CHAPTER 161

STATISTICAL INVESTIGATIONS ON DIKE FAILURE

Ing. P. Roelse[1] and ir. W.T. Bakker[2]

1. ABSTRACT

For the probabilistic design of dikes it is necessary to know the failure probability of the dike as function of the load of the dike (wave attack).

This paper reports on the statistical analysis of the failure behaviour of the dikes around the Eastern Scheldt after the storm surge on February 1, 1953.

2. INTRODUCTION AND BACKGROUND

In 1975 the political decision was made in The Netherlands to construct a storm-surge barrier in the Eastern Scheldt instead of closing off the area completely (Fig. 1).
This lead to the consequence, that the safety of the surrounding area with respect to storm surges would be attained 5 years later than originally anticipated; this because new designs had to be made and because the construction would be more intricate and time-consuming.
Thus, the additional decision was made, that the dikes around the Scheldt should be partially enheightened, in order to stand a storm surge with a probability of occurrence of 1/500 per year.
To compare: Now the storm-surge barrier is completed (1986) the whole area should be safe with respect to storm surges occurring with a frequency of 1/4000 per year.
As a consequence, in a short time it had to be decided, whether for each dike section along a total stretch of about 140 km the section should be enheightened or not.
Figure 2 shows an example of the kind of dikes; Figure 3 shows examples of cross sections, before and after the enheightening. Many of the dikes originally had retaining walls on top (Fig. 4, 5), sometimes with a road landward of it (Fig. 6). Mostly the dikes consisted of clay. The final construction was a sand dike with a clay cover.
As the advice had to be given rather quickly, the design height was determined in a simple way, described in chapter 4.

This paper gives an analysis of the method, showing as well the advantages as its limitations.
Using the method, it is essential to know: the probability of failure as function of the "lack of crest height", i.e., the difference between the real height of the dike and the design height.

1) Project Engineer, Rijkswaterstaat, Tidal Waters Department, Section Middelburg.
2) Scientific Coördinator Coastal Research, Tidal Waters Department Rijkswaterstaat; Principal Scientific Officer Delft Univ. of Techn.

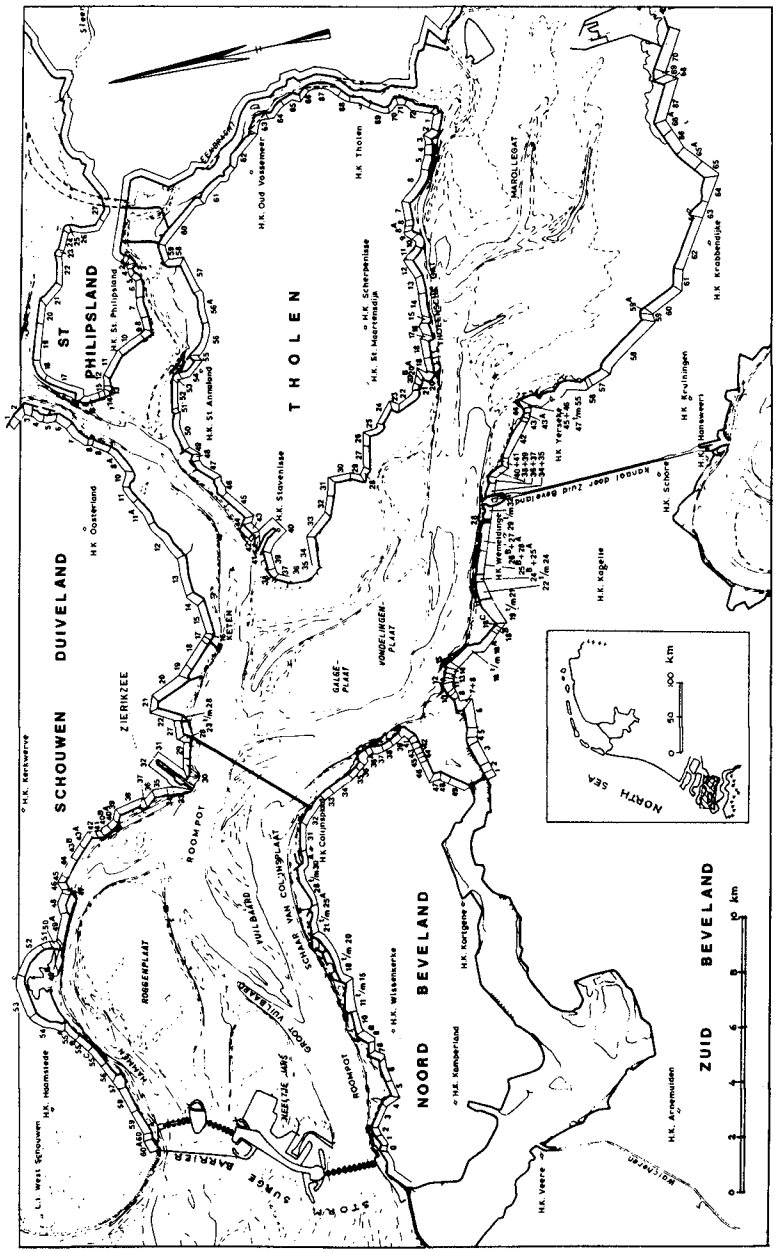

Fig. 1. Situation Eastern Scheldt

In order to get an impression of this function, it has been calculated what should have been (according to the same method) the dike height during the surge of 1953, when many dikes collapsed and 1835 people were killed. The number of dike segments which failed in 1953 was compared with the total number of dike segments having the same crest height deficiency.
In the same way, dikes with different characteristics (with or without return wall, steeper or flatter inner slopes etc.) can be compared.
Of course, the method as used only gives a rough indication.
One might question, whether the lack of crest height (as calculated in the way, given in chapter 4) is decisive for the failure probability.
In the first place, in order to give the failure probability some meaning, the dike considered should be more or less uniform with respect to the construction. Therefore, the dikes have been classified into various categories (chapter 3).
In the second place, dikes with the same lack of crest height should have the same wave attack.
Chapter 6 deals about this matter; it has to be investigated, whether the same lack of crest height implies always the same amount of overtopping. As the design crest height is determined as well by surge level as by wave run-up this is not self-evident.
In 1953, practically all dike failures were caused by wave overtopping, resulting in a failure of the inner slope. Therefore, data as given here only applies for this kind of failure mechanism.

A second question rises, how the extrapolate the results. For Dutch circumstances, one possibly might see the probabilities found as a pessimistic estimate, as the improved dikes have a much flatter inner slope than the former ones; on the other hand, a modern dike is a clay-covered sand dike, where the former dikes consisted of clay.
Therefore, at present a more sophisticated method of probabilistic design is developed in The Netherlands (Bakker & Vrijling, 1980).
How imperfect the present results may be, it is considered useful publishing these data, as these may give an impression of the strength of dikes of a kind which may occur also in other parts of the world.
A warning should be given, that the data refer to the failure probability of dike sections of a length of the order of some hundreds of metres. The failure probability of a dike ring consisting of many sections will be much higher, as a chain is a strong as its weakest link (Bakker & Vrijling, 1980 and Chapter 7).

3. AVAILABLE DATA

Figure 1 shows the investigated area and the various dike sections considered. For 273 dike sections the wave run-up in 1953 could be reproduced in a way described in chapter 4, where the inner slope of the dike in 1953 was known as well. Some (13) dike sections along the area considered had to be omitted because of lack of data.
The dikes were divided into various categories, using the following characteristics:
- with or without return wall;
- with or without road on the crest;
- inner slope flatter than 1:1.5 or not flatter.

Fig. 2 Eastern Scheldt dike (without return wall)

Fig. 4 Eastern Scheldt dike (with return wall)

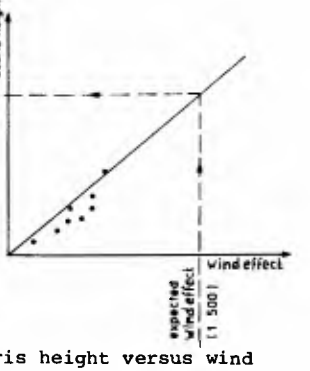

Fig. 8 Debris height versus wind effect

Table 1 shows some characteristics of the dike sections (the dikes mentioned on the second and third line did not have a road on the crest).

Table 1. Characteristics of dike sections.

	without wall		with wall		total	
	total	break-through	total	break-through	total	break-through
road on crest			10	-	10	-
inner slope flatter than 1:1.5	143	17	60	4	203	21
inner slope not flatter than 1:1.5	49	17	11	-	60	17
Total	192	34	81	4	273	38

4. LACK OF CREST HEIGHT

The wave attack, which occurred during the 1953 surge can only be hindcasted by a rough approximation. After many storm surges, before and after 1953, at each dike section along the Eastern Scheldt the level of the debris line has been measured. From extrapolation, the hypothetical height of the debris line after the 1953 storm surge has been derived. This height is hypothetical, since it usually surpasses the crest level of the dike.
The extrapolation has been carried out by plotting for each measured debris height the wave run-up (difference between storm-surge level and debris height) against the wind effect (difference between storm-surge level and astronomical tide)(Fig. 7a, b and 8).

For each dike section, the lack of crest height has been determined, being the difference between the hypothetical debris height in 1953 and the crest level of the dike. Where seawalls were on the dike, the level of the top of the seawall has been taken as crest level (Fig. 9a, b).

In the following, the lack of crest height in 1953 will be denoted by "z".

5. STATISTICAL HANDLING OF DATA

5.1. Dikes without a training wall

The dike sections have been divided into classes with increasing lack of crest height z. The classes have a "band width" of 0.25 m (0 z 0.25 m, 0.25 z 0.50 m, etc.). When x is the number of dike sections in a certain class which break through and n is the number of sections in that class, the probability of break-through x/n has been determined as well as the

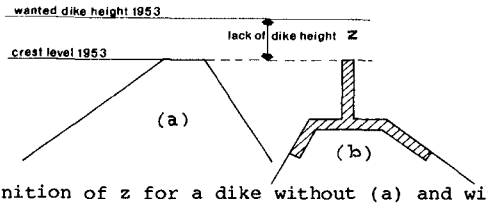

Fig. 9 Definition of z for a dike without (a) and with (b) a return wall

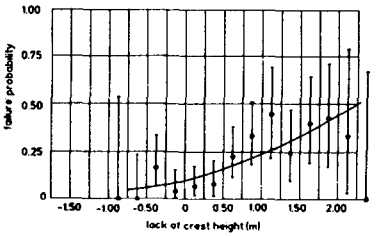

Fig. 10 z versus probability of dike failure (all dikes)

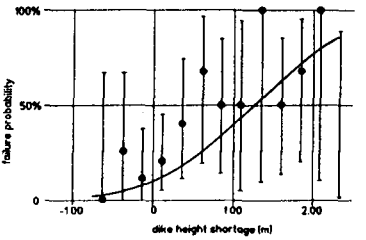

fig. 11 z versus probability of dike failure (dikes with inner slope 1:1.5 or sleeper)

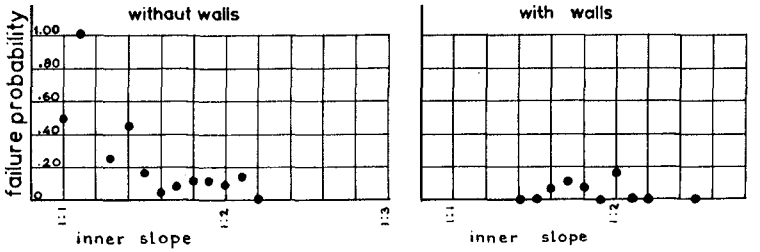

Fig. 12 Effect of slope on failure probability

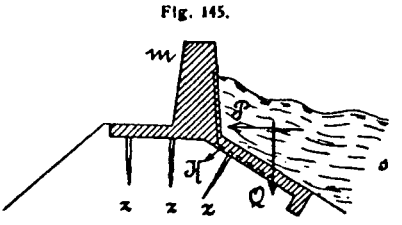

Fig. 13 Performance of return wall according to De Muralt (1913)

confidence interval with a two-sided confidence limit of 20%. Figure 10 shows the relation, valid for all dikes without a training wall. Complete data and elaboration are given by Bakker & Roelse (1981).
The material still offers puzzling results. Even after elimination of a dike section, which collapsed by a second World War gun position, still one finds dike sections with a lack of crest height of 2.25 m which did not collapse. In one of those cases still the dike ring break through at another place (which may have protected the section), but in the other case only a large amount of overflow has been reported. In the cases of break-through with a surplus of crest height either the wave run-up is underestimated, either the crest height overestimated (by reasons, not to be traced after 30 years), either a construction in the dike has been the reason for dike failure. In all cases (a heavy) overtopping has been reported.
Therefore, the results of the following analysis have more the status of "indications" than of "proofs", as correlations found are rather low.
For instance: the correlation between the lack of crest height z and the failure probability appeared to be only 0.35

Where Figure 10 gives z versus probability of dike failure for all dikes, Figure 11 gives the same kind of result for all dikes with an inner slope of 1:15 or steeper.

For the failure probability Pr (failure) a normal distribution has been assumed:

$$\Pr(\text{failure}) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{z^*} e^{-u^2} \, du \qquad (1)$$

with

$$z^* = (z - \bar{z})/\sigma \qquad (2)$$

The values of $\bar{z}$ and σ have been determined with an existing statistical analysis, the "probit analysis" (Finney).
The calculations have been carried out by IWIS-TNO (Technical Physical Research).
The following results were found:

Table 2. Magnitude of $\bar{z}$ and σ for dike sections without walls.

Inner slope	$\bar{z}$	σ
1:1.5 or steeper	1.22 m	1.41 m
flatter than 1:1.5	2.69 m	1.73 m
all slopes	2.25 m	1.76 m

From this table it shows, that dikes without walls with a slope of one in 1.5 or steeper react more predictable than dikes with a flatter slope; the probability of failure is much larger. This is also illustrated by Figure 12, which shows the effect of slope on dike failure more into detail.

5.2. Dikes with return walls

Consider now dikes with return walls, of which figure 5 and 6 give a picture. The height of these walls is of the order of 0.5 to 1 m. Figure

13 shows a cross-section and the anticipated action according to the designer de Muralt (1913). The turning moment by the impact of the wave is neutralized by the normal pressure on the basement plate.

No failures were found for the 11 dike sections, having an inner slope of 1:1.5 or steeper; from the 59 dike sections having a slope flatter than 1:1.5, a number of 3 break through.
Now dikes with the same crest height with return walls and without have been compared.

As an example, Table 3 shows the comparison of all dikes (regardless of inner slope) with or without return walls, classified according to crest height deficiency.

Table 3. All dike segments with $z \geq 0$ classified according to crest height deficiency.

class of z		with walls		without walls	
from	to	total	failure	total	failure
0.00	0.25	21	1	29	2
0.25	0.50	13	0	25	2
0.50	0.75	3	0	22	5
0.75	1.00	3	1	18	6
1.00	1.25	2	0	9	4
1.25	1.50	4	1	12	3
1.50	1.75	1	0	10	4
1.75	2.00	1	0	7	3
Total		48	3	132	29

Table 4. All dike segments without roads (inner slope 1:1.5 or steeper) classified according to crest height deficiency.

class of z		with walls		without walls	
from	to	total	failure	total	failure
0.00	0.25	3	0	10	2
0.25	0.50	4	0	5	2
0.50	0.75				
0.75	1.00	1	0	4	2
Total		8	0	19	6

Data at the same line refer to dikes with equal crest height deficiency z, where, as mentioned, in the case of return walls z refers to the upper side of the return wall.

The statement has been tested, whether both groups being compared belong to the same population. Using Cochran's test (cf. Everitt, 1977), a probability of 5.3% was found, that this was the case; therefore with this confidence limit one might conclude that dikes with return walls are significantly stronger.
Using partial datasets (eliminating dikes with roads on the crest and discrimination on inner slopes) it was found with a confidence limit of 3%, that dikes (without roads) with an inner slope 1:1.5 or steeper with a return wall were stronger than dikes with the same value of z without a return wall (Table 4).
However, evaluating these results, one has to keep the low correlation between dike height deficiency and failure probability in mind.

6. RELEVANCE OF THE CREST HEIGHT DEFICIENCY FOR THE LOAD ON THE DIKE

Let H be the mean wave height, surpassed by 50% of the waves. In the case of a Rayleigh distribution of the waves, H equals:

$$H = 0.59\ H_S \tag{3}$$

where H_S is the significant wave height.
From Fig. IV.5.4 from TAW (1972) the following approximating relationship between dimensionless amount of overtopping q_* and dimensionless dike height K_* can be derived (Fig. 14):

$$q_* = 10^{-(K_* - 1{,}5)/5} \tag{4}$$

in which:

$$q_* = 2\pi\sqrt{\frac{\pi}{10}} \cdot \frac{\bar{q}}{\sqrt{gH^3}} \tag{5}$$

Here q is the amount of overtopping per unit of time and per unit of crest width and g the accelaration of gravity.
Furthermore K_* is per definition:

$$K_* = K(\cot\alpha)^{3/2}/H \tag{6}$$

in which K is the crest height above the still water level.

In the range considered the amount of wave overtopping appears to decrease practical negative-exponentially with the crest-level.
Assuming the debris height analogous to the 1%-wave run-up (according to dutch measurements) and assuming the 2% wave run-up equal to 8 $H_S \tan\alpha$, where α is the revetment slope; furthermore assuming the 1% wave run-up 7.5% higher than the 2% wave run-up, from (3) one finds:

$$y_{dh} = N.H \tan\alpha \tag{7}$$

with:

$$N = 14.6 \tag{8}$$

where y_{dh} is the height of the debris above the still-water level.
The dike height deficiency equals:

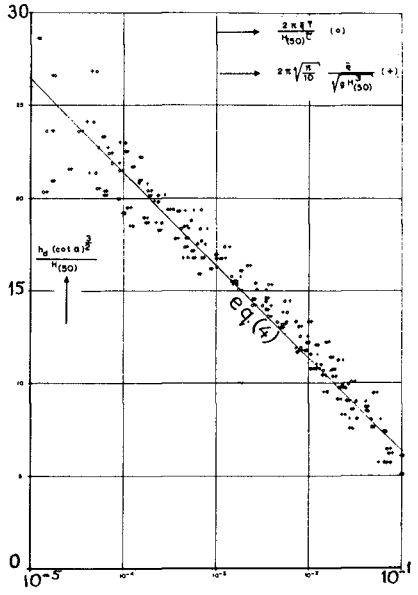

Fig. 14 Exponential relation between demensioless overtopping and dimensionless crestheight. Data from TAW (1972)

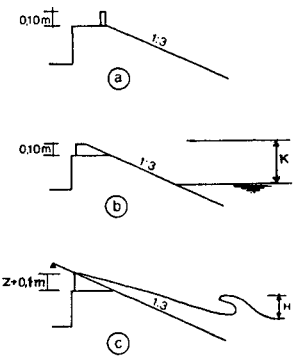

Fig. 16 Experimental set-up Doodeman (1985)

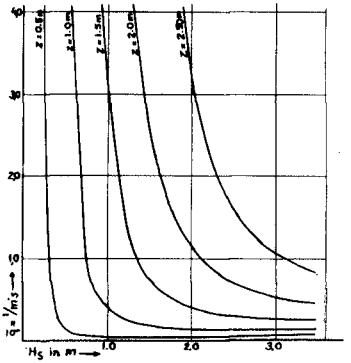

Fig. 15 Relation between dike height deficiency, sign. wave height and wave overtopping

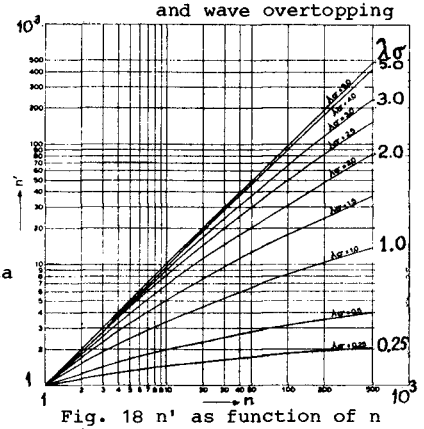

Fig. 18 n' as function of n

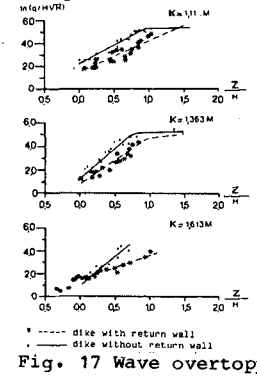

Fig. 17 Wave overtopping with and without return wall according to Doodeman (1985) (exp. scale 1:10)

$$z = y_{dh} - K \tag{9}$$

Using (5), (6), (7) and (9), one may write (4) as:

$$\bar{q} = A \cdot H\sqrt{H} \cdot e^{Bz/H} \tag{10}$$

in which:

$$A = \frac{1}{2\pi}\sqrt{\frac{10g}{\pi}} \cdot 10^{-(N\sqrt{\cot an\alpha}\,-\,1,5)/5} \tag{11}$$

$$B = (\cot an\alpha)^{3/2} \cdot (\ln 10)/5 \tag{12}$$

Thus it shows, that the dike height deficiency z does not determine in its own the amount of overtopping, but that this is also a function of the wave height.
From Figure 15 it shows, that for a large significant wave height and a small deficiency of crest height the deficiency determines the amount of overtopping quite well (it does not depend much on the wave height). However, when the deficiency is of the order of the wave height the lack of crest height gives blurred information on the amount of overtopping. Thus dikes with the same (large) crest height deficiency may have had a quite different amount of overtopping. However, other ways of calculation of amount of overtopping did not give more reliable results.

7. EXPERIMENTS

Because of confined financial means the only experiments with respect to this subject were carried out with regular waves. Therefore, from these experiments only qualitative indications can be derived concerning the amount of overtopping of dikes with a return wall compared to dikes without a wall.
The experiments were carried out by Doodeman (1985) on Delft Technological University.
The experimental set-up, simulating a scale 1:10 with respect to prototype, is shown in Figure 16. In a wave flume with waterdepth (for 3 successive sets of tests) of 0.45 m, 0.425 m and 0.40 m respectively a slope 1:3 was mounted up to a horizontal level of 0.4613 m above the bottom of the flume. Each test was carried out in three options:

a. with a return wall with a height of 10 cm above the original "dike";
b. with an enheightening of the dike with 10 cm, using the same seaward slope;
c. with an extension of the slope in upward direction in order to measure the wave run-up.

For various wave periods, simulating waves of 3 to 5 sec. in prototype, the wave-run up R was determined, resulting in an average value of 1.8 H; here H denotes the wave height.
Furthermore, the amount of overtopping q was measured. In a dimensionless plot, one might display $q/(H\sqrt{gH})$ versus z/H, where z is the crest height deficiency. This has been done in Figure 17, where the constant g has been omitted. H is given in m and q in l/ms. When z is of the order of the wave height one finds a truncation of the exponential increase of the run-up as suggested by (10). This will be clear, as no more discharge as contained in the wave crest will overtop.

Apart from some minor overtopping of the return wall for negative values of z (lowest picture of Fig. 17) Doodeman finds less overtopping for dikes with a return wall than for dikes without for the same value of z. Compare (for dikes without walls) the constants A and B according to (11) and (12) on one hand and according to the experiments on the other hand. It should be kept in mind that in the case of Doodeman the "debris height" would only be at a level of 1.8 H instead of 14.6/3 = 4.87 H for irregular waves (see (7)). Substituting of $N=1.8/\tan\alpha = 5.4$ for N in Doodeman's case one finds from his experiments: $A = 0.00420\sqrt{m/s}$. For B, which should be 2.39 for irregular waves, Doodeman finds 4.38. This means, that eqn (10), thus applied, gives for regular waves too high values for the overtopping discharge when the crest height definciency is small and too small values in the opposite case.

8. FAILURE PROBABILITY OF A DIKE RING

The probability of failure of a dike section differs from the probability of failure of the dike ring, of which the dike section forms a part. Bakker & Vrijling (1980) give an outline of a probabilistic design of sea defences. In order to give an idea of the effect of the length of a dike on the necessary design height, in the following a simple schematization is used.

a. With respect to the water level, an exponential probability distribution is assumed;
b. As the wave run-up is about proportional to the wind velocity for small fetch length and the probability distribution of the wind velocity is negative-exponential, a negative-exponential distribution of the wave run-up is assumed. The above statement is valid in the Eastern Scheldt when hydraulically deep water can be assumed; this is the case where a tidal channel occurs in front of the dike (Fig. 1). However, often shoals at about mean sea level are found in front of the dikes. In that case mostly the waves will be about proportional to the water depth and the probability distribution of waves an wave run-up will be conform the one of the water level, i.e. (again) negative-exponential.
c. Failure could be assumed, when the wave run-up surpasses the crest height; however, several additional inaccuracies are taken into account, as the uncertainty with respect to the strength of the dike (as treated before), the uncertainty with the exact constants in the formula for the negative-exponential distributions mentioned above, uncertaintly with the exact crest level etc.
   With respect to the inaccuracies mentioned ad c, a normal distribution is assumed.
d. In the following it will be assumed that all sections of the dike ring in principal are attacked by the same wave run-up; however, the unaccuracies mentioned ad c can be different for each dike section.

Mathematically, the formulation will be, that it is assumed, that a dike failure occurs when a stochastical quantity $\underline{z}$ (the wave run-up) surpasses a magnitude K (crest height) at one of n sections; here $\underline{z}$ is the sum of a stochastical quantity $\underline{x}$, being the same for all sections and having a negative exponential distribution, and a stochastical quantity $\underline{y}$, having a Gaussian distribution with expectation zero and standard deviation σ:

$$\underline{z} = \underline{x} + \underline{y} \tag{13}$$

$$P_r(\underline{x} > x) = A_o e^{-\lambda x} \quad (x > x_o) \tag{14}$$

$$P_r(\underline{y} > y) = 1-P\ (y/\sigma) \tag{15}$$

in which:

$$P(y) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{y} e^{-t^2/2}\, dt \tag{16}$$

In (16), P(y) is the Gaussian probability function with expectation zero and standard deviation 1.

It is assumed, that $\underline{x}$ and $\underline{y}$ are statistically independent.
Then the failure probability can be defined as:

$$P_r(\text{failure}) = P_r\ (\underline{z}_{max} > K) \tag{17}$$

with:

$$\underline{z}_{max} = \underline{x} + \underline{y}_{max} \tag{18}$$

As calculations in the appendix show, taking the number of sections and the inaccuracies y into account increases the failure probability with a factor $n'.\exp(\lambda^2\sigma^2/2)$. Here n' is a number smaller than the number of sections n; the value of n' is a function of n and $\lambda\sigma$; it is displayed in Figure 18. The ratio n'/n decreases, when $\lambda\sigma$ decreases, i.e., when the standard deviation of inaccuracy $\underline{y}$ decreases with respect to the characteristic height $1/\lambda$, of the exponential distribution of $\underline{x}$.
The amount of n' is smaller than n, because also when more sections collapse during one surge, only one dike-ring failure happens.
Now let K be the necessary crest height of a dike, taking only the distribution of $\underline{x}$ and the failure of one dike segment into account. According to (14) this includes a failure probability of $A_o.\exp(-\lambda x)$.
If one does not want to exceed this probability and still take as well the inaccuracy $\underline{y}$ as the number of sections into account, the dike should be enheightened with $\lambda\sigma^2/2 + (\ln n')/\lambda$.

9. CONCLUSIONS

The following indications deal about dikes and return walls with construction and materials as found in the Netherlands in 1953:

a. During the storm surge of 1953 dikes with a steep inner slope (1:1.5 or steeper) with return walls showed a smaller failure probability than dikes without return walls, when the shortage of crest height (as defined in ch. 3) was the same .
b. On the average, the dikes could stand a crest height deficiency of 1 to 2 m dependent of the inner slope. This holds for sections of a length of ca. 0.5 km. For a dike ring the strength of the weakest dike section will be decisive for the strength of the dike. Ch.8 gives a way to bring this effect into account.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the consent of Mr. Doodeman to publish his results. His experiments on the Delft University of Technology were guided by Ir. A. Paape and ir. J.J. van Dijk. Discussions within the Working Group "Probabilistic Design of Sea Defences" of the Technological Advisory Committee on Sea Defences, (which is preparing guide lines on this subject on a more sophisticated basis than presented here) were most fruitful. Photographs presented here are disposed by ing. M.A. van Dijk and by the Center for Research on Sea Defences.

APPENDIX

Calculation of n' from n

Let the probability of $\underline{x}$ be given by (14).
The probability of failure under the condition that $y<\underline{y}_{max}<y+dy$ equals:

$$P_r(\text{failure}|y<\underline{y}_{max}<y+dy) = P_r(\underline{x}>K-y) \quad (A1)$$

According to (14) this probability equals:

$$P_r(\text{failure}|y<\underline{y}_{max}<y+dy) = A_o e^{-\lambda(K-y)} \quad (A2)$$

Thus the total failure probability is the probability, quoted in (A2), multiplied with the chance on $y<\underline{y}_{max}<y+dy$, integrated over all possibilities of y:

$$P_r(\text{failure}) = \int_{-\infty}^{+\infty} A_o e^{-\lambda(K-y)} . p(y_{max})\, dy \quad (A3)$$

where $p(y_{max})$ is the probability density function of y_{max}:

$$p(y_{max}) = \frac{d}{dy}\,[\,Pr(y_{max}<y)\,] \quad (A4)$$

with:

$$P_r(\underline{y}_{max}<y) = (P(y/\sigma))^n \quad (A5)$$

From (A4) and (16) one finds:

$$p(y_{max}) = \frac{d}{dy}[\,(P(y/\sigma))^n\,] \quad (A6)$$

$$p(y_{max}) = \frac{n}{\sigma}.(P(y/\sigma))^{n-1}.\, Z(y/\sigma) \quad (A7)$$

in which:

$$Z(y) = \frac{1}{2\pi}\, e^{-y^2/2} \quad (A8)$$

Z(y) is the probability density function of the Gaussian distribution.
Substitution of (A6) into (A1) gives:

$$P_r(\text{failure}) = \frac{nA_o}{\sigma}\, e^{-\lambda K} \int_{-\infty}^{+\infty} (P(y/\sigma))^{n-1}.Z(y/\sigma).e^{\lambda y}\, dy \quad (A9)$$

Replacing y/σ by u yields:

$$P_r(\text{failure}) = A_o e^{-\lambda K}.f(n,\lambda\sigma)$$

$$f(n,\lambda\sigma) = n.\int_{-\infty}^{+\infty} (P(u))^{n-1}.Z(u).e^{\lambda\sigma.u}du$$

The function $f(n,\lambda\sigma)$ is calculated numerically and given in Figure 18.
More details are given by Bakker (1981).

CHAPTER 160

A New Design Method of Rubble Mound Structures

Cheong-Ro Ryu[1] and Toru Sawaragi[2]

Abstract

A new design method of rubble mound structures with stability and wave control consideration is proposed, by which the reduction of wave reflection and run-up and increase in rubble stability are assured under the given wave conditions. Wave control and stability increasing functions due to change of the slope shape of rubble mound structures are discussed on the basis of the experimental results for regular and irregular waves.

The new design formula developed here considered the allowable percentage of damage and the wave grouping effects on rubble stability using a new assumption of the mean run-sum as an index of the irregular wave force. The run-sum is defined as the energy sum of a run satisfying a critical wave condition and the mean run-sum is the mean of run-sum for a irregular wave train.

1. Introduction

The selection of statistic design wave height in irregular waves is the most important problem in the design of rubble mound structures using the conventional design formulas. The problem mainly occurs due to the irregularities of ocean waves well known as the spectrum shapes and the grouping characteristics etc.. The effects of irregularity on the stability of rubble monnd structures were pointed out by Johnson et al.(1978) and Sawaragi et al.(1984 and 1985) as an important external force index that should be considered in the design. Furthermore, the stability will depend not only on the wave height but also on the slope controling wave breaking conditions which is greatly affected by the interaction of successive waves and wave period.

The destruction process of rubble mound structures shows a tendency to form a stable equilibrium slope under the given condition. This means that the stability increases due to the formation of equilibrium slope. It is desirable to use a berm type composite slope at the initial design stage for the ease of construction, and is important in a optimal design concept with allowable failure ratio.

Ryu(1984) and Ryu et al.(1986) stressed the reflected wave problems for a calm sea and the reduction of run-up correspond to the necessity

1) Assistant Professor, Department of Ocean Engineering, National Fisheries University of Pusan, Pusan, 608 Korea.
2) Professor, Department of Civil Engineering, Osaka University, Osaka, Japan.

of construction of lower crown-height in the design of coastal structures with an optimal design concept. Considering those irregularity effects on the stability and the reduction of wave reflection and run-up, Sawaragi et al.(1985) and Ryu et al.(1986) developed the design formula introducing the irregular wave force index such as the mean run-sum, but still the formula has a problem that the design rubble weight must be calculated by every design formula for every slope.

In this paper, the characteristics on the reduction of wave reflection and wave run-up, and stability increasing functions by the change of the slope shape are studied through model tests, and new design formulas are developed for the uniform slopes that can apply an universal formula to every slope and for the optimal composite slope considered wave control and stability increasing functions. The new design formulas have considered the allowable failure ratio and the irregularity effects including wave period and wave grouping effects on the stability of rubble mound structures with the conception of the mean run-sum of the conditional run of modified surf-similarity parameter under the condition of significant wave height.

2. Model experiments

A wave tank of 30m long, 70cm wide, and 95cm height was used in the present experiments. An irregular wave generator is installed at an end of the tank. For all experiments, characteristic dimensions of structures with uniform and composite slopes shown as Fig.1 were selected as specified in Table 1. Wave height is initially set at less than 3cm and then it increase until 100% destruction of rubble mound results.

For the test of the sensitivity of rubble mound structures to the wave grouping and other irregularity parameters, an irregular wave simulation technique of the impulse response function method is used. It is basically the same as the method of Kimura(1976) and the spectrum shape of irregular waves can be arbitrarily controlled. The frequency spectrum of ocean waves is normally expressed as:

$$S(f) = S(f_p)\left(\frac{f}{f_p}\right)^{-m} \exp\left[\frac{m}{n}\left\{1 - \left(\frac{f}{f_p}\right)^{-n}\right\}\right] \qquad (1)$$

r_a : thickness of revetment, h_0 : water depth at the toe of breakwater,
* : the composite slope configuration examined under the irregular waves.

where f_p is the peak frequency; m and n are the constants which specify the spectrum shape. The combinations of peak frequency and shape parameters used in this study are also listed in Table 1. Using these basic irregular waves, 200 cases of stability experiments were carried out, and the destruction process and the wave motions on the slope are pictured and analyzed by 16mm high speed cine camera(50 frame/sec) and analyzer.

For the measurement of the water surface elevation in the presence of the breakwaters, the capacity type wave gauges were located at 2cm intervals along them. The reflection coefficient was estimated by the Healy's method under the regular wave conditions, while the two point measuring method proposed by Goda et al.(1976) was used to obtain the reflection coefficient under the irregular wave conditions. The wave run-up and run-down were measured by a run-up meter set on the slope surface. After digitizing all the data of water surface elevation recorded in an analog data recorder, the individual wave analysis and the spectral analysis methods were applied for the investigation of hydraulic characteristics on the slopes.

3. Characteristics of irregular waves

3.1 Reliability of generated waves

Spectrum shape of all experimental waves were in good agreement with those of expected waves given in Table 1. For the probability distribution of wave heights, periods and surf-similarity parameters, experimental and well-known theoretical results on the statistics of ocean waves coincide fairly well. As for the ascertain of the statistical reliability of generated waves and related discussions, readers are referred to Ryu(1984) or Sawaragi et al.(1985).

Fig.2 shows the occurrence probability of run-length of higher waves $j(\ j=1,2,3,\ldots\ldots,\infty\ )$ for the present data, reported field data and predicted results by the well-known stochastic process. The present data is the mean of 200 experimental cases of irregular waves, and field data are referred from the results analyzed by Burcharth(1980) and Rye(1974). The grouping characteristics of experimental waves in the study satisfied also with that of the field data. From these results, the model irregular waves are judged to be satisfactorily simulated the ocean wave trains.

3.2 Mean run-length and mean run-sum

The effects of grouping waves on the stability of coastal structures were considered with the run-length of higher waves by Johnson et al.(1978). However, the effects of wave period and resonance condition on the stability have been verified as a non-negligible one by Sawaragi et al.(1983), Bruun et al.(1978) and many other researchers. Considering these effects, in the study, a new irregularity parameter is proposed by the comparative study of correlations between the irregularity parameters for various definitions of the run, and its significancy is verified by applying to the representation of the stability of rubble mound structures. The new grouping parameter finally used here is a conditional run of ξ_o^* under the condition of critical wave height H_c same as Sawaragi et al.(1985), where ξ_o^* means the relative surf-similarity parameter

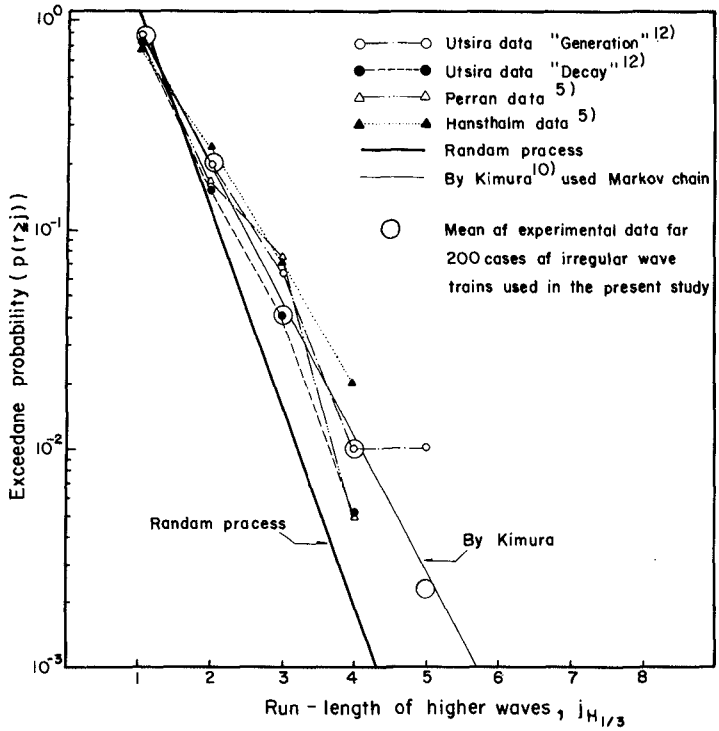

Fig. 2 The occurrence probability of run-length j of higher waves.

such as:

$$\xi_o^* = \frac{\xi}{\xi_o} = \frac{\tan\theta \,/\sqrt{H/L_o}}{\tan\theta \,/\sqrt{(H/L_o)_{max}}} \qquad (2)$$

where θ is the slope of the structures, H the wave height, L_o the deep sea wave length, and subscript max the maximum wave. As for the detail discussions of the run, readers are referred to Sawaragi et al.(1985).

Mean run-length of the run have the linear relationship with the spectrum peakedness parameter Q_p. As the run-length is only the number of group formed waves, it is difficult to introduce the run-length into the design formula as a external force parameter. Hence, a new conception of run-sum is proposed in the study, where the run-sum is defined as the energy-sum of grouped waves. The mean run-sum(E_{sum}) is the mean of run-sum in a irregular wave train expressed as:

$$E_{sum} = \frac{1}{8} \rho_w g \sum_{k=1}^{\infty} H_k \,/ \sum_{j=1}^{\infty} N_j \qquad (3)$$

where N_j is the numbers of run-length j(j=1,2,3,...,∞), H_k(k=1,2,3,..., ∞) denote the k-th wave height of group formed waves in a wave trian, ρ_w is the density of sea water and g is the acceleration of gravity. From the author's another study results on the relations among the mean run-sum, the mean run-length and the spectrum peakedness parameter Q_p , we can estimate the E_{sum} by the following equation(Sawaragi et al.(1985)).

$$E_{sum\ j}(\xi_o^*/H_c) = \rho_w g H_c^3 (0.04Q_p + 0.13), \text{ for } H_c = H_{1/3} \quad (4)$$

$$Q_p = \frac{2}{m_o^2} \int_o^\infty f\ S^2(f)df \quad (5)$$

where, $m_o = \int_o^\infty S(f)df$

4. Effects of the friction coefficient and the slope on the stability

4.1 The effect of friction coefficient

The author(1983,1984), Losada and Gimenez-Gurto(1979), Günbak et al. (1983), Brunn et al.(1976,1978) and Ahrens(1975,1981) pointed out the wave period effects on the stability as a important factor in design. And they reported same tendency of results that the stability number N_s varied with surf-similarity parameter ξ or wave steepness, and the minimum N_s was appeared in the range of $2<\xi<3$. Ryu(1984) suggested the parameter ξ_o^* to present the stability with a universal stability curve for the various slopes instead of ξ because ξ for the minimum point of N_s changed by mainly due to the slope angle.

However, the value of stability number including minimum N_s varies with the change of the initial slope and damage ratio. If this problem can not be improved, the design considering the wave period effects on the stability must be done by using the every stability curve for the every slope. This problem occurs, because the friction coefficient and the slope angle is not included in the stability number indicated as following:

$$N_s = \frac{\gamma_w^{1/3} H_{D(\%)}}{(\gamma_r/\gamma_w - 1) W_a^{1/3}} \quad (6)$$

where γ_r and γ_w are specific weights of rubbles and water, $H_D(\%)$ is the design wave height for the failure ratio in percent, W_a the weight of rubble unit, θ the slope angle, and K_D the stability coefficient in the Hudson's formula(1959).

To estimate the effect of friction coefficient on the stability , the experiments on the variation of friction coefficient was carried out for various armour materials such as quarry stone(W_a=30g, 50g), concrete cube(W_a=100g), and tetrapod(W_a=100g). 50 times of experiments for every materials are repeatedly carried out. The friction coefficient f is

estimated by the relation of

$$f = \tan \phi \tag{7}$$

where ϕ is the repose angle of materials in the water.

As a results, obtained the mean friction coefficients of 1.09, 1.28 and 1.42 for the quarry stone, concrete cube and tetrapod respectively , and the standard deviation was 0.1 for all materials.

On the other hand, when the hydrodynamic force act upon an armour unit, the variance of the destructive force F according tothe change of the slope can estimate by the following equation:

$$F = \left(1 - \frac{\rho_w}{\rho_r} \right) W_a \left(f \cos\theta - \sin\theta \right) \tag{8}$$

From Eq.(8), the calculated results of nondimensional destructive force F/W_a due to the change of relative slope($\tan\theta/\tan\phi$) are shown as Fig.3. In the figure, the correlation between two parameters has almost linear relation regardless the change of the friction coefficient. From the Fig.3, the effects of the friction coefficient and that of slope angle can estimate by using the linear relation.

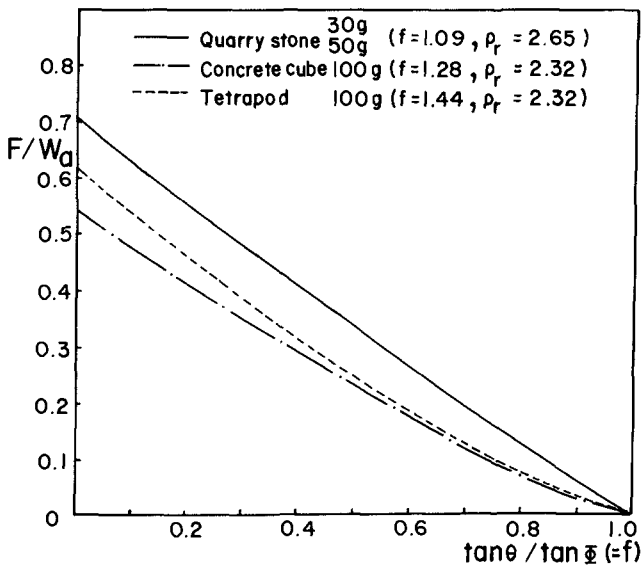

Fig. 3 Variation of the destructive force due to change of slopes.

4.2 The effect of slope angle

The effect of relative slope angle on the stability is considered using the modified stability number N_S' as shown as equation (9) from the linear relation of Fig.3.

$$N_s' = N_s \cdot \frac{\tan\theta}{\tan\phi} \tag{9}$$

Fig.4 corresponds to the correlation between modified stability number and ξ_o^* using the results for regular waves. In the figure, the variation of N_s' by ξ_o^* shows a similar curve regardless the difference of initial slopes for the same ratio of destruction. The minimum N_s' is appeared in the range of $1.5<\xi_o^*<2.5$ and the point of ξ_o^* shown the minimum N_s' is shifted to smaller region according to the progress of destruction. The destruction ratio D(%) is defined as:

$$D = \left(\frac{A_f}{A_o}\right) \times 100 \tag{10}$$

where A_f is the destructed volume of the cover layer and A_o is the destructed volume where the destruction reaches the core layer. The physical meaning of this failure ratio was discussed in the previous work of the author(1983). This shifting of the minimum N_s' is occured caused by the change of the local slope at the destructed area during the formation of equilibrium slope. However, the stability is not correctly presented, the most convenient curves are obtained to consider the wave period effects by using the monochromatic wave conception such as the design wave height and period.

4.3 Equilibrium slope

The characteristics of equilibrium slope formation due to severe waves are important in designing rubble mound structures. For the quantitative discussion of the equilibrium slope, its characteristic length is defined as shown in Fig. 1(b).

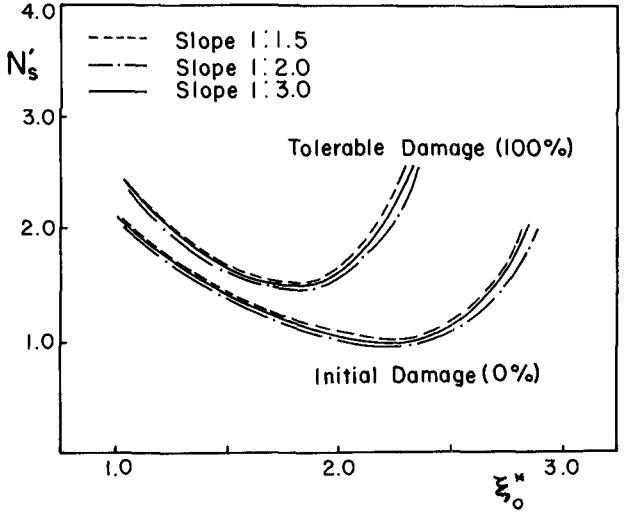

Fig. 4 $N_s' - \xi_o^*$ curves for various slopes.

Since θ_1, θ_2 and θ_3 vary depending on the characteristic depth and width of equilibrium slope, it is necessary first to discuss the width and the depth of berm in an equilibrium slope. Ryu and Sawaragi(1986) discussed these, and as a result, the berm depth and the berm width of equilibrium slopes are formulated as:

$$\left.\begin{aligned} 0.4 \leq h_1/H \leq 0.5 \\ 0.9 \leq h_2/H \leq 1.1 \end{aligned}\right\} \tag{11}$$

$$\frac{l_B}{L_{o\max}} = 2.075 \frac{H_{1/3}}{L_{o1/3}} + 0.04 \tag{12}$$

where h_1 is the minimum water depth of the berm, h_2 the maximum of that, H the incident wave height for the regular wave, l_B the berm width; L_o the deep sea wave length, and the subscripts max and 1/3 denote the maximum wave and the significant wave respectively.

From the Eqs.(11) and (12), rubble mound structures with composite slopes are modelled simulating the characteristics of equilibrium slope under the conditions of regular and irregular waves, and experiments on the stability and the hydraulic characteristics such as reflection and run-up on the slope are carried out under the condition of Table 1 as well as for the uniform slopes.

5. Wave control and stability increasing functions of the composite slope

5.1 Stability increasing function

To applicate the characteristics of Fig. 4 to the presentation of stability for irregular waves, normalized the mean run-sum by the characteristic length of armour unit and relative slope. It is assumed as a index of irregular wave force, and the variation of damage ratio is investigated by the index. Fig. 5 shows the results. In the figure, black circles denote the experimental data for the composite slope and white symbols are that for the uniform slopes.

Although the difference of damage ratio for the same irregular wave force index between the uniform and composite slopes is occured caused by the stability increasing functions on the composite slope. The significant difference is not appeared due to the variation of the slope for the uniform slopes. It means that the index is a very useful and reasonable parameter to present the stability of rubble mound structures under the irregular wave condition as well as the regular wave. From the Fig.5, the stability increasing characteristics of the composite slope is also clarified for the irregular wave. As for the detail discussions of stability increasing mechanism under the regular wave condition, readers are referred to Ryu and Sawaragi(1986).

5.2 Wave control function

If the equilibrium slope is decided and constructed as a shape of rubble mound structures as the initial design stage, the stability is increased more than 50% comparing the stability for the uniform slope, but how is the reflection and the run-up on the slope.

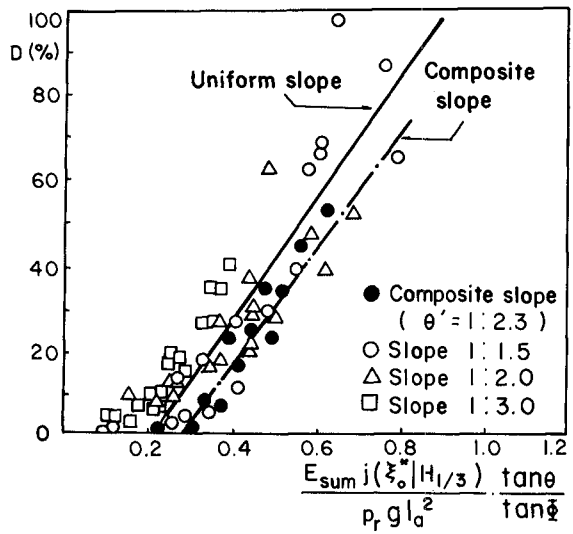

Fig.5 The relations of relative E_{sum} and percentage failure ratio(D%).

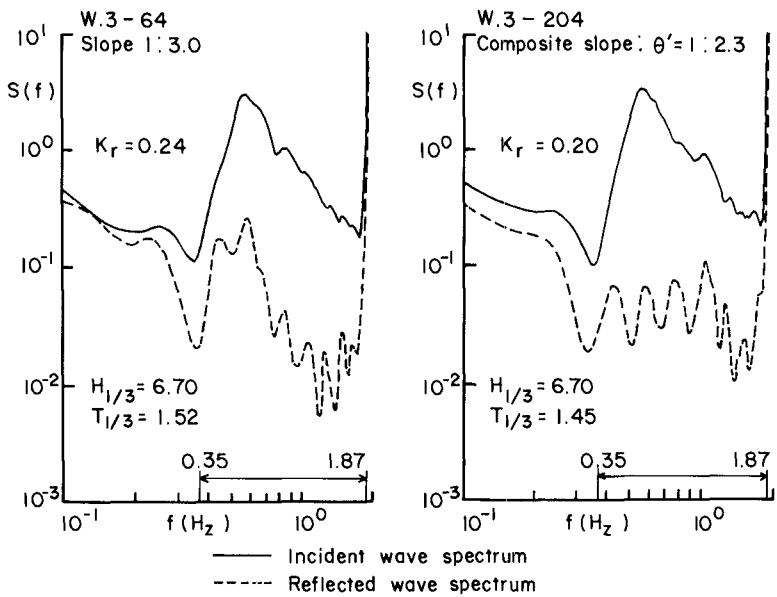

Fig.6 The reflection control function of the composite slope by irregular waves.

The reduction of reflection coefficient and run-up are very important for a calm sea and a low crest height respectively. Ryu and Sawaragi (1986) discussed the wave control functions according to the change of relative depth and width of the berm of composite slope. As a results, it is clarified that the reflection coefficient varies with the berm width l_B and depth h_B, and the minimum value of K_r is always appeared under the condition of $l_B/L_o = 0.2$ and $H/2 < h_B < H$. If the optimum composite slope is selected, the reflection coefficient decreases more than 50%, the run-up height decreases about 10%, and the run-down height decreases about 20-50% comparing the results for the uniform slopes. As for the detail discussion of the reduction mechanisms, readers are referred to Ryu and Sawaragi(1986).

The reflection characteristics of irregular waves on the uniform and composite slopes are now investigated to examine the applicability of the results for regular waves. Fig.6 shows examples of the incident and the reflected wave spectra on an uniform slope and on a composite slope. The reflection coefficient on the composite slope are smaller than that on the uniform slopes. It is noted, however, that the equivalent slope of the composite slope is 1/2.3, which is steeper than the uniform slope 1/3.

As is seen from the spectrum of reflected waves, the predominent frequency can not be identified in case of the composite slope while it appears in case of the uniform slope, being almost the same as that of incident wave spectrum. From the fact that the composite slopes scattered frequency spectral density of reflected waves, it can be stated that the reflection control function of composite slopes for the irregular waves is basically same as for the regular waves.

From the wave control and stability increasing functions of the composite slope, the author emphasize the necessity of composite slope for the constructing of the optimal rubble mound structure.

6. A new design method for the irregular waves

6.1 A new design formula

From the correlation between the mean run-sum and spectrum peakedness parameter and Fig.5, the design rubble weight can be estimated by the following steps. The best fitting line for the variance of destruction ratio due to the irregular wave force from the Fig.5 can be derived empirically as:

$$D(\%) = 153.8\left[\frac{E_{sum}\, j(\xi_o^*|H_{1/3})}{\rho_r\, g\, l_a^2}\,\frac{\tan\theta}{\tan\phi}\right] - 30.1 \qquad (13)$$

for the uniform slopes,

$$D(\%) = 136.4\left[\frac{E_{sum}\, j(\xi_o^*|H_{1/3})}{\rho_r\, g\, l_a^2}\,\frac{\tan\theta'}{\tan\phi}\right] - 36.3 \qquad (14)$$

for the composite slopes.

where θ' is the equivalent slope of the composite slope, and $j(\xi_o^* | H_{1/3})$ denotes the conditional run of ξ_o^* under the condition of significant wave height. To estimate the design weight of a rubble unit, Eq.(13) and (14) can be transformed as;

$$W_a = \rho_r g l_a^3 = \left[\frac{153.8 E_{sum} j(\xi_o^* | H_{1/3})}{(\rho_r g)^{1/3} (D + 30.1)} \frac{\tan\theta}{\tan\phi} \right]^{3/2} \quad (15)$$

for the uniform slopes,

$$W_a = \left[\frac{136.4 E_{sum} j(\xi_o^* | H_{1/3})}{(\rho_r g)^{1/3} (D + 36.3)} \frac{\tan\theta'}{\tan\phi} \right]^{3/2} \quad (16)$$

for the composite slopes.

From the Eqs.(15), (16) and (4), by using the spectrum peakedness parameter Q_p which is calculated directly in the spectrum analysis, we can easily derive the design formula as follows:

$$W_a = \left[\frac{\rho_w g (6.15 Q_p + 20.0)}{(\rho_r g)^{1/3} (D + 30.1)} \frac{\tan\theta}{\tan\phi} \right]^{3/2} H_{1/3}^3 \quad (17)$$

for the uniform slopes,

$$W_a = \left[\frac{\rho_w g (5.46 Q_p + 17.73)}{(\rho_r g)^{1/3} (D + 36.3)} \frac{\tan\theta'}{\tan\phi} \right]^{3/2} H_{1/3}^3 \quad (18)$$

for the composite slopes.

The design formulas Eq.(17) and Eq.(18) reflect the allowable percentage of damage and the wave grouping effects on the rubble stability using a new conception of the mean run-sum as an index of the irregular wave force. For the uniform slopes, the design rubble weight can be calculated by the only a design formula of Eq.(17). It is an epoch-making advantage comparing the author's previous work (Sawaragi et al. (1985)), and only a design formula that introduced or considered directly the irregularity effects of ocean waves and allowable percentage of damage into the design formula until now. Eq.(18) is a design formula for the composite slope, however, this formula can not use to the all type of composite slopes, only can use for the optimal conditions of composite

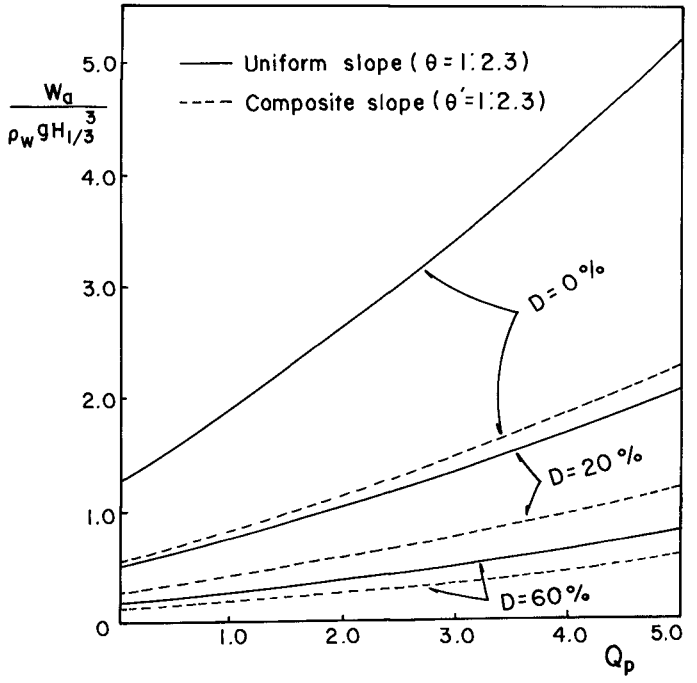

Fig.7 Design example on the variation of ralative design weight according to the spectrum peakedness parameter

slope with stability and wave control consideration such as:

$$\left.\begin{aligned} l_B &= 0.25 L_p \\ 0.4H_{1/3} < h_B &< 0.7H_{1/3} \end{aligned}\right\} \qquad (19)$$

where L_p is the wave length for the peak frequency of the energy spectrum. This condition is a optimal condition of the composite slope in the study of the author(1986).

6.2 Design examples

Using the new design formulas Eqs.(17) and (18), the variation of the relative weight of armour unit is calculated according to the spectrum peakedness parameter considered the allowable damage ratio in percent. Fig. 7 is one example for the uniform slope of 1/2.3 and for the equivalent composite slope of 1/2.3. As can be seen from the fig., the design weight of armour unit becomes heavier due to the increasing of spectrum peakedness parameter and the rubble weight for composite slope becomes more light than that of uniform slope.

Fig. 8 shows the variation of the design weight due to the change of the allowable damage under the design wave conditions of Q_p = 2.5

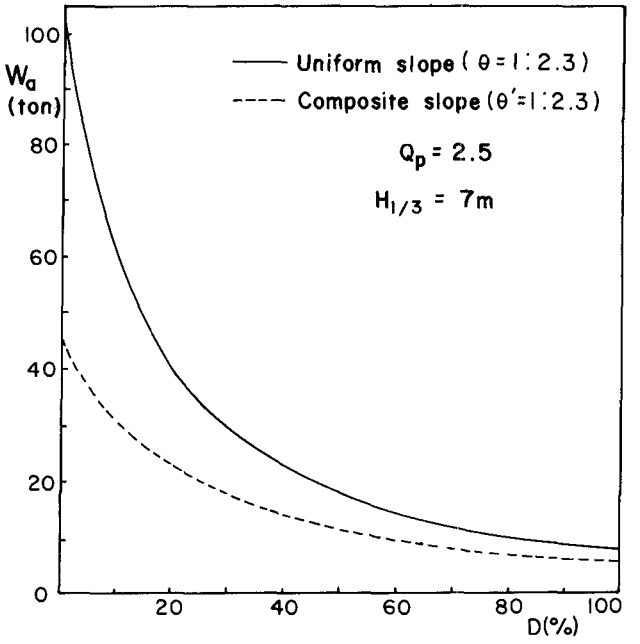

Fig.8 Design example on the variation of design weight according to the allowable failure ratio.

and $H_{1/3}$ =7m for the same slope condition with Fig.7. The design weight becomes heavier according to the decreasing of allowable damage ratio for both slope conditions, and the design weight for the composite slope is half or less of that for the uniform slope in the initial damage(D < 10%). Considering this stability increasing and before mentioned wave control functions, the optimal design concept using the rubble mound with the composite slope should be applied to the design of coastal structures.

7. Conclusions

A new design method is developed based on the results of stability experiments under the regular and irregular wave conditions. The new design formula reflects the effects of spectrum shape, breaking conditions, wave period and wave grouping characteristics on the stability, and can introduce the allowable damage ratio.

The design formula for the uniform slope structure has an advantage comparing the author's previous work, because the present method calculate by a formula for every slope. The importance of the design of composite slope structures is emphasized through the comparative studies of the hydraulic characteristics and the rubble stability on the uniform and composite slopes. A new method of designing composite slope structures with optimum berm width and depth is proposed, by which the reduc-

tion of wave reflection and run-up and increase in rubble stability are assured under the given wave conditions.

CHAPTER 162

REFLECTION OF IRREGULAR WAVES AT PARTIALLY REFLECTING STRUCTURES INCLUDING OBLIQUE WAVE APPROACH

Hans-Joachim Scheffer *

Sören Kohlhase **

1 Introduction and summary

The reflection of irregular seas is increasingly considered in coastal engineering and harbour design as well with respect to wave pattern at the structure and energy dissipation as regarding the dimensioning of structures exposed to waves. It becomes evident that the three-dimensional sea state (oblique wave approach, irregularity of the waves) at partially-reflecting structures of a complex design cannot be described by means of a constant reflection coefficient alone, as is common practice. This is due to the fact that the coefficient is largely frequency-dependent and the physically effective reflection point of the structure cannot be clearly specified.

In the light of this, basic investigations on wave reflection have been performed with different partially-reflecting structures, wave spectra and wave approach angles. In addition to laboratory experiments using both a wave flume and a wave basin, a theoretical solution based on diffraction theory was determined to describe the wave field in the reflection area of various structures. The investigations were restricted to non-breaking wave conditions.

The reflection behaviour of structures is expressed by a complex reflection coefficient, containing two parameters, which have to be determined by model tests.

2 Theory

2.1 Total wave reflection

It has been indicated by BERGER and KOHLHASE (1976) that SOMMERFELD's diffraction theory, which is also applicable to water waves (linear wave motion), describes the wave motion in the reflection area of a totally-reflecting semi-infinite vertical wall for harmonic waves. The theory also explains the so called MACH-effect (local wave height greater than twice of incoming wave height). The modulus of the complex SOMMERFELD solution-function $F(r,\vartheta)$ describes the diffraction coefficient k' as the ratio of the local wave height H_i and the incident wave height H_o

$$F(r,\theta,k) = f(\sigma)\, e^{-ikr\cos(\theta-\theta_o)} + f(\sigma')\, e^{-ikr\cos(\theta+\theta_o)} \qquad (1)$$

$$f(\sigma) = \frac{1+i}{2} \int_{-\infty}^{\sigma} e^{-i\pi t^2/2}\, dt \qquad f(\sigma') = \frac{1+i}{2} \int_{-\infty}^{\sigma'} e^{-i\pi t^2/2}\, dt$$

$$\sigma = 2\sqrt{\frac{kr}{\pi}}\, \sin\left(\frac{\theta-\theta_o}{2}\right) \qquad \sigma' = -2\sqrt{\frac{kr}{\pi}}\, \sin\left(\frac{\theta+\theta_o}{2}\right)$$

$$k' = H_i/H_o = |F(r,\theta,k)| \qquad (2)$$

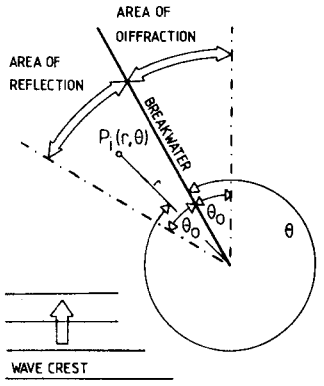

Fig. 1:
Coordinate System of the SOMMERFELD solution

If linear relationships can be assumed (no local wave breaking) and the motion of an irregular wave train can be described as a superposition of harmonic waves of different frequencies and amplitudes (FOURIER representation), this theory can also be applied to the general case of irregular seas.

As described in the literature, the SOMMERFELD solution-function F is a function of the geometrical location r and θ related to the tip of the breakwater (see Figure 1). In general F is dependent upon the relative distance kr (=$2\pi r/L$). Therefore it has a strong frequency characteristic even for constant water depth. The frequency curve for a fixed geometrical location thus describes the transfer function between the local $S_{\eta,i}$ and the uneffected approaching linear wave spectrum $S_{\eta,o}$.

$$F(f) = TF(f) = S_{\eta,i} / S_{\eta,o} \qquad (3)$$

This assumption has been validated by model experiments (GÖTSCHENBERG and SCHEFFER, 1984).

For normal wave approach ($\theta_o = 90°$) and neglecting the contribution of scattered waves ($r \to \infty$) the SOMMERFELD solution gives the k'-values of a standing wave field in which x' represents the distance normal to the structure.

$$k' = |F(\theta_o=90°)| = | e^{ikx'} + e^{-ikx'} | = | 2 \cos (kx') | \qquad (4)$$

2.2 Partial wave reflection

In order to describe the wave motion in front of a partially-reflecting structure the reflection behaviour of the structure is idealized by a two-parametric complex reflection coefficient in a virtual vertical plane trough the seaward base of the structure as shown in Figure 2.

$$K = \kappa e^{-i\phi} \qquad (5)$$

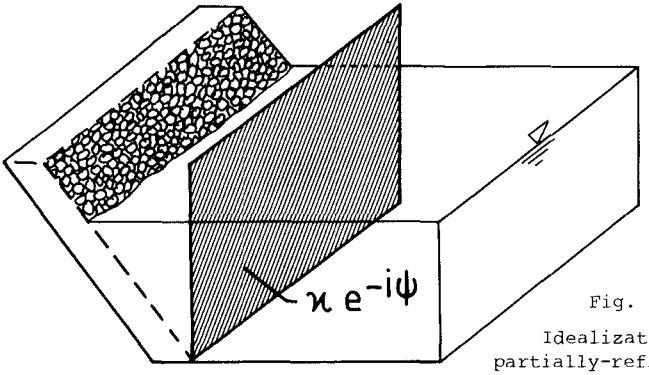

Fig. 2:
Idealization of partially-reflecting structure

In case of normal wave attack (without scattered waves) eq. 4 has to be written

$$k' = | e^{ikx'} + \kappa e^{-i\phi} e^{-ikx'} | \qquad (6)$$

Eq. 6 indicates that the approaching waves leave the seaward region in front of the virtual vertical plane ($x' = 0$) and that waves with reduced amplitudes (κ: amplitude reduction factor) and a phase difference (ϕ: phase angle) enter the region from outside. The phase shift term $e^{-i\phi}$ provides a measure of the distance to the physically effective reflection point.

For the general case of a semi-infinite partially-reflecting structure and oblique wave approach, the wave motion in the reflection region is suggested to be described by an extended SOMMERFELD solution. The terms of the solution (eq. 1) which can be grouped according to the reflected waves, have to be extended by the complex reflection coefficient. In a mathematical sense, the idealization of the structure for calculation of the reflection behaviour as a virtual vertical plane means that the scattered wave term of the incoming waves must be extended with the phase shift term $e^{-i\phi}$. The following solution may be written (SCHEFFER, 1985).

$$
\begin{aligned}
F(r,\theta,k) = \; & e^{-ikr\cos(\theta-\theta_o)} \\
& - e^{-i\phi} f(-\sigma)\, e^{-ikr\cos(\theta-\theta_o)} \\
& + \kappa\, e^{-i\phi}\, e^{-ikr\cos(\theta+\theta_o)} \\
& - \kappa\, e^{-i\phi} f(-\sigma')\, e^{-ikr\cos(\theta+\theta_o)}
\end{aligned}
\qquad (7)
$$

$$
\left.
\begin{aligned}
f(-\sigma') &= 1 - f(\sigma') \\
f(-\sigma) &= 1 - f(\sigma)
\end{aligned}
\right\} \quad \text{see eq. 1}
$$

The frequency characteristic from eq. 7 again represents the transfer function of the linear wave spectrum for a given location and constant water depth.

2.3 Determination of coefficients

Up to now we don't know an adequate theoretical formulation for determining the coefficients of the complex reflection term (eq. 3). For a vertical wave absorber, MADSEN (1983) has presented a theoretical solution for determining the amplitude reduction factor. Similarly to a method applied by MADSEN and WHITE (1976) he linearized the friction term describing the energy loss inside of the absorbing porous front layer using the LORENTZ principle of equivalent work. Both investigations considered only shallow water waves, i.e. the horizontal orbital velocity is independent of the water depth. Furthermore it was not considered by MADSEN (1983) that nearby the structure the vertical water particle velocity is more or less (depending on degree of reflection) predominating. Beyond that, a comparison of his theoretical formulation with model test results shows unneglectable differences.

But according to the results of these investigations, it will be assumed that (for nonbreaking waves) the amplitude reduction factor may be considered to be dependent upon the properties of the structure itself (e.g. porosity, mean stone weight and thickness of the surface layer, revetment slope, water depth and wave length (as a function of wave frequency and water depth)). From the results of our investigations it can be concluded that the amplitude reduction factor is not affected by the wave approach angle. The phase angle ϕ will have the same dependence and will furthermore be strongly affected by the

approach angle.

From extensive model experiments with various partially-reflecting structures (and normal wave attack, GÖTSCHENBERG and SCHEFFER, 1984) it can be concluded that the intersection point between the stillwater level and the impermeable rear slope of the structure can be considered as the physically effective reflection point. From these results SCHEFFER (1985) has set up limiting conditions, which are shown for normal and parallel wave attack in Figure 3. The signed region represents the frequency dependent region of ϕ.

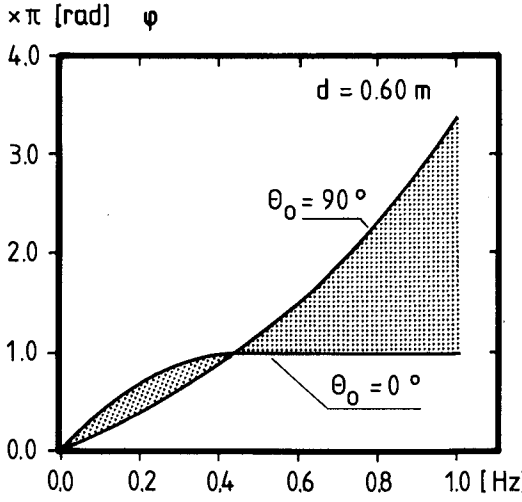

Fig. 3:
Limiting conditions of the phase angle ϕ for oblique wave approach

For the time beeing a determination of both parameters of the complex reflection coefficient by means of hydraulic model tests is recommended. An outline of the conduction of adequate tests is given by GÖTSCHENBERG and SCHEFFER (1984) and SCHEFFER (1985).

3 Model experiments

Within the scope of a basic research programme on the motion of ships at berths, the reflection behaviour of partially-reflecting revetment structures was investigated in a wave flume (length/width/depth = 110/2.0/2.2 m) for normal wave attack and in a wave basin (48/18/1.0 m) for parallel and oblique wave approach. The variation of structural conditions is shown in Figure 4.

The model investigations were carried out comparatively with regular waves and with various theoretically determined wave spectra. Special attention was directed to eliminate the influence of reflected waves and waves re-reflected at the wave maker on the determination of uneffected incident wave spectra. Besides a special arrangement of test performance (see SCHEFFER, 1985), which allows a direct determination of the uneffected approaching wave spectra and the reflection

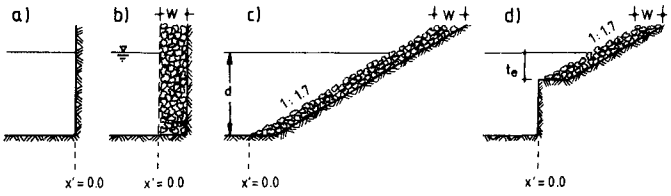

Fig. 4: Reflecting structures investigated

properties by transfer function technique, a 3-wave-gauge-system was installed and the generation technique implied an active absorption control system.

4 Results

4.1 Parameters of reflection coefficient

As a brief summary of the model test results the amplitude reduction factor of a uniform rough slope (see Fig. 4; $t_e = d$) is shown as a function of the wave frequency in Figure 5. The solid line shows the averaged results of tests with different wave spectra. Several tests with regular waves and different wave steepnesses were performed (4-5 wave heights for each frequency). There are no significant differences in the results of regular and irregular wave tests, which confirms the assumed linearity. A slight dependence on the wave steepness can be seen, but there is no clear trend over all wave frequencies within the presented small range of steepnesses, this influence is slight as the influence of the wave length (or for constant water depth the wave frequency).

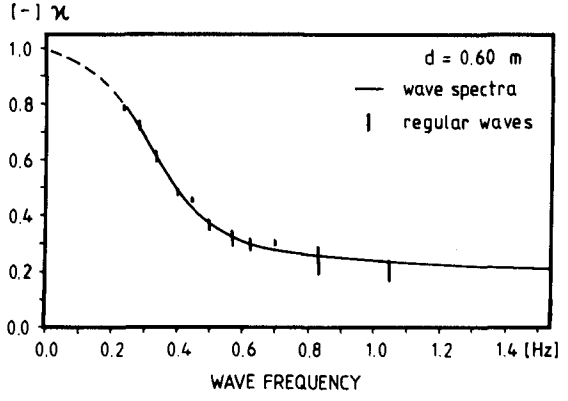

Fig. 5: Amplitude reduction factor κ of the investigated uniform rough slope (Fig. 4c)

The phase angle ϕ of the uniform rough structure is shown in Figure 6 as analyzed from model tests for different wave approach angles. The mentioned limiting conditions shown in Figure 3 are confirmed.

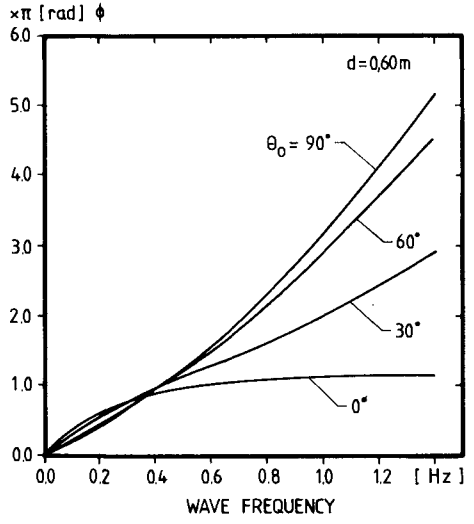

Fig. 6:
Phase angle ϕ of different wave approach directions θ_o

The amplitude reduction factors for all investigated combined structures are shown in Figure 7. The graphs show the interesting effect that in certain frequency range a combined structure will cause a smaller amplitude reduction factor than the continuous slope. This can be explained with the phase shift between the wave proportion reflected at the bottom of the structure at the vertical wall and that one reflected in the upper slope area at the intersection point of stillwater level and impermeable rear slope.

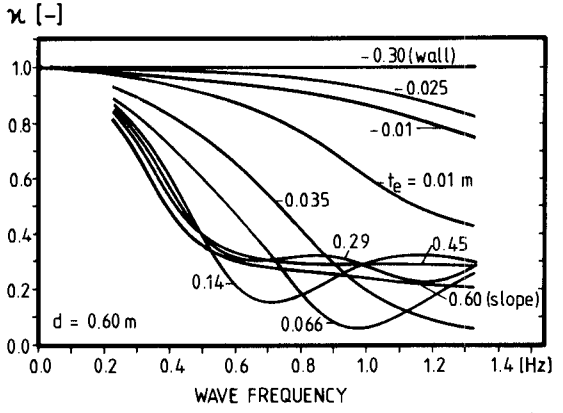

Fig. 7: Measured amplitude reduction factors of various combined structures

4.2 Three-dimensional wave field

As an example of the wide range of experimental results, the transfer function between local linear wave sprectra and uneffected incoming linear wave spectra are shown in Figure 8 for different test alignments. The measured results from different wave spectra and regular waves are presented together with results of theoretical calculations (eq. 7 with measured reflection coefficient, section 4.1).

The results of the investigations show that even the previously inadequate solution to the problem of wave absorption for a wave runnning parallel (θ_o = 0°) to a partially-reflecting revetment can be described. A detailed discussion of this special case may be found by SCHEFFER (1985).

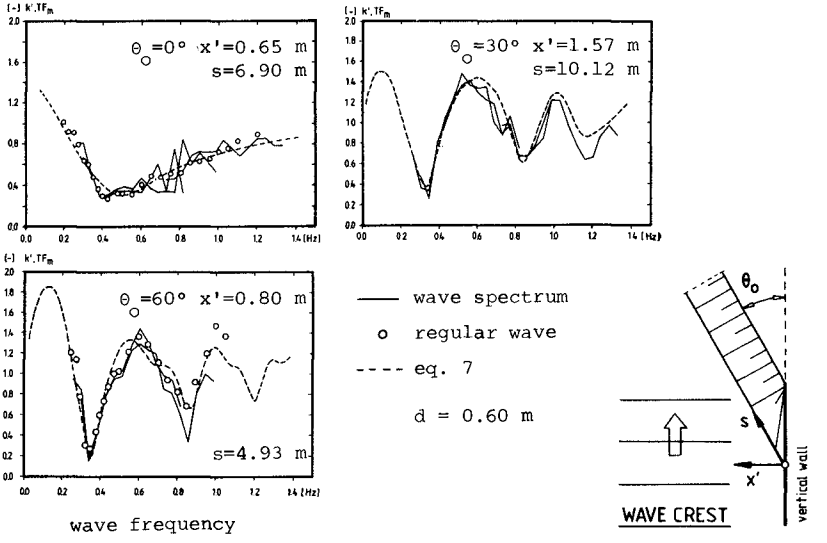

Fig. 8: Measured and calculated k' - values

By way of comparison, Figure 9 shows the wave motion in the reflection area of a totally-reflecting vertical wall (Fig. 9a) and of a partially-reflecting rough slope (t_e = d) (Fig. 9b). In each case, the same time-step of an irregular wave train was calculated. The calculations were carried out in the frequency domain, where the magnitude and the phase of the diffraction coefficient were calculated at each grid point for each component of the 20-frequency component sprectrum adopted here. All components were superimposed true to phase and the inverse FOURIER transfromation gave the wave motion in the time domain as shown in the computer plots.

CHAPTER 163

A UNIQUE INSTRUMENTATION SCHEME FOR MEASURING LOADS IN MODEL DOLOS UNITS

R.D. SCOTT*, D.J. TURCKE** and W.F. BAIRD***

ABSTRACT

An instrumentation scheme for the measurement of the structural response of dolos units in a physical model due to static and quasi-static forces is presented. This was achieved by the development of a specialized armour unit "load cell". The load cell was tested under a variety of loading conditions ranging from static point loads to the complex forces arising from simulated prototype wave action. In the final stage of testing, a model breakwater was constructed and analyzed. The results of these tests demonstrated the accuracy of the developed instrumentation and the feasibility of its use for measurements conducted in physical models. Knowledge of the structural response of armour units in the breakwater environment may be incorporated into an improved overall design procedure for armour units that considers both the hydraulic stability and the structural integrity of the individual units.

1. INTRODUCTION

Concrete armour units have often been employed to protect rubblemound breakwaters and other similar structures exposed to the marine environment. The use of these units has permitted more economic construction of such structures and, in certain cases, has allowed the construction of rubble structures in locations where natural stone of sufficient size could not be found. In recent years, however, extensive damage has occurred to the armour layers of many breakwaters. This damage has often led to a breach of the breakwater structure rendering it only partially effective with finanancial costs for repairs sometimes totalling into millions of dollars. In certain instances, these failures have been attributed to the breakage of the individual concrete armour units and have clearly illustrated the inadequacies of current design procedures for the armour layers of breakwaters. These breakages have occurred predominately in certain

types of armour units, such as the dolos or tetrapod units, but structural failure is not limited to such units. Avoiding the utilization of particular units does not avoid the central problem; there is a complete lack of knowledge regarding the nature and magnitude of the forces occurring in the armour layer of breakwaters.

Concrete armour units are subject to a wide variety of mechanical loads in the breakwater environment, ranging in nature from static to quasi-static to dynamic. There forces arise from a number of sources. Thermal loads are caused by concrete curing and by freeze-thaw action in colder climates. Static forces result from the self-weight of the individual unit and of adjacent units as well as by the settlement of the armour layer and ice action. Quasi-static loads are induced under wave action by the drag and inertial forces during fluid uprush and downrush. A number of dynamic forces may occur due to wave slamming and during the construction phase when the armour units are transported and placed. In cases where the units are in motion on a breakwater subjected to wave action, impulse loads due to inter-unit impact and, potentially, projectile impact can occur. An essential step in the design of an armour layer is to design the individual concrete armour units to withstand these applied loadings. Quantification of the environmental forces has an inherent complexity due to the highly variable interaction between fluid and structure as well as due to the randomness of the armour layer with regard to the location and orientation of the individual units. In an effort to determine these loads, procedures have been reported for measuring loads in model armour units. [Hall, Baird and Turcke (1984); Baird, Hall, Turcke and Chadwick (1983)].

The purpose of this paper is to present a unique instrumentation scheme for measuring the structural response of the dolos unit in a physical model. This was achieved by the development of a special armour unit "load cell". Although this study concentrated on one particular armour unit, the dolos unit, the instrumentation could be readily utilized in a number of different armour unit shapes.

2. LOAD CELL DEVELOPMENT

The method of load measurement that was developed was the result of an experimental program carried out on a previously developed instrumentation scheme that employed small scale physical models composed of an epoxy plastic [Hall, Baird and Turcke (1984); Scott et al. (1985); Scott, Turcke and Hall (1985)]. Out of this initial work, a new "load cell" was developed, based on strain gauge technology, that had much superior load sensitivity and instrumentation protection as compared to the previous instrumentation system. [Scott (1986), Scott, Turcke and Baird (1985)].

This dolos "load cell" consisted of a small physical model employing a distorted section at mid-shank where the instrumentation was located. The key element of the load cell was a strain-gauged, thin-walled aluminum tube. This component was inserted in the mid-shank location between the two halves of a dolos unit fabricated from a steel reinforced epoxy plastic. Unassembled and assembled views of the instrumentation are shown in Figures 1 and 2. The aluminum tube

was designed such that it had the equivalent flexual and torsional rigidity to that of a selected prototype unit properly scaled to the model size. It had twelve strain gauges mounted on its surface which were wired into 3 full bridge circuits. Sufficient clearance was maintained between the two halves to ensure that the internal forces in the dolos shank were completely transferred through the instrumented tube. Lead mass was added to the unit in appropriate locations to compensate for loss of material when holes were bored into the unit for tube placement. Waterproofing was applied to the exterior of the dolos shank to maximize strain gauge protection from water intrusion.

The load cell was calibrated to give directly the bending moments in two orthogonal directions and torque by applying known loads to the instrumented unit and measuring the strain gauge output. This type of procedure is followed in the calibration of any load measuring device.

The instrumentation was developed to determine the structural response of the dolos armour unit at the mid-shank location when subjected to static and quasi-static forces. Its applicability to dynamic loadings must be further examined with tests conducted on instrumented prototype units. As well, the use of such instrumentation implies that failure in the dolos unit occurs due to bending and torque. This has been shown by typical structural failures of such units in prototype and in experimental investigations [Terao et al. (1982)].

Figure 1 - The Instrumentation Prior to Assembly

Figure 2 - Assembled Dolos Load Cell

Load cells of two different sizes were constructed. One had an overall length of 106 mm with a material density of 2500 kg/m^3 while a second dolos unit had a length of 203 mm with a density of 2150 kg/m^3. Signals from the load cells were fed directly into an instrument recorder with a frequency response of 9.5 kHz. The recorded signals were replayed into an analogue to digital (A/D) converter and stored on magnetic disk for visual display and manipulation by computer.

3. TEST PROGRAM AND RESULTS

The instrumented units were put through an extensive series of tests to determine both the accuracy of the measurements of the internal forces and the suitability of the units for use in a hydraulic flume. These tests are briefly summarized in the following sub-sections:

a) Static Point Loads

The initial tests were conducted on the units by restraining the units in a test rig and applying point loads of known magnitude at various locations on the dolosse. The measured responses were compared to theoretical calculations of the internal moments and torques at mid-shank. The load cells displayed high levels of accuracy with the measured forces generally being within 5% of their corresponding theoretical values.

b) Loads Under Self-Weight

The next series of tests were conducted by positioning the load cells in various orientations and measuring the internal forces induced by self-weight alone. Again, the measured response was compared with theoretical computations and the accuracy of the load

cells noted. The load cells were even capable of measuring the internal forces induced due to their over self-weight when resting on a flat surface. A typical example of such a test is shown in Figure 3 and the results are displayed in Table 1. The longer (203 mm) armour unit was consistently more accurate than the smaller unit due to greater accuracy in its manufacture and due to the increased load levels for a unit of this size. Errors in measurement can arise from inaccuracies in dolos and tube fabrication and in small mis-alignments of the strain gauges.

c) Simulated Armour Layer

A section of a model armour layer was constructed in the dry by building a filter layer on a rigid platform sloped at 1:2 over which two layers of 203 mm dolosse were placed. The armour layer was rebuilt entirely for each test with the instrumented unit placed at various locations. Measurements were made of the induced moments and torques then the layer was vibrated, to simulate armour layer settlement, and the forces recorded once again.

Some of the test results are shown in Figure 4 where the measured bending moments have been compared with the theoretical values, scaled to the model size, which would cause concrete cracking in the shank of a 30 tonne dolos unit having the indicated concrete compressive strengths. The results appeared reasonable when considering the randomness of the applied loads and boundary conditions and demonstrated the viability of the instrumentation.

Size (mm)	Horizontal Fluke	Measured Moment (N-mm)	Theoretical Moment (N-mm)	Percent Deviation

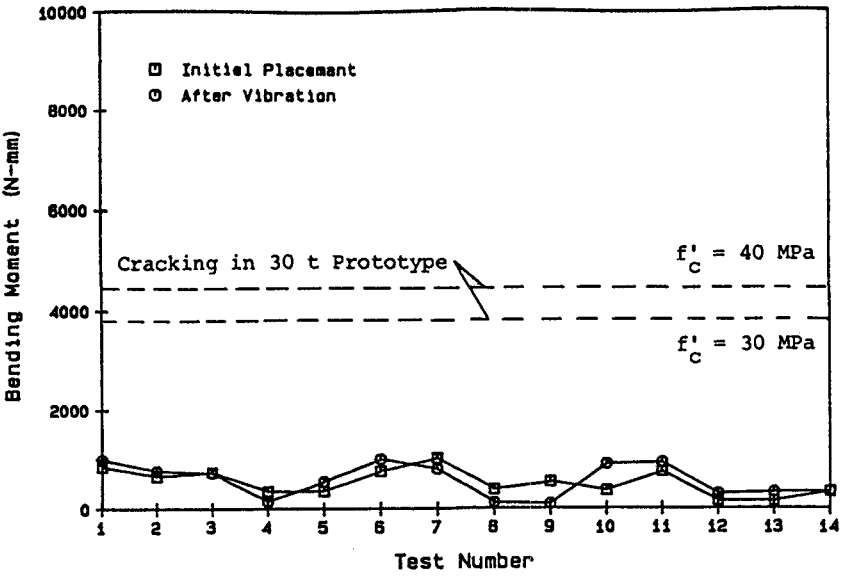

Figure 4 - Typical Results of Simulated Armour Layer

d) Single Dolos in a Hydraulic Flume

The final set of evaluation tests were conducted in a two-dimensional flume using a single instrumented unit rigidly mounted in a specified orientation on a sloped platform, see Figure 5. The purpose of the tests was to examine the change in structural response of the instrumented armour unit due to variations in wave height and dolos location under controlled experimental conditions where the fluid flow was not as complex as which occurs in the armour layer. The dolos unit was placed such that the upper fluke was parallel to the incoming waves and would catch the maximum effect of the wave action.

The load cell was mounted at various locations measured along the slope with respect to the still water level (SWL). Regular waves of three different heights, 15.1 and 19.0 and 24.1 cm, were employed at each test location. The wave period was kept constant at 1.70 seconds for all the tests. At each specified location and wave height, the test was carried out three times.

The typical trace of bending movement versus time displayed in Figure 6 illustrates the excellent correlation of the peak structural response with the wave period. The actual shape of the structural response signal varied depending on the location of the instrumented unit. Placements above and at the SWL gave a response with a strong positive bending movement of short duration. As the unit was placed at lower elevations, the positive movement due to uprush decreased in magnitude while a negative movement due to downrush increased.

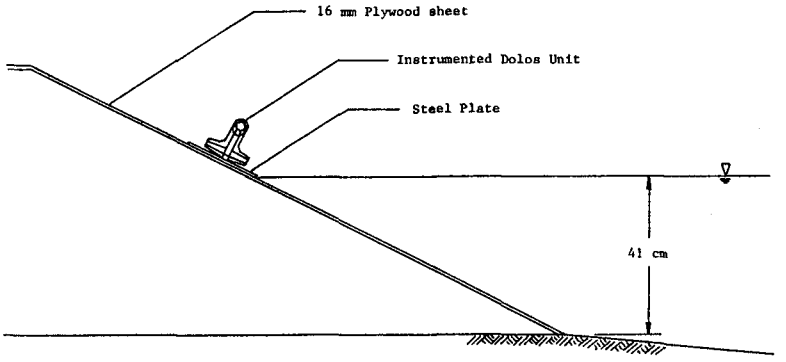

Figure 5 - Single Dolos in Hydraulic Flume

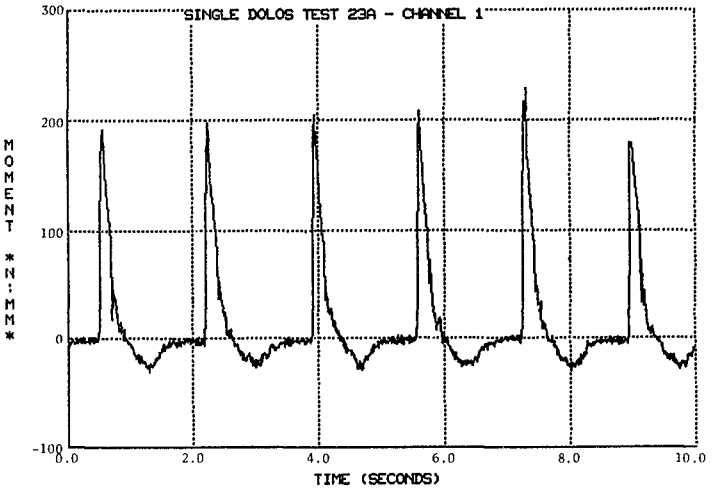

Figure 6 - A Typical Plot of Moment Versus Time

Figure 7 illustrates the variations in peak moment as a function of position for two of the wave heights. It may be noted from the figures that the largest bending moments were measured at positions just below the still water level, a location where many breakwater failures are believed to have been initiated. At any given location, the bending moment increased with increasing wave height.

