17 September tests.

Tests were conducted, using the Sealth, on 17 September. Figure 4, which shows data obtained at the highest speed tested (18 knots) is representative of the results obtained. The values are listed in Table 2. The filtered and unfiltered data are combined on the single plot; it is noted that filtering did not yield any substantial reduction in

the scatter. For the results shown in Figure 4, as with the measurements for the entire program listed in Table 2, errors in measurement of distance will account for only a small amount of the scatter. Even large distance discrepancies would not change the general pattern, especially at larger distances from the sailing line where variations in wave height with distance become smaller. Because ship waves are not entirely regular and repeatable, a number of data sets were obtained for the same ship speed.

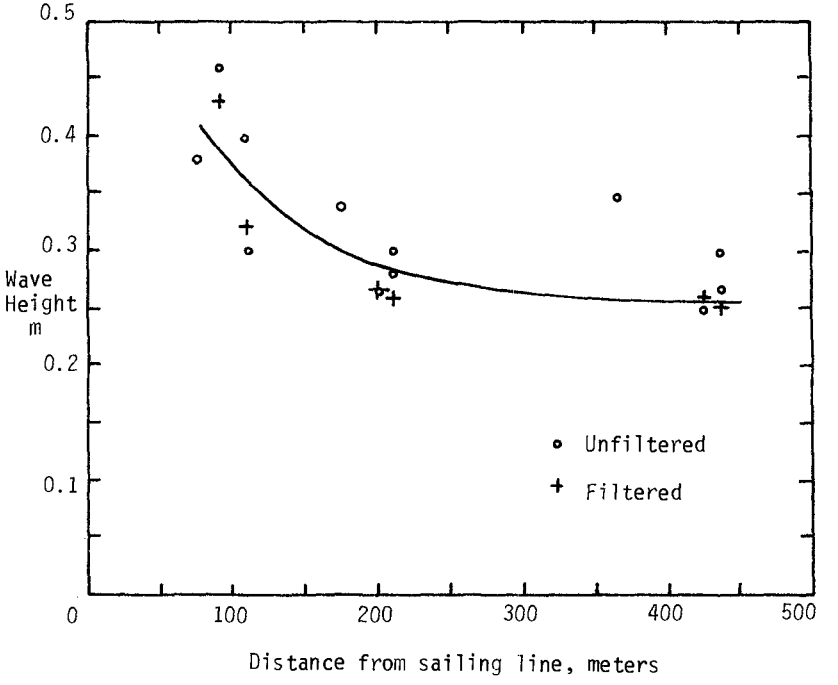

Figure 4. Maximum wave heights, ferry Sealth, 18 knots.

The wave through the plotted points on Figure 4 is strictly a hand-drawn visual fit, as the data were not considered sufficiently numerous to justify use of statistical techniques. The same treatment was applied to all data obtained for the three vessels tested; these curves and further details of the test program have been presented in the project report (Nece et al., 1985).

Mechanical problems experienced by other ferries required rescheduling of ferries, so there was no test vessel available on 18 September. Winds causing wind waves of height about the same as the ferry-generated waves, coupled with electrical problems in the staff array, caused the 19 September tests to be cancelled as well.

Field Tests - October 1984

Anticipated seasonal deterioriation of weather conditions along with uncertainty of availability of ferries for testing led to the selection of a different test location. The site chosen was on the west side of Blake Island, approximately 25 km south of the September site (Figure 5). A fundamental concern was protection from mostly prevalent southerly winds. A permanent mooring buoy provided attachment of the inshore end of the wave staff array which was strung out to the west from shore, so that the workboat was at the end of the string closest to the ferry path. The ferries' path was along a generally north-south line parallel to the west shore of Blake Island. The wave staffs were in depths of 10+ fathoms, and the ferries ran in depths generally of about 20 fathoms, so that deep water conditions prevailed.

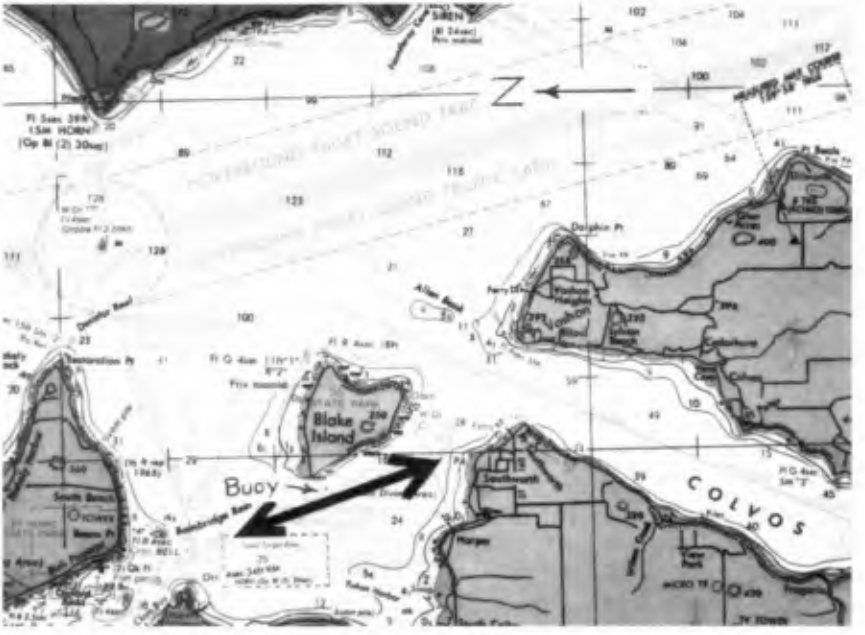

Figure 5. Blake Island site, 23 October tests.

Limited runs were made with the Yakima on the morning of 23 October. Low clouds and rain precluded aerial photography. Unanticipated strong north-flowing tidal currents at the site posed a problem. It was difficult to keep the wave staff array aligned normal to the ferry path. Near the end of the one-hour testing period it was decided to relax the requirement of trying to maintain the angle α at about 90 degrees; for the last runs, α was estimated at 60 degrees.

Maximum wave height vs. distance measurements are shown in Figure 6 for a vessel speed of 14.2 knots. The visual fit solid line curve

through the data reveals apparently anomalous behavior, i.e., increase in wave height with distance from the sailing line. This same anomalous behavior was observed for the one run at a 10.9 knot speed.

Two possibilities were considered to explain this unexpected behavior. One was to consider the direction of ferry movement, and consequently that of its wave pattern as well. The currents could have caused some steepening of the vessel waves. In Figure 6 the dashed line applies to northbound ferry runs only.

Identification of maximum wave heights from the analog records was not clear-cut for the Yakima data. A complex demodulation analysis (see, e.g., Sobey and Liang, 1986, and Bloomfield, 1976) was applied to the 10.9 knot ferry speed data in an attempt to isolate the dominant frequency wave which is the ship wave. Results of this analysis indicated the presence of two dominant frequencies, 0.35 Hz and 0.45 hz. Based on the 10.9 knot vessel speed, the predicted frequency for waves at the boundary of the Kelvin ship-wave wedge was 0.35 Hz. Heights for the 0.35 Hz waves were determined and plotted (dashed curve) on Figure 7; the anomalous behavior indicated by results from the visual inspection of the filtered and unfiltered records (solid line) has been removed.

The complex demodulation analysis was applied to only the one set of data. The procedure holds the potential of isolating bow and stern waves, but was not pursued here because of the pragmatic objectives of the study.

Tests with the ferry Klahowya were conducted in the afternoon of 23 October. The wave staff array was allowed to drift more with the current, so angles α as estimated from the ferry or read from aerial photographs were considerably less than 90 degrees. Distances from the sailing line at which waves were measured then tended to be slightly smaller and more variable. Data for the 10 knot speed are plotted in Figure 8. Again, the curve shown is a visual best-fit line. The trend of decreasing wave height with increased distance from the sailing line is evident, although there is considerable scatter.

Because the currents present during the Klahowya tests were at least as strong as those during the Yakima runs, it is hypothesized that some of the apparently anomalous results obtained with the Yakima were associated with the behavior of the wave staffs when it was attempted to keep the array essentially normal to the direction of the current. Because of uncertainties associated with the Yakima data (all of which are listed in Table 2) they are not included in the summary curves presented in the next section.

Conclusions

Figures 9 and 10 are summary plots of wave height vs. vessel speed at distances of 100 and 300 meters, respectively, from the sailing line. Results are presented for the Sealth and Klahowya only; data for the Yakima are not presented because of the uncertainties discussed previously. The points shown on Figures 9 and 10 do not come from

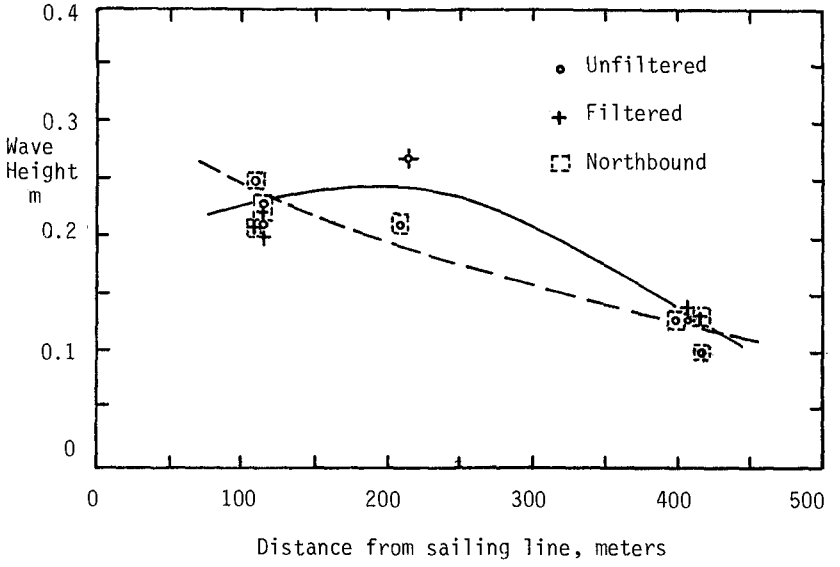

Figure 6. Maximum wave heights, ferry Yakima, 14.2 knots.

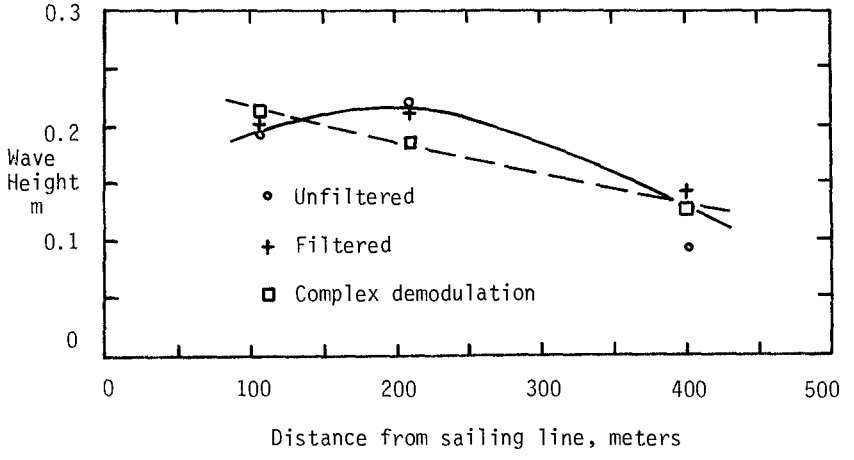

Figure 7. Maximum wave heights, ferry Yakima, 10.9 knots.

Table 2 but have been cross-plotted from the curves such as Figures 4 and 8 and others prepared for the remaining vessel speeds.

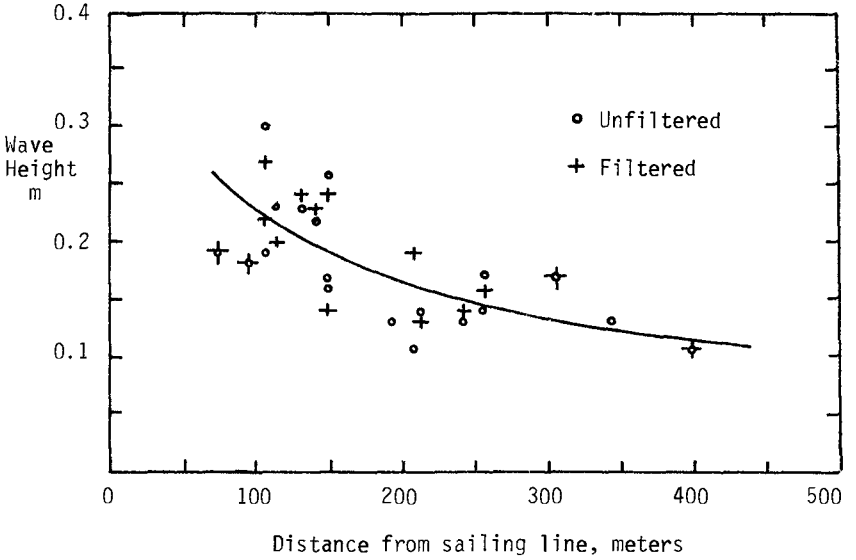

Figure 8. Maximum wave heights, ferry Klahowya, 10 knots.

Results clearly indicate that the different vessel classes do indeed produce waves of different height. Also, despite the uncertainties, it does seem apparent that the Yakima does generate the smallest waves as might be anticipated from comparison of hull geometries in Table 1. The results could also be used as a guide to vessel operation on specific routes in Puget Sound if wave generation is a concern.

Although the waves examined here are smaller than those usually of interest to coastal engineers, given the appropriate conditions the methodology could be applied to measurements of waves from larger vessels.

Acknowledgments

The study was sponsored by the Washington State Department of Transportation, in cooperation with the United States Department of Transportation, Federal Highway Administration. Personnel of the Washington State Ferries participated actively in various phases of the study; the efforts of Frank Vibrans, Captain David Black, and Captain William Haffie in particular are acknowledged. James Walker and Bruce Shaw of the WSDOT Photogrammetric Laboratory were instrumental in the aerial photography work.

CHAPTER 47

Directional Growth for Numerical Wind Wave Models

W.L. Neu[1]
S.H. Kwon[2]

Abstract

This study is concerned with the operation of spectral wind wave models. Many spectral wind wave models use a growth mechanism which operates on the point spectrum with directionality being introduced after the fact by the use of a spreading function. It is recognized here that this approach leads to errors whenever the wind and wave fields are not aligned. This is demonstrated by comparing the performance of two first generation models under various conditions. One makes use of a point spectral growth mechanism and follows the operation of the Spectral Ocean Wave Model (SOWM). The other uses a directional growth mechanism but is otherwise the same as the first. A large difference between the models is noted for swell corrupted seas.

1. Introduction

A number of operational wave forecasting models exist which perform with varying degrees of accuracy depending largely on the complexity of the situation they are asked to model. Since our understanding of the wave generation process is far from complete, wind wave models must rely heavily on empirical formulas. As long as the conditions a model is asked to simulate correspond with those under which the data for its empirical foundation were obtained, the model performs fairly well. When presented with situations of increased complexity, however, the performance of a model is bound to deteriorate. This was nicely illustrated in the Sea Wave Modeling Project (SWAMP Group, 1985).

In order to improve the performance of a wave model, it seems important to retain in the model as much detail and generality of the physics as possible. A large step in this direction was made by Pierson, et al. (1966) with the development of a model which computed directional wave spectra and allowed for the propagation of wave energy. After undergoing several refinements (Inoue, 1967; Lazanoff and Stevenson, 1975) it has evolved into the Spectral Ocean Wave Model (SOWM) as described by Pierson (1982). The SOWM is an operational wave model in use by the U.S. Navy Fleet Numerical Oceanography Center.

The SOWM is classified as a first generation decoupled propagation model in that the wave growth is dominated by wind energy input as

[1]Assistant Professor, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061, USA
[2]Lecturer, Pusan National University, Pusan, 607, Korea

opposed to nonlinear wave interaction effects and the spectrum is discretized into frequency-direction bands. Each band is allowed to evolve more or less independently and propagate at its own group velocity in its own direction. Other models of this type include those of Barnett (1968) and Ewing (1971).

Second generation discrete models, referred to as coupled discrete models rely heavily on nonlinear interactions in their growth mechanisms. These include the models of Resio (1981) and Golding (1983). The remaining class of models, the coupled hybrid models, are parametric models. These attempt to compute a set of parameters of a point spectrum, typically the JONSWAP spectrum (Hasselmann, et al., 1973), to represent the windsea part of the spectrum and require assumptions as to how the windsea becomes swell and vice versa. Thus they implicitly employ nonlinear energy transfer as the dominant mechanism controlling the spectral shape. An example is the model of Hasselmann, et al. (1976). Several models other than those referred to above and falling in all three classes are described by the SWAMP Group (1985).

The focus of this study is on the directional properties of the wave generation mechanism. By the design of the parametric models, the windsea part of the spectrum at least, must obtain its directionality from a spreading function centered on the wind direction. Some of these models allow the existence of swell whose direction of propagation is independent of the windsea, however, the directionality of any energy generated by the model must still be that of a spreading function.

The discrete models are not inherently so confined. Since they are discretized in direction, they may allow the directionality of the energy growth to be determined by the directionality of the growth mechanism. Further, since the growth rate of the spectrum is strongly dependent on sea state, the directionality (and, in general, magnitude) of the energy growth depends on the directionality of the existing spectrum. However many models, including the SOWM, employ a point spectral growth mechanism and spread the energy growth over direction with a spreading function. This is done presumably due to the lack of a form of the atmospheric energy input as a function of the angle between wind and wave.

In this study, such a function is developed and employed in a fully directional wave growth mechanism. A discrete spectral model using this growth mechanism is assembled following the operation of the SOWM. The performance of this new model under several sets of conditions is compared with that of a version of the SOWM written by the authors.

2. Structure of the Model

The rate of change of the wave spectrum can be described by the energy balance equation proposed by Hasselmann (1960)

$$\frac{\partial E(f,\theta;\vec{x},t)}{\partial t} + \vec{C}_g \cdot \nabla E(f,\theta;\vec{x},t) = S(f,\theta;\vec{x},t) = S_{in} + S_{nl} - S_{ds} \qquad (1)$$

where $E(f,\theta;\vec{x},t)$ is the two-dimensional directional frequency wave spectrum being a function of position $\vec{x}$, time t, wave frequency f, and direction of propagation θ. $\vec{C}_g$ is the group velocity of the spectral component and S represents the sum of individual source functions. S_{in}, S_{nl}, and S_{ds} represent the wind input, nonlinear wave interaction and dissipation source functions respectively. As in the SOWM, nonlinear wave interaction is not explicitly modeled. It is generally accepted that the nonlinear interaction is important for wave growth (SWAMP Group, 1985).

The energy input from the wind S_{in} is represented as

$$S_{in} = A(u,f,\alpha) + B(u^*,f,\alpha)E(f,\theta;\vec{x},t) \qquad (2)$$

where u is the wind velocity, u^* is the friction velocity and α is the angle between the wind and wave directions. The A term represents energy transfer from the turbulent pressure fluctuations to the wave field according to the theory of Phillips (1957) and results in a linear growth of the spectrum. The BE term represents the interaction of an already disturbed surface with the wind.

If we consider an infinite ocean with a homogeneous wind field, the wave spectrum is not a function of position. The numerical model for this case requires only one spacial grid point and no propagation scheme. Without the nonlinear interaction and dissipation terms, equation (1) then becomes

$$\frac{\partial E(f,\theta;t)}{\partial t} = A(u,f,\alpha) + B(u^*,f,\alpha)E(f,\theta;t) \qquad (3)$$

Since equation (3) is linear, each spectral component can grow independently. Also, according to equation (3) the spectral component can grow to an infinite value with time, but in the real situation, dissipation will limit the growth. Wave breaking is thought to be the main mechanism of dissipation. The dissipation function S_{ds} is applied implicitly for wave energy propagating within ±90° of the wind direction in a manner analogous to its implementation in the SOWM. The growth of the spectrum is limited by a fully developed spectrum which will be discussed later.

The directional treatment of the wave growth mechanism is the focus of this study. Before we refer to our model, it is helpful to examine the relation of the energy balance used in the SOWM to equation (3). A directional spectrum can be obtained by multiplying the frequency spectrum by a spreading function:

$$E(f,\theta) = E(f)F(\theta) \tag{4}$$

The spreading function used in the SOWM is that which was derived by the SWOP project (Cote, et al., 1960). It was considered to be a function of wind speed and frequency as well as direction and is given by

$$F(\omega,\alpha,u) = \frac{1}{\pi}\left[1 + (0.5 + 0.82e^{-1/2(\frac{\omega u}{g})^4})\cos 2\alpha + 0.32e^{-1/2(\frac{\omega u}{g})^4}\cos 4\alpha\right]$$

$$\text{for } -\frac{\pi}{2} < \alpha < \frac{\pi}{2} \tag{5}$$

where $\omega = 2\pi f$ and $F(\omega,\alpha,u) = 0$, elsewhere.

Using equation (4), equation (3) can be rewritten as

$$\frac{\partial E(f;t)F(\alpha)}{\partial t} = A(u,f,\alpha) + B(u^*,f,\alpha)E(f;t)F(\alpha) \tag{6}$$

Integrating equation (6) over the parameter α from $-\pi/2$ to $\pi/2$,

$$\int_{-\pi/2}^{+\pi/2} \frac{\partial E(f;t)F(\alpha)}{\partial t}\,d\alpha = \int_{-\pi/2}^{+\pi/2} A(u,f,\alpha)d\alpha + \int_{-\pi/2}^{+\pi/2} B(u^*,f,\alpha)E(f;t)F(\alpha)d\alpha \tag{7}$$

If we let

$$A'(u,f) = \int_{-\pi/2}^{+\pi/2} A(u,f,\alpha)d\alpha \tag{8}$$

$$B'(u,f) = \int_{-\pi/2}^{\pi/2} B(u^*,f,\alpha)F(\alpha)d\alpha \tag{9}$$

and consider that

$$\int_{-\pi/2}^{+\pi/2} F(\theta)d\theta = 1 \tag{10}$$

then we have

$$\frac{\partial E(f;t)}{\partial t} = A'(u,f) + B'(u^*,f)E(f)\ . \tag{11}$$

This directionally integrated energy balance equation, modified to limit spectral values to a fully developed limit, is what is used by

the SOWM. Notice that it assumes that the spectrum is always centered on the wind direction, although the SOWM does not constrain it to be. The directional spectrum is obtained by spreading the growth resulting from this directionally integrated equation at each time step about the wind direction and adding it to the pre-existing directional spectrum, thus forcing the new spectral growth to have the angular distribution of the spreading function.

The model presented in this study solves the energy balance equation in the directional form, equation (3). It does not require the introduction of the artificial angular spreading function and it retains the directionality of the growth. Note that the spectral growth rate is highly dependent on the spectral value through the BE term. The directionality (and magnitude) of the growth will thus depend on the directional properties of the spectrum. This dependence is destroyed if the growth is obtained from equation (11).

3. The A Term

The $A(u,f,\alpha)$ term represents the generation of waves on an initially calm water surface through the turbulent atmospheric pressure fluctuations. It is too weak to explain the major growth of the wave field but it can explain the growth of waves from initially calm water to a certain level where other mechanisms become dominant. Within Phillips' theory, the waves develop most rapidly by means of a resonance mechanism which occurs when a component of the surface pressure distribution moves at the same speed as the free surface wave with the same wave number.

The form of the A function used here is similar to that used by Barnett (1968) and is simply a nonintegrated form of the function used in the SOWM. A summary of the mathematical background is as follows.

Hasselmann (1960) has shown that the A function can be represented in terms of the three-dimensional spectrum of the random atmospheric pressure fluctuations $\Pi(\vec{k},\omega)$. That is

$$A = \frac{4\pi^2 k \omega^3}{\rho_w^2 g^3} \Pi(\vec{k},\omega) \tag{12}$$

where k is the magnitude of the wave number $\vec{k} = (k_1,k_2)$, and ρ_w is the density of sea water. From the experiments of Priestly (1965) and discussion of Snyder and Cox (1966), we find

$$\Pi(\vec{k},\omega) = \frac{1.23A^*}{\pi^2\omega^2} u^4 \frac{0.33k^{1.28}}{0.1089k^{2.56} + (k\cos\alpha - \kappa)^2} \cdot \frac{0.52k^{0.95}}{0.2704k^{1.9} + k^2\sin^2\alpha} \tag{13}$$

where κ is ω/u_c, u_c being the convection velocity of the eddies. The value of the coefficient A^* is determined from the measurements of Snyder and Cox with additional data supplied by Cardone (1969). Since this data was related to the wind velocity at 6.1 m above the sea surface the convection velocity is taken as $u_{6.1}$. Priestly's measurements indicate a modification is appropriate for $\kappa < 0.02$. The form of the A function is then

$$A(f,u_{6.1},\alpha) = \frac{4.793\times10^{-16}\,\omega^4 u_{6.1}^3}{Q_1(\omega,u_{6.1},\alpha)R_1(\omega,u_{6.1},\alpha)} \qquad \frac{\omega}{u_{6.1}} \leq 0.02 \tag{14}$$

$$A(f,u_{6.1},\alpha) = \frac{7.167\times10^{-14}\,\omega^{5.25}\,u_{6.1}^{1.75}}{Q_2(\omega,u_{6.1},\alpha)R_2(\omega,u_{6.1},\alpha)} \qquad \frac{\omega}{u_{6.1}} > 0.02 \tag{15}$$

and

$$Q_1 = Q_2 = 0.2704\left(\frac{\omega}{u_{6.1}}\right)^2 + \left(\frac{\omega^2}{g}\sin\alpha\right)^2 \tag{16}$$

$$R_1 = 4.87\times10^{-6} + \left(\frac{\omega^2}{g}\cos\alpha - \frac{\omega}{u_{6.1}}\right)^2 \tag{17}$$

$$R_2 = 0.1089\left(\frac{\omega^2}{g}\right)^{2.5} + \left(\frac{\omega^2}{g}\cos\alpha - \frac{\omega}{u_{6.1}}\right)^2 \tag{18}$$

A is in m^2/rad, $u_{6.1}$ is in m/sec, and g is in m/sec^2.

It should be noted that the numerical constants appearing in equation (14) and (15) are not those given in Pierson (1982). He gives the form of A used in the computer code where for computational convenience it has been multiplied by the minimum frequency bandwidth (1/180 sec) and the number of seconds in his 3 hour time step. His value for A is also off by a factor of two which was applied separately in the SOWM code.

4. The BE Term

The $B(u^*,f,\alpha)E(f,\theta;t)$ term is the result of the interaction of the air flow with the already disturbed water surface. Miles (1957) considered the perturbation of the mean shear flow in the air by the disturbed water surface, but he neglected the effects of atmospheric turbulence. Phillips (1966) extended the analysis to consider the interaction of the wave induced air flow perturbations with the free stream turbulence. He derived an expression in terms of the mean velocity profile of the wind, U, as follows

$$\frac{B}{f} = \frac{\rho_a}{\rho_w} \frac{1}{c^2 k} \left\{ \frac{M_m N^2 k^4}{\cos^2\alpha} \left(\frac{-U''}{(U')^3} \right)_{z_m} \left(\int_{z_m}^{\infty} [U(z)\cos\alpha - c]^2 e^{-kz} dz \right)^2 \right.$$

$$\left. + M \int_0^{\infty} N^2 (-U'') \cos\alpha \left| U\cos\alpha - c \right| e^{-2kz} dz \right\} \qquad (19)$$

where M, M_m and N are constants and z_m is the matched height where the mean wind speed, $U(z_m)$, is equal to the wave phase speed, c. Phillips suggested $M_m = \pi$, $M = 1.6 \times 10^{-2}$, $N^2 = \frac{1}{3}$ for $z > z_m$ and $N^2 = 1$ for $z < z_m$. Inoue (1967) used these values and assumed a logarithmic velocity profile to evaluate equation (19). He found poor agreement with observational data and abandoned this approach. For his B function he fit a curve to data obtained from wave growth measurements. The function he found and that which is used in the SOWM is

$$\frac{B}{f} = 0.00139 e^{-7000\left[\left(\frac{u_*}{c}\right) - 0.031\right]^2} + 0.725 \left(\frac{u_*}{c}\right)^2 e^{-0.0004\left(\frac{u}{u_*}\right)^2} \qquad (20)$$

We repeated the calculations of Inoue (1967) using a logarithmic velocity profile in equation (19) and found directionally integrated results much larger than given by equation (20). Looking at the integrand of the second term in (19), we found that it became very large for small z since the logarithmic profile has a very large curvature near the surface. Note that the lower limit of this integration is actually the roughness height, z_o, for the logarithmic profile. From these calculations, it appears that the mean velocity must have much less curvature near the surface than is given by the logarithmic profile. Takeda (1963) has measured departures from a logarithmic form very close to the water surface.

In this study, rather than attempting to derive a more appropriate mean velocity profile, Gauss-Laguerre quadrature is used in an effort to avoid the contribution to the integration from this strong peak near the origin. Thus we are integrating a polynomial fit to the integrand which does not follow the peak. In effect, we are assuming a

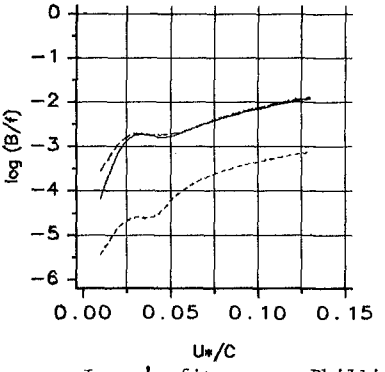

Fig. 1. Evaluation of the B function in directionally integrated form

mean velocity profile which would give us the integrand matching this polynomial fit. The result of evaluating equation (19) in this manner, using the values of the constants suggested by Phillips, and integrating over direction according to equation (9) is shown as the lowest curve in Figure 1. The solid line in this figure is Inoue's curve fit to the observational data, equation (20). The constants M and M_m in equation (19) were adjusted to give agreement with it, requiring the values 1.2 and 12π, respectively. The result using these constants is the remaining curve in Figure 1.

5. Other Details of the Model

As does the SOWM, our model does not explicitly model the dissipation for waves traveling with the wind. A limiting directional wave spectrum is assumed as a function of wind speed. The form used here (and in the SOWM) is the Pierson-Moskowitz spectrum, $E_\infty(\omega,u)$, with the directionality of the SWOP spreading function. The fully developed spectrum is thus

$$E_\infty(\omega,\alpha,u) = E_\infty(\omega,u)F(\omega,\alpha,u) \tag{21}$$

Following Inoue (1967), energy dissipation is assumed to be a function of the ratio of the spectrum to the fully developed spectrum. Then equation (3) can be written as

$$\frac{\partial E(f,\theta;t)}{\partial t} = A(u,f,\alpha) + B(u^*,f,\alpha)E(f,\theta;t) - [A(u,f,\alpha) + B(u^*,f,\alpha)E(f,\theta;t)]\left[\frac{E(f,\theta;t)}{E_\infty(f,\alpha,u)}\right]^2 \tag{22}$$

A closed form solution may be obtained if we multiply A by $[1 - (\frac{E}{E_\infty})^2]^{1/2}$. This has only a small effect on the growth of the spectrum. Equation (23) can then be written as

$$\frac{dE}{dt} = \{A[1 - (\frac{E}{E_\infty})^2]^{1/2} + BE\}[1 - (\frac{E}{E_\infty})^2] \tag{23}$$

with solution

$$E = \frac{A[e^{Bt} - 1]}{B}\{1 + [\frac{A(e^{Bt} - 1)}{BE_\infty}]^2\}^{-1/2} \tag{24}$$

Equation (24) is applied in a directional form in a manner analogous to its directionally integrated application in the SOWM. At each time step, each frequency-direction band that lies within ±90° to the wind direction is allowed to grow if its initial value is less than $0.95E_\infty(f,\theta)$. If $0.95E_\infty \leq E < E_\infty$, E is set equal to its fully developed

value. If the initial value exceeds E_∞, no growth is allowed. Thus under a steady wind, each component will grow until it reaches its fully developed limit. Once all bands have reached saturation, the spectrum reaches a steady state.

If the wind now turns, since the fully developed spectrum is tied to the wind direction, some bands (within ±90° to the wind direction) will exceed their fully developed limit while others will not. If these underdeveloped bands are allowed to grow, the total energy present will exceed that in our fully developed sea. This situation also arises in the SOWM but is given special treatment here. We allow normal growth in those direction bands less than fully developed and attenuate the energy in over developed bands to maintain the same total energy in each frequency band.

Waves traveling at angles greater than ±90° to the wind direction are explicitly dissipated in the same manner as is done in the SOWM. The rate of dissipation depends on the total energy traveling within ±90° to the wind direction and the relative angle between wind and wave. The expression used is

$$E_d(f,\theta,t) = E_o(f,\theta,t)\left[e^{-s\Delta t(E_e(t))^{1/2}f^4}\right]^{r(\theta)} \tag{25}$$

where E_d is the spectral component after dissipation. E_o is the spectral component before dissipation, E_e is the total energy of the wind sea traveling within ±90° to the wind direction. And where $r(\theta) = 0$ for $\theta \leq 90°$, $\theta \geq 270°$. $r(\theta) = 3$ for $90° < \theta \leq 135°$, $225° \leq \theta < 270°$. $r(\theta) = 4.5$ for $135° < \theta \leq 165°$, $195° \leq \theta < 225°$. $r(\theta) = 6$ for $165° < \theta < 195°$. $s = 754.6\ (\frac{\text{sec}^4}{\text{m}})$ and Δt is the time step in hours.

As mentioned in the introduction, two model codes were written. One using the formulation of the SOWM code and one, the directional formulation described above. In the following, the former is referred to as VSOWM while the latter is called VPINK. Both models use 53 frequency bands, each of width 0.005 Hz, from 0.04 Hz to 0.3 Hz and 36 directional bands each 10° wide. In a test of CPU time necessary to complete 14 time steps with the infinite ocean models, VPINK required 2.3 times the time needed to run VSOWM.

6. Computational Results and Discussion

All computations were performed with wind speed at 19.5 m of 40 knots (20.6 m/s) and a time step of three hours. The results are presented in both point spectral form and in polar contour plots of the directional spectra. The point spectra include a dashed curve. This is the Pierson-Moskowitz spectrum which is our fully developed spectrum. The contour plots include an arrow which indicates the wind direction. Contours are drawn at increments of 10% of the maximum spectral value present in each plot.

The first case presented is that of wave growth on an initially calm sea under the influence of a steady wind. Figure 2 shows the evaluation of the frequency spectrum from VSOWM and Figure 3 is the same from VPINK. The VPINK spectra are similar to the VSOWM spectra except that the growth slows as a frequency band approaches the fully developed

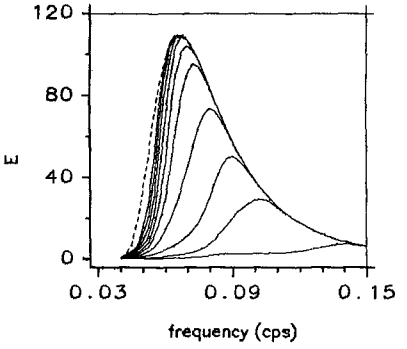

Fig. 2. Point spectrum evolution for a steady wind from VSOWM.

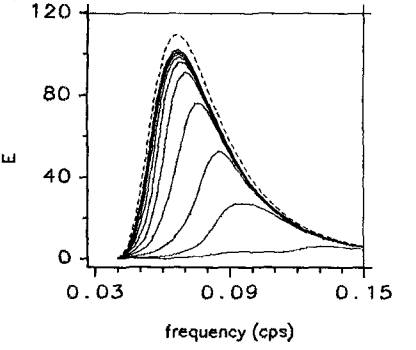

Fig. 3. Point spectrum evolution for a steady wind form VPINK.

limit. The reason for this is that its directional spread is more narrow than the spreading function which we use to define our directional fully developed limit. The direction bands near the wind direction therefore reach saturation first and the more oblique bands continue to grow slowly to fill in the frequency spectrum. This can be seen in the directional spectra of Figures 4 and 5. They are after five time steps from the VSOWM and VPINK respectively. Figure 4, the VSOWM spectrum,

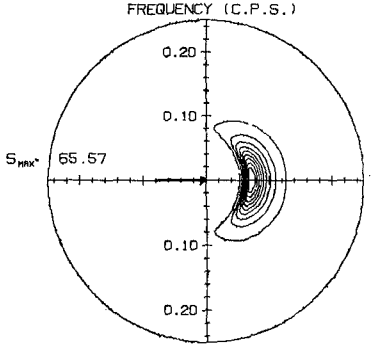

Fig. 4. Directional spectrum at 15 hours from VSOWM - steady wind.

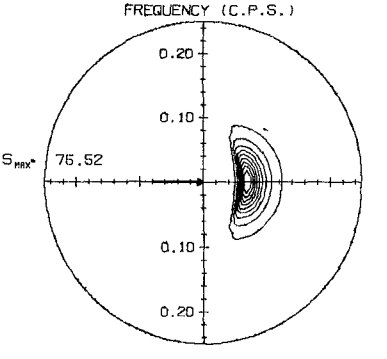

Fig. 5. Directional spectrum at 15 hours from VPINK - steady wind.

has the directionality of the spreading function while the VPINK spectrum in Figure 5 has a narrower spread which was determined by the growth mechanism. The difference in significant wave heights vs. time is small.

For the next case the sea was initially calm and the wind direction was allowed to vary by 10° at each time step, sweeping back and forth between ±20°. This demonstrated two points. First, the frequency spectra agreed more closely; each resembled the VSOWM steady wind case. This suggests that the typical fluctuations of wind direction may have a significant impact on the wave field directionality. The second point is that once the wave energy present within ±90° to the wind direction at a given frequency reaches its saturation level, the evolution of the VSOWM spectrum ceases whereas the directional relaxation mechanism previously discussed becomes active in VPINK. The VSOWM spectrum "freezes" from higher to lower frequencies as each reaches saturation while the VPINK spectrum continues to follow the wind vector (with some time lag). Typical directional spectra are shown in Figures 6 and 7.

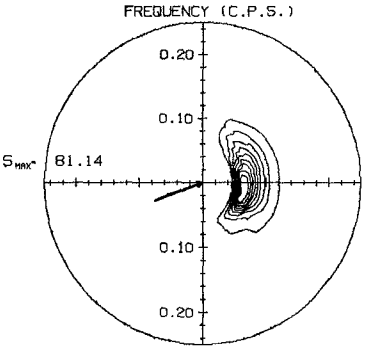

Fig. 6. Directional spectrum at 33 hours from VSOWM - oscillating wind.

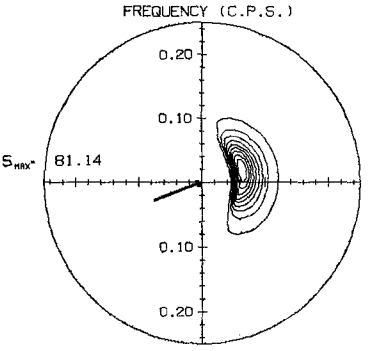

Fig. 7. Directional spectrum at 33 hours from VPINK - oscillating wind.

In the VSOWM spectrum of Figure 6, only those frequencies well below the modal frequency respond to the changing wind direction, quite the opposite of what we would expect to occur naturally. The VPINK spectrum in Figure 7 retains its response to the changing wind direction.

This same problem with VSOWM has even greater consequences when we consider a sudden 90° change of wind direction. We start with a fully developed sea spread about 90° and at $t = 0$ the wind direction changes to 0°. The VSOWM spectrum soon freezes up in a bidirectional form. The wave energy initially travelling in directions $0° < \theta < 90°$ is unchanged, new energy spread about the wind direction quickly grows to saturate each frequency band and thereafter, the only change is the attenuation of the energy initially in the directions $90° < \theta < 180°$. The directional spectrum at $t = 30$ hours is shown in Figure 8. The

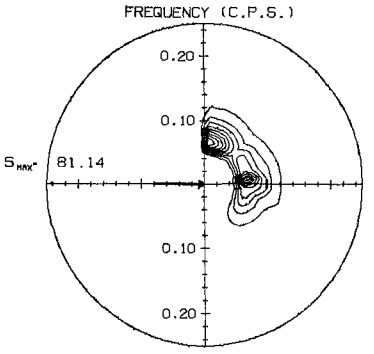

Fig. 8. Directional spectrum at 30 hours from VSOWM - 90° wind direction change.

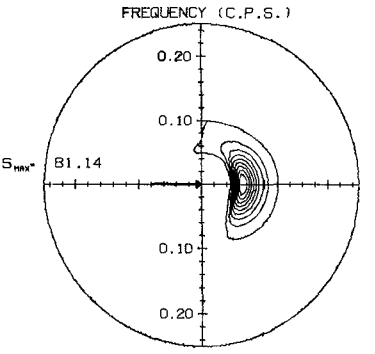

Fig. 9. Directional spectrum at 30 hours from VPINK - 90° wind direction change.

corresponding VPINK spectrum is shown in Figure 9. It evolves more naturally with the gradual growth of waves in the new direction and decay of the other components.

The final, and perhaps most important, comparison case does not involve a freezing up but addresses the fundamental nature of the point spectral growth mechanism. In this case we leave the wind steady but start with an initial low frequency swell on an otherwise calm sea. VPINK is little affected by the swell as can be seen by the point spectral evolution in Figure 10. Directional spectra at t = 3, 9 and 15

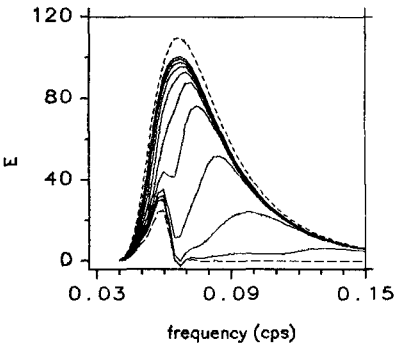

Fig. 10. Point spectrum evolution in the presence of swell from VPINK.

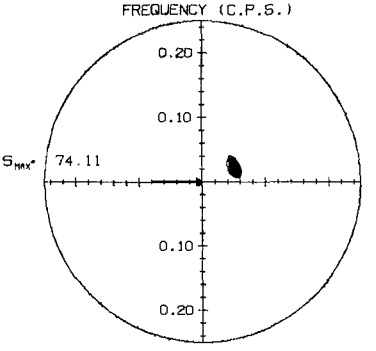

Fig. 11. Directional spectrum at 3 hours from VPINK - initial swell case.

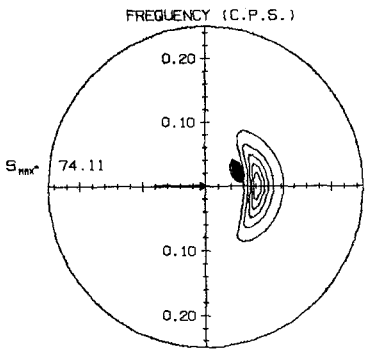

Fig. 12. Directional spectrum at 9 hours from VPINK - initial swell case.

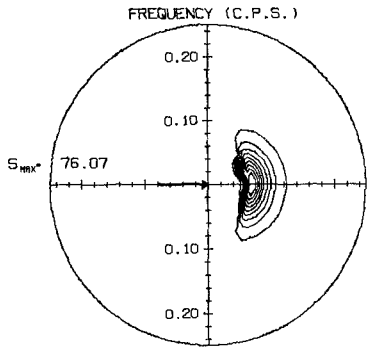

Fig. 13. Directional spectrum at 15 hours from VPINK - initial swell case.

hours are shown in Figures 11, 12 and 13 respectively. Figure 11 is nearly identical to the initial condition. As time proceeds, the wind sea grows to envelope the swell. The point spectral growth mechanism of the VSOWM however assumes that the initial energy present is centered on the wind direction and produces a much larger amount of growth in these frequency bands as can be seen in Figure 14. Figures 15, 16 and 17 are

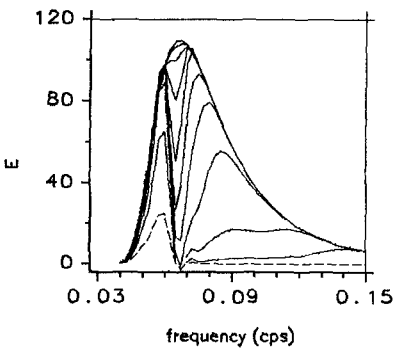

Fig. 14. Point spectrum evolution in the presence of swell from VSOWM.

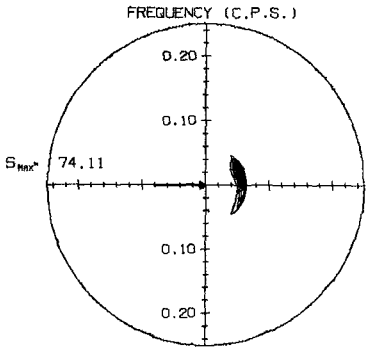

Fig. 15. Directional spectrum at 3 hours from VSOWM - initial swell case.

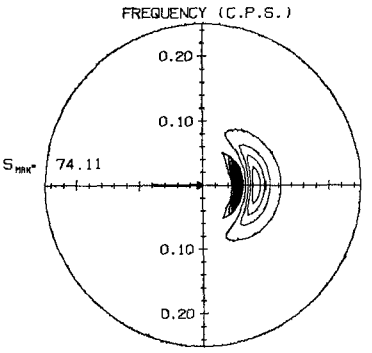

Fig. 16. Directional spectrum at 9 hours from VSOWM - initial swell case.

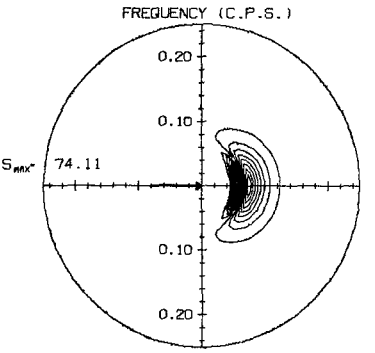

Fig. 17. Directional spectrum at 15 hours from VSOWM - initial swell case.

the directional spectra for t = 3, 9, and 15 hours respectively from VSOWM. From these we see that this new energy is spread widely in direction creating new low frequency components that should take much longer to develop.

These strong low frequency components, spread over ±90° are created due to a swell initially very narrowly spread. If this behavior is coupled with a propagation scheme, as it is in the operational SOWM, and these components are propagated to adjacent grid points, at those points they will act similar to the initial swell here. It is not hard to see that this growth mechanism could quickly corrupt a large area with excess low frequency energy, carried predominantly in the wind direction. Lazanoff and Stevenson (1975) describe several high energy case studies made for verification of the SOWM. Among the inaccuracies noted were the propagation of wave energy in improper directions and frequency shifts of spectral peaks. The problems discussed here may very well be responsible for these discrepancies. It also seems likely that the twenty year hindcast wave climatology produced with the SOWM (Lee, Bales and Sowby, 1985) overestimates both the low frequency wave energy present and its directional spread.

CHAPTER 48

LOCAL APPROXIMATIONS : A NEW WAY OF DEALING WITH IRREGULAR WAVES

by

Peter Nielsen, Ph.D.*

ABSTRACT

The concept of local approximations via locally defined frequencies is introduced as a tool for dealing with irregular, non linear waves. Practical testing has been performed on the problem of estimating surface elevations from measured bottom pressures. In these tests the new method even in its simplest form proves more accurate than the linear spectral method. With respect to computational effort the new method requires orders of magnitude less than spectral methods, or wave by wave analysis of similar accuracy.

INTRODUCTION

Dealing with irregular waves is one of the major tasks of coastal engineers, and doing it in an appropriate way is often a big problem.

Traditionally, two major approaches have been applied namely spectral analysis and wave-by-wave analysis. Spectral analysis relies on essentially "linear thinking" and has therefore got problems with non linear waves. Wave by wave analysis can be non linear, but there are problems of ambiguity with respect to defining the individual waves.

In order to obtain reasonable accuracy for wave-by-wave analysis of non linear waves one must apply a suitable, high order wave theory. But the complexity of such theories makes it desirable for the practicing engineer to find a different method by which reasonable results can be obtained with a simple wave theory e.g. linear wave theory.

This problem was solved by Daemrich et al (1980) who realised that the long flat trough of a non linear wave might be represented by a correspondingly long flat sine wave, and similarly, the short, strongly curved crest section could be represented by a short, steep sine wave. We may call their method "half-wave-by-half-wave-analysis".

In the following we shall take their idea a bit further and not just apply different frequencies to trough and crest, but apply a locally defined frequency to each point in the wave record.

* Coastal Branch, Public Works Department, N.S.W.,
140 Phillip Street, Sydney 2000. Australia.

Once we have a frequency to work with, there are many wave theories to chose from. It seems however that something simple like linear wave theory with a simple stretching term inbuilt does a good job in most cases. Using the concept of the locally defined frequency, it is in fact possible to devise very simple transfer functions, which are essentially only non linear filters. These semi empirical transfer functions can have very good accuracy and hence be very useful for handling data by hand or by micro processor.

As an example the new idea is applied to the problem of estimating water surface elevations from measured bottom pressures under steep irregular waves. The results are encouraging.

THE CONCEPT OF LOCAL FREQUENCY

A basic assumption to most existing wave theories is that the water motion is periodic and can be described by a suitable combination of the simple harmonic functions.

$$\sum_{0}^{\infty} A_m \cos m\omega t + B_m \sin m\omega t \qquad (1)$$

where A_n and B_n are constants and $\omega = 2\pi/T$. Such combinations can (at least assymptotically) describe the shape of natural waves but in the following we shall take a different approach. We shall deal with slowly curving parts of the wave as if they were parts of long sine waves and with strongly curved parts as if they were part of short sine waves. A step in this direction was taken by Daemrich et al (1980) who applied "half wave by half wave analysis" to irregular waves and thus treated the water motion between two consecutive surface zero crossings as part of a sine wave with a period of twice the interval between the zero crossings.

In the following we shall go a step further and apply a locally defined frequency to each individual point in the time series. The local frequency f is defined as that of the sine curve which matches the wave shape locally. Figure 1 shows measured surface elevations and dynamic bottom pressure under a steep wave and the corresponding variation of the locally defined frequency. We see that the local frequency is well behaved in the crest and trough areas but becomes erratic near the zero crossings. Therefore the concept of local frequency is only really useful in relation to problems where the main interest is on the extreme elevations and/or velocities, but fortunately that is most often the case. Among the meaningful local frequencies the extremes are produced by the surface elevation. In the flat trough, $f(\eta,t)$ falls to just under 0.5/T, and at the crest it reaches 1.7/T. For $f(p,t)$ the range is from 0.6/T to 1.2/T. It is interesting to note that even for the very steep wave in Figure 1 which in the spectral sense contains many high harmonics, the upper limit of $f(\eta,t)$ in the crest area is less than 2/T i.e. lower than the frequency of the second harmonic.

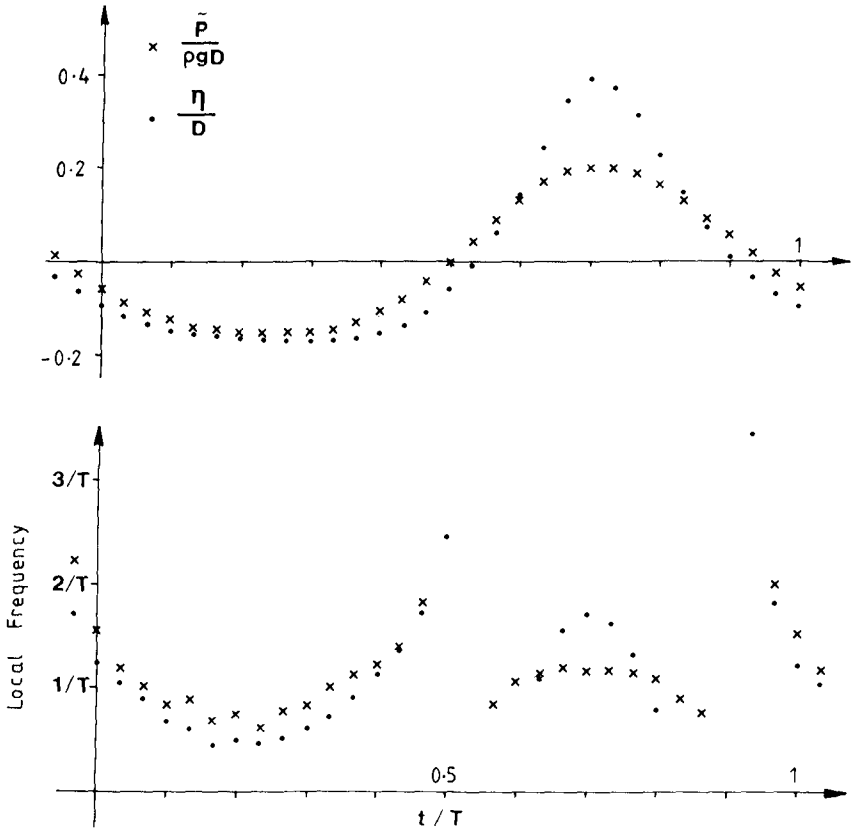

Figure 1 : Top : Measured surface elevations η and dynamic bottom pressures $\tilde{p}$ for a steep 1.8 second wave in 0.4 metres of water. Bottom : local frequencies derived from $\tilde{p}$ and η . The local frequencies $f(\tilde{p},t)$ and $f(\eta,t)$ are well behaved in the crest and trough areas but tend to be erratic near the zero crossings. The well behaved frequencies are typically between half and two times the crest to crest frequency 1/T.

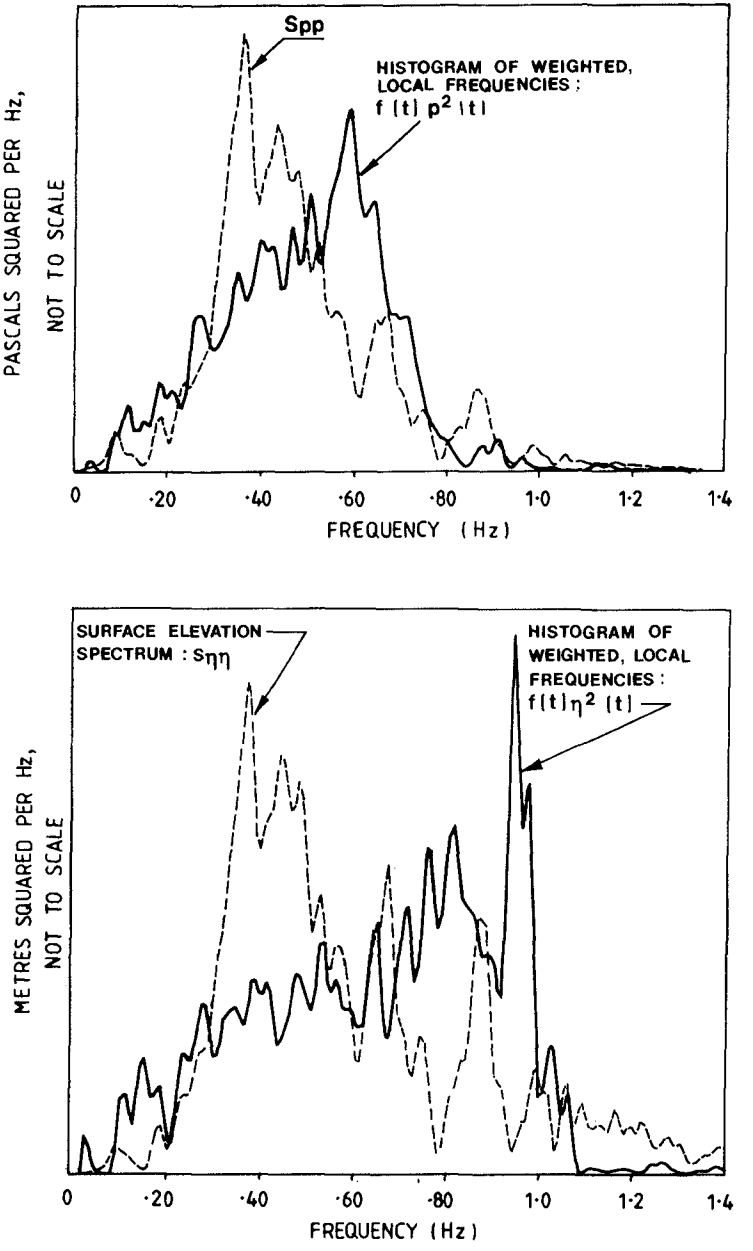

Figure 2 : Histogram of weighted local frequencies and conventional energy spectrum for both $\tilde{p}$ and η from the same irregular wave record.

A histogram of the local frequencies from a wave record weighted with the square of the local amplitude may serve like a spectrum for describing the distribution of wave energy. The meaning of the average frequency is rather obvious but the physical implications of other statistics like the coefficient of variation need further investigation. An example of the histogram of weighted local frequencies is shown in Figure 2 together with the conventional spectrum of the same record. We see that the histogram has a much simpler shape. Possible areas of application for the histogram are break water design where increased attention has been paid to wave shapes recently, see e.g. Bruun et al (1985), and remote sensing of wave climates where the distribution of surface slopes and curvatures influence the surface reflectivity.

CALCULATING THE LOCAL FREQUENCY

A frequency f or radian frequency $\omega = 2\pi f$ can be affixed to any point $x_m = x(t_m)$ in a time series by fitting a cosine curve locally around the point. The simplest fitting proceedure is to pick the uniquely defined curve

$$x(t) = A \cos(\omega t - \varphi) \tag{2}$$

which passes through the point and its neighbour on either side, while more robust estimates may be obtained by least squares fitting to more than three points.

The exact value of ω for a 3-point fit can be found in the following way. Let

$$x_m = A \cos\theta \tag{3}$$

and hence

$$x_{m\pm1} = A \cos(\theta \pm \omega\Delta) \tag{4}$$

where Δ is the time increment between the three points. Then it follows from trigonometric identities that ω can be found from

$$\omega = \frac{1}{\Delta} \cos^{-1}\left(\frac{x_{m+1} + x_{m-1}}{2 x_m}\right) \tag{5}$$

This estimate is always defined if $x_n \neq 0$ but the imaginary values which result if

$$2|x_m| < |x_{m+1} + x_{m-1}| \tag{6}$$

are not immediately interpretable in physical terms. Note that the time interval Δ is not necessarily equal to the sampling interval. Often it is more appropriate to choose Δ a few times larger than the sampling interval.

A slightly simpler estimate, which avoids evaluation of the inverse cosine function in (5) can be obtained via the identity

$$x'' = -\omega^2 x \tag{7}$$

which holds for all functions of the form (2). The second derivative x" is estimated by

$$x'' \approx \frac{x_{m-1} - 2x_m + x_{m+1}}{\Delta^2} \tag{8}$$

Then using (7) we have

$$\omega^2 = -\frac{x''}{x} \approx -\frac{x_{m-1} - 2x_m + x_{m+1}}{\Delta^2 x_m} \tag{9}$$

Again Δ can be a multiple of the sampling interval. The estimate

$$\hat{\omega}^2 = -\frac{x_{m-1} - 2x_m + x_{m+1}}{\Delta^2 x_m} \tag{10}$$

is a biased estimate of ω^2. It under estimates ω in accordance with

$$\hat{\omega}^2 = \omega^2\left[1 - \tfrac{1}{12}(\omega\Delta)^2\right] + O(\Delta\omega)^6 \qquad (11)$$

Hence an improved estimate can be obtained from

$$\omega_1^2 = \hat{\omega}^2\left[1 + \tfrac{1}{12}(\hat{\omega}\Delta)^2\right] \qquad (12)$$

The latter formula is within one percent of error for $\Delta < T/6$ or $\omega\Delta \lesssim 1.0$.

A PRACTICAL APPLICATION

Pressure transducers have several advantages over other field instruments used for wave recordings. They are the most reliable and the easiest to install. It is therefore of interest for practicing engineers to be able to derive other wave properties, such as surface elevations and velocities from measured bottom pressures. We shall now see that local approximations provide a very efficient tool for dealing with this problem.

For a sine wave, the surface elevation $\eta(t)$ is related to the dynamic bottom pressure $\tilde{p}(t)$ by

$$\eta(t) = \frac{\tilde{p}(t)}{\rho g}\cosh kD \qquad (13)$$

where ρ is the fluid density, g the acceleration of gravity and D the water depth. The wave number k is related to the radian frequency through the dispersion relation

$$kD \tanh kD = \frac{\omega^2}{g}D \qquad (14)$$

The traditional way of deriving $\eta(t)$ from $\tilde{p}(t)$ for irregular waves has been by using spectral analysis. The method involves three steps:

1. Find the discrete pressure specturm $S_{pp}(\omega_i)$

2. Transform each spectral estimate in accordance with (13) :

$$S_{\eta\eta}(\omega_i) = S_{pp}(\omega_i) \cosh(k_i D)/\rho g$$

3. Create the $\eta(t)$ time series from $S_{\eta\eta}(\omega_i)$ by the discrete, inverse Fourier transform.

This traditional method is neither fast nor accurate but fortunately we can develop alternative methods involving the use of local approximations which are both faster and more accurate.

The most straight forward approach is to apply the linear-wave formula (13) using a local wave number determined from the local frequency through (14). Such an approach does however systematicly under estimate $\eta(t)$ because linear wave theory, from which (13) is taken, is not geared to handle finite surface elevations. We are free to use any wave theory we like as soon as we have a frequency to work with, but for this purpose it is adequate just to use a modified version of Equation (13)

$$\eta(t) = \frac{\tilde{P}(t)}{\rho g} \cosh k\left(D + \frac{\tilde{P}(t)}{\rho g}\right) \qquad (15)$$

where k is the local wave number determined from the local frequency through (14). Replacing the depth D by $D + \tilde{P}/\rho g$ in the argument of the cosh-function accounts in a way for the fact that the instantaneous water surface can be a finite distance away from the mean water level. Equation (15) based on local frequencies is superior to the traditional spectral method with respect to both speed and accuracy. An example is shown in Figure 3 where estimates from both methods are compared to the actual, measured surface elevations. The local approximations method recovers the crest height a little better and the shape of the troughs is more accurately represented as well. In terms of the normalised deviation dev $(x,y) = \sqrt{\Sigma(x-y)^2/\Sigma y^2}$ based on the full 123 second record, the local approximation estimates gave a deviation of 0.215 while the spectral estimates gave a deviation of 0.242. The fine details of the results depend on the measures applied with each method to overcome noise problems. This aspect will be treated in detail later.

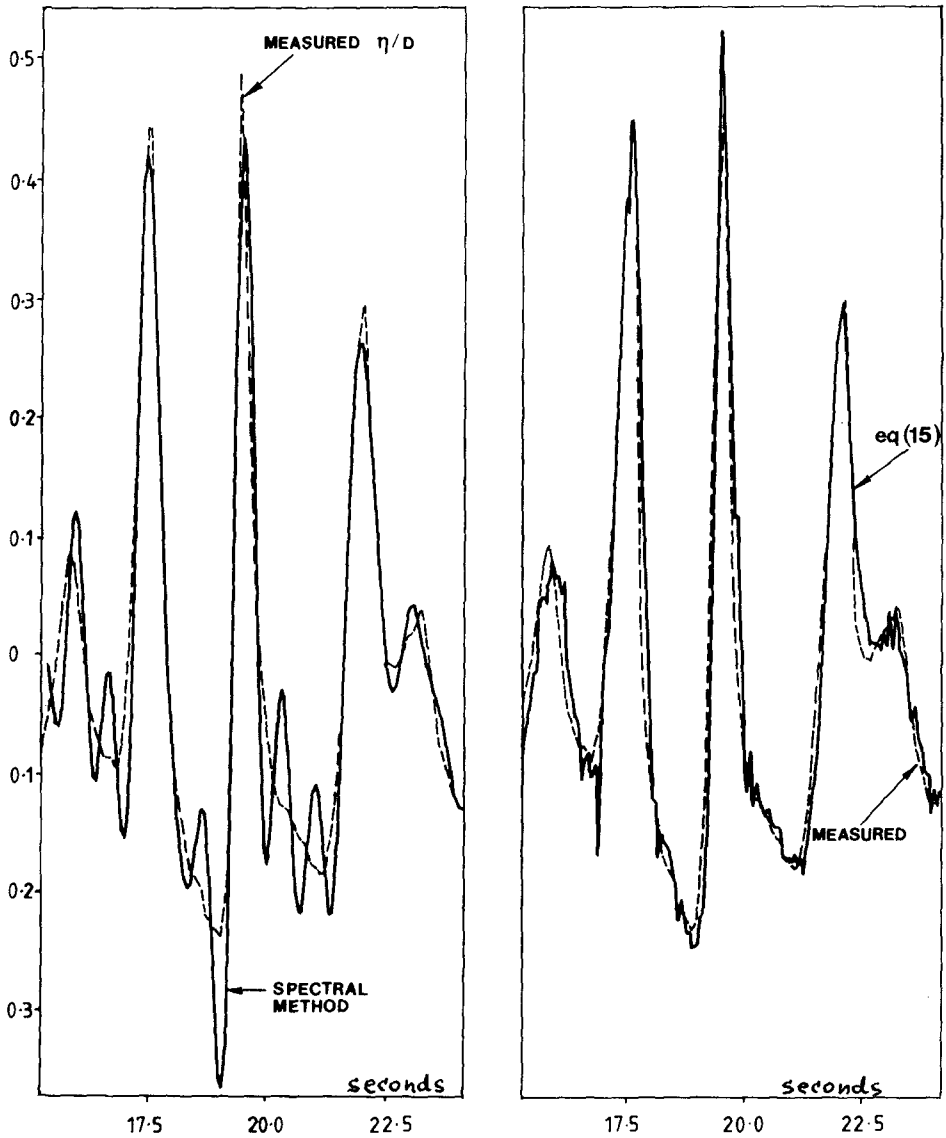

Figure 3 : Estimates of surface elevations from bottom pressures compared to measured surface elevations. The water depth D was 0.38 metres. We see that equation (15) with local frequencies is slightly better at estimating crest heights and much better at estimating depth and shape of the troughs than the spectral method. No smoothing has been applied anywhere in the processing. The cut off frequency of 1.45 Hz applied in the spectral method was deemed optimal.

SEMI EMPIRICAL TRANSFER FUNCTIONS

Semi empirical transfer functions are useful in many practical cases. Also with respect to these can the concept of local frequencies be helpful. Consider again the problem of estimating surface elevations $\eta(t)$ from dynamic bottom pressures $\tilde{p}(t)$ in irregular waves. We want a very simple algorithm for processing data by hand or by micro processor.

From a heuristic physical consideration we may argue that the strength with which a water surface signal is transferred to the bottom depends on the ratio between the radian frequency ω of the signal and the natural frequency of the water column $\sqrt{g/D}$ i.e.

$$\frac{\eta}{\tilde{p}/\rho g} = F\left(\frac{\omega^2}{g} D\right) \tag{16}$$

and here we may replace D by $D + \tilde{p}/\rho g$ in order to account for finite changes in depth hence we have

$$\frac{\eta}{\tilde{p}/\rho g} = F\left[\frac{\omega^2}{g}\left(D + \frac{\tilde{p}}{\rho g}\right)\right] \tag{17}$$

For this purpose we will use the simplest possible estimate of the local frequency, namely

$$\hat{\omega}^2 = -\frac{\tilde{p}_{m-1} - 2\tilde{p}_m + \tilde{p}_{m+1}}{\tilde{p}_m \Delta^2} \tag{18}$$

and hence we have

$$\frac{\eta_m}{\tilde{p}_m/\rho g} = F\left[\frac{-\tilde{p}_{m-1} + 2\tilde{p}_m - \tilde{p}_{m+1}}{\tilde{p}_m \Delta^2 g}\left(D + \frac{\tilde{p}_m}{\rho g}\right)\right] \tag{19}$$

To determine the empirical function F we now plot the left hand side of (19) versus the argument of F for a few accurately known data points, for example taken from Dean's stream function tables (Dean, 1974). That has been done in Figure 4 and we see that F can be adequately represented by a simple exponential, $F(x) = \exp(2x/3)$. Hence the full expression for our transfer function is

$$\eta_m = \frac{\tilde{P}_m}{\rho g} \exp\left[\frac{2}{3} \frac{-\tilde{P}_{m-1} + 2\tilde{P}_m - \tilde{P}_{m+1}}{\tilde{P}_m \Delta^2 g} \left(D + \frac{\tilde{P}_m}{\rho g}\right)\right] \qquad (20)$$

a simple one line expression which compares favourably with the spectral method with respect to accuracy, see Figure 5. The normalised deviation for the eq(20)-estimates was 0.208 while the corresponding value for the spectral estimates was 0.242.

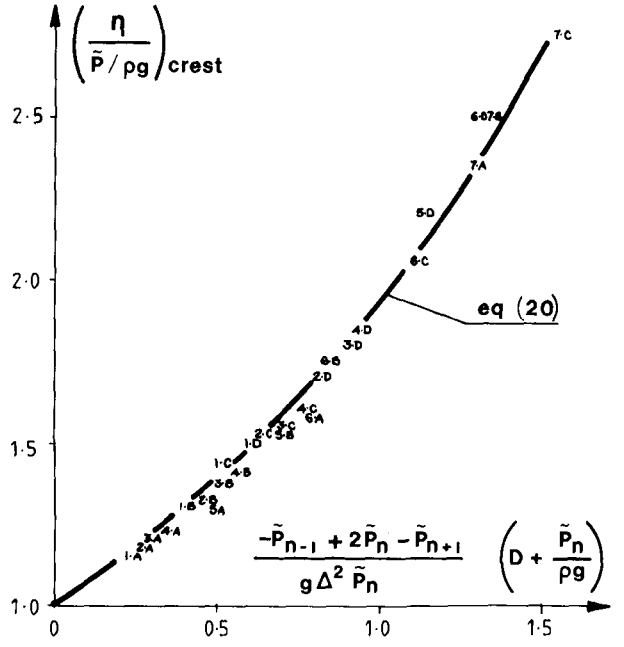

Figure 4 : Data from Dean's stream function tables from which the empirical function in (19) can be determined. We see that equation (20) provides an easy and reliable fit to the data.

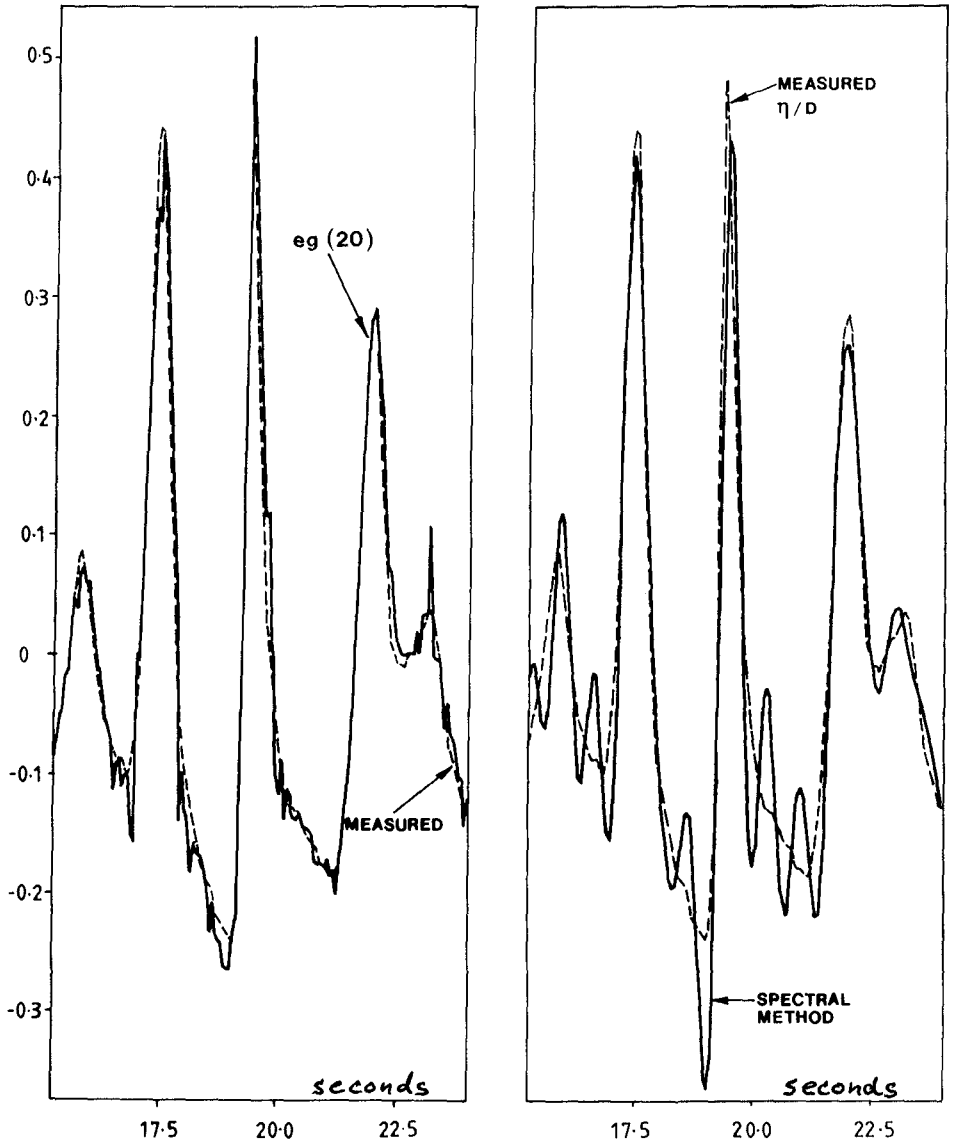

Figure 5 : Surface evaluation estimates by equation (20) and the spectral method compared to actual, measured surface elevations. Equation (20) matches both crests and troughs better than the spectral method and of course it requires much less computational effort.

RESOLUTION VERSUS NOISE

In dealing with real data, there is always a problem of balancing resolution against noise, especially when high frequency signals have to be amplified strongly as is the case when deriving surface elevations from bottom pressures.

The resolution is determined by the time increment Δ. A small Δ gives high resolution while a large Δ overlooks high frequency variations. There is no general rule for the choice of Δ since the optimum must obviously depend on the relative strength and the difference in frequency between signal and noise. However, the following value will generally provide a reasonable first guess.

$$\Delta = \sqrt{D/g} \tag{21}$$

The fact that the meaningful, locally defined frequencies generally occupy a narrower band than all the harmonics needed for a spectral description (see Figure 2) means that it is generally possible to apply a lower cut off frequency when using a local approximations method than with a spectral method.

While the above is true, it must be remembered that there are special problems with defining the local frequency near zero crossings. Unreasonably large or imaginary values of ω may occur. A reasonable upper limit for acceptable local frequencies is $\omega^2 = 1.5\ g/D$, which corresponds to cosh kh = 2.6

When imaginary or unacceptably large values of ω occur it is generally adequate to assign the value zero to ω, at least for those practical problems that have been dealt with so far.

Because the details of the water motion close to zero crossings is generally unimportant, the problem of the local frequency being ill conditioned in this area is of little practical consequence.

DISCUSSION

The use of local approximations via locally defined frequencies is recommended for practical analysis of irregular waves. Firstly because it requires far less computational effort than any other available method, e.g. wave by wave analysis, Fenton's local polinomial method (Fenton 1986) or the previously most popular spectral method. Secondly because it seems to be superior to the spectral method with respect to accuracy.

The strength of local frequency methods such as (15) or (20) relative to the linear spectral method lies first of all in the fact that it is very easy to apply stretching simply by replacing the depth D with $D + \tilde{p}/\rho g$. Secondly, in the fact that the spectral method over

amplifies both signal and noise at high frequencies. This happens because it wrongly assumes that "all waves are free waves" in order to be able to calculate $k(\omega)$ from the disperson relation (14). Talking about the dispersion relation it must be admitted that applying it to a locally defined frequency probably makes very little physical sense. To this one can only reply that the justification for using equation (15) with its reliance on the dispersion relation (14) lies in its proven efficiency.

Semi empirical transfer functions like (20) do not rely on any wave theory but only on a bit of physical intuition and with this somewhat more "unassuming" nature, and their good performance they may turn out to be the most useful area of application for the concept of locally defined frequencies. The conclusions stated in this paper are essentially based on experience with a single practical problem, namely that of deriving water surface elevations from dynamic pressures measured at the bottom. This problem is however a very tough one so it is highly likely that local approximations using locally defined frequencies will prove a useful tool for solving many problems involving irregular, non linear waves.

ACKNOWLEDGEMENTS

Comments and advice from Professor J.D. Fenton has been a great help in the development of this paper. Laboratory data and computor software was kindly made available by Mr I. Varley.

CHAPTER 49

ESTIMATION OF EXTREME SEA SEVERITY FROM MEASURED DAILY MAXIMA

Michel K. Ochi*, David Mesa*, and De-Fu Liu**

ABSTRACT

This paper presents the results of a study to statistically estimate the most severe sea state (significant wave height) expected in 50 and 100 years from analysis of data consisting of the largest significant wave height observed each day by applying the Type III asymptotic extreme value distribution. In applying the Type III asymptotic distribution, the distribution parameters are estimated by three different methods: the maximum likelihood method, the skewness method, and a nonlinear regression method. Since none of these methods estimates values of the parameters which satisfactorily yield a distribution representing well the daily maximum data, a modified Type III asymptotic distribution is newly developed in the present study. The modified distribution yields an excellent fit over the entire range of the cumulative distribution, and the probability density function agrees well with the histogram constructed from the data.

INTRODUCTION

For the design of coastal and ocean structures, it is extremely important to statistically estimate the most severe sea state (the largest significant wave height) expected to occur over a period of time, on the order of 50 to 100 years, sufficiently long to cover the lifetime of the structure. The estimation is usually carried out based on a probability function established from analysis of data accumulated over several years. It should be noted that, in general, the probability distribution derived from an accumulation of significant wave height data is obtained empirically and that there is no theoretical basis for selecting any particular probability distribution to characterize the significant wave height.

However, if the data consist of the largest significant wave height observed every day, and if the number of observations is sufficiently large, then there is a scientific basis to choose particular probability distributions for estimating extreme significant wave

height. That is, the probability distribution applicable for the significant wave height under this situation must be one of three asymptotic distribution functions developed by Fisher, Tippett, and Frechet -- so called Type I, II, and III asymptotic extreme value distributions.

The Type I asymptotic distribution has been by far the most commonly used method for estimating extreme values from an analysis of data consisting of the daily, weekly, and monthly largest values. The results of the present analysis show that the Type I asymptotic distribution demonstrates reasonably good agreement, in general, with significant wave height data. However, the distribution deviates from the data cumulative distribution for large significant wave heights. This results in substantial overestimation of the 50 and 100 year extreme values if the estimation is made by extending the theoretical cumulative distribution function.

The Type III asymptotic distribution has a unique characteristic in that the distribution is bounded from above. This feature of the distribution appears to be pertinent for analysis of wave data, since the height of waves cannot be unlimited in reality due to breaking. For analysis of data by applying the Type III asymptotic distribution, the distribution parameters are estimated by three different methods: the method of maximum likelihood, the skewness method, and a nonlinear regression method. Unfortunately, none of these methods estimates values of the parameters which satisfactorily yield a Type III asymptotic distribution representing well the daily maximum data.

This paper presents a newly developed modified Type III asymptotic extreme value distribution which yields an excellent fit over the entire range of the cumulative distribution.

DAILY LARGEST SIGNIFICANT WAVE HEIGHT AND ASYMPTOTIC DISTRIBUTIONS

The data used in the present study were obtained by the Coastal Engineering Research Center on the eastern coast of the United States, Duck, North Carolina, at a location 450 m off the shoreline where the water depth is 8.8 m as an average. Observations of significant wave height were made four times daily during a 42 month period from 1979 to 1983. A total of 1,061 observations of largest significant wave height for each day was accumulated as shown in Table 1, and the data (for brevity, they may be called the daily maxima) were analyzed through application of Type I and Type III asymptotic extreme value distributions.

Figure 1 shows the plot of data on Type I extreme value probability paper. If the data points lie on a straight line, it may safely be concluded that the data follow the Type I asymptotic distribution, and contain all statistical characteristics thereof. This allows the extrapolation of the data to higher periods to be made very simply merely by extension of the straight line.

Table 1. Daily maximum significant wave height data

Significant wave height (m)	Number of observations
0.2 - 0.4	11
0.4 - 0.6	151
0.6 - 0.8	158
0.8 - 1.0	175

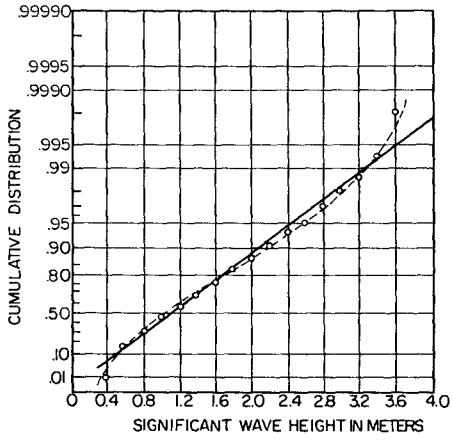

Figure 1. Cumulative distribution function of daily maximum significant wave height plotted on extreme value probability paper

It appears in Figure 1 that the data are represented reasonably well by the Type I asymptotic distribution. However, if we examine the results carefully, the cumulative distribution function of the data (the curved line given in the figure) shows a tendency to slowly deviate with different character from that of the straight line at the higher significant wave heights. Hence, by extrapolating the data and the estimated Type I distribution to comparable return periods, it is seen that the Type I distribution may yield an increasing overestimation of the extreme value prediction. This is a major shortcoming of utilizing the Type I asymptotic distribution for extreme sea state estimation.

Type III asymptotic distribution has three parameters, w, v, and k, as shown in Equations (1) and (2).

Cumulative distribution function

$$F(y) = \exp\left\{ - \left(\frac{w - y}{w - v}\right)^{k} \right\} . \qquad (1)$$

Probability density function

$$f(y) = \frac{k}{w - v} \left(\frac{w - y}{w - v}\right)^{k-1} \exp\left\{ - \left(\frac{w - y}{w - v}\right)^{k} \right\} . \qquad (2)$$

$$-\infty < y < w , \quad 0 < v,k < \infty$$

where, y = random variable, daily largest significant wave height for the present problem.

The distribution is bounded from above by the parameter w. If the parameters w and k become increasingly large, the Type III distribution tends to default to Type I distribution. The Type III distribution has not often been considered for estimating extreme values in engineering problems to the same extent as the Type I distribution. It has a feature, however, that the upper value of the distribution is bounded and thereby the extrapolation of the cumulative distribution function should not overestimate the extreme values.

In order to evaluate the parameters of the distribtuion from the data, the following three different methods are considered in the present study:

(1) Maximum Likelihood Method

The likelihood function of the distribution can be obtained from Eq. (1) as,

$$L(y_i|w,v,k) = \prod_{i=1}^{n} f(y_i) = k^n (w - v)^{-nk}$$

$$x \prod_{i=1}^{n} (w - y_i)^{k-1} \exp\left\{ - \sum_{i=1}^{n} \left(\frac{w - y_i}{w - v}\right)^k \right\} . \qquad (3)$$

Since $L(y_i|w, v, k)$ is a monotonic function, partial differentiation of $\ell n\, L(y_i|w, v, k)$ with respect to the unknown parameters w, v, and k and setting each equal to zero results in

$$\frac{\partial}{\partial w} \ell n\, L = - \frac{nk}{w - v} + \sum_{i=1}^{n} \left[k\left(\frac{w - y_i}{w - v}\right)^k \frac{v - y_i}{(w - y_i)(w - v)} + \frac{k - 1}{w - y_i} \right] = 0$$

$$\frac{\partial}{\partial v} \ell n\, L = \frac{nk}{w - v} + \sum_{i=1}^{n} \frac{-k}{w - v} \left(\frac{w - y_i}{w - v}\right)^k = 0$$

$$\frac{\partial}{\partial k} \ell n\, L = \frac{n}{k} - n\, \ell n(w - v) - \sum_{i=1}^{n} \left[\left(\frac{w - y_i}{w - v}\right)^k \ell n \left(\frac{w - y_i}{w - v}\right)^k - \ell n\left(\frac{w - y_i}{w - v}\right) \right] = 0 . \qquad (4)$$

The three parameters of the distribution can be estimated from the above equations. It is found, however, that the solution cannot be obtained explicitly, but instead involves a lengthy iterative numerical procedure. Furthermore, it is found that the solution is very sensitive to the parameter v. Under these conditions a numerical iterative procedure is developed which initially fixes the parameter v, then determines the corresponding values of the parameters w and k. Since $F(y) = e^{-1}$ for $y = v$ in Eq. (2), the theoretical value of v which satisfies the relationship $F(y = v) = e^{-1}$ is used as a base from which to initiate the iterative algorithm. Graphic and regression analysis indicates a linear relationship exists between the parameters w and k for a given v.

No combination of the w, v, and k parameters determined through the maximum likelihood method, however, represents well the cumulative distribution function obtained from the data as demonstrated in Figure 2. The figure shows a comparison of the data and Type III asymptotic cumulative distribution functions obtained for three values of the parameter v (0.96, 1.00, and 1.04) and the corresponding w and k parameter sets.

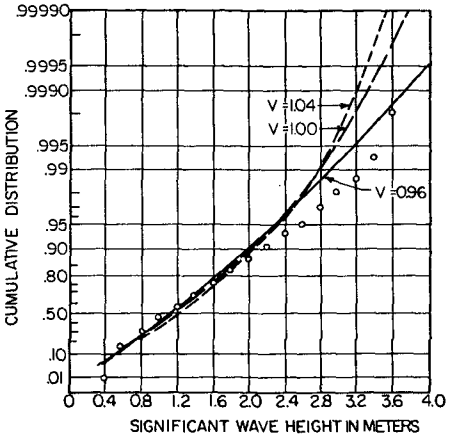

Figure 2. Daily maximum significant wave height and Type III asymptotic cumulative distributions, based on maximum likelihood method

(2) Skewness Method

The principle of the skewness method is based upon the fact that the skewness of the Type III asymptotic distribution can be theoretically expressed solely as a function of the parameter k (Gumbel, 1966). That is,

$$\text{Skewness } \gamma = \{\Gamma(1 - 3/k) - 3\Gamma(1 + 2/k)\,\Gamma(1 + 1/k) + 2\Gamma^3(1 + 1/k)\}\{B(k)\}^3 \qquad (5)$$

where, $B(k) = 1/\{\Gamma(1 + 2/k) - \Gamma^2(1 + 1/k)\}^{1/2}$.

The parameter k therefore can be evaluated from Eq. (5) by calculating the skewness γ from the observed data by

$$\gamma = \frac{E[(y - E[y])^3]}{(\text{Var}[y])^{3/2}} \, . \qquad (6)$$

The parameters w and v are subsequently determined by evaluating the mean and variance with the aid of the following formulae:

$$E[y] = w - (w - v)\,\Gamma(1 + 1/k)$$
$$\mathrm{Var}[y] = (w - v)^2\,\{\Gamma(1 + 2/k) - \Gamma^2(1 + 1/k)\}\,. \tag{7}$$

It should be noted that theoretical background of the skewness method is sound; however, it is sometimes difficult to determine the k-value in practice as is the case for the problem discussed below.

The theoretical skewness expression given in Eq. (5) is shown in Figure 3 as a function of k. The curve is asymptotic at k = 0 and monotonically increases through the zero skewness point (k = 3.602) until reaching its limiting value at 1.139. The skewness increases rapidly up to approximately k = 40, then becomes increasingly insensitive to k as k becomes large. The sample skewness as calculated from Eq. (7) is $\gamma = 1.134$ for the data given in Table 1. This value is very near the limiting value 1.139; hence, a very wide range of k values is possible in this limiting region. For this reason, the skewness method for estimating the parameter k appears to be inappropriate for the present problem.

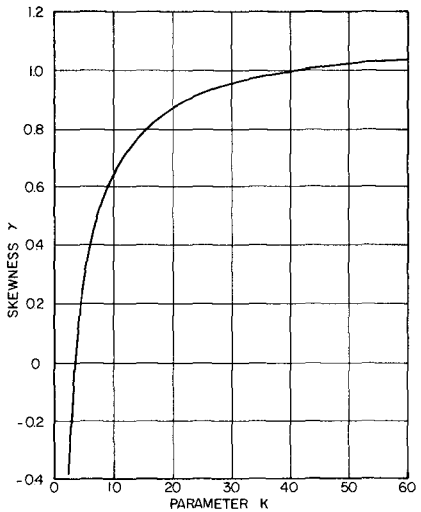

Figure 3. Skewness γ as a function of k

To overcome this difficulty, an alternative method is developed using the skewness approach as a foundation. That is, the parameter v is estimated from the cumulative distribution function constructed from the data such that the parameter v satisfies the condition that the cumulative distribution function $F(y) = e^{-1}$ for $y = v$. The other two parameters are evaluated by using the v-value thusly determined. However, the derived distribution does not well represent the observed data as shown in Figure 4.

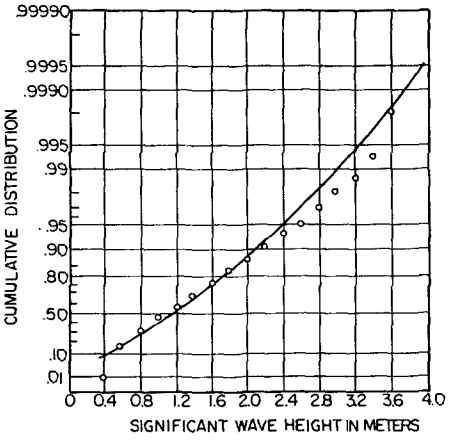

Figure 4. Daily maximum significant wave height and Type III asymptotic cumulative distributions, based on skewness alternative method

(3) Nonlinear Multiple Regression Method

Another method to establish the parameters of the Type III asymptotic extreme value distribution is to apply a nonlinear multiple regression analysis. For this, taking the logarithm of Eq. (1) twice results in

$$\ell n \left[- \ell n F(y) \right] = k \, \ell n \left(\frac{w - y}{w - v} \right) . \qquad (8)$$

The left-hand side of Eq. (8) is determined from the data. The right-hand side is now linear in the parameter k, and monotonic in the parameters w and v. Linearization of the exponent k substantially increases the computational stability in determining the parameter values.

A comparison between the cumulative distribution function obtained by the nonlinear regression method and observed data is shown in Figure 5. Figure 6 shows a comparison between the probability density function and histogram. Although the cumulative distribution function in Figure 5 appears to display a reasonable fit, it is apparent from the probability density function in Figure 6 that the distribution does not well represent the data. The peak does not possess the sharp rapid increase, but instead is much flatter and shifted to the right. Thus, it may be concluded that the Type III asymptotic distribution with the parameters determined by the nonlinear regression method does not well represent.

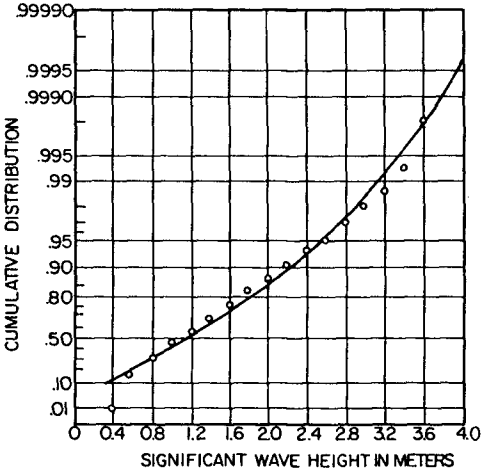

Figure 5. Daily maximum significant wave height and Type III asymptotic cumulative distributions, based on nonlinear regression method

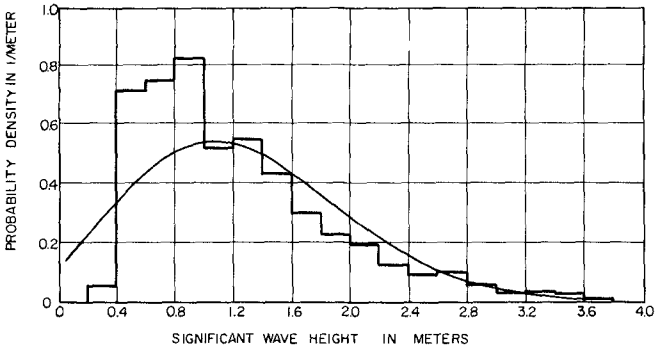

Figure 6. Comparison of daily maximum significant wave height histogram and Type III asymptotic probability density function, based on nonlinear regression method

DERIVATION OF MODIFIED TYPE III ASYMPTOTIC DISTRIBUTION

In order to improve the agreement between the Type III asymptotic extreme value distribution and the observed data, we first examine Eq. (8). Figure 7 shows a comparison between the left-hand side of Eq. (8) presented by using data points, and the right-hand side of the equation expressed using the results of the nonlinear regression method. Writing the difference between the theoretical distribution and the observed data as $\Delta(y)$ results in

$$\ell n\,[-\ell n F(y)] = k\,\ell n\left(\frac{w-y}{w-v}\right) + \Delta(y) \quad . \tag{9}$$

Here, the functional form of $\Delta(y)$ may be expressed in the form of polynomials given by

$$\Delta(y) = a + b(y - y_o) + c(y - y_o)^2 + d(y - y_o)^3 \quad . \tag{10}$$

The values of a, b, c, and y_o are determined again by employing the nonlinear regression procedure. Thus, from Eq. (9), the modified Type III asymptotic extreme value distribution can be written as

$$F(y) = \exp\left\{-\left(\frac{w-y}{w-v}\right)^k e^{\Delta(y)}\right\} \quad . \tag{11}$$

Note that F(y) given in Eq. (11) satisfies the conditions required of the cumulative distribution function. Hence, the addition of $\Delta(y)$ does not affect the basic characteristics of the original Type III asymptotic distribution. If $\Delta(y)$ is zero over the entire variate range, then the modified Type III asymptotic distribution reduces to the original Type III asymptotic distribution.

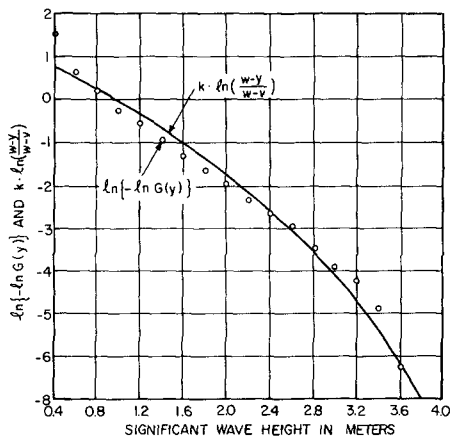

Figure 7. Comparison of cumulative distribution functions of daily maximum significant wave height and Type III asymptotic distribution, based on nonlinear regression method

Figure 8 shows the results of computations using Eq. (10) as applied to the difference $\Delta(y)$ obtained from Figure 6 for which we have $a = -0.314$, $b = 0.513$, $c = 0.464$, $d = -0.171$, and $y_o = 1.687$. The circles in the figure are the differences between the data and the Type III asymptotic distribution obtained from Figure 7.

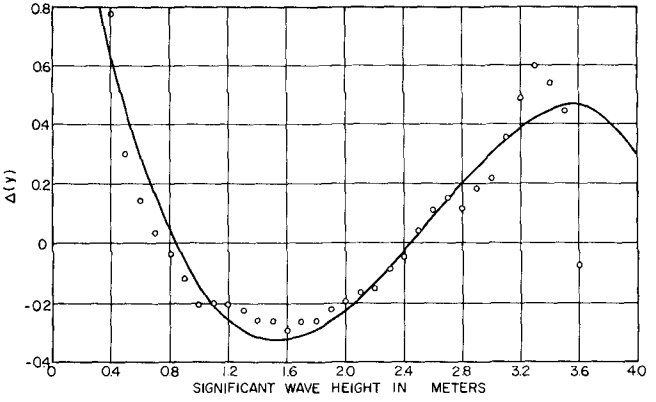

Figure 8. Comparison of $\Delta(y)$ and difference between cumulative distributions of daily maximum significant wave height and Type III asymptotic distribution, based on nonlinear regression method

A comparison between the cumulative distribution function of the modified Type III asymptotic distribution given in Eq. (11) and that obtained from data is shown in Figure 9. Good agreement can be seen between them over the entire data range. The cumulative distribution

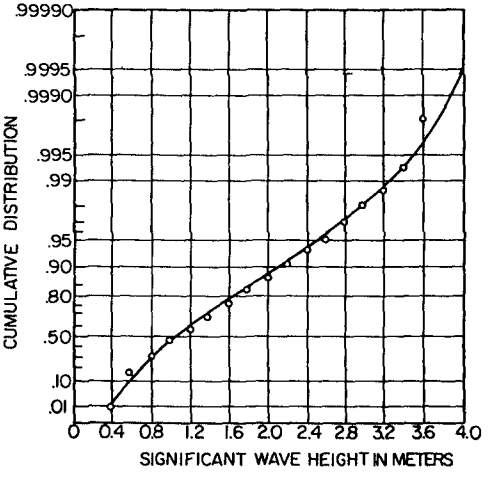

Figure 9. Daily maximum significant wave height and modified Type III asymptotic cumulative distributions

function for large significant wave heights (which is the area of interest) shows asymptotic characteristics as it approaches its limiting value. A comparison between the probability density function of the modified Type III and the histogram is shown in Figure 10 in which a good agreement can be seen over the entire variate range.

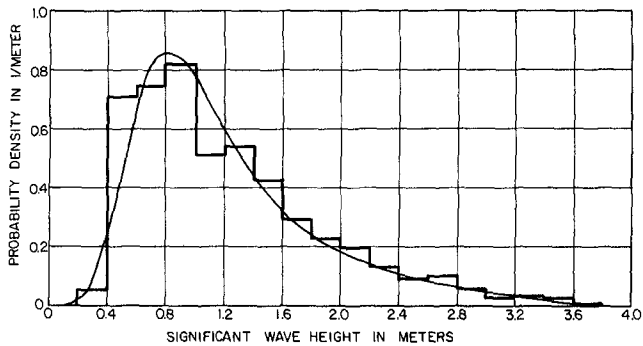

Figure 10. Comparison of daily maximum significant wave height histogram and modified Type III asymptotic probability density function

ESTIMATION OF EXTREME VALUES

The extreme sea severities most likely to occur (modal values of the extreme value distributions) in 50 and 100 years are evaluated from the data given in Table 1 by applying the Type I and the modified Type III asymptotic distributions. The estimated extreme values are tabulated in Table 2.

As can be seen in the table, the extreme significant wave heights estimated by applying the Type I asymptotic distribution are substantially greater than those estimated by applying the modified Type III asymptotic distribution. Since the Type I asymptotic distribution deviates from the data cumulative distribution for large significant wave heights as shown in Figure 1, the distribution yields an increasingly overestimation of the extreme value with increasing variate values.

Table 2 Estimation of 50 and 100 year extreme significant wave heights

Distribution	50 year (m)	100 year (m)
Type I asymptotic distribution	5.8	6.3
Modified Type III asymptotic distribution	4.2	4.3

CONCLUSIONS

This paper presents the results of a study to statistically estimate the extreme sea severity (significant wave height) expected in 50 and 100 years from analysis of data consisting of the largest significant wave heights observed each day. From results of analysis by applying the Type I and Type III asymptotic extreme value distributions, the following conclusions are drawn:

1. The cumulative distribution function of the data shows a tendency to slowly deviate with different character from that of the Type I asymptotic at the higher significant wave heights. Hence, by extrapolating the data and the estimated Type I distribution to comparable return periods, it is expected that the Type I distribution may yield an increasingly overestimation of the extreme value with increasing variate values.

2. The parameters of the Type III asymptotic distribution are estimated by three different methods: the maximum likelihood method, the skewness method, and a nonlinear regression method. None of these methods, however, estimates values of the parameters which satisfactorily yields a distribution representing well the cumulative distribution of the data.

3. The modified Type III asymptotic extreme value distribution newly developed in the present study (Equation 11) yields an excellent fit over the entire range of the cumulative distribution and the probability density function agrees well with the histogram constructed from the data.

4. The extreme significant wave heights in 50 and 100 years estimated by the Type I asymptotic distribution are substantially greater than those estimated by the modified Type III asymptotic distribution.

CHAPTER 50

Velocity Field under Plunging Waves

Akio Okayasu*, Tomoya Shibayama** and Nobuo Mimura***

ABSTRACT

In order to clarify the characteristics of the velocity field in the surf zone, three sets of detailed and precise two dimensional laboratory experiments were performed. Spatial distributions and time histories of velocity were measured by using a hot film velocimeter with a split type probe or a two components laser doppler velocimeter for regular wave conditions. Typical plunging breakers were formed during the experiments. Based on the experimental results, a model was investigated in order to estimate the two dimensional distribution of the on-offshore steady current below the trough level.

1. INTRODUCTION

The velocity field in the surf zone is much concerned with the phenomena there. Therefore, it is a very important technical problem to make it clear. The velocity field there is rather complicated because of its non-uniformities in time and space. However, with the recent development of the velocity measurement techniques, many researches have been carried out to clarify the structure of the turbulent velocity field in the surf zone by measuring the velocity itself [Sakai et al.(1984), Aono and Hattori (1984), Nadaoka et al.(1986) and Mizuguchi (1986)].

Svendsen et al.(1978) separated the surf zone into three regions which were an outer, inner and run-up region. In the outer region, rapid transitions of wave shape occurs, particularly in case of plunging breakers. Sawaragi and Iwata (1974) suggested the existence of a large scale vortex formed just below the wave plunging and it is frequently called "horizontal roller" or "plunging vortex". In the inner region, the breaking wave propagates shoreward with deformation like a bore. Both such bore-like waves and plunging vortexes seem to give strong effect to the generation of turbulence in the surf zone. On the other hand, the existence of "undertow" caused by the mass transport of breaking waves has recognized for many years [see e.g. Hansen and Svendsen (1984)].

* Graduate Student, Dept. of Civil Eng., Univ. of Tokyo, Bunkyo-ku, Tokyo, 113 JAPAN
** Associate Professor, Dept. of Civil Eng., Univ. of Tokyo, Bunkyo-ku, Tokyo, 113 JAPAN
*** Associate Professor, Dept. of Civil Eng., Ibaraki Univ., Hitachi, Ibaraki, 316 JAPAN

Thus we will consider the following factors: (1) plunging breakers, (2) bore-like waves and (3) undertows, which characterize the velocity field in the surf zone in comparison with that in the offshore region. One of the objectives of the present study is to clarify these characteristics of the velocity field through detailed and precise laboratory experiments.

Then, applying the results from these experiments, we will formulate a model to estimate the two dimensional distribution of on-offshore steady current below the trough level.

2. EXPERIMENTS

2.1 Experimental Arrangements and Procedures

Three individual laboratory experiments were performed in a two dimensional wave flume which was 23m long and 0.8m wide and two different beach profiles were used, a step type and a constant slope of 1/20.

For the case 1, the step type beach profile was used for the sake of grasping the behavior of the plunging vortex. The profile consisted of a 1/10 slope and a flat bed. The reasons why we chose this type of beach topography were to fix the breaking point of each wave and to reserve an enough region for the measurement. The beach topography is shown in Fig.1. The measuring area was from 0.5cm to 14.5cm above the bottom and 80cm long in an on-offshore directed vertical plane. The measuring points were arranged to make 2cm grids.

For the case 2 and 3, a constant slope of 1/20 was used to measure the whole area of the surf zone. And it was expected that the effects of the bore-like waves and the undertows would be revealed. The measuring areas were about 250cm long in both cases, but the arrangements of measuring points were different. The 2cm grids arrangement was taken for the case 2. The lowest points were 7mm above the bottom and the detailed arrangement is shown in Fig.2. On the other hand, for the case 3, an arrangement which was rough in the horizontal direction and close in the vertical direction was used for the purpose of detailed measurements of the vertical profiles of the undertow. The measuring points were arranged with 10cm distance in the on-offshore direction and 2.5-10mm distance in the vertical direction. On every measuring line, at least seven measuring points were set below the trough level. The lowest ones were 2mm above the bottom. The arrangement is shown in Fig.3 which is enhanced in the vertical direction.

The x-axis and z-axis were set to be shoreward and vertically upward, respectively. The origin of the coordinates in the case 1 was on the bottom as shown in Fig.1 and in the case 2 and 3, the shorelines at the still water levels were set to be the origins. In the case 3, the breaking point was at x_b=-250cm (indicated by "A" in Fig.3), the plunging point at x_p=-215cm ("B" in Fig.3) in the coordinates. After breaking, the wave propagates shoreward forming successive vortexes on the water surface. And the point where this vortex become a rather stable "surface roller" was around x_i=-170cm ("C" in Fig.3). The point

where the surface roller began to attenuate was at x_d=-80cm ("D"). The mean shoreline was at x_s=50cm in the case 3. In the case 1 and 2, the breaking points were at x_b=10cm, -225cm (indicated by "A" in Fig.1 and 2), and the plunging points at x_p=24cm, -162cm ("B"), respectively.

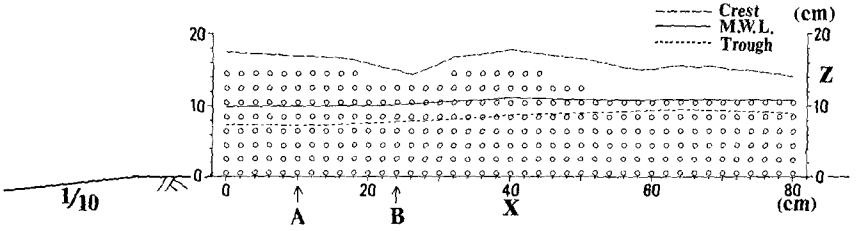

Fig.1 Measuring points arrangement for case 1

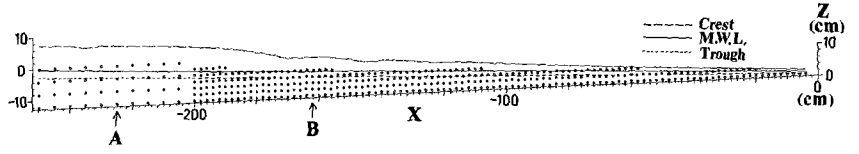

Fig.2 Measuring points arrangement for case 2

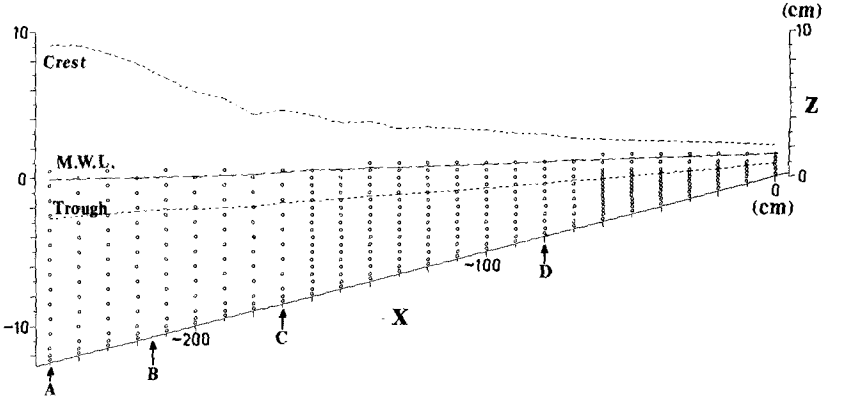

Fig.3 Measuring points arrangement for case 3

The experimental conditions are listed in Table I. In the table, T is the wave period, h_i the water depth in the offshore uniform depth region, H_i the wave height there, H_0/L_0 the deep-water wave steepness, H_b/h_b the depth wave height ratio at the breaking point.

Table I Experimental Conditions

case	beach profile	T(s)	h_i(cm)	H_i(cm)	H_0/L_0	H_b/h_b
1	step	1.55	40.0	6.95	0.0201	1.02
2	const. slope	1.50	40.0	7.36	0.0226	0.901
3	const. slope	1.50	36.4	8.15	0.0249	0.954

2.2 Data Processing and Analysis

A hot film velocimeter with a split film probe (H.F.V.) was used to measure the histories of two dimensional velocity vectors for the case 1 and 2. And a two components laser doppler velocimeter (L.D.V.) was used for the case 3.

By using the H.F.V. we can obtain two components of velocity, which are one component of velocity histories with the plus or minus sign and an absolute value of the other component. Therefore, we cannot get full information about the signs of two components. In the case 1, the sign of the on-offshore component of the velocity was not determined. Therefore, we made an assumption that the surface profile and the on-offshore velocity are in phase. So the sign of the velocity was reversed once in every wave period according to the surface profile. In the case 2, we measured the velocity two times, once for the on-offshore and the other time for the vertical direction to avoid such an uncertainty. In case of using the L.D.V., we can get full information of velocity for two components and there is no problem like that.

The velocity data were sampled every 10ms (for the case 1 and 3) or 12ms (for the case 2) and were converted into digital data. The surface elevation data were also taken simultaneously. The equi-phase-mean values of the velocity over 30 (case 1 and 2) or 100 (case 3) periods were calculated. Each wave period was divided into 150 (or 125 for the case 2) intervals and the equi-phase-mean value was obtained as an average of the velocity values at the same phase of every wave. The turbulence component was determined as the deviation from the equi-phase-mean value.

2.3 Experimental Results

The steady currents, the spatial distributions and time histories of equi-phase-mean velocities, vorticities and turbulent intensities were obtained. Fig.4 gives an example of the results for the case 1. The equi-phase-mean velocity field, the vorticity field and the turbulent intensity field at the time immediately after the wave plunging are shown in the figures. A large scale vortex can be observed obviously by the velocity vectors in the figure. And the high vorticity and turbulent intensity regions are in good agreement with the velocity vectors which suggest the existence of the plunging vortex.

Fig.5 is the successive figures of the equi-phase-mean velocities after plunging. The process that the first plunging pushes up the neighboring water body and the second plunging occurs in a smaller scale is shown. The plunging vortex formed by the first plunging does not move according with the crest and goes downward. The contour maps of the turbulent intensity at the same phases are shown in Fig.6. The high turbulent region goes ahead slowly behind the wave crest and spreads, then dissipates.

Based on these facts, it can be concluded that the generation of the plunging vortex has much influences on the characteristics of the velocity field and is much concerned with the energy dissipation process under plunging waves. Up to now, the velocity field in the surf zone were often described as a form in [steady current] + [wave component (periodic component)] + [turbulence]. This time, however, the measured results point out that the periodic component consists of the irrotational wave component and the organized rotational motion due to

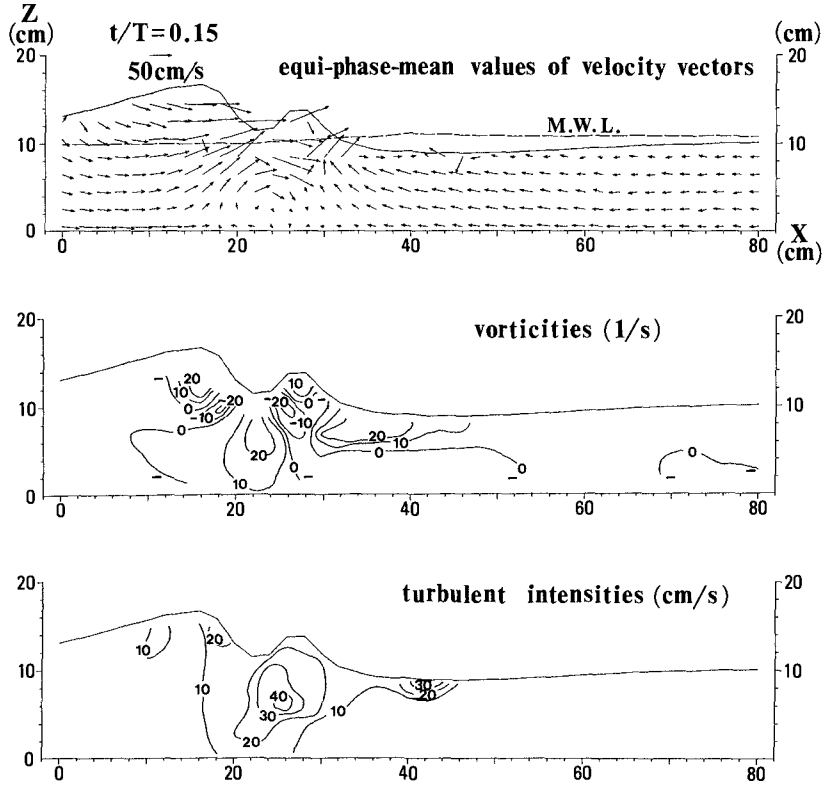

Fig.4 Velocities, vorticities and turbulent intensities immediately after wave plunging

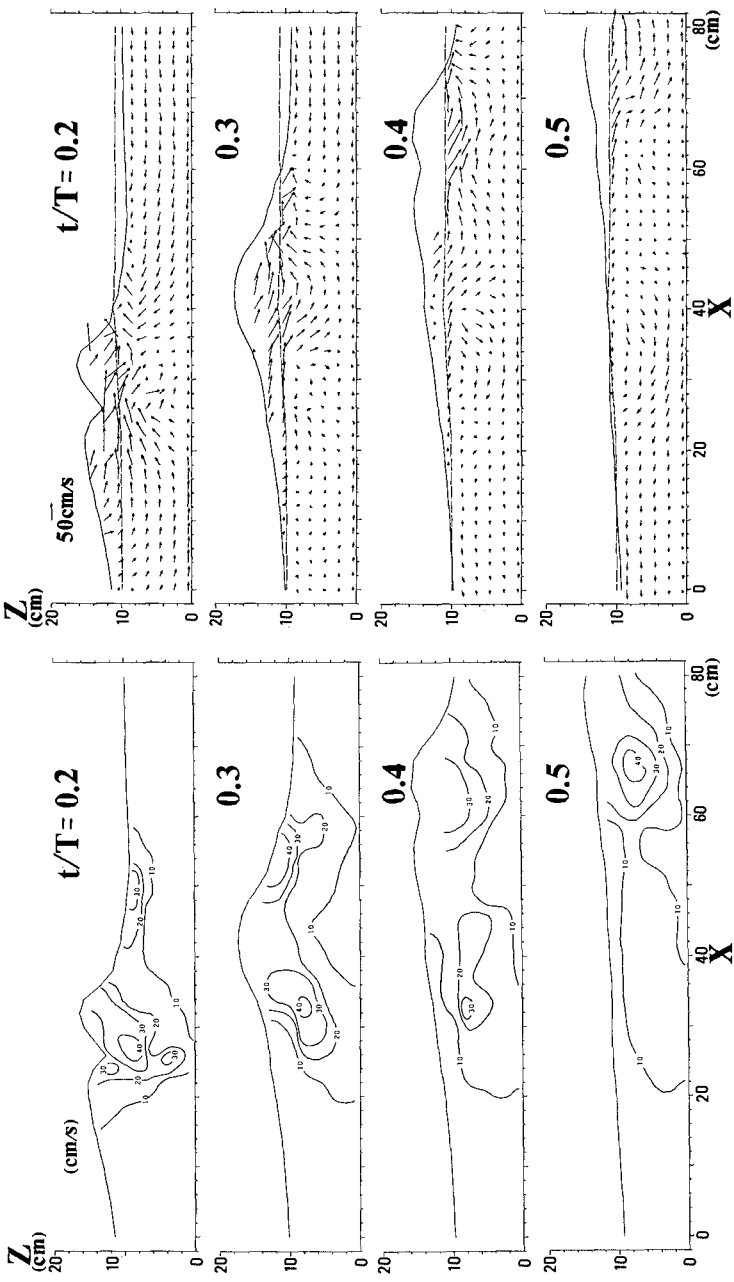

Fig.6 Distributions of turbulent intensities for case 1

Fig.5 Equi-phase-values of velocity vectors for case 1

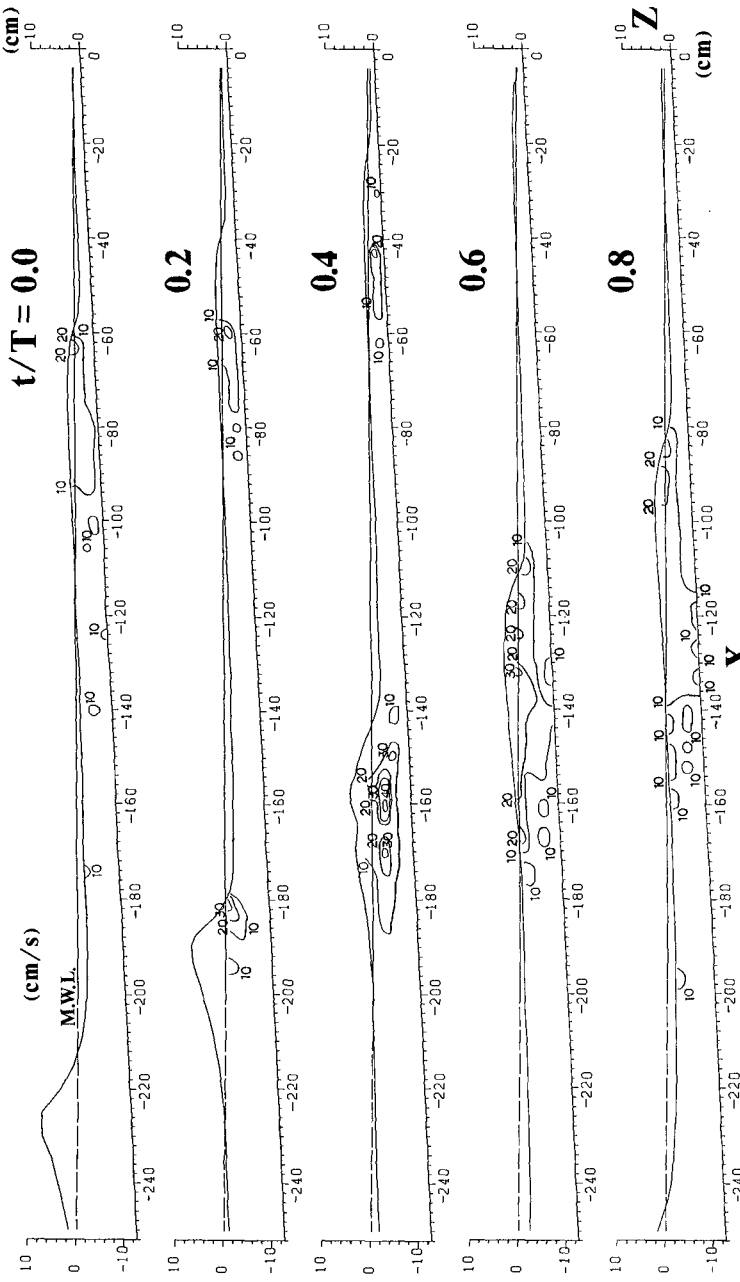

Fig.7 Distributions of turbulent intensities for case 2

the wave plunging. And it can be said that the plunging vortex is an important fluid motion existing between the wave motion and the turbulence or the steady current. Therefore, we propose that the velocity field in the surf zone should be divided into four components as [steady current] + [non-rotating wave motion] + [organized vortex motion] + [turbulence].