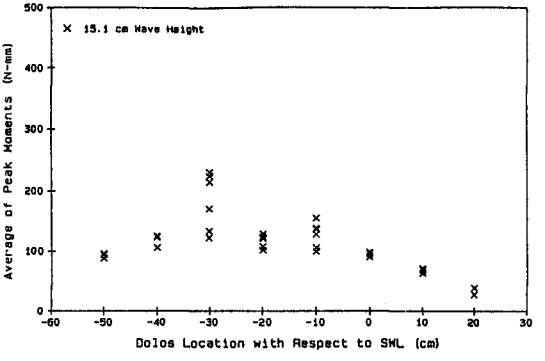

Figure 7 - Effect of Location on Peak Moments - 15.1 cm Wave Height

4. ANALYSIS OF A MODEL BREAKWATER

In the final stage of evaluating the instrumentation system, a model breakwater was constructed and then subjected to simulated prototype wave attack in a two dimensional flume. This exposed the load cell to a wide range of loading conditions ranging from the static loads due to placement in the armour layer to the quasi-static forces created by the fluid motion.

The model breakwater was constructed at a scale of 1:40 in which the model armour units corresponded to 30 tonne dolos units in prototype having a waist ratio of 0.32. The filter layer beneath the dolos armouring consisted of 3 to 30 gram angular stone while the armour layer on the basin side of the breakwater and the toe region was made up of 30 to 60 gram stone. The primary armour layer was formed of 475 gram dolos units of length 106 mm. The dolosse were randomly orientated and dropped into position in an attempt to simulate prototype placement.

Regular waves of height 24 cm and a period of 1.75 seconds were employed in all of the tests, corresponding to waves of 9.5 m height with a period of 11.1 seconds in prototype. The water depth in front of the structure was 40 cm.

The equivalent stability coefficient, K_D, as given by Hudson's formula was approximately 11.0. The armour units did not move under the given conditions.

The instrumented unit was placed at various locations within the armour layer in both the top and bottom layers and both above and below the still water level. A number of waves were allowed to strike the breakwater and the response of the load cell was recorded on an instrument recorder.

A typical response of the instrumented unit to wave action is shown in Figure 8. There was excellent correlation of the peak signal with the wave period and good repeatibility of the results from test to test at any given location. Large stress reversals may occur within the armour unit demonstrating that fatigue may be critical in such units.

Figure 9 displays the static levels of the internal forces as measured prior to wave action in each test. Here, the absolute torque has been plotted against the vector sum of the bending moments. Figure 10 shows a plot of the peak internal forces, which are considerably higher in magnitude than the static forces, as would be expected.

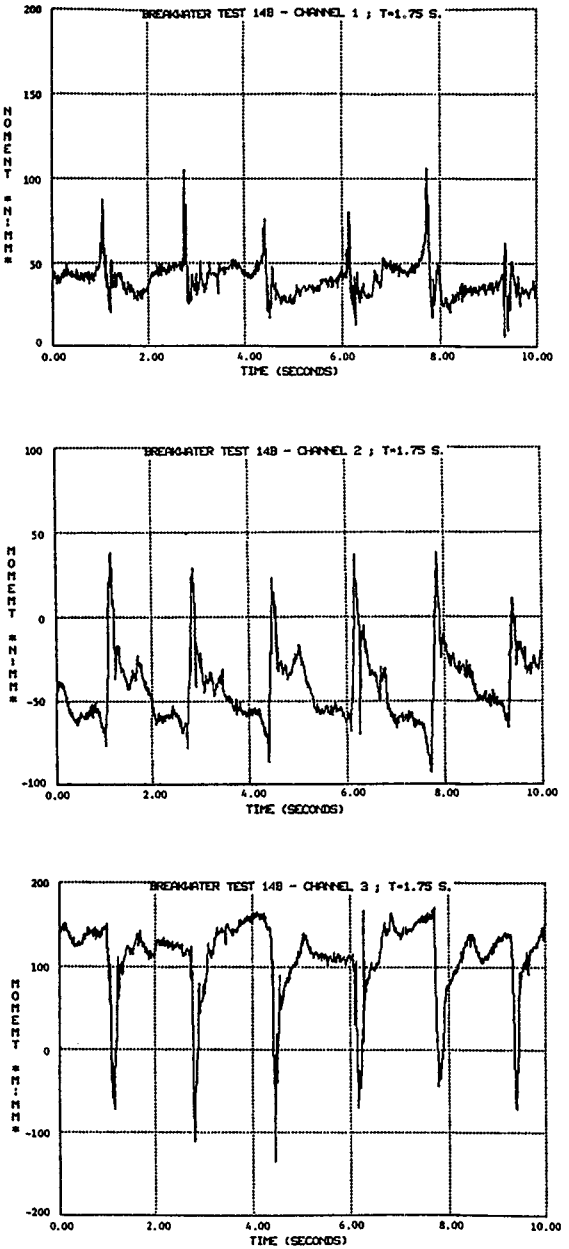

Figure 8 - A Typical Plot of Breakwater Test Results

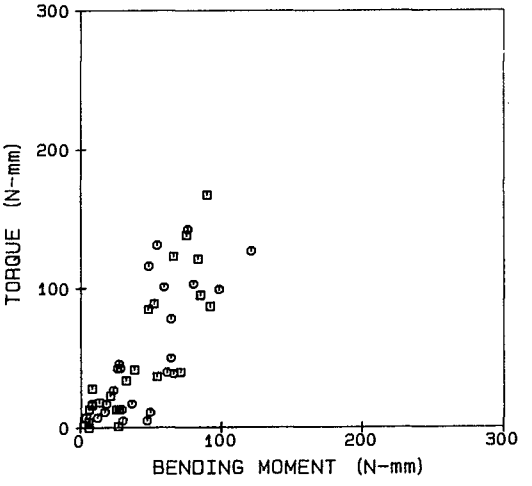

Figure 9 - Static Forces

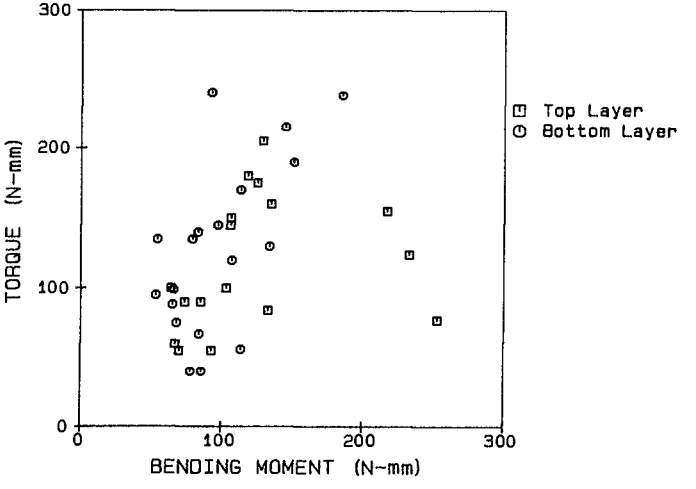

Figure 10 - Peak Internal Forces

CONCLUSIONS

The instrumentation system proved quite capable of measuring the structural response of dolos armour units subjected to static and quasi-static forces in a small scale physical model. The load cell exhibited high sensitivity levels, capable of measuring the response under its own self-weight when resting on a flat surface, but was also quite robust and was able to withstand repeated wave action in a hydraulic flume. The dolos load cells performed with a high degree of reliability and repeatibility throughout the test series.

Various tests were conducted on the instrumented units to evaluate their performance in terms of accuracy of measurement and suitability for use in the hydraulic environment. These tests culminated in the application of the load measurement system to a model rubblemound breakwater armoured with dolosse. Some of the test results were presented but the real value in employing this instrumentation scheme as an analysis or design tool is whether it can determine the structural integrity of armour units in a breakwater. Baird, Scott and Turcke (1986) discusses the incorporation of this instrumentation scheme into an overall design procedure for concrete armour units. Such a procedure must examine scaling of the measured data to prototype and structural failure criteria for the armour units.

CHAPTER 164

CRITICAL RUN-UP HEIGHT ON THE SEA WALL

by Akira Seyama* and Akira Kimura**

ABSTRACT

This study aims at clarifying the difference between irregular and periodic wave run-ups on a slope or a sea wall. Since hydraulic phenomena on a slope are the induced result of an interaction between a running up wave and a back-wash. The run-up height, therefore, has to be investigated in terms of a back-wash properties in addition to run-up wave properties. The experiments which are so designed that waves can run up on a slope without meeting back-wash, were conducted to evaluate the back-wash effects. The relative run-up heights R_r/H_0 of periodic waves in these experiments reached up to about two times as high as those of periodic waves which have the same steepnesses.

The run-up heights of irregular waves on a slope were also investigated experimentally. There are no clear relations between R_r/H_0 and H_0/L_0 as those for periodic waves ordinary observed, and they distributed widely. The upper-most value of R_r/H_0 in the distribution for any H_0/L_0 was almost equal to the value in the above experiment. The uppermost (critical) relative run-up heights R_r/H_0 for the given H_0/L_0 and slope may exist. The differences between the critical and ordinary run-up height of periodic waves on the sea wall were also experimentally investigated. The difference is prominent when a sea wall is set on-shore from the shore-line. It reaches up to about 4 times when a sea wall is set a little on-shore from the shore line.

Some statistical discussion on the probability of the situation in which the critical run-up may be brought about is given at the last part.

1. INTRODUCTION

Traveling time t_d from the maximum run-up point on a slope to the still water level (SWL) is given by Gunbak(1977) as

$$t_d/T = \sqrt{1/\pi} \cdot 1/\cos\alpha \cdot 1/\sqrt{\xi} \qquad (1)$$

where T is a incident wave period, α is an angle of a slope, ξ is the surf similarity parameter. Run-up time t_u to the maximum point from SWL is also given by him as

$$t_u/T = 0.7\ \xi^{-1/2} \qquad (2)$$

The time left t_l for the down-wash front to retreat down to SWL without meeting the next run-up becomes

$$t_l/T = 1 - t_u/T = 1 - 0.7\ \xi^{-1/2} \qquad (3)$$

In the region $\xi < 1.6$, no interaction between run-up and down-wash takes place above SWL on a slope. Roos and Battjes (1976), however, gave a region, $\xi < 2.5$, for the same situation. Consecutive waves in the region $\xi > 1.6 \sim 2.5$, may interact with each other above SWL on a slope more or less.

Although Saville (1962), Van Oorschot et. al. (1968), Battjes (1971), and Gunbak (1977) showed the validity of the Saville's "hypothesis of equivalency" between periodic and irregular wave run-ups in some degree, these values t_d, t_u and t_l may be different from those of irregular waves which have the same zero-up-cross properties. Because the repetitive effect of the back wash to the next run-up is constant in case of periodic wave run-up. On the contrary, due to the random nature, back-wash effect on the next run-up differs wave by wave in case of irregular wave run-up. In this case, waves with the same properties do not bring about the same run-up height, since a deceleration effect of the back-wash differs wave by wave. This random nature of back-washes must be taken into account when irregular wave run-up on a mild slope is investigated.

In this study, irregular wave run-ups are investigated to show that there are large differences between periodic wave run-ups, firstly. Secondly, experiments which is so designed that an incident wave runs up without meeting the back wash, are conducted and the existence of the critical (upper most) value of R_r/H_0 for H_0/L_0 is shown. Thirdly the same technique is used to investigate the critical run-up heights on the sea walls. Lastly the possibility of the chance in which such critical

run-ups may take place is discussed statistically with the theory of wave groups.

(b) f_p=0.6Hz

Fig.1 Distributions of the relative run-up height of the irregular waves

2. IRREGULAR WAVE RUN-UPS

A wave tank used in the experiments was 27m long, 0.75m deep and 0.5m wide with glass side walls. At one end of the tank, an irregular wave generator was furnished (Kimura et al.,1976) and at the other end, a

smooth slope of 1/10 was installed. A channel section of 2m long, 2cm wide and 1 cm deep was mounted into the center of the slope. The run-up wave gauge of a capacitance wire type was so set in the channel that the wire keeps the equal level to the surface of the slope. Wave gauges were set at h=50cm , 45cm, 20cm, 15cm, 10cm, 5cm and 2cm along the slope in which h is water depth. A water depth at the horizontal bottom was 50cm. Five Pierson-Moskowits type wave spectra, the peak frequencies f_p of which were 0.4Hz, 0.6Hz, 0.8Hz, 1.0Hz and 1.2Hz, were simulated. Since the experiments were conducted to investigate the run-up heights in terms of the incident wave properties, one-to-one correspondence between incident and run-up waves is the necessary condition in the present study. Two cases, f_p=0.4Hz and 0.6Hz, were selected among them, which almost fulfilled the condition. On the average, two or more incident waves formed a single run-up in other cases.

Incident wave properties such as zero-up-cross wave height and period were measured at h=20cm (f_p=0.4Hz) and h=15cm (f_p=0.6Hz) respectively. These two points were almost outside of the breaking zones respectively. Measured wave properties were transformed into those for deep water wave by the linear wave theory, e.g. H_0, L_0. Run-up height R_r was measured vertically from SWL to the maximum run-up point of the wave front.

One typical property of the result is that the relation between measured R_r/H_0 and H_0/L_0 in both cases showed wide scattering. No clear relation between them is estimated as in the periodic wave case (Saville,1953). Figure 1 shows frequency distributions of R_r/H_0 in individual narrow ranks of H_0/L_0. The upper and lower bound of the ranks are listed in Table-1. Transformation of irregular waves due to their dispersive nature from the point h=20cm or 15cm where incident waves were measured to the shore-line was observed to be small. Therefore these wide distributions of R_r/H_0 in the figures may depend on a random characteristics of waves.

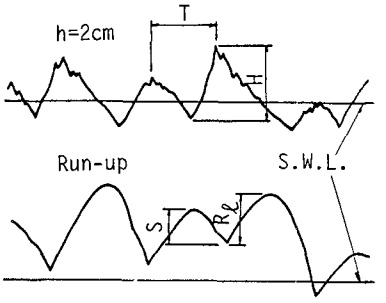

Fig.2 Definition of the properties R_ℓ , S, H and T.

Table-1 Properties of the run-up distributions

f_p=0.4Hz

$H_0/L_0 X10^3$	1-2	2-3	3-4	4-5	5-7
$(H_0/L_0)_i X10^3$	1.52	2.50	3.52	4.48	5.75
R_S/H_0	2.52	1.88	1.58	1.39	1.22
R_r/H_0	2.32	2.13	1.90	1.88	1.77
Prob.$(R_r/H_0>R_S/H_0)$ (%)	38	65	70	72	77

f_p=0.6Hz

$H_0/L_0 X10^3$	3-5	5-7	7-9	9-12	12-20
$(H_0/L_0)_i X10^3$	4.06	6.01	7.94	10.29	14.54
R_S/H_0	1.47	1.20	1.04	0.93	0.74
R_r/H_0	1.94	1.71	1.66	1.54	1.33
Prob.$(R_r/H_0>R_S/H_0)$ (%)	70	77	88	86	87

Another feature is that a significant part of the distribution exceeds the experimental result of periodic waves R_S/H_0 by Saville (i=1/10). The larger H_0/L_0 becomes the higher portion of the data which exceed the Saville's result becomes as listed in Table-1. Nearly 90% of data exceeds the dotted line $R_S/H_0 \sim H_0/L_0$ when $(H_0/L_0)_i$=0.0145 in figure (b).

These wide distributions of R_r/H_0 are presumably brought about by occasionally different effect of back-washes on the next run-up waves.

To investigate the back-wash effects, the relations between the properties in Fig.2 were measured and analyzed. T is an interval of the incident bore crests at h=2cm. This is almost equal to the zero-up-cross wave period measured just outside the breaking zone. H is a height of the bore from its toe to crest. S is a vertical distance from the former crest of the run-up wave to its crossing point with the next run-up. And R_ℓ is a vertical distance from the crossing point to the next run-up wave crest.

Figures in Fig.3 show the averaged relations between measured values. Totally these properties of 1000 waves in the case of f_p=0.4Hz were measured. Measured data were divided into ranks of T and S. The region of the ranks are listed in the figures. Data of H are divided into three groups of the same size in individual ranks of T and S. Symbols in the figures are plotted at the centers of individual ranks. Almost linear relations exist between R_ℓ and H while T is small. And the

slope of their relation increases with decreasing S. Since, the larger S becomes the more back-wash is accelerated on the slope, and the more the next wave which runs up against the back-wash may lose its energy.
The effect of T is indirect on the contrary. The larger T becomes the shorter time interval in which a back-wash acts on the next run-up on the slope reduces. If T is larger than a traveling time of a run-up and -down on the slope, this property gives no effect on the next wave run-up. If T is small, on the contrary, two or more incident waves form a single run-up since the next wave runs up before the former run-up reaches its maximum. In the selected two cases (f_p=0.4Hz and 0.6Hz), these two extreme situations in T were seldom. A run-up wave is, therefore, affected somehow by a back-wash of the former run-up wave. From Fig.3, we may conclude that the smaller the back-wash effect reduces the higher wave runs up. This situations may take place when the former wave height is very small or the time interval of consecutive bores is very large i.e. S is very small or T is very large. The former situation is so called "jump of waves" (Burcharth,1980). Its probability of realization is not negligibly small (Section 5). The latter situation in T is also possible because T has a statistical nature (Longuet-Higgins, 1975, Kimura, 1981 and etc.).

3. CRITICAL RUN-UP HEIGHT

The upper-most (critical) run-up height may take place when run-up wave meets no back-washes on a slope. To investigate the critical run-up height, the facilities shown in Fig.4 was used, which could realize a run-up of waves on a slope with no back-wash effect.

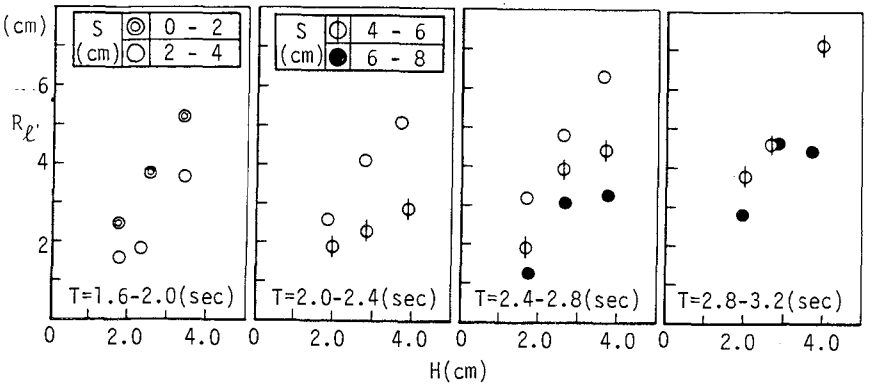

Fig.3 Relation between R_{ℓ} and H.

A water tight wave reflection board which was movable upward, was installed on the slope at h=20cm, (Case-II). A water tight block was put at h=9cm in addition to that for Case-II, and all water shore-side of the block was pumped into the interval between the block and the board, (Case-III). The run-up without these facilities were investigated for comparison, (Case-I). The water depth at the flat bottom was 35cm. Run-up height R was measured vertically from SWL to its maximum run-up point on the slope.

The techniques used in the experiments were as follows. In case-II, the reflection board was removed upward when a water surface of a standing wave just crossed SWL upward at the board. This was the instance when a front of an incident zero-up-cross wave just reached the board. Since shore-side of the board was still water unless the board was removed, the incident zero-up-cross wave propagated and run up on a slope with no effect of the former wave. Although small deformation around wave front was observed, overall deformation due to the discontinuity seemed to be negligibly small within the range of waves used in the present study. In Case-III, a slow oscillation started on the slope when only the shore-side block was removed quickly. The generated wave traveled back and forth within an interval between the slope and the reflection board for a while. The board was removed at the same instance as for Case-II. In addition to the timing in case-II, the timing of the block to remove was so adjusted as a result that the run-up wave just passes

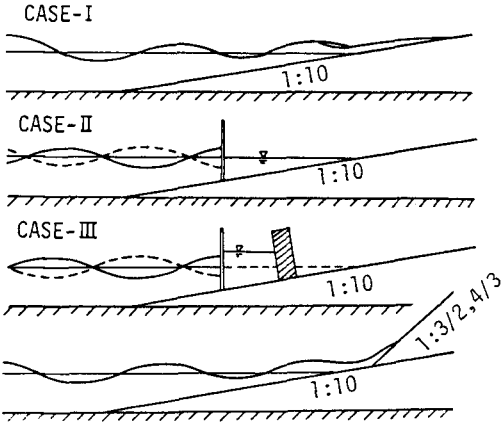

Fig.4 Experimental facilities

over the slow oscillation when it reached the second maximum on the slope. Energy loss of run-up wave due to friction loss on a dry bed might reduce with this technique.

Three different periodic waves T=1.72s, 1.21s and 0.74s were experimented. Wave heights were changed gradually until they started to break in individual cases. Figure 5 shows the relations between experimented values of R/H_0 and H_0/L_0. The solid line shows the result in Case-I. It agrees well with Saville's results.

The broken lines II_1 (T=1.72s), II_2 (T=1.21s) and II_3 (T=0.74s) show the averaged relations between R/H_0 and H_0/L_0 for individual wave periods in Case-11. Individual lines give different relations between R/H_0 and H_0/L_0. R/H_0 keeps an almost constant value where H_0/L_0 is small but decrease quickly when wave starts to break on the slope. In Case-I, plunging or collapsing type break takes place around the shore line. Breaks do not take place, however, when H_0/L_0 is small in Case-II and III. In the larger region of H_0/L_0 than the points where the broken line breaks in individual cases, waves break also and the values of R/H_0 reduce quickly.

Circles in the figure show the relation between R/H_0 and H_0/L_0 for Case-111. The same wave periods and wave heights as in Case-II were used in the experiments. Plotted data form almost the parallel line to those for Case-1. And their values are almost double of those for Case-I for the same H_0/L_0. Incident waves start to break at almost the same value of H_0/L_0 as in Case-II. R/H_0 in the large region of H_0/L_0 also reduces rapidly as in Case-II. The differences between broken lines and circles may not come only from friction loss on the slope. There may be affected

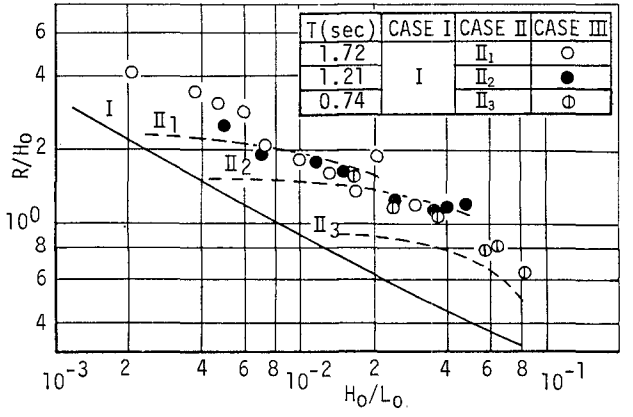

Fig.5 Relation between R/H_0 and H_0/L_0 on the 1/10 slope.

by the slow oscillation in addition, i.e. forward current and apparent water depth induced by this oscillation. These differences may take place in real sea conditions when mean water level changes due to surf beat, for example. Such effects in Case-111 as forward current and apparent water depth change give little change when incident wave properties reach the breaking condition in Case-11 and 1II, since an averaged value of plotted data in Case-III passes through the bends of lines in Case-11. The plotted data in Case-III may give a relation between the upper-most run-up height R/H_0 for H_0/L_0 on the slope of 1/10. The above lines in Fig.1 (a), (b) are the mean relation between R/H_0 and H_0/L_0 for Case-111. These lines almost pass the upper bound of the distributions. Therefore the situations in the Case-I1 and III may take place in irregular wave run-ups. This may be the reason why a large portion of the irregular wave run-ups exceed the values for periodic waves.

4. RUN-UP ON THE SEA WALL

The critical run-up height on a sea wall is investigated in this section using the same techniques in the former section. Two sea walls i=3/2 and 4/3 were used (i is a slope). Run-up height on these sea walls at several locations along the slope (1/10) were measured. Figure 6 shows the relation between relative run-up height R/H_0 of periodic waves on the 4/3 slope and d/L_0 (d is a water depth at toe of the sea wall). The steepness of the incident waves in individual figures are H_0/L_0=0.017 (top), 0.031 (center) and 0.041 (bottom) respectively. Since the wave period (wave length) is constant in each figure, i.e. T=1.72s (top), 1.21s (center) and 0.74s (bottom), d/L_0 practically indicates the water depth at the toe of the sea wall.

Therefore these three figures show practically the change of R/H_0 in terms of water depth. Circles and triangles are the results in Case-1 and 1I respectively. Run-up heights in Case-1 are larger than those for Case-I1 in a offshore region, and gradually decrease with decreasing water depth. The run-up heights for Case-II, on the contrary, keep almost constant value or show a little increasing nature with decreasing water depth unless $d/L_0 < -0.01$. Inequality of plotted values for Case-1 and I1 is reversed a little off the shore-line in individual cases.

Figure 7 shows the relative depth d/L_0 at the reversal points in Fig.6 in terms of H_0/L_0. In the below region of the line, irregular waves may bring about the larger run-up heights than those by periodic waves on the sea wall.

Figure 8 (a),(b) and (c) show the run-up heights on the 3/2 slope. The sea wall was installed (a) at the shore line, (b) 30cm and (c) 50cm on-

shore from the shore line along the slope. The wave periods experimented were 1.72s, 1.21s and 0.74s. In each figure, circles, triangles and circles with an oblique line show that those are the results for Case-I, II and III respectively. The decreasing nature of R/H_0 with respect to H_0/L_0 for Case-I becomes slightly milder than that in Fig.5. Although this tendency reduces with a distance from the shore-line to the sea wall. R/H_0 increases more or less with H_0/L_0 unless waves do not break on the slope in Case-II. When wave start to break, R/H_0 reduce very quickly with H_0/L_0. The upper-most values of R/H_0 are about (a) 2.5, (b) 4.0 and (c) 3.5 times as large as those for Case-I.

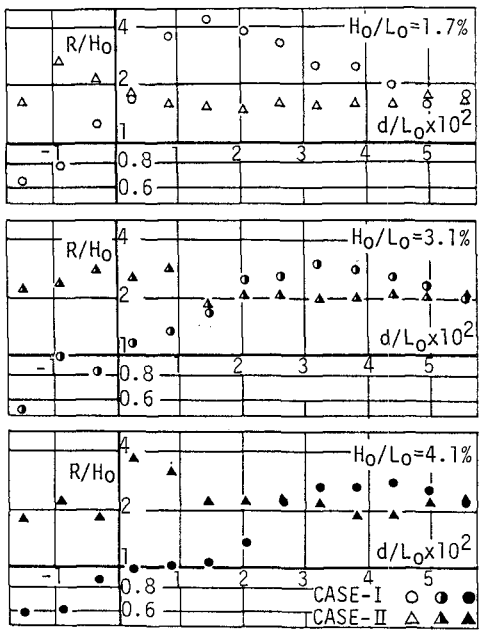

Fig.6 Change in R/H_0 with respect to d/L_0 (sea wall:4/3, slope:1/10)

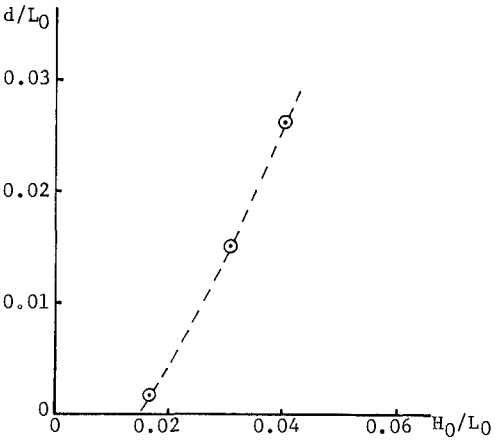

Fig.7 Relative depth at the reversal points of the run-up height.

The relation between R/H_0 and H_0/L_0 for Case-III is different from that for Case-II, however, the maximum R/H_0 value and its H_0/L_0 are almost the same as those for Case-II. The existences of the critical run-up heights shown with the dotted lines in the figures can be presumed.

5. JUMP OF WAVE HEIGHTS

The experiments were so conducted that waves run up without any effects of the back-wash on the slope or sea walls in Sections 3 and 4. And the existences of the critical run-up heights are eventually shown. This situation could practically realize in a real sea condition. For example, when a large wave runs up just after a small wave, i.e. jump of wave heights (Burcharth,1980), the above situation may take place on a slope. Table-2 gives the probability that consecutive wave heights H_1 and H_2 fall in the listed region in the vertical and horizontal column, (Kimura,1980). The correlation coefficient used in the theory is that for the Pierson-Moskowits type irregular waves. Since about 10^4 - 10^5 waves attack on a sea wall within a single storm, mentioned situations may take place with a considerable frequency.

CHAPTER 165

Scale Effects on Stability and Wave Reflection regarding Armor Units

by

Atsuyuki Shimada[1], Toshimi Fujimoto[2], Syozo Saito[3],

Tsutomu Sakakiyama[4], and Hiromaru Hirakuchi[5]

ABSTRACT

In the studies on stability of the armor units and reflection from those, there are some indications on scale effects which are included in the results of small scale experiments. In this study, the fact has been confirmed with large wave flume test, and estimated the critical Reynolds Number where was no scale effect. And by this result on the stability of urmor units, we can evaluated the results in small and middle scale test, and can correct the minimum weight of armor units. So we can design the breakwaters and seawalls rationaly and economically.

However, it has not been confirmed the critical Reynolds Number where the influence of scale effect on reflection became negligible.

1. INTRODUCTION

In recent years, according to enlargement of thermal and atomic power station sited on coastal regions in Japan, breakwaters and seawalls which protect harbour facilities have been constructed in the areas with water depth of more than twenty meters, so it is necessary to design armor units rationaly and economically.

Especially, the concrete Blocks (urmor units) which are used for decreasing the wave force and reflection waves are main structural materials of breakwaters and seawalls, and in deeper areas, many volume of armor units are necessary and the proportion of their cost to the total construction cost is not few.

To design the armor units which are used for coastal structures, it is important to decide the shapes and weight of armor unit considering following three points of view,

---

1),2),3) Principal Research Engineer Structural Hydraulics Section Hydraulics Department Abiko Research Laboratory Central Research Institute of Electric Power Industry.

4),5) Assistant Research Engineer, Current employments are same as above.

(1) the hydraulic characteristics on stability to the wave force and wave reflection
(2) the relation between the shape of armor units and the strength of concrete
(3) the geological characteristic of sea bed soil in the site.

And in respect to the stability on armor units in (1), hitherto, it have been used to estimate the minimum weight of armor units with Hudson's[1] formula. And in this formula, the coefficient K_D was conducted from the result of small scale tests on rubble mound.

However, since he proposed in 1958, now, from the review of actual damage examples, it has been pointed out that the value of K_D had been conservative a little.

And Thomsen[2] et al. (1972) have investigated about scale effects on stability of rubble mound and some kinds of armor units, and they have pointed out the existence. However, there is almost no study about scale effect on stability of armor units which are widely used in Japan. And in the investigation by Alf Torum[3] et al, they have conducted the model test about the revival of damaged breakwater in site. And they reported that there was no scale effect on the deformation of the cross section.

Thus, it has not been obtained to get a general consensus about this theme. And more data about this investigation are needed[4].

We have already investigated the scale effect on stability and reflection of armor units using model tests in small and middle wave flume.

Now, we are going to clarify the hydraulic characteristic of armor units with large wave flume, and to detect the hydraulic range where indluence of scale effect on stability and reflection ratio become negligible. And if the range or criteria of these scale effect are made to clarify, verious results obtained from small model tests will be more applicable.

2. EXPERIMENTAL METHOD AND DIMENSION

The small wave flume is 20m long, 0.6m high and 0.3m wide, and middle wave flume is 77m long 1m high and 0.9m wide. And we have investigated about scale effect in these wave flumes.

The weights of model armor units used in these tests ranged from 16g to 300g. The large wave flume is 205m long, 6m high and 3.4 wide. And it can generate a maximum of 2m wave height.

Figure-1 shows the profile of this flume.

Figure-2 shows an example of cross section model in the test.

The each dimension of model cross section was decided with the scale in proportion to prototype. Three kinds of the armor units were used in the experiment and these weights range from 2kg to 50kg.

The armor units were put at random with two layers thickness.

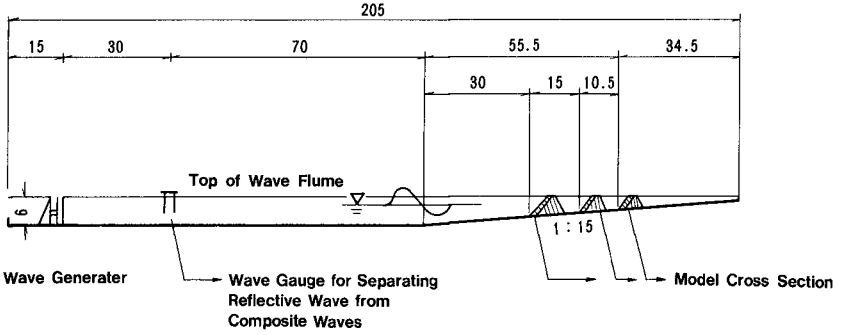

Figure-1 Profile of Large Wave Flume (unit m)

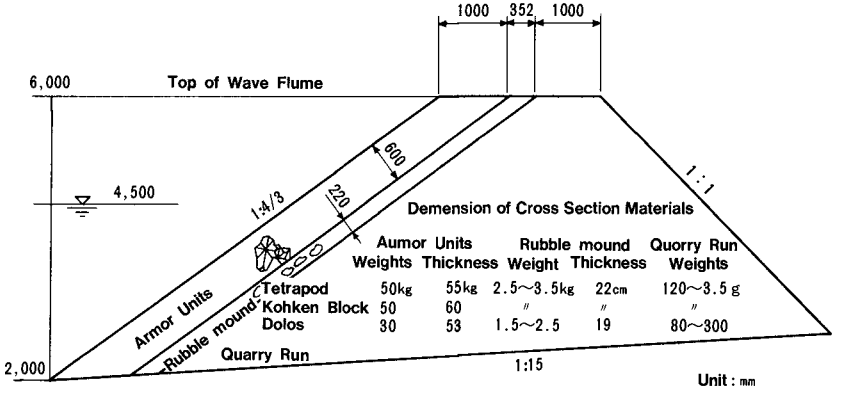

Figure-2 Model Cross Section

Figure-3 shows the shapes of the armor units in the experiment.

The experimental waves are regular waves which are broken at the toe of cross section. To avoid the occurrence of multi-reflection wave in flume, generated waves were stopped in about 2 minutes once a time and were continued to a setting duration. Incident and reflection wave height were measured by the method of separating reflection wave from composite waves at uniform water depth in the flume.

To decide the judgement criteria of the armor units stability, damage percentage was defined as the ratio of removed armor units numbers to the all armor units which were exposed to the wave actions. And the word "removed" means that an armor unit moved over the length of the armor unit height. And using this definition, the removal of up to one armor unit is considered to be zero damage in this experiment. Breaking wave heights Hb which cause 0% and 2% damage were searched in each model cross section.

Table-1 shows conditions of all experiments.
The movements of armor units were observed by video camera and eyes. And run-up heights on surface layer were observed by wave height recorder which was set on the slope.

3. RESULT AND CONSIDERATION

(1) Characteristics of Experimental Wave

The sea bottom slope below model in large flume is 1:15. Before the stability test, characteristics of generated wave were observed.

Figure-4 shows the relation between breaking wave height Hb and breaking depth hb in the large wave flume.

In figure, curves show outline of progressive waves on each sea bottom slope, obtained from general small and middle flume tests.

And dotted points show experimental values in this large flume.

These values show good coincidence and the ratio of Hb/hb are distributed within 0.8 and 1.2..

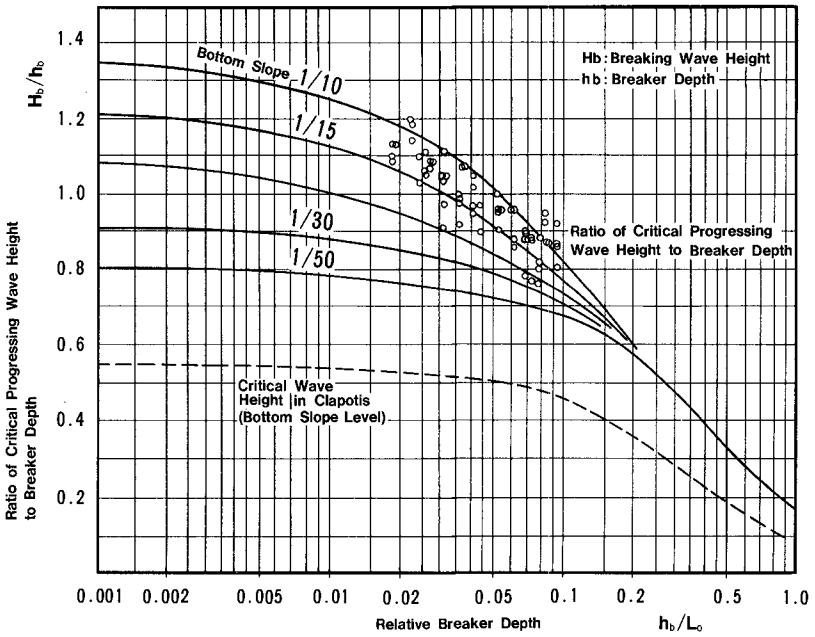

Figure-4 Characteristic of Breaking Wave in the Test

(2) Wave Run Up

Figure-5 shows wave run up heights by which 0% and 2% damages were caused. In figure, curves show the wave run up on smooth surface and the layer covered with armor units at slope of tan θ : 3/4 by the method of the temporary slope which was proposed by T. Saville[6].

Figure-5 shows that the values of wave run up in the experiments are almost below the values in smooth surface but are distributed in fairly higher location than the values in the case of layer covered with armor units. Considering that the curves by Saville's method were obtained from the results in small scale tests, it is recognized that there are scale effects in this behavior.

So it is necessary to consider the relation between the stability of armor units and wave run up.

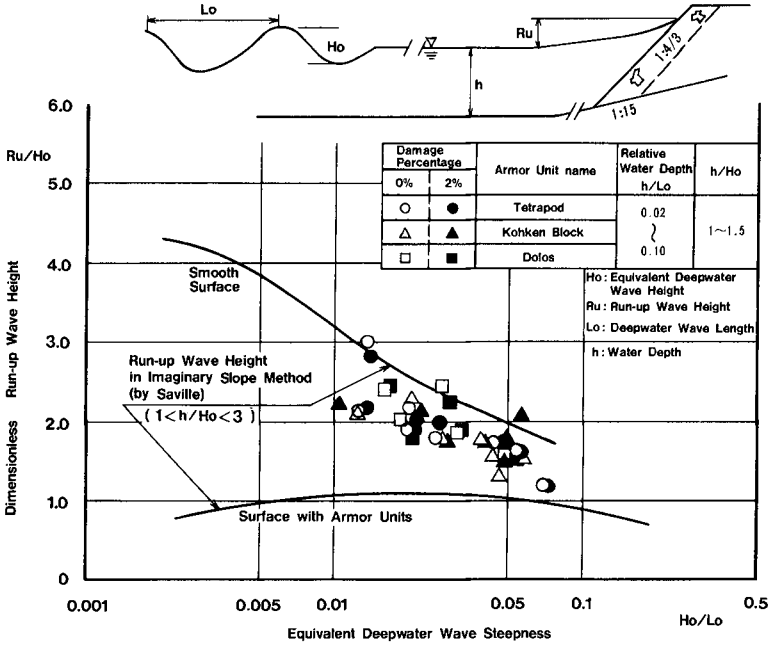

Figure-5 Wave Run-up in the Test Cross Section

(3) Stability of Armor Units

The results of experiments on the scale effect of stability of armor units are shown in Figure-6. The axis of ordinate indicates the stability number Ns. And Ns mean the ratio of wave force which act to

armor units and the resistance force of armor units.

And Ns is difined as following equation.

$$Ns = \frac{Hb \cdot \gamma^{1/3}}{W^{1/3} \cdot (S-1)} \quad \cdots\cdots (1)$$

Where, Hb : breaking wave height at the point where the toe of model section is set after (cm)

γ : the specific weight of the armor units (g/cm^3)

S : the ratio of γ to the specific weight of water

W : the weight of one armor unit (g)

Further, the K_D value in Hudson formula in the case of which cross section slope is θ degree are defined as following equation.

$$K_D = \frac{Ns^3}{\cot \theta} \quad \cdots\cdots (2)$$

The transverse axis indicates the Reynolds Number which show the influence of the force by fluid viscosity around the armor units. In this Reynolds Number, the terms in water particle velocity are estimated first by long wave velocity C: $\sqrt{gh}$, g: gravity acceleration, h: depth, and further, h are displaced by breaking wave height Hb which is nearly equal to h. And the terms of length are estimated by the volume of the armor unit to the one-three power.

So, in this study Reynolds Number are defined as following equation,

$$Re = \left(\frac{\gamma_f}{\mu}\right)\left(\frac{W}{\gamma}\right)^{1/3}\left(\frac{H}{g}\right)^{1/2} \quad \cdots\cdots (3)$$

where, γ_f : the weight in unit volume of water (g/cm^3)

μ : viscosity coefficient of water ($g \cdot sec/cm^2$)

W : the weight of one armor unit (g)

g : gravity acceleration (cm/sec^2)

And wave period T are indicated by nondimensional style, $gT^2/(W/\gamma_f)^{1/3}$. In Figure-6, the results in each kind of armor units which weights range from 16g to 50Kg are ploted.

And the results in smaller than 300g weights have been obtained already from small and middle wave flumes[7].

Figure-6 shows that according to the Reynolds Number increasing, stability Number of each kind of armor units tend upward too, and this feature indicate the scale effect on the stability of armor units. However, where the Reynolds Number take more than nearly 4×10^5, that means the experimental armor unit weights are more than 6.8kg in the case of any armor unit, it is found that the values of Ns approach to a constant value. However, the influence of wave period to the stability of the armor units is not so obvious and as the result, the values of Ns in long waves is smaller rather than in short waves. It is considered that, to this tendency, experimental waves were all limited to the breaking wave at the toe of cross section.

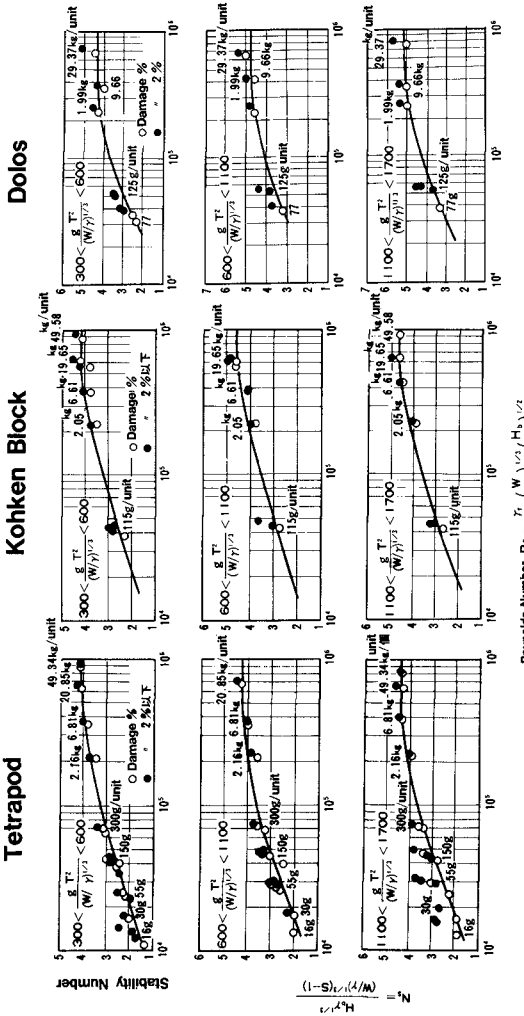

Figure-6 Relation between Stability Number and Reynolds Number

And the long waves breaker at that point are generated in shallower depth than in short period wave breaker. So it is concluded in this study long period wave energy attacking cross section is smaller than short period wave.

Figure-7 shows the stability of each kind of armor units with the expression Hb/D in stead of Stability Number Ns in transverse axis in Figure-6.

Where Hb is breaker height in the stage of stability criteria and D indicates two layers thickness of each armor units. In Figure-7, variable amounts which indicate the scale effect on the each armor units are concentrated on the same curved line.

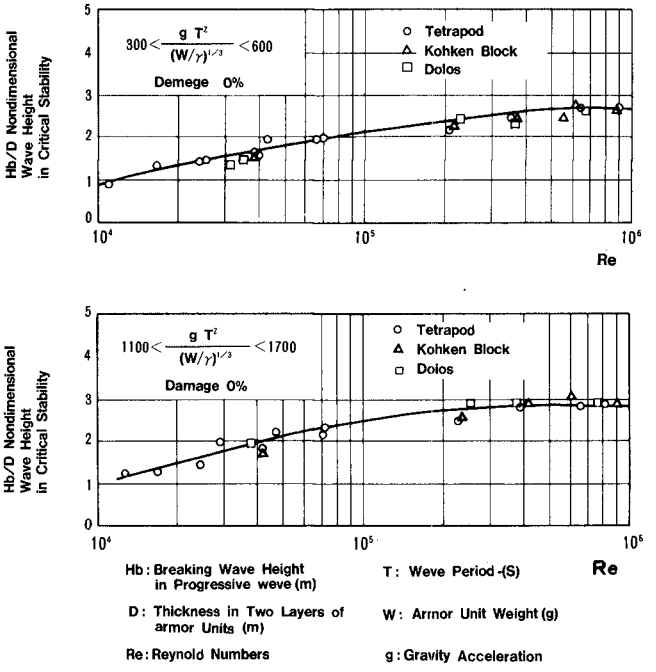

Figure-7 Relation between Reynolds Number and nondimensional wave Height in critical Stability considered Thickness in Two Layers of Armor Units

In this investigation, it was known that the shapes of armor units are connected with the stability of the armor units than that of rubble mound even if interlocking matter were included.

And the value of Hb/D will give the outline in design of the armor units. To give the correct value of Stability Number Ns in prototype from results in small scale experiment.

Figure-8 is presented by rewriting.

Now, Figure-6 and this expression was quoted from Thomsen[2]. For example, if the armor units in weight 100g has been used in test, it will be reasonable in prototype design to take 1.45 times Ns. In Figure-8 the results of rubble mound in CERC are shown, and it's tendency is similar to our results.

And the results of small scale tests will be more applicable by using this result.

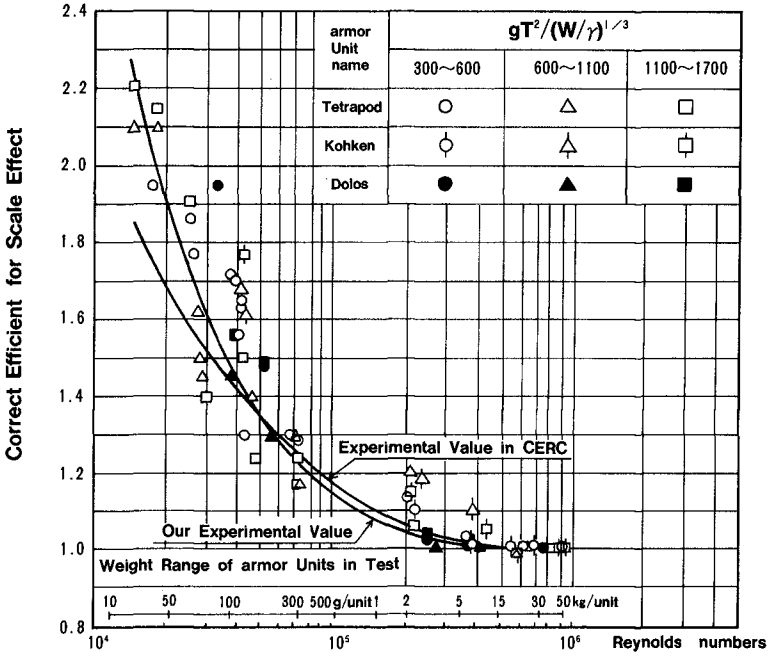

Figure-8 Correct Efficient of Stability number using Re number in no scale Effect

(4) Correction of Coefficient K_D

From experimental investigation on the stability of the armor units by irregular wave[8] which has been conducted by one of authors, it is known that there is a relation shown following equation between regular wave height H and irregular wave significant wave height $H_{1/3}$, which cause the same damage up to several percentage.

that is $H = 1.2\ H_{1/3}$ ..... (4)

And this result is shown in Figure-9.

Now, using this relation, experimental results are revised, and the K_D, coefficient in Hudson Formula (1), are corrected. And the result of correction are shown in Table-2. According to Table-2, it is expected to increase the K_D coefficient to the range of 1.6 ∿ 3.6 times, that is, to lighten the minimum weight of the armor units.

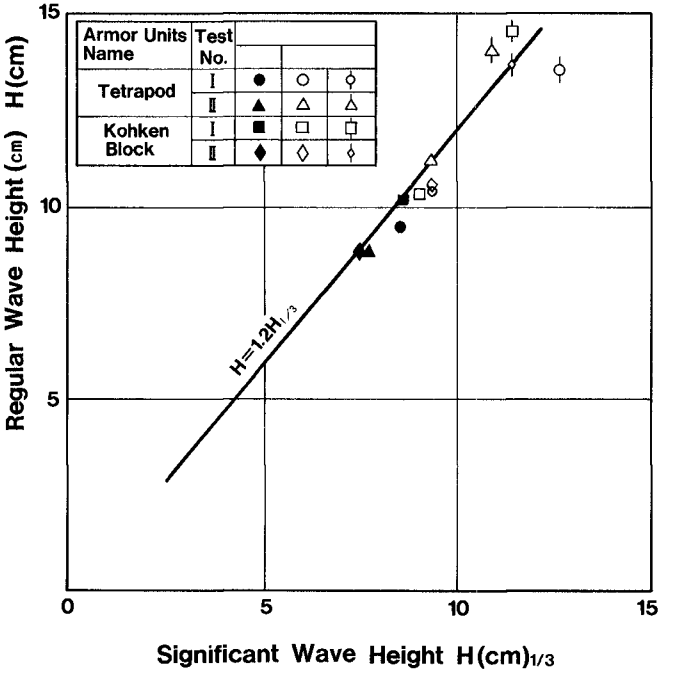

Figure-9 Relation between Regular Wave and Irregular Wave in Same Damage

Table-2 Correct K_D Value with Test Results (0% Damage)

$gT^2/(W/\gamma)^{1/3}$ 300~600

$Re > 4\times10^5$

Armor Unit Name	Hb/D	Ns	K_D	Correct Value by Irregulur Wane	K_D in Present Method
Tetrapod	2.71	4.05	49.8	28.8	8
Kohken Block	2.64	4.05	49.8	28.8	8
Dolos	2.64	4.45	63.9	36.9	22

Ns : Stability Number $Ns = Hb/(W/\gamma)^{1/3}(S-1)$
Hb : Breaking Wave Height
D : Thickness in Two Layers of armor Units

(5) Scale Effect on Reflection Coefficient

It has been conducted to compare the reflection coefficient of the armor units in small and large scale tests likewise as stability test.

Figure-10 shows the results in comparison. The axis of ordinate indicates the reflection coefficient and transverse axis indicate the Reynolds Number Rb which is composed with the long wave velocity, the height of the armor unit and kinematic viscosity also as stability investigation.

The value of Rb is about one and half times of the value of Re in equation (3) in the case of tetrapod and in small wave steepness Rb is larger than Re, because the term gh_t is larger than the term gH_b.

Figure-10 shows the reflection coefficient in same wave steepness and same relative depth.

And if the Reynold's Numbers increase, that mean the case in larger armor units, the reflection coefficients have a little upward tendency.

And the deference is with in 10%. But it is not found to approach to a constant values according as Reynolds Number become high. So it is recognized that there is scale effect on the reflection, but the deference in small and large scale is little.

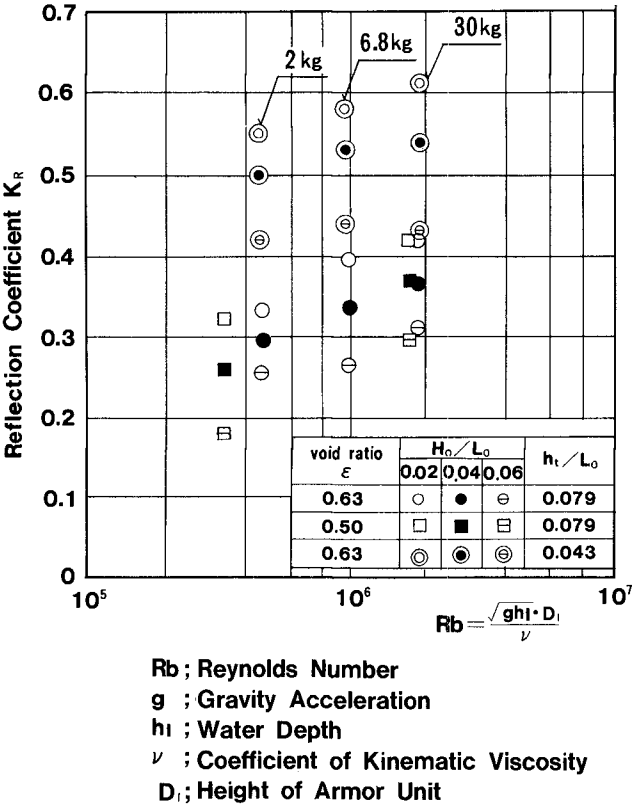

Figure-10 Scale Effect for Reflection Coefficient

4. CONCLUSION

(1) It was recognized from the experiments in small and large wave flumes that there were scale effects on the hydraulic stability and reflection regarding armor units.

(2) The influence of the scale effect on the stability becomes small and will be negligible in more than the Reynolds Number

$$Re : 4 \times 10^5$$

And this Number indicate that the armor unit weights are over than 6.8kg.

(3) It is expected that the minimum weight of armor unit can be calculated under nearly half value as compared with present design method, though irregular wave are considered.

(4) The scale effect on reflection coefficient of the armor unit are recognized in small and large scale tests, however, the deference is smaller than that of stability.

CHAPTER 166

THE INFLUENCE OF OBLIQUE REFLECTION ON BREAKWATERS

by Richard Silvester M. ASCE*

ABSTRACT

The degree of reflection from rubble-mound breakwaters, even those comprising large pre-cast concrete armour units is greater than is usually thought. This is because the bulk of the face consists of smaller stones where water exchange in voids is minimal. Theory and experiment have shown that for 100% reflection of oblique waves the orbital motions are very complex, varying across the crest length of the short-crested system from rectilinear oscillation to circular or vortex motion. Also the influence of these high velocity orbital motions on a sedimentary bed have been shown to have a high scouring capacity. This has been exhibited in hydraulic models and in the field.

1. INTRODUCTION

In most cases of experiments on breakwaters of any form the flume is used to simplify the problem to two dimensions. They assume, therefore, that waves of any consequence are arriving normal to the structure, which often is not the case. For the purpose of discussing sediment transport it is not the short duration storm waves that create the problem but the more persistent swell, even though this varies in height and period continually. Where a structure is angled to the crests of such repetitve waves the scouring can be severe, which is not exhibited in a flume test. In fact, in this case, accretion will occur at the antinode of the standing wave adjacent to the toe (Xie 1981).

As the angle of obliquity increases so the scouring shifts from the nodal area to the antinodal area, next to the structure. Material can be removed until a trough is formed parallel to the face whose profile approaches the angle of repose for the sediment. In any subsequent storm the build-up of pore pressure can cause a slumping of this trough face and concomitant subsidence of the breakwater. It is the author's belief that this could have been the cause of the Sine's breakwater failure, which was sudden over the bulk of its length even with a less than design storm. In any case it behoves the engineer

* University of Western Australia, Nedlands, 6009, Western Australia.

involved in design of these massive structures to conduct 3 dimensional model investigations to observe the scouring that can occur.

2. REFLECTION FROM RUBBLE MOUND BREAKWATERS

Rubble-mound structures, especially those faced with large precast concrete monoliths to just below the water line, appear to dissipate waves very effectively, from observation of the turbulence within the voids of these units. However these larger than normal blocks are not taken down the full depth of the face for economic and constructional reasons. As indicated in the cross-section of the Sines breakwater in Figure 1, the Dolos armour units extended down to only -15 m whereas the bed (which was not rock as indicated in the original figure (Edge et al 1982) but was sand for several metres) ranged down from -30 m to more than -45 m. Thus 5 m thickness of stone was 16-20 ton, another 5 m of 9-20 ton and 20 m of ½ to 6 ton. Hence the lower ½ to ⅔ of the wave action was impacting on rubble material with very small voids. Since the water orbits at these depths are virtually horizontal oscillations little or no energy is dissipated. This is the reason for substantial reflection being experienced.

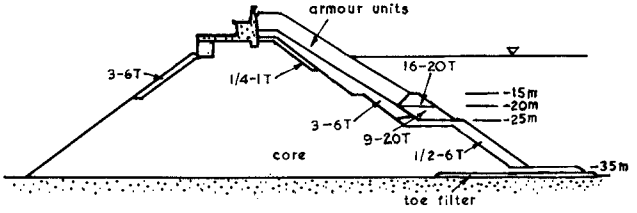

Fig. 1 Cross-section of the Sines breakwater (Edge et al 1982).

Tests have been carried out for normal waves, on breakwaters of differing materials (Gunback 1976, Sollitt & Cross 1972, Hyd. Res. Stn. Wallingford 1970) and summarised by Losada and Giménez-Curto (1981). The reflection coefficient was correlated with the Iribarren No. $Ir = \tan\alpha/\sqrt{H/L_o}$, where α is the face slope, H is the local wave height and L_o is the deep-water wave length. The resulting curves, taking the maxima of the data points rather than the mean, are shown dotted in Figure 2. These data and I_r do not specify the size of the units involved which could make a difference to the degree of reflection. However, it is worthwhile substituting some reasonable values into I_r to see what readings are applicable. Assuming $\tan\alpha = 0.5$, $H = 1$ m (swell), $T = 12$ sec. then $I_r = 7.5$. Hence for rip-rap or dolos the reflection coefficent is 0.8.

It should be noted that Gunback (1976) had armour stone thickness to water depth at 0.18 whilst Sollitt and Cross (1972) used 0.36. Also the former had 0.82 of the depth taken up with these units whilst the latter had 0.57. In a prototype structure, as indicated in Figure

1 these proportions could vary significantly with resulting different reflections.

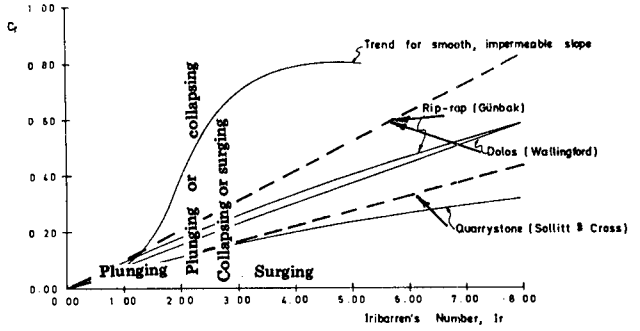

Fig. 2 Reflection coefficient I_r showing the wave type. (Losada and Giménez-Curto 1981).

3. COMPLETE SHORT-CRESTED SYSTEM

The theory of angled waves in which the components are of unequal height is too difficult to solve with the current state of the art. However for two oblique waves of equal height and period, solutions have been found for the kinematics and, also the mass-transport near the bed. (Hsu et al 1979, Hsu et al 1980). This theory to the 3rd order has been verified in a wave basin with a unique window in its bed. (Hsu 1979, Silvester 1977). Such waves might be termed "complete" as for standing waves where this term is used for opposing waves of equal height and period.

But inspite this simplification the orbital motions of the water particles are quite complex as depicted in Figure 3. (Silvester 1972). They vary from rectilinear oscillation to circular across the crest length L', which is finite and not infinite as in a progressive wave. The circular motions on alignments Z/L' = $\frac{1}{8}$, $\frac{3}{8}$, ... are in a constant direction as dictated by their location. Such vortices, even if formed near the surface, as for deep water conditions, will expand along their axes to a boundary, which in this case is the bed. In so doing they exert a strong suction which draws sediment from the floor and throws it out radially into other zones of motion. These whirling bodies of water also generate secondary vortices which make for excessive macro-turbulence which helps keep particles in suspension.

Like any oscillatory motion of wave action short-crested systems have their own specific mass-transport or net motion per wave cycle. This is evident in Figure 4 from tests conductd by Hsu (1979). Even in the alignments (Z/L' = $\frac{1}{4}$, $\frac{3}{4}$, ...), where rectilinear motion is normal to the wall or path of the island crests, there is a net movement along the wall. Theory shows a distribution of mass transport across each quarter crest length as in Figure 5. (Silvester 1985) It is seen that along crest alignments this ratio is maximum

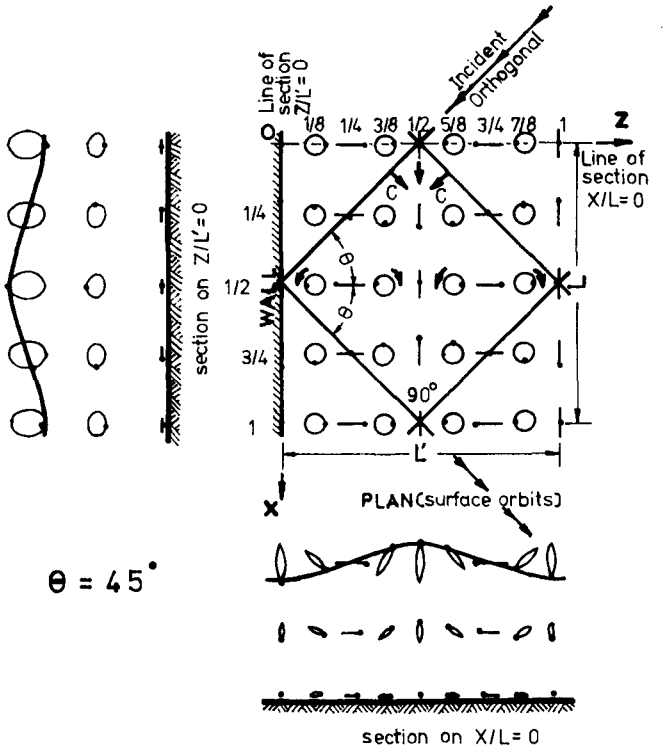

Fig. 3 Water particle motions in a complete short-crested wave system. (Silvester 1972).

and can be 2 or 3 times that of the incident wave. The shearing of material from the floor by the orbital motions at this alignment or half way between (i.e. $Z/L' = \frac{1}{4}, \frac{3}{4}, \ldots$) varies with the wave obliquity. For near standing waves the velocities and hence the scour are greater at $Z/L' = \frac{1}{4}, \frac{3}{4}, \ldots$ but for greater obliquity it is excessive at $Z/L' = \frac{1}{2}, 1, \ldots$.

4. EXPERIMENTAL EVIDENCE OF SCOUR

The movement of sedimentary material on the sea floor can be considered in 3 stages. Firstly, ripples are formed whose orientations and characteristics are dictated by the water particle orbits in the vicinity. (Silvester 1974) Secondly, erosion occurs in alignments parallel to the wall where velocities are excessive. Thirdly the complete region of the ribbon of reflected waves is scoured after accretion has occurred firstly at the downcoast end due to the passage of material from the upcoast end. This last phenomenon requires sufficient duration in model studies for this to be exhibited. Prior to this stage erosion occurs in selected zones for monochromatic waves but is less evident for irregular waves.

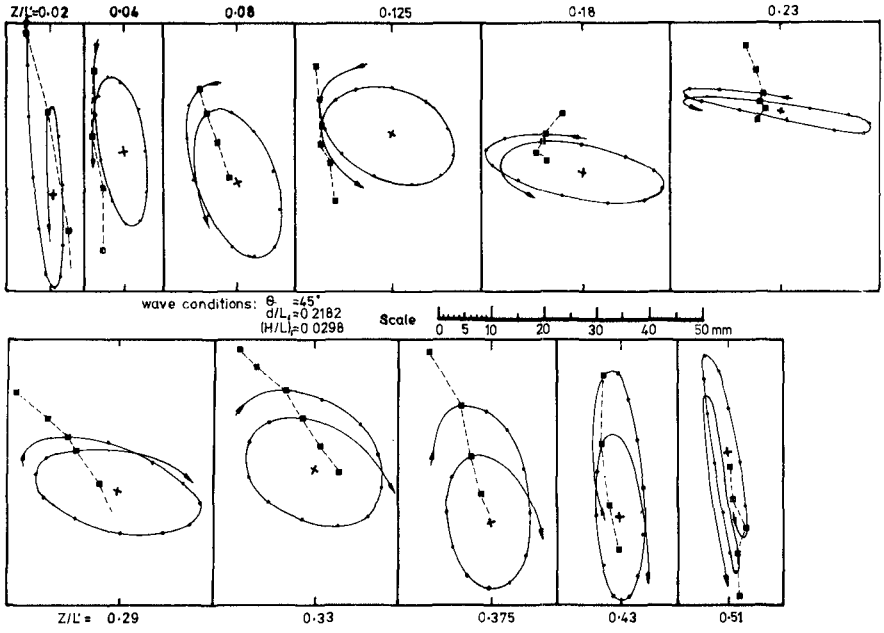

Fig. 4 Orbital motions recorded at the bed for a short-crested system showing the mass transport per wave cycle. (Hsu et al 1979)

Since the persistent swell wave, with its longer periods and good reflection, is the culprit in this removal of sediment, its orbital motions in a short-crested system need to be studied. A factor to be remembered is that such waves are changing in period continually as they travel at different speeds in a dispersal or so-called decay area. (Silvester 1974). These produce variations in orbital amplitudes and hence crest lengths of bed ripples. During such changes more sediment is placed in suspension, which then is subject to the mass-transport of the water in the wave motion.

The crests of any ripple formation will be normal to the water oscillation creating it. Thus those adjacent to the wall and at crest alignments Z/L' = $\frac{1}{2}$, 1, ... will be normal to the wall; whereas those half way between (Z/L' = $\frac{1}{4}$, $\frac{3}{4}$, ...) will be parallel to it. Along alignments between again (Z/L' = $\frac{1}{8}$, $\frac{3}{8}$, ...) the vortices will create circular mounds which make for a snake-like undulation. These are exhibited in Figure 6, where waves have reflected at 45° to the wall on the right of the figure, with the Z/L' distances marked. The slight deviations from these alignments in the figure are due to the partial transport that has occurred which introduced changes in water depth and concomitant refraction.

After some time the zones of high velocity water oscillation causes them to be eroded first which is evident in Figure 7 where

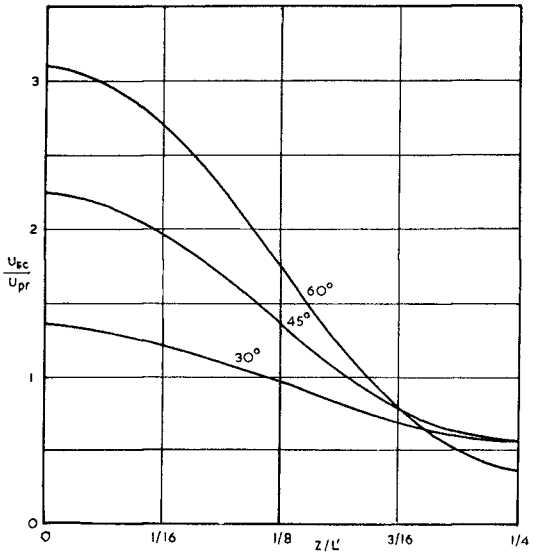

Fig. 5 Ratio of mass-transport in a short-crested wave (U_{sc}) to that in a progressive wave (U_{pr}) for various angles of incident to a reflecting wall. Z is measured normal to the wall across the crest length L'.

removal has occurred at Z/L' = $\frac{1}{4}$, $\frac{3}{4}$, ... where ripple crests are parallel to the wall. It is seen that for this approach angle of 25° scour has taken place for more than 3 crest lengths from the structure. The orthogonal of the reflected wave through the upcoast tip of the reflecting wall is shown. To the right of this these waves are diffracting, so suffering a curved crest pattern and reducing in height. Even so, the short-crested system still exists as exemplified in the scouring that has occurred beyond this ribbon of reflected wave. In other photos a similar expansion occurred from the downcoast limiting orthogonal. (Silvester 1985).

This is not to imply that the reflected wave height remains the same in its propagation from the wall. Its passage can be likened to transmission through a breakwater gap as in Figure 8, the diffraction of which has been determined experimentally for no reflection from adjacent breakwater arms. (Silvester 1981) As the wave travels along multiples of the non-dimensional width B/L its energy is absorbed in diffraction beyond the limiting orthogonals. As seen in Figure 9 the diffraction coefficient reduces so that on the centre-line at R/B = 4 the height has been reduced to half. Thus the incident wave will be double the height of the reflected and will therefore have more effect on the movement of sediment. The water particle orbits will be very complex but still conducive to bed scour.

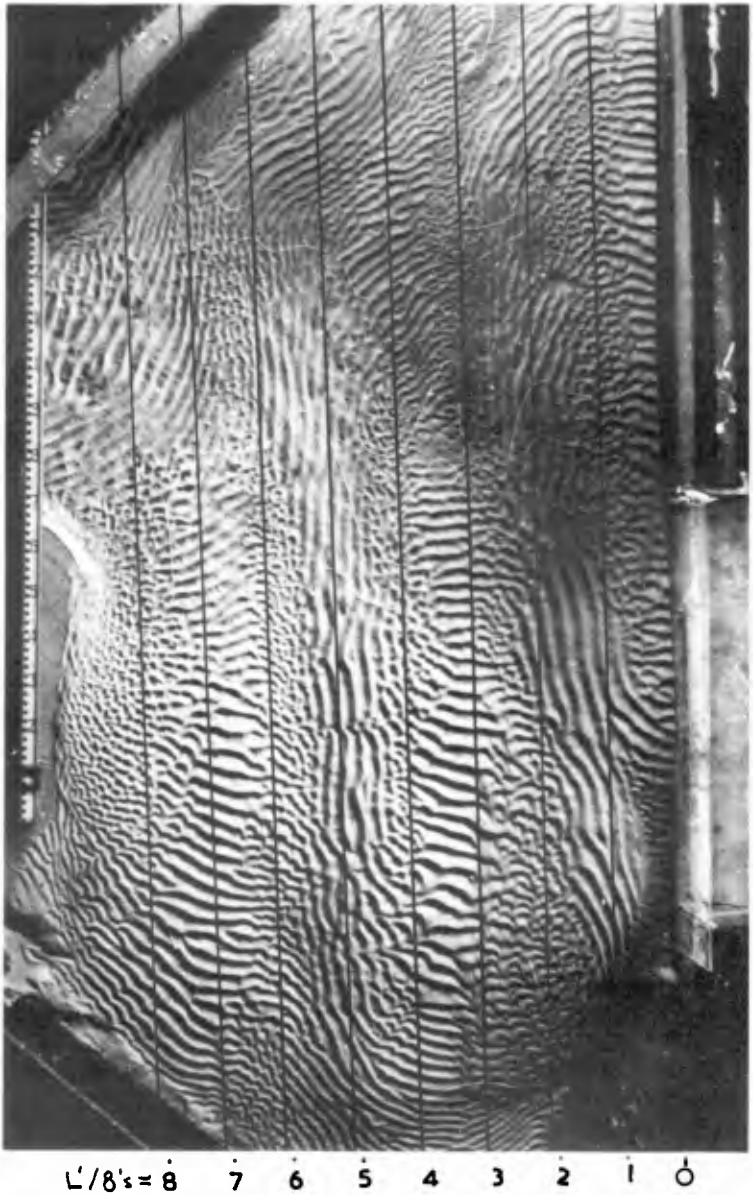

Fig. 6 Bed ripple formations in a short-crested system. (Silvester 1972).

Fig. 7 Differential erosion occurring at quarter crest lengths from the wall.

Tests carried out for 60 hours with waves angled 30° to a wall in water depth of 25 cms, wave period 1.0 sec. and sand bed thickness of 5 cms, resulted in scour as seen in Figure 10. During this limited duration material removed from the RHS is in transit through the area to the left so causing shoaling in that region. Had the experiment been carried out for longer this accretion would ultimately disappear. A similar test has been carried out by Tanaka et al (1972) where sediment 10 cms in thickness and water depth 5.5 cms waves of 2.8 cm height and 0.52 seconds period caused progressive erosion at the upcoast end of a breakwater with approach angle of 30°. As seen in Figure 11 accretion occurred in the downcoast region after 10 hours duration. It is seen, as in Figure 10, that the bed is affected even outside the limiting orthogonal through the upcoast tip of the

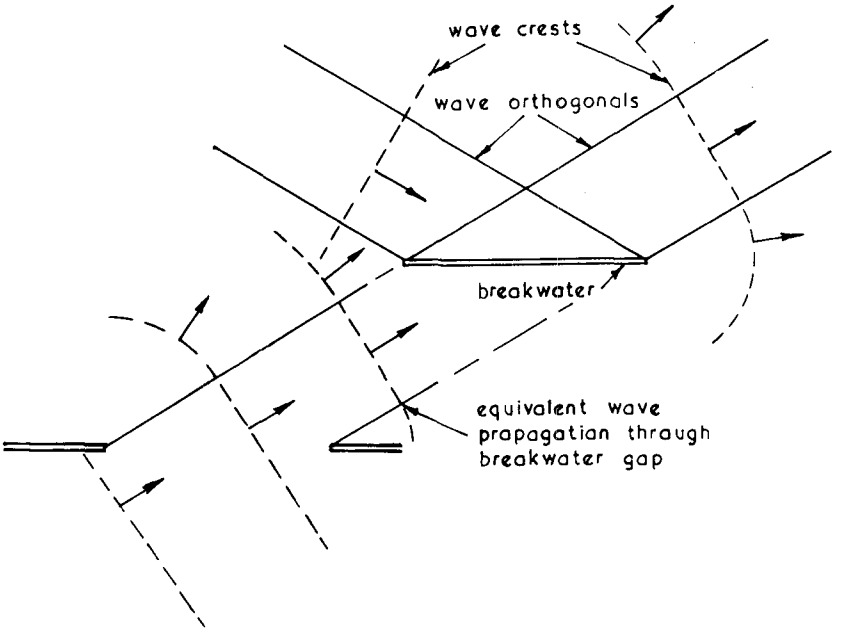

Fig. 8 Comparison of reflected waves to diffraction through a breakwater gap.

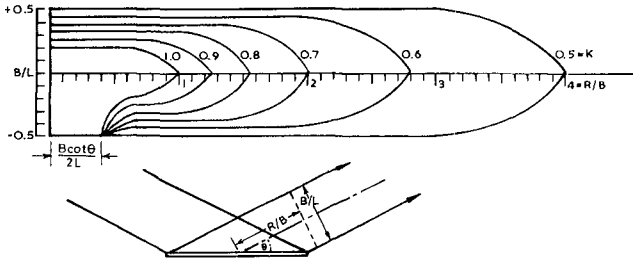

Fig. 9 Diffraction coefficient distribution in front of a reflecting wall.

breakwater. The variations in bed level in the figure are based upon the assumption that a profile recorder had a distance to the original bed of 25 cms in the data provided by the authors. Irie and Nadaoka (1984) have conducted model tests on a breakwater where the bed was sloping upwards towards the downcoast end as seen in Figure 12. The final contours after 11 hours duration are shown from which zones of erosion and accretion can be identified. It is seen that these zones vary across the normal to the breakwater.

More recently Irie et al (1985) have conducted further experiments with angled waves both regular and irregular. The

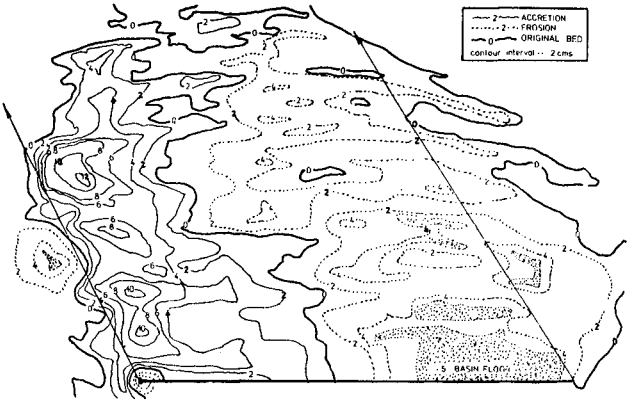

Fig. 10 Scour of bed to concrete floor after 60 hours duration.

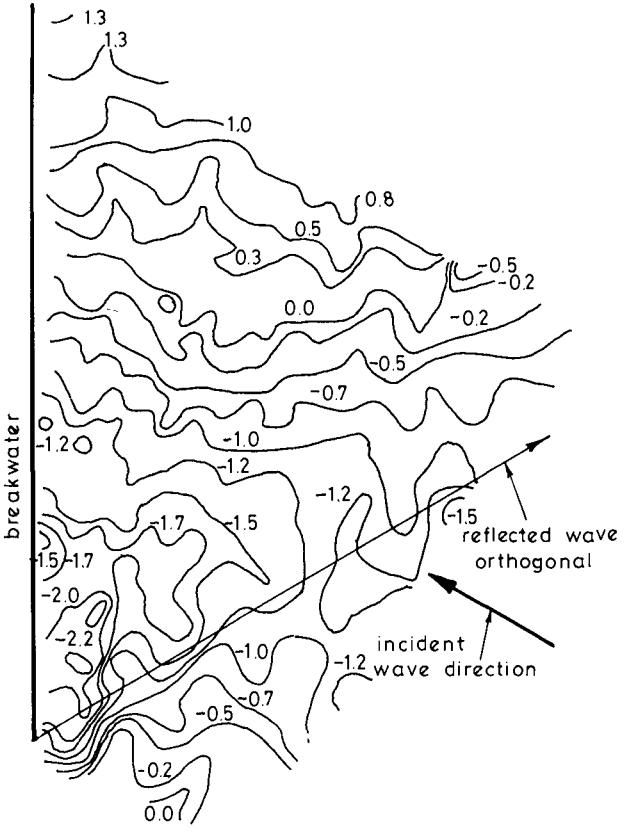

Fig. 11 Contours after 10 hours duration. (Tanaka et al 1972).

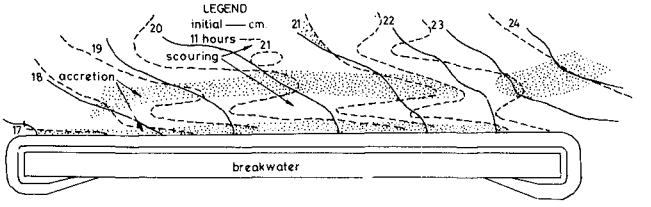

Fig. 12 Tests showing differential erosion and accretion for a duration of 11 hours with irregular waves. (Irie & Nadoaka 1984).

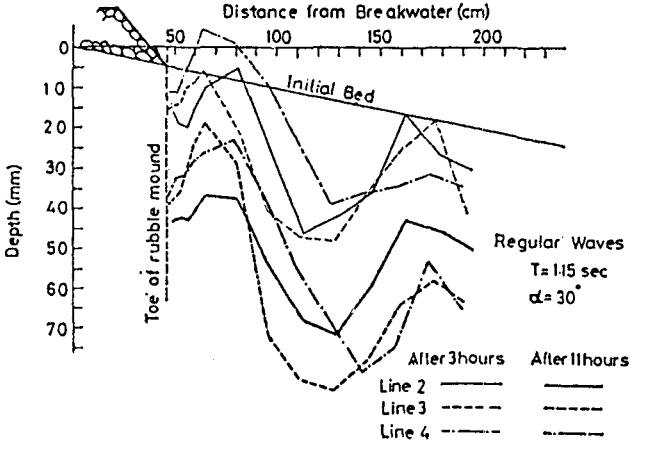

Fig. 13 Profiles normal to the breakwater for regular waves at 30° after specified durations. (Irie et al 1985).

breakwaters were of caisson type with a trapezoidal rock mound on the sea side. Profiles normal to the breakwater at the point of greatest scour were measured after 3 and 11 hours the results of which are reproduced in Figure 13. A significant feature of these profiles is the steep slope of the near side of the major trough which is 1:3.4, even after such a short duration. From tests with irregular waves (Figure 14) the same steep slopes exist near the toe of the rubble mound. In this case the scour is more uniform across the bed. Irie also plotted profiles parallel to the breakwater over certain durations which showed severe erosion at the upcoast end and accretion at the downcast tip. The progressive deepening is illustrated in Figure 15, where it is seen that scouring is rapid over the first hour but slows down with time. An optimum had not been reached for the regular waves after 11 hours duration.

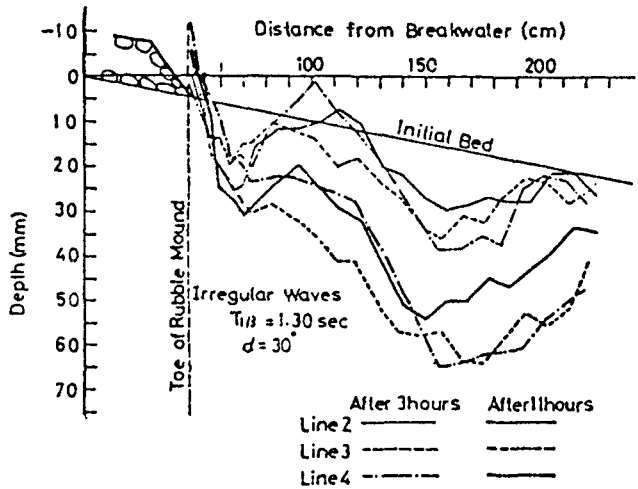

Fig. 14 Profiles normal to the breakwater for irregular waves at 30° after specified durations. (Irie et al 1985).

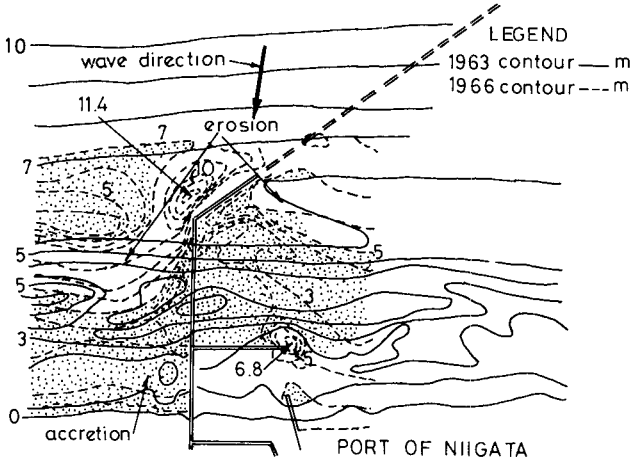

Fig. 17 Erosion and accretion at Niigata between 1963 and 1966. Sato et al 1969, Sato & Irie 1970).

5. FIELD EVIDENCE OF SCOUR

Scouring has been observed by Irie and Nadaoka (1984) in prototype situations. The port of Forkui is angled to the shoreline and to the bulk of the waves arriving. It was completed in 1978 when

a hydrographic survey was conducted, which can be compared to the 1976 contours as in Figure 16, showing the zones of erosion and accretion. Scouring down to 3 metres over a large length of this breakwater took place in a matter of months. It would be interesting to see the contours some eight years later.

Another example of erosion is given by Sato et al (1969) who give contours in 1966 for the port of Niigata, Japan, presumably soon after the completion of the breakwater to this stage. (Figure 17) These bed profiles are compared to those in 1963 provided by Sato and Irie. (1970). Zones of erosion and accretion are hatched and stippled respectively. It is seen that near the corner a depression of 11.4 m has been scoured in an original depth of 6.5 m. In the second reference (Sato & Irie 1970) contours are shown for a slight extension of the breakwater in 1967 and the installation of a rubble mound base for caisson units to the limit shown in Figure 17. These show some accretion in the region previously scoured, probably due to the transmission of sediment along the submerged mound during this short time period. It would be instructive to see hydrographic data for the current situation after some years of completion.

6. CONCLUSIONS

1. The degree of reflection from rubble-mound structures is significant enough in oblique wave approach to generate short-crested wave systems which are conducive to scour.

2. Consultants should not depend solely on flume tests if erosion of a sedimentary bed is possible as these imply normal approach for both storm and swell waves.

3. Theory and experiment have shown that the water particle orbits in a complete short-crested system (equal heights and periods of component waves) to be quite complex and severe in their erosive capacity.

4. Besides high velocity orbital motions the water particles experience a strong mass transport, greatest along the alignment of the island wave crests, which can interact with tidal currents to remove suspended material.

5. Model experiments with obliquely reflected waves have shown their ability to form trenches parallel to a structure that have profiles approaching the angle of repose of the sediment which could cause subsidence if pore pressure is built up during even moderate storm action.

6. Field measurements of scour adjacent to breakwaters have only been carried out soon after construction but even so have exhibited severe erosion which is being blamed on currents rather than waves.

CHAPTER 167

Design and Evaluation of Beach Protection Schemes

D H Swart* and K Horikawa**

ABSTRACT

On the basis of eleven poster presentations on beach protection schemes and/or devices, at the recent 20th International Conference on Coastal Engineering, the various levels involved in the design and evaluation of beach protection schemes are discussed in this paper. These are: (1) the assessment of the problem and processes operative in the area; (2) the establishment of an overall master plan for development; (3) the design stage; (4) the construction phase, and (5) the post-construction phase. It is concluded that it would be useful if some form of international co-operation could be instigated to allow the collation of techniques used at the various levels in one handy location, for dissemination by all contributors.

1. INTRODUCTION

The International Conferences on Coastal Engineering, held every two years at a different venue, have traditionally brought together coastal scientists from more than twenty countries. The 20th such conference, held in Taipei, Republic of China, in November 1986, was attended by about 500 coastal scientists from around the world. During the conference two poster discussion sessions on beach protection devices were held, under the chairmanship of the authors of this paper. On the basis of the contents of the eleven individual poster papers presented in these two sessions, the various aspects related to the design and evaluation of beach protection schemes were discussed at the conference. Significant advances were made in bringing together data on these aspects. This paper contains an overview of the results achieved during the two poster discussion sessions.

It should be pointed out here that the discussions were held in a way which allowed the audience to contribute by filling in any gaps in knowledge that were apparent after the presentation of overviews by the chairmen.

After the discussion of the various levels of evaluation and design a wider perspective is taken in suggesting the comparison of techniques used worldwide. Means of achieving this are discussed.

The eleven papers under discussion can be subdivided as follows:

* Council for Scientific and Industrial Research, P.O. Box 320, Stellenbosch, 7600, Republic of South Africa.
** Department of Civil Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113, Japan.

(1) **those dealing with beachfill**
Möller, Owen and Swart (1986)

(2) **those dealing with offshore breakwaters**
Yeh and Ou (1986)

(3) **those dealing with combinations of beachfill and structures**
Deguchi and Sawaragi (1986); Pui (1986); Kana, Al-Sarawi and Holland (1986); and Suyama, Uda and Yoshimura (1986)

(4) **those dealing with offshore dredging**
Kojima, Ijima and Nakamuta (1986)

(5) **those dealing with river deltas**
Kadib et al. (1986); and Gambardella (1986)

(6) **those dealing with other related topics**
Hayashi (1986); and Kawata and Tsuchiya (1986).

The contributions by the above authors and members of the audience during the discussions helped make these poster discussions very successful and are gratefully acknowledged.

The rest of this section is devoted to a short summary of the key elements of the different papers referred to above, to serve as a basis for the discussion in the further sections of this paper.

Beachfill

Möller et al. (1986) describe a diamond mining operation on the west coast of Africa in Namibia, where a sea-wall of normal beach sand has been built out to a distance of more than 300 m seawards of the original coastline. The wall which runs alongshore (as shown in Figure 1) is maintained in the high energy environment, which is characterized by northbound longshore transport rates, by means of artificial suppletion at a rate of more than 300 000 m^3/month. The question which had to be answered before the project could commence was whether there would be enough overburden sand available on land to allow the completion of the project free of severe damage by wave action. The data set used consisted of wave measurements by Waverider and wave observations obtained from voluntary observing ships; aerial photographs at monthly intervals of the water line in the study area, and soundings of the beach, sea-wall and nearshore topography (using a helicopter as a platform).

The individual survey results were used to establish a sand budget for each survey period. These sand budgets were used as input to a N-line littoral, morphological model. This model was preferred to a one-line coastal model because of the large alongshore differences in profile shape. During the three years that the project has run to date this technique was used to project the required volume of sand to complete the project by the expected completion date of March 1988. The project can serve as a one-to-one scale beachfill test and could prove extremely useful to evaluate techniques for the design of beachfills.

Offshore breakwaters

This type of structure has found widespread application in the protection of eroding beaches. 8ecause of the formation of cuspate forelands behind such breakwaters and the attractive embayments that are formed between them, bathing conditions are created which are both safe and of a varying nature. The design of offshore breakwaters involves the choice of the breakwater length, distance offshore, crest elevation, the gap/length ratio and the necessity of supplementary beachfill landwards of the breakwaters. The paper by Yeh and Ou (1986) discusses the application of offshore breakwaters to the Redhill coast of Taiwan in the Republic of China. The coastline in the area consists of sandy eroding cliffs 6 to 10 m high and has a limited natural sand supply. In 1978 seven detached, offshore breakwaters with a length of 80 m each and a gap spacing of 30 m were built at mean sea level to protect the beaches. Field observations were done over a period of 3 years covering pre- and post-construction phases. The data were analysed using eigenfunction techniques. In 1985 laboratory tests were done to supply design data for determining gap spacings. Substantial improvement in beach stability has been experienced since the construction of the breakwaters.

Combined beachfill/structures

8eachfill is often used in combination with structures, especially in areas where it is expected that the natural littoral drift will transport sediment out of the area too quickly, thereby reducing the effective life-time of the beachfill. Three of the papers listed above fall in this category. Deguchi and Sawaragi (1986) describes how sand was placed in the lee of a 80 m long offshore breakwater in 1984, one year after construction of the breakwater was completed. Surveys were done 4 to 6 times a year. Immediately after construction of the breakwater both longshore and offshore sediment transport took place as the beach reacted to the changed littoral regime. Thereafter longshore transport dominated until the beachfill was placed. Within two months after placement fifty per cent of the beachfill was lost from the area behind the breakwater, and a further 10 per cent of the initial volume lost in the next two months. This study clearly indicated the benefit of using a mathematical simulation model to help interpret the field results. In the model used, wave deformation, wave-induced currents, sediment movement and associated bottom changes were simulated.

Pui (1986), on the other hand, shows how as a result of land reclamation to meet the increasing needs of the fast-growing Singapore population, the shore was built out to such an extent that the littoral processes were accelerated, thereby necessitating the simultaneous construction in some areas of revetments or headland breakwaters. In a few cases additional measures were not required owing to the favourable alignment of the beachfill. An interesting aspect of the work carried out in Singapore is that it is quite possible that beach protection carried out on Singapore beaches could influence beaches in the adjacent Malaya. This aspect was not formally addressed in the paper and poses the question of how such cases should be handled.