Fig.7 gives the successive contour maps of the turbulent intensity for the case 2. The figure shows a high turbulent region in front of the wave crest. It should be noticed that this turbulence is caused by the vortex motion as described by Nadaoka et al.(1986) which is formed there. And in the figure the turbulence spreads downward, so it should influence the turbulent flow field there and the bottom boundary layer. The figure indicates another turbulent region from x=-40cm to x=-80cm at the phases 0.0-0.6. As this high turbulent region stays there after the wave crest passes, it can be said that this turbulence is due to the interaction between the bore-like wave and the return flow from the swash zone. The high turbulent region caused by the wave plunging is also ascertained in this figure.

Fig.8 shows the steady current distribution for the case 3. Observing this figure, we found that the bottom boundary layer develops at the breaking point, but in the region where the bore well develops the bottom boundary layer does not develop any more. And we considered that it is due to the turbulence created by the bore-like waves. The large gradient of the profiles of the undertow shows that large shear stress works at the mean water level.

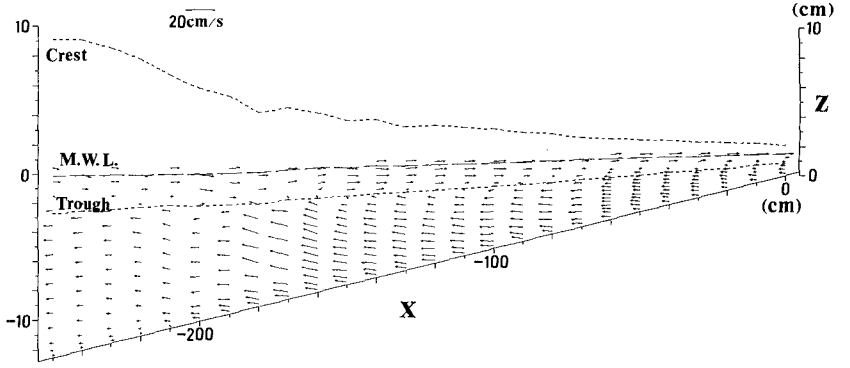

Fig.8 Steady current distribution for case 3

3. MODELING OF UNDERTOW

3.1 On-offshore Variation of Vertically Averaged Undertow

The estimation of the steady current distribution is very important for evaluating such as the convective diffusion of materials or the

sediment transport in the surf zone. However, the steady current distribution in the surf zone is much different from that of any wave theory solved in the invisid condition. The surface roller which is formed just in front of the crest of the bore-like wave propagating in the surf zone affects the mass flux balance and the turbulence generation as shown in the section 2. Now in this section, taking the case 3 as an example, we will try to formulate a model to calculate the profile of the undertow that is the steady current distribution below the trough level.

For the reasons mentioned above, when we consider the mass flux above the trough level which is transported by the bore-like wave, we should take into account both the contribution from the wave component and the contribution from the surface roller. For the wave component, Isobe et al.(1979) reported that the wave component of the velocity in the surf zone fits well to the velocity calculated by the stream function method which is presented by Dean (1965). Accordingly, the stream function method was used for estimating the wave component. We divided the bore-like wave into two parts, the surface roller and the wave component which can be explained by the stream function method. Then as shown in Fig.9, we supposed that the velocity inside the surface roller equals to the wave celerity c in the same manner as Svendsen (1984) did.

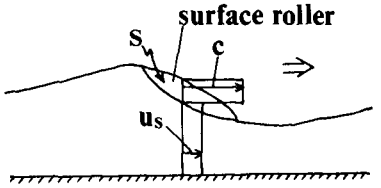

Fig.9 Assumption of velocity distribution of bore-like wave

As the sum of the mass fluxes by the surface roller and the wave component balances to the offshore steady current below the trough, the vertically averaged undertow U_c is calculated by using the projected area S of the surface roller to the xz-plane, the height of the trough d_t and wave length L as

$$U_c = U_S + U_r = U_S + \frac{S}{d_t L} c \quad , \tag{1}$$

where U_S and U_r are the contribution to U_c from the surface roller and the wave component, respectively.

Then we nondimensionalized the projected area S of surface roller by the wave height H and the wave length L. Further more introducing the parameter k,

$$k = \begin{cases} 0 & (x \leqq x_p) , \\ \dfrac{x_p - x}{x_p - x_i} & (x_p < x \leqq x_i) , \\ 1 & (x_i < x \leqq x_d) , \\ \dfrac{x - x_s}{x_d - x_s} & (x_d < x \leqq x_s) , \end{cases} \tag{2}$$

for convenience, as a degree of the development of the surface roller, we presented S as

$$S = kAHL \ . \tag{3}$$

Thus Eq.(1) becomes

$$U_c = U_s + \frac{kAH}{d_t} c \ , \tag{4}$$

where A is a constant and was taken to be 0.06 for the case 3 in order to fit the measured value U_m. And we chose the wave celerity c as

$$c = \sqrt{g (h + H)} \ , \tag{5}$$

based on the solitary wave theory, where g is the gravity acceleration and h the mean water depth.

The comparison between the calculated velocity U_c by Eq.(4) and the measured velocity U_m is shown in Fig.10. As they are in good agreement in the whole area of the surf zone, it can be said that our treatment in which the size of the surface roller is expressed by the parameter k, is adequate.

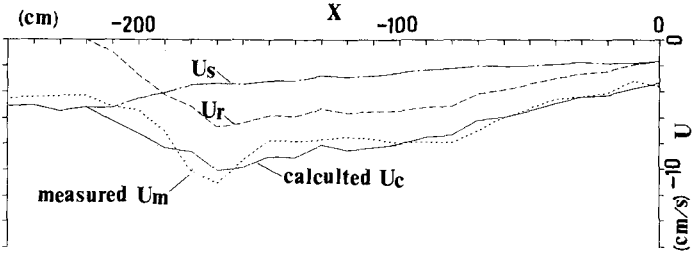

Fig.10 Calculated value of vertically averaged steady current U_c and measured value U_m

3.2 Vertical Variation of Undertow

Svendsen (1984) calculated the vertical variation of the on-offshore steady current by using the eddy viscosity model. But the magnitude of the eddy viscosity was left unknown and the agreement with the measured data near the bottom was not good enough. In the present

study, we will try to estimate the vertical profiles of the undertow with the eddy viscosity ν_t, which is directly calculated from the measured data, the Reynolds stress and the on-offshore velocity.

By using the eddy viscosity model, the relation between the mean shear stress $\bar{\tau}$ acting on the horizontal plane and the steady current U is

$$\bar{\tau} = \rho \nu_t \frac{\partial U}{\partial z} . \tag{6}$$

If the $\partial\bar{\tau}/\partial z$ takes a constant value, Eq.(6) can be written as

$$\frac{\partial \bar{\tau}}{\partial z} = \frac{\partial}{\partial z} \left(\rho \nu_t \frac{\partial U}{\partial z} \right) = \alpha_1 (x) = \text{const.} \tag{7}$$

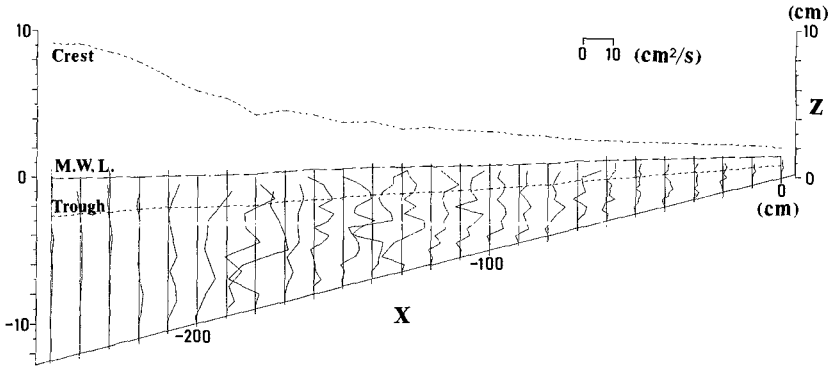

Fig.11 Distribution of mean eddy viscosity averaged over one wave period

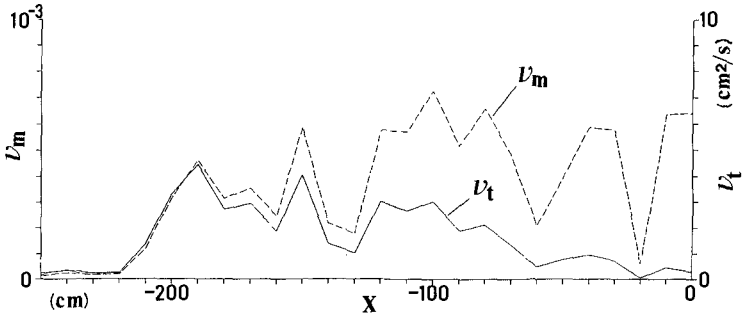

Fig.12 On-offshore distribution of vertically averaged eddy viscosity ν_t and nondimensional value ν_m

Fig.11 shows a distribution of the mean eddy viscosity by averaging the eddy viscosity of each phase over one wave period. In the figure it is possible to take it being constant along a vertical line except close to the bottom. From this reason we made a rather bold assumption that the mean eddy viscosity is constant over the depth. Eq.(7) can be reformed as

$$\frac{\partial \overline{\tau}}{\partial z} = \rho \nu_t \frac{\partial^2 U}{\partial z^2} \ . \tag{8}$$

Furthermore, we obtain

$$\frac{\partial^2 U}{\partial z^2} = \frac{1}{\rho} \frac{\partial \overline{\tau}}{\partial z} \Big/ \nu_t = \alpha(x) \ . \tag{9}$$

The on-offshore variation of the nondimensional value ν_m which is calculated from the vertical average of ν_t below the trough level divided by c and d_t, is shown in Fig.12. It is seen that ν_m progressively increases after the plunging point and then becomes rather stable around 0.005-0.006 in $x>x_i$ (-170cm) except some fluctuations. Therefore, we supposed that

$$\nu_t = 0.005\sim0.006 \ c d_t \ . \tag{10}$$

On the other hand, the nondimensional value obtained from α_1 divided by $\rho c^2/d_t$ can be supposed to be a constant value in $x>x_i$. The value α_1 in Eq.(7) can be expressed as

$$\alpha_1 = 0.0012 \ c^2/d_t \ . \tag{11}$$

Consequently, we denote α in Eq.(9) as

$$\alpha = \frac{1}{\rho} \alpha_1 / \nu_t \simeq 0.2 \ c/d_t^2 \qquad (\ x > x_i \ ) \ . \tag{12}$$

As α is very small in offshore side of the plunging point, it was taken to be 0 in that region. And we linearly interpolated it between the plunging point and the point where a stable surface roller is formed ($x=x_i$). As a result we obtain

$$\alpha = 0.2 \ k' c/d_t^2 \ , \tag{13}$$

where the parameter k' is

$$k' = \begin{cases} 0 & (\ x \leqq x_p \ ) \ , \\ \dfrac{x_p - x}{x_p - x_i} & (\ x_p < x \leqq x_i \ ) \ , \\ 1 & (\ x_i < x \leqq x_s \ ) \ . \end{cases} \tag{14}$$

For the bottom boundary condition, we thought it is appropriate to give it by the slip, i.e., no shear stress condition inside the high turbulent region, because the bottom boundary layer does not develop

there as we mentioned in the section 2. However, the velocity field near the breaking point is not so turbulent that it is better to give 0 to the eulerian steady current on the bottom U_b, as suggested by Isobe (1982). Accordingly, using the bottom steady current U_{b0} which is solved with the slip condition and k in Eq.(2), we calculated U_b as

$$U_b = kU_{b0} \ . \tag{15}$$

Using these three conditions which are, (1) the mean value U_c of the steady current below the trough level, (2) the ratio α of the eddy viscosity ν_t to $\partial\bar{\tau}/\partial z$ and (3) the steady current U_b at the bottom, we can solve Eq.(9). And putting $z'=z+h_0$ where h_0 is the still water level measured from the bottom, we obtain

$$U = \frac{1}{2}\alpha z'^2 + 2(1-k)\ U_{b0}\frac{z'}{d_t} + kU_{b0} \ , \tag{16}$$

where

$$U_{b0} = U_c - \frac{1}{6}\alpha d_t^2 \ .$$

The comparison between the steady current distribution calculated by Eq.(16) and the measured value of it is shown in Fig.13. The calculated and the measured value fit well except in the region between the breaking point and the plunging point. One of the reasons of the discrepancy is that the linear interpolation for α and U_b is not adequate, and another reason is that we neglected the influence of the plunging vortex formed near the plunging point. Anyway we can say that it is difficult to describe the flow field in the outer breaking region where such a violent transition as plunging takes place. And the disagreement near the bottom is due to the assumption of the constant eddy viscosity near the bottom.

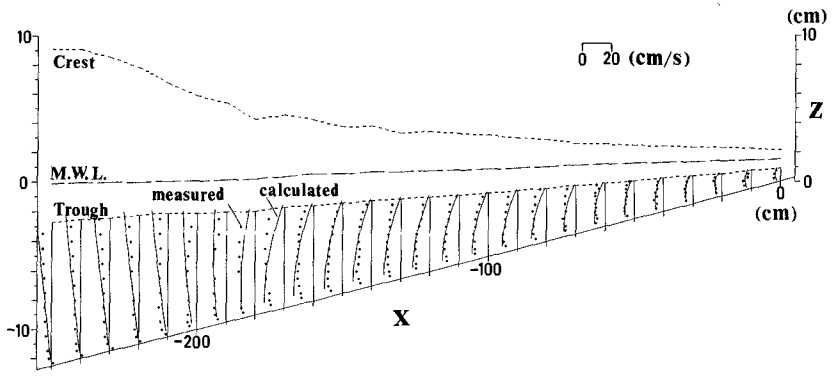

Fig.13 Distribution of calculated steady current and measured value

4. CONCLUDING REMARKS

Through detailed and precise laboratory experiments, we clarified the characteristics of the velocity field in the surf zone with plunging breakers. Then we proposed that the velocity field can be divided into four components, the steady current, wave component, organized vortex motion and turbulence. And this organized vortex motion is an important fluid motion existing between the wave motion and the turbulence.

Based on the laboratory results, we investigated a model for the estimation of the vertical profile of the undertow available in whole the surf zone. We found that the mean steady current over the depth can be divided into the contribution from the wave component and that from the surface roller. The onshore mass flux by the surface roller can be expressed quantitatively by an empirical constant multiplied by the wave length and the wave height and a simple linear interpolation of the constant value. In the region where the surface roller well develops, the vertical variation of the undertow can be estimated by supposing a constant eddy viscosity over the depth and a no shear stress condition on the bottom. On the other hand, the bottom steady current near the breaking point can be taken to be 0. The calculated steady current distribution fits well to that from measured data all over the surf zone, however the agreement is not so good near the bottom and in the outer breaking region.

5. ACKNOWLEDGMENT

The authors thank to Mr. Y. Higuchi who assisted the experiment of the case 2.

CHAPTER 51

Approximate descriptions of the focussing of water waves

D.H. Peregrine*

Abstract

Underwater shoals and spurs focus water waves that propagate over them. The normal theoretical approach to finding a more accurate solution of the linear equations is to interpret the envelope of crossing rays as a cusp of caustics (see Figure 1) and to use Pearcey's function (Pearcey 1946). In practical cases the ray pattern is rarely sufficiently well defined to enable the cusp parameters to be deduced. An alternative approach is presented in which a length of wave crest heading towards the focussing region is approximated by an arc of a circle or parabola (Figure 2). Corresponding approximate solutions for linear and weakly nonlinear waves are described.

1. Introduction

For calculating the refraction of waves the usual method is to use ray theory. It is a common occurrence to find points in wave ray diagrams where rays cross. The point where rays start to cross is usually a focus at the cusp of two caustics. This is illustrated in figure 1. It is unusual to obtain very clear examples in practice and if only a few rays cross a higher density of rays is needed to clarify the ray structure.

Focussing of rays is an indication that ray theory has become invalid. An improved method of solution including at least some diffraction effects is necessary. One approach is to determine the positions of caustics and use Pearcey's (1946) solution for the cusps of caustics; another approach is to use a parabolic approximation; a third method is to solve a fully elliptic form of the wave equation.

Here two simple approximations for finding the wave amplitude at the focus are presented. Both represent the focus as a single point where an angular spread of waves meet as sketched in figure 2. It is much easier to estimate such an angle than to fit an appropriate caustic cusp. The boundary of the focussing wave is also important. Here we suppose that an initial wave crest is made up of a circular arc of angle 2α, radius R, smoothly joining straight crests representing plane waves as sketched in figure 2. Uniform initial amplitude is assumed.

One approximation is based on an exact linear wave solution and includes diffraction effects. The other is based on an exact solution of a weakly nonlinear parabolic equation for refraction, the nonlinear Schrödinger equation. The approximation includes the major nonlinear

*Reader, School of Mathematics, University of Bristol, University Walk, Bristol BS8 1TW, England.

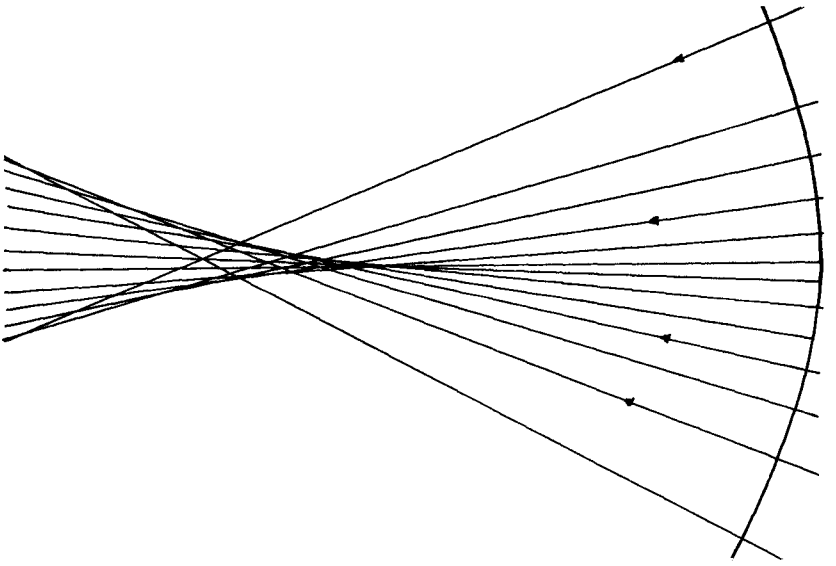

Figure 1. A typical focus.

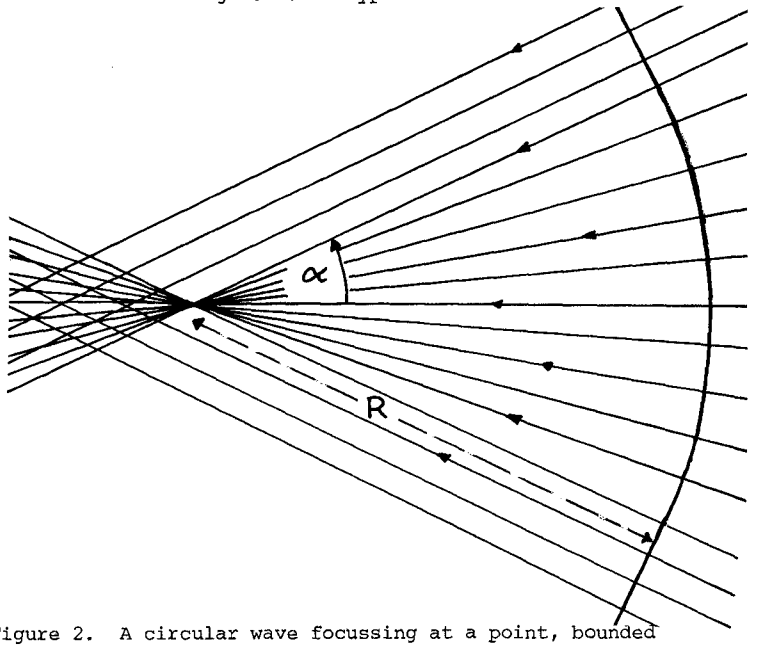

Figure 2. A circular wave focussing at a point, bounded by plane waves.

diffraction effects but neglects some of the linear diffraction. The results are different. It appears that both are likely to give upper bounds on wave amplitude. Both are easy to evaluate once α, R and the initial wave amplitude A_1 are known. The smaller value can be taken as an estimate of wave amplitude at the focus.

2. A linear solution

We consider only water of constant depth, h, and a single Fourier component in time. That is a time variation $e^{-i\omega t}$ is implicit. The wave equation to be solved is then

$$\nabla^2\zeta + k^2\zeta = 0 \tag{1}$$

where k is the wavenumber given by

$$\omega^2 = gk\tanh kh \tag{2}$$

and ζ is the, complex, surface elevation. Introduction of polar coordinates (r,θ) permits expression of the general solution of equation (1) in the form

$$\zeta = \sum_{n=0}^{\infty} (a_n \cos n\theta + b_n \sin n\theta) J_n(kr), \tag{3}$$

where J_n are Bessel functions.

Now take the origin at the focal point of a wave system, and consider a circle of large radius R, such that $kR \gg 1$. Then for all values of n such that $n \ll kR$ the terms of the series (3) can be divided into incoming and outgoing waves by using an asymptotic formula for J_n, for example see Abramowitz and Stegun (1964) equation (9.2.1). In particular:

$$\begin{aligned} J_0(kR) &\simeq (2/\pi kR)^{\frac{1}{2}} \cos(kR - \tfrac{1}{4}\pi) \\ &\simeq (2\pi kR)^{-\frac{1}{2}} \{\exp i(kR - \tfrac{1}{4}\pi) + \exp[-i(kR - \tfrac{1}{4}\pi)]\}. \end{aligned} \tag{4}$$

When combined with $e^{-i\omega t}$ the first exponential term in (4) gives an incoming wave, the second term gives an outgoing wave.

At the origin the only non zero term in the Fourier-Bessel series (3) is the J_0 term, thus we only need to evaluate a_0 to find the wave amplitude there. To evaluate the Fourier coefficients we suppose that on the circle radius R the amplitude and phase of *incoming* waves is known as a complex function of θ, say $A(\theta)$. Then the usual Fourier series evaluation of coefficients and the expression (4) give

$$\int_{-\pi}^{\pi} A(\theta)\, d\theta = 2\pi a_0 (2\pi kR)^{-\frac{1}{2}} \exp i(kR - \tfrac{1}{4}\pi). \tag{5}$$

As an example consider the plane wave

$$\zeta = A_1 e^{ikx} = A_1 e^{ikr\cos\theta}$$

This gives

$$A(\theta) = A_1 e^{ikR\cos\theta} \quad \text{for} \quad -\tfrac{1}{2}\pi < \theta < \tfrac{1}{2}\pi$$
$$= 0 \quad \text{for} \quad |\theta| \geq \tfrac{1}{2}\pi. \tag{6}$$

The integral of equation (5) becomes

$$\int_{-\frac{1}{2}\pi}^{\frac{1}{2}\pi} e^{ikR\cos\theta} d\theta = (2\pi/kR)^{\frac{1}{2}} \exp i(kR - \tfrac{1}{4}\pi), \tag{7}$$

to the same level of approximation as the asymptotic formula (4) for J_o, and thus equation (5) gives $a_o = A_1$ as is expected.

Now consider the wave field sketched in figure 2: that is an arc of a circle of angle 2α of precisely focussed waves bounded smoothly by semi-infinite plane waves. For simplicity let their amplitude at radius R have constant modulus A_1 and continuous phase. The contribution to the integral of equation (5) of the two semi-infinite plane waves is the same as that of a single plane wave, though spread over a different range of angles. The contribution of the focussing arc is simply $2\alpha A_1 \exp(ikR)$ leading to

$$a_o = A_1\{1 + \alpha(2kR/\pi)^{\frac{1}{2}} e^{\frac{1}{4}i\pi}\}. \tag{8}$$

Thus
$$|a_o| = A_1\{1 + 2\alpha(kR/\pi)^{\frac{1}{2}}\} \tag{9}$$

after neglecting terms of an order, k^2R^2, already neglected in the asymptotic result (4).

3. Nonlinear Schrodinger equation

Parabolic approximations are well suited to modelling a focus. A brief derivation for the simple two-dimensional wave equation,

$$\frac{1}{c^2}\frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}, \tag{10}$$

illustrates the nature of the approximation made. Equation (10) can be rewritten:

$$\left(\frac{\partial}{\partial t} + c\frac{\partial}{\partial x}\right)\left(\frac{\partial}{\partial t} - c\frac{\partial}{\partial x}\right)u = c^2\frac{\partial u}{\partial y^2} \tag{11}$$

The first operator on the left-hand side expresses the fact that waves can propagate in the +x direction, and the second operator relates to propagation in the -x direction.

Near a focus most waves are propagating close to one direction, say the +x direction. Thus

$$u(x,y,t) = a(x,y)e^{i(kx-\omega t)}, \tag{12}$$

where
$$k = \omega/c \tag{13}$$

should be a good first approximation. The exponential describes almost all of the "wavy" behaviour in the x direction. Hence one expects

$$ka >> \frac{\partial a}{\partial x} . \tag{14}$$

Substitution of (12) into (11) gives

$$\left(-i\omega + ick + c\frac{\partial}{\partial x}\right)\left(-i\omega - ick - c\frac{\partial}{\partial x}\right) a = c^2 \frac{\partial^2 a}{\partial y^2} . \tag{15}$$

The inequality (14) implies that the x derivative in the second operator of (15) may be neglected compared with the sum of the other two terms, which is $-2ick$ after using (13). The equation then reduces to

$$\frac{2i}{k}\frac{\partial a}{\partial x} + \frac{1}{k^2}\frac{\partial^2 a}{\partial y^2} = 0 \tag{16}$$

which is the parabolic wave equation (also known as the one-dimensional Schrodinger wave equation). For a derivation directly related to water waves see Radder (1979).

Using the full equations for irrotational water waves Yue and Mei (1980) showed that the appropriate extension of equation (16) for weakly nonlinear water waves (equivalent to third-order Stokes waves) is

$$\frac{2i}{k}\frac{\partial a}{\partial x} + \frac{1}{k^2}\frac{\partial^2 a}{\partial y^2} - Kk^2|a|^2 a = 0. \tag{17}$$

This is a nonlinear Schrödinger equation (NLS equation) in which

$$K = \frac{c}{c_g}\cdot\frac{9 - 12p^2 + 13p^4 - 2p^6}{p - kh(1 - p^2)} \tag{18}$$

where $p = \tanh kh$ and $\frac{c}{c_g} = \frac{2p}{1 + kh(1 - p^2)}$.

Note, $a(x,y)$ is still the complex amplitude of the first approximation

$$a(x,y)e^{i(kx-\omega t)} .$$

A further approximation aids interpretation of solutions of the NLS equation. Substitute

$$a = Ae^{iS} \tag{19}$$

in the NLS equation (17), where A and S are real functions of (x,y). Separate real and imaginary parts. Introduce

$$D = k^2A^2 \quad \text{and} \quad v = \frac{1}{k}\frac{\partial S}{\partial y} . \tag{20}$$

A little algebra and differentiation then gives

$$D_x + (Dv)_y = 0, \tag{21}$$

$$v_x + vv_y + \tfrac{1}{2}KD_y = (A_{yy}/k^2A)_y. \tag{22}$$

The final term in equation (22) includes three y derivatives and is thus only important in rapidly varying parts of a solution. If it is neglected equation (22) becomes

$$v_x + vv_y + \tfrac{1}{2}KD = 0. \tag{23}$$

By substituting a time variation for the x variation in equations (21) and (23), they can be recognized as the nonlinear shallow-water equations with the role of gravity being taken by $\frac{1}{2}K$, and D and v equivalent to the depth and the velocity respectively.

Equations (21) and (23) have two sets of characteristics

$$\frac{dy}{dx} = \pm(\tfrac{1}{2}KD)^{\frac{1}{2}} + v \tag{24}$$

which corresponds to a splitting of the rays in linear theory, see Peregrine (1983).

4. A nonlinear focussing solution

Following the qualitative description of focussing given by Peregrine (1983) numerical solutions of the NLS equation (17) with initial conditions corresponding to the focussing in figure 2, were studied. These solutions all showed that where focussing waves were of a uniform amplitude at the initial value of x the amplitude remained uniform in y varying only with x in a substantial region approaching the focus. An example may be found in figure 3 of Stamnes et al (1983).

A solution corresponding to amplitude being independent of y is easily found. For waves of initial amplitude A_1 at $x = R$, focussing at $x = 0$, it is

$$a(x,y) = A_1(R/x)^{\frac{1}{2}}\exp i\{y^2/2kx - Kk^3A_1^2R\log(x/R)\}. \tag{25}$$

This solution is singular and unrealistic at $x = 0$. However, one effect of nonlinearity is that there is "defocussing", and the effective focus may occur before the geometric focus. This feature can be deduced from the characteristics corresponding to solution (25) which are shown in figure 3. The characteristics also show that the singularity at $x = 0$ is due to wave energy coming in from waves originally at unrealistically large values of $|y|$.

For any initial region of focussing at $x = R$ the corresponding domain of dependence is limited to a region with $x > x_o > 0$. Within this domain of dependence solution (25) is likely to be a good approximation. The characteristics of (25) are given by

$$y = \pm A_1 k(2KRx)^{\frac{1}{2}}\{(x/x_o)^{\frac{1}{2}} - 1\}, \tag{26}$$

where x_o, the position at which $y = 0$, identifies pairs of characteristics. The particular characteristics which bound a domain of depend-

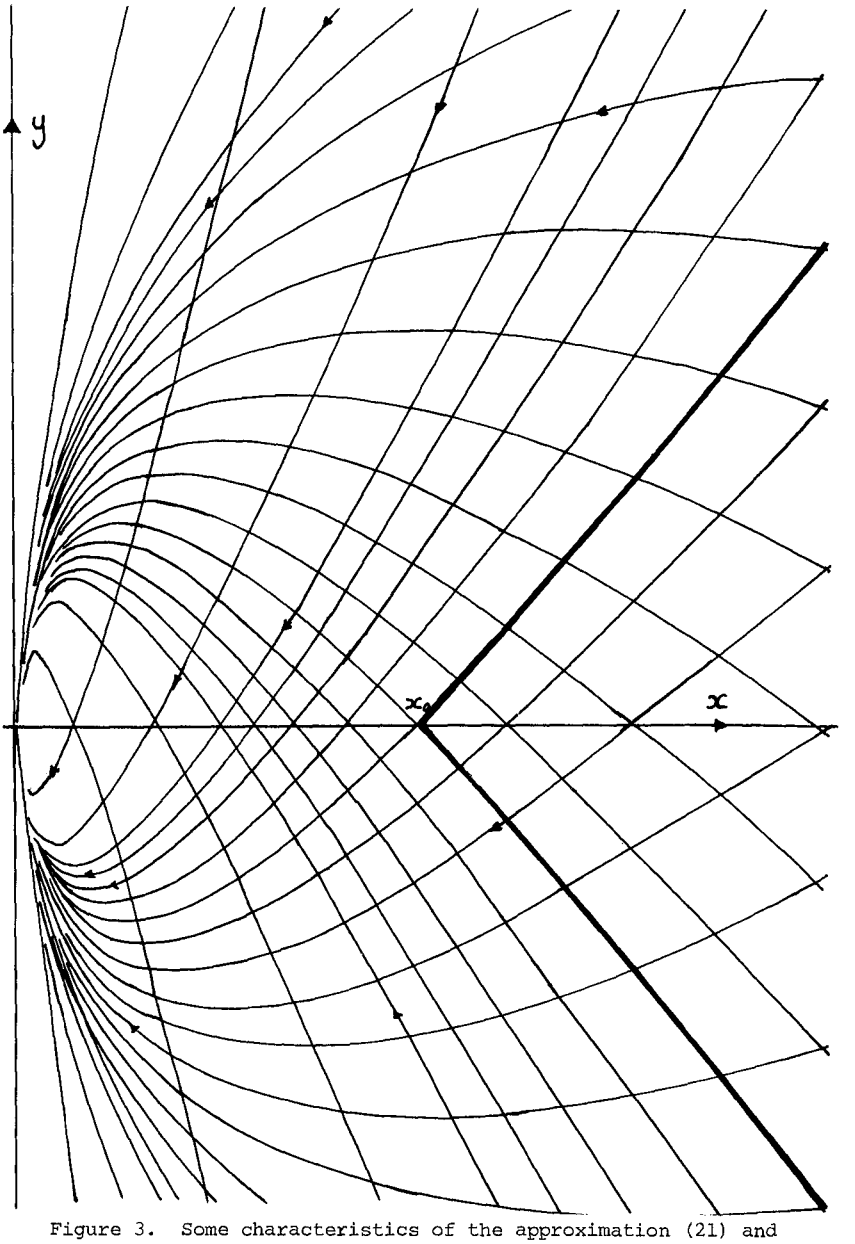

Figure 3. Some characteristics of the approximation (21) and (23) to the nonlinear Schrödinger equation for the solution (25). The boundary of a domain of dependence on initial conditions is outlined.

ence of waves from an angle of 2α at $x = R$, are found by substituting $(x,y) = (R, \alpha R)$ into (26) which gives

$$x_o = \frac{R}{\left\{1 + \frac{\alpha}{kA\ (2K)^{\frac{1}{2}}}\right\}^2}. \tag{27}$$

Unless there are more waves focussing to the same point, $x = x_o$ becomes the effective focussing position, and the corresponding value of amplitude at that point is

$$|a(x_o,0)| = A_1\left\{1 + \frac{\alpha}{kA_1\ (2K)^{\frac{1}{2}}}\right\}. \tag{28}$$

The NLS equation (17) can be scaled to give an identical equation by using the transformation

$$a^* = a/a_o, \quad x^* = a_o^2 x, \quad y^* = a_o y. \tag{29}$$

Thus any one numerical solution can be interpreted in a number of different ways. In particular, some results of computation are shown in figure 4. The amplitude of numerical solutions along $y = 0$ is given for the scaled values $A^* = 1$, $R = 5$, and $\alpha R = 3, 10$ and 20, where k has been set equal to one. Examples of alternative values for these three cases are given in table 1, where L is wavelength and H is wave height.

Table 1.

kA_1	$(H/L)_1$	kR	R/L	α		
0.1	.032	500	80	3.4°	11.5°	22.9°
0.05	.016	2000	318	1.7°	5.7°	11.5°

5. Discussion

Two simple formulae for the maximum amplitude are given. From section 2

$$|a_o| = A\ \{1 + 2\alpha(kR/\pi)^{\frac{1}{2}}\} \tag{30}$$

and from section 4.

$$|a_o| = A_1\left\{1 + \frac{\alpha}{kA_1\ (2K)^{\frac{1}{2}}}\right\} \tag{31}$$

These are different and this difference is due to the different approximations. Expression (30) arises from attempting to include all the linear diffraction effects and is expected to be useful for waves of small steepness, even at the focus. On the other hand expression (31) arises from an approximation which neglects some linear diffraction effects, i.e. the third-order terms in equation (22), but does include

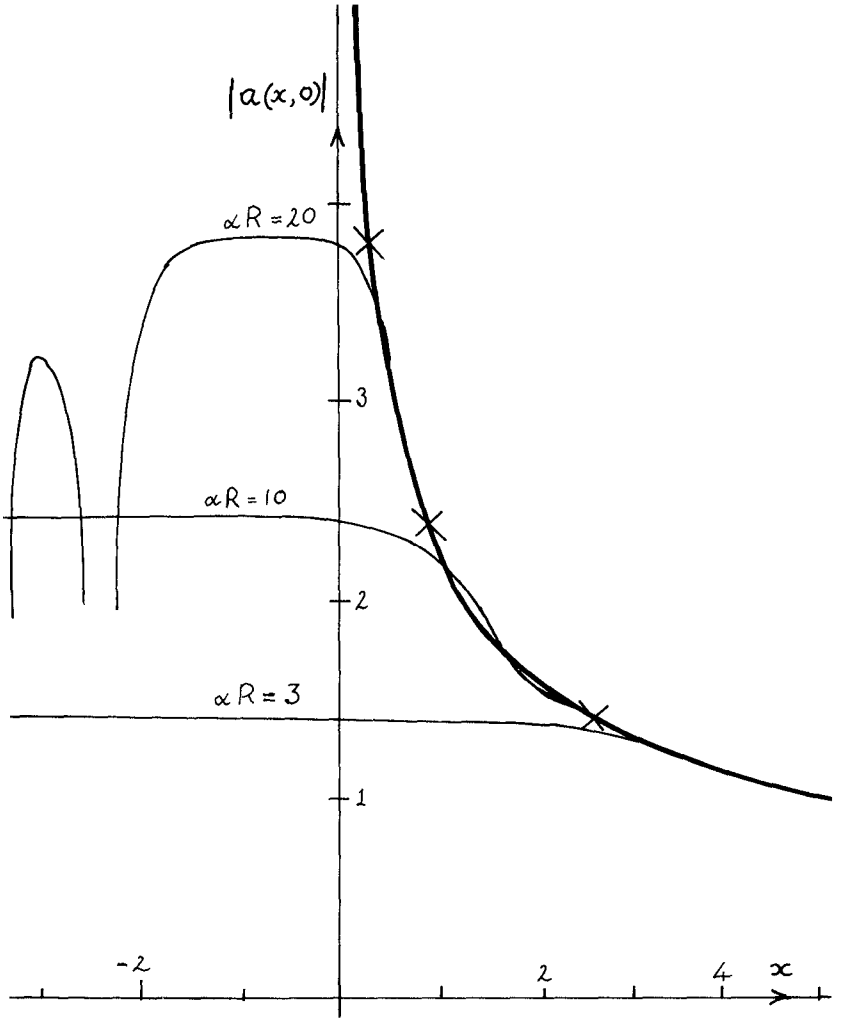

Figure 4. Variation of amplitude of waves along the axis of a focus. Numerical solutions of the NLS equation (17) compared with the solution (25) shown in a heavy curve, with crosses marking the values of x_o, equation (27), corresponding to the numerical examples.

the defocussing effects of nonlinearity.

Both the linear diffraction and nonlinear defocussing spread wave energy so that the singularity at a focus that arises from the ray approximation does not happen in practice. Both expressions (30) and (31) neglect some of the energy spreading so that both of them are likely to be upper bounds on wave energy. To see how they may be used consider a situation where the wave geometry, kR and α, is fixed and the initial steepness is allowed to vary, that is A_1 increases from zero. Initially the linear expression (30) is the lesser value; for zero amplitude waves the nonlinear effects are not relevant, but as steepness increases the two expressions become equal and for steeper waves nonlinear effects are more important and hence expression (31) is the least. This is sketched in figure 5. The initial steepness at which the two expressions are equal is

$$kA_1 = (2\pi/kRK)^{\frac{1}{2}}. \qquad (32)$$

Interestingly, but perhaps in retrospect not surprisingly, this critical steepness is independent of α. As an example, if R is 100 wavelengths and K = 3, i.e. kh = 1.0, then the critical wave steepness kA_1 is 0.06 or $(H/L)_1 = 0.018$.

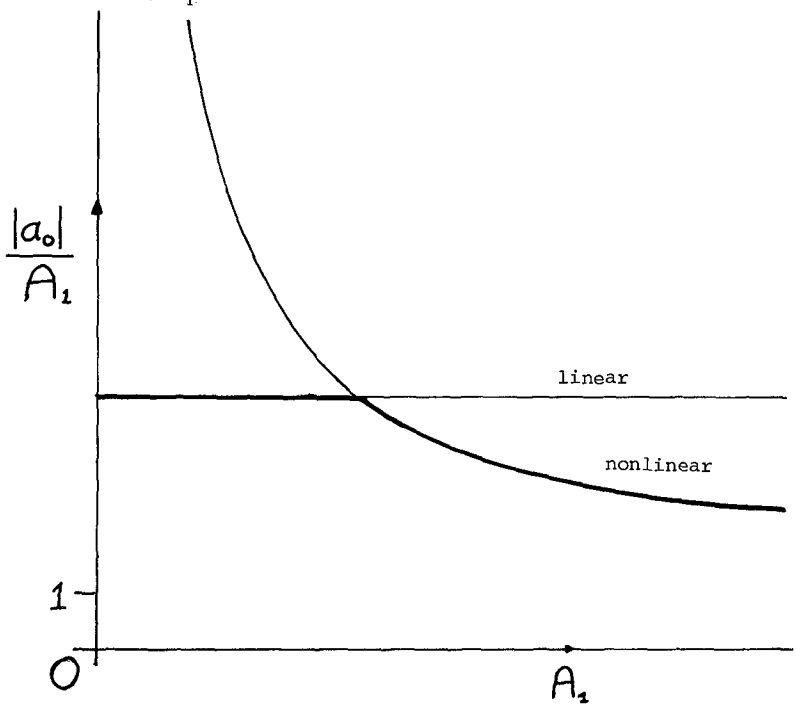

Figure 5. Variation of the linear and nonlinear expressions for amplitude at a focus with the initial wave steepness.

There are limitations in these expressions. They are derived for water of constant depth of initially uniform amplitude. Nonetheless, the author is not aware of any other simple estimates for wave amplitude at a focus and hopes that they may still provide a rough guide in practical situations for assessing the importance, or unimportance, of regions where ray theory shows that waves focus.

CHAPTER 52

WAVE HEIGHT DECAY MODEL WITHIN A SURF ZONE

Shigeki Sakai*, Kouetsu Hiyamizu**, Hiroshi Saeki***

ABSTRACT

A model for wave height decay of a spilling breaker is proposed. The energy dissipation of a breaking wave is approximated by that of a propagating bore. In order to explain the gentle decay of spilling breaker at the initial stage, a development of a foam region, which indicates the amount of foam on the wave profile and determines the rate of energy dissipation, is considered. In addition to this formulation, the energy and momentum balance equations are described by a linear wave theory in shallow water and are simultaneously solved. Comparisons with experimental results show that the model gives a good prediction in both inner and outer regions, and that two coefficients in the present model are related to the deep water wave steepness and the slope of beaches.

1 INTRODUCTION

The height of breaking wave and a rate of its decaying have very important influences on the nearshore wave-induced phenomena, such as the generation of nearshore currents, the transportation of sediments and so on. In order to discuss these phenomena, it is necessary to clarify the characteristics of breaking waves.

Many experimental investigations and several models for breaking wave have been presented. In these models, it is widely used to approximate the energy dissipation of the breaking wave by that of a propagating bore. Originally, this approach was proposed by Le Méhauté(1962). In his study, a conception named "non-saturated breaker" was introduced, and a formulation for the wave energy dissipation of the spilling breaker involving effects of the bottom friction was used to explain the

*** Professor, Civil Engineering Department, Hokkaido University, Kita 13, Nishi 8, Sapporo 060, Japan

wave height index (H=0.78h). Hwang and Divoky(1970) improved this approach by taking a wave set-up into considerations.

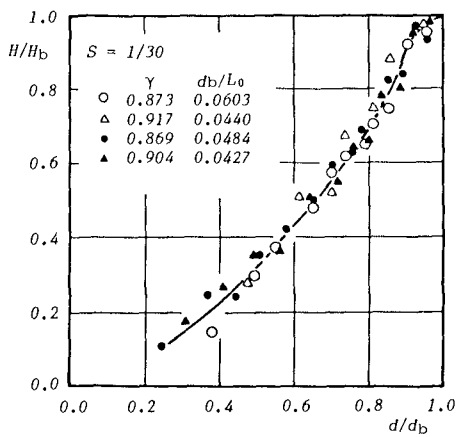
Battjes(1978) gave a model using a dissipation function for breaking waves depending on local wave properties and a local breakerheight (γh). This model showed an overall agreement with results of systematic experiments given by Horikawa and Kuo (1966). It was, however, pointed out that in most cases the initial decay was overestimated by this model.

Svendsen, Madsen and Hansen(1978) indicated that the surf zone is divided into inner and outer regions, and Svendsen (1984) showed that "surface roller" has an important role in the wave decay. The results of the model agreed with experiments well in the inner region.

While this approach has been improved by many studies, some problems still remain. The largest difference between calculations by the model and experiments appears in the outer region. Particularly for spilling breakers, models gave the larger energy dissipation than what were experimentally observed.

In the present study, experimental findings of the gentle decay of spilling breaker at the initial stage and a development of turbulent region, called "foam region", during the breaking are first explained. And a new model for the decay of a spilling breaker is proposed. In the model, the energy dissipation of the breaking wave is approximated by that of a propagating bore and the development of the foam region is mathematically expressed based on several assumptions. Energy and momentum equations are also simultaneously applied.

Finally, two coefficients in the model are determined by comparing with the experimental results.



H : wave height, d : mean water depth
$\gamma = Hb/db$, L_0 : deep water wave length
subscript b denotes conditions at breaking point

2 DEVELOPMENT OF FOAM REGION

Examples of wave height decay of spilling breaker in a surf zone are shown in Figure 1. This figure shows that the wave height decay immediately after breaking points is rather gentle, and the change is rapid after the wave propagates some distance. This tendency was found in the experiments given by Horikawa and Kuo(1966), as well as in our experiments. This refers to a fact that a region of turbulence of the spilling breaker is restricted near the wave crest in the outer region and develops as the wave propagates. And the development of the turbulence region increases the rate of the wave energy dissipation.

The turbulence region in spilling breakers is called a "foam region" in this paper, and Hf indicates the vertical length of a foam region, as illustrated in Figure 2 (a). When the energy dissipation of spilling breakers is approximated by that of the propagating bore(Figure 2 (b)), the bore height Hbore corresponds to the length Hf of the spilling breaker, and therefore the change in the size of the foam region has an important influence on calculated results. Since the foam region immediately after breaking is narrower than that of well-developed breaker in the inner region, the increase of the energy dissipation rate of a spilling breaker can be explained by considering the development of the foam region.

3 WAVE HEIGHT DECAY MODEL

3.1 Foam Region

In order to explain the development of the foam region, it is assumed that a water particle is released from the crest of a wave at a breaking point, and the particle again meets the water surface after a very short time Δt, as shown in Figure 3. Now, the lower boundary of the foam region is defined by this point. Then, the water particle jumps again from this point, and consequently the foam region further develops.

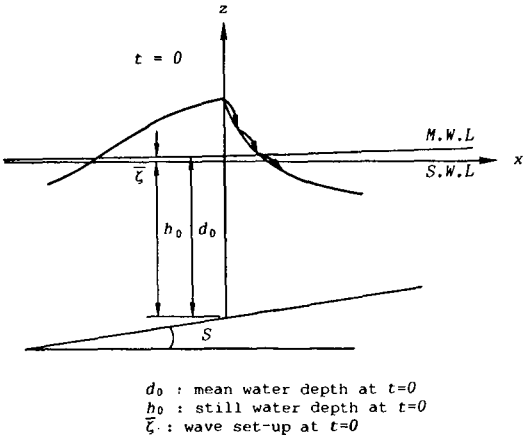

Figure 3 Development of foam region

In the calculations of the time interval and the distance for such action of a water particle, it is assumed that the wave celerity is given by a linear wave theory in shallow water and that the horizontal velocity of the released particle is identical to the wave celerity at the time when it was just released. Thus, the wave celerity C at t=Δt and the horizontal velocity u_0 of the released water particle is given as follows;

$$C = \sqrt{gd_0} - \frac{Sg}{2}\Delta t \quad , \quad u_0 = C_0 = \sqrt{gd_0} \tag{1}$$

where g : the gravitational acceleration, d_0 : a water depth at t=0, and S : a slope of beach.
Therefore, the relative velocities to the wave profile are described as;

$$u' = u_0 - C = \frac{Sg}{2}\Delta t \quad , \quad w' = -g \cdot \Delta t \tag{2}$$

and consequently, the distances measured from the water profile are;

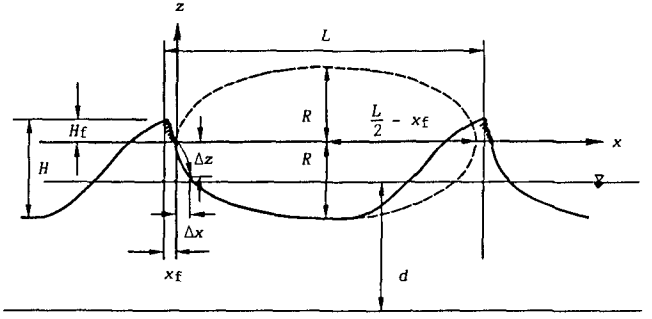
$$\Delta x = \frac{Sg}{4}\Delta t^2 \quad , \quad \Delta z = -\frac{g}{2}\Delta t^2 \tag{3}$$

In addition, the front profile of the wave is approximated as an ellipse. At the time when the released water particle meet again the water surface, the following equation is satisfied.

$$\left(\frac{\Delta z}{R}\right)^2 + \left(\frac{\Delta x - \left(\frac{L}{2} - x_f\right)}{\frac{L}{2} - x_f}\right)^2 = 1 \qquad (4)$$

where notations are explained in Figure 4.
From Equations (3) and (4), the time interval is given, and then the distances are calculated by Equation (3). We further used a coefficient on the time interval, given by Equation (5).

$$\Delta t' = \alpha \cdot \Delta t \qquad (5)$$



Xf, Hf : horizontal and vertical length of foam region
Δx, Δz : horizontal and vertical increment of foam region
L : wave length, R = H-Hf

Figure 4 Approximation of wave profile by ellipse

3.2 Energy and Momentum Balance

In the present model, the energy dissipation of a spilling breaker is approximated by that of the propagating bore. As widely used in the previous studies, the energy dissipation per a unit length is described as a following equation with a coefficient B.

$$D' = -B\frac{\rho g}{4}\frac{1}{Td}H_f^3 \qquad (6)$$

where ρ is a density of the fluid, T is a wave period.
When the energy flux of the wave is calculated by a linear wave theory in shallow water, the energy balance equation is described as follows;

$$\frac{d}{dx}\left\{\frac{1}{8}\rho g H^2 \left(gd\right)^{\frac{1}{2}}\right\} + B\frac{\rho g}{4}\frac{1}{Td}H_f^3 = 0 \qquad (7)$$

Since the development of the foam region is calculated descretely with the time interval Δt as shown in Figure 5, the energy balance is

also considered within this interval. The time interval is so short that the foam region Hf within the interval can be regarded to be constant. Therefore, Equation(7) is integrated, and the change of wave height from t1 to t2 is given as follows;

$$\left(\frac{H_2}{H_1}\right)^{-1} = \left(1 - \frac{2}{3}K\right)\left(\frac{d_2}{d_1}\right)^{\frac{1}{4}} + \frac{2}{3}K\left(\frac{d_2}{d_1}\right)^{-\frac{1}{2}} \qquad (8)$$

$$K = \frac{2B}{S}\left(\frac{d_1}{gT^2}\right)^{\frac{1}{2}}\frac{H_1}{d_1}$$

In order to calculate correctly the wave height near a shore line, the wave set-up is included in calculations. In the present model, a following relationship given by Longuet-Higgins and Stewart(1964) is used to calculate the mean water depth.

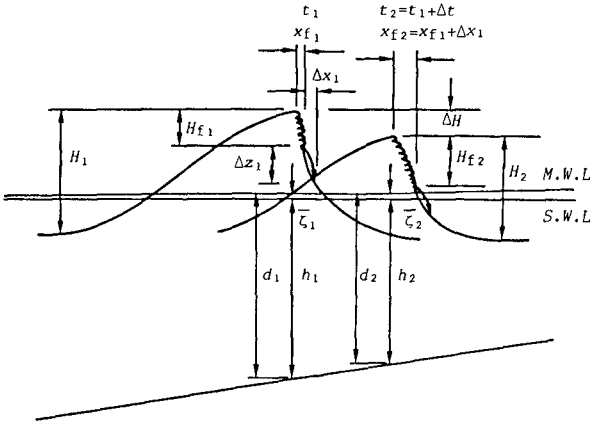
$$\frac{d}{dx}Sxx + \rho g\left(h + \bar{\zeta}\right)\frac{d\bar{\zeta}}{dx} = 0 \qquad (9)$$

Sxx : *radiation stress*

$\bar{\zeta}$: *wave set-up/down*

3.3 Procedure of Calculation

The time interval Δt and the increments of the lower boundary of the foam region Δx_1 and Δz_1, described in Figure 5, are calculated by Equations.(4), (5) and (3). And, the energy and momentum balance equations are simultaneously solved to give Hf2 and $\bar{\zeta}_2$.



Δt : time interval
ΔH : decrement of wave crest height

Figure 5 Description for development of foam region

Successively, the foam region at the next time step is given as;

$$H_{f2} = H_{f1} + \Delta z_1 - \Delta H$$

$$\fallingdotseq H_{f1} + \Delta z_1 - (H_1 - H_2) \frac{\eta_c}{H} \qquad (10)$$

where η_c is a wave crest height.
However, in order to calculate the decrement of the wave crest height, the relationship between the crest height and the wave height should be considered. Hansen's data quoted by Svendsen(1984) indicated that the ratios of the wave crest height to the wave height vary linearly with the change of the depth, while the magnitude of the ratios is different depending on the deep water wave steepness. This qualitative tendency is adopted to calculate the change of the wave crest height, and a following relationship is assumed.

$$\frac{\eta_c}{H} = 0.55 + 0.2 \frac{d}{d_b} \qquad (11)$$

where db is a breaking water depth.

4 VERIFICATION OF MODEL

Two coefficients α and B are used in the present model, to compensate slight uncertainties of the assumptions. In order to determine these coefficients, some experiments were conducted, and in these experiments the slopes of beaches were 1/15,1/30 and 1/50.

Comparisons between the calculations by the model and experimental results indicate that the optimum value of the coefficient B depends on the slope of beach. B has a larger value when the slope is steeper, and the relationship between the coefficient B and the slope of beach is shown in Figure 6. Experiments on the slope 1/65 given by Horikawa and Kuo(1966) were also explained by the present model with the value on the slope 1/50. This implies that this coefficient is constant on the slopes milder than 1/50.

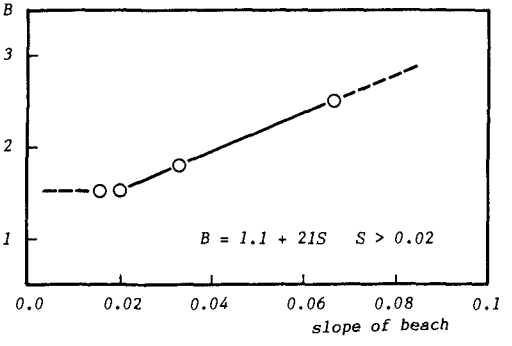


Figure 6 Relationship between coefficient B and slope of beach

For the other coefficient α, the optimum value is 2.5, in the cases where the deep water wave steepness is large and consequently the complete spilling breaker occurs. The decrease of the deep water wave steepness changes the breaker type from spilling to plunging. The spilling breaker with relatively small deep water wave steepness has a somewhat similar properties to plunging breaker. For such breaking waves, the coefficient should be magnified, in order to increase the energy dissipation in the outer region. Within our experiments, a relationship between the coefficient α and the deep water wave steepness is given in Figure 7.

Figure 8 (a),(b) and (c) show comparisons between the calculations by the present model and experimental results on the slope 1/15, 1/30 and 1/50, respectively, in which the deep water wave steepness is large. As shown in these figures, the calculations predict the experimental results fairly well. It is noteworthy that the present model is good, not only in the inner region but also in the outer region.

Figure 9 (a) shows a similar comparison for a spilling breaker on the slope 1/15 with a relatively small deep water wave steepness. The high accuracy of the prediction by the present model still remains. Figure 9 (b) gives a comparison on the slope 1/30. The calculation also agrees with experiments in this case.

Consequently, it was concluded that the present model gives good predictions of the wave height decay of the spilling breaker on the slopes from 1/15 to 1/50.

Figure 10 (a) and (b) show the results with respect to the wave set-up in the surf zone. The earlier models gave rapid increase of the mean water level in the outer region, since the wave energy dissipation was overestimated in this region. While the calculations by the present model still overestimates the wave set-up, the qualitative tendency of the change of the mean water level is explained.

5 CONCLUSIONS

Experimental results show that the development of the foam region characterize the wave height decay of the spilling breaker in the outer region. This development and the energy and momentum balances were formulated by a linear wave theory in shallow water. This model explained the characteristics of wave height decay fairly well, even in the outer region. It was found that the coefficients used in the present model are determined by the deep water wave steepness and the slope of beaches.

CHAPTER 53

IRREGULAR WAVE TRANSFORMATION AFFECTED BY OPPOSING CURRENTS

Shigeki Sakai *, Kouetsu Hiyamizu ** and Hiroshi Saeki ***

ABSTRACT

Transformation of irregular waves affected by opposing currents on a sloping sea bed was discussed, experimentally and theoretically. It was found that representative values of wave height, such as a significant wave height, are larger before breaking and the wave height decaying occurs more promptly in a surf zone as opposing currents become dominant, and that characteristics of a irregular wave transformation are determined by the dimensionless unit width discharge q^* and the deep water wave steepness. This means that the effects of opposing currents on irregular wave transformation are qualitatively identical to that on the regular waves.

A transformation model of irregular waves affected by opposing currents was presented. In the model, formulations for a regular wave transformation, in which the effects of opposing currents were taken into account, were applied to individual waves defined by zero-down-cross-method from irregular wave profiles.

Comparisons between experimental results and the prediction by the model showed that the present model gives a good explanation for wave height distributions and the experimental finding that the surf zone is moved offshore by opposing currents.

1. INTRODUCTION

Many studies on the transformation of irregular waves have been conducted, experimentally and theoretically. Goda(1975), Battjes and Janssen(1978), Thornton and Guza(1983) and Iwagaki, Mase and Furumuro(1983) presented transformation models which deal with irregular waves transformation without currents.

Authors(1984) presented effects of opposing currents on the transformation of regular waves, and Hedge et.al.(1985) investigated an interaction between irregular waves and currents in the deep water.

However, in order to discuss phenomena caused by waves and currents such as the river mouth blocking, it is necessary to take the effects of opposing currents and the irregularity of waves in the shallow water into account.

In this paper, the effects of opposing currents on the transformation of irregular waves are clarified experimentally. Experiments show that the effects of opposing currents on irregular wave transformation are identical to that on regular wave qualitatively. Next, the transformation model of irregular waves affected by opposing currents are presented. In the model, formulations for the transformation of regular waves are applied to individual waves of irregular waves. And, the applicability of the present model is examined by comparing with experimental results, which shows a satisfactory agreement.

2. EXPERIMENTS AND RESULTS

2-1. Experimental Equipment and Procedure

Our experiments were conducted with an experimental setup as shown in Fig.1, which has a length of 35m, a width of 80cm, a depth of 120cm, and a slope of sea bed is 1/30. The water was circulated by a vacuum pump to produce opposing currents. Uniform currents were obtained on a 5m long flat bed located at an onshore end of wave channel, and flowed onto a sloping sea bed as opposing currents. The water depth on the flat bed was about 10cm.

In these experiments, irregular waves had Bretschneider-Mitsuyasu type spectra. Wave profiles were recorded for about 11 minutes, at 20 points with 90cm intervals.

Wave profiles were digitalized with 0.05 second sampling interval, and frequency components over five times of the peak frequency and under one half of the peak frequency were cut off.

Individual waves were defined by applying zero-down-cross-method to filtered irregular wave profiles.

To' : significant wave period in deep water

q* : dimensionless unit width discharge
$q^* = q / g^2 To'^3$

Ho'/Lo' : deep water wave steepness
$Lo' = g\, To'^2 / 2\pi$
(g : gravitational acceleration)

Experimental conditions are shown in Table 1. Capital letters A,B, and C indicate types of irregular wave. Numbers from 1 to 5 mean the condition of opposing currents, and the unit width discharge q was varied from 0 to 300 $cm^3/s/cm$.

Characteristics of irregular waves are defined as follows:
(1) A wave height distribution in the deep water is calculated by adopting a transformation model described in the following section on the individual wave heights at a reference point, which has a largest depth in our experiments. (2) From this wave height distribution, the significant wave height Ho' and period To' are determined.
(3) The deep water wave length Lo' is calculated by To' and the linear wave theory, and the deep water wave steepness is defined as Ho'/Lo'.
(4) q* is a parameter to indicate the magnitude of opposing currents, and is defined by the unit width discharge q and the wave period To'.

Since the deep water wave steepness on Case A is identical to that on Case C, effects of the parameter q* will be examined. And as the deep water wave steepness on Case B is one half of Case A and Case C, the effects of the deep water wave steepness will be able to investigated for cases with a similar value of q*.

2-2. Effects of opposing current on irregular wave transformation

Figure 2 shows a relationship between ratios of the significant wave height to wave height at a reference point and similar ratios with respect to the water depth. Case B has a relatively small deep water wave steepness, and in a region before breaking, wave heights affected by opposing currents are larger than wave heights without currents. It is also seen that the surf zone is moved offshore by opposing currents. In order to examine the effect of currents on wave height decaying in the surf zone, changes of wave heights with a relatively large deep water wave steepness are shown in Fig.3. This figure shows that, in the surf zone, the decaying of wave height with currents takes place more promptly than the decaying without currents.

Therefore it is concluded experimentally that opposing currents increase the shoaling coefficients and cause a prompt wave decaying in the surf zone.

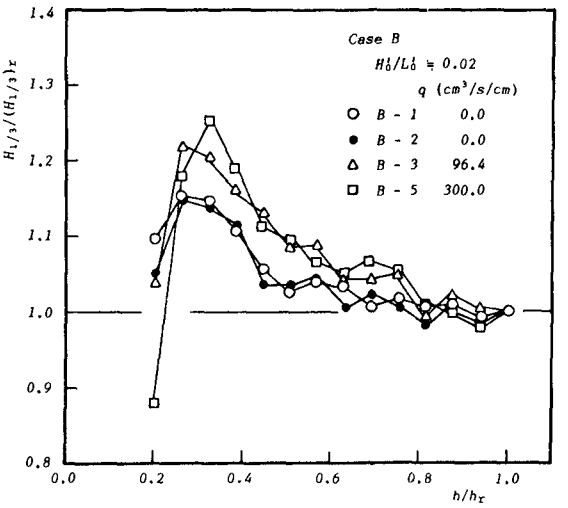

Fig.2 A change of significant wave heights

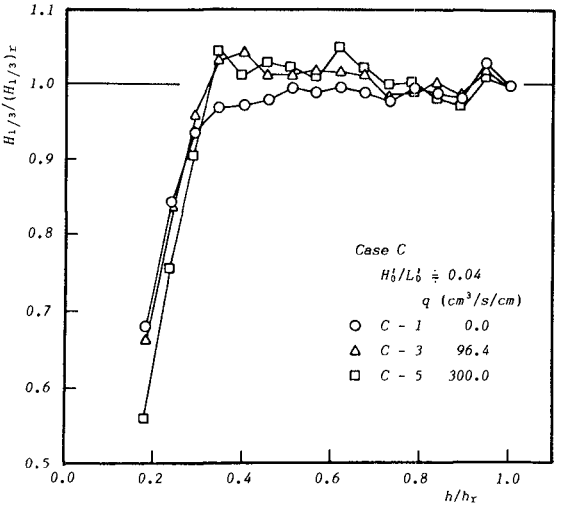

Fig.3 A change of significant wave heights

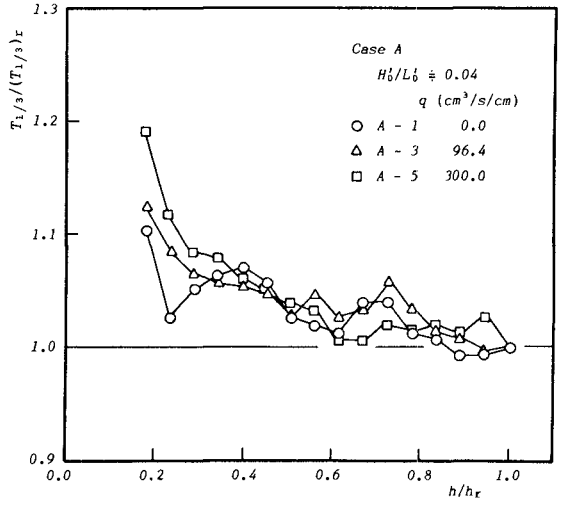

Fig.4 A change of significant wave periods

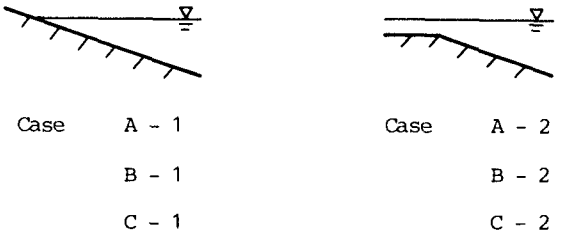

Fig.5 Conditions near the shoreline without currents

Experimental data for the change of the significant wave period, are shown in Fig.4. This figure gives relationships between ratios of the significant wave period to wave period at a reference point and similar ratios with respect to the water depth, and shows that the increase of unit width discharge causes the larger increase rates of the significant wave period especially in the surf zone.

In order to examine the effect of flat bed, which is located onshore of the sloping sea bed, experiments without currents were carried out for two bed configurations. As shown in Fig.5, one condition has a flat bed, and the other condition has an extending slope. The differences due to conditions near the shoreline do not appeared, as shown in Fig.2. Therefore it was regarded that those effects could be ignored in present experiments.

Authors(1984) have indicated the characteristics of regular wave transformation with opposing currents are determined by the dimensionless unit width discharge q^* and the deep water wave steepness, and these parameters will be used to explain the characteristics of irregular wave transformation.

Figure 6 gives a relationship between ratios of significant wave height to the significant wave height in the deep water, and ratios of the water depth to the wave length in the deep water.

If the deep water wave steepness is constant, the shoaling coefficients become larger as the parameter q^* increases.

Further as shown in Fig.7, when q^* is constant, the shoaling coefficient becomes larger and the breaking point is moved offshore as the deep water wave steepness becomes larger.

It was found that the transformation of irregular waves is characterized by q^* and the deep water wave steepness and these two effects are similar to those on regular wave, qualitatively.

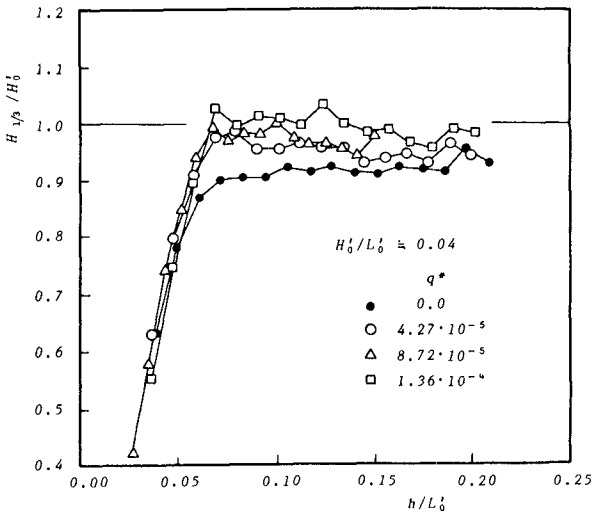

Fig.6 Effects of the dimensionless unit width discharge on irregular wave transformation

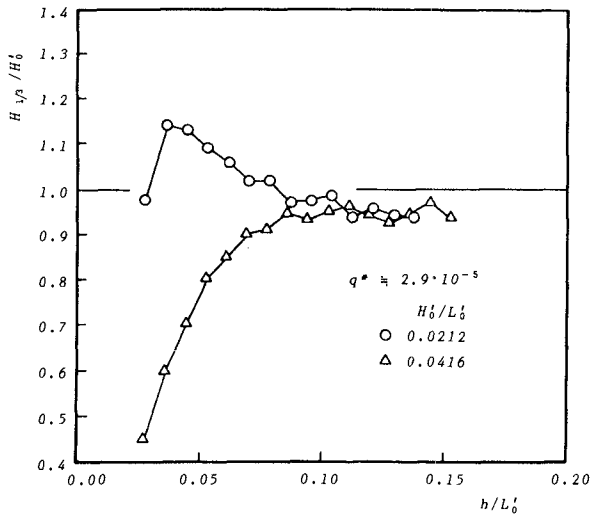

Fig.7 Effects of the deep water wave steepness on irregular wave transformation

3. TRANSFORMATION MODEL FOR IRREGULAR WAVES

In order to examine the effect of opposing currents on transformation of irregular waves quantitatively, a transformation model is proposed. In the present model, to simulate the wave transformation affected by opposing currents, the formulations for a regular wave are applied to individual waves of irregular waves, which have their own wave period and height.

3-1 Shoaling formulation

The formulation for shoaling before breaking is derived from the energy flux conservation law and described, using the linear theory, as follows;

$$E \left(Cg_r - U \right) \left(1 - \frac{U}{Cr} \right) = E_0 \, Cg_{r0} = const. \qquad \text{------- (Eqn.1)}$$

where Cgr indicates a relative group velocity for the water, Cr gives a relative wave celerity, U means the velocity of opposing current, and subscript o indicates a quantities in the deep water.

3-2 Breaking criteria

Miche(1951) indicated that the breaking criteria is expressed by Eqn.2, and the coefficient α without any currents is 0.142.

$$\left(\frac{H}{L} \right)_b = \alpha \tanh \left(\frac{2\pi h}{L} \right)_b \qquad \text{------- (Eqn.2)}$$

Authors(1984) showed that the coefficient with opposing currents is smaller than 0.142. A difference form Miche's coefficient due to the effects of opposing currents is described as $\Delta\alpha$, and a relationship between q* and $\Delta\alpha$ was proposed. However, when the relationship mentioned above was applied to individual waves of irregular wave, the effect of current appeared stronger than what we expected. And after several trials, it was found that the most suitable coefficient α was given by a following equation;

$$\alpha = 0.142 - 0.5 \, \Delta\alpha \qquad \text{------- (Eqn.3)}$$

3-3 Wave height decaying formulation

The wave height decay by the wave breaking is calculated by a bore model with opposing currents. Energy balance equation is given as follows;

$$\frac{d}{dx} \left\{ \frac{1}{8} \rho g H^2 \left(\sqrt{gh} - U \right) \right\} + B \frac{\rho g}{4} \frac{1}{Th} \frac{\sqrt{gh}}{\left(\sqrt{gh} - U \right)} \left(\beta' H \right)^3 = 0 \qquad \text{------- (Eqn.4)}$$

in which the energy flux is calculated by a linear long wave theory and the dissipation of breaking is approximated with the dissipation of propagating bore.

The fraction of turbulence region to the wave height is assumed as follows; (Battjes,J.A. 1978)

$$\beta' = \frac{H}{\gamma h} \qquad \gamma = H_b/h_b \qquad \text{------- (Eqn.5)}$$

After substituting Eqn.5 into Eqn.4, an integration of Eqn.4 results in a following equation;

$$\tilde{H}^{-4} = \frac{1}{(1-A)^2}\left\{1 - \frac{4K}{9(1-A)}\right\}\cdot \frac{(\tilde{h}^{1.5}-A)^2}{\tilde{h}^2} + \frac{4K}{9\tilde{h}^2(\tilde{h}^{1.5}-A)} \qquad \text{------- (Eqn.6)}$$

where,

$$\tilde{H} = H/H_b \quad , \quad \tilde{h} = h/h_b \quad , \quad A = q/h_b \,/\, \sqrt{gh_b}$$

$$K = \frac{2B}{S}\left(\frac{H_b}{h_b}\right)\sqrt{h_b/gT^2} \qquad \text{------- (Eqn.7)}$$

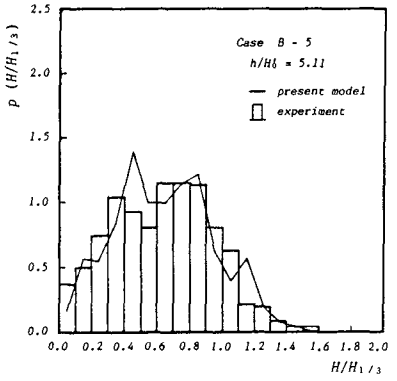
3-4 Procedure of calculation

Wave height is calculated by the shoaling formulation. After a wave height exceeds the breaking criteria, the wave height decay calculation is carried out. These formulations for regular waves are applied to individual waves of the irregular wave. This procedure gives a wave height distribution at each water depth.

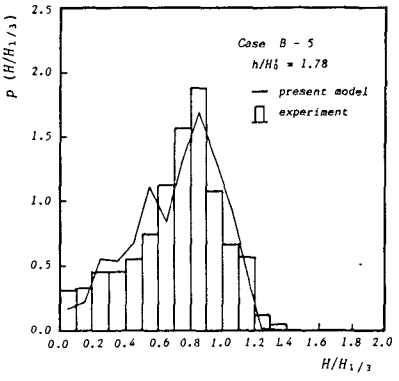
4. COMPARISON BETWEEN CALCULATED AND EXPERIMENTAL RESULTS

Figure 8(A) and 8(B) show comparisons between calculated results and experimental results for wave height distributions at a point offshore of the surf zone and in the surf zone, respectively. The horizontal axis indicates the ratio of individual wave height to the significant wave height, and the vertical axis indicates the probability density. In this case, waves have a relatively small deep water wave steepness. Calculations gives a good prediction for wave height distributions. And comparisons for a case where waves have a relatively large deep water wave steepness are shown in Fig.9(A) and 9(B). A good agreement is also obtained.

Figure 10 indicates some examples of comparisons between calculated significant wave height and experimental results with a relatively small deep water wave steepness. The experimental findings that the surf zone is moved offshore by opposing currents is explained well by the present model. In the case with relatively large water wave steepness, calculated results are compared with experimental results in Fig.11. Fig.10 and Fig.11 also confirm the applicability of the present model.

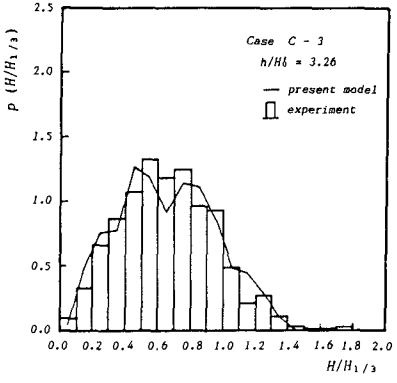


(A) offshore

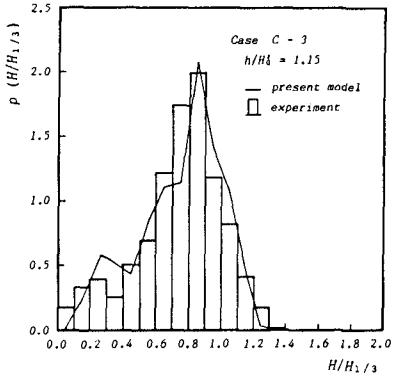


(B) in the surf zone

Fig.8 Comparisons between calculated wave height distribution and experiments (Ho'/Lo' = 0.0211)



(A) offshore



(B) in the surf zone

Fig.9 Comparisons between calculated wave height distribution and experiments (Ho'/Lo' = 0.0411)

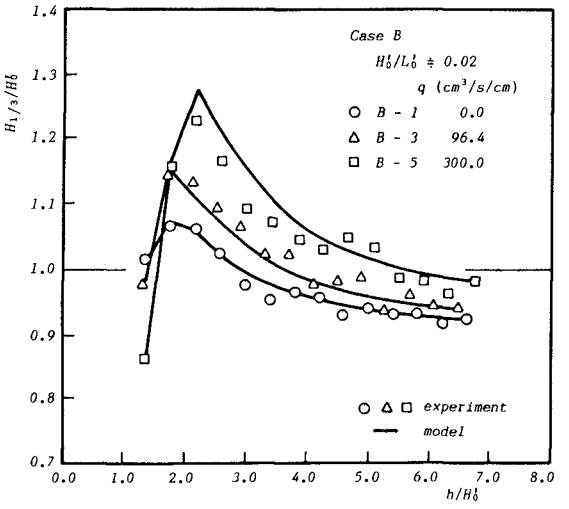


Fig.10 Comparisons between calculated shoaling coefficient and experiments

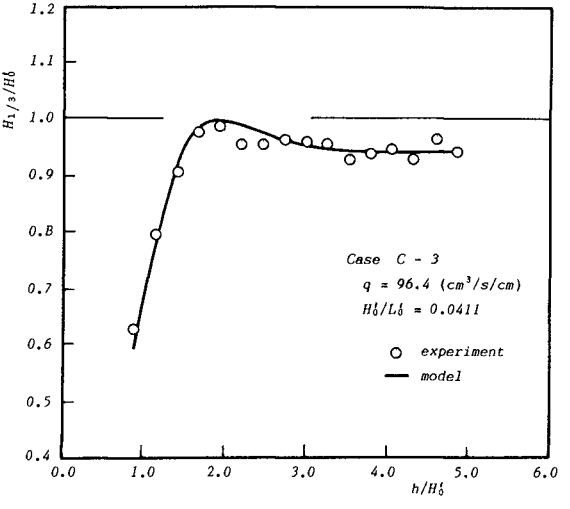

Fig.11 Comparisons between calculated shoaling coefficient and experiments

In order to examine the accuracy of the model for all data, the degree of coincidence between calculated results and experimental results is shown in Fig.12,13 and 14. The horizontal axis indicates calculated results and the vertical axis indicates experimental results, and a 45 degree solid line indicates a perfect coincidence. When the average error is defined by a following equation;

$$E_r = \frac{\sum_{n=1}^{m} \left| \frac{H\ model - H\ exp}{H\ model} \right|}{m} \qquad \text{-------- (Eqn.10)}$$

the average error as shown in Fig.12 is 2.8% of the significant wave height.

The root-mean-square of the wave height is shown in Fig.13, the average error is 2.3%. And even if the one-tenth maximum wave height is examined,the average error is only 3.7% as shown in Fig.14.

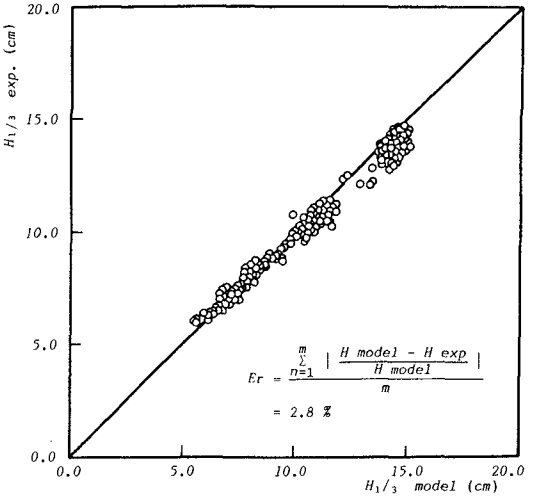

Fig.12 A correlation between calculated $H_{1/3}$ and experimental results

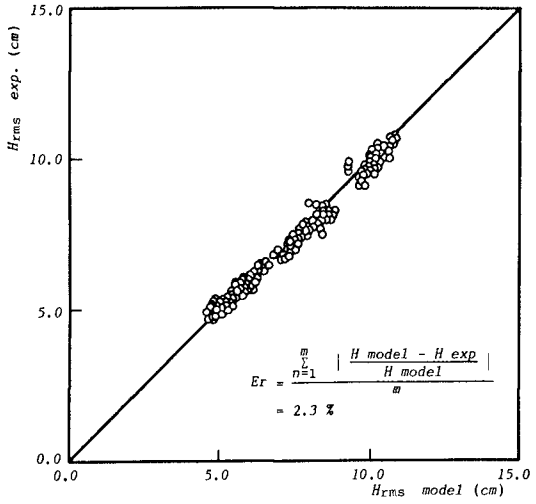

Fig.13 A correlation between calculated Hrms and experimental results

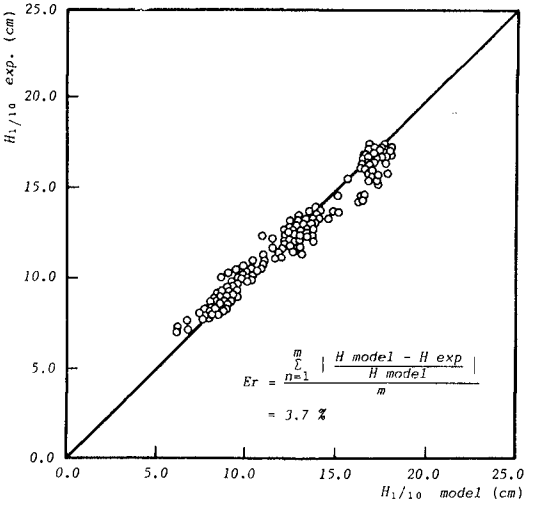

Fig.14 A correlation between calculated $H_{1/10}$ and experimental results

5. CONCLUSIONS

The transformation of irregular waves affected by opposing currents was discussed, experimentally and theoretically. Main conclusions in this paper are as follows:

(1) As opposing currents become dominant, the representative values of wave height, such as the significant wave height, are larger offshore of the surf zone and the wave decaying occurs more promptly after breaking. This tendency is identical to the characteristics of the regular wave affected by opposing currents qualitatively.

(2) The significant wave period also is affected by opposing currents. It was found that the increase of unit width discharge causes the larger increase rates of the significant wave period, and especially this tendency is clear in the surf zone.

(3) The transformation model in which the effects of opposing currents are considered was proposed. In the model, formulations for regular wave affected by opposing currents were applied to individual waves of irregular wave. The comparisons between calculated and experimental results give a satisfactory agreement.

CHAPTER 54

VORTEX FORMATION IN PLUNGING BREAKER

T. Sakai[1], T. Mizutani[2], H. Tanaka[1] and Y. Tada[1]

ABSTRACT

By a flow visualization of a plunging breaker on 1/20 slope beach in a wave tank, an existence of 2nd and 3rd horizontal vortices(Miller, 1976) and slanting vortex(Nadaoka et al., 1986) is confirmed. A MAC method is applied to simulate a violent motion after an impinging of a jet from a crest of a plunging breaker on the trough surface. The calculated maximum water particle velocity in the jet is found to reach three times the linear long wave celerity. Values of circulation of the first four horizontal vortices are calculated and their changes in time are discussed.

INTRODUCTION

Recently the turbulence generated by wave breaking was measured in wave tanks by several researchers (for example, Stive(1980) and Sakai et al.(1982)). Several facts on the turbulence were clarified. The steady current, undertow, was also explained to some extent(Buhr Hansen and Svendsen, 1984). These are useful for our understanding of the so-called inner region of surf zone. In this region, the motion is rather mild.

In the outer region, however, the motion changes very rapidly. The vortex-like motions generated by wave breaking are not yet clarified so much. Especially, the plunging breaker generates large-scale vortex-like motions. This vortex-like motion is important for the sediment movement in the surf zone.

Miller(1976) suggested that several vortices were generated in the shoreward direction. Peregrine(1983) discussed three kinds of possibility for the penetration of plunging water into and the splash from the front trough surface. Nadaoka et al.(1986) pointed out that the vortex having a horizontal axis (horizontal vortex) was unstable and a vortex having a slanting axis (slanting vortex) was developed. Basco(1985) showed a schematical figure of a plunging breaker which contained one horizontal vortex.

In this paper, at first, an existence of the 2nd and 3rd horizontal vortices and the slanting vortex in surf zone suggested by Miller and

2) Res. and Develop. Center, Kawasaki Steel Corp., Naganuma-Cho 351, 281 Chiba, Japan

Nadaoka et al. respectively is examined by a flow visualization on a beach in a wave tank. Secondly, the detail of an impinging of a plunging water upon and a splash from a front face of wave is discussed by using a numerical simulation. The water particle velocity in and around the jet and the circulation of several horizontal vortices are also discussed.

FLOW VISUALIZATION OF HORIZONTAL AND SLANTING VORTICES

A wave tank, 27m long, 50cm wide and 70cm high, in Dept. of Civil Eng., Kyoto Univ., was used. A beach of 1/20 slope was installed in the wave tank.

The experimental conditions are listed in Table 1. i is the beach slope, T the wave period, h_b the still water depth at the breaking point, H_b the breaking wave height, W the width of the surf zone and H_0/L_0 the calculated deepwater wave steepness. The water depth in the uniform depth part was 35cm.

Table 1 Experimental conditions

i	T (sec)	h_b (cm)	H_b (cm)	W (cm)	H_0/L_0
1/20	1.82	15.5	13.5	310	0.021

Pictures of the water motion in the surf zone was taken through the glass side wall of the tank with a video camera and a 35mm still camera. Fig.1 shows the surf zone and the region in which the picture was taken. "b.p." means the breaking point, and "p.p." the plunging point.

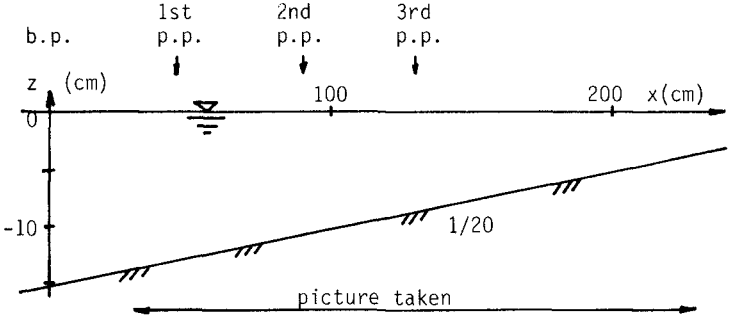

Fig.1 Surf zone and region in which picture was taken

The water motion recorded in a video film was observed carefully by using air bubbles as the tracer. Photo 1 shows a large overturning water mass from the crest. After this overturning mass hits the trough surface, a very violent splash occurs(Photo 2). A part of the overturning mass penetrates into the water body of the trough, and generates a large vortex-like motion having an horizontal axis(Photo 3).

Photo 4 shows a white region in which many air bubbles are contained in the surf zone. The black part is a part of a vertical steel element connecting two neighbouring glass plates of the tank. The upper picture was taken a little bit earlier than the lower one was. The wavy lower edge of this white region indicates an existence of the 2nd and 3rd horizontal vortex-like motions.

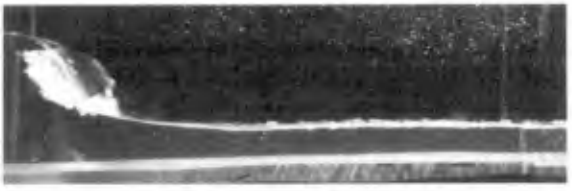

Photo 1 Large overturning mass from crest

Photo 2 Splash from trough surface

Photo 3 Large horizontal vortex

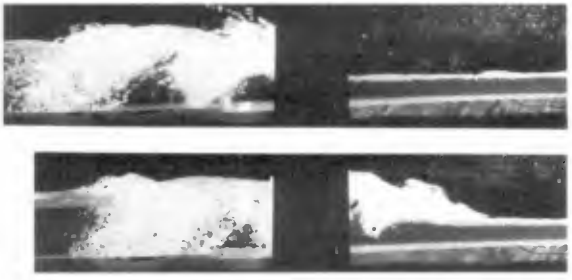

Photo.4 2nd and 3rd horizontal vortices

Photo. 5 shows a picture of a plunging breaker taken from its back. Two or three tails of the white region are seen in the transverse direction of the tank. This indicates an existence of the slanting vortex.

Photo.5 Slanting vortex

MAC METHOD

Physical experimental methods have their limitation for investigating the detail of structure in the outer region, due to the very rapid motion of wave breaking and the entrainment of a lot of air bubbles. An alternative method is numerical experiment.

For the overturning of water mass from wave crest, already many numerical computations have been done. One example is New et al.'s computation(1985)(Fig.2). They calculate a deformation of a overturning water mass, the water particle velocity and acceleration in this water mass, until the tip of overturning mass touches the trough water surface. But after the overturning mass touches the trough water surface, such a calculation fails to simulate the motion. This is because the calculation is based on a potential flow assumption.

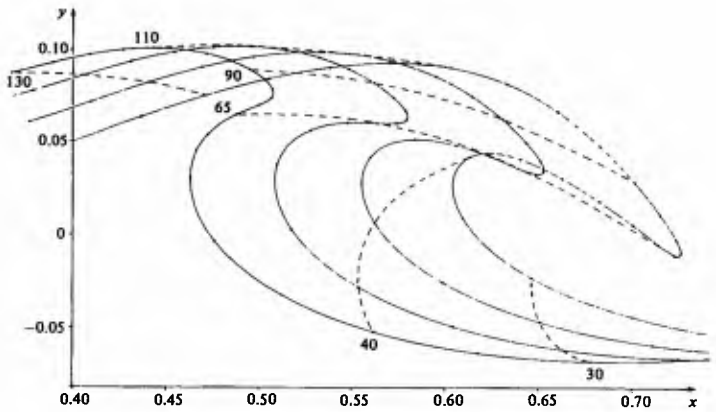

Fig.2 Numerical simulation of overturning mass from crest (New et al., 1985)

Here we used the so-called marker and cell method, "MAC method", to simulate a motion after an overturning mass touches the trough surface. In this method, the full Navier-Stokes equations are calculated. Therefore, the strong shear flow generated by the overturning jet can be calculated. Due to computational limitation, the calculation was done in two dimensional space, a vertical plane. So, the vortex having a slanting axis can not be calculated, because this vortex is generated due to a three-dimensionality of flow. Still, this calculation is expected to simulate the strong shear between the overturning jet and the trough water, the splash and the horizontal vortices.

The used MAC method is the so-called SMAC method(Takemoto et al., 1981). The surface conditions in the numerical model are rather of original type. As the initial conditions, a numerical result computed by Takigawa and Iwagaki(1983) with a finite element method(their figure No.7,(b)) was used(Fig.3). They calculated a propagation on a beach of 1/20 slope of a wave generated by a wave board in a wave tank. The calculation was stopped before the front face of wave becomed steep and the calculation becomed unstable. The conditions of Takigawa et al.'s computation are listed in Table 2. So the breaker type is plunging.

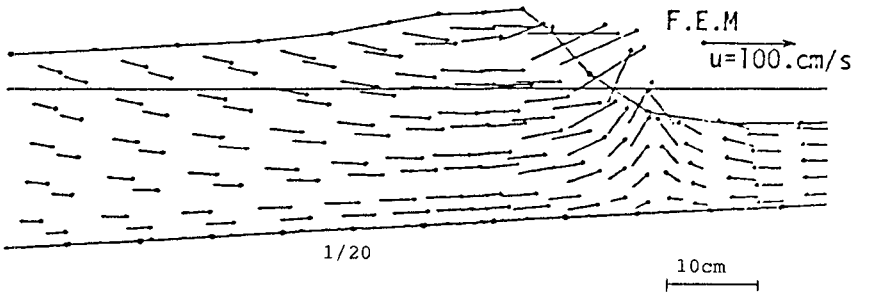

Fig.3 Initial wave profile and water particle velocity of numerical simulation (Takigawa et al., 1983)

Table 2 Conditions of Takigawa et al.'s computation(1983)

i	T (sec)	h_b (cm)	H_b (cm)	H_o/L_o
1/20	2.5	13.5	11.0	0.008

The cell is a rectangle of 1.0cm(Δx) x 0.5cm(Δy)(Fig.4). The time step Δt of the calculation is 0.0025sec. To take into account the existence of beach, the x-axis is taken parallel to the beach face. So the y-axis is not vertical, and the gravity has a x component. The computation region is 92 times 1cm long in x direction and 50 times 0.5cm high in y direction.

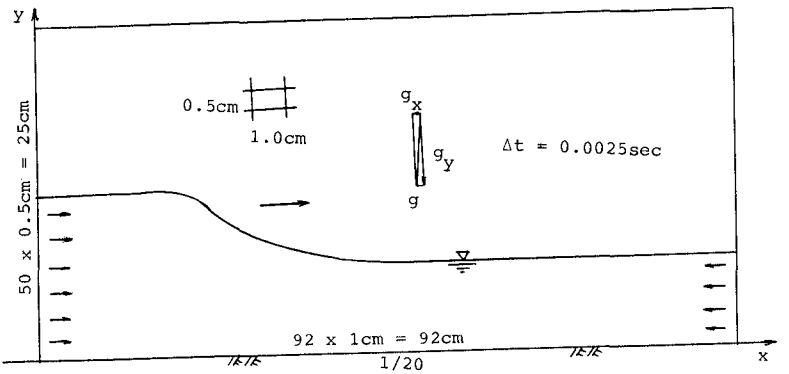

Fig.4 Region and conditions of numerical simulation

RESULTS OF NUMERICAL SIMULATION

Fig.5 shows a result of numerical simulation. The upper figure shows a vector arrow of the water particle velocity and the lower figure shows the location of the markers.

The figure (1) shows the initial condition. The crest height from the bottom is about 22cm. The linear long wave propagation velocity $\sqrt{gh}$ is about 110cm/sec. The maximum velocity in x direction is also about 110cm/sec and equal to the linear propagation velocity.

From the left and right boundaries, uniform currents in x direction flow into the region. This is not the real situation, but it is thought that the difference between the uniform current and the real flow situation does not influence the flow pattern near the plunging point during one run of computation (about 60 time steps).

The figure (2) shows the calculated result of about 0.3sec later. The computation region is shifted 30cm to the right. The uniform inflow current velocity was changed according to the result of calculated velocity at the final time step of the first run. The lower figure shows an existence of the overturning water jet from the crest. The air tube between the overturning jet and the front water surface looks smaller than the real one and the computed result based on potential flow assumption(Fig.2). This can be improved by decreasing the size of cell. Fig.6 is a result in the case of Δx = 0.5cm. The shape of the overturning jet becomes more realistic.

The figure (3) shows the result of 0.4sec later. The jet touches the trough surface, and rebounds. The upper figure shows that the velocity of rebounding and splashing water is very high.

The figure (4) shows the result of about 0.53sec later. The second touching and the second rebound or splash occur. The velocity direction is opposite between the upper jet and the lower trough water. Between these two water bodies, a strong shear exists. Two horizontal vortices

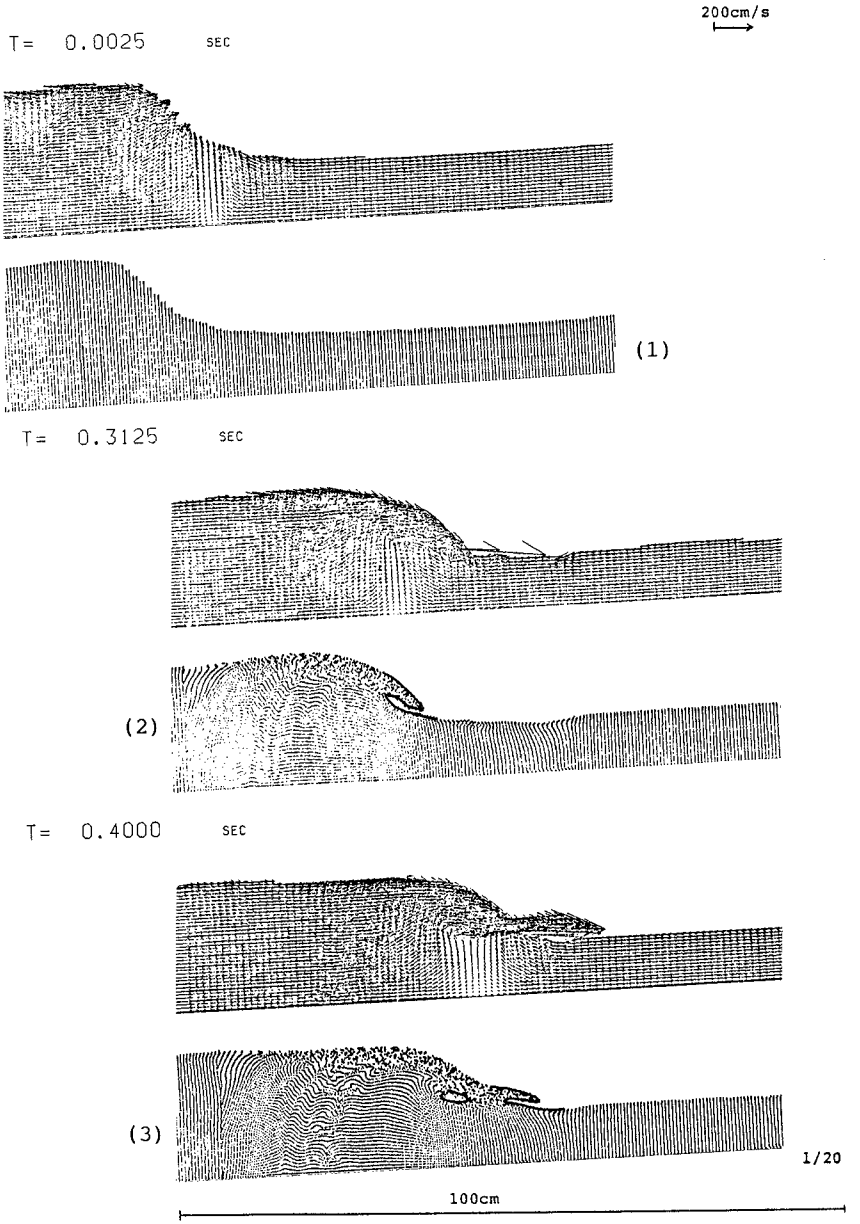

Fig.5,(1)-(3) Result of numerical simulation

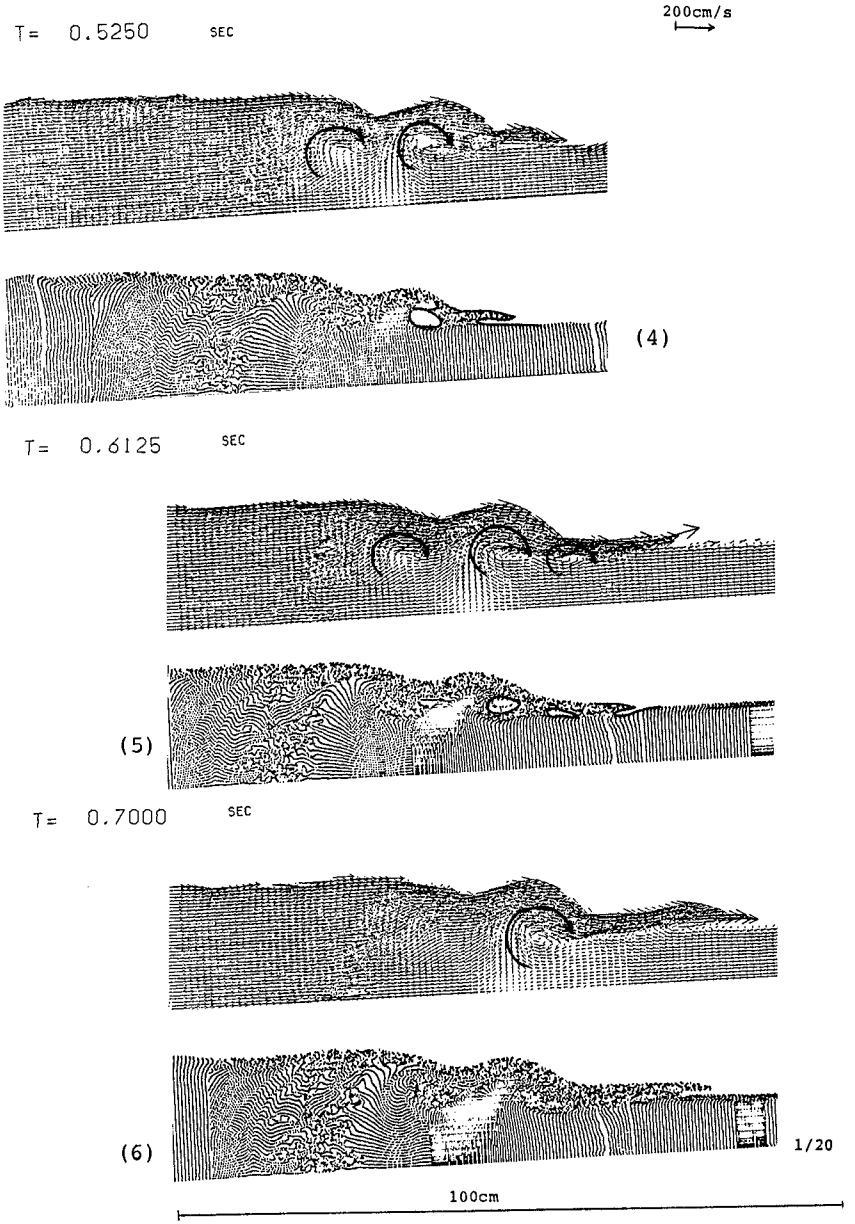

Fig.5,(4)-(6) Result of numerical simulation

are found. They have a horizontal axis rotating clockwise.

The figure (5) shows the result of about 0.61sec later. The computation region is shifted again 25cm to the right. The uniform inflow current velocity was changed again. The third touching and the third splash occur. Totally three horizontal vortices are found.

The figure (6) shows the result of 0.7sec later. Still one large horizontal vortex exists.

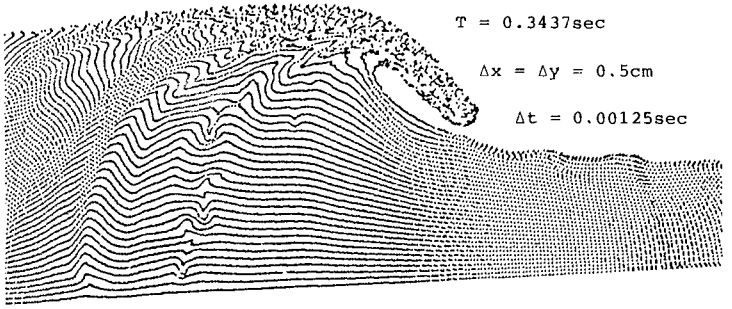

Fig.6 Improvement of shape of overturning jet by decreasing cell size

Photo 3 shows a splash on a 1/20 slope beach in a wave tank, taken from the side of the tank. The wave period is 1.8sec, and the deep-water wave steepness is 0.021(Table 1). So we can not compare this photograph with the calculated results directly. But the splash height in the wave tank is higher than that of the calculated result.

One reason is that the cell size is too large to take into account the existence of small water drop. Also as seen in Photo 3, under the crest, a lot of air bubbles are entrained into the water. The air entrained region reaches near the bottom. This air bubble entrainment is also not reproduced by the numerical calculation.

So, this numerical computation does not simulate the real motion. But, for our understanding of the very rapid motion after wave breaking on beach, these numerical results are useful. In particular, the numerical computation can calculate the instantaneous high speed velocity of water particle. Also the instantaneous value of circulation of the horizontal vortex can be calculated.

DISCUSSIONS

(1) water particle velocity

The maximum water particle velocity in the x direction at the

initial condition(Fig.5,(1)) is about 110cm/sec and occours at the steep front face of the wave. The linear long wave propagation velocity $\sqrt{gh}$ is also about 110cm/sec.

At about 0.15sec later(the result not shown here), it increases to 140cm/sec, and its position is still located at the steep front face. Mizuguchi et al.(1986) measured a velocity field of breaking waves on a beach of 1/20 slope in a wave tank with a laser-doppler velocimeter. A maximum velocity before plunging normallzed by $\sqrt{gh}$ red from their figure is about one. This is comparable with our numerical result.

At 0.29sec later(not shown here), the tip of jet has not yet touches the trough surface. The maximum velocity is about 200cm/sec, and located at the lower surface of the jet. New et al.(1985) said in their paper that the horizontal velocity in the jet are between 1.5 and 2 times the phase speed of the linear wave. In this case, the linear long waves propagation velocity is about 110cm/sec. So our computation result agrees with their result.

Fig.7 shows a contour of water particle velocity in the x direction in and around the jet at 0.33sec later. This instance is just after the first jet touching on the trough surface. Notice that the x direction does not coincide with the horizontal direction. At the tip of the jet, a maximum velocity of more than 300cm/sec occours. It is not easy to find the maximum velocity after plunging from Mizuguchi et al.(1986)'s figure. But the normalized value seems to be still one.

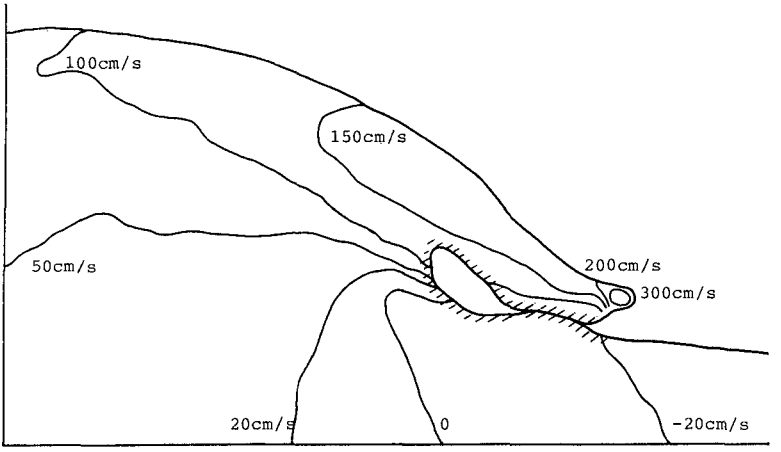

Fig.7 Contour of x component of water particle velocity in and around jet at 0.33sec later(just after 1st jet touching on trough surface)

Jansen(1986) also measured a velocity field in the jet by using fluorescent particles as tracer in a wave tank. From their figure 11, it is found again that the normalized maximum velocity is about one. In our result, the value of $\sqrt{gh}$ is 110cm/sec, and the maximum velocity is more than 300cm/sec. So the normalized value is about 3. It is thought that

the experimentally measured values are underestimated.

Fig.8 shows a similar contour at about 0.47sec later. At this instance the second jet touching on trough surface already finished. The x component of water particle velocity in the jet is still large(about 200cm/sec) in its upper region. But it is small compared with that at the tip at 0.32sec later(Fig.7). It is found that the water particle velocity in the jet decreases gradually in the jet touching and splash process.

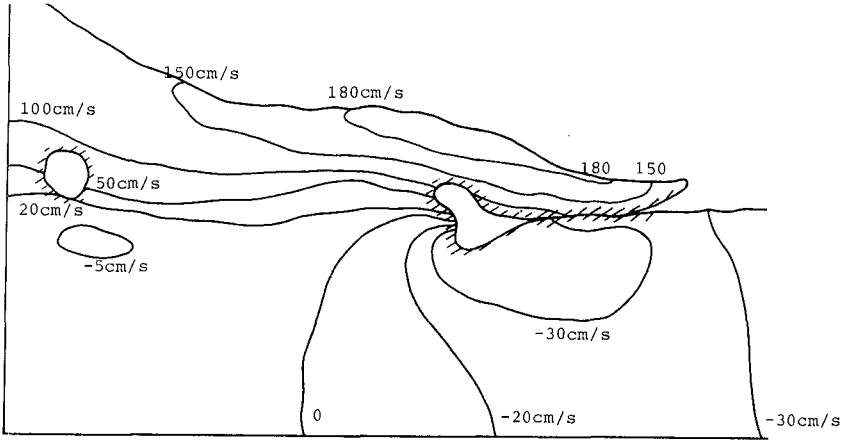

Fig.8 Contour of x component of water particle velocity in and around jet at 0.47sec later(after 2nd jet touching on trough surface)

(2) circulation of horizontal vortices

As seen in Fig.5, several large horizontal vortices are generated between the jet and the lower trough water. Values of circulation of these vortices are calculated. The closed path for the circulation calculation is determined rather arbitrarily.

Fig.9 shows the result. The instance when the vortex is generated is difficult to determine exactly from the figure of marker location. Arrows indicate a possibility that the vortex may be generated earlier. From the figure, it is found that the value of circulation reaches near $2000cm^2/sec$. The circulation of the first vortex decreases gradually, while that of the second vortex grows at first and then decreases. The third and fourth vortices are not so large compared with first two vortices.

Value of circulation of a horizontal vortex was calculated also by Shibayama et al.(1982) using experimental data. The wave period was 1.24sec, deepwater wave height 3.8cm, deepwater wave steepness 0.016, and the initial slope of a movable bed 1/20. They calculated the circulation from a velocity field which was determined from movement of polystyrene particles. From their figure 5, it is found that the

value of circulation is at most 120cm^2/sec. The conditions of their experiment are different from those of our numerical simulation. So a direct comparison is impossible.

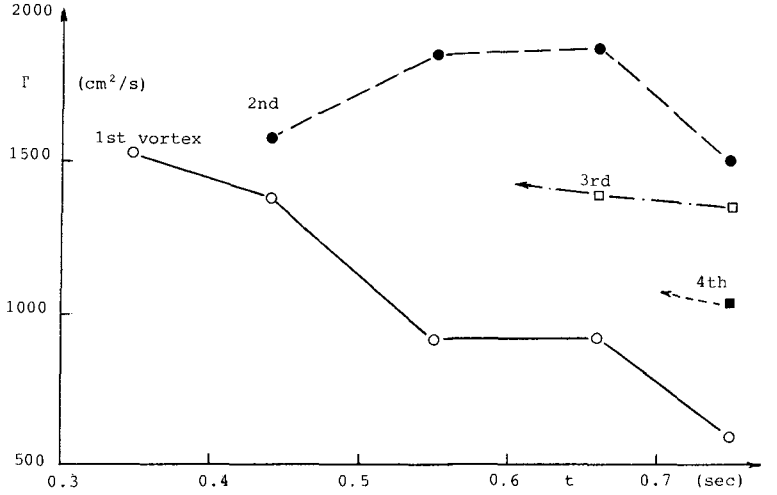

Fig.9 Circulation of four horizontal vortices

CONCLUSIONS

(1) By a flow visualization of a plunging breaker on a 1/20 slope beach in a wave tank, an existence of the 2nd and 3rd vortices suggested by Miller(1976) and the slanting vortex suggested by Nadaoka et al.(1986) is confirmed.
(2) A MAC method is applied to simulate a violent motion after an impinging of a jet from a crest of a plunging breaker on the trough surface. Although the numerical simulation can not reproduce the high splash, the deep air bubble penetration into the trough water and the slanting vortex, it can reproduce the high speed jet on the trough surface and the several horizontal vortices.
(3) The calculated maximum water particle velocity in the jet reaches three times the linear long wave celerity just after the impinging of the jet on the trough surface.
(4) The calculated circulation of the first horizontal vortex decreases gradually. The calculated circulation of the second one is larger than that of 1st one. It increases at first and then decreases. The values of circulation of the third and fourth horizontal vortices are smaller than those of the first and second ones, and become smaller in this order.

CHAPTER 55

Biperiodic Waves in Shallow Water

Norman W. Scheffner*, Member ASCE

Introduction

The propagation of waves in shallow water is a phenomenon of significant practical importance. The ability to realistically predict the complex wave characteristics occurring in shallow water regions has always been an engineering goal which would make the development of solutions to practical engineering problems a reality. The difficulty in making such predictions stems from the fact that the equations governing the complex three-dimensional flow regime can not be solved without linearizing the problem. The linear equations are solvable; however, their solutions do not reflect the nonlinear features of naturally occurring waves. A recent advance (1984) in nonlinear mathematics has resulted in an explicit solution to a nonlinear equation relevant to water waves in shallow water. This solution possesses features found in observed nonlinear three-dimensional wave fields.

The nonlinear mathematical formulation referred to above has never been compared with actual waves, so that its practical value is unknown. The purpose of the present investigation was to physically generate three-dimensional nonlinear waves and compare these with exact mathematical solutions. The goals were successfully completed by first generating the necessary wave patterns with the new U.S. Army Engineer Waterways Experiment Station, Coastal Engineering Research Center's (CERC) directional spectral wave generation facility. The theoretical solutions were then formed through the determination of a unique correspondence between the free parameters of the solution and the physical characteristics of the generated wave.

*Research Hydraulic Engineer, U.S. Army Engineer Waterways Experiment Station, Coastal Engineering Research Center, Vicksburg, Mississippi, USA

Theoretical Background

One of the first mathematical models of nonlinear waves in shallow water with known solutions was presented by Korteweg and deVries in their famous 1895 paper. Their model, known as the KdV equation can be written in the following nondimensional form

$$f_t + 6ff_x + f_{xxx} = 0 \tag{1}$$

in which f represents the water surface displacement, x is the direction of wave propagation and t is time. This equation admits not only solitary wave solutions but also the periodic solutions commonly known as cnoidal waves. These solutions can be written as

$$f(x,t) = 2\sigma^2 k^2 cn^2(\theta;k) - 2\sigma^2\left[\frac{E(k)}{K(k)} - 1 + k^2\right] \tag{2}$$

where each of the terms in the solution are well documented analytic functions which can easily be computed in terms of known wave characteristics such as wave height and wavelength. Unfortunately, cnoidal wave solutions are valid only for long crested waves, e.g., waves which can be described by a single time-dependent one-dimensional surface wave pattern. Natural waves, in contrast, are composed of both long and short crested waves and cannot be adequately described by this theory.

A recent advance in nonlinear mathematics has been reported by Segur and Finkel (1984). They present explicit analytical solutions to a natural three-dimensional extension of the KdV equation proposed by Kadomtsev and Petviashvili (1970), known as the KP equation shown below

$$(f_x + 6ff_x + f_{xxx})_x + 3f_{yy} = 0 \tag{3}$$

where x now represents the primary direction of propagation; however, weak changes in the y-direction are now permitted. When no y-variations occur, the KP equation reverts to the KdV equation.

The KP equation admits an infinitely dimensional family of exact, periodic, solutions (see Dubrovin 1981 and Segur and Finkel 1984) which can be written in the form

$$f(x,y,t) = 2\frac{\partial^2 \ln\theta}{\partial x^2} \tag{4}$$

where θ is a Riemann theta function of genus n. Genus 1 solutions are exactly equivalent to cnoidal waves, they are permanent form, singly periodic, two-dimensional (one vertical and one horizontal) nonlinear waves. Genus 2 waves are biperiodic in that they permit the independent specification of two periodicies in both time and space. The solutions are genuinely three-dimensional, nonlinear, and propagate with permanent form at a constant velocity. Genus 3 and higher order solutions are multi-periodic and cannot be characterized as permanent form with respect to any translating coordinate system as the genus 1 and 2 solutions can. This present investigation is limited to the genus 2 solutions developed by Segur and Finkel.

The construction of a genus 2 solution of the KP equation is based on the specification of the appropriate Riemann theta function. This requires the introduction of a two-component phase variable and a 2 X 2 real-valued Riemann matrix. The first of these, the phase variable, is shown below.

$$\phi_1 = \mu_1 x + \nu_1 y + \omega_1 t + \phi_{10}$$

and (5)

$$\phi_2 = \mu_2 x + \nu_2 y + \omega_2 t + \phi_{20}$$

Where the parameters μ_1, μ_2, ν_1, and ν_2 are wave numbers, ω_1, and ω_2 are angular frequencies, and ϕ_{10} and ϕ_{20} are constants with no dynamical significance. The second ingredient involves the specification of a real-valued, negative definite, symmetric 2 X 2 Riemann matrix as shown below.

$$B = \begin{pmatrix} b & b\lambda \\ b\lambda & b\lambda^2 + d \end{pmatrix} \tag{6}$$

The parameters b, d, and λ represent solution nonlinearity. The genus 2 theta function can now be defined in terms of the above components by the following double Fourier series:

$$\theta(\phi_1,\phi_2,B) = \sum_{m_1=-\infty}^{\infty} \sum_{m_2=-\infty}^{\infty} \exp\left(\frac{1}{2}\, m\cdot B\cdot m + im\cdot\phi\right) \tag{7}$$

The calculation of a general case genus 2 KP solution requires the specification of the 11 parameters shown in Equations 5 and 6. Two of these parameters (ϕ_{10} and ϕ_{20}) have no dynamical significance, their only effect is to shift the origin of the resulting solution. Dubrovin (1981) proved that a genus 2 theta function in

the form of Equation 7 was a solution to the KP equation if, and only if, the solution parameters were related by four additional equations. One of these equations contains a constant of integration. Use of this additional criteria reduces the number of free parameters to 8, representing the minimum number of free parameters required to specify a general case genus 2 solution.

Genus 2 solutions of the KP equation describe a complex two-dimensional surface wave pattern. Similar features were observed by Hammack (1980) to result from the nonlinear interaction of two intersecting waves. The theoretical development by Segur and Finkel was partially prompted, in fact, by these reported waves. The development of an experimental program which would result in the generation of surface wave patterns qualitatively similar to genus 2 solutions was achieved by attempting to experimentally reproduce the conditions reported by Hammack, i.e. intersecting waves. This generation technique can best be described by presenting the analogy of interacting waves. Consider, for example, two periodic waves which intersect and pass through each other as shown in Figure 1. The angles α_1 and α_2 represent the angle of the crest of each wave front with respect to some reference line. The resulting surface wave pattern, according to linear wave theory, would simply be a superposition of the two individual waves. This would produce a diamond shaped surface pattern as indicated in Figure 1. It can be seen that certain of the basic characteristics of the individual waves, wavelength and angle of propagation for example, have been preserved.