Kana et al. (1986) give a very good example of a combined beach-

fill/structures approach. It is most probably one of the most extensive recreational waterfront projects ever designed. The results of a field-monitoring programme, which started in 1977, were used to draw up a master plan for beachfront improvement as well as a series of design criteria. The scheme includes artificial beaches, promenades, revetments, outfalls which also serve as headland breakwaters for the artificial pocket beaches and an artificial island. On the basis of the wave data longshore transport calculations were done and were used to orientate the pocket beaches to the waves, thereby largely eliminating longshore sediment losses. An interesting aspect of the design of the beachfill is that a berm elevation of 1 m above mean high water springs was used. This allowed washover and as a result the beaches attained a natural appearance soon after construction. Two years of post-construction monitoring has been done to evaluate the behaviour of the artificial beaches. Typically, ten days of recordings are done every three months. Wave energy levels are compared with pre-construction levels, and profile data are used to compute sediment budgets for the various beach compartments. The monitoring shows that the sand losses from the scheme are low and it is not expected that renourishment will be required later.

Suyama et al. (1986) describes a field experiment on the Shimoni-Ikawa coast on Toyama Bay in Japan. Downdrift of Miyazaki fishing harbour the coast is eroding owing to the interruption of littoral drift by the harbour. The purpose of the field experiment was to investigate the effectiveness of sand bypassing as a method of combating beach erosion and to evaluate the degree to which offshore breakwaters in the downdrift area can serve to minimize sediment redistribution after replenishment of the beach. The measuring program included wave measurements (height, period, direction), nearshore bathymetric surveys and a tracer experiment. It was concluded that a slow longshore movement of sand took place without appreciable sand losses through the gaps between the three breakwaters, which were situated about 20 m offshore. The artificial sand infill into the area behind the breakwaters helped to create tombolos, which would not have formed otherwise, and reduced wave overtopping of the structures due to shallower water at the structures.

Offshore dredging

The supply of sand for building and other purposes is posing an ever greater problem in many parts of the world. Offshore sand bodies are frequently exploited. In such cases where offshore dredging is done, it is necessary to establish the best location and dimensions for the borrow pit. Aspects which have to be carefully considered are the following:

- the relation of the location of the borrow pit to the dynamic swept prism and the corresponding effect it has, either directly or indirectly, on the sediment transport processes in the area;

- the effect of the borrow pit on wave propagation patterns and the associated effect on wave focusing and hence on beach erosion at the shore; and

- the potential effect of the dredging operation on the general ecology of the area, and the degree to which recovery of the sub-bottom faunal life will take place.

The paper by Kojima et al. (1986) discusses most of these aspects, with the exception of the ecology. Figure 2 shows the areas on the Genkai coast where offshore dredging has been done. Kojima et al. describe a wide range of measurements done to establish whether or not the offshore dredging has accelerated beach erosion in the area. Typical elements of the data gathering and analysis exercises were the following:

- an analysis of aerial photography in the period 1947 to 1982;

- hydrographic surveys and sediment sampling to establish recent trends;

- fluorescent tracer experiments in which the fate of underwater injection at water depth intervals of 5 m in the area between 10 m and 30 m water depth is investigated with the aid of underwater observations; and

- extensive wave and weather surveys, supplemented by a compilation of available old data dating back to 1945, where, amongst others, it has been shown that the frequency of occurrence of high wind speeds (> 10 m/s) has decreased steadily over the last ten years.

It is concluded that although beach erosion has taken place before dredging started due to mainly high incident storm-energy, it was more than likely that offshore dredging did affect shore processes. It was furthermore concluded that borrow pits situated in water depths shallower than 30-35 m filled in readily from the landward direction, thereby showing that the borrow pits should be situated further offshore in deeper water. This is interesting since it is deeper than is traditionally recommended.

River deltas

When dealing with shore protection schemes on river delta coastlines the general problem is compounded because of the added processes associated with the river delta itself. Here specific attention should be focused on current patterns related to the river delta formation and orientation, decrease in the shore area, relative sea-level rise (relative shore drop) and shoreline protrusion with the associated effect on morphological processes.

The papers by Kadib et al. (1986) and Gambardella (1986) serve as reference. Kadib et al. describe the development of the Nile river delta. Up to the end of the 19th century the supply of sediments to the delta generally exceeded the losses due to wind, current and wave processes in the shore area. After construction of the lower Aswan Dam on the Nile in 1912 beach erosion at a rate of 30 m/year commenced. This increased to more than 170 m/year after 1966, when the Aswan High Dam was built. The Egyptian Government recognized the seriousness of the situation, and instigated an extensive investigation programme. On

the basis of an analysis of the field data gathered as part of this programme, the 350 km coastal area was subdivided into six morphological regions. Various shoreline protection schemes are being evaluated against each other, each taking into account the specific morphological behaviour of the region under consideration. Protection devices which are being considered are shoreline hardening with the use of armour units, sand nourishment, groyne systems or detached breakwaters in conjunction with sand nourishment, "no action" with assessment of the economic consequences and other options.

Gambardella (1986) shows that the shoreline of the Po river delta in Italy receded dramatically since the 1950's. Two main processes can be identified as being causative factors. Natural subsidence of the more than 2 000 m thick, unconsolidated post-Pliocene sediments which is about 1,5 mm/year, increased to about 15 mm/year due to water and gas extraction, reaching a maximum of 3 m/40 years locally. Secondly hydraulic works, industrial installations and extensive reclamation works altered the natural equilibrium of the outer coastal area, thereby giving rise to shoreline recession. It is not always possible to shift back the protective sea-walls because settlements have been established in the coastal area immediately behind the sea-walls. Figure 3 shows the cross-section of the standard dike-breakwater construction which was traditionally used as beach defence. Due to the substantial erosion of the delta beachfront the dike/breakwater systems proved ineffective to prevent beach erosion. The application of 1 m to 1,8 m diameter sand-filled "Longard" tubes in a configuration as shown in Figure 4 has to date proved very effective and is considered the mechanism to combat future erosion.

Other beach protection techniques

Two papers fall in this category. Hayashi (1986) described the use of beach-walls as opposed to sea-walls, to serve as an effective beach erosion protection in the Hawaiian situation. Kawata and Tsuchiya (1986), on the other hand, describe the use of a sub-sand filter system as beach erosion control mechanism. Using the Hawaiian experience as an example, Hayashi shows that by using sea-walls with a nearly-vertical seaward face to protect properties and maintain the certified shoreline, beach erosion is frequently enhanced and extends to the adjacent properties, thereby giving rise to the so-called "domino" effect. The use of beach-walls, a concept developed by Hayashi, however, leads to much more natural beach processes. Experience over two years has shown that beaches are retained more readily in front of beach-walls (see Figure 5 for typical cross-section) than in front of sea-walls or other hard structures.

Kawata and Tsuchiya (1986) discuss both theoretical and experimental studies to investigate the effect of a sub-bottom filtration system whereby water is drawn into the bed. As is to be expected, the increased inflow velocity into the bed causes the threshold velocity of bottom sand to be increased, as can be seen in Figure 6. Although the laboratory experiments showed conclusively the benefit of such a filtration or draw-off system, the main problem that remains is the manner in which such a system can be constructed and maintained on a natural beach.

2. PROBLEM/PROCESS ASSESSMENT

The first level at which a beach protection design needs to be addressed is the "problem or process assessment" stage. It is always advisable to know not only what is happening but also how and specifically why it is happening. With this background knowledge it is then possible to proceed with the further steps of the design.

The following types and sources of data can prove useful/essential in acquiring the necessary background knowledge:

- old maps and charts;
- aerial photographs;
- topographic/hydrographic surveys;
- wave/weather data;
- landward needs/problems;
- geomorphology; and
- ecology.

It is always advantageous to review old and/or existing data to gain an idea of the processes/trends operative in the area, before embarking on a new measuring campaign. The same pre-screen of available data also applies to wave data, where observations made by merchant shipping (the so-called VOS wave data) give a good first idea of the wave climate in the area, including seasonal changes, and also helps in designing the measuring exercise. In any beach protection design it is important to make a sediment budget analysis. It is usually possible to make a first stab at such a budget by using the shoreline position on old charts to estimate volumes. With the aid of all the preceding it is possible to design a measuring exercise in relation to old/available data.

Hydrographic data usually play an important rôle in assessing sediment budgets. Because the sediment budget is freguently determined by taking the difference between two large volumes, it is essential that the surveys used for this purpose should be as accurate as possible.

In this respect it is appropriate to examine the closure depth for repetitive surveys carefully, to decide whether the observed closure depth can be explained in terms of physics. Another check for accuracy is to compare elevations in an area of overlap between land-based and sea-bed survey data.

It is important that the coastal engineer should realize that the guality of the project may be vastly improved by close liaison during the problem/process stage with scientists of other disciplines, be they geomorphologists, planners, landscape architects, geographers and/or ecologists. It is also particularly important to the client that he does not get conflicting advice from the various disciplines, but one sensible answer. It is in this respect that the engineer can play an important rôle in bringing together the other disciplines to assess processes and evolve working concepts as a basis for sound coastal engineering design.

3. ESTABLISHMENT OF MASTER PLAN

Having established the exact magnitude and nature of the problem, the next level of attack is to determine an overall master plan which will allow one to foresee future problems in other areas and give one the opportunity of gaining a wider perspective of the beach protection problem. It is important, therefore, never to treat problems in isolation. It is also appropriate to establish future requirements at the site or in the vicinity, and to decide on the optimum manner in which work needs to be phased to best solve the problem in the long run.

Although this may sound rather early to talk about the optimum solution, it is quite foreseeable that there are some specific site problems such as the non-availability of rock, which preclude certain solutions. This may also be the case with the specific culture or requirements of the locals/beach-users.

In all cases it is of the utmost importance to start with a public relations exercise as early as possible to make the public aware of what is at stake and what they can expect from such a beach protection scheme.

In deciding how far to go with the establishment of a master plan, it is important to realise that by deciding on, for example, a long-term policy of beach nourishment, it helps one to phase other activities such as the development of a market, determining dredging capacity, etc.

At this early stage one has to clearly address the question of what the feasible options are for beach protection, with the relative merits of each. One viewpoint expressed during the discussion is that in making this decision one should look to nature to see how it would do it, and what would happen. Dr Silvester, in making this comment, ended up saying that headland embayments are natural features optimizing energy losses in the most efficient manner. However, it is the belief of the authors that this philosophy of looking to nature for the wider clue to the solution is a sound one and may result in different solutions under different circumstances.

4. DESIGN STAGE

The next and most important level in the establishment of a beach protection scheme is the design stage. The following aspects are all relevant in this respect:

- the various elements of the type of solution, and the phasing of the work/needs; which necessitates an evaluation of the alternatives;

- the design technique(s) used, whether involving
  - field data
  - laboratory experiments with fixed and/or movable bed models
  - mathematical/numerical simulations or
  - some (hybrid) combination of the above

- whichever of the above technigues are used, the design approach should include an appropriate calibration condition and a predictive mode/data set;

- it is important to consider the **interaction** between the beach protection scheme and the nearshore environment, that is, the effect of the solution/scheme/structure on the morphology, as well as the effect of the nearshore environment on the solution/scheme/structure, and

- for a proper evaluation of each alternative it is essential that the initial (construction) costs and subsequent maintenance costs should be separated.

The following are some general points related to various types of beach protection device which were discussed in the two sessions:

Filtration systems

The idea of increasing the inflow of water into the bed in order to increase the threshold velocity and reduce the movement of sand is sound and its effectiveness has been demonstrated both numerically and in the laboratory. Before it can be applied in the field, however, the researchers responsible for promoting the idea should collaborate with contractors capable of applying these thoughts in practice, in order to sort out the various problems associated specifically with securing such a system in nature and making it a low-maintenance system.

Beach-walls

With reference to the paper by Hayashi (1986) it would appear that beach-walls would be preferable to sea-walls not only on account of their lesser interference with morphological processes, but also on aesthetic and ecological grounds. The importance of the latter will be appreciated if one recognizes that the ecology reacts to changes in the natural, physical environment. As it is expected that beach-walls will change the natural environment to a lesser extent than sea-walls, the ecology will also be less affected. Although not called beach-walls (a term coined by Hayashi) such structures have been built in numerous locations around the world, with great success. Aspects of beach-walls which need to be addressed further are the optimum crest elevation and the degree of damage which can be tolerated. Obviously the crest elevation will be a function of the application: for example, the Dutch have buried a protective wall in their vulnerable coastal foredunes in areas where the protection afforded by the dunes alone was insufficient. In this case the crest elevation approaches the dune crest elevation. However, for more traditional applications such as those referred to by Hayashi (1986) it should be possible to establish some guidelines for the preferred crest elevation.

Detached breakwaters

Over the last twenty years or so hundreds of detached breakwaters have been constructed in widely different environments. The behaviour of a fair percentage of these has been monitored. Because the design

geometries of these breakwaters, as depicted by breakwater length, gap size, offshore distance, water depth at structure and crest elevation of structure, also vary greatly, it should be possible, and highly profitable, to characterize the behaviour according to design geometry. Rosen and Vajda (1982) and Schoonees in CSIR (1986) have attempted to do so. This does not mean that one can get away without a detailed design stage; it merely allows one to make a very intelligent first guess at a scheme. Aspects of the design of beach protection schemes by means of offshore breakwaters which require specific attention are the following:

- the volume of sediment which needs to be moved by the waves to reshape the beach and, related to this, the time required to do so as well as the extent of possible areas of erosion;

- with the first point in mind, the necessity for artificial nourishment of sand to aid the reshaping process;

- the aesthetic appearance of such offshore structures, with specific reference to the "requirement" of bathers to be able to see the sea, to allow them to feel they are on the beach and not only at some inland water pool, and

- the structural design of these structures, which is frequently neglected and which necessitates either costly maintenance at an early stage or the redesign of the scheme in total.

Groynes

In the first half of this century groynes were mostly seen as the ultimate solution to beach erosion problems. Usually, not enough attention was given to the process assessment stage and the end result was that downdrift beach erosion was enhanced. Groynes are only effective against long-term erosion due to longshore gradients in the longshore transport. Even then they do not prevent erosion but only retard it while the longshore drift fills up the updrift beach before bypassing commences. A major problem with groynes is the extent of the downdrift erosion. Downdrift erosion can be curtailed/minimized by using different types of partially permeable groynes which do not present such an impermeable barrier to the longshore drift. Groynes of this type are low-level groynes which allow part of the drift to pass over the low-level portion of the groyne, which could, for example, be sloped to a desired beach profile, or piled structures which allow part of the drift to pass through the piles, or combinations of these two types, or short groynes which fill quickly and have a shorter offset. In all these uses it is important to assess **quantitatively** beforehand what proportion of the sand will bypass, and when and how, as well as the type of flow field which will be set up updrift of the groyne, for example, an eddy or a rip current, and the extent to which this flow will influence the morphology in the vicinity of the structure.

Another important aspect which needs to be taken into account at the design stage is that if vertical walls (such as closely spaced piles) are to be incorporated in the design, it would be essential to consider the extent of scour which would result on the updrift side of

the structure in the area where increased turbulence results from interactions between reflection off the structure and the updrift rip current, should it occur.

Recently the tendency has been to use permeable groynes of one type or another **in conjunction with** beachfill, to achieve a minimum guaranteed beach width.

Beachfill

Beachfill is perhaps the type of beach protection scheme most-favoured today, mainly because of its natural appearance upon completion. Ecologically this is also preferred because natural habitats can re-establish themselves - although during placement fairly substantial mortalities of sub-bottom communities could occur, mainly as a result of the pumping exercise.

In designing a beachfill it is imperative that the designer understands the processes at work. It is particularly important that he understands the mechanism(s) by which material will be removed out of the fill and where such material will end up.

The traditional techniques advocated for the establishment of the magnitude of the fill required, for example by Krumbein and James (1965), Dean (1974), James (1974) and SPM (1984) do not take the mechanisms of movement into account **and can therefore at best provide a first estimate of the required placement.** In addition, most of these techniques exaggerated the required placement because they depart from the premise that the grain size distributions of native and borrow material must be similar.

Nowadays it is recognized that a more detailed design of a proper beachfill is required, especially as it is now such a popular protective technique and because of the high cost, both in the initial stages and thereafter, if maintenance is required. The Dutch have just published a manual for artificial nourishment (Manual on artificial beach nourishment and coastal processes, 1985) which covers most of the aspects to be considered in a beachfill design very adequately. This document is a must for every designer using beachfill.

The following techniques exist for a more detailed design of beachfills:

- One-line coastline evolution models such as that by Pelnard-Considerè (1954), but modified to include diffraction effects. This type of model will only have limited application because of the nature of the assumptions, that is, transport takes place in one layer, profile shifts as a geometrically undistorted profile, the difficulty of defining the effect of the beachfill on the amount of longshore transport "by-passing" the beachfill and the fact that onshore-offshore transport cannot be accounted for.

- Two-line coastline evolution models such as that by Bakker (1968) are more relevant because of the inclusion of onshore-offshore transport but its application is still limited because the coastal

constants required for predictive purposes with this type of model are functions of the profile geometry, which makes it impossible to use the model in a predictive mode before a series of measurements in the full-scale had been made of the evolution of the beachfill.

- N-line or multi-layer coastline evolution models (N > 4), such as that by Perlin and Dean (1983) may give a very good indication of the reshaping of the coast in the vicinity of the beachfill. Möller et al. (1986) used such a model for Oranjemund with great success. It is essential that good field data are available to calibrate the model. A problem of this and all other predictive models is that it is difficult to cater for the effect of differences in the grain size distribution of the native and borrow materials. It is possible, however, to obtain bracketing answers.

- Longshore transport predictors may have some limited merit to show the extent to which the longshore transport regime in the beachfill area is modified.

- Onshore-offshore predictors such as the method by Swart (1974, 1986) are extremely useful to evaluate the effect of a beachfill geometry that is different to the original beach profile. This technique has been used effectively by Campbell, Macleod and Swart (1985) to bracket the losses from a beach nourishment project in Durban, South Africa.

- Mathematical models which model the nearshore water and sediment movement accurately are better than any of the preceding methods but are very costly to execute and still suffer from the deficiency of not catering adequately for differences in the grain size distribution of the native and borrow materials. References which can be consulted in this regard are Watanabe (1982), Boer et al. (1984), Coeffe and Pechon (1982) and Sheng and Butler (1982).

- Physical models with a movable bed are also a possibility but are expensive to construct and take long (6-18 months) to execute, if one takes into account the construction, calibration and predictive stages. Proper scaling to allow the model to cater for a beachfill of limited geometrical proportions is also a problem.

- Field observations from the area may give a good first indication of the expected behaviour of the beachfill. For all of the above, field data are needed in any case to calibrate the respective techniques.

Experience has shown that in most cases the use of some sort of hybrid technique, that is, a combination of some of the above techniques is the most effective. In this respect a **mathematical or physical model** which will predict only the **water movement** can prove useful in conjunction with some of the above techniques.

Other aspects of beachfill which are important and which were discussed during the poster discussion sessions are:

- How do you define the required volume of sand related to the lifetime of the beach nourishment. In this respect the concept of a beachfill **half-life** was raised. During the design stage one should establish the future behaviour of the beachfill and decide whether it is a once-off exercise, whether it would have to be repeated from time to time (when the so-called half-life principle comes into the picture) or whether it should be maintained continuously. It is also important that these aspects are communicated to the public at an early stage so that they know what to expect.

- The design technique chosen should provide for the evaluation of the actual wave climate, to allow for the inclusion of extreme wave events and the cumulative effect of a number of extreme wave events in a short time span (the El Niño effect reported on by Seymour et al., 1984).

- The choice of a borrow area in relation to the littoral active zone or dynamic swept prism is of extreme importance, particularly as related to possible aggravated beach erosion elsewhere in the vicinity if located too close by. The borrow area also needs to be "designed". From both the physical and the environmental point of view it will be advantageous if the borrow area is a large flat area, that is, if only a thin layer of sand is removed.

5. CONSTRUCTION PHASE

It is not the purpose of this review to discuss the construction phase in detail. The reader is referred to the Dutch beachfill manual mentioned above in the case of beachfill design. Considerations similar to those covered in the manual for the construction phase will apply to other types of beach protection devices. However, the following few items are of particular relevance to the establishment of a good design for a beach protection scheme.

- It is important to decide beforehand on the phasing of the various components of the beach protection scheme, with specific attention to the question of how each completed part of the scheme will influence the rest of the scheme and of the longshore direction in which the scheme should be developed (up- or downdrift) to gain the most benefit from the littoral drift.

- The best construction techniques and their effect on the design should be considered. In this respect it is important for designers and contractors to get together at an early stage to evaluate these aspects and perhaps cater for some predictions in the design stage of construction phases.

- Perhaps the most important aspect related to the construction phase is that of quality assurance. Each element/component of the design/construction phase needs to be evaluated and the risk of failure due to, for example, extreme wave events during construction considered. Alternatives should be provided for. In this way the preparation of the project is more costly but the possible risks are reduced.

6. POST-CONSTRUCTION PHASE

It is necessary in the design stage to address the following aspects and to discuss their importance with the client.

- The necessity for post-construction monitoring should be stressed. Aspects of particular importance are the frequency of monitoring as related to the forcing mechanisms, the nearshore environment and the expected/predicted behaviour of the beach protection scheme, the extent of the monitoring and, last but not least, the body with whom the responsibility rests to pay for the monitoring. It is usually advantageous to include some funds for monitoring in the construction vote, as it is after all this monitoring which is going to determine to what extent the design is successful.

- Linked to the previous point is the need for a re-appraisal of the shoreline stability in the area and again a decision as to whose responsibility it would be.

7. DISCUSSION

From the discussion in the preceding sections it should be clear that although the planning, design and execution of beach protection schemes have come a long way in the past few decades, there are still many areas requiring detailed inputs from scientists and engineers. To allow us as a community to learn from our mistakes, it would be advantageous if we could:

- establish international co-operation and exchange on all the levels mentioned in this review;

- exchange good quality field data suitable for the comparison/verification of different design techniques and beach protection types;

- jointly address the matter of quality assurance and investigate the possibility of using a "half-life" concept as a measure of the effectiveness of any type of beach protection device.

In this respect the Dutch have indicated that they are willing to do the above as far as it relates to beachfill. The discussion at the conference indicated that initially there is no merit in establishing formal working groups, but that this should be done informally.

Let us make it our challenge when we have such a discussion again in the future, to be in a position by having addressed some or all of the points raised herein to say that we have advanced the science of planning, designing and executing beach protection schemes.

8. SUMMARY

With the exception of the paper presented by Kawata et al., all papers related results on the basis of practical experience gained through field works in various parts of the world, namely Eygpt,

Hawaii, Italy, Japan, Kuwait, Singapore, South Africa and Republic of China, Taiwan.

It is true that a lot of case studies have been done during the last decades in various countries, states, counties, prefectures, cities and towns, and extensive data sets have been accumulated. However, only limited data have unfortunately been made available to the relevant scientific and engineering fraternity. At present shore protection problems are the serious concern of not only the inhabitants of the coastal area but also the governmental agencies who have responsibility to maintain or rather improve the coastal environment. Therefore shore protection studies are highly needed world wide in order to understand the coastal phenomena more clearly and then to apply our knowledge to the preservation of beaches as well as the production of a better environment in the coastal zone.

Shore protection studies should cover broad phases in the coastal and nearshore area. These are related not only to the coastal characteristics in the physical sense such as waves, nearshore currents, sediment transport, interaction between coastal structures and natural forces, but also the social circumstances including environmental concern.

Therefore shore protection is one of the important tasks of coastal engineers. At the same time shore protection is a subject of serious debate for other people such as politicians, land owners, property owners, lawyers, bankers, insurers and fishermen. That is to say, shore protection is really a multidisciplinary subject.

From such a view point, coastal engineers should take the heavy responsibility of offering a good service or good guidelines to the people who are seriously concerned with shore protection. Therefore they should always consider the complicated real situations which contain the following two aspects. The first one is the subject related to the natural conditions such as wave climates, beach slope, beach material, and beach width. The second one is that related to the social circumstances such as social demand, economic conditions and environmental impact in the broad sense caused by human activity.

It is natural that these stated conditions are quite different from one location to another. Therefore we should carefully observe the information and data presented here and elsewhere in order to evaluate the adaptability of the measures or the concepts to any given site.

As a conclusion of the present summary paper, we would like to stress the importance of information exchange on shore protection measures not only from the engineering point of view but also from the view point of social demand.

CHAPTER 168

IMPULSIVE BREAKING WAVE FORCES ON AN INCLINED PILE EXERTED BY RANDOM WAVES

by

K. TANIMOTO*, S. TAKAHASHI*, T. KANEKO**, K. SHIOTA**

ABSTRACT

A calculation method of the impulsive breaking wave forces on piles is proposed in this paper. It is derived on the basis of experimental results with some theoretical considerations. Wave forces on a cylinder caused by both regular and irregular trains of waves are measured in a large wave flume. The experimental results are compared with the values predicted by both Wagner and Karman. In the proposed method, it is assumed that the impulsive force acts on the upper half of the pile between the still water level and the wave crest, and that the force distribution along the pile is triangular shape. The peak value in the distribution is expressed by the function of both the breaking force parameter and the inclination angle of the cylinder. The breaking force parameter is the ratio of the bottom slope to wave steepness. The time history of the impact force is given as a triangular pulse with a vertical rise. The duration time is determined as half of the value predicted by Karman's theory.

1. INTRODUCTION

Wave forces which act on cylindrical members supporting coastal and offshore structures are generally predicted as the sum of drag and inertia forces. However, impact forces should be counted in addition to these forces when breaking waves act on a pile.

A prediction method for the impact force is shown in the Shore Protection Manual(1975) on the basis of the experimental studies by Ross(1955,1959) and Hall(1958). According to the method, the total force by a breaking wave can be estimated by Morison's equation with the drag coefficient being 2.5 times the ordinary value. The experiments by Ross and Hall, however, were conducted with a steep bottom slope condition. The impact force is very large if the bottom slope is steep. The value of the impact force estimated by the formula, therefore, may be excessive for a gentle bottom slope condition. The dynamic response of structures resisting such an impact

* Hydraulic Engineering Division, Port and Harbour Research Institute Ministry of Transport, 3-1-1 Nagase, Yokosuka, Japan
** Engineering and Construction Division, Kawasaki Steel Corporation 2-2-3 Uchisaiwai-cho, Chiyoda-ku, Tokyo, Japan

force cannot be predicted, because it provides information only on the peak value of the impact force.

Goda et al. (1966) proposed a calculation method for the impact forces acting on a vertical pile, referring to the virtual fluid mass theory derived by Von Karman(1929). They obtained a diagram for the curling factor, which can evaluate the impact forces for both 1/10 and 1/100 bottom slope conditions. The time history of the impact force can be also predicted by the method.

Many inclined piles are used as the members of sea structures such as sea-berths and jetties. The authors (1986A,B) carried out a series of experiments to investigate the breaking wave force on an inclined pile and proposed a calculation method. The method was an extension of Goda's method.

All of these studies, however, were based on the experiments only by regular waves. Because ocean waves are random, it is important to investigate the wave force exerted by irregular waves. Only Ochi et al. (1984) discussed the statistical characteristics of impact pressure on a pile by random waves.

This paper proposes a calculation method for the impact forces of breaking waves due to random ocean waves. First, some theoretical consideration based on Wagner's theory was given to the impact force which occurs by a collision between the pile and the water surface. Secondly, experiments were conducted to measure the impact forces on the pile due to not only regular waves but also irregular waves. Then, the calculation method was derived. The present method provides information on the impact force including the peak value, the time history, and the distribution along the pile. The method is applicable not only to vertical piles but also to inclined piles.

2. THEORETICAL CONSIDERATION

Wagner (1932) derived a set of equations for the impact pressure due to collision between a rigid body and water surface. Figure 1 shows Wagner's model when the water surface strikes a pile. The water surface "pile-up" along the pile surface can be seen in the figure, which is taken into account in the theory. In this figure, D, R and V are the pile diameter, the pile radius, the uprising velocity of the water surface. An equivalent plate of the width 2b is considered between the two attaching points of the pile surface to the water surface. The axis x is parallel to the plate and the axis y is perpendicular to it. Equations which

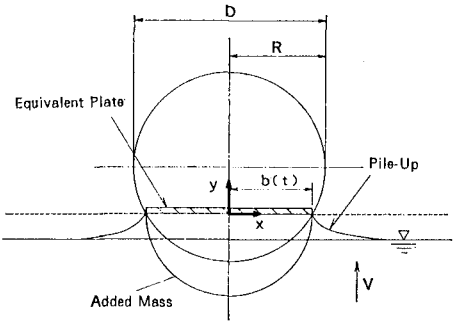

Fig.1 Wagner's model for impact force

determine the water surface profile at time t and the pressure on the pile surface are obtained from the complex potential of the flow around the flat plate.

In the actual calculation of the impact pressure, the pile surface should be expressed as a function of x. Here, the pile surface is approximated by the following equation:

$$\frac{y_1}{R}=\left(\frac{x}{R}\right)^m \qquad (1)$$

where, y_1 is the distance of the water surface from the bottom of the pile. Figure 2 shows the approximated profile of pile surface for several values of the power m in Eq.(1). The broken line, the dot-dash line, the two dots-dash line and the dotted line indicate the cases for m = 1, 2, 3 and 4 respectively. In the case where m =1, the profile by Eq.(1) is actually a wedge with the angle of 45 degrees. The bottom portion of the approximated profile swells as m increases. The profiles for m = 3 and 4 are close to a circle which is drawn by the solid line.

Figure 3 shows the time history of the total impact forces on the pile which are obtained from Wagner's theory. The vertical axis is the non-dimensional force $F/(w_0DV^2/2g)$, where F is the impact force, w_0 is the unit weight of water,and g is the gravity acceleration. The horizontal axis is the nondimensional time t/(R/V). The lines in the figure correspond to the same number of the power m respectively as in Fig.2. The solid line which represents the force on the circular pile based on the Karman's theory is also shown for comparison. Karman's theory neglects the pile-up effect. The followings can be pointed out from the figure:

a) The characteristics of the impact forces change greatly by the change of the pile profile. In the case of the wedge-shape pile (m = 1), the force increases linearly with time. When the pile profile

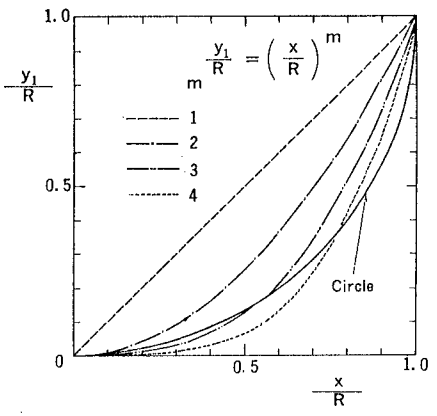

Fig.2 Approximated pile profiles

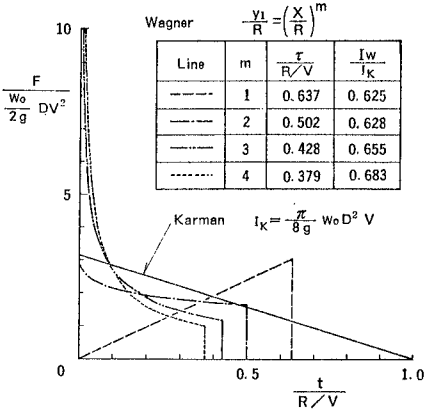

Fig.3 Calculated Impact force

approaches the circular shape (m= 3 and 4), the impact force becomes hyperbolic shape with a steep rise at the instant of collision and a sudden decrease after the peak.

b) The impact force on a circular pile by Wagner's theory is quite different from that by Karman's theory. For example, the peak value when m=3 is 471, which is more than one hundred times the peak value by Karman's theory. This is caused by the fact that the incremental rate of added mass of the equivalent flat plate by Wagner's theory is large because of the pile-up phenomenon, which is not considered in Karman's theory. In the range of $t/(R/V) > 0.09$, however, Wagner's impact force is smaller than Karman's one. This is due to the effect of negative pressure induced by the current along the pile surface. This effect is considered only in Wagner's equations.

c) By the effect of the pile-up, the impact duration time τ by Wagner's theory is shorter than that by Karman's theory. The Wagner's duration time with m = 3 is 0.428 times Karman's one.

d) The impulse of total force by the Wagner's theory is 0.6 - 0.7 times that by Karman' theory. This is also caused by the negative pressure component.

3. EXPERIMENTAL FACILITY AND PROCEDURE

Wave Tank and the Bottom Slope

The experiments were carried out in a large wave tank, which is 105 m long, 3 m wide and 2.5 m deep. The wave tank was divided into 80 and 205 cm wide flumes by a partition wall which was installed 42 m away from the wave generator. The model pile was installed in the 80 cm flume. The piston type wave generator in the wave tank could generate both regular and irregular waves.

The cross sections of the wave flume in the experiments are shown in Fig. 4 (a) and (b). The bottom slope i near the model was fixed at 1/30 or 1/100 as shown in the figure. The model pile was installed 72 m away from the wave generator. The water depth at the pile location h is maintained at 70 cm.

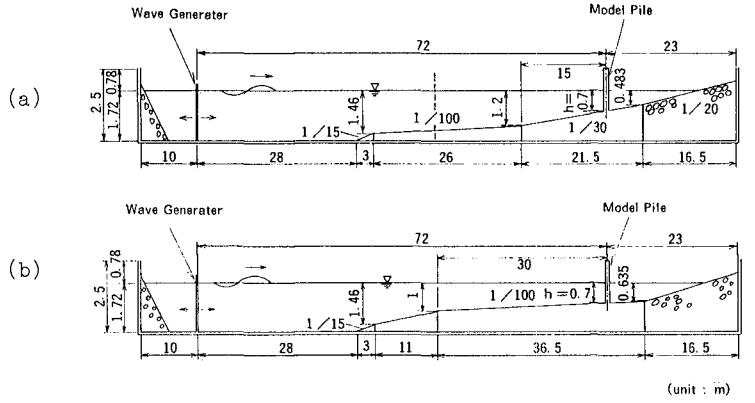

Fig.4 Cross sections of the wave tank

Model Pile and Wave Force Sensors

Figure 5 shows the model pile. The pile inclination was changed at angles $\theta = 0^{\circ}$, $\pm 15^{\circ}$ and $\pm 30^{\circ}$. The bottom end of the pile was fixed on a base plate. The top end was also fixed to the side wall of the wave tank with a steel beam. The pile diameter D was 14 cm. The model pile comprised thirteen wave force sensors (F1-F13) and two dummy pipes.

The details of the wave force sensor are shown in Fig.6. The sensor was an aluminum pipe with 5 mm thickness and 14 mm diameter, which was connected to a rigid steel pillar by 3 mm thick steel plates. When the wave force acted on the pile, the bending strain appeared in the steel plates. The force component perpendicular to the plates was measured with four strain gauges pasted on the plates. The sensitivity of the sensor was $8.7\,\mu$ / Kgf and the natural frequency was 745 Hz in air and 422 Hz in water. The damping factor was 0.026 in air and 0.068 in water.

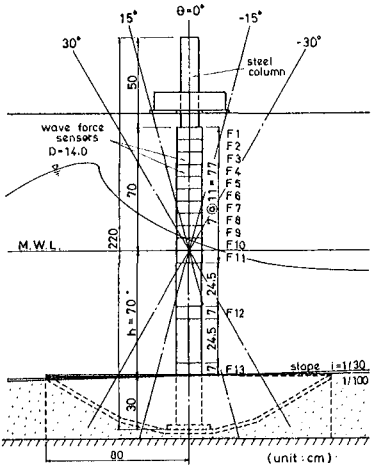

Fig.5 Model pile

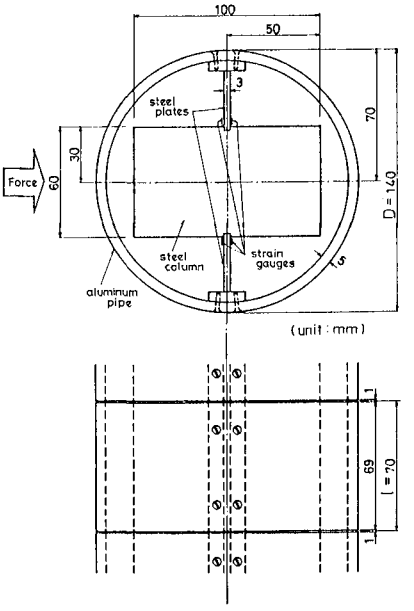

Fig.6 Wave force Sensors

Measurement and Analysis Method

The analogue signal from the wave force sensors was sent to a computer through amplifiers and low-pass filters, and was analysed by the computer. The low-pass filters were used not only to cut off the noise but also to reproduce the correct input force signal eliminating the response effect of the sensors. Although the natural frequency of

the sensors was very high, a dynamic response appeared in the sensors when the impact force is very large. The authors (1983) already investigated a method to obtain the impact force signal from the response data. This method was used in the present experiments. The applicability of the method was examined in the preliminary test. The cut-off frequency was set at 400 Hz for the sensors F1 - F10 , which were installed above the still water level. For the sensors F11 - F13 which were below the still water level, the cut-off frequency was set at 20 Hz since the impact force did not act on them. The sampling time in the analogue-digital conversion in the computer was 0.005 s.

4. CHARACTERISTICS OF WAVES

Regular Waves

The wave period T of regular waves was set at 2, 3 and 4 s. The wave height was fixed at H'/H_b = 0.5, 0.8, 0.9, 1.0, 1.1, 1.2 and 1.7, and the additional values of the wave height were selected near the breaking wave height H_b to obtain the maximum breaking wave force. The term H' is called here " the hypothetical passing wave height",which is the wave height at the measuring point for non-breaking waves but is the breaking wave height at the breaking point for breaking waves. The breaking wave height and the crest elevation η_b were measured in the experiments, which had the values very close to those evaluated by Goda's breaker indices (Goda 1970). The breaking wave velocity C_b measured by 16 mm film agrees very well with the value calculated by

$$C_b=\sqrt{g(h+\eta_b)} \tag{2}$$

Irregular Waves

The irregular waves in the experiments have the Bretschneider-Mituyasu spectrum (see Goda(1985) pp. 23-27). Three wave groups were prepared for the irregular wave tests, namely wave-A, wave-B and wave-C. The significant wave period of the three wave groups $T_{1/3}$ were 2, 3 and 4 s respectively. Each wave group has three wave trains;(A1 - A3), (B1 - B3) and (C1 - C3). Each wave train contains about two hundred waves, and therefore each wave group has about six hundred waves. Three different levels of the significant wave height were employed in the experiments as shown in Table 1. A wave train with the highest level of the significant wave height contains a number of breaking waves, while that of the lowest level has few breaking waves. Six more wave trains were prepared for the wave group B to examine the effect of the number of waves.

Table 1 Significant wave height

Wave Group	$H_{1/3}/h$					
	i = 1/30			i = 1/100		
A	0.307	0.491	0.556	0.311	0.457	0.519
B	0.370	0.601	0.674	0.359	0.539	0.580
C	0.364	0.656	0.766	0.363	0.557	0.623

The relation between the maximum wave height H_{max} and the maximum wave crest height, η_{max} can be expressed as follows from the results of the wave measurement.

$$\eta_{max}/H_{max}=0.5+a\sqrt{H_{max}/h} \tag{3}$$

$$\left.\begin{array}{ll} a\approx 0.247 & : \quad i=1/30 \\ a\approx 0.315 & : \quad i=1/100 \end{array}\right\} \tag{4}$$

5. EXPERIMENTAL RESULTS

Results of Regular Wave Tests

Figure 7 shows profiles of breaking waves striking a pile. This figure was made by tracing the film record for the case of T = 3 s, H' = 55.3 cm, i = 1/30, and θ = 0°. The vertical wave front near the crest is hitting very hardly the sensor F4 in the figure.

Figure 8 shows the time history of the force by the same breaking wave in Fig. 7. F_3 through F_7 indicate the force on the sensors F3 - F7 respectively. F is the total force which is obtained by integration of the forces on the sensors. The forces are presented in non-dimensional form with unit weight of water, w_0, the pile diameter D, the water depth h and the height of the sensor l. Large impact forces are observed in F4 and F5. The time histories of the impact forces are similar to that by Wagner's theory shown in Fig.3. The rising time is about 0.001 s.

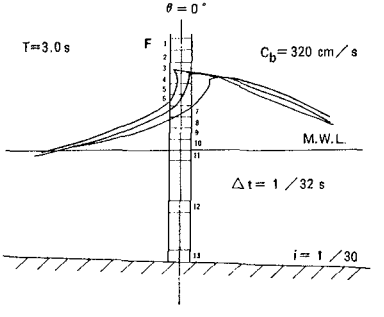

Fig. 7 Profiles of breaking wave striking the pile

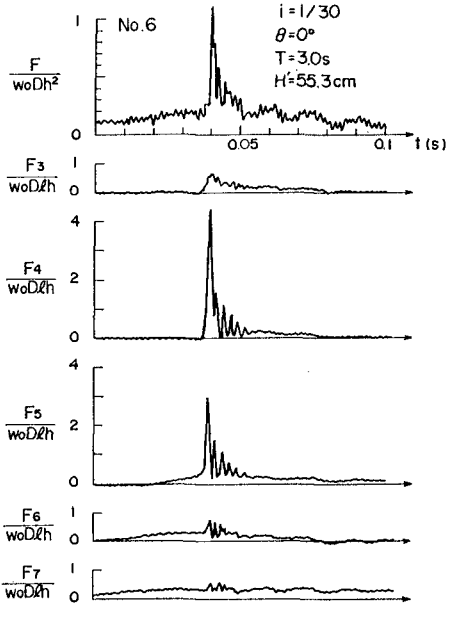

Fig. 8 Time history of impact force by breaking wave

Figure 9 shows the relation between the peak value of the total force F_m and the hypothetical passing wave height H' for the case of i = 1/30, $\theta = 0^\circ$ and T = 3 s. The arrow in the figure indicates the relative breaking wave height H_b/h. When H' approaches H_b, the impact force acts on the pile, and F_m scatters to a great extent. In the range of $H' > H_b$, the impact force decreases because post-breaking waves acts.

Figure 10 shows the relation between the maximum breaking wave force F and the "breaking force parameter" $i/(H_b/L_o)$, where L_o is the wave length in deep water. The breaking force parameter represents the change of the breaker type refering to the results of a series of small scale model tests (Authors 1986) The maximum breaking wave force F increases greatly in the range of $i/(H_b/L_o) = 0.4 \sim 0.7$ where the breaker type changes from spilling to plunging. As the pile inclines seaward, the wave which has a straight and sharp front just before breaking whips the face of the pile, causing a large impact force. When the pile inclines shoreward, however, the impact force is reduced. This is because only a small portion of the curling wave front just after breaking hits the face of the pile, and because the other portion of wave front is disturbed by itself.

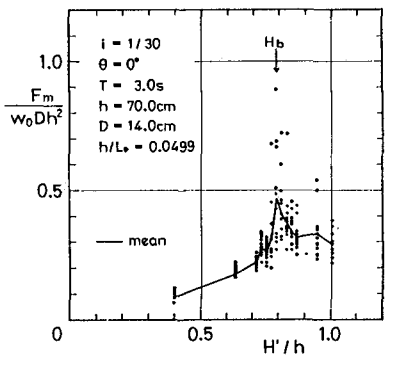

Fig. 9 Wave force vs wave height

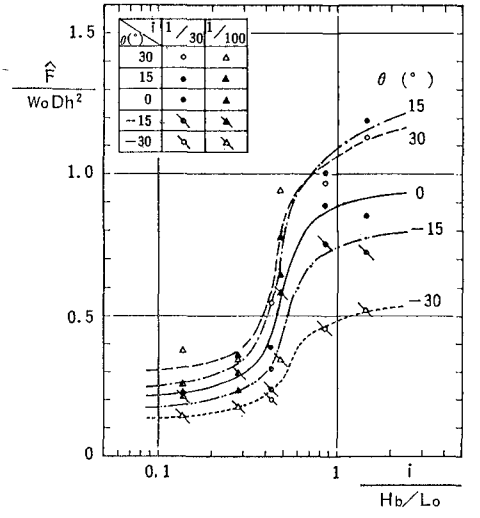

Fig.10 Maximum impact force

Figure 11 shows the breaking wave force distribution for several values of time when i = 1/30, $\theta = 0^\circ$, T = 4 s and H' / h = 0.83. The vertical axis z is the co-ordinate along the pile from the mean water level. When t = 0, a small force acts within the range z = -60 ~ + 20 cm. When t = 0.0825 s, the impact force with a sharp peak is observed just under the crest. The distribution of the impact force is symmetrical and triangular.

Results of Irregular Wave Tests

Figure 12 shows the time history of the water surface elevation

η , the total force F and the force on each wave sensor F_4 - F_{12} for the case of i = 1/30, θ = 0°, wave-B(B5),and $H_{1/3}/h$ = 0.676. Large impact forces are observed when the wave profiles are very steep in the figure. The irregularity of the wave forces is much emphasized compared with the irregularity of the waves.

The individual waves for a train of irregular waves are defined by the zero-upcrossing method. The peak values of the total force F_m for the individual waves were statistically analysed and the representative values of the peaks were obtained. The maximum value of

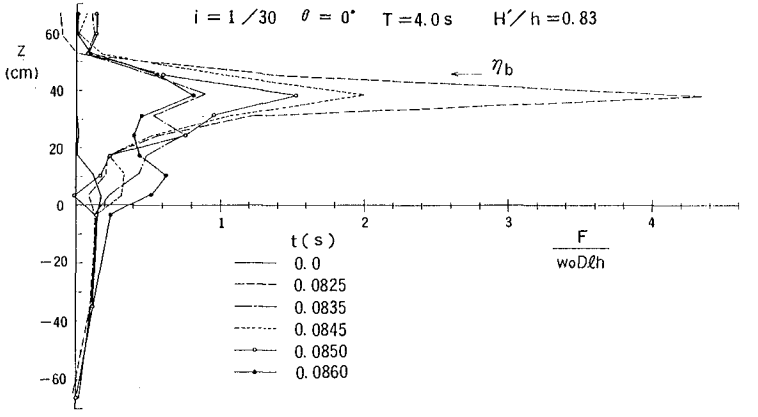

Fig. 11 Distribution of impact force

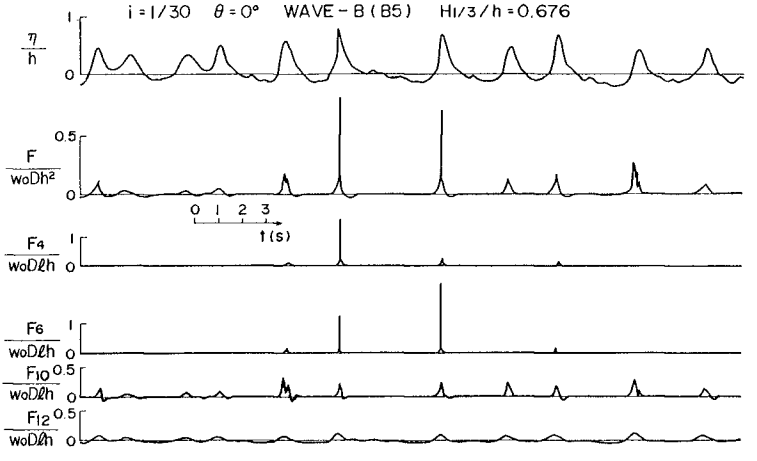

Fig. 12 Wave and wave force profiles by random waves

F_m in a wave train is denoted by F_{max}. The average of F_m from the highest to the 1/10 highest is called the 1/10 largest force $F_{1/10}$. The average of F_m from the highest to the 1/3 highest is called the 1/3 largest force $F_{1/3}$. The average of of all the peak values is denoted by F_{mean} respectively. The average of all the representative values for the different wave trains in the same wave group are expressed by $\bar{F}_{max}$, $\bar{F}_{1/10}$, $\bar{F}_{1/3}$ and $\bar{F}_{mean}$ respectively. The maximum value of F_{max} in a wave group is denoted by $\hat{F}$.

Figure 13 (a) and (b) show the frequency distribution of the peak wave force F_m in the form of probability density for the case of i = 1/30, $\theta = 0^o$ and wave-B(B1-B10). When $H_{1/3}/h$ =0.367 breaking waves were scarcely included, and then maximum value of $F_m/\bar{F}_{mean}$ is 5.3. When $H_{1/3}/h$ = 0.676, a fairly large number of breaking waves were included, and the maximum value of $F_m/\bar{F}_{mean}$ goes up to 7.3. This indicates that the peak values of the impact force vary very widely.

Table 2 shows the mean value and the standard deviation of the maximum force F_{max} to investigate the statistical characteristics of the maximum impact force. This is for the case of $\theta = 0^o$ and wave-B. The ratios between the representative forces are also shown. The mean value of F_{max} increases as the increase of $H_{1/3}$. For the case of $H_{1/3}$ = 0.676 and i = 1/30, the value of $\bar{F}_{max}$ is 0.808 and the standard deviation is 0.172. The columns of B3(Run 1 - 10) show the values when the same wave train B3 was repeated ten times. For the case of $H_{1/3}/h$ = 0.676 and i = 1/30, the values by the B3 wave train are almost the same as the values by the wave trains from B1 to B10.

Figure 14 shows the relation between the maximum force $\hat{F}$ and the breaking force parameter $i/(H_{max}/L_o)$. The maximum wave height instead

$\bar{x}$: mean σ : standard deviation

of the breaking wave height is used to evaluate the breaking force parameter for irregular waves, and the maximum wave height in the figure is the maximum wave height in each wave group. Similar to the results in the regular wave tests, $\hat{F}$ increases as the breaking parameter increases and the pile inclines seaward. However, the increasing curves are more straight in the figure than those for regular waves in Fig.10. That is, the wave force increases gradually with the increase of the breaking parameter. This is because various wave profiles can appear due to the combination of wave period and wave height in irregular waves.

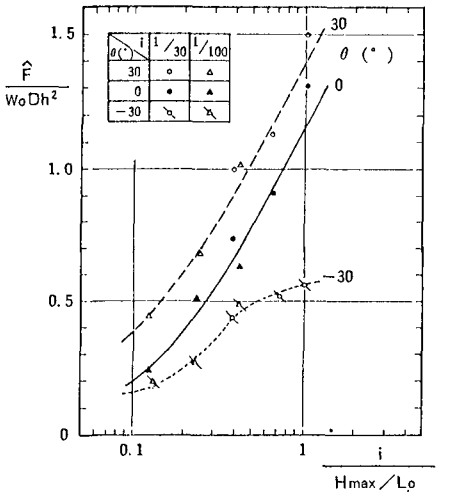

Fig.14 Maximum impact force

6. CALCULATION METHOD

Outline of the Method

The calculation method is proposed in this chapter. The method is based on Karman's and Wagner's theories but is simplified considering the experimental results by regular and irregular waves. As shown in Fig. 15, the impact force is assumed to act on the pile with a triangular distribution. The peak value and the width of the distribution are denoted by f_p and δ. The height of the peak above the still water level is denoted by l_p. The distribution of the impact

force is expressed by

$$f_z=\left\{1-\frac{|l_p-z|}{\delta/2}\right\}f_p \qquad for\ |l_p-z|<\delta/2 \qquad (5)$$

where f_z is the impact force on the pile at the location z .

The impact force is also assumed to vary with respect to time t as a triangular pulse which has a vertical rise. The duration time is denoted by τ . Therefore, the time history of the impact force at the peak location is

$$f_p=f_{pm}\left(1-\frac{t}{\tau}\right) \qquad for\quad 0<t<\tau \qquad (6)$$

where f_{pm} is the peak value of f_p with respect to time. The impact force at a certain point of the pile and at certain time is given by Eqs(5) and (6).The total impact force F_I and the peak value F_{Im} with respect to time in the calculation method are simply expressed by 0.5 δf_p and 0.5 δf_{pm} respectively.

Parameters

The parameters in the calculation method are determined as follows:

a) Peak Value at Peak Location

The peak value at the peak location is assumed to be in the following form:

$$f_{pm}=\nu f_{Km} \qquad (7)$$

where f_{km} is the peak value which is obtained by Karman's theory and ν is the adjustment factor. Karman's peak value is expressed by

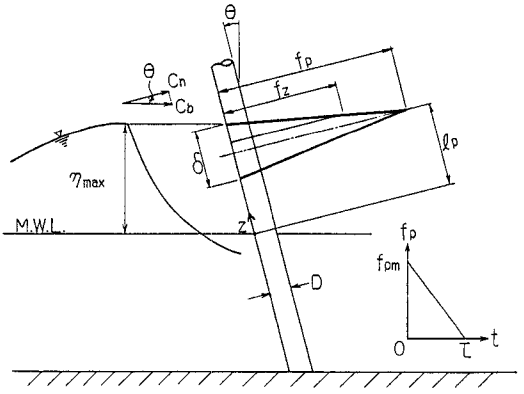

Fig.15 Impact force in the calculation method

$$f_{Km}=\frac{\pi}{2g}w_0 C_n^2 D \qquad (8)$$

where C_n is the wave celerity component perpendicular to the pile, which is

$$C_n=C_b\cos\theta \qquad (9)$$

b) Duration Time

According to Wagner's theory, the duration time and the impulse are about 0.4 and 0.65 times Karman's values respectively. The experimental results agree well with Wagner theory. Therefore, the duration time in the calculation method is assumed to be 0.5 times Karman's one as follows:

$$\tau = 0.25D/C_n \tag{10}$$

c) Height of the Peak Location above the Still Water Level

The height of the peak location above the still water level is averagedly 0.68 times the crest height for irregular waves in the experiments. Therefore, the height in the calculation method is assumed as

$$l_p = 0.75\,\eta_b/\cos\theta \tag{11}$$

d) Distribution Width

The distribution width is averagedly 0.516 times the crest height for irregular waves in the experiments. The distribution width in the calculation method is approximated as

$$\delta = 0.5\eta_b/\cos\theta \tag{12}$$

e) Adjustment Factor

The adjustment factor can be expressed by the following equation if the above relations are considered:

$$\nu = (8g\cos\theta/\pi w_0 C_n^2 D)(F_{Im}/\eta_{max}) \tag{13}$$

The adjustment factor ν was determined by the experimental data of F_{Im} with Eq.(13). It should noted that the value of F_{Im} is the pure impact component which is substracted the ordinary inertia and drag force component from the impact wave force. Two kinds of experimental values of F_{Im} were evaluated which were denoted by $\bar{F}_I$ and $\hat{F}_I$. $\bar{F}_I$ was evaluated by $\bar{F}_{max}$ which is the average of F_{max}, and $\hat{F}_I$ was evaluated by $\hat{F}$ which is the maximum value of F_{max} in each wave group. Two kinds of the adjustment factors denoted by $\bar{\nu}$ and $\hat{\nu}$ are evaluated by $\bar{F}_I$ and $\hat{F}_I$ respectively. The adjustment factor in the calculation method was determined by these two adjustment factors as follows:

$$\nu = (0.8+0.4\sin\theta)\tanh\{2.5\log_{10}\frac{i/(H_{max}/L_0)}{0.25}\}+1.0+1.2\sin\theta \tag{14}$$

Comparison of Results

Figure 16 shows the comparison of the calculated value of the impact force by the above method with the experimental values. In the figure, both $\bar{F}_I$ and $\hat{F}_I$ are shown. The experimental values agree with the calculated values on the average, and the difference between them is regarded to be small if the tendency of the large variation in the impact force is taken into account.

The calculated value by the method can be compared with the

calculated value by the method in the Shore Protection Manual (1975). For example, when h = 8 m, the wave height in deep water H_o = 6 m, $T_{1/3}$ = 10 s, D = 1 m, and i = 1/30 and 1/100, the maximum wave height H_{max} can be obtained as 6.78 m for i = 1/30 and 6.06 m for i = 1/100 by Goda's diagram (see Goda (1985) pp. 71 - 87). The impact forces by the present method are 43.4 tf and 25 tf for i = 1/30 and 1/100 respectively. These values are the pure impact component and the total impact forces become 55.4 tf and 47.3 tf if the ordinary inertia and drag component are evaluated to be 12.0 tf and 10.1 tf respectively. The impact breaking force by the method in Shore Protection Manual are nearly equal to the values by the present method for i = 1/30 but 35 % larger than the value by the method for i = 1/100.

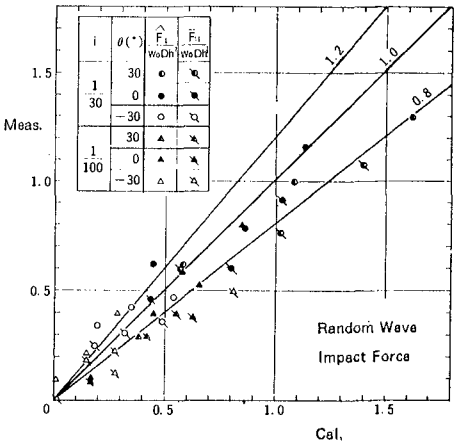

Fig.16 Comparison of the calculated results with experimental results

7. CONCLUSIONS

The major conclusions in the present study are as follows:

1) The peak values of the impact force on a circular pile by Wagner theory is larger than that by Karman's theory. The duration time and the impulse are about 0.4 and 0.65 times Karman's values respectively.
2) As a pile inclined seaward, the impact force increase greatly. As the pile inclined shoreward, the impact force decreases. If the inclination angle is within 30°, the impact force varies 20 ~ 50 % compared with the force on the vertical pile.
3) A new parameter called "the breaking force parameter", which is the ratio of bottom slope to wave steepness, can express the variation of the impact force. For regular waves, the impact force increases suddenly where the parameter is from 0.3 to 0.7. However, the impact force increases gradually with the increase of the parameter for irregular waves.
4) A calculation method of the impact force is proposed. The method is based on Karman's and Wagner's theory, but is simplified considering the experimental results. The distribution shape of the impact force is approximated as a triangle. The impact force is also approximated as a triangular pulse with respect to time. The adjustment factor is introduced in the method which expresses the variation of the impact force due to the breaking parameter and the inclination angle. The calculated results by the method agree with the experimental results as a whole.

CHAPTER 169

Transmission of Random Waves Through Pile Breakwaters

Clifford L. Truitt[1] M.ASCE
John B. Herbich,[2] M.ASCE

Abstract

Several previous investigators have conducted experiments leading to expressions for predicting the transformation of waves passing through closely-spaced pile breakwaters. The present study extends those earlier experiments using monochromatic waves to the case of a spectrum of random waves.

Records of incident waves and of waves after transmission through a model pile breakwater were compared to determine a coefficient of transmission. Results are presented for several cases of pile spacing and pile diameter. Good agreement is found between observed transmission coefficients and those predicted using the expression proposed by Hayashi et al. (1966).

Introduction

During the late 1960's and early 1970's considerable interest was generated in the transmission and reflection of waves from both permeable and impermeable structures such as breakwaters. Several investigators (e.g., Costello 1951; Hayashi et al. 1966; Wiegel 1964; Van Weele and Herbich 1972; Massel 1976; Khader 1978, 1981) conducted experiments which led to expressions or procedures for predicting the transformation of waves passing over or through such structures. Unfortunately, no field data of wave transmission through pile breakwaters are available to allow for quantitative evaluation of their effects on incident waves.

One of the basic problems recognized by the earlier researchers and the designers who have used their results was the character of the laboratory waves used in the experiments. The waves were monochromatic and typically small amplitude, while the prototype wave climate consisted of irregular waves forming a relatively broad spectrum. The work summarized in this paper addressed this problem by repeating the basic study of the transmission of waves through an array of closely-spaced model piles, but using spectra of random waves.

[1]Hydraulic Engineer, Coastal Engineering Research Center, U.S. Army Engineer Waterways Experiment Station, Vicksburg, Mississippi 39180.

[2]Professor of Ocean and Civil Engineering, Texas A&M University, College Station, Texas 77843-3136.

The objectives of the investigation were twofold. First, an evaluation was made of the transmission results calculated using different characteristic parameters of the wave spectra. For example, if the transmission coefficient is defined as the ratio of the height of the transmitted wave to that of the incident wave, the question arises as to what height parameter properly characterizes the transmitted and incident spectra. Results are presented using the root-mean-square height of all waves, the arithmetic mean or average of all waves, and the significant wave height. The second objective was to compare transmission coefficients measured for the random wave case with those predicted by expressions based on earlier work with monochromatic waves (Hayashi et al. 1966).

Experimental Procedure

The Hydromechanics Laboratories at Texas A&M University have fitted their existing 120-ft long by 2-ft wide and 2-ft deep (36.6 m by 0.6 m by 0.6 m), glass-walled, wave tank with random sea-generating equipment. This configuration permits the generation of irregular waves through several "library" spectra, or through user-programmed inputs.

The three basic groups of variables in the experiment are the geometry of the pile arrays, the water depths, and the input wave spectra. No attempt was made to rigorously model the experiment based on any prototype conditions. However, a linear scale on the order of approximately 1/50 was convenient and represents typical commercially available piling used in prototype breakwaters and piers.

Two sizes of standard galvanized steel conduit pipe were used to construct the model pile arrays. Steel conduit was selected to assure rigidity in the model and uniformity from pile to pile. The sizes selected were 15/16-in. O.D. (approximately 24mm) and 1-3/16-in. O.D. (approximately 30mm). At a scale of 1/50, these models would represent piles on the order of 48 to 60 in. (122 to 152 cm.) in diameter. The spacings between the piling in the arrays were chosen to be 5, 10, and 20 percent of the pile diameters. Again, while not rigorous, it was felt that these spacings were generally representative of the practical limits which could be achieved in a prototype structure. Consistent and uniform spacings closer than 3 to 4 in. could probably not be economically realized for piles 4 to 6 ft in diameter and typically over one hundred feet in length. A definition sketch is shown in Figure 1.

The model piles were fitted into drilled templates, one at the bottom of the wave tank and one at the top, well above the water surface. Spacings represent the average of measured values and incorporate some variability, as would a prototype structure. In each test run, the array was placed in the tank, plumbed vertically, adjusted to the desired angle relative to the incident wave orthogonal (in this paper, perpendicular), and rigidly clamped in place. Only single-row arrays and circular piles were investigated.

Tests were run with water depths in the tank of 16, 20, and 24 in. (41, 51, and 61 cm). Wire probes were used to measure the water level

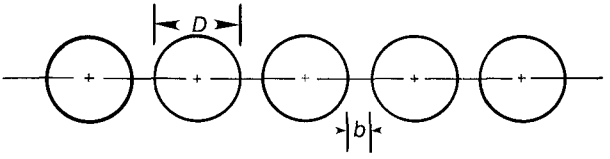
fluctuations resulting from the test waves. Each of the two probes was mounted on a movable carriage with one measuring incident wave heights and the other measuring transmitted waves on the opposite side of the model pile array. Tests were run both with the probe carriages moving and with them stationary. The probes recorded directly on standard oscillographs.

The random sea generator was capable of producing both library spectra and user input spectra. The four pre-programmed library spectra were used for these tests. No detailed discussion of the various spectra will be presented here, since results were calculated from actual wave records prior to incidence and after transmission from the arrays, rather than from the theoretical machine input. It was desired to use relatively short sequences or bursts of waves in the tests to minimize the influence of reflection in the tank. Records of a length of 25 to 30 waves were chosen for analysis. The results were examined statistically to assure that they were indeed random and of a satisfactorily significant length. Techniques are available to measure the combination of incident and reflected waves for longer records. However, the simpler approach described provided acceptable results and did not require an energy-based analysis.

It would seem that Reynolds number effects might be important and cause scale effects when comparing model results to prototype applications since a portion of the decrease in transmission in the model may be attributed to viscous damping. However, for prototype pile sizes and spacings, and for free-surface gravity waves the inertial force would likely predominate over the drag force.

Analysis Procedure

Using the described procedures, a total of 30 records were generated, each consisting of an incident wave spectrum and a transmitted wave spectrum. The waves in each record were then



D - PILE DIAMETER

b - PILE SPACING

RATIO (b/D) CHOSEN TO BE 0.05, 0.10, and 0.20

Figure 1. Definition sketch for pile geometry

characterized by actually measuring all recorded heights and calculating the following three parameters.

Root-mean-square wave height:

$$H_{rms} = \sqrt{\frac{1}{N} \sum_{j=1}^{N} H_j^2} \tag{1}$$

Mean, or average wave height:

$$\bar{H} = \frac{1}{N} \sum_{j=1}^{N} H_j \tag{2}$$

Significant wave height:

$$H_s = \text{average height of the one-third highest waves.} \tag{3}$$

With these parameters calculated, both the incident and transmitted waves in each test could be represented by H_{rms}, $\bar{H}$, or H_s. Thompson and Vincent (1984) point out the need to distinguish between the significant wave height, H_s, as defined in equation 3 and the spectral based significant wave height, H_{m_o}, defined from the variance of the wave record. Certainly wave attenuation by a piled breakwater is an energy-based process and the spectral based H_{m_o} may be more appropriate for actual design. However, for the present laboratory case, the water depth and level bottom slope allow treating H_s and H_{m_o} as interchangable.

One concern was to assure that the relatively short sequence lengths in the wave records were indeed long enough to be significant and reasonably random. It has been shown (e.g. Shore Protection Manual 1984) that for a true Rayleigh distribution the following theoretical relationships exist:

$$\bar{H} = 0.886\ H_{rms} \qquad \text{and} \tag{4}$$

$$H_s = 1.416\ H_{rms}\ . \tag{5}$$

Therefore, once H_{rms} had been determined for each incident record, theoretical values of $\bar{H}$, and H_s were calculated from the above relationships. These theoretical values were compared to the $\bar{H}$ and H_s determined from the records and the agreement was taken as an indicator of the significance of the wave sequence length. Figure 2 presents this comparison for H_{rms} and H_s.

In each case the theoretical and actual parameters were within a few percent of each other. While it is certainly desirable to use as long a sequence as possible, the excellent agreement obtained is an

indicator that the record lengths used were acceptable and of value in characterizing any trends present.

Evaluation of Characteristic Parameters

The degree to which wave heights are influenced during transmission through a structure can be described by the ratio of the height of the transmitted wave to the height of the incident wave, or:

$$\text{Coefficient of transmission} = \frac{H_T}{H_I} \tag{6}$$

When considering a spectrum of irregular waves the question arises as to how to characterize the incident and transmitted wave. If all waves in the incident spectrum are affected equally in the transmission process, then the coefficient of transmission can be based on any characteristic parameter, e.g. H_{rms} , $\bar{H}$, or H_s , as long as the same one is used for the transmitted spectrum (and no breaking occurs). However, if a structure "filters" one portion of the incident spectrum to a greater degree than other portions, the coefficient of transmission may vary depending on which parameter is used in the calculation. If we confine the present discussion to wave height parameters, then

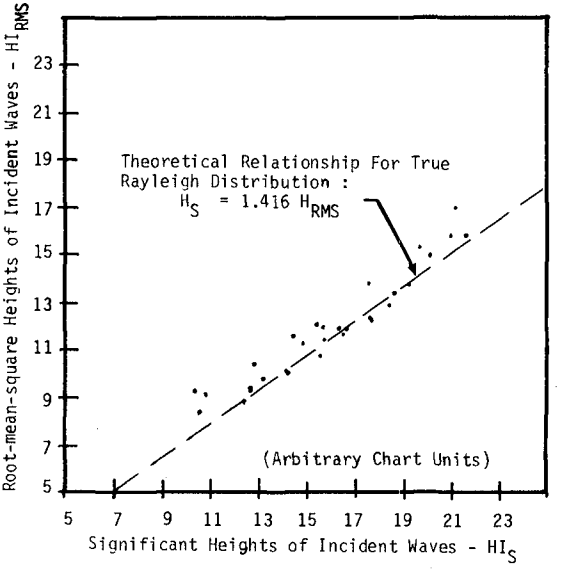


Figure 2. Comparison of observed relationships with theoretical predictors.

the relative variation of the coefficients of transmission calculated using H_{rms} , $\bar{H}$, and H_s may be an indicator of any preferential transmission effects present.

Certainly, other characteristics of the spectra involved may be equally influential and also serve as indicators. Period and wave steepness are proposed most frequently along with analysis of any changes in the relationship between energy density and frequency. All of these procedures require a representation of the wave period. While this may be done for records of actual ocean waves by use of a significant period or similar statistical or numerical methods approximation, such techniques can be difficult for laboratory wave records with all periods in the range of 1 to 2 sec.

For each of the thirty data sets a coefficient of transmission was calculated using the incident and transmitted wave heights given by H_{rms} , $\bar{H}$, and H_s . For a true Rayleigh distribution, linear relationships exist among the mean, root-mean-square, and significant parameters of a function. Therefore, if the Rayleigh distribution is assumed for the incident non-breaking wave spectra, and if the transmitted spectra are not preferentially altered, then the coefficients of transmission for a particular test should be the same whether calculated from root-mean-square, mean, or significant heights. Figure 3 is a comparison of the transmission coefficients calculated using each of the three height parameters. The agreement suggests that the transmission coefficients calculated in this experiment were

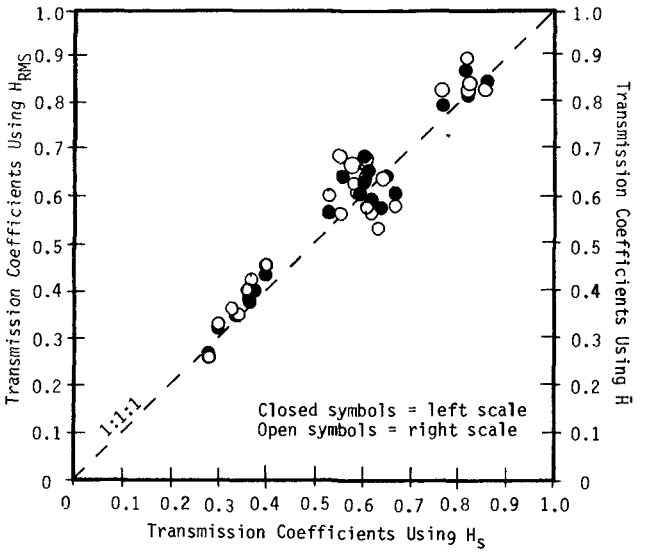

Figure 3. Comparison of transmission coefficients calculated using three different height parameters.

reasonably independent of the parameter used to characterize the wave height spectra. The values based on significant heights were selected for further comparison with predictive models since H_S is widely recognized and easily computed.

Comparison With Predictive Expressions

Wiegel (1961) proposed the following relationship to predict the coefficient of transmission for a single-row pile array:

$$\frac{H_T}{H_I} = \frac{b}{D + b} \tag{7}$$

In this expression b is the spacing and D is the pile diameter as shown on Figure 1. This is a variation on the porosity parameter used in earlier studies of permeable wave absorbers. Wiegel later measured transmitted wave heights typically 25 percent greater than predicted.

Hayashi et al. (1966) proposed the following relationship arising from consideration of the velocity of the water jets discharging through the pile spaces:

$$\frac{H_T}{H_I} = 4\left(\frac{d}{H_I}\right) E \left[- E + \sqrt{E^2 + \frac{H_I}{2d}} \right] \tag{8}$$

$$\text{with } E = C\left(\frac{b}{D + b}\right) \Bigg/ \sqrt{1 - \left(\frac{b}{D + b}\right)^2} \tag{9}$$

The use of b, D, and H are as above, and d is the water depth (still water). The parameter C is a representation of the effects of jet contraction and velocity in Bernoulli's theorem and is recommended as equal to 0.9 to 1.0. It is analogous to a coefficient of discharge, defined as the product of a velocity coefficient, C_v, and a contraction coefficient, C_c. The recommended values of 0.9 to 1.0 suggest that the spacing and well-rounded character of the openings between round piles are such that little decrease in discharge occurs from friction or flow contraction effects. Pile arrays that use other shapes or geometries suggestive of a sharp-edged outlet would require a lower value of C.

For each of the thirty data sets, coefficients of transmission were calculated using the above expression with $C = 0.9$ and again with $C = 1.0$.

The predicted coefficients were then compared to those actually calculated from the observed wave height data. Figures 4 and 5 summarize that comparison. The equation with $C = 1$ tends to predict a somewhat higher transmission coefficient than observed, especially at the closer pile spacings. The use of $C = 0.9$ provided a better general prediction of these tests.

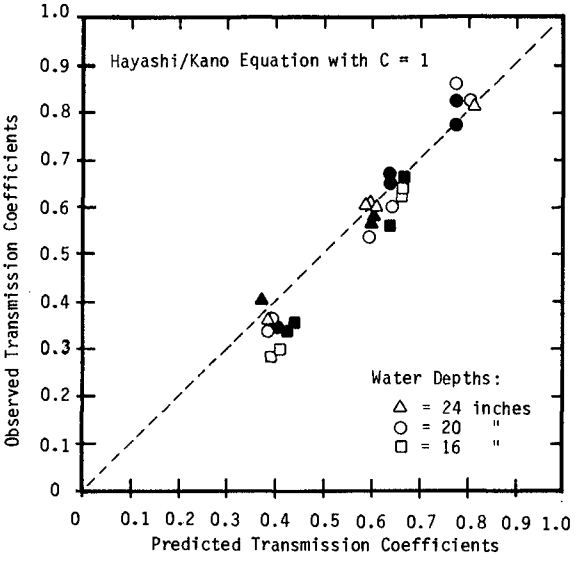

Figure 4. Comparison of observed transmission coefficients with those predicted using equation proposed by Hayashi et al. (1966) (C = 1)

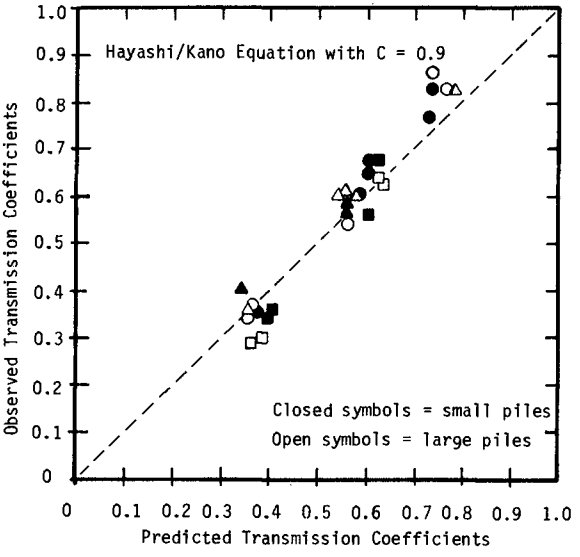

Figure 5. Comparison of observed transmission coefficients with those predicted using equation proposed by Hayashi et al. (1966) (C = 0.9)

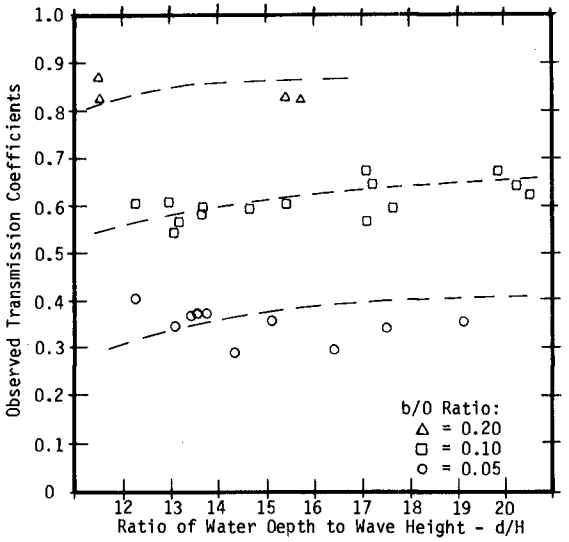

Figure 6. Observed transmission coefficients versus water depth to wave height ratio

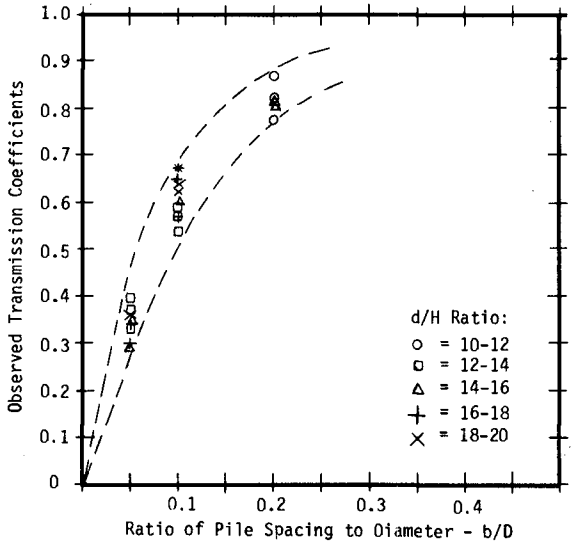

Figure 7. Observed transmission coefficients versus pile spacing to diameter ratio

The additional influences of water depth and of relative spacing were considered. Figures 6 and 7 show the observed transmission coefficients plotted against the ratios of water depth to wave height (d/H_s), and pile spacing to pile diameter (b/D), respectively. Figure 6 clearly shows the influence of the b/D ratio over a range of water depth/wave height values. The influence of d/H_s is not readily apparent in Figure 7. Note that the ratios of water depths to wave heights, d/H_s, in these tests were typically 3 to 5 times larger than those reported by Hayashi et al. (1966). At the lower d/H_s ratios, Hayashi et al. (1966), depicted a strong sorting of the data based on this influence. It appears that as the wave height becomes a smaller precentage of the water depth (larger d/H_s), and/or for random wave spectra consisting of many wave heights, the transmission coefficient is influenced more by the breakwater geometry, b/D, than by the water depth.

Conclusions

As long as the same parameter was used for both incident and transmitted spectra, little difference was noted in transmission coefficients calculated from H_{rms}, $\bar{H}$, or H_s for these laboratory experiments.

The results of these tests indicate that some of the analysis techniques developed earlier for predicting the transmission of monochromatic waves through pile breakwaters can be extended to random waves. Very good agreement was obtained using the equation presented by Hayashi et al., 1966.

The ratio of water depth to wave height (d/H_s) influences the transmission coefficient in the general sense, but the influence of the breakwater geometry, i.e. ratio spacing to diameter (b/D) is more pronounced. Further work should investigate the influences of wave steepness and/or period on transmissions. An energy analysis may be necessary for such an investigation.

CHAPTER 170

An Analytical Model for Ocean Wave-Soil-Caisson Interaction

Yau-Tang Tsai[1], William G. McDougal[2], and Charles K. Sollitt[2]

Abstract

An analytical model is developed to predict the soil responses induced by waves and caisson motion. The caisson is founded on a rubble bedding layer overlying a soil of finite depth. The responses are modeled by the Biot consolidation equations. Two approximations are employed to reduce mathematical difficulties: 1) a boundary layer approximation to decouple pore pressure and soil motion in the Biot equations and 2) a contact solution approximation for a thin elastic layer to address mixed-type boundary-value problems.

1. Introduction

Caisson-type structures are commonly employed as breakwaters, bulkheads, and seawalls. Critical failure areas for these types of structures are the toe and underlying foundation. These failures often result from wave-induced scouring, high porewater pressure, and large stresses developed in the foundation soil. These processes may lead to rapid and deep erosion at the toe as well as liquefaction of the foundation material. Hence, an understanding of the failure mechanisms for the foundation and an evaluation of the foundation stability are necessary.

Durand and Monkmeyer (1982), Liu (1985), and Dias and Monkmeyer (1986) have developed analytical solutions to estimate the wave-induced dynamic porewater pressure underneath a fixed caisson or a fixed plate founded on a porous rigid seabed. However, Stematiu and Stera (1985) pointed out that the structure-soil interaction is extremely significant in the foundation design of a caisson. This interaction results in high local stresses in the soil skeleton. Attempts to model the combined effect of porewater pressure and displacements were made by Lindenberg et al. (1982) and Stematiu and Stera (1985) using finite element methods. Finite element models have the disadvantage that they do not provide the physical insight into the problem which is often revealed in an analytical solution. The first steps toward an analytical solution were presented by Mynett and Mei (1982) for a caisson founded directly on the seabed, assuming the soil to be a poroelastic half-space. These assumptions limit the range of application of the model in some practical applications.

[1]Assistant Professor, Ocean Engineering Program, Department of Civil Engineering, Oregon State University, Corvallis, Oregon 97331-2302.
[2]Associate Professor, Ocean Engineering Program, Department of Civil Engineering, Oregon State University, Corvallis, Oregon 97331-2302.

Therefore, the objective of this paper is to develop an analytical model to estimate foundation stresses, porewater pressure, and structure motions for a wave-loaded caisson founded on a rubblemound bedding layer overlying a soil of finite depth.

2. Formulation of the Model

The wave-soil-caisson interaction problem is depicted in Fig. 1, in which h is the still water depth, d is the thickness of the soil skeleton, b is the thickness of the rubble bedding layer, 2c' is the width of the caisson; and 2c is the width of the mound foundation on the mudline through which the displacement repsonse of the caisson completely transfers to the soil skeleton. 2c is approximated employing a 2V:1H slope (Bowles, 1982) and is termed the effective width of the caisson base.

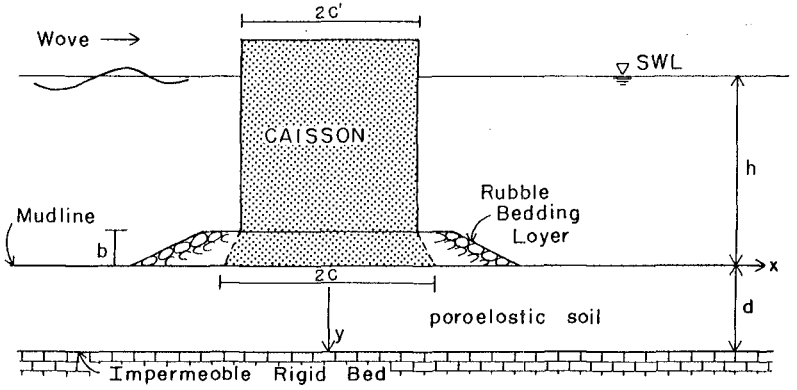

Figure 1. Definition sketch for the coordinate system and wave-soil-caisson system.

The development of the analytical model necessitates a number of assumptions. Among these are:

1. This is a two-dimensional problem.

2. The water depth is constant and small amplitude wave theory is applicable.

3. The soil and wave responses are decoupled.

4. A rigid caisson is founded on a rubble bedding layer which is considered to be hydraulically permeable and mechanically stiff compared with the underlying soil.

5. There is no slip between the caisson and the rubble bedding layer. Caisson displacements are completely transferred to the seabed through the rubble bedding layer.

6. The soil stratum is assumed to be linearly poroelastic, isotropic, and is confined by a horizontal mudline above and a horizontal impermeable, rigid bed below.

Governing Equation

Biot considation theory (Biot, 1941) is applicable to a shift saturated poroelastic medium. It has been successfully employed to model a variety of soil-wave interaction phenomena (Yamamoto et al., 1978; McDougal et al., 1981; and Mei and Foda, 1981). The Biot equations couple the motions of fluid and solid phases. This coupling increases the mathematical difficulty. Mei and Foda (1981) developed a boundary layer approximation which decouples the pore pressure and solid motion. Near the mudline there exists a boundary layer in which drainage is relatively unimpeded and there is significant relative motion between the fluid and the solid. Farther from the mudline there is little drainage so the fluid and solid tend to move in phase. This is termed the outer region problem, which can be reduced to solving a classical elastostatic problem. However, the boundary conditions on the mudline are not satisfied. Hence, corrections are made according to the boundary layer solutions so that the boundary conditions on the mudline are satisfied.

The governing equations for the outer region and boundary layer problems have been developed by Mei and Foda (1981). Their results are summarized in the following.

Outer Region Problem - The governing equations for the outer region problem were derived from the equations of momentum. $()^o$ denotes a parameter in the outer region problem. For sandy sea beds the equations of momentum for the solid and fluid yields

$$\frac{\partial(\tau'^{o}_{ij} - p^o\delta_{ij})}{\partial x_j} = 0 \tag{1}$$

where τ'^{o}_{ij} is the effective stress, p^o is the porewater pressure, δ_{ij} is the Kronecker delta, and x_j is the axis in the Cartesian coordinates system. Introducing the total stress τ^{o}_{ij} to (1) yields

$$\frac{\partial \tau^{o}_{ij}}{\partial x_j} = 0 \tag{2}$$

For convenience, lengths and displacements are scaled by the effective caisson half-width, c, and stresses and pressures are scaled by the mudline pressure amplitude due to the free surface propagating waves, P_o. The dimensionless variables will be denoted by upper case letters.

Applying Hook's law to (2) yields the governing equations for the outer region problem.

$$\nabla^2 U^o + \frac{1}{1-2\nu} \frac{\partial}{\partial X} \left(\frac{\partial U^o}{\partial X} + \frac{\partial V^o}{\partial Y} \right) = 0 \tag{3a}$$

$$\nabla^2 V^o + \frac{1}{1-2\nu} \frac{\partial}{\partial Y} \left(\frac{\partial U^o}{\partial X} + \frac{\partial V^o}{\partial Y} \right) = 0 \tag{3b}$$

in which U^o and V^o are the dimensionless horizontal and vertical displacements, respectively, ν is Poisson's ratio, and X and Y are the dimensionless horizontal and vertical axes in the Cartesian coordinate system, respectively.

First the displacements are determined and then stresses in the soil skeleton may be obtained by applying Hook's law to the displacement solutions. The porewater pressure in the outer region is related to the total stresses by

$$P^o = - \frac{T^o_{xx} + T^o_{yy}}{2 (1+m_o)} \tag{4}$$

in which

$$m_o = \frac{\beta' n_o G}{1-2\nu} \tag{5}$$

and is a parameter indicating the relative stiffness between the solid and pore fluid. In (5) β' is the combined air-water compressibility, n_o is the porosity, and G is the shear modulus.

Boundary Layer Correction - The governing equation for the boundary layer problem was derived from the equation of momentum and the storage equation. Again, $()^b$ denotes a parameter in the boundary layer. The porewater pressure P^b in the boundary layer is governed by the one-dimensional Terzaghi consolidation equation

$$\frac{\partial P^b}{\partial T^b} = \frac{\partial^2 P^b}{\partial (Y^b)^2} \tag{6}$$

in which T^b is dimensionless time scaled by the wave frequency and Y^b is the vertical coordinate and scaled by the boundary layer thickness δ.

The boundary layer correction is summarized as

$$\begin{Bmatrix} P^b \\ T'^b_{xx} \\ T'^b_{yy} \\ T^b_{xy} \end{Bmatrix} = \begin{Bmatrix} 1 \\ \frac{\nu}{1-\nu} \\ 1 \\ 0 \end{Bmatrix} P^b \tag{7}$$

in which T'^{b}_{xx} and T'^{b}_{yy} are the effective dimensionless horizontal and vertical normal stresses, respectively, and T^{b}_{xy} is the dimensionless shear stress. No shear stress correction is required in the boundary layer.

The ratio of the boundary layer thickness and the effective caisson half-width is denoted by

$$\varepsilon = \frac{\delta}{c} \tag{8}$$

in which

$$\delta = \sqrt{\frac{k'}{\sigma}} \left(\beta' n_o + \frac{1}{G} \frac{1-2\nu}{2(1-\nu)}\right)^{1/2} \tag{9}$$

where k' is the intrinsic permeability and σ is the wave frequency. The displacement components for the boundary layer correction are at most of order ε and can be neglected.

Boundary Conditions

The boundary conditions for the wave-soil-caisson problem are:

1. Along the exposed portion of the mudline, the wave pressure and the total normal stress are continuous and the shear stress is negligible (McDougal et al., 1981).

2. Under the structure, the displacements are continuous at the caisson-soil interface.

3. Along the entire mudline, the wave-induced pore pressure is continuous.

4. The soil overlies a rigid bed at which no-slip and no normal fluid flow conditions are imposed.

These boundary conditions are summarized in Fig. 2.

Outer Region Problem - The soil displacement and the caisson motion are coupled. The wave forces along the exposed portion of the mudline induce soil stresses and displacements underneath the caisson. The wave forces on the caisson induce caisson motions which result in stresses and displacements in the soil away from the caisson. Linearity allows these two effects to be decoupled into scattering and radiation problems. In the scattering problem, the caisson is assumed to be fixed and the soil response is completely driven by the wave pressure on the mudline. The forces on the caisson determined in the scattering problem are applied on the caisson in the radiation problem. These forces result in caisson motion on an otherwise static seabed. The sum of these two components, the scattering problem and

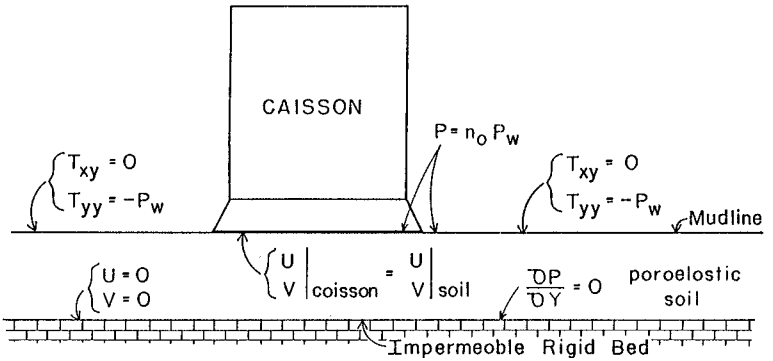

Figure 2. Boundary conditions for the wave-soil-caisson system

the radiation problem, yields the total response. This technique is illustrated in Fig. 3.

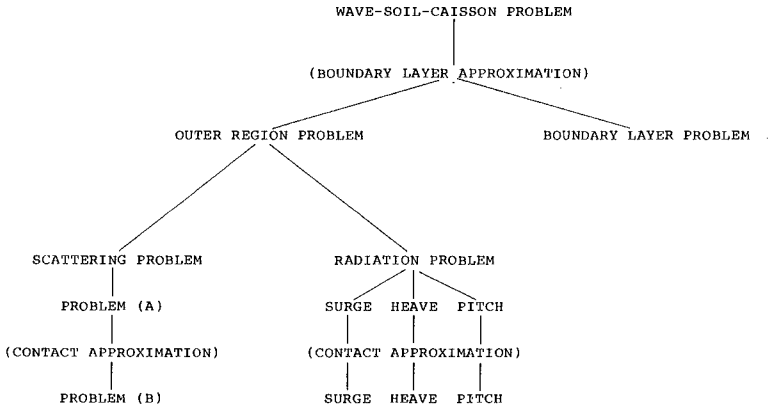

Figure 3. Decomposition of the wave-soil-caisson problem

The Scattering Problem - For the scattering problem the caisson is fixed and the mudline boundary conditions are

$$T^{o}_{xy}(X,0) = 0 \qquad ; 0 \leq |X| < \infty \qquad (10a)$$

$$T^{o}_{yy}(X,0) = -P_{w}(X)e^{-i\sigma t} \qquad ; 1 \leq |X| < \infty \qquad (10b)$$

$$U^{o}(X,0) = 0 \qquad ; |X| \leq 1 \qquad (10c)$$

$$V^{o}(X,0) = 0 \qquad ; |X| \leq 1 \qquad (10d)$$

This results in a mixed boundary-value problem. To solve this problem, a sequence of two solutions is sought: one which satisfies the stress boundary conditions (problem (a)) and then a second solution which satisfies the displacement boundary conditions (problem (b).