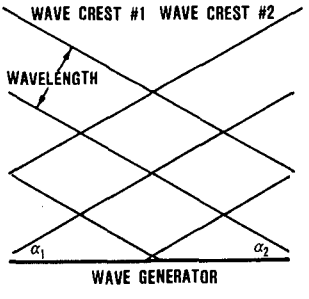

Figure 1. The Linear Intersection of Waves

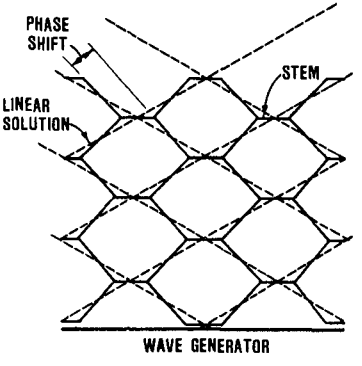

Figure 2. The Nonlinear Intersection of Waves

Now, consider the analagous case in which similarly intersecting waves interact nonlinearily with each other. This scenario is shown schematically in Figure 2. The resulting wave pattern shows that a "stem of interaction" is formed at the point where the two waves

cross each other. The formation of this stem region is a result of a phase shift in the crest line angles of the original waves. This phenomenon is shown in Figure 2 superimposed on the corresponding linear wave solution. The resulting surface wave pattern now assumes a hexagonal pattern in which a third wave crest, separate of the original two, is formed. This phase shift and stem formation are indicative of the nonlinear interaction of the two waves since the exact linear solution does not predict either the phase shift or the new wave crest. Genus 2 solutions of the KP equation predict these features and was tested as a possible model for their description.

Laboratory Facilities and Experimental Procedures

A project was initiated at CERC to generate three-dimensional nonlinear wave fields in the laboratory and then to apply KP theory to the resulting waves in order to determine whether or not the KP equation was a model for these waves and, if so, what was the range of its applicability. This required the use of the CERC directional spectral wave generation facility. This unique wave generator, shown in Figure 3, was designed and constructed for CERC by MTS Systems Corporation of Minneapolis, Minnesota, based on design specifications provided by CERC. The generator is comprised of 60 individually programmable electromechanical wave paddles. Each wave paddle is 1.5 ft wide making the generator a total of 90.0 ft in width. The generator is located in a 98.0 by 184.0-ft wave basin with 2.5 ft high side walls. Computer control of the system is provided by a Digital Equipment Corporation (DEC) VAX 11/750 central processing unit. The above facilities were utilized to generate genus 2 candidate waves in a comprehensive experimental program.

Figure 3. The Directional Spectral Wave Generator

The wave generator was programmed to simultaneously generate intersecting cnoidal wave trains. A variety of wave fields were generated by varying both the wavelength of the individual waves and their angle of intersection. Twelve wave fields, generated in this manner, were used to test the KP equation. The wave fields selected for the experimental program are presented in Table 1. Waves characterized by three wavelengths (7, 11, and 15 ft) were combined with phase shifts between adjacent wavemaker paddles. These phase shifts were approximately equivalent to the angle of the wavecrest with respect to the axis of the wave generator. The angle in the tahle shows the approximate correspondence between the phase lag and the angle of propagation.

CN2015	15.0	20.0	33.75	2.553

Genus 2 solutions can be visualized as a series of repeating two-dimensional permanent form surface patterns, referred to as period parallelograms. These patterns translate at a constant velocity in a constant direction. The global wave field is represented by a tiling of these basic patterns; therefore, the entire wave pattern can be exactly specified by quantifying just one period parallelogram. The location of a basic period parallelogram within the hexagonal wave field of Figure 2 is shown in Figure 4. The phase variables of Equation 5 define the horizontal limits of these patterns such that each side is uniquely defined by ϕ_1 = constant and ϕ_2 = constant. The components of the Riemann matrix define the vertical and horizontal distribution within the period parallelogram.

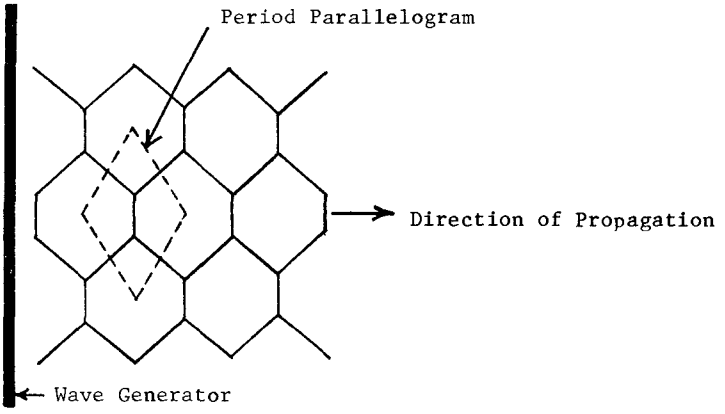

Figure 4. The Period Parallelogram

Detailed measurements of each of the generated wave fields shown in Table 1 were required in order to relate the physical characteristics of the waves to the parameters of the corresponding period parallelogram of the exact solution. This quantification was accomplished by first using overhead photography to determine the dimensions of the period parallelogram and to provide an estimate of the internal features, such as the phase shift and stem length. Knowledge of these horizontal features and their location within the wave tank were then used to locate a linear array of 9 recording wave gages in the wave basin. This approach provided a vertical wave record which could be identified with a known location within the parallelogram.

Comparing Theoretical Solutions To Observed Waves

The experimental program described above generates symmetric cnoidal waves ($\alpha_1 = \alpha_2$ in Figure 1) resulting in a symmetric period parallelogram. This simplification was adopted so that the generated wave patterns would propagate perpendicularly off the face of the wave generator, making it possible to measure all wave forms with a single stationary wave gage array. Symmetry also reduces the number of free parameters which need to be specified, for example, $\mu_1 = \mu_2$, $\nu_1 = -\nu_2$, and $\omega_1 = \omega_2$ from Equation 5. This simplification results in the requirement of only three dynamical parameters and two nondynamical parameters. The parameters chosen were b , μ , and λ along with the phase shift parameters ϕ_{10} and ϕ_{20}. The following sequence of events was used for optimizing these coefficients. Experiment CN3007 will be used to demonstrate the verification process.

Each of the waves of Table 1 were generated in the wave basin. Two overlapping photographs were taken with duel Hasselblad model 500EL/M 70mm cameras equipped with 50mm lenses mounted 23 ft above the floor of the basin. The resulting mosaic photograph, shown in Figure 5, was used to estimate the length and width of the period parallelogram. This resulted in estimates for $\mu_1 = \mu_2$ and $\nu_1 = -\nu_2$. An estimate for the phase shift parameter λ was also determined from the photograph. The accuracy of μ, ν, and λ is a function of the distortions in the photograph. Because of this distortion, their values were considered to be initial estimates. Following the photographing of all waves, a wave gage spacing of 2.5 ft apart and 40.0 ft from and parallel to the generator was selected for use in all tests. The location of each of the gages with respect to wave CN3007 is shown in Figure 5. It can be seen that each gage can be uniquely referenced according to a distance from the center of the parallelogram. Since all parallelograms are identical, wave gages located in an adjacent parallelogram can be referenced to the common center point.

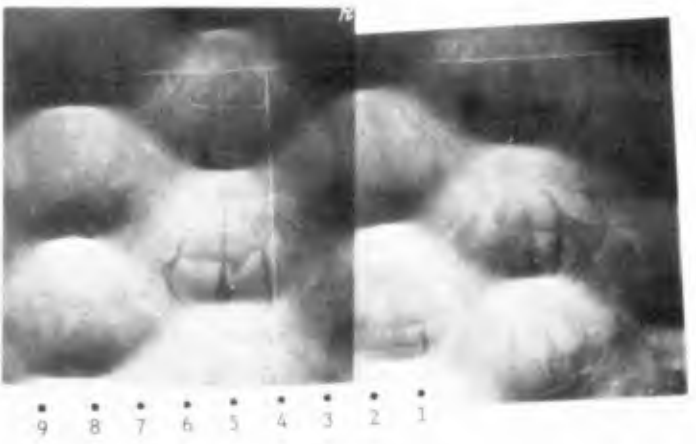

Figure 5. Overhead Mosaic Photograph of Test Wave CN3007

Wave gages were located in the basin and each of the waves of Table 1 were regenerated. Data was sampled for each of the gages at a rate of 50 samples per second for a total of 30.0 seconds. Figure 6 shows the wave traces for one period of wave CN3007. The correspondence between the wave traces and their location within the parallelogram can easily be seen. For example, gage 5 is located on a stem where only one peak per passing of the parallelogram is experienced. Gage 3 is located in the saddle region where two smaller peaks per period are seen. This comparison demonstrates the usefulness of the photographs in interpreting the data since three-dimensional effects are difficult to deduce from two-dimensional data.

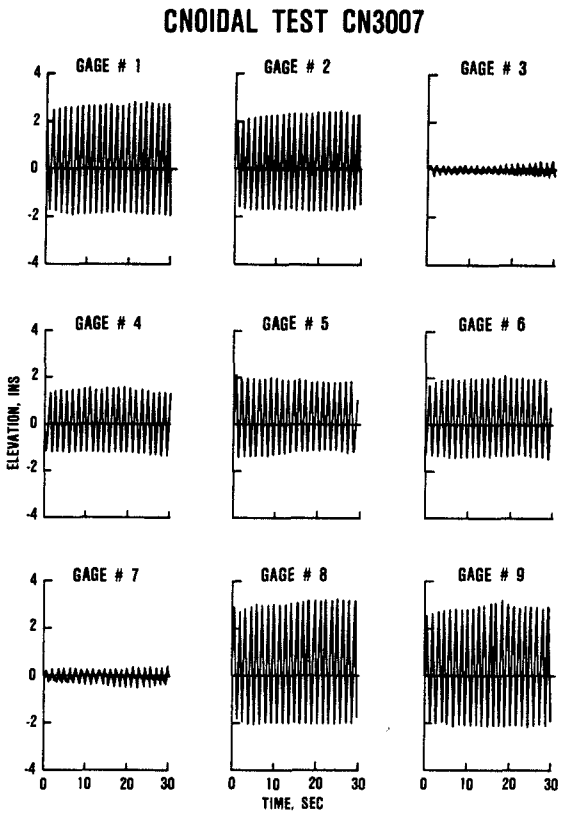

Figure 6. Wave Gage Traces for Test Wave CN3007

The determination of the free coefficients can now be made. Known or estimated data are the period of the wave (determined from the recording wave gages), the length and width of the period parallelogram and an estimate of the phase shift parameter λ determined from the photographs, and a maximum wave height selected from the wave gage data. The following iteration procedure was used to optimize the coefficients:

a. The estimated values for $\mu_1 = \mu_2$ and λ were specified. The nondynamical parameters ϕ_{10} and ϕ_{20} were accounted for by specifying solutions to be computed at location within the period parallelogram corresponding to the location of the wave gages. A value of b was then selected such that the dimensionalized maximum KP solution was within 5.0 percent of the measured value.

b. The value of $\mu_1 = \mu_2$ was adjusted, if necessary, until the dimensionalized period was within 3.0 percent of the measured period.

c. The value of λ was adjusted, if necessary, until the dimensionalized value of $\nu_1 = -\nu_2$ was within 10.0 percent of the estimated value. A 10-percent criteria was used for this iteration since the length of the parallelogram was difficult to determined from the photographs.

d. Because of the nonlinear coupling of the solution coefficients, each adjustment affected all parameters to some extent. If corrections were found to be necessary, steps (a.) through (c.) were repeated until all of the specified tolerances were

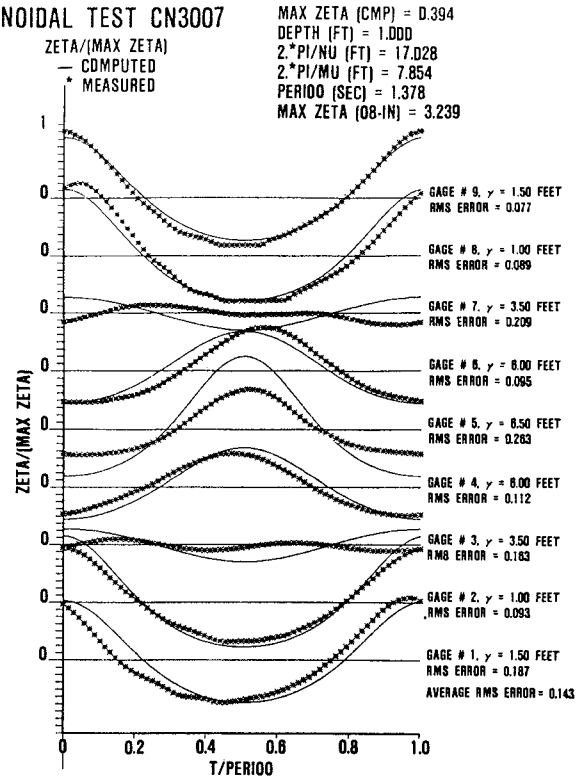

Figure 7. Theoretical and Measured Wave Profiles for Test Wave CN3007

met or exceeded. Possible phasing problems regarding the gage locations within the parallelogram were rectified by adjusting the nondynamical phase parameters.

e. A KP solution corresponding to the location of each of the wave gages was calculated. A normalized plot comparing theory to measurements was made, as shown in Figure 7 for the present example. Included in each plot is the Root Mean Square (RMS) error for each comparison.

f. A normalized contour plot (Figure 8) and a three-dimensional plot (Figure 9) for each wave field was finally prepared as a visual example of the KP solution.

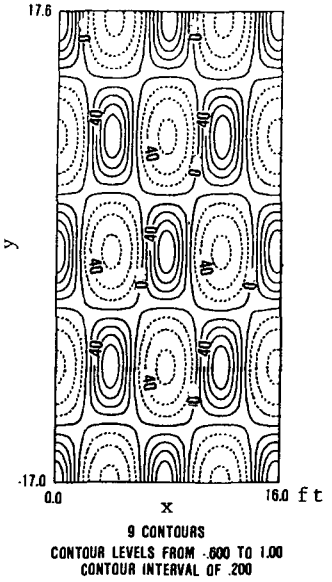

Figure 8. Normalized Contour Plot for Test Wave CN3007

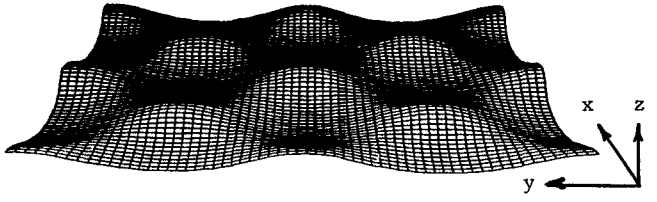

Figure 9. Three-Dimensional Plot of Test Wave CN3007

The above procedures were followed for each of the test wave fields of Table 1. A minimum tolerance of 5.0 percent for waveheight, 3.0 percent for period, and 10.0 percent for the Y-direction wavelength was maintained for all experiments. Table 2 presents those computed results. For each case, an average RMS error is provided which represents a simple average of the 9 RMS values computed for each gage. In no case did this error exceed 20 percent even though variations in the elevation of the basin floor of 10 percent were known to exist. Additionally, the experimental wave fields were generated almost to the point of breaking in order to span the range of solution parameters and investigate the limits of applicability of the genus 2 solutions. In view of these introduced and existing sources of potential error, the degree of fit between the generated wave fields and the exact solutions were found to be very good.

Table 2
Computed wave parameters

Test Number	Max. Height (in)	X-Wavelength (ft)	Y-Wavelength (ft)	Ave. RMS Error
CN1007	2.44	7.0	46.5	0.141

CN1015	2.65	15.0	59.3	0.120
CN1515	2.84	16.1	32.6	0.094
CN2015	2.86	17.1	29.0	0.098

Conclusions

Twelve separate nonlinear wave fields were generated for the purpose of verifying the KP equation to be an accurate model for three-dimensional nonlinear waves. Criteria were developed which provided a unique correspondence between the solution parameters of the KP equation and the physical characteristics of the laboratory generated waves. Results of these experiments showed that both the generated waves and the genus 2 solutions are remarkable robust in that both were stable over a wide range of parameters, including the near breaking of waves. The excellent degree of fit between the observed and computed solutions shows that genus 2 solutions of the KP equation represent a viable model for three-dimensional, nonlinear, shallow water waves.

CHAPTER 56

TROPICAL CYCLONE GENERATED CURRENTS

by

Y. Peter Sheng, M.ASCE[1], and Sherman S. Chiu[2]

ABSTRACT

AXCP data obtained during Hurricane Josephine in 1984 are analyzed in this paper. In addition, wind-driven currents at several XCP's during Josephine are simulated using a one-dimensional ocean current model.

I. INTRODUCTION

An accurate quantitative determination of design environmental conditions is of great importance for offshore design consideration in oil and gas exploration and production, because of the high costs associated with the construction of deepwater offshore structures. For design consideration in such areas as the Gulf of Mexico, offshore China, and the northwest shelf off Australia, tropical cyclone generated forces in water column have been conventionally used as the major factor. Normally, forces generated by the maximum wave (extreme wave condition) and forces generated by the maximum possible wind-driven currents (extreme current condition) at a particular area are calculated for design consideration. The design criteria resulting from such a consideration may be overly conservative since the extreme wave and extreme current generally do not occur at the same time, at the same location, or in the same direction. Due to difficulties in measuring currents during a storm, however, little is known about the concurrent wind-driven current profiles in the vicinity of the maximum wave zone or the time lag between the maximum wave and maximum current conditions at a given site.

Measured currents at a site may be composed of currents driven by tide, wind, density gradient due to temperature and/or salinity distribution, gravity wave and localized circulation patterns such as internal waves and inertial currents. During a severe storm, the wind-driven

[1] Coastal and Oceanographic Engineering Dept., University of Florida, Gainesville, FL 32611
[2] Standard Oil Production Company, Dallas, Texas

currents become dominant over the other currents. Although a number of current models have been and are being used to calculate the wind-driven currents during severe storms, there is insufficient data available to validate these models. Based on extremely scarce data, however, Gordon (1982) claimed that currents in the ocean surface mixed layer (SML) are very uniform and only "slab model" can represent the current profiles in severe storms.

With the recent development of Air-deployed eXpendable Current Profiler, (Feeney, et al., 1985) or AXCP, "snapshots" of detailed ocean current and temperature profiles within storms can now be measured. It is thus possible to perform a systematic observation and analysis of wind- and wave-induced ocean currents at the ocean surface, surface mixed layer and thermocline. In addition, the wind-driven currents can be used for validation of ocean current models. In 1984, current profiles were measured via the systematic deployment of 31 AXCP's during two hurricanes--Hurricane Norbert in the eastern Pacific, and Hurricane Josephine in the western Atlantic.

This paper presents and discusses, from the point of view of practical engineering application, some ocean current and temperature profiles obtained via AXCP's in Hurricane Josephine during October, 1984. In addition, this paper presents a simulation of the wind-driven currents at several locations in Hurricane Josephine by means of a one-dimensional ocean current model (OCM1D) developed by Sheng (1984a and 1985). The results and understanding obtained from systematic studies such as this one will undoubtedly lead to the ultimate improvement of design criteria for offshore structures.

II. THE OBSERVATION PROGRAM

XCP and AXCP

The expendable current profiler (XCP) was originally developed by Dr. Thomas B. Sanford of Horizon Marine, Inc. It is a free-falling magnetic current meter which can be deployed from either a ship or an aircraft (AXCP). Figure 1 shows the major components involved in the XCP and AXCP deployment (Haustein and Feeney, 1985).

The ocean can be considered as many individual vertical layers with different electric fields which arise because of a process known as motional induction, i.e., electric current is generated as seawater flows through the geomagnetic field of the earth. The AXCP, as it falls through the water column, measures the electric current generated in each of the individual vertical layers via the recorded voltage (in nanovolts) between two horizontally spaced electrodes 5 cm apart. The measured electric currents at all layers yield a vertical profile of relative water velocities or "shears". A compass coil within the spin-stabilized probe measures the direction of current once per revolution as the probe falls with a 16 Hz rotation rate. A continuous temperature profile is measured by a thermistor located within the probe. The regular AXCP has a fall velocity of about 5m/sec and measures the current speed, direction and temperature to a depth of 1500 m. The slow-fall XCP has a fall velocity of about 2m/sec and a 200m depth capacity.

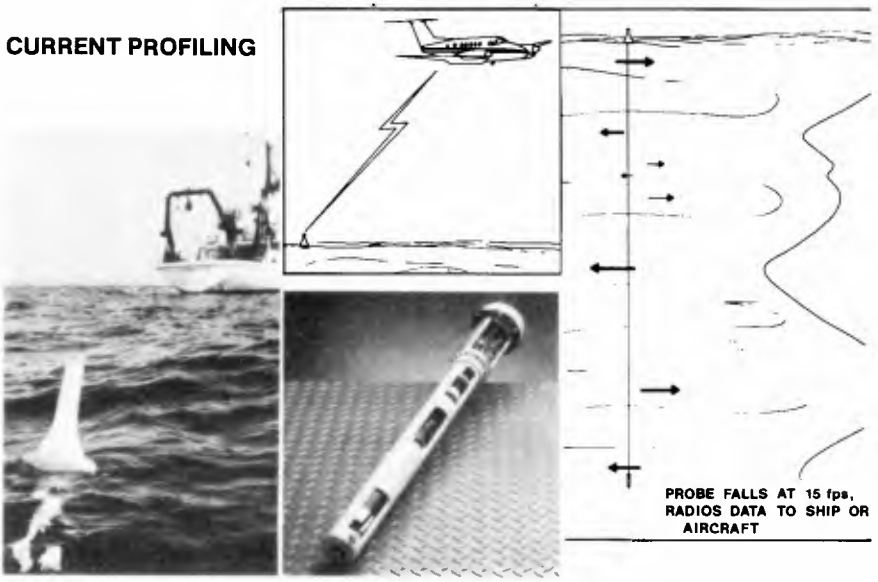

Figure 1 Current profiling using the XCP and AXCP. LEFT: Ship deployment showing attached float bag containing a radio antenna which transmits data back to the ship. CENTER TOP: Aircraft deployment. CENTER BOTTOM: The current profiler, contained within the probe housing. RIGHT: Continuous ocean current profile produced by the descending probe.

Forty seconds after the XCP lands on the water surface, the probe is launched through the bottom of the buoy. Signals measured by the electrodes, compass coils, and thermistor are transmitted from the probe to the surface buoy via a 1500-m or 200-m wire link. The data is then transmitted from the surface buoy, via the RF link, to processing or recording equipment on board a ship or aircraft. However, because the extremely strong winds during storms, the XCP's generally have a rather high failure rate of about 50%.

Ocean Response to a Hurricane

The observation program, "Ocean Response to a Hurricane", was a joint industry program involving nine U.S. oil companies (including Standard Oil, Mobil, Shell, etc.), NOAA's Hurricane Research Division and Office of Aircraft Operations, and Horizon Marine, Inc. (Feeney, et al., 1985). The program was the first systematic effort to measure ocean currents and temperature perturbations under severe meteorological conditions. A total of 31 AXCP's were systematically deployed during two hurricanes in 1984: Hurricane Norbert near Baja Peninsula in the eastern Pacific during September 23-24, and Hurricane Josephine near western Atlantic during October 10-11. While Norbert is relatively stronger, this paper concentrates on the slightly weaker Hurricane Josephine.

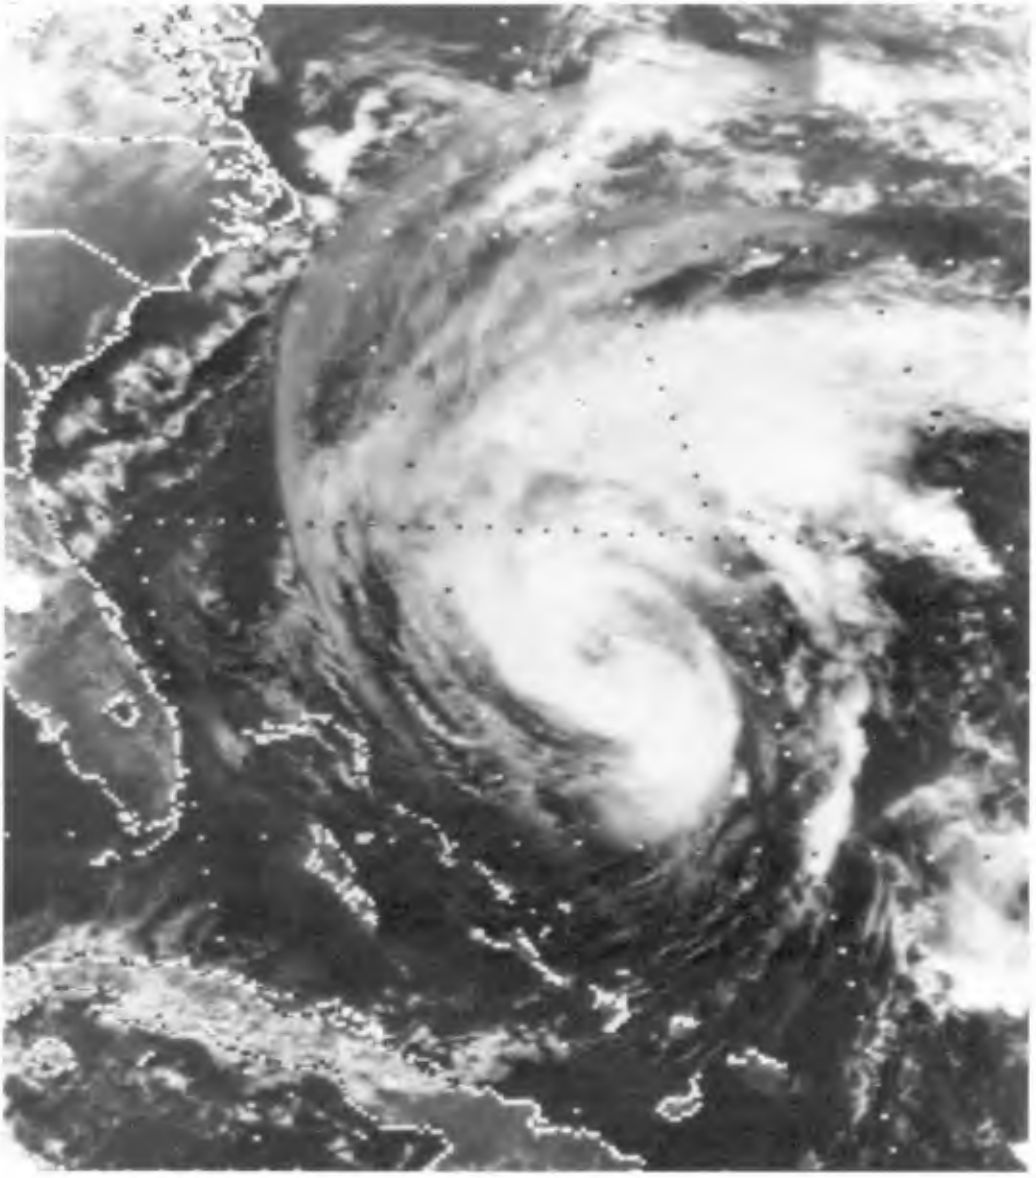

Figure 2 Hurricane Josephine as seen from satellite.

Hurricane Josephine

Flight through Josephine was executed on October 11, 1984, one day after Josephine attained hurricane strength. At that time, Josephine's eye was located near 25.5° N and 72° W with a moderate maximum surface wind of 75 knots and a barometric pressure of about 970 mb. The storm as shown in Figure 2 is located approximately 250 n miles northeast of the Bahama Islands, drifting slowly northward, over waters of approximately 4000 m deep. The survey was conducted with a total of 31 AXCP's which include 17 regular AXCP's with a 1500 m depth capacity and 14 slow-fall AXCP's with a 200 m depth capacity.

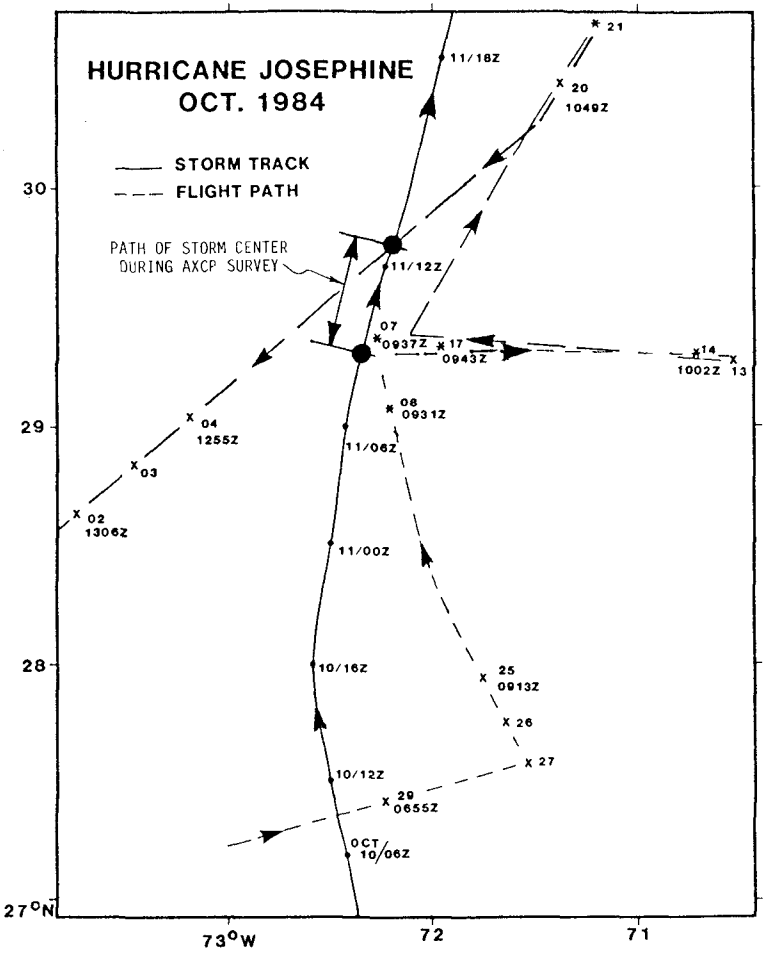

Figure 3 Storm track and AXCP flight path during Hurricane Josephine on October 10-11, 1984.

The flight area of the AXCP survey is shown in Figure 3, where the solid line starting from the south represents the storm track (distance between two adjacent dots represents a 6-hour interval) and the dashed line indicates the flight path between 8:45 AM (Zulu time) and 13:06 PM on October 11, 1984. The highlighted portion in Figure 3 represents the locations of storm center during the flight survey period. During that time, the forward speed of the hurricane was approximately 7 kts and the radius of maximum wind (R) was approximately 35 n miles. The survey covered an area more than 200 n miles (3 degrees) squared. Although a total of 31 AXCP's were deployed, only 50% of the data were usable. Locations with usable XCP data are indicated by the x's in Figure 3. 5 XCP's (XCP07, XCP08, XCP14, XCP17, and XCP21) are of special interest in this paper and are marked by the *'s in Figure 3.

III. XCP DATA DURING HURRICANE JOSEPHINE

All the XCP's were deployed to the right of Hurricane Josephine where the storm effect on current is stronger and where the Gulf Stream has negligible effect, thus allowing easier separation of wind- and wave-induced currents from the background current. Some data are presented in the following.

Current and Temperature Data at XCP17

XCP17 is located at approximately 0.7 R to the east of the storm eye. At the time of the survey, surface wind at XCP17 is about 24 kts toward the north. Several hours before the survey, however, wind exceeded 50 kts at all the XCP's of special interest.

Figure 4 shows the measured current speed, direction, and temperature at XCP17 from surface to 250 m depth. The profiles are plotted from data averaged over every 3 or 4 meters, or approximately 20 raw data points. The current speed (solid line) exceeds 1 m/sec at the surface and decays to about 20 cm/sec below 100 m depth, while the current direction (dotted line) changed form nearly 45^{o} (towards northeast) at surface to about 180^{o} (towards south) below 100 m depth. The effect of surface gravity wave, as is evidenced by the oscillatory velocity profile, is present even below 100 m depth.

Since our primary interest is the wind-driven current, a filtering procedure can be designed to remove the wave-induced orbital velocity from the signal. The filtering procedure makes use of the calculated wave period and the fact that amplitudes of the wave-induced signal decays exponentially with depth. The filtered current speed and direction as shown in Figure 4 are rather smooth and represent the wind-driven current, which will be used for validation of ocean current model. It should be noted that although wave signal can be found even at 100 m depth, the vertical shear associated with the wave orbital velocity is generally rather weak compared to that due to the wind-driven or density-driven currents. Hence, removing the wave-induced signal from current data will have little effect on turbulent mixing in the surface mixed layer.

Figure 4 also shows a thermocline between 70 m and 90 m depths. It is clear that although the temperature is rather uniform within the SML, current profile looks hardly like a "slab". In fact, significant shear

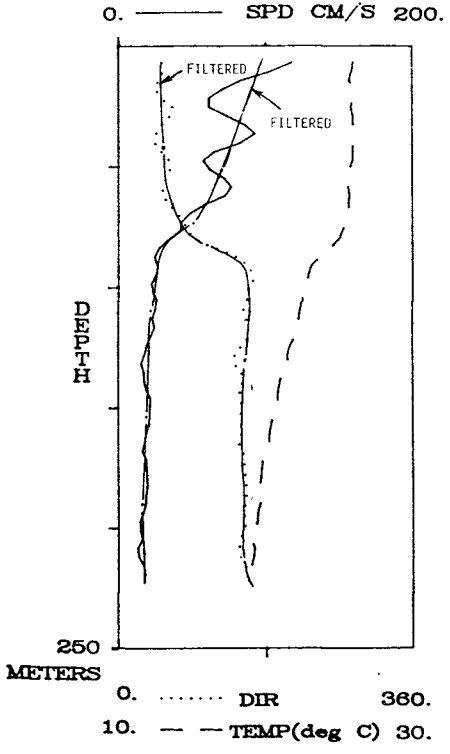

Figure 4 Current speed, current direction, and temperature measured by XCP17 during Hurricane Josephine.

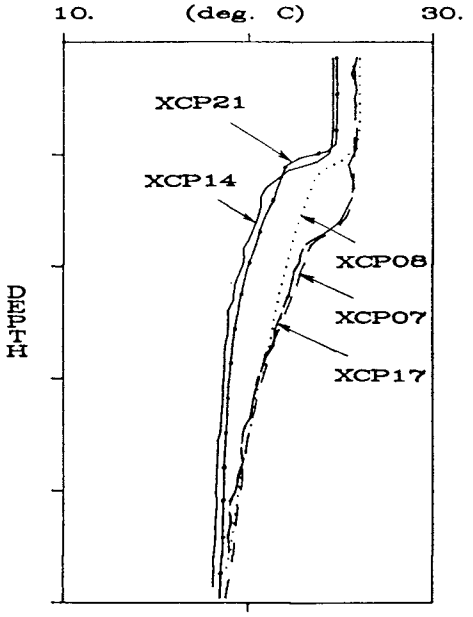

Figure 5 Temperature profiles measured by XCP07, XCP08, XCP14, XCP17 and XCP21.

appears to be present in the mixed layer. It is also noted that the current profile does not quite resemble the classical Ekman layer. Except near the thermocline, little change in current direction is detected.

Temperature Data at XCP07, XCP08, XCP14, XCP17, and XCP21

Temperature profiles at the 5 XCP's are shown in Figure 5. At the three stations within R from storm center (XCP07, XCP08 and XCP17), temperature profiles within the SML are very similar, with XCP07 and XCP17 having almost identical profiles throughout the 250 m depth. At XCP14 and XCP21, more than 2R away from the storm eye, the temperature profiles are similar and relatively undisturbed by the hurricane. The SML temperature at these two XCP's is colder than that at the other three XCP's.

Thermocline at the XCP14 and XCP21 is found at 50 m depth. At XCP07 and XCP17, where winds are 1 kt and 24 kts respectively, but were much stronger several hours before, the thermoclines are found at 80 m depth. At XCP08, where the storm center has passed by about 4 hours ago and the wind is 9 kts, the thermocline is at 50 m depth.

The above data indicate that a time lag on the order of a few hours exists between the occurrences of peak wind and maximum thermocline deepening. As the storm center approaches a location, wind gradually decreases from peak wind to negligible wind when the eye arrives. When the storm center reaches the location, although the wind has decreased substantially, the thermocline continues to be deepened by wind-induced mixing generated during previous hours. At the same time, the positive wind stress curl may produce a positive vertical velocity which tends to move the thermocline upward. This so-called "Ekman suction", however, may also lag behind the arrival of storm center. In addition, lateral pressure gradient within the maximum radius R of the storm eye may also cause geostrophic currents and contribute to the mixing and migration of thermocline. However, the exact manner in which these competing mechanisms operate is not yet clearly understood.

Current Data at XCP07, XCP08, XCP14, and XCP17

Figure 6 shows the unfiltered current and temperature profiles at the 4 XCP's. If one visually removes the wave-induced components from Figure 6, it is apparent that the filtered current profiles in the SML are rather similar. The current decreases gradually with depth in the SML without any resemblance to the so-called "slab".

Current speed in the SML becomes increasingly stronger from XCP08 ($\lesssim$ 50 cm/sec) to XCP07 ($\lesssim$ 75 cm/sec) to XCP17 ($\lesssim$ 1 m/sec). Current direction within much of the SML appears to be at approximately 45° to the right of the wind. Although the wind at XCP14 is the strongest (54 kts) among the 4 XCP's, the wind-driven current is only about 60 to 70 cm/sec. Velocity gradients within the thermoclines are quite different, apparently because of the difference in thermocline shapes. Below the thermocline, there appears to be an anticyclonic gyre around the storm center. Although this could be related to the geostrophic current induced by the pressure gradient, it is unclear as to how

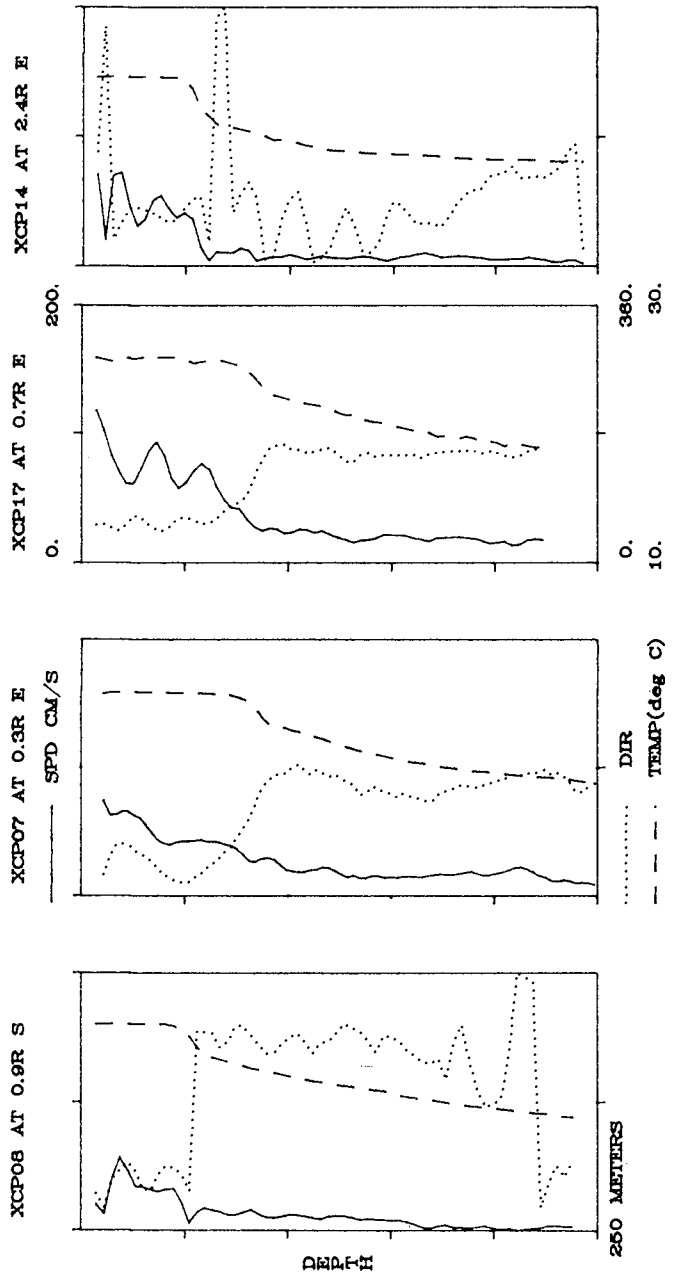

Figure 6 Measured current speed, current direction and temperature at XCP07, XCP08, XCP14 and XCP17.

exactly the pressure gradient and the wind stress interact to cause transient circulation in a hurricane. However, at XCP08, the greater difference (~180°) in current directions below and above the thermocline is consistent with the fact that pressure gradient at XCP08 is stronger than the other XCP's.

II. MODEL SIMULATION OF WIND-DRIVEN CURRENTS IN JOSEPHINE

Wind and Wave Hindcasting

Before simulating the wind-driven currents, the wind and wave field were hindcasted by means of a modified Bretschneider method (1972). With such input values as storm track, central pressure, maximum wind radius R, maximum wind at R, and ambient flows, the model yields the wind and wave conditions. As an example, the hindcast wind and wave data at XCP17 during a 48 hour period prior to the arrival of Josephine are shown in Table 1. At 5:00 AM on October 11, while the storm center is still 41 n m (nautical miles) from XCP17, the wind speed peaked to 60 kts and the significant wave height peaked to 29 feet with a peak period of 11.7 sec. Four hours later at 9:00 AM, the condition has fallen to 24 kts wind speed, 18 feet wave height, and 9.5 sec wave period.

The time-dependent wind fields at all the XCP locations were saved in computer storage and used for simulation of wind-driven currents. Although the pressure was also computed by the hindcast model, it was not used for the present model simulation of wind-driven currents.

A One-Dimensional Ocean Current Model: OCM1D

Sheng (1984a and 1985) developed the OCM1D based on the following mean equations of motion:

$$\frac{\partial u}{\partial t} = fv - \underline{\frac{\partial \overline{u'w'}}{\partial z} - g\frac{\partial \zeta}{\partial x} - \frac{1}{\rho_o}\frac{\partial P_a}{\partial x} + \frac{g}{\rho_o}\int_o^z \frac{\partial \rho}{\partial x}\,dz} \tag{1}$$

$$\frac{\partial v}{\partial t} = -fu - \underline{\frac{\partial \overline{v'w'}}{\partial z} - g\frac{\partial \zeta}{\partial y} - \frac{1}{\rho_o}\frac{\partial P_a}{\partial y} + \frac{g}{\rho_o}\int_o^z \frac{\partial \rho}{\partial y}\,dz} \tag{2}$$

$$\frac{\partial T}{\partial t} = -\frac{\partial \overline{w'T'}}{\partial z} + \underline{\eta(1 - A_s)\frac{\phi_o}{\rho_o C_p}\exp(-\eta z)} \tag{3}$$

$$\frac{\partial S}{\partial t} = -\frac{\partial \overline{w'S'}}{\partial z} \tag{4}$$

$$\rho = \rho(T,S) \tag{5}$$

where (u,v) are the horizontal velocities in (x,y) directions, T is temperature, S is salinity, z is the vertical coordinate pointing upward from z = 0 at the undisturbed ocean surface, ζ is surface displacement, ρ_o is reference density, P_a is atmospheric pressure, ρ is density, (u',v',w') are turbulent fluctuating velocities in (x, y, z) directions, T' and S' are fluctuating temperature and salinity, η is extinction coefficient of solar radiation, A_s is sea surface absorption coefficient, and ϕ_o is solar raditation flux at sea surface. The underlined terms in Eqs. (1) and (2) are non-local terms which can be evaluated if

sea surface slope, atmospheric pressure gradient and density gradient are known (either measured or computed) and specified as input to the model. However, these non-local terms and the solar radiation term in Eq. (3) are not used in the present study.

Turbulent fluxes $\overline{u'w'}$, $\overline{v'w'}$, $\overline{w'T'}$ and $\overline{w'S'}$ are modeled with the so-called "super-equilibrium" version of a second-order closure model of turbulent transport (Sheng, 1984a). The general equations are given in terms of $\overline{u_i'u_j'}$, $\overline{u_i'\rho'}$, and $\overline{\rho'\rho'}$ in tensor notations:

$$0 = -\overline{u_i'u_k'}\frac{\partial u_j}{\partial x_k} - \overline{u_j'u_k'}\frac{\partial u_i}{\partial x_k} - g_i\frac{\overline{u_j'\rho'}}{\rho_o} - g_j\frac{\overline{u_i'\rho'}}{\rho_o}$$
$$- 2E_{ik\ell}\Omega_k\overline{u_\ell'u_j'} - 2E_{jk\ell}\Omega_\ell\overline{u_k'u_i'} \qquad (6)$$
$$- \frac{q}{\Lambda}\left(\overline{u_i'u_j'} - \delta_{ij}\frac{q^2}{3}\right) - \delta_{ij}\frac{q^3}{12\Lambda}$$

$$0 = -\overline{u_i'u_j'}\frac{\partial \rho}{\partial x_j} - \overline{u_j'\rho'}\frac{\partial u_i}{\partial x_j} - \frac{g_i\overline{\rho'\rho'}}{\rho_o}$$
$$- 2E_{ijk}\Omega_j\overline{u_k'\rho'} - 0.75\,q\frac{\overline{u_i'\rho'}}{\Lambda} \qquad (7)$$

$$0 = -2\overline{u_j'\rho'}\frac{\partial \rho}{\partial x_j} - \frac{0.45\,q\,\overline{\rho'\rho'}}{\Lambda} \qquad (8)$$

In addition to the above equations, Λ is computed from three integral constraints, i.e., Λ is bounded by (1) a slope of 0.65, (2) q/Λ, where q is the total turbulent velocity and N is the Brunt-Vaisala frequency, and (3) a fraction of the spread of turbulence. This model was able to successfully simulate the laboratory wind-driven currents (Sheng, 1984a) storm generated currents on continental shelf (Sheng and Szabo, 1986).

A 60 hour model simulation, starting from 60 hours prior to the time of the survey, was performed at all XCP's by assuming XCP21's temperature profile and zero velocity as initial data. The results at XCP17 between hour 42 and hour 57, with a 3-hour interval, are shown in Figure 7. Currents in the SML grow steadily with time in spite of the decrease in wind speed during the last 2 hours. During the 15 hour period, current direction changed from towards NNW to towards NNE as the wind shifted from E to SSE. Thermocline was deepened during the last 6 hours.

Model Results at XCP07, XCP08, XCP14, and XCP17

Model results at the end of 60 hour simulation are shown in Figure 8 for XCP07, XCP08, XCP14 and ACP17. Filtered data are also shown on the same figure. In general, the agreement between model results and data are quite good. The best agreement is at XCP14 which

is at 2.4 times the maximum wind radius from the storm center and hence is not much affected by pressure gradient within the storm center. The current direction at all the XCP's appears to be correctly simulated although current speed at XCP08 seems underestimated. The discrepancy between model results and data at the 3 XCP's within the storm center can be attributed to the following 3 possibilities: (1) uncertainty in the initial condition, (2) pressure gradient not included in the present model simulation, and (3) possible vertical water movement associated with the curl of wind stress was not included in the model simulation.

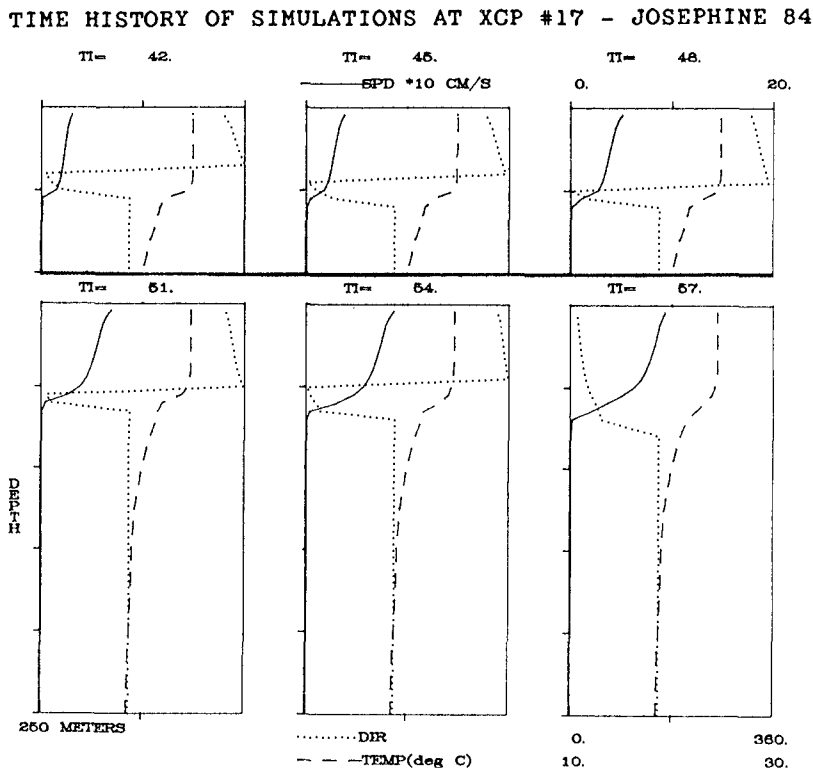

Figure 7 Model simulation of current and temperature at XCP17 during the six 3-hour intervals prior to the arrival of storm center.

V. CONCLUSIONS

During Hurricane Josephine in 1984, a systematic survey of ocean current and temperature within the top 250 m of ocean water was conducted by a joint industry program via the deployment of 31 AXCP's. This paper presents an analysis of the detailed data, which is available

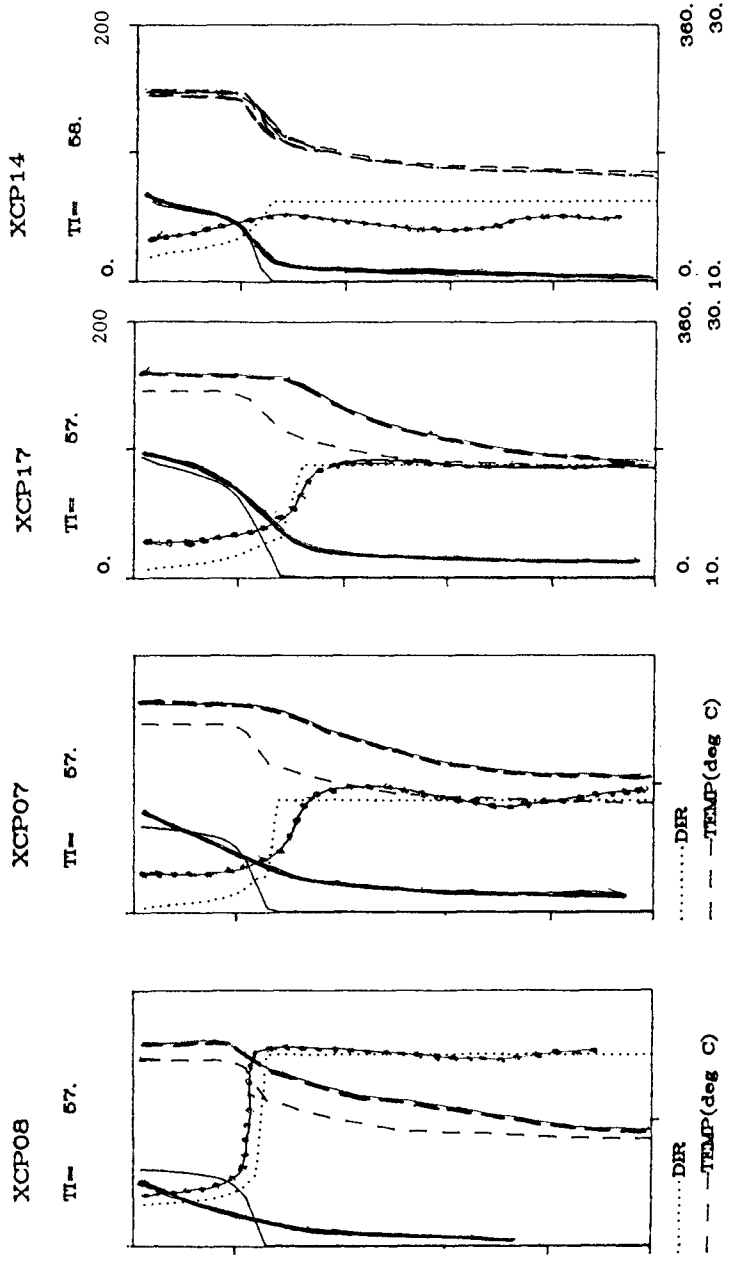

Figure 8. Model simulated and measured current and temperature at XCP07, XCP08, XCP14, and XCP17. Darker lines indicate measured data.

for the first time, and found the data of significant value for further understanding of ocean mixed layer dynamics and for improvement of offshore design criteria.

Model simulation of storm-generated currents at several XCP's was carried out by using the 1-D Ocean Current Model (OCM1D). The results generally are in reasonable agreement with data. It is interesting to note that both XCP data and model results showed significant shear within the surface mixed layer and no "slab"-like current profile was found. Discrepancy between model results and data is attributed to uncertainty in initial condition and neglect of pressure gradient and Ekman-suction in model simulation.

VI. ACKNOWLEDGEMENTS

The first author wishes to acknowledge the support of Standard Oil Production Company and Mobil Research and Development Corporation for the development of the 1-D ocean current model. Sherman Chiu served as the technical monitor for SOPO while David Szabo and Max Sheppard served as technical monitors for MRDC.

CHAPTER 57

COMPLEX ENVELOPE IDENTIFICATION OF WAVE GROUPS

Rodney J. Sobey[1] and Han-Bin Liang[2]

The complex envelope function is presented as the natural analysis technique for wave records where the identification of wave groups is a dominant interest. Algorithms have been developed and confirmed for separation of the complex envelope function, estimation of the dominant frequency and unwrapping of the phase function. Cross-correlograms and coherence spectra reveal a link between the envelope amplitude and phase traces that appears to be an intrinsic property of wave groups. Nevertheless, the majority of the information in typical wave records can be described as random, accounting for the relative success of the Gaussian random wave model.

INTRODUCTION

There is widespread acceptance of wave grouping in coastal and ocean design and considerable recent research effort has been focussed on the statistics of wave groups and the development of alternative analysis techniques to accommodate wave grouping. There is sufficient evidence from field records that wave grouping does exist but the specific nature and extent of wave grouping remains largely unresolved. It has been suggested, for example, that wave grouping is a direct consequence of the Gaussian random wave model, that it is a consequence of finely-tuned focussing of the phases of linear or non-linear wave trains, and that it is essentially a non-linear phenomenon, such as envelope solitons.

The evidence must be sought initially from field data. Care must be taken, however, that the choice of analysis technique does not predetermine the data interpretation. Spectral analysis and zero-up-crossing identification of individual waves, for example, ignore the phase information in the record and implicitly favor the Gaussian random wave model description. This approach has proved to be useful and reasonably successful. It may ultimately prove appropriate but questions remain regarding the existence of useful phase information in the record.

A natural analysis technique for wave grouping would appear to be the complex envelope function A(t), related to the wave record $\eta(t)$ as

$$\eta(t) = \text{Real}\,[A(t)\,\exp(i\omega_0 t)] \tag{1}$$

where $\omega_0 = 2\pi f_0$ is the dominant frequency. No information is lost from the original record and attention can be focussed on the envelope modulation. For typically narrow-banded sea states, mod $A(t)$ is an excellent approximation to the wave envelope, as recognized by Rice (1943, 1945) and Longuet-Higgins (1951) in the theoretical establishment of the Rayleigh distribution as an estimate of the probability distribution of

[1]Professor, Hydraulic and Coastal Group, Department of Civil Engineering, University of California, Berkeley, California, 94720
[2]Graduate Student, Hydraulic and Coastal Group, Department of Civil Engineering, University of California, Berkeley, California 94720

wave amplitude. Full advantage, however, has rarely been taken of the complete complex envelope function. It is the purpose of the present paper to evaluate its potential in the identification and perhaps quantification of wave groups. Several recent studies of wave grouping have adopted an envelope concept, all based on the application of a low pass moving average filter to $\eta^2(t)$, the square of the wave record. Funke and Mansard (1979) used a filter with half-width $1/(2f_p\Delta t)$ points in defining a smoothed instantaneous wave energy history. f_p is the spectral peak frequency and Δt is the discrete time step of the data record. W.C. Thompson, Nelson and Sedivy (1983) and E. F. Thompson and Seelig (1983) extended the filter half-width to $1/(f_p\Delta t)$ points. These studies have shown the utility of the envelope concept but have not taken advantage of the phase information in the record. In addition, filtering removes potentially valuable information from the record.

COMPLEX DEMODULATION

The potential of complex demodulation in the analysis and interpretation of periodic data has been elucidated by Bingham, Godfrey and Tukey (1966) and Hasan (1982). In principle, complex demodulation is a generalization of harmonic analysis, its objective being to extract the slowly varying amplitude $R(t;\omega)$ and slowly varying phase $\Phi(t;\omega)$ of the signal component at frequency ω. In general, the record will not consist solely of a perturbed sinusoid; it may be represented as

$$\begin{aligned}\eta(t) &= R\cos(\omega t + \Phi) + r(t) \\ &= \frac{1}{2} R\{\exp[i(\omega t + \Phi)] + \exp[-i(\omega t + \Phi)]\} + r(t)\end{aligned} \tag{2}$$

where $r(t;\omega)$ is the residual noise signal. Multiplying Equation 2 by $\exp(-i\omega t)$ gives

$$\eta\exp(-i\omega t) = \frac{1}{2} R\exp(i\Phi) + \frac{1}{2} R\exp[-i(2\omega t + \Phi)] + r\exp(-i\omega t) \tag{3}$$

The second and third items in Equation 3 oscillate at frequencies 2ω and ω respectively, so that the smooth component (and hence R and Φ) can be extracted by linear filtering (Bloomfield 1976). This procedure is appropriate in real time, regardless of the nature of the $\eta(t)$ data series. It will extract the slowly varying amplitude and phase at any nominated frequency ω, and the complete spectrum can be established in this manner.

The value of complex demodulation however is its ability to focus on a single frequency and herein lies its utility in wave record analysis. The spectra of surface gravity waves are consistently narrow-banded, to the extent that some dominant frequency ω_0 can be anticipated. The precise definition of ω_0 requires some further consideration but it is clear that it will be near the spectral peak. The complex demodulate at frequency ω_0 is the complex envelope function $A(t)$. The residual $r(t;\omega_0)$ in Equation 2 is consumed into the definition of $A(t)$, so that $A(t)$ represents the influence of all frequencies other than ω_0. This is Equation 1. A narrow-banded data series is clearly essential to the utility of the complex envelope function, as a wide band width would destroy the essential envelope interpretation of $A(t)$.

The complex envelope function appears to have been introduced by Rice (1944). His interest however was only in the amplitude function $R(t)$, which he termed the envelope. This Rice envelope function formed the basis of his establishment of the Rayleigh distribution as the probability distribution for the amplitudes of narrow-banded random noise. This result was adapted to surface gravity waves by Longuet-Higgins (1951) and has proved remarkably successful. Potential information in the phase function $\Phi(t)$ was not considered.

COMPLEX ENVELOPE FUNCTION

The filtering technique implied above is certainly appropriate but advantage can be taken of the computational efficiency of the FFT algorithm (Sobey & Colman 1983). This requires a specific assumption about the data series, namely that it represents a stationary process. This same assumption is also implicit in traditional spectral analysis of wave records leading to the variance spectrum. That it is a reasonable assumption is well established.

The initial step (Deutsch 1962) is to establish the Hilbert transform $\hat{\eta}(t)$ of the data series $\eta(t)$:

$$\hat{\eta}(t) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{\eta(\tau)}{t-\tau} \, d\tau \tag{4}$$

The Fourier transform of $\eta(t)$ is

$$F(\omega) = \int_{-\infty}^{\infty} \eta(t) \exp(-i\omega t) \, dt \tag{5}$$

and it follows from Equation 4 that $\hat{F}(\omega)$, the Fourier transform of $\hat{\eta}(t)$, is

$$\hat{F}(\omega) = \begin{cases} -iF(\omega) & \text{for } \omega > 0 \\ 0 & \text{for } \omega = 0 \\ +iF(\omega) & \text{for } \omega < 0 \end{cases} \tag{6}$$

Computationally, the Hilbert transform can be established from the inverse Fourier transform of $\hat{F}(\omega)$.

The record and the Hilbert transform are combined to establish the pre-envelope function:

$$z(t) = \eta(t) + i\hat{\eta}(t) \tag{7}$$

which in turn can be shown (Deutsch 1962) to be

$$z(t) = R(t;\omega) \exp[i\Phi(t;\omega)] \exp(i\omega t) \tag{8}$$

Multiplying through by $\exp(i\omega t)$ recovers the complex demodulate at frequency ω.

To specifically recover the complex envelope function requires knowledge of the dominant frequency ω_0. Physically, ω_0 must be reasonably close to the peak frequency ω_0, which can be estimated from the variance spectrum (Sobey & Young 1986) as

$$\omega_p = \int \omega \, E^8(\omega) \, d\omega \; / \; \int E^8(\omega) \, d\omega \tag{9}$$

Adopting ω_p as a first guess ω_g at the dominant frequency, the correction of ω_g towards ω_0 follows Bolt and Brillinger (1978). At the dominant frequency, Equation 8 is

$$z(t) = R(t;\omega_0) \exp[i\Phi(t;\omega_0)] \exp(i\omega_0 t) \tag{10}$$

where the complex envelope function is

$$A(t) = R(t;\omega_0)\ \exp[i\Phi(t;\omega_0)] \tag{11}$$

Multiplying both sides of Equation 10 by $\exp(-i\omega_g t)$ gives

$$z(t)\ \exp(-i\omega_g t) = R(t;\omega_0)\ \exp\{i[\Phi(t;\omega_0) + (\omega_0 - \omega_g)t]\} \tag{12}$$

The estimate ω_g may be corrected to ω_0 by estimating and removing any linear trend, identified as $(\omega_0 - \omega_g)t$, in the phase record. In practice, this procedure requires phase unwrapping as an initial step.

UNWRAPPING THE PHASE FUNCTION

Phase unwrapping refers to the modulo 2π operation on phase angles. The phase returned by the FFT and any coded trigonometrical algorithm is in the range $-\pi$ to π and is termed the principal phase $\Phi_p(t)$. Any principal phase angle may in fact be $\Phi_p(t) + 2\ell\pi$, where ℓ is any signed integer, without changing the complex envelope function. The "true" phase is obtained by "unwrapping" the principal phase through addition or subtraction of multiples of 2π; this phase is called the unwrapped phase, $\Phi_u(t)$. The subscript u has been dropped but is implied in the subsequent discussion.

The procedure adopted to determine the signed integer ℓ is closely analogous to that adopted by Read and Sobey (1985) in unwrapping the phase spectrum of $\eta(t)$. From the time derivative of the natural log of Equation 11, it follows that

$$\frac{d\Phi}{dt} = \text{Imag}\left[\ \frac{1}{A}\ \frac{dA}{dt}\ \right] \tag{13}$$

Given the slope of the phase function, numerical integration will provide an estimate of Φ_u at the new time. Integration proceeds by the trapezoidal rule, consistent with its adoption in the definition of the discrete Fourier and inverse Fourier transforms. A raw estimate of the principal phase Φ_p is also available from the Hilbert transform/FFT procedure. In principle, the integer ℓ is

$$\ell = (\Phi_u - \Phi_p)/2\pi \tag{14}$$

In practice, ℓ will not be an integer as Equation 14 utilizes raw estimates of both Φ_u and Φ_p. To retain the same value of principal phase at each time step, ℓ is adjusted to the nearest integer and the raw estimate of the unwrapped phase adjusted to

$$\Phi = \Phi_p + 2\ell\pi \tag{15}$$

It remains to estimate the right hand side of Equation 13. From the definition of the pre-envelope function,

$$A(t)\ \exp(i\omega_0 t) = \frac{1}{2\pi}\int_0^\infty 2\ F(\omega)\ \exp(i\omega t)\ d\omega \tag{16}$$

Differentiating both sides with respect to time leads to

$$\frac{1}{A}\frac{dA}{dt} = \frac{\exp(-i\omega_0 t)}{A(t)}\left[\frac{1}{2\pi}\int_0^\infty 2i\omega F(\omega)\exp(i\omega t)\,d\omega\right] - i\omega_0 \tag{17}$$

The term in square brackets can be computed from the inverse FFT algorithm, noting that the kernel is zero for negative frequencies. The slope $d\Phi/dt$ follows from Equation 13.

The success of this algorithm is demonstrated by Figure 1. The record is a smooth paper wave with a dominant frequency of $2\pi/10.24$ *rad/s* and envelope defined by

$$\text{mod } A(t) = 1.5 + 1.0 \sin \Omega_1 t + 0.75 \sin \Omega_2 t$$

$$\arg A(t) = 2\pi \sin \Omega_3 t + 0.75\pi \sin \Omega_2 t \tag{18}$$

where $\Omega_1 = 24\pi/T$, $\Omega_2 = 40\pi/T$, $\Omega_3 = 10\pi/T$ and $T = 1024$ *s*, the duration of the simulated record. The time step is 0.5 *s*. The paper wave record was established from Equations 1 and 18; it exhibits substantial groupiness. The computed modulus and unwrapped phase records are included in Figure 1. The result is identical with the target envelope, Equation 18.

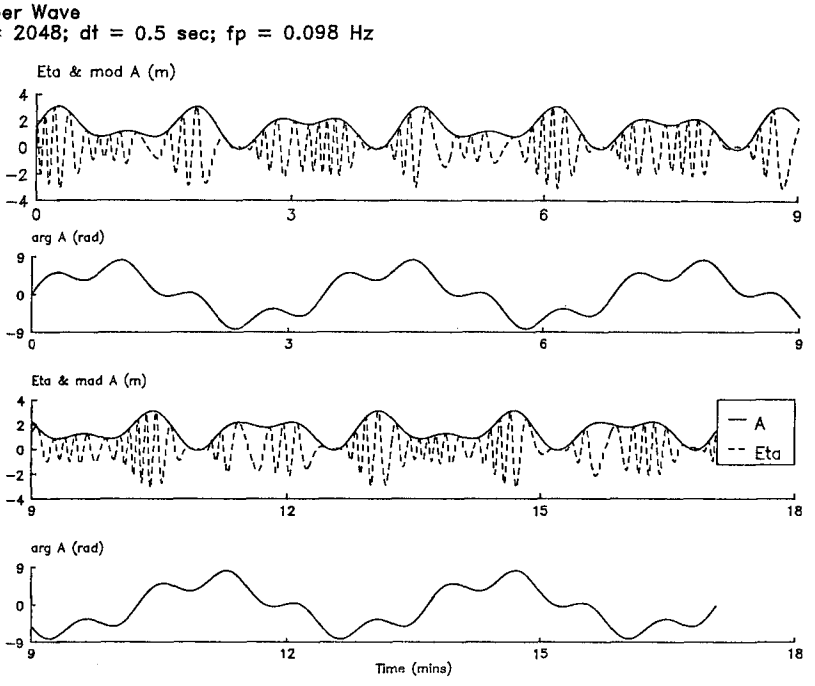

Fig. 1 Complex Envelope for Paper Wave

ALGORITHM EVALUATION

From a purely computational viewpoint, the algorithm described above appeared to be successful. The mod $A(t)$ trace was a consistently good visual representation of the envelope of the record. Visual confirmation of the arg $A(t)$ trace does not seem possible, at least not without considerable experience in complex envelope analysis. One measure of success of the phase unwrapping procedure is the difference $\Delta\ell$ between the real number estimate computed from the right hand side of Equation 14 and the nearest integer ℓ adopted in Equation 15. The differential $\Delta\ell$ was computed at each time step. The mean of the series is closely zero by definition but the standard deviation

$$s = \langle \Delta\ell^2 \rangle^{1/2} \tag{19}$$

is a reasonable measure of the success of the phase unwrapping. For Figure 1, s is zero.

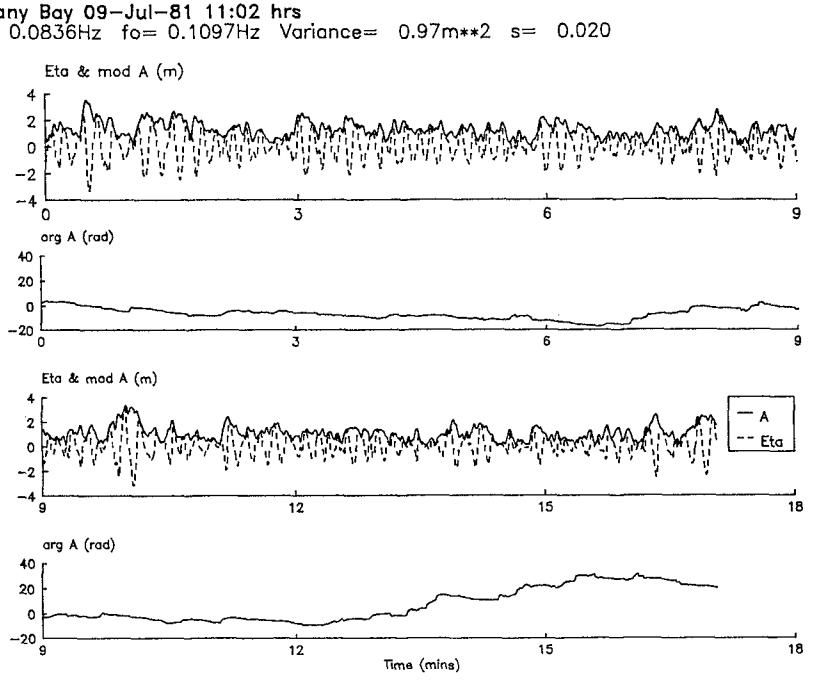

Fig. 2a Complex Envelope for Botany Bay, 9 July 1981, 11:02 hrs.

Figures 2 and 3 are analysis results from field records. The Figure 2 record was measured off Botany Bay on the east coast of Australia in 75 m of water. The record variance is 0.97 m^2, the peak frequency is 0.0836 Hz, the computed dominant frequency is 0.1097 Hz and the standard deviation s is 0.020. The Figure 3 record was measured off Wilson Bluff on the south coast of Australia, the record variance and peak frequency being 1.61 m^2 and 0.0550 Hz respectively. This record is predominantly long period Southern Ocean swell. The computed dominant frequency is 0.0719 Hz and the standard deviation is 0.025. The computed dominant frequencies were typically about thirty percent greater

than the record peak frequencies, but there did not seem to be any apparent physical significance that could be attached to the dominant frequency. The significance of the computed standard deviations might be established by comparison of typical values with expected values if $\Delta\ell$ were a random variable, uniformly distributed in the interval - 0.5 to + 0.5. The theoretical mean and standard deviation of such a distribution would be 0.0 and $12^{-1/2}$ = 0.289, respectively (Ang and Tang 1975). The Figure 2 and 3 results are indeed small with respect to 0.289. These are typical values and clearly demonstrate the relative success of the algorithm.

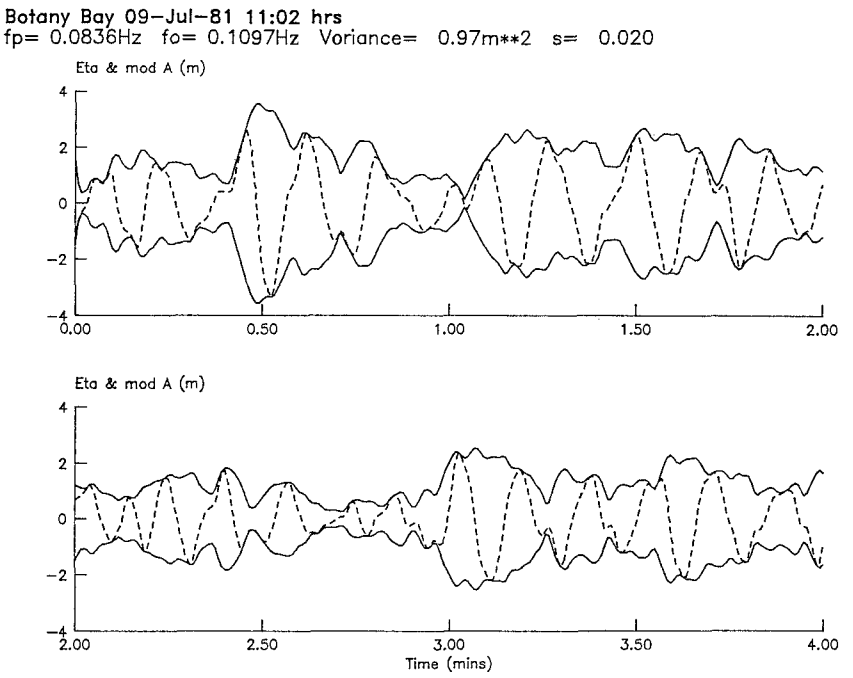

Fig. 2b Expanded Complex Envelope for Botany Bay

An occasional problem was identified in the phase unwrapping procedure where mod $A(t)$ was close to zero. The $d\Phi/dt$ estimate from Equation 13 became very large, resulting in a sudden step change in the $d\Phi/dt$ trace and correspondingly in the Φ trace. This discontinuity could be accommodated by a L'Hospital's rule procedure, as adopted by Read and Sobey (1985) in unwrapping the phase spectrum of the original record, but near zero magnitude points were found to be much less of a probelm for the complex envelope function. A technique suggested by Brillinger (1962) proved to be satisfactory in the vicinity of near-zero $A(t)$ points. This is based on the trigonometrical identity

$$\frac{d\Phi}{dt} = \cos\Phi \frac{d}{dt}(\sin\Phi) - \sin\Phi \frac{d}{dt}(\cos\Phi) \tag{20}$$

A forward difference approximation to the right hand side gave an alternate estimate of

$d\Phi/dt$ that avoided any sudden steps in the $d\Phi/dt$ trace. This procedure was not suitable for general application however as the discrete approximation restricted the estimate of the phase derivative to the range - 1 to + 1.

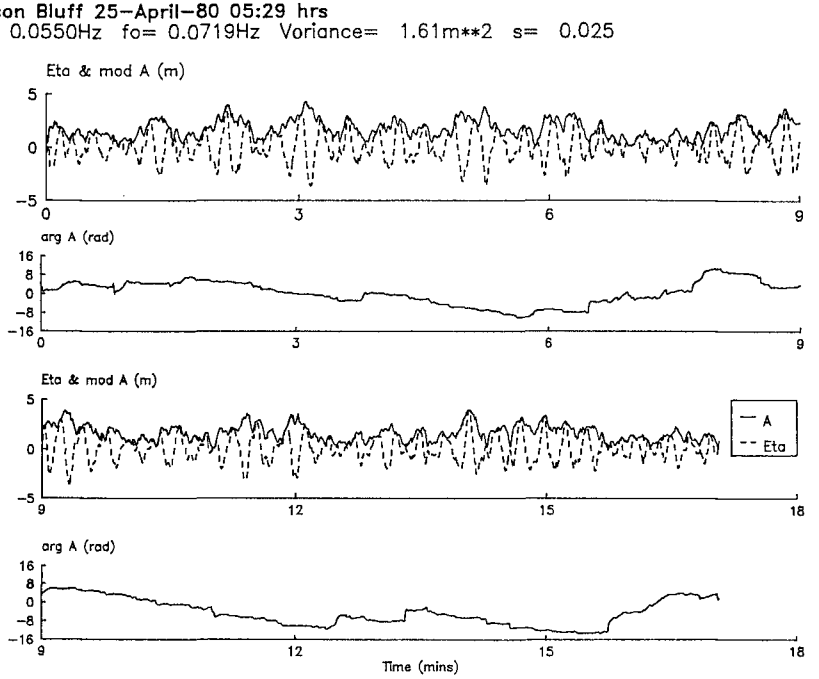

Fig. 3 Complex Envelope for Wilson Bluff, 25 April 1980, 05:29 hrs.

In practice, it was necessary to adopt a rational definition of a near-zero magnitude point. If the envelope amplitudes followed the Rayleigh distribution (Longuet-Higgins 1952), then a characteristic amplitude would be the mean amplitude $(2\sigma^2)^{1/2}$, where σ^2 is the variance of the record. The Equation 20 algorithm was used when mod $A(t)$ was smaller than one-tenth of this value. This tolerance level was not found to be critical.

The value of the mod $A(t)$ traces is clear from Figures 2 and 3, and particularly from Figure 2b which shows only the first four minutes of the Figure 2a results. The removal of the dominant frequency focusses attention quite sharply on the envelope modulations is a very natural manner. Wave grouping is clearly identified, conveniently in a manner that (unlike low pass filtering of $\eta^2(t)$) does not remove potentially valuable information from the record. With only casual experience, the identification of wave grouping in the phase trace alone does not seem possible but some assistance may be forthcoming from the cross-correlation and the cross-spectra between the modulus and argument traces. It is apparent from Figure 2b in particular that there remains potentially significant detail imbedded in the complex envelope amplitude and phase traces.

CORRELATION AND CROSS-CORRELATION

In the time or lag domain, the appropriate statistical summary is the cross-correlogram, plotting the normalized cross-correlation

$$\rho_{R\Phi}(\tau) = C_{R\Phi}(\tau)/\left[C_{RR}(o)C_{\Phi\Phi}(o)\right]^{1/2} \tag{21}$$

against the time lag τ. The cross-correlation $C_{R\Phi}(\tau)$ is the expectation $E[(R(t)-\bar{R})\Phi(t+\tau)]$, where $\bar{R}$ is the average modulus of the envelope. The $C_{RR}(\tau)$ and $C_{\Phi\Phi}(\tau)$ are similarly defined. In practice, the correlograms were computed from the inverse Fourier transform of the variance spectra and cross-spectrum of R and Φ, to take advantage of the FFT algorithm. It is reasonably common in complex demodulation (Hasan 1983) to consider $\ell n\ R(t)$ rather than $R(t)$, as the probability distribution of $\ell n\ R(t)$ is more nearly Gaussian. This practice was considered but not adopted as the range of R in the present problem is relatively small.

Figure 4 shows the correlograms corresponding to the Botany Bay record in Figure 2. The normalized form of the cross-correlation $C_{R\Phi}$ is presented together with the normalized C_{RR} and $C_{\Phi\Phi}$ autocorrelations; $C_{R\Phi}$ is not an odd or even function and there are different traces for positive and negative lags. The correlograms are truncated at $20/f_p$, a typical record length being $100/f_p$.

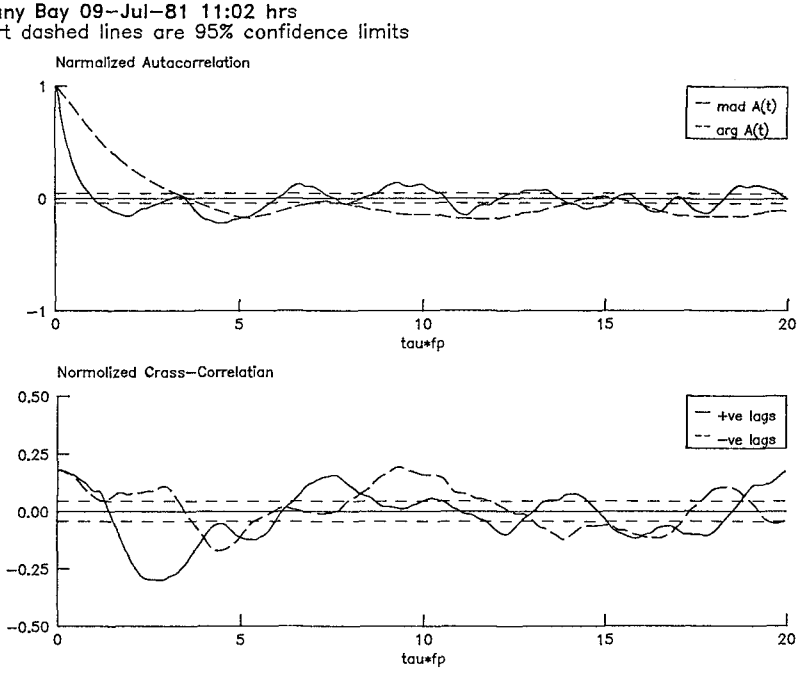

Fig. 4 Correlograms for Botany Bay, 9 July 1981, 11:02 hrs.

The initial part of the C_{RR} trace is typical of random noise. The tail however does not decay but evolves into an irregular long period oscillation with a period of order $4/f_p$. Referring back to the envelope trace in Figure 2, this is the anticipated result, the correlogram oscillation corresponding roughly to the envelope modulations. Similar, but longer period, oscillations are observed in the $C_{\Phi\Phi}$ traces, indicating that the envelope modulations are perhaps a feature of the phase trace as well as the amplitude trace. Periodicity of order $4/f_p$ remains the dominant feature of the cross-correlogram $C_{R\Phi}$, implying some residual coupling between the envelope amplitude and phase. This would appear to impose some qualification on the Gaussian random wave model, which explicitly assumes that the phase trace is completely random. The magnitude and residual periodicity of the cross-correlations imply that the record involves a little order against a lot of background disorder.

The detailed interpretation of correlograms however must acknowledge a number of uncertainties. It is well known (Kendall & Stuart 1966, Jenkins & Watts 1968) that correlograms for short series can be unreliable and may not decay as rapidly as expected; as a rule of thumb, only the first twenty percent might be given any credence. Wave records are moderately long series however, typically 2048 points over seventeen minutes; the maximum lag presented in Figure 4 is $20/f_p$, corresponding typically to less than twenty percent of the record length. These potential uncertainties may be addressed in two ways, the first being the estimation of confidence limits on the correlogram tail. Kendall and Stuart (1965) show that the variance of a normalized auto-correlation estimate is dependent on all autocorrelations in the series, even for large samples with the simplifying assumption of normality. However for a random series where all parent autocorrelations are zero, the expectation of the mean approaches $-1/N$ and the variance $1/N$. The 95 percent confidence limits are accordingly $-1/N \pm 2/(N)^{1/2}$. The width of this confidence band decreases with the length of the series, but is already moderately small at $\pm$ 0.044 for typical 2048 point records. These 95 percent confidence limits are included as the short-dashed lines on Figure 4. Note that rather more than five percent of the autocorrelogram and cross-correlogram tails falls outside this band.

A second approach to these potential uncertainties for moderately small lags is to compute the correlograms from a longer sample, significantly in excess of the typical $100/f_p$. The nominal twenty minute record has become a field measurement standard and longer records are not commonly available. Long records also introduce another problem, in that the record may no longer be statistically stationary. Sea states typically develope at time scales of order hours (Sobey 1986). A record of twenty minutes could reasonably be expected to be stationary, a record of one hour may or may not be stationary according to circumstance, but a record of several hours is unlikely to be stationary. An attempt to solve one problem unfortunately introduces another. Non-stationarity appears as very low frequency trend in the Fourier transform. There is a sharp spectral spike at near-zero frequency, whose magnitude increased substantially with longer records and accordingly finer frequency resolution. This was a particular problem in the phase trace. Jenkins and Watts (1967) recommend removal of such very long period trend prior to analysis by high-pass filtering of the record; this approach was adopted with a cutoff frequency of $0.05\ f_p$. The phase trace was first low-pass filtered by a moving average filter of width equivalent to a $0.05\ f_p$ cutoff. This filtered record was then subtracted from the original phase trace to yield the detrended phase trace. Without detrending, the very low frequency trend completely dominated the Fourier transform and just as completely negated any advantage from a longer record. Detrending was adopted with considerable reservation however, as a developing sea state will likely be accompanied by physical developments in the wave grouping structure which will also negate any advantage from a longer record. An excessively long record (say several hours) is clearly inappropriate. A one hour record might be a reasonable compromise, provided the record is reasonably stationary and due

attention is given to the analysis uncertainties.

The record presented in Figure 2 and again in Figure 4 is the central 2048 points (nominal twenty minutes) of a 8000 point (nominal one hour) record. The variance of this extended record was computed in 1000 point blocks, being 1.40, 0.98, 0.77, 0.99, 0.75, 0.94, 1.06 and 1.18 m^2 for the Botany Bay record. This variation is typical of visually-stationary wave records. Figure 5 is a repetition of the correlogram analyses for the 8000 point record. Record length is of order $400/f_p$ and lags up to $20/f_p$ now represent only five percent of the record length. The confidence band is also somewhat narrower, reflecting the larger sample size. The general trend of the correlogram however remains largely unchanged.

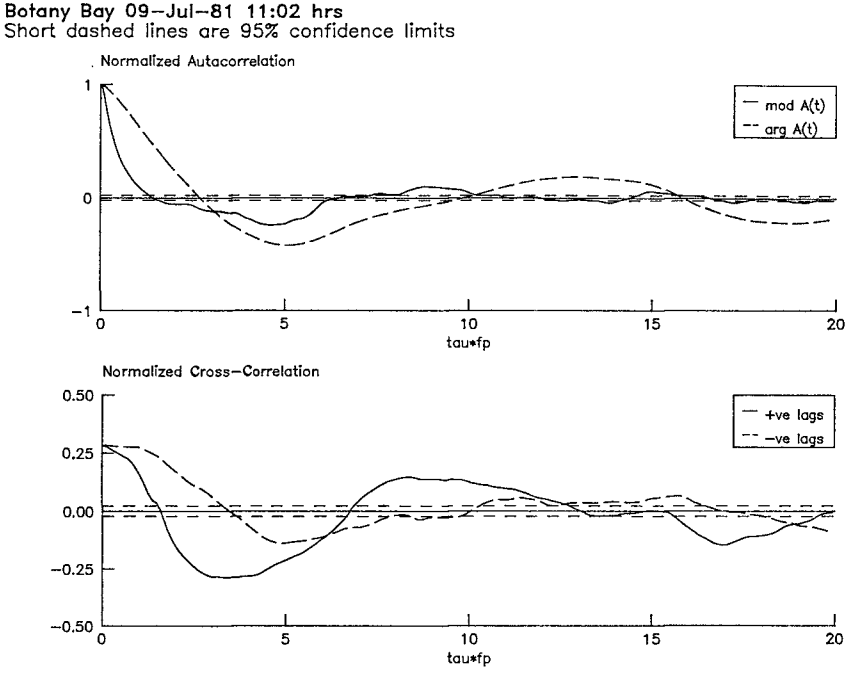

Fig. 5 Correlograms for Botany Bay, 8000 point record.

The Figure 4 correlogram is quite a typical result. It provides a useful perspective on the nature of wave groups in surface gravity waves. A large part of a typical wave record can reasonably be described as random; of order ninety percent of the information can be so described. The residual ten percent or so would appear to be nonrandom, involving long period modulations of the complex wave envelope. The implied low-level correlation between the envelope amplitude and envelope phase traces appears to be an intrinsic property of wave groups.

SPECTRA AND COHERENCE

In the frequency domain, the statistical summary is the cross spectrum

$$E_{R\Phi}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} C_{R\Phi}(\tau) \exp(-i\omega\tau)\, d\omega \tag{22}$$

$E_{R\Phi}(\omega)$ is a complex function with a real part (the cospectrum) and an imaginary part (the quadspectrum). A useful real function is the coherence

$$\gamma_{R\Phi}(\omega) = \text{mod } E_{R\Phi}(\omega) \,/\, [E_{RR}(\omega) E_{\Phi\Phi}(\omega)]^{1/2} \tag{23}$$

or the squared coherence, the square of Equation 22. The squared coherence approaches unity when the two traces are strongly correlated and it is zero when the traces are uncorrelated. High squared coherence levels suggest some relationship between the phase and amplitude traces, a relationship that is assumed by the Gaussian random wave model to be very small.

The variance spectra $E_{RR}(\omega)$ and $E_{\Phi\Phi}(\omega)$ and the cross-spectrum were estimated directly from the Fourier transforms of the envelope amplitude and phase traces, taking advantage of the FFT algorithm. Raw spectral estimates resulting from the FFT algorithm have only two degrees of freedom and the raw estimate of squared coherence is identically one for all frequencies (Bloomfield 1976). Statistically reliable spectral estimates require a significant increase in the degrees of freedom, achieved by frequency domain smoothing of $E_{RR}(\omega)$, $E_{\Phi\Phi}(\omega)$ and $E_{R\Phi}(\omega)$ prior to estimation of the squared coherence. Frequency domain smoothing (specifically here a moving average filter of half-width L points) increases the degrees of freedom from 2 for the raw FFT estimates to 4L + 2. The widths of 95 percent confidence bands on variance spectral estimates and on squared coherence estimates are accordingly reduced (Jenkins and Watts 1968). A filter half-width L of the nearest integer to $1/(5f_p\Delta t)$ proved to be a suitable compromise between statistical confidence and resolution of detail.

The complex demodulation procedure introduces an immediate problem of frequency resolution in spectral analysis of the complex envelope. A typical 1024 *s* wave record imposes a frequency resolution of 0.000977 Hz, more than adequate to accommodate peak frequencies of order 0.1 Hz. Complex demodulation however removes these frequencies and shifts the spectral peak to frequencies of order 0.01 Hz, where the frequency resolution is distinctly marginal. Frequency resolution is enhanced by a longer record, specifically 8000 points where the frequency resolution is 0.000150 Hz. While this resolution remains marginal, longer record lengths will again introduce problems of non-stationarity.

The frequency domain description for the Botany Bay record is shown in Figure 6, which includes four spectra. Part (*a*) is the variance spectrum for $R - \bar{R}$, the solid line being the raw estimate and the dash-dot line the smoothed spectral estimate, 95 percent confidence bars being shown at selected frequencies for the smoothed spectral estimates. Part (*b*) is an analogous presentation of the variance spectrum for the envelope phase trace. Part (*c*) is the smoothed squared coherence estimate, the dotted line being the 95 percent confidence limit on zero coherence between the amplitude and phase traces. Part (*d*) is arg $E_{R\Phi}(\omega)$, the smoothed phase of the cross spectrum between R and Φ. Variance levels at frequencies above the spectral peak are very small and these presentations are terminated at f_p.

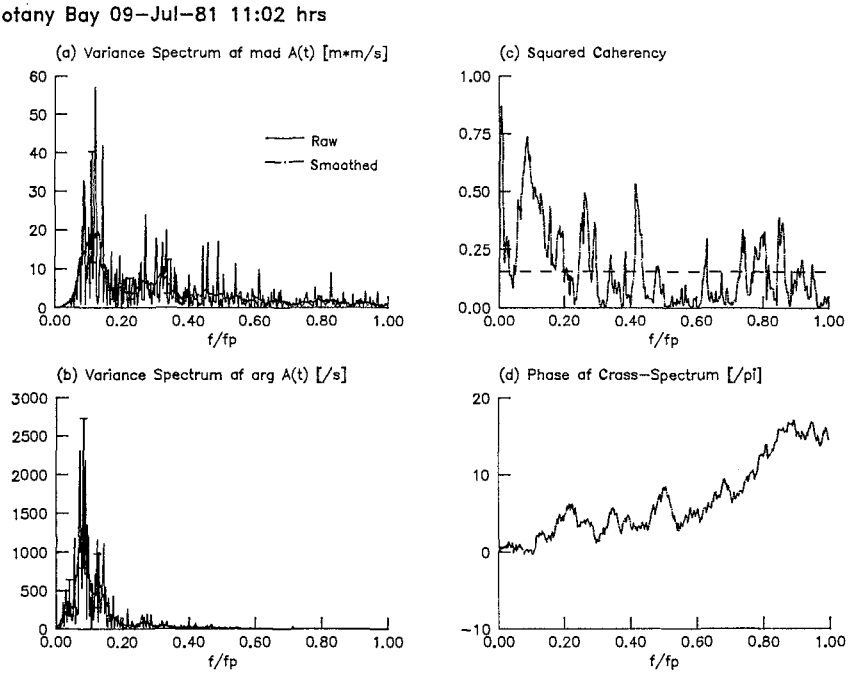

Fig. 6 Spectra for Botany Bay, 8000 point record.

The E_{RR} spectrum for Botany Bay is the result that is anticipated from the correlograms in Figure 4 and 5; it is dominated by short frequencies about an order of magnitude less than the peak frequency. Short frequencies are also clearly dominant in the phase trace in Figure 2 and this is confirmed in Figure 6. The squared coherence spectrum shows moderate coherence in excess of the 95 percent confidence limit on zero coherence at frequencies of order 0.2 f_p to and also 0.8 f_p. The Gaussian random wave model would suggest negligible coherence throughout. Coherence levels are small but not entirely negligible. Analysis of the cross-phase spectrum was not pursued, as marginal frequency resolution and low coherence levels indicated that results would most likely be inconclusive. The higher frequency peak might perhaps be the result of non-linear interactions near the spectral peak. Moderate coherence levels around 0.2 f_p seemed to be a reasonably typical result, at least for waves off Botany Bay.

CONCLUSIONS

The complex envelope function is a very useful analysis technique for wave records where the identification of wave grouping is a relevant interest. The removal of the dominant frequency concentrates attention directly on the envelope modulations without removing potentially useful information from the record. Wave groups are clearly identified against a predominantly random background. An algorithm has been presented for extraction of the complex envelope function, identification of the dominant frequency and unwrapping of the phase trace.

Cross-correlogram and cross-spectral analyses of the simultaneous envelope amplitude and unwrapped phase traces has associated wave grouping with low level phase locking between the amplitude and phase traces. The ordered structure comprises about ten percent of the information contained in a wave record. The balance of the record can reasonably be described as random, as assumed by the Gaussian random wave model. This dominant random component is clearly responsible for the relative success of the Gaussian random wave model.

ACKNOWLEDGMENTS

This work is a result of research sponsored in part by NOAA, National Sea Grant College Program, Department of Commerce, under grant number NA85AA-D-SG140, project number R/CZ-70, through the California Sea Grant College Program, and in part by the California State Resources Agency. The U.S. Government is authorized to reproduce and distribute for governmental purposes. The wave records were provided by the Maritime Services Board of New South Wales and by Esso Australia Ltd. Computations were undertaken on microcomputers provided in part to the University of California, Berkeley, through grants from IBM and from Standard Oil of California (Chevron).

CHAPTER 58

Extreme Wave Groups in Storm Seas Near Coastal Water

Ming-Yang Su *

We discuss statistics of wave groups containing the maximal wave height over wave records of 20 minutes. These wave groups are called extreme wave groups (EWGs). The concept of the EWG combines the two previously separately considered design factors of extreme waves and wave groups into a more severe storm seas wave action. The wave data used in this investigation consists of near 540 records of wave staff measurements in the Gulf of Mexico. Specifically, we shall present (a) the dependence of EWG properties on the bandwidth of wave spectra, (b) the mean envelope shape of EWGs, exhibiting distinct differences from the envelope shape of regular basis.

Introduction

The study of wave groupiness has gained increasing attention in the past decade, because of its importance for long-period excitations to marine fixed and/or floating structures. Statistical analyses of ocean waves in storms (Rye, 1974; Goda, 1976; Su, et al., 1982) have firmly established the dependence of wave groupiness, such as its distributions and mean length, on the associated spectral bandwidth. Theoretical analyses (Longuet-Higgins, 1984, Kimura, 1980; Goda, 1976, 1983; Nolte and Hsu, 1972) have further related these properties in terms of either the linear narrow-band Gaussian process, or Markovian process. On the other hand, the most important classical design factor for marine structures is the estimation of extreme waves which are usually assumed to occur singly in nature (see Ochi, 1982 for a review on this subject). It can be convincingly argued, however, that a wave group containing an extremely large wave, if exists, would be an even more appropriate environmental design factor than either the single extreme wave or the "regular" wave group. For the sake of easy reference, we shall call this special type of wave groups, each containing an extremely large wave (to be defined more precisely later) by the name of "extreme wave groups" (EWG) in contrast to the "regular wave group" (RWG) which is normally defined to be a sequence of successive waves whose heights all exceed some prescribed critical value (H_c).

Goda (1976) seems to be the first investigator who made a statistical comparison of these two different types of wave groups. He noted that the mean length of runs for EWG is 2.36 when the critical value $H_c=H_{1/3}$, while the corresponding mean length for RWG is only 1.4. In other words, the highest wave does not appear singly, but is frequently accompanied by two to three high waves. Furthermore, the probability for the highest wave occurring in a group is even higher than regular high waves.

Wave Data

The first set of wave records used in this investigation was obtained by wave staffs from an offshore platform about 60 miles offshore in the Gulf of Mexico (Ocean Data Gathering Program (OOGP), Station #1) during 1969-1971 under the sponsorship of a consortium of eight oil companies (Ward, 1974). The station is located in South Pass Block 62A, at a depth of about 340 feet. The second set of wave records was measured from a North Sea Platform (Forties Field) at the water depth of 150 ft and was kindly provided to us by UKOOA.

Each wave record is 19.85 minutes long and has been digitized into 4096 data points at the rate of 3.41 samples per second. For this analysis, we selected a total of 533 wave records (from the first set), each with the significant wave height ($H_s=H_{1/3}$)$\geq$2 meters in order to emphasize storm waves. These wave records were measured mostly in winter months, with the exception of during three hurricanes occurring in summer months. The eye of one of the hurricanes, Camille, happened to pass within 10 miles of the measuring platform.

Data Classification

The individual waves with their heights (H_j) and periods (T_j) for j=1,2...N in each wave record are determined by the standard up zero-crossing method. In the set of wave records we used, the value of N lies between 100 and 240 with the average close to 200. The power spectrum E(f) for each wave record is also computed by the Fast Fourier Transform, and is used in turn for computing two parameters indicative of the average bandwidth of the power spectrum. The first parameter was proposed originally by Longuet-Higgins (1984) and called the spectral bandwidth parameter, ν, and defined by

$$\nu = (m_2 m_0/m_1^2 - 1)^{1/2} \tag{1}$$

where m_0, m_1 and m_2 are spectral moments as defined by

$$m_i = \int_0^\infty f^i E(f)df \tag{2}$$

When $\nu^2 << 1$, the power spectrum is said to be narrow. The second parameter was proposed by Goda (1976) and called the spectral peakedness parameter, Q_p, and defined by

$$Q_p = \int_0^\infty 2fE^2(f)df/m_0 \tag{3}$$

The value of Q_p is always greater than unity, and increases with decreasing spectral bandwidth. We have used certain specified ranges of ν and Q_p, independently, to classify the set of wave records into

several subsets in order to see dependence of the statistical characteristics of wave groupiness on the spectral bandwidth.

Definition of Extreme Wave Group (EWG)

For the purpose of our analysis which is constrained by the availability of each wave record being about 20 minutes long, the extreme wave group (EWG) is defined as the wave group containing the largest wave height in the wave record. For convenience of data analyses, we first assume that the EWG may cover up to seven waves and can be expressed as

$$W_{-3}, W_{-2}, W_{-1}, W_0, W_1, W_2, W_3$$

where W_0 is the wave with the largest wave height, the three waves with negative subscripts are waves preceeding W_0, and those with positive subscripts are waves following W_0. The corresponding wave heights, periods, wavelengths, and steepness are denoted by H_i, T_i, L_i and S_i;

$$S_i = a_i k_i = (H_i/2) \times (2\pi/L_i) = \pi H_i/L_i \tag{4}$$

where a_i is the wave amplitude and k_i the wave number (see Figure 1).

Results

We shall present the computed results which show the mean values (denoted with an overbar) of H_i, T_i and S_i for subsets of wave records with prescribed ranges of Q_p or ν. The majority of the wave records had the values of Q_p between 1.3 and 4.0, or has the values of between 0.40 and 1.0. Based on this distribution, we have classified the wave records into the following subsets: (1) for Q_p;

$$\begin{array}{ll} \text{(a)} & 1.0 \leq Q_p \leq 2.0 \\ \text{(b)} & 2.0 \leq Q_p \leq 3.0 \\ \text{(c)} & 3.0 \leq Q_p \leq 4.0 \\ \text{(d)} & 1.0 \leq Q_p \leq 5.0 \text{ (the entire data set)} \end{array} \tag{5}$$

and (2) for ;

$$\begin{array}{ll} \text{(a)} & 0.40 \leq \nu \leq 0.50 \\ \text{(b)} & 0.50 \leq \nu \leq 0.60 \\ \text{(c)} & 0.60 \leq \nu \leq 0.70 \\ \text{(d)} & 0.60 \leq \nu \leq 0.80. \end{array} \tag{6}$$

Table 1 gives the mean values of the wave heights, periods and steepness of the extreme wave groups for each of the three subsets according to the spectral classification of Q_p, plus the entire data set. Note that the wave heights given here have been normalized by the root-mean square of wave surface displacement $(m_0)^{1/2}$ of each corresponding wave record. The wave periods are normalized by the mean wave period of the corresponding wave record.

Table 1. Extreme Wave Group Analysis for Gulf of Mexico Wave Data. $H_{1/3} \geq 2.0$ m. Based on Q_p classification.

	j = -3	-2	-1	0	+1	+2	+3

(b) $\overline{H}_j$	2.491	2.735	3.943	6.335	3.931	2.677	2.361
$\overline{T}_j$	1.024	1.083	1.369	1.289	1.364	1.105	1.014
$\overline{S}_j$	0.154	0.137	0.125	0.195	0.138	0.136	0.146
(c) $\overline{H}_j$	2.667	2.997	4.325	6.352	4.435	3.156	2.704
$\overline{T}_j$	1.085	1.177	1.314	1.233	1.318	1.163	1.059
$\overline{S}_j$	0.122	0.117	0.133	0.208	0.128	0.142	0.136
(d) $\overline{H}_j$	2.506	2.753	3.864	6.325	3.929	2.699	2.418
$\overline{T}_j$	1.047	1.093	1.334	1.291	1.348	1.104	1.022
$\overline{S}_j$	0.153	0.134	0.129	0.196	0.134	0.139	0.143

We shall start with case (d) in Table 1, which includes the entire set of wave records in order to see the overall mean characteristics first, before discussing their dependence on spectral bandwidth. From the mean values of wave heights, H_j, one can see the envelope of the EWG is rather symmetric with respect to the highest wave height, H_0. The mean wave heights for the three central waves are $H_0 = 6.3$ and $(H_{-1}, H_1) = 3.9$, while the mean wave heights for outlying waves; $(H_{-2}, H_2) = 2.7$ and $(H_{-3}, H_3) = 2.5$, are much smaller. Recalling that the mean wave height for a linear narrow band Gaussian process is $H = \sqrt{2\pi} = 2.506$ (Arhan et al., 1976), we can infer, based on the height distribution alone, that (W_{-1}, W_0, W_1) is definitely distinctive from $(W_{-3}, W_{-2}, W_2, W_3)$.

The mean wave periods for the three central waves are $(T_{-1}, T_0, T_1) = 1.3$, while the outlying waves are $(T_{-3}, T_{-2}, T_2, T_3) < 1.1$. Since the expected value of the wave periods for a linear random process would be unity, by definition, we find again that the three central waves (W_{-1}, W_0, W_1) are qualitatively different from the other waves. We also note that $T_0 = 1.29$ is appreciably smaller than $(T_{-1}, T_1) = 1.34$.

The mean wave steepness for the highest wave is $S_0 = a_0 k_0 = 0.2$, while the other waves are about 0.14. (The wave steepness for the highest Stokes waves is 0.443.) So, the highest wave turns out to be also the steepest, in the mean, a very significant feature indeed.

Taking together the above observed properties of both wave heights and wave periods, we may suggest that each extreme wave group, in the mean, contains three waves. Furthermore, if we use a threshold wave height $H_c = H_{1/3} = 4m_0^{1/2}$ for determining a wave group, then the mean (run) group length of the extreme wave group would be slightly less than 2.5. (Since $H_{-1} = 3.86$ and $H_{+1} = 3.93$ are only slightly smaller than the threshold value of 4.0, W_{-1} and W_{+1} will have slightly less than 50% of chance exceeding the prescribed threshold.) This estimated value is thus in good agreement with the value of 2.36 found by Goda (1976). The mean wave group length for EWG is considerably larger than that of regular wave groups ($\approx$1.5) (Goda, 1976; Su and Bergin, 1983).

Next, we shall examine the effects of spectral bandwidth on the above group characteristics by comparing cases (a), (b) and (c) against (d) in Table 1. As the spectral bandwidth becomes narrower, i.e., Q_p increasing from 1.0 to 4.0, or from case (a) to case (c), H_{+1} is found to increase from about 3.2 to 4.4, and H_0 increases from 6.28 to 6.35, and S_0 increases from 0.186 to 0.208, and T_0 decreases from 1.37 to 1.23. Therefore, one may conclude that the specific features noted for the extreme wave group from the entire data set (case d) becomes even more prominent as the wave power spectra becomes narrower as parameterized by Q_p. In other words, for narrower spectral bandwidth, the mean group length will become longer, and the highest waves become steeper, and, increasingly, the wave period of the central waves become shorter than those of the surrounding waves.

It is well known that power spectra have narrower bandwidth in the fetch-limited growth stages than in either the fully saturated stages or in decaying stages. (Here we have excluded the consideration of swells which could have extremely sharp narrow spectra for which the beat phenomenon can be suitably applied.) One thus expects to find most clearly the unique feature of the extreme wave group in the rapidly growing sea.

Table 2 gives the statistics of the extreme wave groups as given in Table 1 with the exception that the wave records are grouped by the spectral bandwidth parameter, ν . We found much the same group characteristics as noted in Table 1 in all three cases, (a), (b) and (c), for ν = 0.4-0.5, 0.5-0.6, and 0.6-0.8, respectively, but the effects of spectral bandwidth based on ν is not as clear as based on Q_p. One possible reason for this relative sensitivity between the classifications of Q_p and ν is as follows: by its definition, Q_p emphasizes the contribution from the peak of the spectrum due to the square of E(f), while ν , by its definition, considers equally the contribution from the higher frequency range due to the factor of f^2 in the m_2 computation. In our determination of individual waves by the zero-crossing method which acts roughly as a low-pass filter, these individual waves thus obtained are primarily energy-containing

Table 2. Extreme Wave Group Analysis for Gulf of Mexico Wave Data. $H_{1/3} \geq 2.0$ m. Based on classification.

lower-frequency waves centering around the spectral peak. Hence, Q_p will be a more sensitive parameter than γ in our analysis.

In Table 3(a,b), we show the statistical results of EWG from the wave data from the Forties Field in the North Sea for $H_{1/3} \geq 2.5$ m. Similarly, in Table 4(a,b) we show the results for the same set of wave data, except only for those records with $H_{1/3} \geq 5.0$ m, in order to emphasize the truly extremely large storm waves. Comparing the results from both Table 3 and 4, with those from Table 1, we have found very little difference among them.

Interpretation of Large Waves and Extreme Wave Groups

Several unique features of the extreme wave group, particularly for the case with narrower spectral bandwidth normally expected for growing seas, prompt us to consider a hypothesis that these extreme wave groups may be caused by nonlinear wave instabilities, rather than simply due to the linear beat phenomenon. In this section we shall present some reasoning in support of this hypothesis.

The side-band instability is characterized by two perturbations with the frequencies $f_1 = f_0 - \Delta f$ and $f_2 = f_0 + \Delta f$, where f_0 is the original primary (unperturbed) freqeuncy of a wave train and/or wave

packet under consideration. Furthermore, the Δf is related to the wave steepness, a_0k_0, of the original primary waves by

$$\Delta f = a_0k_0f_0. \tag{8}$$

Experimental observation under laboratory-controlled conditions (Su, 1982 and 1984) showed that at the maximum modulation due to the side-band instability the amplitudes for the two side-band components, a_1 and a_2, are approximately equal to each other, and further related to the amplitude, a_0, of the primary wave at the particular moment by

$$a_1^2 = a_2^2 = 1/2a_0^2. \tag{9}$$

Hence, the time series of the surface displacement, $\zeta(t)$, of the wave train under the maximum modulation of the side-band instability can be expressed as

$$\begin{aligned}\zeta(t) &= a_0 \sin(2\pi f_0 t) + a_1 \sin(2\pi f_1 t) + \\ &\qquad a_2 \sin(2\pi f_2 t) \\ &= a_0 \sin(2\pi f_0 t) \\ &\quad + \sqrt{1/2}\, a_0 \sin[2\pi(1-a_0k_0)f_0 t] \\ &\quad \sin[2\,(1+a_0k_0)f_0 t] \\ &= a_0\,[1+\sqrt{2}\cos(2\pi a_0k_0f_0t)]\sin(2\pi f_0 t).\end{aligned} \tag{10}$$

Note that the expression in the square bracket is the slower varying envelope of the wave group, which have a repitition period equal to $(a_0k_0)^{-1}$ number of primary wave periods. Now, the mean wave steepness for the case (c) with $3.0 < 4.0$ in Table 1 is equal to $S = 1/3\ (0.133 + 0.208 + 0.128) = 0.156$. If we take the average $S = 0.16$, then the repetition length of the wave group is nearly 6 waves. The corresponding wave heights for the seven waves centering around the maximum of the wave envelope are then given by

$$\begin{aligned}H_0 &= a_0(1+\sqrt{2}\cos 0^0) = 2.41\, a_0 = H_0 \\ H_{-1}, H_1 &= a_0(1+\sqrt{2}\cos 60^0) = 1.707\, a_0 = 0.7\, H_0 \\ H_{-2}, H_2 &= a_0\,(1+\sqrt{2}\cos 120^0) = 0.293\, a_0 = 0.121\, H_0 \\ H_{-3}, H_3 &= a_0\,(1+\sqrt{2}\cos 180^0) = 0.41\, a_0 = 0.170\, H_0\end{aligned} \tag{11}$$

The most significant feature of the distribution of the above wave heights is the considerable smallness of $(H_{-3}, H_{-2}, H_2, H_3)$ in comparison to (H_{-1}, H_0, H_1). This feature agrees remarkably well with the observation of the extreme wave group consisting of three high waves, in the mean, as presented in the last section. The ratio $(H_{-1},$

$H_1)/H_0 = 4.435/6.352 = 0.698 = 0.7$ for case (d) in Table 1 agrees almost exactly with the $(H_{-1}, H_1) = 0.7\ H_0$ of the nonlinear model. The observed fact that $T_0 < (T_{-1}, T_1)$ in Table 1 is also consistent with the experimental observation in the side-band instability.

On the other hand, let's consider a wave train consisting of two sine waves with equal amplitudes but with a difference in frequencies by an amount of $f = a_0 k_0 f_0$ the same as in the side-band instability. The time series of the corresponding surface displacement for the beat phenomenon will be

$$(t) = a_0 \sin (2\pi f_1 t) + a_0 \sin (2\pi f_2 t)$$

with $f_1 = f_0 - 1/2\Delta f$, and $f_2 = f_0 + 1/2\Delta f$. Hence,

$$(t) = a_0[2 \cos (\pi\, a_0 k_0\, f_0 t)] \sin (2\pi f_0 t). \qquad (12)$$

The envelope for the beat phenomenon is a simple cosine shape with a repetition period twice longer than the period for the side-band modulation. With the same value of $a_0 k_0 = 0.16$, the seven waves centering around the maximum of the envelope are, approximately,

$$\begin{aligned} H_0 &= 2a_0 \cos 0^0 = 2a_0 = H_0 \\ (H_{-1}, H_1) &= 2a_0 \cos 30^0 = 1.732a_0 = 0.866\ H_0 \\ (H_{-2}, H_2) &= 2a_0 \cos 60^0 = a_0 = 0.5\ H_0 \\ (H_{-3}, H_3) &= 2a_0 \cos 90^0 = 0 \end{aligned} \qquad (13)$$

Note that $(H_{-2}, H_2) = 0.5\ H_0$ in this case is much larger than the corresponding values for the side-band instability. Of course, when Δf used smaller than the $a_0 k_0 f_0$, the value of H_{+2} will increase, and vice versa.

Conclusions

We have analyzed two large sets of ocean wave records collected in storm conditions for the structure of wave groups each containing the highest wave height in that wave record, called the extreme wave groups. We found that the extreme wave group predominantly consists of three high waves with heights greater than the significant wave height, and with the mean periods equal about 1.3 times the average period for the entire collection of individual waves determined by the standard up zero-crossing method, and with the mean wave steepness for the highest wave equal to about 0.20. Furthermore, as the spectral bandwidth becomes narrower, these features of the extreme wave groups become more prominent. Based on a previous knowledge of experimental studies on nonlinear side-band instability of finite-amplitude waves, the extreme wave groups are found to be explainable better as the manifestation of

the maximum modulation under this type of nonlinear instability, than as the simple linear beat phenomenon.

The experimental results, statistical analyses of field data and theoretical findings, led to suggest that spilling wave breaking for large energy-containing waves near the peak frequency can occur due to nonlinear coupling of instabilities for average wave steepness near 0.14 to 0.18.

In summary, large giant waves, wave groups and wave breaking are most likely the different aspects of the same dynamical process due to the intrinsic instabilities of nonlinear steep waves.

CHAPTER 59

Practical Method For Evaluating Directional Spectra After Shoaling and Refraction

Frederick L.W. Tang* and C.F. Lin**

ABSTRACT

Different Methods have been developd to calculate the deformation of spectrum as waves advance to the shallow water. Wave ray method is a traditional way to compute the change of wave ray after refraction. It is restricted to the regular wave. After slicing the linear spectrum, a lot of components of spectrum can be gained, and each component can be considered as a monochromatic wave. And then after the deformed components are worked out at the same point in sea, a deformed spectrum in shallow water is gained by summing up them. Therefore the wave ray method could be extended to the irregular wave in ocean. In real bathymetry, the difficulty in applying such method is to solve the wave ray which must pass through the assigned point. In this paper, calculation approach as well as computer program are contrived to adopted in real bathymetry. The results of computation reveal some significant characteristics of directional spectra in shallow water. Furthermore, the statistical features of waves at the point of interest are to be evaluated.

Introduction

For design of offshore structures on continential shelf or shallow water area, it is necessary to evaluate the design spectrum at the location of construction. As waves propagate from deep water into shallow water, they are modified by their interaction with the bottom topography. Provided that the directional wave spectrum in deep water region is known by forcast or measurement, it can be sliced to rectangular columns of finite number as linear spectrum is assumed. Every column represents small amplitude monochromatic wave, its shoaling and refraction are to be calculated by traditional procedures, then the columns are changing their height, and shifting their directions. Summing up the new columns, a wave spectrum at the point of interest is worked out.

With a straight uniform parallel bottom contour model, such method has been used by others (Nagai, 1972, etc). In real bathymatry, more effort must be paid due to the unexpected wave direction as wave advanced into shallow water. A try and error method is adopted in this calculation.

Deformation of spectrum

* Professor, Dr. Eng., Department of Hydraulics & Ocean Eng.,National Cheng Kung University, Tainan, Taiwan, 70101, R.O.C.

** Dr. Eng., Department of Hydraulics & Ocean Eng., National Cheng Kung University, Tainan, Taiwan, 70101, R.O.C.

The basic assumptions needed in this computation are:
(1) Waves are generated in deep sea and diminished on shoreline.
(2) Waves are in steady state, in which the time dependency which may result from wind generation is negligible.
(3) Energy dissipation is disregarded due to wave-seafloor interaction, white cap and breakers.
(4) The mathematical model implies no transfer of energy across orthogonals.

Ocean waves are composed of different frequency component waves in all direction. Its spectral density function can be defined as:

$$D(f,\theta)=S(f)\ F(f,\theta) \qquad \cdots\cdots(1)$$

where S(f): frequency spectrum
$F(f,\theta)$: directional function

in which the directional function is such that

$$\int_{-\pi}^{\pi} F(f,\theta)\,d\theta = 1 \qquad \cdots\cdots(2)$$

therefore, the one-dimensional frequency density function S(f) results from the integration of:

$$s(f) = \int_{-\pi}^{\pi} F(f,\theta)\,d\theta \qquad \cdots\cdots(3)$$

Linear spectrum can be sliced to numerous components. Each component has its representative frequency and can be considered as a regular wave. In practice, we divide the spectrum into finite components which depend on the accurancy of calculation and consumption of computer time.

There are three methods used in slicing the spectrum: (1) equal frequency interval method (2) equal energy interval method (3) combination of those mentioned above. Report indicated that over ninety percentage of spectrum energy concentrated in neighborhood of peak frequency fop, bounded in 0.7 fop $\sim$ 1.6 fop, see Mitsuyasu, 1984. For this reason, it seems more desirable to adopt method(3), but it will take much computer time. In this calculation, we apply the equal energy interval method.

The sketch of sliced spectrum is shown on Fig.1. The representative frequency of every component can be calculated with its second moment as following:

$$f_{en}^2 \cdot \Delta E = \int_{f_{n-1}}^{f_n} f^2\, s(f)\,df \qquad \cdots\cdots(4)$$

where f_{cn}: representative frequency of component spectrum
f_{n-1}, f_n: Lower, upper bounded frequency of component spectrum
spectral energy of component

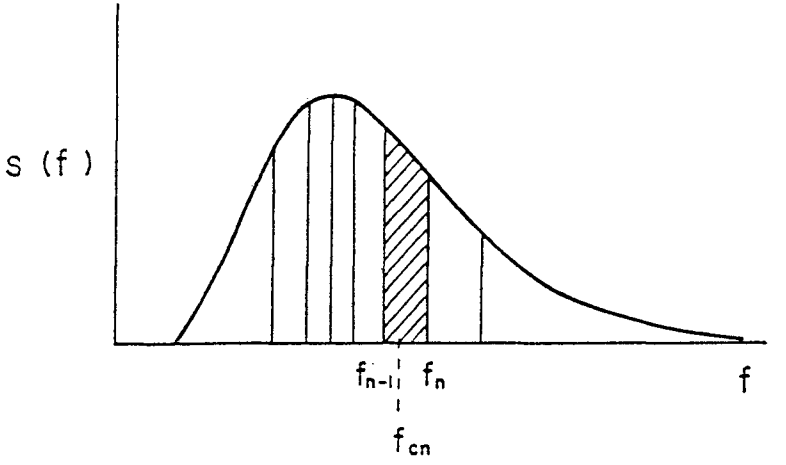

Fig.1 Sketch of sliced spectrum

Directional function can be divided by equal small angle $\Delta\theta$, as shown on Fig.2, then

$$\Delta\theta = \frac{|\theta_{max}| + |\theta_{min}|}{N} \qquad \cdots\cdots(5)$$

N: total dividing number
$\theta_{max}, \theta_{min}$: Max, Min. distribution angle with principal direction respectively.

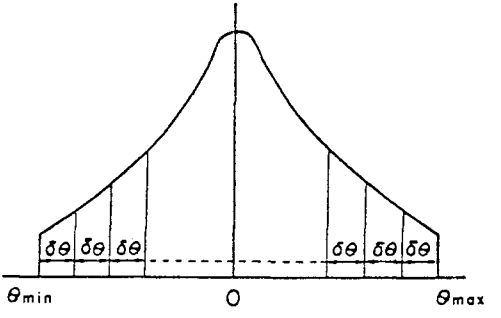

Fig.2 Sketch of sliced directional function

After slicing the known spectrum and directional function in deep sea, we can gain finite numbers of component spectrum with different incident directions and frequcies. Each component is a monochromatic wave, then the traditional wave ray method can be available for computing the deformation of component spectrum at the interesting point.

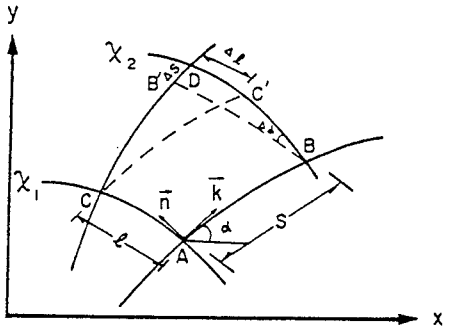

Fig.3 Sketch of wave ray and front

Fig.3 shows the sketch of wave ray and wave front, then the wave ray equation and wave intensity equation are given:

$$\left.\begin{aligned} \frac{d\alpha}{ds} &= \frac{1}{c}\left[\sin\alpha\frac{\partial c}{\partial x}-\cos\alpha\frac{\partial c}{\partial y}\right] \\ \frac{d^2\ell}{ds^2} &- p(s)\frac{d\ell}{ds}+q(s)\ell=0 \end{aligned}\right\} \qquad \cdots\cdots(6)$$

where

$$\left.\begin{aligned} p(s) &= \frac{1}{c}\left[\cos\alpha\frac{\partial c}{\partial x}+\sin\alpha\frac{\partial c}{\partial y}\right] \\ q(s) &= \frac{1}{c}\left[\sin^2\alpha\frac{\partial^2 c}{\partial x^2}-\sin 2\alpha\frac{\partial^2 c}{\partial x\partial y}\right. \\ &\quad \left.+\cos^2\alpha\frac{\partial^2 c}{\partial y^2}\right] \end{aligned}\right\} \qquad \cdots\cdots(7)$$

C: wave celerity
ds: increment along wave ray
$d\ell$: increment along wave front

By solving equation (6), we can find width between two rays, ℓ, refracting angle α. Then the shoaling coefficient, refraction coefficient of component wave are calculated by definition:

$$\left.\begin{aligned} K_s &= \sqrt{\frac{C_o}{2nc}} \\ K_r &= \sqrt{\frac{\ell_o}{\ell}} \end{aligned}\right\} \qquad \cdots\cdots(8)$$

where ℓ_o : initial value of width of two adjacent rays
C_o : wave celerity in deep sea.

$$n: \text{ factor} = \frac{1}{2}\left[1 + \frac{2kd}{\sinh(2kd)}\right]$$

The shoaling coeff., K_s , and refraction coeff., K_r , of deformed spectra can be solved as following:
For unidirectional spectrum:

$$\left.\begin{aligned} K_s &= \sqrt{\sum_{i=1}^{M} (K_s^2 \cdot S_o^*(f^*) \cdot \Delta f_n^*)_i / E_o^*} \\ K_r &= \sqrt{\frac{\sum_{i=1}^{M} (K_s^2 K_r^2 \cdot S_o^*(f^*) \cdot \Delta f_n^*)_i}{\sum_{i=1}^{M} (K_s^2 \cdot S_o^*(f^*) \cdot \Delta f_n^*)_i}} \end{aligned}\right\} \qquad \cdots\cdots(9)$$

For directional spectrum:

$$\left.\begin{aligned} K_s &= \sqrt{\sum_{i=1}^{M}\sum_{j=1}^{N} (K_s^2)_{ij} \cdot (\Delta E_o^*)_i / \sum_{i=1}^{M} (\Delta E_o^*)_i} \\ K_s K_r &= \sqrt{\sum_{i=1}^{M}\sum_{j=1}^{N} (K_s^2 K_r^2)_{ij} \cdot (\Delta E_o^*)_i / \sum_{i=1}^{M} (\Delta E_o^*)_i} \end{aligned}\right\} \qquad \cdots(10)$$

Dimensionless analysis of spectrum

JONSWAP spectrum:

$$S(f) = \frac{\alpha'}{(2\pi)^4} \frac{g^2}{f^5} \exp\left[-\frac{5}{4}\left(\frac{f}{f_{op}}\right)^{-4}\right] \times \gamma^{\exp\left[-\frac{1}{2\sigma_0^2}(f/f_{op}-1)^2\right]} \quad \cdots\cdots(11)$$

SWOP directional function:

$$F(f,\theta) = \begin{cases} \frac{1}{\pi}\{1+(0.5+0.82\exp[-\frac{1}{2}(\frac{2\pi f}{\omega'})^4]\cos 2\theta) \\ +0.32\exp[-\frac{1}{2}(\frac{2\pi f}{\omega'})^4]\cos 4\theta\} & |\theta| \le \frac{\pi}{2} \cdots(12) \\ 0 & |\theta| > \frac{\pi}{2} \end{cases}$$

where $\omega' = g / U_{5.0}$

$U_{5.0}$: wind velocity at 5.0m above sea surface

For the convenience of calculation, we introduce a dimensionless analysis to the known spectrum and directional function. If significant wave height ($H_{1/3}$) and siginificant wave period ($T_{1/3}$) are choosen as parameters, then the dimensionless spectrum S*(f*) is:

$$S^*(f^*) = \frac{S(f)}{H_{1/3}^2 T_{1/3}}$$

For JONSWAP spectrum, Wang et al (1976) derived an approximate value of zero-order moment of spectrum is:

$$m_o \simeq 0.305 \cdot k_1 \cdot f_{op}^{-4} \quad \cdots\cdots(13)$$

$$k_1 = \frac{\alpha' g^2}{(2\pi)^4} \qquad (\alpha' = 0.0081)$$

Introducing coefficients D_1, D_2, then we can establish following expressions:

$$\left.\begin{aligned} H_{1/3} &= D_1 \sqrt{m_0} \\ f_{op} &= \frac{1}{D_2 T_{1/3}} \end{aligned}\right\} \qquad \cdots\cdots(14)$$

From equation (11),(13) and (14), we can gain the dimensionless form:

$$S^*(f^*) = \frac{1}{0.305 \cdot D_1^2 \cdot D_2^4} \cdot f^{*-5} \cdot \exp\left[-1.25 (D_2 \cdot f^*)^{-4}\right] \times \gamma^{\exp\left[-\frac{1}{2\sigma_0^2}(D_2 f^* - 1)^2\right]} \qquad \cdots\cdots(15)$$

In West Taiwan Strait, Ou (1977) analyzed the measured data and deduced the spectrum of a JONSWAP type, those coefficients of spectrum are:

$$\left.\begin{aligned} H_{1/3} &= 3.8 \sqrt{m_0} \\ f_{op} &= \frac{1}{1.13 T_{1/3}} \\ \gamma &= 2.08 \\ \sigma_0 &= \begin{cases} 0.07 & f \le f_{op} \\ 0.09 & f > f_{op} \end{cases} \end{aligned}\right\} \qquad \cdots\cdots(16)$$

A dimensionless from of SWOP directional function is given by Nagai (1972):

$$F(f^*,\theta)=\frac{1}{\pi}\cdot\{1+[0.5+0.82\cdot\exp(-0.4416f^{*-4})]\times\cos 2\theta+0.32\cdot\exp(-0.4416f^{*-4})\cdot\cos 4\theta\} \quad \ldots(17)$$

Numerical computation

Finite difference method is used in solving wave ray equatio and intensity equation. Adopting central-difference method, hence

$$\left.\begin{aligned}\frac{d\ell}{ds}&=\frac{\ell_{n+1}-\ell_{n-1}}{2\Delta s}\\ \frac{d^2\ell}{ds^2}&=\frac{\ell_{n-1}-2\ell_n+\ell_{n+1}}{(\Delta s)^2}\end{aligned}\right\} \quad \ldots\ldots(18)$$

And equation (6) yields:

$$\ell_{n+1}=\frac{4-2(\Delta s)^2 q_n}{2-(\Delta s)p_n}\ell_n-\frac{2+(\Delta s)p_n}{2-(\Delta s)p_n}\ell_{n-1} \quad \ldots\ldots(19)$$

In regular wave, the relationship among wave length, period and water depth is:

$$L=\frac{gT^2}{2\pi}\tanh\left(\frac{2\pi d}{L}\right)$$

Wave celerity C=L/T angular frequency $\omega=\frac{2\pi}{T}$
Then,

$$C=\frac{g}{\omega}\tanh\frac{\omega d}{C} \quad \ldots\ldots(20)$$

From which, following partial derivatives can be establish:

$$\left.\begin{aligned}
&\frac{\partial C}{\partial x} = H(C)\,\frac{\partial d}{\partial x}\\
&\frac{\partial C}{\partial y} = H(C)\,\frac{\partial d}{\partial y}\\
&\frac{\partial^2 C}{\partial x^2} = H(C)\left[\frac{\partial^2 d}{\partial x^2} + \left(\frac{\partial d}{\partial x}\right)^2 \frac{dH(C)}{dC}\right]\\
&\frac{\partial^2 C}{\partial x\,\partial y} = H(C)\left[\frac{\partial^2 d}{\partial x\,\partial y} + \frac{\partial d}{\partial x}\frac{\partial d}{\partial y}\frac{dH(C)}{dC}\right]\\
&\frac{\partial^2 C}{\partial y^2} = H(C)\left[\frac{\partial^2 d}{\partial y^2} + \left(\frac{\partial d}{\partial y}\right)^2 \frac{dH(C)}{dC}\right]
\end{aligned}\right\} \quad \cdots\cdots(21)$$

in which:

$$k_1 = \frac{1}{2\omega} \qquad k_2 = \frac{\omega}{g}$$

$$H(C) = \left[\,2k_1 C\,\frac{k_2}{1-(k_2 C)^2} + 2k_1 \tanh^{-1}(k_2 C)\right]^{-1}$$

$$\frac{dH(C)}{dC} = \frac{-4k_1 k_2 [H(C)]^3}{[1-(k_2 C)^2]^2}$$

With step-by-step procedure, the width of wave ray ℓ_n, refracting angle α_n can be solved. The wave ray and Ks, Kr of component spectrum will be traced and calculated. In uniform slope or parallel straight topography, all the deformed wave on contour line is the same. Therefore, the computation is rather simplified and shallow spectrum of interesting point can be solved easily. In real bathymetry, the deformation varies from point to point, a try and error technique is adopted ingeneuously. Fig.4 shows the schematic grid points of topography, in which COMX, COMY represents X-, y-axis of interesting point respectively. 1~No, 1~Mo are node numbers.

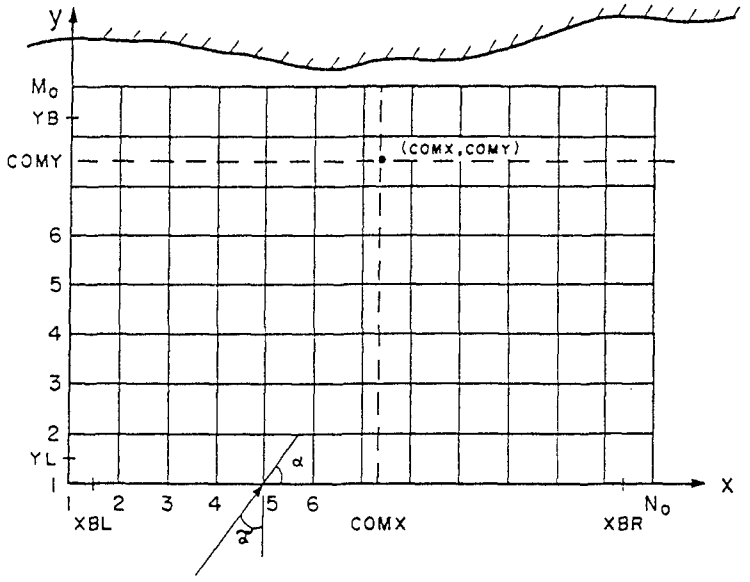

Fig.4 Schematic representations of coordinate

Try and error procedure:

First, setting the initial coordinate $(X_o)_1$ as starting point of computation in deep sea as following:

$$(X_o)_1 = X_o' \pm \left(\frac{90^\circ}{\alpha} - 1 \right)$$

where Xo' is a initial coordinate based on the assumption of no refraction of wave. Last term in above equation is a revised term of refraction, "+" is taken as Xo'<COMX, "-" as Xo'>COMX. When the computation comes to the neighborhood of y=COMY, the Lagrangian interpolation method is applied to abtain the Ks, Kr and α on y=COMY, then the corresponding WXN(1) in X-axis is also obtained. If (COMX-WXN(1))<0.1, it is considered that the wave ray goes pass through the interesting point and the computation of the component is completed. if not, revised the initial point for next step by:

$$(X_o)_2 = (X_o)_1 + (COMX - WXN)\, K_r^2$$

As repeating the same procedure only few times, the results could be gained. In few cases, a least square curve fitting may be avail-

able to solve the problems.

Due to the local drastic variation of topography or other reasons, there may occur the crossing of wave orthogonals. In such case, topographical smoothing is always used. However, A different way is adopted to treat this situation in this paper. It is by shifting the initial point several times to avoid or by-pass where the crossing is occurred, and a numerical approach is applied to get the solution at the interesting point with those results from different initial point.

Results and Conclusions

This model is applied to the slowly varying topography which ray theory is valid. A computer program is developd to fit this approach. As the coordinate of interesting point and wave spectrum in deep sea are given, the deformed spectrum at interesting point could be gained.

Fig.5 shows the topography off Hsing-Ta Harbour in West Taiwan Strait used in this calculation.

Considering the one-dimensional spectrum in deep sea, where incident angle of waves is 30 degree, and twenty dividing numbers are adopted, the deformed spectrum of interesting point as well as the original spectrum in deep sea is shown on Fig.6. It shows clearly that the peak frequency is different. SWOP directional is a distribution function related to frequency. Fig.7 shows the deformed directional function at various frequencies. The shapes of function in shallow water are more sharp. The energy of component spectrum is more concentrated to principle wave direction as waves advance to the shallow water when directional distribution of wave energy is considered. Table 1 is the comparison of results by applying regular wave and directional spectrum (SWOP directional function) There has a large difference at 0° and 180° between regular wave and directional spectrum. It is partly due to the effective income of energy when directional function is considered.

CHAPTER 60

Shoaling and Reflection of Nonlinear Shallow Water Waves

Padmaraj Vengayil[1] and James T. Kirby[2]

The formulation for shallow water wave shoaling and refraction-diffraction given by Liu et al (1985) is extended to include reflected waves. The model is given in the form of coupled K-P equations for forward and backward propagation. Shoaling on a plane beach is studied using the forward-propagating model alone. Non-resonant reflection of a solitary wave from a slope and resonant reflection of periodic waves by sinusoidal bars are then studied.

Introduction

Recently, Liu et al (1985) have developed a set of coupled parabolic equations to study the combined refraction and diffraction of time-periodic waves in shallow water over two-dimensional topography. Derivations in that study were based both on the Boussinesq equations for variable depth (Peregrine, 1972) and a variable depth form of the equation of Kadomtsev and Petviashvili (1970) (K-P), leading to similar results. The resulting equations model only the incident wave and neglect the reflected wave component. The problem of the neglected reflected wave component is important, both to the prediction of shoaled wave heights over gentle slopes and to the prediction of waves propagated over undular nearshore topography, which can lead to significant reflection by means of a resonance mechanism.

In this study, we address several questions of accuracy of predictions of the forward-scattered parabolic approximation which were not addressed in the previous study. In particular, we study the shoaling of a normally incident wave on a plane beach and analyze results both in terms of wave-height and wave form prediction in comparison with laboratory data. We then formulate coupled equations for incident and reflected waves and study wave reflection in several situations.

Model Formulation

Following a usual procedure for obtaining coupled parabolic equations for strictly monochromatic waves, we instead study the linear

[1]Graduate Student, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL (presently, Department of Civil Engineering, Massachusetts Institute of Technology, Cambridge, MA)

[2]Assistant Professor, Coastal and Oceanographic Engineering Department University of Florida, Gainesville, FL

nondispersive wave equation for arbitrary surface displacement $\eta(x,y,t)$. Letting $\eta = \eta^+ + \eta^-$, with $\eta^{+(-)}$ denoting forward (backward) propagating components of the wave field (with respect to direction x), we obtain a set of equations which are coupled through the local bottom variations. The equations are extended to include weakly dispersive and weakly nonlinear effects, yielding model equations of the form

$$\frac{1}{c}\eta_t^+ + \eta_x^+ + \frac{h_x}{4h}(\eta^+ - \eta^-) + \frac{3}{2h}\eta^+\eta_x^+ + \frac{h^2}{6}\eta_{xxx}^+ - \int_x^\infty \frac{1}{2h}(h\eta_y^+)_y dx = 0 \quad (1a)$$

$$\frac{1}{c}\eta_t^- - \eta_x^- + \frac{h_x}{4h}(\eta^+ - \eta^-) - \frac{3}{2h}\eta^-\eta_x^- - \frac{h^2}{6}\eta_{xxx}^- + \int_x^\infty \frac{1}{2h}(h\eta_y^-)_y dx = 0 \quad (1b)$$

where $h(x,y)$ is the local water depth and $c(x,y) = (gh)^{1/2}$. We subsequently neglect y-variations and study x-direction propagation alone for the remainder of this study. Details of the derivation may be found in the report by Vengayil and Kirby (1986). For the case of time-aperiodic motions, equations (1) are altered to RLW form and solved conveniently using a variation of the three time level scheme of Eilbeck and McGuire (1977). For the case of wave forms η^+, η^- which vanish as $|x| \to \infty$, it is further possible to show that equations (1) lead to the mass conservation law

$$\frac{d}{dt}\int_{x_0}^\infty (\eta^\pm)dx = \pm \tilde{Q}^\pm \pm \int_{x_0}^\infty c_x \eta dx \quad (2)$$

where x_0 is some arbitrary station and

$$\tilde{Q}^\pm(x_0) = \left\{c\eta^\pm + \frac{3c\eta^{\pm 2}}{4h} + \frac{ch^2}{6}\eta_{xx}^\pm\right\}\Big|_{x_0} \quad (3)$$

represents the flux of mass across station x_0. Taking the limit $x_0 \to -\infty$ then gives

$$\frac{d}{dt}\int_{-\infty}^\infty \eta^+ dx = -\frac{d}{dt}\int_{-\infty}^\infty \eta^- dx = \int_{-\infty}^\infty c_x \eta dx$$

or

$$\int_{-\infty}^\infty \eta dx = \text{constant} \quad (4)$$

indicating exact mass conservation. For the case of weak reflection with $O(|\eta^-|)\sim O(h_x)\cdot O(|\eta^+|)$, the source (sink) term is altered to

$$\int_{-\infty}^{\infty} c_x \eta dx = \int_{-\infty}^{\infty} c_x \eta^+ dx + O(|c_x|^2) \tag{5}$$

and the conclusions on mass balance in the variable coefficient KdV equation given by Miles (1979) are recovered.

For the case of time-periodic motions, the surface displacements η^+, η^- may be expanded in Fourier series with slowly-varying modal amplitudes; we then solve the coupled O.D.E. evolution equations for the amplitudes.

Shoaling of Regular Waves

We first study the shoaling of a regular wave on a plane beach as a means of further testing the accuracy of the model developed by Liu et al (1985). Data for the height and wave-form of shoaling waves were obtained from the results presented by Buhr Hansen and Svendsen (1979) and further described by Svendsen and Buhr Hansen (1978) and Buhr Hansen (1980). Figure 1 shows the configuration of the wave flume used in the tests. The five longest wave conditions were chosen for study; parameters for the chosen tests are shown in Table 1.

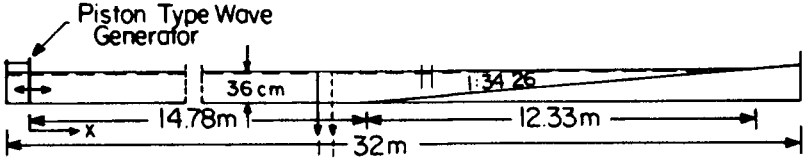

Figure 1. Experimental set-up of Buhr Hansen and Svendsen (1979).

Table 1 Wave parameters at the wavemaker for the test considered from Buhr Hansen and Svendsen (1979).

Buhr Hansen & Svendsen Test No.	H_0(m) (actual)	$\varepsilon = \frac{H_o}{2h_0}$	T(sec)	$\mu^2 = \frac{\omega^2 h_0}{g}$	U_{r_0}
051071	0.067	0.090	2.0	0.362	0.248
051041	0.037	0.051	2.0	0.362	0.140
041071	0.070	0.097	2.5	0.232	0.418
041041	0.040	0.056	2.5	0.232	0.242
031041	0.040	0.056	3.33	0.130	0.445

The model equations were developed by neglecting the wave reflected from the slope, which has been shown to be small (Vengayil and Kirby, 1986). The incident wave η^+ is represented by the Fourier series

$$\eta^+(x,t) = \sum_{n=1}^{N} A_n(x) e^{in(\int k dx - \omega t)} + c.c. \quad ; \quad \omega = ck \tag{6}$$

The series is substituted in equation (1a) (neglecting η^-) to give

$$A_{n_x} + \frac{h_x}{4h} A_n - \frac{in^3 k (kh)^2}{12} A_n +$$

$$+ \frac{3ink}{8h} \left\{ \sum_{\ell=1}^{n-1} A_\ell A_{n-\ell} + 2 \sum_{\ell=1}^{N-n} A_\ell^* A_{n+\ell} \right\} = 0$$

$$n=1,\ldots,N \tag{7}$$

The model equation may be extended to include laminar frictional damping due to bottom and sidewalls by the addition of the term

$$\frac{(1+i)}{2h} n^2 k^2 \left(\frac{2\nu}{n\omega}\right)^{1/2} \left\{1 + \frac{2h}{b}\right\} A_n \tag{8}$$

to equation (7). Here, ν is the kinematic viscosity and b is the channel width.

Figure 3. Comparison of wave profiles predicted by the numerical model including bottom and side wall friction effects with the experimental results of Buhr Hansen and Svendsen (1979). —— numerical, ---- experimental. Distances are from wavemaker in Figure 1.

Results for shoaled wave heights are shown in Figure 2a-c for the three longest waves studied. Results are shown for undamped waves, damping due to bottom friction alone, and damping due to bottom and sidewalls. Also included are plots of component amplitudes $|A_1|-|A_{10}|$ for the case with sidewall damping. The reproduction of shoaling wave height is good for the damped cases.

Figure 3 shows computed wave forms in comparison to experimentally measured waves for the cases with bottom and sidewall damping. Reproduction of measured wave form is quite good except in regions close to wave breaking. In these regions the forward face of the wave tilts towards a vertical position and vertical accelerations become quite large, thus invalidating the Boussinesq approximation locally. However, the model has no apparent difficulty in predicting shoaled wave height up to the breaking limit. An investigation of the higher order skewness and asymmetry properties of the shoaled waves is presently underway and will be reported subsequently.

Gradual Reflection of Solitary Waves

A test of the coupled equations was performed by comparing results for reflection of a solitary wave by an underwater slope with experimental data obtained by Goring (1978). Goring also computed theoretical results for reflection coefficients based on numerical

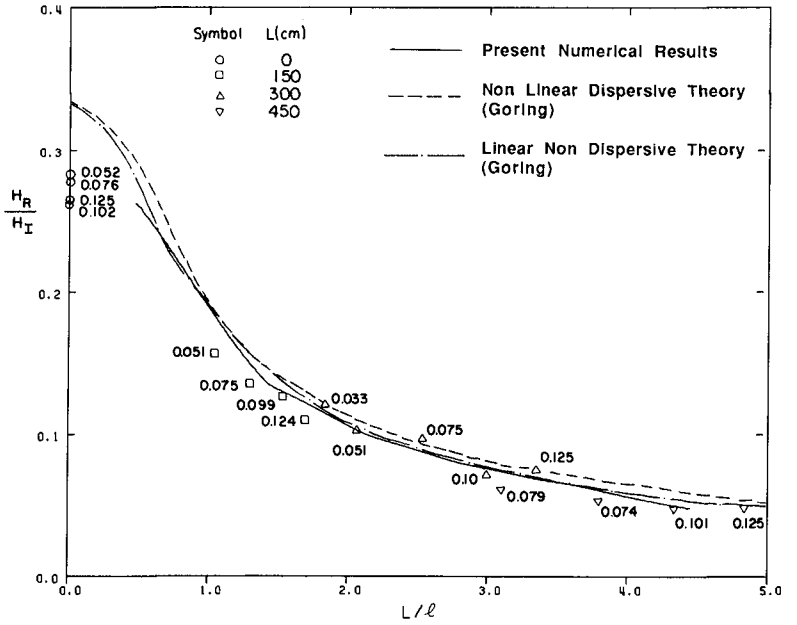

Figure 4. Reflection coefficients for solitary waves propagating over a submerged slope. Data from Goring (1978).

solution of the Boussinesq equations (weakly nonlinear-weakly dispersive case) and on the Bessel function solution of the linear-nondispersive shallow water equation. Figure 4 gives results of reflection coefficient based on the ratio of height of reflected wave to height of incident wave for varying values of slope length L to incident wavelength ℓ, for a particular case of a depth reduction $h_1/h_2 = 4$. The incident wave length is estimated here according to

$$\ell = 1.5\ (H_I/h_1)^{-1/2} h_1 \tag{9}$$

Results of the present study agree most closely with the linear nondispersive theory, indicating the overall dominance of the slope effect in the scattering process. The present theory and Goring's linear theory each deviate slightly from Goring's nonlinear theory, indicating that there is some effect due to nonlinear coupling between the incident and reflected wave. This discrepancy is presently being investigated using a version of the present theory which retains nonlinear coupling between the opposite-going waves.

An example of the time history of a solitary wave reflection for a particular case of a fairly abrupt slope is given in Figure 5. The development of the reflected wave, moving to the left with increasing time, is apparent, as is the nonlinear evolution of the incident wave after it moves onto the shelf. This evolution involves the generation of three soliton modes which are rank-ordered in height and subsequently disperse due to the nonlinear evolution. The reflected wave is seen to have about the same width as the incident wave (as would be expected for a short slope) and evolves only slowly due to its low initial amplitude (scale on right). The presence of a high frequency tail following each wave train is just becoming apparent on the top trace of the picture.

Resonant Reflection by Sand Bars

Recently, Mei (1985) has investigated the resonant interaction which occurs between an incident wave of wavenumber k, a synchronous reflected wave with wavenumber -k and a bar field with dominant wavenumber $\lambda = 2k$. Mei's investigation was for the case of linearized, intermediate depth theory. Here, we have extended the investigation to the case of nonlinear, weakly-dispersive waves. The topography studied had the form

$$h(x) = \begin{cases} h_0 & x<0 \ ; \ x>L \\ h_0 + D\sin \lambda x & 0\leq x\leq L \end{cases} \tag{10}$$

where D is the bar amplitude and $\lambda = 2\pi/\ell_b$ is the bar wavenumber. Results are presented here for $L = 4\ell_b$ (four bars in the patch). The relevant governing equations are developed by using equation (6) for the incident wave η^+ and

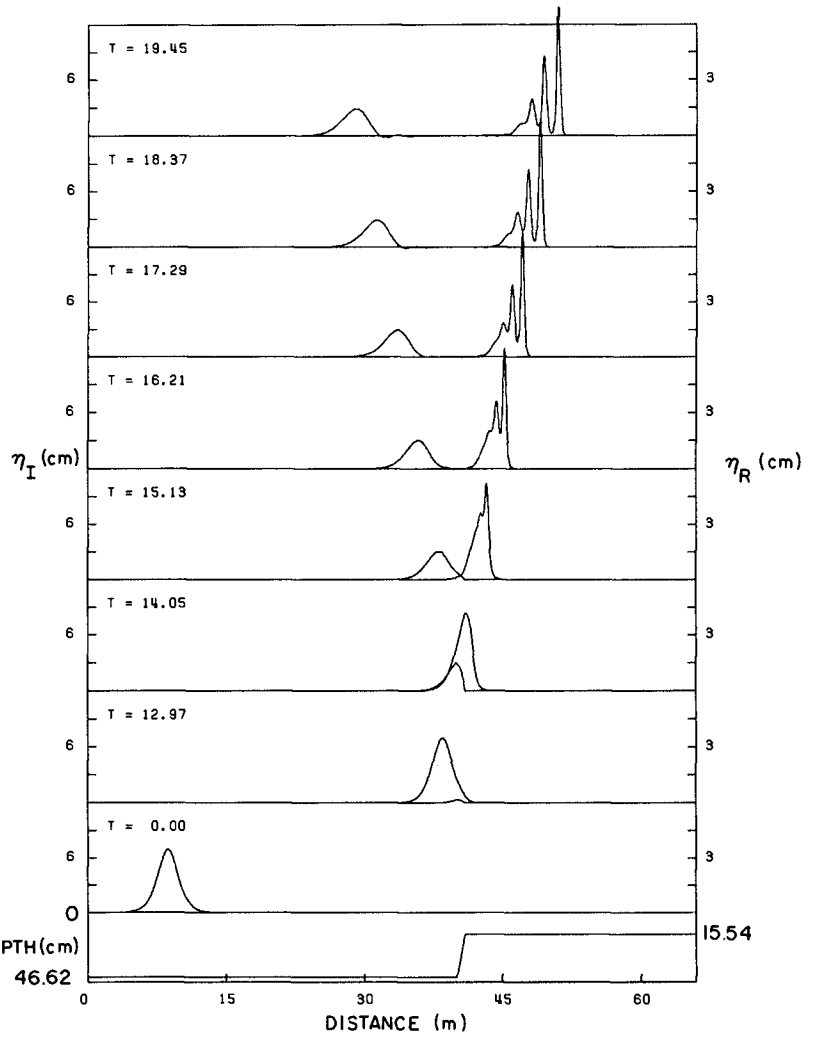

Figure 5. Evolution of a solitary wave. Incident wave propagates to the right.

$$\eta^{-}(x,t) = \sum_{n=1}^{N} B_n(x)\, e^{-in(\int kdx - \omega t)} + c.c. \qquad (11)$$

for the reflected wave. Substitution of (6) and (11) in the governing model equation (1) leads to the coupled system of evolution equations

$$A_{n_x} + \frac{h_x}{4h}\left(A_n - B_n e^{-2in\int kdx}\right) - \frac{in^3k^3h^2}{12} A_n + \frac{3ink}{8h}\left[\sum_{\ell=1}^{n-1} A_\ell A_{n-\ell} + 2\sum_{\ell=1}^{N-n} A_\ell^* A_{n+\ell}\right] = 0 \qquad (12)$$

and

$$B_{n_x} + \frac{h_x}{4h}\left(B_n - A_n e^{2in\int kdx}\right) + \frac{in^3k^3h^2}{12} B_n - \frac{3ink}{8h}\left[\sum_{\ell=1}^{n-1} B_\ell B_{n-\ell} + 2\sum_{\ell=1}^{N-n} B_\ell^* B_{n+\ell}\right] = 0 \qquad (13)$$

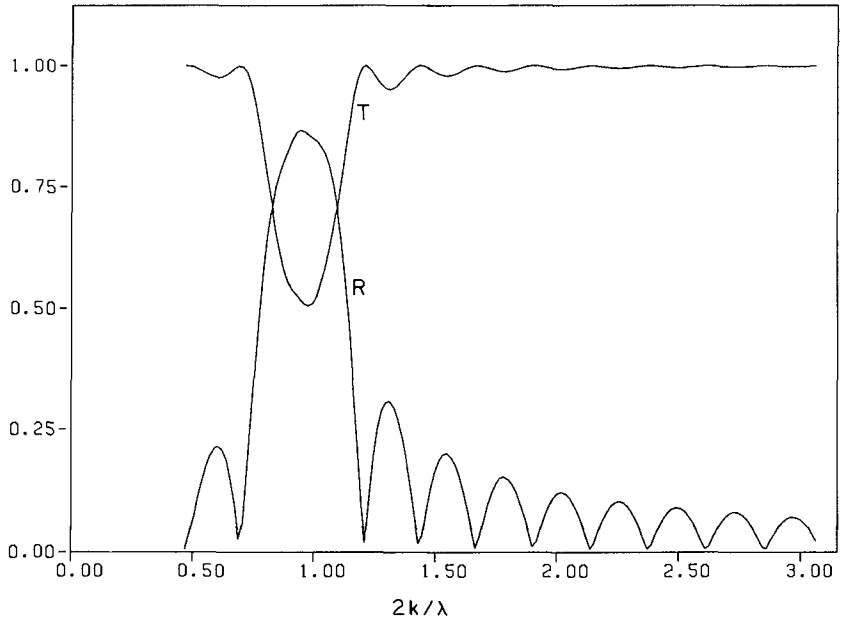

Figure 6. a) linear theory

The incident wave $A_n(0)$ is specified according to a spectral solution for permanent waves in the RLW equation (Vengayil and Kirby, 1986). The $B_n(L)$ are set equal to zero, representing the case of no waves arriving at the patch from large positive x.

Figure 6 shows results for $D/h_0 = 0.4$ and n=4 for a range of bar lengths relative to a fixed wavelength. The plots give calculated reflection coefficient $R_1 = |B_1(0)/A_1(0)|$ and transmission coefficient $T_1 = |A_1(L)/A_1(0)|$ as solid lines. This represents the complete solution for linear theory (Figure 6a). The presence of the resonant peak at $2k/\lambda = 1$ is apparent. In Figure 6b (nonlinear theory), the results for the reflection coefficient R_1, which now represents only one component of the wave field, does not differ greatly from the linear result. This result may be of some importance since it indicates that the linear scattering process dominates the nonlinear effects over the relatively short bar field, which would allow the application of the linear scattering theory in a nearshore, nonlinear wave field.

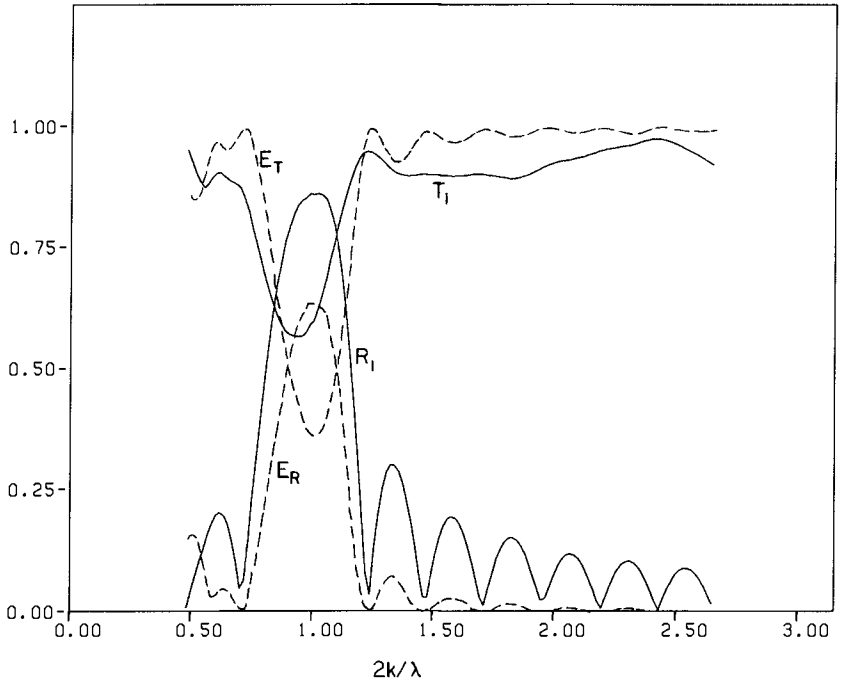

Figure 6. Reflection and transmission of waves by a sinusoidal bar patch. n=4, D/h = 0.4.
b) nonlinear theory.

Also shown in Figure 6b are traces of the total transmitted energy E_T and reflected energy E_R normalized by the total incident energy. The numerical scheme was found to satisfy the requirement

$$E_R + E_T = 1 \tag{14}$$

to several decimal places for suitably fine discretizations of the physical domain. The only effect due to nonlinearity which is readily apparent in the results in Figure 6b is the drop in T_1 below one for $2k/\lambda > 1$. This effect represents a transfer of energy to higher harmonics following from destabilization of the incident wave during its shoaling over the bar crests.

Finally, Figure 7 shows the evolution of the spectral amplitude components during nonlinear evolution at the resonant condition in Figure 6. Only the growth $|B_1|$ is strongly forced by the reflection process; the growth of $|B_2|$ and $|B_3|$ may be partially due to reflection but also is influenced strongly by the nonlinear transfer of energy from $|B_1|$ as it grows. Likewise, $|A_1|$ may gain energy from its harmonics as the incident wave loses energy over the bar field, which would tend to increase the apparent reflection. These two nonlinear effects thus compete in the overall reflection process, and their possible near-cancellation may contribute to the relatively small change in reflection coefficients noted in shifting from linear to nonlinear theory. This effect is presently being investigated in the context of resonantly-reflected solitary waves.

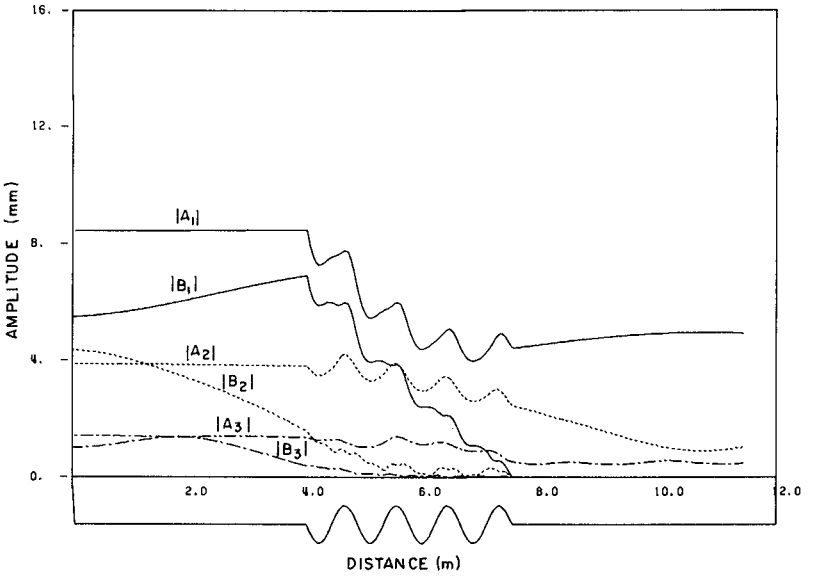

Figure 7. Evolution of component amplitudes $|A_1|-|A_3|$ and $|B_1|-|B_3|$ for the resonant peak of Figure 6. Nonlinear theory.

CHAPTER 61

WAVE BASIN EXPERIMENTS ON BOTTOM FRICTION DUE TO CURRENT AND WAVES

Paul J. Visser*

ABSTRACT

Results are presented of experiments in a wave basin on the increase of the mean bottom frictional stress in a flow when a wave field is superimposed on a current. The bottom friction was derived from the mean water level measured at various places. Measurements of wave orbital and mean current velocities were done both with a micro-propeller and with a new type immersible Laser Doppler Anemometer.

The data indicate an increase of the mean bottom shear stress due to the presence of the waves, but less than predicted by Bijker (1967). A suggestion is made to improve the accuracy of this theory. The bottom stresses as predicted by Fredsøe (1984) are somewhat larger than the experimental results.

1. INTRODUCTION

Since many years it is known that when a wave field is superimposed on a current (see fig. 1), the mean bottom friction will increase.

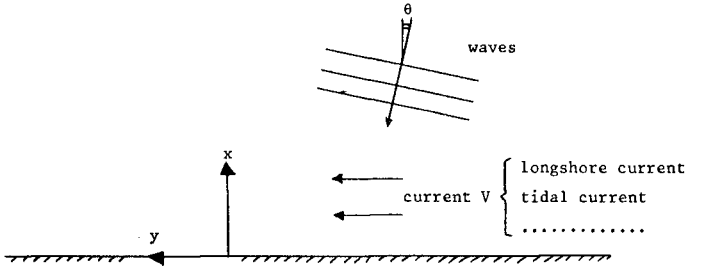

Fig. 1 - Combination of a current and a wave field; θ = angle of incidence, x = coordinate normal to the coast, y = coordinate in longshore direction.

* Scientific Officer, Department of Civil Engineering, Delft University of Technology, P.O. Box 5048, 2600 GA Delft, The Netherlands.

In the pioneering work of Bijker (1967), this phenomenon was investigated both theoretically and experimentally. Since then many investigators have attacked the problem, both theoretically: Lundgren (1973), Bakker and van Doorn (1979), Grant and Madsen (1979), Fredsøe (1984), Tanaka and Shuto (1984) and van Kesteren and Bakker (1985), and experimentally: Bakker and van Doorn (1979) and Kemp and Simmons (1982, 1983). The studies of the wave boundary layer in case of waves alone have much contributed to the present achievements. In this respect the theories of Kajiura (1968), Jonsson and Carlsen (1976) and Brevik (1981), the experiments and analysis of Jonsson (1963, 1967, 1980), Kalkanis (1964), Horikawa and Watanabe (1969), Kamphuis (1975), Jonsson and Carlsen (1976), Sleath (1982) and van Doorn (1982, 1983) and the empirical analysis of Nielsen (1985) should be mentioned.

The most accurate descriptions of the bottom friction due to current and waves are the models of Fredsøe (1984) and van Kesteren and Bakker (1985). These models also allow an arbitrary angle between the directions of the current and the wave field. Van Kesteren and Bakker assume Prandtl's mixing length hypothesis. Nielsen (1985), however, shows that this hypothesis fails in case of oscillatory flow. The model of van Kesteren and Bakker is also rather complicated. Therefore Fredsøe's model is preferable.

For engineering practice the Bijker (1967) model is often used because of the simplicity and handiness of its solution. Applications of Bijker's description to laboratory data of longshore currents, see Visser (1984, 1985), and to field observations by the Delft Hydraulics Laboratory have, however, indicated that this model overestimates the influence of the waves on the bottom frictional stress.

The present paper describes wave basin experiments on the mean bottom friction due to current and waves. The (effect of the) bottom shear stress was measured by determining the mean water level slope from mean water level observations:

$$\rho g h \frac{\partial h}{\partial y} + \bar{\tau}_{by} = 0 \quad \text{in y-direction} , \tag{1}$$

where ρ = density of water, g = acceleration of gravity, h = mean water depth, τ_{by} = mean bottom frictional stress in y-direction (= direction of mean current velocity). Equation (1) assumes uniformity along the coast and zero gradients of radiation and Reynolds shear stresses.

The investigation has been restricted to $\theta = 0^{o}$ in order to prevent recirculation flows on the constant depth part of the wave basin, see Visser (1982). These recirculation flows may disturb the mean water level slope measurements significantly. A further restriction is the application of regular waves.

Actually the investigation is a continuation of Bijker's work. The most important motivations for this study have been: 1. the above mentioned failure of the Bijker model, and 2. the shortage of detailed experimental data in case of small values of θ, in particular for the direct verification via equation (1). The investigation has been carried out within the framework of the Applied Coastal Research programme of the Dutch Public Works Department.

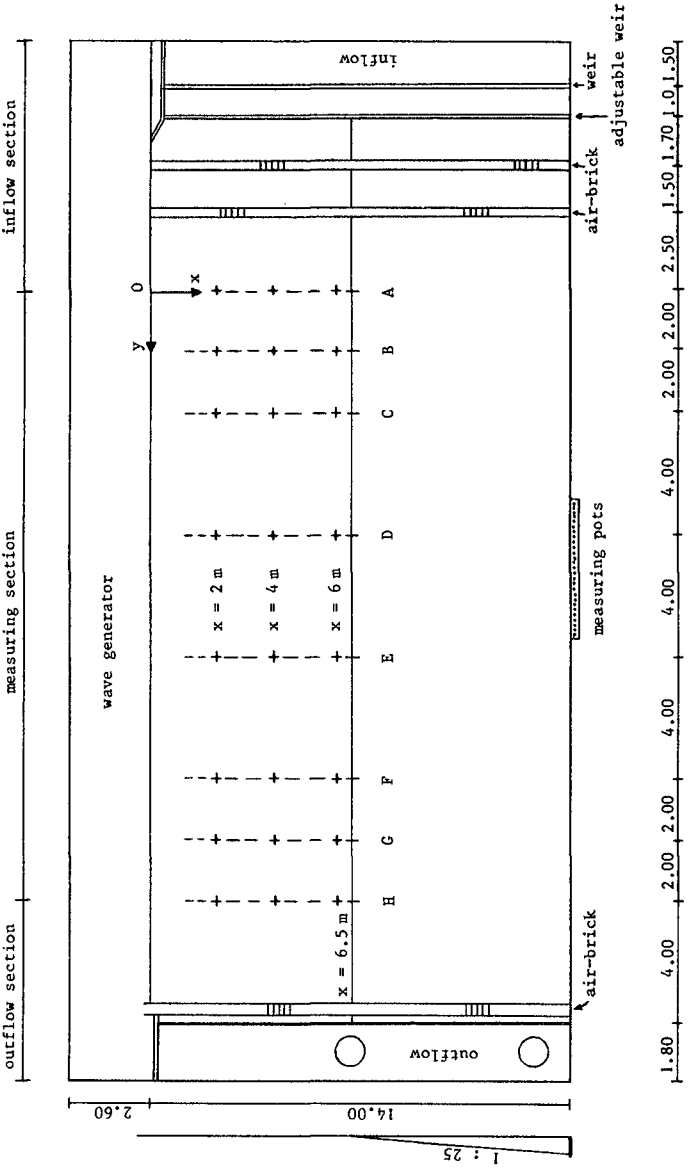

Fig. 2 - Plan view of wave basin (measures in meters, + = tapping for mean water level measurement).

2. DESCRIPTION OF THE EXPERIMENTS

The experiments were performed in the 16.60 * 34.00 m^2 wave basin of the Civil Engineering Department of the Delft University of Technology, see fig. 2. A concrete 1 : 25 beach was built opposite to the wave board in order to minimize reflection of the waves.

A mean current was established in the basin flowing parallel to the shore and the wave board. Much attention was given to the in- and outflow conditions in order to obtain uniformity of this current in the horizontal plane (on the constant depth part of the basin). The details of the experimental set-up are shown in fig. 2. The inflow section of the wave basin consisted of:

- two supply-pipes with a maximum flow rate of 0.8 m^3/s,
- two weirs to distribute the flow over the width of the basin,
- two rows of air-bricks to reduce the turbulence in the current caused by the inflow from the supply-pipes,
- small-mesh wire-netting against one row of air-bricks to adjust the proper vertical velocity distribution at the upstream end of the measuring section.

The outflow section consisted of one row of air-bricks, a small weir and two wells.

The details of the measuring techniques are summarized in table 1. Measurements of orbital and mean current velocity were done with a micro-propeller current meter (in situations with current or waves alone) and with a new type immersible Laser-Doppler Anemometer (LDA),

measurements of	measuring method	sections	number of measuring points per section	number of measuring points per vertical
mean current velocities (current alone)	micro-propeller	D, F(1)	6 ~ 12	10
	LDA	F	2	14
orbital velocities (waves alone)	micro-propeller	D, E(2)	4 ~ 7	1(3)
	LDA	F	2	8 ~ 14
vertical velocity profiles (current and waves)	LDA	D, F	2 ~ 6	8 ~ 14
mean water levels	static head in pots connected with tappings in the bottom	A, B, C, D, E, F, G, H	3	measured 5 times
wave heights	resistance wave probes	D, E	4 ~ 7	

(1) in exp. 1 also in sections C, E and H

(2) in exp. 1 also in sections C, F and G

(3) about 3 cm above the bottom (measurement of u_m, see sketch)

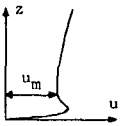

Table 1 - Experimental procedure.

developed by the Delft Hydraulics Laboratory, see Godefroy and Vegter (1984).

This LDA is a very useful tool for velocity measurements in wave basins. A micro-propeller, for instance, fails if there is an angle between mean current direction and wave propagation direction. A disadvantage compared with LDA-measurements through glass side-walls of flumes is the inevitable small disturbance of the flow. An accurate calibration of the instrument, however, can reduce this problem.

The LDA and the probes of the micro-propeller current meter and wave height meter were installed on the measuring carriage of the wave basin.

Six pits were made in the wave basin bottom in sections D and F to be able to measure velocities with the immersible LDA near the bottom, see fig. 3. The pits were covered with perspex plates in order to prevent disturbances on the flow. The perspex plates allowed an exact positioning of the measuring point above it (the contact of the measuring point with the surface of the perspex plate gave a 100% Laser-Doppler signal; in water this was 50 - 60%).

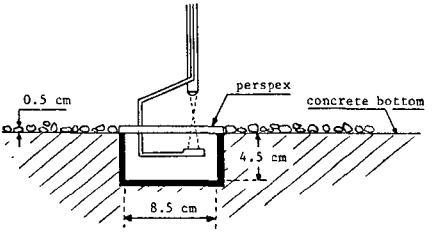

Fig. 3 - Pit in the gravel bottom for the LDA- measurements near the bottom.

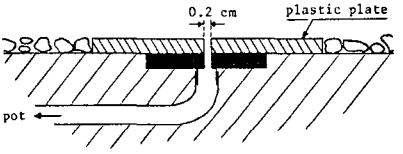

Fig. 4 - Tapping for the mean water level measurement on the gravel bottom.

The mean water level measurements were done in 24 points (see fig. 2) in order to achieve a high accuracy. These observations were made at least five times, since the water level differences were very small and the measuring results showed some scatter.

Experiments were done with a smooth concrete bottom and with a gravel (d_{90} = 8 mm) bottom. Fig. 4 shows a cross-section over a tapping in the gravel bottom. Plastic plates, 10 * 10 cm^2 and 0.6 cm thick were fixed on the concrete bottom in order to obtain horizontal velocities at the tappings (so to prevent dynamic pressures by vertical velocities).

Wave height measurements were only done on the constant depth part of the basin. The observational time was 100 seconds for each measurement.

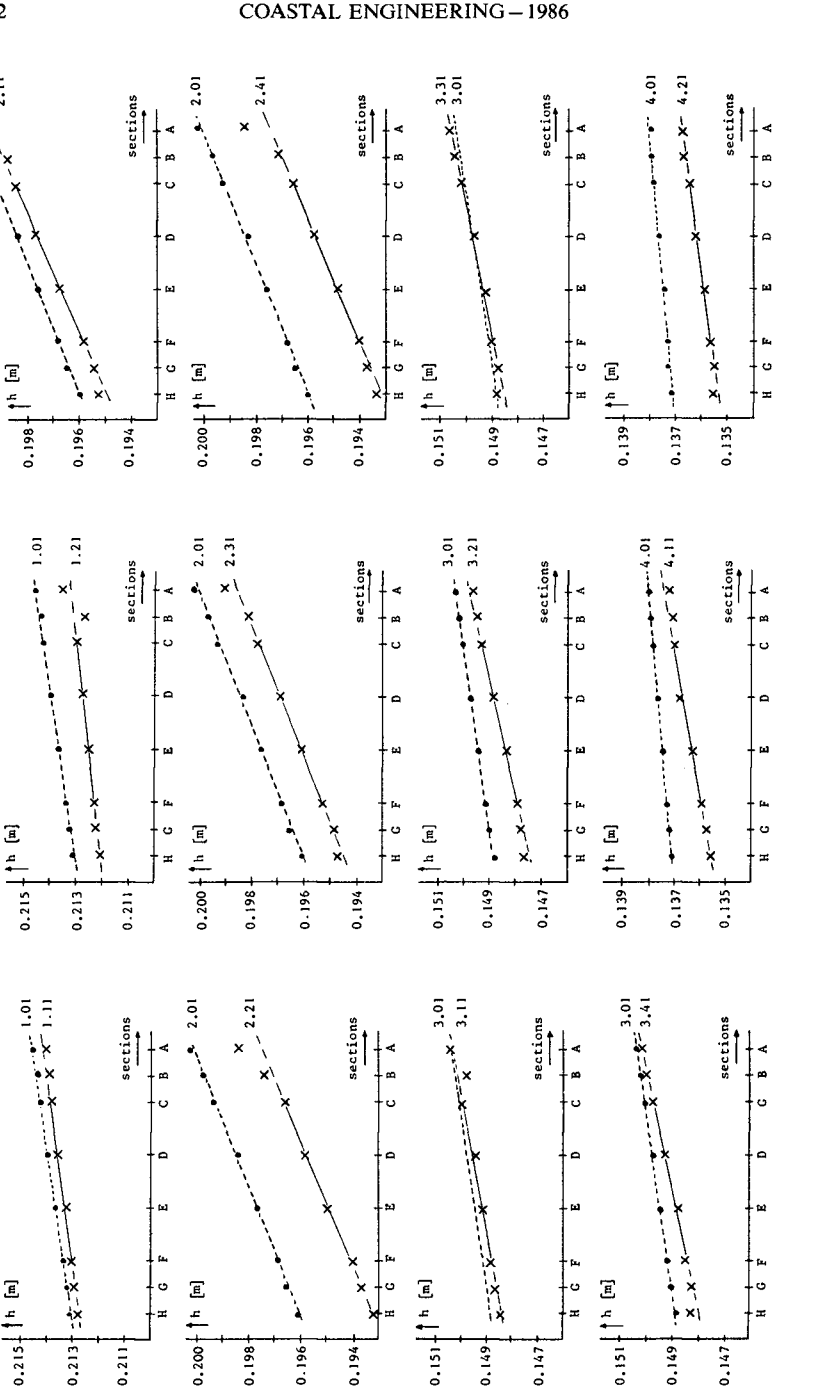

Fig. 5 - Averaged (over width of wave basin) results of mean water level measurements.

3. EXPERIMENTAL RESULTS

The experimental conditions and the main results of the measurements on the constant depth part of the basin regarding averaged wave heights H, mean water depths h, depth-averaged mean current velocities V (V_c in case of current alone, V_{cw} in case of current and waves) and averaged amplitudes of orbital velocities near the bottom u_m are given in table 2. A current alone was present in the experiments 1.01, 2.01, 3.01 and 4.01. The other experimental data of table 2 represent situations of current and waves. V_{cw} was not measured in all experiments. The data (H, u_m) of the experiments with waves alone correspond with those of current and waves. By averaging these data have been incorporated in table 2.

Fig. 5 shows the averaged (three points per section, in time observed at least five times) results of most of the mean water level measurements. The mean water level slopes i (i_c or i_{cw}) in table 2 were calculated by linear regression from the mean water level observations in the sections C, D, E and F. Upstream of section C and downstream of section F the mean water level measurements were influenced by the inflow and outflow conditions, respectively, see fig. 5.

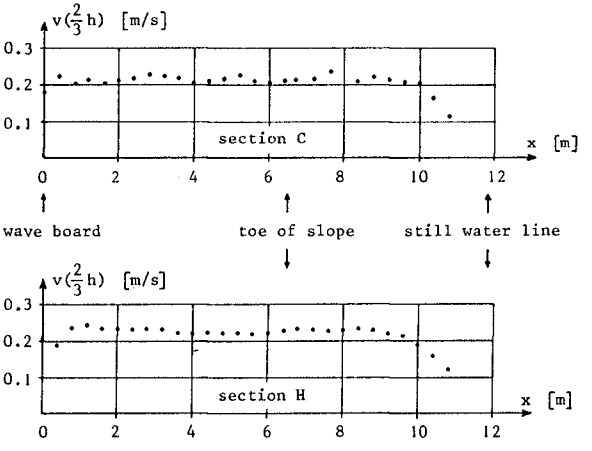

Fig. 6 - Distribution of mean current velocity v at a height of z = 2h/3 in sections C and H in exp. 1.01 (current alone).

Fig. 6 shows the distribution of the mean current velocity v in x-direction at a height of 2h/3 above the bottom in exp. 1.01, measured with the micro-propeller in sections C and H. On the constant depth part of the basin the uniformity of this velocity in x-direction is satisfactory, especially in section H.

Fig. 7 gives examples of the width-averaged results of the

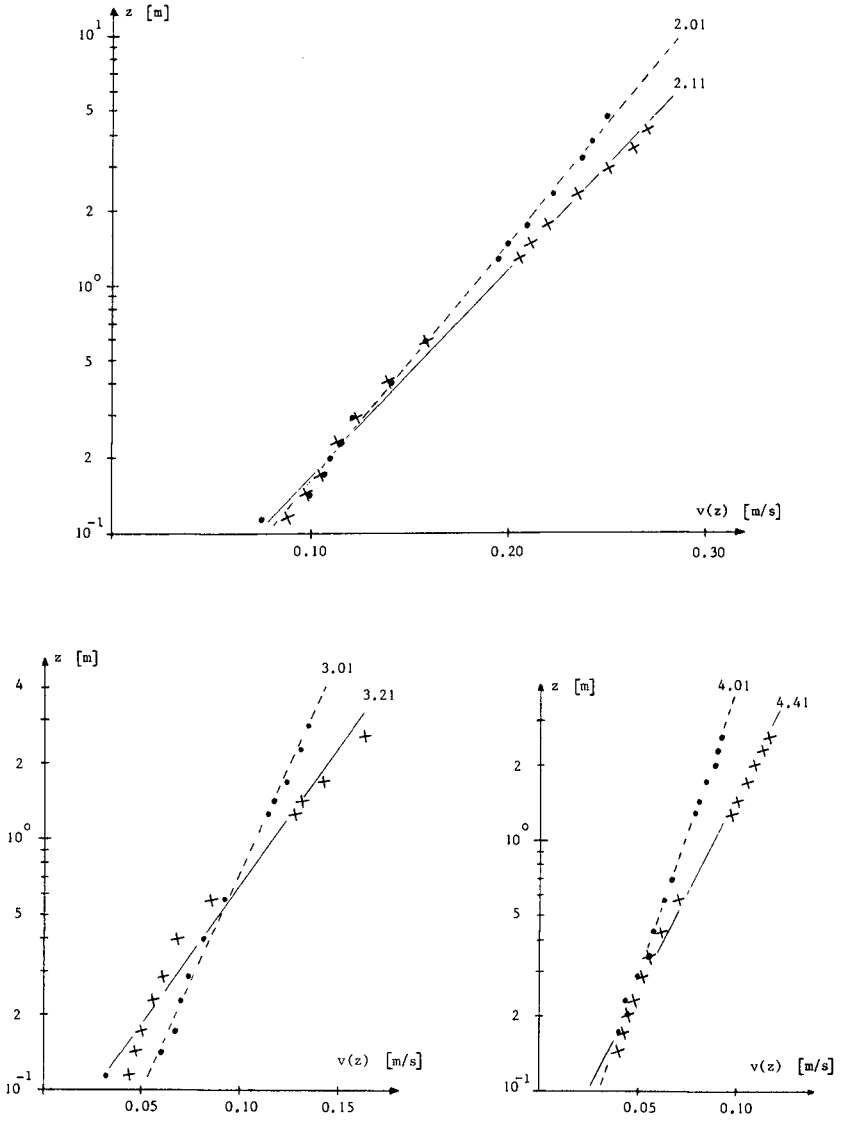

Fig. 7 - Mean current velocities v(z) in section F, averaged over two measuring points x = 3.0 m and x = 5.0 m; z = vertical coordinate, z = 0 at surface of perspex plate (see fig. 3), • • • = current alone, X X X = current and waves.

measurements (in the points x = 3.0 m and x = 5.0 m in section F) of mean current velocity profiles with the immersible LDA.

Fig. 7 reveals also a problem with the mean current velocity data of the experiments on the rough bottom: the velocities on the constant depth part of the basin were larger in the situation with current and waves than in case of current alone, especially at the downstream end of the basin. As such this was not unexpected. Due to the waves the bottom friction on the slope increased more than on the constant depth part of the basin (see also chapter 4). The flow rate Q was the same as in the current alone case and so this gave rise to this larger velocities. But the resulting non-uniformities of the mean current were hard to suppress and therefore the experimental data of V_{cw} (see table 2) are less accurate.

These non-uniformities have also unfluenced the mean water level slope observations. The maximum relative error occurs in exp. 4.21 (see table 2) and is estimated at

$$\frac{V\frac{\partial V}{\partial y}}{g\frac{\partial h}{\partial y}} \simeq \frac{0.09\,(\frac{0.096 - 0.083}{20})}{10 * 0.69 * 10^{-4}} \simeq 0.085 ,$$

which is, fortunately, not extremely large.

A suggestion to avoid this problem in further research is given in chapter 5.

4. COMPARISON WITH THEORETICAL RESULTS

For the combination of a mean current in longshore direction and a wave field (fig. 1), Bijker (1967) has proposed to combine the horizontal mean current and orbital velocity vector in the hypothetical boundary layer (viscous sublayer) at a height z' = e r/33 (r = Nikuradse bottom roughness parameter) above the bottom. Bijker determined the mean current velocity at this height with Prandtl's mixing length theory and put the horizontal orbital velocity at the height z' equal to $p\,u_m \cos \omega t$, with ω = angular frequency and p ≃ 0.4, both theoretically and experimentally. In this way Bijker has derived for the mean bottom frictional stress in y-direction τ_{by}:

$$\tau_{by} = C\,\rho\,V^2\,f(\theta, \xi\frac{u_m}{V}) , \qquad (2)$$

where

$$f(\theta, \xi\frac{u_m}{V}) = \frac{1}{T}\int_0^T \{1 + 2\,\xi\frac{u_m}{V}\sin\theta\cos\omega t + (\xi\frac{u_m}{V})^2\cos^2\omega t\}^{\frac{1}{2}} * \\ * (1 + \xi\frac{u_m}{V}\sin\theta\cos\omega t)\,dt , \qquad (3)$$

$$\xi_B = \frac{p\kappa}{\sqrt{C}} \simeq \frac{0.16}{\sqrt{C}} , \qquad (4)$$

$$C = \left(\frac{\kappa}{\ln\frac{12\,h}{r}}\right)^2 \quad , \tag{5}$$

t = time, T = wave period, C = dimensionless bottom friction coefficient.

The parameter ξ can be condidered as a dimensionless factor depending on how the mean current and orbital velocty near the bottom are combined. If the depth-averaged mean current velocity V and the amplitude of orbital velocity near the bottom u_m are combined, see Visser (1984), then: $\xi = 1$.

Swart (1974) modified Bijker's model to Jonsson's (1963, 1967) experimental results for waves alone and arrived at (2) with (3), (5) and

$$\xi_S = \sqrt{\frac{f_w}{2C}} \quad , \tag{6}$$

in which

$$f_w = \exp\{-5.977 + 5.213\left(\frac{r}{a_b}\right)^{0.194}\} \qquad \text{for} \quad \frac{a_b}{r} > 1.57 \quad , \tag{7}$$

$$f_w = 0.30 \qquad \text{for} \quad \frac{a_b}{r} < 1.57 \quad , \tag{8}$$

where f_w = Jonsson's wave friction factor and a_b = amplitude of orbital particle excursion near the bottom.

The elliptic integral $f(\theta, \xi u_m/V)$ represents the increase of the bottom friction due to the presence of a wave field. Its dependence on θ and $\xi u_m/V$ is shown in fig. 8. The dashed line in fig. 8 represents an analytical expression with which the elliptic integral can be approximated with an error smaller than 3 %, see Visser (1984).

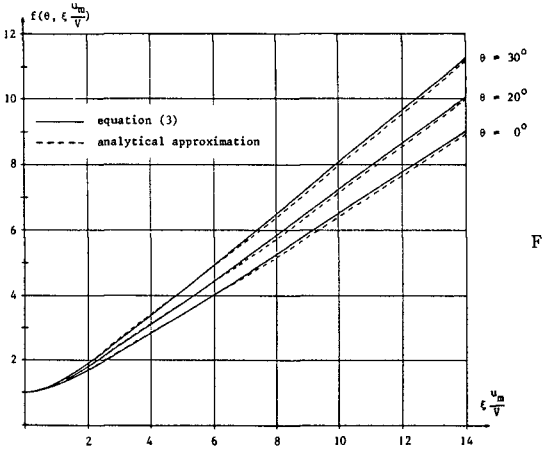

Fig. 8 – $f(\theta, \xi\frac{u_m}{V})$

Table 2 - Experimental conditions and results and comparison of i_{cw}/i_c with theoretical predictions.

Assuming a logarithmic velocity distribution inside as well as outside the wave boundary layer (but with different slopes), Fredsøe (1984) has calculated the mean current profile by use of a depth-integrated momentum equation. Fredsøe derived for the mean bottom frictional stress in y-direction τ_{by} (in the notation of the present paper):

$$\tau_{by} = C_{cw} \rho V^2 , \tag{9}$$

where C_{cw} = dimensionless bottom friction coefficient in case of current and waves:

$$C_{cw} = \{ \frac{\kappa}{\ln(\frac{30 h}{r_w}) - 1} \}^2 , \tag{10}$$

in which r_w = apparent bed roughness (which is different from the grain roughness r as the wave boundary layer acts as a larger roughness element). The apparent bed roughness r_w can be determined from fig. 7 in Fredsøe's (1984) paper if V, h, u_m, a_b and r are known. The increase of the bottom friction in a flow due to waves can be expressed from (5) and (10) as:

$$\frac{C_{cw}}{C} = \{ \frac{\ln \frac{12 h}{r}}{\ln(\frac{30 h}{r_w}) - 1} \}^2 . \tag{11}$$

Table 2 gives the comparison of the measured increase of the bottom friction caused by the presence of waves (i_{cw}/i_c) and the theoretical predictions given by equation (3) with $\xi = 1$, $\xi = \xi_B$ and $\xi = \xi_S$, respectively, and those given by Fredsøe (= C_{cw}/C).

The bottom roughnesses r have been calculated from the experiments with current alone using (2) with $f(\theta, \xi u_m/V) = 1$ and (5), see table 2. The value of the diameter of the "roughness elements" of the concrete bottom is estimated at 0.5 - 1.0 mm, d_{90} = 8 mm for the gravel bottom. Thus

$$r/D_{90} \simeq 3, \tag{12}$$

which is in reasonable agreement with Kamphuis' (1975) ratio of 2. With $r/h \simeq 0.01$ and $Re \simeq 5 * 10^4$, the flow on the smooth concrete bottom is practically complete rough turbulent.

Table 2 shows that the measured i_{cw}/i_c are somewhat smaller than predicted by Fredsøe (1984), and lower to much lower than the predictions of Bijker (1967) and Swart (1974). The best agreement is obtained with equations (2) and (3) if $\xi = 1$.

The comparison of theoretical and experimental results for the increase of the bottom friction due to waves has been done using measured V_c in case of current alone. The data of V_{cw} have been ignored for this since these are less accurate (see chapter 3).

Substitution of V_{cw} in $f(\theta, \xi u_m/V)$ and use of it to determine C_{cw}/C will lead to smaller values for both parameters. But these smaller

values should also be compared with corrected values for i_{cw}/i_c:

$$\frac{i_{cw}^*}{i_c} = \frac{h_{cw}}{h_c} \left(\frac{V_c}{V_{cw}}\right)^2 \frac{i_{cw}}{i_c} \quad . \tag{13}$$

5. CONCLUSIONS AND SUGGESTIONS FOR FURTHER RESEARCH

A set of data is presented of wave basin experiments on the increase of the mean bottom frictional stress in a flow when waves are superimposed on a current (angle between directions of current and wave propagation is 90^o). Especially the accuracy of the mean water level slope observations (direct measurement of effect of bottom friction) between sections C and F (fig. 5) is satisfactory. The decrement of the mean current velocities on the slope in case of current and waves has decreased the uniformity of the mean current velocities on the constant depth part of the basin, so also the accuracy of the mean current data (particularly V_{cw}) in this situation.

The following conclusions can be drawn from this investigation:

1. A rather laborious adjustment of the inflow is necessary to obtain uniform mean current velocities.
2. An immersible Laser Doppler Anemometer is a very useful instrument for wave basin experiments. Problems can be expected inside the surf zone caused by air-bubbles in the water.
3. The models of Bijker (1967) and Swart (1974), which are practical for engineering applications, do overestimate the bottom friction in case of current and waves.
4. The equation $\tau_{by} = C \rho V^2 f(\theta, \xi u_m/V)$ with $\xi = 1$ gives rather good agreement with the experimental results. This conclusion has also been followed from a comparison of longshore current data with a mathematical model including this expression, Visser (1984, 1985).
5. The bottom stresses as derived by Fredsøe (1984) are somewhat larger than the experimental results.

The following recommendations for further research are given:

1. The present experimental set-up can be improved by reducing the velocities on the slope significantly (for instance by making the bottom of the slope much more rough than the bottom of the constant depth part of the wave basin).
2. It is recommended to compare the model of van Kesteren and Bakker (1985) with the present experimental data.

ACKNOWLEDGMENT

The author is grateful to J.A. van der Stel, who performed the experiments.

CHAPTER 62

FRICTION IN HURRICANE-INDUCED SURGES

Shang-Yih Wang[1] and B. A. Christensen[2]

ABSTRACT

With the increasing development of coastal areas, it is necessary to have a sound method for predicting hurricane-induced flooding in these areas, especially for studies such as the coastal construction set-back line, flood insurance rate-making and county land use planning. The objective of this study is to develop the capability of describing the friction factor in coastal areas for improved representation in numerical models of storm surges.

Five types of areas are considered: A, ocean bottom with bed forms and some vegetation; B, mangrove fringes and areas; C, forested areas and cypress swamps; D, grassy areas and saltwater marshes; and E, developed residential and commercial areas. The friction factors, which incorporate both the bottom friction coefficient and drag coefficient due to the submerged parts of obstructions were verified by conducting laboratory experiments for mangrove and developed areas, using the typical distribution found in each of these coastal areas. The formulas of the friction factor for the ocean bottom, forested areas and grassy areas are determined by adopting results from previous investigations and discussed with the results of the current study.

INTRODUCTION

Through history flood prone areas in the worlds coastal regions have had an almost magic attraction on man. Today the trend is still towards a more intense utilization of coastal areas with high risk of flooding due to hurricanes than of the safer inland areas. The result is increasing flood losses. Such losses have grown from about $60 million at the turn of the century to more than $1 billion today in the United States alone.

The accurate prediction of local elevations of the 100 year flood plain is therefore more and more important for insurance

[1]Assistant Engineer, Beaches and Shores Resource Center, Florida State University, Tallahassee, Florida, U.S.A.

[2]Professor, Hydraulic Laboratory, Department of Civil Engineering, University of Florida, Gainesville, Florida, U.S.A.

purposes in the coastal zone. In a rapidly developing coastal county a one foot error in the predicted flood elevation may easily result in unnecessary construction and insurance costs in the millions of dollars per year. In an otherwise correct numerical model such an error may be introduced by an erroneous representation of the influence of friction in shallow ocean and overland flows. The present paper addresses itself to this problem.

The first numerical models of storm-induced surges in the ocean did often neglect the influences of bottom friction. While such a simplifying omission of a friction term in the governing equations appears to be acceptable in the parts of the ocean where depths are substantial it does result in errors in the shallow near-cost ocean and, of course, in the even shallower overland flow.

More recently developed models are therefore including this term. For instance, the Tetra-Tech model described by Chen et al. (1977) and widely used in the National Flood Insurance Program, takes bed friction into consideration by using the Manning formula. Other models use the Darcy-Weisbach formula for the bed shear stress τ_b

$$\tau_b = f' \rho \, u_m^2 / 2 \tag{1}$$

where ρ = density of water, u_m = the spatial mean velocity in the local vertical, and f' = the friction factor.

The approach using the Manning formula for evaluation of the bed shear stress leads to the expression

$$\tau_b = \gamma \, n^2 u_m^2 / d^{\frac{1}{3}} \tag{2}$$

using S.I. Units. In Eqn. (2) γ = unit weight of water, n = Manning's n and d = local depth. Elimination of τ_b by combination of Eqns. (1) and (2) shows that the friction factor must be a function of the local depth and, of course, of n that again depends on the equivalent sand roughness of the bed. The method of using a constant value of the friction factor in the ocean, regardless of depth, does therefore not seem satisfactory, although it has given quite decent results in many cases, especially in relatively deep ocean areas.

Using the Manning formula and thereby Eqn. (2) for the bed shear stress may also lead to errors when the apparent sand roughness is not sufficiently small compared to the depth as shown by Christensen (1970). The approach using the Darcy-Weisbach equation for the bottom shear stress is therefore chosen in this paper.

MODEL EQUATIONS

Friction Factor for Surges in Unobstructed Areas

Unobstructed areas include the ocean bottom and grassy areas, the latter of which are assumed to be completely submerged in water during floods. Practically all flow in hurricane-induced surges is in the hydraulically rough flow range. A velocity profile based on a modification of Prandtl's mixing length theory proposed earlier by Christensen (1972) may therefore be applied

$$\frac{\bar{u}}{u_f} = 2.5 \ln \left(\frac{29.73z}{k} + 1\right) \tag{3}$$

where $\bar{u}$ = time-mean velocity in the direction of flow at a distance z from the bed, u_f = friction velocity, and k = Nikurades's equivalent sand roughness. This modification provides a velocity profile that satisfies the no slip condition at the bed where the classic profile yields unrealistic negative velocities approaching minus infinity.

For practical purposes, the time-mean velocity profile is transformed to a depth averaged velocity profile using the fact that the mean velocity (depth averaged), u_m, occurs theoretically at a distance z = 0.368d from the bed also for the modified logarithmic vertical velocity profile, where d/k is larger than 1. Therefore at z = 0.368d Eqn. (3) yields

$$\frac{u_m}{u_f} = 2.5 \ln \left(\frac{10.94d}{k} + 1\right) \tag{4}$$

The friction factor may in general be related to the velocity profile by introducing the Darcy-Weisbach formula into the definition of the friction velocity by

$$\frac{u_m}{u_f} = \left(\frac{2}{f'}\right)^{\frac{1}{2}} \tag{5}$$

Solving Eqn. (5) for f' and introducing Eqn. (4) gives the following expression for the friction factor

$$f' = \frac{0.32}{\left[\ln \left(\frac{10.94d}{k} + 1\right)\right]^2} \tag{6}$$

Friction Factor for Surges in Obstructed Areas

Obstructions in these areas, e.g. mangroves, woods and buildings, are defined as roughness elements with significant heights which either protrude through the water layer or consist of relatively rigid elements with height that are sufficient to cause a form drag that is much larger than surface friction on the same area. The equation presented here is based on the assumption of steady or quasi-steady flow in the rough flow range.

Consider a design flow that passes over an obstructed area where the density is M per unit area, average diameter of the obstruction in the projected plane normal to the flow is D, and average drag coefficient is C_D. The head loss per unit weight of fluid over a bed length of L, ΔH, may be written as

$$\Delta H = f'_e \frac{u_m^2}{2g} \frac{L}{R} = f' \frac{u_m^2}{2g} \frac{L}{R} (1-\varepsilon) + MC_D dD \frac{u_m^2}{2g} \frac{L}{R} \tag{7}$$

in which R = hydraulic radius, ε = fraction of total area occupied by obstructions. An equivalent friction factor, f'_e, which includes the effects of bottom friction and form drag in the form of the Darcy-Weisbach formula is introduced. From Eqn. (7) it is seen that

$$f'_e = f' (1-\varepsilon) + MC_D dD \tag{8}$$

where, according to Eqn. (6),

$$f'_e = \frac{0.32}{\left[\ln \left(\frac{10.94d}{k} + 1\right)\right]^2}$$

EXPERIMENTAL VERIFICATION OF FRICTION FACTOR

According to the principle of conservation of energy, the total energy head at an upstream section 1 should be equal to the total energy head at the corresponding downstream section 2 plus the head loss between the two sections, i.e.,

$$d_1 + \frac{u_{m1}^2}{2g} = d_2 + \frac{u_{m2}^2}{2g} + \Delta H \tag{9}$$

where subscripts 1 and 2 refer to sections 1 and 2, respectively. Relating the measured results of head loss to the Darcy-Weisbach equation

$$\Delta H = f'_e \frac{u_a^2}{2g} \frac{L}{R_a} \qquad (10)$$

in which $u_a = (u_{m1}+u_{m2}) / 2$ and $R_a = (R_1 + R_2) / 2$, the equivalent friction factor f'_e can be determined for the designed roughness elements. To measure the velocities, a Novonic-Nixon type velocity meter was employed. The range of this velocity meter is from 3 to 150 cms^{-1} with an accuracy of $\pm$ 1 % of true velocity. A siphon type depth measuring device is designed to measure the water surface elevations to an accuracy of one millimeter. All the model tests were conducted in the hydraulic laboratory flume of the Civil Engineering Department at the University of Florida. The main channel of this flume is 36.6 meters long, 2.44 meters wide, and 0.81 meter deep.

Model Setup

Mangroves

Based on the average parameters obtained from eleven sampling areas in San Carlos Bay on the southwest coast of Florida, patterns of red and black mangroves were designed as shown in Figures 1 and 2. The dimensions of all stems and roots, including height and diameter of the prototype, are reduced to 1/10 for the model based on the undistorted Froude Law. The legends listed in these figures were the actual dimensions used in the model setup.

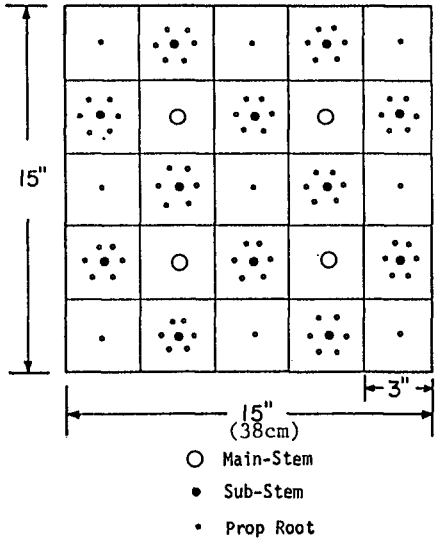

Figure 1: Model Setup for Red Mangroves

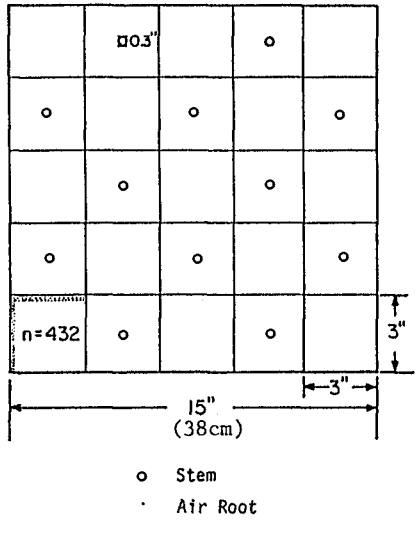

Figure 2: Model Setup for black Mangroves

The stems of red and black mangroves were simulated by dowels of the specified diameters and heights. The substems and prop roots were simulated by galvanized nails with heads removed. A manufactured nylon door mat whose strings have the same height (1.5 cm) and the same thickness (0.06 cm) as the design model dimensions of air roots was used. These dowels, nails and mats were fixed on three 2.4 meters by 1.2 meters marine plywood sheets, which covers half the flume width.

Buildings

Prototype data for the three kinds of buildings: high-rise, medium-rise and residential buildings, were taken and analyzed from aerial photographs of Broward and Dade counties, Florida. Table 1 shows a summary of the average parameters for these three categories. In this case a distorted madel with depth scale N_d and horizontal scale N_ℓ was used.

Table 1: Average parameters of Prototype and Model for Building Areas

Type of Buildings	PROTOTYPE			MODEL (N_d = 10)			
	Approximate Dimension (m)		Density	N_ℓ	Dimension (cm)		Density
	length	width	no. / 46452 m^2		length	width	no. / 2.1 m^2
High-Rise	69	33	7.19	174	39.4	19.1	10
Medium-Rise	31	15	23.62	80	39.4	19.1	7
Residential	19	9	68.87	48	39.4	19.1	7

Since the vertical dimension scale cannot follow the horizontal dimension scale in building models as the flow depth would be much too small for measurements to be made, or the viscous force would become important and cannot be neglected for the small flow depth. Therefore, a model with different vertical scale than horizontal scale is used to keep the model Reynolds numbers in the turbulent flow range. The concrete blocks with dimensions 19.1 cm x 19.1 cm x 39.4 cm were used to simulate the buildings. Figure 3 shows 21 patterns to be tested in which Nos. 1 to 13 were designed to simulate high-rise buildings, while Nos. 14 to 21 were for medium-rise buildings and residential areas. The design densities are started from low to high and cover at least the average densities obtained from the prototype. The whole width of the flume was used in this part of the experiments.

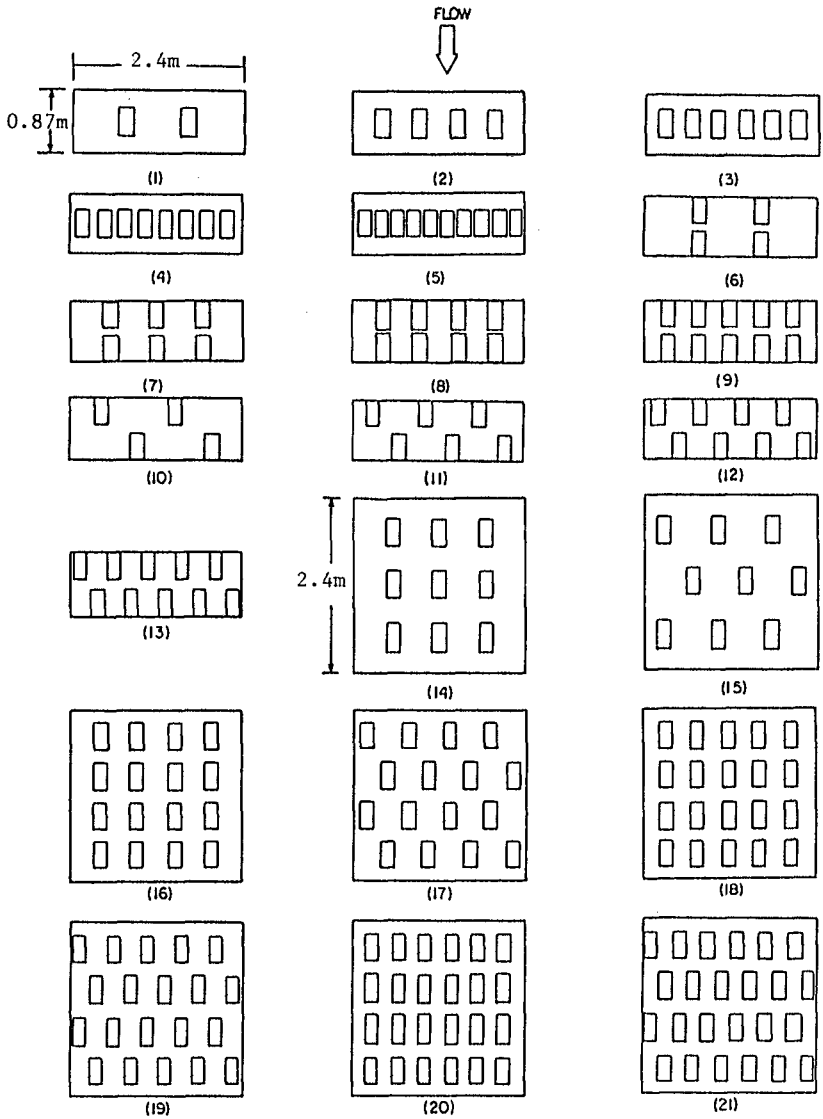

Figure 3: Building Patterns Designed for the Tests

Experimental Runs and Results

Mangrove Areas

During the first part of the experiments, 7 runs were conducted for the air roots of the black mangrove area to determine its apparent roughness height and friction factor. In the second part of the experiments, 38 runs were performed for the red mangrove area and black mangrove area by adjusting the discharge valve and changing the still water depths so that the flow Reynolds numbers covered a range from 20,000 to 55,000 while the Froude numbers varied from 0.14 to 0.44. Table 2 lists the mean values of the results and their corresponding standard deviations for the equivalent friction factors, drag coefficients and apparent roughnesses, k_a.

Table 2: Statistical Values of Experimental Results for Mangrove Areas

Mangroves	Statistical Values	f'_e	C_D	k_a (cm)	
				Model	Prototype
Red	Mean	0.129	0.732	42.69	426.9
	Standard Deviation	0.013	0.077	6.14	61.4
Black Stems	Mean	0.132	1.001	38.53	385.3
	Standard Deviation	0.020	0.090	9.72	97.2
Black Air Roots	Mean	0.028		5.26	52.6
	Standard Deviation	0.003		0.65	6.5

Building Areas

At least 10 runs were conducted for each of the 21 patterns shown in Figure 3. These runs for each pattern were controlled by adjusting the flume discharge valve and the tail gate so that they covered a range of Reynolds numbers from 20,000 to 70,000, while the Froude numbers varied from 0.1 to 0.5. The results obtained for medium-rise building areas can be converted using appropriate scaling factors to use in residential areas since these two areas are presumed to have the same relative distributions and have only dimensional differences. The statistical values of the experimental results for 21 patterns are listed in Table 3.

Table 3: Statistical Values of Experimental Results for Building Areas

Drag Coefficient - Building Density Relations

The data obtained from pattern 1 through 13 were analyzed and plotted in Figure 4, which shows three possible relations between the drag coefficients and densities for high-rise building areas. Figure 5 shows two relations between drag coefficients and densities for the medium-rise building area and residential area, respectively.

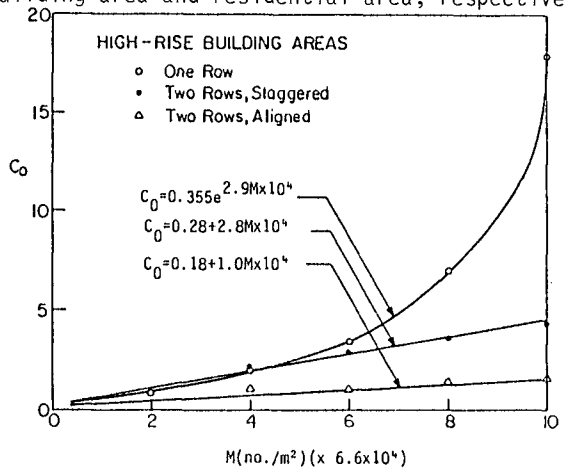

Figure 4: Relation Between C_D and Density M for High-Rise Building Areas

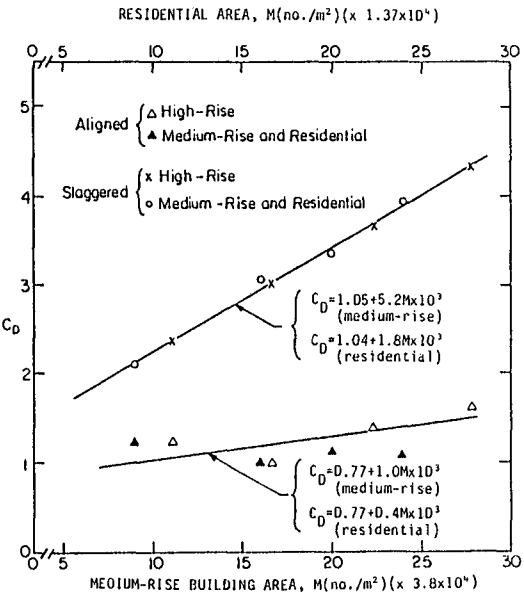

Figure 5: Relation Between C_D and Density M for Medium-Rise Building and Residential Areas

Drag Coefficient - Disposition Parameter Relations

Measuring the diagonal distance between the roughness elements in adjacent transverse rows, S_d, from building pattern 6 to 21, it is found that S_d/D and C_D show a good correlation for both aligned and staggered cases, as shown in Figure 6. This is attributed to the nature of the diagonal spacing, S_d, whose magnitude not only provides a measurement of density but also reveals a difference of disposition for the evenly distributed roughness elements. Therefore, the higher the building density, the smaller the disposition parameter, S_d/D, therefore a larger drag coefficient results. For buildings with the same dimensions and density, the disposition parameter, of the staggered pattern is smaller than that of aligned pattern, which also results in a larger drag coefficient. The same result was also substantiated by Shen (1973) who measured the mean drag coefficient of two cylinder patterns (aligned and staggered) in open channel flow.

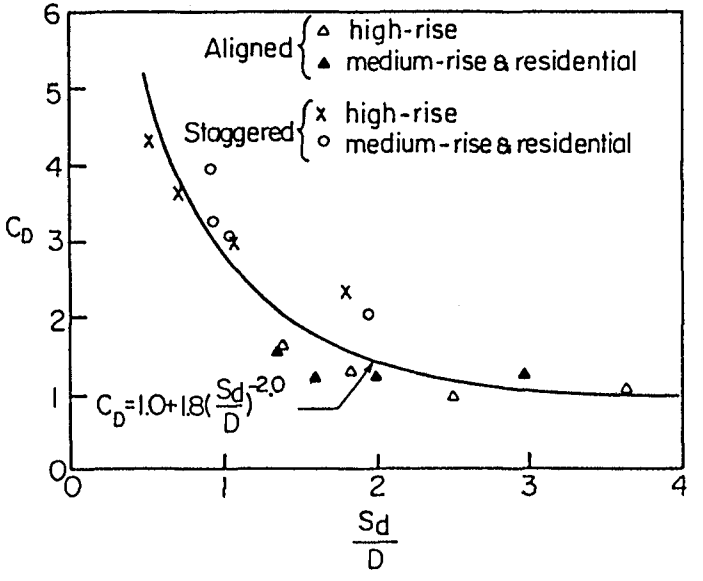

Figure 6: Relation Between C_D and S_d/D

DISCUSSIONS AND CONCLUSIONS

Ocean Bottom

The ocean bottom is mainly composed of different sizes of sands, on which vegetation and sand ripples vary with location. Hydraulic measurements in the field are the best way to determine the friction characteristics, but such measurements of velocity distributions and water depths are nearly impossible during a storm. Therefore, field measurements under normal conditions similar to a storm tide are needed. One possible instance is the flood and ebb flows through a tidal entrance in which the flow is in the fully rough range, and the effect of the temporal acceleration of the flow is generally of a lesser magnitude than the effect due to bed friction; therefore a correspondence between entrance flow and storm flood is expected. Three tidal entrances, John's Pass, Blind Pass and O'Brine's Lagoon Entrance, located on the Gulf coast of Florida were selected for hydraulic measurements to determine the bed friction characteristics (Mehta, 1978).

The values of Manning's n obtained for these three entrances are in the range from 0.020 to 0.026, which corresponds to the following bed morphologic features in open channel flows: clean, straight stream on plain (n = 0.025), gravel uniform excavated channel (n = 0.022), and uniform dredged earth channel with short grass (n = 0.022). This correspondence not only suggests that the values of n in the Manning's n table can be applied to tidal entrance, but that they can also be used for the ocean bottom during storm events. Therefore, for a rough ocean bottom, where the vegetation is significant or other roughnesses such as rocks or reefs exist, the n value is assumed to equal to 0.035, which represents an irregular, rough stream, a clean, winding stream on a plain with some weeds and stones, a dredged channel with light brush on banks, or a flood plain with scattered brush and heavy weeds in open channel flows.

As a results, the k values corresponding to the recommended n values are 0.03 m (n = 0.022) and 0.55 m (n = 0.035) for smooth and rough ocean bottoms, respectively. The friction factors for ocean bottoms can then be estimated using the equations

$$f' = \frac{0.32}{[\ln(365d + 1)]^2} \quad \text{for smooth ocean bottom} \qquad (11)$$

and

$$f' = \frac{0.32}{[\ln(20d + 1)]^2} \quad \text{for rough ocean bottom} \qquad (12)$$

Mangrove Areas

In general, the red mangroves only extend about 15 meters inland

from the shoreline and it is hard to distinguish them from black mangroves on aerial photographs and conventionally used city maps. Examining the case of fine grid system for numerical models whose grid elements are usually chosen to be 1,610 meters square, the average friction for each grid element on the mangrove fringes should be represented by the sum of 1 % of the red mangrove and 99 % of the black mangrove. For engineering applications, therefore, it is not necessary to consider the small difference between red and black mangroves. The equivalent friction factor derived for black mangroves then can be used for all the mangrove areas, i.e.,

$$f'_e = \frac{0.32}{[\ln(21d + 1)]^2} + 0.07d \qquad (13)$$

Forested Areas

Forested areas may consist of many different species, like oaks, magnolia, cedar, palm, pine and cypress, where each species has different representative features. However, for a general view, some typical values of the parameters for evaluating the equivalent friction factor are suggested by Christensen and Walton (1980)

$$k = 0.5 \text{ m} \; ; \; M = 0.1 \text{ m}^{-2} \; ; \; D = 0.6 \text{ m}$$

$$\varepsilon = 0.028 \; ; \; C_D = 0.8$$

It is worthwhile to examine the drag coefficient recommended for forested areas. In Figure 6, it is seen that the drag coefficient has a tendency to become constant and equal to 1.0 when the disposition parameter S_d/D is larger then 4. This relation derived initially for the rectangular roughness elements may also be used for circular roughness elements and can be proved by comparing the measured drag coefficient (1.0) for black mangroves as seen in Table 2. For black mangroves, the disposition parameter is about 17, and the corresponding drag coefficient is 1.0 according to Figure 6, which agrees well with the measured results. Applying the same reasoning to forested areas, whose disposition parameter equals to 12, the drag coefficient can be expected to be approximately 1.0. therefore, the drag coefficient 0.8 proposed by Christensen and Walton is conservative and reasonable. Adopting these values, the equivalent friction factor can be expressed in the form

$$f'_e = \frac{0.31}{[\ln(22d + 1)]^2} + 0.048d \qquad (14)$$

Grassy Areas

Saw grasses are the dominate plant community occurring in the world's coastal zones where water stands all or part of a year. The

results of studies of the flow of water over various grass covers by Palmer (1946) may provide some information to evaluate the roughness characteristics of saw grass. Palmer found that a completely submerged surface of Bermuda grass has a Manning's n of about 0.04, which corresponds to a k-value of about 1.25 m. If it is assumed that there is geometric similitude between Bermuda grass and about three times taller saw grass, Palmer's experiment with Bermuda grass may be considered as a model test of the prototype saw grass. As a results, a k-value of about 4 m for saw grass is expected. Christensen's (1980) indirect observation of the equivalent roughness of grass covered beds of estuaries on Florida's west coast have indicated a k-value ranging from 3 m to 5 m, which is in good agreement with the value derived from palmer's experiments with Bermuda grass. Introducing a k-value of 4 m in the friction factor equation, as suggested by Christensen and Walton (1980), yields

$$f' = \frac{0.32}{[\ln(2.7d + 1)]^2} \tag{15}$$

Developed Areas

The equivalent sand roughness, k, for developed areas cannot be determined by a single value, since the space between the buildings cover many different roughnesses. These roughnesses, in general, consist of pavements, grasses, light brush and trees, whose values of Manning's n are 0.013, 0.025 and 0.040, respectively. Assuming these roughnesses are evenly distributed, then an average value of n equals to 0.026 is assigned for these developed areas which gives k = 0.09 m using the Manning Strickler equation. As a result, the equivalent friction factor for developed areas may be represented as

$$f'_e = \frac{0.32}{[\ln(122d + 1]^2}(1-\varepsilon) + MC_D dD \tag{16}$$

The water depth d should be introduced in meters in all of the above expressions. The mean values of ε, M and D can be determined from the information in Table 2, or from the aerial photographs of the study areas.

The following three drag coefficient equation are suggested for friction factor calculations in developed areas:

$$C_D = 0.355\, e^{2.9M \times 10^4} \quad \text{for the one row high-rise building areas;} \tag{17}$$

$$C_D = 1.05 + 5.2M \times 10^3 \quad \text{for the staggered medium-rise building areas;} \tag{18}$$

and $C_D = 1.04 + 1.8M \times 10^3$ for the staggered residential areas; (19)

in which M is in number per meter square. The particular equation is recommended because on row high-rise buildings are the most predominate type of buildings found in highly developed coastal areas such those in Broward and Dade counties, Florida. For medium-rise buildings and residential areas, most buildings can be assumed to be staggered, since aligned buildings are scarce and the probability that floods will flow normal to the aligned building areas is very small in the field.

CHAPTER 63

Real-Time Wave Forecasting with adaptive ARMAX models

H.Wensink* and T. Schilperoort

Abstract

A method is described for improving the accuracy of the wave predictions which are required for the operational guidance of the shipping traffic in approach channels to harbours and to support offshore activities.
The method, as being described here, is based on the assimilation of wave physics and real-time hydrometeorological observations into a statistical time series model called ARMAX.

1 Introduction

In many practical situations operational wave prediction systems are needed, which have an accuracy that cannot be met by the prediction systems generally used in practice.
One way to improve existing methods is to integrate available hydrometeorological data and numerical wave prediction models into one prediction system.
This idea has been worked out by Poulisse and Schilperoort (1983), who investigated the potential of Kalman-filtering and adaptive time series (ARMAX) modelling for wave prediction purposes.

Schilperoort and Strating (1985) have described an adaptive modelling technique based on a correlation of wave observations, measured at different locations along the dominant propagation path of the wave energy.

More insight into the modelling of the wave processes and the development of new measuring instruments as well as the experience in an operational environment necessitated an improvement of the existing (ARMAX) method. These improvements are described by Wensink (1986a, 1986b and 1987).

The purpose of this paper is to describe an improved wave prediction system based on the adaptive time series modelling technique.
In paragraph 2 a short overview is given and the extensions of the wave prediction model are described. Paragraph 3 presents the results of the prediction system in an operational situation.
Finally in paragraph 4 the conclusions and some operational aspects are described.

2. The ARMAX system

The adaptive time series modelling technique as described by Schilperoort and Strating (1985) is a method that can be used for complex physical systems in which diffusion and advection plays an important role.

*Delft Hydrulics Lab, Delft, The Netherlands

The first parameter for which such a system has been developed is the 'low frequency wave energy', E_{10}, a parameter indicating the variance which is present in the wave spectra above the 10 s wave period.

This parameter has been chosen because of its pronounced influence on the motion of large ships and because of its low accuracy of prediction using existing prediction sytems.

The ARMAX prediction system for 'low frequency wave energy' is based on six elements:

- a data pre-processing module, in which, for each individual monitoring station, the raw hydrometeorological observations are transformed using simple wind-wave relationships;
- a data correction module;
  * in which, for each individual monitoring station the hydrometeorological data are reviewed and corrected for missing values
  * which determines the stations in the monitoring network to be coupled by ARMAX models;
- a correlation module, in which the transformed data of two neighbouring monitoring stations are correlated with each other using an ARMAX time series model
- a coupling module, in which a number of correlation modules is coupled, depending on the number of stations in the monitoring network and the quality of the input data;
- an identification module, in which the parameters of the ARMAX models used are estimated using an adaptive modified recursive least squares estimation method;
- a prediction module which generates the E_{10} predictions using the last identified ARMAX models;

2.1 Data pre-processing module

Wave fields not propagating in line with the monitoring stations affect the statistical relations between the observed 'low frequency wave energy' parameter (LFE) at two neighbouring monitoring stations and therefore reduce the maximum possible prediction accuracy.
To account for these secondary wave fields, at each individual monitoring Station i, crude estimates are made of the incoming E_{10} from Station (i-1), the locally generated E_{10} and the outgoing E_{10}, propagating to Station (i + 1).
These estimates are obtained by a direct processing of the online observed wind-velocity, wind-direction and directional wave spectra at that station using simple wind-wave relationships (WWR).
These physical relations include:

i) the calculation of the energy of growing sea, E_s and the growth stage, ξ, from the local wind data using a fetch limited exponential suturating growth curve and assuming a $\cos^2$-distribution function for the wind-sea directions, ϕ_s;

ii) the calculation of the average sea direction, $\bar{\phi}_s$, from the wind data using a directional relaxation function according to Günther et al. (1981);

iii) the calculation of the parameters of an assumed spectrum model (Kruseman model) from the growth stage, using relationships according to Sanders et al. (1980);

iv) the calculation of the locally generated E_{10}, u_1^i, by integrating the spectrum model over the frequency range $0 \leq f \leq 0.1$ Hz;

v) the assumption of an exponential decay of u_1^i in the case of a vanishing or rapidly veering wind, with the decay rate being dependent on the wind and wave direction;

vi) the calculation of incoming E_{10}, u_2 by assuming a $\cos^{2s}\frac{\Theta}{2}$ directional model; the time delay Δ^{i-1}, is calculated by the first and second moment of the directional wave spectra.

vii) the calculation of the modulations of E_{10} generated by the tides in shallow water by using a frequency dependent dissipation function according to Lighthill (1978).

2.2 Data correction module

A prediction system based on real-time hydrometeorlogical observations requires reliable input data. This condition cannot always be fulfilled in an operational situation. Therefore the ARMAX system includes procedures to detect and correct missing data and outlayers.

These wind-wave correction procedures can only be used for missing or bad data over short time intervals. For long time intervals without reliable or without any wind-wave information, the data correction module selects only those stations which posesses reliable input data.

2.3 Correlation module

The ARMAX model structure is based on the assumption that the observed E_{10} at Station i at time k is due to both locally generated E_{10} at time k and the outgoing E_{10} from the preceding Station (i-1) at time $(k - \Delta^{i-1})$ i.e.

$$y^i(k) = u_1^i(k) + u_2^{i-1}(k - \Delta^{i-1}) \tag{1}$$

By introducing the time delay, Δ^{i-1}, in the u_2-contribution, the E_{10} propagation time is taken into account explicitly. However, the model given by equation (1) is much too simple to give an accurate description of the complex phenomena involved. For instance, features like energy dispersion and refraction are not considered.

The simple model equation (1) therefore has been generalized by defining the following ARMAX model

$$y^i(k) = \underbrace{a_1^i y^i(k-1) + \ldots + a_{p_i}^i y^i(k-p_i)}_{\text{autoregressive part}} +$$

$$+ \underbrace{b_o^i u_1^i(k) + \ldots + b_{q_i}^i u_1^i(k-q_i)}_{\text{local sea contribution}} +$$

$$+ \underbrace{c_o^i u_2^{i-1}(k-\Delta^{i-1}) + \ldots + c_{r_i}^i u_2^{i-1}(k-\Delta^{i-1}-r_i)}_{\text{distant swell contribution}} +$$

$$+ d_o^i w^i(k) + \ldots + d_{s_1}^i w^i(k-s_1) + e_1^i \cdot 1 \qquad (2)$$

noise contribution bias term

The autogressive (AR) part acts like a filter for the input signals u_1, u_2 and w, which, for appropriate values of the AR-parameters, $a_1 \ldots a_p$, introduces a certain energy dispersion.
Variable growth rates and small variations in the time delays can be realized if the parameters, $b_o \ldots c_r$, are allowed to be time dependent. Energy dissipation occurs automatically for small values of $c_o \ldots c_r$.
The noise components $w^i(k) \ldots w^i(k-s)$ serve to model the residuals of $y^i(k)$ which cannot be explained by the autoregressive and the exogeneous input. By formulating the noise contribution as a moving average process (MA), residual autocorrelations can be used to improve the model predictions. Finally, the bias term, e_1^i, is added to improve tracking of the E_{10} observations. The combination of autoregressive (AR), moving average (MA) and exogeneous inputs (X) explains the name ARMAX model.

2.4 Coupling module

Because of the structure of the ARMAX models, in which y^i is related explicity to u_2^{i-1}, it is easy to build a sequence of ARMAX models covering all the stations being considered. This is represented schematically in Figure 1, which is explained in more detail in the following sections.

2.5 Parameter estimation module

The ARMAX model (equation 2) can be used to predict the output y^i recursively from known inputs if the model parameters
$a_1^i \ldots e_1^i$ and the model order (p_i, q_i, r_i, s_i) are known.
In the present system the model order has to be specified by the user. The specification of the parameter q_i and r_i requires an understanding of the physical processes involved. The specifications of the parameters p_i and s_i can be obtained from the hydrometeorological observations. Some criteria of best fit for the model order parameters p_i and s_i are described in Haykin (1986).

For a specified model order, the model parameters are estimated using a recursive adaptive estimation algorithm.
Recursive estimation is required because in an operational situation, there is a continuous data stream entering the prediction system, which must be processed on-line in order to avoid unnecessary delays.

In addition, the algorithm must be adaptive because the model (equation 2) is, as yet, too simple to give an accurate description of the E_{10} processes under all hydrometeorological situations. The ARMAX parameters $a_1^i \ldots e_1^i$ are therefore to be adapted to the hydrometeorological situation in order to garantee that the prediction is made with a model which best fit the actual wind and wave conditions.

The performance of a prediction system, which is based on time series modelling depends, to some extent, on the amount of information contained in the input data.

However, a prediction system, operating in real-time situations, must operate under all possible conditions.
Therefore techniques are incorporated to minimize the effect of redundant input data on the performance of the model (Wensink, 1986a). Some of this techniques are described by Goodwin and Sin (1984).

When hydrometeorological observations are used as the input for parameter estimation, the ARMAX system works in the identification mode. In this case there is no through-coupling of the various ARMAX elements. Instead, the model parameters are estimated separately for each individual element.

2.6 Prediction module

The ARMAX model parameters identified from the most recent observations always give the best description of the actual hydrometeorological situation; therefore, these must be used to generate the E_{10} predictions. As a consequence, the prediction system switches constantly from the identification mode to the prediction mode, and vice versa: In the identification mode E_{10} observations are used to estimate the ARMAX model parameter values whereas in the prediction mode these values are used to generate the E_{10} predictions, see Figure 1. In the prediction mode there is a through coupling, of the various elements. The prediction procedure is as follows, see Figure 1.

- Based on the observations from the most remote station, available up to the present time t, the u_2^0 signal is calculated which then serves as an input for the first ARMAX element after a time delay Δ^0;
- the u_1 input for the first ARMAX element should then be known up to time $t + \Delta^0$. Since $t + \Delta^0$ is Δ^0 time steps into the future, the u_1 calculations required are only possible when wind predictions are also available for the second station up to time $t + \Delta^0$;
- the identified first ARMAX element is then used to calculate recursively the E_{10} value y^1 at the second station up to t_1 time steps ahead, where t_1 corresponds to the maximum possible prediction time at the second station, Δ^0.
  The predicted value of E_{10} is subsequently used in the calculation of u_2^1 which serves as an input for the second ARMAX element after a time delay Δ^1;
- the u_1 input for the second ARMAX element should then be known up to the time $t + \Delta^0 + \Delta^1$, etc.

Hence, the maximum possible prediction time $T_p(\max)$ at the final station is determined by the summation of the delays Δ^i.

3. Some results

The ARMAX system is fully in operation and processes the data of four stations in the North Sea Monitoring Network. These stations, AUK, K13, LEG and BG2, are located in line with the dominant swell direction in the southern part of the North Sea, see Fig. 2. A typical performance of the prediction system is illustrated in Figures 4 and 5, which, for the period between 30 december 1984 and 5 january 1985, compare the E_{10} observations and the 5-hours ahead predictions. Figure 3 presents the meteorologic situation on weather charts at that period (Wensink 86a,

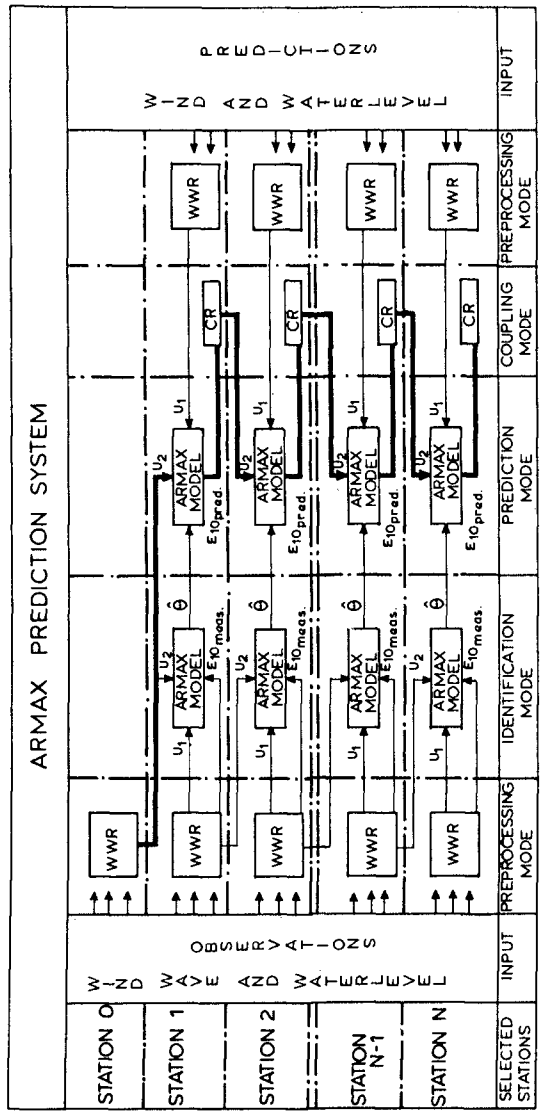

Fig. 1 Schematic representation of the ARMAX prediction system for N monitoring stations

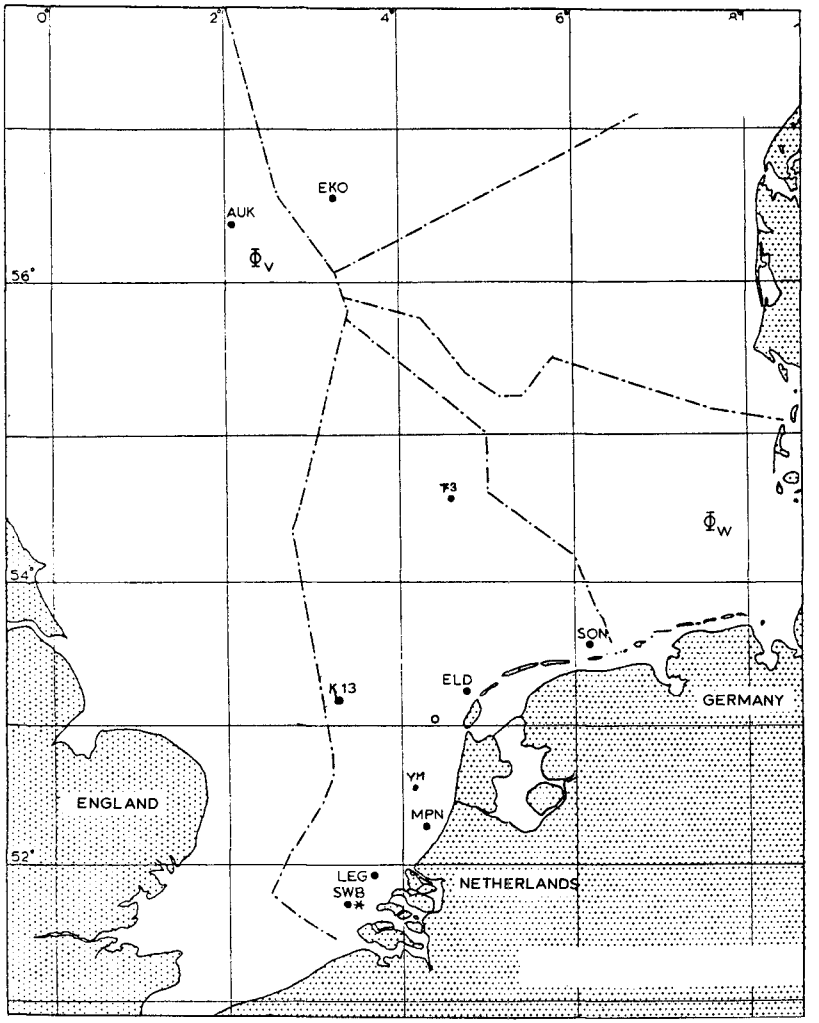

Fig. 2 The North Sea wave monitoring network

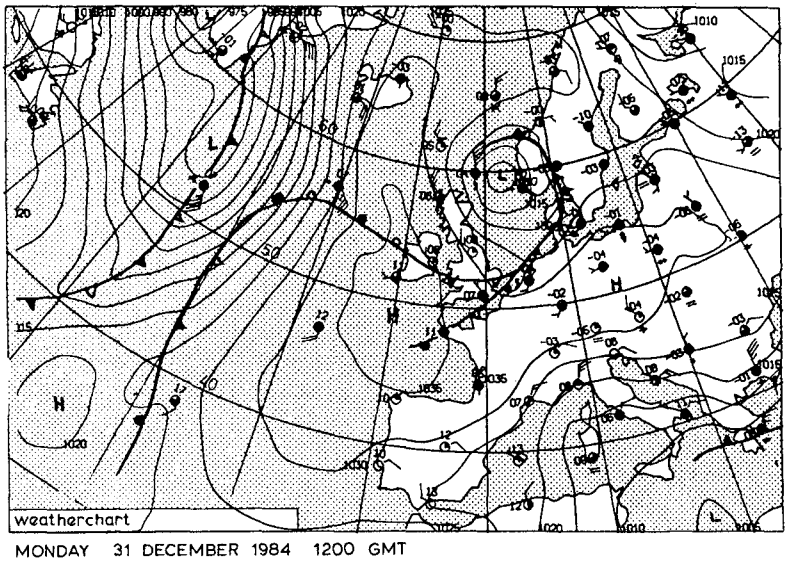

Fig. 3 Meteorological situation

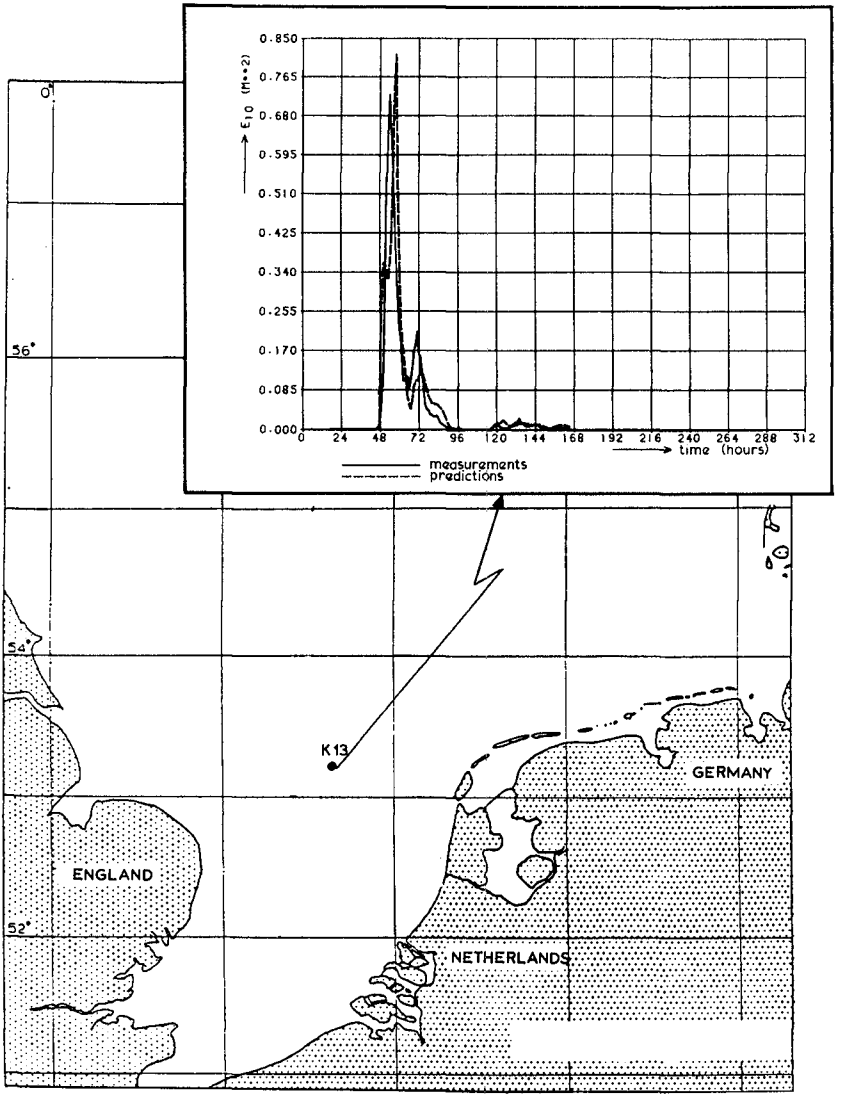

Fig. 4 The North Sea wave monitoring network

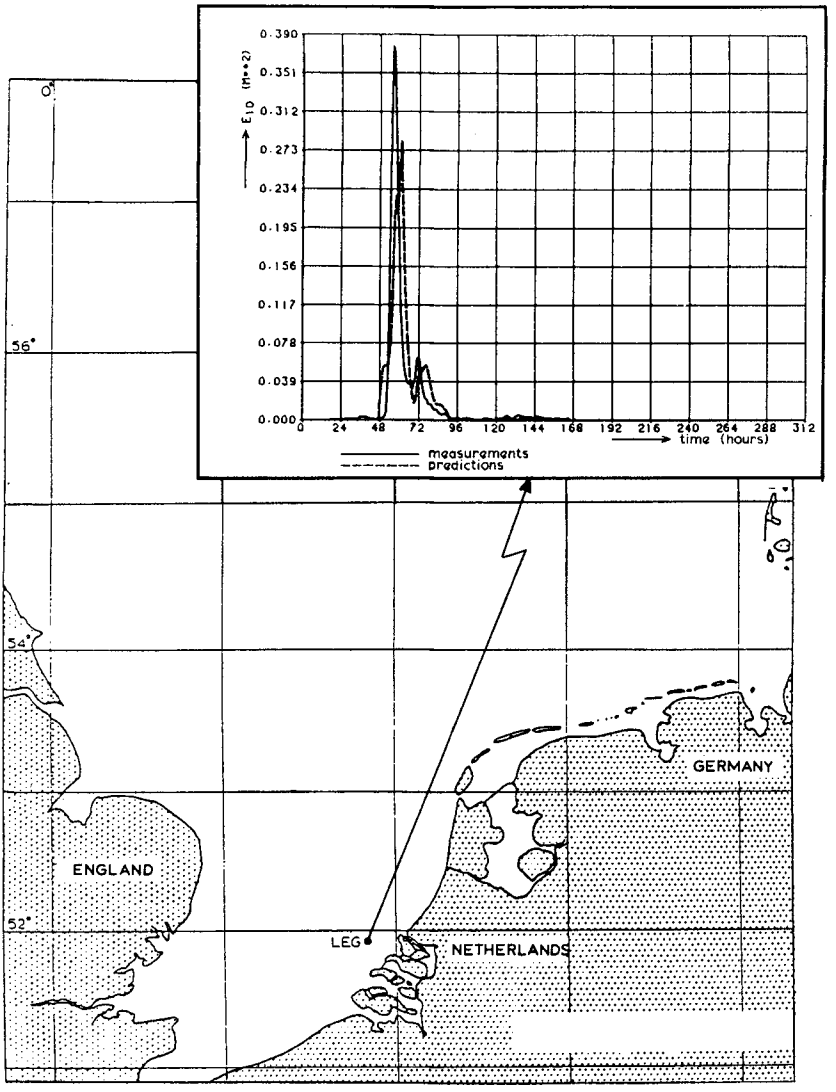

Fig. 5 The North Sea wave monitoring network

86b). Before the Norwegian coast a through of low pressure is moving to the South. On the west side of this through the wind speed increases from 2 m/s to 19 m/s. A combination of sea and swell is propagating into the North Sea. As can be seen in the Figures 4 and 5 the agreement is quite good. The differences between the predictions and observations are caused in part by an incorrect number of dispersion terms (r_1) and by an incomplete modelling of the wave physics.