The boundary conditions for problem (a) and (b) are shown in Fig. 4. The displacements along the mudline, ${}^{a}U^{o}(X,0)$ and ${}^{a}V^{o}(X,0)$, from the solution for the problem (a) are modified to provide the boundary conditions for problem (b). The first modification is that under the structure the displacements are set equal to zero. The second modification is based on the solution to the contact problem on a thin elastic layer developed by Alblas and Kuipers (1969). This solution provides appropriate displacements adjacent to the structure. Details are presented in Appendix I. The solution to problem (b) satisfies both stress and displacement conditions along the mudline. Thus, it is the solution for the scattering problem.

The Radiation Problem - The radiation problem is a moving caisson on an otherwise static soil. The response of the soil must satisfy the caission displacement conditions on the mudline. The caisson responds to both wave and soil loadings from the scattering problem and a restoring force in the radiation problem. The scattering loads are known but the motion is still unknown. A dynamic boundary condition must be prescribed to solve for the unknown caisson motion. This condition yields the amplitude of the caisson motion. Linearity allows the soil response to be decomposed into three problems corresponding to each of the three degrees of freedom of caisson motion. The caisson is assumed to be rigid and the effects of the structural damping in the caisson are assumed to be negligible compared with the soil.

Underneath the caisson the motions are specified while along the exposed portion of the mudline zero stress conditions apply. The boundary conditions for the radiation problem are depicted in Fig. 5. The respective boundary conditions along the mudline for the problems of surge, heave, and pitch may be defined by appropriate displacement and stress conditons. Displacement conditions over the entire upper boundary may be written by introducing ${}^{1}U^{o}_{f}$, ${}^{2}V^{o}_{f}$, and ${}^{3}V^{o}_{f}$, which account for the unknown displacements along the exposed portion

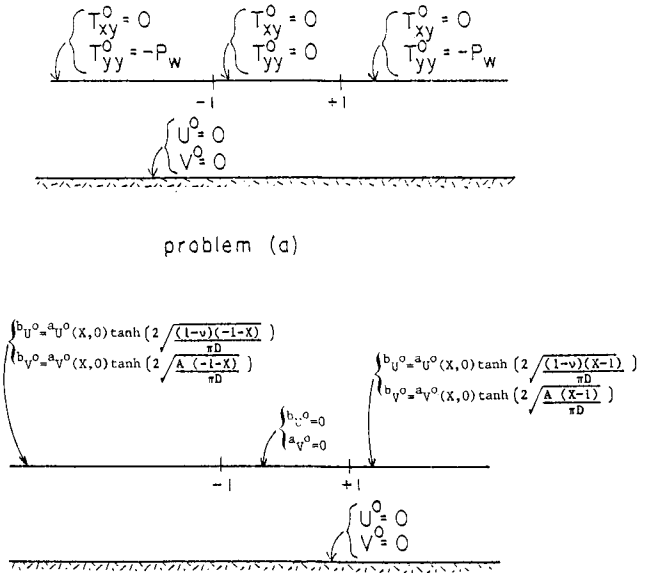

Figure 4. Boundary conditions for the scattering problem

of the mudline. Stress conditions for each degree of freedom of the caisson motion are also reasonably approximated as given by Alblas and Kuipers (1969 and 1970).

(1) surge

$$T^o_{yy}(X,0) = 0 \qquad ; \ 0 \leq |X| \leq \infty \qquad (11a)$$

$$U^o(X,0) = U_c + {}^1U^o_f \qquad ; \ 0 \leq |X| < \infty \qquad (11b)$$

(2) heave

$$T^o_{xy}(X,0) = 0 \qquad ; \ 0 \leq |X| < \infty \qquad (12a)$$

$$V^o(X,0) = V_c + {}^2V^o_f \qquad ; \ 0 \leq |X| < \infty \qquad (12b)$$

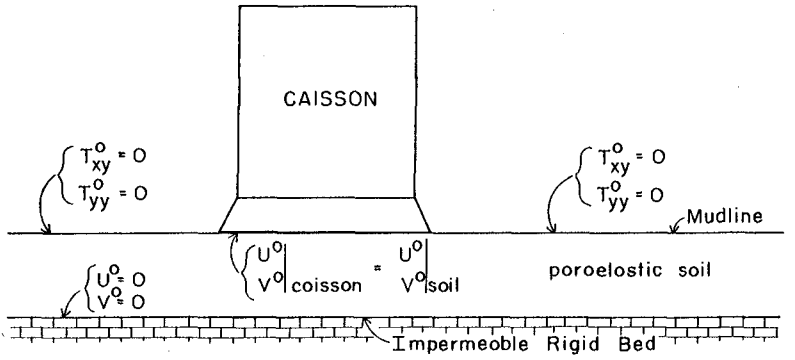

Figure 5. Boundary conditions for the radiation problem

(3) pitch

$$T^o_{xy}(X,0) = 0 \qquad ; 0 \leq |X| < \infty \qquad (13a)$$

$$V^o(X,0) = -\alpha_c X + {}^3V^o_f \qquad ; 0 \leq |X| < \infty \qquad (13b)$$

These are no longer mixed-type boundary conditions, and the boundary-value problem can easily be solved. The displacements ${}^1U^o_f$, ${}^2V^o_f$, and ${}^3V^o_f$ can be evaluated by employing the thin soil layer contact problem solution technique presented in Appendix I.

$${}^1U^o_f = U_c \begin{cases} 1 - \tanh\left(2\sqrt{\dfrac{(1-\nu)(-1-X)}{\pi D}}\right) & ; -\infty < X \leq -1 \\ 1 - \tanh\left(2\sqrt{\dfrac{(1-\nu)(X-1)}{\pi D}}\right) & ; 1 \leq X < \infty \end{cases} \qquad (14a)$$

$${}^2V^o_f = V_c \begin{cases} 1-\tanh\left(2\sqrt{\dfrac{A(-1-X)}{\pi D}}\right) & ; -\infty < X \leq -1 \\ 1-\tanh\left(2\sqrt{\dfrac{A(X-1)}{\pi D}}\right) & ; 1 \leq X < \infty \end{cases} \qquad (14b)$$

$$ {}^{3}V_f^o = \alpha_c \begin{cases} 1-\tanh\left\{2\sqrt{\frac{A(-1-X)}{\pi D}}\,(1 + i\,\hat{S}'_{-}(0))\right\} & ; -\infty < X \leq -1 \\ 1-\tanh\left\{2\sqrt{\frac{A(X-1)}{\pi D}}\,(1 + i\,\hat{S}'_{-}(0)\right\} & ; 1 \leq X < \infty \end{cases} \tag{14c} $$

In (11b), (12b), and (13b), U_c, V_c, and α_c are the displacements of the caisson in surge, heave, and pitch, respectively. Positive α_c is defined as counterclockwise. These displacements are unknown, but may be determined from the dynamic boundary conditions on the soil-caisson interface, i.e., the equation of motion for the caission.

$$ \begin{bmatrix} m & 0 & 0 \\ 0 & m & 0 \\ 0 & 0 & I_m \end{bmatrix} \begin{Bmatrix} \ddot{U}_c \\ \ddot{V}_c \\ \ddot{\alpha}_c \end{Bmatrix} = \begin{Bmatrix} f_{w1} \\ f_{w2} \\ f_{w3} \end{Bmatrix} + \begin{Bmatrix} f_{s1} \\ f_{s2} \\ f_{s3} \end{Bmatrix} + \begin{Bmatrix} f_{r1} \\ f_{r2} \\ f_{r3} \end{Bmatrix} \tag{15} $$

where m and I_m are the mass and mass moment of inertia of the caisson, respectively, $\ddot{U}_c$, $\ddot{V}_c$, and $\ddot{\alpha}_c$ are the accelerations of surge, heave, and pitch of caisson motion, f_{wj} and f_{sj} are the wave and soil loads on the caisson determined in the scattering problem, and f_{rj} are the restoring forces on the caisson. The soil loads are obtained by integrating the stresses along the caisson-seabed interface.

The Boundary Layer Correction - Along the mudline, the summation of the pressure from the boundary correction and outer region solution is equal to the wave-induced porewater pressure. Along the rigid bed underlying the soil, the normal derivative of the pore pressure must be zero, i.e.,

$$ \text{at } Y = 0 \qquad P^o + P^b = n_o\, P_w(X) \qquad ; 0 \leq |X| < \infty \tag{16a} $$

$$ \text{at } Y = D \qquad \frac{\partial(P^o + P^b)}{\partial Y} = 0 \qquad ; 0 \leq |X| < \infty \tag{16b} $$

3. Solution to the Model

The poroelastic layer occupies the strip space $-\infty < X < \infty$; $0 \leq Y \leq D$. A Fourier transform is applied with respect to X in Eq. (3). It follows that the general solution for the outer region problem is in the form of Fourier transform

$$\hat{U}^o(s,Y) = a_1 ch(sY) + a_2 sh(sY) + a_3 Ych(sY) + a_4 Ysh(sY) \qquad (17a)$$

$$\hat{V}^o(s,Y) = -i\{a_1 sh(sY) + a_2 ch(sY) + a_3[Ysh(sY) - \frac{3-4\nu}{s} ch(sY)]$$

$$+ a_4[Ych(sY) - \frac{3-4\nu}{s} sh(sY)]\} \qquad (17b)$$

in which s is a Fourier transform parameter and functions ch and sh are abbreviations of cosh and sinh. The coefficients a_1, a_2, a_3, and a_4 may be quantified by applying boundary conditions for the scattering and radiation problems, respectively. The inverse Fourier transform of the solution can be evaluated with a fast Fourier transform.

For simple harmonic waves, the solution for the boundary layer problem can also be easily solved.

$$p^b = \{[n_o P_w(X) - P^o|_{Y=0}] \frac{\cosh[\frac{1-i}{\sqrt{2}} \frac{D-Y}{\varepsilon}]}{\cosh(\frac{1-i}{\sqrt{2}} \frac{D}{\varepsilon})}$$

$$- \frac{1+i}{\sqrt{2}} \varepsilon \frac{\partial P^o}{\partial Y}|_{Y=D} \frac{\sinh(\frac{1-i}{\sqrt{2}} \frac{Y}{\varepsilon})}{\cosh(\frac{1-i}{\sqrt{2}} \frac{D}{\varepsilon})}\} e^{-iT^b} \qquad (18)$$

The superimposition of the solutions for the scattering problem, radiation problem, and boundary layer problem yields the total solution to the original problem. Since the response of the soil to waves and caisson motions is not readily apparent from the analytical solution, a numerical example will be presented to examine the solution behavior. For this examination the conditions given in Table 1 are assumed.

Contours of the soil response are presented in Fig. 6. These plots are for the wave crest at the face of the caisson (x = -c). Figures 6(a) and (b) show the horizontal and vertical displacements. The horizontal displacement is rather symmetrical with respect to the caisson center line. The surge motion of the caisson tends to dominate this displacement. The vertical displacement is antisymmetrical with respect to the caisson center line because the pitch motion is dominant in this displacement. However, the wave-induced vertical displacement is also significant near the caisson toe. Figures 6(c) through (e) show the shear stress, effective horizontal and vertical normal stresses, respectively. High stress concentrations occur at the caisson toe and heel. Both the shear stress and the effective horizontal normal stress decay with the depth much faster than the

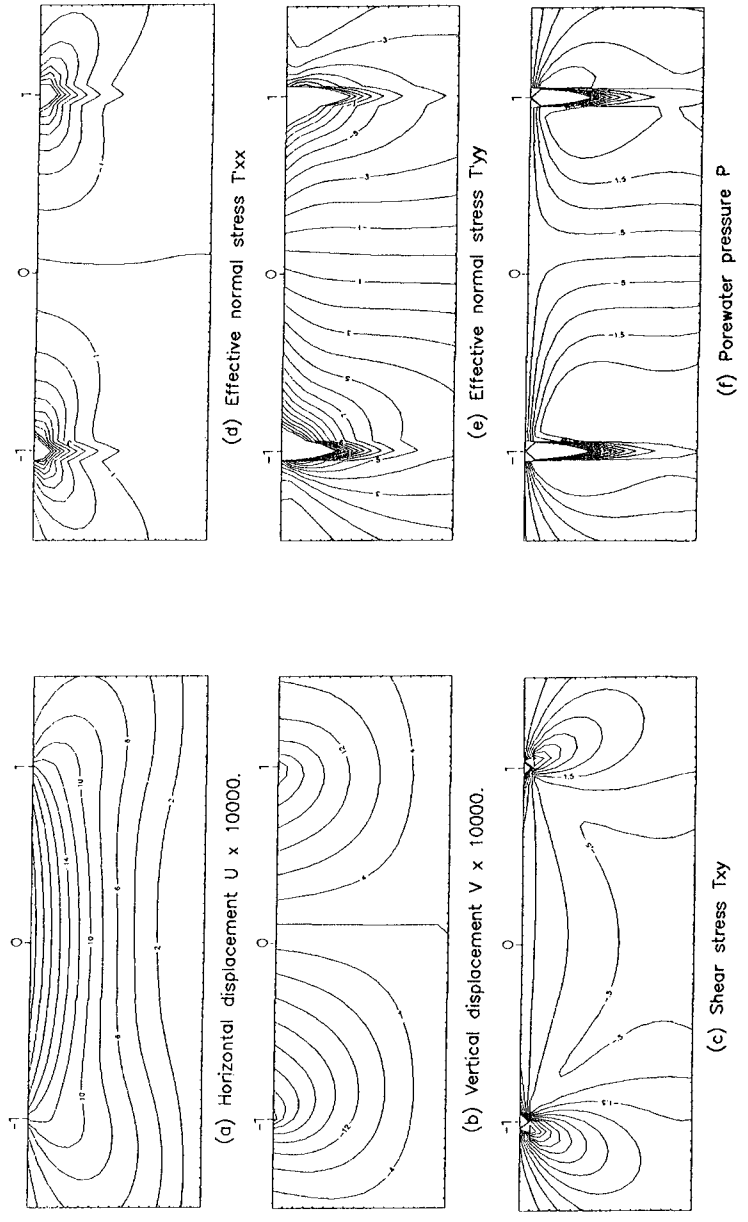

Figure 6. Contours of the soil responses for the total solution

β'	4.53 x 10^{-10} m^2/N

effective vertical normal stress. Figure 6(f) shows the porewater pressure. Due to the influence of the impermeable rigid bed on the porewater pressure, higher porewater pressures are developed near the impermeable underlying bed rather than near the mudline.

4. Conclusions

1. A linear, two-dimensional analytical model for wave-soil caisson interaction has been developed. The caisson is founded on a rubble bedding layer overlying linearly poroelastic soil of finite depth.

2. Soil displacements, stresses, and porewater pressure as well as caisson motion are predicted.

3. Two approximations are employed: a boundary layer approximation and a contact solution approximation for a thin elastic layer.

4. The pitch motion of the caisson develops the largest soil response while heave is the least significant.

5. The caisson motion induces much larger displacements, stresses, and porewater pressure in the soil than the wave alone. This indicates that a static analysis may significantly underestimate stresses.

Appendix I. Displacement Boundaries along the Exposed Mudline

A contact solution approximation has been developed for a rectangular block on a thin elastic layer by Alblas and Kuipers (1969). The boundary conditions along the upper boundary of the elastic material are of the mixed type. The displacement condition along the block elastic-layer interface is defined while the stress along the exposed portion of the upper surface are known. Under the assumption of a thin elastic layer, Alblas and Kuipers (1969) developed an approximate solution for the displacement of the elastic layer surface adjacent to the block.

heave

$$V_2'(X) = V_o\left[1-2\sqrt{\frac{A(X-1)}{\pi D}}\right] \qquad ; 0 < X-1 << 1 \qquad (I.1)$$

pitch

$$V_3'(X) = \alpha_c\left\{1-2\sqrt{\frac{A(X-1)}{\pi D}}\,[1 + i\,\hat{S}_-'(0)]\right\} \qquad ; 0 < X-1 << 1 \qquad (I.2)$$

where $A = 2(1-\nu)^2/(1-2\nu)$ and $\hat{S}_-'(0)$ is a function dependent on Poisson's ratio and the layer depth (Alblas and Kuipers, 1970). These solutions are only valid near the structure. Hence, a tanh function is introduced to modify (I.1) and (I.2) to yield approximate solutions which approach the original solutions near the structure and approach the undeformed upper surface at large distances. The tanh function also satisfies the no stress condition along the exposed portion of the elastic layer.

heave

$$V_2(X) = V_c\left\{1-\tanh\left[2\sqrt{\frac{A(X-1)}{\pi D}}\right]\right\} \qquad ; 1 \leq X < \infty \qquad (I.3)$$

pitch

$$V_3(X) = \alpha_c\left[1-\tanh\left\{2\sqrt{\frac{A(X-1)}{\pi D}}\,[1+i\hat{S}_-'(0)]\right\}\right] \qquad ; 1 \leq X < \infty \qquad (I.4)$$

Alblas and Kuipers (1969) did not develop a solution for the surge of the block motion when the block is subjected to a horizontal load. Therefore, an approximate solutions for the horizontal displacement is developed from the solution for the heave, (I.1)

$$U_1'(X) = U_c\left[1-2\sqrt{\frac{(1-\nu)(X-1)}{\pi D}}\right] \qquad ; 0 \leq X-1 << 1 \qquad (I.5)$$

Introducing the tanh function yields

$$U_1(X) = U_c\left[1-\tanh\left(2\sqrt{\frac{(1-\nu)(X-1)}{\pi D}}\right)\right] \quad ; \; 1 < X < \infty \qquad (I.6)$$

CHAPTER 171

ANALYSIS OF BEACH EROSION AROUND LARGE-SCALE COASTAL STRUCTURES

T. UDA*, M. SUMIYA** and Y. KOBAYASHI**

ABSTRACT

The coast of Ibaraki Prefecture, facing the Pacific Ocean, has an alongshore stretch of 181 km. On this coast many structures associated with harbors have been constructed since early 1960s. Since then 25 years have passed, and some notable beach changes due to the influence of the construction of the coastal structures have been observed. This study aims to examine the actual situation of the beach change around large-scale structures and the damages of the coastal structures selecting the coast of Ibaraki Prefecture as the study area. For the purpose aerial photographs were taken along the coast, and the topographic surveys and measurements of median diameter of beach-face materials were made. Data of the soundings having been conducted once a year since 1975 around Oharai Port and Hazaki Fishery Harbor were collected in order to study the beach changes around the large-scale coastal structures. For the analysis of these data the comparison of the shoreline changes were performed by using four sets of aerial photographs since 1947 to the present. Moreover, temporal and spatial changes of the beach topography were investigated by the sounding data.

I. INTRODUCTION

In recent years beach erosion is severe in Japan due to the influences of the decrease of the fluvial sediment supply from rivers and the construction of various large-scale coastal structures built on the coast. Generally the beach should change its form to attain to the new equilibrium condition because the movement of littoral drift is restricted, when coastal structures are built on a coast dominating littoral drift. For the countermeasures against beach erosion concrete armour units have been frequently placed along the coastlines. Furthermore, they have been often placed at the downdrift side of the most severely eroded location, and sometimes deep consideration of keeping the stable beach is lacking. Continuous placement of concrete blocks along the coast brings about the disappearance of the natural sandy beach. These situations can be seen on many Japanese coasts.

The aim of the study is to examine the actual situation of the beach change around large-scale structures and the damages of the coastal structures selecting the Ibaraki Coasts as the study area. On the coast many structures associated with harbors have been constructed since the early 1960s. Since then 25 years have passed, and some notable beach changes due to the influence of the construction of the harbor structures

* Dr. Eng., Head, Coastal Eng. Div., Public Works Research Institute, Ministry of Construction, Ibaraki 305 Japan.

** Public Works Department, Ibaraki Prefectural Office, Ibaraki 310 Japan.

have been observed. In this study the actual situation of the beach erosion on the Ibaraki Coast is investigated using the topographic survey data, aerial photographs and coastal pictures taken in the past.

II. METHOD OF INVESTIGATION

The investigated region of 181.4 km long extends from Ohtsu Fishery Harbor to the mouth of the Tone River (Fig. 1). The region is separated into two coasts: Joban Coast north of Oharai Port and Kashimanada Coast south of the port. First, aerial photographs were taken along the coast, and the soundings and the samplings of beach-face materials were conducted between Oharai Port and the mouth of the Tone River. Second, the sounding data in the past were gathered in order to compare the past with the present state of the beach at three locations around Ohtsu Fishery Harbor (①), Oharai Port (②) and Hazaki Fishery Harbor (④) as expressed in Fig. 1, where the beach was recently eroded to a large extent. The changes of the shoreline positions along the coast were measured from the aerial photographs having been taken 4 times between 1947 and 1984. Temporal and spatial changes of the shoreline positions were also examined at locations where sounding data in the past were obtained. On the north coast of Kashima Port (③ in Fig. 1), pictures of the beach taken in the past were gathered in order to examine the beach condition qualitatively.

III. BEACH EROSION ALONG THE JOBAN COAST

The shoreline changes between Ohtsu Fishery Harbor and Hitachi Port along the Joban Coast are investigated. The shoreline positions were degitalized at 50 m intervals continuously from the aerial photographs, and the changes of the shoreline positions during each subsequent period are calculated (Fig. 2). Regarding the general condition of the coastal landform, there protrude some capes between Ohtsu Fishery Harbor and Unomisaki Cape, and the sandy beaches extend between these capes. The coasts south of Unomisaki Cape generally consist of the coastal cliffs, but locally there exist narrow sandy beaches. For instance, the sand spit is formed around Kawarago Port because of the shelter effect of the offshore rocks[1]. The shoreline changes at locations north of Unomisaki Cape are comparatively larger than those between Unomisaki Cape and Ohse Fishery Harbor, which is mainly due to the types of the coast. The former coast consists of the sandy beach, and the latter one the cliff coast, so that the shoreline change is small. Here, the region between Ohtsu Fishery Harbor and Unomisaki Cape, showing the large shoreline changes, should be discussed in detail. In the region there are three capes, Tenpisan Cape at the mouth of the Ohkita River, Takado and Unomisaki Capes. The existence of the rocky head of the capes, projecting offshore, prevents the longshore sand movement across the head, and thereby some characteristic shoreline changes are noted.

First, it is seen from Fig. 2(a) that the shoreline retreats south of Ohtsu Fishery Harbor and it advances north of Tenpisan Cape. To the contrary the shoreline south of the cape retreats, and again the shoreline north of Takado Cape advances except the

adjacent part of the cape. In addition to these changes, the same features can be observed between Takado and Unomisaki Capes. The shoreline changes as described above have a distinct feature that the shoreline north of the cape advances and that south of it retreats. The shoreline change is due to such reason that the southward longshore drift caused by incident waves from northeast was obstructed at the capes. On the other hand, it is found in Fig. 2(b) that the shoreline changes are totally reversed. Due to the field observation of wave direction having been conducted over 10 years at Ajigaura Beach located south of Joban Coast, southeastern wave direction prevails in summer and northeastern wave direction in the other seasons, and the wave direction has a periodic feature of one year[2]. Taking these features into account, it is concluded that Figs.2(a) and 2(b) designate the shoreline changes after the northeastern and southeastern wave incidences prevailed, respectively. Figure 2(c) shows the different feature from those in Figs.2(a) and 2(b). Between Tenpisan and Takado Capes the shoreline in a region next to the capes retreats and the shoreline advances at the central part of each stretch of the coast. Between Takado and Unomisaki Capes the influence of the river mouth jetty of the Hananuki River to the adjacent beach is newly observed, and the beach is eroded south of the capes and the coastal structure, and vice versa

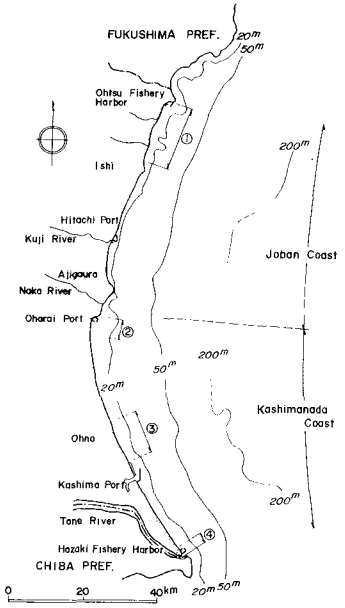

Figure 1 Investigated region along coasts in Ibaraki Prefecture.

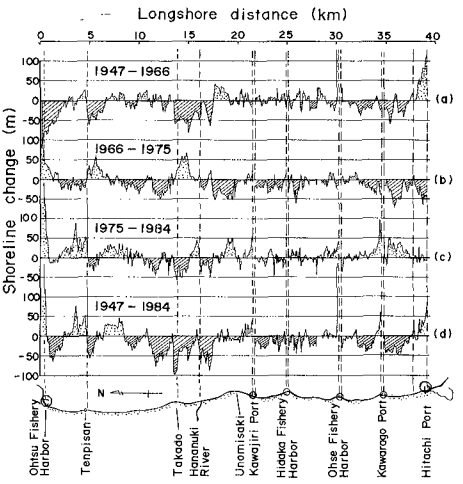

Figure 2 Shoreline changes between Ohtsu Fishery Harbor and Hitachi Port during 37 years from 1947 to 1984.

north of them. The pattern of the shoreline change differs each other. This might be mainly due to the difference of the overall direction of the shoreline configuration, assuming that the incident angle of the waves at far offshore zone is relatively small and takes almost the same value along the coast.

Regarding the shoreline change in Fig.2(d) between 1947 and 1984, the shoreline advances to a great extent on the south side of Ohtsu Fishery Harbor, whereas it retreats far from the harbor. The main cause is considered to be the influence of the construction of the breakwater as described in the following section. In addition, the shoreline retreats in south and north regions around Takado Cape, but the cause of the extensive beach erosion is not known at present.

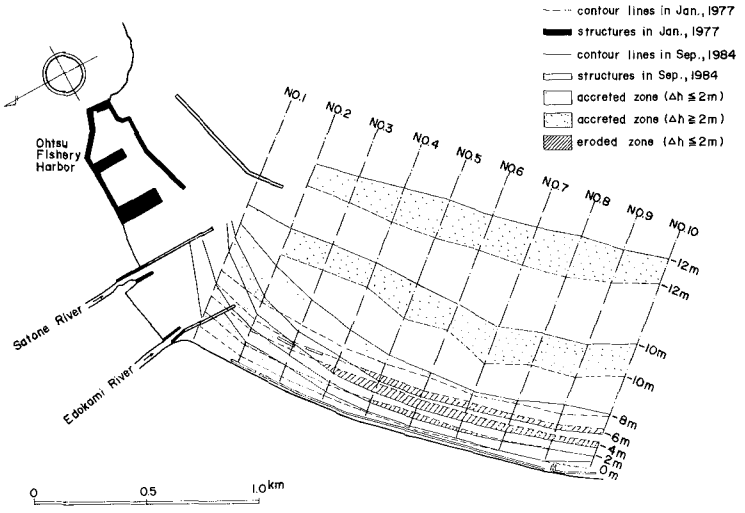

Figure 3 Changes of some contour lines around Ohtsu Fishery Harbor.

Since it is found that the shoreline change is large around Ohtsu Fishery Harbor, the change of the bottom contours is compared as shown in Fig.3, using the sounding data obtained in 1977 and 1984. The construction work of the offshore breakwater finished in 1974, and thereafter large amount of sand accumulated on the southwest side of the harbor. On the other hand, the beach up to 6 m deep below the mean sea level was eroded at No.5 through No.10. The beach erosion at No.7 is so severe in recent years that the coastal revetment fell down in 1983. In the same figure the contours of 10 and 12 m deep have a large change, but they are thought to be the error accompanied with the bottom sounding and not to be the significant change of the beach, considering that large onshore-offshore change of the contours could be observed at a small depth change at the mild slope beach, and that the contours advanced in all region without the difference of the locations. The beach changes stated above are considered to be

caused by the influence of the construction of the breakwater, taking the facts into consideration that sand accumulate inside the harbor and the beach far from the breakwater is eroded. Namely, the nearshore circulation directing toward inside the harbor from outside the shadow zone of the breakwater may develop due to the existence of the offshore breakwater, and the current induces the sand movement toward the lee of the breakwater[3].

In constructing the harbor structures it is necessary to perform the countermeasure works rapidly to prevent the adjacent beach from being eroded. It is ineffective to place the wave breaking works after the initiation of the beach erosion. There are some countermeasure works to be selected. For example, some groins can be constructed to prevent longshore sand movement from outside the harbor and to form a stable shoreline, of which tangent is at right angles with the incident wave direction.

IV. BEACH EROSION ALONG THE KASHIMANADA COAST

The shoreline change along the coast is expressed in Fig.4 with reference to that in 1947. Since there exists Kashima Port at the central part of the coast, the shoreline changes around the port are not shown in the figure. The construction of the breakwater of Kashima Port began in 1963[4], and almost completed in 1976. Regarding the shoreline changes between 1947 and 1965, the beach at 3-4 km south of Oharai Port was eroded locally, and the shoreline tends to advance to the location, of which longshore distance is around 26 km. In further south the shoreline has a tendency to be eroded

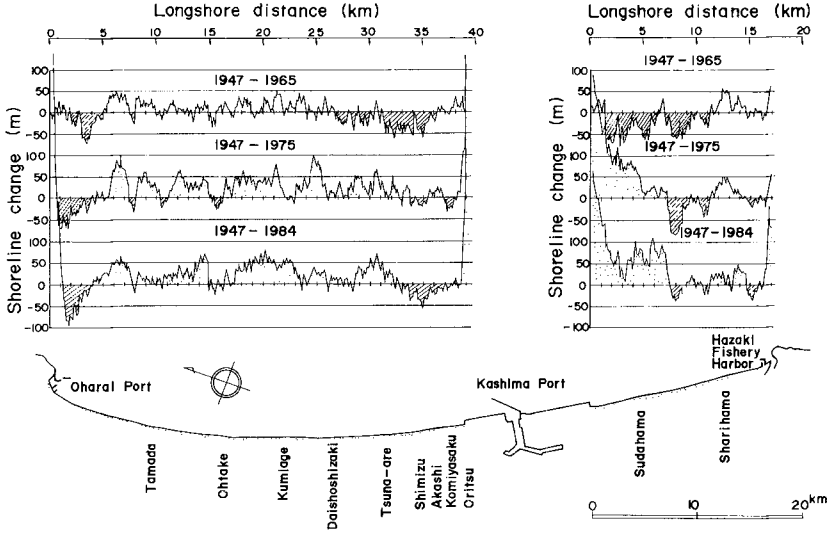

Figure 4 Shoreline changes along the Kashimanada Coast during 37 years from 1947 to 1984.

except the vicinity of Kashima Port and the region between Hazaki Fishery Harbor and the location 5 km north of the harbor. The construction work of Kashima Port began in 1963, and therefore littoral drift could move up and down alongshore freely before 1963. As a result, it may be concluded that for an overall feature of the beach erosion the coasts between Oharai Port and 5 km south of it, and the coasts far south of the longshore distance of 26 km were eroded, and the coasts between the longshore distance of 5 through 26 km were accreted. On the shoreline change around Kashima Port some local changes due to the influence of the existence of the breakwater may be considered to superimpose over the large-scale beach changes as described above.

Comparing the shoreline changes in 1947 and 1975, it is found that the shoreline advanced around 300 m on the south side of Kashima Port. This is due to the artificial nourishment of sand produced by the excavation of the Harbor[4]. Regarding the shoreline changes between Oharai and Kashima Ports, the shoreline tends to advance generally, whereas the shorelines south of Oharai Port and in the vicinity of Kashima Port retreat.

On the shoreline changes between 1947 and 1984, the amount of the retreat increases at the south coast of Oharai Port and the north coast of Kashima Port. Between Kashima Port and Hazaki Fishery Harbor part of sand nourished on the south side of the harbor may have moved southward, and the shoreline inside Hazaki Fishery Harbor advanced to a great extent. Consequently, it is concluded that the littoral cell along the coast was separated into two portions by the existence of the breakwater of Kashima Port, although before the construction of the harbor there existed a northward longshore drift south of the location, of which longshore distance is about 26 km.

In order to study the cause of the shoreline change, wave directions measured at Oharai and Kashima Ports are investigated (Fig.5). The wave gauges of both positions are placed at a depth of around 20 m off the coast as shown by the solid circles in the figure. At Oharai Port the wave data from January, 1980 to February, 1982 are referred[5),6)], and at Kashima Port those in 1980 are used[7)]. The ratio of the period when the wave data were obtained to the total period at Oharai Port is 24%, considering the significant wave height over 1 m, and that at Kashima Port is 97% with regard to the total period. It is clearly understood from Fig.5 that the dominant wave direction is from ENE at both locations. This means that waves are incident from counterclockwise direction with respect to the normal to the coastline in the vicinity of Oharai Port and from clockwise direction near Kashima Port. These wave incidences induce southward and northward longshore transport, respectively, at both locations.

Next, seasonal changes of significant wave height and wave period are examined based on wave observation data of Onahama Port, Ajigaura Beach and Kashima Port during January, 1980 and February, 1982[8),9),10)]. Mean wave height ($\bar{H}1/3$) and wave period ($\bar{T}1/3$) averaged monthly are expressed in Fig.6. Significant wave height measured at Kashima Port is slightly larger than those at two other locations, but almost similar seasonal changes of wave height are observed at Onahama Port and Ajigaura Beach. In summer and winter $\bar{H}1/3$ takes on around 1 m, and in spring and autumn it increases to about 1.4 m. The difference of wave period between three locations is relatively small, and dominant wave period is about 7-8 sec.

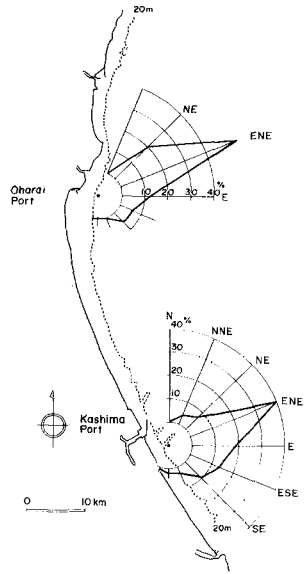

Figure 5 Wave directions at Oharai and Kashima Ports.

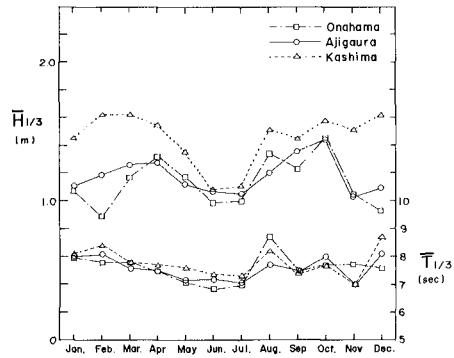

Figure 6 Monthly change of the averaged significant wave height and wave period at Onahama Harbor, Ajigaura and Kashima Port.

In the present study the topographic surveys and the sampling of beach-face materials along the Kashimanada Coast have been carried out. Corresponding to the advance or retreat of the shoreline position, the foreshore slope and the median diameter of the bed materials on the foreshore have also changed to a great extent. Using the topographic survey data, the foreshore slope, defined by the mean slope between 1 m above the mean sea level and 1 m below it, is calculated (Fig.7). The foreshore slope is steep between Oharai Port and the Tamada Coast. On the south of the coast mild slope of around 1/70 continues to the Daishoshizaki Coast, and again the beach slope steepens near Kashima Port. On the south of Kashima Port the beach slope is mild, but again the slope steepens in the vicinity of Hazaki Fishery Harbor. Comparing the foreshore slope with the shoreline changes between 1947 and 1984 shown in Fig.4, it is found that the foreshore slope steepens in the eroded region and it becomes mild in the accreted region. In the comparison between the shoreline change and the foreshore slope, it should be noted that the region of steep foreshore slope is wider than the one where the shoreline actually retreated. This may be partly due to the relatively low accuracy of measurement of the shoreline position, and partly due to the fact that actually the foreshore slope begins to steepen before the change of the shoreline position accompanying with the beach erosion.

The longshore distribution of the median diameter of beach face materials sampled along the shoreline is also expressed in Fig.7. The median diameter takes a

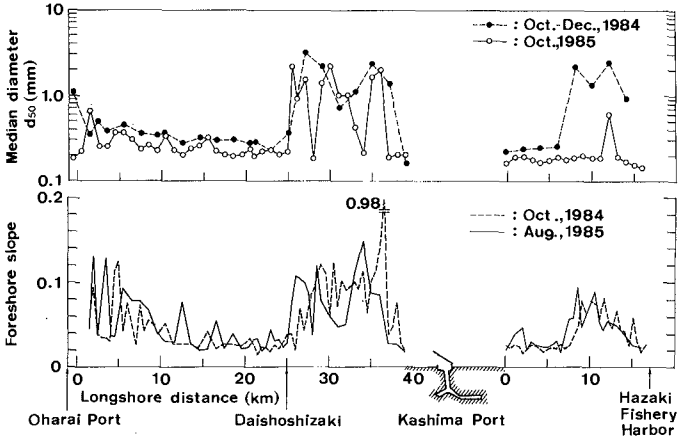

Figure 7 Longshore distribution of median diameter (d_{50}) and foreshore slope along the Kashimanada Coast.

large value between Oharai Port and 5 km south of the port, and the same between the Daishoshizaki Coast and Kashima Port. The median diameters between these areas are fine, that is, $d_{50}=0.2$-0.3 mm. Coaser materials are found between Hazaki Fishery Harbor and the location 10 km north of the harbor, and on further north coast fine materials are seen again. It is found from Figs.4 and 7 that the longshore distribution of the median diameter corresponds well with that of the shoreline change, because large and small grain sizes are found on the eroded and accreted beaches, respectively. It is also understood from Fig.7 that coaser materials can be found on steep beaches. This reason is given by the sorting effect of bed materials due to waves, in which finer materials are carried away first and coarser materials are left on the eroded beach. Furthermore, the region of steep foreshore slope extends in the longshore direction through 1984 and 1985. This means that the eroded region extended in the longshore direction, taking the fact into consideration that the foreshore slope steepened on the eroded beach. It is clear that the foreshore slope and the median diameter on the foreshore become good parameters on judging whether the beach has been eroded or not.

V. DETAILED ANALYSIS OF BEACH CHANGES AROUND COASTAL STRUCTURES

In previous chapter the overall features of beach changes along the Kashimanada Coast were discussed. In the analysis some notable beach changes were observed in the vicinity of Oharai and Kashima Ports, and Hazaki Fishery Harbor. In the following the beach changes of each region will be studied in detail.

5.1 Beach changes around Oharai Port

Oharai Port has been annoyed with the deposition of sand for a long time[3]. The extent of the beach change increased with the completion of the offshore breakwater having been constructed until July, 1984 in order to enlarge the port facility. The shoreline changes of each year with reference to the shoreline positions in April, 1978 are shown in Fig.8. On the coast the wave incidence from ENE dominates as in Fig.5 and in the lee of the breakwater the breaker height lowers, so that clockwise nearshore circulation may develop behind the breakwater and sand accumulate from outside of the port to inside of it. Particularly the accreted zone has expanded southward since the beginning of the construction work of the offshore breakwater in September, 1981. At the same time the beach south of No.9 was eroded. A large part of the eroded sediment may be considered to be transported toward the harbor, taking into consideration that the retreat of the shoreline position decreases with the distance from the port. Moreover, it is found from Fig.8 that the retreat of the shoreline position is much

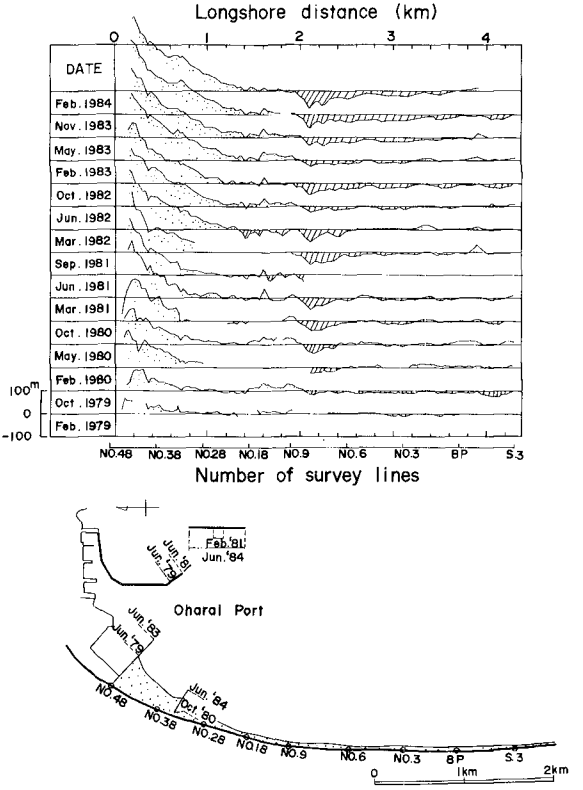

Figure 8 Temporal and spatial change of shoreline position around Oharai Port.

smaller than the advance. This may be interpreted by the reason that high beach cliff was formed by the erosion and therefore the sand supply from the cliff into the sea was large enough not to bring large retreat of the shoreline. The beach erosion is severe between No.9 and No.3 in Fig.8. The coastal revetment fell down over around 300 m long at No.6 in the midst of the region since 1984 due to the beach erosion.

Finally the actual situation of beach erosion will be studied using pictures taken on the coast. Due to Picture 1 taken on the south of Oharai Port in July, 1984, a large amount of sand accumulate inside the harbor accompanying with the construction of the offshore breakwater. In June, 1984 there was a wide beach in front of the coastal revetment at No.6 south of Oharai Port, so that the revetment was stable (Picture 2). Then abrupt change occurred, the foreshore totally disappeared on October 5 in the same year, and the foot of the coastal revetment was exposed to the wave uprush (Picture 3). Finally on February 27, 1985 the revetment fell down (Picture 4) and beach cliff of around 5 m high was formed on the natural sandy beach next to the position of the revetment. It is understood that the coastal revetment may be fallen down easily when the foreshore disappears due to the beach erosion.

Picture 1 Aerial photogragh of Oharai Port taken in July, 1984.

Picture 2 Situation of the beach at survey line No.6 in June, 1984.

Picture 3 Same location as Picture 2. The picture was taken on October 5, 1984.

Picture 4 Same location as Picture 2. The picture was taken on February 27, 1985.

5.2 Beach changes north of Kashima Port

The north coast of Kashima Port has been eroded and particularly the beach erosion was severe in the summer and autumn of 1986, because high waves generated by the tropical storms attacked the coast frequently. In this study many pictures, showing the historical changes of the beach since 1938, were gathered. In order to examine the beach condition qualitatively, the pictures are compared. Picture 5, taken in July, 1980, shows the situation of the beach at the Akashi Coast (For location, see Fig.4) adjacent to Kashima Port. At this stage wide foreshore extends in front of the coastal revetment, and the vegetations can be seen on the foreshore, expressing that the beach has been stable for a fairly long time. On September 15, 1986, the foreshore totally disappeared as shown in Picture 6 due to the beach erosion. These change may be attributed to the beach erosion caused by the imbalance of the littoral transport. Because at the south of the coast a large breakwater of Kashima Port is located, and the northward longshore sediment transport is obstructed at this location.

Picture 5 Situation of the beach of the Akashi Coast north of Kashima Port in July, 1980.

Picture 6 Same location as Picture 5. The picture was taken on September 15, 1986.

5.3 Beach changes around Hazaki Fishery Harbor

The construction work of the breakwater of the fishery harbor began in 1974 at Hazaki next to the mouth of the Tone River. The breakwater was elongated year by year, and until 1984 south and north breakwaters had been completed (Fig.9). With the elongation of the breakwater sand accumulated inside the harbor, and at the same time the north coast of the harbor was eroded. The temporal and spatial changes of the shoreline positions can be examined as shown in Fig.9 because the topograghic surveys around the harbor have been conducting twice a year since 1974. In September, 1976 the lengths of the north and south breakwaters were elongated until about 470 m and 360 m respectively. During the period the shoreline advanced in the vicinity of both breakwaters. On the other hand, the beach between No.12 and No.26 north of the breakwater was eroded. Thereafter both breakwaters were further elongated in the offshore direction until January, 1981 and simultaneously the shoreline inside the harbor gradually advanced. Furthermore, the eroded region extended north over No.0. The

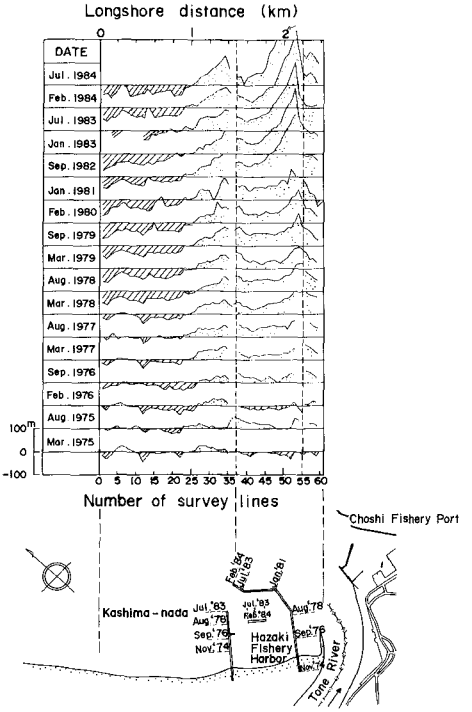

Figure 9 Temporal and spatial changes of shoreline position around Hazaki Fishery Harbor.

breakwater was elongated normal to the direction of the shoreline until January, 1981. During 1981 and 1984 the parallel part of the breakwater was constructed and the north breakwater was also elongated. With these construction works, the shoreline inside the harbor advanced to a great extent to reach to 263 m at maximum. The shoreline on the north side of the harbor advanced with the elongation of the breakwater, but the amount of the advance is smaller than that inside the harbor. The cause may be given by the following reason. First, the predominant direction of the littoral transport is considered to be northwestward at the coast, judging that the eroded zone extended in the northwest direction. In other words, the diminant wave is incident from clockwise with respect to the normal to the initial shoreline. Under such a condition of wave incidence, longshore current directing southeast develops in the lee of the breakwater, and sand accumulate on the north side of the breakwater. Regarding the cause of the beach changes inside the harbor, not only the littoral drift turning around on tip of the breakwater due to the mechanism, but also the deposition of a part of the sediment outflow from the Tone River is thought to be important. Because it is not until 1981, when wave condition inside the harbor was getting calm by the construction of the offshore breakwater, that the shoreline advanced quickly.

VI. DISCUSSIONS

In the previous chapters the actual situation of large-scale beach erosion along the Ibaraki Coast were studied. The types of the beach erosion are separated into two groups. The first is the case, in which the distributions of wave height and wave direction vary due to the influence of the construction of the breakwater first, and hence the beach changes are induced by the littoral drift corresponding to the changed distributions of wave height and wave direction. The second is the case, in which beach change is caused by the obstruction of the longshore drift accompanying with the construction of the coastal structure on a coast, where dominant littoral drift in one direction exists. The former includes the beach changes around Ohtsu Fishery Harbor or Oharai Port, and the latter is the case around Kashima Port or Hazaki Fishery Harbor. Comparing both types, it is considered in the first case that the beach erosion might be confined in a comparatively narrow region, and the construction of a structure to control littoral drift such as a groin is effective for the measures against the beach erosion, if the structure is built in time. To the contrast in the second case the countermeasure work is considerably difficult. If a structure obstructing littoral drift is built along the coast of a long stretch, where littoral transport is dominant and the continuous movement of littoral drift is cut, then there is a high possibility that its influence expands extensively in a long term. In this case the shoreline will change its form to attain to the equilibrium state, in which the normal to the shoreline becomes paralell with the wave direction at the breaker line.

In Japan the sand bypassing method is conducted only experimentally for the measures to ensure the continuity of littoral drift. It is not used for a general method, and therefore it is impossible to maintain the continuity of littoral drift artificially at present. Instead of the sand bypassing method, groins and detached breakwaters are

widely used for the countermeasure works against the beach erosion. In other case concrete armour units or coastal revetments are merely set along the shoreline. In selecting the former method, if once a structure is built along the coast to obstruct the littoral drift, the beach erosion will extend to the downdrift coast. In order to prevent further beach erosion many structures of some longshore intervals have to be built along the coast. Furthermore, the selection of the latter case is not effective only for maintaining the sandy foreshore. The sandy coast of a long stretch will disappear and the sandy beach will be finally replaced by the concrete armour units, since the eroded region extends alongshore gradually. Taking these points into account, fundamentally it is important to consider the method to ensure the continuity of littoral drift. However it is difficult to select the plan for the present because the sand bypassing method is not acknowledged for the countermeasure works in Japan. In addition, it should be noted that the eroded region will extend further with the time elapsing. For the second selection of the measures, a method is considered, in which some coastal structures are built on the coast and the coast is altered to such a coast of stable planform, even if the littoral drift from downdrift end of the structure located on the updrift side becomes zero. At least wider beach could be kept by the method compared with the way using concrete armour units setting along the shoreline.

VII. CONCLUSIONS

Main results of this study are summarized as follows:

(1) Cyclic beach changes of accretion or erosion were observed on both sides of the headlands located between Ohtsu Fishery Harbor and Unomisaki Cape. The cause is considered to be due to the fact that the predominant wave direction changes seasonally from northeast to southeast on the coast.

(2) Severe beach erosion and accretion were caused by the elongation of the offshore breakwater at Ohtsu Fishery Harbor and Oharai Port.

(3) Along the Kashimanada Coast beach erosion is severe at the south site of Oharai Port, the north of Kashima Port and Hazaki Fishery Harbor. It is found quantitatively that the slope of the beach face becomes steep and the armouring of the bed materials on the shore is under way on the eroded beach on the downdrift side of the structure.

(4) A large amount of sand accumulated inside Hazaki Fishery Harbor with the elongation of the breakwater. Especially the shoreline advanced very much after the completion of the construction work of the parallel offshore breakwater with respect to the shoreline. Regarding the cause of the beach changes inside the harbor, the deposition of a part of the sediment outflow from the Tone River is considered to be important because of the formation of the calm water inside the harbor.

(5) The types of the beach erosion along the Ibaraki Coast are separated into two categories. The first is such a case that the beach changes are produced by the littoral transport induced by the longshore changes of wave height and wave direction, which are caused by the influence of the construction of the breakwater. The second is the case, in which the beach change is caused by the obstruction of littoral drift due to the construction of the coastal structure. For the first case, the construction of a coastal

structure to control littoral drift like a groin is effective for the measures against beach erosion, if the structures are built in time. For the second case fundamentally it is important to consider a method to ensure the continuity of littoral drift, and if not, a method to form the shoreline of stable configuration against wave attack by the construction of a structure should be considered.

CHAPTER 172

ENERGY DISSIPATION AND WAVE FORCE AT SLOTTED WALL

Saburo URASHIMA[1], Koichi ISHIZUKA[2] and Hideo KONDO[3]

Abstract

The hydrodynamic coefficients are computed based on the measured total force on the single slotted wall in the wave field, or on the measured head loss in the uniform flow channel. The reflection, transmission and force coefficients on the single slotted wall are computed based on the mean values of the hydrodynamic coefficients. The correlations between these calculated values and measured values are found to be good. A design procedure of the single slotted wall is given the paper.

1 INTRODUCTION

Many studies on wave energy dissipating structures using a pervious wall have been carried out mainly for caisson-type breakwaters, which have a chamber between the pervious front wall and the solid backwall. Although the hydrodynamic characteristics of the single pervious wall are not well-known, it is not so well-known that it can serve as a breakwater itself. The objective of this paper is to establish the optimum form of the vertical parallel piled slits by obtaining the coefficients of reflection, transmission and wave force which are estimated by the drag and mass coefficients.

The hydrodynamic coefficients are computed by measuring the total force on the slotted wall and then employing Morison's equation and the small amplitude wave theory in the wave field, or by measuring the head loss in the uniform flow channel. The reflection and transmission coefficients are determined by making use of the analytical approach to the small amplitude shallow water wave deformation at the pervious wall as explained by the last author in 1979.[1)]

2 EXPERIMENTAL SETUP

The experiments were conducted in a wave flume 0.8 meter deep, 0.4 meter wide and 19.7 meter long. For each test a slotted wall orientation was kept perpendicular to the incident wave direction. The range of wave parameters were as follows:

Wave steepness H_I/L : 0.002 to 0.056
Relative depth h/L : 0.100 to 0.281

The water depth was kept constant at 0.5 meter throughout the experiment. The test apparatus which was used for measurement of wave force is illustrated schematically in Fig. 1. The slotted wall which was tested for measurement of wave force consisted of an acrylic wall, 0.4 meter in width and 0.6 meter long, supported on two frames which were

1 Assistant Professor of Civil Engineering, Tomakomai College of Technology, 443 Nishikioka, Tomakomai, 059-12 JAPAN
2 Professor of Civil Engineering, ditto
3 Professor of Civil Engineering, Muroran Institute of Technology, 27-1 Mizumoto-Cho, Muroran, 050 JAPAN

suspended from the wave flume. These frames were made of steel, 25 by 16 millimeter in section. The wave force was transmitted to the strain-gauges on these frames. Two-dimentional flume tests were made. The reflection coefficients have been computed using Heal's formula.

In addition, the head loss was measured in the uniform flow channel. 21 types of the models with various void ratios and wall thicknesses were tested, as shown in table 1.

3 PROCEDURES EMPLOYED

The ratio of reflected wave amplitude a_R and the incident wave amplitude a_I can be estimated analytically as

$$\frac{a_R}{a_I}=\frac{A_{0,1}}{2+A_{0,1}}=\frac{\frac{\sigma}{kh}\left[\frac{C_l}{2g}|u_{1,1}|+i\frac{\sigma\mathcal{Z}}{g}\right]}{2+\frac{\sigma}{kh}\left[\frac{C_l}{2g}|u_{1,1}|+i\frac{\sigma\mathcal{Z}}{g}\right]} \tag{1}$$

Also the ratio of transmitted wave amplitude a_T to incident wave amplitude is given by

$$\frac{a_T}{a_I}=\frac{2}{2+A_{0,1}}=\frac{2}{2+\frac{\sigma}{kh}\left[\frac{C_l}{2g}|u_{1,1}|+i\frac{\sigma\mathcal{Z}}{g}\right]} \tag{2}$$

where σ is $2\pi/T$ and k is $2\pi/L$. The absolute value of the water particle velocity $|u_{1,1}|$ is approximated by

$$|u_{1,1}|=\frac{8}{3\pi}U_{1,1} \tag{3}$$

where $U_{1,1}$ is the amplitude of horizontal water particle velocity, C_l is the head loss coefficient and $\mathcal{Z}$ is the apparent orifice length.

The forces are divided into two parts, one due to the drag in the case of constant flow, and the other due to acceleration or deceleration of the fluid. The horizontal total force on a slotted wall is given by

$$F_T(t)=F_D(t)+F_I(t)=C_D\cdot f_D(t)+C_M\cdot f_I(t) \tag{4}$$

in which

$$f_D(t)=\int_{-h}^{\eta}\rho\frac{u|u|}{2}dA \tag{5}$$

and

$$f_I(t)=\int_{-h}^{\eta}\rho\dot{u}\,dV \tag{6}$$

and $F_T(t)$ is the horizontal total force, $F_D(t)$ is the horizontal drag force, $F_I(t)$ is the horizontal inertia force, ρ is the mass density of water, η is the water surface elevation, dA and dV refer to the small projected area and volume, u and $\dot{u}$ are particle velocity and acceleration and C_D, C_M are the drag and mass coefficients, respectively.

The force coefficient f is defined as

$$f=\frac{Fmax}{\rho g(1-\lambda)Bhd_w} \tag{7}$$

where $Fmax$ is maximum total force, g is acceleration of gravity, B is wall width and h is water depth.

The relationship between the head loss coefficient C_l and the drag coefficient C_D is given by

$$C_l=(1-\lambda)\cdot C_D \tag{8}$$

and the relationship between the apparent orifice length $\mathcal{L}$ and the mass coefficient C_M is given by

$$\mathcal{L}=\left[1+\frac{(1-\lambda)}{\lambda}\cdot C_M\right]\cdot d_w \tag{9}$$

where λ is the void ratio, d_w is the wall thickness.

4 RESULTS

4.1 Hydrodynamic Coefficient

Fig. 2 presents the head loss coefficients from the wave and from the uniform flow tests. The head loss coefficients from wave test and those from uniform flow test formed smooth continue curve. Evidently, there is a remarkable correlation between the head loss coefficients and Reynolds number. The head loss coefficient is estimated with the Reynolds number Re, as follows.

$$C_l=\frac{A_1}{Re}+B_1 \tag{10}$$

where A_1 and B_1 are constants determined by the experiment. Reynolds number Re is defined by the following equation.

$$Re=\frac{u_{r.m.s}\cdot S}{\nu} \tag{11}$$

where

$$u_{r.m.s}=\frac{1}{T}\sum^{N}\frac{\sqrt{\int_{-h}^{\eta}u^2dy}}{h+\eta}\Delta t \tag{12}$$

and $u_{r.m.s}$ is the root-mean-square velocity. Here $u_{r.m.s}$ is adapted as the presentative velocity.

Fig. 3 shows the head loss coefficient for a standard slotted wall, and Fig. 4 shows one for an array of square columns in uniform flow. In turbulent flow, the head loss coefficient is constant. The head

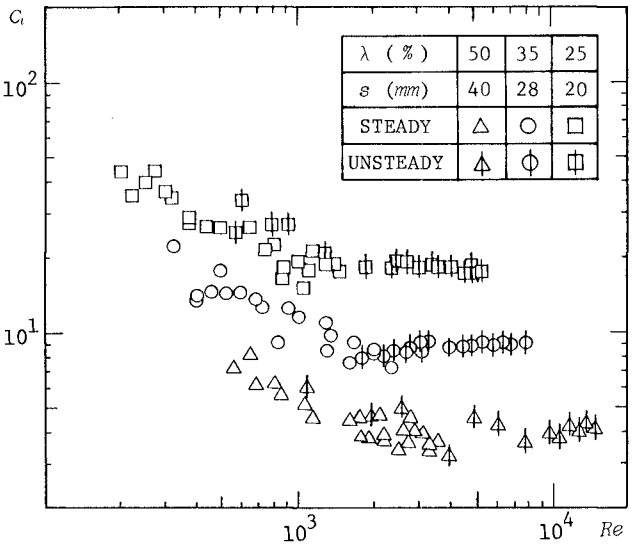

FIG. 2 HEAD LOSS COEFFICIENT VERSUS REYNOLDS NUMBER (d_w = 30 mm)

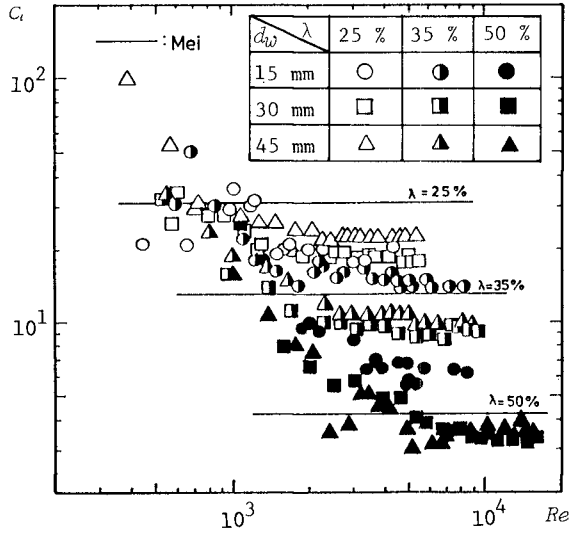

FIG. 3 HEAD LOSS COEFFICIENT VERSUS REYNOLDS NUMBER

loss coefficient is considered to be a function of the void ratio, wall thickness and slit width. The head loss coefficient is approximated by

$$C_l = B_1 = \frac{0.52}{\lambda^{3.0}(d_w/s)^{0.46}} \tag{13}$$

Fig. 5 shows the apparent orifice length versus Keulegan-Carpenter number KC. Evidently, there is a remarkable correlation between the apparent orifice length, wave length and Keulegan-Carpenter number. The apparent orifice length is given as a function of the wave length and the Keulegan-Carpenter number as follows.

$$\frac{\chi}{L} = \frac{A_2}{KC} + B_2 \tag{14}$$

where A_2 and B_2 are constants determined by the experiment. Keulegan-Carpenter number is defined by the following equation.

$$KC = \frac{u_{r.m.s} \cdot T}{d_w} \tag{15}$$

where T is the wave period and d_w is the wall thickness. The constant B_2 is given as a function of the wall thickness as follows.

$$\frac{\chi}{L} = B_2 = 0.00567 \cdot d_w + 0.0033 \tag{16}$$

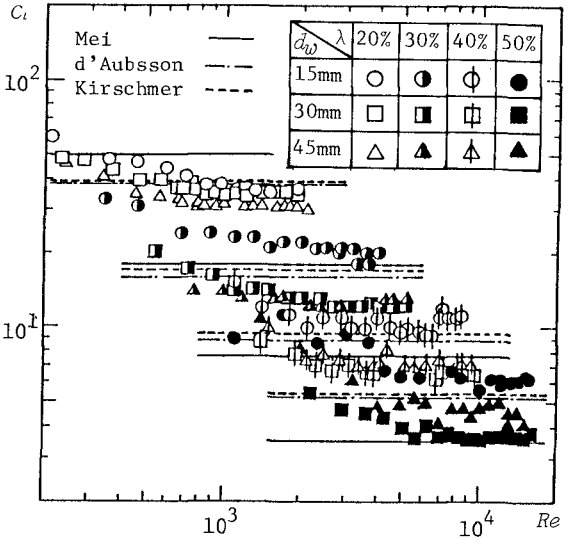

FIG. 4 HEAD LOSS COEFFICIENT VERSUS REYNOLDS NUMBER

4.2 The Reflection Coefficient and Transmission Coefficient

Fig. 6 shows the reflection coefficient K_R and the transmission coefficient K_I versus the wave steepness H_I/L for the various values of relative water depth h/L. The theoretical results of Kondo(1979) using an experimental coefficient are superinposed for comparison with the results of the experiment. The agreement between the theoretical and actual results of the experiment is found to be relatively good. In this figure, as the incident wave height increases in the range of smaller height, the reflection coefficient decreases to a certain minimum value, and then increases as the wave height further increases, meanwhile, the transmission coefficient increases to a certain maximum value, and decreases afterwards. It is seen that the wave steepness has an important influence on the reflection and transmission coefficients.

Fig. 7 shows the dependence of reflection and transmission coeffi-

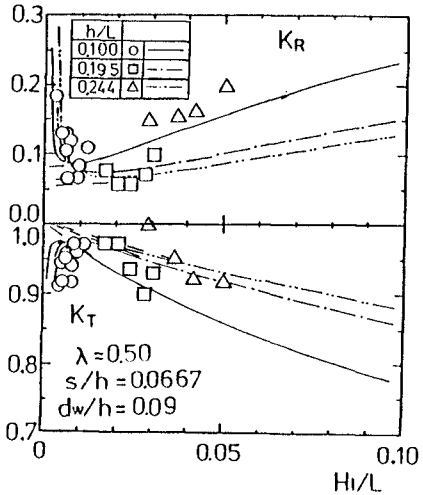

FIG. 6 REFLECTION AND TRANSMISSION COEFFICIENT VERSUS WAVE STEEPNESS

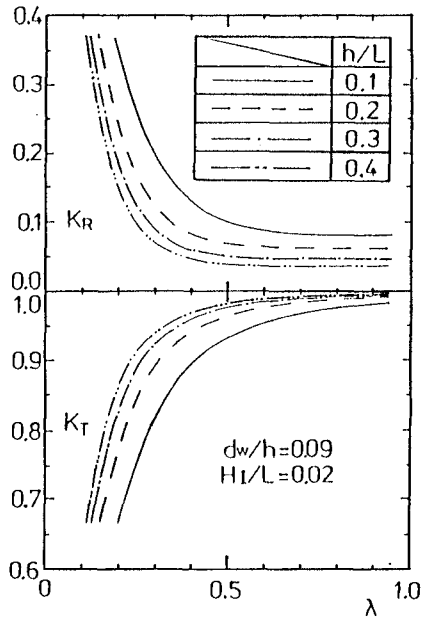

FIG. 7 REFLECTION AND TRANSMISSION COEFFICIENT VERSUS VOID RATIO

cients on the void ratio λ for the various values of relative depth. In this figure, the reflection coefficient decreases rapidly as void ratio increases and gradually decreases to a certain value, while the transmission coefficient increases in the similar manner. It is seen that the void ratio has a great effect on the reflection and transmission coefficients. With wider spacing between the square piles greater energy will be transmitted than reflected or lost and hence the transmission coefficient increases with the void ratio. As the slit size becomes very large, however the effectiveness of the slotted wall as an energy dissipator decreases. The reflection coefficient decreases with increasing slit size as was expected. This can be attributed to the reduction in the net projected area of the slotted wall normal to the direction of wave advance giving rise to greater transmitted energy

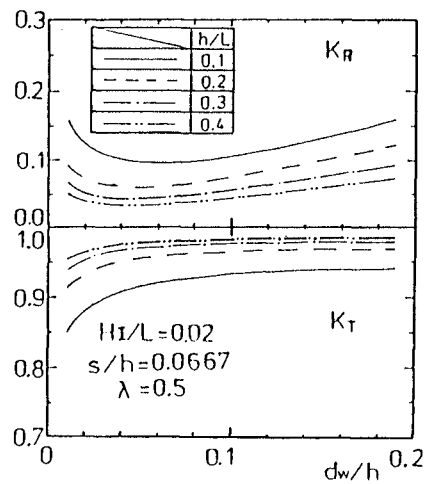

FIG. 8 REFLECTION AND TRANSMISSION COEFFICIENT VERSUS d_w/h

and lesser reflected energy.

Fig. 8 shows the variation of reflection and transmission coefficients with the ratio of wall thickness to water depth d_w/h for the various values of relative depth. In this figure, the reflection and transmission coefficients are not sensitive to the wall thickness. The reflection coefficient decreases as relative water depth increases, and the transmission coefficient increases slightly as relative water depth increases.

4.3 The Force Coefficient

Fig. 9 shows the force coefficient f of Eq.7 versus the wave steepness for the various values of relative depth. The force coefficient increases with wave steepness as expected. The theoretical values which are indicated by the lines on the chart show good agreement with the experimental results within the range of lower values of wave steepness.

Fig. 10 shows the force coefficient versus the void ratio λ for the various values of relative depth. In this figure, the force coefficient decreases at first, then keeps almost constant and increases afterwards, as the void ratio increases. It decreases as the wall thickness increases, and as relative water depth increases.

5 CONCLUSIONS

There is a remarkable correlation between the head loss coefficient and Reynolds number. There is a remarkable correlation between the apparent orifice length, Keulegan-Carpenter number and wave length.

We suggested that the head loss coefficient is given as a function of the void ratio, wall thickness and slit width. We suggested that the apparent orifice length is given as a function of wall thickness.

The theoretical results using these experimental coefficients show relatively good agreement with the results of the experiment.

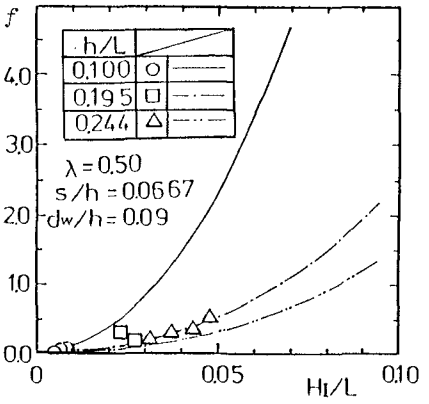

FIG. 9 FORCE COEFFICIENT VERSUS WAVE STEEPNESS

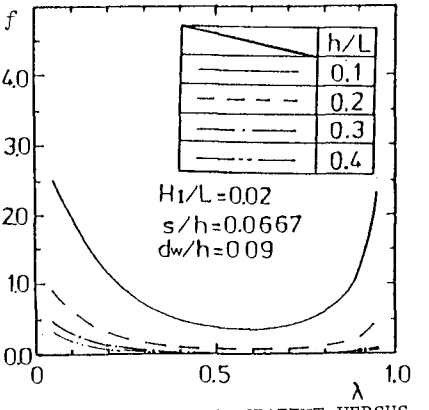

FIG. 10 FORCE COEFFICIENT VERSUS VOID RATIO

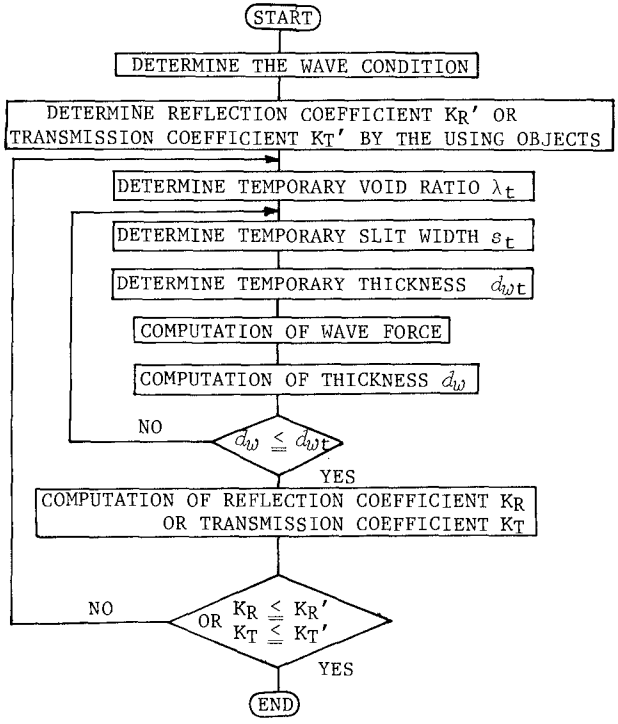

FIG. 11 DESIGN PROCESS OF THE SINGLE PERVIOUS WALL

The optimum void ratio of the slotted wall lies around 0.2 to 0.4 and corresponds to the required conditions of the wall, since the rates of change of the force, reflection and transmission coefficients are large in that range. It can therefore be concluded that using the design process for a single pervious wall to serve as a breakwater, as indicated in Fig. 11 will be effective. The initial value of the void ratio, slit width and thickness may be obtained from Fig. 6 to 8 . However, the actual wall thickness must take into account the level of wave force. In the case of a constant wall thickness, the reflection coefficient can be decreased by increasing the slit width.

CHAPTER 173

Wave Interception by Sea-Balloon Breakwater

by

Takahiko Uwatoko , Takeshi Ijima , Yukimitsu Ushifusa
and Haruyuki Kojima

Abstract

When a submerged, flexible bag is filled with air about 60～70 % of its full volume (it is called " sea-balloon "), it has a stable shape with vertical axis of symmetry,on which several vertical wrinkles appear with folds of membrane. If two or more such sea-balloons are arranged to the direction of wave travel and connected pneumatically,balloons are deformed periodically and the air flows reciprocally in connecting pipe, following to the fluid pressure fluctuation due to incident waves. Such a system of sea-balloon intercepts incident waves effectively (it is called " sea-balloon breakwater ").

The wave interception by the breakwater is analyzed numerically by three-dimensional boundary integral method, assuming that the fluid motions both in- and out-side of the balloon are potential and that the tension in balloon membrane is proportional to the apparent elongation of membrane with virtual elastic constant.

After analysis and experiments, it is made clear that in relatively long waves the incident wave is canceled by the radiation wave which is generated by volumetric change of sea-balloons, being affected by air-flow resistance in connecting pipe. In short waves, sea-balloons seem to behave like as rigid piles and the incident wave is absorbed by air-flow resistance in pipe and by the turbulence of fluid motion around balloons. Moreover, the effect of gaps between sea-balloons along wave crest on wave interception for relatively long waves is expressed by a simple empirical formula, by which the transmission coefficients at various types of sea-balloon breakwater is easily estimated by two-dimensional computation.

For the improvement of wave interception effect and from the point of practical use, the effects of other sea-balloon breakwater system are investigated by two-dimensional computation and experiments.

1. Introduction

Usual breakwaters are rigid and fixed structures to protect harbours against waves. In contrast with such a rigid structure, the floating breakwater intercepts waves by radiation waves induced by its floating

motion. And the radiation wave is generated not only by floating motion of rigid structures but also by the deformation of flexible bodies due to incident waves. Therefore, if the breakwater of flexible structure is able to generate radiation waves of large amplitude enough to reduce the diffraction waves or transmitted waves, it will be able to intercept effectively the incident wave. The authors propose a method of wave interception by flexible bodies in completely submerged state and intend to make clear the wave interception mechanism.

Few years ago, French[1] proposed a method of electric power generation, where a series of flexible air bags in semi-submerged state induces air-flow in the duct under air bags and the air-flow generates electric power. French's air-bag system seems to be similar to the authors' method but is quite different in that the former is semi-submerged, partly exposed in atmosphere and each bag is not isolated but in contact with each other in wave direction. Seymour and Hanes[2] tried to reduce the transmitted waves by great many small, moored balls but they were in effect only to waves of shorter periods than two or three seconds.

2. Construction of the Authors' Method[3]

If a bag 1, as shown in Fig.1, with semi-spherical upper part and cylindrical lower part made by thin, flexible membrane is submerged and filled with air about 60 % of its full volume, it shows a stable shape with vertical axis of symmetry O-O' in Fig.2, which is called " sea-balloon". Points M and M' are inflection points between upper and lower part, where the former is almost spherical and the latter seems like a neck. The air pressure inside the balloon is equal to the hydrostatic pressure at the depth of inflection point M and M'. The most important feature of the sea-balloon is the existence of several vertical wrinkles " 3 " with folds of membrane, as shown by the cross-section

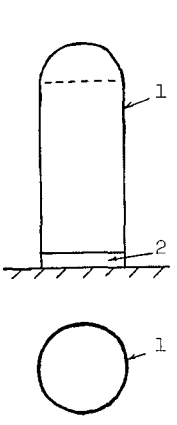

Fig.1 Sea-balloon membrane.

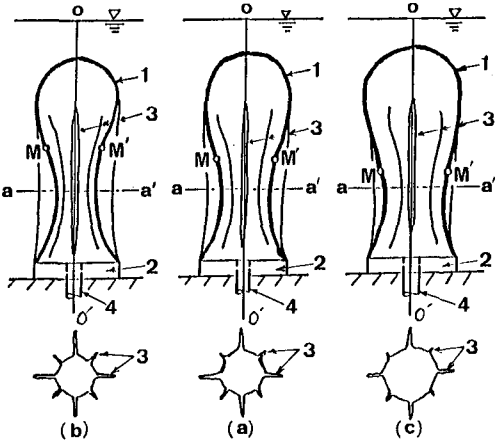

Fig.2 Shape of sea-balloon.

through horizontal plane a-a'. If the air flows out or flows in through the pipe " 4 ", the wrinkles close and grow larger or open and decay smaller, and the volumetric change of the balloon is caused not by the elastic deformation of the balloon membrane but by the growing and the decaying of wrinkles. Therefore, the membrane needs not to be elastic but to be flexible. Many systems of a pair of sea-balloon connected pneumatically by a pipe with length B, if arranged in parallel with the incident wave crest, constitute a " sea-balloon breakwater ", as shown in Fig.3 .

If a train of waves comes into the breakwater, the fluid pressure fluctuation induces shape- and volume-change of sea-balloons and generate radiation waves which affect and decay the transmitted waves. At the same time, a part of wave energy is dissipated by air-flow turbulence in the connecting pipe.

3. Wave Interception Performance of Sea-Balloon Breakwater by Experiments and Calculations [3]

Wave transmission coefficient K_t (= transmitted wave height/incident wave height) at a sea-balloon system fixed on the sea bottom were measured in wave channel with water depth h(=35cm) and width W(=15cm). Two balloons of diameter R(= 11cm),height F(= 20cm),volume of air Q(= 1000cc) made by rubber membrane were attached to base disks with distance B(=3h=105cm) and crown depth A(=2cm from water surface),where the base disks were fixed on the bottom with height c(=13cm) and h_o(=0). Both balloons were connected by a pipe of diameter d(=2.2cm). Measured transmission coefficients are shown with respect to relative depth h/L in Fig.4, where L is wave length and circle O is for the sea-balloon

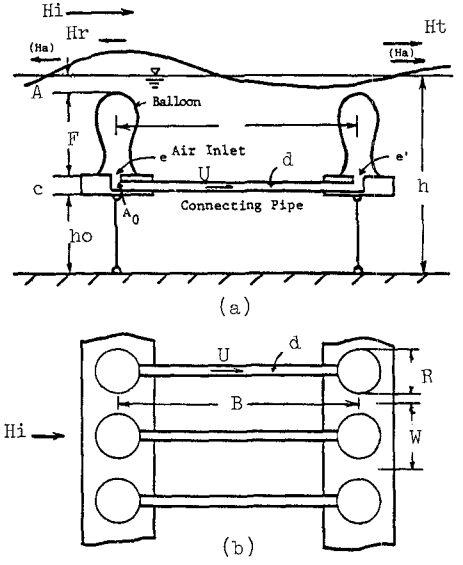

Fig.3 Construction view of sea-balloon breakwater.

system, square □ is for the case when the connecting pipe is removed and balloons are isolated, black square ■ is for the case when sea-balloons are replaced by wooden rigid bodies of the same shape.

It can be seen from the figure that K_t at rigid bodies varies around the value 0.9 without any tendency and K_t at isolated balloons steadily decreases with h/L for $h/L \geq 0.20$. At sea-balloon system, K_t shows the minimum at $h/L \fallingdotseq 0.17$ and then a steep decrease from $h/L \geq 0.3$. Such a tendency is remarkable for the case of a pair of double sea-balloons as shown by black circle ●. These tendencies in the change of K_t with h/L are characteristic in the facts that for long wave region ($h/L < 0.3$) the effect of radiation waves prevails due to the volume change of paired sea-balloons and for short wave region ($h/L \geq 0.3$) the interception effect of nearly isolated submerged balloons prevails by small deformation in shapes.

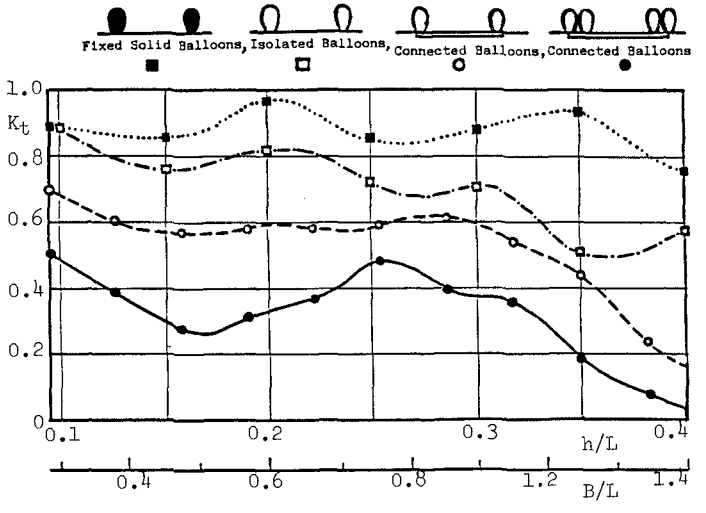

Fig.4 Measured transmission coefficients at fixed solid balloon and various sea-balloon systems.

Fig.5 is another example of measured K_t at sea-balloon breakwater which consists of sea-balloon system with six balloons in floating state moored in wave channel with depth h = 80cm, width W = 60cm. Measured K_t shows the effect of balloon distance B for the height of balloon F = 20cm, volume V = 700cc and crown depth A = 2cm. The distance B is taken as 1.5h and 2.0h. Horizontal axis is shown by $kh = 2\pi h/L$ and B/L for B/h = 1.5 and 2.0.

It can be seen that the minimum point of K_t with respect to kh moves to lower values of kh for larger value of B/h. Furthermore, the minimum point of K_t appears $B/L \fallingdotseq 0.5$ for both value of B/h.

The authors have performed three-dimensional numerical analysis to estimate K_t and reflection coefficient K_r and to clarify the mechanism of wave interception, assuming that the fluid motions outside and inside of the balloons are both potential and then using the boundary integral

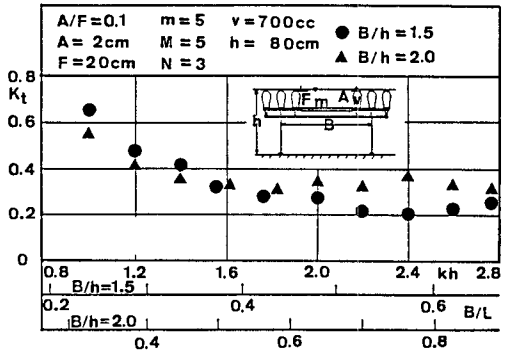

Fig.5 Effect of the distance between grouped balloons on the transmission coefficients.

method by Green's identity formula[4]. Wave interception effects remarkably appear on waves of length about 2·B and waves shorter than 2·B decay monotonically with shortening of wave length as shown in Fig.6, where K_t and K_r are computed (full and broken lines) and measured (plotted for K_t only) for breakwater by a pair of balloons with the same sizes and conditions as those in Fig.4 . Following to the proposed method, the sea-balloon systems of a pair of balloons with different distances between fore- and rear-balloon are computed to give transmission coefficients, which are found to be in good agreement with measured ones.

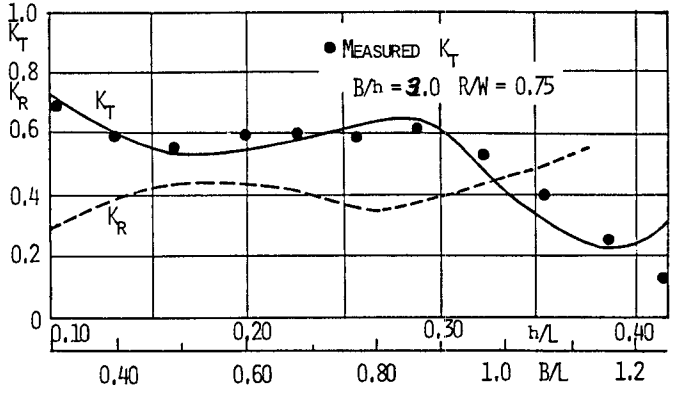

Fig.6 Measured and calculated transmission and reflection coefficients at a system of two balloons.

Fig.7 is the calculated and measured transmission coefficients at a pair of isolated balloons. Comparing Fig.6 with Fig.7, it is made clear that the radiation wave due to the volumetric change of balloons plays the important role of wave interception for relatively long waves.

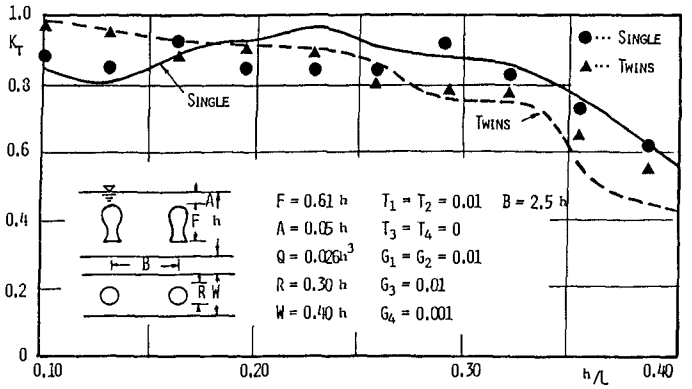

Fig.7 Measured and calculated transmission coefficients at single and a pair of isolated balloons.

4. The Principle of Wave Interception[3)]

The principle of wave interception at a sea-balloon breakwater is interpreted in the following ways as illustrated in Fig.8 :

(1) When the incident wave comes from the left of the figure, the wave crest is at the left balloon and the wave trough is near the right balloon, the fluid pressure around the left and the right balloons is respectively higher and lower than the hydrostatic pressure. When both of the balloons are isolated one by one, their volumes are invariable, though their shapes vary, and most of the incident wave energy travels through the sea-balloon breakwater and the remaining part is reflected. However, if both balloons are connected pneumatically by a pipe, the air in the left one flows to the right due to the pressure gradient between them. Then, it follows that the left and right balloons are compressed and expanded in volume, respectively, and the free water surface falls around the left balloon and rises around the right balloon. The periodical repitition of such a fluctuation of water surface produces the radiation wave, which is composed of two component waves, the one proceeding to the right and the other to the left with the same amplitude as each other. The component wave to the left constitutes the main part of the reflected wave at the breakwater and the one to the right cancels the transmitted wave which is to appear if both balloons are isolated, because of the inverse phase relation between the two waves. Consequently,it is necessary to make the radiation wave amplitude grow as large as possible, in order to improve the wave interception effect of the sea-balloon breakwater.

(2) The equilibrium shape of the sea-balloon is shown by a thick full line in Fig.2(a). Then, as shown in Fig.2(b),(c), if the air inside the balloon flows out through the air inlet " 4 ", the folds grow and the cross-section by the horizontal plane a-a' decays and if the air flows in, the folds decay and the cross-section grows. In this way, most of the volume changes of the sea-balloon occur at its neck part.

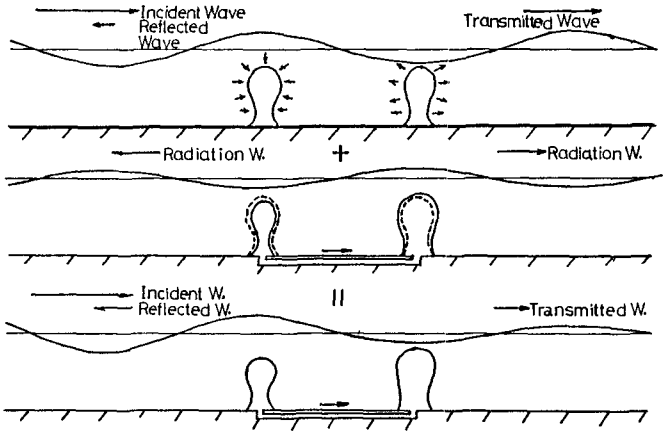

Fig.8 Principle of wave interception by radiation waves.

5. Effect of Gap Width between Adjacent Sea-Balloon Systems on Wave Interception[3)]

So far the width W of fluid region of sea-balloon system and the diameter of balloon R in Fig.3 have been held as constant. However, the wave interception ability of sea-balloon breakwater is greatly influenced by the gap width (W - R) between adjacent sea-balloon systems.

(1) Empirical results on the effect of gap width

In Fig.9, full lines represent computed transmission coefficients at sea-balloon system of three balloons with the same sizes as those in Fig.4, and only the channel width is changed as W/h = 0.30, 0.40, 0.50, 0.75 for balloon diameter R = 0.3h and so as R/W = 1.0, 0.75, 0.60, 0.40,respectively. In the same figure,measured transmission coefficients are illustrated for R/W = 0.90, 0.70, 0.50 and 0.44 .

Comparing the measured with computed values, it is deduced that transmission coefficients at various gap width is empirically expressed as follows:

$$K_t = (W/R)^{1/2} \cdot K_t^* + (W/R - 1.0) \cdot h/L \qquad (1)$$

where K_t^* is the transmission coefficient at W/R = 1.0.

Above representation should be regarded as available for $W/R < 2.0$ and $h/L < 0.4$.

(2) Two-dimensional analysis for sea-balloon system

Since the shape of sea-balloon is, as stated before, three-dimensional with vertical axis of symmetry, the dynamical analysis should be three-dimensional. However, for simplicity, assuming the balloon shape to be two-dimensional with the same cross-section as the three-dimensional one, the breakwater effect of that assumed air bag is analyzed as two-dimensional problem.

(3) Comparison of the results by three-dimensional analysis with those by two-dimensional one and with empirical formula

The broken line in Fig.9 is the computed transmission coefficient by two-dimensional analysis for the same size as those for three-dimensional analysis. It is found that this line almost coincides with the full line by three-dimensional analysis for R/W = 1.0 and it is suggested that the transmission coefficients will be computed through Eq.(1), where K_t^* is replaced by the one obtained by two-dimensional analysis.

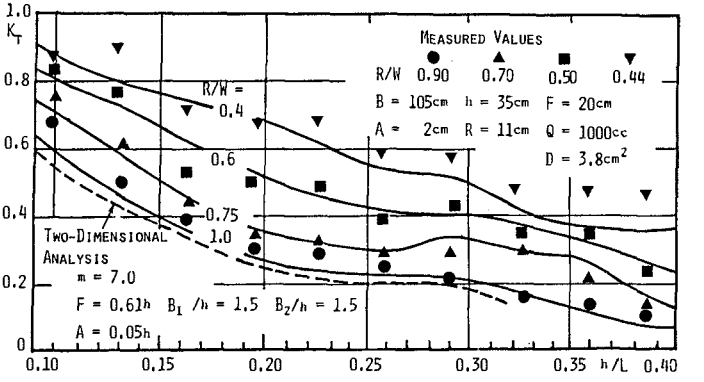

Fig.9 Transmission coefficients at a system of three balloons.

6. The Improvement of Wave Interception Effect of Sea-Balloon Breakwater[3]

In the above description, it is made clear that a pair of sea-balloons connected pneumatically with a distance B between the fore- and the rear-balloons in the direction of wave travel, as shown in Fig.3, has the performance to intercept waves as a kind of breakwater with low reflected waves. For the improvement of wave interception effect of sea-balloon system, the following method are developed by the experiments and the computations of two-dimensional boundary integrals by Green's identity formula.[3][4]

(i) Each balloon is sheltered by a vertical pipe.

(ii) The grouped balloons with small distances or gaps are used in place of the system of the paired balloons.

(iii) The horizontal frame to which balloons and pipes are attached is made impermeable.

(iv) As shown in Fig.10, an impermeable plate is moored in submerged and horizontal conditions in front of the sea-balloon breakwater, instead of making the frame impermeable.

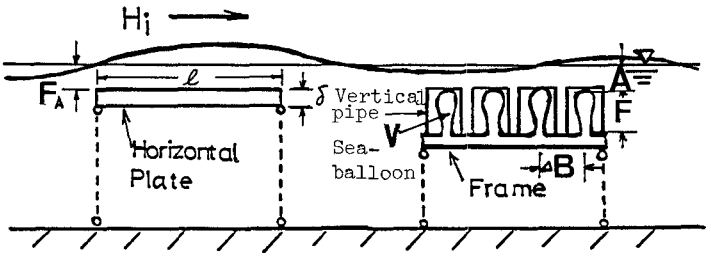

Fig.10 Moored horizontal plate and moored groupe of sea-balloons with vertical pipes.

By the method (i), the vertical pipe has a role to regulate the fluid flow pattern around balloons so as to generate radiation wave efficiently. In the method (ii) , the transmission coefficient with respect to relative depth h/L decreases monotonically with the increase of h/L . In the method (iii), the impermeable frame partly reflects relatively long waves and lowers the transmitted waves. By the method (iv), a flat horizontal plate splits a long incident wave into short waves, which are absorbed effectively by the proposed breakwater of grouped sea-balloons.

6.1 Wave Interception by the Vertical Pipes [5]

Fig.11 (a),(b) illustrates the side and plane views of a system of the sea-balloon breakwater constructed by a pair of two balloons with ΔB =20cm, B =(1.5,2.0,3.0,4.5)h, connected by a pipe with inner diameter Di = 25mm and fixed on the bottom of the wave channel of depth h =35cm, width W = 30cm. The sea-balloon is R = 10cm in diameter, F = 21cm in height, V = 1200cc in volume and A = 4.0cm in crown depth.

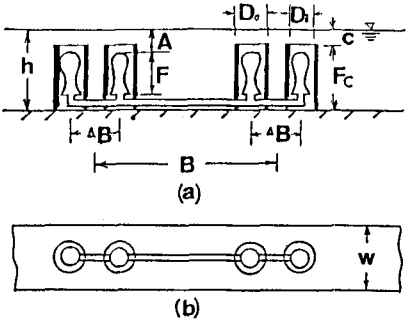

Fig.11 Sea-balloon breakwater provided with vertical pipes.

Fig.12 is the measured transmission coefficient K_t with respect to relative water depth h/L for the above sea-balloon breakwater without a vertical pipe. It is found that K_t falls slowly down with the increase of h/L, showing the minimum value for each B/h, then growing up to the maximum value and finally decaying. For larger values of B/h, the minimum value of K_t appears at smaller value of h/L with K_t value greater than that for smaller B/h.

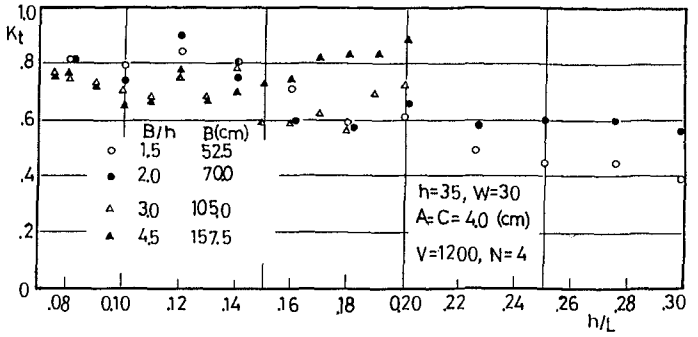

Fig.12 Transmission coefficient at paired-balloon breakwater without vertical pipes.

The transmission coefficients K_t at the sea-balloon breakwater, whose balloons are provided with the vertical pipe of inner diameter Di= 15cm, outer diameter Do = 16.5cm, height Fc = 31.0cm, are measured as shown in Fig.13, where the crown depth of the pipe is the same as that of balloon. Comparing with Fig.12, the effect of the pipes is remarkable, especially for large h/L.

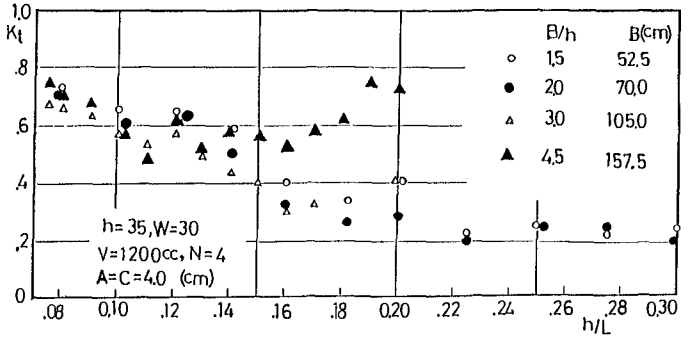

Fig.13 Transmission coefficient at paired-balloon breakwater with vertical pipes.

Fig.14 shows the calculated transmission coefficient for the sea-balloon breakwater whose balloons are provided with the vertical pipe of inner diameter Di = 0.5h, outer diameter Do = 0.6h, height Fc = 0.65h and for the one without the vertical pipe. These systems are constructed by a pair of balloon with B = (3.0,4.0)h, connected by a pipe and assumed to be fixed on the bottom of the wave channel of depth h = 35cm, width W = 30cm. The sea-balloon is R = 0.30h in diameter, F = 0.61h in height, V = 0.13h in volume and A = 0.35h in crown depth. K_t are computed by the method of two-dimensional analysis and it is found that the tendencies of K_t for relatively long waves are similar to those of measured values in Fig.12 and Fig.13 .

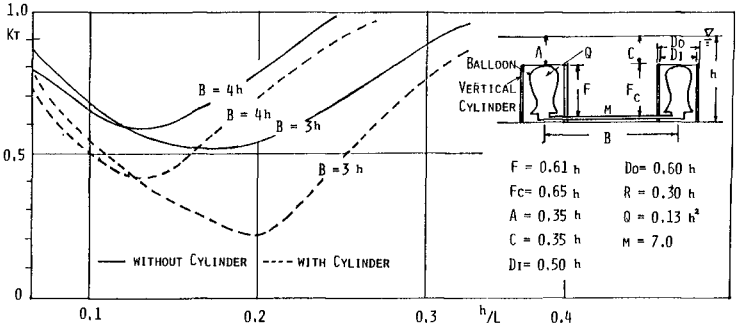

Fig.14 Calculated transmission coefficients at a paired-balloon breakwater with or without vertical pipes.

The above results of experiments and computations are interpreted in the following ways as illustrated in Fig.15. Fig.15(a) shows schematical flow patterns around the balloon,where the shape of the balloon in still state by chain line changes to the shape by full line following to the air inflow and changes to the shape by broken line after the air flows out. Corresponding to the in- and out-flow of the air, arrow lines illustrate the flow patterns around the balloon. And the expansion and reduction of the neck will induce mainly the horizontal direction of fluid flow, which is not so effective to induce the vertical flow for

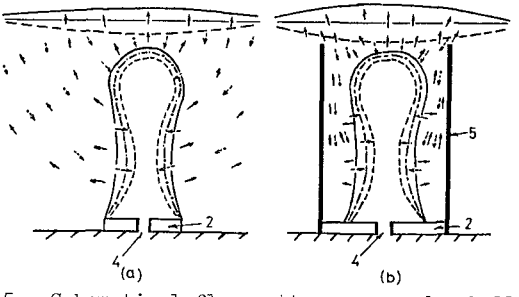

Fig.15 Schematical flow patterns around a balloon.

the water surface fluctuation. While, if the balloon is surrounded with a vertical pipe as shown in Fig.15(b), the horizontal flow due to the volume change of the balloon will be regulated to the vertical flow and then accelerate the formation of surface fluctuation, that is, the generation of radiation waves. It is certified by calculation as shown in Fig.16 that the coefficients of radiation wave height for the sea-balloon system with vertical pipe with the same sizes as those in Fig.14 are larger than those for the sea-balloon without vertical pipe.[3)]

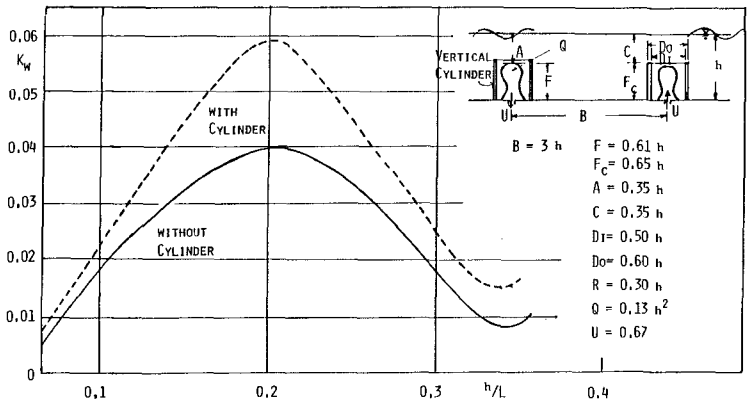

Fig.16 Computed radiation wave height by a pair of balloon with or without vertical pipe.

6.2 Effect of Submerged Horizontal Plate

The question is how to interpret the effect of the submerged plate on the wave interception of the sea-balloon breakwater. To answer the question, a flat plate is submerged and moored at 50cm in front of sea-balloon breakwater as shown in Fig.10. The length of every structure is taken as ℓ = 40.7cm, the depth of upper surface of the plate F_A is as 4.4cm and thickness of the fixed and moored plate δ is 2.4cm. A system of four balloons as shown in Fig.10 with equal distance ΔB to the direction of wave travel is investigated, where balloons are sheltered by pipes. In the experiment, four balloons with diameter R =6.0cm, height F = 10cm, volume V = 175cc are sheltered by vertical pipes with inner diameter Di =8.3cm, outer diameter Do = 8.9cm, height Fc = 14.5cm and arranged with distance ΔB = 13cm. The breakwater system is moored in submerged state with the crown depth of a balloon and pipe as A = C = 4.0cm, in wave channel with depth h = 35cm, width W = 30cm. As shown in Fig.17, the transmission coefficients are measured for five conditions of sea-balloon system with constant incident wave height Hi = 4.0cm as follows:

(1)○ is the case of balloon fixed to the permeable frame and represents the effect of sea-balloon only.

(2)-○- shows the case when the horizontal plate is moored in front of the balloon-breakwater.

(3) □ shows the case when sea-balloons with vertical pipes are fixed to the permeable frame.
(4) ■ is the case when the above permeable frame is changed to impermeable.
(5) -□- is for the case whem the flat plate is moored in front of the balloons with vertical pipes attached to a permeable frame.

The measured K_t values are shown in Fig.17 and the results are explained as follows:
(i) It is clear for case (2) that the moored plate is effective even to the relatively long waves.
(ii) It is shown for case (3) that the vertical pipe is more effective than the flat plate, particularly to the short waves.
(iii) It is shown for case (4) that the horizontal flat plate as the balloon frame is effective to the relatively long waves.
(iv) It is clear for case (5) that the flat plate moored in front of the balloons with vertical pipes is effective to the waves of $h/L > 0.15 \sim 0.2$.

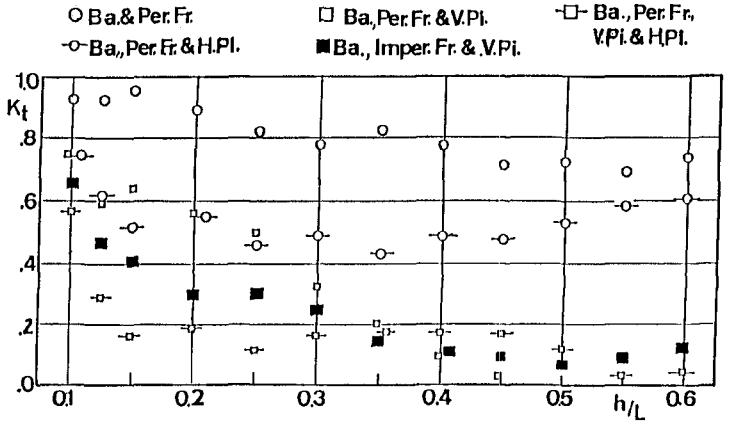

Fig.17 Measured transmission coefficients at sea-balloon breakwater with vertical pipe, permeable or impermeable frame, and with or without horizontal plate.

This means that for waves with small h/L the horizontal flat plate separated from the sea-balloon breakwater is more effective than when it is used as the frame. The reason why the separated plate is so effective is that the incident wave grows in height in fluid region above the plate and the ratio of wave height to wave length becomes so large that the wave deforms sharply due to the nonlinearity with small value of h/L. And after passing the flat plate, the sharply deformed wave splits into two or three trains of solitons, which advance in deep water region and are absorbed effectively by the breakwater of grouped balloons.

A similar tendency of measured K_t is shown theoretically in Fig.18, which is calculated by two-dimensional analysis for similar conditions of sea-balloon systems as shown in Fig.14 and Fig.17 .

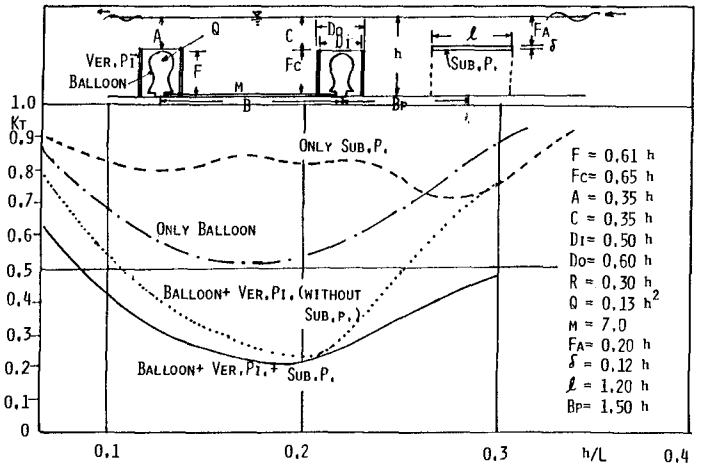

Fig.18 Calculated transmission coefficients at submerged plate and at sea-balloon breakwater with or without vertical pipe, and with or without horizontal plate.

7. Conclusions and Acknowlegement

Above description is summarized as follows:

(1) It is suggested in experiments that almost of the repeating deformation of sea-balloon induced by incident waves is not the elastic deformation of the membrane but caused by the alternate opening and closing of folds along wrinkles on the membrane of balloon.
Therefore,it is certified by experiments on transmission and reflection coefficients that the sea-balloon by polyethylene membrane is similarly effective to the one by rubber membrane. This means that the necessary condition for membrane is not elasticity but flexibility.

(2) Furthermore , fluid motions in- and out-side of sea-balloon are assumed to be potential, so that the boundary integral method by Green's identity formula is applied to numerical analysis of the problem.

(3) After the examination on the accuracy of numerical computation, the results by the authors'method of computation will be almost satisfactory for the estimation of transmission and reflection coefficients in the region of relatively long waves, where the radiation waves due to the deformation of sea-balloon has prevailing effect on wave interception by sea-balloon system.

(4) Following to the proposed method,sea-balloon systems of two balloons with distances between fore- and rear-balloon are computed to give transmission coefficients, which are found to be in good agreement with measured ones. It is clear by the experiments and calculations that the sea-balloon system is able to intercept waves with low reflected waves.

(5) To make clear the mechanism of wave interception, the radiation wave component is computed for the case of two sea-balloons system. After analysis, it becomes clear that the interception of relatively long wave by sea-balloon breakwater is interpreted by the fact that the radiation wave induced by the volume change of sea-balloon under incident wave is

canceled by the transmitted wave at sea-balloon without volume change, due to the anti-phase relation between them. To the contrary, the reflected wave by sea-balloon system without volume change is so small compared with the radiation wave that the resulting reflection coefficient is determined mainly by the latter.
(6) It is found that the transmission coefficient at a sea-balloon breakwater with arbitrary gap width between adjacent sea-balloon system is expressed by a simple empirical formula in terms of the transmission coefficient at sea-balloon breakwater without gap width, the relative water depth and the ratio of gap width to the balloon diameter. Accordingly, the transmission coefficient at sea-balloon breakwater with arbitrary gap width can be easily estimated by simple computation for the virtual two-dimensional sea-balloon breakwater, and various properties of the breakwater are estimated by two-dimensional computation.
(7) A method of sheltering each balloon by a vertical pipe is successful to depress the transmission coefficient for short wave length. This seems to be due to the flow regulation around the balloon and to the effective generation of radiation waves.
(8) The submerged flat plate is more effective to long waves when it is moored in front of the sea-balloon breakwater. This seems to be due not only to the reflection effect of the submerged flat plate, but also to the splitting of long incident waves into two or three short waves which are absorbed individually by the sea-balloon breakwater.

It is concluded that the proposed method to intercept waves by sea-balloon system with connecting pipe has the possibility to be a kind of breakwater with low reflected waves in complete submerged state.

The authors express heartfelt thanks to the following gentlemen who cooperated in experimental works and computations in ages of student at Kyushu University: Mr.Toshiharu Tanaka(Nippon Kokan Co.), Mr.Hitoshi Kitayama (Ministry of Transportation), Mr.Takeshi Nakatsuka (Taisei Kensetsu Co.), Mr.Mitsuyoshi Zaizen (Takenaka Doboku Co.), Mr.Yasuhiro Yoshizuka (Toyo Kensetsu Co.), Mr.Masayuki Niki (The official at Fukuoka Prefecture), Mr.Yuuichi Nishiuchi (The master course student).

CHAPTER 174

STRUCTURAL BEHAVIOUR OF TEN TON DOLOS ARMOUR UNITS

S.M. Uzumeri[1] and R. Basset[2]

ABSTRACT

This paper summarizes the results of a research program conducted to examine the structural behaviour of nine full scale ten ton Dolos armour units subjected to a well defined loading regime. Three unreinforced and six reinforced units were tested. The effects of three different types of reinforcement (rebars, hollow steel tubes, and prestressing bars) on the behaviour of the units was determined. Different design approaches for armour units are discussed and one possible new approach is presented.

1. INTRODUCTION

Rubble-mound breakwaters have been used extensively in Canada and throughout the world for harbour protection. The seaward faces of such breakwaters can be subjected to extremely destructive wave actions and thus require some form of protection. This protection is achieved by placing a cover, called the 'armour layer', over the breakwater to help dissipate wave energy and thus protect the breakwater core from direct wave attack. In environmentally demanding locations the armour layer usually consists of concrete armour units which have some interlocking capability. One of the most common is the **'DOLOS'** armour unit developed by Eric M. Merrifield and first used in South Africa (Merrifield, 1968). These units dissipate energy very efficiently and can be manufactured with standard construction contractors' equipment.

During the 1970's a series of failures occurred in breakwaters utilizing Dolosse. One likely cause for these failures was the fracture of individual armour units which lessened their interlocking capability and thus lowered their hydraulic efficiency.

As a result of the situation described it was decided to examine the strength and behaviour of Dolosse from a structural engineering perspective. This paper summarizes the results of a research program (Uzumeri et. al. 1985) conducted to examine the structural behaviour of nine full-scale Dolos armour units subjected to well defined loading regimes. The major variable considered in this project was the effect of different types of reinforcement on the structural behaviour of the armour units.

2. EXPERIMENTAL PROGRAM

2.1 Specimens

A unit weighing ten tons (proportions shown in Figure 1) was selected for the test program so as to eliminate any scale effects. A total of nine units (designated specimens 0 through 8) were tested with specimen 0 being used as a pilot test to gain familiarity with the handling and testing of the units. Four different types of units were studied in the test program as follows:

Specimens 1,2,3	Unreinforced
Specimens 0,4,5,6	Reinforced with eight rebars
Specimen 7	Reinforced with a steel tube
Specimen 8	Prestressed, Post-tensioned

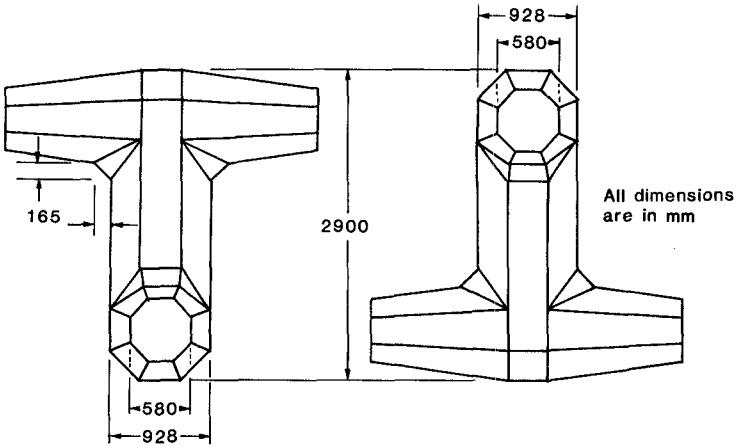

Figure 1: Proportions of Test Unit

All of the reinforcement had a minimum clear cover of 100 mm. The layout of the reinforcement was chosen so as to provide maximum structural benefit combined with ease of fabrication. Table I gives the reinforcement details for the test units.

2.2 Materials

2.2.1 Concrete

The concrete used in this test series was obtained from a ready-mix supplier. The strength was specified to be 25 to 30 Mpa at 28 days with no air entrainment used as only the structural behaviour of the units was being investigated. Table II gives the average observed concrete properties for each of the specimens.

TABLE I

REINFORCEMENT DETAILS

Specimen	Shank Reinforcement		Fluke Reinforcement	
	Number and Type	Total Area (mm^2)	Number and Type	Total area (mm^2)
0,4,5,6	8 - 25 mm dia. rebars	4000	8 - 25 mm dia. rebars	4000
7	1 - Hollow tube 114.3 mm OD 88.9 mm ID	4054	1 - Hollow tube 63.5 mm OD 38.1 mm ID	2027
8	1 - 36 mm dia. Dywidag bar	1018	1 - 26 mm dia. Dywidag bar	548

5	25.9	0.0016
6	31.3	0.0022
7	30.9	0.0018
8	28.2	0.0022

2.2.2 Steel

Three different types of longitudinal steel (rebars, hollow steel tubes and prestressing bars) were used in this investigation. The average properties for each of these types of steel are given in Table III. Values for the rebars were obtained from a minimum of three tensile coupon tests. Since only one each of the hollow tube and prestressed units were tested, it was possible to determine the strength characteristics of the actual bar (or tube) used in the specimen. The results for the prestressing bars were obtained from tensile tests while the tube results were obtained using a compression (stub column) test.

2.3 Test Procedure

The tests were conducted in the Sandford Fleming Structural Laboratory of the Department of Civil Engineering at the University of Toronto. The laboratory contains a 5 metre by 5 metre reaction wall and an 18

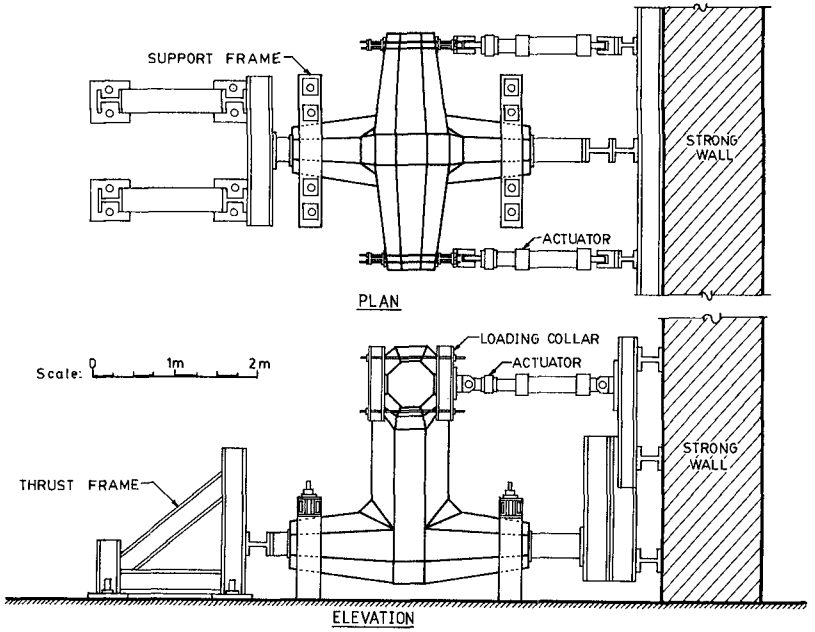

Figure 2: Test set-up

metre by 12 metre strong floor with two-way patterned anchor points on the floor. The test units were placed on the strong floor with the shank in a vertical position. The bottom fluke was supported by concrete pedestals attached to the strong floor. The top fluke was loaded by actuators reacting off the strong wall. The details of the test set-up are shown in Figure 2 while Figure 3 shows a typical test in progress.

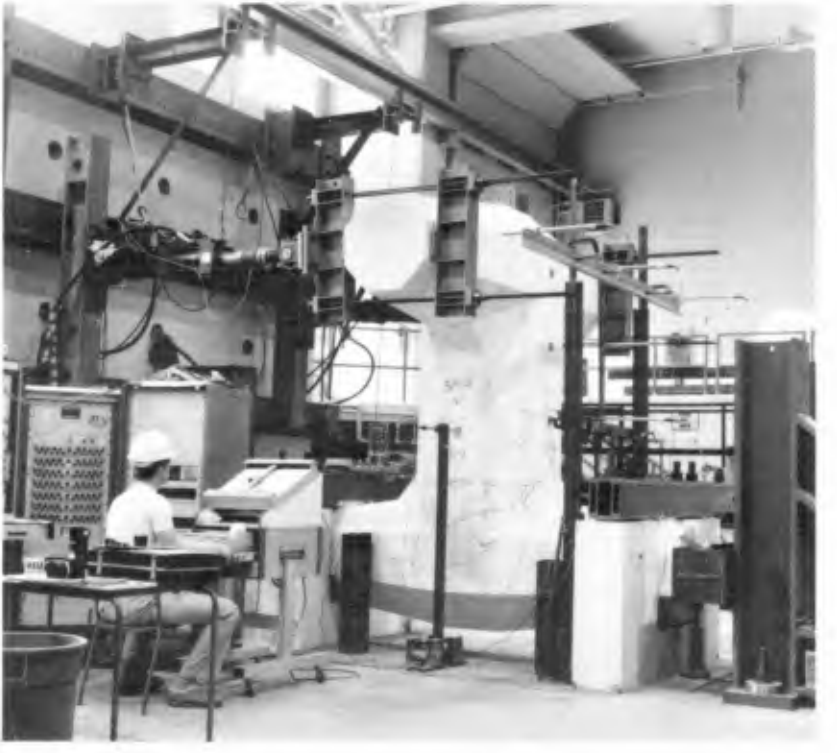

Figure 3: Test in Progress

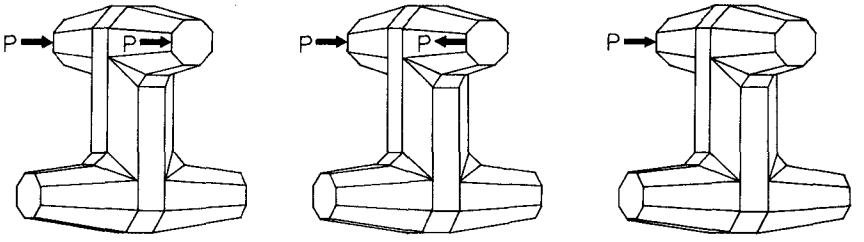
Three different load combinations were utilized in this investigation as follows:

TYPE I Both ends of top fluke loaded. Loads equal in magnitude and direction. (Bending moment and shear forces generated in the shank).

TYPE II Both ends of top fluke loaded. Loads equal in magnitude but opposite in direction.(Pure torsion generated in the shank).

TYPE III One end of top fluke loaded. (Bending moment, shear and torsion forces generated in the shank).

A schematic representation of the loading types is given in Figure 4.



Type I: Moment and Shear | Type II: Pure Torsion | Type III: Moment, Shear and Torsion

Figure 4: Load Types Considered

For each of the three load combinations the same six stage loading sequence was used as follows:

STAGE 1 Monotonic to cracking of specimen in the initial direction.

STAGE 2 Monotonic to cracking in the direction opposite to that in Stage 1.

STAGE 3 Cycle between the two cracking displacements (+/-) for 100,000 cycles.

STAGE 4 Monotonic to overall yielding of specimen in the initial direction.

STAGE 5 Monotonic to yielding of specimen in the direction opposite to that in Stage 4.

STAGE 6 Cycle between the two yield loads until major stiffness deterioration is noted.

The total time required to test each specimen varied from two hours for the unreinforced units to an average of thirty hours for the reinforced specimens.

3. EXPERIMENTAL OBSERVATIONS

3.1 General

Table IV lists the observed cracking and ultimate load capacities for each of the specimens. Figures 5 through 13 show the appearance of the specimens at the end of the tests and the observed response for each of the nine specimens. To give an indication of behaviour, a short summary of the experimental observations for each type of reinforcement will be presented in turn.

TABLE IV

CRACKING AND ULTIMATE STRENGTH SUMMARY

Spec. No.	Force Applied by Actuators (kN)			
	At Cracking		At Ultimate	
	Initial Direction	Opposite Direction	Initial Direction	Opposite Direction
0	241	168	418	417
1	185	---	185	---
2	255	---	255	---
3	130	---	130	---
4	199	190	464	466
5	263	260	263	261
6	153	138	236	228
7	150	149	293	264
8	260	239	332	334

3.2 Unreinforced Specimens

Since specimens 1,2 and 3 were unreinforced, the first crack coincided with failure as expected. The specimens had each separated into two pieces by the end of the test. No ductility was exhibited by any of the unreinforced specimens.

3.3 8-Bar Reinforced Specimens

The four 8-bar reinforced specimens (specimens 0,4,5 and 6) exhibited similar behaviour. They were all very stiff (slightly stiffer than the unreinforced units) up to the appearance of the first crack in the initial direction. During the third stage of loading no stiffness degradation was observed.

Subsequent loading to yield in each direction caused extensive cracking in the shank and a rapid deterioration in stiffness. Maximum crack widths ranged from 30 mm to 40 mm by the end of the test.

3.4 Tube Reinforced Specimen

The first crack for specimen 7 appeared at the base of the shank as expected. Subsequent testing indicated a slight loss in stiffness with continued cycling but difficulties with the control equipment caused the first portion of the test regime to be shortened to 3100 cycles. During stages 4,5 and 6 of the load regime the stiffness deteriorated rapidly. Maximum crack widths were approximately 80 mm.

3.5 Post-Tensioned Specimen

Specimen 8 was very stiff until the first crack developed and remained

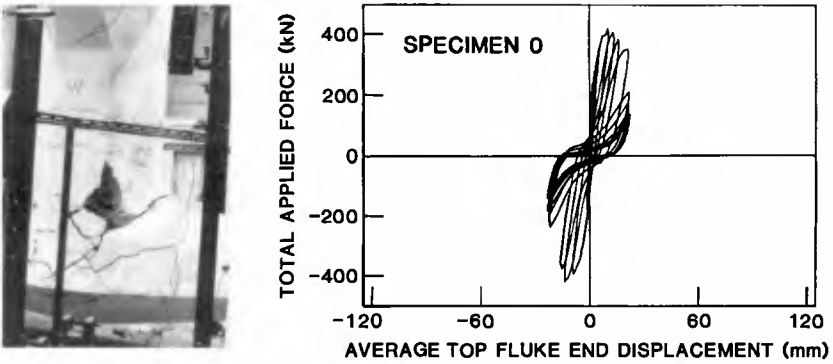


Figure 5: Final Appearance and Observed Response of Specimen 0

stiff with little deterioration during stage 3 of the loading regime. During the final three loading stages the existing crack became wider but no new cracks were formed. Maximum crack widths were of the order of 70 mm.

4. DISCUSSION

4.1 Specimen Comparisons

When one considers the three different load cases applied to both the unreinforced and the 8-bar reinforced specimens it seems apparent that loading type III (combined bending, shear and moment) was the most severe with lower initial cracking loads and ultimate loads. This generalized type of loading is the most likely to occur in the prototype due to the random placing of armour units in a breakwater.

The unreinforced specimens did not behave satisfactorily in a structural sense since they failed as expected at the first crack. No cycling was possible. This brittle behaviour could contribute to breakwater failures.

The reinforced specimens behaved in a satisfactory manner, withstanding 100,000 cycles of low level load reversals and several cycles of high level load reversals. The behaviour of the reinforced specimens was quite similar for the first 100,000 cycles with the units being initially quite stiff and exhibiting little stiffness loss during low level cycling. During the high level load reversals, the stiffness of the reinforced specimens dropped quite rapidly and the cracks became very large. By the conclusion of testing the reinforced specimens had sustained a high degree of damage but were still intact.

Comparing the three different types of reinforcement used in this study it was evident that the 8-bar reinforced units behaved in the most satisfactory manner with the highest resisted loads and the smallest initial crack widths (desirable for corrosion control). This behaviour occurred as a result of the even distribution of the reinforcement located nearer the perimeter of the cross-section as compared to the tube reinforced and prestressed specimens. In all cases the crack widths could have been further reduced by the introduction of reinforcing steel at the shank-fluke intersection.

Considering the effort required to fabricate the test specimens it is evident that the unreinforced units were the simplest to construct. Of the reinforced units, the 8-bar reinforced specimen was the simplest to produce followed by the tube and finally the post-tensioned specimen. All of the specimens were quite simple to cast and strip.

4.2 Alternative Design Approaches For Armour Units

4.2.1 Current design approach

Historically, the design of armour units has been performed by hydraulic and/or coastal engineers. Breakwater design is based partially on results obtained in hydraulic laboratories where the common practice has

been to construct scale models of the actual breakwater and armour units. Unfortunately, although the armour unit can be scaled for size and weight it is very difficult to accurately scale the strength of the unit. Thus, scale armour units used in model breakwaters usually have significantly higher strength than the corresponding prototype units.

The higher strength of the scale armour units results in model tests in which the armour unit rarely fails. Thus, the design of a breakwater is usually based on the assumption that the armour units will not fracture. This assumption is not consistent with prototype experience in which failures of armour units and breakwaters have been observed (Magoon et. al., 1974, and Anonymous, 1982). The effect of armour unit breakage on the performance of a breakwater is not fully understood but it clearly has an effect on performance.

If one were to design an unreinforced concrete armour unit with the criterion that no breakage should occur then the unit will necessarily be larger than optimum since the uncertainties in the determination of the possible loads and the expected concrete strengths must be estimated conservatively to allow a reasonable safety factor. If some of the units were allowed to break then the effects on the stability of the breakwater as a whole must also be examined.

4.2.2 Design based on determination of expected loads

One approach to the design of an armour unit is the determination of the expected loads that the unit will be subjected to. The unit could then be designed to resist these loads.

The determination of the expected loads on the prototype unit is a complex and expensive process which is of questionable value as the loads obtained may only be applicable to the specific site measured. Different wave heights, wave regimes, and breakwater geometries could significantly affect the magnitude and nature of the loads in a manner which is not understood. Thus the loads may not be transferable to another site.

The determination of the loads on a model unit is somewhat easier than for the prototype since one is working under laboratory conditions. Using a model breakwater has the advantage of being able to use different wave heights and regimes and being able to alter the breakwater design. This would allow the determination of the loads for different sites. Unfortunately, the scaling of the loads from the model to the prototype and the determination of a safety factor based on the strength of the units introduces many uncertainties.

4.2.3 Design based on determination of desired response

It may be advantageous to approach the design of concrete armour units from the viewpoint of the response desired from the unit. Thus, if the desired response for the prototype unit is that it emulate the model unit and maintain it's integrity then one must examine the steps required to meet this objective.

In order to maintain it's integrity the unreinforced concrete armour unit must resist the load effect that causes cracking since cracking effectively causes failure of the unit. The load effect which causes cracking for a particular size of unit can be easily calculated and thus the amount of reinforcement required to sustain this load level can be determined. This would be the minimum amount of reinforcement required for ductile behaviour. An additional requirement for reinforcement may be necessary in order to control crack widths since crack sizes could be large, leading to possible corrosion problems. Thus, some level of reinforcement greater than the minimum required for ductile behaviour would seem to be desirable. Placement of additional steel will lead to enhanced ductility, improved crack control, and an increase in load carrying capacity. It is important to note here that the increase in ductility is the fundamental reason for adding reinforcement.

In summary, rather than design unreinforced units for the maximum expected loads, with uncertainties in quantification of both the loads and the resistance of the unit, one could ensure that the armour unit will not fail after cracking and be ductile enough to endure further deformation by the addition of reinforcement. In this manner a ductile unit would spread the load to adjacent units but still remain in one piece thus satisfying the performance objective.

5. CONCLUSIONS

Based on the experiments described in this paper the following conclusions can be drawn:

1) The best approach to the design of Dolosse is likely to be the definition of a desired response and the determination of the amount of reinforcement required to achieve this response.

2) The use of steel reinforcement leads to an increase in both the ultimate strength and ductility of a Dolos concrete armour unit as compared to an unreinforced unit.

3) The best results are obtained when steel is well distributed throughout the unit as close to the perimeter as possible consistent with corrosion control.

4) The cost of a reinforced unit should not be substantially higher than an unreinforced unit since they are simple to construct. The relative cost of reinforcement represents a very small proportion of the cost of a breakwater.

ACKNOWLEDGEMENTS

The research described in this paper was funded by Public Works Canada under a Department of Supply and Services contract (No. 05SU.EN280-2-3-707). The experimental work was performed in the Sandford Fleming Structures Laboratory of the Department of Civil Engineering of the University of Toronto.

CHAPTER 175

Composite Type Breakwater at Taichung Harbor, R.O.C.

Chung-Chuang Wu*

The composite type breakwater used in Taichung Harbor contributes economical cross section and better consideration of drifting sand control. Also, with the plan of making caissons on the sand beach and installing caissons by using an unprecedented "Island" method, it shorten the construction period of breakwater significantly.

1 Introduction

The government of Rep. of China decided to build a new port in the central part of the west coast of Taiwan, known as Taichung Harbor, about two decades ago. Its purpose was to cope with the problems caused from the rapid economic growth; such as to balance the population distribution, to alleviate inland traffic congestions and to release the burdens of other ports.

Shallow beach and straight coast line with strong seasonal wind and heavy brifting sand are the typical features along the west coast of Taiwan. The variety of meteorology is not only influencing the configuration of the port but also demanding special alternatives to the selection of materials, construction methods, etc.

The design and construction methods of the composite type breakwaters used in Taichung Harbor were trying to triumph most of the meteorological and geographical disadvantages encountered as well as to meet the urgent construction schedule. The effort has been considered successful. The construction processes have appeared highly efficient. Fig. 1 shows the location of Taichung Harbor and the configuration of its breakwaters.

2 Relationships Between Caisson Composite Type Breakwater and Meteorology

During the winter, from October each year to February of the next year, the previaling wind comes from North and North-North-East with average speed of 10 m/sec at Taichung port. The prevailing wind in the summer used to come from South-West with considerably lower speed, not exceeding 9 m/sec except hitting by typhoon. Typhoons attack Taiwan in summer almost every year. They create much more significant waves than the prevailing wind does in the winter. Therefore, the methods of breakwater design of Taichung port were based on the waves created by the typhoons instead of the seasonal prevailing winds. Table 1 gives

* Assistant Engineer, Taichung Harbor Bureau, Taiwan, R.O.C.

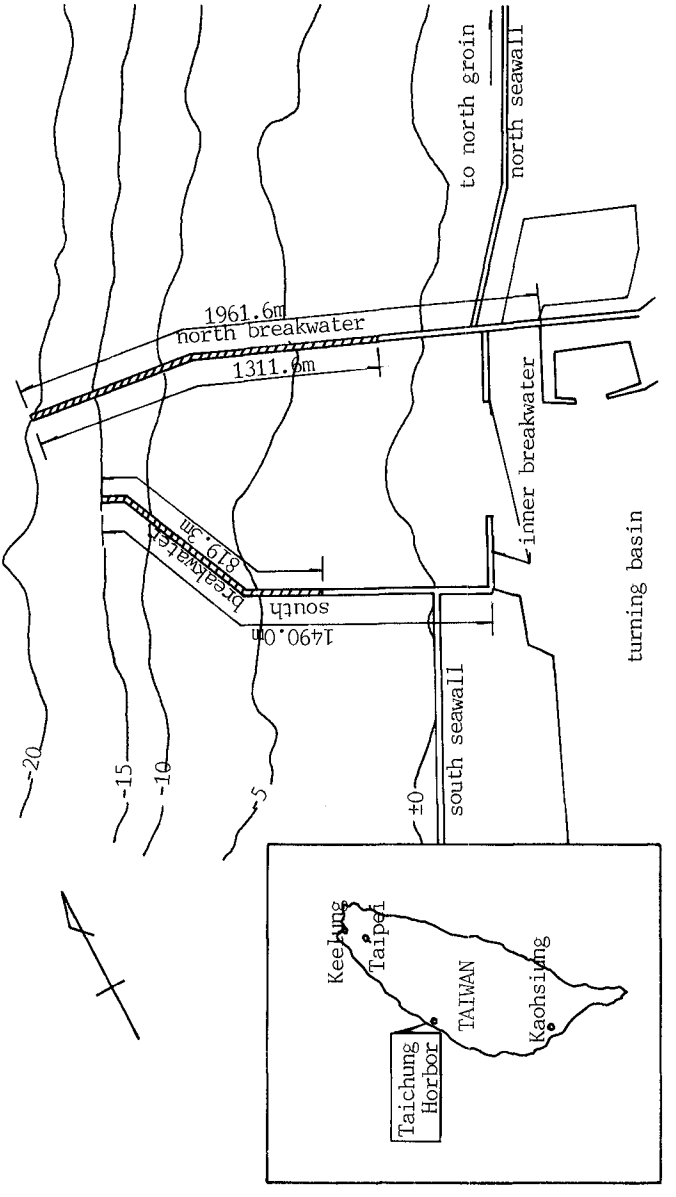

Figure 1. Location of Taichung Harbor and Layout of breakwater, shadow part indicates composite section

the significant wave height, at water depth -20m, of typhoons around Taichung Harbor, which was estimated by the "Wave Tracing Method" suggested by Dr. Ijima [3]. The max. tidal level of +6m was adopted as the H.H.W.L. (highest high water level) for the design.

Table 1. The estimated significant wave height & period at Taichung Harbor.

	Direction	Height (m)	Period (m)	Remarks
During typhoon	NNE	5.0	9.2	water depth = -20 m
	N	5.7	9.7	
	NNW	5.8	9.9	
	NW	5.4	9.9	
	WNW	5.0	9.8	
	W	4.7	9.3	
	WSW	4.6	8.7	
	SW	4.3	8.4	
During winter monsoon	N	4.0	8.0	water depth = -20 m
	NNW	4.0	8.0	

Drifting sand comes from two adjacent rivers; one is Tatu river on the south which carries about 0.2 million m^3 sand drifts northward in the summer, the other is Tachia river on the north with the sand amount around 0.8 million m^3 which goes southward particularly in the winter. There is about 1 million m^3 of sand being transported to the port and vicinity annually. Hence, the effect of preventing sand from settling in this harbor was considered being part of the function of breakwater.

The layout of this port was selected through a series of Model Experiment of Protection. The entrance width is 350m, navigation channel angles with 65°44' westward from the north, i.e. on the skew to the direction of prevailing wind. The length of breakwaters were determined accordingly with that the depth at the seaward end of north breakwater should reach -20m, and should be -15m deep at the end of south breakwater. Also, according to the Sand Drifting Model Test, the breakwater with vertical wall was chosen as typical cross section at places where the water depth is over-4m. The waves reflected by vertical wall breakwater could affect part of the approaching sand load away to the deep water (over -20m) area and the reserved settling place which located between north breakwater and north groin with the area more than 350 hectares. The reserved areas are dredged annually to provide adequate space for future sand deposits. This method provides good means to control sand free from drifting into the harbor [5].

Besides considering of harbor calmness, drifting sand control, vessel operation and construction economy ..., there was another reason for choosing composite type breakwater in Taichung Harbor; to account the property of its faster construction progresses and invulnerable characteristics.

3 Features of Caisson Composite Type Breakwater

3.1 Corresponding Data

The wave pressure acts on breakwater was computed by using Sainflou's Formula at the zoon where the wave is under the non-breaking condition. The Hiroi's Formula was used to calculate the wave pressure wherever the water depth is smaller than twice the height of approaching waves. The initial dimension of the proposed cross sections of composite type breakwater was determined through the estimated wave pressure and the Itoh's Expected Sliding Theory which checked out the possible lateral sliding displacement at any place of the breakwater with the maximum tolerance not exceeding 5 cm [4].

For easily constructing and conveniently towing, also for taking the full usage of caisson dock (its 115m long, 28m wide and 8.9m deep, can cast 4 caissons in one batch), the lengths of concrete caissons were setup to 18m and 24m, the widths varied from 14m to 18m depending on the water depth at the post position.

Final elevation of crown tops for northern and southern breakwaters, according to the estimated overtopping condition at north breakwater during monsoon season and at the south breakwater in the Typhoon period, are +10.2m and +8.6m, respectively [1].

The thickness of rubble mounded foundation was determined to be larger than 2m at any position, despite the good bearing capacity of sea bed around this area (silty sand, the blow count of penetration test at top 10 meters layer, $N > 10$; others $N > 30$) [1]. Mean while, to prevent the sand being washed out from the bottom of foundation by current and tide, vinyl mattress was unfolded to cover the surface of sea bed before rubble mounding. Fig. 2 illustrates the typical cross section of composite type breakwater at Taichung Harbor.

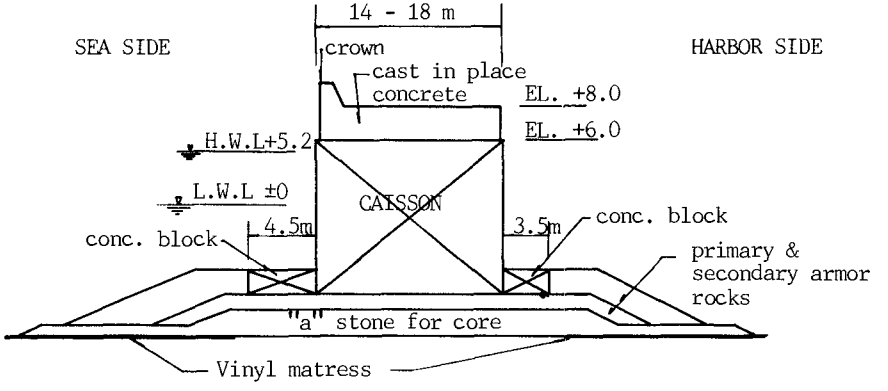

Figure 2. Typical cross section of composite type breakwater at Taichung Harbor

The length of north breakwater is 1961.6 meters with 1311.6 m in composite type. South breakwater is 1490 meters long with composite type 819.3 m.

3.2 Construction Procedure

Totally, 102 breakwater caissons had been completed within the first construction stage (1972-1977); 59 at north, 37 at south, 2 caissons at north groin and 4 at both inner breakwaters. In order to meet the urgent schedule, about 2/3 (71 caissons) of the total amount were built up on the sand beach instead of using dry dock, because the available work yard on beach was almost unlimited for each construction batch. In average, it took only 9.5 days to complete a caisson on the beach -- much shorter than erecting it in dock. Fig. 3 shows the caissons being made on beach were ready for floating out.

A well designed procedure which can be used to float out the caissons safely is the key for successful beach-made-caissons. Experiments of Model Floating and detailed survey during each caisson's floating out were made [2]. At the beginning, the Sit-to-Float method was used on the first two caissons of south breakwater. This kind of method was leading to low down the caisson into water levelly, then enable it floating out at high tide, by dredging and washing out the sand around the bottom of caisson at the same time. Fig. 4 indicates the steps of Sit-to-Float procedure. Unfortunately, stress concentrations were found on the bottom of that two caissons. Therefore, an alternative technique, so called Slide-to-Float method, was adopted as the proper way for all the other beach-made-caissons.

Figure 3. Caissons made on the beach where is dredged for harbor basin later

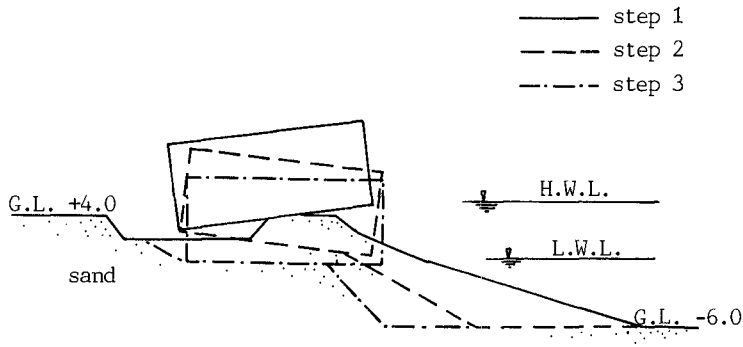

Figure 4. Procedure of caisson floating out -- Sit-to-Float. Steps: 1) dredging and washing out sand around caisson bottom; 2) caisson lowing down at L.W.L.(lowest water level) on its own weight; 3) caisson floating out at H.W.L.(highest water level)

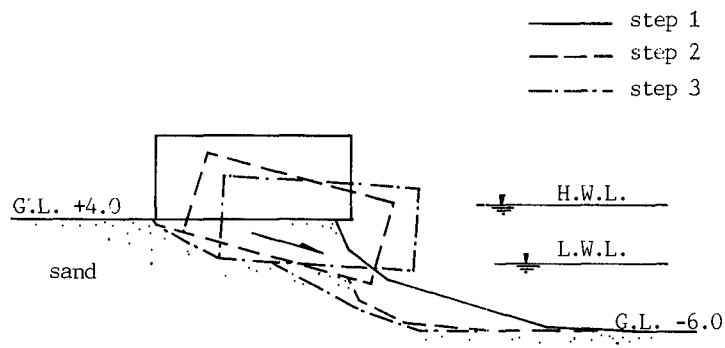

Figure 5. Procedure of caisson floating out -- Slide-to-Float. Steps: 1)dredging out sand under front toe of caisson; 2) caisson sliding toward water deeply at L.W.L.: 3) caisson floating out naturally at H.W.L.

In the method of Slide-to-Float, dredgers were used to cut the sand out from the front toe of each caisson to guide it sliding into water. Then, the caissons would float up for towing when tide flood. Because of the large tidal range (mean spring tide range: 4.59m) and the high friction of sand (angle of friction, ϕ, between 30° and 34°) at this area, caissons would not slide down abruptly. This process neither damaged the structure of the caissons nor hurt the working vessels. Fig. 5 illustrates the processes of Slide-to-Float method. Fig. 6 shows a caisson is sliding toward water under the operation of Slide-to-Float.

Because of the limits of water depth around the caissons' casting yard, wherever at dock or on beach, the constructed height of the caissons should not exceed 14m to ensure the floating out of caissons. Hence, for those caissons which final height beyond 14m were constructed up closely to 14m first. After that, they were towed to the high layer construction site and temporary storage area for continuously completion.

The whole construction sequence of composite type breakwater started from deploying center line, sounding out the elevation of sea bed, and paving PVC mattress. Cobble "a" - the stones with diameter around 30 cm were dumped to the site to constitute as the core of foundation before secondary armor rocks (0.3 - 1 ton) were casted. After the caissons were settled to position, they were filled with sand and gravels. The finishing procedures included pouring cap concrete, placing protective concrete blocks, tetrapods, and primary armor rocks (size 1 - 5 ton). It was considered to be totally completed after the crown had been concreted.

Figure 6. Caisson slides toward water under process of Slide-to-Float method

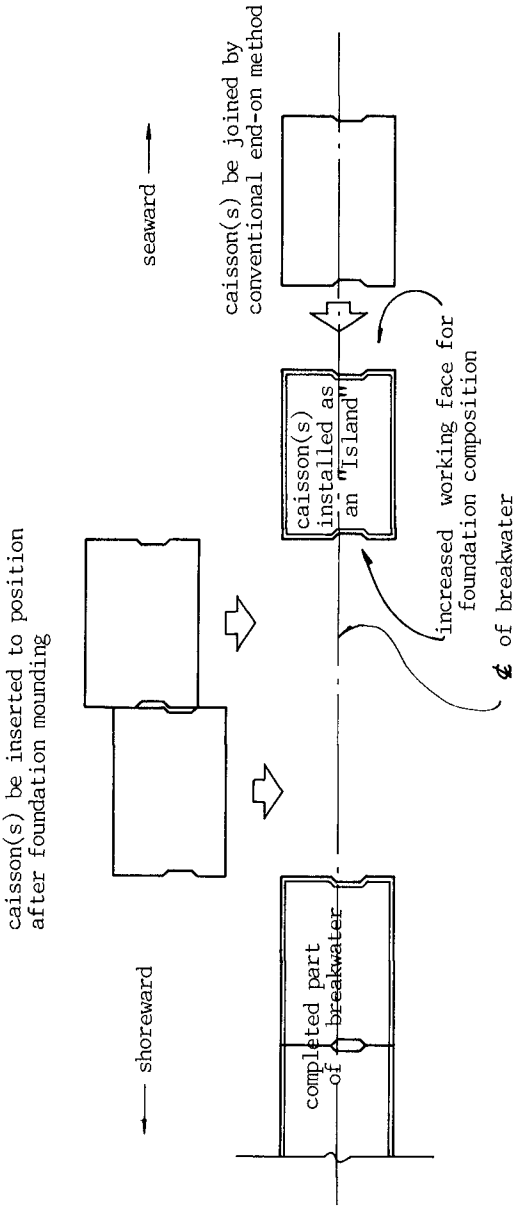

Figure 7. "Island" method of caisson installation

Figure 8. Installation of an "Island" caisson, which is aided by a pre-anchored 80 MT pontoon

Figure 9. Behind an "Island", a caisson is inserting to its position

Since the manufacturing of caissons was shortened significantly, and the workable time on the sea was comparably insufficient (96 caissons should be installed within 3 years), the disposition of installing caissons became critical. In addition to the conventional end-on progressive method, an "Island" method (or might call "Jumping" method) was introduced to increase the working faces to these breakwater construction project. The concept of this scheme, different from the conventional end-on method, is to post caissons some distance apart from the already installed breakwater, promise more working space to conduct consequent foundation rubble mounding, and then to complete this section of breakwater by inserting other caissons [6]. Fig. 7 illustrates the scheme of "Island" method. Fig. 8 shows an "Island" caisson is adjusting its position with the aid of a pre-anchored 80 MT pontoon. Fig. 9 shows a caisson is towed on the way to fill the space between "Island" and the end-on caisson.

4 Conclusion

The workable time on the sea of this project, 120-140 days per year averagely, was very short and urgent. Fortunately, however, the project was smoothly and punctually completed. The success should attribute to the careful and thorough planning, good use of long term and short term weather forecasting informations, etc. The most outstanding tact among these procedures are considered as successfully casting most caissons on the beach area where would be dredged as the channels later, and taking an unprecedented "Island" method to place the caissons.

5 Acknowledgements

The author would like to express his appreciation to Mr. C.C. Sha, Chief Engineer of Taichung Harbor Bureau, for his suggestions and the most help in the successful collection of historical records and data which enabled completion of the work.

CHAPTER 176

METHOD OF ESTIMATING THE POWER EXTRACTED BY FIXED COASTAL TYPE WAVE POWER EXTRACTORS

Kenji YANO,[1] Hideo KONDO,[2] M.ASCE and Tomiji WATABE[3]

ABSTRACT

Study is performed on a vertical flap type energy converter, "Pendulor System". The power absorbed with the system in random waves is estimated using a transfer function of absorbed power (absorption coefficient) in regular waves and wave spectrum. A boundary element technique is applied to compute the hydrodynamic problem associated with the system which is placed in regular waves. The applicability of the method has been examined by a series of field test at a test plant caisson. The agreement between estimation and experiment was found to be good except near the resonance frequency of the system.

1. INTRODUCTION

A large variety of apparatus have been proposed for absorbing wave power and converting to other usable power. These absorbers may be classified roughly into two types, namely, floating type and fixed ones. Initially the fixed type ones had been discarded since the incident wave energy at shallow water area becomes less than that at the deep water. So, they unlikely seem to be attractive. However, since the floating type absorbers accompanies with difficult problems such as mooring or positioning system, energy transportation to land and maintenance which raise the cost of energy. This leads us to a bottom standing fixed type device at the coastal area which can serve as a breakwater and may save the energy cost.

With this point of view, we have studied the fixed type absorbers which can be set within coastal structures and had developed a few systems such as the "Pendulor System", a kind of pendulum with a flat plate. The system has an excellent power absorbing capacity, which had been introduced at the 19th Conference (Kondo et al, 1984). The present report deals with the method to estimate quantitatively the power absorbed by the pendulor system which will be set linearly alongshore in coastal area. This is one of the major problems to be solved in advance of realizing the commercial systems of fixed type.

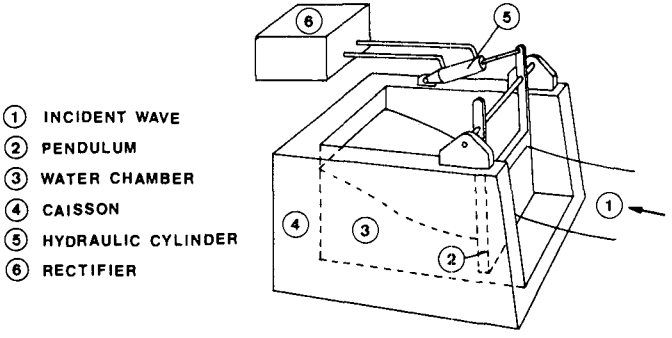

Fig. 1 Schematic diagram of pendulor system

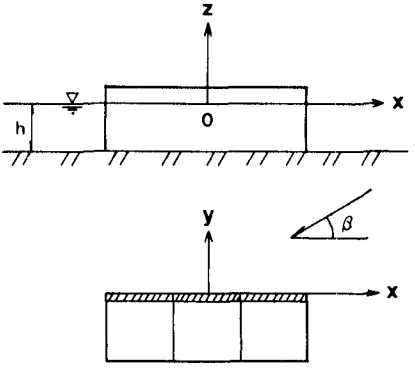

Fig. 2 Co-ordinate system

2. PENDULOR CONCEPT

Fig. 1 shows a concept of the pendulor system. The device consists of an oscillating pendulum around a horizontal axis, a double acting hydraulic cylinder connected to the pendulum, hydraulic circuit, that is a power takeoff mechanism, and a caisson in which a closed water chamber is formed. A kind of standing wave is produced in the chamber by the oscillating pendulum. At the node of standing wave, the pendulum is less affected reacting moment by the wave. Thus the device has high absorption capability under this hydrodynamic condition.

3. THEORETICAL MODEL

3.1 Absorbed Power in Regular and Random Waves

Let's consider m identical pendulor devices connected together to form a string as shown in Fig. 2. Each pendulum is allowed to move roll mode alone in response to regular wave with amplitude a. It is assumed that the mechanism for wave power absorption can be described

by a simple external damper connected to pendulum and that the damping moment caused by power absorption is linearly related to the velocity of the motion of the pendulum.

The motion of pendulums in waves, with their amplitudes varying sinusoidally in time, are calculated by the following equations

$$I_k\ddot{\theta}_k+N_k\dot{\theta}_k+K_k\theta_k=M_k \qquad k=1,2,\cdots,m \tag{1}$$

where I_k, K_k and N_k are the moment of inertia, the restoring moment coefficient of the kth pendulum and the damping moment coefficient of the damper attached to the kth pendulum and θ_k is the angular displacement with complex amplitude $\bar{\theta}_k$. M_k is the hydrodynamic moment acting on the kth pendulum and is represented, as follows

$$M_k = M_{0k} - \sum_{\ell=1}^{m} (I_{k\ell}\ddot{\theta}_\ell + N_{k\ell}\dot{\theta}_\ell) \tag{2}$$

where M_{0k} is wave exciting moment associated with incident and scattering waves and the terms in the parentheses are moments on the kth pendulum due to a radiation wave produced by a motion of the ℓth pendulum. The coefficients I_k and N_k are known as the added moment of inertia and the damping moment coefficient, respectively. The simultaneous linear equations of 1 can be solved for the pendulum motions $\bar{\theta}_k$. Hence, the transfer function of the kth pendulum is defined by Eq. 3.

$$Z_k(f,\beta)=\bar{\theta}_k/a \tag{3}$$

The total power absorbed P_a is given by

$$P_a=\sum_k \frac{1}{2}\omega^2 N_k|\bar{\theta}_k|^2 \quad , \quad \omega=2\pi f \tag{4}$$

The absorbing coefficient κ is defined as

$$\kappa=P_a/(P_w\cdot B_0) \tag{5}$$

where P_w is mean power per unit crest length of incident wave train and B_0 is total width of the series of devices.

It is important for the design of wave power absorbers to know how effectively they absorb power from random waves. In random waves absorbed power $\bar{P}_a$ with the system can be estimated by

$$\bar{P}_a=\rho g\int_0^\infty\int_0^{2\pi}\kappa(f,\beta)S(f,\beta)C_g\,df\,d\beta \tag{6}$$

where $\kappa(f,\beta)$ the absorbing coefficient in waves at frequency f in direction β, and $S(f,\beta)$ the directional wave spectrum, ρ the density of the fluid, g the acceleration of gravity and c_g is the group velocity of waves.

For a case that the wave dimensions are known only at deep water, the following relationship is useful for the transformation of a deep water directional spectrum into a shallow water directional spectrum.

$$S(f,\beta)\,df\,d\beta C_g = S_0(f,\beta_0)\,df\,d\beta_0\,C_{g0}K_r^2 \tag{7}$$

where K_r the refraction coefficient and subscript 0 is used for the symbols at deep water. Substituting Eq. 7 into Eq. 6, the absorbed

power at shallow water area is estimated by deep water spectrum using Eq. 8.

$$\overline{P}_a = \rho g \int_0^{\infty}\int_0^{2\pi} K_r^2(f,h,\beta_0) S_0(f,\beta_0) \times \kappa(f,\lambda(f,\beta_0)) C_{g0}\, df d\beta_0 \qquad (8)$$

$$\beta = \lambda(f,\beta_0)$$

where $\lambda(f,\beta_0)$ is a function of the wave direction.

If we used a spreading function D, the directional spectrum is rewritten as follows

$$S_0(f,\beta_0) = S_0(f) D(f,\beta_0,\overline{\beta}_0) \qquad (9)$$

where $\overline{\beta}_0$ is the dominant wave direction, $S_0(f)$ is a usual frequency spectrum.

The absorbed power with the system is calculated by finite set of directional and frequency-wise components of the absorption coefficient, the wave spectrum, and so on.

3.2 Hydrodynamic Loads

The hydrodynamic loads acting on the pendulums are computed from the velocity potential along the body boundaries. To obtain the potential, we consider separately the fluid region exterior of the string (outer region) and the region interior of the closed chambers (inner region, excluded "harbor" which is shown below).

In the usual manner the velocity potential in the outer region can be decomposed into

$$\Phi(x,y,z;t) = (\phi_0 + \phi_d + \sum_{k=1}^{m} \overline{\theta}_k \phi_k)\, e^{-i\omega t} \qquad (10)$$

where ϕ_0 is the known potential of the incident wave and ϕ_d is the diffraction potential corresponding to scattering of the incident waves by the string with fixed pendulums. ϕ_k represents the radiation potential induced by the forced motion of the kth pendulum in the absence of the incident waves. The boundary condition at the body surface are given by

$$\frac{\partial \phi_d}{\partial n} = -\frac{\partial \phi_0}{\partial n} \qquad \text{on } \Gamma \qquad (11)$$

$$\frac{\partial \phi_k}{\partial n} = -i\omega(z_0 - z) n_y \qquad \text{on } \Gamma_k$$
$$= 0 \qquad \text{on } \Gamma - \Gamma_k \qquad (12)$$

where z_0 represents a depth of the point of rolling axis of the pendulum, Γ_k a wetted surface of the kth pendulum, Γ a wetted surface of the body, n the distance in the direction of the unit normal vector $\mathbf{n}$ directed outward from the boundary and n_y the y-component of $\mathbf{n}$. In the chamber, the potential ϕ' associated with the unit motion of the pendulum can be treated as two dimensional wave making problem and the solution was obtained by Asano (1980).

Assuming the each chamber has same dimensions, the hydrodynamic

loads and the coefficients are expressed as follows

$$M_{0k} = i\omega\rho e^{-i\omega t}\int_{\Gamma_k}(\phi_0+\phi_d)\bar{h}\,d\Gamma \tag{13}$$

$$I_{k\ell} = \frac{1}{\omega^2}\,\mathrm{Re}\left[i\omega\rho\int_{\Gamma_k}(\phi_\ell+\delta_{k\ell}\phi')\bar{h}\,d\Gamma\right] \tag{14}$$

$$N_{k\ell} = \frac{1}{\omega}\,\mathrm{Im}\left[i\omega\rho\int_{\Gamma_k}(\phi_\ell+\delta_{k\ell}\phi')\bar{h}\,d\Gamma\right] \tag{15}$$

in which $\delta_{k\ell}$ is the Kronecker delta function, $\bar{h} = (z_0-z)n_y$, Re[ ] and Im[ ] indicate the real and imaginary parts, respectively.

3.3 Numerical Determination of Potentials

The most general method for calculating the potentials is a boundary element method. A Green's function, G, is chosen as a source potential of unit strength which satisfies the same boundary conditions as the wave potential. As a result of Green's Theorem, the solution for wave potential can be represented as follows

$$-\frac{1}{2}\phi_k(P) = \int_\Gamma\left[\phi_k(Q)\frac{\partial}{\partial n}G(P,Q) - G(P,Q)\frac{\partial}{\partial n}\phi_k(Q)\right] \tag{16}$$

in which P and Q represent points on the boundary of the body Γ. The corresponding integral equation for ϕ_d is obtained from Eq. 16 by replacing ϕ_k by ϕ_d.

Let ψ represents the unknown potential above mentioned and $\hat{\psi}$ is its derivative. Equation 16 is numerically solved for a ψ at a number of discrete points. The surface Γ of the body is divided into N boundary elements. The values of ψ and $\hat{\psi}$ are assumed to be constant on each element and equal to the values at the element center called "nodes". Hence, the integral Eq. 16 for a particular node 'i' can be approximated as

$$\sum_j \hat{H}_{ij}\psi_j = \sum H_{ij}\hat{\psi}_j \tag{17}$$

$$\hat{H}_{ij} = \frac{1}{2}\delta_{ij} + \int_{\Gamma_j}\frac{\partial}{\partial n}G(i,j)\,d\Gamma$$

$$H_{ij} = \int_{\Gamma_j}G(i,j)\,d\Gamma \tag{18}$$

where Γ_j is the boundary of element 'j'. The whole set of equations for N nodes can be expressed in matrix form as follows,

$$\mathbf{\hat{H}U = HQ} \tag{19}$$

where

$$\mathbf{\hat{H}} = [\hat{H}_{ij}] \quad , \quad \mathbf{H} = [H_{ij}]$$

$$\mathbf{U} = \{\psi_1, \psi_2, \cdots, \psi_N\}^T \quad , \quad \mathbf{Q} = \{\hat{\psi}_1, \hat{\psi}_2, \cdots, \hat{\psi}_N\}^T \tag{20}$$

If a single pendulor system has a "harbor" (Ambli et al,1982), consisting of two parallel projecting sidewalls as shown in Fig. 3, corresponding potentials are obtained by a method of combination of regions (e.g. Brebbia, 1980). Consider two separate solution regions, the open sea (region 1) and inside the harbor (region 2). For the first region, the Eq. 16 can be partitioned as follow,

$$[\,\hat{\mathbf{H}}_0^1 \;\; \hat{\mathbf{H}}_I^1\,] \begin{Bmatrix} \mathbf{U}_0^1 \\ \mathbf{U}_I^1 \end{Bmatrix} = [\,\mathbf{H}_0^1 \;\; \mathbf{H}_I^1\,] \begin{Bmatrix} \mathbf{Q}_0^1 \\ \mathbf{Q}_I^1 \end{Bmatrix} \tag{21}$$

where superscript 1 indicates that it belongs to region 1,subscript I and $_0$ indicate the mouth of harbor and other boundary of the region 1, respectively. For the second region we have

$$[\,\mathbf{H}_0^2 \;\; \mathbf{H}_I^2 \;\; \mathbf{H}_P^2\,] \begin{Bmatrix} \mathbf{U}_0^2 \\ \mathbf{U}_I^2 \\ \mathbf{U}_P^2 \end{Bmatrix} = [\,\mathbf{H}_0^2 \;\; \mathbf{H}_I^2 \;\; \mathbf{H}_P^2\,] \begin{Bmatrix} \mathbf{Q}_0^2 \\ \mathbf{Q}_I^2 \\ \mathbf{Q}_P^2 \end{Bmatrix} \tag{22}$$

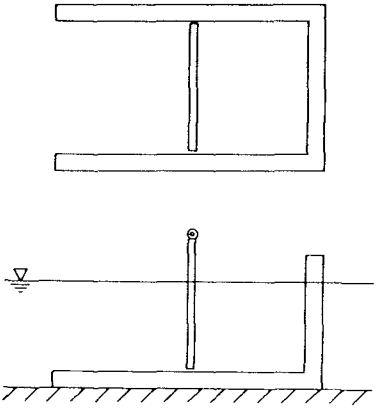

Fig. 3 Geometry of a system added "harbor"

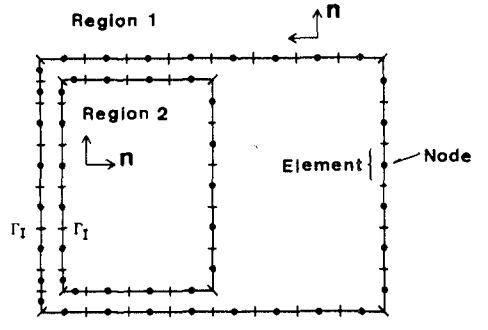

Fig. 4 Body divided into two regions

where subscript P indicate the pendulum part of region 2. According to the definition of the direction of the unit normal vector shown in Fig. 4, the conditions of the mouth of harbor are given by

$$\left.\begin{aligned} U_I^1 &= U_I^2 \\ Q_I^1 &= -Q_I^2 \end{aligned}\right\} \qquad \text{(radiation problem)} \tag{23}$$

$$\left.\begin{aligned} U_I^1 + \underline{U}_I &= U_I^2 \\ Q_I^1 + \underline{Q}_I &= -Q_I^2 \end{aligned}\right\} \qquad \text{(diffraction problem)} \tag{24}$$

where

$$\underline{U} = \{\phi_{0,1}, \phi_{0,2}, \cdots, \phi_{0,N}\} \qquad \underline{Q} = \{\hat{\phi}_{0,1}, \hat{\phi}_{0,2}, \cdots, \hat{\phi}_{0,N}\} \tag{25}$$

Using Eq. 11, 12 and these conditions, Eq. 21 and Eq. 22 can be rewritten as follows.

$$\begin{bmatrix} \hat{H}_0^1 & \hat{H}_I^1 - H_I^1 & 0 & 0 \\ 0 & \hat{H}_I^2 & H_I^2 & \hat{H}_0^2 & \hat{H}_P^2 \end{bmatrix} \begin{Bmatrix} U_0^1 \\ U_I^1 \\ Q_I^1 \\ U_0^2 \\ U_I^2 \end{Bmatrix} = \begin{bmatrix} 0 \\ H_P^2 \end{bmatrix} \{Q_P^2\} \tag{26}$$

(radiation problem)

$$= -\begin{bmatrix} 0 & 0 \\ \hat{H}_I^2 & H_I^2 \end{bmatrix} \begin{Bmatrix} \underline{U}_I \\ \underline{Q}_I \end{Bmatrix} - \begin{bmatrix} H_0^1 \\ 0 \end{bmatrix} \{\underline{Q}_0\} \tag{27}$$

(diffraction problem)

4. FIELD TEST

4.1 Experimental Set-Up

The test plant caisson employed in the field experiment had been constructed seaward of the south breakwater of Port Muroran, as shown in Fig. 5 and Fig. 6. Since the port faces to a bay on the Pacific south west coast of Hokkaido Island, the waves of which significant wave height is greater than 1.0 meter is approximately 12 % and appear mostly in winter.

Fig. 7 shows the dimensions of the caisson. The caisson is partitioned into two chambers by sidewall, and the pendulum had been installed at 2.5 meter inside from the front face of the right hand chamber. The pendulum is of 2.5 ton in weight. Distance between the center of the rolling axis and lower edge of the pendulum is 7.2 meter. The plate to receive wave force at the lower part of it is 2 meter wide and 3.5 meter high.

The wave-induced motion of pendulum is converted into hydraulic

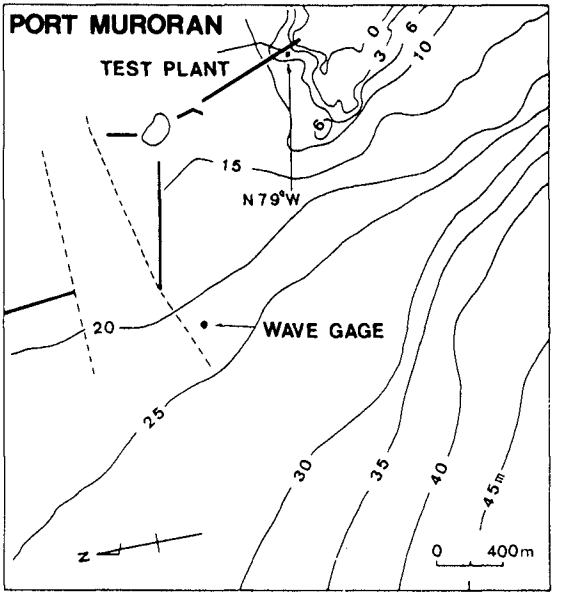

Fig. 5 Location map

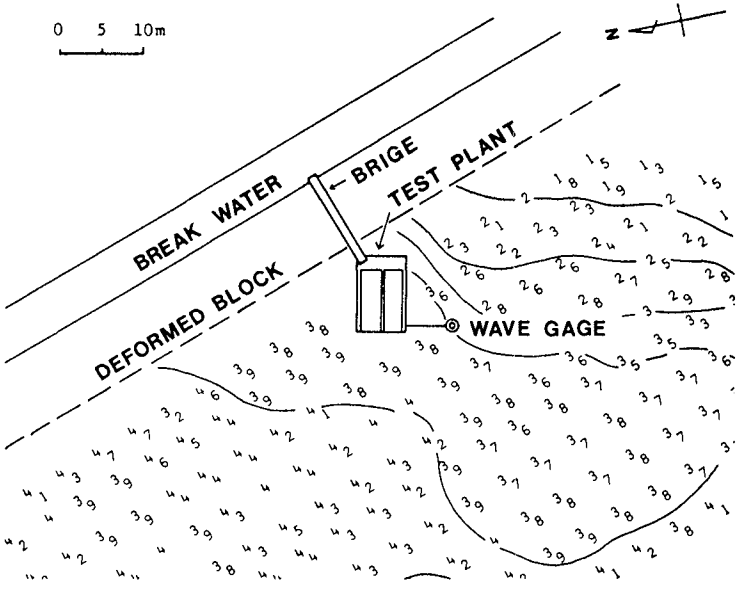

Fig. 6 Bathymetry around test plant

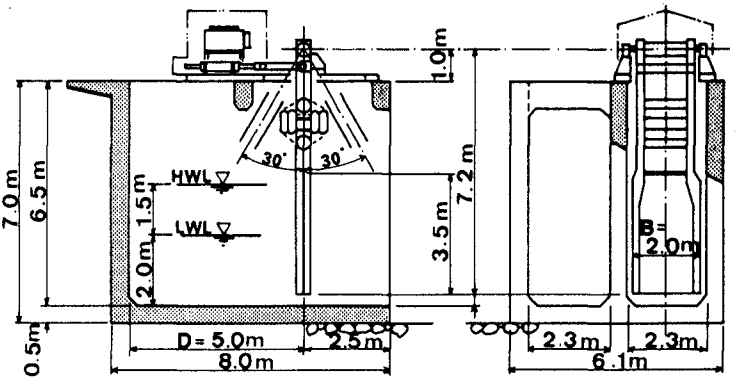

Fig. 7 Dimensions of test plant

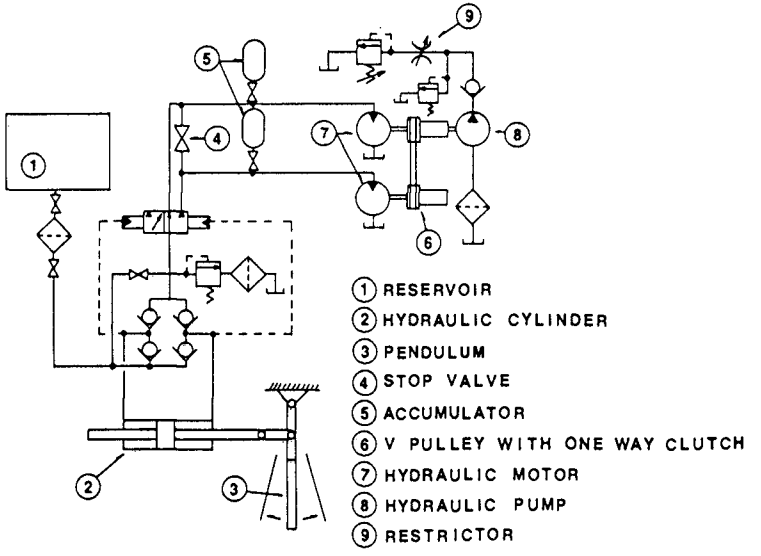

Fig. 8 Hydraulic circuit of test plant

power by the hydro-static power transmission circuit shown in Fig. 8. An electric generator was not equipped in the circuit. The energy absorption is achieved by combination of the hydraulic pump 8 and the restrictor 9, and the energy is finally absorbed by heating oil. In this circuit, the reaction moment of the energy absorption mechanism is non-linear due to the effects of the accumulators 5. Details of the power extracting facilities had been shown by Watabe, et al, in 1986.

The measured quantities in the field tests are the incoming wave profile, displacement of the piston rod, the cylinder pressures P1, P2, total torque of the motors, and the speed of motors. The wave data were measured 5 meter apart from the caisson with the ultrasonic wave gage above sea surface. In addition, the dominant wave direction is measured visually with a compass. In some experiments, the wave data were collected at the location of 1.8 km offshore form the test plant. The data signals were recorded on a magnetic-tape recorder. The measured records were digitized with the sampling rate 2 Hz for a period 1200 seconds giving 2400 data points per measured channel.

4.2 Test Results

(1) Pendulum Motion with/without Damper

Fig. 9 shows the comparison of theoretical and experimental spectra of pendulum motion under the condition of no-load. The former were calculated from the transfer function using measured wave spectrum and a cosine-power spreading function. The influence of the sidewalls protruding in front of the pendulum is considered in the calculation. In the figure, $S_{\theta\theta}$ denotes the power spectrum of the angular displacement of the pendulum and the broken line shows the numerical result for the present pendulor system.

Fig. 10 gives the example of the spectra of wave and pendulum motion with power absorption. In this case, it is necessary a suitable linear approximation of reaction moment of damper to calculate the motion from the mathematical model.

Let's assume that the load system of damper can be defined as follows,

$$M = (i\omega N + K)\bar{\theta}\, e^{i\omega t} \tag{28}$$

where N and K are an equivalent linearized load damping coefficient and restoring moment coefficient, respectively. So, they are given by

$$\begin{aligned} N &= \frac{1}{\omega}\, \mathrm{Im}[S_{\theta M}/S_{\theta\theta}] \\ K &= \mathrm{Re}[S_{\theta M}/S_{\theta\theta}] \end{aligned} \tag{29}$$

where $S_{\theta M}$ is the cross-spectrum of angular displacement of pendulum and the reaction moment from the cylinder. Of course, the coefficients N and K are functions of frequency. For simplicity, we used the values of N and K at peak frequency of the spectrum of reacting moment for calculation at arbitrary frequency.

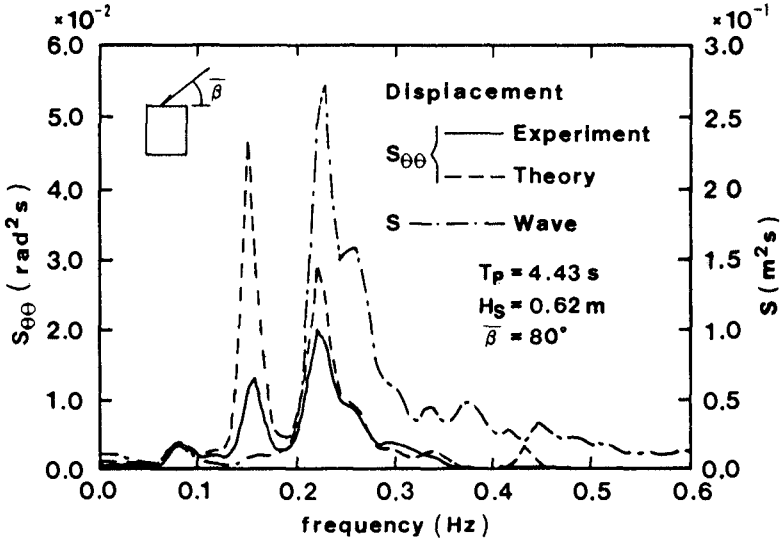

Fig. 9 Spectra of wave and pendulum motion (no-load condition)

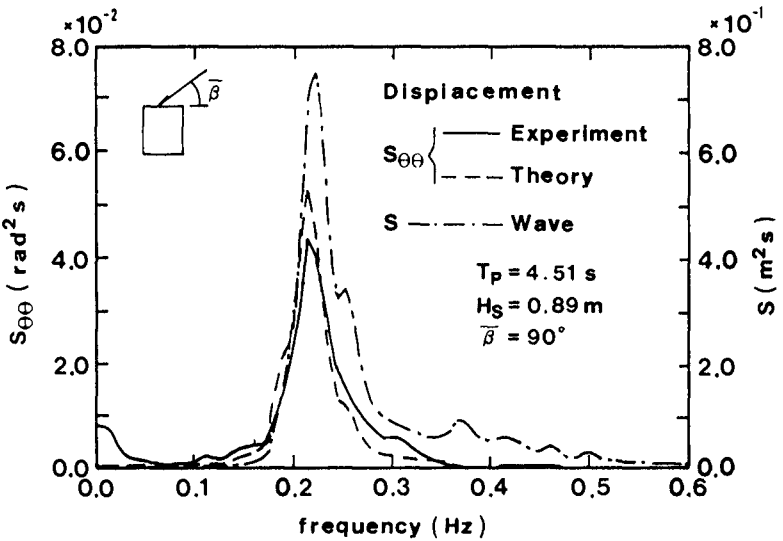

Fig. 10 Spectra of wave and pendulum motion (with power absorption)

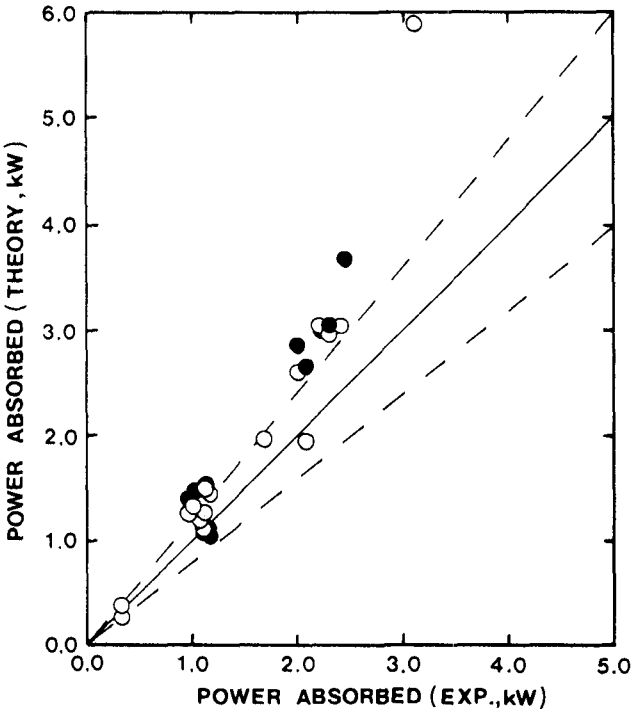

Fig. 11 Comparison of theory with experiment of absorbed power

(2) Absorption Characteristics

Using the estimated spectrum of pendulum motion and the linearized load damping coefficient, we can obtain absorbed power theoretically.

Fig. 11 represents the result of comparison of the theoretical power absorbed with experimental ones at the cylinder. The latter is obtained numerically as follows,

$$\overline{P}_a = \frac{1}{T_m} \int_0^{T_m} A_S (P1-P2) V \, dt \tag{30}$$

where T_m denotes the recording time of data signals, P1,P2 are cylinder pressures, A_S the cross sectional area of piston and V is the velocity of piston.

In the figure, the symbol of solid circle indicates the value estimated from the deep water spectrum. The broken lines represent the range within 20 percent error.

The dominant wave direction of deep water is estimated from wind

direction collected at a small island located nearby the wave gage. The refraction coefficients and wave angles at the plant associated with the deep water waves were determined from wave refraction diagrams.

As concerns the one extreme overestimation plot in the figure, the experimental data was obtained on condition that significant wave height is 1.16 meter and peak frequency of the wave spectrum is near the resonance frequency predicted in the theory.

5. CONCLUDING REMARKS

We have shown a numerical approach to estimate quantitatively the power absorbed by pendulor system of coastal type and confirmed its applicability by the field tests. As expected, one of the main cause of the overestimation above mentioned probably lies that the theory ignores the viscous loss with water motion near the pendulum and that at the mouth of the protruding sidewalls. Another probable cause is due to the partial reflection from the inside surface of the protruding sidewalls, especially the surface of pendulum.

The data obtained from field tests are not enough to allow a more detailed discussion. It is necessary subsequently to asses behavior of the system including the sources of the reduction of absorption in a full range of wave conditions. Stability of the caisson as well as durability of moving components of the system against wave force has been studied and will be disclosed in the near future.

CHAPTER 177

Wave Diffractions by Rows of Vertical Cylinders of Arbitrary Cross Section

Akinori Yoshida*, Norio Iida**, and Keisuke Murakami***

1. Introduction

Wave diffractions by a number of (a group of or a row of) vertical cylinders have been investigated in connection with, e.g., multilegged offshore structures (Spring and Monkmeyer(1974), Ohkusu(1974), Chakrabarti(1978), Mciver and Evans(1984), etc.); Wave-Power absorption devices (Miles (1983), Falnes(1984), Kyllingstad(1984), etc.); Wave barrier systems (Massel(1976), Kakuno and Oda(1986), etc.). Most of the previous works were, however, mainly aimed at the wave diffractions by cylinders of circular cross section and/or by cylinders of relatively small dimensions compared to wave length.

In this paper, we describe a simple yet versatile analytical method to solve wave diffractions by infinite rows of vertical cylinders. In the method, it is assumed, in addition to usual linearised small amplitude assumptions, that: the row of cylinders is composed of infinite number of surface-piercing evenly spaced equal cylinders fixed on sea bottom; incident wave direction is perpendicular to the row; the number of rows may be arbitrary, at least in principle; the cross sectional shape of the cylinders may be arbitrary as long as it is symmetrical with respect to the incident wave ray; and the cylinders are relatively large compared to incident wave length so that inertial forces are predominant to drag forces.

2. Formulation

We consider the diffractions of a regular plane wave by a row or rows of surface-piercing vertical cylinders fixed in water of uniform depth h. It is assumed that the row is composed of infinite number of equal cylinders evenly spaced (2b distance between adjacent cylinders) and that a plane

* Associate prof., Dept. of Civil Engineering Hydraulics, Kyushu University, 812 Fukuoka, Japan
** Engineer, Japan Port Consultant Ltd., Japan
*** Graduate Student, Kyushu University, 812 Fukuoka, Japan

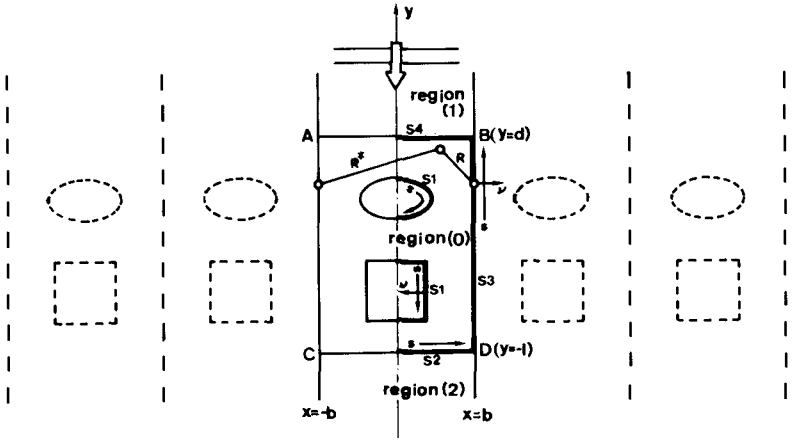

Figure 1. Definition sketch

wave of small amplitude ζ_0, radian frequency σ, wave number k, is incident on the row at right angle. Thus, the wave motion is periodic along the row of cylinders. This situation is equivalent to wave diffraction for a cylinder placed midway in a wave tank of the same width as the spacing interval 2b (e.g., See Sorokosz (1980), Taylor and Hung(1986)).

In the following formulation, we solve the equivalent problem by using an integral-equation and Fourier expansion techniques similar to that adopted by Sorokosz(1980): here in the present method, however, complicated mathematical form of Green function is not needed.

Cartesian co-ordinates are taken with the x and y axes in the horizontal plane of the water surface and the z axis directed vertically upwards. The row is arranged along x axis. A sketch of the horizontal section is given in figure 1.

The fluid is assumed to be inviscid and incompressible and the fluid motion irrotational so that it can be described by a velocity potential which may be expressed in the form

$$\Phi(x, y, z, t) = (g\zeta_0/\sigma)\phi(x, y)Z(z)\exp(i\sigma t) \quad \cdots\cdots\cdots\cdots(1)$$

in which g is acceleration of gravity; $\phi(x,y)$ is dimensionless function which represents horizontal distribution of the velocity potential; $Z(z)=\cosh(k(z+h))/\cosh(kh)$; i = imaginary quantity ($\sqrt{-1}$).

Since the velocity potential satisfies Laplace equation, $\phi(x,y)$ satisfies the following Helmholtz equation,

$$\nabla^2\phi(x, y)+k^2\phi(x, y)=0 \qquad \cdots\cdots\cdots\cdots(2)$$

Now, introducing imaginary boundaries AB (indicated by S4 at y=d) and CD (indicated by S2 at y=-1) as shown in figure 1, we divide the fluid region into three regions, upstream region (1), downstream region (2) and truncated inner region (0).

The inner region (0) is a closed fluid region enclosed with the imaginary boundaries S2 and S4, the cylinder (indicated by S1) and the walls of the wave tank (indicated by S3). Thus, applying Green's theorem to the dimensionless function $\phi_0(x,y)$ in the inner region (0) which satisfies Helmholtz equation (2), it can be expressed by the following Green's Identity Formula:

$$\phi_0(X)=-\frac{i}{\alpha}\int_{S1+S2+S3+S4}\left\{\phi_0(X_b)\frac{\partial}{\partial\nu}G(kR)-G(kR)\frac{\partial}{\partial\nu}\phi_0(X_b)\right\}ds \qquad \cdots(3)$$

where $G(kR)=H_0^{(1)}(kR)+H_0^{(1)}(kR^*)$;

$H_0^{(1)}$ is the Hankel function of the first kind and of order 0; X denotes the co-ordinates (x,y) of any point in the inner region (0) and X_b on the boundary; $R=|X-X_b|$ and $R^*=|X-X_b^*|$ (X_b^* denotes the reflected image point of X_b with respect to the center line of the wave tank.); ν is the outward normal to the boundary; $\alpha=2$ when X is on the boundary and othewise $\alpha=4$.