4. Conclusions

The ARMAX system as described in this paper integrates, to a certain extent, observations and physical knowledge in one system. The system processes point measurements to predict wave energy at pre-selected locations.
Although the physical modelling as applied in the data pre-processing module is rather simple, the predictions are quite good.

The operational aspects of the prediction system can be summarized by:
- because of its size the system can be easily implemented on small computer systems
- because of its recursive parameter estimation algorithm the model has a short computing time
- because of its cascade structure it can be easily extended with more monitoring stations.

Because of its fast processing of new information the advantage of the model, as described here, is that in difficult meteorological conditions the ARMAX system gives immediate insight in the new hydrometeorological situation.

CHAPTER 64

A NUMERICAL MODEL OF NEARSHORE CURRENTS BASED ON A FINITE AMPLITUDE WAVE THEORY

by

Masataka Yamaguchi*

ABSTRACT

A numerical model of wave-induced nearshore currents taking into account the finite amplitude effect is developed, with a cnoidal wave theory used for the estimation of wave characteristics. The model is applied to the computation of wave transformation and nearshore currents on uniformly sloping beaches and on two-dimensional model topographies. The comparison with the results obtained by a linear model shows that wave nonlinearity has a strong influence on wave transformation in shoaling water and in the surf zone and on the strength of nearshore circulation, but that it does not have much effect on the longshore current profile. Moreover, the validity of the present model is supported by the quantitative agreement with the experiment for wave height variations, and the qualitative correspondence with the experiment for mean water level variation and longshore currents and the observation for nearshore currents.

1. INTRODUCTION

In most nearshore current models, the small amplitude wave theory has been used for the calculation of wave transformation in shoaling water, the resulting radiation stress which is a driving force of nearshore currents, and the wave-induced bottom shear stress. Since the effect of wave nonlinearity becomes more and more predominant just outside and inside of the surf zone, a nearshore current model taking account of the finite amplitude effect is needed for the purpose of better understanding and description of the coastal phenomena. Nevertheless, there have not been any such numerical models of nearshore currents applicable to an arbitrary bottom topography, although a few analytical models by James(1974) and Tsuchiya et al.(1979) using a finite amplitude wave theory, are available.

Because of the above-mentioned situation, the aim of this study is to develop a numerical model of nearshore currents taking the effect of wave nonlinearity into account, in which cnoidal wave theories derived by both the Stokes first and second definitions for wave celerity are used for the estimation of wave characteristics and to clarify the model behaviour and its applicability by comparison with the results based on a linear numerical model, experiments of wave transformation and longshore currents and observations of nearshore currents.

2. MODEL DESCRIPTION

(1) Wave transformation model

When the waves with wave number components (k_x,k_y) propagate on two-dimensional current (U,V), the governing equations of wave number components are derived from the irrotational condition of wave number components, the conservation equations of wave number components and the nonlinear dispersion relation of finite amplitude wave theory as

$$\begin{aligned}
&\frac{\partial k_x}{\partial t}+\frac{\partial}{\partial x}\left\{k_x\left(\frac{\partial \sigma_m}{\partial k}\cos\theta+U\right)\right\}+\frac{\partial}{\partial y}\left\{k_x\left(\frac{\partial \sigma_m}{\partial k}\sin\theta+V\right)\right\}\\
&=k_x\left[\frac{\partial|(\partial\sigma_m/\partial k)\cos\theta|}{\partial x}+\frac{\partial|(\partial\sigma_m/\partial k)\sin\theta|}{\partial y}\right]\\
&\quad+k_x\frac{\partial V}{\partial y}-k_y\frac{\partial V}{\partial x}-\frac{\partial\sigma_m}{\partial D}\frac{\partial D}{\partial x}-\frac{\partial\sigma_m}{\partial H}\frac{\partial H}{\partial x}\\
&\frac{\partial k_y}{\partial t}+\frac{\partial}{\partial x}\left\{k_y\left(\frac{\partial \sigma_m}{\partial k}\cos\theta+U\right)\right\}+\frac{\partial}{\partial y}\left\{k_y\left(\frac{\partial \sigma_m}{\partial k}\sin\theta+V\right)\right\}\\
&=k_y\left[\frac{\partial|(\partial\sigma_m/\partial k)\cos\theta|}{\partial x}+\frac{\partial|(\partial\sigma_m/\partial k)\sin\theta|}{\partial y}\right]\\
&\quad+k_y\frac{\partial U}{\partial x}-k_x\frac{\partial U}{\partial y}-\frac{\partial\sigma_m}{\partial D}\frac{\partial D}{\partial y}-\frac{\partial\sigma_m}{\partial H}\frac{\partial H}{\partial y}
\end{aligned}\tag{1}$$

in which k is the wave number, θ the wave direction, $\partial\sigma_m/\partial k$ the propagation velocity corresponding to the group velocity in the case of small amplitude wave theory, σ_m the relative angular frequency, D(=h+η) the total water depth including the mean water level variation η, h the still water depth and H the wave height. It is seen that the effect of wave nonlinearity is introduced into eq. (1) explicitely through $(\partial\sigma_m/\partial H)\partial H/\partial x$ and $(\partial\sigma_m/\partial H)\partial H/\partial y$ and implicitely through $\partial\sigma_m/\partial k$ and $\partial\sigma_m/\partial D$. The equations are written in the conservative form for the convenience of their numerical integration using a finite difference method.

The energy balance equation with the energy dissipation term due to wave breaking is given by Phillips(1969) as

$$\begin{aligned}
&\frac{\partial}{\partial t}\left(E_n-\frac{M_x^2+M_y^2}{2\rho D}\right)+\frac{\partial}{\partial x}\left(UE_n+F_x-\frac{M_x^2+M_y^2}{2\rho D}\tilde{U}\right)\\
&\quad+\frac{\partial}{\partial y}\left(VE_n+F_y-\frac{M_x^2+M_y^2}{2\rho D}\tilde{V}\right)+S_{xx}\frac{\partial U}{\partial x}+S_{xy}\frac{\partial V}{\partial x}\\
&\quad+S_{yx}\frac{\partial U}{\partial y}+S_{yy}\frac{\partial V}{\partial y}-\frac{M_x}{\rho D}\frac{\partial S_{xx}}{\partial x}-\frac{M_y}{\rho D}\frac{\partial S_{xy}}{\partial x}\\
&\quad-\frac{M_x}{\rho D}\frac{\partial S_{yx}}{\partial y}-\frac{M_y}{\rho D}\frac{\partial S_{yy}}{\partial y}=-E_{bw}
\end{aligned}\tag{2}$$

in which E_n is the wave energy, M_x and M_y the wave-induced mass flux components, $\tilde{U}$ and $\tilde{V}$ the nearshore current components including the effect of mass flux, F_x and F_y the energy flux components, S_{xx}, S_{xy} and S_{yy} the radiation stress tensor including the effect of mass flux and ρ the density of fluid. The nearshore current components and the integral properties are defined by the following expressions.

$$\tilde{U}=U+M_x/\rho D,\ \tilde{V}=V+M_y/\rho D$$

$$M_x=M\cos\theta,\ M_y=M\sin\theta,\ M=\overline{\int_{-D}^{\xi}\rho u dz}$$

$$E_n=E_p+E_k,\ E_p=\rho g\overline{\xi^2}/2,\ E_k=\overline{\int_{-D}^{\xi}\rho(u^2+w^2)dz}/2$$

$$F_x=F\cos\theta,\ F_y=F\sin\theta \tag{3}$$

$$F=\overline{\int_{-D}^{\xi}|\rho(u^2+w^2)/2+p+\rho gz|udz}$$

$$S_{xx}=S_{11}\cos^2\theta+S_{22}\sin^2\theta-M_x^2/\rho D$$

$$S_{xy}=S_{yx}=(S_{11}-S_{22})\cos\theta\sin\theta-M_xM_y/\rho D$$

$$S_{yy}=S_{11}\sin^2\theta+S_{22}\cos^2\theta-M_y^2/\rho D$$

$$S_{11}=\overline{\int_{-D}^{\xi}(\rho u^2+p)dz}-\rho gD^2/2,\quad S_{22}=\overline{\int_{-D}^{\xi}pdz}-\rho gD^2/2$$

in which ξ is the surface displacement, u and w the wave-induced horizontal and vertical water particle velocity components, p the wave pressure, g the acceleration of gravity, E_p the potential energy, E_k the kinetic energy, and the overbar means time average over one wave period.

The estimation of energy dissipation due to wave breaking is done by either of two methods. The first one is to assume that the wave height exceeding the breaking wave height specified by the local characteristics of waves and water depth does not exist in the surf zone, and the breaker index used for the estimation of breaking wave height is

$$\frac{H_{br}}{L_{br}}=a\tanh\frac{2\pi D_{br}}{L_{br}} \tag{4}$$

in which L is the wave length and subscript 'br' means breaking waves. The coefficient in eq. (4) is the constant depending on the beach slope i, and a=0.131 for i=1/50 and a=0.142 for i=1/30 are chosen from the consideration of the Göda breaker index respectively.

The second method is to rely on the bore model proposed by Battjes (1978). The energy dissipation rate due to wave breaking is expressed as

$$E_{bw}=\frac{B}{4\gamma^3}\frac{\rho gH^3\sqrt{gD}}{L}\left(\frac{H}{D}\right)^4,\ \gamma=0.7+5i \tag{5}$$

The coefficient for i<1/20 is given by Iwagaki et al.(1981) as

$$B=\begin{cases}11-10D/D_{br}\ ;\ 0.6\le D/D_{br}\le 1\\ 5\qquad\qquad\ ;\ D/D_{br}\le 0.6\end{cases} \tag{6}$$

In the numerical computation, the beach slope including the water surface slope $\partial D/\partial x$ is used rather than the beach slope itself.

(2) Nearshore current model

The equations used in the computation of nearshore currents are vertically-integrated continuity and momentum equations and they are written as

$$\frac{\partial \rho D}{\partial t}+\frac{\partial \tilde{M}_x}{\partial x}+\frac{\partial \tilde{M}_y}{\partial y}=0$$

$$\frac{\partial \tilde{M}_x}{\partial t}+\frac{\partial}{\partial x}(\tilde{U}\tilde{M}_x)+\frac{\partial}{\partial y}(\tilde{U}\tilde{M}_y)=-\rho g D\frac{\partial \eta}{\partial x}+\frac{\partial}{\partial x}\left(\bar{L}D\frac{\partial \tilde{U}}{\partial x}\right)$$

$$+\frac{\partial}{\partial y}\left(\bar{L}D\frac{\partial \tilde{U}}{\partial y}\right)-\left(\frac{\partial S_{xx}}{\partial x}+\frac{\partial S_{xy}}{\partial y}+\tau_{bx}\right) \tag{7}$$

$$\frac{\partial \tilde{M}_y}{\partial t}+\frac{\partial}{\partial x}(\tilde{V}\tilde{M}_x)+\frac{\partial}{\partial y}(\tilde{V}\tilde{M}_y)=-\rho g D\frac{\partial \eta}{\partial y}+\frac{\partial}{\partial x}\left(\bar{L}D\frac{\partial \tilde{V}}{\partial x}\right)$$

$$+\frac{\partial}{\partial y}\left(\bar{L}D\frac{\partial \tilde{V}}{\partial y}\right)-\left(\frac{\partial S_{yx}}{\partial x}+\frac{\partial S_{yy}}{\partial y}+\tau_{by}\right)$$

in which $\tilde{M}_x=\rho D\tilde{U}$, $\tilde{M}_y=\rho D\tilde{V}$.
The Longuet-Higgins expression(1970) is used as the lateral mixing term.

$$\bar{L}=N_c\rho l_x\sqrt{gD} \tag{8}$$

in which l_x is the distance measured from the shoreline and N_c the lateral mixing coefficient. The bottom shear stress is assumed to be proportional to the squared velocity, taking the wave orbital velocity into account. The definition of bottom shear stress components are given in

$$\tau_{bx}=\rho c_f(u_b\cos\theta+U)\sqrt{(u_b\cos\theta+U)^2+(u_b\sin\theta+V)^2}$$
$$\tau_{by}=\rho c_f(u_b\sin\theta+V)\sqrt{(u_b\cos\theta+U)^2+(u_b\sin\theta+V)^2} \tag{9}$$

in which C_f is the bottom friction coefficient in the wave-current system. Eq. (9) is numerically integrated by the Causs-Legendre formula in each iterative computation. In the actual simulation, the values of N_c and C_f are fixed to be 0.01 and 0.01 respectively.

3. WAVE CHARACTERISTICS AND INTECRAL PROPERTIES OF CNOIDAL WAVES

In the model, the wave characteristics and integral properties of waves are estimated from the second order solutions of the cnoidal wave theories derived using both the Stokes first and second definitions for wave celerity by Chappelear(1962) and by Tsuchiya & Yamaguchi(1972).

The wave characteristics based on the Chappelear theory using the first definition for wave celerity are given for wave celerity c, wave length L and horizontal water particle velocity at the bottom u_b as

$$c/\sqrt{gD}=1+L_2+L_0(1-e)+5L_0L_2(1-e)+L_0^2\{5+4\kappa^2-5(1+\kappa^2)e\}/3$$

$$L/D=4K/\sqrt{3L_0}$$

$$u_b/\sqrt{gD}=L_0(1-e)+L_0^2(5+4\kappa^2)/3-5L_0^2(1+\kappa^2)e/3+5L_0L_2(1-e) \tag{10}$$

$$-\{L_0\kappa^2+L_0^2\kappa^2(1+\kappa^2)+5L_0L_2\kappa^2\}\mathrm{sn}^2\beta x-L_0^2\kappa^4\mathrm{sn}^4\beta x$$

in which κ the modulus of the Jacobian elliptic function, e=E/K, K and E the complete elliptic integrals of the first and second kinds, sn the Jacobian elliptic function and $\beta x=2K(x-ct)/L$. The expansion parameters L_0 and L_3 in the above expressions can be obtained from the following

equations as a function of κ and H/D.

$$L_0\kappa^2\{1+L_0(10+7\kappa^2)/4+6L_2\}=H/D$$
$$2L_2+L_0(\kappa^2+e)+L_0^2\}-(1-6\kappa^2-9\kappa^4)/5+2(1+\kappa^2)e\}+6L_0L_4(\kappa^2+e)+L_2^2=0 \tag{11}$$

Considering the relation that $\sigma_m\sqrt{D/g}=(c/\sqrt{gD})kD$, the partial derivatives in eq. (1) can be computed from

$$\frac{1}{\sqrt{gD}}\frac{\partial\sigma_m}{\partial k}=\frac{-2\pi}{k^2D^2}\frac{\partial\{(c/\sqrt{gD})kD\}}{\partial(L/D)}$$
$$\sqrt{\frac{D^3}{g}}\frac{\partial\sigma_m}{\partial D}=-\frac{1}{2}\frac{c}{\sqrt{gD}}kD-\frac{H}{D}\frac{\partial\{(c/\sqrt{gD})kD\}}{\partial(H/D)}-\frac{L}{D}\frac{\partial\{(c/\sqrt{gD})kD\}}{\partial(L/D)} \tag{12}$$
$$\sqrt{\frac{D^3}{g}}\frac{\partial\sigma_m}{\partial H}=\frac{\partial\{(c/\sqrt{gD})kD\}}{\partial(H/D)}$$

These expressions are estimated by the numerical differentiation of $\sigma_m\sqrt{D/g}$ computed as a function of L/D and H/D.

The integral properties of the cnoidal waves were calculated by Yamaguchi(1977). However, it was found that the results for mass flux and radiation stress are not sufficient in order estimation. Recalculation of these properties was attempted by using the exact relations between the integral properties of finite amplitude waves. For example, the exact relation derived by Crapper(1979) was used in the calculation of radiation stress.

$$S_{11}=4E_k-3E_p+\rho D\overline{u_b^2},\quad S_{22}=E_k-E_p+\rho D\overline{u_b^2}/2 \tag{13}$$

Fig. 1 shows two examples of the wave characteristics and integral properties non-dimensionalized by the results based on the small amplitude wave theory. The dimensionless propagation velocity $\partial\sigma_m/\partial k$ in-

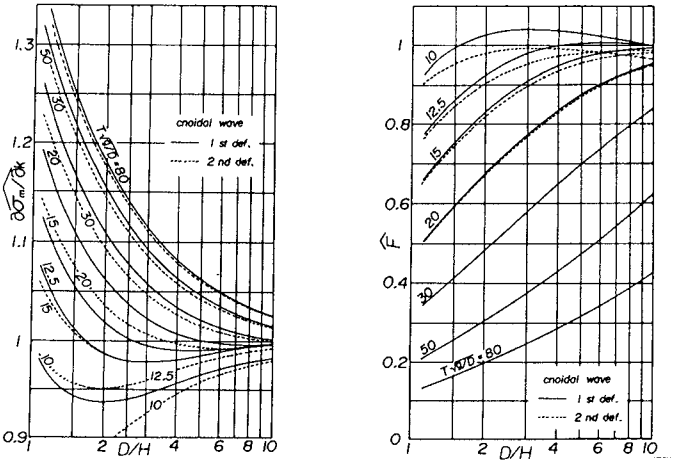

Fig. 1 Examples of wave characteristics and integral properties of cnoidal waves.

creases and the dimensionless energy flux $\hat{F}$ decreases with increasing values of $T\sqrt{g/D}$ and H/D in the case of larger values of $T\sqrt{g/D}$. The effect of the definitions for wave celerity on the wave characteristics and integral properties becomes more significant in the case of smaller values of $T\sqrt{g/D}$ and D/H, and the difference becomes negligible with the increase of these parameters. It is noted that the small amplitude wave theory overestimates or underestimates the wave characteristics including the integral properties of waves and that because of the limitation to practical applicability, the cnoidal wave theory should be used in the range of $T\sqrt{g/D}>12$.

4. NUMERICAL MODEL OF NEARSHORE CURRENTS

(1) Finite difference formulation

A finite difference method is used to solve the governing equations. Fig. 2 is the coordinate system used, in which x axis and y axis are taken in the offshore direction and in the longshore direction respectively. Finite difference approximation for the equations of wave number components and the energy balance equation which constitute the wave transformation model is made by forward difference in time and x direction and by central difference in y direction. The continuity and momentum equations which make up the nearshore current model are discretized by the forward difference with respect to the time variable and by the central difference with respect to the space variables, and finite differencing of these equations is lagged a half step in time. Fig. 3 shows the configuration of variables in the finite difference model. Current components and bottom shear stresses are defined on the grid sides and all other variables are estimated at the grid center.

The initial condition and the conditions for the offshore fixed boundary used in the nearshore current model are the usual ones. In the longshore direction, the periodic boudary condition proposed by E. Noda (1974) is imposed on all the variables relevant to the computation. In

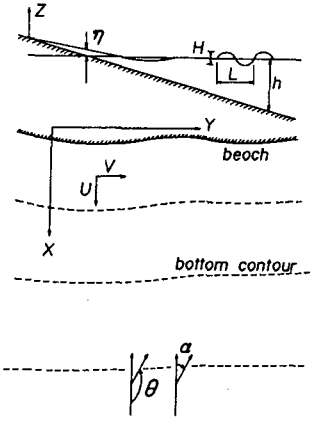

Fig. 2 Coordinate system used in nearshore current model.

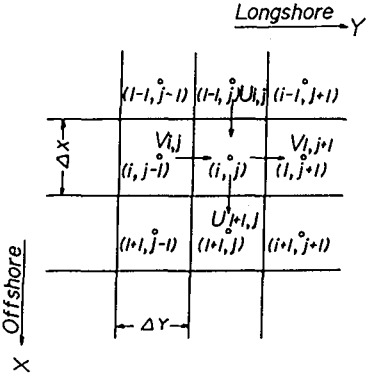

Fig. 3 Configurations of variables in finite difference model.

the wave transformation model, the specified values of wave characteristics are given at the offshore boundary, but any conditions of wave characteristics at an onshore boundary are not required in the case of a straight shoreline because of the property of the finite difference method used.

The computer program starts with determining the spatial distribution of wave characteristics according to the analytical solution of wave transformation on the parallel bottom contour based on the small amplitude wave theory, and the wave characteristics at the first step are computed from the nonlinear wave transformation model. Then, the nearshore current computation is carried out using the radiation stress estimated from the wave transformation model. Thus, one iteration is completed by these computations.

A steady state solution is obtained by 1400 to 2000 iterations of alternating computations between wave transformation and nearshore currents. At an early stage of iterative computation, the input wave height is increased gradually in order to avoid the appearance of numerical instability and to accelerate the convergence to a steady state solution. In the computation of wave transformation, the energy dissipation due to wave breaking is estimated by either the bore model or the breaker index model, when the wave height exceeds the breaking wave height given by eq. (4).

(2) Interpolation of wave characteristics

The wave information obtained directly from each computation of wave transformation is k_x, k_y (L and θ) and E_s ($=E_n - M^2/2\rho D$). When the small amplitude wave theory is used, the effect of mass flux is usually neglected and then the wave height is easily computed from the relation that $E_n=(1/8)\rho g H^2$. On the contrary, when a cnoidal wave theory is used, it is not easy to transform from E_s to H and the numerical computation of the other wave characteristics is also time-consuming, because their expressions are lengthy and contain the elliptic integrals.

In this study, the following method is adopted to save computer processing time. First, the numeric tables of the wave characteristics including the integral properties of waves computed in the range of L/D =5 - 150 every 1 increment and of H/D=0.01 - 1.30 every 0.01 increment are prepared in advance. The wave characteristics tabulated are $c/\sqrt{gD}$, $(\partial\sigma_m/\partial k)/\sqrt{gD}$, $\sqrt{D^3/g}\,\partial\sigma_m/\partial D$, $\sqrt{D^3/g}\,\partial\sigma_m/\partial H$, $E_n/(\rho g D^2/8)$, $E_s/(\rho g D^2/8)$, $M/\rho D\sqrt{gD}$, $S_{11}/\rho g D^2$, $S_{22}/\rho g D^2$, $F/(\rho g D^2\sqrt{gD})$, and κ, L_0, L_3, K and E required in the computation of u_b. Next, a two-dimensional linear interpolation formula is applied to estimate the wave characteristics corresponding to the values of L/D and H/D obtained in each iteration.

$$
\begin{aligned}
&f=a'f_{ij}+b'f_{ij+1}+c'f_{i+1j}+d'f_{i+1j+1}\\
&a'=(1-r)(1-s),b'=r(1-s),c'=(1-r)s,d'=rs\\
&i=[L/D],\ \ j=[100(H/D)]\\
&r=L/D-[L/D],\ \ s=100(H/D)-[100(H/D)]
\end{aligned}
\tag{14}
$$

in which f is the interpolated value, f_{ij} the value of f on the numeric table for the i-th L/D and the j-th H/D and [ ] the Gauss's symbol. The computation of sn function in the expression of u_b is obtained through the theta function in the usual manner, although an approximation such as $\mathrm{sn}\,\beta x \approx \tanh \beta x$ is used in the case of $\kappa > 1-10^{-6}$.

A similar method can be used in the conversion of E_S to H. As $E_S/(\rho g D^2/8)$ is a function of H/D for a fixed L/D, the numeric table of H/D inverted as a function of $E_S/(\rho g D^2/8)$ can be made by applying the linear interpolation formula to the numeric table of $E_S/(\rho g D^2/8)$. Two kinds of tables of H/D given as a function of L/D and $E_S/(\rho g D^2/8)$ are produced to keep the accuracy of interpolated results and to save computer storage memory, in which the range of $E_S/(\rho g D^2/8)$ are 0.001 - 0.15(0.001 increment) and 0.15 - 1.50(0.01 increment) respectively.

After all, the value of H/D corresponding to L/D and $E_S/(\rho g D^2/8)$ computed in each iteration can be interpolated from the H/D-tables, and then the wave characteristics for L/D and H/D can be evaluated by the application of the linear interpolation formula, eq.(14). It is emphasized that since this method is applicable for not only a cnoidal wave theory but also another higher order finite amplitude wave theory, the incorporation of the theory into a nearshore current model is easily possible for its improvement.

5. COMPUTATIONAL RESULTS AND CONSIDERATION

(1) Uniformly sloping beach

The computation is carried out on a plane beach with the slope of 1/30 and constant water depth of h=8 m in the offshore region. The following input conditions are used; the incident wave height H_M=2 m, the wave period T_M=12.5 s and the incident angle of waves $\alpha_M(=\pi-\theta_M)$=30°. Suffix 'M' means the value at the offshore boundary.

In Fig. 4, the results in the nonlinear model are depicted with those in the linear model developed by the authors(1983). Rapid increase of the wave height before wave breaking due to nonlinear shoaling and rapid decay of the wave height due to wave breaking are observed in the nonlinear model using the bore model, and the wave height after wave

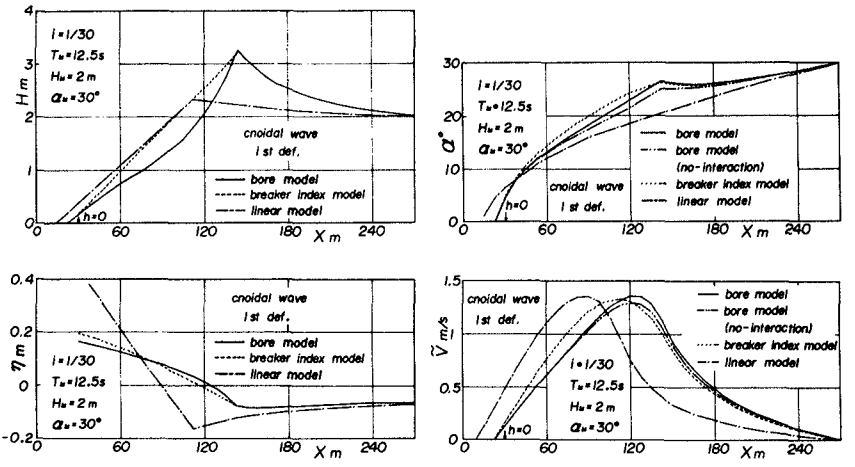

Fig. 4 Change of wave height, wave direction and mean water level variation and longshore current profile on a uniformly sloping beach.

breaking based on the bore model diminishes more rapidly than that based on the breaker index model. While the wave direction in the linear model decreases steadily toward the shore, the wave direction in the nonlinear model slightly increases just before wave breaking and it decreases steadily as well after wave breaking. This is mainly due to the wave-current interaction, because the tendency almost disappears when the effect of the interaction is omitted in the computation.

The wave setup and setdown in the vicinity of the breaking point in the linear model is much greater than those in the nonlinear model, because the small amplitude wave theory overestimates the radiation stress in comparison with a finite amplitude wave theory, as is well known. It is also interesting to note that the current profile and the magnitude in the nonlinear model are similar to those in the linear model, although the peak position of the current profile in the nonlinear model is at a greater water depth.

From the above argument, it is summarized that the wave nonlinearity has a strong influence on the offshore distribution of wave height, wave direction and mean water level variation, and the peak position of longshore currents, but that it does not have much effect on the longshore current profile itself.

Fig. 5 shows the results of wave height variation and the longshore current profile computed on a uniformly sloping beach with a longshore bar. The input conditions are the same as those for a uniformly sloping beach. It is assumed in the computation that the energy dissipation due to wave breaking does not occur on the inversely sloping beach. In the nonlinear model, the waves break after rapid increase of the wave height due to nonlinear shoaling on the offshore regularly sloping beach and propagate with loss of their heights on the inversely sloping beach. Then, the waves again increase their heights due to nonlinear shoaling on the onshore regularly sloping beach and finally dissipate their energy after the second wave breaking. On the other hand, in the linear model, the waves break on the onshore regularly sloping beach after gradual change of the wave height with water depth variation. As a result, the longshore current profile in the nonlinear model has a two peak structure, while the one in the linear model has a single peak structure as well as the result on a uniformly sloping beach.

Thus, it can be said that the correct estimation of the breaking point is of great importance in the longshore current prediction on a bar-trough beach profile.

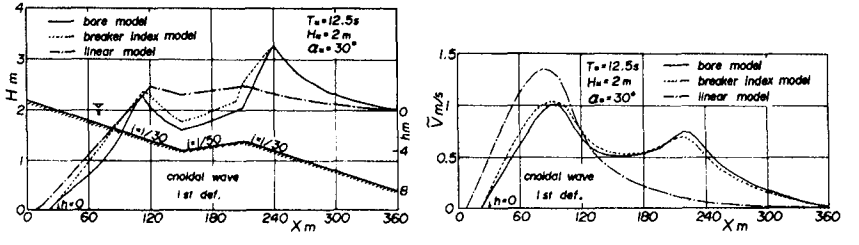

Fig. 5 Change of wave height and longshore current profile on a uniformly sloping beach with a longshore bar.

(2) Two-dimensional bottom topography

The bottom topography model developed by E. Noda(1974) is chosen to the computation of nearshore currents on a two-dimensional topography and it is expressed as

$$h(x,\ y)=ix\left[1+A_0\exp\left\{-3\left(\frac{x}{45}\right)^{1/3}\right\}\sin^2\left\{\frac{\pi}{\lambda}(y-x\tan\varepsilon)\right\}\right] \tag{15}$$

in which i is the mean beach slope of 0.015, λ the longshore beach length of 400 m, A_0 the maximum amplitude of the bottom undulation of 20 m and ε the skewness of the bottom undulation of 0° or 30°. It should be noted that the above expression has different constants from the original one by E. Noda(1974). The model topography with ε=0° and the one with ε=30° are referred to as symmetrical concave topography and asymmetrical concave topography respectively.

Fig. 6 describes the nearshore current pattern on a symmetrical concave topography with normal incidence of waves computed by both the linear and nonlinear models, in which the solid line is the contourline of water depth, and the dotted line indicates an approximate breaker line evaluated from eq. (4). Incident wave height H_M is 1 m and the other conditions are the same as in the case for a uniformly sloping beach. In both the figures, we can see the formation of a pair of dominant nearshore circulation cells centered on a breaking point and a pair of very weak and flat cells near the shoreline. But, the strength of current velocity in the nonlinear model is relatively weaker than that in the linear model and the center of the dominant circulation cell in the nonlinear model also locates in farther offshore region with the movement of the breaking point.

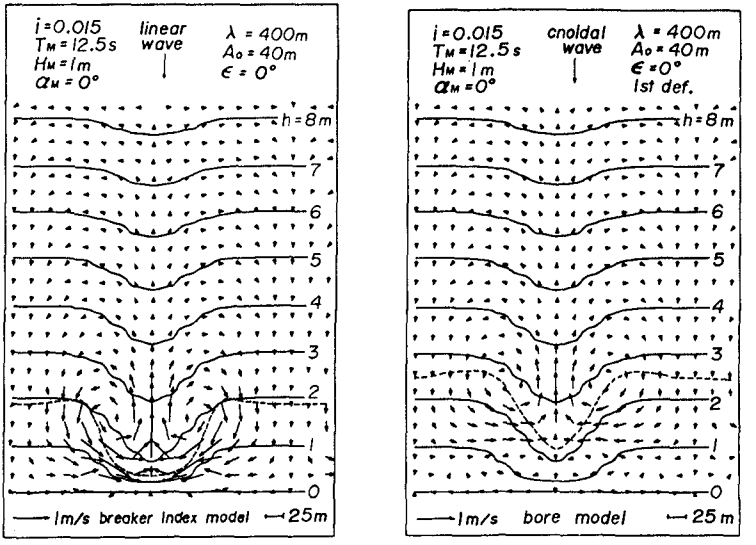

Fig. 6 Nearshore current pattern on symmetrical concave topography.

Fig. 7 is the nearshore current pattern on an asymmetrical concave topography with oblique incidence of waves, in the case where the input wave height H_M is 2 m. It is found in both the figures that the meandering longshore current is predominant and that a counterclockwise circulation cell is formed in the trough region near the shoreline by the effect of concave bottom topography. The scale and strength of a circulation cell in the linear model are greater than those in the nonlinear model.

It can be said from the two examples mentioned above that the wave nonlinearity acts so as to suppress the formation and growth of the nearshore circulation cell.

When a method combining a wave ray technique with a linear interpolation formula is used for the numerical integration of the equations of

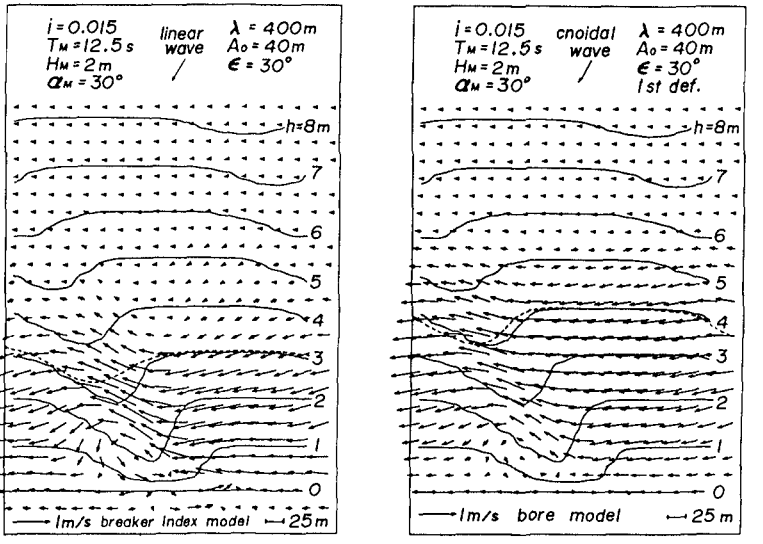

Fig. 7 Nearshore current pattern on asymmetrical concave topography.

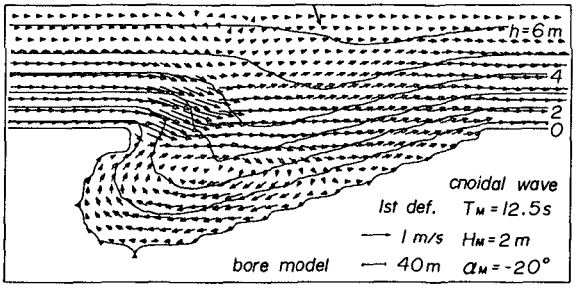

Fig. 8 Nearshore current pattern on curved bay.

wave number components and the energy balance equation, nearshore current pattern on a two-dimensional bottom topography with an arbitrary shoreline can be obtained as shown in Fig. 8, which demonstrates the predominant longshore currents in the outer region and a clockwise nearshore circulation in the inner region.

6. VERIFICATION OF NEARSHORE CURRENT MODEL

(1) Comparison with experiment

Fig. 9 is the comparison of the computed results with the experimental ones for the change of wave height and mean water level variation on a uniformly sloping beach of 1/34.26 conducted by Hansen & Svendsen(1979). As for the wave height variation, the result in the nonlinear model using a cnoidal wave theory of the second definition for wave celerity rather than the first definition for wave celerity gives slightly better agreement with the experiment, and the linear model can not explain rapid increase of wave height before wave breaking.

On the contrary, the nonlinear model underestimates the wave setdown and setup, although it can reproduce the qualitative trend in the experiment. In general, it has been known from experiments that the transition of wave setdown to setup does start from the plunge point rather than the breaking point. However, the present model, as well as the previous models, does not formulate this phenomena. The linear model overestimates the wave setdown in the vicinity of the breaking point and wave setup near the shoreline, although some fraction of the wave setup seems to agree well with the experimental results in appearance.

Fig. 10 indicates the comparison of the computed result with the experimental one for longshore currents on a uniformly sloping beach

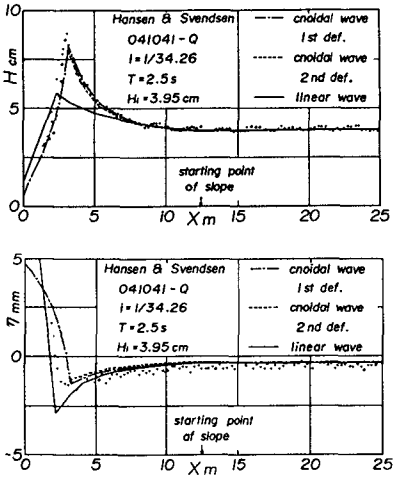

Fig. 9 Comparison between computation and experiment for wave height and mean water level variation.

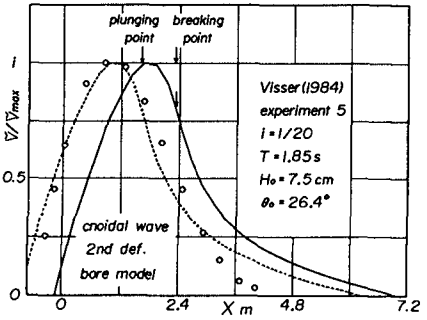

Fig. 10 Comparison between computation and experiment for longshore currents.

with the slope of 0.05 measured by Visser(1984). The current profile itself in the nonlinear model is similar to the experimental profile and the location of the breaking point in the model is in good agreement with that in the experiment. However, in order to get a close agreement with the experiment, the computed result has to be shifted toward the shoreward by approximately the amount of the plunge point distance.

(2) Comparison with observation

Fig. 11 shows the nearshore current pattern re-evaluated from the observation of transport velocity by Sonu(1972) and the corresponding nearshore current pattern computed by the nonlinear model. In the model, the energy dissipation due to wave breaking is estimated by the bore model, and a cnoidal wave theory based on the first definition is used. The input wave conditions given at the offshore boundary are that T_M=5 s, H_M =0.2 m and α_M=0°. The bottom topography used in the computation is slightly modified to be periodic in the longshore direction and to have a straight shoreline. The model reproduces well the qualitative features of the complicated nearshore current pattern found in the observation, such as the onshore currents in both sides of the region and the rip currents in the central part of the region. But, in a quantitative sense, the model appears to give less velocity than the observation.

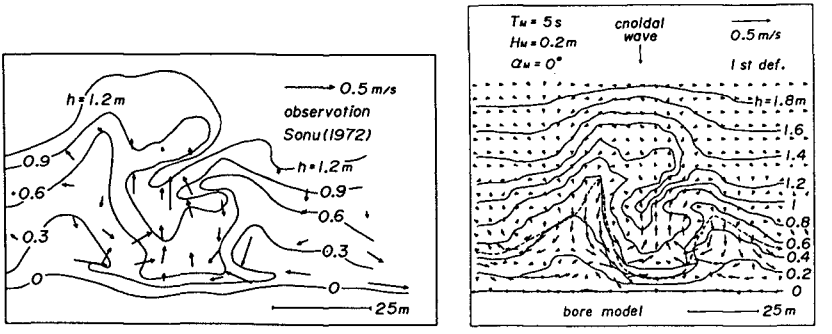

Fig. 11 Nearshore current pattern observed by Sonu(1972) and the corresponding result computed by the nonlinear model.

7. CONCLUSIONS

The main conclusions of this study are summarized as follows.

i) A nonlinear model of nearshore currents was developed, in which the estimation of wave characteristics is based on a cnoidal wave theory.

ii) The wave nonlinearity has a strong influence on the offshore distribution of wave height, wave direction and mean water level variation and the peak position of longshore currents, but it does not have much effect on the longshore current profile itself.

iii) The wave nonlinearity acts so as to suppress the formation and growth of nearshore circulation currents.

iv) The nonlinear model quantitatively predicts the change of wave height in shoaling zone and in the surf zone. It also qualitatively produces the mean water level variation, longshore current profile and nearshore circulation pattern.

v) It is necessary to make allowance for the effect of plunge point distance in the model formulation in order to obtain better agreement with the experimental data on wave setup and longshore currents.

8. ACNOWLEDGEMENT

Thanks are due to Mr. H. Kawahara, Graduate Course student of Ocean Engineering, Ehime University for his valuable help during the study. A part of this study was accomplished with the support of the Science Research Fund of the Ministry of Education, for which the authors express their appreciation.

CHAPTER 65

Grouping Waves and Their Expression on Asymptotic Envelope Soliton Modes

T. Yasuda[1], M. ASCE , N. Nakashima[2] and Y. Tsuchiya[3], M. ASCE

ABSTRACT

An approach, that treats natural sea states with remarkable groupiness as random sequences of envelope solitons, is suggested here to explain their dynamical and statistical properties from the viewpoint that wave packets contained in the states have their own characteristics and should be regarded as elementary modes. Some examinations are made on its applicability to the temporally observed waves. And the approach is shown to be effective also for waves with a non-zero nonlinearity and finite spectral band-width. Further, a formulation based on envelope solitons is made on the wave drifting force and is shown to be useful for analyzing the time series of drifting forces.

INTRODUCTION

The wave grouping such as runs of consecutive high waves or small waves in nature has been shown to occur more often and to contain more waves than would be expected if waves are completely random. The potential consequences are often quite significant in both offshore and coastal activities. It is well-known, [for example, Spangenberg, 1980] , that many moored offshore structures and floating vessels suffer a great influence of the wave grouping and their responses become maxima when the period of the wave groups is equal to or lies in the vicinity of the natural periods of the moored systems. With the progress of ocean development and coastal activities, the concern on the wave grouping has been grown and various investigations have been made theoretically and experimentally on wave grouping characteristics. However, usual investigations in engineering sides are based on the assumption of a narrow banded Gaussian process and lack the fact that the wave grouping is due to weak but non-zero nonlinearity and should be treated as a nonlinear phenomenon, so that they have limits in evaluating dynamical characteristics of grouping waves.

Wave systems that depend on the band-width and nonlinearity may exhibit component dispersion ranging from that given by the linear dispersion to that of an effectively nondispersive phase-locked system in which wave components propagate essentially with a single speed. This demonstrates that the Fourier spectrum representation and the

associated Gaussian random wave theory do not comprise an entirely satisfactory analysis technique forsea states with non-zero nonlinearity. Recent researches on waves with a weak nonlinearity and narrow band-width [for ex. Yuen & Lake, 1982] made clear that the description of grouping waves contained in the wave field provided by the nonlinear Schrödinger(NLS) equation and the Zakharov equation is qualitatively and quantitatively correct and nonlinear effects on the formation of wave groups are significant. It has been already stated [Sobey & Colman, 1982] that the envelpe soliton bears a remarkable resemblance to the common appreciation of wave groups. However, waves in field have spectra with a finite band-width and nonlinear aspects such as peaking of wave crests and flattening of troughs, so that it is difficult to apply directly the NLS equation to them and some trials[for ex. Stiassinie and Shemer, 1984] using the Zakharov equation has not been applied successfully in describing them.

The nature of wave groups in field is a little bit made clear, although their natural occurrence is not in doubt. It is not also clear whether the wave groups are spatially stable or not and they can be regarded as wave packets with soliton properties, that is, envelope solitons or not. However, it is the well-known fact that a nonlinear wave packet, that is, envelope soliton is a stable grouping although linear wave packets are destroyed eventually by dispersion and are spatially unstable. It is, therefore, natural to suppose that waves after having travelled a long distance are generally in a stable state and may have a coherent structure making some stable mode elementary excitation and that the stable wave group contained in the waves can be regarded as a kind of such elementary excitation. This viewpoint is quite different from usual ones interpreting the wave group as a consequence of a mere superposition of some carrier waves and a stochastic sequence of zero-crossing waves. If the wave group has its own characteristics and can be treated as elementary mode of waves with remarkable groupiness, an approach for treating the wave group as elementary mode may become possible for explaining properties of the grouping waves. This approach may be expected to be effective for analyzing the time series of the wave drifting force caused by the existence of wave groups.

In this study, by investigating wave grouping characteristics of waves observed at various locations, we show that they remarkably depend on nonlinear effects and the frequency of carrier waves associated with each wave group is not necessarily identical with the peak frequency of the spectrum and distributes over a finite band-width. Then, all wave groups accompanied with the waves are treated as envelope solitons and their envelope profile is represented as a random train of asymptotic envelope solitons. Some examinations are made on the applicability of the theoretical result to the waves observed temporally at fixed positions and the envelope soliton mode representation is shown to be possible for their envelope profiles. Further, this representation is extended to the formulation of the wave drifting force.

GROUPING CHARACTERISTICS OF OBSERVED WAVES

1. Spectral Band-Width and Nonlinearity

Field data were collected from various observatories locating off Gobo coast (G1-8, Oct. 1979) facing the Pacific ocean, off Ogata coast (O1-12, Mar. 1981) facing the Japan sea, off Caldera Port in Costa Rica (C1-4, May 1981) facing the Pacific ocean and at Lake Biwa (B1-10, Oct. 1975). The data were obtained by the temporal observations of water surface displacements at fixed positions. Table 1 summarizes values of wave parameters calculated from these data. In the table,

h denotes the mean water depth, f_p the peak frequency of the power spectra, ν the spectral band-width parameter defined by

$$\nu=[1-m_2^2/(m_0m_4)]^{1/2} \quad , \qquad m_n=\int_0^\infty f^n S(f)df \quad , \tag{1}$$

in which f is the wave frequency, k_p the wave-number corresponding to f_p through the linear dispersion relation, $\sqrt{\beta_1}$ the skewness, U_r the Ursell number, GF the Groupiness Factor defined by Funke and Mansard 1979 , p the probability of the wave-height H of zero-up crossing wave exceeding

the average wave-height $\bar{H}$, and $\bar{j}_1$ the average run length of the zero-up crossing waves exceeding $\bar{H}$. It is easily noticed from this table that all values of ν exceed 0.7 and are near unity rather than zero , that is, observed waves to be used here have not a narrow but finite spectral band-width. The values of skewness $\sqrt{\beta_1}$ of the observed waves except for G5 exceed 0.01 and indicate that their water surface displacements are influenced by nonlinearity. The values of U_r also show that the observed waves have a finite nonlinearity in comparison with a frequency dispersion. Hence, it may be said from these results that the observed waves can not be analyzed on the basis of a narrow-banded Gaussian process.

2. Wave Grouping Characteristics

GF and $q\bar{j}_1$ are used here as the criteria representing wave grouping characteristics. q is the complementary number of p and is defined as 1-p. The value of $q\bar{j}_1$ is unity when the time series of the wave-heights of zero-up crossing waves are completely random. Since a modulational instability occurs when kh>1.36 in the wave field provided by the NLS equation and then envelpoe solitons are formed, kh is used here as the instability criterion relating to the formation of envelope solitons. Figure 1 shows the relation of GF and $q\bar{j}_1$ vs. kh. The value of $q\bar{j}_1$ is slightly inclined to increase with the increasing of the value of 1/kh, although varying remarkably in the region of kh<1.36. While, the value of GF is almost independent of kh. If wave groups possessed in one wave record have the identical carrier frequency with the peak frequency f_p and are governed by the single NLS equation, their envelope profiles shoud be flattened when the value of kh falls below 1.36. That is, as the value of kh gets to be below 1.36 and further decreases, GF should decrease and $q\bar{j}_1$ should increase. However, such a definite trend can not be found out and the outward profile of wave groups is supposed to be still stable even under the value of kh being below 1.36. It, therefore, may be said that wave groups possessed in the waves with a finite nonliearity and finite spectral band-width are still stable in the region, kh<1.36 and that the wave grouping characteristics are almost independent of the value of kh calculated from the peak frequency f_p and

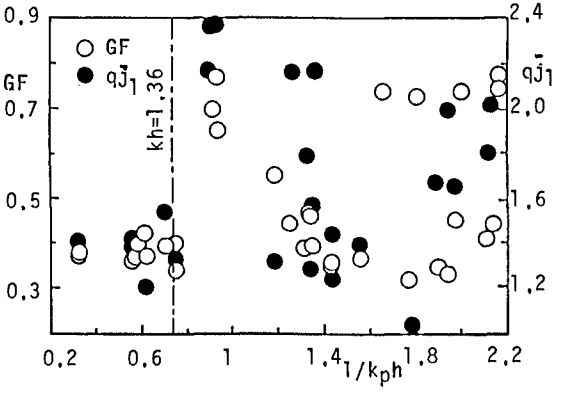

Fig. 1 Relation of kh vs. GF and $q\bar{j}_1$

should be investigated in relation to nonlinearity.

Figure 2 shows the relation of GF and $q\bar{J}_1$ vs. the Ursell number U_r. It is easily noticed from the figure that the wave grouping characteristics evaluated by $q\bar{J}_1$ and GF definitely depends on the ursell number, that is, both values of $q\bar{J}_1$ and GF increase as the value of U_r increases until reaching about 8 and then they suddenly begin to decrease just after the value of U_r exceeds about 8. This states that the degree of groupiness of random waves with a finite nonlinearity and spectral band-width depends on the nonlinearity itself. It, further, is imagined that the wave groups once formed are conserved as stable modes and may be regarded as elementary modes of waves with a non-zero nonlinearity when U_r is less than 5 or 6 and that their associated carrier waves turn to a train of solitons when U_r exceeds about 8 and then are made stable .

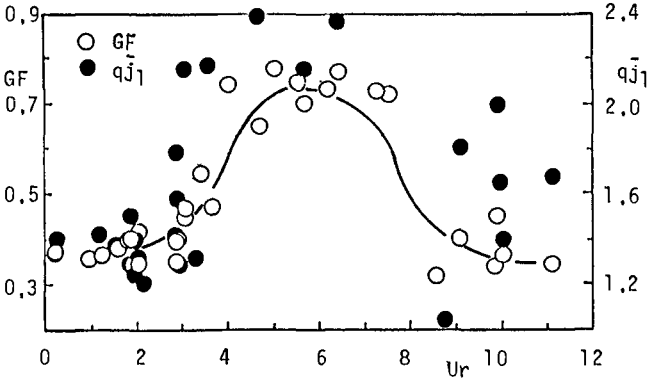

Fig. 2 Relation of U_r vs. GF and $q\bar{J}_1$

Figure 3 shows the relation between the run length j_1 and the ratio $T/\bar{T}$. Where, T is the zero-up crossing period averaged over the consecutive high waves constituting one wave group. $\bar{T}$ is the zero-up crossing period averaged over one record of the observed waves. If all wave groups included in the observed wave can be described by the multi-soliton solution of the single NLS equation, each wave group has the identical carrier frequency with the peak frequency f_p and T agrees with $\bar{T}$. However, it is seen that the ratio $T/\bar{T}$ is not necessarily unity and there is a definite correspondence between j_1 and $T/\bar{T}$. The period of carrier waves associated with one wave group becomes larger as the run length j_1 increases, that

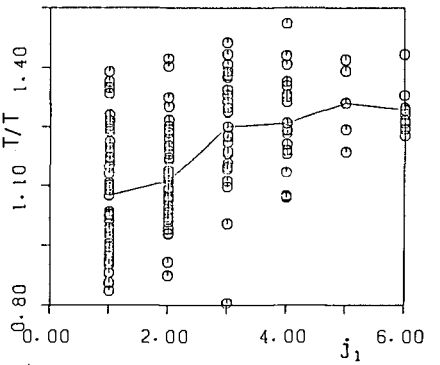

Fig. 3 Relation between the run length and wave period of carrier waves of each wave group

is, the wave group grows up. This says that each wave group accompanies a carrier wave with its own wave period independent of other wave groups.

ASYMPTOTIC ENVELOPE SOLITON MODE REPRESENTATION

1. Fundamental Assumptions

The observed results shown in the preceding chapter revealed that the wave grouping depends on U_r rather than kh and can not be sufficiently explained by the modulational instability under a narrow-band spectrum . This states that the wave groups are formed on the basis of nonlinear dynamics and behave as stable wave packets. Hence, we suggest an approach to treat them as envelope solitons governed by the plural NLS equations, although we can not verify its validity. The motive of this approach is based on the viewpoint that waves with remarkable groupiness have a dynamical structure making envelope soliton elementary excitation. Under the viewpoint, in order to represent them as a sequence of envelope solitons of which amplitudes and phase constants are random variable dependent on an initial probability, the following assumptions are made.

i) All wave groups possessed in observed waves behave as envelope soltons and are composed of the multi-envelope soliton solutions of the plural NLS equations.
ii) The envelope profile of the waves observed temporally at a fixed position can be approximately represented as a random sequence of asymptotic envelope solitons.

A schematic diagram of the sea state corresponding to these assumptions is shown in Fig. 4. The diagram explains that the sea state is governed independently by the L-NLS equations having N_l-envelope soliton solutions ($l=1,2,\ldots L$) and the observed waves are composed of a train of envelope solitons with the number of ΣN_l.

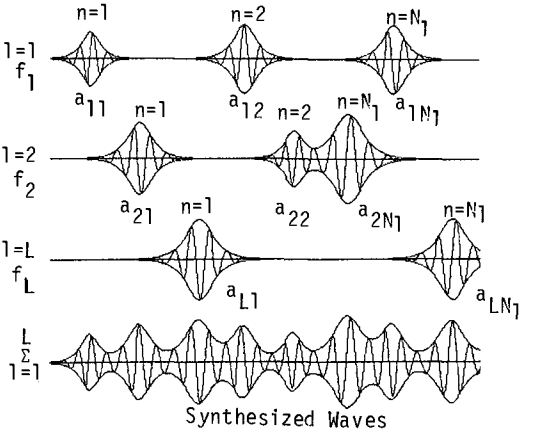

Fig. 4 Schematic diagram of wave field represented as random train of envelope solitons

2. Formulations

Since the wave data are obtained by the temporal observations at fixed positions as mentioned above, the NLS equation of spatial evolution type is required to analyze them and is expressed as follows:

$$-i\partial A/\partial X+\alpha\partial^2 A/\partial\xi^2+\beta|A|^2A=0\cdot\ , \tag{2}$$

where

$$\left.\begin{aligned}
&\alpha=(1/2)[c_g/c-(gh/c^2)\,\mathrm{sech}^2 Kh(1-Kh\tanh Kh)]\ ,\\
&\beta=(\cosh 4Kh+8-\tanh^2 Kh)/(16\sinh^4 Kh)\\
&\quad-(2c\cosh^2 Kh+c_g)^2/[2\sinh^2 2Kh(gh-c_g^2)]\ ,\\
&c=[(g/K)\tanh Kh]^{1/2}\ ,\\
&c_g=(c/2)[1+2Kh/\sinh 2Kh]\ ,\\
&X=\varepsilon^2 Kx\ ,\qquad \xi=\varepsilon 2\pi f(x/c_g-t)\ ,
\end{aligned}\right\} \tag{3}$$

in which K is the wave-number corresponding to the central frequency f of a narrow-band spectrum, εA the amplitude of a carrier wave non-dimensionalized by K, h the mean water depth, c the wave-celerity, c_g the group-velocity, ε the small parameter denoting the degree of nonlinearity, x the horizontal coordinate, t the time and g the acceleration of gravitation.

The asymptotic N_1-soliton solution of eq.(2) is written as

$$\frac{\varepsilon A_l}{K_l}=\sum_{n=1}^{N_l} a_n\,\mathrm{sech}\,[\sqrt{\beta/2\alpha}\cdot a_n(2\pi Kf/c_g)\,\{x-c_g(t-\delta_n)\}]_l\exp(-i\beta_l a_n^2 Kx)\ , \tag{4}$$

where the parameters with the subscript 1 are the quantities related to the envelope soliton with the central frequency f_1, δ_n the phase constant determining the position of the soliton on the temporal coordinate, and a_n the amplitude of the envelope soliton. If all the spacings between two consecutive wave groups are enough wide to make asymptotic approximation possible, the asymptoic expression based on the above assumptions becomes possible. Hence, the leading order profiles η of the observed waves with remarkable groupiness are expressed by using eq.(4) and defining the phase constant σ_1 of carrier waves:

$$\eta=\sum_{l=1}^{L}\frac{|\varepsilon A_l|}{K_l}\cos(K_l x-2\pi f_l t+\sigma_l) \tag{5}$$

Similar expressions of horizontal water particle velocity and water pressure, which are necessary to calculate the wave drift force etc. reflecting wave grouping charqcteristcs, can be easily obtained.

$$u=\sum_{l=1}^{L}|\varepsilon A_l|c_l\left\{\frac{\cosh K_l(h+z)}{\sinh K_l h}\right\}\cos(K_l x-2\pi f_l t+\sigma_l) \tag{6}$$

$$\frac{p}{\rho g}=\sum_{l=1}^{L}\frac{|\varepsilon A_l|}{K_l}\left\{\frac{\cosh K_l(h+z)}{\cosh K_l h}\right\}\cos(K_l x-2\pi f_l t+\sigma_l)-z \tag{7}$$

The envelope profile R(t) of observed waves is expressed as a sequence of M-asymptotic envelope solitons, if eqs.(4) and (5) are used.

$$R(t)=\sum_{m=1}^{M} R_m\,, \qquad R_m=a_m \operatorname{sech}[\gamma_m(t-\delta_m)]\,, \tag{8}$$
$$\gamma_m=2\pi f_m K_m a_m(\sqrt{\beta/2\alpha})_m\,.$$

The above equation states that both the envelope profile and the associated carrier waves are governed by the values of the random variables, a_m, f_m and δ_m. Hence, by investigating statistical characteristics of these random variables, we can make a statistical description both for the envelope profile and carrier waves and a simulation of random waves with a given groupiness. Probability distribution function $F(R_c)$ of the envelope profile R(t) is defined as the probability of R(t) being below the critical value R_c and expressed as

$$F(R_c)=p[R\leq R_c]=\sum_{m=1}^{M}\frac{1}{\gamma_m} \times\int_0^{R_c}\ln\{[1+\sqrt{1-(R_m/a_m)^2}/(R_m/a_m)\}\,dR_m\Big/\sum_{m=1}^{M}(1/\gamma_m) \tag{9}$$

Since the differentiation of $F(R_c)$ by R_c yields the probability density function f(R), a statistical approach becomes possible for runs of consecutive high waves by using f(R). The averaged run length $\bar{j}_1$ making R_c the critical value is expressed as

$$F^*(R_c)=1-\left\{\sum_{m=1}^{M}\frac{2}{\gamma_m}[\ln(1+\sqrt{1-Y_m^2})-\ln Y_m]\right\}\Big/T_0\,, \qquad Y_m=R_c/(2a_m)\,, \tag{10}$$

$$j_1=[(2f_m/\gamma_m)\{\ln(1+\sqrt{1-Y_m^2})-\ln Y_m\}]\,, \tag{11}$$

where brackets [ ] denote the integral representation.

3. Application to observed waves

In order to represent the envelope profile of the observed waves using eq.(8), the values of a_m, δ_m and f_m governing an envelope soliton must be determined from each wave group. Hence, deriving the linear envelope function $R_o(t)$ based on the narrow-band spectrum from the wave record band-pass filtered so as to eliminate both frequencies higher than $1.5f_p$ and lower than $0.5f_p$, we first determine the number of envelope solitons possessed in the record and the values of δ_m from the crest positions expressed by the function $R_o(t)$. And then, we determine both values of a_m and f_m so as to minimize the error energy between the linear envelpe function $R_o(t)$ and the nonlinear envelope function R(t) defined by eq.(8).

$$E=\int_0^T\{R(t)-R_0(t)\}^2 dt \tag{12}$$

That is, both values of a_m and f_m are determined by solving the following simultaneous equation with 2M-dimensions.

$$\partial E/\partial a_m = 0\,, \qquad \partial E/\partial f_m = 0\,. \qquad m = 1, \cdots, M \tag{13}$$

Figure 5 shows some comparisons between the profiles of the observed waves and the envelope profiles represented as a train of the envelope solitons of which parameters were calculated as mentioned above. The comparisons state that the expression based on eq.(8) can be applied to the observed waves with a non-zero nonlinearity and remarkable groupiness instead of the linear envelope function $R_o(t)$ although it utilizes $R_o(t)$ to determine the values of a_m, δ_m and f_m.

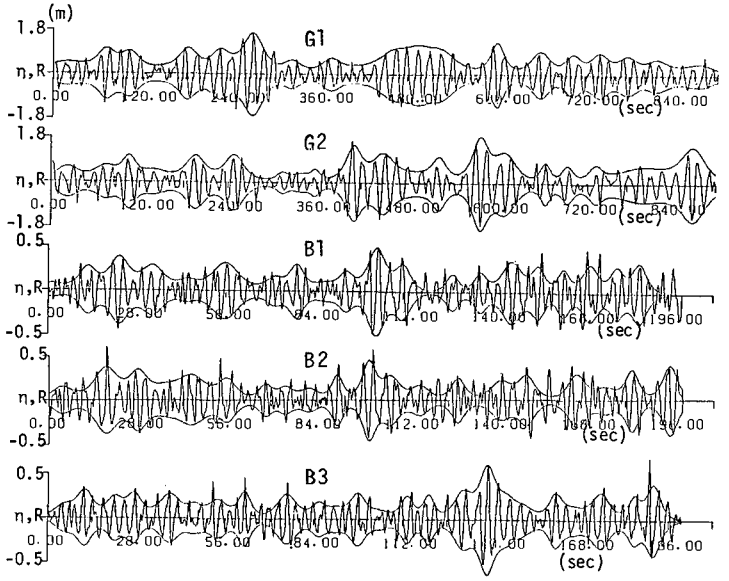

Fig. 5 Comparisons between profiles of the observed waves and the envelope profiles calculated by the present approach

Figure 6 shows comparisons between the envelope profile 2R(t) calculated by eq.(8) and the temporal variations in wave-heights of zero-up crossing waves. It is seen that the properties of the time series of zero-up crossing waves can be easily evaluated on the basis of eq.(8). This states that the statistical approach briefly shown above has a possibility of its application to the observed waves.

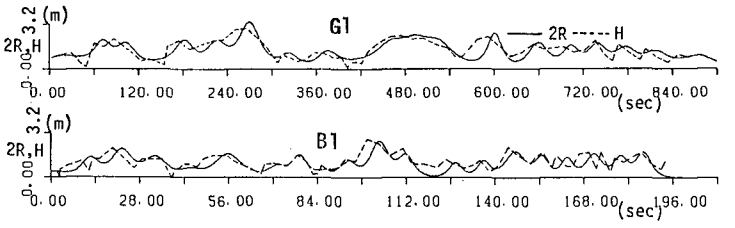

Fig. 6 Comparisons of a train of wave-heights of zero-up crossing waves with the envelope profile represented by the present approach

Figure 7 shows the relation between f_m/f_p and $(\bar{a}/a_m)/k_ph$. Here, f_m is the frequency of carrier waves associated with an envelope soliton corresponding to one wave group and $\bar{a}$ is the averaged amplitude of envelope solitons included in one record of the observed waves. It is noticed that a functional relation equivalent to the regression curve, defined by

$$\left.\begin{aligned} f_m/f_p &= 0.38+2.55x-0.67x^2+0.07x^3, \\ x &= \bar{a}/K_phha_m \end{aligned}\right\} \quad (14)$$

exists between f_m/f_p and $(\bar{a}/a_m)/k_ph$, nevertheless, the values of a_m and f_m are determined only by the conditions shown in eq.(13). This states that grouping waves in field are governed by some dynamics slightly similar to the assumpsions mensioned above and the value of f_m can be estimated using eq.(14).

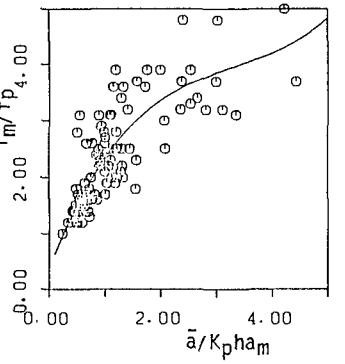

Fig. 7 Relation between peak frequencies of the observed waves and carrier frequencies associated with envelope solitons

As shown above, it is seen that the assumptions i) and ii) hold at least for the observed waves used here and the schematic diagram drawn in Fig.1 reflects partially a correct statement of the physics of the waves with a weak nonlinearity and finite band-width. This states that the approach treating envelope solitons as elementary modes can be applied to the waves with remarkable groupiness. The approach, which may be called as the envelope soliton mode approach, suggests that there is a possibility to explain simply dynamical and statistical properties of the waves and to simulate numerically waves with a expected groupiness. Further, it is expected that the time series of grouping waves can be analyzed by making clear the statistical characteristics of random variables a_m and δ_m, instead of usual approach based on the run theory of zero-crossing waves and the linear envelope function.

DRIFTING FORCE BASED ON ENVELOPE SOLITONS

1. Formulations

It is well-known that the wave grouping is closely related to the slow drift oscillation of moored systems. Pinkster[1975] formulated the wave drifting force under the assumption of a narrow-banded Gaussian process and showed that the slow drift oscillation is due to the resonance between the natural frequency of a moored system and the peak freguency of the spectrum of the drifting force. However, waves with remarkable groupiness have generally a weak nonlinearity and finite spectral band-width and are not suitable for Pinkster's approach based on a narrow-banded Gaussian process. Further, Pinkster's approach is not effective for evaluating the time series characteristics of the drifting force because the spectral analysis itself is not useful for the investigation on time domain. While, the envelope soliton mode approach suggested in the preceding chapter is applicable to such waves and effective for investigating the time series characteristics.

A formulation based on the envelope soliton mode is made on the computations of the wave drifting force based on the direct integration method of pressure acting on the wetted surface of a body with reference to Pinkster's approach. Assuming as well as Pinkster that the envelope profile of the waves slowly varies and using egs.(5), (6), (7) and (8), we can represent the drifting force $F_S(t)$ based on the present approach as

$$F_s(t)=\frac{1}{2}\rho g \sum_m \sum_n a_m a_n C_{FD} \operatorname{sech}[\gamma_m(t-\delta_m)] \operatorname{sech}[\gamma_n(t-\delta_n)] \cos(\omega_m-\omega_n)t \ , \quad (15)$$

where spatial coordinate x is set to be zero for simplicity, and the parameters with the subscript m denote the quantities concerned with m-th envelope soliton with carrier frequency f_m, C_{FD} the drifting force coefficient to be determined experimentally, ω_m the angular frequency $2\pi f_m$, ρ the density of fluid.

If each envelope soliton is independent of others, eq.(15) is further simplified and is rewritten as

$$\left.\begin{aligned} F_s(t)&=(\rho g/2)C_{FD}R(t)^2 \ , \\ R(t)&=\sum_{m=1}^{I} a_m \operatorname{sech}[\gamma_m(t-\delta_m)] \end{aligned}\right\} \quad (16)$$

This expression states that the time series characteristics of the drifting force can be explained in a direct relation with a statistical properties of random variables a_m and δ_m governing dynamically each envelope soliton and that the envelope soliton mode approach is very effective for investigating the properties of the drifting force in a time domain.

2. Characteristics

In order to investigate the properties of the drifting force expressed in eq.(15) and the relation with wave grouping characteristics, comparisons of the drifting force are made among Hsu & Blenkarn's approach[1972], Pinkster's one and authers' one. Figure 8 shows the comparison. Here, the value of the drifting force coefficient C_{FD} is set to be unity commonly for each case. It is found that both results of Pinkster and authors do not suffer the influences of small deviations independent of wave groups and are superior to Hsu and Blenkarn's approach in evaluating the influence due to wave groups themselves. The drifting force by the present approach agrees well with the one by Pinkster's appoach and the former may be used instead of the latter which has been put widely to practical use.

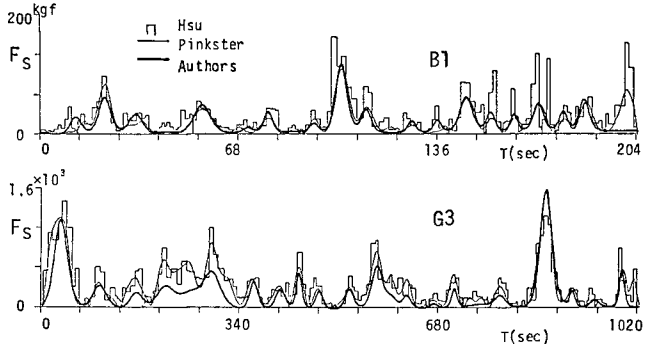

Fig. 8 Comparisons of the wave drifting force calculated by authors approach with the ones by Hsu and Pinkster

CONCLUSION

The approach, regarding an envelope soliton as an elementary mode of grouping waves and representing them as a train of envelope solitons of which amplitudes and phase constants are random variables, is suggested here and is shown to be applicable to the temporally observed waves with a non-zero nonlinearity and finite band-width. It, further, is extended to a formulation of the wave drifting force caused by the existence of wave groups and the fomulation based on the envelope soliton mode is signified to be put to practical use as well as Pinkster's one based on a narrow-banded Gaussian process.

The present study containes some debatable points such that the intutitive picture shown in Fig. 4 is not verified to be a correct statement of the physics of grouping waves and the approach can not describe their propagation process because based on the asymptotic soliton solutions of the plural NLS equations. In order to establish the envelope soliton mode approach, it is required to verify that grouping waves in field have a dynamical structure making an envelope soliton an elementary mode and overcome the above debatable points. However, it should be emphasized that the approach is useful for analyzing the

problems mainly dependent on wave grouping characteristics at a fixed position, such as the slow drift oscillation of moored systems. It, further, is supposed to be effective for evaluating simply statistical properties of grouping waves and simulating numerically waves with an expected groupiness because parameters governing each envelope soliton are random variables expressing directly wave grouping characteristics and statistical quantities concerned with carrier waves and zero-crossing waves can be written as functions of the parameters.

As mentioned above, the approach suggested here remains some points to be examined. But it can be stated at least that the envelope soliton mode approach has a possibility to carry out a new statistical description on waves with a remarkable groupiness.

CHAPTER 66

NEARSHORE BEHAVIOR OF BORE ON A UNIFORMLY SLOPING BEACH

Harry H. Yeh and A. Ghazali*

Using the laser-induced fluorescent method, the detailed transition process from bore to run-up mode is clarified experimentally. The transition process is found to be different from the previous predictions, and might provide an explanation for the discrepancies of the run-up height between the theory and laboratory measurements. Turbulence generated in a bore appears to be highly three-dimensional and sporadic. Turbulence generated close to the shore is advected with the bore-front motion and violent turbulent actions result during the transition from bore to run-up mode.

Introduction

A bore and the ensuing run-up on a uniformly sloping beach have been analyzed based on the inviscid theory with the shallow-water approximation; the shallow-water equations are basically depth-integrated conservation equations of mass and momentum with the assumption of a hydrostatic pressure field. The governing equations form a hyperbolic system, which is often solved by the method of characteristics. A bore front is usually treated by the jump conditions, i.e. the conservation of mass and momentum at the methematical discontinuity. (Note that energy across the jump is not conserved.) Using this formulation, Whitham (1958) found that the height of the bore tends to vanish as it approaches the shoreline while the fluid velocity, u, remains finite. Furthermore, Ho and Meyer (1962) found that singularity of the fluid acceleration occurs at the shoreline, while both the fluid and bore velocities approach their common finite value u* in which the value of u* is totally dependent on the offshore boundary condition. This behavior at a shoreline involving rapid conversion of potential to kinetic energy is often called "bore collapse". Shen and Meyer (1963) extended Ho and Meyer's analysis to the wave run-up after the bore collapse. They found that the maximum run-up height, R, is simply, $R = u^{*2}/2g$. Note that the predicted run-up height is independent of the beach slope.

Using the Lax-Wendroff numerical technique, the behavior of a bore on a beach was solved by Hibberd and Peregrine (1979). Because the jump conditions are not used to model a bore front, energy can be dissipated only via numerical dissipation. Their predictions of the maximum run-up heights appeared to be in excellent agreement with the analytical predictions. This indicates that the numerical dissipation involved is comparable to the energy dissipation involved in the jump

*University of Washington, Seattle, Washington, U.S.A.

conditions. Nonetheless, the analytical and numerical predictions of the maximum run-up height are considerably greater than the experimental results measured by Miller (1968). Packwood and Peregrine (1981) extended Hibberd and Peregrine's (1979) numerical model to incorporate viscous effects by using the Chézy friction term. While good agreements with Miller's (1968) experimental results were obtained for the steep beach-slope condition ($\beta = 15°$), for the mild slope condition ($\beta = 2°$) it was found that the friction effects alone cannot be an explanation for the discrepancy of the maximum run-up heights, i.e. the numerical predictions of the viscous model still considerably exceed Miller's experimental results.

The numerical results reported by Hibberd and Peregrine (1979) could not model the complete bore-collapse phenomenon due to the discretization involved in the numerical scheme which limits resolution of the details. In fact, just like the bore front being a discontinuity in the analytical model, Hibberd and Peregrin's numerical model does not provide physical information about the shape and structure of the front itself; the length of the front is artificially determined by the choice of the discretization in the Lax-Wendroff numerical scheme. However, we also conjecture that the complete bore collapse may not take place in a real fluid environment. First, as Hibberd and Peregrine pointed out, a real bore is not a perfect discontinuity but has a finite width which obscures the sharp transition of a predicted bore-collapse phenomenon. Second, a rapid conversion of potential to kinetic energy must involve significant vertical fluid motion; consequently, the applicability of the shallow-water approximation to that local phenomenon is in question. In his extensive experimental study, Miller (1968) reported that there is no complete collapse of a bore but the transition from bore to run-up mode is a rather gradual process. However, because of the measuring technique available to Miller, the detailed transition process was not revealed.

A qualitative description of turbulence involved in a bore in a uniform depth was suggested by Peregrine and Svendsen (1978). According to their description, turbulence is generated at the toe of the bore front and the initial stage of turbulent flow resembles a mixing layer. After the generation, the turbulence spreads and then interacts with the free-surface and, if the water is shallow enough, the bottom boundary. After the interactions, the turbulence behaves like a wake and decays. Applying the k-ε turbulence model to the depth-integrated governing equations, Svendsen and Madsen (1984) attempted to model a turbulent bore on a mildly sloping beach with $\beta = 1.66°$. A similarity profile of the flow velocity in the turbulent region was assumed based on the results for the hydraulic jumps provided by Madsen and Svendsen (1983). (In coordinates moving with the front, a bore in a uniform depth is often considered to be equivalent to a hydraulic jump.)

In this paper, we investigate behaviors of the bore near the shoreline, in particular, the transition from bore to run-up mode. The necessary definitions for this problem are shown in Fig. 1. Here, the x-coordinate points in the inshore direction from the shoreline, $u(x,t)$ is the depth-averaged fluid particle velocity, $h(x,t)$ denotes

the depth of the water and $h_0(x)$ is the quiescent water depth in front of the bore, and g is the acceleration of gravity. Using the laser-induced fluorescence technique (described in the next section), a detailed transition process is revealed experimentally in a precisely controlled laboratory environment. The generation and evolution of turbulence associated with a bore nearshore are also investigated.

Experiment

A series of experiments was performed in a 9.0 m long, 1.2 m wide, and 0.9 m deep wave tank. A schematic view of the experimental setup is shown in Fig. 2. A plane beach is constructed of 1.9 cm thick plexiglass plates bolted on an aluminum frame. This construction assures rigidity of the beach with its precise slope of 7.5 degrees.

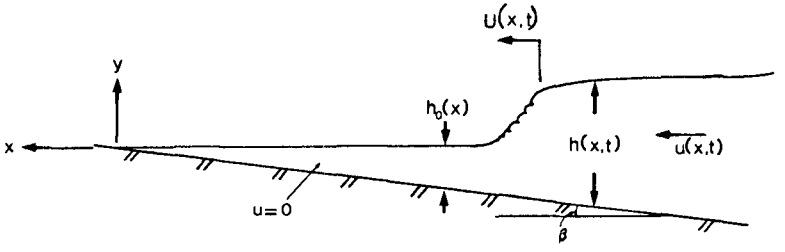

Figure 1. Definition Sketch

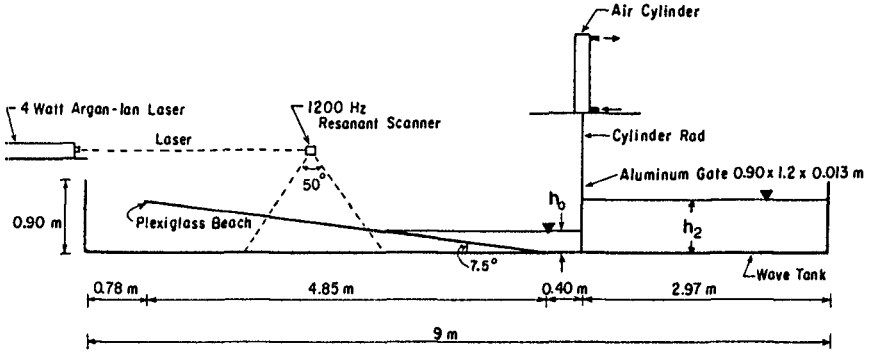

Figure 2. Schematic Drawing of Wave Tank

A single uniform bore is generated by lifting the gate (made of a 12.7 mm thick aluminum plate) which initially separates the quiescent water on the beach from the deeper water behind the gate. This bore-generation scheme has an advantage since the theoretical prediction of the bores can be made without difficulty from the classical dam-break problem. The gate is maintained in a vertical position with the aid of 25.4 mm brass guide channels along the side walls as well as the bottom floor of the tank; the gate itself is sealed against the channel slots by 4.8 mm O-ring rubber embedded in the channels. A pneumatic cylinder with a 10.16 cm bore is used to lift the gate in a controlled manner. The cylinder is electrically activated by a single solenoid valve with the operating air pressure of 650 kPa. It was found that the opening timing is sensitive to bore formation generated at the gate; the faster the opening, the more developed the resulting initial bore. The system is capable of lifting the gate fast enough (the lift-up time of 0.0708 ± 0.0012 sec in 20 cm of travel distance) that developed bores can be generated on the beach.

A 4-watt Argon-ion laser is used for the flow visualization. The emitted laser beam is converted to a thin sheet of laser light through a resonant scanner. The scanner is capable of sweeping the beam at 1200 Hz projected from above in the cross-shore (or longshore) direction and illuminates the vertical longitudinal (or transverse) plane of the water dyed with fluorescein. The fluid motions illuminated with the laser-induced fluorescence were recorded by the 35-mm photo camera. In order to record time directly using photography, a special digital clock was developed; the clock is activated by the initiation of the gate motion with the aid of a photo cell sensor. In addition, an electrical shutter release for the photographic camera was developed; the shutter release is synchronized with a wave sensor in the tank so that the motion at an exact time can be captured by the camera.

Two sets of experiments were performed: experiments for the bore collapse and for the turbulence generation and its development. In the latter experiments, a thin layer (approximately 3 mm thick) of a slightly lighter fluid (diluted ethanol, 0.99 specific gravity) was placed on the water on the beach. Only the upper layer was dyed with fluorescein. When a bore front propagates over the dyed layer, the laser-induced fluorescence indicates the motion of the water engulfed by the toe of the bore. This technique is similar to the one used by Peregrine and Svendsen (1978) who used detergent bubbles as the flow tracer. However, the present laser-induced fluorescence technique can provide the flow visualization in a virtually two-dimensional plane (the laser sheet is approximately 1 mm thick). The flow patterns were recorded by the photographic camera with the motor drive so that evolution of the turbulence can be analyzed. The camera (Nikon F2A Photomic) is capable of taking photographs at the rate of 4 frames per second.

In order to block scattered laser light (mainly at the 488 and 515 nm wave lengths) caused by unwanted particles and, more importantly, air bubbles entrapped in the bore front, the camera was equipped with a high-pass optical glass filter throughout the experiments. Because a relatively fast shutter speed (1/250 and 1/500 sec.) is

required to capture the detailed bore motions, fast-exposure professional photographic films (Fujichrome P1600 D) were used.

Results

The performance of the bore generating system was examined with a variety of the initial conditions. It was found, from visual observations, that developed bores can be generated when $h_2/h_0 \geq 2.0$, where h_2 and h_0 are the initial water depths in front of and behind the gate, respectively. In the case of $h_2/h_0 < 2.0$, linear effects of frequency dispersion become significant, hence bores generated were undular instead (although the leading wave is breaking at its crest when $1.6 < h_2/h_0 < 2.0$). It was also found that when $h_2/h_0 > 2.8$, the behavior of generated bores appears to be too transient for measurements. Perhaps this is due to the limited propagation distance available and the finite time involved in lifting up the gate, i.e. the bore could not have enough time to be developed before it reaches the shore. Nonetheless, qualitative behaviors of bores generated with $2.0 \leq h_2/h_0 \leq 2.6$ appeared to be similar in all aspects investigated in the experiments discussed below. Hence, we concentrate hereafter on the examination of the bore generated with the following initial conditions: $h_0 = 9.75$ cm and $h_2 = 22.5$ cm. With this initial condition, the corresponding initial bore height in the uniform depth, h_1, is predicted to be 15.4 cm and the Froude number, $F = U/\sqrt{gh_0}$, is 1.43, where U is the speed of the bore front. (The values of h_1 and U were computed by solving the dam-break problem.) It is noted that the offshore bore strength characterized by F = 1.43 is comparable to F = 1.45 and 1.37 used in the numerical studies by Hibberd and Peregrine (1979) and Svendsen and Madsen (1984), respectively. Furthermore, $F \simeq 1.4$ seems to be typical of bores on a beach according to the results provided by Svendsen, Madsen, and Hansen (1978).

According to Ho and Meyer (1962), as the bore approaches the shore, the bore height diminishes to zero and the fluid velocity, u_1, behind the front approaches that of the front itself. Note that the values of U and u_1 are finite at the shore although the acceleration becomes singular. This complete bore-collapse phenomenon is thought to be unrealistic since the bore front is not really a discontinuity. To circumvent this difficulty, Hibberd and Peregrine (1979) implemented the Lax-Wendroff numerical scheme without using the jump conditions for the bore front. Their results indicate that the transition from bore to run-up mode is rather smooth and gradual. However, it is emphasized that the detailed shape of the front is determined basically by the discretization of the numerical solution but not by the physical causes. The experimental results of the bore near the shore and the transition from bore to run-up mode are shown in the sequence of photographs in Fig. 3. With repeated experiments, each photograph was taken by shifting the probe location for the electric shutter release at 5 cm intervals from x = -15 cm to x = 15 cm. The experimental results clearly indicate discrepancies from the predictions. The bore front itself never reaches the shoreline, but the small wedge-shaped water body along the shore ahead of the front is suddenly pushed forward. This pushed water mass, involving the violent turbulence, initiates the run-up process. During the transition, the bore

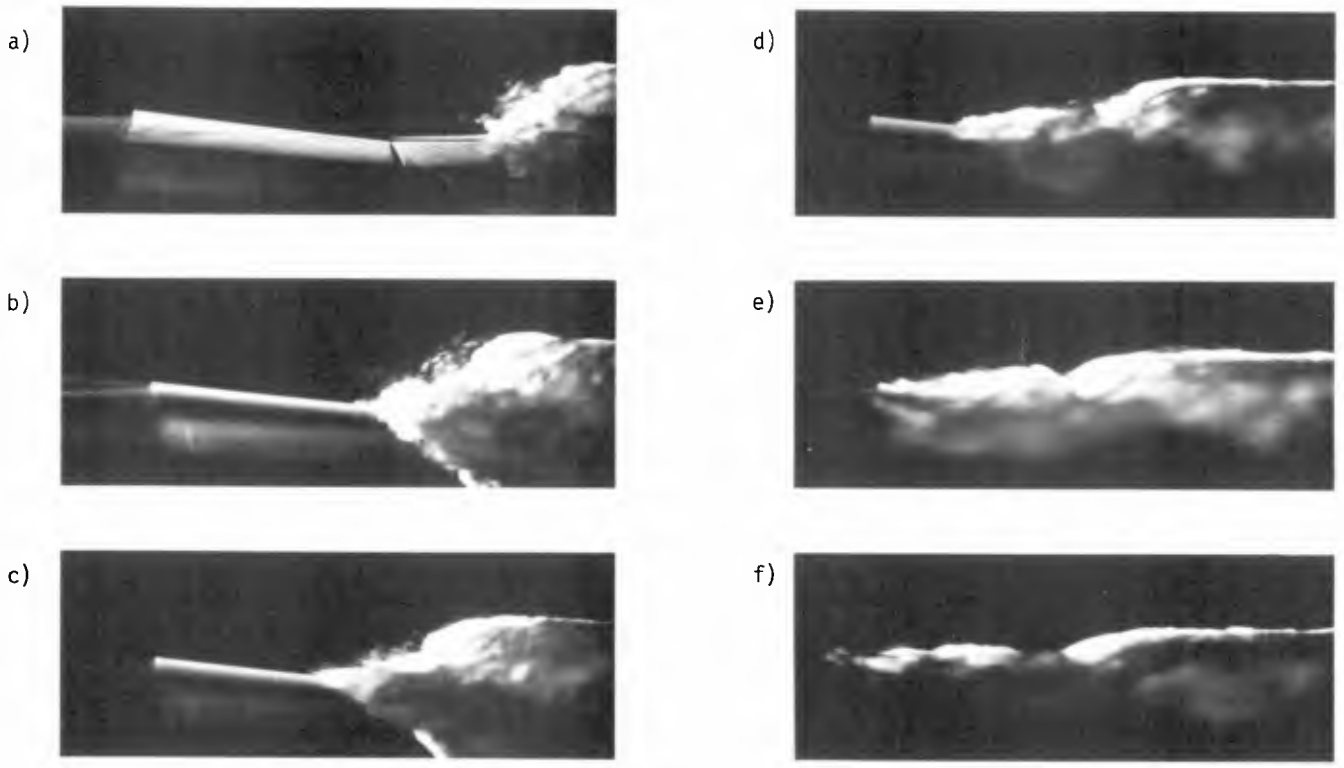

Figure 3. Transition Process from Bore to Run-up Mode. a) x = -15 cm; b) x = -10 cm; c) x = -5 cm; d) x = 0 cm; e) x = +10 cm; f) x = +15 cm

front first steepened and reduces its height. In order to verify this process, we performed another experiment by placing the narrow strip of water dyed with Rhodamine B along the shoreline so that the location of the dyed water can be identified by the red color. It was found that the water along the shore is indeed pushed forward instead of being engulfed by the bore front. By the following argument, this transition process may provide an explanation for the discrepancy on run-up heights between the inviscid theory and experimental measurements as mentioned in the introduction.

Suppose a bore approaching a shore is as shown in Fig. 4. At this instant (t = 0), the water in front of the bore is still quiescent. We assume that, when the ratio h_o/h_1 reaches a certain value, the water in front of the bore is pushed forward with a uniform velocity, u_o. Then, based on the conservation of total energy, the rate of change of kinetic energy of the water in front of the bore is the difference between the energy flux, F, transferred into the control volume through section 1 and the rate of change of energy of the bore, I, i.e.

$$\frac{d}{dt}\left(\frac{1}{2}\rho V_o u_o^2\right) = F - I$$

where ρ is the fluid density, and V_o is the fluid volume of the water pushed forward. Since $V_o = 1/2\ h_o^2/\tan\beta$, integrating the equation yields the maximum value of u_o at $t = t^*$:

$$u_o^{*2} = (2\tan\beta)/(\rho h_o^2)\int_o^{t^*}(F - I)dt.$$

Note that, from the initial and final conditions, $F - I = 0$ at $t = 0$ and t^*. Hence this suggests that u_o^* is dependent on the beach slope, and then the maximum run-up height is also dependent on the beach slope. (u_o^* appears to be proportional to $\tan\beta$, although the real relation remains unknown unless the integration is evaluated.) Together with the viscous effect and the effect of the air-water-beach contact line, this bore collapse process may be an additional explanation for the discrepancy which appeared between Miller's (1968)

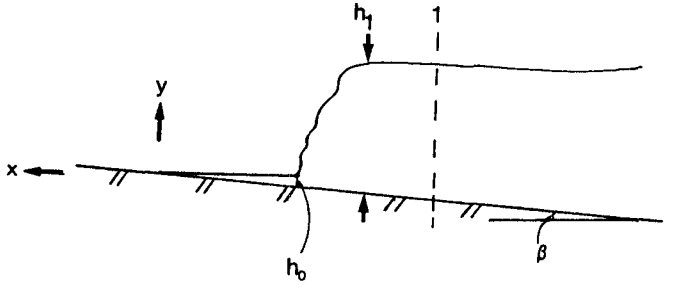

Figure 4. Simplified Model of a Transition from Bore to Run-up Mode.

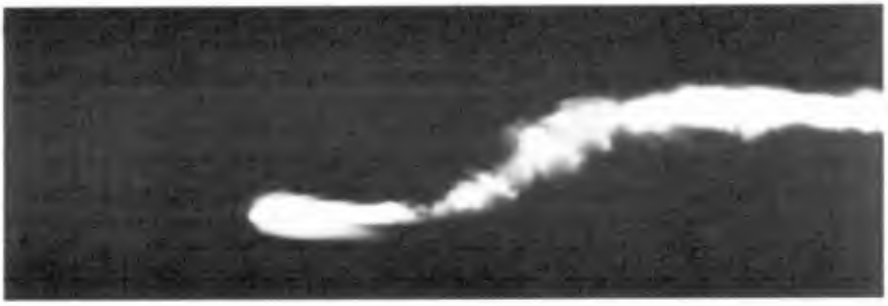
experimental results and the numerical solutions provided by Hibberd and Peregrine (1979) and Packwood and Peregrine (1981).

It is also noticed in Fig. 3 that the bore front becomes very steep (almost vertical) but smooth (less turbulent), while the water in front of it is extremely turbulent. This suggests that the turbulence generated at the front near the shore is advected forward on the beach instead of being left behind. This conjecture is further supported by the experimental results which follow.

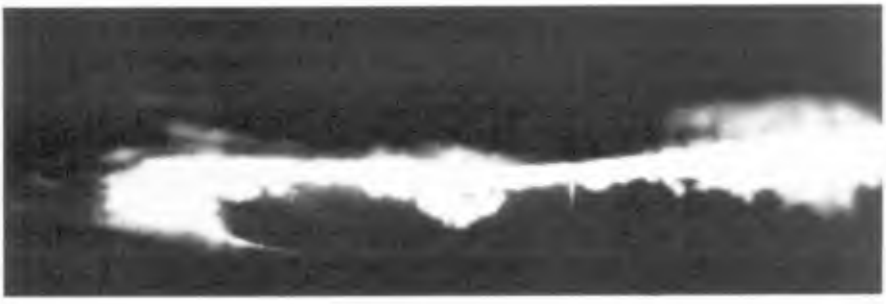
In the experiments for turbulence, a thin dyed layer of diluted ethanol was placed on the water to identify vortices formed at the toe of the bore front. A sequence of photographs for generation and development of bore turbulence are shown in Fig. 5. The first photograph, Fig. 5a, shows that the toe of the front is passing at $x = -20$ cm. The mixing-layer type of turbulence generation cannot be detected in the photograph but the turbulent region is extremely thin and limited near the surface. It appears that the turbulence spreads at a much smaller rate than the change in the water surface. Svendsen and Madsen's results appear to form a thicker turbulent region than that in Fig. 5. However the direct comparison cannot be made because of the different beach slope involved (Svendsen and Madsen used $\beta = 1.66°$ whereas the experiments were performed with $\beta = 7.5°$). The observed turbulence behind the bore front is sporadic rather than forming a distinct turbulent region. A clear spread of turbulence can be observed in Figs. 5b and c at a relatively offshore position; these eddies must be generated when the bore was still propagating in the offshore region. Note that the water-particle velocity offshore is substantialy slower than the bore-propagation velocity. Hence, the generated turbulence is advected behind the front. When the bore reaches the shoreline in Fig. 5b, the turbulence behind the front seems to be weak; turbulent motions appear to be concentrated at the front. These behaviors are not limited to this particular case, but also occurred in the experiments with different initial bore strengths in a range of $1.31 < F < 1.48$. Since the magnitude of u_1 approaches the magnitude of U as the bore approaches the shore, the generated turbulence advected by the fluid velocity also tends to move closer with the front. This indicates that the turbulence generated near the shore is accumulated at the front and then released at the transition from bore to run-up modes. On the other hand, less turbulence is left behind the front and stretched horizontally by the velocity difference, hence relatively calm flow pattern results here.

By following the small turbulent eddy which appeared right behind the front in Fig. 5b, it is observed in the subsequent figure the eddy is stretched in a slanting vertical direction; similar behavior was observed in a broken wave in a uniform depth by Nadaoka et al. (1985).

In order to see more definite behaviors, the flow patterns in a vertical plane perpendicular to the propagation, i.e. in the longshore direction, were examined. (This is achieved by rotating the resonant scanner by 90 degrees.) The results are shown in Figs. 6 and 7. Note that the photographs were taken from the side wall so that the resulting images are somewhat distorted. In Fig. 6, the vertical laser



a) t = 0.76 sec



b) t = 1.00 sec

c) t = 1.23 sec

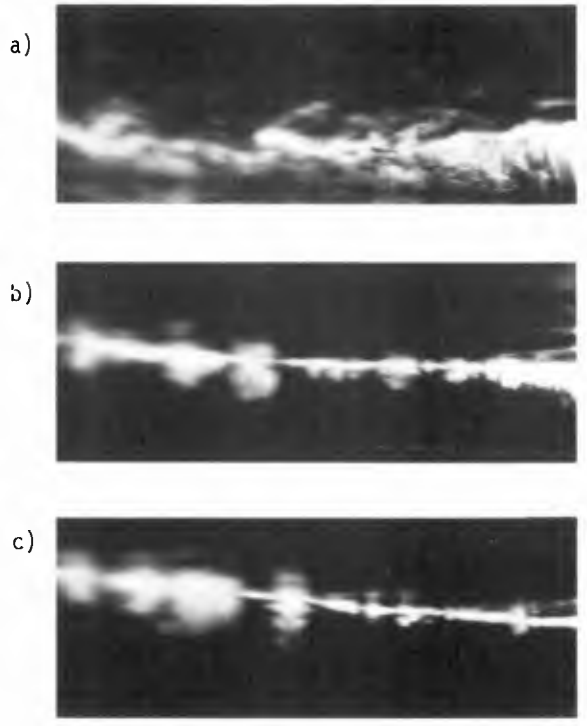

Figure 7. Visualization of Turbulence in a Transverse Plane along x = 0 cm, a) at the front; b), c) 0.25 and 0.50 sec later, respectively

sheet parallel to the shoreline was emitted offshore, x = -12 cm. Three-dimensional and sporadic turbulence structures are evident. In Fig. 7, the vertical laser sheet was emitted along the initial shoreline. Figure 7a shows the flow along the bore front at the shoreline; it is evident that the turbulence there is intense. Nonetheless, once the front passes by, the turbulence left behind the front is surprisingly weak and sporadic as seen in Figs. 7b and c. This confirms the observations made for Fig. 5.

The present results suggest that the turbulence is concentrated in the roller at the surface and the vortical motions generated within the roller are advected sporadically behind the bore front. From this point of view, the generation of the turbulence resembles that involved in a flow separation just as assumed by Longuett-Higgins (1973) for his analysis of steady breaker. This evidently differs from the one suggested by Peregrine and Svendsen (1978). The reason is not clear but it is probably because Peregrine and Svendsen observed the turbulence integrated in the tank width whereas the present observation is that in a virtually two-dimensional plane by the laser-induced fluorescence technique.

Conclusion

The detailed process of the transition from bore to run-up mode, i.e. bore collapse, was revealed. It was found that the bore front itself does not reach the shoreline before the large mass of the bore pushes the small wedge-shaped water body along the shore. During the pushing, the bore height decreases with steepening the front face (to almost vertical). The turbulence located on the front face appears to be advected forward onto the beach. This totally different transition process from the previous predictions may provide an additional explanation for the discrepancies of the resulting maximum run-up height between the theory and measurements. The turbulence generated at the bore front near the shoreline seems to resemble that for a flow separation. The generated turbulence is advected behind the bore; there, the turbulence is weak, three-dimensional, and sporadic. Very close to the shore, the generated turbulence is advected with the front. Hence violent turbulent motion results during the transition from bore to run-up mode, whereas right behind the bore front, a relatively calm motion occurs.

The author wishes to thank Mr. McKay of the University of Washington for his assistance in setting up the experimental facility. The work for this paper was supported by the U.S. National Science Foundation Grant no. ECE-8503436.

CHAPTER 67

MAGNITUDE OF THE β-FACTOR UNDER WAVE ACTION

by

J. van de Graaff [1] and

R.C. Steijn [2]

Abstract

The sediment transport due to waves and currents depends on the distribution of sediment concentration and on the distribution of the velocity over the water depth. Our knowledge of both phenomena for practical applications is still rather poor. Some results of wave flume tests concerning the distribution of sediment concentrations due to wave action will be discussed. It turns out that the sediment size of the bottom material has a rather unexpected effect hereupon. With respect to the velocity distribution only some qualitative remarks can be made at the moment.

1. Introduction

The sediment transport (per m) due to waves and currents parallel to the coast can be described in principle with:

$$S = \int_0^h \overline{v(z)}\ \overline{c(z)}\ dz \qquad (1)$$

where:

S	:	sediment transport rate
$\overline{v(z)}$	:	time averaged current velocity (function of z)
z	:	height above the bed (z = 0 being the bottom)
$\overline{c(z)}$	:	time averaged sediment concentration (function of z)
h	:	water depth

[For simplicity reasons the over-bars in $\overline{v(z)}$ and $\overline{c(z)}$ have been omitted further.]

---

[1] Senior Scientific Officer; Delft University of Technology

[2] Student Assistant; Delft University of Technology
(present position: project engineer; Delft Hydraulics)

Eq.(1) is a simplification of the general description according to:

$$S = \frac{1}{t_o} \int_0^{t_o} \int_0^{h} v(z,t)\ c(z,t)\ dzdt \qquad (2)$$

where: t_o : integration time (long with respect to the wave period T)

$v(z,t)$: current velocity (function of z and t)

$c(z,t)$: sediment concentration (function of z and t)

t : time.

For the cross shore sediment transport description Eq.(2) should be applied in principle. The orbital motion affects the parameter $v(z,t)$ continuously and thus in fact the simplifications according to Eq.(1) cannot be made. However, Stive and Battjes (1984) do apply an equation like Eq.(1) also in cross shore transport cases with some success. [The use of Eq.(1) instead of Eq.(2) has great advantages since our knowledge of the parameter $c(z,t)$ on the wave period scale is nearly completely insufficient; see Bosman (1986).]

In longshore sediment transport cases the orbital motion hardly affects (due to refraction) the parameter $v(z,t)$ in Eq.(2), thus the simplification of Eq.(1) seems allowed. Apart from possible applications in cross shore transport cases, we restrict ourselves in the present paper to Eq.(1) (the longshore transport application).

According to Eq.(1) two topics affect the actual rate of sediment transport, viz.:

$v(z)$ - distribution over the water depth

$c(z)$ - distribution over the water depth

(see Fig.1).

In arbitrary coastal engineering applications $v(z)$ as well as $c(z)$ are highly dependent on the boundary conditions like wave height H, wave period T, water depth h, bottom particle size D_{50} and average current velocity v. Although some proposals for possible relationships can be found in literature, general accepted (and soundly proved) formulations are not yet available. That is, in fact, not surprising since many rather simple basic questions cannot be answered up till now. Some examples of these questions are:

- what is the effect of the grading of the bottom material on the c(z) distribution?
- do we understand the behaviour of different particle sizes in a same wave and current generated 'turbulence field' ?

Nielsen (1979) already mentioned the effect of the rate of grading of the bottom material on the apparent diffusion coefficient distribution over the water depth [$\varepsilon_s(z)$ - distribution]. Van de Graaff and Roelvink (1984) showed, with the help of some practical examples, that even in quite normal graded cases ($D_{90} / D_{10} \simeq 2$), completely different

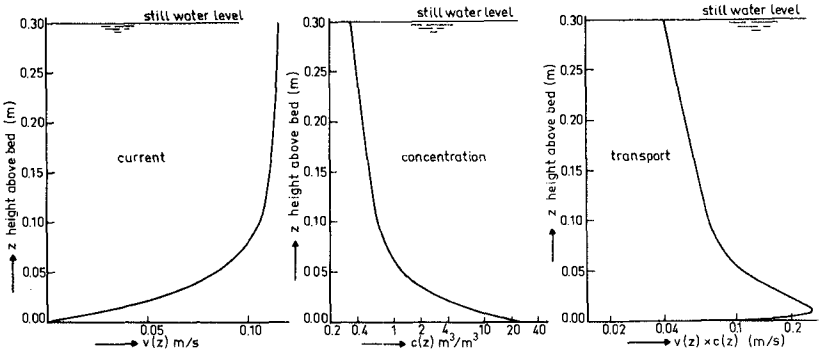

Fig.1 Velocity x concentration = transport

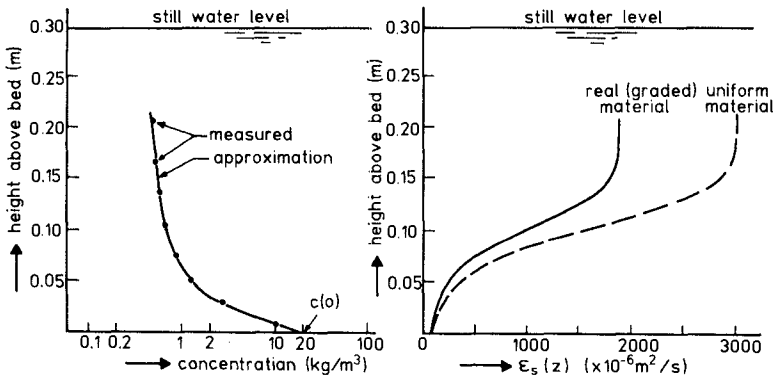

Fig.2 Effect of grading on $\varepsilon_s(z)$ distribution

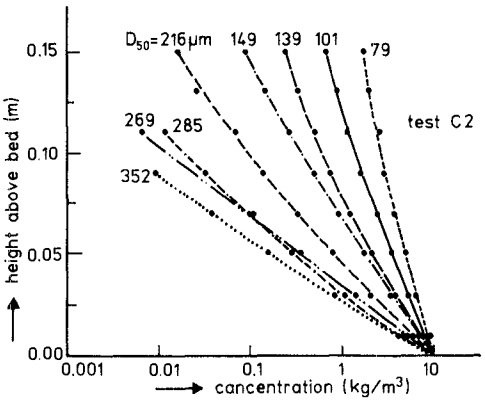

Fig.3 Concentration as function of diameter

$\varepsilon_s(z)$ distributions are found when the actual grading is taken into account in comparison with the $\varepsilon_s(z)$ distribution as calculated under the assumption of uniform bottom material.
Van de Graaff and Roelvink also mentioned a single test result from which it became clear that different particle sizes react quite unexpectedly on the same turbulence field (cf. second question). Since the answer on the second question affects the results arising from the first question, one should know the answer on the second question first.

In the present paper some results, of mainly experimental research in laboratory wave flumes, will be discussed. The tests are aimed to disclose the relationship between the diffusion coefficients holding for the fluid and for the sediment:

$$\varepsilon_s = \beta\, \varepsilon_f \tag{3}$$

where: ε_s : diffusion coefficient for sediment
ε_f : diffusion coefficient for fluid
β : factor.

It will turn out (see Section 2) that β depends (among others) on the sediment size.

Knowledge of the β-factor is important if one likes to know the c(z) distribution as mentioned earlier in the present Section.

In Section 3 some remarks will be made on the possible v(z) distribution for the combination of waves and currents.

2. The β-factor

A uniform flow, a pure horizontal oscillatory flow (e.g. in a wave tunnel), regular waves, irregular waves and a combination of waves and currents, in all cases, together with a sandy bottom, sediment suspensions will be formed in the water column.
When a steady state is considered, convective processes as well as diffusion effects will maintain the concentration distribution. For the time being the concentration distribution, even under wave conditions, will be described by the well-known diffusion equation:

$$w\, c(z) + \varepsilon_s(z)\, \frac{\partial\, c(z)}{\partial\, z} = 0 \tag{4}$$

where: w : fall velocity
c(z) : time averaged concentration at level z above the bed
$\varepsilon_s(z)$: diffusion coefficient for the sediment (function of z)
z : vertical upward directed ordinate; the bottom being z = 0.

It should be stressed that the parameter $\varepsilon_s(z)$ in Eq.(4) is, in fact, an auxiliary parameter in the description of the sediment concentration distribution. It is nearly for sure that not only diffusion processes maintain the concentration distribution.

When one 'knows' the $\varepsilon_s(z)$ distribution and a concentration at a certain level (e.g. the bottom concentration), the entire c(z) distribution can be calculated. However, it is impossible at the moment to predict the $\varepsilon_s(z)$ distribution as a function of the boundary conditions like H, T, h and v. Our knowledge is still completely insufficient to do that.

All over the world a mainly experimental approach is followed to acquire more insight in the concentration distribution. The next sequence is followed in that way:

- Measuring of c(z) distributions
- Find the characteristics of the underlying $\varepsilon_s(z)$ distribution
- Try to relate these characteristics to the boundary conditions
- Try to 'understand' the relationships as have been found.

In Fig.2b the resulting $\varepsilon_s(z)$ distributions are shown belonging to the real measured c(z) distribution as given in Fig.2a. From this example it becomes clear that it is quite important to take the real grading (D_{90} / D_{10} = 2 in this example) into account. Different $\varepsilon_s(z)$ distributions appear whether real graded or uniform material is taken into account. Many problems will undoubtedly arise in relating the boundary conditions with the $\varepsilon_s(z)$ characteristics as found when the real grading is not taken properly into account. [The present example holds for an irregular (non-breaking) wave case in a laboratory wave flume. Notice that even high in the water column apparently rather high diffusion coefficients are present. Straight forward 'theories' predict diffusion coefficients often in a restricted zone close to the bed only.] The diffusion coefficient distributions as found in Fig.2b hold strictly for the bottom sediment as applied. However, the 'fluid' may contain different diffusion coefficients [see Eq.(3)]:

$$\varepsilon_s(z) = \beta\ \varepsilon_f(z) \qquad (3a)$$

where: β : factor.

Depending on the value (or better: the behaviour) of β, one is able to derive the $\varepsilon_f(z)$ distribution from measured concentration distributions. In fact that $\varepsilon_f(z)$ distribution should be related to the boundary conditions. That is more realistic than such a relationship with $\varepsilon_s(z)$, since, depending on the behaviour of β, $\varepsilon_s(z)$ might be dependent on the particle size.

What about β ? If β = 1 (as sometimes is assumed, however, without sound evidence) things become rather simple. The Delft University of Technology has carried out many tests in wave flumes to disclose the β behaviour. In these tests the same mixing activity should be generated by the waves holding for different particle sizes. The dimensions of the bottom ripples (to be formed) will most likely affect the mixing activity. Since these dimensions depend on the particle size, tests with 'natural' sandy bottoms will not fulfill the requirements. In the tests, therefore, artificial roughness elements have been mounted on the flume bottom. During the tests a small amount of sand was maintained on the bottom. The amount was that small that no 'own'

ripples could be formed, but large enough to shape a measurable sediment concentration distribution over the water column. The concentrations have been derived from 'time- and bed averaged' suction samples [see Bosman (1982)]. The suction direction was perpendicular to the orbital plane. In that case the actual concentration differs from the measured one. However, if the intake velocity of the water-sand mixture is large enough compared with the orbital motion, a constant factor is found between measured and actual concentrations [Bosman et al. (1987)]. In the present paper concentration *distribution* aspects are considered rather than *absolute values*, so the application of correction factors is not necessary.

Up till now 3 series of tests have been carried out in several wave flumes (Delft Hydraulics and Delft University of Technology). In Table I the most important parameters of the tests have been summarized.

Test	Wave characteristics			Ripple characteristics			Number of bed materials
	h (m)	H (m)	T (s)	λ (m)	η (m)		
A1 DH	0.30	0.080	2.0	0.07	0.017	*	8

η ripple height.

Fig.3 shows an example of a set of measured concentration distributions (test C2 of Table I). All test results have been normalized, yielding an (arbitrary) bottom concentration of 10 kg/m^3. The measuring points

have been approximated by a mathematical function according to the method as has been described by Van de Graaff and Roelvink (1984).

Fig.3 shows, as could be expected, a fan-shaped set of concentration distribution lines. The finer material goes 'easier' into suspension than the coarser material. Taking into account the (slight) grading of the bottom material, the apparent $\varepsilon_s(z)$ distributions of each of the bottom materials can be calculated with the help of Eq.(4).
Due to inevitable experimental scatter, quite identical $\varepsilon_s(z)$ curves for the different particle sizes cannot be expected. However, in reality distinct trends could be observed. In Fig.4 some examples of $\varepsilon_s(z)$ values (holding for a constant z level above the bed) are shown as a function of the fall velocity of the bed material. The values of w in Fig.4 correspond with the D_{50} values of the bed materials.

A theoretical basis is still lacking for this, but the measuring points in figures like Fig.4 can be approximated by a straight line. If it is allowed to extrapolate that line to w = 0 m/s, the intersection point can be considered as ε_f, the diffusion coefficient holding for the fluid. This consideration is rather speculative since the diffusion process of water particles will undoubtedly differ from that of very small sediment particles. Density differences between water and particles being a reason.
Lines like drawn in Fig.4 can be represented by (a least square fit procedure):

$$\varepsilon_s = \varepsilon_f + m\, w \tag{4}$$

where: ε_s : diffusion coefficient (sediment)
ε_f : diffusion coefficient (fluid)
m : slope of approximation line
w : fall velocity.

Eq.(4) can be compared with Eq.(3):

$$\varepsilon_s = \beta\, \varepsilon_f \tag{3a}$$

From Eqs.(3a) and (4) follows:

$$\beta = 1 + \alpha\, w \tag{5}$$

where: α : m/ε_f ; non-dimensionless parameter (α in s/m)

It can be seen from Eq.(5) that, depending on the α value (direction of slope m), $\beta > 1$ as well as $\beta < 1$ can be found. Furthermore the actual β value depends on the fall velocity of the bed material.

For many points in a vertical ε_f and α values have been determined for each of the tests. Each $\varepsilon_f - \alpha$ combination has been plotted in Fig.5. A lot of scatter can be seen. It is, however, clear that for relatively small ε_f values positive α values are predominant. For large ε_f values negative α values occur.

Fig.6 shows a typical $\varepsilon_f(z)$ distribution as could be derived for test B2 from Table I. Notice again the relatively large $\varepsilon_f(z)$ values high in the vertical; these values are large in comparison with the $\varepsilon_f(z)$ values close to the bed.

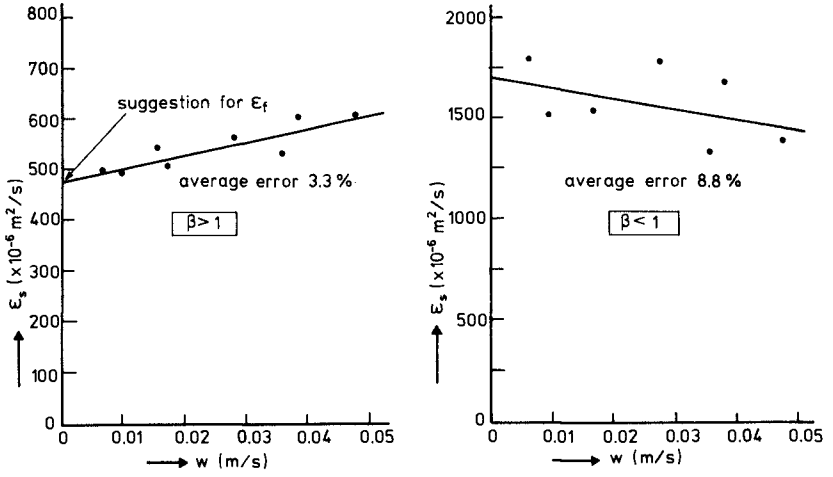

Fig.4 ε_s as function of fall velocity

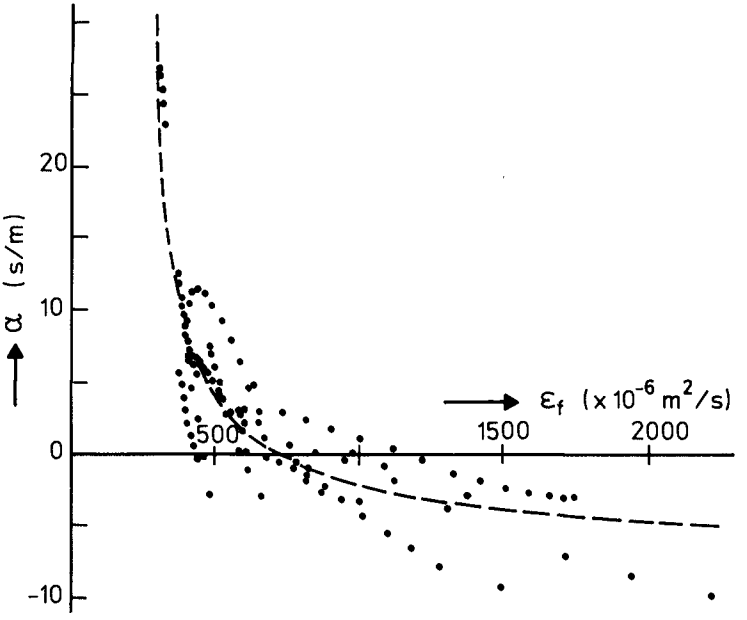

Fig.5 Effect of ε_f on α value

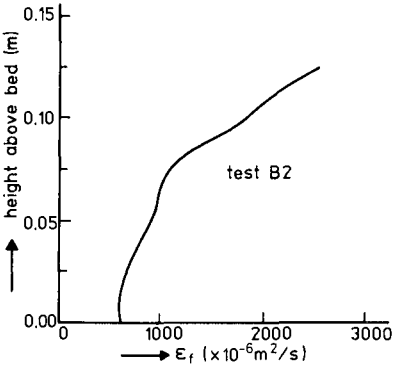

Fig.6 Typical ε_f distribution

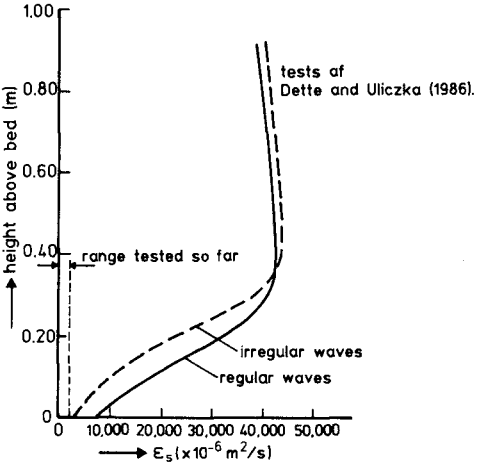

Fig.7 ε_s for large scale tests

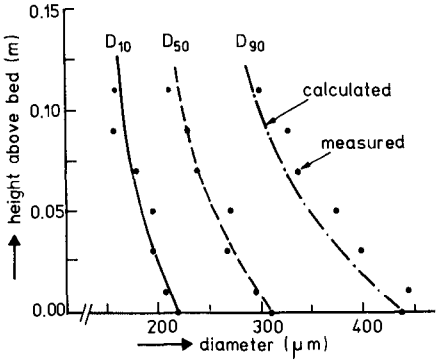

Fig.8 Degradation

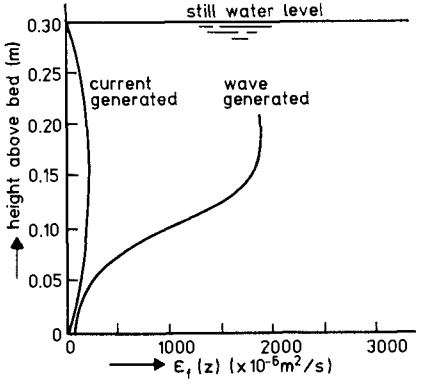

Fig.9 Wave- and current generated ε_f distributions

A convincing explanation for the results of Fig.5 with respect to α (and thus β) cannot yet be given. However, some remarks can be made. Probably the behaviour of α as a function of ε_f is related to the position above the bed. The relatively smaller ε_f values are normally present close to the bed (cf. Fig.6). Due to the 'rippled' bottom, eddies are formed in the bottom layer. These eddies (laden with bottom particles) move as a whole in an upward direction during some phases of the orbital motion. During these phases distinct convective transport processes occur through which, also in the tests with coarse bottom material, the particles can reach rather high levels. Such a process has the same effect as if rather high diffusion coefficients occur for coarse material, thus leading to $\beta > 1$.
Far from the bed (in most cases the zone with relatively large ε_f values) the bottom generated eddies have lost their energy. Probably there occurs a more or less 'normal' diffusion concept according to Eq.(4). In that case $\beta = 1$ could be expected. At this moment the authors cannot formulate a reliable explanation for $\beta < 1$ for these high ε_f values.

The research in the behaviour of β is far from ended. Up till now only some first ideas have been found. The range of ε_f values as have been encountered during the present test series is, in fact, very restricted. For practical applications in future, insight in the behaviour of α for far larger ε_f values should be acquired. That can be demonstrated with the results of some tests by Dette and Uliczka (1986) carried out in the large wave flume of Hannover ($H \simeq 1.5$ m).

Fig.7 shows the ε_s distribution as have been derived from two series of sediment concentration distribution measurements. The analyses have been carried out with the assumption of $\beta = 1$. Fig.7 shows ε_s values in a total different range compared with these found during the tests as discussed so far.