The integration is taken counterclockwise and along a half of the boundary (indicated by thick lines in figure 1) because the fluid motion is symmetric with respect to the center line of the wave tank.

By representing the dimensionress function of the reflected wave potential and the transmitted wave potential with φ_1 and φ_2, respectively, the function ϕ_1 in the upstream region and ϕ_2 in the downstream region may be written as

$$\phi_1(x,y)=\exp(iky)+\varphi_1(x,y) \qquad \cdots\cdots\cdots\cdots\cdots(4)$$

$$\phi_2(x,y)=\varphi_2(x,y) \qquad \cdots\cdots\cdots\cdots\cdots(5)$$

The function φ_1 and φ_2 also satisfy Helmholtz equation

$$\nabla^2\varphi(x, y)+k^2\varphi(x, y)=0 \qquad \cdots\cdots\cdots\cdots\cdots(6)$$

Applying the method of the separation of variables ($\varphi(x,y)=x(x)Y(y)$) to (6), we obtain the following ordinary differential equations,

$$\left.\begin{aligned} &d^2X/dx^2+k_x^2X=0 \\ &d^2Y/dy^2+k_y^2Y=0 \\ &k_x^2+k_y^2=k^2 \end{aligned}\right\} \qquad \cdots\cdots\cdots\cdots\cdots\cdots(7)$$

Solving (7) under now-flow condition on the wave tank wall and under condition that $\varphi_1(x,y)$ represents waves propagating toward the upstream direction and $\varphi_2(x,y)$ waves propagating toward the downstream direction, we obtain

$$\varphi_1(x,y)=\sum_{n=0}^{\infty} C_n\beta_n(y)\cos(n\pi x/b) \qquad \cdots\cdots\cdots\cdots\cdots\cdots(8)$$

$$\varphi_2(x,y)=\sum_{n=0}^{\infty} D_n\bar{\beta}_n(y)\cos(n\pi x/b) \qquad \cdots\cdots\cdots\cdots\cdots\cdots(9)$$

where

$$\left.\begin{aligned} &\beta_n(y)=\exp\{-iy\sqrt{k^2-(n\pi/b)^2}\} \\ &\bar{\beta}_n(y)=\exp\{iy\sqrt{k^2-(n\pi/b)^2}\} \end{aligned}\right\} \qquad \cdots\cdots\cdots\cdots\cdots\cdots(10)$$

For n which satisfies kb>n (n=0,1,...), $\beta_n(y)$ and $\bar{\beta}_n(y)$ represent progressive wave modes, and otherwise (except for n when kb=n) exponentially decreasing stationary wave modes. For the case of kb=n, (8) and (9) give no-propagating wave mode and imply a standing wave exists across the wave tank.

Equations (8) and (9) show the Fourier series expansion of the dimensionless functions φ_1 and φ_2 across the wave tank, thus for example on the imaginary boundary S4 (at y=d), the coefficients $C_n\beta_n(d)$ can be written as

$$C_n\beta_n(d)=\frac{2e}{b}\int_0^b \varphi_1(x,d)\cos\frac{n\pi x}{b}\,dx \qquad \cdots\cdots\cdots\cdots\cdots\cdots(11)$$

where e=1/2 (n=0) and e=1 (n≠0).
Consequently, we obtain the expression of the dimensionless function $\phi_1(x,y)$ in the upstream region (1) as

$$\phi_1(x,y)=\exp(iky)+\sum_{n=0}^{\infty}\frac{\beta_n(y)}{\beta_n(d)}\left\{\frac{2e}{b}\int_0^b \varphi_1(s,d)\cdot\cos\frac{n\pi s}{b}\,ds\right\}\cos\frac{n\pi x}{b} \qquad \cdots(12)$$

In the same way, in the downstream region (2), we obtain

$$\phi_2(x,y)=\sum_{n=0}^{\infty}\frac{\bar{\beta}_n(y)}{\bar{\beta}_n(-l)}\left\{\frac{2e}{b}\int_0^b \varphi_2(s,-l)\cdot\cos\frac{n\pi s}{b}\,ds\right\}\cos\frac{n\pi x}{b} \qquad \cdots(13)$$

The boundary conditions for the inner region (0) can be written

$$\partial\phi_0/\partial\nu=0 \qquad (S1 \qquad S3) \qquad \text{.....(14)}$$

$$\left.\begin{aligned}&\phi_0=\phi_2\\&\partial\phi_0/\partial\nu=\partial\phi_2/\partial\nu\end{aligned}\right\} \quad (S2:\ y=-l) \qquad \text{.....(15)}$$

$$\left.\begin{aligned}&\phi_0=\phi_1\\&\partial\phi_0/\partial\nu=\partial\phi_1/\partial\nu\end{aligned}\right\} \quad (S4:\ y=d) \qquad \text{.....(16)}$$

By applying (4),(5),(12) and (13) to (15) and (16), equations (15) and (16) are rewritten as

$$\left.\begin{aligned}&\phi_0(x,-l)=\varphi_2(x,-l)\\&\left.\frac{\partial\phi_0}{\partial\nu}\right|_{y=-l}=\sum_{n=0}^{\infty}\frac{2e}{b}\alpha_n\left\{\int_0^b\varphi_2(s,-l)\cdot\cos\frac{n\pi s}{b}ds\right\}\cdot\cos\frac{n\pi x}{b}\\&\phi_0(x,d)=\exp(ikd)+\varphi_1(x,d)\\&\left.\frac{\partial\phi_0}{\partial\nu}\right|_{y=d}=ik\exp(ikd)+\sum_{n=0}^{\infty}\frac{2e}{b}\alpha_n\left\{\int_0^b\varphi_1(s,d)\cdot\cos\frac{n\pi s}{b}ds\right\}\cos\frac{n\pi x}{b}\end{aligned}\right\} \qquad \text{...(17)}$$

where $\alpha_n=\sqrt{k^2-(n\pi/b)^2}$

In order to solve the integral equation (3) under these boundary conditions, we divide the boundary, S1, S2, S3 and S4, into a number of small elements ΔS_j (j=1-N1, 1-N2, 1-N3, 1-N4 on S1, S2, S3 and S4, respectively). Now, assuming that ϕ_0 and its normal derivative $\partial\phi_0/\partial\nu$ are uniform on each element, and denoting them by $\phi_0(j)$ and $\bar{\phi}_0(j)$, we can approximate (3) by the following discretaised equation,

$$\phi_0(X)=\left\{\sum_{j=1}^{N1}+\sum_{j=1}^{N2}+\sum_{j=1}^{N3}+\sum_{j=1}^{N4}\right\}\left(\bar{G}_{Xj}\phi_0(j)-G_{Xj}(j)\,\bar{\phi}_0(j)\right) \qquad \text{.....(18)}$$

where

$$\left.\begin{aligned}G_{Xj}&=-\frac{i}{\alpha}\int_{\Delta S_j}\{H_0^{(1)}(kR)+H_0^{(1)}(kR^*)\}\,ds\\\bar{G}_{Xj}&=-\frac{i}{\alpha}\int_{\Delta S_j}\frac{\partial}{\partial\nu}\{H_0^{(1)}(kR)+H_0^{(1)}(kR^*)\}\,ds\end{aligned}\right\} \qquad \text{.....(19)}$$

When the point X is on the center of any element ΔS_i, equation (18) gives a finite set of linear relations between $\phi_0(j)$ and $\bar{\phi}_0(j)$ as

$$\phi_0(i)=\left\{\sum_{j=1}^{N1}+\sum_{j=1}^{N2}+\sum_{j=1}^{N3}+\sum_{j=1}^{N4}\right\}\left(\bar{G}_{ij}\phi_0(j)-G_{ij}\bar{\phi}_0(j)\right) \quad \cdots\cdots\cdots\cdots(20)$$

$$(i=1\sim N1,\ 1\sim N2,\ 1\sim N3,\ 1\sim N4)$$

Applying the boundary conditions (14) and (17) to (20), we obtain

$$\sum_{j=1}^{N1}(\bar{G}_{ij}-\delta_{ij})\phi_0(j)+\sum_{j=1}^{N2}\left\{(\bar{G}_{ij}-\delta_{ij})-\sum_{p=1}^{N2}G_{ip}Q_{jp}\right\}\varphi_2(j)$$

$$+\sum_{j=1}^{N3}(\bar{G}_{ij}-\delta_{ij})\phi_0(j)+\sum_{j=1}^{N4}\left\{(\bar{G}_{ij}-\delta_{ij})-\sum_{p=1}^{N4}G_{ip}Q_{jp}\right\}\varphi_1(j)$$

$$=-\exp(ikd)\sum_{j=1}^{N4}\{(\bar{G}_{ij}-\delta_{ij})+ikG_{ij}\} \quad \cdots\cdots(21)$$

where $\delta_{ij}=1$ (i=j) and $\delta_{ij}=0$ (i≠j);

$$Q_{jp}=\sum_{n=0}^{\infty}\frac{2e}{b}\alpha_n\Delta S_p\cos\frac{n\pi x_j}{b}\cos\frac{n\pi x_p}{b} \quad \cdots\cdots\cdots\cdots(22)$$

Since equation (21) holds for every i-th element, it provides (N1+N2+N3+N4) linear equations with respect to the same number of unknown quantities, ϕ_0(j) on S1, φ_2(j) on S2, ϕ_0(j) on S3 and φ_1(j) on S4. Thus, solving these linear equations and using the boundary condition (17), we can obtain ϕ_0(j) and $\bar{\phi}_0$(j) for all of the boundary element. The function (X) at any point in the inner region (0) can be evaluated by (18), and ϕ_1(X) and ϕ_2(X) by discretaised form of (12) and (13), respectively.

The ratio of the wave amplitude ζ(X) at any point X to the incident wave amplitude ζ_0 is given by

$$|\zeta(X)/\zeta_0|=|\phi(X)| \quad \cdots\cdots\cdots\cdots(23)$$

The pressure p at the cylinder surface are evaluated from the relation $p=-\rho(\partial\Phi/\partial t)$. Thus, the wave force F acting on the cylinder can be obtained from the integration of p around the cylinder surface

$$F/2\rho g\zeta_0 h^2[\tanh kh/kh]=\left|\sum_{j=1}^{N}\phi_0(j)\Delta x_j/h\right| \quad \cdots\cdots\cdots\cdots(24)$$

where ρ is the density of water; Δxj is the x-compornent of ΔS_j on the cylinder; N is the number of the elements on the cylinder.

The reflection and transmission coefficients can be evaluated from energy flux of the reflected wave and the transmitted wave across the imaginary boundaries. The energy

flux of the reflected wave E_r may be written as

$$E_r=\frac{1}{bT}\int_0^b\int_0^T\int_{-h}^0\left\{\rho Re\left[\frac{\partial\Phi_r}{\partial t}\right]Re\left[\frac{\partial\Phi_r}{\partial y}\right]\right\}dz\,dt\,dx \qquad \text{.....(25)}$$

where Φ_r denotes the velocity potential of the reflected wave and it is given from (1), (4) and (8) by

$$\Phi_r=\frac{g\zeta_0}{\sigma}\left\{\sum_{n=0}^{\infty}C_n\beta_n(y)\cos\frac{n\pi x}{b}\right\}Z(z)\exp(i\sigma t) \qquad \text{.....(26)}$$

Substituting (26) into (25), we have

$$\frac{E_r}{E_i}=\sum_{n=0}^{n^*}\frac{\bar{\varepsilon}\alpha_n}{k}|C_n|^2 \qquad \text{.....(27)}$$

where E_r indicates the energy flux of the incident wave given by $(\rho g\zeta_0^2/8)(1+2kh/\sinh 2kh)(\sigma/k)$; $\bar{\varepsilon}=1$ (n=0) and $\bar{\varepsilon}=1/2$ (n≠0); n is the largest integer value among n's satisfying kb>n. Thus the reflection coefficient K_r is given by

$$K_r=\sqrt{\sum_{n=0}^{n^*}\frac{\bar{\varepsilon}\alpha_n}{k}|C_n|^2} \qquad \text{.....(28)}$$

In the same way, from the energy flux of the transmitted wave across the imaginary boundary CD, the transmission coefficient K_t is given by

$$K_t=\sqrt{\frac{E_t}{E_i}}=\sqrt{\sum_{n=0}^{n^*}\frac{\bar{\varepsilon}\alpha_n}{k}|D_n|^2} \qquad \text{.....(29)}$$

and the following relations should be satisfied

$$\sum_{n=0}^{n^*}\frac{\bar{\varepsilon}\alpha_n}{k}\{|C_n|^2+|D_n|^2\}=1 \qquad \text{.....(30)}$$

3. Numerical Calculations and Experimental Verifications

For the numerical analysis, the infinite series of (17) and (22) are replaced by a finite sum upto N*. The integrations in (17) are evaluated with the following discrete form

$$\int_0^b\varphi(s,d)\cos\frac{n\pi s}{b}ds\approx\sum_{p=1}^{N4}\varphi(p)\cos\frac{n\pi\xi_p}{b}\Delta S_p \qquad \text{.....(31)}$$

and this shows discrete Fourie Transform of φ, thus, it is clear, from the theorem of Finite Fourier Series approximation, that N* should be the same number as that of thek^*

divided elements on the imaginary boundary.

Because the set of the imaginary boundaries is only for the creation of the enclosed fluid region to which Green's theorem is applied, the location of the imaginary boundaries has no physical grounds. Thus, the distance of the imaginary boundaries from the cylinder may be arbitrary and no significant difference occurs in numerical results. In the following numerical calculations, the locations of the imaginary boundaries were taken 3h away from the side of the cylinder and the size of the boundary elements were taken about $\Delta s_j/h=0.2$,

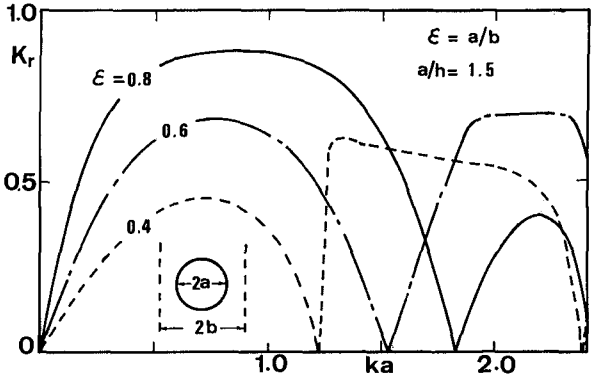

Figure 2. Reflection coefficient for a row of circular cylinders

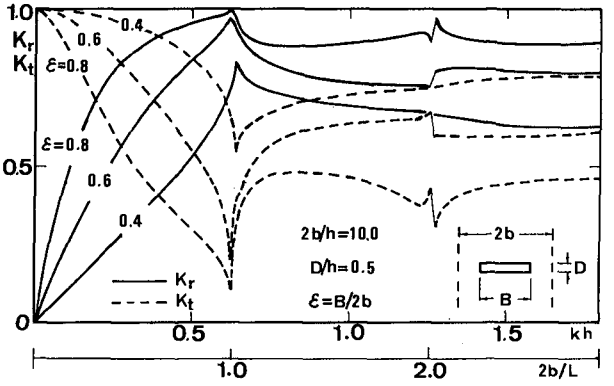

Figure 3. Reflection and transmission coefficients for a row of rectangular cylinders

Figure 2 shows the reflection coefficient for a single row of circular cylinders. The diameter of the cylinder 2a is fixed to 2a/h=3.0 and three different spacing between the cylinders are made to give ε(=2a/2b) of 0.4, 0.6 and 0.8. The reflection characteristics are very much dependent on the incident wave number. Near singular wave number (kb=n) K_r decreases to zero, namely, waves transmits through the cylinder barrier with almost no wave reflection. It is noted that the smaller spacing between the cylinders does not necessarily mean the larger wave reflection.

Figure 3 shows the reflection and transmission coefficients for a single row of rectangular cylinders. The spacing 2b is fixed to 2b/h=10.0, and the width B of the cylinder is changed to give ε(=B/2b) of 0.4, 0.6 and 0.8. The reflection characteristics much differ from those of the circular cylinders, and this shows that the cross-sectional shape of the cylinder is one of main factor for wave reflection-transmission characteristics. At the singular wave numbers where 2b/L=1.0, 2.0,...(L is the incident wave length), it is possible for a standing wave to exist across the wave tank (that is, along the row of the cylinders).

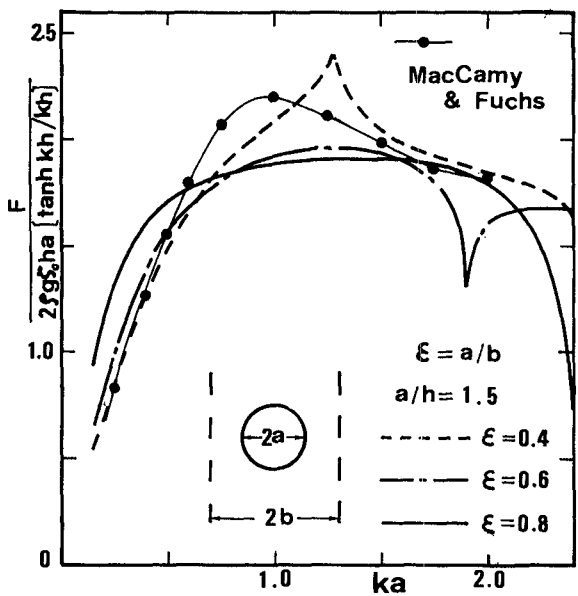

Figure 4. Wave forces for a row of circular cylinders

Wave forces corresponding to figures 2 and 3 are given in figures 4 and 5, respectively. Naturally the forces acting on the cylinders are in line with the direction of the incident wave. Thin solid curve with closed circle in figure 4 represents wave forces acting on a single cylinder in an open-sea given by MacCamy and Fuchs.

Figure 6 shows numerically calculated free surface amplitude around a square cylinder placed on the center line of the wave tank (the case of a row of square cylinders). It is noted that satnding waves appear in the x direction as well as in the upstream direction.

To verify the present method, we conducted wave tank experiments for a row of circular cylinders, a row of rectangular cylinders and two rows of circular cylinders. The wave tank (4m wide × 20m long × 0.6m deep) in the laboratory of Civil Engineering Hydraulics, Kyushu University was used. The diameter of the model cylinders

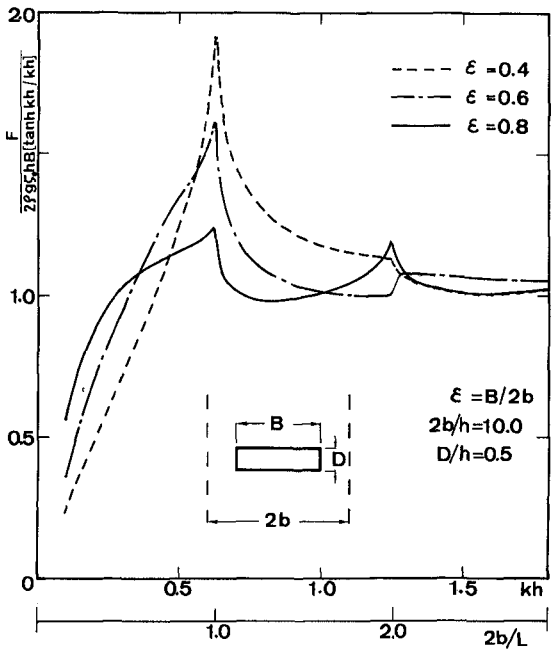

Figure 5. Wave forces for a row of rectangular cylinders

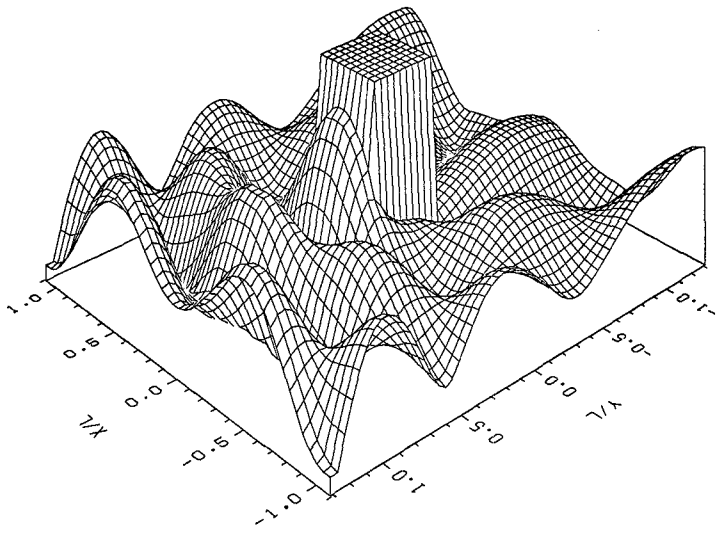

Figure 6. Perspective view of free surface amplitude for a row of square cylinders (kh=1.4, b/h=5.0, B/h=2.0; B is the side length of the square)

were 1.2m, and the size of the rectangular model was 2m by 0.2m. The water depth was kept 0.4m throughout the experiments.

Setting the model cylinders midway of the wave tank, we measured water surface elevation around the cylinders at 20cm by 20cm grid points with 6 capacity type wave gages. The total number of measured grid points were about 200.

The comparisons for perspective view of free surface amplitude between the theory and the experiments are shown in figures 7, 8 and 9. Although the free surface amplitudes drawn from experimental data show rather rough surface compared to the theoretically obtained ones, especially when the free surface is seriously disturbed (for example, figure 9.) because of measured grid points are coarse, overall agreements between the theory and experiments for free surface amplitude are very good.

More precise comparison is given in figure 10 with respect to a contour map of water surface elevation. The number in the contour lines indicates the ratio of free surface amplitude to the incident wave amplitude. Again, very good agreement between the theory and experiment is confirmed.

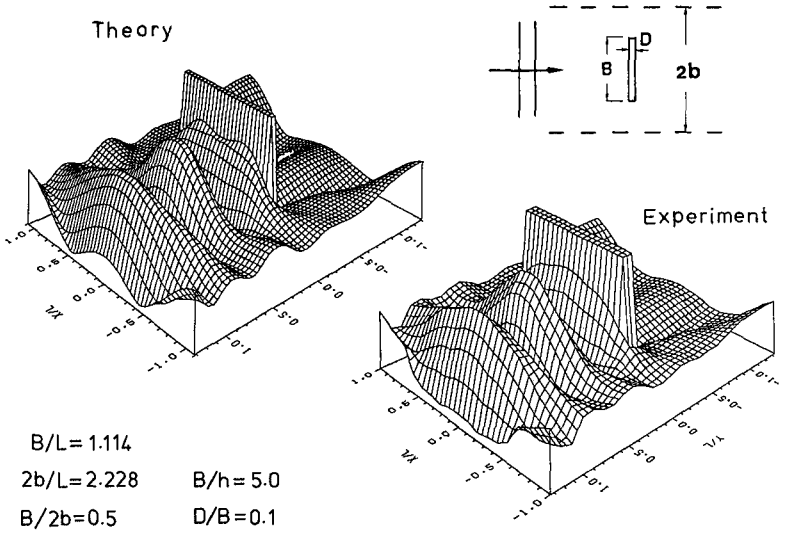

Figure 8. Comparison between theory and experiment for a row of rectangular cylinders

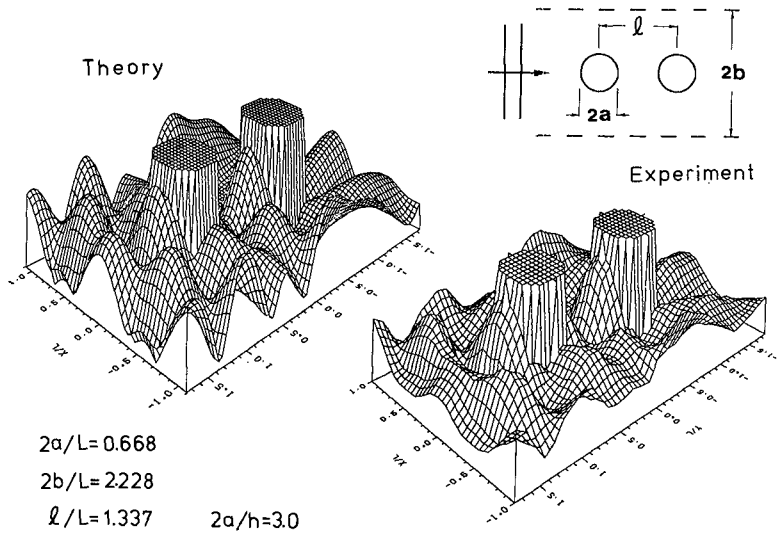

Figure 9. Comparison between theory and experiment for two rows of circular cylinders

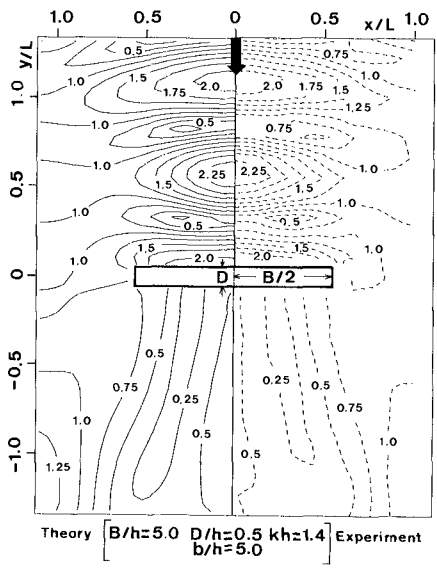

Figure 10. Contour map of free surface amplitude corresponding to figure 8.

4. Conclusions

A simple analytical method using an integral-equation technique has been described for solving wave diffractions by rows of surface-piercing vertical cylinders evenly spaced on sea bottom. The feature of the present method is its easiness to treat diffraction problems of rows of cylinders of arbitrary cross-section and plural row of cylinders: changing the co-ordinates of the boundary elements along the cylinder is the only requirement for variations in the number of the rows and the cross sectional shape of the cylinders.

The method can be easily extended to the case for floating cylinders with flat bottom and for submerged cylinders with flat top, by further applying the Green's Identity Formula for the expression ofthe wave motion in the region between the sea bottom and the bottom of the cylinder and in the region between the free surface and the top of the submerged cylinder. Such cases are related to the problems that frequently occur in Coastal Engineering field, e.g., reflection and transmission problems for rows of floating breakwaters, rows of submerged breakwaters, etc.

The present method is limited to the case that an incident wave direction is perpendicular to the rows of cylinders. More realistic case of oblique incidence needs further study though several studies have been made for a row of circular cylinders by, e.g., Massel (1976) and Miles (1983).

CHAPTER 178

DOLOS ARMOUR DESIGN CONSIDERATIONS

J A ZWAMBORN* and J D P SCHOLTZ**

ABSTRACT

The dolos armour unit has been used all over the world and, although most projects have been successful, there have also been some major failures. When moved around, armour units in general and the rather slender dolosse in particular are prone to structural damage and when dolosse break through the shank, one is left with very unstable pieces of rubble. It is shown in this paper that a safe and economic dolos structure can be obtained if the correct design process is followed. The "optimum" design is based on a reasonable degree of dolos movement which must be established in detailed and representative model tests.

To ensure that the dolosse can withstand these movements, prototype dolos behaviour must be monitored, and such monitoring must be supplemented by representative structural tests, analytical studies and special prototype measurements.

To increase the structural strength of dolosse, the waist to height ratio can be increased and some (simple) form of reinforcing can be included.

1. INTRODUCTION

Much thought has been given to the design of rubble mound breakwaters and considerable effort has gone into obtaining a better understanding of the processes at work and the design techniques after the initial major failures of the Bilboa breakwater in 1976 (35 m depth, 65 t concrete blocks) and the Sines breakwater in 1978/79 (up to 50 m depth, 42 t dolosse; Zwamborn, 1979). In the ten years since these failures progress has been made, particularly in identifying the relevant parameters and in defining the many problems which remain to be solved regarding wave climate, model studies (wave structure interactions), material strength and geotechnical aspects (PIANC, 1985).

Much research will still have to be done on these aspects before a fully reliable design procedure can be developed. In the meantime, however, breakwaters have to be designed with the techniques that are available and particular attention will have to be given to **sensitivity analysis.** This means that the design of the structure should be checked for **realistic variations in the relevant parameters.** The results of this analysis will provide data on the risk of failure or major damage and, at the same time, give an idea of the cost involved in reducing/increasing this task.

* Head, Maritime Structures Division, National Research Institute for Oceanology, Council for Scientific and Industrial Research, South Africa.
** Research Engineer, National Research Institute for Oceanology, Council for Scientific and Industrial Research, South Africa.

These remarks apply to rubble mound breakwaters in general, whether covered with rock armour, simple-shape concrete units (cubes) or complicated-shape units (dolosse) but particularly to the rather slender **dolos armour units.**

It is generally accepted that dolosse have a high hydraulic stability and, in many cases, they offer the most economical solution for breakwaters/shore protection works. Incorrect application of dolosse, however, has resulted in excessive damage due to armour unit breakages.

2. DESIGN APPROACH

There are three different approaches to achieving a safe dolos structure design, namely:

(i) **"No Movement" Design**
In this case the units have to be made to withstand the **in situ** static loads only and the stability can be based on comprehensive and representative hydraulic model tests, using conventional unbreakable model dolosse.

(ii) **"No Breakage" Design**
With this approach the dolosse have to be made "unbreakable" by heavy reinforcing, in one form or other, and stability can be checked by conventional hydraulic model tests aimed at determining acceptable profile changes or unit displacements (the long-term durability of the units/reinforcement must also be considered).

(iii) **"Optimum" Design**
This approach is aimed at a practical and safe design at minimum costs. This is achieved by accepting certain dolos movements, including rocking, and ensuring that the units can withstand these movements without breakage (minimal breakage).

"No Movement Design

Static loading tests on 15 t and 30 t **unreinforced** dolosse have shown that these dolosse can carry 4 to 6 times their own weight under the worst possible loading condition without breakage (Grimaldi and Fontana, 1984).

As no particular problems have been encountered in handling unreinforced dolosse up to 50 t in the casting and placing process (breakages did not exceed 1 to 2 per cent) and because the direct wave forces are of the same order or less than the dead weight forces, a dolos armour consisting of several layers can be designed safely on the basis of hydraulic model test results if these show that there is no significant movement (rocking). In determining the "no movement" criterion, however, **detailed tests** would have to be done, taking into account:

a) realistic and representative design conditions, particularly for waves (wave spectrum/groupiness),
b) possible variation (reliability) of design conditions,
c) storm duration and cumulative effects
d) near-shore effects,
e) variation in test results,
f) the extent of the structure and

g) three-dimensional effects.

Because the "no movement" criterion basically mean that the design must be based on H_{max}, the result could become rather uneconomical.

"No Breakage" Design

The other extreme would be to ensure that the dolosse are **unbreakable** under prototype loading conditions. In this case the design can be based on conventional hydraulic model tests which have to prove that armour displacement will be within acceptable limits, for instance, Figure 1 indicates K_D factors between 25 and 30 for 1 to 2 per cent displacement. **Detailed tests,** as described above, will be necessary to ensure a safe design. The results of these tests could also be used to optimise the design, that is to minimise the total cost (capital investment plus maintenance cost).

This approach is the easiest with regard to model testing but there are two major problems, namely, to determine the **prototype loading conditions** and to make the dolosse **unbreakable** for these conditions without losing the coast advantage of the units' high stability.

Extensive tests have been done with different types of reinforced dolosse (Burcharth, 1981 and Grimaldi and Fontana, 1984). The test results showed limited improvement in impact strength with from 30 kg/m³ up to 120 kg/m³ (0,4 to 1,6 per cent by volume) **steel fibres,** that is, an increase in drop heights from about 20 to 150 per cent at "failure" (major damage and/or breakage). **Conventional steel reinforcement** of 77 to 138 kg/m³ (1 to 1,8 per cent by volume), however, was found to make the dolosse virtually unbreakable. Although first crack formation occurred at drop heights only about 50 percent higher than for unreinforced units, serious damage (major cracking and spalding which exposed the main reinforcing bars) occurred for drop heights 4 to 8 times those of the unreinforced units (0,8 to 1,6 m for 30 t dolosse at Gioia Tauro). Moreover, tests at Gioia Tauro, where a 30 t dolos with a waist ratio of 0,37 and reinforced with conventional steel reinforcement (77 kg/m³ or 1 per cent by volume) was dropped on the breakwater core, showed no serious cracks up to a drop height on 10 m. Although the **in situ** loading is not known, one would intuitively consider this dolos to be strong enough (mechanically) to withstand the **in situ** forces caused by movements/rocking.

Drawbacks of conventionally reinforced dolosse are additional **cost** (50 to 100 per cent more expensive, which could make dolosse unattractive in many applications) and the possibility of **corrosion** causing possible deterioration of the units with time.

"Optimum" Design

It seems obvious that there should be an "optimum" design between the two extremes discussed above whereby a certain amount of **movement/rocking is accepted** while the dolos units are made strong enough to withstand these limited movements without increasing their cost too much.

As early as 1972 it was suggested that the **waist-to-height ratio** (r) of larger dolosse be increased according to:

$$r = 0{,}34\sqrt[6]{\frac{W}{20}}$$

where W is the mass of the dolos in tons, to compensate for the higher stresses occurring in larger dolosse (Zwamborn and Beute, 1972). A simple analysis showed that, when using this formula, dolos stresses would remain about the same with increased dolos mass (Zwamborn, **et al**, 1980). The more rigid structural analysis by Burcharth (1981a) supports this finding (Zwamborn, 1985). The beneficial effect on the structural strength of the dolos was also confirmed by prototype tests on 15 to 30 t units at Gioia Tauro (Grimaldi and Fontana, 1984).

It is obvious that, to get greater unit strength, even larger waist-ratios could be used. However, stability tests with regular waves on dolosse with waist ratios of 0,33, 0,38 and 0,43 showed a gradual reduction in stability for the larger waist ratios, which was to be expected. The reduction in stability from r = 0,33 to 0,38 was relatively small but the test results indicate a significant reduction in K_D for dolosse with r = 0,33 to 0,43 (Scholtz, Zwamborn and Van Niekerk, 1982). As a waist ratio of 0,43 corresponds to an 82 t dolos unit, there is still considerable scope in using the waist ratio in the optimisation of the design (Burcharth, 1981b). Structural performance of dolosse can also be significantly improved by proper mix design and good quality control (Zwamborn, **et al**, 1980).

Single central scrap **rail reinforcement** was used in the original East London dolosse, mainly to lift the units out of the mould. In the redesign of the Gioia Tauro breakwaters (Grimaldi and Fontana, 1984) it was decided (1979) to introduce single-scraprail reinforced 30 t dolosse in the more critical areas on the breakwater heads for extra safety and to reduce maintenance (27,4 kg/m³ steel or 0,35 per cent by volume). Subsequently, the designers (Polytecna Harris of Milan) developed the so-called **double-V rail reinforcement** which consists of a frame with four scraprails in the dolos trunk and one scraprail each in the flukes (53 kg/m³ steel or 0,7 per cent by volume). This solution proved to be both very effective and economical; the critical drop heights were found to come fairly close to those of the conventionally reinforced units while the possibility of corrosion was minimized and the extra cost for the reinforcing was reasonable (extra cost for double-V reinforced dolosse being about 60 per cent in Italy and about 26 per cent in South Africa).

Various relatively cheap methods to improve the strength of dolosse have been discussed above. Unfortunately, it is not possible to define the exact dolos strength required when a certain amount of moving/rocking is allowed to occur under design conditions. Prototype observations have provided reasonable proof that dolos structures designed on the basis of a few per cent (2 to 3) total damage (displacement plus rocking) performed satisfactorily. There is no doubt that strength-improved (e.g. scraprail-reinforced) units will be able to withstand considerably greater movement/rocking but more observations and (full scale) tests are needed to confirm the effectiveness of these improvements, that is, to arrive at the "optimum" design.

3. STABILITY MODEL TESTS

The results of a comprehensive series of dolos stability tests for regular waves are shown in Figure 1. The figure shows damage as a function of

model wave height for different degrees of dolos movements, that is, displacements and rocking. For easier use of the data, a scale for the Hudson stability factors (K_D) has been added.

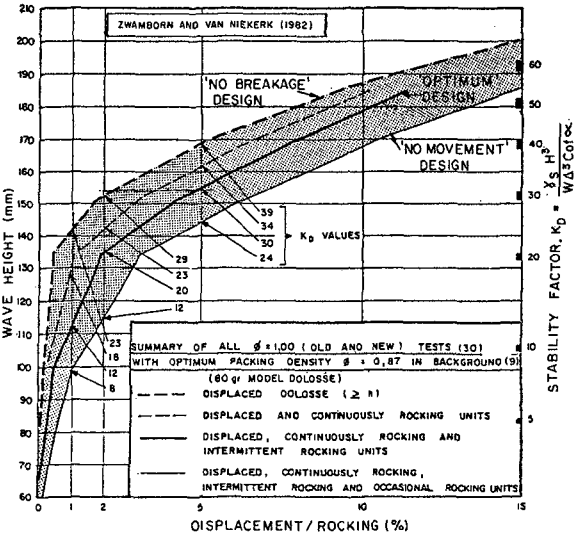

Figure 1: Damage (Displacement/Rocking) versus wave height/stability factor

A similar test programme for irregular waves, under otherwise identical conditions, is underway at present. Results of these tests will become available during 1987.

Although the results shown in Fig. 1 may be used for a first design, detailed and preferably three-dimensional model tests of a specific application using representative wave conditions are a prerequisite for a good design. In these tests, dolos motions/accelerations should be determined as accurately as possible. Dolos motions can be recorded with the now well-known cine and overlay techniques. Alternatively, more advanced measuring techniques can be used to measure accelerations and stresses in individual model armour units but a large number of units would have to be instrumented for each test condition to get statistically reliable results and these results will have to be compared with prototype measurements, as planned in Table Bay and Crescent city (Howell, 1986).

4. PROTOTYPE DOLOS BEHAVIOUR

Details of the behaviour of dolos structures around the world, including ten South African structures, are included in a report entitled "Survey of Dolos Structures" (Zwamborn and Van Niekerk, 1981) which was used extensively for the later survey carried out for PIANC (PIANC, 1985). Further data, for selected South African projects, covering the period 1979 to 1982, are included in Zwamborn (1985) while an update of these projects is given below.

Prototype monitoring in other parts of the world include measurements at Gioia Tauro, Italy (Grimaldi and Fontana, 1984), monitoring of the 2 t dolos breakwater at Cleveland, USA (Markle and Davidson, 1984) and the planned extensive monitoring programme at Crescent City, USA (Howell, 1986).

Richards Bay Breakwater

The Richards Bay main breakwater is protected with 5 t, 20 t and 30 t dolosse placed to slopes of 1 in 1,5 and 1 in 2. This breakwater was completed in Frebruary 1976 and has been monitored at regular intervals since 1978. The monitoring was concentrated on the above-water part of the dolos armour, with the 20 t dolosse on the trunk and the 30 t dolosse on the head of the breakwater. Techniques used were vertical and horizontal photography, visual observations and profiling with a spherical cage, made of reinforcing steel, with a diameter of 2,5 m (0,6 h, were h is the dolos height).
The following survey and storm data have become available since the 1982 review (Zwamborn, 1985):

Breakwater Monitoring		Storm Data						
Date	Type of Survey	Date	H_{s-r} (m)	T_p (s)	Direction (°deep sea)	H_{s-b} (m)	H_{max} (m)	Tide (m+CD*)
24-6-83	Vertical photography	17-2-84	4,3	11,9	140	5,3	10	0,4

24-6-86	Vert. photo.							

*Chart Datum

Only storms with significant wave heights exceeding 4 m have been included in this table. The wave heights (H_{s-r}) and the wave periods (T_p) were recorded by waverider anchored in the 20 m water depth, about 1,5 km seaward of the south breakwater head. Wave directions were recorded by wave clinometer. H_{s-b} values are the wave heights directly in front of the breakwater head, determined from actual measurements made in the original physical model during three-dimensional breakwater stability tests. Because the wave height measurements apply to a 6-hour period, H_{max} = 1,9 H_{s-b} (Longuet-Higgins, 1952). Most of the storms occurred at high tide. The depth at the breakwater head decreased from the original -17 to -12 m CD about 300 m from the breakwater head. This means that at high tide (+1,8 m CD) the maximum breaker height can be about 0,9 x 13,8 = 12,4 m (Jackson, 1968).

Detailed analyses of a section of the breakwater head on which were placed 1 045 30 t dolosse with a waist-to-hight ratio of 0,36 were possible with the use of large-scale vertical photographs. The results of these analyses can be

summed up as follows ("damage" is taken as the sum of the lost and broken units):

Monitoring Date	Storm Data (H_{s-r} > 4 m)		Damage (%)*			
	Date	H_{max} (m)	Lost	Broken	Moved	"Damaged"
28-6-79	24-7-79	8				
	17-4-80	10				
18-6-81	17-8-81	9	0,6	0,8	0,8	1,4
5-12-81	-	-	0	0,2	0,2	0,2
5-6-82	-	-	0	0	0	0
24-6-83	-	-	0,4	0,4	0,2	0,8
	17-2-84	10				
	9-4-84	5				
	10-4-84	8				
	27-4-84	10				
4-7-85	30-5-84	10	0,8	0	0	0,8
24-6-86	12-7-85	5	0	0	0	0
TOTAL OVER 7 YEARS			1,8	1,4	1,2	3,2

*Damage above Low Water based on 500 30 t dolosse

Gansbaai Harbour

The Gansbaai harbour breakwater, described in Zwamborn and Van Niekerk (1981), was repaired between 1979 and 1982 with 505 20 t and 1 630 25 t dolosse at slopes of 1 in 2 and 1,75 respectively. The performance of these dolosse was closely monitored by regular visual observations, including underwater diver surveys, during construction and after the occurrence of large waves (Zwamborn, 1985).

The following data on conditions since completion of the repair work were made available to the Fisheries Development Corporation (no local wave data available after 1982):

Breakwater Monitoring			Storm Data						
Date	Dolos Breakages (%)		Date	H_{s-r} (m)	T_p (s)	H_{s-b} (m)		H_{max} (m)	Tide (m+CD)
	20 t	25 t				WSW	11°N of W		
July 1982	0,2	0,1	12-7-82	3,4	12	1,7	6,0	8	0,6
			17-7-82	3,7	18	2,3	6,4	8,5	1,2
			29-7-82	4,2	14	2,6	6,7	8,5	0,9
April 1984	-	0,25							
May 1984	1,2	0,7	15-5-84	10,8	15,5	(Slangkop)		8,5	1,5
TOTAL	1,4	1,05	Breakages over about 4 years*						

*Some repair work was done after the 16th May 1986 storm.

Koeberg Cooling-Water Intake Basin

The breakwaters forming the Koeberg intake basin are protected with 6 t, 15 t and 20 t dolosse placed at a slope of 1 in 1,5 (Zwamborn and Van Niekerk, 1981). Some 2 295 20 t dolosse were used to armour the main breakwater from chainage 750 to 912 m, which includes the head. The entire main breakwater has depth-limiting design conditions; the depth at its head is -8 m CD and waves with $H_s \geq 3,2$ m were assumed to start breaking on the head (H_{max} = 6,4 m). This means that the design waves (6,4 m breaking waves) occur on average 15 days per year, which was taken into account in deciding on acceptable damage criteria.

The following data have been collected since the previous review (Zwamborn, 1985):

Breakwater Monitoring			Storm Data (H_{s-r} > 3 m)				
Date	Type of Survey	Damage (20 t)	Date	H_{s-r} (m)	T_p (s)	H_{max} (m)	Tide (m+CD)
11-11-81	Horizontal photography						
	(37 storms)		2-1-82 to 10-6-83	3,2 to 5,9	8,8 to 15,5	5,7 to 6,9	0,2 to 1,8
14-6-83	Visual Inspection (9 storms)	(No change)					
			25-6-83 to 31-1-84	3,6 to 5,4	11,9 to 15,5	5,6 to 6,5	0,4 to 1,3
	("100 year" storm)		16-5-84	6,7	15,5	7,4	2,5
29-5-84	Visual, above and below water (11 storms)	0,44					
			29-6-84 to 5-10-84	3,4 to 7,2	11,9 to 18,3	5,9 to 6,6	0,5 to 1,4
17-10-84	Horizontal photography	(No change)					

Concluding Remarks

Prototype measurements of dolos behaviour have provided evidence that 30 t dolosse with a waist ratio of 0,36 placed on the Richards Bay breakwater head can withstand 10 m waves with only about 3 per cent "damage". Applying Figure 1, the expected total damage would be 3 per cent displacement plus all types of rocking, or about 2 per cent when excluding occasional rocking (heavy line in Figure 1).

The newly placed 20 and 25 t dolosse at Gansbaai (waist ratios 0,34 and 0,35 respectively) have withstood four storms with waves reaching 8,5 m with only 1,4 and 1,05 per cent breakages respectively (including the underwater part). For this wave height, Figure 1 indicates 2,5 and 2 per cent "total damage", or 1,5 and 1 per cent excluding occasional rocking, for the 20 and 25 t units respectively.

The 20 t dolosse at Koeberg (waist ratio 0,34) showed little damage (only 0,44 per cent for the "100 year" storm of May 1984) over a period of three years when 6 and 7 m breaking waves attacked the breakwater on 58 occasions. For these wave heights, Figure 1 would indicate 1 per cent "total damage" or 0,5 per cent excluding occasional rocking.

These observations, together with experience in the USA (Markle and David-

son, 1984), provide evidence that well-designed dolos structures (that is, considering different dolos movements) can withstand severe and sustained wave action with nominal damage. However, considerable damage has occurred in certain cased which emphasizes the need for a special and detailed design effort for major dolos projects.

5. STRUCTURAL TESTS ON DOLOSSE

Drop Test on Solid Concrete

In the foregoing, reference has been made to structural tests which provide invaluable data regarding the relative strengths of dolosse of different design, concrete quality and reinforcing. A standard drop test on a solid concrete base has been proposed for dolosse by Burcharth (1981a). Burcharth found that trunk breakage occurred for drop heights (centre of gravity) of 0,12 to 0,17 m using 1,5, 5,4, 10 and 20 t unreinforced dolosse.

The results of similar drop tests carried out at Gioia Tauro, Italy, on 15 t (r = 0,32) and 30 t dolosse (r = 0,37) (Grimaldi and Fontana, 1984) showed a considerable improvement in dolos strength with time (pozzuolana cement was used), the positive effect of the larger waist ratio of the 30 t units, the limited benefit of the steel fibres and the effectiveness of, particularly, the double-V reinforcement.

Gioia Tauro Free Fall Test

The standard drop test is carried out on a rigid base and failure is virtually due to impact loading only. In a breakwater armouring, a dolos will either drop on underlayer stone or on another dolos, both of which will probably move under the impact. A dolos breakage test which more closely represents conditions on an actual breakwater, should, therefore, include a realistic yield comparable to movement of the underlaying dolos and/or stone. Further drop tests and free fall tests were, therefore, done at Gioia Tauro onto a 50 to 1 000 kg rock fill bed and onto the breakwater core (Figure 2).

Test on Rock Test on Core Material

Figure 2: Free-fall tests with 30 t dolosse

The mean results of the tests on 30 t dolosse as interpreted by the author, are given below:

Age (months)	No. Repeat Tests	Type of test	Test bed material	Reinforcement type (kg/m³)	Failure or Damage	
					Fall Height L (m)	Impact Velocity V (m/s)
2,5	2	drop	rock	-	2,4*	5,9*
3,5	1	drop	rock	Twisted fibres (75)	2,4*	5,9*
2,5	3	free fall	rock	-	1,5	5,4+
3,5	2	free fall	rock	Twisted fibres (75) and steel fibres (95)	2,5	7,0
2	1	free fall	rock	Double-V (53)	2,6	7,1
2	2	free fall	core	Double-V (53)	2,5/5,0	7,0/9,9
2	1	free fall	core	Conventional (77)	10	14

*Maximum possible lifting height, no visual damage.

The most significant result of these tests is that the critical fall heights with a realistic yield are about 10 times greater than for the rigid-base case which means that unreinforced dolosse should be able to withstand considerable movements/rocking without breakage, a fact which is born out by prototype observations.

Controlled Yield Tests on 9 t Dolosse

Because tests on rubble are difficult to control fully and because the inclusion of a certain yield is essential to get results more directly comparable with the actual breakwater situation, a test technique by which the impact deceleration is controlled by a given yield has been developed for full scale tests on 9 t dolosse at Cape Town. The test configurations shown in Figure 3 were used for the Table Bay tests, that is, the swing test configuration.

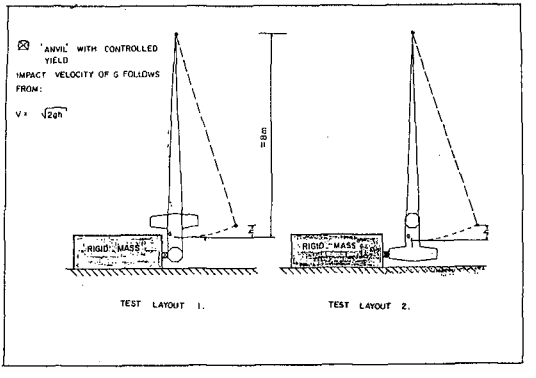

Figure 3: Dynamic Impact Test Arrangements

The height of the 9 t test dolosse was 2,9 m and the waist-to-height ratio was 0,30. The units were made of 40 MPa concrete (28 days). The tests included dolosse without reinforcing and with three types of 43 kg/m **scrap rail reinforcing**, that is a single central rail, the so-called double-V reinforcing designed by Grimaldi and Fontana (1984) and the X-type reinforcing developed by the NRIO (see Figure 4).

Single-rail Reinforcement Double-V Reinforcement X-Type Reinforcement

Figure 4: Rail Reinforcement in 9 t Dolosse

The purpose of the tests, carried out in co-operation with the South African Transport Services, were:

a) to develop a test procedure closely resembling conditions in a breakwater armour;

b) to determine the effectiveness under representative loading conditions of the different types of reinforcement;

c) to determine the effect of repeated impact loading, and

d) to decide on the type and extent of reinforcing for the 25 t dolosse to be used for the breakwater repair.

Figure 5: Free-fall tests on 0,5 to 3 t rock.

To determine a realistic yield, representing the impact of dolosse on underlayer stone or other dolosse, the first test series involved dropping a 9 t (reinforced) dolos onto 0,5 to 3 t underlayer stone (Fig. 5). Decelerations on impact were measured during these tests with two PCB Piezotronics shock accelerometer with 500 g range, fitted on the trunk and on the top shank (Fig. 5).

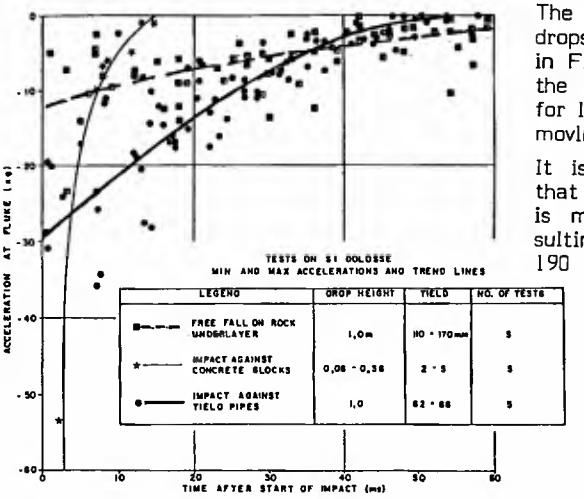

Figure 6: Comparison of accelerations for different test procedures

The results of 5 repeated drops, over 1 m, are plotted in Fig. 6, which also includes the recorded decelerations for impact against solid, non-moving concrete blocks.

It is clear from this figure that the impact on the rock is much more "gentle" (resulting in ayiled of 110 to 190 mm) than that against the rigid concrete blocks and thus, the **resulting stresses in the dolosse are therefore much smaller.**

Because the impact on rock will depend largely on the rock packing and will thus be variable (see spread of points in Fig. 6 for large impact time values), swing test were done using a representative "cushioning device". Considering that, in reality dolosse could either fall onto underlayer rock or on parts of other dolosse, a "cushioning device" consisting of three collapsible "yield pipes" (Fig. 7; 3 pipes: 89 mm OD, 4,5 mm thick and 250 mm long) was designed to give approximately twice the initial deceleration of the free drop-on-rock case but with a similar ultimate impact time of 40 to 60 ms. In this way, a conservative test condition was developed representing breakwater conditions quite realistically.

Figure 7: Cushioning Device

The actual test configuration is shown in Figures 8 and 9. The tests are still underway at present but preliminary results of the tests, according to the Test Layout 2 of Fig. 3, are given in the following table:

Figure 8: General Test Arrangement

Figure 9: Dolos (9t) at impact

Age (Months)	No. Repeat Tests	Type of Tests	Test Bed Material	Reinforcement (kg/m³)	Failure or Major Damage		Mean Yield (m)
					Fall Height (m)	Impact Velocity (m/s)	
19	3	Swing	Yield Pipes		2,3/2,6/2,9	6,7/7,1/7,5	0,16
12/15/18	3	Swing	Yield Pipes	Single Rail (85)	2,6/2,9/2,9	7,1/7,5/7,5	0,17
12	2	Swing	Yield Pipes	X-Rail (115)	3,5/3,5	8,3	0,18
18	2	Swing	Yield Pipes	Double-V (168)	3,8/4,1	8,6/9,0	0,18

The above results show:

(i) similar "failure" drop heights as found at Gioia Tauro,
(ii) the results of repeat tests do not differ much,
(iii) whereas unreinforced dolosse break in the "rigid" drop test for drop heights exceeding about 0,2 m, with a representative yield, the critical drop heights are well above 2 m,
(iv) there appears to be little difference between unreinforced and singrail reinforced dolosse but the latter will be damaged rather than fail,
(v) the double-V and X-type rail reinforcing increase the critical fall heights by 50 to 80 per cent and these are only damaged and did not fail.

Thus the **rail reinforcement** is found to be **very effective** in increasing the dolos strength and preventing dolos failure.

Burcharth (1984) has shown that repeated impact loading rapidly weakens the dolosse. For instance, impact failure will occur after three repeat loadings causing stresses of 10 per cent of the ultimate impact strength compared with 20 loadings in the case of a "pulsating" load/normal fatigue, see Figure 10.

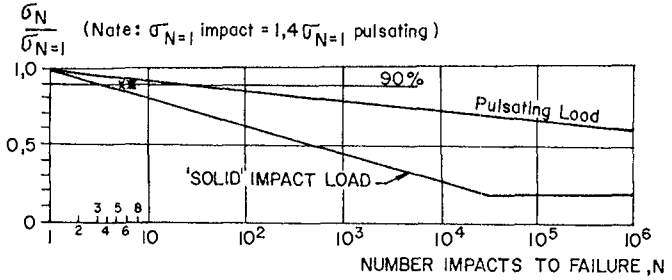

Figure 10: Average Results of Impact Tests on Dolosse (Burcharth)

The results of the first series of fatigue tests done on the 9 t dolosse are:

Type of Dolos	Number of tests	Fall Height	Number of impacts until failure
Unreinforced	2	2,0 m	5 and 7
Double V-reinforcing	1	3,2 m	7

These tests were done with a fall height of 80 per cent of the failure height and the results are plotted in Figure 10*. As expected, considering the inclusion of the cushioning device, the results fall between the pulsating and "rigid" impact lines which means that, in the breakwater situation the dolosse should be able to withstand about twice the number of impact loads predicted by the rigid impact test.

6. CONCLUSIONS

It is concluded that carefully designed dolos structures can withstand large waves with only minor (a few per cent) damage. Shortcomings in the design and/or construction and a lack of understanding of the structural limitations of dolosse can, however, result in significant damage or even local failure of the structure. A detailed and careful design process, as discussed above, will therefore have to be followed to arrive at a safe yet economical design.

An "optimum" dolos armour design should be based on a limited degree of movement using increased waist ratio and/or simple rail reinforcement to strengthen all the dolosse or only those in the more critical areas. Detailed information on **in situ** dolos movements and resulting structural dolos behaviour are required to achieve this. The results of measurements underway in South Africa and elsewhere should provide this information.

7. ACKNOWLEDGEMENT

The assistance of the Harbour Engineer and staff (Cape Town) with the prototype tests is gratefully acknowledged.

*Burcharth (1984) assumed stresses proportional with square root of drop height, thus, for 80 per cent case, $\frac{\sigma N}{\sigma N=1} = \sqrt{0,8} = 0,9$

CHAPTER 179

Verification of the Consequences of Wavedirectionality on the Loading of Long Coastal Structures by Field Experiments

J. van Heteren *
H.C. Botma **
A.P. Roskam ***
J.A. Battjes ****

Summary

Field measurements were done at the Haringvliet barrier to verify the theory that loading on long structures shows a considerable reduction if wave directionality is taken into account instead of calculating with uniform long crested waves.

Wave loads were measured with a row of pressure meters at the barrier. Directional parameters of the incoming wave field were calculated from the signals of a 3-component acoustic current meter, mounted 7.5 meter in front of the barrier. These calculations were different from those used for an open sea, since the waves near a reflecting structure are formed by two highly correlated wave fields.
The agreement between the results of the measurements and theory is good.

1. Introduction

In the Oosterschelde, one of the sea arms in the southern part of the Netherlands, a storm surge barrier is being built with a length of 4,500 m and an entrance aperture of 14,000 m^2. At the design of this barrier it turned out that the wave loads on the structure are probably influenced by wave directional properties.

To determine these influences a mathematical model has been developed by Battjes, with the incoming main wave direction, the short crestedness, the wave frequency and the length of the structure element as inputs (Battjes, 1982). It appeared that considerable reductions of wave loads can be expected if wave directionality is incorporated. The mathematical model was verified by comparison with emperical data, but the number of useful data available for this purpose was rather limited. Therefore a field campaign was held at a similar barrier in 1982/1983, covering simultaneous measurements of wave pressures at the barrier and the wave directional spectrum of the approaching waves.

* J. van Heteren, Senior Engineer, Road and Civil Engineering Department, Rijkswaterstaat, The Hague, The Netherlands.
** H.C. Botma, Senior Engineer, TNO-Institute of Applied Physics, Delft, The Netherlands.
*** A.P. Roskam, Project Engineer, Tidal Waters Directorate, Rijkswaterstaat, The Hague, The Netherlands.
**** J.A. Battjes, Professor, Dpt. of Civil Engineering, Delft University of Technology, Delft, The Netherlands.

To eliminate the influence of the foreland in front of the barrier, the wave directional spectrum had to be measured close by the barrier. As a consequence these measurements were made in a combination of two highly correlated wave fields: the incoming and the reflected wave field. This complicates the derivation of the wave directional parameters from a 3-component orbital velocity measurement considerably.

2. Measurements

The measurements were made at one of the gates of the storm surge barrier in the Haringvliet, a sea arm near the Oosterschelde. This barrier is directed from south-west to north-east and is sheltered by shoals from the North Sea and for south-westerly gales also by one of the islands (fig. 1). The local water depth ranges from 12 m close by the barrier to 4 m at the shoals.

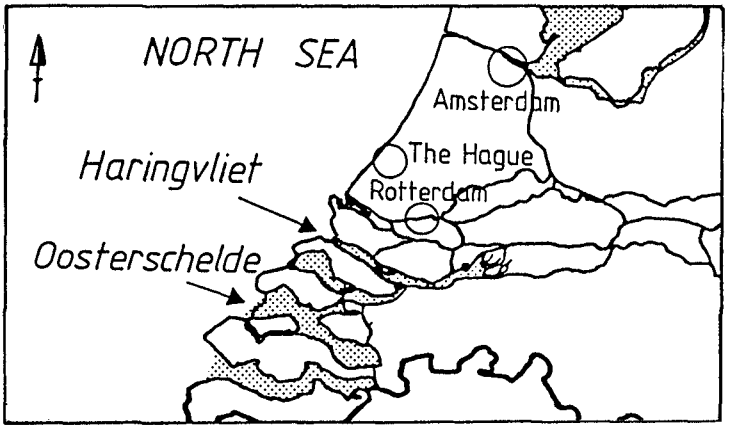

Figure 1. General Topography

Since the depth in the region close to the barrier is relatively large and the bottom is rather flat, the directionality of the wave field close by the barrier is not influenced by refraction. The tidal range in the area is about 1.8 meter. The front of the barrier is not a plane vertical wall, but a smooth cylindrical shaped steel surface.

Pressure was measured at five positions, distributed horizontally along the barrier, covering a width of 14 m.

In front of the barrier a simple steel frame was fixed, carrying 3 pressure gauges A, B and C and the 3-component acoustic current meter V, see figure 2.

In fact the bodies of all four meters were fixed to the central pole of the frame and the pressure intakes and the velocity sensor were fixed to beams, welded to the pole. This ensures that the measurements are taken in parts of the water where the movements are not disturbed too much by the instrument bodies.

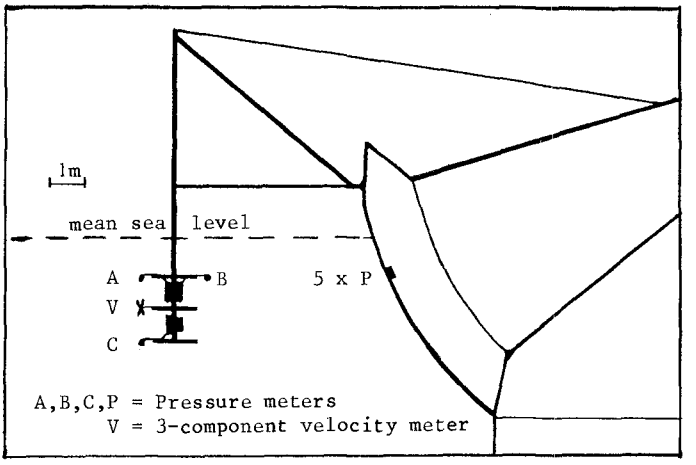

Figure 2. Location of the sensors.

Pressuremeter inlets A and C were positioned in one vertical with 2 m spacing. From pressure signal A the surface waveheights are calculated using linear wave theory. By combining signals A and C linear wave theory could be checked locally. However, afterwards another experiment was performed with simultaneous measurement of surface waves and the associated pressures. The results of these measurements were in good accordance with linear wave theory.

The third pressure gauge B was intended to test standing wave features but it turned out that much more information could be derived from the orbital velocities, so the signals of B were used.

The sensor of the current meter was mounted between pressure intakes A and C. The sensor of this meter is constructed in such a way that it offers little obstruction to the water movements, resulting in good omnidirectional characteristics. It has four pairs of transducers, forming the ends of four measuring lines; the watervelocities along these lines are measured using the average traveltime and the traveltime differences for acoustic pulses in both directions.
The length of the lines is 23 cm and they are directed parallel to the body diagonals of a cube. Because of the redundancy of using four lines instead of three orthogonal lines, a better omnidirectional uniform sensivity has been achieved. In case of steady currents one of the lines can be in the wake of one of its own transducers and then it is an advantage not to use that line for the conversion to orthogonal velocities. (In our case the advantage was that the measurements could be continued when one of the four lines became inoperative).

Signals from the 3 pressure gauges A, B, C, the 5 pressure gauges at the barrier and the 4 velocity signals were recorded during 30 minute intervals with a sampling rate of 8 Hertz.
Wave height seaward of the shoals was measured too, as well as the wind speed and direction.

During the measuring days, the wind directions ranged from south-west to north-west and speeds from 12 to 19 m/s. The significant wave height seaward of the shoals varied between 0.5 and 3 meters.

3. Calculations

The overall scheme of calculations is given in figure 3.

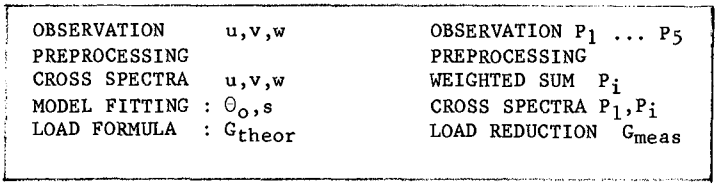

Figure 3. The overall calculation scheme

With one procedure the wavefield parameters are estimated and used as inputs to the theory of Battjes to find the wave loading reduction.

With the other procedure the actual wave loading reduction is derived from the pressures at the barrier. Finally the results are compared.

Cross spectral calculations with the three orbital velocity components are the basis of a method for estimating the wave directional parameters. However, the usual method can not be applied in this case, since it is based on the random phase statistical wave theory which does not hold for correlated wave fields. Therefore, the following method has been used. We assume an incoming unimodel directional wave field which is reflected by the barrier. The directional wave energy distribution in this hypothetic wave field is the well known cos-2s model, modified by cancelling all directions from behind the barrier.

For a given wave frequency the wave length is calculated with linear wave theory. Next, the wave field is split up into a series of elementary waves coming from directions at discrete intervals of 4 degrees. Per elementary wave the orbital velocities of the incoming and reflected waves are easily defined taking into account a reflection coefficient R and the distance to a vertical reflecting wall X_o. (See appendix A).

(In fact, the value of X_o is not simply the distance between the velocity sensor and the barrier, because of the shape of the front of the barrier. In general, the deviation from the vertical at the water-surface is dependant on the mean water level, which implies a variation in the effective value of X_o. Without going into details, it can be further assumed that longer waves will show a stronger influence of the deeper, more tilted part of the barrier, increasing the effective tilt compared to the tilt at the surface.

An investigation was made what this implies for waves with directions normal to the barrier and it appeared that the wavelengths as derived from the measured standing wave patterns fit quite well to the wavelenghts that can be calculated from linear theory. In fact, the waves are not coming from one normal direction, but as a first estimate this is resonable).

Per elementary wave the auto and cross spectral components of the orbital velocities are calculated and these spectral components are integrated for all discrete directions. A finer discrimination than 4 degrees did not alter results significantly, it may be that for the smaller values of s even larger directional steps would have been acceptable.

Since the absolute wave height is not relevant to the directional energy distribution, the spectral components from the calculations as well as from the measurements were normalized by dividing with the sum of the 3 autocorrelation components.

Altering the main wave direction Θ_o, the coefficient s, the effective distance X_o and the reflection coefficient R results in different sets of integrated spectral components. This is used to search for a combination that shows a minimum of the sum of the squared differences between the normalised spectral components of model and measurements. This part of the method is rather similar to that described by Borgman, (1981). In fact, the reflection coefficient R can be estimated also from the phase relation between the vertical velocity-component w and the horizontal component u, perpendicular to the barrier.

As a result we have per frequency a value of Θ_o, s and X_o for a best fit between model and measurements. The parameter X_o is only used to see if it has a reasonable value, taking into account the influence of wavelength and variable tilt of the reflector plane. It can hardly be expected that the fit of the spectral components will be perfect. This can be illustrated if we look at some special features.
In the theoretical model several components can be zero:

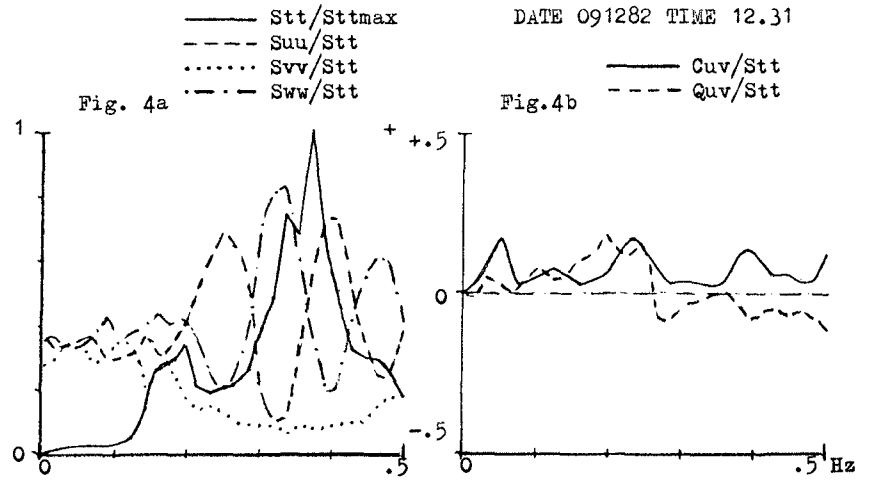
$C_{vw} = 0$ in all cases; $C_{uv} = Q_{uw} = 0$ if $R = 1$ and

$C_{uv} = Q_{uv} = Q_{vw} = 0$ if $\Theta_o = 0$.

w = vertical orbital velocity component
u = horizontal component normal to barrier
v = horizontal component parallel to barrier
C_{ij} = co-spectrum of i and j
Q_{ij} = quad-spectrum of i and j
(S_{ii} = auto spectrum of i)
R = reflection coefficient
Θ_o = central wave direction in cos-2s distribution.

Figure 4 shows an example of spectral calculations for one measuring interval. Figure 4a shows the sum of the autospectra $S_{tt} = S_{uu} + S_{vv} + S_{ww}$ divided by the peak value of S_{tt}, together with the three auto-spectra divided by S_{tt}.

Discrepancies with the model are found where the wave energy becomes small relative to the velocity noise. E.g. at low frequencies S_{uu} and S_{ww} show about the same value, where S_{uu} should become much smaller than S_{ww}.
In the frequency range of interest S_{vv} is small, indicating a wave direction nearly normal to the barrier, which is confirmed by the fact that Q_{uv} and Q_{vw} are also small; see figure 4b and 4d.



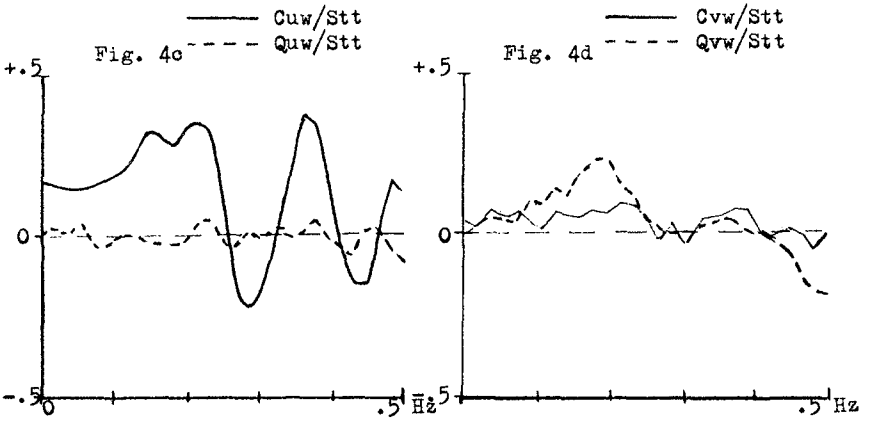


Figure 4. Normalised cross spectra of the orbital velocities.

When comparing the spectra S_{uu} and S_{ww}, the typical standing wave pattern with its nodes and loops can be seen quite distinctly. In general, Q_{uw} is very small; see figure 4c. This means that reflectioncoefficient R is about 1. Values of R greater than 1 do occur. Physically this means that during the measuring interval the reflected parts of the waves were a bit larger than the incoming parts that swept past the velocity meter. In a short crested wavefield that is quite well possible.

According to the theoretical model C_{vw} should be always zero. The measurements do not show this and this again illustrates that the fit can not be perfect.

Nevertheless the results of this best fit procedure give sufficient confidence to use the central wave direction Θ_o and the spreading parameter s as meaningful values.

A confirmation was found from the fact that the values of Θ_o at high frequencies corresponded to the wind direction. At low frequencies the direction of swell, entering from the North Sea, was found.

With Θ_o and s the wave load reduction can be calculated using the formulae given by Battjes (Ref 1). The results of a typical case are given in figure 5 as G_{theory}.

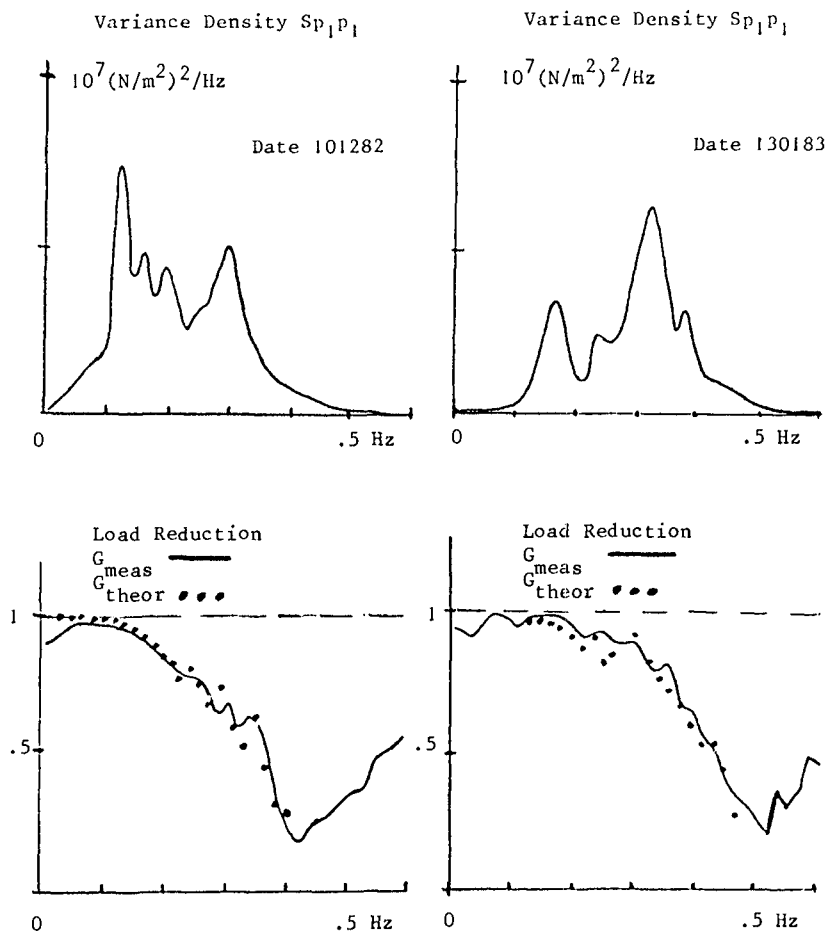

Figure 5. Some results of the waveload verification.

The other calculation path in figure 3 starts with the measured pressure signals at the barrier. After the same preprocessing applied to the other signals, in order to filter out tide and non relevant high frequency noise, the wave load reduction is calculated. The reduction is characterized by the fact that the coherence between pairs of pressure signals decreases if the spacing increases.

By applying to each pressure signal a weight factor, that is representative for a partial area of the barrier, the load reduction can be calculated. The actual load is the sum of products of the partial areas multiplied by the associated pressure signals. The reference load corresponds to the total area multiplied by one of the pressure signals. The results are given in figure 5 as G_{meas}.

Discussion

The agreement between the theoretical and measured load reduction G_{theory} and G_{meas} is very good in the frequency range where the spectral energy is relatively high. At very low frequencies in the formula of Battjes the reduction is 1; the measurement will not reach that value.
Beyond 0.4 Hertz the reduction factor, as calculated from the pressure signals, increases again. This effect is most probably the result of resonant vibrations of the barrier gate and not related to the wave loading.

Conclusions

1. The decrease of the coherence of the wave pressures at the barrier with increasing distance qualitively indicates that the total load will be lower than the product of one local pressure and the total barrier surface.
2. The quantitative verification shows that the wave load reduction as calculated by Battjes, taking into account the effect of short crestedness, does agree with full scale measurements.
3. In spite of the strong interaction between the incoming and reflected waved due to the short distance to the barrier, the main direction and spreading of the incoming wavefield can be estimated well from the three orthogonal velocity components.
   The method for this is the fitting of the spectral components from the measurements to the corresponding spectral components of a theoretical wave field that is a combination of the incoming and the reflected waves.

APPENDIX A

The elementary case of reflection of a long-crested periodic wave is illustrated in fig. A1.

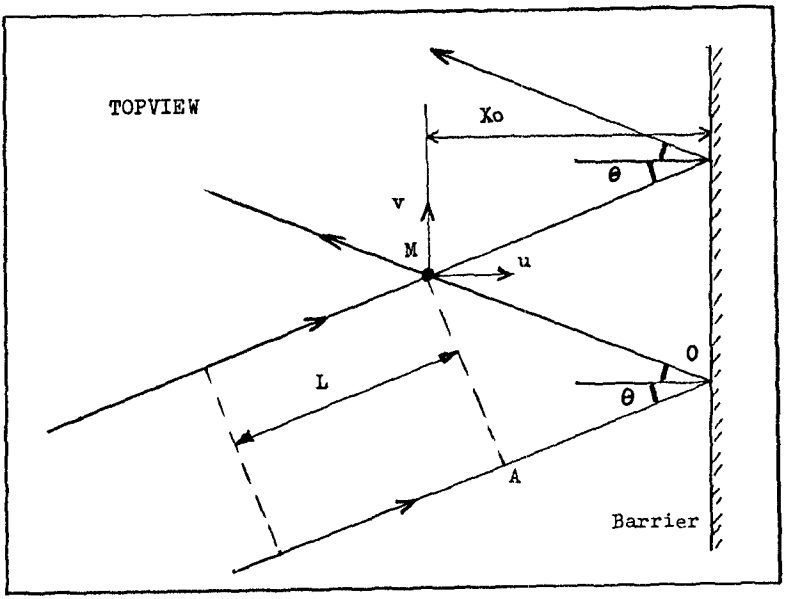

Figure A1. Definition of configuration.

M measuring point
X_o distance from M to the barrier
(The barrier is assumed to be a flat vertical wall)
L wave length
Θ incoming wave direction
u velocity component in direction normal to the barrier
v velocity component in direction parellel to the barrier
w vertical velocity component
R reflection coefficient
a surface elevation amplitude
ω frequency
t time
H_{uv} ratio between surface elevation and horizontal velocity
H_w ratio between surface elevation and vertical velocity

In M the distance between the incoming and reflected waves in the direction of propagation is

$$AO + OM = (\cos 2\Theta+1)OM=(\cos 2\Theta+1)X_o/\cos\Theta = 2X_o\cos\Theta \quad (1)$$

This corresponds to a phase difference

$$\phi = 4\pi X_o \cos\Theta/L \quad (2)$$

For the incoming waves in M, we have

$$u = a\, H_{uv} \cos\Theta \sin\omega t \quad (3)$$

$$v = a\, H_{uv} \sin\Theta \sin\omega t \quad (4)$$

$$w = a\, H_{w} \cos\omega t \quad (5)$$

At the barrier the wave changes direction in such a way, that the phase of u changes π , while the phase of v and w does not change. We assume that the reflection coefficient R is not associated with a phase shift and that R has the same value for u, v and w. This is a simplification.

So the reflected waves in M are described by

$$u = R\, a\, H_{uv} \cos\Theta \sin(\omega t - \phi - \pi) \quad (6)$$

$$v = R\, a\, H_{uv} \sin\Theta \sin(\omega t - \phi) \quad (7)$$

$$w = R\, a\, H_{w} \cos(\omega t - \phi) \quad (8)$$

Adding the incoming and reflected wave signals gives:

$$u = a\, H_{uv} \cos\Theta((1-R)\cos\phi/2 \sin(\omega t-\phi/2) + (1+R)\sin\phi/2 \cos(\omega t-\phi/2)) \quad (9)$$

$$v = a\, H_{uv} \sin\Theta((1+R)\cos\phi/2 \sin(\omega t-\phi/2) + (1-R)\sin\phi/2 \cos(\omega t-\phi/2)) \quad (10)$$

$$w = a\, H_{w} (-(1-R)\sin\phi/2 \sin(\omega t-\phi/2) + (1+R)\cos\phi/2 \cos(\omega t-\phi/2)) \quad (11)$$

These velocities give the following spectral components

$$S_{uu} = 0.5\, a^2\, H_{uv}^2\, (1-2\,R\cos\phi + R^2)\, \cos^2\Theta \quad (12)$$

$$S_{vv} = 0.5\, a^2\, H_{uv}^2\, (1+2\,R\cos\phi + R^2)\, \sin^2\Theta \quad (13)$$

$$S_{ww} = 0.5\, a^2\, H_{w}^2\, (1+2\,R\cos\phi + R^2) \quad (14)$$

$$C_{uv} = 0.5\, a^2\, H_{uv}^2\, (1-R^2)\cos\Theta \sin\Theta \quad (15)$$

$$Q_{uv} = 0.5\, a^2\, H_{uv}^2\, (-2\,R\sin\phi)\, \cos\Theta \sin\Theta \quad (16)$$

$$C_{uw} = 0.5\, a^2\, H_{uv}H_{w}\, (-2\,R\sin\phi)\, \cos\Theta \quad (17)$$

$$Q_{uw} = 0.5\, a^2\, H_{uv}H_{w}\, (1-R^2)\cos\Theta \quad (18)$$

$$C_{vw} = 0 \quad (19)$$

$$Q_{vw} = 0.5\, a^2\, H_{uv}H_{w}\, (1+2\,R\cos\phi + R^2)\sin\Theta \quad (20)$$

In any case $C_{vw} = 0$.
If R = 0 the formulae reduce to the normal single wave case.
If R = 1 then $C_{uv} = 0$ and $Q_{uw} = 0$ (21)

if $\Theta = 0$, then $S_{vv} = 0$, $C_{uv} = 0$, $Q_{uv} = 0$ and $Q_{vw} = 0$ (22)

For each frequency the value of ϕ is calculated via the wavelength L. Then the elementary results (12) to (20) are integrated for various values of Θ , at the same time taking a^2 inaccordance to a cos-2s directional distribution. For $\Theta_o = 0$ again $C_{uv} = 0$, $Q_{uv} = 0$ and $Q_{uw} = 0$ but S_{vv} is no longer zero, except for infinite s.

Abstract

A system composed of two buoyant flaps hinged at the sea floor and coupled with weighted mooring lines is modeled analytically and experimentally. The system behavior is described theoretically utilizing an eigenseries representation of linear wave theory in the vicinity of the breakwater. The structure dynamics are modeled in terms of structure weight, inertia, buoyancy, damping, mooring line tension and the wave pressure field.

The mechanically coupled system provides shelter by reflecting incident waves and by attenuating wave energy through structural and viscous damping. The structure can be tuned to minimize wave transmission within a particular frequency range by changing the flap spacing and adjusting the mass and equilibrium position of the mooring line weights.

The theory is validated with experimental results for models fabricated from inflatable, parallel-tube membranes. Buoyancy and inertia are changed by filling tubes with air and/or water. Single and double flaps are examined with and without mooring lines. Incident, reflected, and transmitted waves are measured as well as flap motion. Theoretical results are corroborated by the experiments and the importance of including damping in the model is demonstrated.

Introduction

Floating breakwaters have the desirable characteristics of being transportable, relatively inexpensive, and reusable and rapidly deployable. However, most floating breakwaters are relatively transparent to the incident wave field, e.g., floating parallelepipeds (Adee, 1976), tire-mazes (Harms, 1979), and tethered spheres (Seymour and Harms, 1979). In order to improve the behavior of floating breakwaters, it is necessary for the structure to occupy a major fraction

of the water column or incident wave length. The effectiveness of a floating structure can also be improved by constraining some modes of structural deflection and by tuning the structure natural frequency to avoid design wave frequencies (Leach, McDougal, and Sollitt, 1985).

In this study, a flap-type floating structure is examined which occupies the entire water column and which is hinged at the sea floor. Buoyancy provides a vertical equilibrium position for the structure and additional stiffness is afforded by weighted mooring lines. Wave interference between two structures is obtained by locating the flaps at appropriate spacings. Wave reflection is increased and wave transmission decreased by coupling the flaps with a common weighted mooring line; refer to Fig. 1. The coupled flap system can be tuned to optimize performance by varying the spacing, buoyancy and inertia as well as the mass and equilibrium position of the mooring weights.

The model structure examined during the experimental phase of this study was fabricated from a parallel tube air mattress. The inertia and buoyancy of the flap was changed by filling adjacent tubes with air or water. The membrane fabric which composed the air mattress was cut and glued to change the height and width of the structure and grommets for mooring line attachments were added by gluing additional fabric to the face of the mattress. The structure was anchored with a weighted plate at the sea floor. The utility of the air mattress model has some readily apparent implications for prototype applications in terms of portability and constructibility.

The behavior of the flap system is modeled analytically utilizing an eigenseries representation of linear wave theory in the vicinity of the structure. This contrasts to the numerical solution procedure of Raichlen and Lee (1978) used for inclined plate structures. Linear flap dynamics are modeled in terms of structure weight, inertia, buoyancy, damping, mooring line tension and the wave pressure field. This contrasts to the undamped, unconstrained solution of Evans (1979) and Skrokosz and Evans (1979) for wave power absorbing bodies.

Theoretical and experimental results are compared for single flaps and double flaps, for air and air/water filled mattresses. Examples with and without moorings are included. Both damped and undamped solutions are illustrated. Experimental and theoretical results confirm that structural and viscous damping are important considerations in describing the system behavior.

Theory

Potential Flow Boundary Value Problem (BVP)

In this study, the fluid is considered to be inviscid and incompressible and the flow is assumed to be irrotational. Then a single-valued velocity potential Φ_ℓ, ℓ = I, II, III, can be defined for each flow field separated by the flaps in Fig. 2 as

$$\vec{u}_\ell = -\vec{\nabla}\Phi_\ell \quad ; \qquad \ell = \text{I, II, III} \tag{1}$$

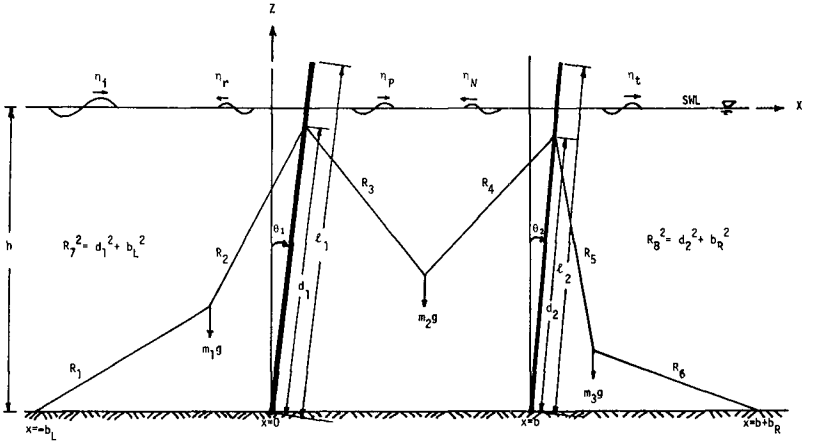

Figure 1. Definition sketch.

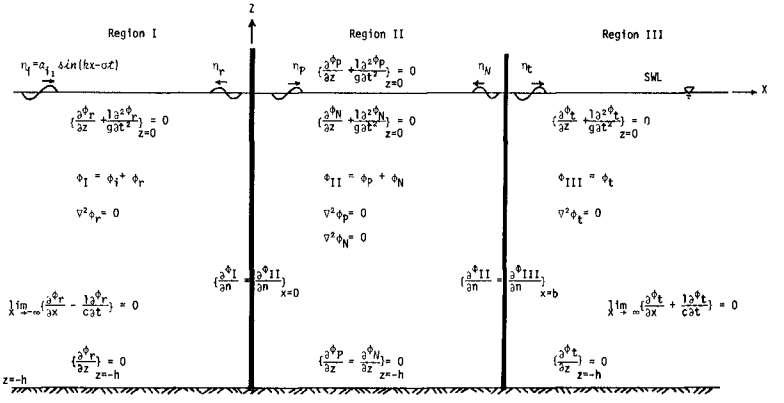

Figure 2. Linearized boundary value problem.

When small amplitude waves are considered, the velocity potentials satisfy the Laplace equation and the boundary conditions shown in Fig. 2. Kinematic boundary conditions, which require continuity of normal velocity across boundaries, are imposed on the impermeable bottom, rigid flaps, and free surface. Dynamic boundary conditions, which require continuity of pressure across a boundary, are imposed on the free surface. An additional radiation condition requiring only outgoing progressive waves at infinity is imposed on the reflected and transmitted waves.

The incident wave velocity potential and water surface profile are specified as

$$\phi_i = R_e\left\{\frac{a_{i1}g}{\sigma}\frac{\cosh K_1(z+h)}{\cosh K_1 h}e^{-(K_1x+i\sigma t)}\right\} \tag{2a}$$

$$\eta_i = R_e\left\{-ia_{i1}e^{-(K_1x+i\sigma t)}\right\} = a_{i1}\sin(kx-\sigma t) \tag{2b}$$

where $K_1 = -ik$, $k = \frac{2\pi}{L}$, L is the wave length, $\sigma = \frac{2\pi}{T}$, T is the wave period, and a_{i1} is the wave amplitude. The velocity potentials satisfying the BVP shown in Fig. 2 are found as follows:

$$\Phi_I = \phi_i + \sum_{j=1}^{\infty}\frac{ga_{rj}}{\sigma}\frac{\cosh K_j(z+h)}{\cosh K_j h}e^{(K_jx-i\sigma t)} \tag{3}$$

$$\Phi_{II} = \sum_{j=1}^{\infty}\frac{g}{\sigma}\frac{\cosh K_j(z+h)}{\cosh K_j h}\left\{a_{pj}e^{-[K_jx+i\sigma t]} + a_{nj}e^{[K_j(x-b)-i\sigma t]}\right\} \tag{4}$$

$$\Phi_{III} = \sum_{j=1}^{\infty}\frac{ga_{tj}}{\sigma}\frac{\cosh K_j(z+h)}{\cosh K_j h}e^{-[K_j(x-b)+i\sigma t]} \tag{5}$$

where the eigenvalues K_j can be determined from the dispersion equation:

$$K_1 = -ik \tag{6a}$$

$$(2j-3)\frac{\pi}{2} < K_j h < (j-1)\pi \quad \text{for } j \geq 2 \tag{6b}$$

$$\sigma^2 = -gK_j \tan K_j h \tag{6c}$$

and

$$a_{rj} = \delta_{j1} a_{i1} - i\beta_j S_1 \tag{7}$$

$$a_{pj} = i\beta_j \left(\frac{S_1 e^{K_j b} - S_2}{2 \sinh K_j b}\right) \tag{8}$$

$$a_{nj} = i\beta_j \left(\frac{S_1 - S_2 e^{K_j b}}{2 \sinh K_j b}\right) \tag{9}$$

$$a_{tj} = i\beta_j S_2 \tag{10}$$

$$\beta_j = \frac{2 \sin K_j h}{K_j^2 h^2 \left(1 + \frac{\sin 2K_j h}{2K_j h}\right)} \left[K_j h \sin K_j h + \cos K_j h - 1\right] \tag{11}$$

for $j \geq 1$ and δ_{j1} is Dirac delta. a_{rj}, a_{pj}, a_{nj}, and a_{tj} are the complex amplitudes of the reflected waves, right-going and left-going waves between the flaps and the transmitted waves, respectively. S_1 and S_2 are the complex amplitudes of the two flaps, referenced to the still water, and related to the flap angle of inclination as

$$\theta_1 \cong \frac{S_1}{h} e^{-i\sigma t} \tag{12}$$

$$\theta_2 \cong \frac{S_2}{h} e^{-i\sigma t} \tag{13}$$

for periodic small motions. S_1 and S_2 are determined by solving the coupled equations of motion of the breakwater flaps.