More or less as a by-product of the calculation methods as have been used, the degradation over the water column of the bottom material can be computed. Fig.8 shows a confrontation between computation results and measurements. The rather good fit seems to support to some extent the diffusion-type description of the tests.

3. The v(z) distribution

From the analyses as have been discussed in Section 2 also so-called $\varepsilon_f(z)$ distributions are found (cf. Fig.6 and Fig.7 to some extent). The shape of these distributions is in many cases quite different from 'theoretical' $\varepsilon_f(z)$ distributions as can be found in literature. An $\varepsilon_f(z)$ distribution is frequently used to derive the horizontal velocity distribution over the water depth, viz.:

$$\tau(z) = \rho\ \varepsilon_f(z)\ \frac{\partial\ v(z)}{\partial\ z} \qquad (6)$$

where: $\tau(z)$: shear stress at level z above the bed

ρ : density of the fluid

$\varepsilon_f(z)$: diffusion coefficient (fluid) at level z

$v(z)$: horizontal current velocity at level z

z : vertical upward directed ordinate; the bottom being $z = 0$.

The well-known logarithmic velocity distribution for uniform current is, for instance, found with a triangular $\tau(z)$ distribution [$\tau(z=0)$:maximum; $\tau(z=h)$:zero] and a parabolic $\varepsilon_f(z)$ distribution (ε_f reaches its maximum value for $z = \frac{1}{2} h$).

The test results as have been discussed in Section 2 yield $\varepsilon_s(z)$ [and $\varepsilon_f(z)$] distributions 'generated' by waves only. Waves are obviously able to maintain sediment concentrations at levels rather high above the bed. It can be *assumed* (only an assumption can be made for the time being since a sound proof and verification is still missing) that waves are also very effective in transferring shear stresses in cases of a combination of waves and currents. If that assumption is true, a practical calculation example can clarify the consequences.
The graded material $\varepsilon_s(z)$ distribution of Fig.2b strictly holds for the particular sediment and for waves only. It is, however, assumed that this distribution can be considered as an $\varepsilon_f(z)$ distribution (so taking $\beta = 1$) which holds also for a combination of that wave and a modest current making an arbitrary angle with the wave propagation direction. The distribution of $\varepsilon_s(z)$ in Fig.2b holds for a water depth $h = 0.30$ m and a maximum orbital velocity near the bed, $\hat{u}_o \simeq 0.2$ m/s. The mean velocity of the current is assumed to be $\bar{v} = 0.1$ m/s. Fig.9 shows also the $\varepsilon_f(z)$ distribution which belongs to a mere current situation with $\bar{v} = 0.1$ m/s. It can be seen that the wave generated $\varepsilon_f(z)$ distribution reaches far larger values than the mere current $\varepsilon_f(z)$ distribution. In the further analysis it is assumed that the current contribution can be neglected in comparison with the wave contribution. The resulting $\varepsilon_f(z)$ distribution is not parabolic at all and together with a triangular $\tau(z)$ distribution a non-logarithmic $v(z)$ distribution (with $\bar{v} = 0.1$ m/s) will be found (see Fig.10).

Up till now a physical verification is not yet carried out. Tests are in preparation by the Delft University of Technology. Just to show at least the qualitative agreement, in Fig.11 a comparison has been made between the calculated curve of Fig.10 and actual measurements of Van Doorn (1981) with only roughly comparable boundary conditions. [Same water depth; same average velocity; regular waves with slightly different characteristics; artificial roughness elements instead of natural rippled bed.]

It will be clear that a velocity distribution like Fig.10 has severe consequences for the resulting sediment transport. A quite different transport will be calculated in that case in comparison with a situation where a logarithmic velocity distribution is assumed.

Since only some first thoughts are formulated, all implications cannot be overseen at the moment by the authors.

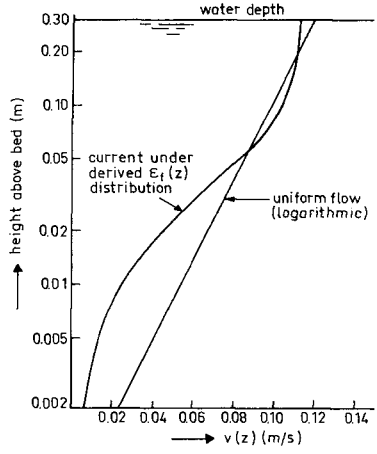

Fig.10 Velocity distributions

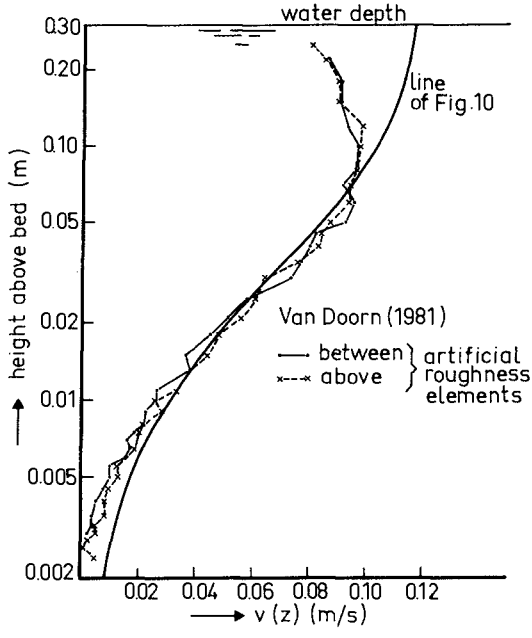

Fig.11 Measured and 'theoretical' distributions

4. Conclusions

- Wave flume tests with artificial roughness elements and different sediment sizes have revealed that the diffusion coefficient distribution for the sediment $\varepsilon_s(z)$ is different for different particle sizes.
- With $\varepsilon_s = \beta \cdot \varepsilon_f$ this means that β differs from unity. Cases with $\beta > 1$ and $\beta < 1$ have been found, probably also depending on the 'level' of ε_f (the diffusion coefficient for the fluid).
- A sound explanation of the behaviour of the β-factor cannot be given at the moment.
- The wave generated diffusion coefficients are far larger than the mere current contribution.
- If a combination of waves and current is considered and the wave generated diffusion activity is also available to transfer shear stresses, a velocity distribution can be calculated which differs totally from a logarithmic distribution. If those ideas are true, te resulting sediment transport will also be affected.
- Verification tests are in preparation by the Delft University of Technology.

CHAPTER 68

RANDOM BREAKING WAVES - HORIZONTAL SEABED

HANS PETER RIEDEL[1] & ANTHONY PAUL BYRNE[2]

ABSTRACT

According to wave theories the depth limited wave height over a horizontal seabed has a wave height to water depth ratio (H/d) of about 0.8. Flume experiments with monochromatic waves over a horizontal seabed have failed to produce H/d ratios greater than 0.55. However designers still tend to use H/d 0.8 for their design waves. Experiments have been carried out using random wave trains in the flume over a horizontal seabed. These experiments have shown that the limiting H/d ratio of 0.55 applies equally well to random waves.

1. INTRODUCTION

Coastal structures are often located in water depths where the limiting wave height is determined by the maximum water level at the toe of the structure. In Australia there are many regions, particularly those with high tidal ranges, where the approach to a proposed coastal structure site has a slope in the range of 1 in 100 or flatter. Presently the breaking wave height used for design by a large percentage of designers is based on Coastal Engineering Research Centre (1984). For near horizontal seabeds the value of H/d is based on classical theories for wave breaking such as McCowan (1894).

However when monochromatic waves have been propagated over horizontal beds in flume studies, the researchers have typically found that a H/d ratio of 0.78 cannot be obtained. Nelson (1983) reviewed the available literature and presented the results of flume studies on wave breaking on horizontal and near horizontal seabeds. He found that for seabed slopes of 1:250 and flatter the H/d ratio did not exceed 0.55. Published data thus far has been for monochromatic waves.

The difference between a H/d ratio of 0.55 and 0.78 will have an enormous impact on the design wave possible on a coastal structure. In order to start applying these less conservative methods for estimating design waves it is important to ensure that random waves occurring in nature behave in a similar manner to monochromatic waves.

1, 2. Directors of Riedel and Byrne Consulting Engineers P/L
1. 146 Leichhardt Street, Spring Hill, Qld., Australia.
2. 396 Rokeby Road, Subiaco, W.A., Australia.

The study and results presented in this paper provide a start to extending the range of applicability to random waves. A limited number of tests were undertaken, for a horizontal seabed and for a slope of 1:100.

2. EXPERIMENTAL PROCEDURE

The wave flume at the Manly Hydraulics Laboratory of the Public Works Department, N.S.W. was used. Random and monochromatic wave generation is possible. The flume is 30m long, 1m wide and 1.4m deep. The bed is constructed of 1.5m long segments, each segment being supported by a pair of screw jacks. The flume floor can be jacked up to form any desired seabed profile. The slopes used in the test section were a horizontal bed and a 1:100 slope.

Near the paddle, the flume is 2m wide, allowing waves to be generated which will be large enough to retain their height after passing through a wave filter in a transition section.

An aluminium sliding wedge mounted on linear bearings is used as the wave paddle. Driving the paddle is a two sided hydraulic piston, whose position is controlled by a servo valve. The servo system consists of the servo valve, a linear voltage displacement transducer for feed back and the servo electronics, which compare the feedback signal with a drive signal provided by a PDP-11 computer.

Waves were generated in relatively deep water and propagated up an approach ramp to the test section. A beach with a reflection coefficient of less than 10% was used to dissipate the waves.

The floor of the flume was accurately levelled to ensure that the test section was horizontal or had a slope of 1:100 for at least 3 wavelengths (based on the peak period of the spectrum) between the approach ramp and the measurement station. Figure 1 shows a typical test arrangement.

Most of the tests were done with random waves with peak periods of 8 to 12 seconds at a model scale of 1:40. A Pierson - Moskowitz spectral form was adopted and its shape modelled on measured wave spectra during cyclones off the north Australian coast. All results are quoted in prototype dimensions. Some comparative tests with 8 to 14 second monochromatic waves were also completed.

For each test, measurements of wave heights were made by a series of capacitance wave probes along the flume. With random waves it is not possible to pick the section at which the wave is likely to break so the limiting wave heights were obtained by extracting the maximum wave height from a number of sections for each test over a 20 minute sampling period. For monochromatic waves the wave generator was adjusted progressively until the waves first began to break over the test section.

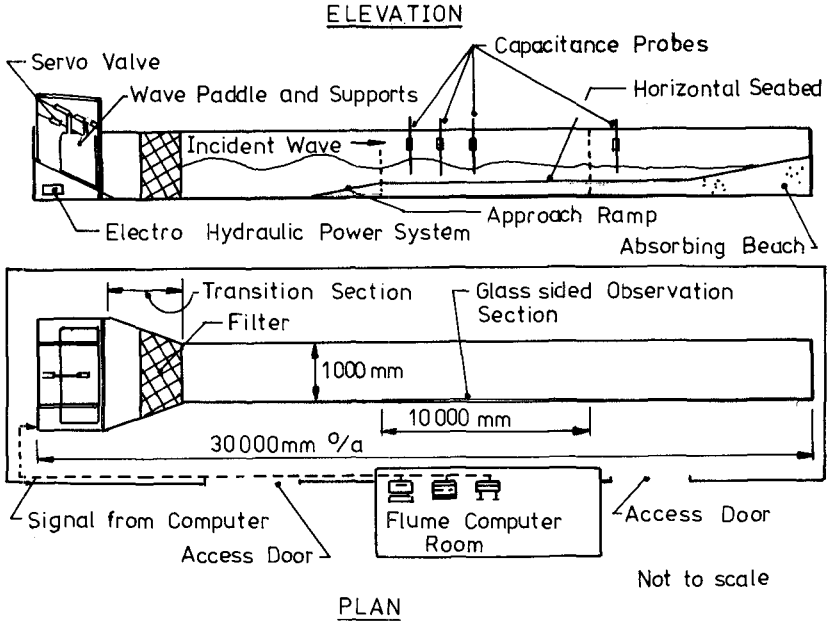

Figure 1. Experimental Setup.

Videotape recordings were made of a number of tests to assist in the interpretation of the results. A measured grid was marked on the side of the flume.

3. EXPERIMENTAL RESULTS

The most convenient method of presenting results in terms of measurable parameters is to use the non-linearity parameter (Fc) of Swart and Loubser (1979). This parameter is a function of T(wave period), d and H.

$$Fc = \left(\frac{H}{d}\right)^{0.5} \left[T\left(\frac{g}{d}\right)^{0.5}\right]^{2.5}$$

Waves of equal Fc have approximately the same relative wave shape.

Table 1 summarizes the results obtained for a horizontal bed. There are 3 data points for each peak period representing three different energy levels in the spectrum. At the lowest energy level only a few waves passed through unbroken. At each higher energy level the proportion of breaking waves increased.

TABLE 1.
TEST RESULTS

Test No.	Wave Type	Peak or Nominal Period	Energy Level	$\frac{Hmax}{d}$	Fc
1	Random	8	Low	0.46	50
2	Random	8	Medium	0.49	52
3	Random	8	High	0.44	49
4	Random	10	Low	0.50	92
5	Random	10	Medium	0.52	93
6	Random	10	High	0.53	94
7	Random	12	Low	0.54	150
8	Random	12	Medium	0.52	147
9	Random	12	High	0.52	148
10	Random	8	Low	0.48	52
11	Random	8	Medium	0.47	51
12	Random	8	High	0.52	54
13	Random	12	Low	0.49	143
14	Random	12	Medium	0.53	148
15	Random	12	High	0.52	148
16	Monochromatic	9	-	0.55	74
17	Monochromatic	10	-	0.56	97
18	Monochromatic	11	-	0.52	118
19	Monochromatic	12	-	0.51	146
20	Monochromatic	13	-	0.55	185

For the random waves the highest value of H/d measured was 0.54 and the values ranged from 0.44 to 0.54. The monochromatic waves had H/d ranging from 0.51 to 0.56 which is in agreement with Nelson's (1983) conclusions.

The tests for random waves over the horizontal seabed show a weak dependent of H/d on Fc. Note that the second sets of test results for each wave period correspond to different cut-off frequencies for the spectrum.

Figure 2 shows our data superimposed on the results presented by Nelson (1983). It is evident that for waves within a random wave train the limiting value of H/d is 0.55. There appears to be slightly less dependence on the non-linearity parameter than shown for experiments with monochromatic waves.

Figure 2. H/d versus Fc.

In a separate set of tests about a year before the above tests were undertaken, some observations were made of the limiting breaking wave heights on 1:100 slope. The same facility and wave spectra were generated as described above. These tests produced a range of wave height to water depth ratios which showed quite a strong dependence on Fc. These observations were made less rigorously than the test results already discussed. Wave heights and water depth were measured off replays of video tapes.

The results are also shown on Figure 2.

4. DISCUSSION AND CONCLUSIONS

The ratio of limiting wave height to water depth over a horizontal seabed is 0.55 for both monochromatic and random waves. This can be important in the determination of extreme waves in shallow water where the seabed is horizontal or nearly horizontal. These results apply to a unidirectional wave train.

At slopes of 1 in 100 there is already a significant increase in the ratio of H/d and there is also a dependence on the non-linearity parameter Fc.

The extent of testing undertaken was limited and there may be other wave spectral forms that will not produce the same results. The spectra adopted here related to measured spectra in the area where the results were applied.

Most real sea conditions consist of more than one wave train where each wave train has an independent wave direction. It is not clear whether the same limits of H/d would apply. Also superimposed steady currents may have an influence.

There is an urgent need for continued research of depth limiting breaking wave heights

CHAPTER 69

Influence Of Breaker Type On Surf Zone Dynamics

A.S.Arcilla, A.Vidaor and J.L.Monso *

1.Introduction

Two of the most significant variables for surf zone hydrodynamic analyses are the mean rate of wave energy dissipation, D, and the longshore current velocity, Vl . A detailed theoretical model is extremely difficult to establish (definition of bottom and free surface boundaries, stochastic forcing terms, intense turbulent mixing, etc). The type and amount of existing measured values (laboratory and field) also preclude any accurate calibration, particularly for the more complex formulations.

The paper, therefore, presents an average (cross-shore) comparison among state-of-the-art models for D and Vl. This illustrates the dependence of these variables on the surf zone dynamic state (closely related to the beach stage, (Short, 1978)), characterized by Iribarren's parameter, Ir. Well defined relationships with Ir are obtained for these variables. An expansion of the range of validity of certain models is also attained by calibration of their characteristic free parameters as functions of Ir using a large set of field and laboratory data, and by comparing their general expresion with that of (Losada and S.Arcilla, 1985), which does not include any free parameter.

Therefore, theoretical laws for D and Vl as simple functions of beach, wave and dynamic state parameters are presented, together with an improved estimation of the empirical coefficients appearing in the various models, suitable for prediction in all ranges of Ir, even though data on the collapsing-surging range are scarce and should require further calibration.

2.Rate Of Wave Energy Dissipation (D)

No complete theoretical models for the rate of wave energy dissipation (i.e. including bottom friction and percolation, turbulent mixing, front roller, etc.) are nowadays available. Most of them just consider turbulent (mixing) dissipation and have been indirectly calibrated, via the computed longshore current velocity or transport, the corresponding wave attenuation and set-up, etc., as local values of D require accurate local measurements (difficult to encounter).

To get a better insight of the relationship between D and the dynamic state, a cross-shore average value, $\bar{D}$,has been derived from the selected models. It has been obtained assuming stationary and longshore

* A.S.Arcilla, A.Vidaor and J.L.Monso. Harbour and Coastal Eng. Dept., E.T.S.I.C.C.P. Univ. of Catalonia in Barcelona, 31 Jordi Girona Salgado, 08034 Barcelona.

uniform conditions together with a constant bottom slope, m :

$$\bar{D} = \frac{1}{xb} \int_0^{xb} D(x)dx \qquad (1)$$

$\bar{D}$ being the average (cross-shore) value for D , and xb the width of the surf-zone. It is shown that this value is easily related to the dynamic state via the Iribarren's parameter Ir (or Irb when referring to breaking conditions), defined as:

$$Ir = m / (H/Lo)^{1/2} \qquad (2)$$

where m is the bottom slope (assumed to be constant through surf-zone), H wave height and Lo the deepwater wave length.

To get a better insight of the relationship between D and the dynamic state, a non-dimensional value, $\hat{D}$, is defined, refering $\bar{D}$ to an order of magnitude rate of wave energy dissipation Do:

$$Do = \rho g \frac{Hb^2}{T} \qquad (3)$$

where T is the wave period, g is the gravity acceleration and ρ is the water density.

Do may be obtained from dimensional analysis or bore (hydraulic jump) dissipation theory. This reference value can be also obtained via an energetic balance in the surf zone, relating eddy viscosity coefficients to wave energy dissipation:

$$D \; < > \; \text{Stress x velocity} \qquad (4)$$

Characteristic stresses for this problem are, typically, the Reynolds stresses (related to eddy viscosity coefficients):

$$\tau_r = - \rho \overline{u' v'} = - \rho A \frac{dV}{dx} \qquad (5)$$

where A is the eddy viscosity coefficient, and u', v' are the (x,y) components of the turbulent velocity. The eddy viscosity coefficient has the dimension of a typical length times a typical velocity:

$$A \sim l \, . \, V' \qquad (6)$$

Following (Harris et al, 1962) typical scales for length and velocity can be respectively H and H/T . The eddy viscosity coefficient must therefore be of order H^2/T .

The characteristic velocity, V', is assumed to be a typical scale of the turbulent velocity, that can be related, in the surf zone, to the shallow water wave celerity:

$$V' \simeq \hat{B} (g\ hm)^{1/2} \qquad (7)$$

where $\hat{B}$ is a dimensionless constant accounting for breaker type (therefore related to Ir) and hm is an average or characteristic depth through the surfzone.

The energetic balance can be set as in (Battjes, 1975):

$$\frac{\text{Rate of wave energy dissipation}}{\text{Area}} = \frac{\text{Rate of turbulent energy produced}}{\text{Area}} =$$

$$= \frac{\text{Rate of turbulent energy dissipated}}{\text{Area}}$$

(neglecting bottom friction, percolation or any other dissipation phenomena than turbulence).

From this and (5):

$$D < > \text{Stress} \cdot \text{velocity} = \rho A \frac{dV}{dx} \cdot V' \qquad (8)$$

Following the control volume approach presented in (Losada, S.Arcilla and Vidal, 1986) to estimate the partial derivative in (8), the rate of wave energy dissipation can be written as follows:

$$D = \rho A \frac{Vlb}{xb} \cdot \hat{B} (g\ hm)^{1/2} \qquad (9)$$

Vlb being the longshore current velocity at the breaker line, depending on wave, beach and dynamic state parameters.

Assuming (Losada, S.Arcilla and Vidal, 1986) that A , $\hat{B}$, and other parameters involved in the Vlb formulation (γ,Kr,etc.) are Ir functions, it is easy to show that:

$$\frac{D}{\rho g A} = F(Ir) \cdot \cos \Theta b \qquad (10)$$

where Θ is the angle of wave incidence.

In this dimensionless equation F(Ir) is a known function that comes from the formulation used to evaluate Vlb. If we choose (Losada, S.Arcilla and Vidal, 1986), $F(I_r)$ can be written as follows:

Author	$\hat{0}$	Free parameters and order of magnitude or suggested values
Longuet-Higgins, 1970	$\frac{(2\pi)^{1/2}}{8}\gamma^{1/2}\,Irb$	---
Losada, S.Arcilla and Vidal, 1986	$\frac{(2\pi)^{1/2}}{8}\gamma^{1/2}\,(1-Krb^{2})\,\cos\theta b\;Irb$	---
Dally, Dean and Dalrymple, 1984	$\frac{(2\pi)^{1/2}}{8}\gamma^{1/2}\,Irb$	---
Battjes, 1978	$\beta\cdot\frac{B\gamma_B^4}{4\,(0,7+5m)}\;,\beta=0,1134$	$B\sim O(1)$ or $B\gamma_B^4\sim O(1)$
Battjes and Janssen, 1978	$\frac{1}{xb}\int_0^{xb}\left[1-\frac{\alpha}{4}Qb\,.\left(\frac{Hm}{Hrms}\right)^2\right]dx$	$\alpha\sim O(1)$
Stive, 1982	$\beta\cdot\frac{\gamma}{4}\,.\,A_\varepsilon\;Ad$	$A_\varepsilon\sim$ 2tanh (5 Iro) or 2tanh (5 Irb) if Irb < 0,4
Svendsen, 1984	$\beta\cdot\frac{\gamma}{4}\,.\,As\left[1+\gamma\left(\frac{\eta c}{H}\right)\left(1+\gamma\left(\frac{\eta c}{H}-1\right)\right)\right]^{-1}$	$As\sim O(1)$
Guza and Thornton, 1985	$\frac{1}{xb}\int_0^{xb}\left[\frac{3(\pi)^{1/2}}{16}\,.\,B^3\,\gamma\,\left(\frac{Hrms}{Hb}\right)^2\right]dx$	$B\sim O(1)$ or $B^3\sim O(1)$

Table 1. Expressions of non-dimensional average rate of wave energy dissipation, D, as functions of Irb dependant variables, for various analytical models.

$$F(Ir) = \frac{\hat{B} \cdot \tilde{A}}{4 \quad (2)^{1/2}} \cdot \gamma^{1/2} \cdot (1-Kr^2)\, m^2 \qquad (11)$$

where Kr is the reflection coefficient and γ is the breaker index.

Then, assuming that $A \simeq H^2/T$, it follows that:

$$\frac{D}{\rho g H^2/T} = F(Ir) \cdot \cos \theta b \qquad (12)$$

and the reference rate of wave energy dissipation, Do, can be correctly expresed by $\rho g H^2/T$.

Using this reference value, average non-dimensional expressions for the rate of wave energy dissipation can be obtained for all formulations considered, even though some of them require numerical evaluation. These expressions are shown in table 1, together with their free parameters, suggested values for them, and range validity. The dimensionless $\hat{D}$ values are known functions of parameters that depend on Ir. It follows that $\hat{D}$ itself is a function of Ir for all models.

The only formulation including reflection and large angles of wave incidence, without any free parameters, and being valid for the whole range of Ir values, is that of (Losada, S.Arcilla and Vidal, 1986). It will be, therefore, compared to other models to enlarge their range of validity via an estimation of their free parameters as functions of Ir. Values of Kr are taken from (Battjes, 1974). The comparison is made numerically in all cases using laboratory and field data taken from:

Laboratory (Putnam, Munk and Traylor, 1949) (Galvin and Eagleson, 1965) (Mizuguchi et al., 1978) (Kamphuis and Readshaw, 1978) (Vitale, 1981) (Kamphuis and Sayao, 1982)

Field (Komar and Inman, 1970) (Kraus and Sasaki, 1978) (Kraus, Isobe et al, 1982) (Guza and Thornton, 1983)

Results from (Losada, S.Arcilla and Vidal, 1986), (Battjes and Janssen, 1978) and (Guza and Thornton, 1985) are shown in figures 1a to 1c, as an example of the results of some of the models analysed.

To test the models, wave, beach and dynamic state measured parameters are used to estimate the average non-dimensional rate of wave energy dissipation. It is shown that $\hat{D}$ is greater for laboratory than for field data, because viscosity and bottom efects are overestimated in laboratory tests.

The adjustment of free parameters as Ir functions is shown in Table 2. Figures 2a to 2c illustrate the results for (Battjes and Janssen, 1978), (Stive,1982) and (Guza and Thornton, 1985) models, being an example of the fit made for all models.

as functions of the Iribarren's parameter Irb

As final remark, a bell-shaped behavior is expected for $\hat{D}$ vs Ir due to:

- incipient spilling breakers, corresponding to low Ir values, produce small dissipation per unit horizontal area (wide surfzone together with a small depth affected by turbulence)

- collapsing-surging breakers, in the higher Ir range, produce small dissipation per unit horizontal area (highly reflecting beach conditions).

- maximum dissipation corresponds to late spilling and plunging breakers, generating maximum turbulence

3. Longshore Current Velocity

Analytical (state-of-the-art) models for the longshore current velocity are based on time and vertically-integrated conservation equations for stationary and longshore uniform conditions with constant beach slope. Most of them also use shallow water linear wave theory.

All formulations depend on two poorly known coefficients, each representing one of the two main retarding terms considered in the momentum balance equation:

- cf, bottom friction coefficient

- M, lateral mixing coefficient, related to eddy viscosity

From the given definition for Iribarren's parameter Ir, (2), an Ir-dependent expression for Vlb may be obtained for each of the selected longshore current velocity models (Table 3). These equations depend on Ir directly or via other parameters related to it (γ, Kr, etc).

From these expressions and order of magnitude considerations, a reference velocity Vo can be defined to obtain a non-dimensional value for Vl:

$$Vo = \frac{Hb}{T} \sin \theta b \qquad (13)$$

$$\hat{V} = Vl / Vo = \frac{Vl}{(Hb/T \cdot \sin \theta b)} \qquad (14)$$

Testing these formulae with the set of data mentioned in section 2, general trends for a relationship between Vlb and Irb may be obtained (an example of them being figure 3):

- lower values of Vlb appear associated to incipient spilling breakers (low range of Irb values)
- stabilized or decreasing values for collapsing-surging breakers (high values of Irb)
- maximum values for Vlb are attained for late spilling and plunging

breakers (Irb ~ 1)

In the formulations presented, the friction coefficient is shown to be the numerically most significant parameter, defining the order of magnitude for Vl, while lateral mixing, through its caracteristic coefficient, governs the profile shape. Thus, to study the variation of the friction coefficient with the dynamic state, an order of magnitude estimate for the characteristic lateral mixing coefficient is used. With this, the friction coefficient is adjusted by comparing estimated and measured values, taken from the mentioned data set (being figure 4 an example of a good and a bad parameter fit).

In these conditions a general formulation for Vlb can be written as:

$$Vlb = Vo \cdot G(Ir) = \frac{Hb}{T} \sin \theta b \cdot G(Ir) \qquad (15)$$

where G(Ir) is a function of the Iribarren's parameter, to be obtained by calibration with measured data.

4. Conclusions

4.1. Rate of wave energy dissipation, D

A general formulation for $\bar{D}$ can be written as:

$$\bar{D} = Do \cdot Fl(Irb) = \rho g \frac{Hb^2}{T} \cdot Fl(Irb) \qquad (16)$$

where Fl(Irb) is a function of the dynamic state that must be calibrated from laboratory and field data.

The relationship between $\hat{D}$ and Irb appears to be bell-shaped from physical considerations and using the (Losada, S.Arcilla and Vidal, 1986) model, that considers reflection (Kr estimation is critical for the formulation results). Comparing this model to other formulations expands their original range of validity, by obtaining Ir dependent expressions for their free parameters.

The values of $\hat{D}$ estimated for the set of field data are always lower than those obtained from laboratory data, because viscosity and bottom friction effects are overestimated in model tests.

4.2. Longshore Current Velocity, Vl

The driving term in the time-and vertically-integrated momentum conservation equation is well defined using the radiation stress concept. The dependance of this term on Ir is shown through the relationship between D and Ir:

$$\frac{\partial Sxy}{\partial x} = D.\left(\frac{\sin\theta}{C}\right) = D(Ir).\left(\frac{\sin\theta}{C}\right) \qquad (17)$$

where Sxy is the (x,y) component of the radiation stress tensor.

Bottom friction is the (numerically) most significant retarding term in longshore current velocity estimation. Therefore a good estimate of Cf is critical for all model results. No theoretical model is available to obtain this coefficient as a function of Ir, which hinders prediction (only qualitatively through flow conditions which determine bed forms).

Lateral mixing, through not very significant numerically, cannot be neglected. The use of an order of magnitude value appears to provide more accurate results than neglecting lateral mixing.

The bottom friction coefficient determines the order of magnitude of Vl while the lateral mixing coefficient defines the shape of cross-shore profiles. A measured Vl profile can therefore be used for a joint bottom friction and lateral mixing coefficients evaluation, while if there are only two measured values of Vl through the profile, such a joint fitting may have a non-unique solution.

The relationship between $\hat{Vlb}$ and Ir appears to be bell-shaped from: i) physical considerations , ii) obtained formulae and iii) field and laboratory data (figures 3a and 3b). Further measurements are required, particularly for large Ir values (collapsing-surging) to confirm and calibrate the behaviour of $\hat{D}$ and $\hat{Vl}$ vs Ir, as well as to determine a predictive relationship between the bottom friction coefficient, Cf, and Ir (figure 4). Finally a general formulation for Vl is presented:

$$Vlb = \frac{Hb}{T} \sin\theta b.\ G(Irb) \qquad (18)$$

where G(Irb) is a function of the dynamic state to be calibrated from laboratory and field data.

Changes in Current Properties due to Wave Superimposing

Toshiyuki Asano[1)]

Masahiro Nakagawa[2)]

Yuichi Iwagaki[3)], M. ASCE

ABSTRACT

Changes in current properties due to wave superimposing are investigated experimentally. Variations of the mean water level gradient and the current velocity profile after wave superimposing are examined. Experimental results are discussed in relation to the energy conservation equation including the bottom friction term. It is found that changes in current properties can be well explained by increase in the time averaged bottom shear stress.

1. INTRODUCTION

Compared with studies on wave transformation due to currents, there are few studies which discussed the effect of waves on current properties. In wave-current co-existing fields, there exist mutual energy exchanges between wave and current components, so that current properties do not remain the same as in case of current only after waves are superimposed.

Phillips(1977) derived the momentum and energy conservation equations in the co-existing field; however, he did not consider frictional terms in his analysis. It should be noted that the increase in the time averaged bottom friction due to wave superimposing is the key point to represent the wave-current co-existing field. That is, the current feels larger resistance due to presence of the waves than in the current only field. Lundgren(1972) proposed an approximate theory for the reduction of the current velocity due to wave superimposing. Grant-Madsen(1979) presented an analytical model to represent the velocity field in wave-current co-existing systems.

1) Research Associate, Dept. of Civil Eng., Kyoto Univ.,Yoshida Honmachi, Sakyo-ku, Kyoto, 606, Japan
2) Engineer, Bureau of Port and Harbour Eng., Osaka Municipal Office 2-8-24, Chikuko, Minato-ku, Osaka, 552, Japan
3) Professor, Dept. of Civil Eng., Kyoto Univ., Yoshida Honmachi, Sakyo-ku, Kyoto, 606 Japan

However, the experimental verifications on the model have not been sufficiently yet. Thus, the knowledges on the changes in current properties due to wave superimposing are not enough up to the present.

This paper investigates the water surface gradient and the velocity profile of the current in the co-existing field experimentally, and discusses the results in relation to the energy conservation equation including the bottom frictional term.

2. ENERGY CONSERVATION EQUATIONS

The energy conservation equations including the bottom friction term are obtained after Phillips' derivation. The enery balance equation for waves is given by,

$$\frac{\partial}{\partial t}\{E+\frac{M_\alpha^2}{2\rho(h+\bar{\eta})}\}+\frac{\partial}{\partial x_\alpha}\{U_\alpha E+F_\alpha-\frac{\tilde{U}_\alpha M_\beta^2}{2\rho(h+\bar{\eta})}\}+S_{\alpha\beta}\frac{\partial U_\beta}{\partial x_\alpha}$$

$$=\tilde{U}_\alpha\bar{\tau}_{\alpha,z=-h}-\overline{\int_{-h}^{\eta}\frac{\partial\tau_{\beta\alpha}}{\partial z}u_\alpha^+dz} \qquad (1)$$

in which,
u_α^+ : the composite velocity of the wave and the current components $u_\alpha^+=u_\alpha+U_\alpha$, u_α : the wave velocity component, U_α : the current velocity component,
E : the wave energy density
F_α : the wave energy flux,
M_α : the mass flux due to the wave motion,
$S_{\alpha\beta}$: the radiation stress,
h : the water depth,
$\bar{\eta}$: the displacement of the mean water level due to wave superimposing.

The right hand side of Eq.(1) denotes the energy dissipation due to the time averaged bottom shear stress $\bar{\tau}_{\alpha,z=-h}$ and the internal viscosity and the Reynolds stress component $\tau_{\beta\alpha}$. As the other symbols are the same as those used by Phillips, further explanations on the symbols are omitted.

The energy balance equation for the current is,

$$\frac{\partial}{\partial t}\{\frac{1}{2}\tilde{U}_\alpha\tilde{M}_\alpha+\frac{1}{2}\rho g(\bar{\eta}^2-h^2)\}+\frac{\partial}{\partial x_\alpha}\{\tilde{M}_\alpha(\frac{1}{2}\tilde{U}_\beta^2+g\bar{\eta})\}+U_\beta\frac{\partial S_{\alpha\beta}}{\partial x_\alpha}=-\tilde{U}\bar{\tau}_{\alpha,z=-h} \qquad (2)$$

The second term of the right hand side of Eq.(1) is approximated after Jonsson's(1966) or Brevik-Aas'(1980) simplification.

$$\overline{\int_{-h}^{\eta}\frac{\partial\tau_{\beta\alpha}}{\partial z}u_\alpha^+dz}\approx(\overline{\tau_{\beta\alpha}u_\alpha^+})_{z=-h} \qquad (3)$$

The following consideration is limitted for two dimensional flow. The bottom shear stress τ_b in the streamwise direction is assumed to be presented by the following equation:

$$\tau = \frac{1}{2}\rho f_{cw}(U+\hat{u}\cos\sigma t)|U+\hat{u}\cos\sigma t| \tag{4}$$

in which, U is the depth averaged current velocity, $\hat{u}$ the velocity amplitude of the wave component at the bottom, σ the angular frequency of the waves, ρ the densityof water and f_{cw} the wave-current friction factor.

The following assumptions are introduced for the simplification of Eqs.(1) and (2).
(1) The energy density of the waves, the current velocity and the mean water level are independent of time.
(2) The current is treated as a uniform flow in depth.
(3) The ratio of the wave amplitude a to the spatial averaged mean water depth h_0 is small. This ratio is used as a small parameter in the following consideration.
(4) The spatial variation of the current is small. That is, $dU/dx=O\{(a/h_0)^2\}$.

Ignoring higher terms than $O(a/h_0)^2$, the energy conservation equation for the wave component is obtained as follows:

$$\frac{d}{dx}\{E(U+c_g)\} = -\frac{1}{2}\rho f_{cw}\{\overline{|U+\hat{u}\cos\sigma t|^3} - U\overline{(U+\hat{u}\cos\sigma t)|U+\hat{u}\cos\sigma t|}\} \tag{5}$$

On the otherhand, the equation for the mean current is given by,

$$\frac{d}{dx}\{\frac{\rho}{2}U^3(h+\bar{\eta})\} + \frac{3}{2}U^2\frac{dM}{dx} + \rho ghU\frac{d\bar{\eta}}{dx} + U\frac{dS_{xx}}{dx} = -\frac{1}{2}\rho f_{cw}U\overline{(U+\hat{u}\cos\sigma t)|U+\hat{u}\cos\sigma t|} \tag{6}$$

The right hand side of Eq.(5) means the energy dissipation of the wave component $(E_w)_{cw}$. The ratio of $(E_w)_{cw}$ to that without current $(E_w)_w$ is given by,

$$\frac{(E_w)_{cw}}{(E_w)_w} = \frac{f_{cw}\overline{(|U+\hat{u}\cos\sigma t|^3 - U(U+\hat{u}\cos\sigma t)|U+\hat{u}\cos\sigma t|)}}{f_w\overline{|\hat{u}\cos\sigma t|^3}} = \frac{f_{cw}}{f_w}\frac{(E_w)'_{cw}}{(E_w)'_w} \tag{7}$$

Concerning the current energy dissipation, the similar expression for the ratio of with waves $(E_c)_{cw}$ to without waves $(E_c)_c$ is obtained as follows:

$$\frac{(E_c)_{cw}}{(E_c)_c} = \frac{f_{cw}\overline{U(U+\hat{u}\cos\sigma t)|U+\hat{u}\cos\sigma t|}}{f_c U^3} = \frac{f_{cw}}{f_c}\frac{(E_c)'_{cw}}{(E_c)'_c} \tag{8}$$

The further analytical considerations are possible both for $(E_w)'_{cw}/(E_w)'_w$ and $(E_c)'_{cw}/(E_c)'_c$ by dividing the condition $\hat{u}\geqq|U|$ and $\hat{u}\leqq|U|$. Fig.1 shows the relation between $(E_w)'_{cw}/(E_w)'_w$ and $|U|/\hat{u}$, and Fig.2 the variation of $(E_c)'_{cw}/(E_c)'_c$ with $\hat{u}/|U|$. It is noted from Fig.2 that the current energy dissipation in the co-existing field becomes larger than that in the current only field for the same current velocity. The velocity reduction of the current due to wave superimposing is not considered here.

Next, the similar calculation is performed on the ratio of the wave energy dissipation to the total energy dissipation. Fig.3 shows

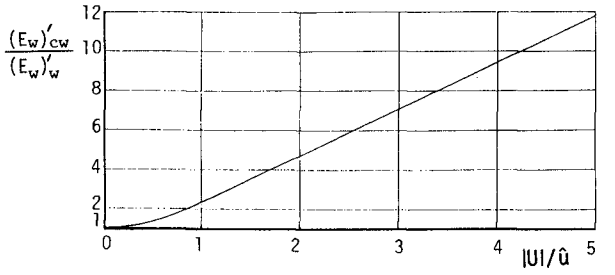

Fig. 1 Energy dissipation ratio for wave component

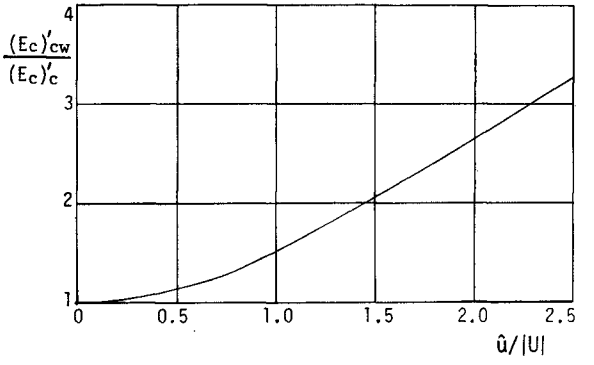

Fig. 2 Energy dissipation ratio for current component

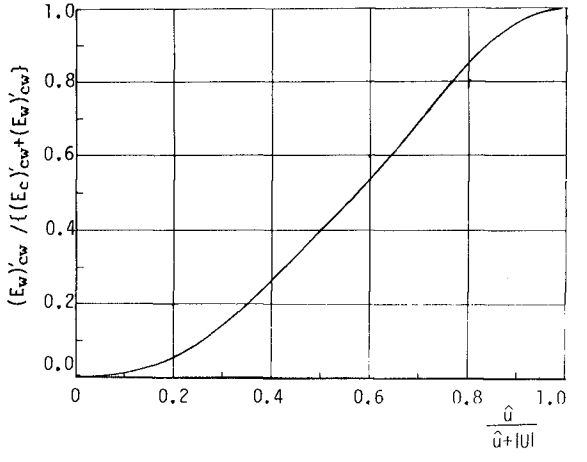

Fig. 3 Composite ratio of wave energy dissipation to total energy dissipation

the relation of the ratio with the wave-current composite ratio $\hat{u}/(\hat{u}+|U|)$. The figure indicates $(E_w)_{cw}/\{(E_w)_{cw}+(E_c)_{cw}\}$ is 0.4 when the wave velocity component is equal to the current one which means that $\hat{u}/(\hat{u}+|U|)=0.5$. It implies that the energy dissipation of the current is 1.5 times of that of the wave component under the condition of $\hat{u}=|U|$.

3. VARIATION OF TIME-AVERAGED WATER SURFACE DUE TO WAVE SUPERIMPOSING

3.1 Experimental apparatus and procedure

The experiment was carried out in a 27m long, 0.5m wide and 0.7m high wave tank(Fig.4), in which circulating flow could be generated by a power pump. In order to produce large energy dissipation in the tank of limited length ,two dimensional artificial roughness elements of 12mm×12mm in cross section and 10cm intervals were added on the bottom over a distance of 16m. Six capacitance type wave gauges were equipped at 2.5m intervals. The water depth is kept 30cm constant for all the cases.

The measurements were conducted for the following three cases; waves without current, current without waves and wave-current combined flow. The signals from the wave gauges were analysed to obtain the wave damping ratio and the gradient of the mean water level. In the experiments, only those waves of a wave train which did not contain reflection effects were used. Since the contamination effect is known to be a cause of wave damping[12], special attention was paid on the cleanness of both water and the surfaces of side walls.

3.2 WAVE-CURRENT CO-EXISTING SYSTEM

Svendsen(1985) has pointed out several difficulties in generating a wave-current system without any disturbance. For example, the ratio of the width of the flume to the water depth should be large enough to avoid the side wall effect on the current component. However, some extent of the water depth is required for wave generating. Therefore, a wide wave tank and a large capasity power pump are needed for both requirements.

The changes in current properties depend on how the wave-current co-existing system is generated. In this experimental facility, the total mass of water in the wave tank and the pipe system is kept constant after wave superimposing; therefore, the increase in the time averaged bottom shear stress due to wave superimposing causes the reduction of the water discharge through the wave tank. Meanwhile, if the discharge is kept constant by a head tank, the increase in the time averaged bottom shear stress changes the water depth and the gradient of the time averaged water surface.

In the present wave-current system, the head raised by the power pump is balanced with the head losses due to the frictions on the

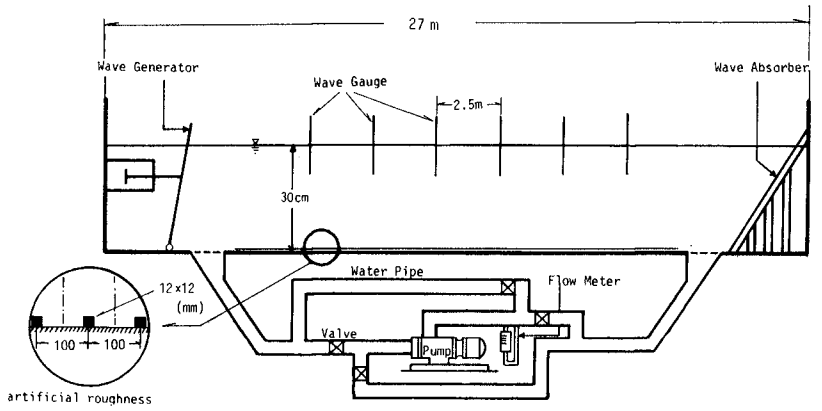

Fig. 4 Experimental apparatus

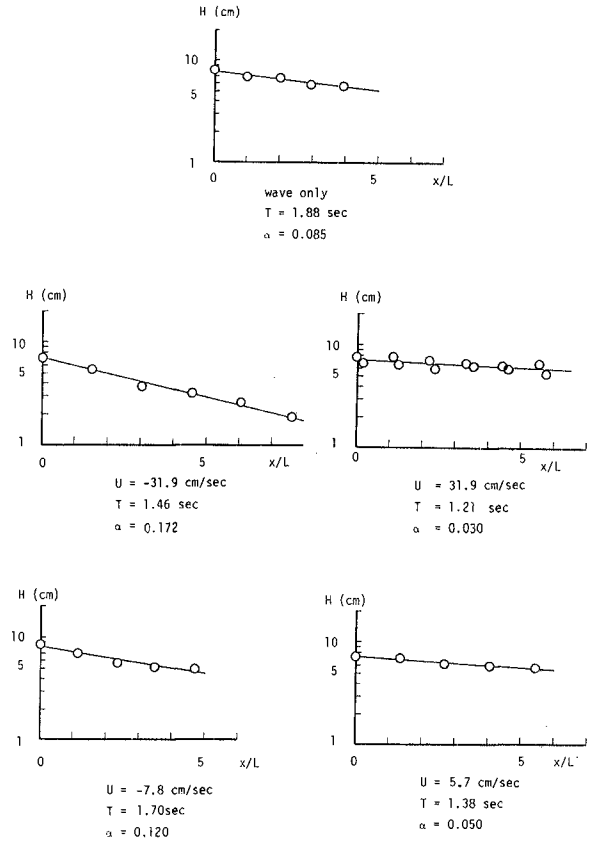

Fig. 5 Wave attenuation profiles

bottom, on the side walls, on the surface of the pipe system, etc. The reason why the large bottom roughness was equipped on the bottom is to make the other losses small compared with the loss by the bottom friction. It is natural to consider that the driving power of the pump is kept constant for both the case of current without waves and the case with waves. Therefore, the both cases are considered to be comparable systems dominated by the same driving power of the pump and the respective properties of the bottom shear stress. Consequently, it is possible to discuss the changes of the current properties due to wave superimposing by comparing the both cases.

3.3 Experimental Results

Preliminary experiments were conducted to investigate the wave damping properties in the fields with and without current. Some examples are shown in Fig.5. It is found that the waves attenuate exponentially even in the wave-current co-existing field, and the damping becomes significant in the opposite current cases. The wave decay modulus α was calculated for the each run by the least square method. The results on α are shown in Fig.6, in which β is defined as $\sqrt{\sigma/2\nu}$ (ν : kinematic viscosity) and L is the wave length. Meanwhile, the water surface variation in the current only field was also measured as a preliminary experiment. The results are shown in Fig.7, in which Δh is the relative water level to that at x=5m. It is noted that the variation of the water surface in the upper stream region than the position x=10m seems to be expressed by a straight line.

The results on the time averaged water surface with and without waves are shown in Fig.8. It is found that the slopes of the water surface become steep after wave superimposing regardless of the current direction. The gradients of the straight lines $d(h+\bar{\eta})/dx$ are determined, then the properties of $d\bar{\eta}/dx$ are discussed as follows. Fig.9 shows the results on $d\bar{\eta}/dx$ with the wave-current composite ratio $\hat{u}/(\hat{u}+|U|)$ as an abscissa. The results indicate that $d\bar{\eta}/dx$ increases with increase in $\hat{u}/(\hat{u}+|U|)$. As shown in Eq.(6), not only the $d\bar{\eta}/dx$ term but also the following terms ; the gradients of the kinematic energy, the radiation stress and the mass flux are related to the energy conservation for the current component. Since dM/dx and dS_{xx}/dx are related to the wave height variation dH/dx , dH/dx becomes one of the factors to contribute to the energy conservation for the current. The ratio of the current energy dissipation in the co-existing field $(E_c)_{cw}$ to that in the current only field $(E_c)_c$ can be calculated on the basis of the left hand side of Eq.(6) from the experimental data of the water surface gradient $d(h+\bar{\eta})/dx$ and the decay modulus α. The results are shown in Fig.10. It is found that the results of $(E_c)_{cw}/(E_c)_c$ are well arranged by the wave-current composite ratio $\hat{u}/|U|$. As the wave component dominates in the composite velocity, $(E_c)_{cw}/(E_c)_c$ becomes large due to the increase in the time averaged bottom friction.

Meanwhile, $(E_c)_{cw}/(E_c)_c$ can be also computed by the right hand side of Eq.(8). The friction factors f_{cw} and f_c are estimated by the

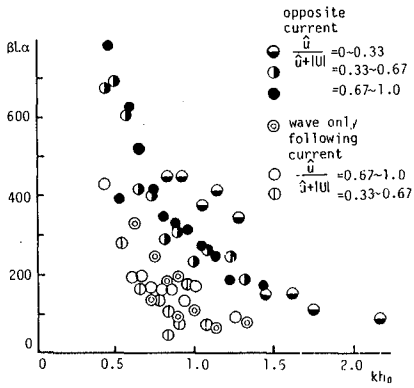

Fig. 6 Wave decay modulus

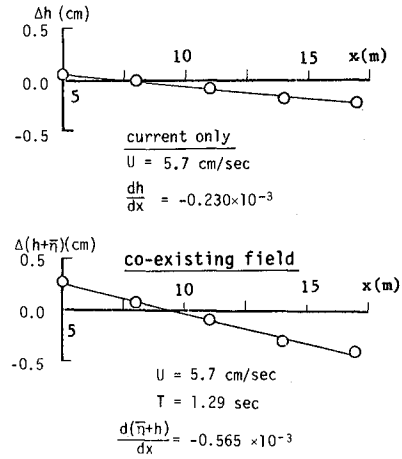

Fig. 8 Mean water level with and without waves

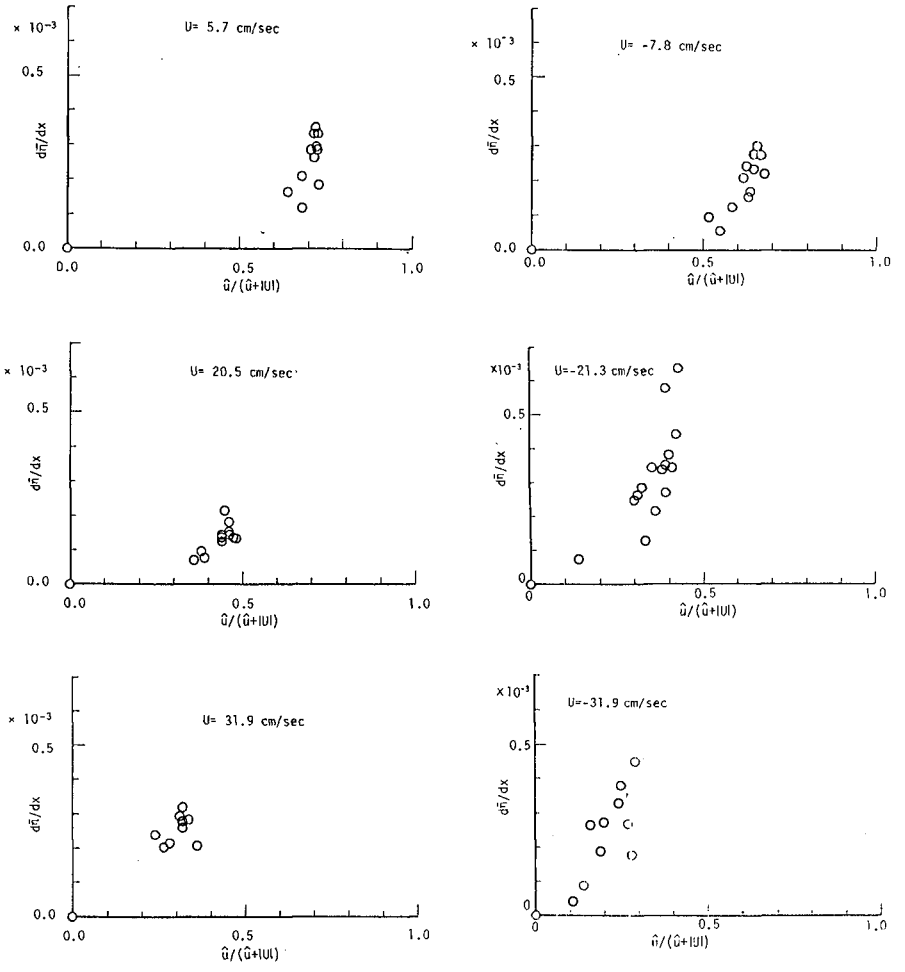

Fig. 9 Variations of gradient of mean water level with wave-current composite ratio

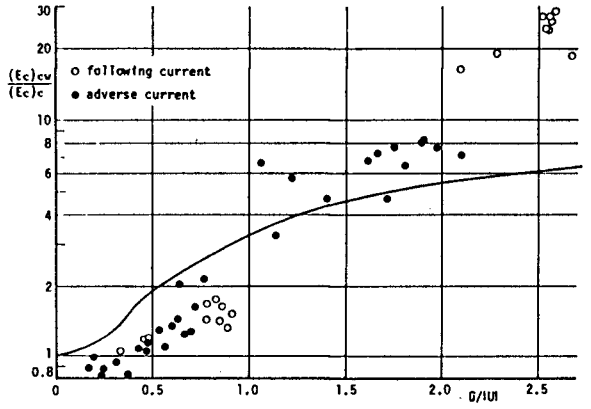

Fig. 10 Energy dissipation ratio for current component

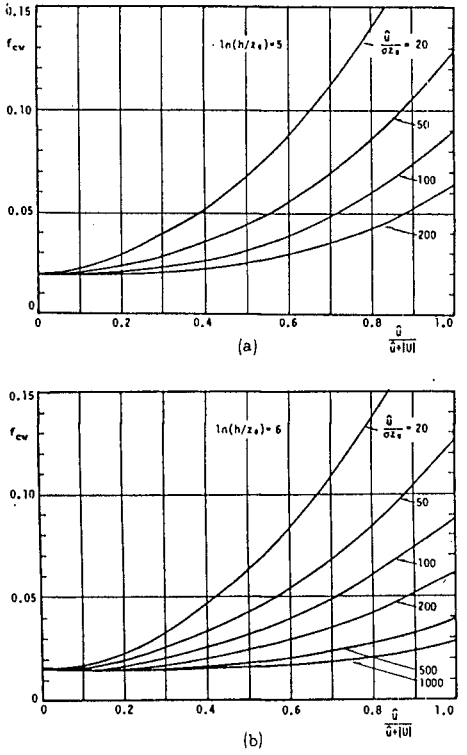

Fig. 11 Friction factors in wave-current co-existing fields

turbulent boundary layer theory in the co-existing field[1]. For fully rough turbulent flow, the friction factor f_{cw} is a function of h/z_0, $\hat{u}/\sigma z_0$ and $\hat{u}/(\hat{u}+|U|)$. Fig.11 shows an example of the properties on the friction factor f_{cw}. The curve in Fig.10 is the calculated result of $(E_c)_{cw}/(E_c)_c$ where f_c and f_{cw} are estimated under the condition of $ln(h/z_0)=4$ and $\hat{u}/\sigma z_0=10$ which are the average values of the present experimental conditions. The current velocity in the numerator of Eq.(8) should be replaced by $\overline{U}_{mod}$ which can be estimated by Eq.(12). Although the present calculation of $(E_c)_{cw}/(E_c)_c$ is only rough estimation, it agrees fairly well with the experimental results for the range of $\hat{u}/|U|\leqq 2$.

4.DEFORMATION OF VERTICAL VELOCITY PROFILE OF CURRENT COMPONENT DUE TO WAVE SUPERIMPOSING

4.1 Experimental procedure

The experiment was carried out in the same wave tank mentioned in 3.1. Two dimensional roughness elements of 2mmx2mm in cross section were added on the bottom at 15mm intervals. A laser-doppler anemometer was used to measure the velocities both in the wave-current co-existing field and in the current only field. All the currents used in the test were in the opposite direction to the wave propagation. The test condition is shown in Table 1.

In addition to the present experimental results, the data by Bakker-van Doorn(1980) and Kemp-Simons(1982) obtained under the similar experimental conditions are used for the analysis.

4.2 Results and Discussion

Fig.12 shows one example of the current profiles measured by authors(1984), and Fig.13 shows that by Bakker-van Doorn(1980). In order to discuss the effect of wave superimposing on current profile quantitatively, several characteristics should be introduced. These characteristics indicated schematically in Fig.12, are defined as follows.

Table 1 Experimental conditions

		$\overline{U}$ (cm/sec)	H (cm)	T (sec)	h (cm)

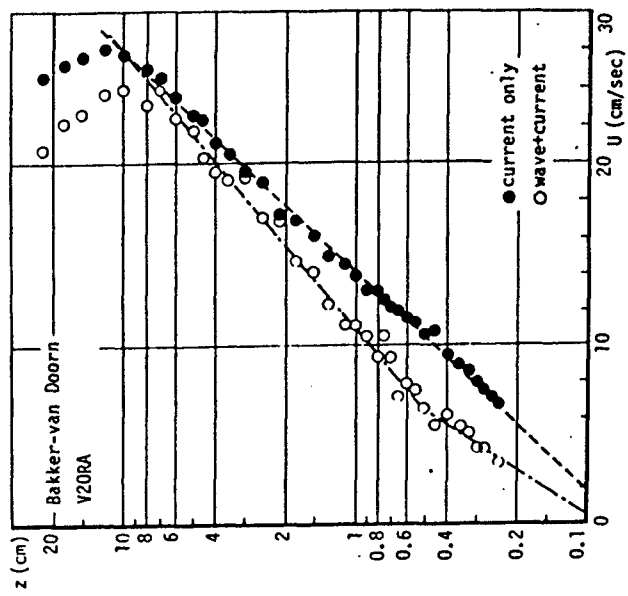

Fig. 13 Velocity profiles of current without and with waves (Bakker-van Doorn; 1980)[2]

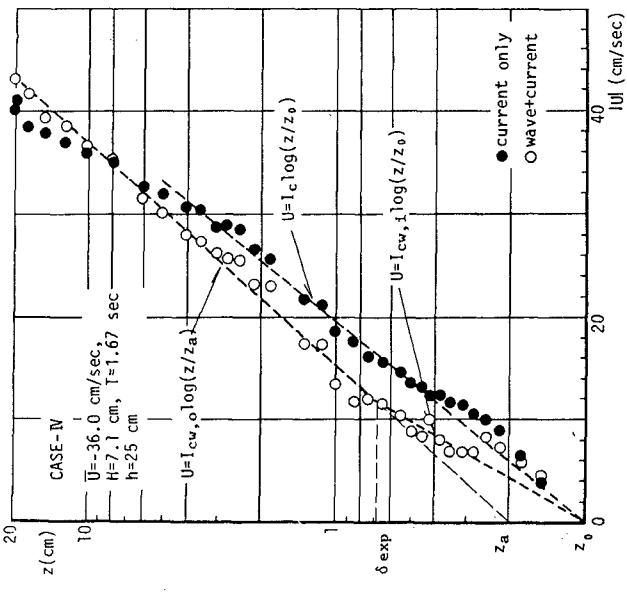

Fig. 12 Velocity profiles of current without and with waves (authors; 1984)[1]

The familiar logarithmic current profile can be found in the current only field. The gradient is defined as I_c and the zero intercept of the logarithmic profile as z_0. Meanwhile, the current velocity in the co-existing field increases more slowly with z in the region of $z \leqq \delta_{exp}$; however, in the range of $z > \delta_{exp}$ the gradient is found to be larger than that of the current only field I_c. The gradients of the current profile in the co-existing field are defined as $I_{cw,i}$ for $z \leqq \delta_{exp}$ and $I_{cw,o}$ for $z \geqq \delta_{exp}$. The zero intercept is obtained by extending the upper velocity profile. The height is named z_a, which means the apparent bottom roughness when waves superimpose on the current.

In the existing analytical model, $I_{cw,o}$ has been treated to be equal to I_c and it has been considered that the gradient of the upper current profile is unchanged and the profile only shifts towards smaller velocity after wave superimposing. However, both of authors' and Bakker-van Doorn's data show that $I_{cw,o}$ is always larger than I_c. This property can be explained by the increase in the time averaged bottom shear stress due to wave superimposing.

In the following, the properties of $I_{cw,i}$, $I_{cw,o}$, δ_{exp} and z_a are discussed. These characteristics are obtained from the Authors', Bakker-van Doorn's and Kemp-Simons' data. Figs. 14, 15, 16 show the relations between these characteristics and the wave current composite ratio $\hat{u}/|U|$. These properties may depend on the other parameters such as $\hat{u}/\sigma z_0$, h/z_0 etc.. However, the dependence on $\hat{u}/|U|$ is only discussed here.

The variation of δ_{exp}/z_0 with $\hat{u}/|U|$ can be expressed by the following equation:

$$\delta_{exp}/z_0 = 1 + 7\,\hat{u}/|U| \tag{9}$$

The following relation between z_a/z_0 and $\hat{u}/|U|$ is found from Fig.15:

$$\frac{z_a}{z_0} = 1 + 1.85\,(\hat{u}/|U|)^2 \tag{10}$$

Meanwhile, the ralation between $I_{cw,o}/I_c$ and $\hat{u}/|U|$ can be expressed in the following equation:

$$I_{cw,o}/I_c = 1 + 0.22\,(\hat{u}/|U|)^{1.4} \tag{11}$$

The reduction of the depth averaged current velocity due to wave superimposing is discussed as follows. Since the velocity in the region $z \leqq \delta_{exp}$ is small enough to be disregarded, the ratio of the depth averaged velocity in the co-existing field $\bar{U}_{mod}$ to that in the current only field $\bar{U}$ is given by,

$$\frac{\bar{U}_{mod}}{\bar{U}} \simeq \frac{I_{cw,o}}{I_c}\,\frac{\ln(\frac{h}{z_a}) - 1}{\ln(\frac{h}{z_0}) - 1} = \frac{I_{cw,o}}{I_c}\left\{1 - \frac{\ln(z_a/z_0)}{\ln(h/z_0) - 1}\right\} \tag{12}$$

Invoking Eqs.(10) and (11), $\bar{U}_{mod}/\bar{U}$ can be calculated as a function of $\hat{u}/|U|$ and h/z_0.

5. Conclusions

This study investigates changes in current properties due to wave superimposing. The variations of the gradient of the mean water level and the current velocity profile in the co-existing field are examined in relation to the consideration on the energy conservation equation including the bottom stress term. The main results obtained in this study are as follows:

1) The gradient of the time averaged water level becomes steep after wave superimposing due to increase in the time averaged bottom shear stress.
2) The experimental results on the energy dissipation for the current component can be well arranged by the wave-current composite ratio. The estimated energy dissipation based on the energy conservation equation agrees fairly well with the experimental results.
3) Several characteristics representing current profiles with and without waves are introduced. Arranging the existing measurements of the current profiles, the relations between the characteristics and the wave-current composite ratio are obtained. The gradient of current profile after wave superimposing above the wave boundary layer is found to be larger than that without waves.

CHAPTER 71

THE DYNAMICS OF OSCILLATING SHEETFLOW

by ir. W.T. Bakker [1] and ir. W.G.M. van Kesteren [2].

1.ABSTRACT.
Two mathematical models for the simulation of the dynamics of sheetflow are presented, an analytical and a numerical one.
In the analytical model the theory of Bagnold (1954) is implemented: a constant ratio between shear stress and normal stresses is assumed.
In the numerical model the motion of each layer of grains is considered separately; each layer exists of a rigid rectangular structure of spherical grains. Grain- grain interaction between the successive layers occurs in two ways: on one hand viscous interaction forces, comparable with squeezing forces in lubrication problems and on the other hand direct contact with elastic response when the distance between the grains becomes less than .01 of the grain diameter. When the relative motion of adjacent layers results into compression or dilatation, a resistant force analogous to the Darcy law is assumed.The numerical model has been combined with the turbulent-boundary layer model of Bakker and v. Kesteren (1984).
Results of computations are compared with measurements of Bagnold (1954) and Horikawa et al (1982).
The analytical model predicted the concentration in the sheet flow layer and the intrusion depth rather well, where the numerical model gave reasonable results with respect to the velocity pattern above the sheetflow layer.
It is concluded, that up to now the more sophisticated assumptions of the numerical model do not lead as yet to higher accuracy with respect to the intrusion depth of the sheet flow, probably because the separation between sheet flow and the turbulent boundary layer above has been assumed too smooth.

2. INTRODUCTION.

In this paper two mathematical models for the simulation of the dynamics of sheetflow are presented, an analytical and a numerical one.
Apart from the approach, also the physical schematization of both models is quite different.
In both models it is taken into account, that at high velocities a thicker layer is moving than during the time lapses with lower velocities.
In the analytical model (Ch. 3) the theory of Bagnold (1954) is implemented: a constant ratio between shear stress and normal stresses is assumed.
In the numerical model (ch.4) the motion of each layer of grains is

[1])Scientific Coordinator Coastal Research, Tidal Waters Department Rijkswaterstaat; Principal Scientific Officer Delft University of Technology
[2])Engineer Delft Hydraulics Laboratory

considered separately; each layer exists of a rigid rectangular structure of spherical grains.
Grain- grain interaction between the successive layers occurs in two ways: on one hand viscous interaction forces, comparable with squeezing forces in lubrication problems and on the other hand direct contact with elastic response when the distance between the grains becomes less than .01 times the grain diameter. When the relative motion of adjacent layers results into compression or dilatation, a resistant force analogous to the Darcy law is assumed.
Results of computations are compared with measurements of Bagnold (1954) and Horikawa et al (1982) (ch.4.2). This leads to the conclusions, given in ch 5.

3. ANALYTICAL COMPUTATIONS.

3.1 Assumptions

For the analytical computations the theory of Bagnold (1954),(1956), concerning bed load in a uniform flow, is used. According to this theory it is assumed that a dispersive pressure P proportional to the grain shearstress T is exerted on the grains. In the viscous region Bagnold finds:

$$T = .75\ P \tag{1a}$$

where T is related to the velocity gradient $\frac{du}{dz}$ in the following way:

$$T = 2.2\ \lambda^{3/2} \rho_w \nu \frac{du}{dz} \tag{1b}$$

in which ρ_w=spec. density water, ν=kin. viscosity, u=horizontal velocity, z=vertical coördinate (pos. upwards); λ is the linear concentration as defined by Bagnold (1954):

$$\lambda = [(c_0/c)^{1/3} - 1]^{-1} \tag{1c}$$

Here c is the concentration, having a maximum c_0.This maximum belonging to the maximum packing density, equals .74, assuming a tetrahedral rectangular piling as depicted in fig 1 and 8.
The validity of the viscous region for the sheetflowphenomena can be estimated with the Bagnold-number:

$$N = \frac{\rho_s \sqrt{\lambda}\ D^2}{\rho_w \nu} \frac{du}{dz} < 40 \tag{2}$$

in which D = grain diameter and ρ_s= spec. density sand.
Substitution of ρ_s/ρ_w=2.65, λ=10, D=.2 mm, ν=10^{-6}m^2/s and $\frac{du}{dz}$ =100 s^{-1} yields: N = 34 .
In a first order harmonic solution the shear stress T is given by:

$$T = \hat{T} \sin \omega t \tag{3}$$

Starting with the assumption in eq.(1), eq.(3) yields for the dispersive pressure:

$$P = \hat{P}\ |\sin \omega t| \tag{4}$$

where ω is the angular frequency of the motion and t is the time; the superscript "^" denotes a top value. Furthermore it is assumed, that

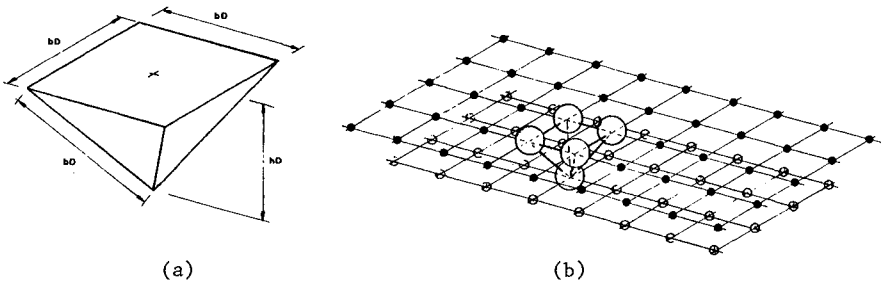

Fig.1 Configuration of moving grain layers.

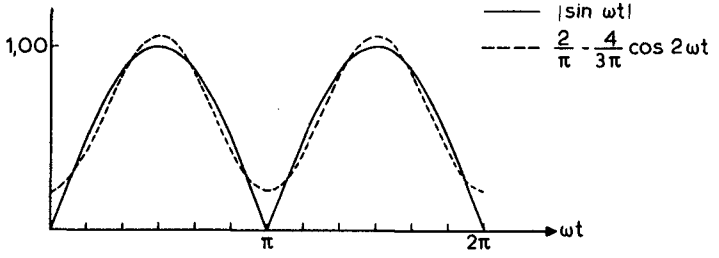

Fig.2 Mean and second harmonic of vertical pressure gradient (p).

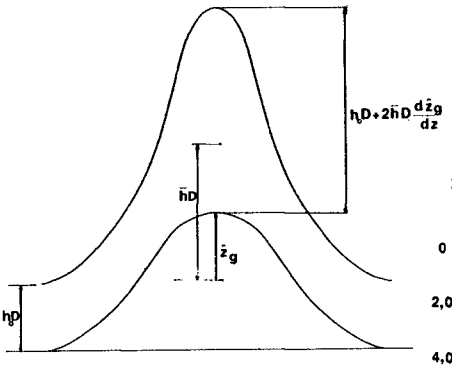

Fig.3 Vertical motion of two adjacent grain layers.

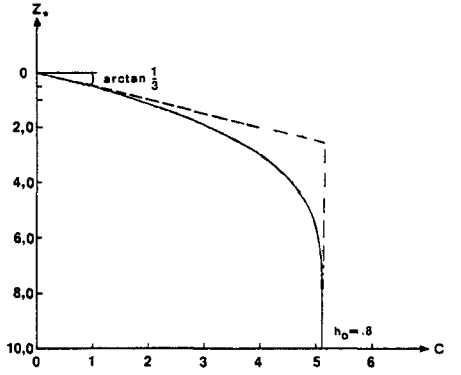

Fig.4 Mean concentration profile in the sheetflow (anal.sol.).

at the moments of rest during the changing of the direction of the oscillation the concentration is constant over the height of the sheet flow layer. The mixture of sand and water in this layer is assumed to be uniformly distributed in horizontal direction and is supposed to oscillate by means of the horizontal pressure gradient and the drag force acting on the grains.

3.2. Analysis.
Where D is the grain diameter, let hD be the mutual vertical distance between the center of two adjacent layers of grains of the sheet flow, when the grains attain their time-averaged vertical position (fig.1a). Then the vertical force p, acting on a layer of grains equals:

$$p = - hD \frac{\partial P}{\partial z} |\sin \omega t| \tag{5}$$

This vertical force can be approximated by its time-average p_0 and its second harmonic, having an amplitude $\hat{p}_2$ (fig 2):

$$p_0 = \frac{2}{\pi} hD \frac{\partial \hat{P}}{\partial z} ; \quad \hat{p}_2 = \frac{4}{3\pi} hD \frac{\partial \hat{P}}{\partial z} \tag{6}$$

Averaged over the wave period, p_0 should balance the weight of one layer of grains.
Furthermore, the second harmonic is counteracted by the vertical drag force $a.\dot{z}_g$, where $\dot{z}_g$ denotes the time-derivative of the vertical position z_g of a grain and "a" denotes a drag coefficient:

$$a = \frac{3\pi \rho_w \nu}{b^2 D (1-c)^3} \tag{7}$$

The drag coefficient is according to Stokes, only hindered settling has been taken into account by means of $(1-c)^3$, where c is the concentration. In (7) bD denotes the horizontal distance between the grains. From the dynamic equation for the second harmonic, $\hat{z}_g$ can be expressed in p_2 and a:

$$\hat{z}_g = \hat{p}_2/(2\omega a) \tag{8}$$

Let the grains in closest packing have a distance $h_0 D$ to each other: $h_0 \cong .8$. This is reached everywhere at the moment of turning of the direction of the orbital velocity. However, $^1/_4$of a wave period later, the porosity is different everywhere, because of the vertical gradient of the vertical motion: the upper grain dances more vigorously than the lower one (fig 3). Therefore, the time-averaged distance between the grains equals:

$$\bar{h}D = h_0 D + \bar{h}D \frac{\partial}{\partial z} (\hat{z}_g) \tag{9}$$

Thus the time-mean vertical spacing between the grains can be expressed in the variation of the vertical pressure p_2. However, this value $\hat{p}_2$ equals $(2/3)p_0$, according to (6), p_0 being equal to the weight of a grain layer. Thus from (8) it shows, that z_g only varies in vertical sense because the concentration varies in vertical sense. One thus understands, that (9) is essentially a differential equation in the concentration, as also h can be expressed in the concentration:

$$h = (1/\sqrt{2})(c_0/c)^{1/3} \tag{10}$$

After some elaboration (cf. Bakker & v.Kesteren (1982)), one finds the dimensionless equation:

$$\frac{\partial c}{\partial z^*} = \{h_0\sqrt{2}.(c/c_0)^{1/3} - 1\}/\{3(1 - c^2)\} \tag{11}$$

$$z^* = z/Z; \quad Z = \frac{1}{54}\,\frac{\rho_s - \rho_w}{\rho_w}\,\frac{g\,D^2}{\omega\,\nu} \tag{12}$$

Eq (11) has been solved, using Simpson's integration method, thus giving c as function of z (fig 4)
A first approximation for the time dependent concentration can be found from the mean concentrationprofile resulting from eq.(11).
Neglecting phase shifts a first order time dependent distance between the grains is given by ($\bar{h}$ denoting the mean value of h):

$$h(t)D = \bar{h}D + (\bar{h}D - h_0D)\sin(2\omega t) \tag{13}$$

Substituting eq.(10) into (13) gives for the timedependent concentration (fig 4) (c_ℓ denoting the limiting value of the concentration in the sheetflow):

$$\frac{c(t)}{c_\ell} = [(\frac{\bar{c}}{c_\ell})^{-1/3} - \{(\frac{\bar{c}}{c_\ell})^{-1/3} - 1\}\sin 2\omega t]^{-3} \tag{14}$$

$$\text{where } c_\ell = \frac{c_a}{(h_0\sqrt{2})^3} \tag{15}$$

Also a first approximation for the intrusiondepth of the sheetflow layer as function of time can be made. Schematizing more rigorously than before, the concentration in the moving sheet layer can be assumed as constant.
As the pressure increases linearly with the depth the grain shear stress also increases linearly and thus (for viscous flow) a parabolic velocity distribution is found (fig 5):

$$u = \hat{U}\,(1 - \frac{z^2}{H^2})\cos\omega t \text{ when } z \leq H \tag{16}$$

$$u = 0 \qquad \text{when } z > H$$

where $\hat{U}$ is the maximum velocity at the top of the sheetflow layer and equals the maximum velocity in the wave boundary layer; H is the time-dependent intrusion depth or thickness of sheetflow layer given by:

$$H = \hat{H}\sqrt{|\cos\omega t|} \tag{17}$$

where $\hat{H}$ is the maximum intrusion depth.
From eq. (1b), (1c) and (16) results for the shear stress:

$$T = 4.4\,\rho_w\nu\,[(\frac{c}{c_0})^{1/3} - 1]^{-3/2}\,\frac{\hat{U}.z}{H^2} \tag{18}$$

This is accompanied by a dispersive pressure gradient given by:

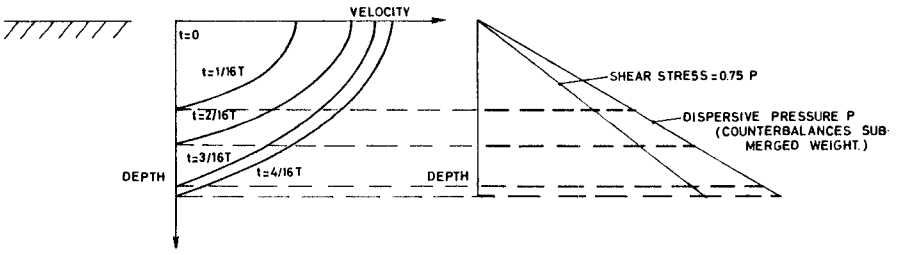

Fig.5 Assumed velocity and stress distribution in the sheetflow (anal.)

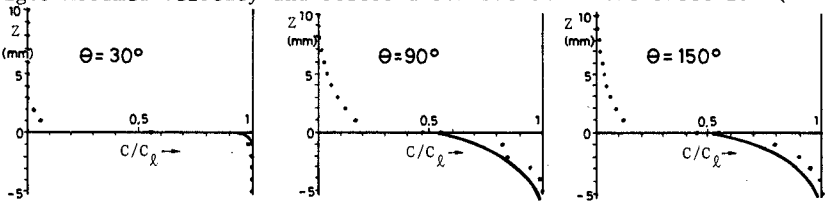
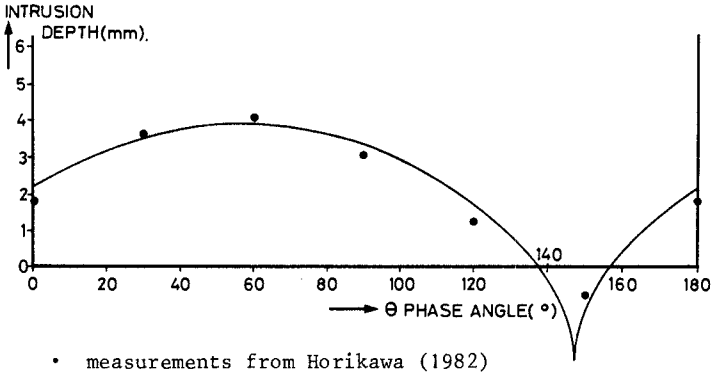


• measurements from Horikawa (1982)
—— analytical theory

Fig.6 Concentration profiles in the sheetflow (anal. comp.).



• measurements from Horikawa (1982)
—— analytical theory

Fig.7 Intrusion depth as function of time (anal. comp.).

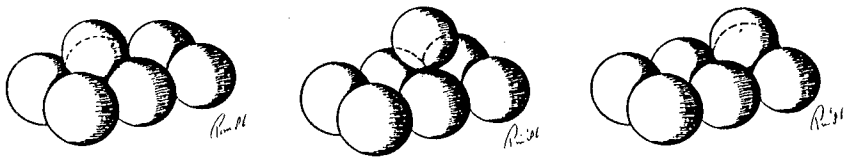


Fig.8 Relative grain motion in two adjacent layers.

$$\frac{\partial P}{\partial z} = 4.4\ \rho_w \nu\ [(\frac{c}{c_0})^{1/3} - 1]^{-3/2}\ \frac{\hat{U}}{H^2}\ \text{cotan}\ \alpha \qquad (19)$$

where α is the angle of internal friction. (tan α = .75; eq (1a))
Because this pressure gradient must counterbalance the gravity forces on the (submerged) grains an expression for H can be found:

$$\hat{H} = \sqrt{4.4\ \frac{\rho_w}{\rho_s - \rho_w}\ \frac{\nu\ \hat{U}}{c\ g}\ [(\frac{c}{c_0})^{1/3} - 1]^{-3/2}\ \text{cotan}\ \alpha} \qquad (20)$$

The time-dependent intrusiondepth H is given by eq.(17).

3.3. Results.
Figure 6 shows some results of the calculated variation (according eq.(14)) of the concentration during half a wave period, compared with the measurements of Horikawa et al (1982). In an oscillating water tunnel Horikawa carried out a series of laboratory experiments under sheet flow condition. The following deals with his experiment 1-1 with a period of 3.6 sec and a maximum orbital velocity of 1.27 m/sec.
Figure 7 gives the intrusion depth (point of zero velocity) of the sheet flow layer as function of time, also compared with the results of Horikawa et al. The depth H has to be taken, starting from a time-averaged bottom level, which is higher than the still bottom level. (The zero-level in the plots of Horikawa). The maximum intrusion depth is assumed to occur at the time of maximum velocity at level z=0 (phase angle $\theta = 60^0$). The theory would predict "still-water-concentration" for $\theta = 15^0$ (60^0 minus a phase shift of 45^0). This tendency also follows from Horikawa's data and from the numerical method treated below (fig 13b).

4. NUMERICAL COMPUTATIONS.

4.1. Grain-grain interactions in the numerical model
In the numerical model the motion of each layer of grains is considered separately; each layer exists of a rigid rectangular structure of spherical grains (Fig 1b). Grain- grain interaction between the successive layers occurs in two ways: on one hand viscous interaction forces, comparable with squeezing forces in lubrication problems and on the other hand direct contact with elastic response when the distance between the grains becomes less than .01 of the grain diameter. When the relative motion of adjacent layers results into compression or dilatation, a resistant force analogous to the Darcy law is assumed The viscous interaction forces are reproduced in the following way.
Let F_s be the Stokes force, exerted on a sphere, moving with velocity u in a fluid:

$$F_s = 6\ \pi\ \rho_w\ \nu\ u\ R \qquad (21)$$

in which R is the radius of the sphere.
Many scientists investigated the increase of this force, when this sphere move to a wall, for instance Lorentz (1907).For the behaviour of the compression force in the immediate vicinity of the wall. Cox and Brenner (1967) find as asymptotic expansion:

$$F/F_s = \varepsilon^{-1} \ (1- .2\varepsilon \ln \varepsilon + .9712 \ \varepsilon \ ) \tag{22}$$

$$\text{where: } \varepsilon = e_1/R \tag{23}$$

and e_1 is the distance between wall and sphere.
Truncating still earlier, one finds a lubrication limit, attributed to Taylor by Ambari et al (1984)

$$F/F_s = 1/\varepsilon \tag{24}$$

In the numerical model, in the contact points between the grains of two successive layers a contact force according to (24) has been assumed, where e_1 is taken as the distance between the spheres.
This force acts on the grains, resulting in a elastic compression, according to Timoshenko and Godier (1951) equal to:

$$\Delta s = A \ F^{2/3} \tag{25}$$

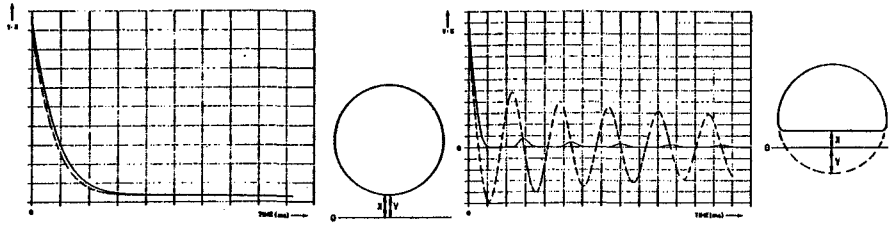
$$\text{in which: } A = \frac{9}{2}\left[\frac{(1 - \nu_c^2)^2}{E^2 \ R}\right]^{1/3} \tag{26}$$

where ν_c is the contraction coefficient
Thus the distance between the centers of two grains becomes $2R - \Delta s$; from the two equations (22) and (25) for F the quantity Δs may be eliminated; F can be related to the distance between the centers of the grains of two successive layers.
In order to demonstrate the resulting way of collision, fig.$9^{a..d}$ shows the motion of the center of gravity y and of the grain surface x when a (smooth) sphere approaches a wall, starting with a certain velocity; this velocity increases in the various figures a..d. In fig. $9^{a..c}$ the sphere comes to rest at a certain distance from the wall, eventually after some elastic rebound. In fig 9^{d} the suction forces between sphere and wall exceed the cavitation limit of the fluid, which liberates the sphere from the wall: an elastic rebound occurs.

Also in the numerical model for the grain piling a tetrahedral piling is assumed.The effect of protuberances is taken into account, with direct contact with elastic response when the distance between the grains becomes less than .01 times the grain diameter. Fig 8 shows the way of motion of the grains. Each grain falls in the hole, shaped by 4 other grains on a lower level. In the equation of motion in horizontal direction sand and water are taken together; in vertical direction sand and water are treated separately, where inertia effects have been taken into account. With respect to friction, a drag coefficient similar to eq. (7) is assumed.
Apart from the friction, resulting from the horizontal components of the pressures in the contact points, viscous friction between the various layers is taken into account

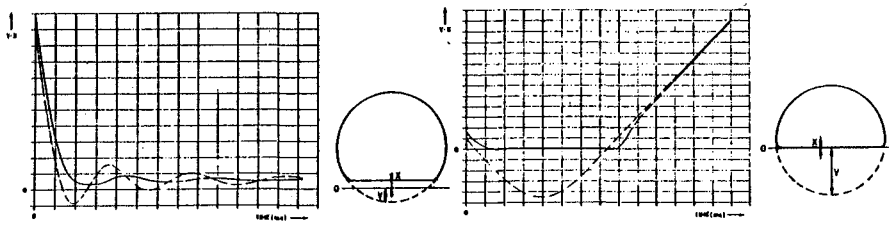
The model of the sheetflow layer disposed here has been combined with the near- bottom velocity model, exposed by Bakker and van Kesteren (1984). In this implicit model, the shear stress τ_b at the top of the sheet flow layer has been determined from the local velocity gradient:

$$\tau_b = \rho_w \kappa^2 z^2 \ \frac{u_2 - u_1}{\Delta z} \ \left|\frac{u_2 - u_1}{\Delta z}\right| \tag{27}$$



(a) U=.01 m/s

(c) U=.1 m/s



(b) U=.05 m/s
R=.1 mm, E=10 GPa, $\nu=10^{-6}m^2/s$

(d) U=1 m/s

—— x = distance sphere surface to wall
----y = distance sphere centre to wall minus sphere radius

Fig.9 Visco-elastic collision of sphere with wall.

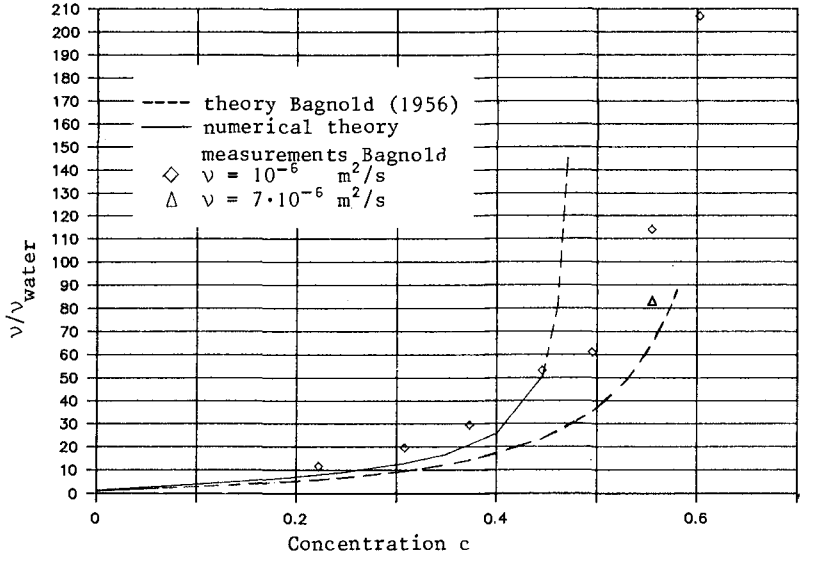


Fig.10 Increase of appearent viscosity as function of the concentration

where u_1 is the velocity of the upper sheet flow layer and u_2 of the first grid point in the (pure) water; the constant κ is the von Karman constant. The level "z=0" has been chosen at the still- sand level, starting from the intuitive feeling that the mixing length κz should be of the order of the vertical motion of the top of the sheetflow layer.

4.2. Results.

In this chapter the results of the numerical model are compared with experiments of Bagnold (1956) and Horikawa (1982)

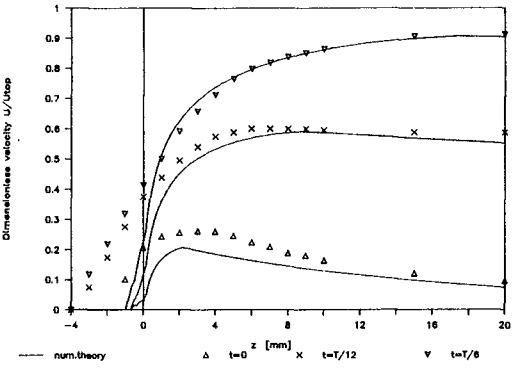
Fig. 10 shows the results of a numerical simulation of plain shear, applied on grains with the same weight as the surrounding fluid. From this the increase of the concentration on pseudo- viscosity can be investigated. With the assumption of uniform shear between two parallel planes the motion becomes symmetrical, thus giving parallel motion of all the layers. Thus blocking is found when the grains in the layers can not slide between each other without transversal displacement. This occurs for a concentration higher than 48 %. Furthermore the increase in viscosity agrees rather well with Bagnold 's theory and measurements (fig 10).

However, where Bagnold experimentally finds a ratio between normal stress and shear stress equal to .75, the numerical model gives time-averaged normal stresses which are much lower. This is about as could be expected: for concentrations less than 48 % the grains move straight forward without hindering each other too much.

Fig 11 to 14 show the results of an experiment of Horikawa (1982), which has been numerically simulated.

Fig 11^a shows a comparison between measurements and numerical results concerning the velocity profile. Fig 11^b shows the velocities in the various sheetflow layers as function of time; totally 9 layers were mobilized. Layer 1 is the upper one. For the elasticity module a value of 10 MPa has been taken; however, similar computations with soft grains with an elasticity modulus of .1 MPa gave similar results. This indicates, that the effect of the viscous squeezing is much more of importance than the elasticity. Fig 13^a shows the concentration in the grain layers; the numerical model "chooses" its own concentration, depending on the interaction forces between the various layers. In the Horikawa experiment, this concentration is 74 % when the material is in rest (densiest packing) and about 60 % when the material is moving. The same appears from fig 13^b, giving the concentration profiles at various times.

Fig 12 gives the shear stress in the course of time for layer 1 and layer 9. Because in this case gravity takes care for vertical shifting of the layers (different from the Bagnold case), the pattern.is rather irregular. Therefore also the first harmonics are drawn; from this it shows, that the result of the analytical theory, a shear stress , constant per layer and increasing with the depth is too naive. The shear stress as found from the numerical model is not determined by the own weight of the grains, but by the shear stress on the surface. The result of the Bagnold theory of the constant ratio between shear stress and normal stress is checked also in fig 14, giving this ratio as it follows from the mathematical model. In the lower layers, which keep in rest, this ratio decreases gradually (starting from .75)



measurements from Horikawa (1982): exp.(1-1)

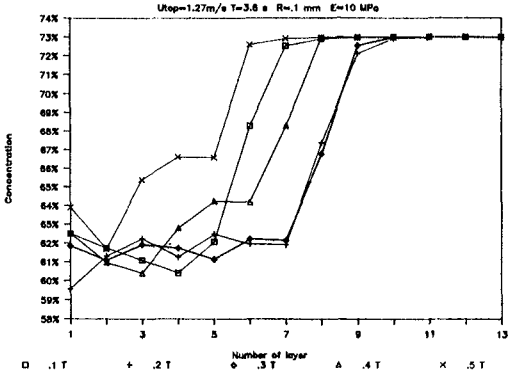

Fig.13a Concentration profiles at various times (num.comp.).

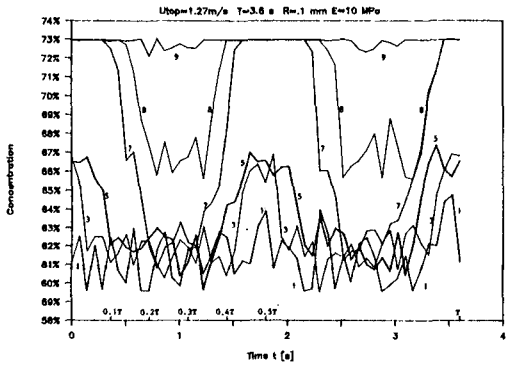

Fig.13b Concentration in the grain layers 1,3,5,7,8 and 9 (num.comp.).

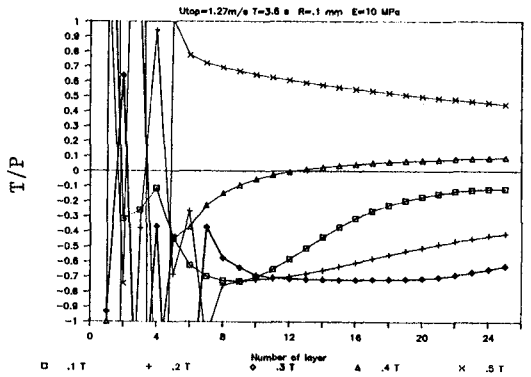

Fig.14 Ratio "shear stress / normal stress" at various times (num.comp).

because of the increasing own weight. In the higher layers, which are in motion, the ratio varies randomly between +10 and -10
It shows, that the numerical model does not tally quite with Bagnold's theory with respect to the dispersive stress.However, the physics of the Bagnold theory is not quite clear.
Indeed, one finds in the viscous region a "transverse pressure analogous to that which occurs in the static arching of grains in contact ", as stated by Bagnold (1954) ("a transverse dispersive tendency of a dense overtaking motor traffic along a one-way road"). However, in the numerical model grains moving from each other after a "collision" tear the layers from each other, by inertia of the grains, combined with viscous forces. This gives tension forces between the grains of the same order as the pressure forces. Where the pressure forces are more vigorous, the tension forces are more persistent, resulting in a very small value of the normal pressure. This appears from calculations with simplified models.
Furthermore dispersive forces are created by the convective terms in the equation of motion for the water in the pores between the grains. In the numerical model, these terms appear to be only a few percent of the shear stress. On one hand this follows from calculations in which the convective terms were left out, on the other hand by simplified calculations in which only this effect was taken into account.
From these calculations one finds a timeaveraged vertical pressure gradient of the order of magnitude of the energy of the vertical motion on the top of the shear flow layer.This vertical motion appears to be in the model only a few mm/sec.
Altogether the impression arises, that the motion on the top of the shear flow layer is too small; the motion is too smooth with as a result, that the shear stresses are too low and therefore the intrusion depth too small: in the numerical model the intrusion depth is 1.5 mm and in the Horikawa experiments 5 mm.
On the other hand Horikawa et al might have overestimated the transport somewhat, although this certainly will not explain the difference in order of magnitude.
Before the grains are able to move the grain structure first has to adopt a somewhat higher porosity. Therefore the highest point with zero amplitude, which determines the lower boundary of the velocity profile of the sheetflow-layer will be higher than the highest point of zero dilatation (cp. fig 11 and 12). This has not been taken into account by Horikawa et al (1982).

5. CONCLUSIONS.

Comparing analytical and numerical model with one of the experimental results of Horikawa et al (1982) leads to the following conclusions:

a. The analytical model reproduces concentration profiles and intrusion depth reasonably well (fig 6 and 7)). Assumptions about velocity profile and shear stress distribution however are too primitive (cp. fig 5 and fig 11 for analytical and numerical computations respectively).

b. Use of the Bagnold theory of constant shear stress ratio in the analytical model leads to better approximation of the intrusion depth than in the numerical model. The numerical model underestimates this depth.
However, the physics of the Bagnold theory is not quite clear.

Indeed, one finds in the viscous region a "transverse pressure analogous to that which occurs in the static arching of grains in contact ", as stated by Bagnold (1954). However, in the numerical model grains moving from each other after a "collision" tear the layers from each other, by inertia of the grains, combined with viscous forces. This gives tension forces between the grains of the same order as the pressure forces. Where the pressure forces are more vigorous, the tension forces are more persistent, resulting in a very small value of the normal pressure.

Furthermore dispersive forces are created by the convective terms in the equation of motion for the water in the pores between the grains. In the numerical model, these terms appear to be only a few percent of the shear stress.

In the numerical model the ratio between pressure and shear stress as found by Bagnold is only a continuous function of depth in the region with no significant motion (fig 14). In the sheetflow layers, the ratio varies at random between +10 and -10.

The increase of viscosity as found by Bagnold reproduces rather well in the numerical model (fig 10). However, simulating numerically the experimental set-up of Bagnold (grains with the same weight as the fluid) in the model a total blocking occurs at a concentration of 48 %, due to a schematization, which is too regular.

c. Of the two possibilities of the numerical model for transferring grain forces from one layer to another: (by "lubrication" or by direct elastic contact), the effect of lubrication appears to be the most important. This appears from comparitive calculations with various values of the elasticity of the grains, which did not have much effect on the intrusion depth of the sheetflow

d. The impression rises, - as well from the velocity distribution as from the intrusion depth - that the present numerical model is too smooth. In this model the transition between sheet flow layer and the uper layer is not yet well reproduced. One might expect here a transition layer with high turbulence, as occurs in density currents. This will give higher shear stress and higher vertical gradients of time- averaged vertical pressures, probably resulting in a higher intrusion depth of the sheetflow.

e. Before the grains are able to move the grain structure first has to adopt a somewhat higher porosity. Therefore the highest point with zero amplitude, which determines the lower boundary of the velocity profile of the sheetflow-layer will be higher than the highest point of zero dilatation (cp. fig 11 and 12). This has not been taken into account by Horikawa et al (1982). This might lead to overestimation of the transport.

f. A more extensive experimental verification of the theory under a broad range of circumstances is needed. For this goal a large pulsating water tunnel is constructed in the Delft Hydraulics Laboratory.

6. ACKNOWLEDGEMENT.

The authors are indebted to prof. K. Horikawa for sending additional information about his experiments. Mr. E. Haak carried out very useful computations. Financial support by the Royal Dutch Society for Sciences and by Rijkswaterstaat is gratefully acknowledged.

CHAPTER 72

Toward A Simple Model of the Wave Breaking Transition Region in Surf Zones

David R. Basco[1] and Takao Yamashita[2]

Abstract

Breaking waves undergo a transition from oscillatory, irrotational motion, to highly rotational (turbulent) motion with some particle translation. On plane or monotonically decreasing beach profiles, this physically takes place in such a way that the mean water level remains essentially constant within the transition region. Further shoreward a rapid set-up takes place within the inner, bore-like region. The new surf zone model of Svendsen (1984) begins at this transition point and the new wave there contains a trapped volume of water within the surface roller moving with the wave speed. This paper describes a simple model over the transition zone designed to match the Svendsen (1984) model at the end of the transition region. It uses a simple, linear growth model for the surface roller area development and semi-empirical model for the variation of the wave shape factor. Breaking wave type can vary from spilling through plunging as given by a surf similarity parameter.

The model calculates the wave height decrease and width of the transition region for all breaker types on plane or monotonically depth decreasing beaches.

1.0 Introduction

A general understanding of the mean flow fields in the transition region of breaking-broken water waves has yet to be achieved. The wave character undergoes a transformation from irrotational, orbital particle motion to rotational, highly turbulent motion with some particle translation. We shall herein define the transition region width from the break point to the point (transition point) where the mean water surface changes from essentially level to an increasing slope (wave set-up). This paper presents relatively simple relationships to calculate the wave height decrease and width of the transition region for plane beaches.

After the transition, the broken wave propagates as a moving bore containing a trapped volume of water in the surface roller moving with the wave speed (Svendsen, 1984). Plunging breakers have an identifiable plunge point where the overturning, falling jet impacts the oncoming trough. Thereafter, a relatively short and violent flow redistribution occurs to develop the bore-like wave character. Spilling breakers have essentially zero plunge distance to begin rotation, but then a relatively long and gradual flow redistribution

[1]Professor Civil Engineering and Director, Coastal Engineering Institute, Old Dominion Univ., Norfolk, VA 23508
[2]Instructor, Diaster Prevention Research Institute, Kyoto University Kyoto 611, Japan.

takes place over the water column. In general, the transition width for spilling breakers is greater than for plunging breakers. We shall tacitly assume that the end of the transition region for both plungers and spillers is also identifiable by the bore-like character of the broken wave within the inner-surf zone region.

Wave height change within and the width of the transition region are not insignificant quantities. Figure 1 shows the wave height, H; celerity, c; and mean water level, $\bar{\eta}$ (set-down, set-up) variations before and through the surf zone (courtesy J. Buhr Hansen) for laboratory scale waves breaking on a plane beach. Zone I is the transition region where $\bar{\eta}$ is (relatively) constant. In this example, roughly one-third of the wave height decrease takes place in a transition distance that is approximately one-quarter of the surf zone width. Galvin (1969) presented a method to estimate the plunge distance from laboratory data on plane beaches. Visser (1984) developed a mathematical model for the wave-induced longshore current which critically hinged on the physical fact that dissipation of wave energy begins at the plunge point and not over the entire surf zone. His laboratory experiments for plunging breakers resulted in plunge distances ranging from 22-43% of the total surf zone width. By definition, the transition width will be an even greater percentage.

We limit this discussion to waves breaking on plane or monotonically (depth) decreasing beaches. In deep water or for waves breaking on bars, the excessive depths after the break point will result in completely different internal physical processes. A fully developed, bore-like wave character may never be achieved, the mean water level may not stay constant and consequently, the transition width may have to be redefined.

2.0 Qualitative Description

A qualitative description of processes and mechanisms within the transition region has been presented by Basco (1985). Both classic spilling and plunging type breakers were found to have similar initial breaking motions, but at vastly different scales. Two primary vortex motions were identified. A plunger vortex is initially created by the overturning jet, which in turn causes a splash-up of trough fluid and subsequent formation of a surface vortex of similar scale. Figure 2 schematically depicts a strong plunging breaker. For plunging breakers, this plunger vortex translates laterally to push up a new surface wave with new wave kinematics that continues propagating into the inner surf zone. For spilling breakers, the small scale plunger vortex creates a small scale disturbance masked by the larger carrier wave. However, the resulting surface roller at the crest slides down and grows in size on the face of the main wave. The end result is also a new wave kinematic structure.

This sequence of events is schematically depicted in Figure 3 for a plunging breaker. Two new key features were introduced for the first time by Basco (1985). The overturning jet is deflected down and to the rear by the onrushing trough to create a rotating fluid mass system (steps 1-5). This plunger vortex translates horizontally much

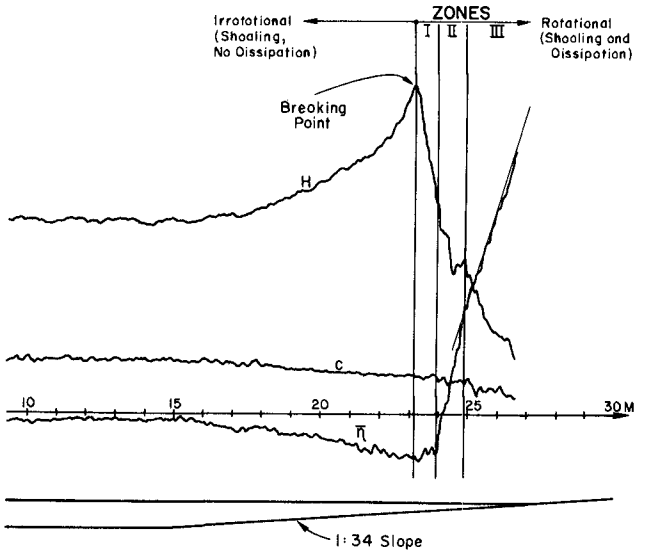

Fig. 1 Example of wave height, celerity and mean water level variations before and after breaking (Test No. 053074 courtesy J. Buhr Hansen, 1982)

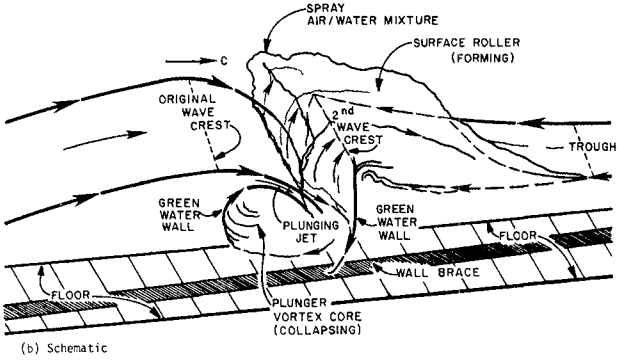

Fig. 2 Schematic of strong plunging breaker

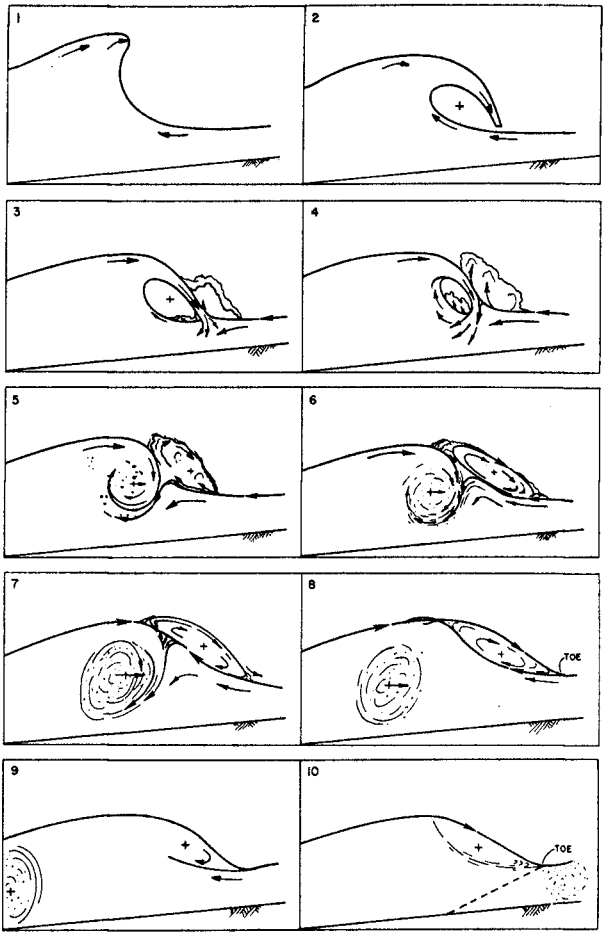

Fig. 3 Schematic sequence of breaking wave events (From Basco, 1985)

like a piston wave board to push up a rising water surface and simultaneously create a new, secondary surface disturbance (5-8). The plunger vortex comes to rest and is left behind which marks the end of the original propagating wave (8-10). The transition point occurs somewhere near step 8.

A new wave has been created (9-10) with kinematic structure that results from mean momentum redistribution and turbulence transport in both vertical and horizontal dimensions. Turbulance production, advection, diffusion and dissipation are locally in a nonequilibrium state. The turbulent redistribution of the mean, internal velocity field results in a trapped, concentration of mass within the surface roller that moves with the wave. Beneath the roller, fluid particles retain their orbital character but in a highly turbulent state.

The transition region can now be viewed as the zone where the original, irrotational, wave like motion comes to rest and simultaneously generates a new, secondary, bore-like wave with completely different wave kinematics as in the Svendsen (1984) model discussed below.

3.0 Recent Theory and Paradoxes

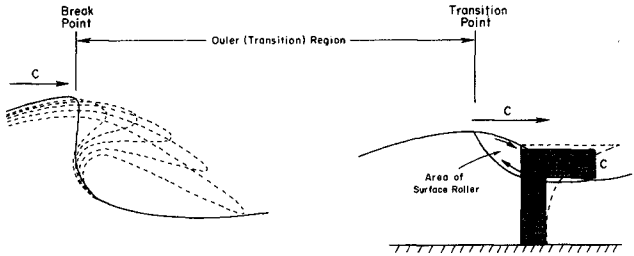
The surf zone model of Svendsen (1984) begins at the transition point. Here, the mean velocity profile relative to a fixed observer is as shown by the dashed line in Figure 4 and area, A. Svendsen found a correlation between A and wave height squared from laboratory data as shown in Figure 4b. The presence of the trapped surface roller was modeled by the simple velocity profile (Figure 4b) and significantly altered both the momentum flux (radiation stress) and energy flux over that determined by linear wave theory. In fact, the radiation stress, S_{xx} increased by 50-100% and the energy flux, E_f essentially doubled.

The resulting conservation equations when solved together permitted calculation of the wave height decrease and mean water surface increase across the inner region. An example comparison of theory (solid line) and laboratory experimental data is reproduced as Figure 5 (from Svendsen, 1984). Note that the theory begins at the transition point, not at the break point. And, that the theory without the surface roller effect (dashed line) gives incorrect results.

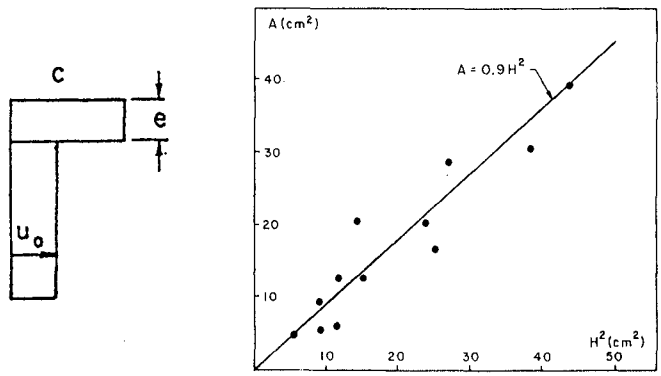
Consider the cross-shore momentum balance equation for depth-integrated and time-averaged wave motion

$$\frac{dS_{xx}}{dx} + \rho g h \frac{d\bar{\eta}}{dx} = 0 \qquad (1)$$

where: $h = \bar{\eta} + d$, the mean water depth,
d = the still water depth,
$\bar{\eta}$ = the mean water level change (set-up, set-down),
ρ = the fluid mass density, and
g = the gavitational acceleration.



(a) Velocity profile at end of transition (transition point)



(b) Correlation between surface roller area and wave height, H^2 (from Svendsen, 1984)

Fig. 4 Schematic of wave breaking profiles through transition region

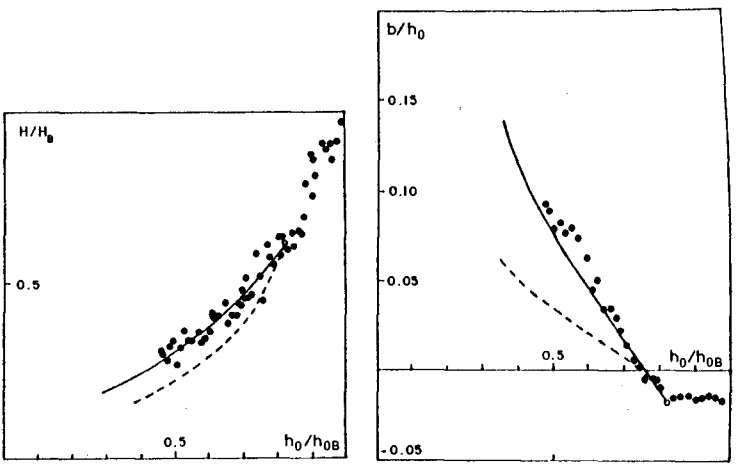


Fig. 5 Wave heights and set-up for a wave with deep water steepness (From Svendsen, 1984, Fig. 13, p. 322)

The data in Figures 1 and 5 reveal that $\bar{\eta}$ is essentially constant across the transition region. This means from Eqn. (1) that S_{xx} is proportional to the wave height squared (e.g. Longuet-Higgins and Stewart, 1964). This presents a paradox. How can $\bar{\eta}$ (i.e. Sxx) remain constant when H decreases rapidly across the transition region? We shall return to this point below.

A second point of emphasis concerns the common misconception that breaking wave height decrease is solely due to energy dissipation through turbulence. Using time-averaged conservation laws of momentum and energy across the transition region considered as one control volume (analogous to the hydraulic jump), Svendsen (1984) demonstrated that about one-third of the energy change due to wave height decrease was actually lost as dissipation. The remaining two-thirds was energy redistribution between potential (pressure) and kinetic (velocity) forms. Thus to continue to view wave breaking as the same wave propagating with some energy dissipation is to miss the fundamental physical transition taking place internally between the velocity and pressure related terms in the momentum and energy balance equations.

4.0 Elements of a Simple Quantified Model

It is instructive to first quantify the momentum flux distribution due to velocity and pressure related components across a steady hydraulic jump.

4.1 Stationary Hydraulic Jump

The total momentum, m (per unit mass density and sectional area) at any section before, within, and after a hydraulic jump can be written

$$m = m_v + m_p \tag{2}$$

or

$$m = \frac{\alpha q^2}{d} + \frac{1}{2} g d^2 \tag{3}$$

where: $q \equiv \int_0^d u\,dz$, the volumetric flowrate,
u = the horizontal velocity component,
d = the local water depth,
z = the vertical coordinate, and
$\alpha \equiv \frac{d}{q^2}\int_0^d u^2\,dz$, the momentum correction coefficient.

Total momentum is the sum of that due to velocity, m_v and that due to an assumed hydrostatic pressure distribution, m_p.

Using the definition of a Froude number, F along with known jump entrance conditions, u_1, d_1, it can be easily show that

$$\frac{m_{v_1}}{m} = \frac{F_1^2}{F_1^2 + \frac{1}{2}} \tag{4}$$

from which it follows that

$$\frac{m_{p_1}}{m} = 1 - \frac{m_{v_1}}{m} \tag{5}$$

From the sequent-depth equation the subcritical downstream depth, d_2, can be determined and similar expressions for m_{v2} and m_{p2} established in terms of F_2. The key fact is that total momentum, m is constant across the hydraulic jump.

Svendsen and Madison (1983) present a new hydraulic jump theory in which the momentum correction coefficient, α is given by the relationship

$$\alpha \equiv \zeta\left[1 + \frac{1}{2F_1^2}(1-\zeta^2)\right] \tag{6}$$

where $$\zeta = \frac{d(x)}{d_1}$$

Using their method, one can calculate d(x) for a given F_1 and consequently, using (6), (3), (4) and (5), in that order, we can also calculate the theoretical partition of m_v and m_p across the jump. Figure 6 presents the results for some representative inlet Froude numbers. For example, when F_1=3 almost 95% of the total momentum at the inlet is due to velocity and only 5% from pressure. Whereas, at the exit, now only 25% is velocity related while nearly 75% is due to pressure. We also see that the jump roller which contains a flow reversal creates $\alpha > 1$ through the jump and is responsible for the nonlinear distributions of m_v and m_p components.

4.2 Broken Waves in Inner Surf Zone Region

Next, consider the time-averaged and depth-integrated excess momentum flux, i.e. the radiation stress for the inner region. For the simplified velocity profile through the trapped surface roller (Fig. 4b), Svendsen (1984) found that

$$\begin{aligned} S_{xx} &= S_v + S_p \\ &= \left[\rho g H^2\left(B_o + \frac{A}{H^2}\frac{h}{L}\right)\right] + \frac{1}{2}\rho g H^2 B_o \end{aligned} \tag{7}$$

where

L = the wave length, and

$$B_o \equiv \frac{1}{T}\int_0^T \frac{\eta^2}{H^2}\,dt \tag{8}$$

with

T = the wave period.

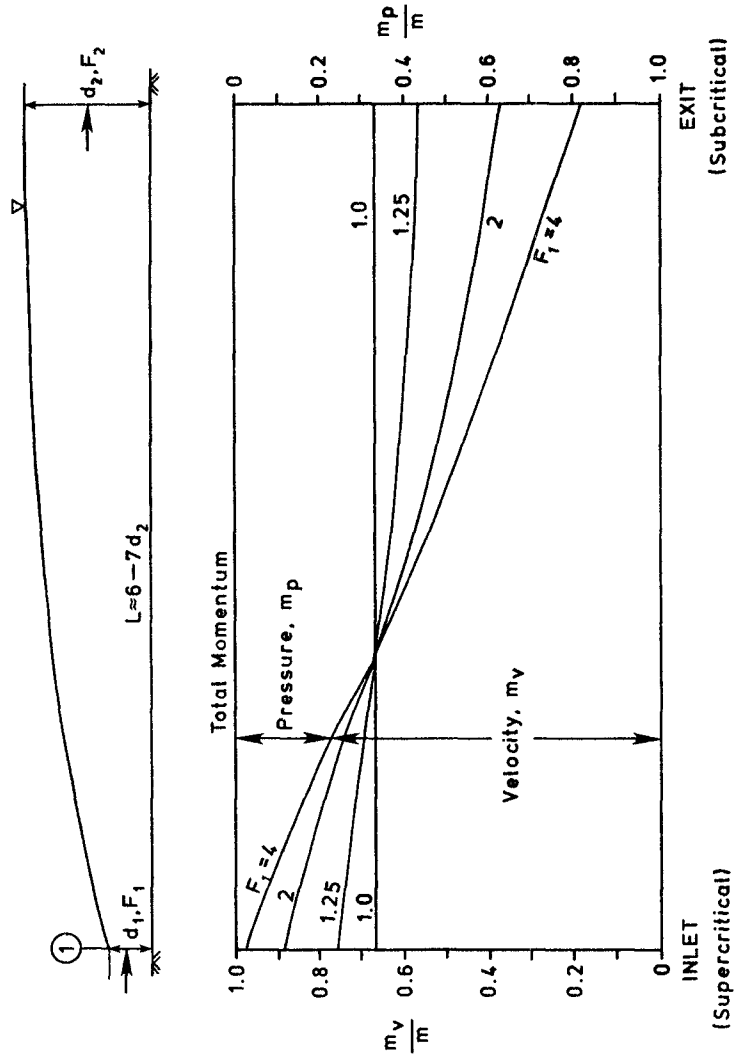

Fig. 6 Partition of velocity and pressure momentum components through a steady, hydraulic jump

B_o is a wave surface shape factor discussed in further detail below. The first part of Equation (7) is that part of S_{xx} due to velocity, S_v and the latter is due to pressure, S_p. Recall that by definition, S_{xx} is the total flux of horizontal momentum across a vertical plane minus the stillwater hydrostatic pressure force. Hence the total force (per unit length) at any section is given by

$$M_{xx} = S_{xx} + \frac{1}{2}\rho g d^2 \tag{9}$$

This results in a total pressure related component, F_p for total momentum given by

$$\begin{aligned} F_p &= S_p + \tfrac{1}{2}\rho g d^2 \\ &= \tfrac{1}{2}\rho g H^2 B_o + \tfrac{1}{2}\rho g d^2 \\ &= \tfrac{1}{2}\rho g (H^2 B_o + d^2) \end{aligned} \tag{10}$$

As an example, consider the partition of a normalized radiation stress, P given by

$$P = P_v \text{ (velocity)} + P_p \text{ (pressure)}$$

$$= \frac{S_{xx}}{\rho g H^2} = \left(B_o + \frac{A}{H^2}\frac{h}{L}\right) + \frac{1}{2} B_o \tag{11}$$

From typical values for plunging breakers, as given by Svendsen (1984) for A/H^2, h/L and B_o, the ratio of P_v/P_p was about 3.5 at the transition point. This means that about 80% of the total excess momentum flux at the transition point is due to velocity. However, when total momentum is considered, the broken waves account for only 20% of the total present.

4.3 Breaking/Broken Waves in Transition Region.

We now return to the first paradox, namely how the mean water level, $\bar{\eta}$ and hence S_{xx} from Equation (1) can remain constant when H decreases rapidly across the transition region. From Equation (7) it becomes apparent that both the A/H^2 ratio and B_o must vary considerably to keep S_{xx} at a constant level. In what follows we tacitly assume that h/L remains essentially constant within the transition region, for a give situation.

Surface Roller Area. For plunging breakers, the surface roller begins forming at the plunge point. For spillers, it grows in size right from the break point. No experimental information is available. We therefore assume a linear growth of the A/H^2 ratio as depicted in Figure 7 from a zero level to a peak of 0.9 at the transition point. Consequently, we match the Svendsen (1984) model at the start of the inner surf zone region.

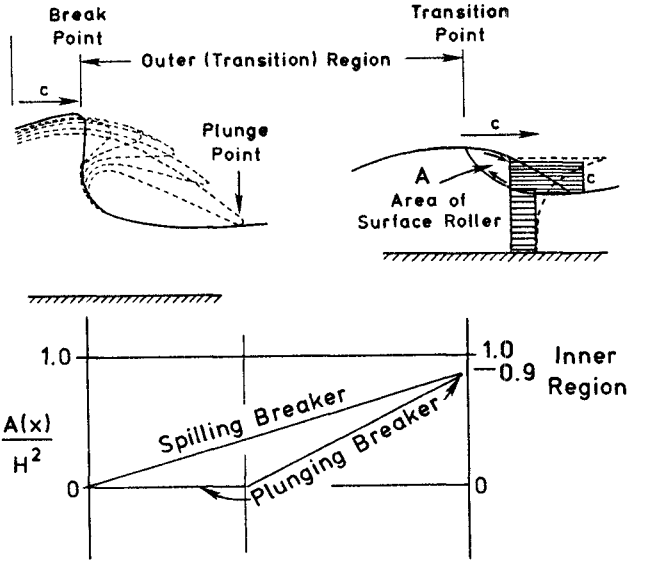

Fig. 7 Empirical $A(x)/H^2$ distribution through transition region for spilling and plunging breakers

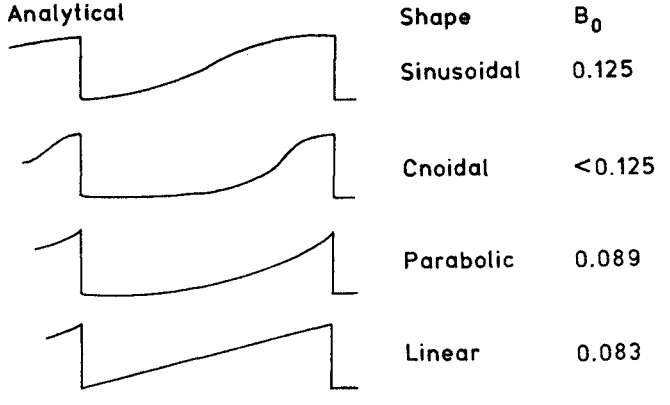

Fig. 8 Theoretical breaking wave shapes and resulting wave shape factor, B_0 as defined by Eqn. (8)

Surface Shape Factor, B_o. Figure 8 depicts some possible breaking wave shapes (sinusoidal, cnoidal, parabolic, linear) that can all be treated analytically within Equation (8) to calculatetheoretical values of B_o at the moment of wave breaking (vertical front face). The resulting B_o values are also shown in Figure 8 and are always less than 0.125.

Using the laboratory measurements of Hansen (1982), values of B_o for various positions across the surf zone were calculated by Svendsen (1984) as reproduced here in Figure 9. For this data, peaky wave profiles produced B_o values as low as 0.035 at the break point (h_o/h_{ob}=1.0). Then, B_o values increased rapidly towards values around 0.06-0.09. Svendsen (1984) noted some variation of B_o with deep water steepness, H_o/L_o.

The surf similarity parameter (i.e., the Iribarren number) defined as

$$\xi \equiv \frac{\text{Bottom Slope}}{(\text{Deep Water Steepness})^{1/2}} = \frac{\tan\beta}{(H_o/L_o)^{1/2}} \qquad (12)$$

is useful to further quantify the possible B_o variations. Figure 10 presents combined theoretical and experimental results (Figure 9) in an heurestic fashion for B_o versus h_o/h_{ob} for spilling (small ξ) through plunging (large ξ) breakers.

In the wave shoaling region ($h_o/h_{ob}>1$) the waves begin with near sinusoidal shape (B_o=0.125) and are transformed in shape to become spilling (relatively high B_o values) or plunging (relatively low B_o values) breakers. Further theoretical results are needed using numerical wave shoaling simulations and experimentally determined data to further quantify this region.

After breaking ($h_o/h_{ob}<1$) the experimentally measured results from Figure 9 have been replotted and smooth curves drawn in Figure 10. Much more experimental data is needed to confirm these trends. Ultimately, the smallest waves running up the beach return to a sinusoidal form. Figure 10 can be used to estimate B_o values for various positions (h_o/h_{ob}) and wave types (ξ) found in surf zones.

Transition Width,W. Figure 10 also shows a curve marking the width of the transition region. At best, this is only a very crude estimate based upon some limited data presented in Svendsen (1984). Spilling transitions are shown to be wider than plunging transition regions. Much further experimental and theoretical research is needed to quantify this estimate. For example, ongoing work is attempting to quantify the partition between momentum flux due to velocity and that due to pressure (wave induced plus static) in a reference frame moving with celerity, c across the transition region. When coupled with a proper energy dissipation model (recall second paradox above), it should be theoretically possible to predict the transition width. The procedure being followed is essentially that used by Madsen and Svendsen (1983) to calculate the length of the stationary hydraulic

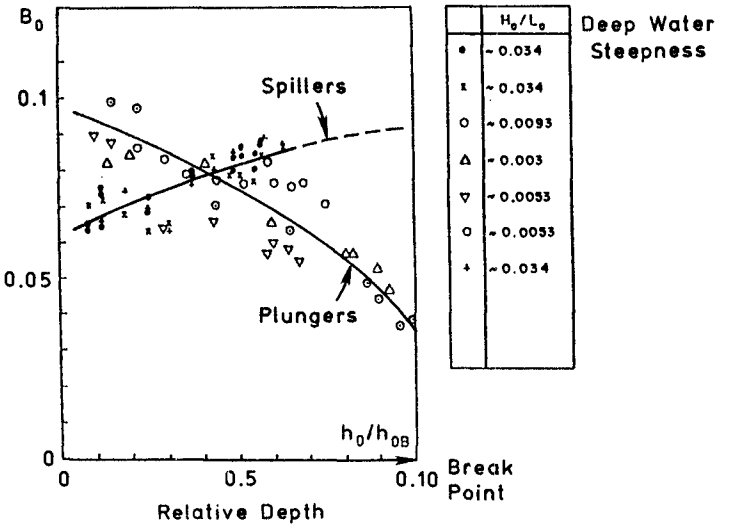

Fig. 9 Measured values of B_0 as defined by Eqn. (8) (From Svendsen, 1984, Fig. 9, p. 316)

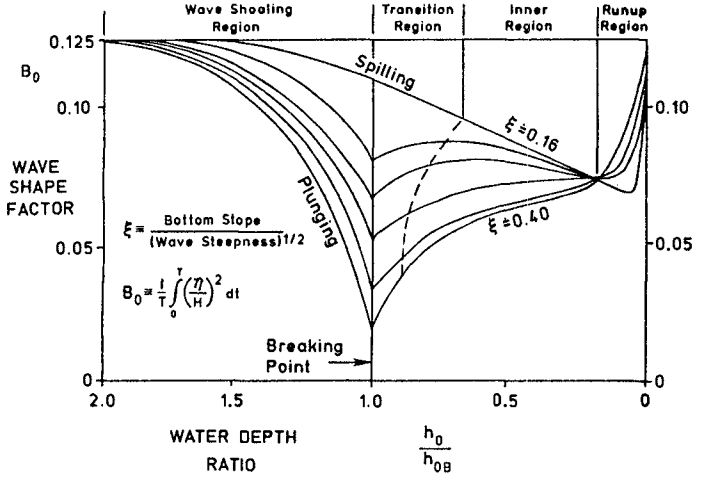

Fig. 10 Variation of wave shape factor, B_0 before and after breaking of spilling through plunging type breakers

jump. Results of numerical model simulations of breaking wave overturning and jet falling up to the plunge point will be employed to calculate the plunge distance.

4.4 An Example Computation

Equation (7) can be rewritten

$$S_{xx} = \rho g H^2 \left(\frac{3}{2} B_o + \frac{A}{H^2}\frac{h}{L}\right) \qquad (13)$$

Given the breaking wave height, H_b, the fluid mass density (fresh or sea water) and the $(h/L)_b$ ratio at breaking, it is now possible to calculate the wave height decrease and width of the transition region. Keeping in mind, of course, these result are only for plane beaches. The key fact is that S_{xx} remains constant across the transition. Figure 7 and 10 are utilized to estimate the $A(x)/H^2$ and $B_o(x)$ variables required.

Plunging Breaker. Assume the deep water steepness (H_o/L_o) and beach slope produce a similarity parameter, ξ equal to 0.35. This is a fairly strong plunging breaker. The computation proceeds as follows (H_b=2.5m, sea water, $(h/L)_b$=0.057):

$$\begin{aligned}
(B_o)_b &= 0.035 \\
A(x) &= 0 \\
(S_{xx})_b &= 0.32 \times 10^4 \text{ N} \\
A/H^2 &= 0.9 \\
(B_o)_T &= 0.045 \\
(S_{xx})_T &= 0.32 * 10^4 \\
&= 10^4 H_T^2 \left[\tfrac{3}{2}(0.045) + 0.9(0.057)\right] \\
H_T &= 1.6 \text{ m} \\
\therefore \quad H_T/H_b &= 0.65
\end{aligned}$$

For all intermediate locations between H_b and H_T, use A equal to zero up to plunge point and Figure 7 beyond linear by interpolation. The resultant H(x) is nonlinear (Eqn. 13).

Spilling Breaker. Now assume the incoming wave gives ξ equal to about 0.2 on the same beach. Using the same values as before (H_b=2.5m, sea water, $(h/L)_b$=0.057 gives:

$$\begin{aligned}
(B_o)_b &= 0.10 \\
A(x) &= 0 \\
(S_{xx})_b &= 0.94 \times 10^4 \text{ N} \\
A/H^2 &= 0.9
\end{aligned}$$

$$(B_o)_T = 0.09$$

$$H_T = 2.2\ m$$

$$\therefore\ H_T/H_b = 0.88$$

Now all intermediate points use linear interpolation for A(x). The resulting H(x) curve is also nonlinear.

These results can now be used as input to the surf zone model of Svendsen (1984) to calculate the H(x) and h(x) distribution over the remainder of the surf zone.

5.0 Summary Conclusions

A simple, quasi-empirical model for the wave breaking transition region of plane and monotonically decreasing beach profiles has been developed. The nonlinear wave height decrease and transition width for various breaker types can be estimated. The key element in the model is the fact that the mean water level is constant. Consequently, the wave ray, radiation stress component is also constant. An empirical, linear formulation is postulated for the surface roller area development. And, a semi-empirical formulation is developed for the wave shape factor. These two variables are taken so that the resulting model matches that developed by Svendsen (1984) at the end of the transition region, i.e. the start of the inner, bore-like wave region. The weakest part of the model is the limited empirical data available to estimate the transition width.

The research effort is ongoing and now focusing on theoretical means to determine the transition width.

The model is limited to plane or monotonoically decreasing beach profiles. But it is seen as a necessary first step to develop similar methods for bar/trough beaches.

CHAPTER 73

A Numerical Investigation of The Longshore Current Profile for Multiple Bar/Trough Beaches

Steven K. Baum[1] and David R. Basco[2]

Abstract

A numerical model is developed which calculates the longshore current profile for an arbitrary bottom profile. The basis of the model is the use of radiation stress theory in a longshore momentum balance equation which includes a driving stress, a bottom stress, and a lateral mixing stress. Each of the stresses is derived from previously developed formulations, rederiving them to take into account separate cross shore variations in the wave height and the water depth, as well as the wave approach angle. This is done to dispense with the constant wave breaking index assumption used to model wave decay in the surf zone, which is rejected as unrealistic for natural beaches. A numerical model is used to calculate distributions of the wave height and water depth across the surf zone for arbitrary, yet realistic, bottom profiles. A numerical model of the theoretically derived longshore momentum balance equation is developed and solved using the distributions obtained from the wave decay model. The profiles calculated are compared to previous theoretical models and to laboratory and field measurements.

1.0 Introduction

All present-day longshore current models are based on concepts of radiation stress as first introduced by Longuet-Higgins and Stewart (1964). Longuet-Higgins (1970) and others applied these time-averaging principles to the depth-integrated momentum balance equation to obtain the longshore current profile. The component stresses (radiation shear stress, bottom stress and lateral turbulent mixing stress) in the alongshore momentum equation are expressed in terms of three key variables to obtain the current profile as a function of distance from the shoreline. These three variables are the mean water depth, the wave height and the wave angle. More accurately, the gradient of the longshore current across the surf zone is computed using the gradients of water depth, wave height and wave angle across the surf zone.

The original model of Longuet-Higgins (1970) employed many simplifying assumptions regarding these three variables. This permitted an analytical solution to be obtained which facilitated

[1]Ph.D. Candidate, Department of Oceanography, Texas A&M University, College Station, TX

[2]Professor and Director, Coastal Engineering Institute, Department of Civil Engineering, Old Dominion University, Norfolk, VA 23508

physical understanding. For example, Longuet-Higgins (1970) related the wave height to the water depth using a constant wave breaking index model. He also assumed a small incident wave angle and neglected the wave-induced set-up (set-down) effects on the mean water depth which became the sole variable of interest.

Subsequent investigators have relaxed or eliminated many of these assumptions. However, all investigators to date have continued to use the wave breaking index simplification which requires specification of either a linear or monotonically decreasing bathymetric profile. Most natural beaches have single or multiple bar-trough features at sometime during yearly cycles. Multiple wave breaking and reforming regions across these surf zones produce a complex wave height distribution that is clearly not amenable to the use of the wave breaking index to specify the wave height as directly proportional to the water depth.

A mathematical model has been developed that makes no simplifying assumptions regarding the three above mentioned key variables. Water depth, wave height and wave angle can vary separately across the surf zone. Section 2 presents all the theoretical details including the wave height decay (and recovery) model for use across arbitrary, realistic bottom profiles. Because an analytic solution is not possible for realistic bathymetry, Section 3 discusses the computer algorithm based on a finite-difference analog of the governing ordinary differential equation and the solution method. All test results are summarized in Section 4 including those for an artificially devised beach profile with three wave breaking-reforming regions and one final breaker zone on the exposed beach face.

The results are for depth-averaged, longshore current profiles induced by uniform breaking waves on infinite beaches of arbitrary cross-sectional shape. A complete report of this entire study is available (Baum, 1985).

2.0 Theoretical Development

Consider the depth-integrated and time-averaged horizontal momentum balance equation for steady, uniform motion as depicted schematically in Figure 1.

Cross-shore(x)
$$\frac{dS_{xx}}{dx} + \rho g h \frac{d\bar{\eta}}{dx} = 0 \qquad (1)$$

Alongshore(y)
$$\frac{dS_{xy}}{dx} - \bar{\tau}_B + \frac{dT_L}{dx} = 0 \qquad (2)$$

where: S_{xx} = the shorenormal radiation stress component;
S_{xy} = the shear radiation stress component;
$\bar{\eta}$ = the mean water level set-up (set-down);
$\bar{\tau}_B$ = the time-averaged bottom shear stress;
T_L = the lateral, turbulent mixing stress;

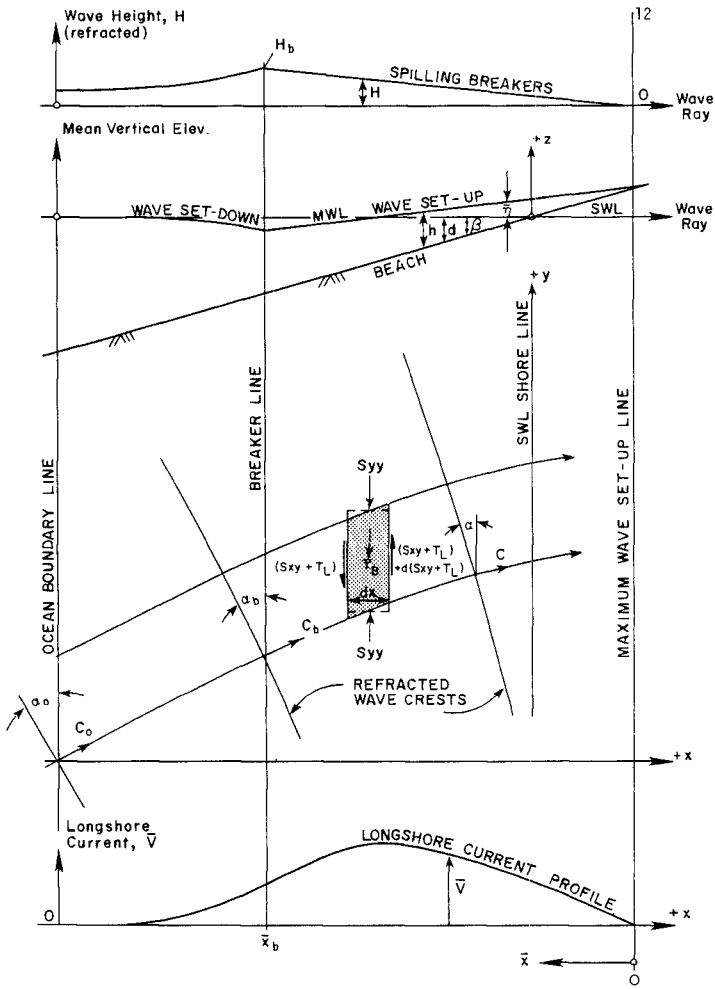

Figure 1. Schematic of surf zone (from Basco, 1982)

ρ = the water mass density; and
g = the acceleration due to gravity.

Equations (1) and (2) are decoupled in the sense that feedback effects of the currents on the wave heights are normally neglected. The cross-shore equation (1) is solved for the wave set-up as part of the method for obtaining the wave height and mean water depth as described below. Equation (2) is then solved for the longshore current profile using the results from (1) and the expressions for the stresses also described below. The complete, unsteady flow, two-dimensional forms of these equations can be found in Basco (1982).

2.1 Wave Energy Decay and Reforming Model

A model is needed to shoal a wave to the breaking point and then calculate the wave energy decay to a point of wave reformation where wave shoaling begins anew to a new break point or the shoreline. For this purpose the newly developed model of Dally et al. (1984) was employed.

The physical idea behind this model is that after a wave breaks it dissipates energy continuously until some stable wave height is reached where breaking stops and wave reforming and shoaling begins. The key assumption in this empirical approach is that the energy dissipation during breaking is proportional to difference between the actual and stable wave energy flux at any point. Using the definition of wave energy density and after integration this gives

$$(H^2 - H_s^2)_2 = (H^2 - H_s^2)_1 \exp\left(\frac{K}{d}\Delta x\right) \qquad (3)$$

where: H_s = the stable wave height
d = the still water depth
Δx = the distance step between points (1) and (2) where evaluation of the new wave height, H takes place, and
K = a wave energy decay factor.

A laboratory investigation conducted by Dally et al. (1984) to calibrate the model obtained best values for K of 0.17 and for H_s to be 0.4h. These coefficients we employed in the present model. Equation (3) reveals this to be an exponential wave energy decay model.

2.2 Cross-Shore Momentum Balance

Using the classical, linear wave theory definition for S_{xx} and wave energy density, E, Equation (1) when rearranged becomes

$$\frac{d\bar{\eta}}{dx} = \frac{2 + \cos 2\theta}{16\, h} \frac{d(H^2)}{dx} \qquad (4)$$

to relate the mean water level set-up to the wave height. The wave

angle distribution across the surf zone was obtained from classic refraction methods using Snell's law.

An iterative procedure was followed in that first Equation (3) using the still water depth was employed to estimate the H(x) distribution. From (4) this gave $\bar{\eta}(x)$ from which a second iteration using $h=d+\bar{\eta}$ in (3) produced convergence to an acceptable tolerance after only 2-3 iterations. At this point, distributions of mean water depth, h(x), wave height, H(x) and wave angle, $\theta(x)$ are completely specified across the surf zone.

2.3 Longshore Momentum Balance

Equation (2) expresses a balance between the driving stress gradient, bottom stress and lateral (turbulent) mixing stress gradient. Previous formulations judged best in each case have been rederived to take into account separate variations of h, H and θ across the surf zone.

Driving Stress. Using classical, linear, shallow water wave theory, the shear radiation stress component can be shown to be (Longuet-Higgins, 1970)

$$S_{xy} = \frac{1}{8}\rho g^{3/2}\left(\frac{\sin\theta}{c}\right) H^2 h^{1/2} \cos\theta \qquad (5)$$

where we now also have c, the wave celerity. Using chain rule differentiation the driving stress gradient becomes

$$\frac{dS_{xy}}{dx} = \frac{1}{8}\rho g^{3/2}\left(\frac{\sin\theta}{c}\right)\left\{h^{1/2}\cos\theta\,\frac{\partial H^2}{\partial x} + H^2\cos\theta\,\frac{\partial h^{1/2}}{\partial x} + H^2 h^{1/2}\,\frac{\partial \cos\theta}{\partial x}\right\} \qquad (6)$$

Bottom Stress. We adopt a bottom stress formulation for large wave approach angles as originally formulated by Liu and Dalrymple (1978) and modified to accommodate separate variations of h and H. The expression employed is

$$\overline{\tau_B} = \frac{\rho f g^{1/2} H (1+\sin^2\theta)}{8\pi h^{1/2}}\, V \qquad (7)$$

where: f = a dimensionless friction coefficient, and
v = the time-averaged, depth-integrated longshore current.

Lateral Mixing Stress. We adopt a lateral mixing stress formulation using a classical, eddy viscosity approach. Following Battjes (1975), we take the water depth as reference length scale and reference velocity related to the local energy dissipation rate, D, where

$$D = \frac{\partial}{\partial x}\left[\frac{1}{8}\rho g^{3/2} H^2 h^{1/2}\cos\theta\right] \qquad (8)$$

Again using chain rule differentiation (8) yields

$$D = \frac{1}{8}\rho g^{3/2} G(x) \tag{9}$$

where

$$G(x) = \left\{ h^{1/2}\cos\theta \frac{\partial H^2}{\partial x} + H^2\cos\theta \frac{\partial h^{1/2}}{\partial x} + H^2 h^{1/2} \frac{\partial \cos\theta}{\partial x} \right\} \tag{10}$$

From the basic relationship

$$T_L = \rho \epsilon h \frac{dv}{dx} = \rho \left(M h \left(\frac{D}{\rho}\right)^{1/3} \right) h \frac{dv}{dx} \tag{11}$$

where: ϵ = the turbulent eddy viscosity, and
M = a turbulent closure coefficient

the gradient of the mixing stress becomes

$$\frac{\partial T_L}{\partial x} = M\rho\left(\frac{1}{8} g^{3/2}\right)^{1/3} \left\{ \frac{\partial h^2}{\partial x} G(x)^{1/3} \frac{dv}{dx} + h^2 \frac{\partial \left[G(x)^{1/3}\right]}{\partial x} \frac{dv}{dx} + h^2 G(x)^{1/3} \frac{d^2 v}{dx^2} \right\} \tag{12}$$

2.4 Longshore Current Profile Equation

Combining equations (2), (6), (7) and (12) gives with $\hat{G}(x)$ given by (10)

$$\frac{d^2 v}{dx^2} + \left[\frac{\beta_1(x)}{\beta_2(x)}\right] \frac{dv}{dx} - \left[\frac{B\beta_3(x)}{A\beta_2(x)}\right] v + \left[\frac{C\, G(x)}{A\beta_2(x)}\right] = 0 \tag{13}$$

where:

$$\beta_1(x) = \frac{\partial h^2}{\partial x} G(x)^{1/3} + h^2 \frac{\partial G(x)^{1/3}}{\partial x} \tag{a}$$

$$\beta_2(x) = h^2 G(x)^{1/3} \tag{b}$$

$$\beta_3(x) = \frac{H\left[1 + \sin^2\theta\right]}{h^{1/2}} \tag{c}$$

$$A = \frac{1}{2}\rho g^{1/2} M \tag{d}$$

$$B = \frac{1}{8}\frac{\rho f g^{1/2}}{\pi} \tag{e}$$

$$C = \frac{1}{8}\rho g^{3/2}\left(\frac{\sin\theta}{c}\right) \tag{f}$$

Equation (13) is a nonhomogeneous, ordinary, second-order differential equation inside the breaker line. It becomes homogenous outside the breaker line because the group of coefficients given by CG(x) is zero there.

The boundary conditions are identical to those employed by Longuet-Higgins (1970) in the original theory. This means taking zero velocity at the new (set-up) shoreline, matching both velocity and its gradient at the breaker line for inner and outer solutions and letting the velocity approach zero far outside the breaker line.

3.0 Numerical Solution

Equation (13) can be written

$$\frac{d^2V}{dx^2} + C_1\frac{dV}{dx} - C_2V + C_3 = 0 \qquad (15)$$

and must be solved numerically because the coefficients, C_1, C_2 and C_3 are nonconstant in x. The numerical method employed falls in a general class called "shooting" methods whereby the slope at a known value of the dependent variable (v=0 at x=0) is first assumed thereby creating an initial value problem which is solved by the fourth-order, Runge-Kutta method. This procedure is repeated until the calculated value at the second boundary point is within a specified tolerance of the actual function value at this location. An estimate of the initial slope was made using the original, analytical solution of Longuet-Higgins (1970) from which two bracketing guesses permit a linear interpolation to accelerate convergence. Because of the two internal, boundary conditions at the breaker line, the numerical algorithm adopted utilized two "shooting" methods, one for the region inside and a second for the zone outside the breaker line. For practical reasons, a distance of approximately three surf zone widths proved reasonable for the limit of the outer region where the current velocity returned to nearly zero values.

4.0 Test Results

4.1 Basic Tests

A series of basic tests were initially conducted to compare numerical model results with those previously published for simple cases using a constant wave breaker index.

Plane Beach. An initial comparison was made to the original analytical results of Longuet-Higgins (1970) for a plane beach. This required making the same simplifying assumptions (constant breaker index, neglect of wave set-up and refraction effects) and conversion of the bottom friction and lateral mixing coefficients to those employed by Longuet-Higgins. In the original model, the mixing parameter, P is defined as

$$P = \frac{N\pi \tan\beta}{c_f\gamma} \qquad (16)$$

where: $\tan\beta$ = m, the beach slope;
$c_f = \frac{1}{8} f$, the bottom friction coefficient;
$N = M\left(\frac{5}{16}\right)^{1/3} \gamma (\tan\beta)^{4/3}$ the lateral mixing coefficient
and $\gamma = \frac{H}{h}$, the wave breaking index.

The curves for both the analytical model of Longuet-Higgins (1970) and the present numerical model for identical data sets are shown in Figure 2. The chosen data results in P = 0.106 for this case. Both curves are identical in shape and size inside the breaker line (dimensionless distance of unity) but slightly different outside. The difference in the results outside the breaker line is simply due to different wave transformation models being used to shoal the wave so that equivalence is theoretically not possible. In Figure 2 and subsequent plots, all velocities are normalized by the breaker line, longshore current with no mixing as first used by Longuet-Higgins (1970).

Large Wave Angle. The model of Liu and Dalrymple (1978) included wave set-up and refraction effects on the velocity profile because their main intent was to study the effects of large incident wave angles. Consequently, they neglected lateral mixing but revised the bottom friction stress formulation to account for strong longshore currents. Figure 3 presents numerical model results from this study (P=0.106) and reveals a decrease in velocity with increasing wave angle, as expected. No comparison with the published results of Liu and Dalrymple (1978) was possible since it was learned that their values are incorrect by some factor (Vemulakonda, 1986). However, both models for very small incidence angle gave nearly identical results compared to the reference velocity profile (triangular with no mixing) of Longuet-Higgins (1970).

Wave Decay Model. A final base test compared differences due to the specification of the wave decay model. A plane beach, small wave angle and no set-up test was devised with P=0.10 but using a slightly different combination of variables. These specifications assured that the differences in the velocity profile were due only to differences to the wave height field.

Using identical data sets, the current profiles from both the numerical model and the original, analytical model of Longuet-Higgins (1970) are shown in Figure 4. Considerable differences now exist. These can be explained from the fact that the wave height decreases linearly in the analytical model and exponentially in the numerical model. In general, the wave decay model of Dally et al. (1984) flattens the profile inside and steepens it outside the breaker line on a plane beach.

4.2 Laboratory Tests

The present numerical model has been compared to laboratory measurements by Mizuguchi et al. (1978, Case 3) as shown in Figure 5. Coefficients for friction and lateral turbulent mixing as determined to give a "best fit" at the maximum velocity by Kraus and

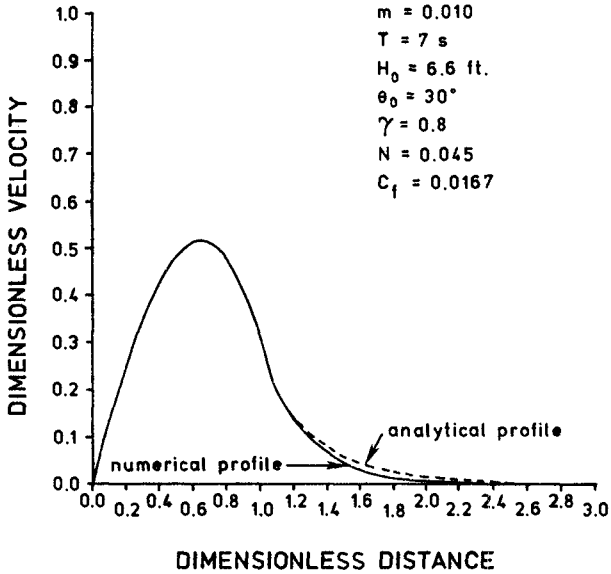

Figure 2. Comparison of numerical model to analytical solution of Longuet-Higgins for identical parameters

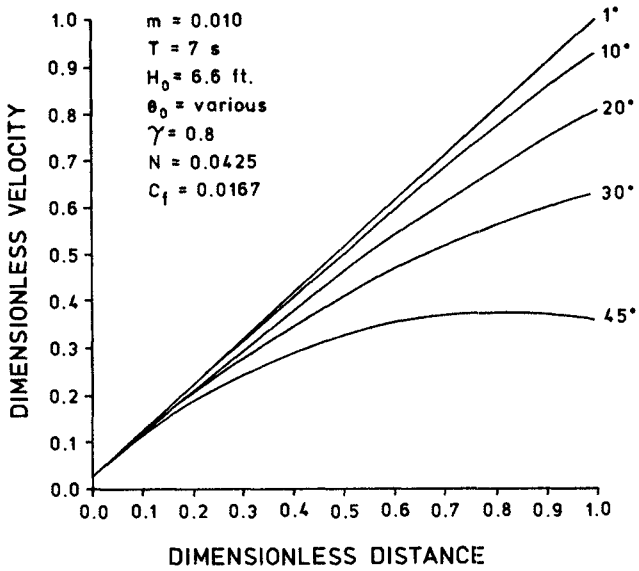

Figure 3. Numerical model results for large angle effects without lateral mixing

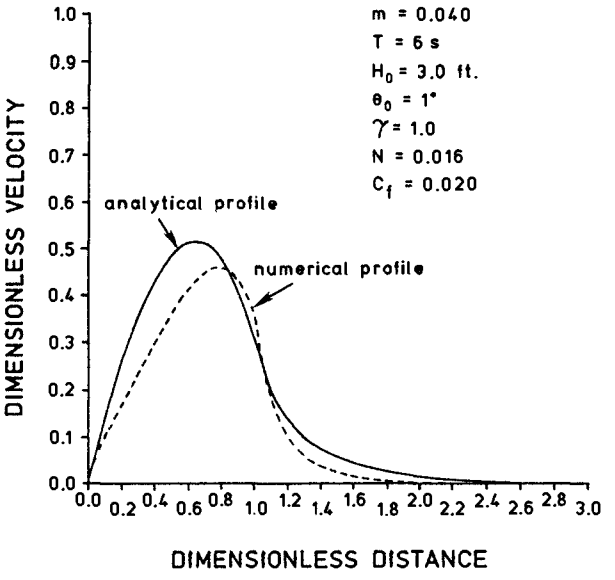

Figure 4. Comparison of differences in velocity profiles due to wave decay specification

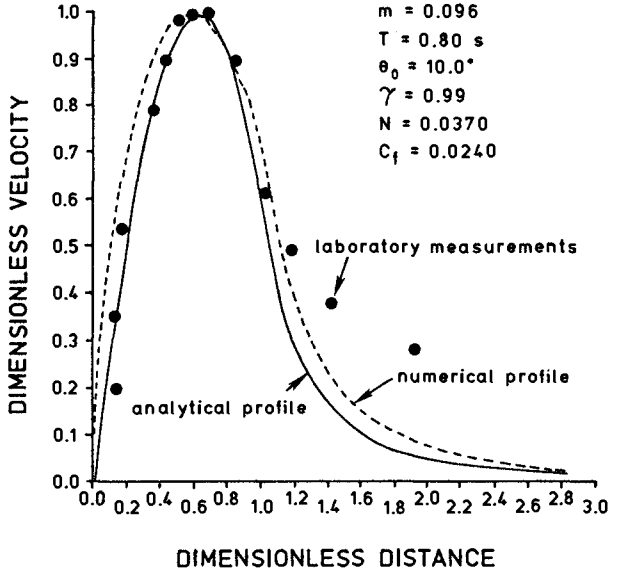

Figure 5. Comparison of predicted velocity profile with laboratory measurements of Mizuguchi et al. (1978 Case 3)

Sasaki (1979) for their model were employed. The analytical solution of Longuet-Higgins (1970) is also shown (P=0.47). The results of the Kraus and Sasaki (1979) model fall somewhere between those shown on Figure 5 and all three give good agreement with measured values inside the breaker line.

The discrepancies outside are primarily due to laboratory-scale effects as discussed by Basco (1982), Battjes (1978) and Kraus and Sasaki (1979) in their use of this data set to test their model. Additional laboratory-scale data sets are now available for plane beaches to test numerical models (e.g. Visser, 1984). No laboratory data is available for a bar-trough beach profile.

4.3 Field Tests

Field measurements of wave-induced longshore currents under uniform and steady wave conditions are difficult to obtain. Because of continuously varying field conditions including local winds not modeled and scales of velocity traces recorded by modern instruments, a standard, universally accepted averaging time to define the longshore current has yet to be determined. We show one comparison here of the numerical model with the field measurements performed by Kraus and Sasaki (1979) in a surf zone with two observed wave breaking lines. Their measured velocity and bottom profiles are displayed in Figure 6. Figure 7 displays the numerically predicted longshore profile using bottom friction and lateral mixing parameters as specified by these same investigators (Kraus and Sasaki, 1979) for use in their model. Both numerical and field plots show a secondary velocity maximum near the shoreline. It is evident that a "best fit" profile could be obtained for the present model by appropriate manipulation of the friction and mixing parameters to values different than those suggested by Kraus and Sasaki (1979) for their model. This has not been done since the objective was simply to simulate a multiple-peaked, longshore current profile.

4.4 Multiple Bar-Trough Beaches

In the absence of a laboratory data-set under controlled conditions for a bar-trough beach profile with multiple breaker and reforming regions, no definitive answer is yet possible as to the adequacy of the present numerical model. Never-the-less, an artifical yet realistic profile was constructed with three offshore bars as depicted in Figure 8. The average slope is 0.048. This profile is typical of those found on lower energy, Gulf of Mexico beaches. Waves broke over the three bars and within the inner slope to give four breaker lines and theoretically, four peaks in the longshore current profile.

The current profile predicted by the numerical model for the contrived bathymetry and representative parameters is shown in Figure 9. Also shown is the analytical model profile of Longuet-Higgins (1970) for an average slope of the entire profile. The profile of the multiple breaker case is seen to be similar overall to the profile developed from the analytical solution for a constant slope.

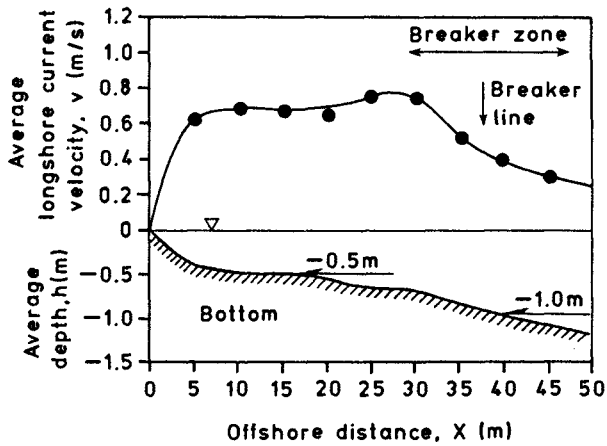

Figure 6. Measured velocity and depth profiles for two breaker Line situation in field (from Kraus and Sasaki, 1979)

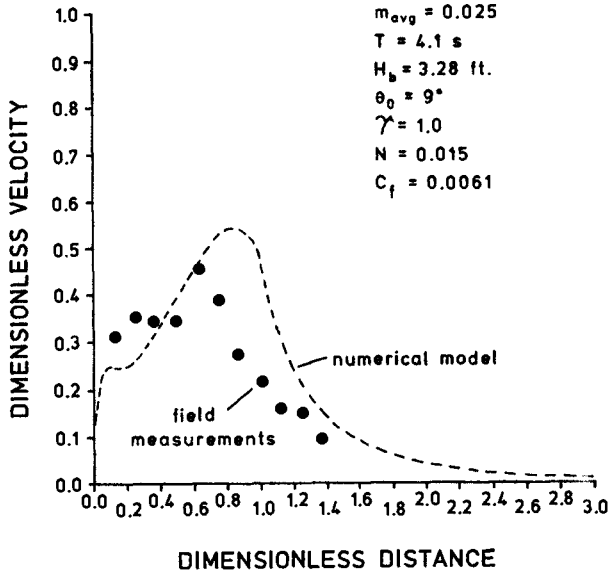

Figure 7. Comparison of predicted velocity profile to measured field profile for two breaker line case.

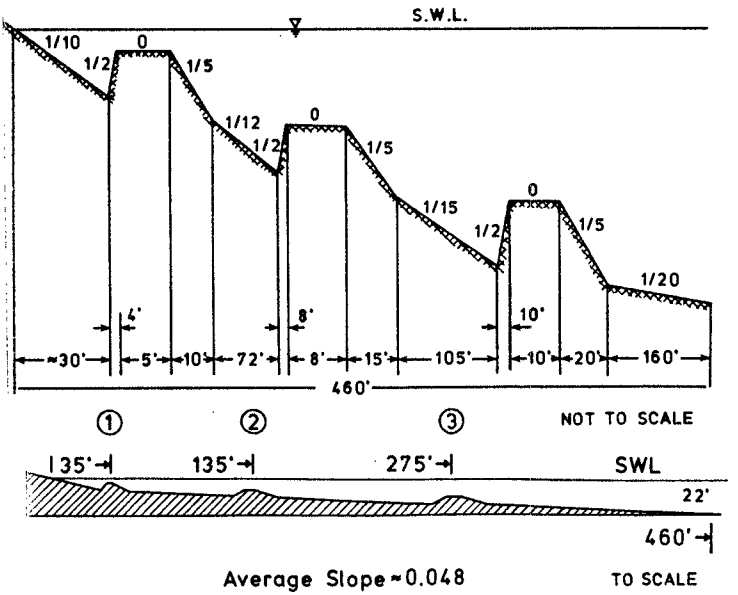

Figure 8. Artificial bottom profile to induce multiple wave breaking

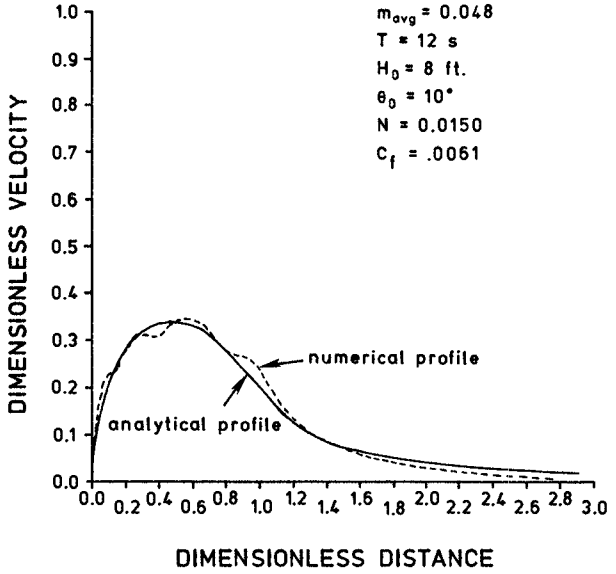

Figure 9. Comparison of velocity profiles due to artificial bathymetry.

The difference is simply four smaller humps present in the overall profile developed by the present model.

The scale of these perturbations is relatively small and similar to the scatter found in field measurements. No attempt was made to make more runs with fewer yet larger bars in lieu of the fact that no laboratory data exists to check the results.

5.0 Summary

A longshore current model for realistic, multiple bar-trough beach profiles has been developed. It permits wave breaking and reforming and this feature in turn produces multiple peaked profiles of the current distribution as found across natural beaches. The model reduces to closed form, analytical solutions for plane beaches. And, it incorporates those components for the stresses that remove the simplifying assumptions made by Longuet-Higgins (1970) in his original model.

It is recommended that more realistic driving stress terms be investigated using radiation stress components derived from nonlinear wave theory outside and broken wave theory inside the surf zone. Svendsen (1984) has shown that the presence of a surface roller in broken surf zone waves increases the radiation stress by 50-100% over that found from linear wave theory. Although limited in scope due to neglect of feedback of currents on the wave field, wind stresses and other natural phenomena, the model is helpful in the development of more general two-dimensional, horizontal models.

CHAPTER 74

TIME AND BED AVERAGED CONCENTRATIONS UNDER WAVES

Jan J. Bosman*, research physicist, Delft Hydraulics,
Henk J. Steetzel**, MSc-student, Delft University of Technology,

Abstract:

Four types of sediment concentration under waves are discussed: (a) instantaneous, local, (b) time-averaged, local, (c) instantaneous, bed-averaged and (d) time and bed averaged. The first three mentioned are either hard to interpret or difficult to obtain experimentally. The time and bed averaged concentration is discussed in particular, both its interpretation and its measurement. Two features are discussed: the vertical concentration distribution and the bottom concentration.

1. Introduction

Kennedy and Locher (1972) reviewed the suspension of sediment under waves, and they concluded that the physical understanding is only poor. They specifically paid attention to the vertical distribution of sediment concentration, and they analysed measured concentration profiles relative to theoretical profiles based on different diffusion models. They concluded that the analysis seems to be overwhelmed by success, but that it is more spurious than real. It means that the theoretican can make practically any guess about the distribution or nature of diffusivities. The experimentalist, on the other hand, must achieve extreme precision in his data before they can be used as the basis for selecting one diffusion model over another.

It seems that not much has changed after almost fifteen years. Here the problem is discussed again from an experimental point of view. A simple technique is applied to measure sediment concentrations, which are averaged both over time and over the bed. Without pretending to answer all questions, the present results allow to reconsider the statements of Kennedy and Locher quoted above.

2. The practical relevance of concentrations

2.1 The instantaneous, local concentration

Apart from a cross-flow dependence, the instantaneous, local concentration depends on the longitudinal position (parallel to the water motion), x, on the height above the bottom, z, and on the time, t: $C(x,z,t)$. Several studies have been reported on $C(x,z,t)$ due to wave action. The water motion being partly random (e.g. turbulence) and the bed being a loose boundary, the question rises: 'How large is the random

* presently: head R&D-section, Dept. of Hydro-Instrumentation, Tidal Waters Division-Rijkswaterstaat
** presently: project-engineer, Delft Hydraulics

component in C(x,z,t)?'. Answering the question requires to measure C(x,z,t) under a purely periodic water motion above a so-called 'stable' bed. The deterministic component in C is defined by the periodic part of the concentration. The non-periodic part is the random concentration component.

Wave flumes are not suitable to generate water motions which are exactly periodic. In this respect a wave tunnel is. Only two such experiments are known in which the deterministic and random components of C(x,z,t) have been determined: Nakato et al. (1977) and Bosman (1982) who both performed measurements by an optical probe and in the ripple regime of bed forms under 'equilibrium conditions'. From both experiments it has been concluded that the sediment concentration under waves is largely random (30-100%). The random concentration component contains two contributions:

- from the applied instrument due to the statistical properties of light attenuation;
- from the physical process due to (small) changes in the local water motion and bed geometry.

Nakato et al. (1977) suggested that the large random component is mainly from instrumental origin. Bosman (1982) showed that, although this contribution cannot be neglected, it is almost purely due to changes in the (entrainment) process. Two reasons for this are obvious:

- Ripples are not fixed as they move (slightly) back and forth about their mean positions, viz. the longitudinal position, x, is not a constant relative to the bed geometry. As the concentration (at fixed height) varies strongly along the longitudinal position, see e.g. Nakato et al. (1977), and as the ripple motion is unlikely to be purely periodic, a random concentration component enters through x.
- Even if the ripple positions were fixed, their shapes are not: from one (wave) period to the next one a ripple may be slightly larger or smaller, steeper or smoother. So the water motion (vortices) between the ripples is not purely periodic (even apart from turbulence). Quite likely the amount of entrained sediment is not periodic either. As a result, a random concentration component enters through the time, t.

The instantaneous, local concentrations having such a large random component, its practical relevance is questionable. Under purely periodic waves, the random component can be reduced by ensemble averaging maintaining both the longitudinal and temporal resolution. But what about the relevance? Suppose the ensemble mean concentration is determined above the crest of a selected ripple. As the next ripple is certainly different, the concentration will be different too. Why is the ripple measured more decisive than is another ripple? Anyway, the ensemble mean concentration cannot be determined for natural (irregular) waves.

As the random concentration contribution enters through both t and x, there are three more ways to reduce it:

- Time-averaging of the concentration at a fixed position: $\bar{C}(x,z)$
- Bed-averaging (at fixed height along the longitudinal position) of the concentration at fixed time intervals: C(z,t),
- Time and bed averaging of the concentration at fixed height, z, above the bed: $\bar{\bar{C}}(z)$, where the double overbar indicates the averaging over the two entries, x and t.

2.2 The time-averaged, local concentration $\bar{C}(x,z)$

Such a measurement is easily performed (e.g. by suction at a fixed position). The temporal resolution is lost, but the longitudinal one is kept. As the time-averaged concentration varies with the longitudinal position, see e.g. Nakato et al. (1977), there is still a random contribution to $\bar{C}(x,z)$ due to the bed mobility. This longitudinal influence is often forgotten in the interpretation of $\bar{C}(x,z)$. This will be discussed in Section 3.2.

2.3 The instantaneous, bed-averaged concentration $\bar{C}(z,t)$

To perform such a measurement requires a 'sensitive slit' mounted horizontally at fixed height above the bed and covering several ripples. The slit should respond fast (instantaneously) to the concentration. Such measurements may be useful to study the instantaneous, vertical mixing of sediment, but for the time being there is no method to measure $\bar{C}(z,t)$. (It may be possible by measuring the attenuation/scattering of a horizontal, acoustic beam).

2.4 The time and bed averaged concentration $\bar{\bar{C}}(z)$

For convenience, the time and bed averaged concentration will be abbreviated by TABAC. It can be measured e.g. by a suction system moving horizontally at fixed height above the bed and covering several ripples. With suction at 6 to 8 different heights simultaneously, this is how the present measurements have been carried out. A few details concerning the measuring performance should be emphasized:

- The suction opening is 3 mm $\emptyset$. The suction direction is normal to the ambient water motion. The suction velocity is more than 2.5 times the main flow velocity. Under these conditions the suction calibration is defined well, see Bosman et al. (1987).
- The suction system moves slowly relative to the main flow, but fast relative to the bed form motion: approx. 5 mm/s. The suction system moves back and forth at constant velocity to obtain a fair average over the longitudinal positions.
- Reproduction tests, see Steetzel (1984), showed that (in order to reduce the relative random concentration error under 10%):
  * the averaging time interval should cover at least 100 waves,
  * the averaging bed length should cover at least 3 ripples.

3. Vertical mixing of sediment under waves

3.1 Theoretical approach

The vertical mixing of sediment is usually described by the steady state diffusion equation for the time-averaged concentration, $\bar{C}$:

$$\varepsilon(z) \frac{d\bar{C}}{dz} + w.\bar{C} = 0, \qquad (1)$$

where

$\varepsilon(z)$ = the sediment diffusion coefficient (under waves) depending on the height above the bed, z, in general,

w = sediment fall velocity, in general (unsorted sediment), depending on z as well.

The equation simply states that sediment goes vertically upwards by turbulent diffusion, the first term in Eq. (1), which is compensated by the downward flux due to gravity, the second term. Under definite assumptions for ε (constant, linear, parabolic) and usually with w not depending on z, Eq. (1) can be solved resulting to the concentration profile, $\bar{C}(z)$.
The diffusion equation can be understood quite simply. Let the steady state concentration at level z be denoted by $\bar{C}$, and that at level z+dz by $\bar{C}-d\bar{C}$ (the minus sign indicates that the concentration decreases with increasing height). For small values of dz it may be assumed that the concentration decay ($-d\bar{C}$) is proportional to:
- $\bar{C}$ itself (the larger the concentration, the larger the difference in concentrations is between the levels z and z+dz),
- dz (the larger the distance between the two levels, the larger the difference in concentrations is).

This can be expressed as $d\bar{C} = -\gamma \cdot \bar{C} \cdot dz$, where γ is a positive proportionality factor. Considering an other level, the same expression still holds, although γ may be different, viz. γ depends on the height: $\gamma(z)$. Letting dz diminish, Eq. (1) is obtained with $\gamma(z) = w(z)/\varepsilon(z)$. So Eq. (1) can be established without making any assumption on the suspension mechanism (either turbulent diffusion, or convection by vortices or orbital motion; or both).

The 'classical' theoretical approach has been reconsidered by Kennedy and Locher (1972) under a few assumptions, ending up with a modified diffusion equation. They compared concentration profiles measured to those calculated through their diffusion equation for various 'diffusion models'. They found good agreement between the profiles measured and the ones predicted, no matter on which diffusion model the prediction is based (see Introduction).
Considering this problem, two questions are raised here:
* What is the concentration meant in the diffusion equation? (Section 3.2).
* How is a diffusion model tested in comparing concentration profiles predicted to the ones measured? (Section 3.3).

3.2 The concentration in the diffusion equation

In general, the concentration $\bar{C}$ in a diffusion equation is defined simply by a time-averaged concentration as a steady state is assumed. Recalling Chapter 2, it means that $\bar{C}$ denotes either the time-averaged, local concentration, $\bar{C}(x,z)$, or the time and bed averaged one, the TABAC $\bar{\bar{C}}(z)$. When testing a diffusion concept, the concentration measured is usually a time-averaged one obtained at a fixed longitudinal position, viz. $\bar{C}(x,z)$ which depends definitely on x, see e.g. Nakato et al. (1977). The question should be raised whether this is the concentration meant in the diffusion equation. In the equation, it is not accounted for any longitudinal influence, viz. it is assumed that $\varepsilon(z)$ is identical 'everywhere' along the bed. Stated alternatively: the diffusion equation relates the concentrations at different heights, no matter where the sediment comes from. This concept is often illustrated by the (turbulent) exchange of a water parcel (level z) with some sediment content and an upper parcel (level $z+\Delta z$) with smaller sediment content, see Fig. 1a (the magnitude of the sediment concentration in a parcel is indicated by the cross section of a bold circle).

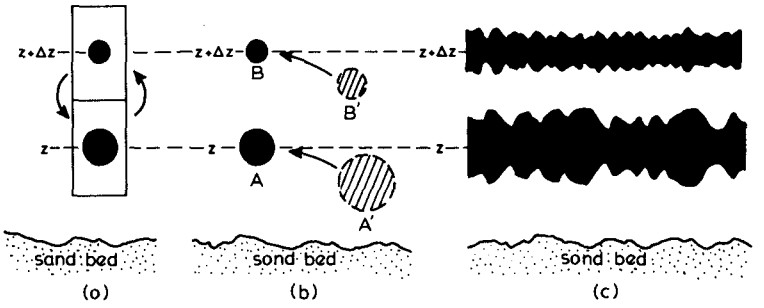

Fig. 1 Sediment exchange due to diffusion (a), motion of sediment concentration under waves (b), and time-averaged local concentrations at levels z and z+Δz (c).

To demonstrate that $\bar{C}(x,z)$ conflicts with this concept, consider Fig. 1b showing the concentrations at positions A and B (levels z and z+Δz) at some instant t. The concentration C_A at time t originates from the concentration $C_{A'}$ (partly dispersed) at time t−Δt. Similarly C_B originates from $C_{B'}$. Near the bed the upward motion of sediment is mainly due to vortices between the ripples. Far from the bed the upward sediment motion is due to the wave orbital velocity (and due to turbulence, if any). Considering the concentrations C_A and C_B (measured at the same longitudinal position), the relationship is determined by $C_{A'}$ and $C_{B'}$ (A' and B' not necessarily at the same longitudinal position), viz. the relationship depends on vertical and longitudinal concentration gradients. (At other moments C_A and C_B may originate from quite different positions A' and B').

To eliminate the longitudinal influence, the concentration must be averaged over all longitudinal positions (at fixed level). These concentrations are the TABAC-s as defined before. So Eq. (1) describes the relationship between TABAC-s at different levels. The time-averaged local concentrations are illustrated in Fig. 1c, where the magnitude of the time-averaged concentration at level z is presented by a vertical bar for all longitudinal positions. The result is a 'cloud' at level z. By averaging over the longitudinal positions it is eliminated from the sediment transfer between two levels, no matter where and when the sediment comes from. So after bed-averaging Fig. 1c is essentially identical to Fig. 1a.

It should be noted that the situation close to the bed under unidirectional flow is not essentially different. But measuring time-averaged concentrations, a bed-averaging is more or less carried out simultaneously (without the experimentalist being aware of it) since 'other longitudinal positions' are passing along the measuring position both due to the nett flow and due to the moving bed.

3.3 Testing concentration profiles

When concentration profiles are compared to an analytical model, the conclusion is usually drawn in terms of 'good or bad fit', whatever it means. Here a general criterion is defined to establish whether a model

is 'realistic' or not. The test on descriptions of concentration profiles can be formulated, in general, by

$$C(z) = f(z) + \Delta C(z), \tag{2}$$

where
$C(z)$ = measured TABAC at level z (dropping the double overbar),
$f(z)$ = some analytical concentration profile,
$\Delta C(z)$ = random measurement error of $C(z)$.

The error ΔC is often forgotten in such tests. However, it represents the realistic scatter of $C(z)$-values measured around the profile $f(z)$ (measured if the analytical profile were exact and the measurements were infinitely precise). This scatter must be reflected properly when comparing $C(z)$ (measured) and $f(z)$ (predicted). Only then the model $f(z)$ is realistic. A realistic model is not necessarily the 'best fit' model. This is easily illustrated by considering an 8-points profile. The best fit is a seventh order polynomial in z, as it passes exactly through all data-points, leaving no scatter. As a result, ΔC is zero which is not realistic.
This acceptance demand for a model requires ΔC to be known in advance.

Concentrations under waves vary over a wide range and the concentration measurement accuracy varies over a wide range too. It is reasonable to assume that large concentrations carry a large random measurement error and that small concentrations have a small one (when there is not much sediment, the absolute error cannot be large). Hence it will be assumed that the relative concentration error, $\Delta C/C$, is of the same magnitude for both small and large concentrations. With this assumption, it is sensible to replace Eq. (2) by a test-equation of the form
$\ln C(z) = g(z) + \Delta(\ln C)$, where $g(z) = \ln f(z)$ and $\Delta(\ln C)$ = random error in $\ln C = \Delta C/C$, since $d(\ln C)/dC = 1/C$.

To simplify the notations, the data $\ln C_i$ obtained at level z_i will be denoted by y_i. Also, the test-equation will be linearized by replacing $g(z)$ by a linear function $\beta_o + \beta_1 x$. If the model tested, $g(z)$, is linear in z, it is obvious to define $x = z$. If the model tested is non-linear, x must be defined by a proper transformation. For example, for the Rouse-distribution (see section 4.3) $x = \ln (h/z-1)$ is a proper transformation, where h is the local water depth. With these definitions the test-equation becomes

$$y(x) = \beta_o + \beta_1 x + \Delta y, \tag{3}$$

As $\Delta y = \Delta C/C$ is assumed to be approximately constant, all measurement results y are equally weighted when testing a model in the form of Eq. (3), which simplifies the testing procedure. Usually concentration profiles are fitted in the form of Eq. (3) without weighing for practical reasons. Thus without being aware of it, the common procedure assumes implicity that $\Delta C/C$ is constant.
The standard procedure to fit the model to the data is the least squares method, viz. to minimize the sum of squared deviations of the data-points y_i form the prediction $\hat{y}_i$, that is $S_E = \sum(y_i - \hat{y}_i)^2$, where the summation is over all data i(i=1, ..., N). The prediction $\hat{y}(x)$ is defined by choosing β_o and β_1 in the model such that S_E is minimum, viz. $\hat{y}$

is the fitted line. Quantitative tests on the goodness of fit can be carried out by regression analysis. A discussion of regression analysis is beyond the scope of the present work, so the reader is referred to one of the handbooks on that topic, e.g. Draper and Smith (1966). Two important quantitative measures are the percentage of explained variation, R^2 (R is the correlation coefficient) and the F-parameter.
The parameter R^2 should be near to 100% for a close fit. However, it is a relative measure, since there is no reason to select a model yielding R^2 = 96% over a model yielding R^2 = 94%.
The F-parameter measures the significance of a regression obtained (with a chosen probability). Thus F-tests can detect a false model, but they do not verify a true model. So in a sense, such tests are relative too.

Under the assumptions that:
- the distribution of y_i is normal for each level z_i,
- the values of Δy_i at different levels are uncorrelated,
- and the variance of y_i does not depend on the level z_i (remember that $\Delta y = \Delta C/C$ does not depend on C, viz. it does not depend on z),

it can be shown that the sum of squares about regression, S_E, is a fair (unbiased) estimator for $(N-2)(\Delta C/C)^2$, see Draper and Smith (1966). Thus $\Delta C/C$ can be estimated from a concentration profile measured, and it can be compared to the value expected. This provides a mean to classify a model to be realistic or not. When testing a two-layer model (see section 4.3) the total sum of squares about regression is an unbiased estimator for $(N-4)(\Delta C/C)^2$.

4. TABAC-results from a wave flume

4.1 Experimental conditions

Time and bed averaged concentrations have been measured in a laboratory wave flume (length x width x depth = 50m x 1m x 1m) for a single bed material (unsorted sand, D_{50} = 0.1 mm) with different bottom slopes (horizontal, 1:80, 1:25) and with local water depths between 0.1 m and 0.6 m. The irregular waves (two different spectra) in the experiments were either non-breaking or breaking (plunging or spilling) at or near the measuring location. Wave heights (significant) were typically in the range 0.1 m - 0.4 m and the averaged zero-crossing wave period was near 2 sec. The experiments have been performed for waves without nett current, for nett current without waves and for waves combined with a nett current. In the wave/current combinations the nett flow velocities were near $\pm$ 0.2 m/s and $\pm$ 0.4 m/s, the plus-minus signs indicating that wave direction and nett flow were both parallel and antiparallel.

The averaging time interval in each measurement was 6 min. and the averaging bed length was 0.3 m. Except for locations in or near breaking waves, the bed was covered with ripples with lengths in the range 0.08 m - 0.12 m. The averaging time interval (approx. 180 wave periods) and the averaging bed length (3 to 4 ripple lengths) are slightly too short to reduce the relative random concentration error under 10%. Nevertheless, the accuracy obtained is sufficient for the present purposes.

The concentration profiles have been obtained by continuous suction at eight levels (see Section 2.4). The distances (in mm) between the suction openings are from bottom to top: 20, 20, 25, 30, 30, 30 and 40.

The lowest measuring height is either 10 or 20 mm above the mean bed level. The total number of concentration profiles measured amounts 134.

4.2 Estimation of concentration accuracy

The acceptance of a 'theoretical' concentration model requires (see Section 3.3) that it yields a realistic value for the relative random concentration error, $\Delta C/C$. As it cannot be measured directly, it must be estimated in advance. For this purpose, four concentration profiles have been chosen arbitrarily out of 134, see Fig. 2. (To separate the profiles the horizontal axis is logarithmic without absolute values.) As the concentrations over the height are related somehow, 'smooth curves' (of arbitrary shape) have been sketched through the data-points. For the moment, these curves are believed to represent the 'true concentration profiles'. Thus the averaged scatter of the data-points around the curves represents the relative random concentration error, $\Delta C/C$ (as the horizontal scale is logarithmic).

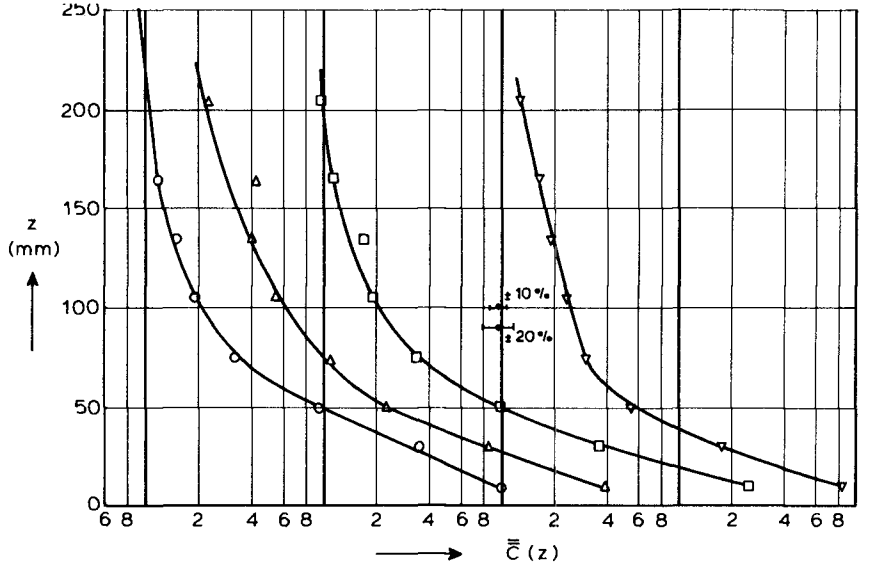

Fig. 2 Four TABAC-profiles 'fitted' by smooth curves

To give some impression, it is indicated in the figure how much scatter on the average corresponds with $\Delta C/C$ = 10% and 20 %. Considering the figure, it is estimated that $\Delta C/C$ is certainly less than 20%, and that it is close to (or probably even less than) 10%. This is the estimate made for $\Delta C/C$ in advance.

4.3 Models tested

Two curved concentration distributions are known from literature:
- The well-known Rouse-distribution:

$$C(z) = C(a)\ \left[\frac{h-z}{z}\ \frac{a}{h-a}\right]^{w/\varepsilon_m}, \qquad (4)$$

where w = sediment fall velocity, h = local water depth, ε_m = maximum diffusion coefficient (at half the water depth) and a = reference level.

- The Bhattacharya-distribution, see Kennedy and Locher (1972):

$$C(z) = C(a)\ \left(\frac{a}{z}\right)^{w/\varepsilon_m}, \qquad (5)$$

where ε_m = maximum diffusion coefficient (at the surface).

In addition a simple two-layer model is considered, which is mainly a guess and which is based only partly on common sense (Section 4.5):

$$C(z) = C(0)\ \exp\ (-z/r_l)\ \text{for } z < A$$
$$C(z) = C(A)\ \exp\ (-z/r_u)\ \text{for } z > A \qquad (6)$$

where A = transition level of the two layers which is defined by the continuity of C(z) for z = A,

r_l, r_u = concentration decay length for the lower and upper layer, respectively. In terms of a diffusion concept, r_i (i = l or u) can be interpreted as $r_i = \varepsilon_i / w_i$ with ε_i being constant and w_i denoting the fall velocity in the specific layer.

These three models have been tested on the TABAC-profiles.

4.4 Results of model tests

From visual comparison of the data-points to the least squares fits, it is concluded that all models fit quite well, except for 2 profiles measured (out of 134). As these profiles may be due to some experimental failure they will be omitted furtheron.

Considering the explained variations, R^2, it is found:

- for the Rouse-distribution: (92 ± 8)%,
- for the Bhattacharya-distribution: (96 ± 5)%,
- for the two-layer distribution: (97 ± 4)%.

Considering, the F-tests it is found that all models provide significant regression except for one to three profiles.

Thus far no model can be selected over another, as stated before by Kennedy and Locher (1972).

The test on the prediction of ΔC/C yields quite remarkable differences as illustrated in Fig. 3. It shows for each profile measured (measurement number) what ΔC/C should be if the specific model were true.

Obviously, ΔC/C (and its scatter) is largest for the Rouse-distribution, and smallest for the two-layer distribution. Averaging over 132 measurements yields for ΔC/C from:

- the Rouse-distribution: (31 ± 15)%,
- the Bhattacharya-distribution: (23 ± 11)%,
- the two-layer-distribution: (13 ± 6)%.

Recalling that ΔC/C has been estimated in advance to be near 10%, it is concluded that the two-layer model describes the concentration profiles in the most realistic way.

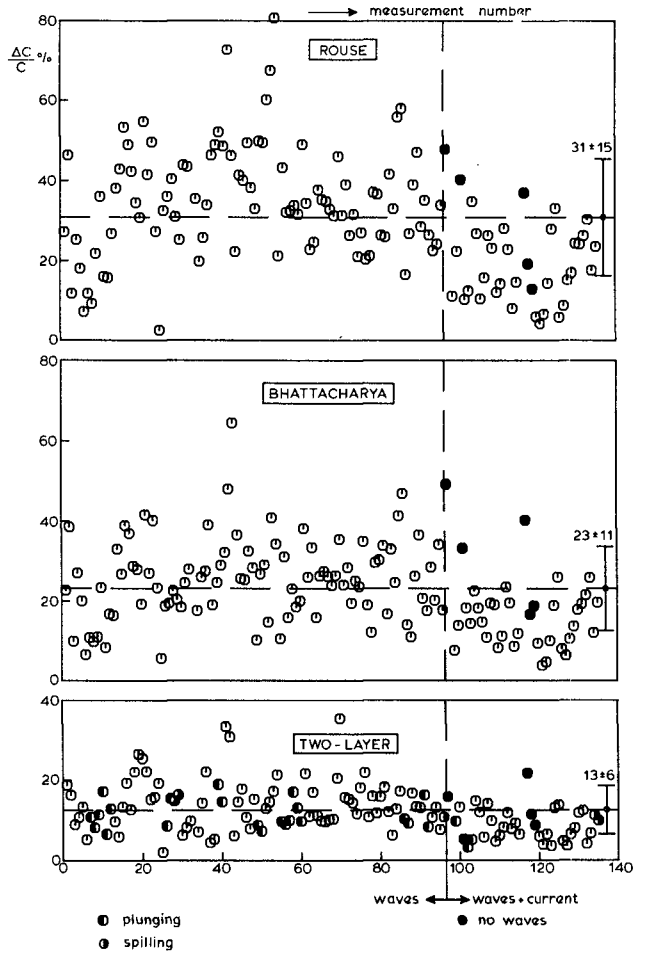

Fig. 3 Results for ΔC/C for the various models

In the two-layer approach the averaged values for ΔC/C for the lower and upper layer yield (7 ± 5)% and (9 ± 5)%, respectively. Since the concentrations in the two layers often differ by two orders of magnitude, the result seems to confirm the assumption that ΔC/C does not depend on C itself.

4.5 The realistic concentration profile

In the former section it has been concluded that the two-layer model provides a 'realistic' description of the concentration profile under widely varying conditions. It means that it fits to the data in a 'natu-

ral way', generating the random concentration error as it should be approximately. It is not the 'best fit', see Section 3.3.
Neither is it the 'true profile', since it yields a concentration gradient which is not continuous, and such gradients occur rarely in nature.
The results show that the two-layer model approaches the truth closely. Therefore it is called 'realistic', viz. it provides a simple mathematical description which is close to the more complicated truth.

The two-layer concentration model states that two layers must be distinguished in the suspension mechanism. This corresponds to the statements by Kennedy and Locher (1972) that two different mechanisms determine the sediment suspension by waves, viz. the turbulence production at the bed and the wave induced orbital velocities, and that the relative importance of the two mechanisms varies with depth. In view of the present results these statements are slightly adjusted: sediment suspension under waves is determined by vortices (and turbulence) near the bed, and by the orbital velocities (and some turbulence) at higher levels. The transition level A indicates a rather abrupt change in the relative importance of the two mechanisms.

5. TABAC-results from a wave tunnel

5.1 Experimental conditions

In order to study near-bottom concentrations in more detail, TABAC-profiles have been measured in a wave tunnel, see Hulsbergen and Bosman (1980). The test results have been described extensively by Steetzel (1984). Here only a few important characteristics will be given. For sinusoidal water motions the periods have been varied over the range 1-7 s and the (maximum) horizontal orbital velocities over the range 0.2-0.6 m/s. The bed (unsorted sand; D_{50} = 0.21 mm) was covered with ripples up to velocities of 0.5 m/s. At larger velocities the ripples changed into bumps: irregular with large heights and lengths. For each condition the experiment started with a flat bed and the height of the suction device was adjusted relative to the flat bed level. The lowest measuring height was chosen such that the lowest suction line did not touch the ripple crests after the suction system had started to move once the bed had reached the equilibrium stage. Only then the actual measurement was started. The averaging time interval in the concentration measurements was 6.5 min. and the averaging bed length was 0.6 m. More than 275 TABAC-profiles have been measured.

5.2 Concentration profiles

In a wave tunnel only the near-bed water motion under waves is simulated. Hence the attention is focussed to this region. Some examples of near-bed TABAC-profiles are shown in Fig. 4. The profiles were found to be exponential (over the height) explaining typically over 99.5% ($=R^2$) of the variation. The relative random concentration errors found were typically less than 5%.

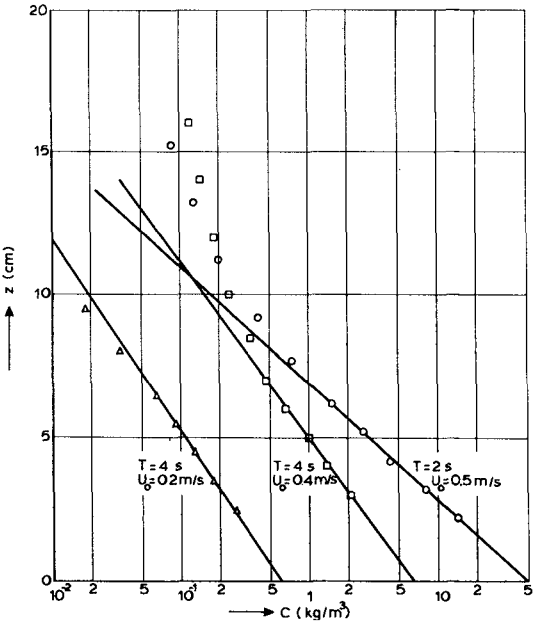

Fig. 4 Some examples of TABAC-profiles near the bed (T = wave period; u_o = peak orbital velocity)

5.3 Bottom concentrations

Analytical descriptions for the concentration profile are only relative, viz. they describe the height dependence of the profile and the magnitude of the concentration is determined by the concentration at some reference level, see for example Section 4.3. Usually the reference concentration is hard to obtain experimentally, also because the choice of the reference level is rather arbitrary (a few grain diameters, or the ripple crest level). The exponential decay of TABAC-s near the bed (if generally valid) permits a good definition of the reference concentration. The measuring heights in TABAC-s are defined relative to the mean bed level (z=0) which can be measured rather easily. Exponential extrapolation (to z=0) of the near-bed TABAC-profile as measured yields a well defined 'bottom-concentration', C(0). This definition of bottom-concentration is a mathematical one rather than a physical one, viz. it determines the magnitude of the concentration, and it is not important whether or not it represents the true TABAC at the mean bed level (defined partly by sediment in suspension and partly by settled sediment). With this unique definition C(0) is expected to be consistently related to the physical process i.e. to the hydraulic conditions. Hence, it has been investigated how C(0) depends on the peak orbital velocity and on the wave period for the conditions described in Section 5.1. It has been found that (over almost 4 orders of magnitude) C(0) can be described well by:

$$C(0) = G.u_o^{3.5}/T^2, \tag{7}$$

where u_o is the peak orbital velocity for purely sinusoidal water motion, and T is the wave period. To be complete, the velocity exponent was found to be 3.5 ± 0.1 and that for the wave period 2.0 ± 0.1. The proportionality factor G, depends on the sediment grain size. For the single sediment type in the measurements (see Section 5.1) it was found that 97% of the variation in C(0) is explained by choosing

$$G = (3000 \pm 8)\ kg.m^{-6\frac{1}{2}}.s^{5\frac{1}{2}} \tag{8}$$

In Fig. 5 the values of C(0) as measured for given u_o and T are related to the values of C(0) as calculated through Eqs. (7-8). The drawn line represents the measured and calculated values being identical. Some of the data in the figure are placed between brackets to indicate that the measured values are somehow suspected since one of more other parameters (e.g. concentration gradient, ripple height or length) showed a discontinuity occurring at larger velocities ($u. \gtrsim 0.5$ m/s). Without going into further detail, this is thought to be due to the limited height (0.4 m) of the wave tunnel which may be troublesome when the ripples grow.

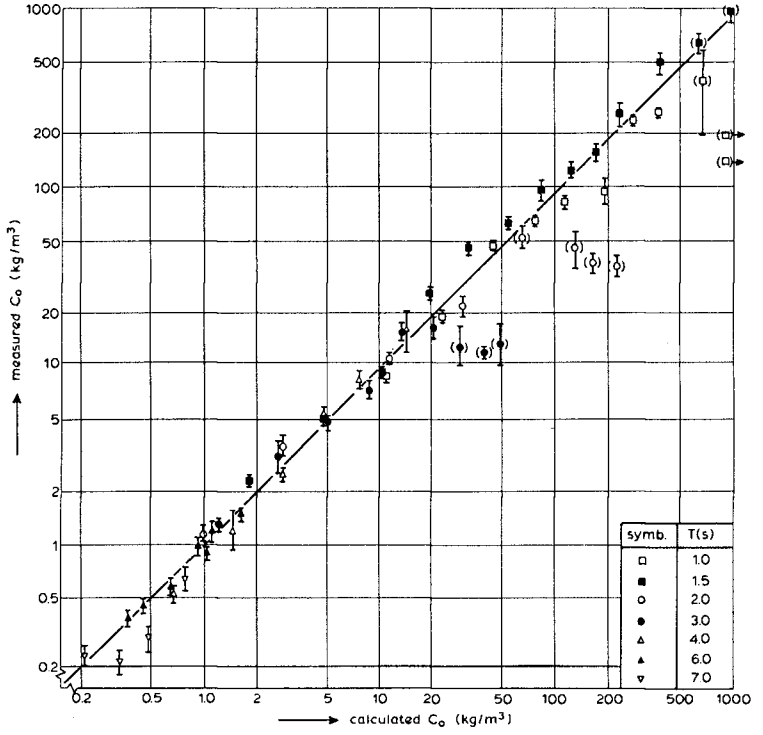

Fig. 5 C(0) measured vs. C(0) calculated

It is hoped for that Eq. (7) is more generally valid, viz. that the influence of the water motion on C(0) can be described fully by $U_0^{3.5}/T^2$ and that the grain size dependence can be fully accounted for through G. So the tests have been continued for other grain sizes. The results are still to be reported.

6. Conclusions/Recommendations

From the present work it is concluded that
- care should be taken in measuring the proper parameter (concentration here) when comparison is made to theory,
- tests on the goodness of fit should be defined well to enable qualification of the goodness of test.

It is concluded more tentatively (because only a few conditions have been examined yet) that
- time and bed averaged concentration profiles under waves/currents look like two-layer distributions with a height-independent relative concentration gradient,
- near the bed, time and bed averaged concentrations under waves/currents depend very consistently on the water motion.

The experiments reported here (wave flume, Chapter 4, and wave tunnel, Chapter 5) are rather limited as they apply to only two (unsorted) sediment types (D_{50} = 0.1 mm and 0.21 mm, resp.) and to mainly rippled beds due to the only moderate orbital velocities. Furthermore, the wave tunnel tests deal with sinusoidal water motions only. Many more tests are required to obtain more evidence. Hence it is recommended to perform similar experiments for
- other grain sizes (sorted/unsorted),
- both regular and irregular water motions,
- higher velocities (with other bed forms).

In principle, the experiments can be carried out easily without requiring sophisticated instruments.

Acknowledgements

The present work is part of the Applied Research Program (T.O.W.) of the Dutch Ministry of Transport and Public Works - Rijkswaterstaat. The wave flume experiments have been carried out in the framework of the project Geomor of Rijkswaterstaat and the cooperation with Messrs. Kohsiek and Misdorp is much appreciated. The authors are grateful to the operators of the Scheldt wave flume at the De Voorst Laboratory (Messrs. Tulp, Pasterkamp, Dokter). Our special gratitude is towards Mr. Th. E. van Maar for his technical assistance in carrying out all TABAC-measurements.

CHAPTER 75

Simulation of sandfill building stages with numerical flow models

G.J.Bosselaar *
R.A.H.Thabet **
A.J.G.M.van Roermund ***
L.Bijlsma ****

The paper describes the application of two dimensional vertically integrated models (WAQUA system), the results being used for the calculation of sandlosses during sandfill closure operations.
Investigations with test models, physical scale models as well as numerical models, are presented to prove that the WAQUA system is not only suitable for large scale applications, but also for the simulation of detailed flow patterns.

1. Introduction

A large part of the Netherlands lies below mean sea level. It is protected from floods by dikes and dunes (see figure 1).
In the twentieth century massive construction programs have been carried out to increase the safety of the low lands against storm floods. In former ages the defence merely consisted of building dikes. Only this century projects have been executed to shorten the exposed coast-line. This began in 1932 with the closure of the Zuiderzee, and continued more recently with the Delta Plan in the south-west of the Netherlands.

The rivers Rhine, Meuse and Scheldt formed the Dutch Delta. By its nature the area is flat and low. In the past the Delta was flooded several times. The most recent catastrophic flood disaster happened in 1953 when 150.000 hectares were inundated and more than 1800 people lost their lives (see figure 2).
Immediately after the situation had been restored, the Delta Plan was drawn up to prevent future disasters. According to the plan, all the estuaries had to be closed, except for the entrances to the harbours of Rotterdam and Antwerp.

figure 1 The Netherlands without dykes

figure 2 Situation flood 1953, flooded area are shaded

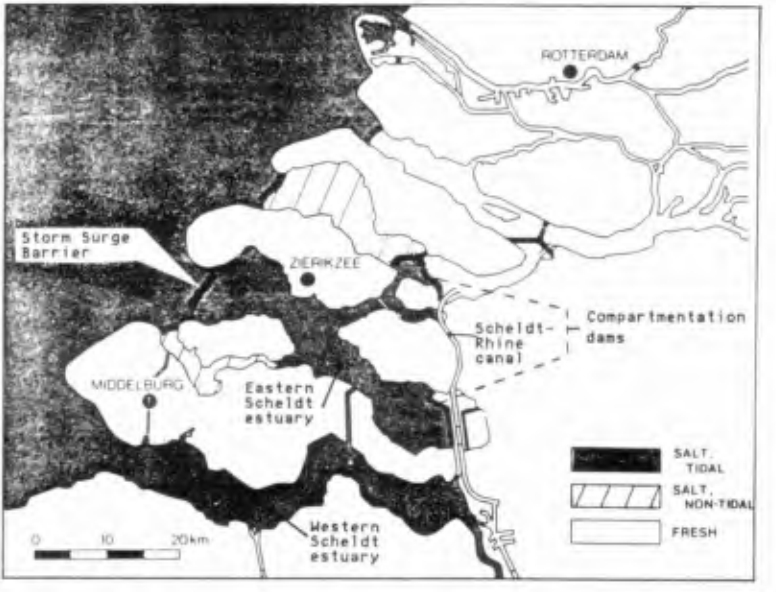

figure 3 The Delta project.

All planned closures but one were executed between 1956 and 1972.

However, contrary to the initial plan, the Government decided in 1976 to build a storm surge barrier in the mouth of the Eastern Scheldt instead of a massive dam. This with the aim to maintain the tide in the estuary under normal conditions, but to eradicate the chance of flooding of the country during storm surges.
The reason for this decision was that it became apparant that the Dutch society in the mean time came to realize that preserving the original environmental conditions in the Eastern Scheldt, with its unique aquatic life and its function as a nursery room for the North Sea, must be considered as a goal, equally important to the safety requirement.

The construction of the storm surge barrier implies the division of the Eastern Scheldt estuary into compartments. In the largest western compartment the tide is maintained, but the eastern part will become a tide-free fresh water lake:
- to prevent salt intrusion into the (agricultural) hinterland
- to provide a tide-free Scheldt-Rhine canal.
The ultimate lay-out of the Delta project is shown in figure 3.

The costs of the projects in the Eastern Scheldt amount to about $4,000,000,000.-. The construction of the storm surge barrier requires the major part of the budget. Related to the compartmentation projects approximately $300,000,000.- are to be spent.

The design and execution of major hydraulic structures is only possible when sufficient data are available.
Until now physical scale models were built to study flow conditions, and in some cases other relevant hydraulic phenomena, during building stages and in the future situation. The past decade, however, numerical flow models developed rapidly.
For the design of the storm surge barrier both physical scale models and numerical models were built. The principles of the applied numerical model based on the WAQUA system will be explained in chapter 2.
The confidence gained in the capability of numerical models to reproduce current patterns nearby the storm surge barrier (Klatter e.a., 1986) led to the decision to investigate whether numerical models can be used to compute current pattern near the planned sandfill closures of the compartmentation dams, without the additional use of tests in physical scale models. The performed tests will be descripbed in chapter 3.
The results of the tests led to the decision to rely entirely on numerical models for the design and execution of the sandfill operations in the closure gaps of the compartmentation dams (see for location figure 3).
Chapter 4 will discuss the results of these investigations.

2. WAQUA system

2.1. Numerical formulation

The model is based upon the so-called vertically integrated semi-momentum equations:

$$u_t + uu_x + vu_y - fv + gz_x + gu(u^2+v^2)^{0.5}/(C^2H) - K(u_{xx}+u_{yy}) = F^{(x)}$$

$$v_t + vv_y + uv_x + fu + gz_y + gv(u^2+v^2)^{0.5}/(C^2H) - K(v_{xx}+v_{yy}) = F^{(y)}$$

$$z_t + (Hu)_x + (Hv)_y = 0$$

in which:

- u = velocity in x direction (vertically integrated)
- v = velocity in y direction (vertically integrated)
- z = water elevation above some plane of reference
- h = water depth below plane of reference
- H = h + z = total water depth
- f = coriolis parameter
- g = acceleration due to grafity
- C = Chezy coefficient for bottom roughness
- $F^{(x,y)}$ = external forcing functions of wind stress or barometric pressure
- K = viscosity coefficient

The computations are made on a staggered rectangular grid system. The equations are solved by means of an Alternating Direction Implicit Method (Leendertse 1967, Stelling 1983).

2.2. Modeling system

For successful model investigations with numerical models a system of interlocking programs is required for data handling, simulation and graphical representation. The system used in this investigation has three major parts, namely, the Input Data Processor, the simulation program and the Simulation Data Display system.
Particularly noteworthy is that the WAQUA system possesses a number of facilities for simulating physical phenomena and the effects of hydraulic structures. The most important are:

- several procedures for the simulation of flooding and drying of intertidal flats (moving boundaries);
- a facility to simulate weirs and sluices whose flow characteristics can be varied with time;
- the possibility to represent narrow dams like groynes and breakwaters;
- the possibility to simulate the discharge of heat and effluents and the intake of cooling water at any location in the computational grid;
- (offline) nesting of models.

The system is designed to be used by civil engineers. Its operation requires no special knowledge of the computer science aspects of data handling and manipulation.

A large number of successful models have already been set-up and operated for tidal regions all over the world (ROOS et.al. 1985, Verboom et.al. 1984, Thabet et.al. 1985).

3. Detail models for sandfill closure gaps

3.1. Theoretical background

Numerical models based on the vertically integrated semi-momentum equations (which are based on the assumption of nearly parallel flow lines and hydrostatic pressure distribution) cannot be straightforward applied in the direct vicinity of hydraulic structures. The flow pattern is basically three dimensional, with flow separation and vertical and horizontal vortices directly downstream of the structure. These three dimensional effects and the additional dissipation of energy in the deceleration zone of the flow are responsible for the pronounced drop in the energy line (or water surface) at the structure. In civil engineering practice, these losses are usually refered to as "form losses", and expressed in terms of weir or gate formulae.
When applying two dimensional models, special measures have to be taken to introduce the energy drop at structure site. This is usually done by expressing "internal boundary conditions" based on the - presumably known - weir or gate formulae. This was the case for the storm surge barrier at the estuary mouth (Klatter et.al. 1986).

The case is different for sandfill closures. Sandfill bodies have flat slopes (1:15 or flater) in all directions. Hence no flow separation and associated "form losses" will take place. Accordingly two dimensional models can in principle be applied for such "structures", provided that the local energy losses not counted for in the semi-momentum equations can be locally incorporated.
These additional local losses are discussed below (see also figure 4).

First the friction losses. This factor dominates the energy drop over the closure gap. Because of the accelerating flow at the closure gap, the boundary layer will become thinner, causing the Chezy factor to drop and hence friction losses to (relatively) increase in the area around the closure gap. Downstream of the gap the change in the friction depends very much on the topography. The corresponding value of C will increase up to its original value over some distance.

Another coefficient which appears to be important is the viscosity factor K. From theoretical approximations we know, that this factor is 0.1 to 10 m2/s, dependant upon the local flow condition. This is only valid, when the numerical viscosity of the system is zero.

A coefficient which is not incorporated in the equations given in section 2.1 is the factor which described the influence of the vertical distribution of the velocity on the advection terms, $B(uu_x+vu_y)$ and $B(vv_y+uv_x)$. Under normal conditions the B value is approximately 1.1. In strongly diverging flows this factor may increase up to a maximum of 1.4. Because the B value is not implemented in the WAQUA system, the resulting energy losses were taken into account by adapting the friction coefficient, see section 3.2.

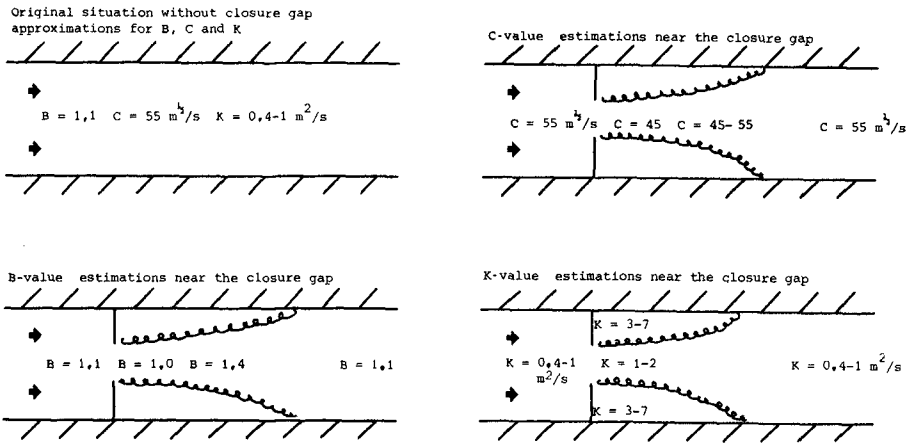

figure 4 Distribution of the values of some coefficients near the closure gap
note: Given C-value corresponds to water depths of the channels at compartmentation dam site

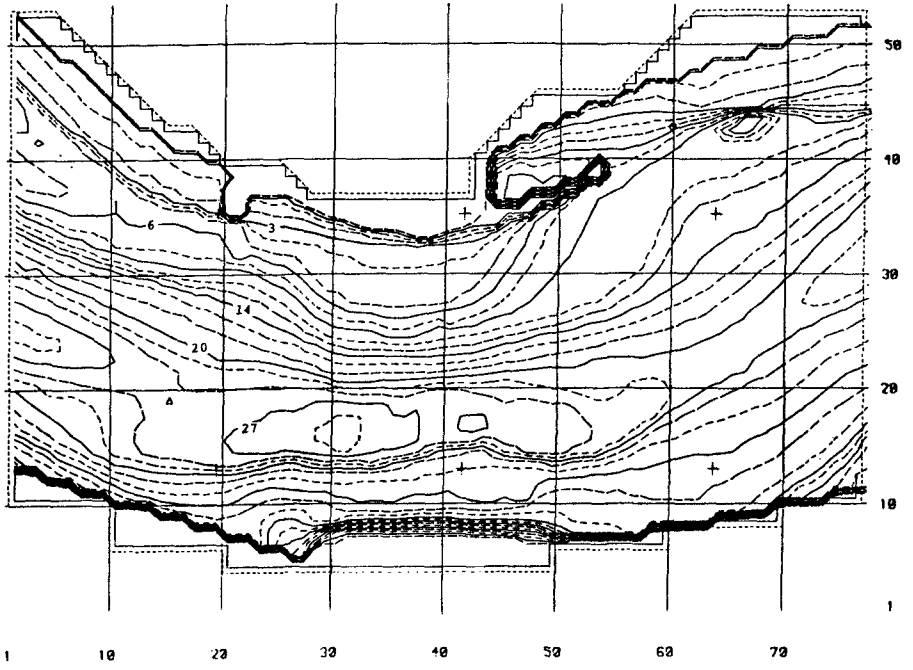

figure 5 Bathymetry of the test model

3.2. Verification tests

The test program

After the decision to investigate whether the WAQUA system is able to compute flow patterns around a sandfill closure, a test program was designed, based upon the comparison between a physical scale model and a numerical model of the same area.
An existing physical scale model was temporaraly changed in order to simulate the characteristics of a sandfill closure gap, see figure 5.
At the same time a numerical model with a grid size of 45 meters of the same area was built, to be able to compare measurements and calculations.
Five representative building stages of a sandfill closure were defined and one after another tested in the physical scale model.
The measured velocity distribution at the upstream and downstream edge of the physical scale model were used as boundary conditions for the numerical model.

Test results

The numerical model proved to be able to reproduce the current pattern fairly accurately.
Figures 6 and 7 show some of the investigated flow patterns. The measured flow pattern as well as the calculated distribution are shown.

As discussed in section 3.1., extra energy losses due to changes in the boundary layer and to the influence of the vertical velocity profile on the advection terms were introduced by increasing the bottom friction of the model.
Experiments proved that the Chezy factor must be decreased to a value of 35-40 to make up for these effects. Note that this value is only valid for geometries and water depths like the ones investigated.

Very low viscosity factors proved to give the best results, as far as the horizontal distribution of the velocity and diversion of the flow downstream of the gap are concerned.
After some tests we decided to use for all the applications a viscosity factor of 1 m2/sec.

The physical scale model is a stationary model. This implies that a changing tidal situation could not be simulated, only max. flood tide and max. eb tide were therefore investigated.

4. Applications

4.1. Tholense Gat model

In 1985 a fine grid model of the final gap in the southern compartmentation dam was built.
The model is situated at the northern edge of the dam, near the coast of the island of Tholen. It has a grid size of 30 meters and a time step of 20 seconds. The number of active grid cells is approximately 3000.
The boundary conditions of the model are generated by a 100 meter grid sized far field model.

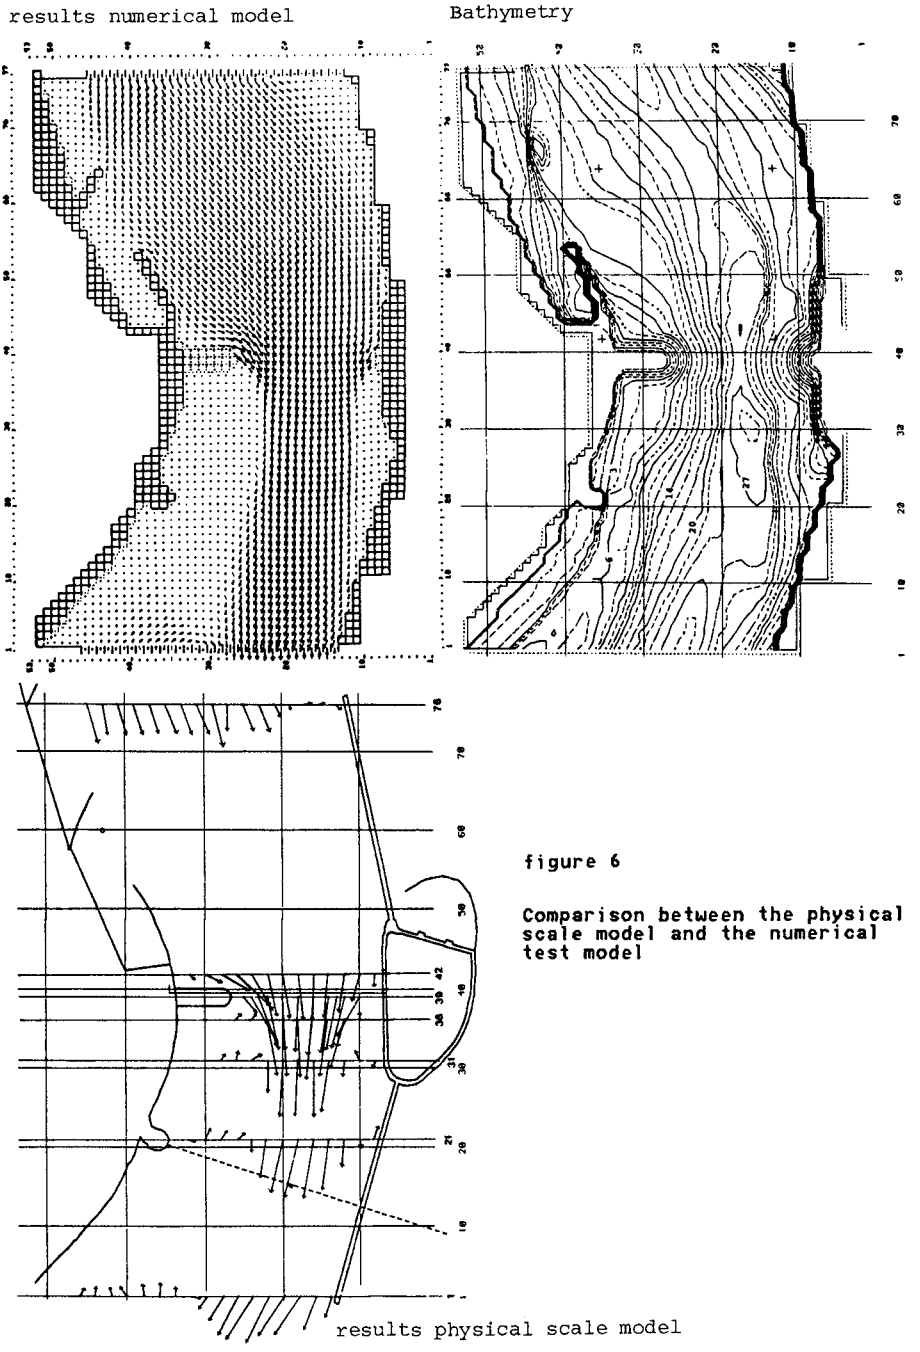

figure 6

Comparison between the physical scale model and the numerical test model

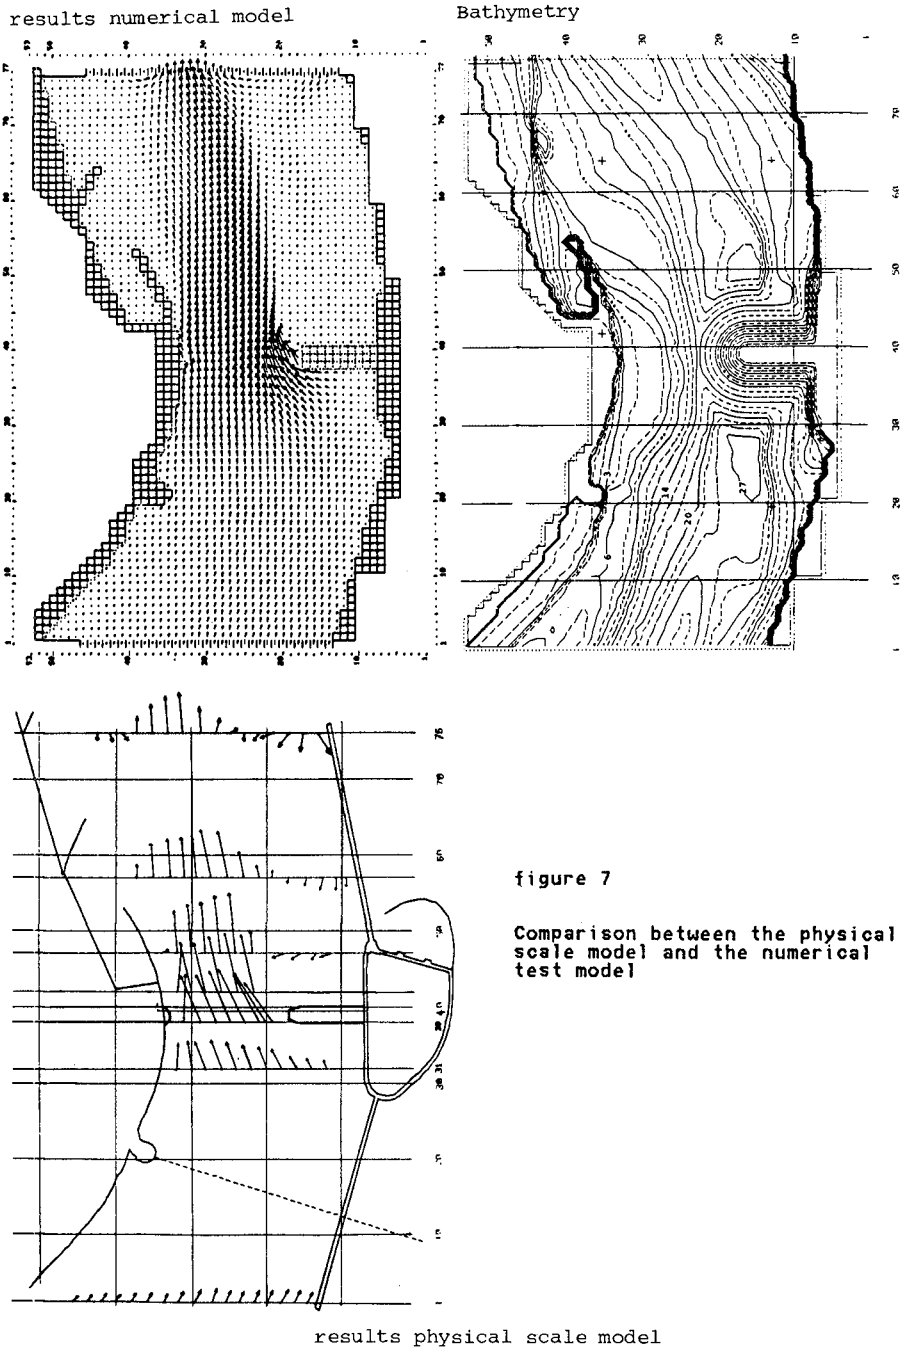

figure 7

Comparison between the physical scale model and the numerical test model

The investigations with the model had two purposes:
- prediction of the flow conditions in the closure gap, the results being used as input for the calculation of sand losses during the sandfill operation and prediction of the flow along the bank of the island of Tholen, in order to prevent possible problems with the existing, rather, weak dykes;
- prediction of the discharge coefficient of the closure gap (as a function of construction stage), such data being used as input for the one dimensional model covering the entire estuary up to the North Sea.

Figure 8 shows one of the investigated building stages.
The closure operation was successfully performed in October 1986.

4.2. Krammer model
Figure 9 shows the situation at the northern compartmentation dam in July 1986. Two gaps are still open.
The model of the area has a grid size of 50 meters, a time step of 30 seconds and some 25000 active grid cells.
The boundary conditions of the model are generated by the overall one dimensional model of the Eastern Scheldt (see also section 4.1.).
In September 1986 the smallest gap in the dam was closed. In figure 10 the flow pattern at the smallest gap, calculated by the model is compared with prototype measurements.
Although the grid size of the model is rather large in relation to the width of the gully, the model was able to simulate the flow pattern quite well.

After the successful closure of this small gap in September 1986 and the completion of the southern compartmentation dam, described in section 4.1., only the gully called the Krammer is still open.
The closure of this gap is planned in April 1987. The planned building stages have been thoroughly investigated. An example of the situation to be expected is shown in figure 11, where the flow pattern is plotted during an average maximum flood tide, when 70% of the gap is closed.
Figure 12 shows the flow pattern during maximum eb tide and maximum flood tide in more detail.
In the remaining cross section of 3000 m2 the average velocity is 2,0 m/sec, but localy 2,75 m/sec will occur.

The described flow pattern with an average velocity of 2,0 m/sec is only possible if the tide in the Eastern Scheldt estuary could be reduced. This is planned to be done by partial closure of the gates of the storm surge barrier.
A large amount of investigation effort has been invested in selecting the tide reducing measures that would reduce the velocities in the closure gap and at the same time would minimise the damage to the ecology of the estuary.
Figure 13 shows the expected (reduced) water elevation in the Eastern Scheldt during the last days of the closure operation of the Krammer Gap.
After completion of the dam, the storm surge barrier will be opened again completely and the tide will be fully admitted to the estuary.

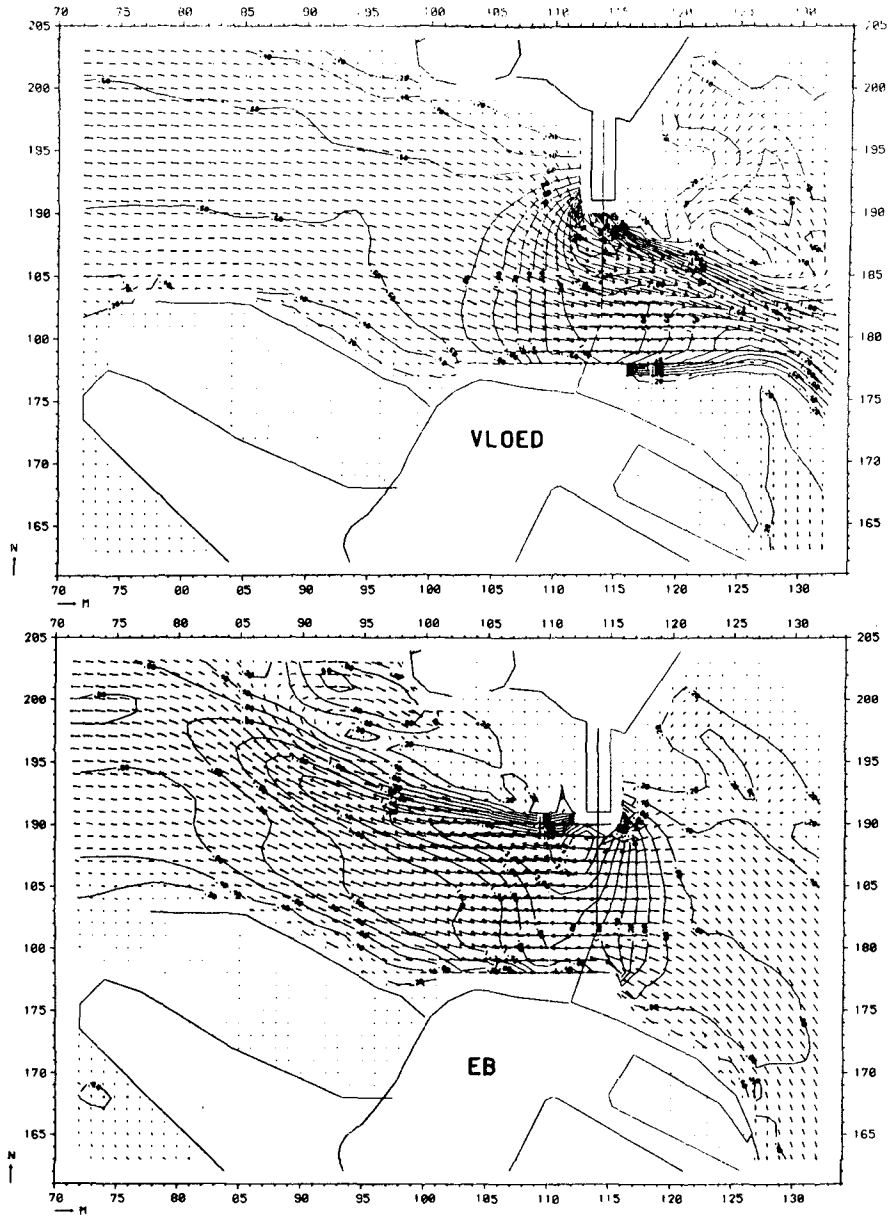

figure 12 Detailed calculated flow patterns during maximum eb tide and maximum flood tide.

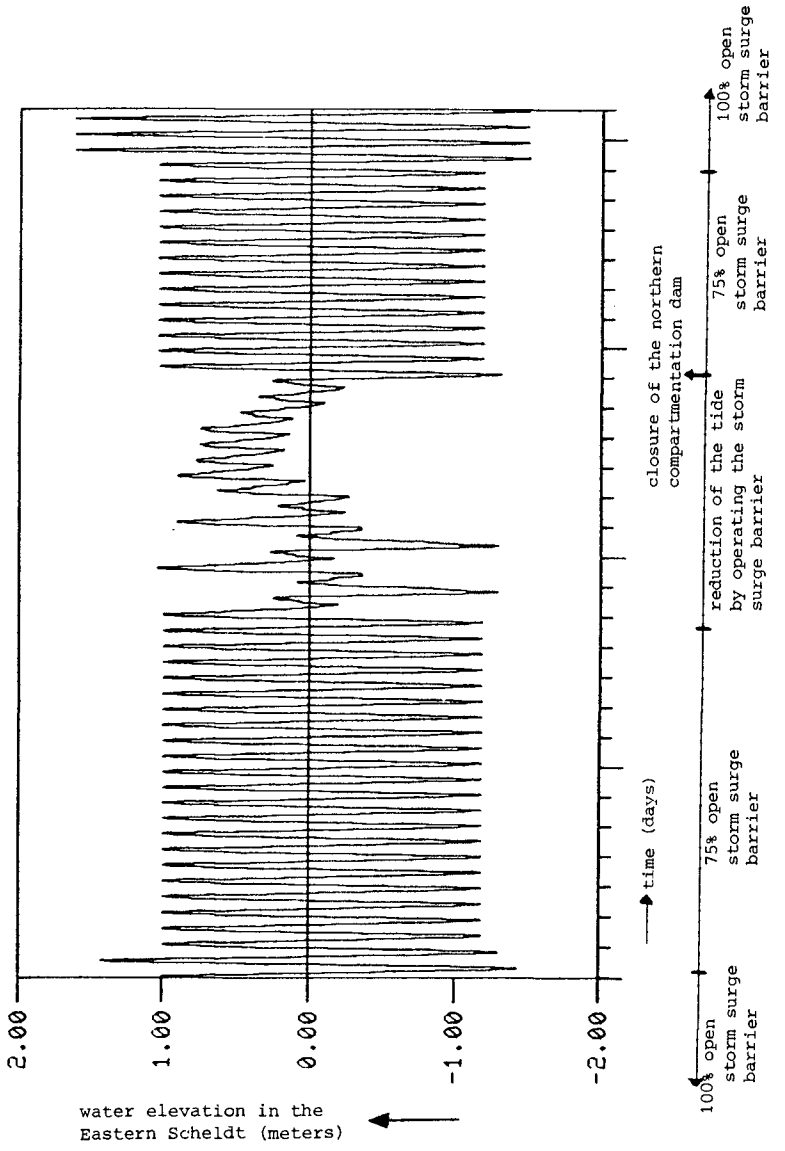

figure 13 Expected (reduced) water elevation in the Eastern Scheldt during the closure of the Krammer gully in the northern compartmentation dam.

5. Conclusions

Extensive tests with the WAQUA system, in comparison with prototype measurements and physical scale model results, have shown that the system is also reliable for small scale applications, provided that governing mechanisms are correctly simulated.
Models of sand closure building stages proved to be able to calculate the flow patterns accurately.
For the first time in the Netherlands, major closure operations were carried out without the use of physical scale models, but entirely based on calculations with numerical flow models.
The system proved to be a very useful engineering tool, accepted by and operated by civil engineers.

INTRODUCTION

One of the function of the offshore breakwater is to protect the coast from wave action. By dissipating the wave energy along its entire length, the breakwater causes sediments in its lee to deposit and a shore salient is formed. If the offshore breakwater are placed in a series along a coast with a gentle offshore slope and a substantial littoral drift tombolo will form behind the breakwaters between which bays will be sculptured by waves to form stable shapes (1). These attached breakwater would thus form a series of artificial headlands.

In nature, beaches between headlands are influenced by the position of the headlands. Where the headlands are closely spaced and a limited sediment supply exists, small pockets beaches are formed. Where the headlands are far apart and an adequate sediment supply exists, long and wide beaches are formed. Generally, between these two extremes most beaches between natural headlands take a shape that is related to the predominant wave approach; on the downcoast sector is a long and straight beach, while on the upcoast end is curbed beach. Silvester (2) in his model study established a relationship between the logarithmic spiral constant (α) and the angle of predominant wave approach (β). A quasi-permanent shape was reached when waves broke simultaneously around the model bay. As it is difficult to measure the curve sector in nature, Silvester and Ho (3) suggested the use of an indentation ratio to relate the bay's shape to wave approach.

The afore-mentioned concepts of headland breakwaters and beach formation between them were applied in 1968 along the Southeast Coast of Singapore (Fig. 1), where a series of headland breakwater are used to protect about 14 km of the newly reclaimed land (4,5) under the East Coast Reclamation Scheme (Phases I to VII) where 1525 hectares of foreshore was reclaimed at a total cost of $613 million from 1966 to 1985. Rip Rap headland breakwaters of length varies from 55 m to 67 m and spaced at 300 m to 360 m were constructed in series along the edge of the fill. Under wave action, the fines are removed leaving behind sand and gravels to form sandy bay beaches between the headland breakwaters. (see Figs. 2a, 2b and 2c).

The successful implementation of the headland breakwater concept at the Southeast Coast lead to similar technique being used for the reclaimed land at Pasir Ris. Between 1978 and 1980 Housing and Development Board reclaimed 44 hectares of the shallow foreshore at Pasir Ris and Loyang areas in two separate parts on both sides of Sungei Tampines on the northeast coast of Singapore to provide additional land for a park (Figs. 1 and 3). Approximately 2.4 million cu m of earth excavated from existing hills about 6 km away was utilised for the reclamation. The fill material, which is a semi-consolidated mass of gravel, sand and clays, disintegrates rather easily in contact with water. The fines are removed by wave action and coarser material is left behind for beach formation.

PASIR RIS RECLAMATION

The existing coast at Pasir Ris prior to reclamation was a relatively flat muddy coast with pockets of sandy beaches, the entire shallow foreshore up to a distance of 150 m from the existing shore was exposed during low tide.

To provide recreational facilities for residents around the area, it was decided to reclaim the shallow foreshore to creat land for the development of a park. In 1978 Housing and Development Board proceeded with the reclamation of 44 hectares of the foreshore at Pasir Ris and Loyang in two separate parts on both sides of Sungei Tampines and works was completed in 1980 (Fig. 3). The extent of the reclamation was confined mainly to the shallow area which was exposed at low tide. The profile of the reclamation was determined using the existing offshore topography as a guide, ie the edge of the reclaimed area was more or less parallel to the existing offshore contour (see Figs. 4a, 4b and 4c). The concept of rip-rap headland breakwaters which had been successfully implemented at the East Coast Reclamation was adopted for Pasir Ris Reclamation. A series of 10 numbers rip-rap headland breakwater was constructed along the edge of the reclaimed area to creat sandy bay beaches.

The fill material for the reclamation was excavated from existing hills some 6 km away from the reclamation site. The fill material is of Quarternary age and consists of semi-consolidated gravels, sands and clay. Boreholes carried out at the cut site showed that the material was dense to very dense medium to coarse silty clayey sand. Mechanical analysis showed approximately 75% was sand and gravel and 25% was silt and clay.

The material for reclamation was conveyed from the cut site to the reclamation site by lorry. An earth bund of approximately 20 m width was constructed initially along the perimeter of the reclamation site commencing from the existing shoreline and proceeded toward the sea by direct dumping from the lorries. Upon completion of the perimeter bund, filling within the bunded area was then proceeded, an opening in the bund was constructed to facilitate the inflow and outflow of sea water, area around the opening was reclaimed last. The level of the fill was 102.70 m or approximately 4.7 m above the existing seabed level.

Rip rap headland breakwaters constructed dry in the fill material along a near straight edge of fill and subsequently become wet (Fig. 5). The area upon which each rip-rap structure is to be constructed is first overfilled, compacted and thereafter excavated in stages to form an earth mound with a seaward slope of 1:2 and a landward slope of 1:1 1/2. A non-woven filter cloth of thickness 3.5 mm was used as a filtering medium to prevent removal of fill material by wave action was then spread loosely over the entire mound. On top of it were placed 0.1 m of 0.05 to 0.1 m stones, a second 0.25 m layer of 0.1 m to 0.15 m stones and lastly a layer of 0.40 m stone properly pitched. The rip-rap structure extends 1.18 m below LWOST to 1.5 m above HWOST. Subsequent wave action removes the fill materials which was overfilled and exposed the rip-rap breakwater which are spaced at about 200 m. Under wave action, the fines are removed leaving behind sand and gravels for beach formation between the headland breakwaters. The length of the rip rap breakwater is 25 m which has to be such that it would not subsequently become an "offshore island". This can be predetermined using Silvester's relationship between logarithmic spiral constant (α) and the predominant wave approach angle (β). The maximum limit of fill seaward of the rip-rap breakwater was 25 m from the centre of the breakwater. The overfilled material was removed and spread onto the seaward face of the rip-rap headland breakwater upon completion of construction to provide a gentle sloping seaward appearance.

COASTAL ENVIRONMENT

The northeast coast of Singapore is relatively clam as it is located at Johore Strait bound by the southern boundary of Johore and northern boundary of Singapore. Johore Strait is a long and narrow strait with a length of 30 km and an average width of 2 km. Winds from the north during the northeast monsoon do not have a large influence except through refracted swell from South China Sea which enter the Johore Strait from the east. It is essentially a low energy environment throughout the year with refracted waves coming from the northeast quadrant, so that westward littoral drift is present (see figure 3).

WINDS

The wind conditions in Singapore are governed by the two monsoon seasons. The SW-monsoon season prevailing in the months June through Sept. The NE-monsoon season prevailing in the months December through March. Separating these monsoon seasons there are two inter monsoon periods.

Winds were records at the Paya Lebar Airport at a point about 2 km from the sea and 28.0 m above mean sea level and at Changi Airport at a point 1.2 km from the sea and 13.0 m above mean sea level. Sharp contrasts in direction and velocity of winds were recorded for the northeast monsoon (December to March) and the other periods. Long term wind frequency data obtained from Meterological Services Singapore at Paya Lebar Airport from 1956 to 1980 and at Changi Airport from 1972 to 1982 were used to produce the wind rose for the annual average wind speed and direction (Fig. 6a). Southwest monsoon during the period June to September (Fig. 6b) and northeast monsoon during the period December to March (Fig. 6c) for Paya Lebar Airport and the annual average wind speed and direction for Changi Airport (Fig. 6d).

Winds during the northeast monsoon are predominantly from N-NNE and are less than 5.4 m/sec. Wind speed exceeding 10 m/sec only 2 - 3% of the time. Wind during other period are from S-SSE with speeds of less than 3.3 m/sec. The annual wind rose showed a similar pattern to that of the northeast monsoon which indicated that the predominant wind is from the north quadrant.

TIDES

The tides are essentially a combination of diurnal and semi-diurnal (ie a high tide is followed by a not so high tide) with a range of approximately 2.3 m during spring tide, 1.0 m during neap tide and a mean range of 1.7 m. The typical tidal velocity is 0.7 m/sec during spring tide and 0.4 m during neap tide based on information available from Admiralty Chart.