Each flap is assumed to be rigid yet free to rotate about a fixed point on the seabed. The equation of motion for each flap is found by taking the moment about its hinge point at the seabed as

$$I_\ell \ddot{\theta}_\ell + M_{B\ell} - M_{G\ell} - M_{w\ell} + M_{m\ell} + C_{d\ell} \dot{\theta}_\ell = 0 \quad , \ell = 1,2 \tag{14}$$

where $I\ddot{\theta}$ is the mass moment of inertia of the flap, M_B and M_G are the moments due to the buoyancy F_B and the weight of the flap, M_w is the moment due to wave force, M_m is the moment due to the mooring line, and the last term represents energy dissipation which may be caused by nonconservative forces. For small motions, the moments are found as follows:

$$M_{B\ell} \cong F_{B\ell} B_\ell \theta_\ell \tag{15}$$

$$M_{G\ell} \cong m^*_\ell g G_\ell \theta_\ell \tag{16}$$

$$M_{w\ell} \cong -\frac{h}{S_\ell} \rho g M_\ell \theta_\ell \tag{17}$$

where m* is the mass of the flap per unit width, and B and G are defined in Fig. 3, and

$$M_1 = \sum_{j=1}^{\infty} r_j \{2i\delta_{j1} a_{i1} + \beta_j [S_1 (1+\coth K_j b) - S_2 \operatorname{csch} K_j b]\} \tag{18}$$

$$M_2 = \sum_{j=1}^{\infty} r_j \beta_j [-S_1 \operatorname{csch} K_j b + S_2 (1+\coth K_j b)] \tag{19}$$

$$r_j = \frac{K_j h \sin K_j h + \cos K_j h - 1}{K_j^2 \cos K_j h} \tag{20}$$

The moment due to mooring lines can be found from Fig. 4 as

$$M_{m1} \cong m_1 g d_1 Q_{11} + m_1 g d_1 Q_{12} \theta_1 + m_2 g d_1 Q_{13} \theta_2 - m_1 d_1^2 \theta_{14} \ddot{\theta}_1 + m_2 d_1 d_2 Q_{15} \ddot{\theta}_2 \tag{21}$$

$$M_{m2} \cong m_2 g d_2 Q_{21} + m_2 g d_2 Q_{22} \theta_1 + m_2 g d_2 Q_{23} \theta_2 + m_2 d_1 d_2 Q_{24} \ddot{\theta}_1 - m_2 d_2^2 Q_{25} \ddot{\theta}_2 \tag{22}$$

The subscripted Q_{ij} variables are determined relative to the position of the mooring line weights (Lee et al. 1986).

For a system which has vertical flaps at static equilibrium, a steady-state solution exists as described by Eqs. (12) and (13). The coupled equations of motion are obtained by substituting Eqs. (15), (16), (17), and (21) or (22) into Eq. (14), providing

$$C_{11} S_1 - C_{12} S_2 = -2i a_{i1} \gamma_1 \tag{23}$$

$$C_{21} S_1 - C_{22} S_2 = 0 \tag{24}$$

where

$$C_{11} = C_{01} + P_{11} - \frac{i\sigma}{\rho g h^3} C_{d1} \tag{25}$$

$$C_{12} = C_{02} - P_{12} \tag{26}$$

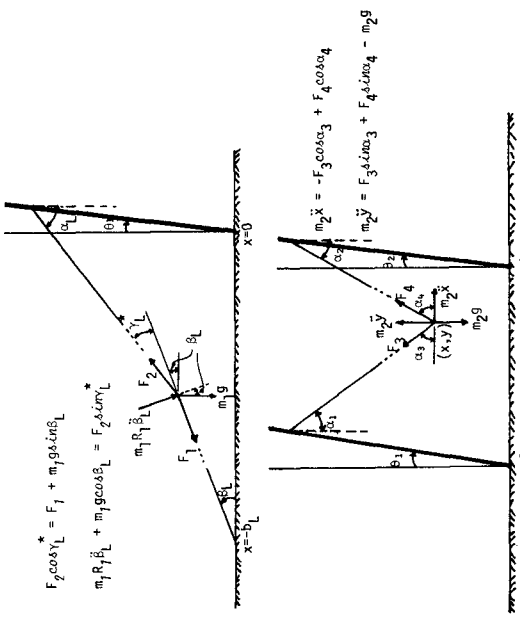

Figure 4. Free body diagrams of mooring weights.

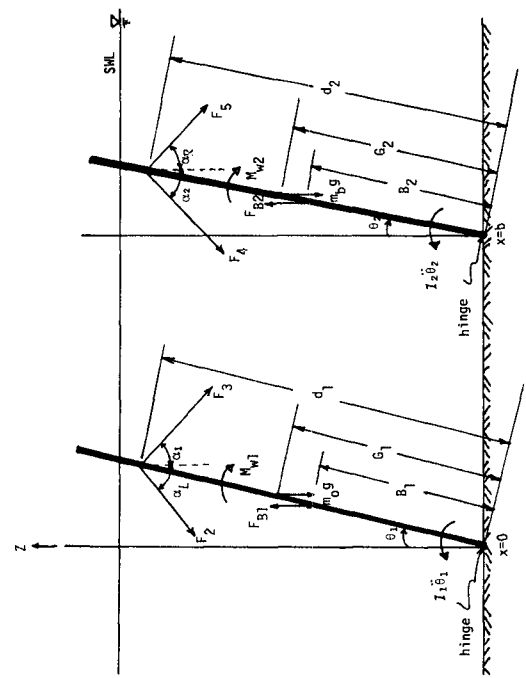

Figure 3. Free body diagrams of buoyant flaps.

$$C_{21} = C_{02} - P_{21} \tag{27}$$

$$C_{22} = C_{01} + P_{22} - \frac{i\sigma}{\rho g h^3} C_{d2} \tag{28}$$

$$C_{01} = \sum_{j=1}^{\infty} \beta_j \gamma_j (1 + \coth K_j b) \tag{29}$$

$$C_{02} = \sum_{j=1}^{\infty} \beta_j \gamma_j \operatorname{csch} K_j b \tag{30}$$

$$P_{11} = \frac{1}{\rho g h^3} [F_{B1} B_1 + m_1 g d_1 Q_{12} - m_1^* g G_1 - \sigma^2 (I_1 - m_1 d_1^2 Q_{14})] \tag{31}$$

$$P_{12} = \frac{1}{\rho g h^3} [m_2 g d_1 Q_{13} - \sigma^2 m_2 d_1 d_2 Q_{15}] \tag{32}$$

$$P_{21} = \frac{-1}{\rho g h^3} [m_2 g d_2 Q_{22} + \sigma^2 m_2 d_1 d_2 Q_{24}] \tag{33}$$

$$P_{22} = \frac{1}{\rho g h^3} [F_{B2} B_2 - m_2 g d_2 Q_{23} - m_2^* g G_2 - \sigma^2 (I_2 - m_2 d_2^2 Q_{25})] \tag{34}$$

Solving Eqs. (23) and (24) simultaneously yields

$$S_1 = i\left[\frac{2\gamma_1 C_{22}}{C_{12} C_{21} - C_{11} C_{22}}\right] a_{i1} \tag{35}$$

$$S_2 = i\left[\frac{2\gamma_1 C_{21}}{C_{12} C_{21} - C_{11} C_{22}}\right] a_{i1} \tag{36}$$

The flap amplitudes are specified by Eqs. (35) and (36). The flap amplitudes are substituted into Eqs. (7) and (10) for j=1 to solve for the reflected and transmitted wave amplitudes, respectively.

Experimental Facilities and Procedures

Experiments were conducted in the Graf Hall wave channel at Oregon State University, USA. The channel is 36 feet long, 2.0 feet wide and 2.2 feet deep. The models were located midway between the wave generator and a 1:10 slope beach. Waves were generated by a flap-style wave board, powered by variable speed electric motor with a right angle gear reduction box and variable eccentric drive shaft. Monochromatic waves were generated in a period range of 0.5 to 1.1 seconds, with wave heights up to 0.27 feet. All tests were conducted in a water depth of 1.5 feet.

Individual flaps for the model breakwaters were constructed from inflatable air mattresses, 1.8 feet wide and 6.0 feet long. The mattresses were composed of seven parallel tube chambers running the length of the mattress, with separate valves in each chamber. The mattresses were fabricated from a woven synthetic textile, sealed with an internal coating.

Mattresses were modified to become breakwater models by cutting each mattress in half to reduce the length and by adhesive fastening a seventh air chamber to provide a flap width equal to the wave channel width. Additional fabric patches were adhesive fastened to each chamber at the water surface to provide a grommet attachment for braided nylon mooring lines. A three yoke bridle distributed the load from each mooring line to three tubes. Two mooring lines were attached to both sides of the moored flaps. Four pound lead weights were suspended from each mooring line to provide a positive restoring force.

The inflated dimensions of the breakwater flap were 2.75 feet high, 2.04 feet wide and 0.22 feet thick. Flaps were inflated to a common pressure head of three feet of water. Some experiments were conducted with all tubes filled with air. Other experiments were conducted with four tubes filled with water to the SWL and three tubes filled with air. Five different breakwater configurations were examined. The characteristics associated with each configuration are identified in Table 1.

Wave profiles were monitored with acoustic water surface sensors, sampling at a rate of 60 hertz. A single fixed wave sensor was placed two water depths beyond the leeward flap to measure the transmitted wave height. A single wave sensor on a sliding carriage was placed on the seaward side of the breakwater to profile the envelope resulting from the superposition of the incident and reflected waves. The incident wave height was calculated from one-half the sum of the relative maxima and minima of the envelope. The reflected wave height was calculated from one-half the diffrence of the relative maxima and minima. Breakwater flap amplitudes were measured visually by scaling flap motion at the still water level.

Table 1. Model characteristics per unit width (ft)

Case	Breakwater Configuration	Weight in Air (lbf/ft)	Displaced Water Weight (lbf/ft)	Center of Gravity (ft)	Center of Buoyancy (ft)	Mass Moment of Inertia ($slug \cdot ft^2/ft$)	Distance Between Breakwaters (ft)	Mooring Weight (lbf/ft)	Damping Coefficient (lbf•ft•sec/ft)

Experimental and Theoretical Results

Reflected and transmitted wave amplitudes are the basis for comparing measured and predicted breakwater performance in this study. The amplitudes are reduced to dimensionless reflection and transmission coefficients by division with the incident wave amplitude. Results are expressed relative to wave frequency in terms of the dimensionless ratio of water depth divided by the linear wave theory deep water wave length, h/Lo. The deep water wave length is the progressive wave solution to the dispersion equation (6), for large water depths, yielding

$$Lo = \frac{gT^2}{2\pi} \tag{37}$$

Results for a single flap, inflated with air without moorings are presented in Fig. 5. This corresponds to Case 1 in Table 1. In general, the reflection coefficient is shown to increase with decreasing wave length (increasing h/Lo) while the transmission coefficient decreases with decreasing wave length. Experimental results are plotted as points in the figure while theoretical results appear as continuous lines. The breakwater becomes a dynamic barrier to high frequency waves (high h/Lo) due to the structural stiffness. However, the breakwater theoretically becomes a kinematic barrier to low frequency waves because breakwater buoyancy can accommodate a head difference across the flap, effectively creating a tidal barrage. The theoretical solution displays this trend at very low frequency; no experimental results are available at this frequency. Note that theory and experiments do follow the same trend, although the theory does overestimate the transmission coefficient for the undamped solution in the upper half of Fig. 5.

A damped solution is compared to experimental results in the lower half of the figure. The damping coefficient is determined empirically by requiring the theoretical solution to dissipate the same energy as the experimental results over the full range of measured data. Resulting damping coefficients are reported in the right hand column of Table 1. Damping does decrease the transmission while increasing the reflection coefficient to a lesser degree. In general, the correlation between theory and experiment is improved for the damped case.

Results for a single flap without moorings but with water to the SWL in four of the seven buoyancy chambers are shown in Fig. 6. This condition (Case 2 in Table 1) tends to give somewhat higher reflection coefficients and slightly lower transmission coefficients at all frequencies. The damped solution in the lower half of the figure more closely follows the experimental results.

A two flap system is illustrated in Fig. 7. The flap spacing is equal to the water depth. The breakwaters are filled with air and water and no moorings are attached. This corresponds to Case 3 in Table 1. The results show that the two flap system is much more frequency selective than the one flap system. Both theory and

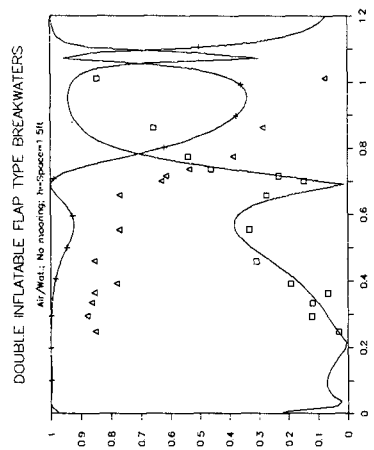

Fig. 7. Experimental and theoretical reflection and transmission coefficients for two flaps without mooring, Case 3.

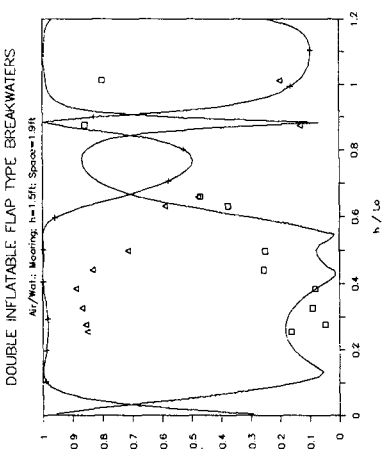

Fig. 8. Experimental and theoretical reflection and transmission coefficients for two flaps with weighted moorings, Case 4.

experiment follow this trend with relative maxima and minima occurring at two points over the data range. Damping improves correlation with the transmission coefficient in the lower figure while the undamped case appears to better reproduce the reflection coefficient behavior at intermediate frequencies.

The effects of moorings for a two flap system, filled with air and water, is shown in Fig. 8. This corresponds to Case 4 in Table 1. The mooring dynamics add additional relative maxima and minima to the breakwater behavior. Damping improves the correlation between theory and experiment at intermediate wave frequencies. The general effect of the mooring is to reduce wave transmission at intermediate frequencies. This is made evident by comparing experimental results in Figs. 7 and 8.

Conclusions and Recommendations

Mechanically coupled buoyant flaps have been proposed and constructed from inflated membranes connected with weighted mooring lines. A closed-form, linear analytical solution to the system behavior has been presented. A model has been constructed from currently available materials, demonstrating the practicality of the application. Comparisons between theoretical and experimental wave reflection and transmission coefficients have validated the analytical model. Theoretical and experimental results suggest that structural and viscous damping are important features in the system behavior.

Damping was quantified with a semi-empirical displacement rate coefficient in the model. This coefficient requires a more deterministic approach for evaluation, utilizing drag force relationships for mooring line motion. Also, signficiant bending of the hinged flap was observed during the experiments, suggesting that the rigid flap approximation may be an oversimplification. Future studies will evaluate the flap behavior as an elastic beam with structural damping quantified relative to the plastic properties of synthetic membranes.

CHAPTER 181

INNOVATIVE DETERMINATION OF NEARSHORE FLOOD FREQUENCY

H. Lee Butler*, and Mark D. Prater**, Members ASCE

ABSTRACT

Reliable estimates of coastal flooding from tides and storm surges are required for making sound engineering decisions regarding the design, operation and maintenance of many coastal projects. A recent investigation of flood frequency along the coast and within the bays of southern Long Island, New York, produced new and optimal approaches to obtain meaningful statistical estimates of flood levels. This paper summarizes various elements of the study and concentrates on the problem of stage-frequency computations in the inland bay areas. Methods for optimizing the number of necessary storm/tide simulations and estimating the accuracy of results are presented.

INTRODUCTION

Efficiency in design of coastal protection is becoming more and more important. Development of coastal regions, costs of damages from storm induced water levels, and costs of protection from these waters are all increasing. Adequate protection for coastal regions is desired; however, due to financial constraints the amount of flood level protection that can be considered adequate becomes a question for which there is no easy answer. Therefore, inherent in any coastal protection project is a need to develop the most accurate possible stage-frequency (frequency of storm/tide induced still-water level above a fixed datum) relationship estimate for the project area, as well as an estimate of the error in this relationship.

The technique in widespread use for the development of coastal flood frequency, especially from hurricane induced water levels, is the joint probability method (JPM) (Myers, 1970). A method to develop error estimates from meteorological uncertainty for stage-frequency relationships derived through the JPM was presented by Prater, et al. (1984). However, a generally accepted method to judge the correctness of the produced flood frequency, or to estimate the error of these frequencies, is not available.

**Graduate Research Associate, School of Oceanography, University of Washington, Seattle, WA.

A study to investigate the frequency of storm-plus-tide flood levels along the coast and within the bays of southern Long Island, New York, was recently completed at the U.S. Army Engineer Waterways Experiment Station (WES). The offshore study domain is the New York Bight whereas the nearshore area of interest covers a coastal reach of approximately 125 km and includes three inlet/bay systems (Great South, Moriches, and Shinnecock Bays) with interconnecting channels. The problem is further complicated by a variable height dune system along the bayfront barrier islands which is susceptible to overtopping and deterioration during a storm passage.

The approach adopted for estimating stage frequency due to storm-induced surge and wave effects involved conjunctive use of several models. A numerical storm surge model calculated the still water level. A dune breach model permitted an ad hoc determination of dune overtopping and destruction. Several probability models were used to choose events to simulate, assign probabilities to those events, and construct the stage-frequency relationships. Each element of the study is briefly discussed; however, attention here is focused on the optimal methods used for estimating nearshore and inland bay flood frequencies and errors in the development process. A complete report on the study is given in Prater, et al. (1987).

STORM SURGE MODELING

Simulations required in the Long Island study involved application of two numerical surge models, collection of field data for model calibration, and analysis of alternative barrier and inlet configurations. The primary model applied in the study is the WES Implicit Flooding Model (WIFM). The numerical and hydrodynamic features of WIFM are discussed in Butler (1978) and the application to coastal studies is documented in numerous reports including Butler (1980, 1983). WIFM solves the vertically integrated time-dependent shallow water wave equations of fluid motion using an alternating direction implicit finite difference algorithm. The code allows subgrid barriers to be exposed, submerged, or overtopped. An important feature of WIFM is the capability to create an exponentially stretched grid which permits concentration of grid resolution in areas of interest. Also included in the code is the capability to flood or dry individual low-lying cells during a simulation.

A coarse global grid (Figure 1) was constructed to cover the New York Bight from a point south of Atlantic City, New Jersey, to beyond Cape Cod, Massachusetts (and includes New York Harbor and Long Island Sound). The purpose of the global grid is to model large-scale tidal and meteorological events, providing results for input to a small, high-resolution nearshore grid of the main study area. The high-resolution nearshore grid stretches from near Jones Inlet to beyond Shinnecock Inlet (including all back-bay and channel systems) and has variable grid size resolution of 200 to 1200 m.

Both numerical grids were calibrated for the primary M2 astronomical tidal constituent, and verified for a mixed tide condition. Typical results for comparing observed and computed surface elevations are

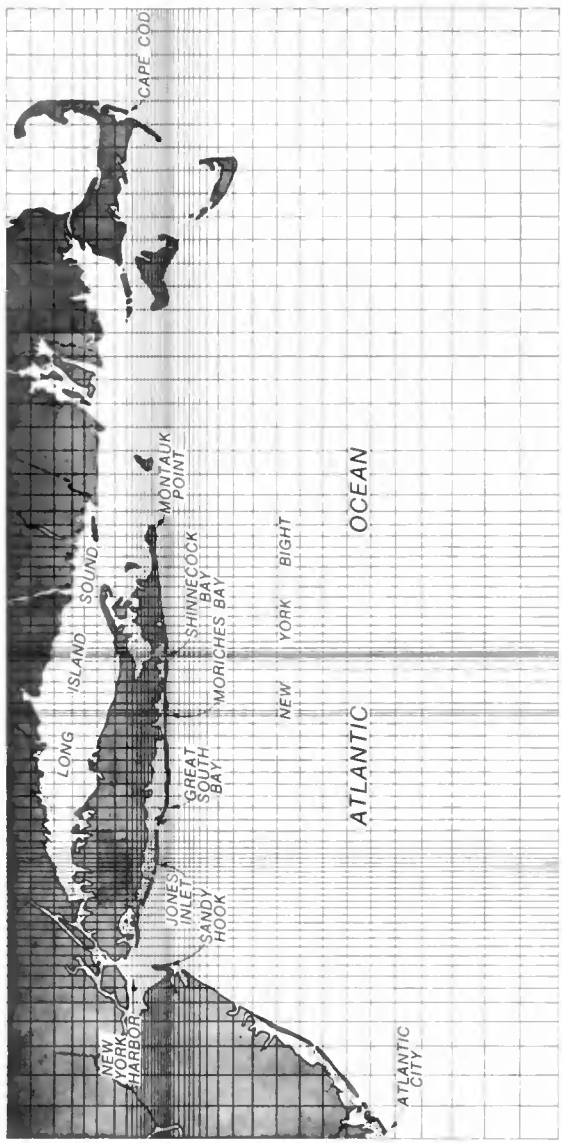

Figure 1. Global grid for storm tide simulations

displayed in Figure 2. Figure 2a shows a comparison of global results to measured data at Sandy Hook, New Jersey, and Figure 2b compares nearshore grid results to measured data at a gage within Great South Bay. Bathymetric and topographic data describing barrier island and inlet configurations for five severe historical storms (hurricanes of 1938, 1954 (Carol), and 1960 (Donna), and the extratropical storms (northeasters) of November 1950 and March 1962) were developed. These storms were hindcasted to verify both the global and nearshore numerical models for storm-plus-tide events.

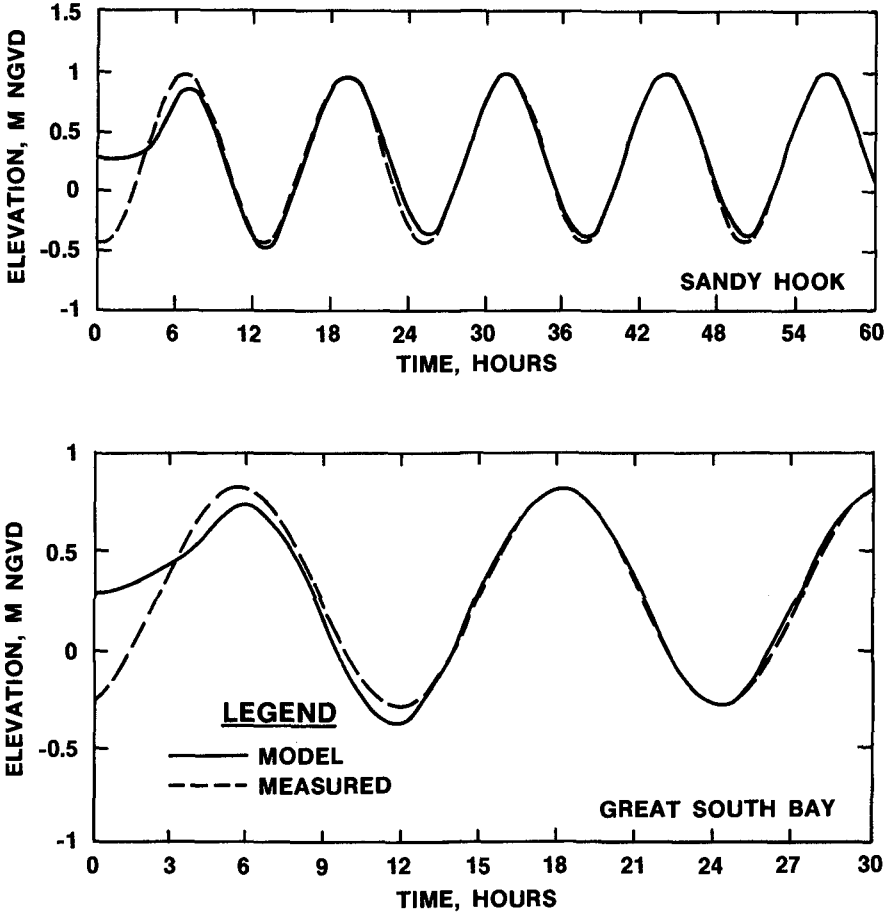

Figure 2. Comparison of global model results to measured data

To provide wind stress from hurricanes to the hydrodynamic model, a parametric model was used to represent the windfield as specified by the Standard Project Hurricane (SPH) criteria (NWS, 1979). Wind speed and direction computed by the SPH model are appropriate to open-coast conditions. The model version used in WIFM permits a reduction of the open-water wind speed at the land-water interface and inland over low-lying land and embayments. For historical northeasters, wind speed and direction and atmospheric pressure were available from archived data (Brooks and Corson, 1984).

Extreme water levels on the coast produce substantial dune destruction and breaching, contributing to higher embayment water levels. In order to simulate these extreme events it was necessary to develop a mechanism to account for dune destruction and breaching. A simple, but deterministic method was adopted to lower the barrier island dunes and permit more water to enter the bays. Using methods given in the Shore Protection Manual (SPM, 1984), an effective water level during wave attack of the dune system is computed and allowed to trigger the lowering (or breaching) of a dune on a cell-by-cell basis. The method was calibrated using historical data from several storms. Destruction/breaching was considered a function of the dune type, height, and base width.

Good comparisons between observed and computed water levels were obtained at open coast gages (Figure 3 displays sample comparisons for Sandy Hook for all five storms mentioned above). Comparison at inland bay gages involve contributions from wave effects and dune breaching as discussed above. Flood potential is increased by the capability of storm-induced waves to enter the inland bays through inlets or over breached dune systems and of waves to develop on shallow inland bays. A method devised by the National Academy of Science (1977) was used to estimate the maximum flood height at inland gages due to surge plus tide plus wave contributions. Table 1 gives an example of comparisons obtained for inland gages spanning the entire nearshore grid domain.

STATISTICAL APPROACH

The two most common approaches to establish frequency curves are called the historical method and the JPM. In the historical method a series of historical events is recreated with pertinent data being saved at necessary grid locations. In effect, it is analogous to operating a "time machine" with the hindsight to know what data to collect and where to collect it. Probability is assigned to each event by a standard ranking method. For the JPM, the storm type is parameterized. For example, hurricane windfields can be defined by three parameters: central pressure deficit (DP), radius to maximum winds (R), and forward speed (F). Then an ensemble of synthethic events is simulated representing those events which are possible in the study area. Probability is assigned to individual events by assigning probabilities to parameter values which determine that event. If the parameters are independent, then the probability of the event will be the product of the probabilities of the component parameters. If dependency among parameters exist, the ensemble is subdivided into sets of events, each containing independent component parameters.

Hurricanes

The JPM approach was adopted to develop hurricane stage frequencies for this study. Five storm parameters were used to describe hurricanes: F, R, DP, track direction, and landfall point. Probability distributions for each parameter were obtained by a thorough review of the historical occurrence of hurricanes in the New York Bight. It was determined that three F's, three R's, six DP's, and five landfall points with three track directions and two track directions for bypassing storms were needed to represent the range of hurricane parameters which could occur. This selection gives a total ensemble of 918 hurricane events to be modeled, each with its own probability of occurrence. The actual number of storm events modeled was reduced. Sensitivity tests determined that water levels resulting from different pressure deficits could be linearly interpolated. Therefore, only two values of DP, values near the extremes of the DP probability distribution, were used in forming the actual computational ensemble of 306 hurricanes.

Northeasters

Because of the difficulty in parameterizing northeasters and the availability of data from frequent storm events, a historical approach was adopted. From previous studies performed for the New York Bight (Myers, 1970; and Camp Dresser and Mckee, 1980) and from historical records, a stage-frequency curve constructed from both northeaster- and hurricane induced water levels show northeasters dominate the higher frequency, lower magnitude events but are generally ineffective in producing the rarer, higher stage events. Consequently, the length of historical record chosen (the 41-year period from 1940 to 1980) is sufficient to adequately cover the area of dominance on the combined event stage-frequency curve.

Historical data from 101 storms over the 41-year span that produced at least a 0.7 m surge at Sandy Hook, New Jersey, were used to develop a partial duration exceedence (PDE) curve. Twenty-seven storms from this set were selected (storms representative of the entire set of 101 storms) and assigned probability masses in proportion to the amount of the PDE distribution each storm is to represent. The mean difference (for the 27 events) between simulated surge elevations and observed values was 8 cm at Sandy Hook and 9 cm at Montauk, New York.

Tide Convolution

Global grid simulations were carried out for surge without tide. Tides were incorporated through the convolution of tidal values with output of the surge-only numerical simulation. This procedure is valid in the open Bight where nonlinear effects of combining surge and tide are negligible. The convolution procedure produced more than 600,000 possible hurricane surge-tide combinations and over 18,000 northeaster surge-tide combinations. These storm-tide event sets were ranked by elevation, and through the use of their probabilities, stage-frequency relationships were developed for open-coast locations throughout the study area.

COASTAL STAGE FREQUENCIES

The surge-tide convolution was performed at all locations in the global grid where a frequency relationship was desired. From these data a probability of exceedence distribution for water levels was developed, from which stage frequencies could be deduced. By adding exceedence probabilities from the hurricane and northeaster curves, the return period between occurrences of water levels equal to or exceeding the specified level from either hurricanes or northeasters were computed. The northeaster storm of record (November 1950) was an outlier for the events chosen. Sensitivity tests on assignment of probability of occurrence for this rare event indicated insignificant impact on the combined stage-frequency curve above the 50-year return period due to the dominance of hurricane events on the longer return periods. Hence, the uncertainty of the return period of the 1950 event will not affect the combined stage-frequency curves in the study area. Figure 4 displays sample combined stage-frequency curves for open-coast locations at Sandy Hook, on the coast fronting Great South Bay, and for the eastern end of the study area (Montauk). Prior to this investigation, a single frequency curve similar to that for Sandy Hook was used for evaluating coastal projects on southern Long Island. These results can reduce costs of future projects by being a yardstick for accurately assessing risk associated with different protection levels. Figure 5 compares stage-frequency curves computed from model results with curves deduced from measurements at Sandy Hook. Historical data used to produce Figure 5 only provide a combined frequency curve out to the 25-year return period.

As stated above, adequately monitored hurricane occurrences are scarce in the north Atlantic Ocean and the development of accurate parameter distributions with limited data becomes difficult. By using a bootstrap technique (Prater, et al., 1984), error estimates on the stage-frequency curve were obtained from the uncertainty of these

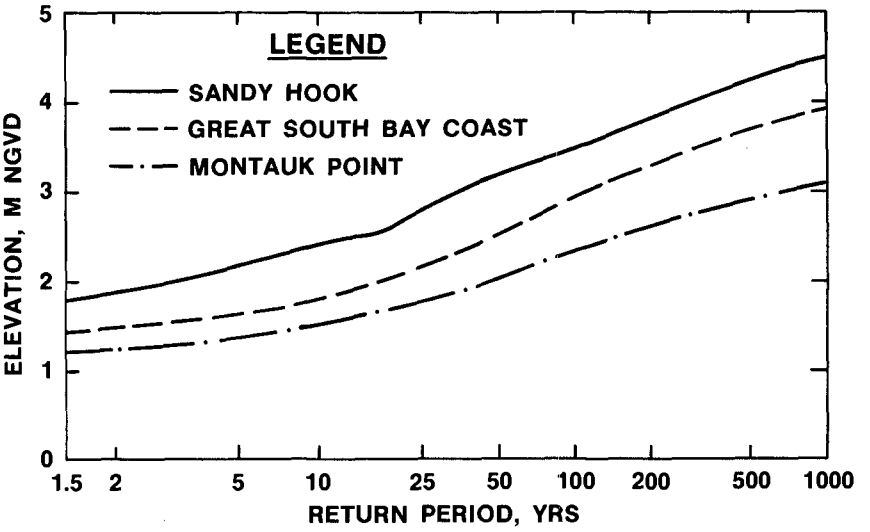

Figure 4. Computed JPM curves for three locations along coastal reach of southern Long Island

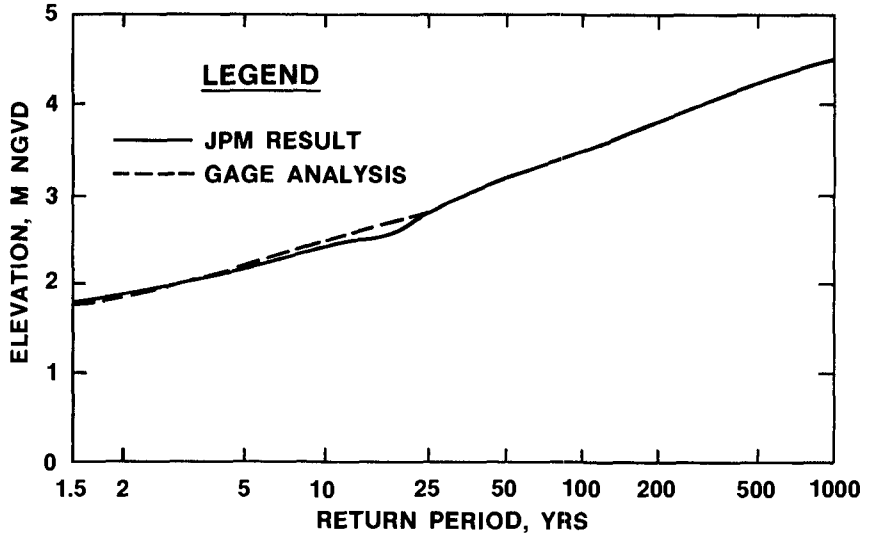

Figure 5. Comparison of computed JPM curve and gage analysis at Sandy Hook, New Jersey

parameter distributions. The procedure consists of assuming the unknown storm population distribution for each hurricane parameter is the same as the parameter distribution obtained from historical information. Synthetic parameter distributions are created by repeated sampling from this assumed population. The variation in the synthtic parameter distributions is due to the small sample sizes. Synthetic stage-frequency curves are then generated by randomly selecting a synthetic distribution for each parameter. About 1000 such curves gave very stable results (little change in final result with increased number of bootstrapped samples) and provided an estimate of error in the selection process. When the process is examined for each return period, an estimate of the uncertainty (due to limited size of sample population) of a stage-frequency curve is obtained (Figure 6).

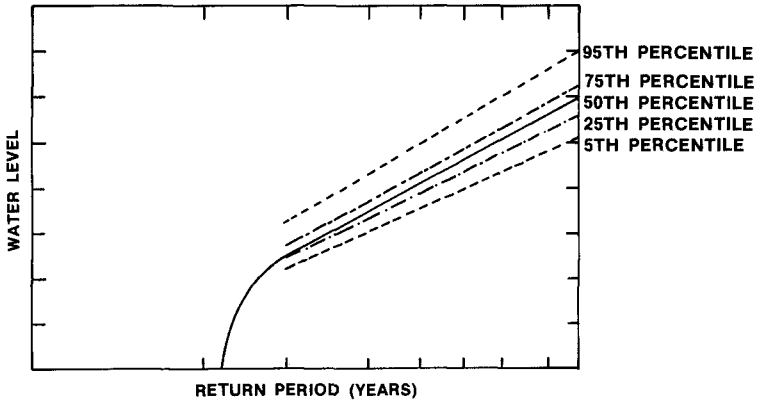

Figure 6. Bootstrapped stage-frequency confidence intervals

INLAND STAGE FREQUENCIES

For nearshore grid simulations, it was necessary to represent the statistics of the thousands of possible global surge-tide events with a much smaller ensemble of events for nearshore simulation. A random sampling of roughly 6000 hurricane-plus-tide events was further reduced to three sets of 17 storm-tide events, with each set chosen to represent a range of storms from moderate to very severe. Weaker events were not emphasized due to the dominance of northeasters for return periods below 50 years. Tests showed that 40 northeaster-plus-tide simulations could reliably represent the full set of extratropical events. Statistical justification in the selection process involves the concept of reduction in dimensionality. Probabilities of each nearshore event were assigned according to what portion of the nearest open-coast stage-frequency curve each event represented. Stage frequencies were developed from results of these simulations. This procedure replaced the typical approach of routing all the open-coast surge events into the back-bay

areas. It provided a clean statistical method to account for the nonlinear effects involved in routing flood waters through inlets and over the barrier islands.

As for the historical storm simulations, the contribution to flood water potential from wave effects was taken into account. Wave set-up estimates were made by applying standard practices in the SPM (SPM, 1984). A procedure was developed which would process previously generated storm simulation output and compute additional bay elevations on a storm-by-storm basis. The accuracy of these results suffers because of the simplifying assumptions made as well as a lack of information available as to the physical processes involved. The results give a good indication of the size of the influence wave setup has on the back-bay stage frequencies. At the 100-year return period, maximum additional water elevation in back-bay areas from influence of wave effects is on the order of 1 m.

CONFIDENCE INTERVALS

Confidence limits on the upper portion of nearshore stage-frequency curves were estimated by observing variability in stage frequencies generated by each of three nearshore sets of 17 hurricane-plus-tide events. The stage frequency curves from these sets were regressed and compared with each other. Assuming for any given return period the calculated stage is a normally distributed random variable, an estimate of the probable error can be calculated using the three stage-frequency curves generated independently from the three sets of selected events. The accepted stage-frequency curve with error bands is formed by processing all 51 events as one set. Figure 7 shows an example of the results obtained for a typical open-coast gage location. Results were presented for specified regions rather than for specific model gage locations. Thus a given stage-frequency curve is applicable, within a specified tolerance level, for a region defined by two endpoints. Regional averages were determined by a weighted average of nearby model gage results. Figure 8 presents an example regional stage-frequency curve for the far eastern region (one of 16 regions) showing the minimum and maximum stages of the data used to develop the curve.

PROJECT ALTERNATIVES

Various project dune heights and other structural alternatives were examined for impact on stage-frequency within the inland bays. Among these were included the 1979 dune configuration, non-overtopping dunes (conservatively built), variable height dune systems design to offer 25-, 50-, 100-, 200-, and 500-year protection, leeved back-bay areas, and inlet and channel surge barriers. Stage-frequency curves for the 1979 dune congiguration were used as a baseline for comparing alternative plan impacts. The non-overtopping dune alternative provided information on the highest level of protection to be obtained in the back bays. A basic result from examining all plan tests is that back-bay flood levels are more effectively minimized by increasing heights of the barrier dune system. Interior channel gates tend to increase flood levels in areas local to the gate. Inlet barriers will reduce surge levels within the gated bay, but unless dune heights are raised inlet gates will not give much protection against severe events. Inlet gates

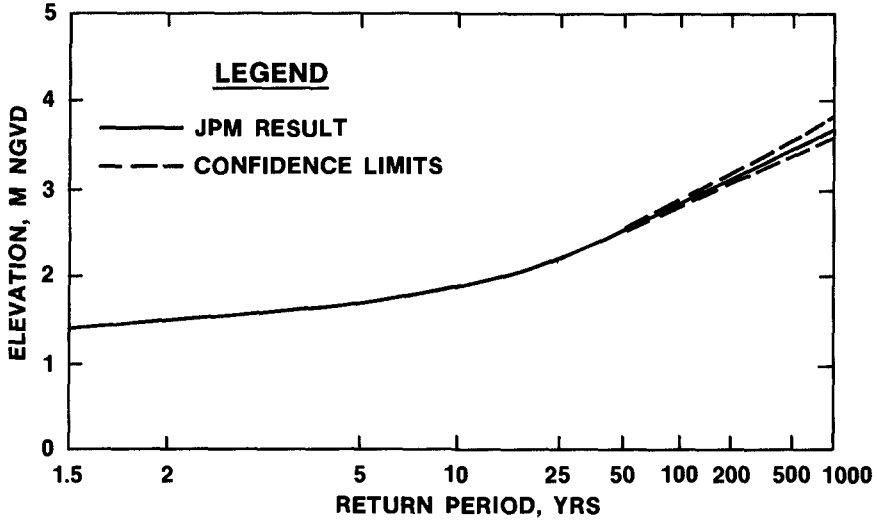

Figure 7. Confidence intervals for the hurricane selection process for a typical open-coast model result

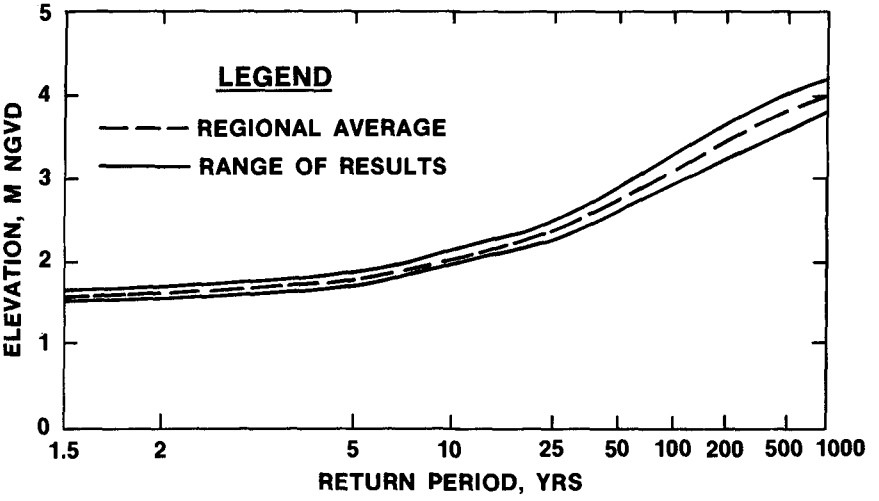

Figure 8. Regional JPM result for southeastern Long Island

do protect against the lower energy events because flood waters are primarily transmitted through the inlets during these events. A plan to levee back-bay areas did not significantly increase bay flood levels.

Variable height dunes were examined by simulating the effect of barrier islands whose protective dune heights are designed according to elevations corresponding to the above mentioned return periods. The design heights include the effect of wave setup. To minimize computational effort, two sets of 17 hurricanes and one set of 13 northeasters (representative storms) were simulated for each of the five alternative barrier conditions. After processing the 25- and 50-year barrier simulations, the number of storms simulated was decreased because the northeaster and several moderate hurricane events have no effect on the higher return period plans. All results were presented in a regional format as exemplified in Figure 8.

SUMMARY AND CONCLUSIONS

A comprehensive investigation of storm-induced flood levels on the southern coast of Long Island, New York was successively completed. Efficient global and nearshore storm surge models were developed to simulate selected storm events. A dune breach model was used to more realistically simulate severe storm events. The most significant development in the progress of the study was the procedure to minimize the computational effort to predict nearshore and inland bay stage frequencies. This procedure permitted economical testing of various alternatives including variable-height dune systems and gated interior channels and inlets. The procedure also permits an estimation of confidence limits in the results. The methods used in this investigation require additonal research, particularly in delineating all sources of error in the estimation of confidence bands. Substantial research is required to accurately simulate contribution of wave setup, wave transmission, and inland bay wave effects. The results from this study also point to the importance of accurately modeling dune erosion and breaching.

ACKNOWLEDGMENTS

The methods developed in this paper were part of a numerical investigation of extreme water levels along the southern coast of Long Island funded by the U.S. Army Engineer District, New York. Permission was granted by the Chief of Engineers to publish this information.

CHAPTER 182

2-D CIRCULATION IN THE SARONIC GULF

George C. Christodoulou[1], A.M. ASCE
Athanassios E. Kouloumbis[2],
Alice O. Aza[3]

ABSTRACT

The paper refers to mathematical modeling of the 2-D hydrodynamic circulation in the Saronic Gulf, in Greece. The finite element method is followed to evaluate the flow behaviour. Two grids are employed, a coarse one for initial model adaptation and a finer one for a more detailed study of circulation patterns. Actual tide data are obtained at the boundary of the domain and a typical compound tide is introduced; however residual tidal currents are found to be negligible. Wind-generated flow fields under several prevailing wind directions are determined and their comparison to qualitative field evidence is satisfactory. Furthermore, a possible surface tilt along the open boundary associated with large scale circulation in the Aegean Sea, is studied and shown to produce significant motion in the Gulf. Based on circulation patterns obtained, preliminary estimates of dispersion from a proposed sea outfall for Athens sewage can be made. Further work proceeds towards quantitative verification of the model in connection with the proper description of forcing mechanisms and their superposition.

INTRODUCTION

The Saronic Gulf is a coastal water body located in the vicinity of Athens, the capital of Greece, as shown in Fig. 1. Due to its location

1 Assoc. Prof., Dept. of Civ. Engrg., Natl. Tech. Univ. of Athens, Athens, Greece.
2 Grad. Stud., Dept. of Civ. Engrg, Mass. Inst. of Technology, Cambridge, Mass., U.S.A.
3 Res. Collabor., Dept. of Civ. Engrg., Natl. Tech. Univ. of Athens, Athens, Greece.

and the natural beauty of its coastlines and islands it has a high recreational value for over 4 million inhabitants of Athens and nearby towns as well as for many thousands of visitors. Besides, it has economic importance associated with a variety of human activities in the area. However, the marine environment has been threatened in recent years due to increasing pollution loads discharged into the water body, coming from domestic sewage, industrial effluents and also ship traffic to and from the port of Piraeus. Environmental concerns have risen in connection with the planning of a new treatment plant and sea outfall for the sewage of Athens metropolitan area, which could provide the opportunity for significantly reducing one of the major sources of pollution of the gulf. In this context it is desirable to examine the large scale characteristics of flow in the gulf, so that the far field impact of substances introduced into it may be assessed.

Up to now the hydrodynamic behaviour of the gulf is not well understood [1]. Despite considerable field measurement efforts undertaken since the mid-seventies the data base is yet insufficient for evaluating the overall circulation. This is so because the gulf seems to be an extremely complex water body, both in terms of geometrical configuration and in terms of flow-generating mechanisms. In fact, in the absence of a strong tide, as is typical in the Mediterranean Sea, several forcing mechanisms are potentially important, resulting in generally weak but highly variable currents.

The complexity of the problem suggests a mathematical modeling approach. As a first approximation a two-dimensional description of the circulation is sought in this paper, through adaptation of pertinent finite element models. The determination of the circulation patterns under a variety of conditions allows an assessment of the major forcing mechanisms. Furthermore, preliminary estimates of the extent of contamination from the proposed new outfall can be made.

PHYSICAL CHARACTERISTICS OF THE GULF

As shown in Figure 1, the Saronic gulf has an area of approximately 2600 Km^2 and is connected to the Aegean Sea through a 42 Km opening at the SE. Its bathymetry and geometry are highly complex, with irregular boundaries and many islands. The two main islands of Salamina and Aegina essentially divide the gulf into three major parts. The outer gulf, at the SE, is connected to the open sea and has depths gradually decreasing from about 200 m at the boundary to 100 m towards the inner gulf. The latter, at the NE, has depths generally less than 100 m and is of major interest from the environmental point of view. Finally the western gulf has a pronounced depth variability, with depths locally exceeding 400 m; its water masses are only indirectly connected to the open sea, being exchanged through the passages north and south of Aegina island with the inner and outer gulf, respectively.

Temperature and salinity measurements taken at various stations in the gulf have indicated that the density distribution over the water column is essentially uniform during the winter season, while considerable stratification develops during the summer. Therefore the assumption of vertically well-mixed conditions, inherent in the implementation of 2-D model-

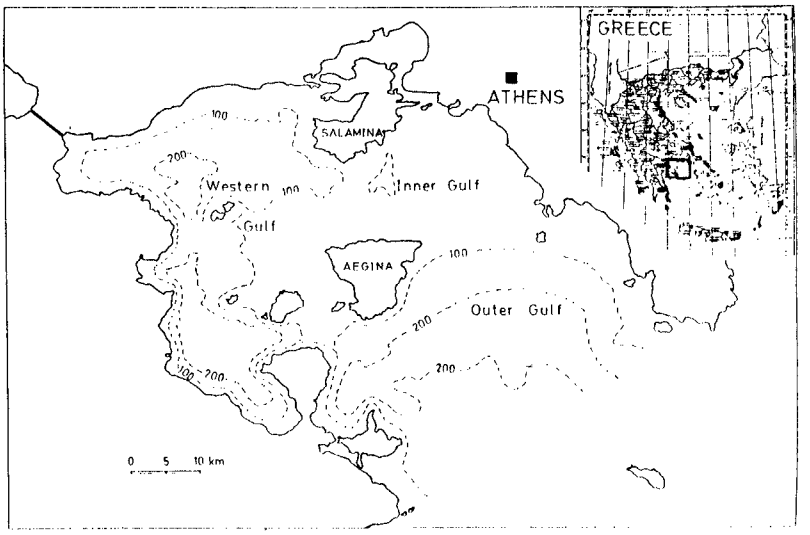

Figure 1. Map of the Saronic Gulf.

ing, is justified by available observations for the winter months, i.e. December to March.

NUMERICAL MODELING

The geometrical complexity of the Saronic Gulf suggests the application of the finite element method. At this stage, a simple and reliable finite element model with linear traingles, code-named CAFE [3], was implemented. The model solves the following depth-integrated equations of continuity and momentum, under the assumptions of constant density and hydrostatic pressure distribution, as described in detail by Wang and Connor [4]:

$$\frac{\partial n}{\partial t} + \frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} = 0 \tag{1}$$

$$\frac{\partial q_x}{\partial t} + \frac{\partial}{\partial x}(\bar{u}q_x) + \frac{\partial}{\partial y}(\bar{v}q_x) - fq_y = -\frac{\partial F_p}{\partial x} + \frac{\partial F_{xx}}{\partial x} + \frac{\partial F_{xy}}{\partial y} + \frac{1}{\rho}(\tau_x^s - \tau_x^b) + \frac{1}{\rho}(p^s \frac{\partial H}{\partial x} - gn\frac{\partial h}{\partial x}) \tag{2}$$

$$\frac{\partial q_y}{\partial t} + \frac{\partial}{\partial x}(\bar{u}q_y) + \frac{\partial}{\partial y}(\bar{v}q_y) + fq_x = -\frac{\partial F_p}{\partial y} + \frac{\partial F_{xy}}{\partial x} + \frac{\partial F_{yy}}{\partial y} + \frac{1}{\rho}(\tau_y^s - \tau_y^b) +$$

$$+ \frac{1}{\rho} \left(p^s \frac{\partial H}{\partial y} - gn \frac{\partial h}{\partial y} \right) \qquad (3)$$

where:

$-h$, n = bottom and free surface elevation with respect to mean sea level

H = $h + n$ = total depth

q_x = $\int_{-h}^{n} u\,dz = \bar{u}H$ = specific flux along x

q_y = $\int_{-h}^{n} v\,dz = \bar{v}H$ = specific flux along y

$\bar{u}$, $\bar{v}$ = depth-average velocities along x,y

f = $2\omega \sin\varphi$ = Coriolis parameter

p^s = atmospheric pressure, acting on the free surface

τ_x^b, τ_y^b = bottom shear stresses

τ_x^s, τ_y^s = surface shear stresses, due to wind

$F_p = \frac{1}{\rho} \int_{-h}^{n} p\,dz - \frac{1}{2} gh^2$ = hydrostatic force relative to $n=0$

$F_{xx} = \int_{-h}^{n} \left(\nu \frac{\partial \bar{u}}{\partial x} - \overline{u'^2} - u''^2 \right) dz$ = integrated internal stress due to molecular viscosity, turbulent velocity fluctuations and spatial deviations of velocity from depth-average value.

F_{yy}, F_{xy} = respective integrals of internal stresses along yy, xy.

The above equations, with proper parametric expressions for the bottom, surface and internal stresses, are transformed through the Galerkin method to a system of ordinary differential equations in time for the unknowns n, q_x, q_y, which is solved by a split-time integration technique [3,4].

The problem was approached at two levels of detail. Initially a coarse grid was used for model adaptation and calibration in the study area and to obtain an understanding of the importance of the forcing mechanisms at minimum computational effort. The coarse grid is shown in Figure 2. It consists of 112 nodes and 160 triangular elements, with a grid size of the order of 2 to 5 Km. Only two major islands are represented, while the narrow passes between Salamina island and the mainland are considered as closed. Subsequently, a finer grid was applied, in order to study in sufficient detail the circulation generated by the dominant forcing mechanisms and further proceed to preliminary estimates of dispersion from the new sea outfall. This finer grid is shown in Figure 3. It consists of 233 nodes and 373 triangular elements, with a grid size ranging from 0,8 to 3 Km, and it includes three more islands.

In both grids, a zero flux normal to all land boundaries was prescribed, while at the open boundary a specified water level variation was introduced. The computational time step for the coarse grid was 100 sec. and for the fine grid 50 sec. The modeling applications were performed on the CDC Cyber-171 computer of NTUA. The computer time required for the simulation of 1 day real time was about 15 cpu min. for the coarse grid and 60 cpu min. for the finer grid.

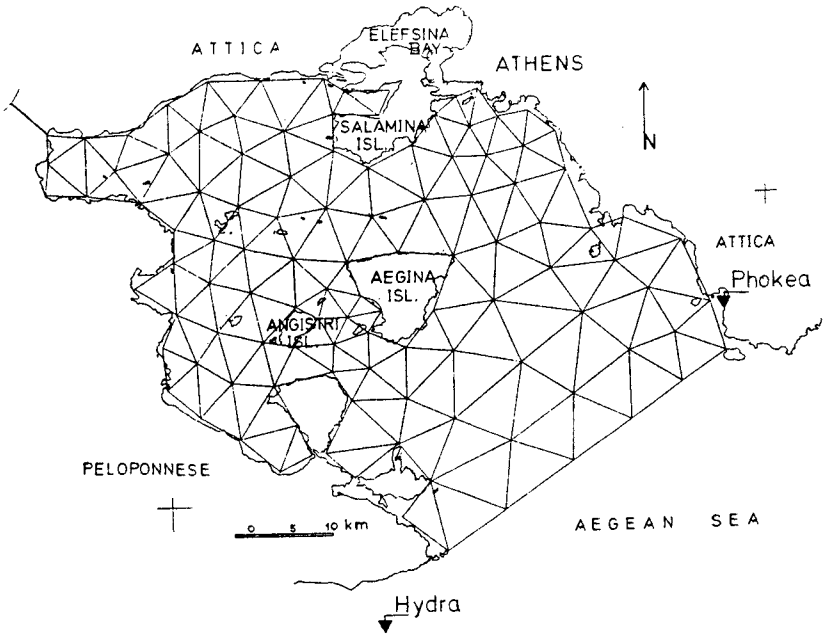

Figure 2. Coarse finite element grid

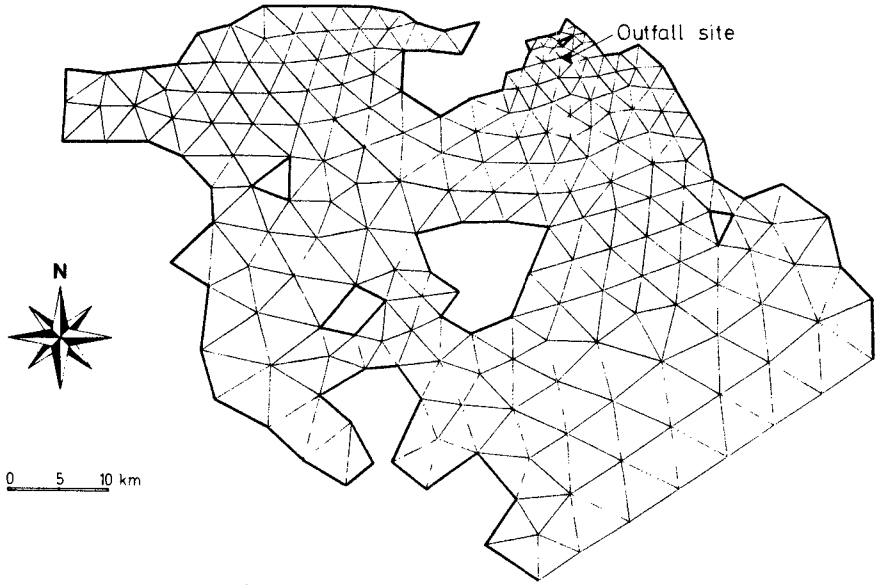

Figure 3. Fine finite element grid

CIRCULATION STUDIES

Coarse grid

Three main forcing mechanisms were examined at a preliminary level with the coarse grid: Tide, wind and a surface filt along the open boundary. In particular, with respect to tide, earlier estimates based on tidal data from Piraeus harbour, at the northern coast of the gulf, have indicated a mean tidal amplitude of about 10cm. Employing such a uniform sinusoidal tidal forcing was found to produce weak and reversing tidal currents resulting in practically no net motion over the entire gulf. In order to determine possible amplitude and phase differences along the open boundary an effort to obtain actual tide data was undertaken. Two self-recording tide gauges were installed near the two ends of the boundary, at Phokea and Hydra, as shown in Fig. 2. Measurements were taken for a period of about three months, from September to December 1984. The half-hourly readings were subsequently analysed by means of Fast Fourrier Transform and harmonic analysis. Four main components were clearly identified, corresponding to two diurnal and two semidiurnal tides, which were found to contain almost all the energy of the signals. These components were then synthesized to produce a "typical" tidal water level variation at the two points, as shown in Figure 4. This typical compound tide of duration 4T= 180,000 sec. was then assumed to repeat itself for numerical modeling purposes. To obtain elevations at intermediate boundary nodes linear interpolation was used at each time step.

As evident from Fig.4, there is a variable elevation difference along the open boundary, therefore some residual currents are to be expected in this case. Figure 5 shows depth-averaged water particle motion obtained for the "typical" tidal forcing acting for 2 weeks. It is seen that appreciable net movement occurs only close to the boundary. Consequently, it may be concluded that tidal flushing cannot be relied upon to reniew the water masses of the Gulf, and especially those of the inner gulf where most of the pollution loads are introduced.

After the above findings, it is clear that the wind-driven circulation should be of primary importance. Still, the resulting depth-averaged currents cannot be very strong due to the relatively large depths of the study area. According to long-term wind records the prevailing winds in the area are from northerly directions. In particular for the winter, excluding periods of no wind, the most frequent wind directions are: N 26.5%, NE 19.0% and S 12.3%. Since reliable wind measurements were available from one station only, a study of uniform wind from several directions over the entire gulf was conducted. In all cases a zero surface elevation at the open boundary was specified. It was found that steady state flow was reached about 1.5 day after the initiation of forcing.

As a third circulation mechanism, a possible small surface tilt along the open boundary was tried. The response of the gulf was found to be quite sensitive to such a forcing. The physical justification for introducing a surface tilt lies in observational evidence of a "permanent" inflow along the eastern coastline of the gulf associated with the large-scale circulation in the Aegean Sea. No quantitative information on this

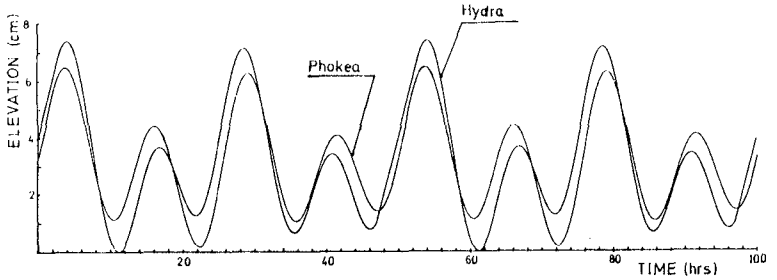

Figure 4. Typical compound tide at open boundary.

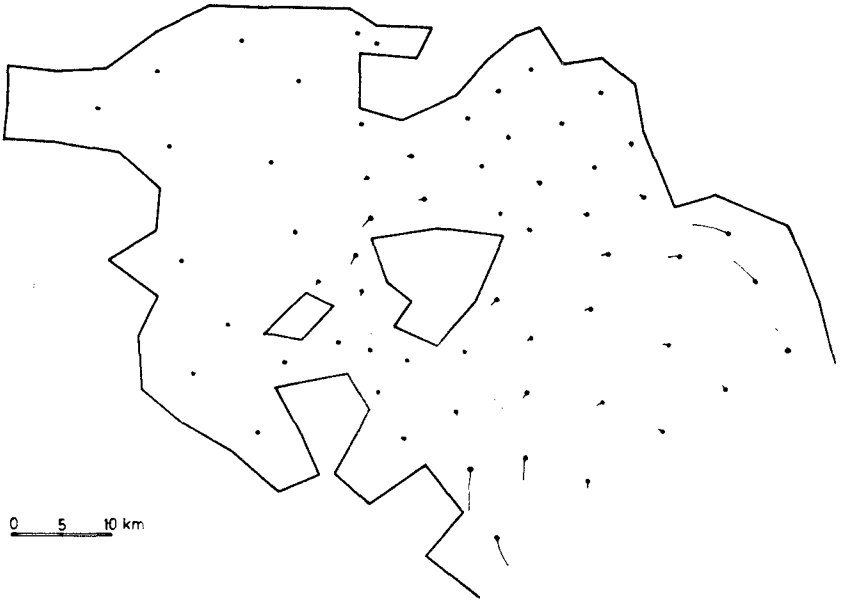

Figure 5. Mean water particle paths under typical tidal forcing for 14 days.

inflow is presently available, and it presumably has significant long-term variability. Yet, its qualitative effect on the circulation of the Saronic Gulf can be possibly simulated by the specification of a higher surface elevation at the eastern end of the open boundary.

Fine Grid

The fine grid was implemented for obtaining more detailed circulation patterns and as a necessary level of discretization for introducing the source of effluent dispersion. With this grid primarily the wind-generated circulation was examined. Figures 6,7 and 8 present the steady-state mean velocity field for the three most frequent wind directions in the study area, that is N, NE and S, respectively. The upper part of each figure, denoted by (a), presents the model results for a constant 20 knot wind, while the lower part, denoted by (b), shows the respective circulation patterns near the surface estimated by Dugdale and Hopkins [2] based on a qualitative synthesis of available oceanographic data and observational evidence at the time.

For the most common north wind the model (Fig. 6a) indicates an inflow from the middle part of the opening and outflow near the two ends. A clockwise gyre develops in the eastern part of the inner gulf and an incomplete counterclockwise motion to its left, leading to outflow towards the western gulf. The upper part of the latter is covered by an extensive clockwise gyre, while a small counterclockwise gyre is seen near the westernmost corner. Two other notable features are the outward coastal current from Athens to the SE and the counterclockwise motion around the island of Aegina. As seen in Fig. 6b the above findings agree reasonably well with the estimates of Dugdale and Hopkins. The major discrepancy lies in the appearance of an opposite current along the northern coast of Aegina, associated with the development of a second, clockwise gyre in the inner gulf.

Results of the model for NE wind (Fig. 7), and S wind (Fig.8) also show generally satisfactory overall qualitative agreement with the respective patterns of Dugdale and Hopkins. Discrepancies are observed primarily in the area between Salamina and Aegina and the adjacent part of the inner gulf. These may well be due to spatial variability of the wind associated with the mountains and other topographical features surrounding the gulf; they could also be caused by local bathymetric detail or even by small horizontal density differences which are not accounted for in the model.

Figure 9 presents the steady-state velocity field for a 1cm elevation difference between the ends of the open boundary. The resulting motion is more pronounced in the outer gulf with inflow at the eastern part and outflow at the western part. An opposite, clockwise, gyre is seen to develop in the inner gulf; flow towards the west is observed in the passage between Salamina and Aegina, while motion continues around Aegina in a counterclockwise sense. It is seen that the effect of such a small surface tilt can be comparable to that of moderate to strong winds and therefore further study is warranted.

Quantitative verification of the model predictions has not yet been made. To this end, limited current meter data obtained at certain locations of the gulf are being analysed; however, preliminary evidence indicates that the model generally underpredicts the velocity magnitude. It is anticipated that satisfactory verification will require further numerical experimentation with improved quantification and superposition of forcing

mechanisms as well as adjustment of some model parameters and boundary conditions.

DISPERSION STUDIES

The dispersion of effluent from the proposed sea outfall was studied with the fine grid shown in Figure 3, where the source is represented by the shaded triangle. The projected annual average discharge of sewage is about $10m^3/sec$. Assuming only preliminary treatment prior to sea disposal, the concentration of coliform in the effluent would be of the order of 10^7 counts/100 ml. Assuming further a decay rate of $k=0.8x10^{-4}sec^{-1}$, corresponding to an average day-night time T_{90}= 8 hrs, and an estimated constant dispersion coefficient of the order of $E = 40m^2/sec$, the dispersion of coliform may be examined for any desired circulation pattern already obtained.

Figure 10 presents steady-state depth-averaged coliform concentration results (in counts/100 ml) under conditions of N wind. It is seen that appreciable concentrations, over 100 counts/100 ml, are confined to a small area around the source, so that no significant contamination of beaches in Attica (to the SE) or Salamina (to the SW) should be expected under the conditions examined. It is further noted that results of other wind cases show little sensitivity of steady-state isoconcentration patterns with wind direction. The above findings strongly depend on the high decay rate used. Evidently, for showly decaying pollutants, e.g. nutrients, the dispersion patterns would be much more extensive and more influenced by meteorological conditions.

CONCLUSIONS

In this paper, the implementation of finite element models for studying the hydrodynamic behaviour of the Saronic Gulf was presented. It was found that wind and a possible surface tilt along the open boundary are of major importance in determining the 2-D circulation in the gulf Actual tide data at the opening were collected and analyzed; yet, the contribution of the tide in the net circulation was found to be negligible. Limited verification with available field evidence was satisfactory in terms of qualitative agreement with model results. But more work is needed on quantitative verification against current meter data, as well as on further examination and quantification of forcing mechanisms, such as the spatial variability of the wind over the study area, the long-term inflow from the Aegean Sea, or any small horizontal density differences that could appreciably change the results of the 2-D circulation. Eventually, the examination of vertical variability will be required for studying the hydrodynamic behaviour under stratified conditions.

The accuracy of circulation patterns will be critical for assessing the dispersion of slowly decaying substances from the proposed sea outfall. However, for fast decaying pollutants, such as coliforms, the extent of appreciable contamination, based on the results presented, is expected to be restricted within the inner gulf.

ACKNOWLEDGMENTS

CHAPTER 183

Numerical Simulation on Thermal Diffusion Concerning Air-Sea Heat Exchange Effects

By

P.C. Chyen[1] C.S. Yang[2]
I.L. Wang[3] H.H. Hwung[4]

Abstract

The numerical simulations on thermal diffusion always concentrated upon the raised temperature and temperature distributions after the heated water discharged from outlet into surrounding water, and the surrounding water temperature was assumed to be a constant. Actually, the water temperature on surface layer in shallow water area varies several centigrade degrees depended upon the weather conditions during a whole day. In order to obtain the absolute water temperature prepared for the ecological changes assessment and even provided for the operation basis of the cooling water system that air-sea heat exchange has to be considered in the numerical simulation of thermal discharges.

For the practical application of this numerical simulation, the first nuclear power plant in Taiwan was taken as an example and simulated in this paper. And the results were presented in figures.

1. Introduction

The temperature rise due to air-sea heat exchange is a important factor on the water body where the warmed water discharged from the outlet of a power plant. We know, different species exhibit different tolerant temperature ranges and are restricted within different temperature zones. Under this condition, as the increase in temperature of water body resulting from the discharge of warmed water and air-sea heat exchange is out of the upper tolerant limits that the species will move away and induce ecological changes.

In general, the thermal discharges can be obtaind from numerical model calculations based on the boundary conditions (topography and water depth of computational domain, tide variation and current motion) and initial conditions (include ambient water temperature , intake and outlet discharge and temperature rise of the outlet). However, the variations of water surface temperature resulting from air-sea heat exchange are influenced by solar radiation, water temperature, air temperature, humidity, cloud and wind action. Now, we take the air-sea heat exchange as a source term in the numerical model that the thermal diffusion concerning air-sea heat exchange effects can be obtained in the simulations. And a practical example on the first nuclear power plant in Taiwan was simulated in this paper.

2. Governing Equations

The hydrodynamic equations and equation of heat conservation used in the model for thermal discharge can be written in time-averaged form:

$$\frac{\partial(\rho u)}{\partial t}+\frac{\partial(\rho uu)}{\partial x}+\frac{\partial(\rho uv)}{\partial y}+\frac{\partial(\rho uw)}{\partial z}=-\frac{\partial p}{\partial x}+f\rho v+\frac{\partial \tau_{xx}}{\partial x}+\frac{\partial \tau_{yx}}{\partial y}+\frac{\partial \tau_{zx}}{\partial z} \tag{1}$$

$$\frac{\partial(\rho v)}{\partial t}+\frac{\partial(\rho uv)}{\partial x}+\frac{\partial(\rho vv)}{\partial y}+\frac{\partial(\rho vw)}{\partial z}=-\frac{\partial p}{\partial y}-f\rho u+\frac{\partial \tau_{xy}}{\partial x}+\frac{\partial \tau_{yy}}{\partial y}+\frac{\partial \tau_{zy}}{\partial z} \tag{2}$$

$$\frac{\partial p}{\partial z}+\rho g=0 \tag{3}$$

$$\frac{\partial T}{\partial t}+\frac{\partial(uT)}{\partial x}+\frac{\partial(vt)}{\partial y}+\frac{\partial(wT)}{\partial z}=e_x\frac{\partial^2 T}{\partial x^2}+e_y\frac{\partial^2 T}{\partial y^2}+e_z\frac{\partial^2 T}{\partial z^2}+S_T \tag{4}$$

and the equation of continuity is

$$\frac{\partial \rho}{\partial t}+\frac{\partial(\rho u)}{\partial x}+\frac{\partial(\rho v)}{\partial y}+\frac{\partial(\rho w)}{\partial z}=0 \tag{5}$$

where e_x, e_y, e_z are thermal diffusion coefficients in x,y,z, directions respectively. And S_T is the source terms of heat content flux per unit mass which includes solar radiation, evaporation, heat conduction and so on.

Now, integrating the above equations from bottom to water

surface, that they could be reduced to a two-dimensional flow motion and expressed as follows:

$$\frac{\partial U}{\partial t}+U\frac{\partial U}{\partial x}+V\frac{\partial U}{\partial y}-fV+g\frac{\partial \zeta}{\partial x}+g\frac{U(U^2+V^2)^{1/2}}{C^2H}-\frac{1}{\rho H}\tau_x^s-(K_{x,x}\frac{\partial^2 U}{\partial x^2}+K_{x,y}\frac{\partial^2 U}{\partial y^2})=0 \quad (6)$$

$$\frac{\partial V}{\partial t}+U\frac{\partial V}{\partial x}+V\frac{\partial V}{\partial y}+fU+g\frac{\partial \zeta}{\partial y}+g\frac{V(U^2+V^2)^{1/2}}{C^2H}-\frac{1}{\rho H}\tau_y^s-(K_{x,y}\frac{\partial^2 V}{\partial x^2}+K_{y,y}\frac{\partial^2 V}{\partial y^2})=0 \quad (7)$$

$$\frac{\partial \zeta}{\partial t}+\frac{\partial (HU)}{\partial x}+\frac{\partial (HV)}{\partial y}=0 \quad (8)$$

$$\frac{\partial (HT)}{\partial t}+\frac{\partial (HTU)}{\partial x}+\frac{\partial (HTV)}{\partial y}-\left[\frac{\partial (HD_x\frac{\partial T}{\partial x})}{\partial x}+\frac{\partial (HD_y\frac{\partial T}{\partial y})}{\partial y}\right]-S_T=0 \quad (9)$$

where

$$U=\frac{1}{H}\int_{-h}^{\zeta}u\,dz,\quad V=\frac{1}{H}\int_{-h}^{\zeta}v\,dz$$

3. Air-sea Heat Exchange

The rate of heat exchange on the water surface can be formulated from the algebraic sum of the rates at which heat is transported across the water surface by solar radiation, back radiation, evaporation, heat conduction and so on, it is

$$Q_v=Q_s-(Q_b+Q_e+Q_h) \quad (10)$$

where Q_v is the net rate of heat perpendicular to the water surface, Q_s is the net incoming radiation, Q_b is the back radiation emitted from water surface, Q_e is the heat loss due to evaporation and Q_h is the heat loss or gain due to conduction. All of the above terms have to be obtained from field measurements and will be described as follows.

Since the reflected radiation from water surface is about 6-8% of the total incoming radiation at 25 degree of the latitude that the net incoming radiation can be expressed as

$$Q_s=0.93Q_{s0} \quad (11)$$

And the back radiation is dependent on air and water temperature, cloud, air-vapor pressure and so on. According to the studies

from Central Research Institute of Electric Power Industry (1974), that the back radiation would be

$$Q_b = 1.32\times10^{-12}\theta_a^4(0.49-0.066\sqrt{e(T_a)})(1-0.65n^2)+5.27\times10^{-12}\theta_w^3(T_w-T_a) \quad (12)$$

where $\theta_w=(273°+T_w°C)$, T_w and T_a indicates the water and air temperature respectively, n is the cloud and $e(T_a)$ is the air-vapor pressure which can be calculated from the relationships of humidity and temperature.

As for the heat conduction, it is easy to obtained as

$$Q_h = K_c(T_w - T_a) \quad (13)$$

$$K_c = 2.77\times10^{-4}(0.48+0.272w) \quad (14)$$

here, K_c is the coefficient of heat conduction and W is the wind velocity. And the heat loss due to evaporation can be estimated as

$$Q_e = K_e[e_a(T_w) - fe_a(T_a)] \quad (15)$$

where K_e is the transfer coefficient of evaporation and its value is about $1.5K_c$. f is the relative humidity, $e_a(T_w)$ and $e_a(T_a)$ is the saturation vapor pressure corresponding to the water and air temperature respectively.

According to the above equations the net heat flux between air and sea water surface can be calculated to provide the numerical calculations.

4. Practical Example

For the practical application of this numerical simulation, the first nuclear power plant located in the northern coast of Taiwan was taken as an example and simulated in this paper. Fig-1 is the schematic diagram of the first nuclear power plant and the location of current measurements. Fig-2 is the tide variation of coastal water around this plant. Based on the field measurements of metorological conditions which provided by Taipower Survey Team that the heat flux hour by hour was calculated and listed in Table-1. The currents boundary conditions were set at the east and west sides of the finite-difference grid domain, but the boundary condition at the south was controlled by tides. The numerical model covered an area of 2.88Km×2.88Km with a grid size of 120m. And the numerical simulations were accomplished throughout 4500 time-steps with a value of time step by 30 seconds. Fig-3∿Fig-5 show the simulated flow pattern on the water area of the first nuclear power plant under no wind condition. Fig-6 ∿ Fig-8 are the flow pattern at the same conditions under 5m/sec wind action. And the corresponding temperature distributions were shown in Fig-9∿Fig-14 respectively.

From the results of temperature distributions, we can see the

ambient water temperature rise is about 3.08^{0}C (the initial ambient water temperature is 25^{0}C) for no wind condition and 3.73^{0}C for 5m/sec wind action.

5. Conclusion

From this numerical model simulations, not only the water temperature rise resulting from the thermal discharges of the power plant can be obtained, but also the temperature rise due to air-sea heat exchange will be calculated simultaneouly. That it is more significant to provide enough information for the assessment of ecological changes before a power plant will be planned.

CHAPTER 184

Effect of Breaking Waves on Dissolved Oxygen and Organic Matter

Yoshihiko HOSOI* and Hitoshi MURAKAMI**

Abstract

Water pollution in the near shore area has become a serious problem in coastal engineering. In such a situation, not only wave dissipation but also the functioning of water pollution control is expected from the coastal structure. Since breaking waves are accompanied by many bubbles and intense water turbulence, they promote the contact between organic matter and bacteria and between water and air. Therefore the water quality related to organic matter seems to change under the effect of breaking waves. In this study the variation of the dissolved oxygen and the organic matter near the surf zone were considered. First, a self purification model in the surf zone was developed. Second, the efficiency of breaking waves on reaeration and organic matter decomposition was estimated by an experiment in the laboratory flume and numerical simulation.

1. Introduction

With the expansion of human activities, water pollution in the nearshore area has increased. Organic contaminants discharged into water are decomposed by aerobic bacteria through their metabolic process, which results in the utilization of the dissolved oxygen. The deficit oxygen is compensated for by reaeration which occures through the water surface exposed to the atmosphere. When the rate of oxygen utilization in the decomposition of organic contaminants is within the limit recoverable by the reaeration, the water environment is maintained under desirable conditions. In that sence, the evaluation of natural purification is important in water quality control. Many studies concerning this have been made in rivers.(O'Connor and Dobbins(1956), Churchill et al.(1962), Dobbins(1964)) However, studies of this kind in the sea are few, because the great dilution within a large amount of water plays a principal role in sea water purification.

In general, water turbulence accelerates the contact between the organic matter and bacteria and also between water and air. Therefore it promotes the decomposition of organic matter and the oxygen absorption. Breaking waves produce many bubbles and intense water turbulence. Thus they seem to play a significant role in water purification near the coast, particularly in a bay or water enclosed by breakwaters, where the water exchange with the outer ocean is relatively limited.

* Associate Professor, Technical College, The University of Tokushima, Minamijosanjima, Tokushima, 770 Japan

** Professor, Technical College, The University of Tokushima

Therefore, if we know the characteristics of the natural water purification caused by breaking waves, we can design artificial coasts or coastal structures from the viewpoint of water quality control.

In this study, in order to examine the effect of breaking waves on water quality, we considered the changes of water quality related to organic pollution near the surf zone.

2. Self purification in the nearshore area

As for the decomposition of organic contaminants in a river, the attached bacteria on the bed are considered to play a more significant role than suspended ones. In the case of the coastal area, there are many sites where attached bacteria can grow, for example beaches, breakwaters and so forth. Therefore we can suppose that organic matter is decomposed there by the activity of attached bacteria. Here we propose a model of self purification near the coast as shown in Fig.1.

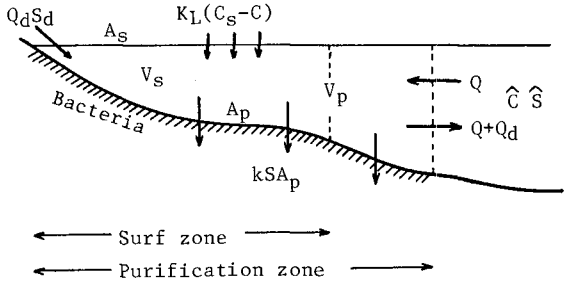

Fig.1 Model of self-purification in nearshore area

The volume of discharged water is represented by Q_d, which includes organic matter whose concentration is S_d. The organic matter is decomposed by the biofilm with the rate of kSA_p. The water volume per unit width in this decomposition zone (which we call in this paper the purification zone) is described by V_p.

The oxygen is supplied through the water surface. As we will describe later, the reaeration efficiency in the surf zone is still greater than that in other areas. Therefore we assume the oxygen is absorbed only at the surf zone whose surface area is A_s.

The mass conservation equations describing the dissolved oxygen and the organic matter are as follows, respectively,

$$d(CV_p)/dt=-kSA_p+K_L(C_s-C)A_s+Q_dC_d+Q\hat{C}-(Q+Q_d)C \quad (1)$$

$$d(SV_p)/dt=-kSA_p+Q_dS_d+Q\hat{S}-(Q+Q_d)S \quad (2)$$

where C and S are the dissolved oxygen concentration and the organic matter concentration, respectinely. $\hat{C}$ and $\hat{S}$ represent the quantities of the outside of the purification zone and C_s the saturated dissolved oxygen concentration. C_d represents the dissolved oxygen in the

discharged water.

We introduce the nondimensional form:

$$C^*=C/C_s, \quad S^*=S/S_r, \quad t^*=t/T \tag{3}$$

where S_r and T are the representative concentration of organic matter and the wave period, respectively.

We rewrite Eqs.(1) and (2) by Eq.(3) as follows,

$$dC^*/dt^*=-k_1TS^*S_r/C_s+k_2T(1-C^*)+TQ_dC_d^*/V_p+TQ\hat{C}^*/V_p-T(Q+Q_d)C^*/V_p \tag{4}$$

$$dS^*/dt^*=-k_1TS^*+TQ_dS_d^*/V_p+TQ\hat{S}^*/V_p-T(Q+Q_d)S^*/V_p \tag{5}$$

where $k_1=kA_p/V_p$ (6), $k_2=K_LA_s/V_p$ (7)

k_1 and k_2 stand for the overall rate constants of decomposition and reaeration in the purification zone, respectively. When the role of suspended bacteria cannot be disregarded, we can include their effects in k_1.

The initial condition is given as follows,

$$t^*=0 : S^*=S_0^*, \ C^*=C_0^* \tag{8}$$

We solve Eqs.(4) and (5) and obtain the following equations.

$$S^*=S_\infty^*+(S_0^*-S_\infty^*)\exp(-\alpha t^*) \tag{9}$$

$$C^*=C_\infty^*-\gamma\exp(-\alpha t^*)+(C_0^*-C\infty^*+\gamma)\exp(-\beta t^*) \tag{10}$$

$$\gamma=(k_1S_r/C_s)(S_0^*-S\infty^*)/(k_2-k_1)$$

α shows water purification efficiency by bacterial decomposition and the water exchange with the outer region, and β shows the efficiency of oxygen supply in reaeration and the water exchange. Each of them are writen as follows, respectively.

$$\alpha=k_1T+T(Q+Q_d)/V_p \tag{11}$$

$$\beta=k_2T+T(Q+Q_d)/V_p \tag{12}$$

The steady state solutions, $S\infty^*$ and $C\infty^*$, are given as follows, respectively,

$$S_\infty^*=F/\alpha=(Q_dS_d^*+Q\hat{S}^*)/(k_1V_p+Q+Q_d) \tag{13}$$

$$C\infty^*=(F+k_2T-k_1TS\infty^*S_r/C_s)/\beta=\frac{Q_dC_d^*+Q\hat{C}^*+k_2V_p-k_1V_pS\infty^*S_r/C_s}{k_2V_p+Q+Q_d} \tag{14}$$

F is the total discharged contaminant load writen as

$$F=(Q_dS_d^*+Q\hat{S}^*)T/V_p \tag{15}$$

The oxygen sag curve obtained by Eq.(10) is shown in Fig.2 and t_1^*, t_2^* and C_{min}^* are given as followas, respectively.

$$t_1^* = \frac{1}{\beta-\alpha} ln \frac{\beta(F+C_\infty^*-C_0^*)}{\alpha F} \tag{16}$$

$$t_2^* = \frac{1}{\beta-\alpha} ln \frac{\beta^2(F+C_\infty^*-C_0^*)}{\alpha^2 F} \tag{17}$$

$$C_{min}^* = C_\infty^* - \gamma \{\frac{\beta(C_0^*-C_\infty^*+\gamma)}{\alpha\gamma}\}^{\frac{\alpha}{\alpha-\beta}} + (C_0^*-C_\infty^*+\gamma)\{\frac{\beta(C_0^*-C_\infty^*+\gamma)}{\alpha\gamma}\}^{\frac{\beta}{\alpha-\beta}} \tag{18}$$

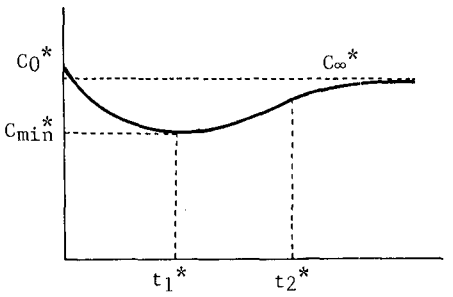

Fig.2 Oxygen sag curve in nearshore area

When C_{min}^* is greater than the critical concentration in which the self purification is possible, the desirable water environment can be recovered. Generally, the minimum DO concentration where aerobic decomposition takes place is said to be 2 mg/l. Thus C_{min} must be greater than 0.15-0.3 (C_s depends on the water temperature and salinity).

In the steady state case, the amount of discharged contaminants into the purification zone is $Q_d S_d^*$ and the amount going out from the purification zone toward the offing is $(Q+Q_d)S_\infty^*$. When we can regard $\widehat{QS}$ as negligibly small compared with $Q_d S_d$, the ratio of both amounts, which gives the purification efficiency, is shown as

$$\frac{(Q+Q_d)S_\infty^*}{Q_d S_d^*} = \frac{1}{1+(k_1 V_p)/(Q+Q_d)}$$

Thus $k_1 V_p/(Q+Q_d)$ is the index which indicates the purification capacity when C_{min}^* satisfies the condition mentioned above.

3. Experimental apparatus and procedure

We examined the behavior of water quality in and near the

purification zone by experiments.

The experiments were performed in a two dimensional wave flume, 14.8 m long, 18.5 cm wide. The water depth was 15.0 cm. The model beach with a plane slope 1/20 was placed in it. Two kinds of experiment were performed as follows.

1) The experiments on reaeration

After the dissolved oxygen (DO) concentration in the flume was reduced with sodium sulfite, waves were generated and broken on the beach. The spatial-temporal DO distribution was observed. The detailed method was reported in Hosoi et al.(1984).

2) The experiments on the decomposition of the organic matter

The aerobic bacteria were added to the water in the flume and waves were generated. Under the presence of waves they were cultured for about 20 days with skim milk fed as a substrate. After the bacteria had grown attached to the sloping bottom, the experiment on the oxidization was conducted as follows.

The initial concentration of organic matter was promoted by skim milk, and waves were generated. The water samples were collected at fixed intervals to capture the spatial-temporal change of DO and the organic matter. The amount of the organic matter was estimated by the chemical oxygen demand (COD) using potassium dichromate.

One series of experiments continued for not longer than 3 days to avoid the influence of the change of biofilm condition.

After one series of experiments was finished, we collected the attached bacteria and observed the biomass and the bacterial activity. The bacterial activity was examined as follows. We put the collected bacteria into a beaker of water which contained organic matter. The water was stirred to suspend bacteria and the temporal changes of COD were observed.

The experiments of 1) and 2) were conducted under some different deep water wave heights.

4. Reaeration

4.1 Theoretical consideration

According to Danckwerts' surface renewal thoery, which explains the gas transfer across the gas-liquid interface in the turbulent flow, the oxygen flux across the interface j and the oxygen transfer coefficient K_L are expressed as follows, respectively,

$$j=K_L(C_s-C) \qquad (19), \qquad K_L \sim (Dr)^{1/2} \qquad (20)$$

where D is the molecular diffusion coefficient. r is the renewal rate which means that water elements near the surface are replaced by the bulk water, and has the dimension of the minus first power of time. It has a close relationship to the turbulent motion.

We assumed the dependence of r on the turbulence as follows (Hosoi et al.(1984)),

$$r \sim (\varepsilon/\nu)^{1/2} \qquad (21)$$

where ε and ν are the energy dissipation rate and the kinematic viscosity, respectively.

If we assume all of the energy which is transported by the wave from the offing toward the shore dissipates in the surf zone, we obtain

$$\varepsilon=g^2H_0^2T/(32\pi V_s) \tag{22}$$

where V_s represents the water volume of the surf zone per unit width.

Placing Eqs.(20), (21) and (22) into Eq.(7), we obtain

$$k_2\sim(T/\nu V_s)^{1/4}(DgH_0)^{1/2}A_s/V_p$$
$$=(T/\nu V_s)^{1/4}(DgH_0)^{1/2}(V_s/V_p)/\overline{h_s} \tag{23}$$

where $\overline{h_s}$ is the mean depth of the surf zone and H_0 the deep water wave height.

If the surf zone has a plane slope, we can say $\overline{h_s}=h_b/2$, where h_b is the breaker depth.

4.2 Experimental results

Fig.3 shows the temporal changes of the dissolved oxygen profile in the experiment on reaeration. The increase rate in the dissolved oxygen is the greatest in the surf zone and becomes smaller as the distance from the shoreline increases.

As we previously indicated (Hosoi and Murakami(1981)), this figure makes us believe that the effect of oxygen absorption in the surf zone is so much greater than in other areas that the oxygen is absorbed only in the surf zone and transferred offshore.

On the basis of this consideration we evaluated the reaeration coefficient (Hosoi et al.(1984)). When we divided the examination area into the boxes as shown in Fig.4, we could obtain the following equation in the i box.

$$dC_iV_i/dt=V_ik_{2i}(C_s-C_i)+q_{i-1}(C_{i-1}-C_i)-q_i(C_i-C_{i+1}) \tag{24}$$

where suffix i represents the quantity in number i box and q_i the water exchange across the boundary between i and i+1 boxes. The box is divided so that the innermost box whose number i=1 becomes the surf zone, i.e., the area between the breaking point and the shoreline, and define the box i=2,3,4,$\cdots\cdots$ in order towards the offing.

Summing up Eq.(24) from i=1 to n, and taking into consideration that the reaeration efficiency in the surf zone is so much greater than other parts that we can neglect their contribution, we obtained

$$d\Sigma C_iV_i/dt=V_1k_{2,1}(C_s-C_1)+q_n(C_{n+1}-C_n) \tag{25}$$

As we saw in Fig.3, the influence of the reaeration in the surf zone did not extend far into the offing. Thus if n-box is taken far from the breaking point where C_n can be regarded as equal to C_{n+1}, Eq.(25) is rewriten as

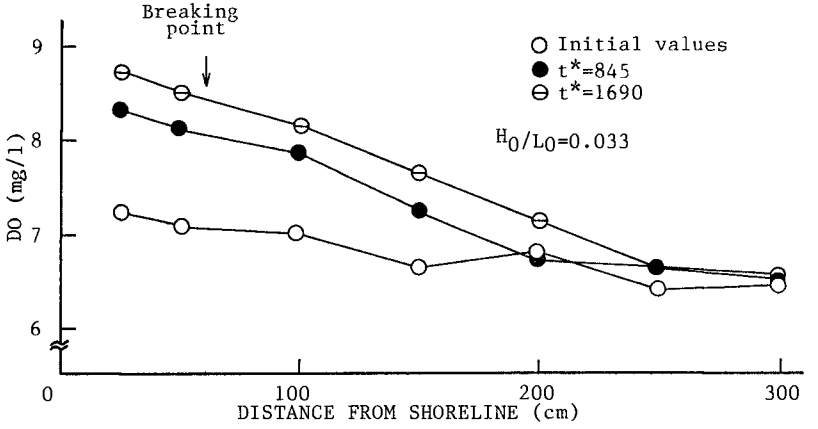

Fig.3 Variation of dissolved oxygen concentration

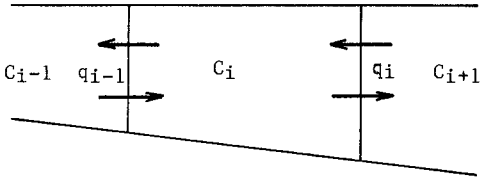

Fig.4 Box model

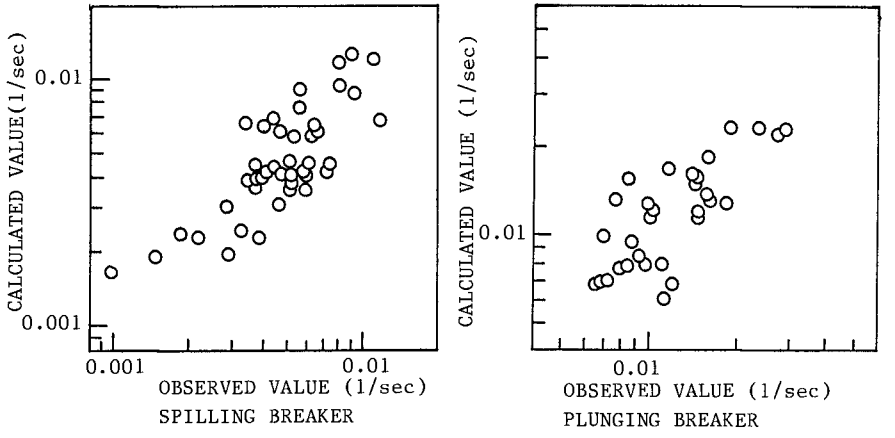

Fig.5 Relationship between observed k_2 and calculated k_2

$$d\Sigma C_i V_i/dt = V_1 k_{2,1}(C_s - C_1) \tag{26}$$

We calculated the reaeration coefficient in the surf zone by Eq.(24) and transformed it to the value at 20°C.