TIDAL CURRENTS

A non-contact current meter manufactured by Koyowa Shoko Co Ltd Japan was installed at the study area at 3 m below surface during the period 7.2.86 to 10.3.86. The current meter is able to measure both the direction and mean current velocity continuously. Current velocity, however, is counted for three minutes at every twenty minutes striped graphically on scratch paper. Measuring range for current velocity is 0.05 - 3 m/sec as mean current velocity with one constant-pitched impeller.

A scatter plot of current speed against direction (Fig. 7a) for all recordings indicated that the current is mainly in the southeast and northwest direction. A cumulative current speed distribution curve (Fig. 7b) showed that 85% or more of the current speed is less than 0.3 m/sec. A plot of west going and east going current together with hourly tide observation for 8.2.86 were shown in Figs. 8a and 8b. From these two figures it can be seen that during ebb tide the current is east going and during flood tide the current is west going. In general, the tidal elevation curve lead the velocity curve by about 3 hours which is approximately one-quarter of the semi-diurnal period. This is an expected observation because it shows that during extremes of tides, ie when the tides are about to change direction, the velocity are almost zero. Also, when the tides are flowing in or ebbing out of the strait, ie at mean sea level, the velocities are maximum.

WAVES AND WAVE REFRACTION

Pasir Ris Reclamation was along a coastline facing north which is subject to refracted swell wave from South China Sea arriving the beach from the north east direction. This results in a net littoral draft from east to west (as indicated by the offshore topography in Fig. 3) whether the waves are generally locally or are swell from South China Sea, they entering the Johore Strait from the east (Figs. 9a and 9b). The wind rose for the area indicates a predominance of winds from NE quadrant. The largest proportion of these are wind of less than 5.4 m/sec. Winds in excess of this velocity from this NE quadrant occur for less than 4% of the time.

The major wave incidence would therefore appear to be swell arriving from South China Sea. The predominance of this wave and current action is indicated by the offshore contour. These clearly indicate an east to west drift of sediment. Considering the general orientation of the bed contour at the study area, a refraction computation indicates a deepwater approach from a north easterly direction, S.Y. Chew (4) measured the waves at Southeast Coast of Singapore, the result indicated that during the northeast monsoon the highest value of H_{max} was 1.1 m and for more than 65% of the time, H_{max} did not exceed 0.6 m. During other period H_{max} exceed 0.6 m for less than 10% of the time. 90% of T_z fell between 2.5 and 4 seconds during northeast monsoon while T_z was predominantly around 3 seconds during other period. A wave period of 4 seconds was used for the plotting of the wave refraction diagram in Figs. 3, 9a and 9b. The wave period is close to that reported in South China Sea of 4 to 7 seconds. Such swell is predominant in the months from December to March when northeast monsoon exist in the area. Figs 10a and 10b showed the wave height exceedence distribution curves and H_s - T_p relations for prevailing system off Changi coast respectively.

IMPLICATION AND EFFECTS OF PROCESSES ON RECLAMATION PROJECT

The northeast coast of Singapore is a sheltered area and local winds do not have a large influence except through refracted swell from South China Sea. It is essentially a low wave energy environment throughout the year with waves coming from the northeast, so that a westward littoral drift is present.

The swell from South China Sea enter the Johore Strait from the east after travelling through the deep water, the waves are refracted toward the reclaimed area, as the offshore topography is almost parallel to the coast, the refracted waves reach the coastline almost perpendicular, this together with the fact that the tidal current is flowing westward during flood tide and eastward during ebb tide with a duration of approximately 15 hours during flood tide and 9 hours during ebb tide, there is a tendency for a net movement toward the westward. In view of the almost perpendicular approach of the wave orthogonal and the weak current, the movement of the sediment is a very slow processes as indicated by the slow beach formation at Pasir Ris Beach. The formation of the beach between the headland breakwaters is slower when it is compared to the coast at East Coast which is more exposed than the beach at Pasir Ris.

GRAIN SIZE DISTRIBUTION OF BEACH MATERIAL

The fill material, which is a semi-consolidated mass of gravels, sand and clays, disintegrates rather easily in contact with water. The fines are removed by wave action and coarser material is left behind for beach formation.

The grain size characteristic of the beach material varied from 0.06 mm to 10 mm. The median size (D50) varied from 0.4 mm to 1.1 mm and the average median size was 0.68 mm (Figs. 11a and 11b). There is a systematic variation of mean grain size normal to the beach, from medium sand at the berm to coarse sand at the step. The average mean grain size is 0.39 m for berm samples, 0.59 m for foreshore samples and 0.88 mm for step samples.

While size variation normal to beach is present, the material is not well sorted. The average berm sample is moderately sorted (0.96) whereas the foreshore and step samples are poorly sorted (1.22 and 1.23 respectively). Poor sorting is attributed to the incomplete process of selective removal of fine grains under low wave energy environment and the short period of beach development (1980 - 84).

There is no systematic alongshore variation of mean grain size and sorting. The lack of alongshore variation in grain size characteristics is due to low wave energy and absence of littoral currents to sort out the beach material.

BEACH PROFILES

The formation of beaches along the reclaimed Pasir Ris coast is essentially similar to a situation where the scarp retreat along the fill will not produce a seaward concave curve until the strip of fill between the headland breakwaters and the sea is removed and the seaward sides of the breakwater are exposed to wave action. The berm is of fairly uniform width along the entire shore in the model proposed for beach formation along reclaimed Southeast Coast of Singapore (8). Basically, a strip of fill material placed seaward of a pair of breakwaters retreats under wave action; as the shoreline retreats in form of a scarp, a sloping abrasion ramp is left behind; the clastic deposits which is derived from the fill covers the abrasion ramp. The extent of development of clastic deposits in form of a beach between a pair of breakwaters varies from cell to cell (See Figure 3 showing cells along Pasir Ris reclaimed coast).

Beach profiles were taken at the upcoast, midcoast and downcoast ends of cells at the Pasir Ris coast (see Figure 12 showing profiles from cells A and F). They are slightly concave and represent profiles of under-nourished beach based on Bruun's (9) classification of beach profiles. The beaches are poorly formed because of an inadequate supply of clastic material from the fill.

The backshore (berm) is present at parts of the cells and is very narrow, averaging 2.4 metres wide. The landward ends of the profiles are marked by active scarp erosion. The foreshore average 7.8 metres wide and consists of a thin layer of clastic material that gets progressively thinner towards the step. The foreshore slope ranges from 4°10' to 8°40'. Exposed abrasion ramps are found mainly in the foreshore zone; generally, they have a sparse cover of pebbles, cobble-sized and boulder-sized pieces of Old Alluvium. The slope of the abrasion ramp is less than that of the foreshore.

Certain features on beach profiles display consistent pattern: the upcoast fill scarp is usually inactive whereas ongoing erosion marks the fill scarps at the midcoast and downcoast sections. The berms are usually located at the upcoast ends and occasionally in the midcoast sections.

BEACH PLANS

With reference to position of the step, most of the beach planforms display a slight seaward concave curvature with an almost straight downcoast sector and a more indented upcoast sector. With development of berms in the upcoast sector, the step at that part of the cell is prograded and straightened.

Active scarps characterized almost the entire length of the cells, with most scarp height between 0.25 and 0.75 metres. The persistence of these active scarps indicates that beaches are still retreating. Small lengths of inactive scarps are found in the upcoast sectors of cells A, C, E, F and G and the downcoast sectors of cells B and C. They occurred at locations where they are protected by berms, bars or mangroves. The height of active scarps tend to increase progressively with distance from monactive scarp until the highest scarp height in the cell is reached (usually in the middle of the cell).

For planning purposes, Silvester's (2) criterion of the logarithmic spiral to determine the maximum position of the beach between the breakwaters was adopted.. These lines of maximum positions are based on a logarithmic spiral of 1.05 with a constant agnel (α) at 72° to a wave approach (β) of 10°. (See Figs 13a and 13b showing lines of maximum positions compared with planform of the scarps of all the cells).

BEACH DEVELOPMENT

Beach platform and changes at cells A and F are shown in Figs 13a and 13b. The profile indicated that there is minor variation of the beach profile between high and low water where a accretion and erosion have occurred. From Fig. 3 it can be seen that the offshore profile is more or less parellel to the edge of the reclamation profile and the wave direction is almost perpendicular to the beach, this together with the weak current resulted in slow erosion and minimum littoral drift which explain the slow formation of the beach development between the rip-rap headland breakwaters. Although the changes is slow, there is still a tendency for westward movement as the duration of the current flowing eastward is generally shorter than the westward movement. For land use purposes, it is necessary to determine the limit of erosion. Silvester (7) has suggested that the relationship between logarithmic spiral constant and the wave obliquity can be used to determine the equilibrium shape of the beaches between headland breakwaters.. The probable shapes based on this criterion of the three bays for wave approach from north are given in Figs 13a and 13b. This assume that the westward drift is reduced or cut off. From Figs 13a and 13b it can be seen that further erosion is expected to take place especially around the curved portion.

DISCUSSION

Even with a longer time period, the beaches at Pasir Ris are unlikely to attain the equilibrium shape according to the logarithmic spiral criterion. This is confirmed by the presence of inactive scarps protected by berms along parts of the cell and the straightening and progradation of the shoreline with berm development. The logarithmic spiral criterion therefore cannot be used to determine beach equilibrium at the Pasir Ris coast because of the low wave energy and a very weak littoral drift. Given the low wave energy and a very gentle offshore gradient, beach type similar to East Coast of Singapore is unlikely to be attained by all the cells at Pasir Ris.

The slow progress in the development of the beach at northeast coast is due to weak current and almost perpendicular approach of the waves. It is most likely that the beach will only reach its anticipated platform after prolong period. Monitoring of the beaches will be carried out to observe the beach development.

ACKNOWLEDGEMENT

The authors wish to thank the Chairman, Hsuan Owyang and the Chief Executive Officer, Mr Liu Thai Ker and the Chief Civil Engineer, Mr Yao Chee Liew of the Housing and Development Board for their encouragement and permission to present this paper.

CHAPTER 77

Beach fill at two coasts of different configurations

Ichiro Deguchi[+] and Toru Sawaragi[++]

ABSTRACT

Movements of borrow sand replenished at two coasts of different configurations are investigated by analyzing the topographic data which were surveyed periodically after the beach fill placements. One is a long straight beach and borrow sand was placed behind a submerged breakwater. Another is a pocket beach which has an arc-shoreline with a groyne at one end and a headland at another.

It is found that the amount of borrow sand moved in the long-shore direction surpasses the amount of borrow sand transported in the cross-shore direction regardless of the shape of the coast. A clear correlation is also found between displacements of shoreline and changes of sectional areas. These results imply that the deformation of the artificially nourished beach and the dissipation rate of borrow sand can be predicted by the so-called one-line theory.

1. Introduction

Artificial beach nourishment is a commonly utilized approach for treatment of shore protection problems such as beach erosion, wave over-topping and so on. It is also the direct method to maintain and improve recreational benefits in the coastal zone.

In Japan, there are many coasts where beach fill have been already replenished. At these coasts, structures such as an off-shore submerged breakwater, a detached breakwater and a groyne have been constructed simultaneously in order to prevent beach fill from flowing out from the replenished field.

However because the effective beach fill design involves so many physical factors, the precise degree of beach fill utilization to stabilize a shoreline is not always predictable.

The objective of this study is to investigate behaviors of beach fill replenished at two coasts of different configulations by analyzing successively measured beach profiles to offer informations as to what is the governing factor in the determination of the effctiveness of beach fill.

2. Configulations of Two Coasts and Location of Beach Fill

Locations of two coasts are shown in Fig.1.

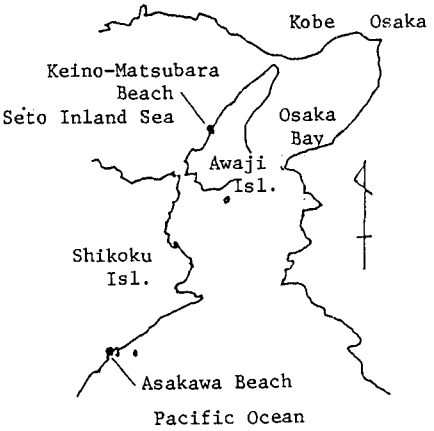

Fig.1 Locations of investigated two beaches

One is Keino-Matsubara-Beach which is on the east side of the Awaji Island facing the Seto Inland Sea and has a long straight beach of about 5km long as shown in Fig.2(a). In this coast, a test offshore submerged breakwater of 80m long and 20m wide was first constructed in 1983 and borrow sand of about 5000m^3 was replenished behind it about one year after the construction of the breakwater.

The upper surface of the submerged breakwater is about 1.5m below D.L.. H.W.L., M.W.L. and L.W.L. correspond to D.L.+1.8m, D.L.+1.2m and D.L.+0.5m. The water depth was measured upward from D.L.. The average beach slpoe is about 1/7 to 1/10 in the shallow water region(shallower than -2m) and about 1/30 in the deeper resion. Mean grain size d_{50} ranges from 0.2mm to 3mm and there is no correlation between d_{50} and water depth. Mean graion size of borrow sand is 1.5mm. These data are summerized in Table 1.

Figure 2(b) indicates a location of the submerged breakwater and the region where beach fill would be placed based on the measured beach profile just after the construction of the submerged breakwater.

Another is Asakawa-Beach which is a so-called pocket beach and has an arc-shoreline of about 400m long and the radius of which is 260m as shown in Fig.3. There is a rockey head land at the south end of the beach and a groyne of 150m long was constructed in 1974 at the other end. A beach slope in a shallow region (shallower than -3m) is about 1/7 to 1/10 and about 1/30 in the deeper region.

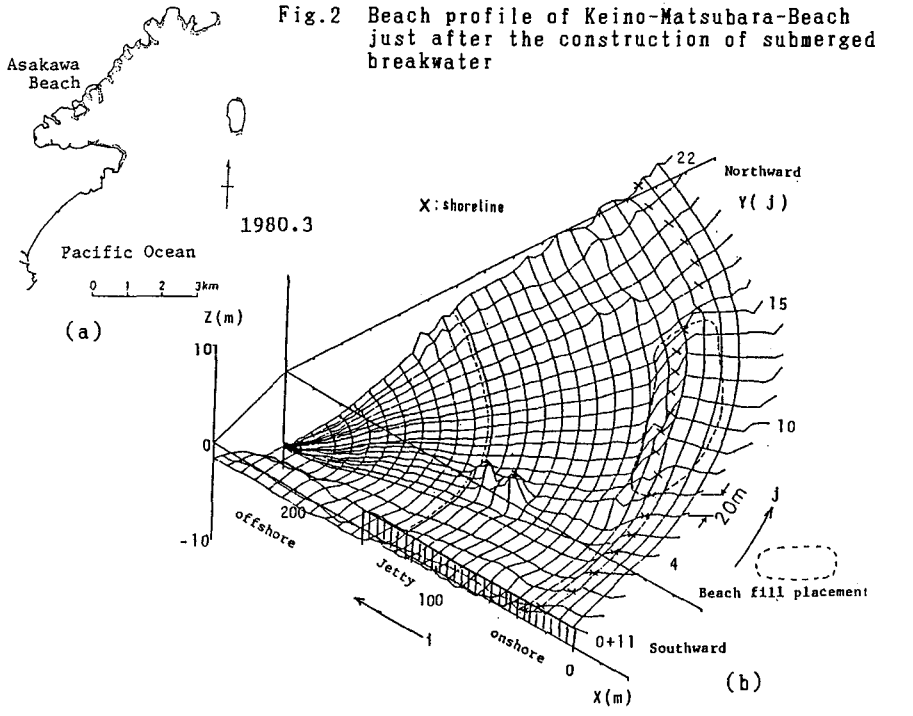

Fig.3 Beach profile of Asakawa-Beach just after the beach fill placement

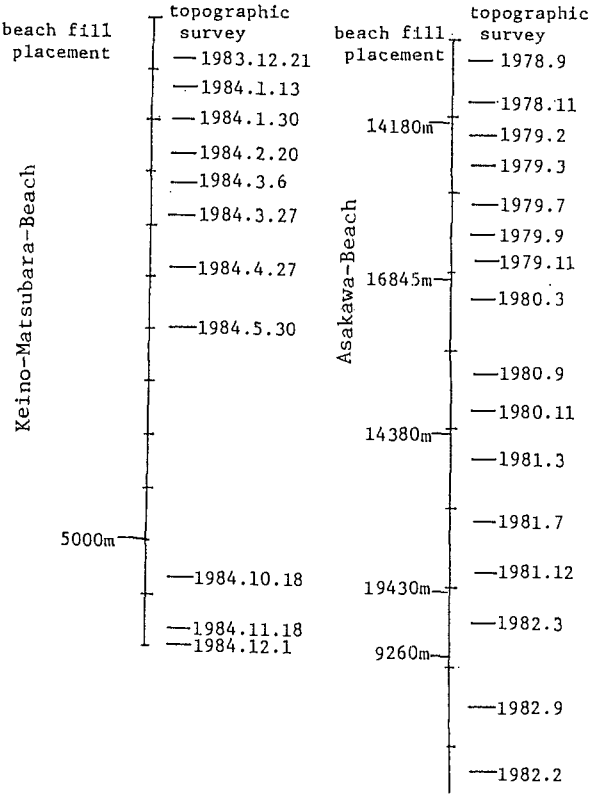
Table 1 Characteristics of two beaches

	Keino-Matsubara-Beach	Asakawa- Beach
[d_{50}]		
native sand	0.2mm-3mm	0.5mm-3mm
borrow sand	1.5mm	0.4mm and 0.8mm
[Beach slope]		
shallow region	1/7-1/10	1/7-1/10
deep region	1/30	1/30
[waves]		
winter-spring	probability of appearance of waves higher than 1m is 35%.(from W-NW)	large part of waves are less than 40cm
summer-autumn	large part of waves are less than 40cm	waves higher than 1m incidents several times a year in a typhoon seasons.(from SE-E)

Table 2 Progress of beach fill and topographic survey



Water depth was measured upward from D.L.. H.W.L. and L.W.L. correspond D.L.+2m and D.L.+0.8m. Mean grain size of native sand d_{50} ranges from 0.5mm to 3mm. These data are also summarized in Table 1.

Figure 3(b) is a bottom topography drawn based on the measured water depth in Sept.1978 just before the continuous sand replenishments began. Since then, beach fill of about 15000m³/year has been continuously placed in the center of the beach. From 1982, a submerged breakwater of 14m width has been constructing along a broken line shown in the figure from the north end of the beach and the construction of total 170m length are finshed in 1984. In this coast, two kinds of barrow sands of which mean grain sizes were 0.4mm and 0.8mm were used.

3. Method of Analysis and Data used

At Keino-Matsubara-Beach, a series of topographic survey have been conducting just after the construction of submerged breakwater. Water depth was measured on 26 surveying lines at the interval of 2.5m. The surveying lines were set at the distance of 20m along the shoreline. Beach profile measured just after the construction of the submerged breakwater in Dec.1983 which is shown in Fig.2(b) is selected as a initial profile in the following analyses.

At Asakawa-Beach, topographic survey has also been conducted periodically from Nov.1977. Water depth was measured on 24 surveying lines at the interval of 5m. Surveying lines were spaced as shown in Fig.3(b) which was drawn based on the water depth measured in March 1980. Beach profile measured in Sept. 1978 is used as a initial profile in the following analyses.

Progresses of the constructions of structutes, beach fill placements and topographic surveys at these beaches are shown in Table 2.

Based on the measured beach profiles, the following are investigated :

a) characteristics of the beach deformation around artificially nourished beach and behaviors of beach fill, and
b) remaining or dissipation rate of beach fill $\alpha(t_n)$ or $1-\alpha(t_n)$.

To investigate these, changes of water depth $\Delta h(i,j,t_n)$ and $\delta h(i,j,t_n)$ were first calculated from the measured water depth $h(i,j,t_n)$ where i indicates the i-th measureing point on the j-th surveying line and n shows the water depth measured at n-th topographic survey. That is,

$$\delta h(i,j,t_n) = h(i,j,t_n) - h(i,j,t_0) \quad (1)$$

$$\Delta h(i,j,t_n) = h(i,j,t_n) - h(i,j,t_{n-1}) \quad (2)$$

where t_o means the initial beach profile.

These topographic changes were also investigated by the empirical eigenfunction method by expanding Δh and δh as linear combinations of products of functions of the distance normal to the shoreline $e_k(i,t_n)$ and those of the distance parallel to the shoreline $c_k(j,t_n)$ as follows;

$$\Delta h(i,j,t_n) \quad \text{or} \quad \delta h(i,j,t_n) = \sum e_k(i,t_n)\, c_k(j,t_n) \qquad (3)$$

Remaining rate of replenished barrow sand $\alpha(t_n)$ is defined in this paper as follows;

$$\alpha(t_n) = \delta V(t_n) / \sum Vb \qquad (4)$$

where $\sum Vb$ is the total volume of replenished borrow sand and $\delta V(t_n)$ is a volumetric change within the analyzing area, that is,

$$\delta V(t_n) = V(t_n) - V(t_o), \quad V(t_n) = \iint h(i,j,t_n)\, dx\, dy. \qquad (5)$$

4. Characteristics of beach deformations around artificially nourished beach and behaviors of beach fill

i) Keino-Matsubara-Beach

Figure 4 shows the topographic change took place during 2-month after the beach fill placement.

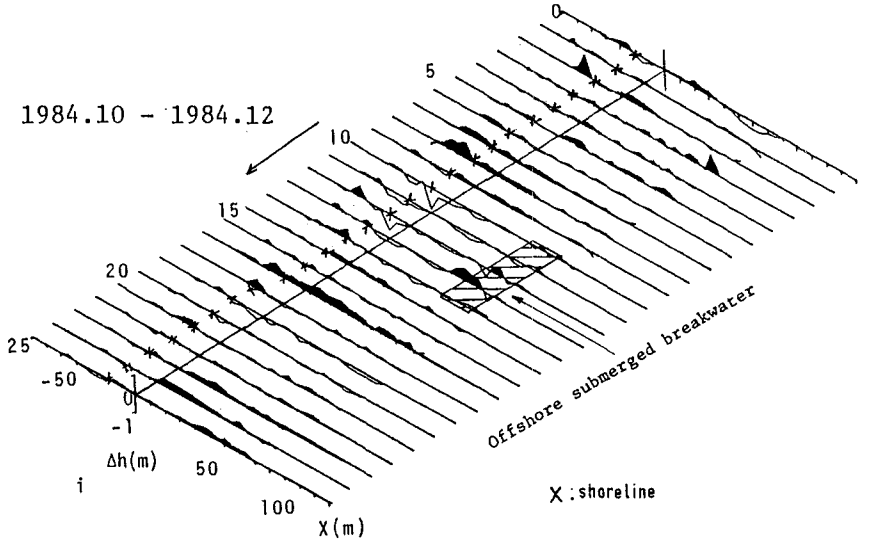


Fig.4 Change of water depth took place during 1-month after beach fill placement at Keino-Matsubara-Beach

In this figure, accreting resions are painted black. At the end of Sept.1984, borrow sand of about 5000m³ was replenished behind the submerged breakwater between the surveying lines No.10 to No.14. Figure 4 indicates that replenished sand mainly moved in the longshore direction and deposited in the landwards of the shoreline and behind the submerged breakwater. However, the amount of those sand is not so large.

Figures 5 and 6 show cross-shore and longshore eigenfunctions $e_1(i,t_n)$ and $c_1(j,t_n)$ calculated from $\Delta h(i,j,t_n)$ which correspond to the largest eigen value.

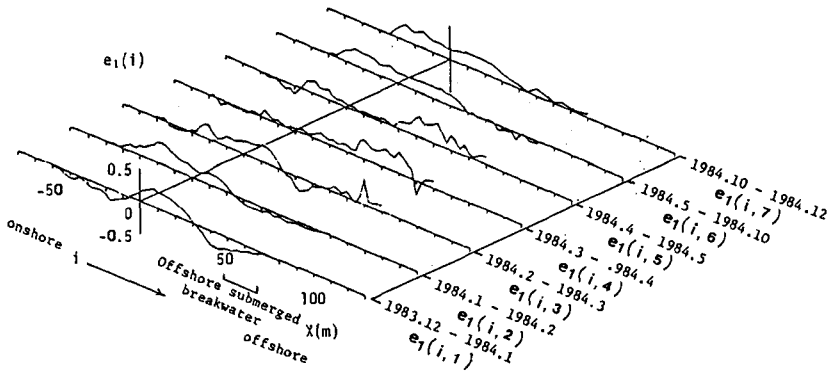

Fig.5 Cross-shore empirical eigenfunction corresponding to the largest eigenvelue

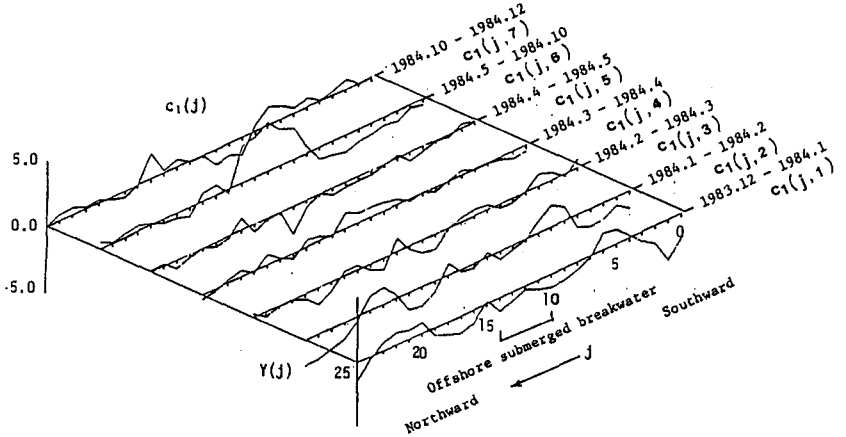

Fig.6 Longshore empirical eigenfunction corresponding to the largest eigenvalue

$e_1(i,1)$ calculated from the topographic changes took place during 1-month after the construction of the submerged breakwater changes its sign negative - positive - negative with the increase of the distance from the shoreline. $c_1(i,1)$ at this duration also alters its sign in the longshore direction. These results imply that both on-offshore and longshore sediment transports took place just after the construction of the submerged breakwater.

As can be seen from $e_1(i,2)$ and $c_1(j,2)$, on-offshore sediment transport became less significasnt and only longshore sediment transport remained when one month passed after the construction of the submerged breakwater. Because $e_1(i,2)$ does not change its sign with increasing the distance from the shoreline.

$e_1(i,6)$ and $c_1(j,6)$ calculated from the topographic change took place before and after the replenishment of beach fill clearly show the effect of beach fill placement.

Finally, $e_1(i,7)$ which corresponds to the topographic change took place during 2-month after the replenishment of beach fill shows positive through the whole cross-shore region and $c_1(j,7)$ is negative behind the submerged breakwater and positive in the out side of the submerged breakwater. This implies again that the replenished borrow sand moved off in the longshore direction from the replenished place and no significant offshore sediment transport beyond the submerged breakwater did not take place.

However, because the ratios of eigenvalues of these eigenfunctions to the trace become 0.4 to 0.5, only 40% to 50% of the whole topographic change can be interpreted by these eigenfunctions.

The authors further conducted numerical simulation concerning wave deformation and wave-induced current around the artificially nourished beach at Keino-Matsubara-Beach. In the simulations, wave direction and height are first calculated using equations of wave kinamatics and wave dynamics based on a linear wave theory at grid points. Then, depth averaged velocities of wave-induced current and displacements of the water level are calculated from the equations for concervations of depth and time averaged momentum and mass fluxes (Sawaragi et al.(1984)).

Some results are illustrated in Fig.7. Wave height H_o and period T used in the similation are 2m and 5sec and wave direction together with the calculated wave breaking points are shown in the figures.

From these figures, it is found that forced wave breaking takes place on the submerged breakwater and strong wave-induced current in the longshore direction is generated behined the submerged breakwater. It seems that replenished borrow sand were easily transported by these current in the longshore direction.

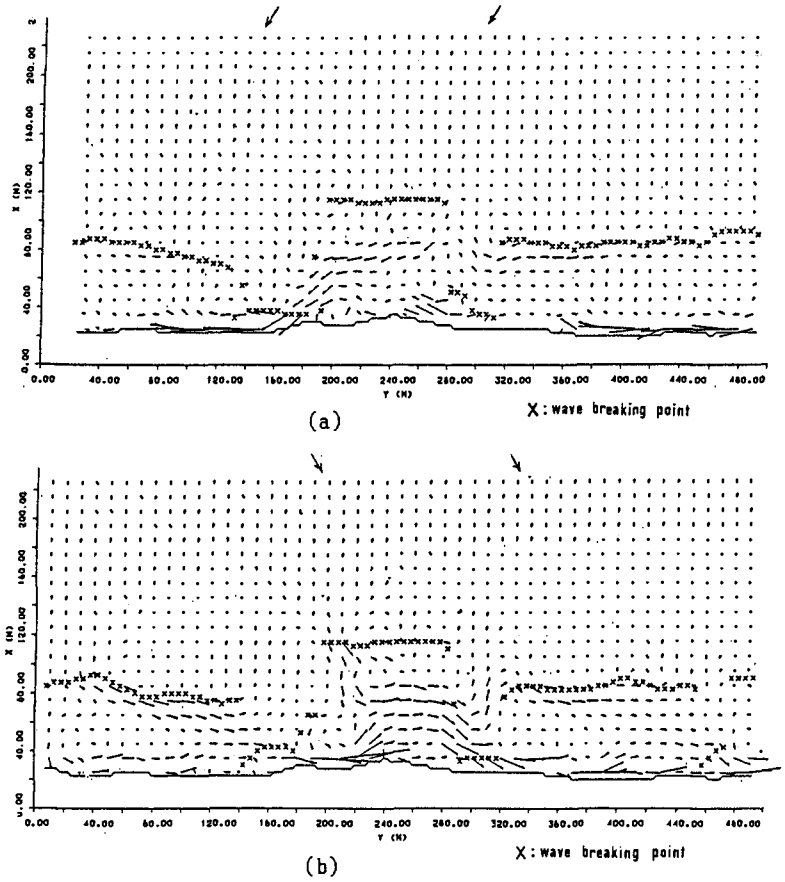

Fig.7 Simulated wave-induced current at Keino-Matsubara-Beach

At this coast, a close correlation between the displacement of shoreline and the change of sectional area at each surveying line is found through out the investigated beach.

ii) Asakawa Beach

As indicated in Table 2, borrow sand of about 15000m³ was placed once a year in winter between the surveying lines No.8 and No.14 above L.W.L.. Figure 8 shows the topographic change took place during Sept.1979 and March 1980 when borrow sand of 16845m³ was placed around the shoreline between surveying lines No.7 and No.15. Figure 9 indicates the topographic change tookplace during 6-month after the beach fill placement.

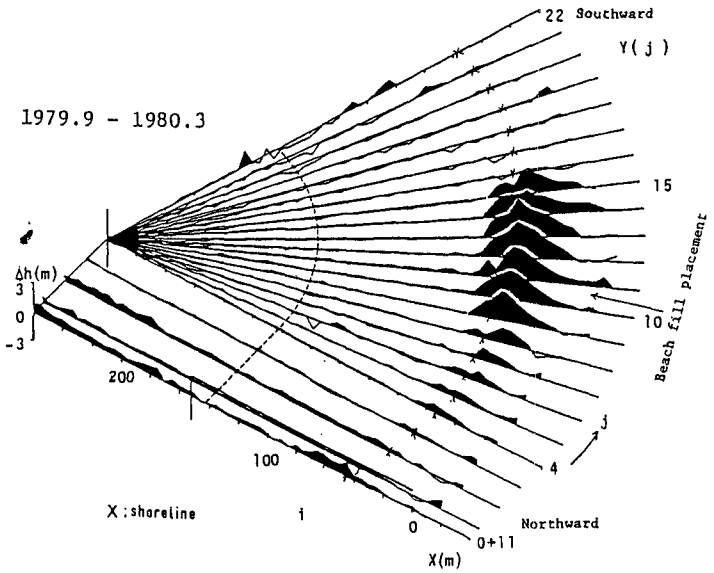

Fig.8 Change of water depth took place during Sept.,1979 and March, 1980 when borrow sand of 16845m^3 was placed around shoreline between surveying lines No.7 and No.15 at Asakawa-Beach

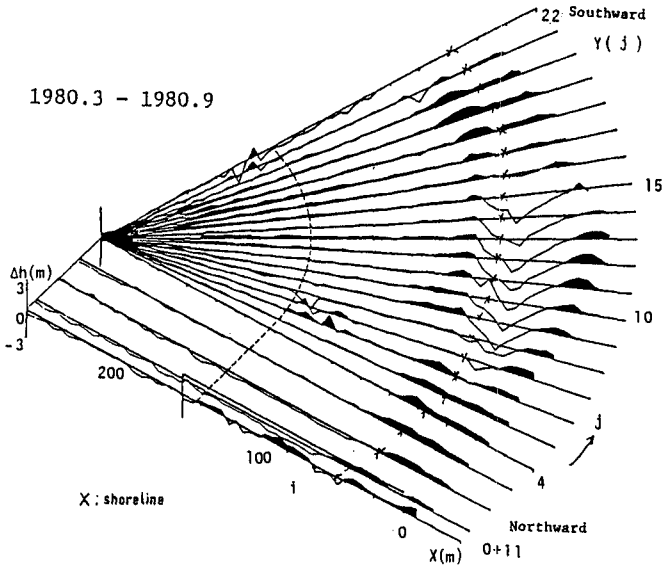

Fig.9 Channge of water depth took place during 6-month after beach fill placement at Asakawa-Beach

From these two figures, it is easily found that the replenished borrow sand moved from the replenished region mainly toward both southward and northward along the shoreline. As is the case of Keino-Matsubara-Beach, a few portion of borrow sand seemed to be transported in onshore and offshore directions.

Figures 10 and 11 show cross-shore and longshore eigenfunctions $e_1(i,t_n)$ and $c_1(j,t_n)$ which correspond to the largest eigenvalues.

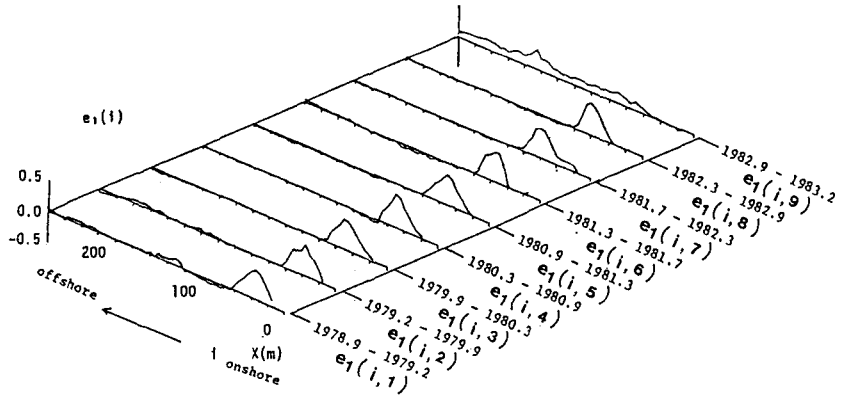

Fig.10 Cross-shore empirical eigenfunction corresponding to the largest eigenvalue.

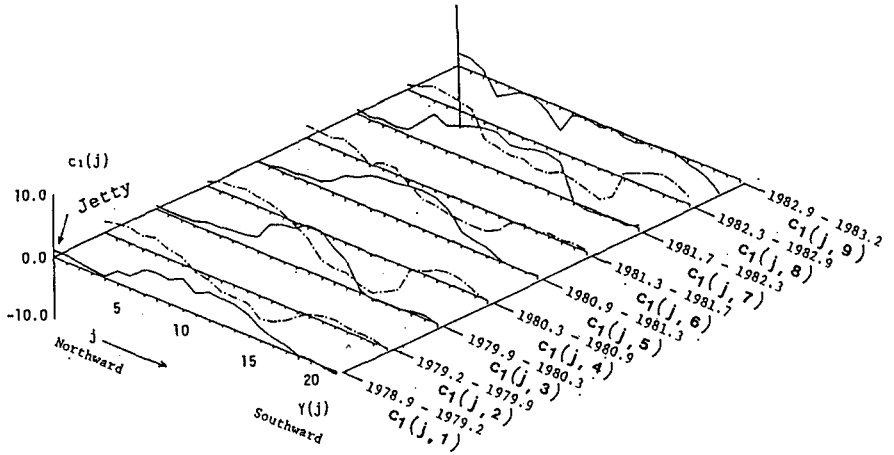

Fig.11 Longshore empirical eigenfunction corresponding to the largest eigenvalue

$e_1(i,t_n)$ has only positive values in narrow regions near the shoreline in all the investigated region and through the whole duration. On the other hand, $c_1(j,t_n)$ calculated from the topographic changes took place during autumn and winter and during spring and summer indicate clear contrast. That is, $c_1(j, t_n)$ in autumn and winter represents the topographic change corresponding to the beach fill placement and $c_1(j,t_n)$ in spring and summer shows the movements of borrow sand towards both ends of the pocket beach along the shoreline.

Further, the positive region of $c_1(j,t_n)$ in spring and summer is larger in the north end of the beach (near the groyne) than that in the south end. This implies that the magnitude of northward sediment transport is larger than that of the southward transport.

It is also found that any significant on-offshore sediment transport took place in the pocket beach.

About 65% to 80% of the total topographic change can be expressed by the product of these cross-shore and longshore eigenfunctions which correspond to the largest eigenfunction.

Fugure 12 illustrates some numerical results of wave-induced currents on a modeled pocket beach with a groyne at one end. Wave height and period used in the simulation are 2m and 5sec and wave diretion is shown in the figure together with the wave breaking points.

As can be seen from these figures, the direction of wave-induced flow near the groyne are always toward the groyne in the pocket beach regardless of the wave directions. This result will be of some help to explane why the magnitude of northward (toward the groyne) sediment transport is larger than that of southward sediment transport.

Again, at this beach, a clear correlation between displacements of shorelines and changes of sectional areas at eachsurveying line can be found.

5. Remaining (or Dissipation) rate of borrow sand

Finally, the remaining rate $\alpha(t_n)$ of replenished borrow sand is investigated in this section.

Figure 13 shows the volumetric change and remaining rate of borrow sand at Keino-Matsubara-Beach. Full and broken lines in the figure indicate the volumetric change δV behind the submerged breakwater between the surveying lines No.10 and No.14 and δV between the surveying lines No.8 and No.16 which appart 40m from region where beach fill was replenished.

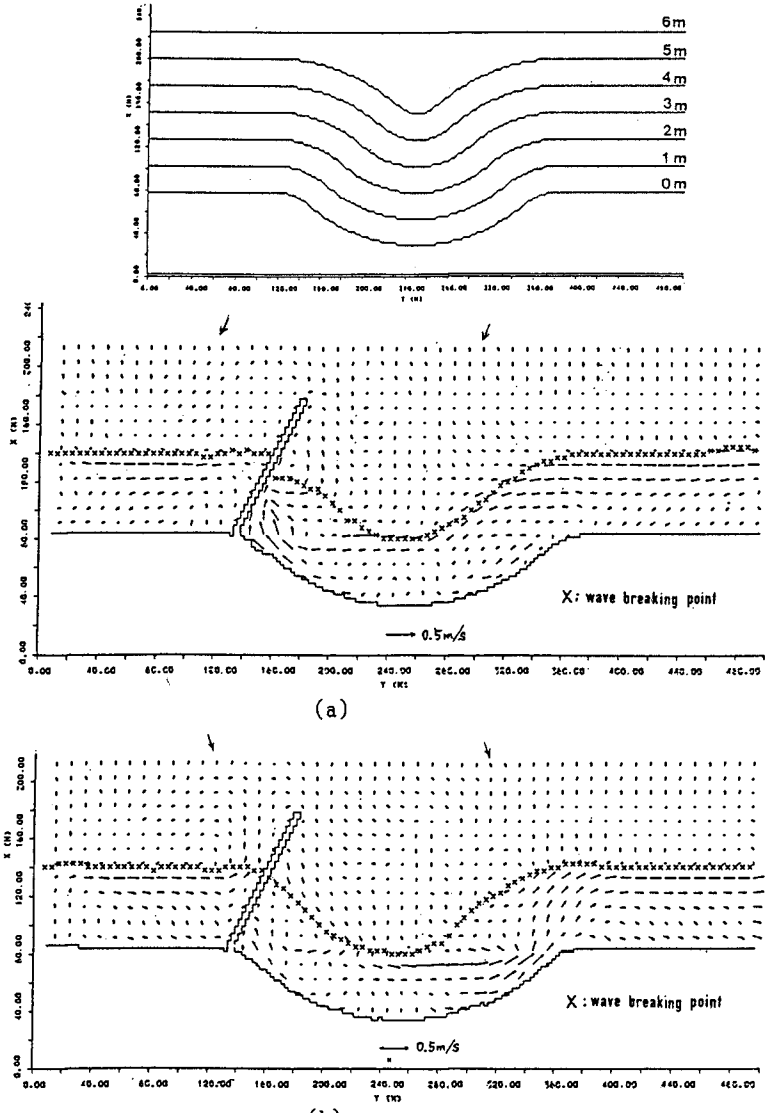

Fig.12 Simulated wave-induced current at Asakawa-Beach

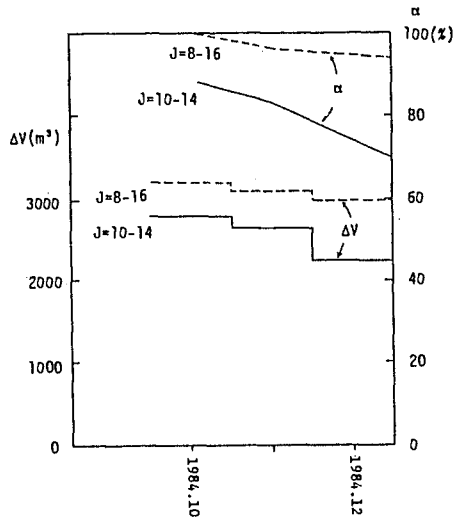

Fig.13 Remaining rate of borrow sand and volumetric change at Keino-Matsubara-Beach

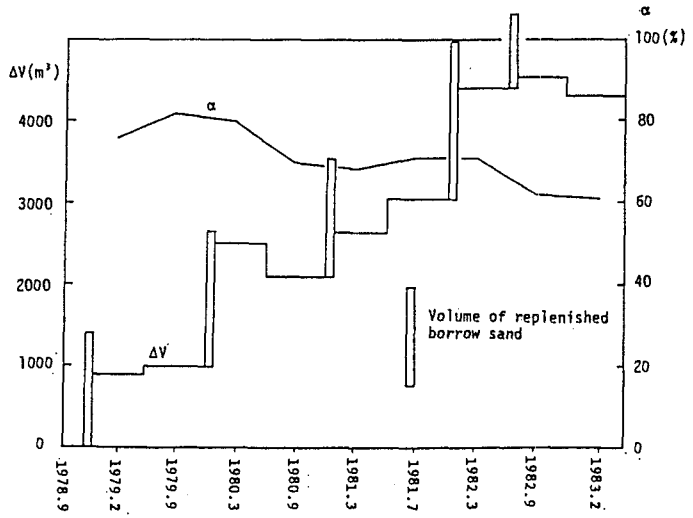

Fig.14 Remaining rate of borrow sand and volumetric change at Asakawa-Beach

Although borrow sand of 5000m³ was placed behind the submerged breakwater, the increase of the sand volume between the surveying lines No.8 and 16 was about 3300m³. Therefore, in the calculation of $\alpha(t_n)$ from eq.(4), we used 3300m³ for Vb.

It is found from this figure that the sand volume just behind the submerged breakwater decreased fast and only 70% remained two month after the beach fill placement. On the other hand, more than 90% of the borrow sand remained between the surveying lines No.8 and No.16. This means that the migration speed of borrow sand is not so fast and only 10% of borrow sand moved off more than 40m from the replenished region.

Figure 14 shows the volumetric changes and remaining rate of borrow sand at Asakawa-Beach. At this beach, the volume of sand in the whole beach increased at every beach fill placement. However, the remaining rate of the total borrow sand replenished in the beach from eq.(4) decreases gradually from 80% and finally reaches 60%. This implies that there is a certain limit to keep sand within a pocket beach which will be determined by the geometrical property of the beach, wave climate and so on.

6. Conclusions

Movements of borrow sand replenished at a long straight beach and a pocket beach which has an arc-shoreline are investigated by analyzing the periodically measured bottom topography after the beach fill placements.

It is found that the amount of borrow sand moved in the longshore direction surpasses the amount of borrow sand transported in the cross-shore direction regardless of the shapes of the shorelines. A clear correlation is also found between the shoreline displacements and the changes of sectional areas.

CHAPTER 78

Offshore Sand Waves

Rolf Deigaard, *) and Jørgen Fredsøe, **)

Abstract

A theoretical model for the equilibrium dimensions of offshore sand waves is presented. The model is an adaptation of the dune model by Fredsøe (1982) to the marine environment, making use of the physical analogies between offshore sand waves and river dunes. The predicted sand wave heights and lengths conform well with the observations of sand wave formation reported in the literature. One of the results from the model is that for a given wave climate sand waves will only be formed under a certain range of mean current velocities. This range becomes narrower for increasing wave height or decreasing water depth and grain size.

1. Introduction

A sea bed on which active sediment transport is taking place will normally not remain plane. Different types of bed forms will be formed depending on the hydrodynamic environment and the characteristics of the bed material.

The dimensions of the bed forms are highly variable. Wave generated ripples may have wave lengths and heights of a few centimetres, while the linear tidal sand banks can have a length of tens of kilometres and a height of up to about 50 m. One of the important bed forms in connection with offshore structures and pipelines is the sand wave, which at the same time can be large enough and migrate fast enough to cause bed level changes around a structure which can give problems during its lifetime.

A comprehensive review of the characteristics of sand waves and other tidal bed forms has been presented by Stride (1982). In the following a brief resume of the conclusions is given, without reference to the original contributions forming the basis for the work by Stride.

Sand waves can be formed in a bed sediment ranging from fine sand to gravel. Sand waves can be symmetrical or asymmetrical depending on the relative strength of the opposing tidal currents. The asymmetric sand waves, generated where the tidal current from one direction is dominant, are the most common and will be treated in the following.

*) Rolf Deigaard, Ph.D., Senior Hydraulic Engineer, Danish Hydraulic Institute, Agern Allé 5, DK - 2970 Hørsholm, Denmark.

**) Jørgen Fredsøe, Ph.D., Dr. Tech., Professor in Marine Hydraulic Engineering, Technical University of Denmark, DK - 2800 Lyngby, Denmark.

An example, taken from Houbolt (1968), of an echo sounding showing a train of sand waves is given in Fig. 1. These asymmetric sand waves have a height of 5-7 m at 25-30 m water depth; the wave length is approx. 200 m.

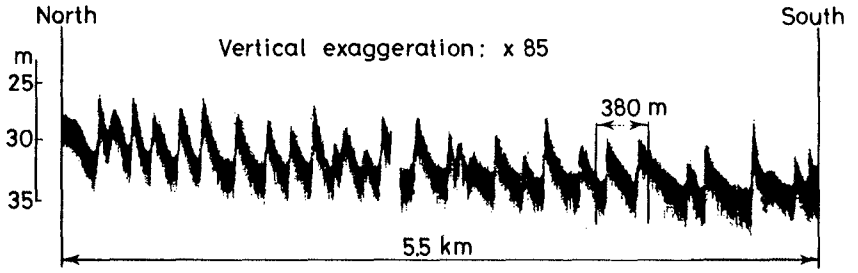

Figure 1. Example of echo sounding showing asymmetric sand waves, West of Imuiden, the Netherlands, from Houbolt (1968).

Sand waves are generally observed to migrate in the direction faced by the steep slopes, which is also the direction of the net sediment transport. The slopes of the steep fronts lie in the range of 5^{o} to 35^{o}, and generally the higher sand waves (> 2 m) have more gentle fronts, less than 20^{o}, and the smaller sand waves have slopes of more than 20^{o}. The gentle slopes lie in the range of 0.5^{o}-4^{o}; generally the more steep slopes are found on the active, migrating sand waves.

The height of the sand waves can vary considerably. It may be only a few centimetres, while the upper limit appears to be determined by the water depth. The highest sand waves are about one third of the water depth.

The sand wave length has also a large variaton, lying between 2 and 20 times the water depth, D, with an average of about 6 D. The ratio between the length and height of a sand wave is generally larger than 15 and may be as high as 100.

The formation and the dimensions of the sand waves will depend on the current velocities and the wave climate. According to Stride (1982) sand waves are not formed at very small current velocities. The lower limit for sand wave formation is given as $\bar{V}_m = 0.65$ m/s, $\bar{V}_m$ being the mean spring tide near surface peak speed. Small sand waves can be formed

at slightly lower speeds, and sand waves formed in gravel require larger flow velocities. It is supposed that a strong current can smooth out the sand waves similarly to the smoothing out of dunes in rivers, but the evidence from field observations is rather weak. The effect of waves is more well documented. The wave action during a storm can reduce the sand wave height at water depths of more than 20 m, and it can be observed that the relative height of the sand waves decreases in the shallower areas, where the near bed wave action increases, Terwindt (1971), Stride (1982). The smoothing out of sand waves by current or by waves is often assumed to be connected with the ratio between the suspended load and the bed load, which increases as the sediment transport rate increases.

The general behaviour of the sand waves, or the physical mechanisms behind the formation of sand waves seems not in any significant way to deviate from the processes associated with dunes formed under unidirectional current. The large sand waves formed by a tidal current can according to Stride (1982) be considered as unidirectional current formed ones, which have been modifed to a lesser or greater extent by the reversing current.

2. The Theory for Dune Dimensions, Current Only

A theory for the dimensions of sand waves (dunes) under steady current conditions has been presented by Fredsøe (1979) and Fredsøe (1982). A key point in this theory is the use of the continuity equation for the sediment :

$$\frac{\partial h}{\partial t} = - \frac{1}{1-n} \frac{\partial q}{\partial x} \qquad (1)$$

where h is the bed level, t is the time, q is the sediment transport rate, x is the coordinate in the transport direction, and n is the porosity of the bed sediment. By applying Eq. (1) to periodic, steadily migrating bed forms, the following relation emerges :

$$q = q_o + a\,(1-n)h \qquad (2)$$

where q_o is the sediment transport passing the trough of the sand waves and a is the migration velocity.

For dunes and sand waves a is determined by the amount af sediment, q_D, which is deposited at the front of the sand wave, Fig. 2 :

$$a = \frac{q_D}{(1-n)A} \qquad (3)$$

where A is the dune height.

The magnitude of q_D depends on the rate of sediment transport at the dune crest and the relative amount of suspended load, q_s, and bed load transport, q_b.

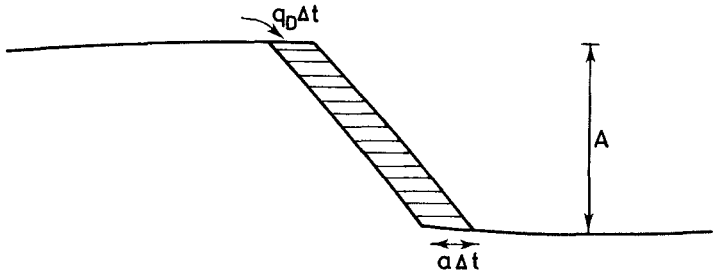

Figure 2. Migration of the dune front.

The bed load transport consists of the grains which move in almost continuous contact with the grains in the bed, and will be deposited at the front where flow separation occurs. The suspended sediment grains move above the bed without contact and will not settle immediately. A suspended grain will contribute to q_D and the dune migration if it by settling or diffusion moves into the separation 'bubble' before it is carried past the separation zone by the flow. Whether the grain is deposited at the front or not will thus depend on its distance from the bed when it passes the dune crest.

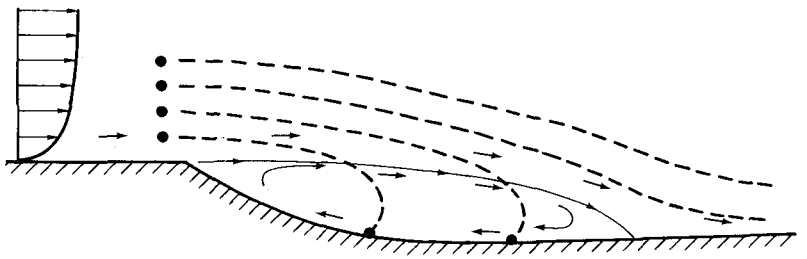

Figure 3. The probability for a suspended grain to settle in the trough depends on its height.

In the model by Fredsøe (1982) the detailed shape of the dune is determined from the requirement that Eq. (2) must fit with the sediment transport rate calculated from the shear stress distribution along the long, gentle upstream slope of the dune. The sediment transport is calculated by the model of Engelund and Fredsøe (1976). This sediment transport model calculates the suspended load and the bed load transport separately. The variation of the bed shear stress along the dune is deter-

mined on basis of flow measurements downstream of a rearward facing step, e.g. Smith (1970). In a recent paper McLean and Smith (1986) presented an analytical treatment of this flow situation.

The length of the separation zone at the steep front is about 6A. The bed shear stress increases gradually in the flow direction from zero at the reattachment point. The bed shear stress attains a local maximum at a distance of 16-20A from the step. Fig. 4 gives an example of the measured shear stress coefficient, $C_f = \tau/\rho V^2$, behind a rearward facing step, and a dune profile calculated by the theory by Fredsøe (1982).

In the following the details concerning determination of the dune shape will not be treated, the emphasis will be put on the main dimensions : the height, A, and the length, λ.

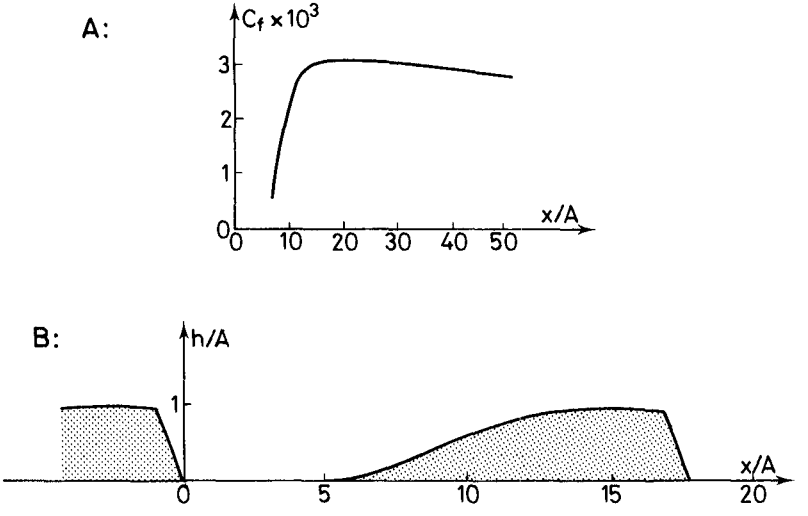

Figure 4. A: Shear stress coefficient downstream of a rearward facing step with the height. B: Example of dune profile calculated from the theory by Fredsøe (1982).

2.1 The Dune Height

Near the dune crest the influence from the preceeding dune is weak and the bed shear stress can be calculated by the logarithmic resistance law :

$$\frac{V}{U_f} = \frac{1}{\kappa}\left(\ln\left(\frac{30\,D}{k}\right) - 1\right) \qquad (3)$$

where V is the local depth averaged flow velocity, U_f the shear velocity: $U_f = \sqrt{\tau_b/\rho}$, κ is V. Karman's constant, D is the local flow depth and k is the bed roughness taken to be 2.5 times d, the grain size of the bed sediment.

The sediment transport model of Engelund and Fredsøe (1976) can for a given bed sediment be expressed in dimensional form :

$$q = q(V, D) \tag{4}$$

The local change in the bed level near the crest can be expressed in two ways :

I) Purely geometrical :

$$\frac{\partial h}{\partial t} = - a \frac{\partial h}{\partial x} = \frac{-q_D}{A(1-n)} \frac{\partial h}{\partial x} \tag{5}$$

II) Through the continuity equation :

$$\frac{\partial h}{\partial t} = \frac{-1}{1-n} \frac{\partial q}{\partial x} = \frac{1}{1-n} \frac{dq}{dD} \frac{\partial h}{\partial x} \tag{6}$$

By combining Eq. (5) and (6) an expression for the dune height is obtained:

$$A = \frac{-q_D}{\frac{dq}{dD}} = \frac{-q_D}{\frac{\partial q}{\partial D} + \frac{\partial V}{\partial D}\frac{\partial q}{\partial V}} = \frac{-q_D}{\frac{\partial q}{\partial D} - \frac{V}{D}\frac{\partial q}{\partial V}} \tag{7}$$

This result for the dune height results in a migration velocity of the dunes given by :

$$a = \frac{1}{1-n} \frac{dq}{dD} \tag{8}$$

2.2 The Dune Length

According to Eq (2) the sediment transport attains a maximum at the top of the dune; immediately after the top the flow separates and the dune ends. At situations with dominant bed load transport the sediment transport is in local equilibrium with the hydraulic conditions, and the point of maximum transport coincides with the maximum in bed shear stress, τ_b. According to the measurements described previously the bed shear stress has a local maximum at a distance of about 16A downstream of the preceeding crest. At dominant bed load transport the dune length, λ, is thus given by :

$$\lambda = 16 A \tag{9}$$

Fredsøe included the effect of gravity in his analysis. The gravity acting on the moving grains will tend to retard the bed load transport moving up the dune, modifying the transport relation which gives a pre-

dicted dune length larger than Eq. (9). The effect of gravity is notable at very low transport intensities.

The suspended load transport cannot be adjusted immediately to changes in the hydraulic conditions, as it takes time for the suspended sand grains to settle out from the concentration profile or be entrained into it. The maximum in the suspended load will therefore have a lag distance, L_s, behind the maximum in the bed shear stress. The dune length in case of both suspended and bed load transport can thus be expressed as :

$$\lambda = 16\ A + \frac{q_s}{q} L_s \qquad (10)$$

3. Sand Wave Dimensions in Wave and Current

3.1 The Sand Wave Height

The physics behind the offshore sand waves are as described in the introduction very similar to the dunes in river, and the relations for dune dimensions can be applied directy if a model for sediment transport under the combined action of waves and current is introduced.

The present calculations are based on the sediment transport model by Fredsøe et al. (1985). This model converges towards the model by Engelund and Fredsøe (1976) for decreasing wave action.

In case of current without waves the first term in the denominator of Eq. (7) can be neglected because the flow resistance, Eq. (3), is insensitive to variation in D. In case of combined waves and current this term can be significant due to the relation between the water depth and the near bed orbital motion induced by waves of given height and period.

Sand wave heights predicted by Eq. (7) using the transport model by Fredsøe et al. (1985) are shown in Fig. 5. The calcualtions have been made for a water depth of 10 m and a bed material grain size of d = 0.20 mm. The direction of the wave motion is normal to the mean current, $\gamma = 90^{\circ}$. Two wave heights are considered : H = 2 m and 4 m with periods of 7.2 s and 10.1 s respectively.

Different assumptions for the settling of suspended sediment at the sand wave front is presented in Fig. 5 A, B and C.

In Fig. 5A it is assumed that all transported sediment is deposited at the sand wave front : $q_D = q_b + q_s$.

In Fig. 5B the sand wave height is calculated, assuming that only the bed load is deposited. For current only, the sand wave height, A, is the same for the lower current velocities because the bed load transport is dominant. For higher current velocities the suspended load transport becomes dominant and the sand wave height decreases if only the bed load is deposited. Under wave action sediment will be suspended in the wave

boundary layer even for small current velocities, and the calculated sand wave heights are different in Fig. 5A and B for all current velocities.

In Fig. 5C the amount of suspended sediment which is deposited at the sand wave front is estimated on basis of the lag distance, L_s, and the length of the separation zone downstream of the front. q_D is calculated as :

$$q_D = q_b + q_s \exp(-L_s/6A) \tag{11}$$

The length scale for the lag of the suspended sediment, compared with the hydraulic conditions can be estimated from the concentration profile as :

$$L_s = \frac{U_c \cdot y_c}{w} \tag{12}$$

where y_c is the height of the centroid of the concentration profile, c(y) :

$$y_c = \frac{\int_a^D cy \, dy}{\int_a^D c \, dy} \tag{13}$$

U_c is the mean current velocity at the height y_c from the bed. w is the settling velocity of the suspended sediment.

For small current velocities L_s is small compared with A, and the calculated sand wave heights correspond to Fig. 5A. For increasing current velocities, L_s increases and the sand wave height converges towards the results in Fig. 5B.

3.2 The Flow Separation at the Sand Wave Front

The key assumption for the theory predicting the sand wave height is that the deposition of sediment at the front and thus the migration rate of the sand wave can be calculated directly on basis of the sediment transport at the crest of the sand wave. The basis for this assumption is that flow separation occurs at the dune front, leading to a vanishing sediment transport capacity at the toe of the dune front.

In case of combined wave and current motion the strong fluctuating pressure gradients associated with the wave motion can under certain circumstances be expected to suppress separation of the mean current.

In the present model a crude approximate criterion is used for the suppression of flow separation by the wave orbital motion. In steady

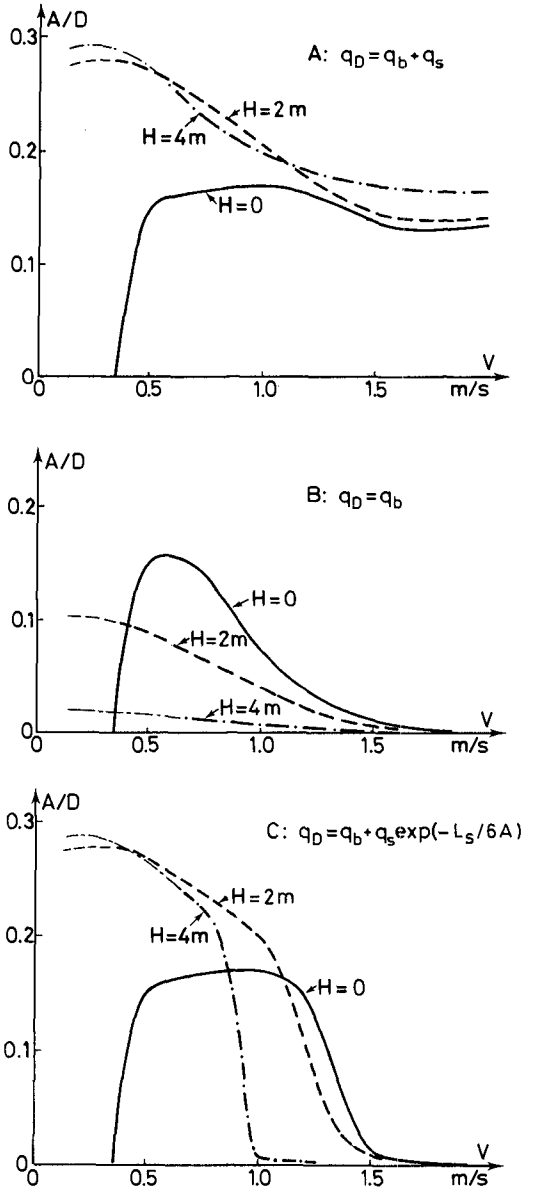

Figure 5. Sand wave height as function of V and H; d = 0.2 mm, D = 10 m, $\gamma = 90^{\circ}$.

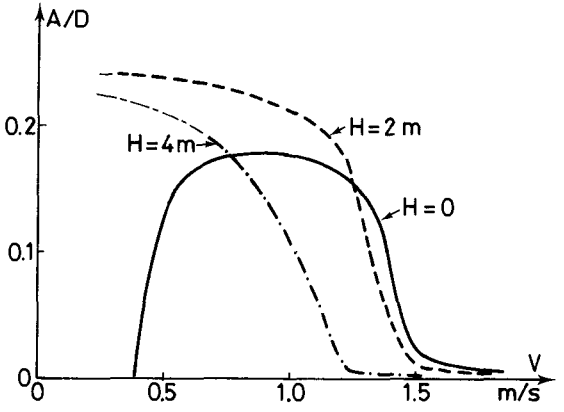

Figure 6. A/D as function of V and H, d = 0.2 mm, D = 20 m, $\gamma = 90^{o}$.

diffusor flow the largest possible diverging half angle without flow separation is about 5^{o}. The sand wave front can be much steeper, close to the angle of repose of the bed material, about 30^{o}.

The effect of the orbital motion is that the near bed water particles move along a much longer path than the straight line of the mean current. The 'effective' angle of divergence will therefore be reduced in combined wave-current motion. If the path travelled by the particle is about 7 times the straight course the average angle of divergence experienced by the water particles on the 30^{o} slope will correspond to the 5^{o} which causes no separation. The criterion for suppression of the flow separation has therefore been taken to be that the oscillating part of the shear velocity, U_{fw}, associated with the wave motion is larger than 7 times the shear velocity, U_{fo}, characterising the mean current in the wave boundary layer.

In the figures showing the results from the model, the part of the curves, where no flow separation is expected to take place due to the wave motion, is shown as thinly drawn lines.

3.3 Sensitivity to Changes in the Parameters

The number of parameters entering the description of the sand waves is too large to allow for the preparation of general dimensionless diagrams for prediction of sand wave heights.

The influence of varying a number of parameters is illustrated in Figs. 6, 7 and 8. In these figures the deposition of suspended sediment has been estimated by Eq. (11).

It can be seen from Fig. 6 that for similar near bed orbital motions the sand waves at 20 m have relative heights close to the sand wave height at 10 m. The transition due to the decrease in settling suspended sediment occurs at a higher current velocity at 20 m water depth because the sand waves are higher, and the ratio L_s/A is smaller for a given transport intensity.

The effect on A/D of changing the angle, γ, between the waves and the current is rather small, Fig. 7.

The most significant changes can be observed when the grain size, d, of the bed material is reduced to 0.15 mm. The range of current velocities, where sand waves are formed become more narrow than for the 0.2 mm sand. For the highest waves considered no sand waves are formed at all, Fig. 8.

For a given wave climate the range of current velocities under which sand waves are formed will gradually become narrower as the water depth decreases, because the near bed orbital motion and the suspended sediment load increase. This is in agreement with the observation that sand waves are decreasing or absent in the shallow parts of the southern North Sea, e.g. McCane and Langhorne (1982), Terwindt (1971) and Houbolt (1968).

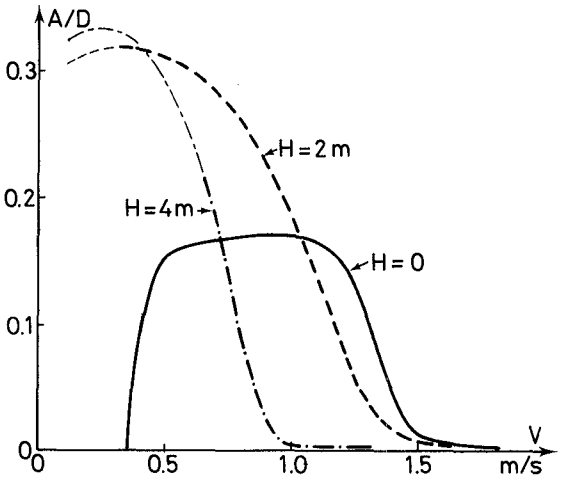

Figure 7. A/D as function of V and H, d = 0.2 mm, D = 10 m, $\gamma = 0^{\circ}$.

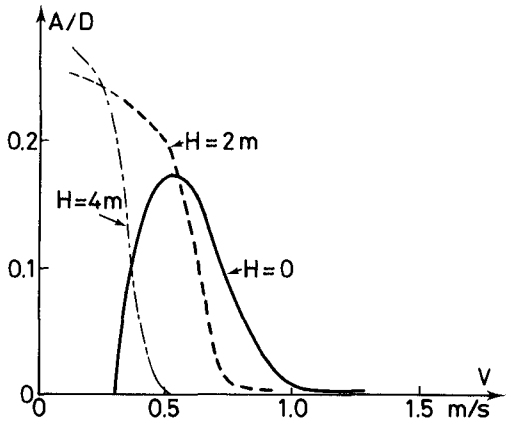

Figure 8. A/D as function of V and H.
d = 0.15 mm, D = 10 m and $\gamma = 90^{o}$.

3.4 The Sand Wave Length

As a first approximation the sand wave length is calculated by Eq. (10). The calculated steepness, A/λ, of the sand waves treated in Fig. 5C are shown in Fig. 9. As the suspended load increases the height decreases and the length increases. The sand wave steepness therefore drops rapidly for increasing current velocity. The effect of gravity on the bed load transport in case of pure current is indicated by the dotted line. In combined waves and current the suspended load is dominant even at small current velocities, and the gravity effect is not expected to be of importance.

Under field conditions the tidal current and the wave conditions will generally vary so fast that the sand waves at a given location reflect a temporal average of the different combinations of waves and current. When estimating this average each combination shall be weighted according to the strength it has in the process of forming the sand waves. A measure which can be used for such a weighting procedure is the quantity : dq/dD, which is proportional to the migration rate, a, of the sand waves. Fig. 10 shows the calculated migration rate for the sand waves treated in Fig. 5.

It can be seen how the wave condition, especially at moderate current velocities have strong influence on the formation of sand waves. It can also be noted that the relation between a and V is non-linear. The asymmetry in the tidal current can therefore be rather small and still produce asymmetric sand waves dominated by the direction of the strongest tidal current.

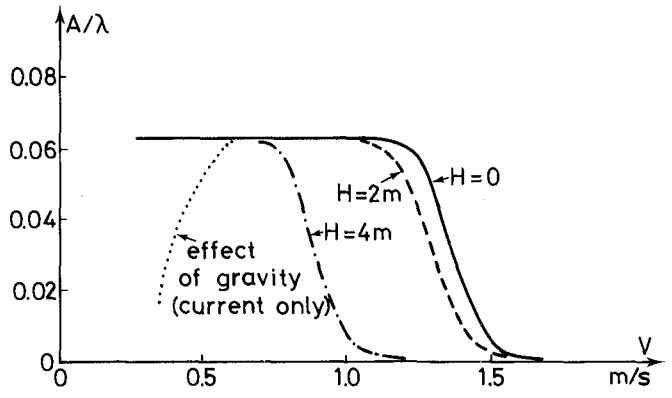

Figure 9. The sand wave steepness as function of V and H, d = 0.2 mm, D = 10 m, $\gamma = 90^{o}$.

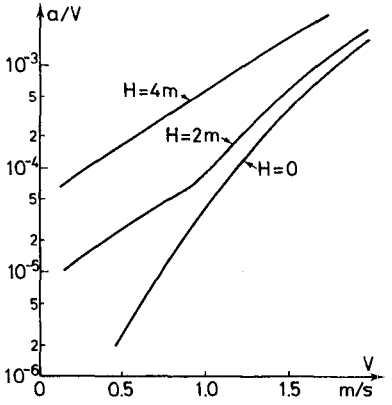

Figure 10. The sand wave migration rate as function of V and H. d = 0.2 mm, D = 10 m, $\gamma = 90^{o}$,

4. Conclusion

A theoretical model for the dimensions of offshore sand waves has been presented. The model is based on a model for dunes in rivers and a sediment transport model for combined waves and current.

At present no data has been published, which are comprehensive enough to allow for a detailed calibration of the different elements in the model. The predicted trends for the sand wave heights and lengths are, however, in general agreement with the observations reported in the literature.

According to the model there will for a given wave condition be a range of current velocities, under which sand waves will be formed. The upper limit for the sand wave formation is caused by the increasing amount of suspended sediment which passes the sand wave without being deposited, and thus does not contribute to the building-up of the sand wave.

For small water waves the lower velocity limit is associated with the initiation of sediment transport.

For large water waves the lower limit is caused by the suppression of flow separation at the front of the sand wave.

For a given wave climate the range of velocities where sand waves are formed become narrower for decreasing water depth or grain size of the bed material and at a certain water depth no sand waves may be formed at any current velocity at all.

CHAPTER 79

VELOCITY AND SEDIMENT CONCENTRATION FIELDS ACROSS SURF ZONES

Hans - H. Dette *
Klemens Uliczka **

Abstract

Wave-induced currents and sediment concentrations in suspension across the surf zone were investigated at prototype scale in the BIG WAVE FLUME in Hannover for combined beach and dune profiles as well during the development phase until quasi-equilibrium stage as after beach equilibrium conditions had been reached. The selected initial profiles were partly investigated in repeated tests with regular and irregular waves. Based upon the obtained experimental data a comparison is presented between the measured and calculated landward displacement of sediment volume through a selected point on the beach into seaward areas. The discrepancies in between the results for measured profile change and for calculated sediment transport volume derived from vertical current and suspension distributions are discussed.

Introduction

The description of coastal processes in the surf zone depends upon the understanding of interactions between the beach profile and the breaking waves, the wave-induced currents, and the associated movements of beach material. In order to calculate the net cross-shore sediment transport it is necessary to describe both the horizontal orbital velocity field $u(x, z, t)$ and the sediment concentration field $c(x, z, t)$ in space and time. As it is very difficult to measure these parameters under storm conditions in the field, prototype tests were carried out in the BIG WAVE FLUME in Hannover in order to study these processes at essentially full scale. In the paper first results of measurements on suspended sediment concentrations and wave-induced currents on beaches are presented.

Scope of Investigations

Two test series were carried out in the BIG WAVE FLUME, which is 324 m long, 7 m deep and 5 m wide. The initial profiles - illustrated in Fig. 1 - were called "dune without foreshore" (a) and "dune with foreshore" (b):

* Chief Engineer, Dr.-Ing., Leichtweiss-Institute, Technical University Braunschweig, POB 33 29, M.A.S.C.E.

** Assistant Scientist, Dipl.-Ing., Sonderforschungsbereich 205 "Coastal Engineering", Univ. of Hannover, Fed.Rep. of Germany

(a) + 2 m above still water level (SWL) and 30 m wide dune with a 1 to 4 seaward slope down to channel floor (- 5 m)

(b) + 2 m above SWL and 10 m wide dune with 1 to 4 seaward slope down to 1 m below SWL and following 1 to 20 slope down to channel floor.

Both profiles were subjected to regular wave attack ($\bar{H} = H_{rms} = 1.5$ m, $T = 6$ s, $d = 5.0$ m). The similarity index using the initial profile and $H_o/L_o = 0.04$ yielded $\xi_o = 1.48$ (dune without foreshore) and $\xi_o = 0.29$ (dune with foreshore). Additionally to these tests with regular waves the dune without foreshore experiments were repeated with irregular waves (JONSWAP-Wave-Spectrum, $H_{1/3} = 1.5$m, $T_p = 6$ s, $d = 5.0$ m).

The sand used had a mean diameter $D_{50} = 330$ µm and geometric standard deviation of $\sigma_g = 1.47$.

The experiments were carried out by increments of up to 80 waves as by then the initial wave form became significantly affected by reflection. Therefore, the test series was interrupted and restarted after the water had come to rest; the interval was used for the profile levelling.

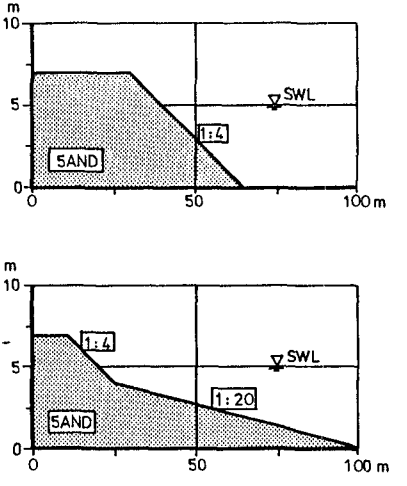

Figure 1. Initial beach profiles: Dune without foreshore (above) and dune with foreshore (below).

The tests with regular waves were stopped whenever the wave height variation reached ± 20 % of the originally generated wave height. Above this limitation it was observed in preceding tests that the breaker-line started to move from its original position. The experi-

ments with the JONSWAP-Wave-Spectrum were interrupted after three repetition intervals totalling nearly 12 minutes.

Sediment Concentration at Equilibrium Profile

Samples of the material suspended due to wave action were extracted by pumps at elevations from 0.02 m to 1.0 m above the bed at selected positions within the surf zone. The prototype of the pumping-system was developed by the DELFT HYDRAULICS LABORATORY (BOSMAN, 1986). The extraction nozzles (diameter: 3 millimeter) were fixed on a vertical pipe and orientated horizontally and perpendicularily to the flow direction of wave-induced currents. The intake-velocity at the nozzle reached about 1.0 m/s which was approximatly equal to the orbital velocities.

The samples were taken during each test increment at one fixed position on the beach profile without taking into consideration the method of bed averaging extraction as suggested by BOSMAN (1986) derived from small scale test in order to eliminate the effects of bed features.

Dune without Foreshore

Results due to Regular Waves

The results presented in the following are thus time-averaged data each from a sequence of about 80 waves (8 minutes). Fig. 2 illustrates suspension distributions over the equilibrium profile (dune without foreshore, Fig. 1 above) at four positions within the breaker zone at different points within the surf zone.

Generally it can be stated from the test results:

- the maximum suspension rate was recorded near the crest of the bar
- in the offshore direction and shoreward of the bar the sediment concentration decreased remarkably
- the breaking-point approximately coincided with the crest of the bar
- the breaker type on the quasi-equilibrium profile, which developed from 1 to 4 slope of the dune without foreshore was the plunging breaker
- the averaged wave heights at the measuring points (A to D) were: $\bar{H}_A$ = 0.8 m, $\bar{H}_B$ = 0.8 m, $\bar{H}_C$ = 1.6 m and $\bar{H}_D$ = 1.9 m
- the water-depths were: d_A = 0.96 m, d_B = 1.48 m, d_C = 1.25 m and d_D = 1.60 m

In Table 1 the sediment concentration data from the investigations at the dune without foreshore with regular waves are summarized.

Results due to JONSWAP-Wave-Spectrum

The sediment concentration data are time-averaged values over three-times the spectrum-repetition-interval (nearly 12 minutes) which is equal to 125 times the peak period T_p = 6 s. Similar to the results for the beach profile due to regular waves, the maximum sediment concentration was observed shoreward of a so-called step in the beach profile (Fig. 3). The breaker zone varied in between 38 m and 15 m from the

shoreline. The significant wave heights at the points A to D were as follows: A: $H_{1/3}$ = 1.0 m, B: $H_{1/3}$ = 1.2 m,
C: $H_{1/3}$ = 1.7 m, D: $H_{1/3}$ = 1.5 m.

The water depths were as follows: d_A = 1.0 m, d_B = 1.15 m, d_C = 1.45 m, d_D = 1.75 m.

Table 2 gives the sediment concentration data associated to the JONSWAP-Wave-Spectrum and the test series "dune without foreshore".

Dune with Foreshore

Results due to Regular Waves

The sediment concentration data obtained over the quasi-equilibrium profile which developed from the dune with foreshore are time-averaged values from a sequence of about 70 waves (7 minutes). The breaker type over the equilibrium profile was the plunging breaker due to the steep seaward slope of the bar. The breaking point was approximately located near the crest of the bar. The averaged wave heights at the points A to C yielded:

$$\bar{H}_A = 1.1 \text{ m}, \bar{H}_B = 1.5 \text{ m}, \bar{H}_C = 2.1 \text{ m}$$

The water depths were: $d_A = 1.95$ m, $d_B = 1.4$ m and $d_C = 2.6$ m.

Fig. 4 illustrates the suspension distribution over the equilibrium profile and in Table 3 the measured data are summarized.

The Accuracy of Concentration Measurements

The accuracy of the measured concentrations depends significantly upon the kind of the selected measuring system and upon the suitablity of system to be used in the laboratory or in the prototype. BOSMAN (1986) recommends on the basis of extensive investigations the TABAC method which means Time-And-Bed-Averaged-Concentration.
BOSMAN (1986) writes:

> The "effect on the local concentration is purely random and can be reduced by averaging either over space or over time".

For the prototype investigations in the BIG WAVE FLUME the time-averaging method was applied by means of a stationary pump system with which suspended sediment samples over 7 to 12 minutes were extracted.

Figure 5. Repeated concentration measurements at the same position over the quasi-equilibrium profile developed from the dune without foreshore and JONSWAP-Wave-Spectrum

Near the bed the mean value of concentration from 4 measurements is $\bar{c} = 30 \pm 10$ g/l (approx. $\pm$ 30 %), at a position nearly 1.0 m above the bed the sediment concentration was about $\bar{c} = 3 \pm 1$ g/l (approx. $\pm$ 30 %).

This example of varying suspended sediment concentration may illustrate the problem of "accuracy". Even in laboratory at a prototype scale, i.e., in the BIG WAVE FLUME a stable equilibrium beach profile and constant measuring data cannot be expected. In all tests it was observed that the profile shape fluctuates and that the location of each breaker influences the concentration in a random way and thus the net sediment transport in the surf zone.

Velocity Fields in the Surf Zone

The measurements of wave-induced on-/offshore currents were carried out simultaneously at several fixed positions within the surf zone. Records were obtained from 0.1 m up to 0.6 m above the actual sand bed at the dune without foreshore and up to 1.0 m at the dune with foreshore. The single velocities are time-averaged values obtained from a single test increment (7 to 12 minutes). Fig. 6 shows as an example the distribution of wave-induced on-/offshore currents measured in the surf zone over the equilibrium profile from dune without foreshore and the JONSWAP-Wave-Spectrum. The difference between the averaged seaward and shoreward velocities $\bar{u}$ yields the net velocity u_R.

The location of the breaker zone, the significant wave heights and water depths at the points of measurements (A to D) are documented in the previous chapter.

Cross-Shore Sediment Transport Rate

The sediment volume passing at one position of the beach profile which developed from dune with foreshore from shoreward to seaward location is used in the following to compare calculated and measured data to discuss the reliability and to point out the order of magnitude of the sediment transport rates obtainable by means of this method.

Sediment passing a given Location of the Beach

The measurements were carried out after 50 waves had already run on the initial profile of the dune with foreshore. At this stage (after 50 waves) the beach profile was surveyed (= initial profile) and then another 80 waves were run. During this time sediment concentration samples were extracted at a location of x = 26 m from the shoreline and 2.0 m apart from the side wall of the flume. Afterwards the profile was resurveyed in three profiles of the 5 m wide flume, in the centre-line and 1.5 m to either side as basis for the calculation of removed sediments. During the test run the water depth at the point of measurement remained constant with d = 1.9 m. The averaged wave height of the regular waves was $\bar{H}$ = 1.3 m.

Cross-Shore Current

The velocities were measured at the same location (x = 26 m) in the middle of the channel, at elevations between 0.1 m to 1.0 m above the bed. The velocity at one elevation was measured over each increment of 70 waves. It was assumed that during consecutive test increments up to a total of 760 waves the velocities at the selected elevations remained more or less constant. The measured net velocity distribution is illustrated on Fig. 7. It is seen that the seaward column (below 1 m over the bed) is approximately constant at $\bar{u}_R$ = 0.53 m/s. The standard deviation of the measured values was σ = 0.11.

Suspended Sediment

Due to the high turbulence, particulary at macro scale, in the surf zone the sediment moves in whirls and clouds. Therefore no separation of suspended-load and bed-load was made for the following analysis. The measured vertical profile of the suspended sediment was fitted to the exponential function as suggested by v.d.GRAAFF and ROELVINK (1984). Table 5 shows the measured and calculated data together with the computed bottom concentration c_o.

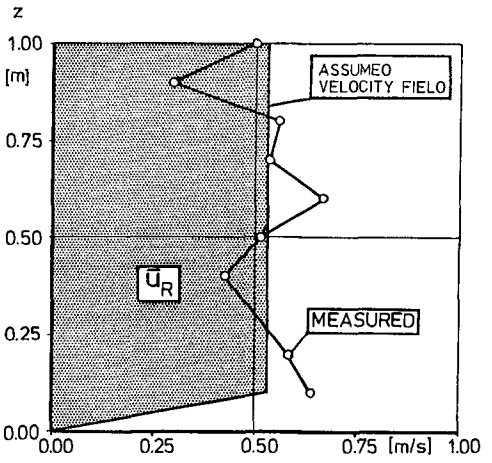

Figure 7. Distribution of the measured data u_R and assumed velocity profile $\bar{u}_R$ for calculation

0.06	10.50	7.25
0.085	8.53	6.49
0.11	6.25	5.86
0.16	5.77	4.93
0.26	5.34	3.83
0.385	4.40	3.17
0.585	3.60	2.72
0.91	2.89	2.41
Bottom concentration:		c_0 = 9.95 g/l

Net On-/Off-Shore Transport

The net sediment transport was calculated with the total transport formula:

$$S = \int_0^z c\,(z,t) \cdot u\,(z,t) \cdot dz \qquad (1)$$

which for the present case may be written as

$$\dot{S} = \int_0^z \bar{c}_{cal} \cdot \bar{u}_R \cdot dz \qquad (2)$$

The time-averaged sediment movement seaward past the measuring position during the initial test increment of 80 waves was calculated from the superposition of the beach profiles before and after the test run and referred to 1 m width of beach. The result yielded a volume of $A = 1.14\ m^3/m \pm 30\ \%$. The suspended sediment transport was calculated with the data in Table 5 to $S = 1.57$ kg/s or $S = 0.45\ m^3/m \pm 30\ \%$. From this comparison a difference of 60 percent between measurement and computation is obtained, this is less than one order of magnitude. Fig. 8 illustrates for the point of measurement the relevant data for the analysis.

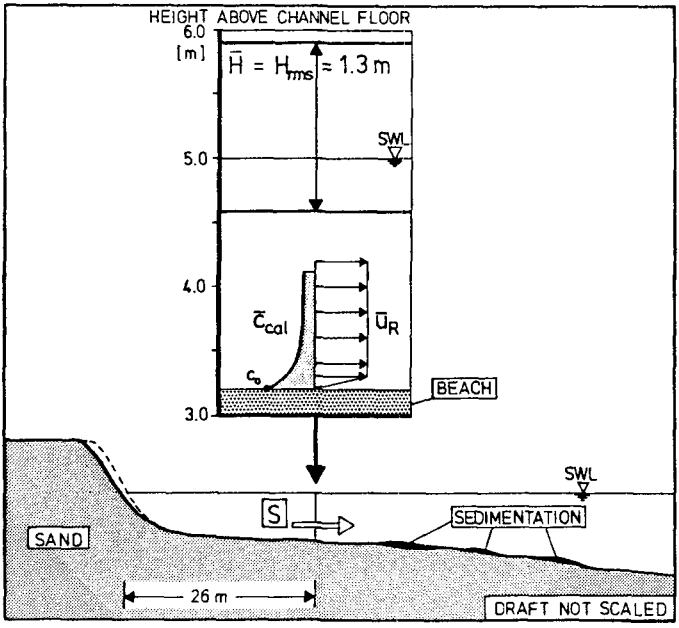

Figure 8. Schematic layout of applied data at the point of measurement for comparison of sediment transport during a test increment of 80 waves

With respect to discrepancies it has to be pointed out that the sediment concentration was measured only up to 0.91 m above the bed which is only 48 percent of the total water depth of d = 1.9 m. From visual observation it was obvious that suspended sediment were moved up to the water surface in the presence of large eddies (Fig. 9 and 10).

Figure 9. Breaker in front of the dune without foreshore initial

Figure 10. Broken wave impinging on backrush water

Sediment Transport during the Development of Beach Profile

Notwithstanding already the difficulties which are connected to the calculation of sediment volume through one point of the beach during first increment of 80 waves this method was also applied for another 10 increments with a total of 760 waves. By this means the variation of sediment volume during the developing phase of the beach profile shall be demonstrated. Fig. 11 shows the comparison of both time-averaged results from the calculation and from the development of the beach profile. The measured and averaged value of sediment transport computed from profile changes over 760 waves yielded $\overline{A}$ = 1.07 m³/m ± 30 % (σ = 0.199) and $\overline{S}$ = 0.3 m³/m ± 30 % (σ = 0.063) for the calculated sediment transport. The difference between the averaged values is Δ = 0.77 m³/m or about 72 % (per increment = 70 waves).
The calculation with the average of instantaneous products of the sediment concentration and the water velocity

$$S = \int_0^t \int_0^z c(z,t) \cdot u(z,t)\, dz\, dt \qquad (3)$$

is not possible, since the data of the sediment concentration are only time-averaged values.

It may be pointed out, that from the averages of instanntaneous products - obtained from 2-dimensional measuring systems - the sediment transport will not be described more accurately than the product of time-averaged sediment concentration and water velocity because measuring errors due to large vortex components have to be taken into account. In the present calculation these errors are compensated.

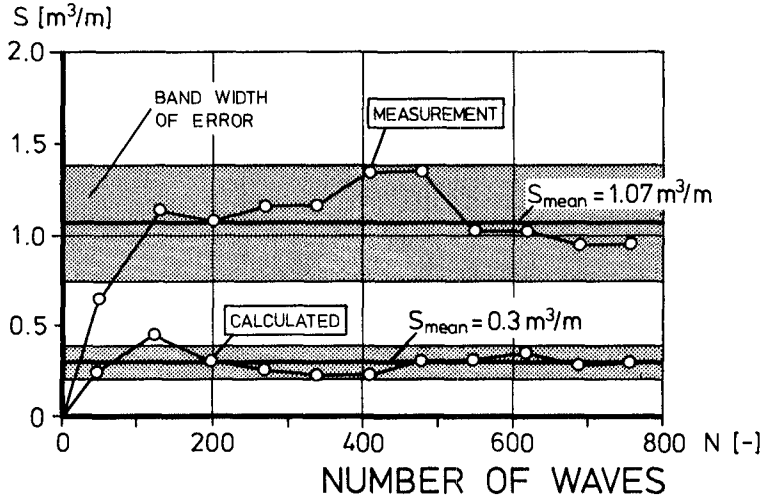

Figure 11. Comparison of sediment transport between the calculated transport and that computed from profile changes during development phase of beach profile (each value represents approx. a sequence of 70 waves)

Conclusion

The BIG WAVE FLUME in Hannover enabled prototype measurements of wave-induced velocities and sediment concentrations across the surf zone during the development phase of beach profile and over the equilibrium profile under regular and irregular waves.

In the paper first results of measurements obtained from two test series: "dune with and without foreshore" are presented.

At one position on the beach the calculated sediment transport was compared with the measured volume changes of the beach profile.

In order to minimize the differences between the calculated and measured values, it is necessary, to study in more detail the sediment transport in the bottom layer and to carry out measurements over the total column of water depth in the surf zone.

Acknowledgment

The "GROSSER WELLENKANAL" GWK (Big Wave Flume) was constructed by the Deutsche Forschungsgemeinschaft (DFG = German Research Association). The DFG also sponsored the investigations described here (Sonderforschungsbereich 205). The authors are very much indebted to the DFG for this support.
The authors like to express their sincere thanks also to Professor

Dr.-Ing. E.h. A. J. RAUDKIVI, University of Auckland, for his generous support and his stimulating remarks during the preparation of this paper.

CHAPTER 80

A NEW EQUILIBRIUM ANALYSIS FOR NEARSHORE TIDAL BASINS

R. Dieckmann[*1] and H. W. Partenscky[*2]

Abstract

A large tidal flat area of about 40 tidal basins with catchment areas of between 10 and 790 km^2 exists along the coast of the German Bight. Not all of these tidal basins are morphologically stable.

The main parameter necessary for determining the state of equilibrium is the volumetric capacity of the concave portions of the tidal basin. In order to examine the equilibrium state it is necessary to compare the volumetric capacity of the tidal basin determined from hydrographic charts (measured volume) with a theoretical volume given by newly developed stability criteria representing averaged conditions (volume balances). Significant deviations between the theoretical and the measured volumes indicate a state of non-equilibrium.

Using stability criteria it is possible to desribe the state of equilibrium of a tidal basin in a stepwise manner either from the bottom of the tidal basin to the datum plane MHW in order to obtain a cross-sectional stability profile, or from the shore to the seaward boundary of the basin in order to obtain a longitudinal stability profile.

The applicability of the new method for analyzing the equilibrium of a tidal basin will be demonstrated by the example of the Süderau tidal basin in the north of Germany.

1. Introduction

The North Sea is a shallow marginal sea of the Atlantic Ocean. In the south eastern part of the North Sea, known as the German Bight, the coast is formed over a length of 480 km by a tidal flat area of 7500 km^2 consisting of approximately 40 tidal basins with catchment areas of 10 to 790 km^2.

The tidal flats of the German Bight are regions of extensive alluvial activity which has never ceased over many centuries of history. In their composition and form the tidal flats are the result of the constructive and destructive actions of the North Sea. The severe storms surges of the 13th and 14th century, as well as during the 17th and 18th centuries, have caused considerable loss of land along this

*2 Prof. Dr.-Ing. Dr.phys, Director of the FRANZIUS-INSTITUTE for Hydraulic Research and Coastal Engineering, University of Hannover, Nienburger Str. 4, D-3000 Hannover 1, FRG.

coast. Land reclamation measures and offshore dykes have only been able to offset a portion of these erosional losses. Therefore not all of the tidal basins in this area are morphologically stable.

In order to clarify the morphological behaviour of the nearshore zone and to be able to estimate the degree of further erosional losses, sub-regions of the tidal basins have been systematically investigated for about 10 years in relation to their equilibrium state. Further erosional losses must be prevented by appropriate construction works in order to safeguard this unique natural landscape. In addition, the tidal flats are of great importance in the coastal protection system since they considerably reduce the hydrodynamic loading on the coastal dykes.

The initial results of this long-term investigation programme were presented at the Coastal Engineering Conference in Copenhagen, 1984/1/ and in Cape Town, 1982/2/.

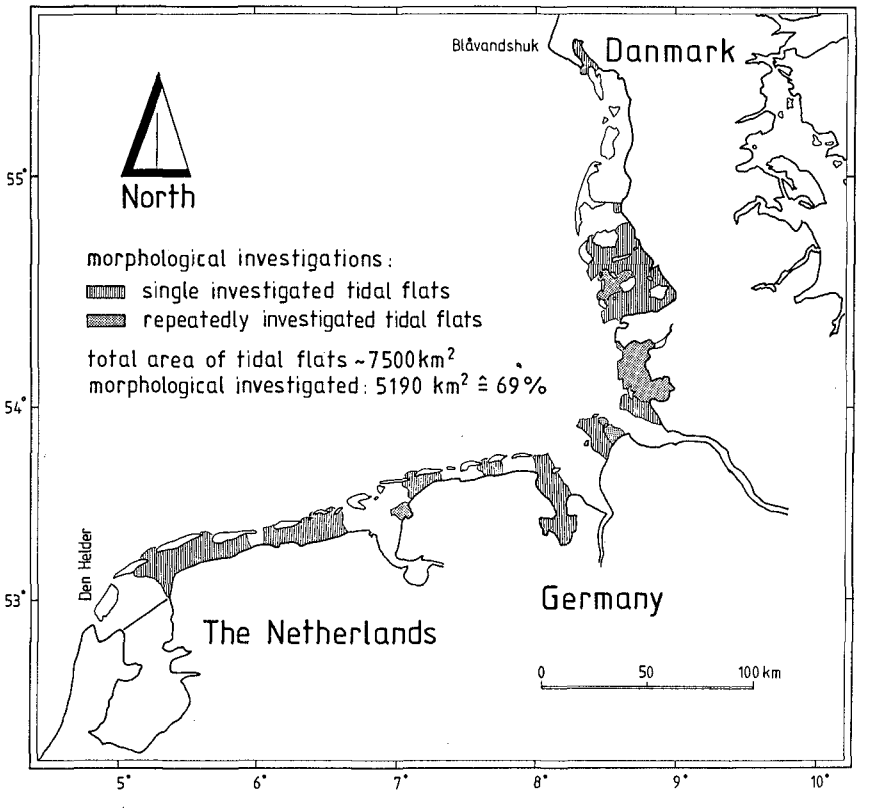

Fig. 1: Morphologically investigated areas along the coast of the German Bight.

2. Concept of the Investigations

2.1 Geomorphological and hydrological Boundary Conditions

The surface shape of a tidal flat area is very complicated. To describe it, the definition of basis units for data collection is necessary. Such basis units are the drainage basins of the tidal creeks and gullies (tidal basins).

Today, the investigated tidal basins of the German Bight represent approximately 69 % of the whole tidal flat area. In addition to this, some tidal basins have been repeatedly investigated. A total data volume from 6250 km^2 of tidal flats is available (see Fig. 1).

The main task of the morphological investigations is to generalize the morphology of the tidal basins by determining the so called constant-level area distribution (CLAD)/3/.

The constant-level area distribution for a tidal basin may be obtained by assigning the included area of a particular closed contour to the geodetic height corresponding to that contour. A distribution function is obtained from a graphical representation of the latter areas which is similar in form for all tidal basins having the same characteristics (see Fig. 2).

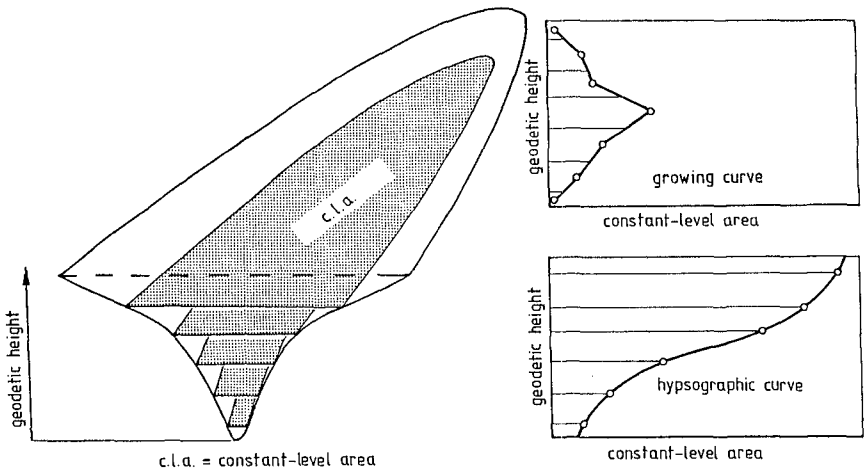

Fig. 2: Determination of the constant-level area distribution (CLAD) of a tidal basin (schematic) /3/.

In order to determine the CLAD, it is necessary to measure the constant-level areas from charts using a planimeter. In the case of larger investigation areas or those having a more complex morphology, the CLAD may be determined for a region as a whole by the summation of the individual contributions of a number of sub-areas.

By numerical integration of the CLAD, the volumetric summation curve (VSC) for a tidal basin may easily be determined (see Fig. 3).

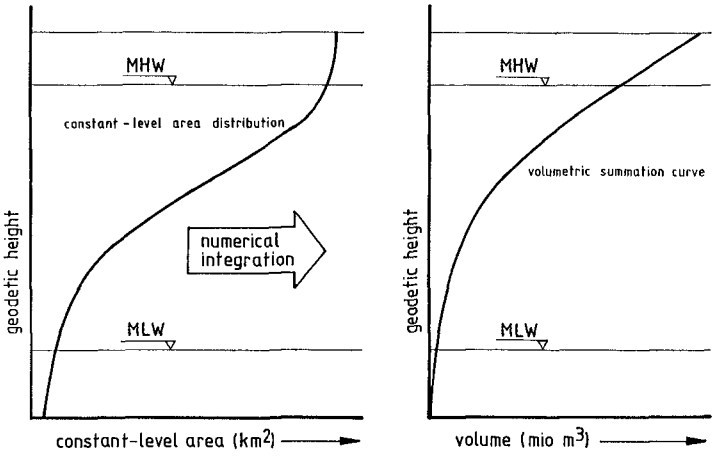

Fig. 3: Constant-level area distribution (CLAD) and volumetric summation curve (VSC) of a tidal basin /3/.

The VSC represents the total volumetric capacity of a hollow-shaped tidal basin with respect to different depths. Values of special importance are the volumetric capacity below the datum planes MLW and MHW /4/.

Applying to HAYES tidal classification /5/, it is possible to subdivide the shallows along the coast of the German Bight into the following 4 classes:

CLASS	TIDAL RANGE
Microtidal coast	< 1 m
Low mesotidal coast	1 - 2 m
High mesotidal coast	2 - 3 m
Low macrotidal coast	3 - 5 m

This classification is of great importance, especially from the geomorphological point of view. On the mesotidal coast, the flats of the German Bight are bordered by barrier islands. In passing from the low mesotidal to the high mesotidal coast the islands of the barrier island chain become smaller. Along the low macrotidal coast no barrier islands are present. This coast is open to the sea (see Fig. 4).

For the comparision of CLAD- or VSC-curves of different tidal basins, the tidal classification mentioned above has to be taken into account.

In Fig. 5, typical CLAD-curves of the 3 types of tidal basins are plotted as a function of the relative surface area (constant level area). When considering the intertidal area between MHW and MLW, the curves clearly show the decrease of this part of the tidal basins with decreasing tidal range. These differences in the morphological structure of several tidal basins can be shown clearly by comparing CLAD- and VSC-curves of the Meldorfer Bucht, which is situated in the low macrotidal range of the West Meep, which represents a tidal basin of the low mesotidal coast. Although both tidal basins have nearly the

same surface area and volumetric capacity at MHW, the CLAD- and VSC-curves are totally different (see Fig. 6).

a) Differences in the course of the CLAD - functions

b) Differences in the course of the VSC - functions

Fig. 6: General morphological structure of the Meldorfer Bucht and West Meep tidal basins /3/.

2.2 Regime Theory Basis for the Investigations

River drainage basins or tidal creeks (tidal basins) may be considered as open passive systems (regimes), the states of which may be described by parameters. An open system allows the transport of material and energy across the system boundaries (tidal basin boundaries). Passive systems only change their state when an external disturbance enters the system /6/. Theoretically, such systems are in a time-independent state of equilibrium, which in the case of a tidal basin must satisfy three essential physical conditions:

-- the continuity condition,
-- the relationship between the flow velocity, the depth, the slope and roughness of the channel and
-- the relationship between the flow velocities and the sediment transport.

If external influences disturb the regime of the tidal basin, this must alter to comply with the new boundary conditions and attain a new state of equilibrium within a particular time interval.

Since, however, tidal basins are subjected to many varying boundary conditions and disturbances which have apposing effect, a final state of equilibrium is never reached. Due to the feedback mechanisms between the disturbances and the reactions of the regimes, time delays occur. Self-correcting processes therefore fluctuate about a mean condition representing the modal value, i.e. a dynamic state of equilibrium develops /7/ which corresponds to the mean equilibrium state.

In the case of disturbances, the regime parameters behave in different ways. Only few but important system parameters react very sensitively to disturbances. It is well-known from regime theory, the size of the drainage area is the most important parameter of a channel system.

Accordingly, a strict mathematical relationship (Fig. 7) exists between the drainage area and the volumetric capacity of a tidal basin. The regime of a tidal basin reacts thereby by altering its drainage area by erosion or sedimentation depending upon whether the drainage area has increased or decreased until a new state of equilibrium has been established.

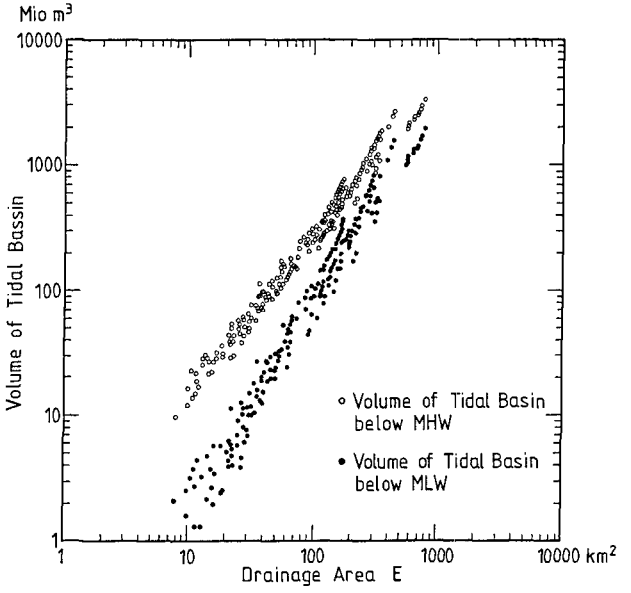

Fig. 7: Relationships between the volumetric capacity below MLW and MHW and the drainage area of tidal basins in the German Bight /3/.

2.3 Approach and Method

The main parameter necessary to determine the state of equilibrium is the volumetric capacity of the concave portions of the tidal basins. The stability criterion for a tidal basin of given dimensions is given by the following equation:

$$V = \alpha^* \cdot (d_z \cdot a_z)^{\beta^*} \qquad (1)$$

where

V = volumetric capacity of the tidal basin for the state of equilibrium,

α^*, β^* = regression coefficients, which are functions of tidal conditions and the tidal section under consideration,

d_z = maximum depth in the tidal basin with respect to the constant level elevation (z) and

a_z = size of the constant level area at the elevation (z).

In order to examine the equilibrium state of a tidal basin and to make predictions of the expected degrees of sedimentation and erosion for a region which may not be in a state of equilibrium, it is necessary to

compare the theoretical volumetric summation curve with a measured curve based upon hydrographic charts.

In the event that significant deviations are revealed through a comparision of the theoretical and measured volumetric summation curves (volumetric balance) for the tidal basin under consideration, this implies that the area concerned is in a non-equilibrium state.

For the case of a volume deficiency, i.e. the measured volume is less than the theoretical volume, the tidal basin is in a state of erosion. In this case, erosion continues until the volume corresponding to the equilibrium state is attained. Conversely, a tidal basin with a volume excess reacts by undergoing gradual sedimentation until a state of equilibrium (theoretical volume) is reached /2/.

As a basis for determining the actual volumetric summation curve, accurate computations of the volumetric capacity are necessary for the channel system under investigation. For this purpose, accurate contour maps of the tidal basins are essential.

3. Stability Criteria for Tidal Basins

3.1 Determination of Regression Coefficients

In order to determine the theoretical volume which characterises the mean equilibrium state of a tidal basin, it is necessary to determine the regression relationship between the actual existing volume (see Section 2.1, Figs. 2 and 3) and the value given by the product $(d_z \cdot a_z)$ from the relationship (1) for all 71 of the tidal basins and sub-regions investigated. The regression coefficients α^* and β^* for the individual tidal basins were determined by the least squares error method of GAUSS from altogether 450,000 data values by means of a special computer program.

In order to obtain a good approximation of the geomorphological boundary conditions, it is necessary to consider the following parameters:

-- the seaward boundary of the tidal basin (see /3/),
-- the differences in the structure of the tidal basin with respect to tidal conditions (Section 2.1),
-- seperate evaluations of the channnel regions and the flat sections of the tidal basin.

The regression coefficients determined for the investigated tidal basins with varying tidal ranges were represented in relation to tidal range under consideration of the height domains channel region (section 1) and flat section (section 2), as shown in Figs. 8a, 8b. From these diagrams, the regression coefficients α and β were determined for an evaluation of the theoretical volume of a tidal basin in relation to the particular mean tidal range (MTR).

The results were as follows:

channel region $\alpha_1 = 0.383 - 0.0133 \text{ MTR}$ (2)

$\beta_1 = 0.883 - 0.004 \text{ MTR}$ (3)

flat section $\alpha_2 = 1.115 - 0.161 \ MTR$ (4)

$\beta_2 = 0.989 - 0.026 \ MTR$ (5)

It is noted that the quality of the approximation for the region 2 (flat section), as expressed by the correlation coefficients, is generally slightly worse. This is not related to errors in the method used but to the "particular morphological characteristics" of the investigated drainage areas which were particularly abundant in the cases considered and which could not be described in terms of the parameter "volumetric capacity".

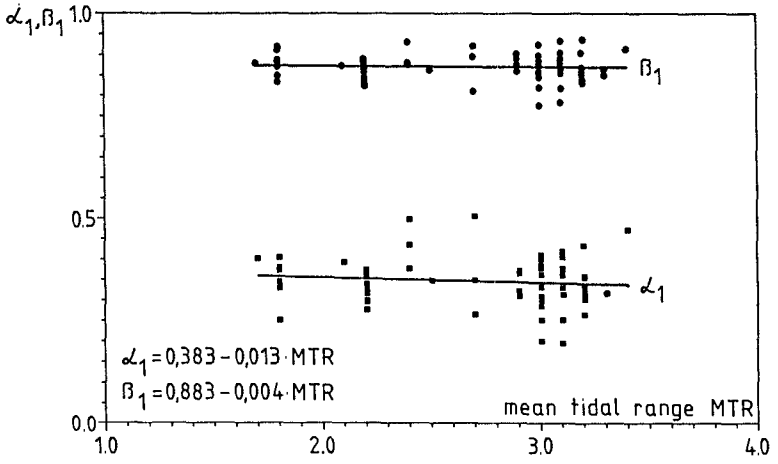

Fig. 8a: Regression coefficients α_1 and β_1.

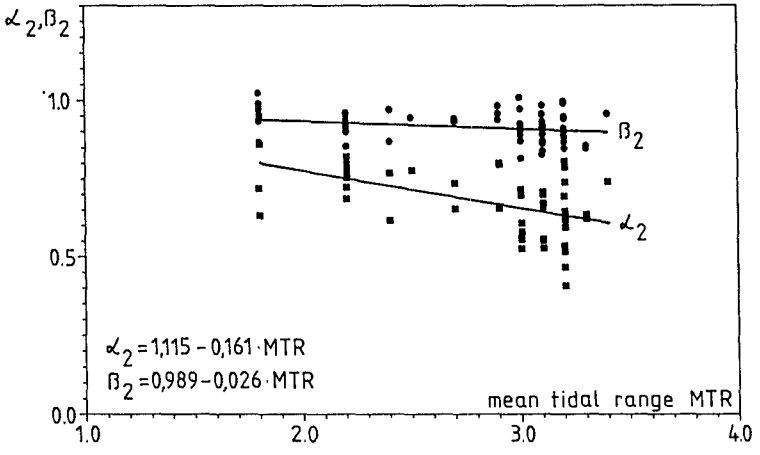

Fig. 8b: Regression coefficients α_2 and β_2.

3.2 Formulation of the stability criteria

The volumetric capacity (nominal volume), which represents mean conditions for the given tidal range, may be regarded as a criterium for the hydrological-morphological stability of a drainage area. This nominal volume may be represented on the basis of the previously described general formula for the region below MLW as follows:

$$V_{z_1} = \alpha_1 \cdot (d_z \cdot a_z)^{\beta_1} \quad \text{(Mio m}^3\text{)} \qquad (6)$$

For the tidal range region, the following holds:

$$V_{z_2} = \alpha_2 \cdot (d_z - d_{MLW})(a_z - a_{MLW})^{\beta_2} \quad \text{(Mio m}^3\text{)} \qquad (7)$$

where

d_{MLW} = depth below MLW (m),

a_{MLW} = constant level area of the reference plane MLW (km^2)

Here, the two sections 1 (channel bed to MLW = channel region) and 2 (MLW to MHW = flat section) must be considered. The coefficients α_i and β_i which should be substituted in the Equations (6) and (7) for the particular case in question may be obtained from Figs. 8a and 8b.

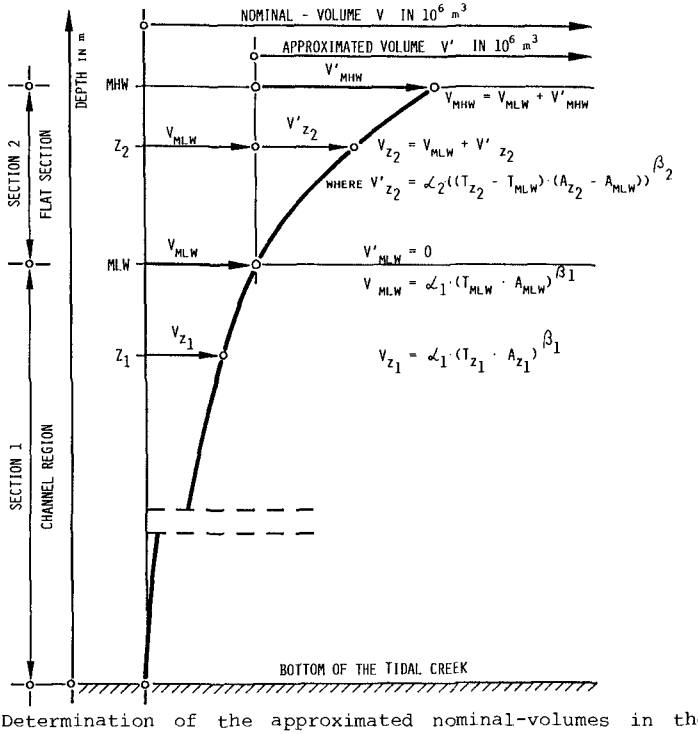

Fig. 9: Determination of the approximated nominal-volumes in the two investigation sections: channel region (section 1) and flat section (section 2) /3/.

Figure 9 shows by way of example the method of determining the approximated nominal volumes in both sections. In section 2 (flat section) a transformed coordinate system based upon the particular value of V_{MLW} is used. By this means, discontinuity in the approximated nominal volumes in the transition zone between sections 1 and 2 is avoided.

Special investigations have shown that the stability criteria not only apply to complete tidal basins, but also to parts thereof (see /8/).

Using the stability criteria, it is possible to describe the state of equilibrium of a tidal basin in a stepwise manner either from the bottom of the channel to the datum plane MHW in order to obtain a cross-sectional stability profile of the basin or from the shore to the seaward boundary of the basin in order to obtain a longitudinal stability profile.

To what extent the composition of bed material influences the stability criteria cannot be stated with any certainty at the present time. In view if this, the given relationship (Equation 6 and 7) can be applied with confidence only for tidal basins of the German Bight.

4. Examples of Application

4.1 General Information

The predictive capability of the stability criteria will be demonstrated by application to the Süderau, which is an approximately 200 km^2 tidal basin on the north coast of the German Bight (Fig. 10).

Along this part of the coast, erosional processes prevail as a result of the geomorphological development of the tidal region since the catastrophic storm surge of 1634. Today this erosion poses a danger to the stability of the tidal areas, the shore protection structures of the mainland, and the entire ecosystem.

Special problems exist in the region of the "Strand", which is a 200 m wide and about 10 m deep channel connecting the two channel systems Norderhever and Süderau (Fig. 10). Due to the tidal conditions in this region, a residual discharge of approximately 50 Mio. m^3 per tide passes through the Strand from the Norderhever into the Süderau. This residual discharge acts as a flushing mechanism in the Süderau. Owing to the large load-carrying capacity of this flushing discharge, the Süderau has been transformed into a very wide and deep tidal basin. At low tide, an additional tidal volume of $10 \cdot 10^6$ m^3 flows to the west from Norderhever into the neighbouring Rummelloch-West (see Fig. 10).

Owing to the historical development and the widening of the Süderau by the flushing discharge, it is to be expected that this tidal basin is in a hydrological-morphological state of non-equilibrium.

4.2 Stability Investigations of the Süderau

The stability criteria make it possible to make predictions of the stability behaviour of a tidal basin from the bed of the channel up to the reference plane MHW. For this purpose, extensive preliminary work was necessary, as given in detail in Section 2.3.

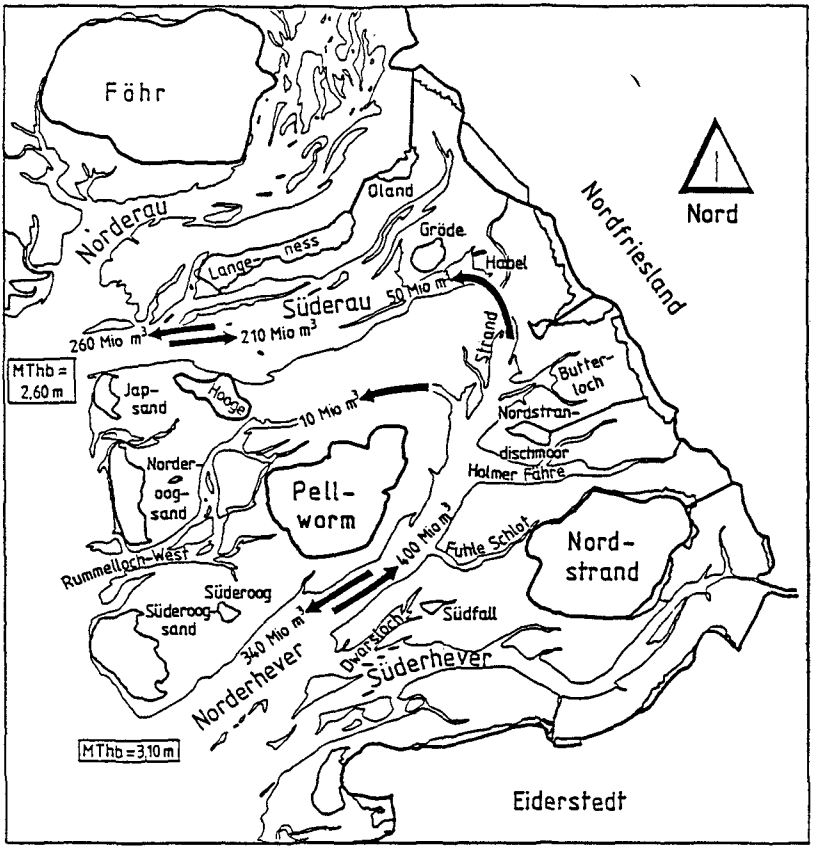

Fig. 10: Balance of tidal discharge in the region of the mudflat channel systems Norderhever-Strand-Süderau and Rummelloch-West.

The results of the evaluations and the subsequent necessary computer analysis are presented in the form of output listings which contain amongst other parameters the theoretical and measured volumes and the volume balances.

With this data, the stability profile of a tidal basin may be represented. The latter shows in the form of a volume balance summation curve the overall degrees of sedimentation or erosion to be expected until an equilibrium state is reached landwards of the profile considered. The stability profile (Fig. 11a) of the Süderau tidal basin indicates a clear volume excess, i.e. the measured volumes are greater than the theoretical ones. On the basis of this, sedimentation in the order of $39 \cdot 10^6$ m^3 is to be expected below MLW (channel region), whilst in the tidal range region (flat section), $(212 - 39) \cdot 10^6$ m^3 = $173 \cdot 10^6$ m^3 is to be expected. The clear non-equilibrium state, particularly above MLW, is mostly due to the flushing capacity of the tidally-induced