We decided the value of the proportinal constant in Eq.(23) when $V_p = V_s$, from the experimental results. Fig.5 is the comparison between the calculated and the observed values. We obtained the following relation.

$$k_2 = \begin{cases} 0.144(T/\nu V_s)^{1/4}(DgH_0)^{1/2}(V_s/V_p)/\overline{h_s} & \text{(Spilling breaker)} \\ 0.184(T/\nu V_s)^{1/4}(DgH_0)^{1/2}(V_s/V_p)/\overline{h_s} & \text{(Plunging breaker)} \end{cases} \tag{27}$$

The difference in the value of the proportional constant between spilling and plunging breakers is due to the difference of bubble distribution in the surf zone. In spilling breakers, bubbles distribute only near the water surface, while, in plunging breakers, they reach down to the bottom (Hosoi and Murakami(1981)). Thus plunging breakers have a larger area of gas-liquid interface and a greater turbulent intensity than spilling breakers. It may affect the proportional constants in Eq.(27).

5. Decomposition of organic matter

5.1 Variation of COD and DO

The variation of COD and DO is shown in Fig.6. The plane slope extends 3 m from the shoreline, on which there is attached bacterial film.

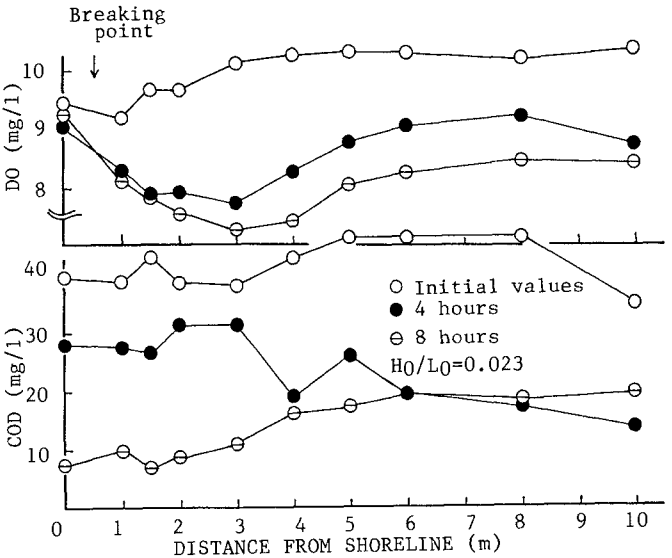
In the case of Fig.6(a), the initial COD is higher near the shoreline. After 2 hours, COD near the shoreline becomes low, but it scarcely changes at the sites far from the shoreline. As a result the COD profile becomes flat. This shows that the decrease in the organic matter is due to the oxidization in the slope area and not to the diffusion to the offing.

With the decomposition of organic matter the dissolved oxygen is consumed. The decline of DO is noticeable near the site 3 m away from the shoreline. As we have already described, oxygen absorption is far greater in the surf zone. Therefore at this point the main source of oxygen is from the transfer from the surf zone rather than the aeration occurring there. Thus the oxygen supply is not so large as compared with the surf zone. Neverthless here exists the slope with a biofilm and here oxidization of organic matter takes place. As a result the oxygen deficit becomes noticeable in this area.

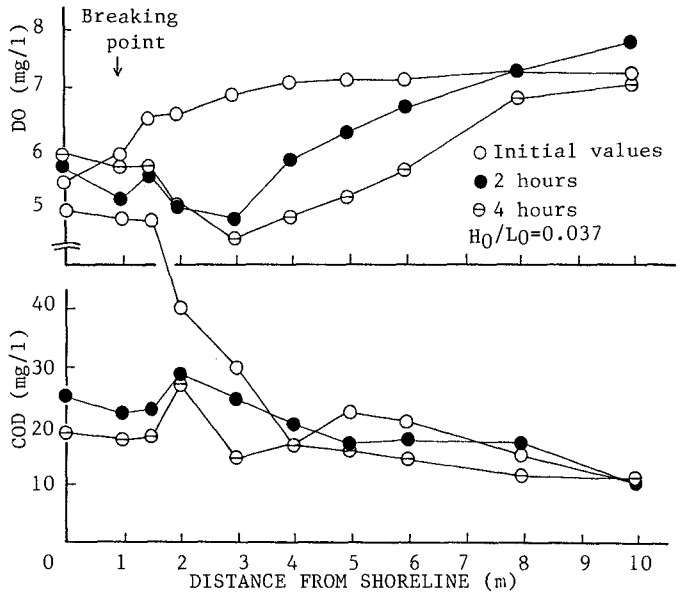
Fig.6(b) is another example which shows that the initial COD is rather uniform from the shoreline to the offing. COD decreases relatively uniformly. The decrease in DO shows the same trend as in the former case. Here again, we can assume that organic matter is decomposed in the slope area and purified water is transfered to the offing.

5.2 Attached bacteria

The attached biomass on the unit area of the slope bottom is shown



(b)



(a)

Fig.6 Variation of DO and COD

in Fig.7. Less biomass grew at the points where wave breaking happened during experiments (0.5-1.0 m away from the shoreline). This shows that the intense turbulence induced by wave breaking prohibits the development of bacterial attachment in the surf zone.

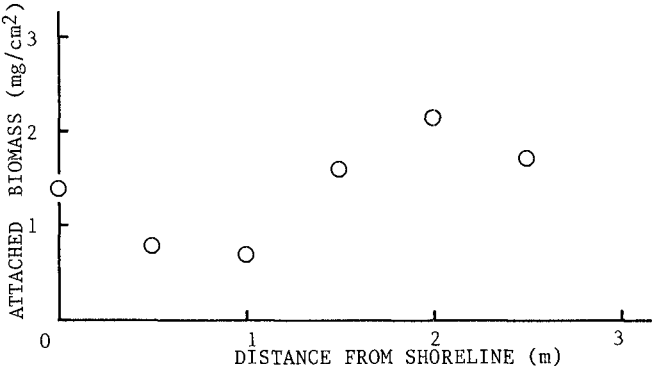


Fig.7 Biomass attached on slope bottom

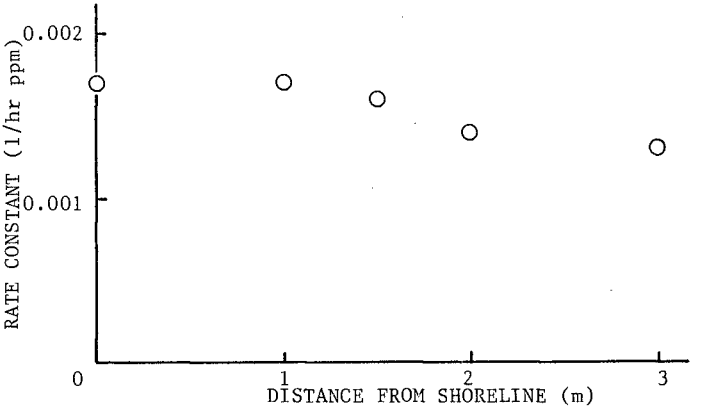

Fig.8 Bacterial activity

The activity of attached bacteria is shown in Fig.8. This shows the decomposition rate to be constant of bacteria suspended in the beaker. There was no significant difference found in the oxidization ability as to the distance from the shoreline.

5.3 Decomposition rate of organic matter on the beach

Generally, the reaction of organic matter oxidization is expressed

as the first power of its concentration. Therefore we write the changes of COD by the following equation.

$$\frac{d}{dt}\int SdV=-kA_pS_p \tag{28}$$

where S_p is the concentration of organic matter in the purification zone. From Eqs.(6) and (28) we obtain

$$k_1V_p=-\frac{1}{S_p}\frac{d}{dt}\int SdV \tag{29}$$

This shows the overall oxidization ability in the purification zone.

Fig.9 shows the relation between the decomposition constant k_1 and the deep water wave steepness. We can see there is a positive relationship. It indicates that the water movement renews the water near the biofilm and promotes the supply of organic matter and DO to the biofilm. It is necessary to examine k_1 in relation to the quantities which represent the water movement structure in the surf zone. Here, however, we obtained the linear relationship shown in Fig.9 for the sake of the next consideration.

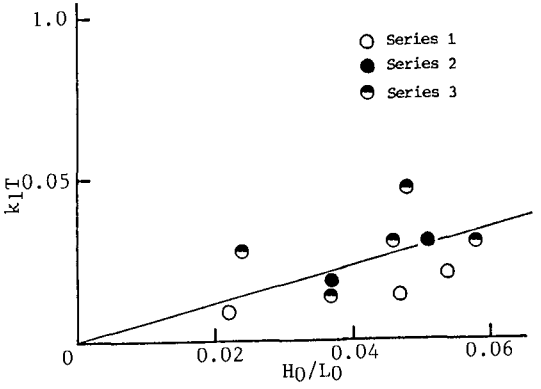

Fig.9 Decomposition rate constant

6. Numerical consideration

In order to consider the effect of incident waves on water quality we used a numerical model. When we take up the box model as shown in Fig.4, we obtain the following equations for DO and COD, respectively,

$$dC_i^*/dt^*=-k_1TS_i^*(S_0/C_s)+k_2T(1-C_i^*)$$
$$+(q_{i-1}T/V_i)(C_{i-1}^*-C_i^*)-(q_iT/V_i)(C_i^*-C_{i+1}^*) \tag{30}$$
$$dS_i^*/dt^*=-k_1TS_i^*+(q_{i-1}T/V_i)(S_{i-1}^*-S_i^*)$$
$$-(q_{i-1}T/V_i)(S_i^*-S_{i+1}^*) \tag{31}$$

where S is transformed into nondimensional form by the initial concentration S_0. The first terms on the right hand side of Eqs.(30) and (31) express the utilization of DO or organic matter through bacterial metabolism. Thus they appear only in the purification zone. The second term on the right hand side of Eq.(30) describes reaeration, and therefore exists only in the surf zone.

The same beach condition as in this experiment was given, i.e., the water depth is 15.0 cm, and the beach slope is 1/20 and there is attached bacteria on the beach.

For the given condition of the deep water wave and the beach slope, the breaker depth was determined by the figure presented by Goda(1970). The wave transformation due to the shoaling effect was calculated by the small amplitude wave theory. The exchanging rate was given with reference to Nadaoka and Kondoh(1982) as follows.(Hosoi et al.(1984))

$$q_i = 0.2\omega\left(\frac{H}{2}\right)^2 \frac{\{1-(H/2h)\}coth kh}{1-(H^2k/8h)coth kh} \tag{32}$$

where H is the wave height, k the wave number and ω the angular frequency with reference to the fixed frames.

The reaeration coefficient was obtained by Eq.(27) and the decomposition rate constant was obtained from the regressive relationship shown in Fig.9.

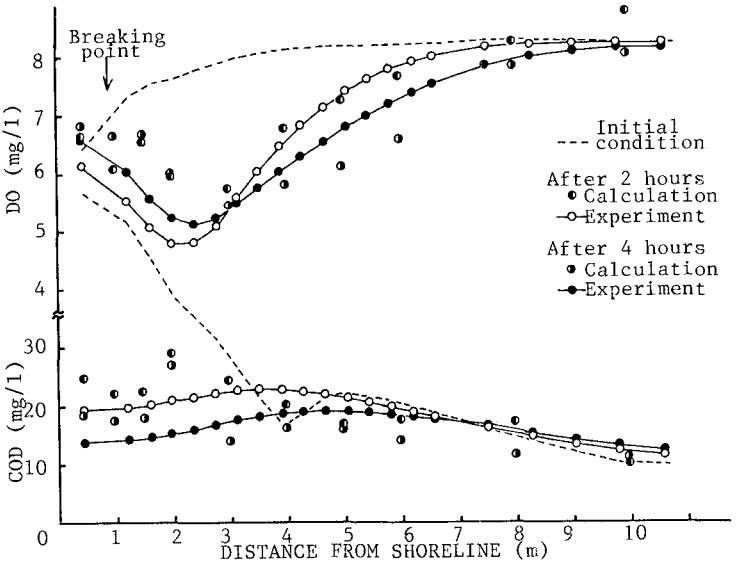

Fig.10 Water quality profiles

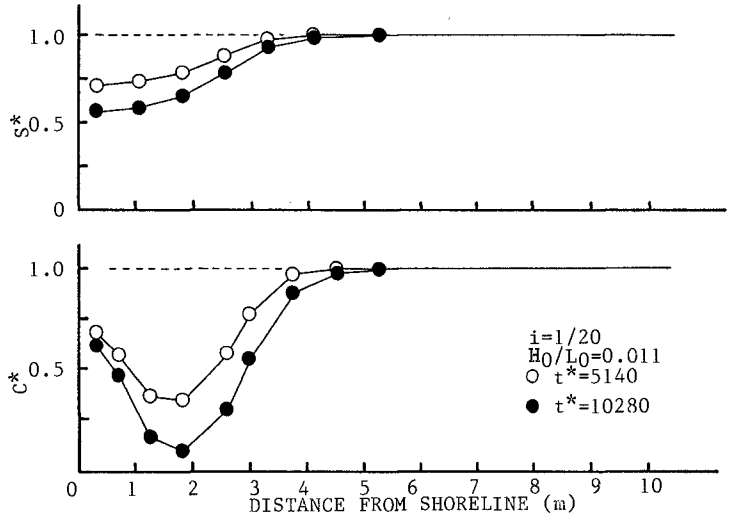

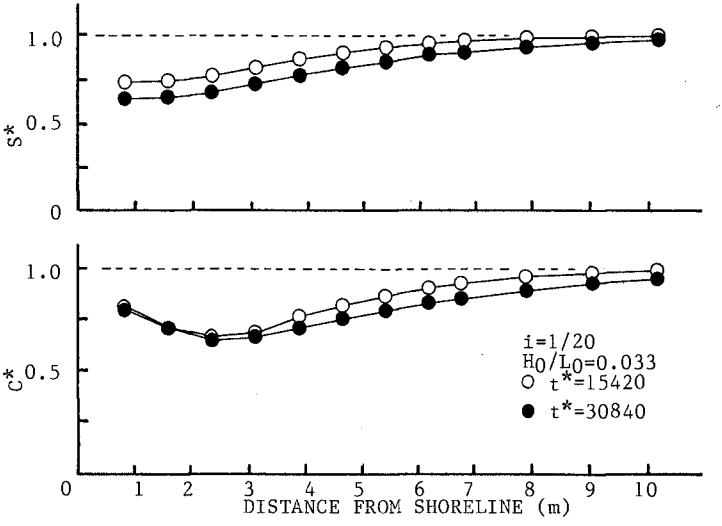

Fig.11 Results of water quality calculation

Fig.10 shows the comparison of water quality profiles between the experiment and the numerical simulation. The simulated results approximately agree with the experimental results. In particular, we could find the feature that DO has a minimum concentration a little outside of the surf zone.

Fig.11 shows the results of calculation under the initial condition that DO is saturated and organic matter distributes uniformly from the shoreline to the offing. In the case of smaller H_0/L_0 (the deep water wave steepness of the incident wave), the area where COD decreases is smaller. The decrease in DO is noticeable a little outside of the surf zone in both cases. When H_0/L_0 is small, the decrease in DO is remarkable and it shifts to the anaerobic condition.

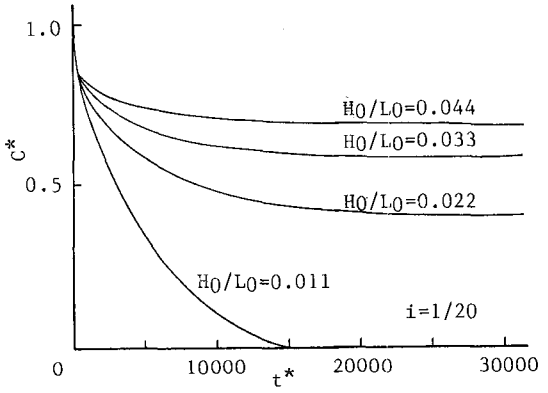

Fig.12 Change of the minimum concentration of the dissolved oxygen

Fig.12 shows the change of DO concentration at the point where it has the minimum value. Under the condition in our consideration, DO is used up completely when $H_0/L_0=0.011$ and the water environment is deteriorated to some extent even when $H_0/L_0=0.022$.

From the considerations so far we suppose that the water pollutant accomodation capacity in the nearshore area can be estimated from the beach shape, the incident wave and the bacterial activity.

7. Conclusions

We have considered the role of breaking waves in water quality near the surf zone. The general expression on DO and organic matter in nearshore area was derived. The variation of DO and organic matter was examined by experiments and a numerical model. Both the relationship between the reaeration coefficient and wave characteristics, and that between the decomposition constant and wave characteristics were shown. At this stage, our conclusion is limited in the experimental flume. The problem of how to apply these results in the field, hereafter still remains.

Acknowledgement

The authors would like to acknowledge the continuing guidance and encouragement of Professor Hisashi Sumitomo, Kyoto University. We were also favored to have the assistance of Tetsushi Iwasaki who contributed his effort to the accomplishment of the experiments and the computer works.

Feasibility Study of Deep Water Port of Taiwan District, R.O.C.

H.-S. HDU
Institute of Transportation, Ministry of Communications, Republic of China

ABSTRACT

Taiwan is now served by five international ports, two of which were newly opened since 1970. They have been under continuous expansion in recent years to meet the needs of the island's burgeoning foreign trade. Due to recent trend of vessel developed to huge load-capacity, the existing port of Taiwan district is inconvenient to the ULCC or VLCC. For decreasing the shipping cost and accomodating the cargo handing of over 100,000 DWT, the deep water port is urgent to be developed in order to promote the competent capability of port cargo handling.

This research is divided into two parts, at first, the prediction of cargo handling and the cargo sources which are adapted to the huge vessel shipping need to be studied for the development of deep water port. the next, then the oceanographical data for the design and the planning of deep water wharf and breakwater need to be surveyed around this Island for possible site of deep water port.

This study deals with the related problems of deep water breakwater construction and discusses how to apply the present design and construction method to the deep water wharf and breakwater. Further analyses are conducted for this research in the coming three fiscal years.

1. Introduction

In general, relatively small ships are employed in the principal five ports except Kaohsiung. The shipping industry has anticipated the nautical restrictions of the ports of Keelung, Suao, Hualien to receive the range of larger ships and the navigational constraints are much less severe than in the other four ports. Nautical constraints have severe effects on the large vessels, the container trade. Special attention is thus required to keep one or two of Taiwan's ports accessible to larger container vessels in the near future. A deepwater port provides Taiwan with several, distinct advantages. First of all, it allows coal transportation by large bulk carriers, resulting in savings in the costs of transport to Taiwan. For Taichung port the additional costs of inland transportation by barge are more than compensated for by these savings; central handling of coal at other deepwater locations would yield approximately the same outcome. Furthermore, the development of a deepwater port, either in Taichung or Keelung or at another location, would enable Taiwan to create or to include the possibility for creating extra port capacity, which could be used to boost the country's transshipment function in containers and bulk commodities. Moreover, it would facilitate Taiwan's

adequate reaction to suddenly emerging trade opportunities in the region. The proposed "Free Trade Zone" would also fit in well with the deepwater port concept. Finally, such a port can provide the special facilities required for the landing of LNG.

2. Research Procedure

1. Research of requirement and capacity of five international trade-ports in Taiwan district
   (a) Reduce all the data of the future developing plan, facilities, wharves and navigational channel, and then evaluate the present and future burdening operation capacity.
   (b) From the economic growth rate and all item products (including in the agricultural and industrial huge plan), based on the import and export cargo guantity of all harbors and then predict the future (10 or 25 yrs) total gross import and export cargo guantity and operation requirements and finally determine the site of deep water port.

2. Research of the field survey and investigation of the alternative sites of deep water port.
   (a) Investigate and measure all the occanographic data including wind climate, offshore waves, currents, bathymetry, tide, geotechnical conditions and the tansportation system around the hinterland.
   (b) Based on the Taiwan district and international cargo transportation and transshipment, and deal with the requirement guantity of harbor, for considering the long-term developing of port policy, and then the scale of the deep water port and engineering feasibility is determined.

3. Study Under Going

To promote the port integrated development of the Taiwan district, it is suggested that the deep water port construction is necessary in the very near future for the demand of coal import as shown in Table 1. and stevedoring of the large container vessel. To this end, the feasibility study of deep water port of Taiwan district is initiated and studied by the Institute of Transportation, Ministry of Communications and therefore, the author is appointed to take charge of the project research of the deep water port of Taiwan district. This is the first phase study of the project.

The research is divided into three parts. The first part is to study the capacity and requirement of five international ports and predict the future demand, now this part of preliminary study is completed. The second part is based on the study of the first part, if the future demand is required, the result show a positive answer, therefore, the excavation of the deep water port is necessary. So the hydrographic survey and oceanographic measurement is planned and will be under way in the coming fiscal year. The collection and analyses of data on its conditions are necessary for this phase study.

The third part is then proceeded to the harbor planning and detail design. Therefore, the feasibility study will be the base for the future deep water port construction.

4. Coal Terminal is a Part of Deep Water Port

Based on the income requirement of the future coal import until 2000 D.C., in the eastern Taiwan district, coal import to Hualien harbor and then distributed to coal required plants. Accomodation of the construction of coal terminal of the Hualien harbor it does meet the requirement. In the northern Taiwan district, import from Su-Ao harbor could accomodate the civil use, and the coal restoration center of Su-Ao harbor area has much space to use. Therefore, there is no need of any harbor extension for the purpose of coal import either in Hualien port or in Su-Ao harbor.

In the middle of Taiwan district, Taichung harbor could be enlarged as the large scale of coal port. Since coal supplied to Seng-Ao power plant, Linkou power plant and Taichung thermal power plant (under construction) etc., need to use Taichung port coal terminal as the transshipment station. For the demand of huge coal carrier, it is economic to select the vessel of 200,000 DWT or over (See Table 2 & 3) Then, coastal shipping system is need to be planned for transshipment of coal to the above mentioned area. For constructing the deep water coal port, it would be a good idea to take the coal port as the coal storage center and then transferred by coastal shipping or inland transportation toward the concumption unit or power plant as shown in Fig.5. The alternative deep water harbor sites are 1.)the outer area of Taichung port industrical water front, dredging the outer navigational channel and reclaiming the coal wharf space., the layout of the Taichung deep water port is shown in Fig. 1. 2.) An offhore island of the Wai-San-Ding Sand Barrier, is planned as a deepwater coal terminal., the layout is shown in Fig. 2. 3.) Hsin-Ta thermal power plant or LNG terminal will be another deep water port site. 4.) For the northern port site Taoyuan coast offshore area including the single mooring buoy (SMB) for oil unloading toward Taoyuan oil refinery plant will be also the alternative harbor site of deep water port., it is shown in Fig. 4. For the above harbor sites, their orientation and arrangement are determined by using the typhoon attacking track (see Fig. 9) and wind rose and wavedistribution as shown in Fig 10 a & b). Coal import and shipping cost are also analyzed as shown in Fig. 6 & Fig.7 o

5. An Idea of a Central Deepwater Port

The main characteristic of a deepwater port is its ability to permit large vessels of over 100,000 DWT to enter the port by virtue of its depth, entrance channel, turning basin and other special provisions. The primary advantage of a deepwater port lies in its capability to receive large bulk carriers, thus reducing shipping costs for the commodities considerably. The lower handling cost per unit of cargo is, the higher flexibility of a large terminal will be. Therefore, the large investment required for opening up and developing a deepwater port makes it necessary to adopt policies to concentrate

the handling of certain commodities as to make the port feasible by the savings thus gained.

For a deepwater port of the Taiwan district, it may be of interest for the extended quantities of coals (see Fig. 8) and containers (Since Keelung port is conjested) to be handled in the near future. A deepwater port would create a large, additional capacity, which would serve as a buffer for Taiwan port developments which cannot be foreseen at this moment. It may become possible to concentrate the capital outlays in one location and to construct, at a lower level of total costs, a safe and well-designed deepwater port instead of having a number of ports complete for the status of deepwater port ---- at a far higher combined cost ---- a status which most of the ports can never attain as a result of their physical and hinterland limitations.

Transshipment of containers, fertilizer and other products are considered as potentially promising port activities of Taiwan district. If transshipment for the East or South-east Asia region is to play an important role, an additional amount of port capacity is to be created over, Taiwan may be called upon to take over one or more port and economic functions from Hong Kong. In the future, Taiwan will import LNG for which a port with relatively large dimensions would be required.

The combined effect of these arguments, an investigation into a possible deepwater port of Taiwan district is warranted to be necessary.

5. Economical and Technical Adaptability of the Proposed Deepwater Harbor Sites.

A. Domestic transportation patterns of export and import commodities

In order to carry out system analysis of the proposed deepwater harbor sites from the viewpoint of transportation economics, domestic transportation patterns of export and import commodities must be estimated. For this purpose, it is desirable to investigate the commodity flow in detail, and to make up the tables of origin and destination. Thereafter, regional demand for international cargo transport is estimated on major items of export and import by above-mentioned pattern.

It is difficult to assume that the present pattern of regional distribution can be applied for the future without adjustment, but the changes are considered to be usually gradual. Our investigation based on present pattern, and modified cases are also calculated for check.

B. Study on proposed deepwater harbor sites based on transportation economics.

The investigation made clear that all the four sites are technically feasible and can reasonably be taken up as alternatives.

Thereafter, adaptability of each proposed site is divided by her locational characteristics as a deepwater port.

C. Natural conditions at the proposed deepwater harbor sites.

For the field occanographic measurements, it is scheduled to be surveyed for the coming fiscal year, the items is listed as follows:

(1) Hydrographic survey: The deeper part from - 20M to - 30M or - 20M to - 40M need to be thoroughly surveyed. Since for the previous data, even nautical chart, there is not so detailly described.

(2) Coastal morphological investigation: The measurement includes the shoreline change, and topographic change of the nearshore area.

(3) Geotechnical investigation: Subsurface boiling, soil sampling and foundation exploring are included.

(4) Wind, wave and current measurements: The offshore measurements are emphasized in each proposed deepwater harbor site.

(5) Coastal hydrology survey: The survey consists of measurements of water temperature, salinity, concentration, conductivity etc., for sufficiently analyzing horizontal & vertical distribution.

(6) Tidal records: This measurement need to be long-term records, at least one-year continuous record.

(7) Sea-bottom topographic change process: The survey need be detailly measured for realizing the deposition and scour around the proposed deepwater harbor sites, especially, for evaluating the littoral transport rate of the harbor sites.

(8) Seismic measurement: Geological distribution of deep layer of the sea-bottom need to be surveyed in detail. For complete seismic survey of the deepwater harbor sits, the design of breakwater and wharf could be carefully considered. The construction of those harbor structure will be safe.

From the above measurement and investigation, the natural conditions of the proposed deepwater harbor sites could be compared, the best conditions of the harbor site is then determined.

CHAPTER 186

Shore Protection Plan for the Nile Delta Coastline

A.L. Kadib, Member, ASCE[1], A.T. Shak, A. Member, ASCE[2], A.A. Mazen[3], and M.K. Nadar[4]

A Shore Protection Master Plan (SPMP) for the Nile Delta Shoreline, extending from 30 kms west of the city of Alexandria (Arab Republic of Egypt) to 30 kms east of Port Said, is developed and reported. The SPMP was developed in three stages: (1) collection and analysis of relevant data to identify existing and future coastal problems and limits of needed shore protection, (2) development of shore protection alternatives with costs and economic evaluations, and (3) detailed design and technical specifications for the selected shore protection schemes along the SPMP zone. This paper summarizes Tetra Tech, Inc./Honeywell work and achievements on this project while under contract with the Egyptian Shore Protection Authority (SPA). The SPMP considered the Egyptian Government and the SPA national needs to the year 2000.

Introduction and Background

The Nile Delta coastline extending from the western borders of the city of Alexandria to the eastern side of the Port Said (see Figure 1), is presently experiencing some coastal changes. The existing two branches of the River Nile (Rosetta and Damietta) have succeeded over the years in forming two natural sea defense protrusions by depositing a rich supply of sediment load from each branch. In the previous century, the supply of sediment exceeded the natural losses due to wave and current action, and thus resulted in relative land gain from the sea. This trend was reversed around the turn of the 19th century with observed losses from both protrusions.

The principal cause of the shoreline changes presently occurring along the Nile Delta coastline is generally accepted to be the loss of sediments resulting from the construction of control works along the River Nile. Chronic erosion was first observed at the end of the 19th century at several important points along the coast, including the promontories at the mouths of the Rosetta and Damietta branches. This erosion continued during the first half of the 20th century, coinciding with the installation of the first dam at Aswan and the development of

other dams and barrages, and the increasing diversion of river water for irrigation.

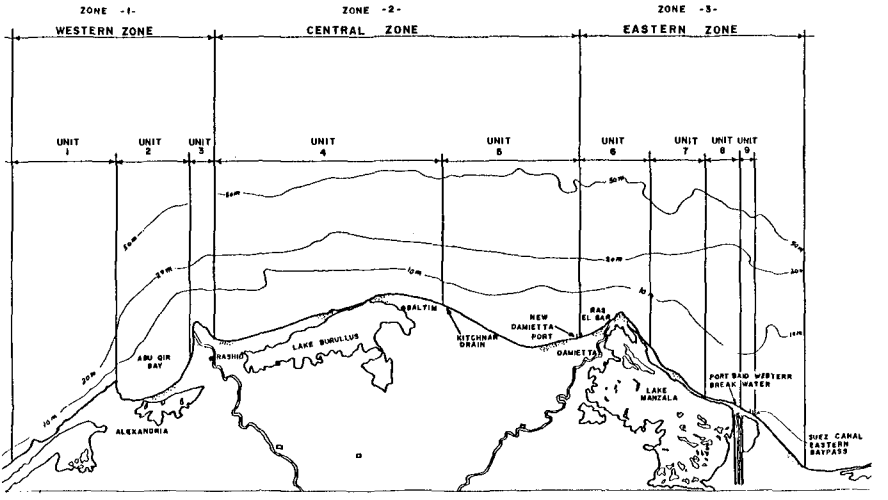

Figure 1. Shore Protection Master Plan Zones and Locations

After the completion of the Aswan High Dam in 1966, erosion along some locations of the Delta coastline accelerated. This erosion has resulted in the loss of resort beach property and flooding of coastal villages. Economic damage to date has been substantial and further serious economic loss is expected if erosion is not controlled. Figures 2 and 3 give examples of the shoreline changes along Rosetta Promontory since 1800 to 1983 (Tetra Tech Progress Report No. 1, ref. 1).

In recognition of the importance of the coastal zone, the Egyptian Government quickly instituted a plan to conduct studies and formulate approaches to manage shoreline erosion. The agency within the Egyptian Government which oversees shore protection projects is the Shore Protection Authority (SPA) of the Ministry of Irrigation formed in 1981. The SPA's responsibilities cover:

1) Planning and design of shore protection works for both short- and long-term considerations.
2) Maintenance and repair work for existing coastal structures.
3) Development and implementation of a shore protection Master Plan for the Nile Delta Coast.

To understand, quantify and assess the recent changes along the Nile Delta Coastline, the Egyptian Government has undertaken many studies since the early 1960's. In 1971, this effort was greatly enhanced when the Egyptian Government secured assistance from the United Nations

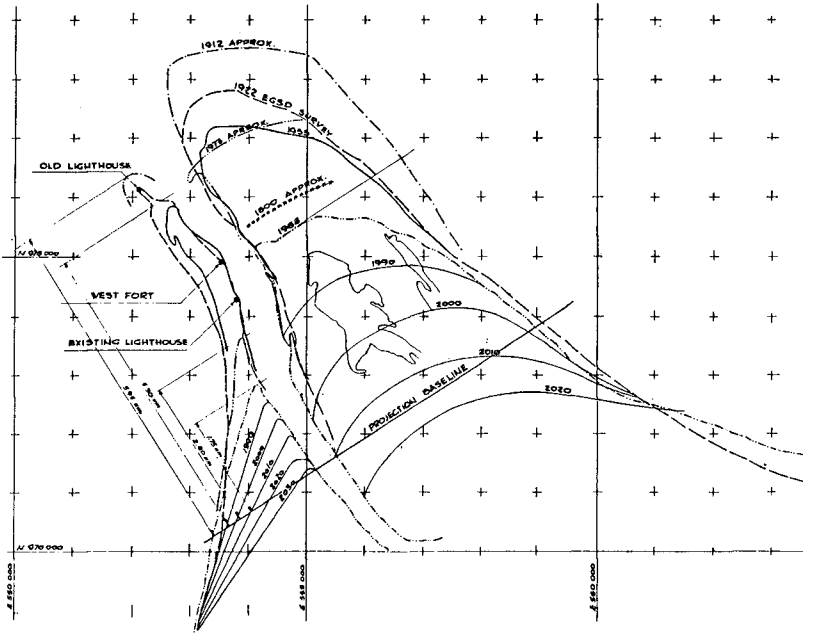

Figure 2. Shoreline Changes along Rosetta Promontory (1800-1983)

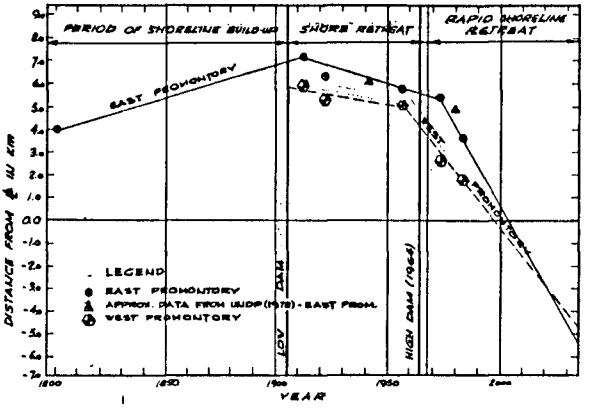

Figure 3. Effect of the Aswan Low and High Dams on Shoreline Changes at Rosetta

Development Programme (UNDP). The UNDP project, which lasted for seven years (1972-1978), conducted geographical, geological, geomorphological, oceanographic, meteorological and hydrodynamic studies of coastal processes along the study area. Coupled with the above effort, the Egyptian Government created the Coastal Research Institute (CRI) to act as the focal point for collection, analysis and monitoring of field information. The CRI has assumed additional responsibilities to assist in the planning and design of a number of shore protection projects along the Delta Coast.

Since its initiation in 1981, the SPA has undertaken many shore protection and maintenance projects and in 1984 awarded a contract to Tetra Tech, Inc. of Pasadena, California, U.S.A., to develop a Shore Protection Master Plan for the Nile Delta Coastline, which is the subject of this paper.

Overall Objectives and Tasks

The objective of this project is to prepare a Shore Protection Master Plan (SPMP) for the Nile Delta Shoreline to manage existing and projected shoreline erosion problems to the year 2000, with special attention to some specific and critical areas such as the Alexandria Coast, Rosetta Promontory, Burullus inlet, Baltim Beach, Ras El Bar, and the coastal strip from Damietta to Port Said. This plan is developed through tasks which were carried out in four stages:

Stage 1 - Collection and Review of Relevant Data
a) Review and evaluation of available data.
b) Detailed field reconnaissance survey.
c) Identification of additional data necessary for the development of the Shore Protection Master Plan.
d) Data analysis and problems definition.

Stage 2 - Preparation of Alternative Shore Protection Schemes
a) Development of alternative shore protection schemes.
b) Assistance to the SPA in the economic evaluation of alternative schemes.
c) Selection of viable shore protection schemes (by SPA).

Stage 3 - Detailed Design of Selected Schemes
a) Elaboration on the detailed design of the selected schemes with technical specifications and tender documents.
b) Identification of needed physical models.

Stage 4 - Final Report
This includes preparation of a comprehensive report describing the detailed aspects of the Master Plan resulting from the analysis of the above activities covering design documents and technical specifications for the selected schemes.

Establishment of SPMP Zoning

Development of the Shore Protection Master Plan for the study area considered three main factors: (a) the existing coastal problems, (b) the proposed uses of the coastal areas; and (c) the physical changes

within each area due to natural and "man-induced" morphological changes. Based on the analysis of these factors, the SPMP was divided into three main planning zones and a number of sub-zones as depicted in Figure 1 and summarized below:

a) Western Zone
The Western Zone extends from Alexandria Western Harbor to the Rosetta Promontory and includes: Alexandria Western Harbor, Alexandria Eastern Harbor, Alexandria Beaches, Montaza Cove, Mamura Beach, Abou Quir Point and Abou Quir Bay and Rosetta Promontory.

b) Central Zone
The Central Zone extends from the east of the Rosetta Promontory to the new Port of Damietta and includes: the saddle area east of Rosetta to Burullus Estuary, Burullus Inlet, El Burg Village, Baltim Beach, 45 kms reach between Baltim and Gamasa and the 20 kms reach from Gamasa to Damietta Port.

c) Eastern Zone
The Eastern Zone extends from the new port of Damietta to 30 kms east of the Port Said area and includes: the new port at Damietta, Ras El Bar Beaches, Damietta Estuary, Damietta Eastern Promontory, Lake Manzala Coastal Barrier, El Gamil area, Port Said Beaches, Port Foad Beaches and the area east of the Suez Canal Eastern Bypass.

Problem Identification

An important aspect of the SPMP development, is the identification of the existing coastal problems along the different planning zones and sub-units. The areas with specific shore protection needs were identified and their problems summarized in Table 1.

Table 1 Summary of SPMP Existing Problems

Planning Sub-units	Specific Problem Definition
	1) WESTERN ZONE
Alexandria western harbor	No major shore protection problem identified.
Alexandria Eastern Harbor	Mooring problems and wave overtopping of parts of the Corniche during storm wave activity.

Table 1 (Continued)

Planning Sub-units	Specific Problem Definition
Alexandria Beaches,	1) Shatbi/Ibrahimiya Lack of recreational beach area due to narrow beach width.
	2) Camp chezar beach Local scour and storms wave action is being corrected by the placement of 1.8m concrete blocks. This effort should continue.
	3) Stanley beach Lack of recreational area and heavily congested beach during summer seasons.
	4) El Asafra beach Recreational and bathing beach areas are very narrow or non-existent.
	5) Mandara beach Beach widths fronting the cabins are narrow and the beach is heavily congested during the summer season.
	6) Montaza Cove a) Inadequate bathing beach area. b) Debris pollution problems adjacent to the Palestine Hotel.
	7) Mamura beach Beach widths are adequate for recreational uses and no erosion problems are identified, however, monitoring is recommended.
Abou Quir point and Abou Quir Bay	1) Abou Quir beaches The beaches are narrow and suffering from the ongoing pollution caused by unauthorized dumping of sewage.
	2) Idku Outlet Sedimentation problem along the navigation channel was corrected by the 2 groins constructed in 1985. Future performance of the outlet should be monitored to evaluate project effectiveness.
	3) Mohamed Ali Seawall Maintenance and monitoring of the existing and ongoing protection is essential for this industrialized area.
Rosetta Promontory	The Rosetta promontory has experienced severe erosion since 1966 and beyond. In 1986 the SPA started a shore protection project using dolosse and stone protection.

Table 1 (Continued)

Planning Sub-units	Specific Problem Definition
	2) CENTRAL ZONE
Saddle area and Lake Burullus coastal barrier	Most of the length of this reach is experiencing accretion, which is expected to continue for at least the next 20 years or so period. Two local areas along the coastal barrier are vulnerable to breaching during severe storm activities, which would affect the existing tidal dynamics of Lake Burullus. Monitoring of this reach is recommended.
Burullus inlet,	The navigation channel in the existing inlet shoals and meanders causing a hazard to navigation.
El Burg area	The existing seawall needs maintenance and rehabilitation. SPA is presently undertaking an extensive rehabilitation program at this reach which seems to be adequate.
Baltim Beach Resort	Long term shoreline observations have indicated an average net recession rate of 4m/year, with superimposed short-term fluctuations of up to 60 m threatening resort property.
Baltim to Gamasa	No coastal engineering problems are identified for this reach.
Gamasa to New port at Damietta	No shore protection problems are identified except for the possibility of some local scour caused by the recently constructed Damietta breakwaters.
	3) EASTERN ZONE
New port at Damietta	Adjustment in shoreline planforms of the shore areas adjacent to the new breakwaters is expected as a result of the adverse effects of these breakwaters.
Ras El Bar	Erosion and storm damages to Ras El Bar summer resort coastal area have resulted in building damages, loss of recreational bathing beach area, and lost tourism and economic development opportunities.
Damietta Estuary	Shoaling along the navigation channel.
Damietta Eastern Promontory	Since 1966, this reach has been deprived from the rich supply of sediment by the Damietta Nile branch. Consequently, the Damietta promontory has experienced continuous erosion.

Table 1 (Continued)

Planning Sub-units	Specific Problem Definition
Lake Manzala coastal barrier	The coastal barrier located to the southeast of Damietta promontory is a low lying sandy area subjected to a strong easterly longshore transport. The spit area next to Damietta promontory is expected to supply Lake Manzala barrier with sediment for many years in the future. The barrier shorelines are, however, unstable and erosional/ accretional fluctuations are occurring along this reach.
El Gamil area	1) Flooding of the Port Said-Damietta road between km 6 to km 10 as measured from Port Said western breakwater. 2) Near km 9, storm waves could damage the road shoulders over a length of 600 m due to the proximity of the road, at this area, to the sea.
Port Said	This Port Said beach area extends from the Suez Canal west breakwater westward, over a shore length of about 6 km. This reach is slowly accreting as longshore sediment transport is impounded by the west breakwater. No shore protection problems are identified for this reach.
Port Foad area	The 2 kms Port Foad area has undergone progressive erosion prior to the construction of the eastern Suez Canal bypass channel and protective breakwaters. However, the above works were completed in the late 1970's, the Port Foad beach area has been confined and is expected to adjust to an equilibrium plan form within the next few years. Consequently, no shore protection work is identified for this area except for some monitoring requirements.
Eastern side of the Suez Canal new bypass	Shoreline retreat is expected due to the adverse effect of the recently constructed Suez Canal breakwaters. No known developments exist in this area and needs for shore protection are not warranted for the next 10-15 years except for shoreline monitoring.

Development of Alternative Solutions

A total of 38 alternative shore protection projects were developed for locations with identified needs or beach enhancement opportunities as shown in Table 1. The development of these alternatives considered the existing problem, beach restoration opportunities, and projections of expected damage under the "no action" alternative. Cost for each of the 38 developed alternatives was estimated and their economic evaluations were computed by the SPA, with Tetra Tech's assistance. Table 2 summarizes the developed shore protection alternative for each planning location.

Table 2 Summary of Developed Shore Protection Alternatives (a)

Main Zone	Planning Location	Alternatives
Western Zone	Alexandria Eastern Harbor	1) 180m Extension of the West Breakwater (b)
		2) 240m Detached Offshore Breakwater
		3) 300m long Corniche Protection
	Chatby/ Ibrahimiya Beach	1) 700m Beachfill retained by detached breakwaters
		2) 700m Beachfill retained by segmented break waters
		3) 700m Beachfill retained by 75m eastern end groin (b)
		4) 1200m Beachfill
	Stanley Beach	1) Beach restoration to add 4,600m^2 of bathing area (b)
	El-Asafra	1) Beachfill retained by west-end groin
		2) Beachfill retained by west end groin and groin pier (b)
	Mandara Beach	1) 700m Beachfill with detached breakwaters (b)
		2) 700m Beachfill
	Montaza Cove	1) 200m wide Beachfill
		2) 50m wide Beachfill with pier extension
		3) Annual Dredging
		4) Dredging with Groin retained Beachfill (b)
Central Zone	Burullus Inlet	1) Trained Eastern Channel
		2) Trained Western Channel (b)
		3) Maintenance dredging
	Baltim Beach Resort	1) Coarse sand nourishment
		2) Beach nourishment from offshore sand sources
		3) Fine sand beach nourishment
		4) T-Groins with sand nourishment
		4A) Above, but sand from offshore sources
		5) Offshore breakwaters and sand nourishment (b)
		5A) Above, but with sand from offshore sources
Eastern Zone	Ras El Bar	1) Groin field starting from existing second groin with Beachfill
		2) Groin field starting from existing third groin with Beachfill
		3) Offshore breakwaters with Beachfill (b)
		4) Artificial Headland
	Damietta Eastern Promontory	1) 11 kms of revetment
		2) 6 kms of revetment (b)
	Lake Manzala Coastal Barrier	Three alternatives are suggested: Shoreline revetment, regulation of construction and relocation, and groins or offshore breakwaters.
	El Gamil Area	1) Revetment and flood dike (b)
		2) Revetment and raise road elevation
		3) Groins field

(a) For more details, see Tetra Tech's Progress Report 2 dated December 1985, Ref. 2.
(b) SPA selected alternative.

Detailed Design and Technical Specifications

Detailed engineering drawings and technical specifications were developed for the 13 selected shore protection projects along the SPMP zones. The engineering designs followed the latest established international and U.S.A. standards. The technical specifications considered the practical application of the International and American specifications to local conditions, including reference to the use of the Egyptian Standard Specifications (ESS) as may be applicable. Both the engineering drawings and technical specifications for each project are given in Reference 3. Examples of some developed projects are shown in Figure 4.

Setting Priorities for Projects Execution

An important element of the SPMP is the establishment of a framework of implementation priorities for the developed projects. This framework should consider a set of measurable objectives such as: a) gains to the national economy; b) encouragement to tourism; (c) degree of protection to valuable developments and land, and (d) the Egyptian government national needs and plans.

As a result of the economic analysis and based on the needed degree of shore protection or beach restoration afforded, the following recommendations are reached:

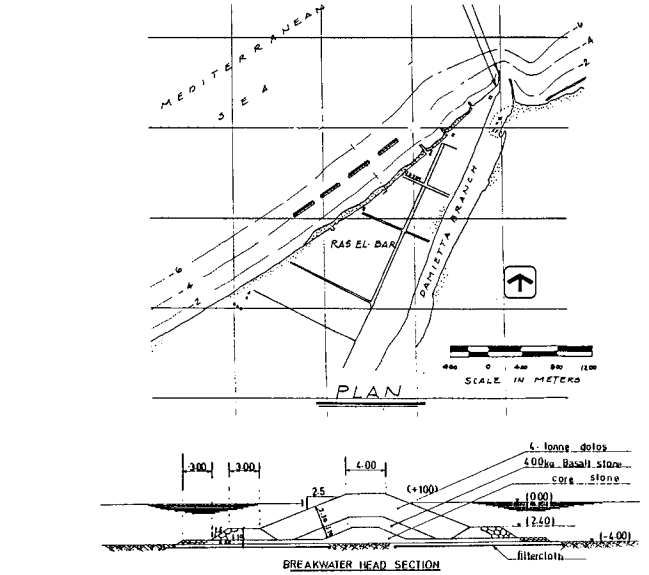
(1) Projects which may be characterized by "first priority projects" are:

a) With the exception of the Alexandria Eastern Harbor West Breakwater Extension Project, all of the developed beach restoration projects along the Alexandria and Abou Quir area are economically feasible and their implementation should have first priority.

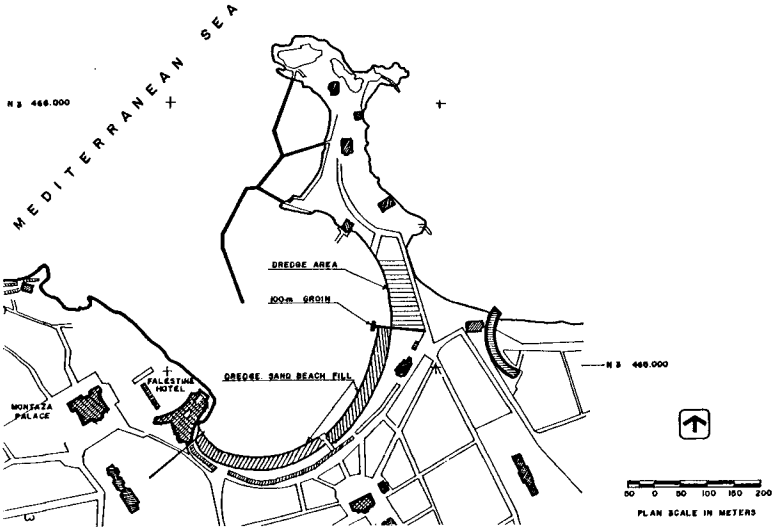
b) Ras El Bar Shore Protection
This relatively exposed and eroding beach, at Ras El Bar, is in urgent need of a shore protection scheme without compromising the availability of bathing areas. The selected project, using detached breakwater and sand nourishment, would solve this problem and enhance the present economic and tourism opportunities.

c) El Gamil Shore Protection and Flood Control Works Project
This project will protect a critical stretch of the Port Said/Damietta road against flooding and localized erosion. Therefore, its implementation should be given first priority.

d) Burullus Inlet Stabilization and Channel Deepening Project
The economy of the Burullus fishing village is centered around securing safe and uninterrupted navigation through this troubled



(a) Ras El Bar detached BW and sand nourishment



(b) Montaza Cove groin and dredging and sand nourishment

Fig. 4 Example of Shore Protection Projects

inlet. The present hydraulic and sediment situation needs immediate correction to insure safe navigation through a trained channel to check the present sedimentation problem and control channel meandering. This project deserves first priority considerations.

(2) Projects which may be characterized as "second priority projects" are:

a) Alexandria Eastern Harbor West Breakwater Extension
Presently, the Alexandria Eastern Harbor is utilized only by small fishing boats and few pleasure crafts. Under the present level of harbor utilization, additional sheltering is not warranted and only the protection of the Corniche road against spraying and overtopping by waves appears justified. Until future plans for the commercial utilization of the inner harbor area are identified and developed, the economic viability of the selected and designed project would be difficult to justify.

b) Baltim Beaches Replenishment and Stabilization
Due to the complexity of the coastal processes along this beach, the behavior of sand nourishment along this rapidly changing near-shore beach cannot be confidently predicted without further investigations. In addition, the SPA's selected scheme of detached breakwater system could possibly have adverse effects on the surrounding shorelines. It is suggested that before the implementation of the designed project, the SPA has to consider:

- An additional sand nourishment pilot project, with accurate monitoring to gain better understanding of the ongoing beach behavior.

- Employ the use of physical and numerical models combinations to test the relative performance of the other alternatives developed in Tetra Tech's Progress Report No. 2.

The results obtained from the above would give direction for implementation or modification of the designed project. It is therefore recommended that this project deserves a second priority classification until the above additional studies are completed.

c) Damietta Eastern Promontory Shore Protection Project
The Eastern Damietta Promontory is an erosional area supplying sediment to the downdrift sand spit located to the east. Very little information is available on the economic value and the location of the development to be protected along this reach. Priorities of implementation of the developed project lie with the SPA and should consider the Egyptian government overall national interest.

Identification of Model Test Requirements

Table 3 summarizes the SPMP model test requirements and their objectives. These model tests are needed to assist in the alignment of the

protective structures, check their performance and refine the design section's stability and their run-up characteristics.

To date, none of these models have been conducted with the exception of a model for Ras El Bar. It is anticipated that some preliminary model test results could be made available in the near future.

Table 3 Model Test Requirements

Project	Model test requirements and objectives
Alexandria Eastern harbor west breakwater extension (model 1)	* 2-D stability test for the designed cross-section(s). * 3-D physical model to check the alignment of the west breakwater extension and optimize its length.
Asafra and Mandara beach restoration and retention (model 2)	* 3-D physical model with the use of tracers to study the relative performance of the retention structures using variable alignments, spacings and lengths.
Montaza Cove restoration (model 3)	* 3-D fixed bed model with tracers to study wave agitation and circulation conditions under the selected scheme and assist in proper location alignment and extension of the retention groin.
Baltim Beaches Replenishment and stabilization (model 4)	* 3-D physical model with tracers (dye and light density materials) to check the relative performance of a number of alignments, lengths and spacings of the selected protective structures. * For this complex problem, and due to the limitations of the reliability of the available techniques of describing and modeling sedimentation mechanisms in numerical models, their use should be limited as a compliment to the physical model results only with possible future calibration using field and laboratory data on the performance of the executed projects. Another purpose of using numerical models would be the advancement and introduction of related technologies and "state of art" to the SPA technical staff in this field.
Ras El Bar shore protection (model 5)	Same as for Baltim beaches (model 4, above).

Development of a Comprehensive Field Monitoring Program

In coastal engineering, more than one shore protection scheme can be developed to solve the same coastal problem for a given location. The wisdom and merit of using either physical or numerical models or both to assist in the evaluation of these schemes, can be debated for ages before an agreeable and convincing conclusion is reached. This is basically true due to the present degree of complexity of this subject and the practical and academic factors influencing the decision making and the people concerned. Most of these problems can be relaxed if useful field data are available on the performance of similar projects.

There is too much to learn from a well developed and implemented field monitoring program. In addition, monitoring the performance of any selected coastal protection scheme will have considerable benefits in future modifications, maintenance and models calibrations of that scheme.

It is, therefore, essential to carry out a field monitoring program to check, analyze and modify the performance of each project, on an as-needed basis. The field program should be supported by periodic controlled aerial photography for the entire shore protection Master Plan area at, say, 5 year intervals.

"Set-Back Lines"

The so-called "Set-Back Line" or "Red Line" is a concept of delayed and deterent protection. It is used along some areas where long-term future developments are anticipated along eroding shorelines or other areas which could be affected by the adverse effects of projected shore protection structures. In most cases, the establishment of a "Set-Back Line" is based on historical data on shoreline change and its future projections, previous experience on the performance of executed protective structures and other judgmental factors. In this scheme, further projected developments or relocation of existing ones should be regulated or placed at a safe distance back from the existing shoreline.

Other Requirements and Recommendations

Other requirements and recommendations include:

(a) Geotechnical investigations.
(b) Near-shore beach profiling for Alexandria and Abou Quir beaches.
(c) Identification of sand sources for beach nourishment. Presently, the only proven sources of relatively coarse sand (D 50 $\simeq$ 0.5mm) are land sources (Khatatba, Ismailia and others). The costs of mining and transporting this sand to the different project sites are expensive (20-22 LE/m^3). It is estimated that about 1.6×10^6 m^3 of this sand would be needed in the implementation of the SPMP projects. It is, therefore, essential for SPA to consider other sources of medium or coarse sand. Specifically, both offshore and on land sand deposits should be surveyed and the economy of these sources studied, including transportation costs considering available local transportation means, river and inland navigation possibilities, and offshore dredging.

(d) Funding for the SPMP projects
The SPA may elect to approach some of the international financing organizations to secure necessary funds for some of the SPMP aspects. Funding support could consider such subjects as model testing, training, numerical modeling techniques and computer applications and assistance in projects execution, monitoring and construction management.

(e) Other coastal areas outside the present SPMP Zones
It is recommended that the SPA extend the SPMP to the other Egyptian northern coastlines such as the area west of Alexandria to Saloum, the Sinai coasts, and the Red Sea coasts.

(f) Research and developments
The SPA, in cooperation with the Coastal Research Institute, should involve local Egyptian Universities and institutes in sponsoring specialized research and studies on subjects related to the SPMP activities.

(g) Guidelines for coastal developments
SPA should establish guidelines for construction and development regulations along the SPMP Zones guided by the recommended "Set-Back Lines" and coordinate that effort with the concerned Governorates.

(h) Survey and monitoring facilities
SPA should secure the necessary equipment, survey instruments and hydrographic survey facilities at each of the three SPMP Zones.

Acknowledgment

The authors express their appreciation to the UNDP and the U.S. TDP for their financial assistance with this study.

CHAPTER 187

DESIGN AND PERFORMANCE OF ARTIFICIAL BEACHES FOR THE KUWAIT WATERFRONT PROJECT

Timothy W. Kana,[1] Mohammad Al-Sarawi,[2] and Michael Holland[3]

Introduction

One of the largest recreational waterfront projects ever designed (Sasaki Associates, 1979) is located along 20 kilometers (km) of the City of Kuwait on the Arabian Gulf (Fig. 1). Planning and design were initiated in 1976, and the first phases of construction were completed in 1985. Amenities included artificial beaches, promenades, waterfront parks, and an artificial island. Extensive armoring has also been installed, ranging from 10-ton, dolosse breakwaters to large, quarry-stone revetments. Total investment in the first two phases is upwards of US $100 million.

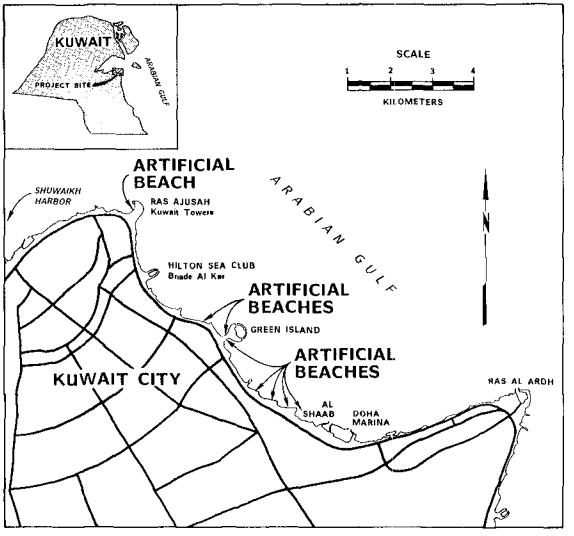

FIGURE 1. Location map of the Kuwait waterfront showing principal features.

2) Faculty of Science, Kuwait University, Safat, Kuwait
3) Sasaki Associates, Inc., 64 Pleasant Street, Watertown, MA, USA 02172

One aspect of the master plan--recreational beaches--required special consideration because of the moderately high tide range of 3.5 m, typical of Kuwait Bay. The present paper describes the participation of the authors since 1977 in developing design criteria [Research Planning Institute, Inc. (RPI), 1979], supervising engineering (Holland, 1981), and monitoring performance (Al-Sarawi et al., 1986) of eight pocket beaches constructed for the waterfront project.

Project Setting

The study area (Fig. 1) is located along the southeast margin of Kuwait Bay at the head of the Arabian Gulf. This is a clastic shoreline composed of sediments derived from the Shatt al-Arab mouth of the Tigris-Euphrates River approximately 50 km to the north. The natural waterfront along Kuwait City consists of a series of perched beaches and low headlands formed of intertidal coral rock. Ras al Ardh, the most prominent headland, marks the division between Kuwait Bay and The Arabian Gulf. West of Kuwait Towers is a commercial shoreline of dhow harbors which predate the rapid build-up of the oil-export industry. With a tide range varying from (est.) 3.0 m to 3.5 m from Ras al Ardh to Shuwaikh, a broad intertidal terrace is exposed at low tide.

East of Kuwait Towers, the project area forms a broad arc bounded by the headland at Ras al Ardh. Midway along the shoreline near the location of Green Island (Fig. 1) is a slight bulge produced by a less prominent headland (beach rock terrace). Between Green Island and Kuwait Towers, Bnade al Kar Sea Club divides the shoreline between recreational beaches to the northwest and a steep rubble edge to the southeast. This area is part of Phases I and II of the Kuwait waterfront (KWF) project.

Coastal Processes

Tide plays a dominant role in the shoreline dynamics along the KWF because of its moderately high range [3.5 m between mean higher, high water (MHHW) and mean lower, low water (MLLW); British Admiralty (1982)]. This limits exposure of the beach to wave action at middle and upper tide levels only. The principal driving force for currents in the Arabian Gulf are the tides which enter through the Strait of Hormuz, 950 km southeast of Kuwait. Local winds play an important secondary role in establishing circulation patterns. Galt et al. (1983) report a net surface flow which is counterclockwise at the head of the gulf under the northwest and southeast winds which are most common. This produces a net ebb-directed flow (time-averaged) in the nearshore area of the KWF project.

Coastal processes and longshore transport are highly variable, being dependent on local winds, nearshore bathymetry, and wave-refraction patterns. Hayes et al. (1977) found that wave energy and longshore transport are low in magnitude along the developed waterfront of Kuwait City. Waves at the shoreline in Kuwait Bay average less than 15 centimeters (cm) and thus produce net sand transport rates on the order of 10^3-10^4 cubic meters per

year (m^3/yr). Longshore transport is higher along the Arabian Gulf shoreline of Kuwait where inshore waves are typically 20-30 cm high. Kana et al. (1986) estimate net southerly rates of 5×10^4 m^3/yr for a site 70 km south of Ras al Ardh.

Long-term erosion rates are unavailable but, based on site-specific data for the Kuwait City shoreline (Hayes et al., 1977), rates are low because of:

1) Protection by the rocky, low-tide terrace.

2) The compartmentalized nature of the shoreline.

3) Low wave energy.

Lacking tropical storms and associated storm surges, beach erosion is limited to periods of highest tides and infrequent shamal winds from northerly components.

Sediments and Beach Morphology

Sediments along the KWF are a mixture of sand, building blocks, rock, and other debris (Hayes et al., 1977). Gravel-sized sediment was found to occur at the base of eroding scarps, the upper swash line (limited small sizes), at the toe of the beach, and at various positions on the low-tide terrace depending on exposure or mining of the beach platform. Sand was found to occur as a thin veneer over the mid-beach face and also as intertidal sand bars on the low-tide terrace. Most remaining beaches prior to construction of the KWF project had moderately to poorly sorted sand ranging from 0.25 millimeters (mm) to 1.0 mm diameter. The principal mode occurs at the break between medium and fine sand (Hayes et al., 1977).

With low wave energy, the active beach slope tends to be steep where beaches exist along the KWF. Hayes et al. (1977) found that slopes ranged from 0.08 to 0.13, or roughly 1 on 10. Berms were widest between Shuwaikh Port and Bnade Al Kar. Typical high-tide berm widths in 1977 were 20-30 m. From a recreational standpoint, Kuwait City beaches are normally usable for bathing only during higher tide stages because of exposure of the low-tide terrace.

Design Planning

A field-monitoring program was initiated in 1977 (Hayes et al., 1977) in order to provide basic criteria for design of improvements to the waterfront edge. These measurements became the basis for a set of design criteria and recommendations for artificial beaches as well as larger-scale structures such as a 400-m-diameter artificial island. Beaches were designed to accommodate the high tide range and high-density recreational use.

A key aspect of the early, field-survey program was measurement of littoral processes over ten days, every quarter for two years at six represen-

tative stations along the KWF. Beach profiles were also measured at over 30 stations every quarter (Fig. 2). For the most part, Kuwait coastal processes are exceedingly weak and changes in the beach profile are minimal (Hayes et al., 1977). However, Kana and Sexton (1978) measured storm processes during a moderate shamal in February 1978 and found that this one event accounted for 25 percent of the gross annual longshore transport. It also produced 2-4 m^3/m of erosion along the active profile where sand beaches existed. These field data provided confirmation of the predominance of northwesterly winds and waves along the waterfront.

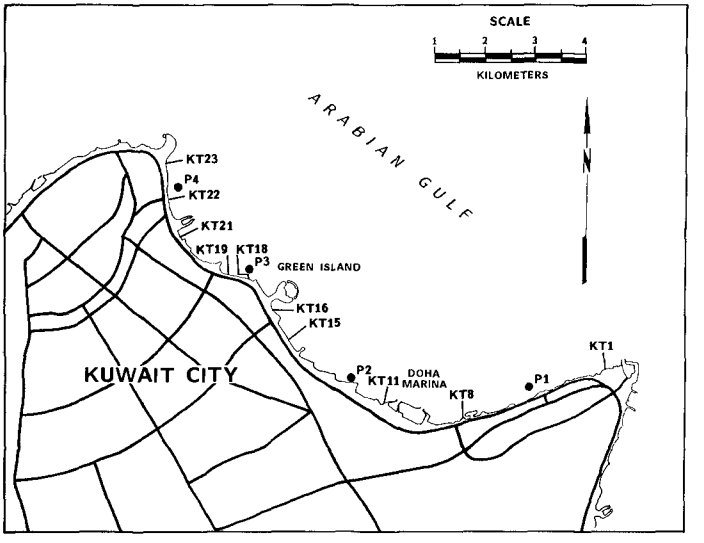

FIGURE 2. Coastal process and selected beach profile stations monitored along the Kuwait waterfront.

Wave-refraction models were developed for Kuwait Bay and the waterfront shoreline by RPI (1979) and Al-Sarawi et al. (1986). Galvin (1979) prepared the original estimate of design waves, using standard hindcasting procedures which were applied in the earlier refraction analysis. The models provided guidance on local longshore transport rates and directions, and the presumed stable configuration of artificial beaches into the incident wave field. Example regional and inshore diagrams are given in Figure 3. These were prepared with a program written by S.J. Siah using a finite-element grid scheme (Al-Sarawi et al., 1986).

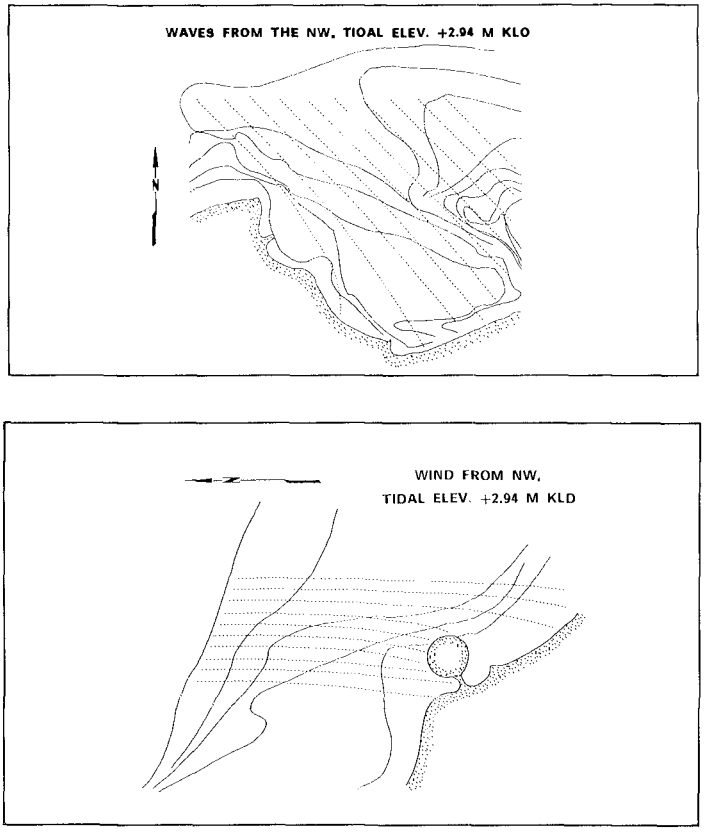

FIGURE 3. Regional (upper) and example inshore refraction diagram (lower) for the area around Green Island. Input parameters are $H_{1/3} = 1.37$ m, $T_{1/3} = 4.6$ s. Tidal elevation approximates MHHW.

It was found that limited reaches of the Kuwait City shoreline would accommodate recreational beaches. Some areas were considered unsuitable because of exposure or proximity to tidal channels. Other areas were eliminated from consideration because of alternative land use such as a marina or aquarium which were integral parts of the master plan. RPI (1979) recommended 6-8 pocket beaches bounded by groins which could double as pedestrian promenades and outfall jetties for upland drainage. Sand compatibility analyses indicated that an inland source would be required since nearshore deposits were considered unsuitable for environmental reasons. Sasaki Associates (1979) incorporated these conceptual designs into the final master plan. Final design proceeded through 1981 with construction of Phase I beginning that year.

Construction

Phases I and II of the KWF project (Kuwait Towers to Doha Marina, Fig. 1) were essentially complete by late 1986. Infrastructure and the major design elements--retaining groins, the artificial island, and the "hook" at Kuwait Towers--were completed before placement of sand in each artificial beach.

Figure 4 illustrates a typical pocket-beach design and postconstruction configuration in December 1985 (Fig. 4b). Given the local orientation of the shoreline oblique to predominant waves refracting from the northwest, a typical configuration consisted of a broad downdrift end with the widest part of the berm measuring 150± m. Typical length of each beach was 500 m. Each beach is backed by a revetment designed to +6.5± m Kuwait Land Datum (KLD). The datum approximates local MLLW, thus placing the crest of each structure about 2.5 m above highest still-water levels. Design berms were set at +4.5 m KLD.

Figure 5 illustrates various stages of sand placement by land-based equipment. The fill was placed in accordance with the design planform of each beach to minimize losses. The beach face and lower part of the profile were allowed to adjust naturally to an equilibrium slope (Fig. 5c).

Comparative profiles (Fig. 6) show the final configuration of two representative beaches in relation to the original profile. Sediment sampling by the authors in 1985 indicated the nourishment sand from upland matched the native sand very well (Fig. 7).

Innovative Features

Two innovative design elements of the KWF project are shown in Figures 8 and 9. The first, Green Island, consists of a 400-m-diameter artificial "island" armored with dolosse and connected to the mainland by a "tombolo" beach. Originally, the master plan called for a tidal channel between the island and shore, but this concept was abandoned in favor of recreational beaches. This design imitates the natural tendency of a shoreline to develop an isthmus (tombolo) in the lee of an offshore island where sediment supply is plentiful.

A second, unusual design element was the "hook" built on the exposed, low-tide terrace adjacent to Kuwait Towers (Fig. 9). This feature anchors a pocket beach facing west into the principal fetch direction.

Postconstruction Monitoring

Postconstruction surveys have been initiated by Al Sarawi et al. (1986) in order to develop preliminary estimates of erosion and changes in local coastal processes produced by the KWF project. These surveys include quarterly rod-and-level measurements and coastal process measurements over ten-day periods. Additional measurements have been taken to monitor inshore

turbidity levels adjacent to the beach fill. Surveyed profiles have been analyzed to compute sediment budgets for several compartments along the shoreline.

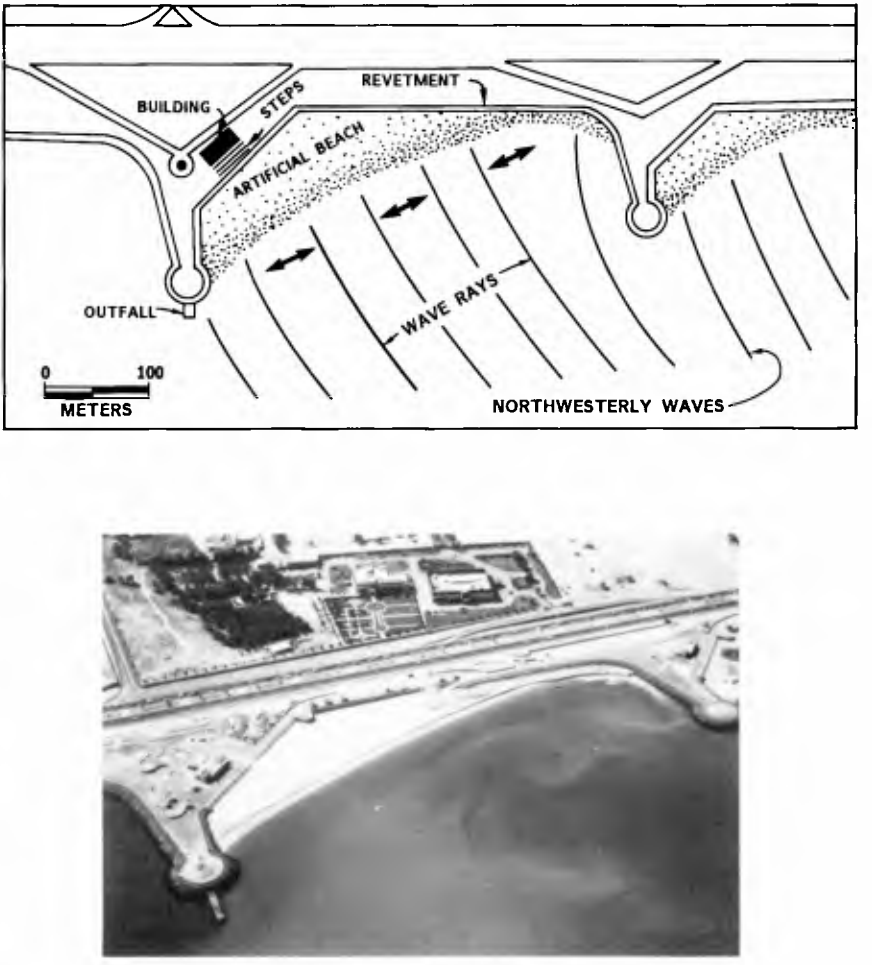

FIGURE 4. (a) Typical pocket beach designed for the KWF project. Alignment is into the predominant wave direction to minimize longshore sand losses. Retaining structures double as promenades and outfalls. (b) Pocket beach nearing completion on 12 December 1985 along the KWF project.

FIGURE 5. Stages of beach construction by land-based equipment beginning with spreading along the profile (top), natural adjustment of the beach face (middle), and final completion in an equilibrium planform (bottom). Photos taken at low tide in March 1985 by T.W. Kana.

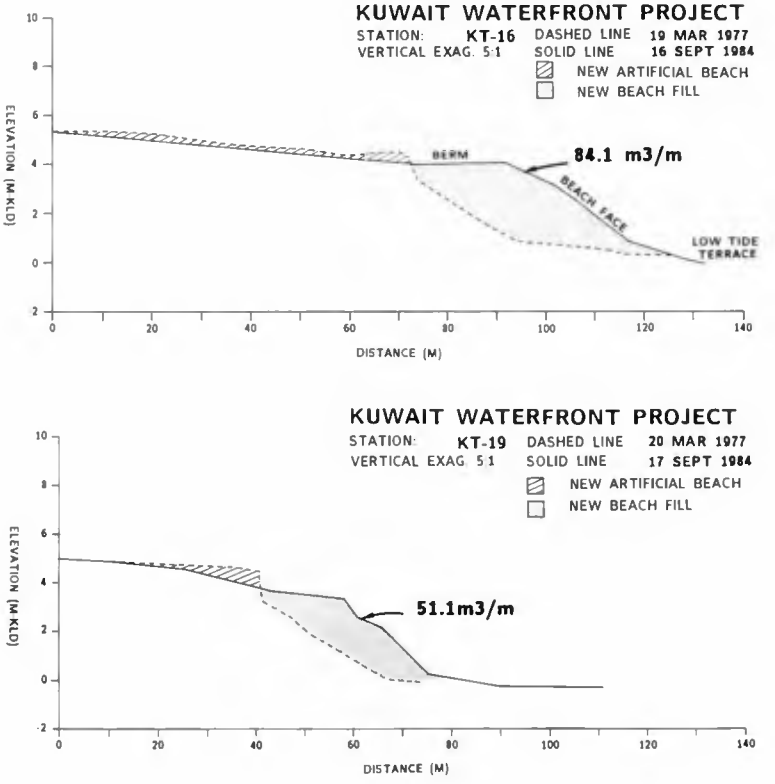

FIGURE 6. Comparative profiles from two representative artificial beaches showing the fill in relation to the preconstruction profile (see Fig. 2 for station location).

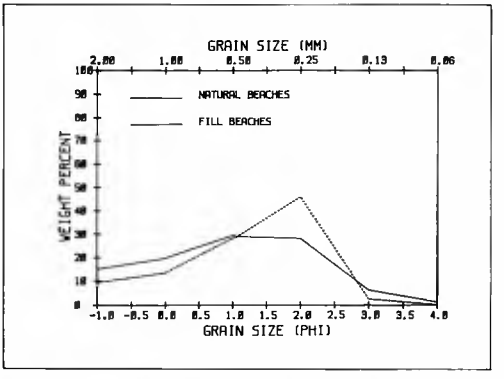

FIGURE 7. Frequency-size curves for composite samples of artificial and natural beach sediments along the KWF study area. Note the slightly better sorting of natural deposits, but generally very good correspondence between the two curves.

FIGURE 8. Conceptual plan for Green Island (Sasaki Associates, 1979) and an aerial photo of the feature nearing completion on 12 December 1985. Note the connecting beaches shaped into a tombolo. Kuwait Towers is in the upper right corner.

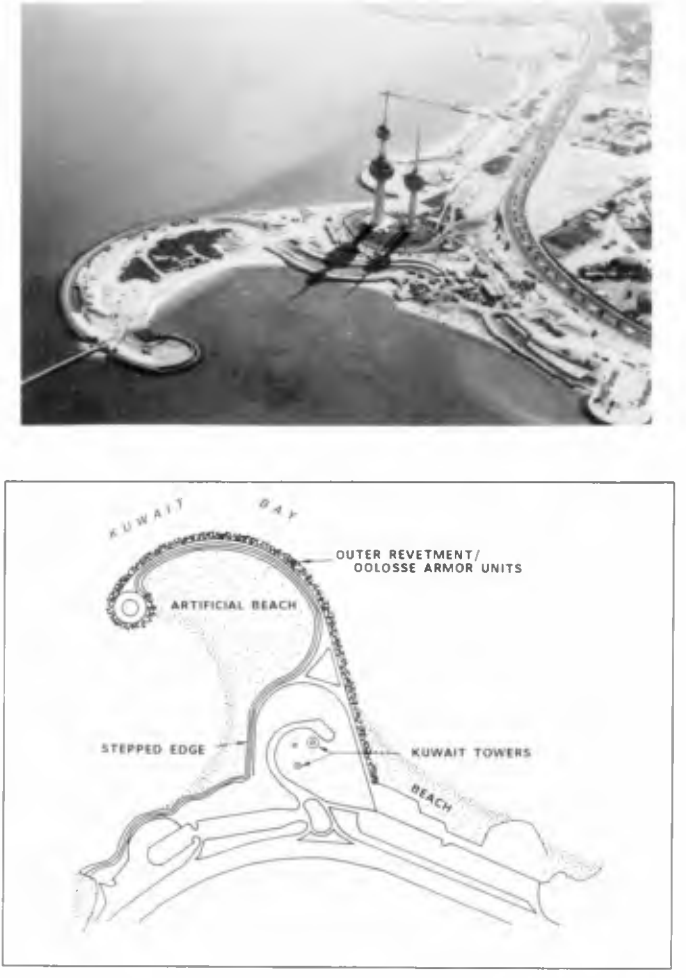

FIGURE 9. Conceptual plan for the artificial beach at Kuwait Towers and an aerial photo of construction on 12 December 1985. The beach is oriented into the primary fetch direction from the west. The jetty shown extending from the hook in the photo is a temporary feature for loading rock imported from Oman for the project.

The typical unit-fill volume for artificial beaches was 50-85 m^3/m. Interestingly, this volume was less than might be expected because each of the new beaches was "perched" on a low-tide terrace. This eliminated much of the profile adjustment normally associated with profile renourishment. On the other hand, the high-tide range required construction of the berm at elevations much higher than typical for beach nourishment. Total quantities of beach fill were unavailable at the time of this writing because some of the beaches had not been completed by the time of the most recent survey (July 1985). However, through that date, approximately 300,000 m^3 of sand had been added to the KWF project in the beach zone. For beaches which had been in place for at least one year, the extent of profile movement (sweep zone) was typically less than 5 m^3/m, or about 6-10 percent of the average, unit-nourishment volume. This compares with typical adjustments of 50 percent or more of the initial fill volume during other beach nourishment projects in order to build up subtidal portions of the profile.

Compared with the 1977-1979 period, measurements of coastal processes indicated little change in wave-energy flux at three monitoring stations (P3 just west of Green Island; P2 at the easternmost pocket beach; and P1, 3 km from Ras al Ardh along the hardened, existing shoreline). Only one station monitored (P4, 1 km southwest of Kuwait Towers) experienced a significant decrease in wave energy, with mean breaker heights decreasing by 40 percent. This is probably a result of construction of the hook at Kuwait Towers which tends to shift incident waves refracting around the headland further downdrift.

Despite the similarities in wave-energy flux at most stations, there was measurably reduced net longshore transport at P3 near Green Island and at P2 near Al Shaab Sea Club (the only two sites where processes were routinely measured along new beaches for comparison with the 1977-1979 surveys). This could be attributed, in part, to sheltering by Green Island during winds from easterly components. Westerly component winds produced comparable wave heights as the 1977-1979 data set, but lower longshore transport rates because of the realignment of the pocket beach into the predominant approach direction. At the other pocket beach, P2, the new shoreline alignment is offset about eight degrees from the strandline, reducing the incident wave angle into the compartment. Thus, net longshore transport has also decreased.

Although long-term monitoring is needed to determine the ultimate success and longevity of each artificial beach, preliminary evidence suggests the fill has rapidly adjusted to an equilibrium planform and profile. Aerial overflights in December 1984 and December 1985, as well as periodic ground inspections, showed no evidence of large sediment plumes, sand spits, or other geomorphic indicators of rapid longshore transport. This contrasts with a situation documented by Hayes et al. (1977) in which a small-scale nourishment project at Al Shaab Sea Club experienced rapid loss of fill because of improper sediment size (too fine) and a design which presumably was out of equilibrium with a natural planform into the predominant wave direction.

Conclusions

Early surveys after construction of artificial beaches along the Kuwait waterfront indicate:

1) It is possible to construct artificial beaches in high tide-range settings (up to 3.5 m) which are usable for swimming throughout most of the tidal cycle.

2) Orientation of artificial beaches should be aligned into the predominant wave approach to minimize sand transport. Wave-refraction models using appropriate hindcast wind frequencies is a minimum design requirement. However, site-specific littoral process measurements should be made to confirm local sand transport patterns, especially where inshore bathymetry is subtle and irregular such as Kuwait's shoreline.

3) Retaining structures were necessary in the Kuwait situation because of other design elements which required separation from recreational beaches. The design of shore-perpendicular structures in this case was modified to incorporate stormwater outfalls, pedestrian promenades, and decorative lighting. Onshore amenities were sited at the downdrift end of each beach where more people would be likely to congregate along the wide part of the berm.

4) Construction of perched beaches on a stable, low-tide platform is facilitated in low-energy, mesotidal areas if the fill is placed at an equilibrium planform and profile slope. Nearby natural beaches provide the best guidance for berm elevations and slope. Provided beach quality fill is used, this reduces turbidity in the nearshore zone and allows artificial beaches to achieve a natural look much faster. Construction by land-based equipment also reduces turbidity levels in comparison to a dredging operation.

Recommendations for Further Study

Given at least eight discrete and independent beaches constructed for the KWF project, it will be possible to develop a controlled data base on each one's response to the prevailing wave and tide regime. Additional profile survey stations should be set up and monitored 2-4 times each year to develop sediment budgets for each compartment. Such surveys will demonstrate whether each beach seeks an equilibrium planform, is retained within the control structures, or tends to shift in the longshore direction under seasonal wave patterns. The low-energy shoreline along Kuwait Bay and the compartmented beach system also provide a workable prototype setting to conduct experiments of onshore/offshore sand transport and the role of natural low-tide sills in stabilizing the profile (i.e., a perched beach). Experience gained from the KWF project beaches should be useful in the design of artificial beaches in other high, tide-range settings.

Acknowledgments

The Kuwait Waterfront Project is being developed by the Municipality of Kuwait. The authors thank the director of the project for permission to publish this work. Monitoring funds included a grant to Dr. Al-Sarawi from the Kuwait Environment Protection Council. We acknowledge the many people from the Municipality of Kuwait, Kuwaiti Engineers' Office, Kuwait University, Sasaki Associates, Research Planning Institute, and Coastal Science & Engineering, Inc., among others, who have assisted in the project.

Wave Interaction with Moored Sloping Breakwater

S. Kharaghani* and J.J. Lee**

1. ABSTRACT

Interaction of periodic waves with a moored inclined floating breakwater has been studied theoretically and numerically. The floating breakwater is inclined at a well defined angle with the sea bottom; its seaward end in protruding above the water surface. In static equilibrium, without incoming waves, the body weight, the buoyance force, and the restoring forces from the mooring lines which are modeled using linear springs keep the breakwater at a fixed angle. The theoretical formulation is based on a suitable variational principle. For the numerical solution a combination of finite element approximation as well as eigen function expansion technique is used.

The result is obtained in terms of wave transmission and reflection coefficient as well as the sway, heave and roll motion of the breakwater. The sensitivity of the solution on the parameters such as the bottom gap size, angle of inclination, and the mooring line stiffness are investigated over a range of incident wave transmission coefficient for dimensionless wave number $hk > 0.60$ (k is wave number, h is the water depth). The results suggest that a certain degree of sheltering effect can be realized by employing this type of sloping breakwater.

2. INTRODUCTION

Many marine structures are built in the coastal region to withstand the attack of the ocean waves and to proide a sheltered environment. Rubble mound breakwaters are examples for such applications. For certain applications this type of permanent structure might not be the most efficient. For example, during the construction of certain harbor facilities when only temporary protection is needed for a certain period, and when such protection is no longer needed after the construction it would be reasonable to assume that a permanent breakwater would not be necessary. Portable breakwaters could provide the need for such applications. Among many types of portable breakwater, one possible type is the moored inclined floating breakwater which consists of a pontoon structure whose density is so designed that the structure would be neutrally buoyant and

* Research Engineer, University of Southern California, Los Angeles, CA 90089-0231

** Professor of Civil Engineering and Director of the Foundation of Cross-Connection Control and Hydraulic Research, University of Southern California, Los Angeles, CA 90089-0231.

it is placed such that the pontoon is oriented as a well defined angle with the bottom; the seaward side of the pontoon is above the water surface. In static equilibrium, without incoming waves, the body weight, the buoyancy force, and restoring forces from the mooring lines which are modeled using linear springs keep the floating breakwater at a fixed angle. The effectiveness of the floating breakwater described above under the attack of periodic incident waves is studied theoretically and numerically. The bottom edge of the pontoon maintains a varying height of clearance so that it is not necessarily resting directly on the bottom. This clearance would extend the use of the same structure even for a deeper water depth. Of course, the effectiveness of these breakwaters deployed at such water depth must be carefully studied.

3. MATHEMATICAL AND NUMERICAL FORMULATION

For the analysis, the fluid is considered inviscid, incompressible and irrotational. Therefore, the governing equation is the Laplace equation with a mixed boundary condition on the free surface, the homogeneous Neumann condition at the sea bottom, as well as appropriate radiation conditions at infinity which require that the scattered waves are outgoing from the body. An additional boundary condition which requires that the normal velocity of the fluid and the body to be equal of the floating breakwater is also necessary. The boundary conditions are linearlized, the radiation boundary conditions are replaced by a suitable matching boundary condition in the associated functional.

The equivalence of the variational principle and the differential formulations allows for us an adoption of a well known variational form to be applied for the solution of Laplace's equation and its boundary conditions. The associated functional based on the suitable variable variational principle for the present study can be expressed as follows:

$$F(\phi_1,\phi_2,\phi_3)=\int\int_{R_1}\frac{1}{2}(\nabla\phi_1)^2dxdy-\frac{\sigma^2}{2g}\int_{S_F}\phi_1^2dx-\int_{S_R}(\phi_1-\frac{1}{2}\phi_2)\phi_{2,n}dy-$$

$$\int_{S_L}(\phi_1-\frac{1}{2}\phi_3)\phi_{3,n}dy-\int_{S_0}V_n\phi_1ds \qquad (1)$$

where V_n is the normal velocity of floating object, and $\phi_1(x,y)$, $\phi_2(x,y)$, and $\phi_3(x,y)$ are the complex velocity potential describing the flow field in the regions 1, 2 and 3, respectively.

A definition sketch of a moored inclined floating breakwater with its designated boundaries for regions 1, 2, 3 is shown in Fig.1. For the numerical

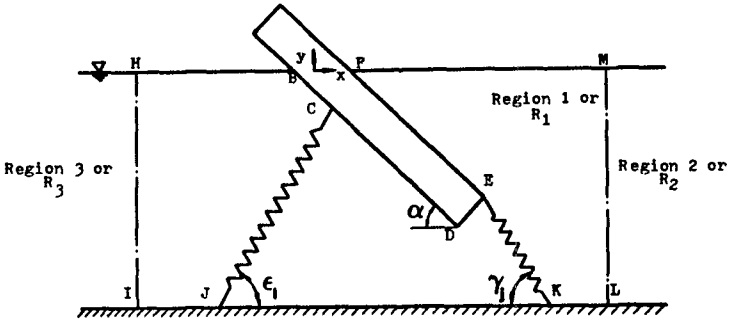

Figure 1. Definition sketch of a moored inclined floating breakwater with its designated boundaries.

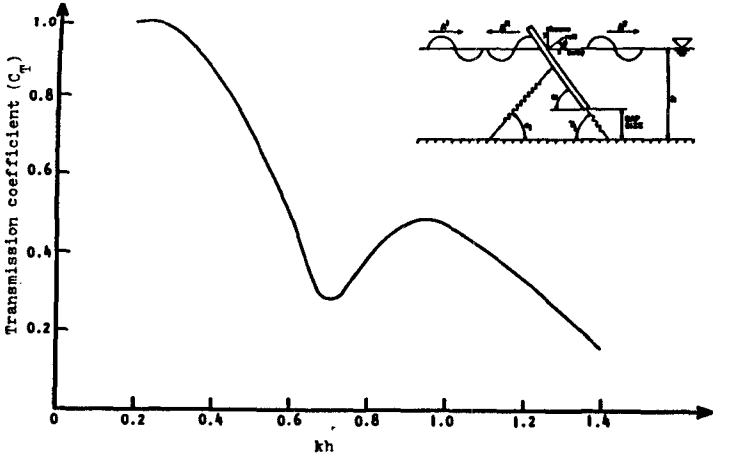

Figure 2. Transmission coefficient for 30% gap size and α=18.43 degree angle of inclination as a function of dimensionless wave number (kh).

computation, the entire fluid region for the present study has been subdivided into regions 1, 2, 3 by drawing two auxilliary vertical lines on both sides of the floating breakwater such that an inner region 1 enclosing the breakwater is formed. This inner region indicates the finite domain of direct computational interest where the functional equation 1 is integrated over with its boundaries. Regions 2 refers to the region to the right of the imaginary boundary line, thus wave would propagate in positive x-direction toward infinity. Region 3 refers to the region to the left imaginary boundary line, thus the scattered waves propagate toward negative x-direction. As a result of impact of an incident wave in the presence of the moored floating body, the total velocity potential can be decomposed as the sum of three components

$$\phi = \phi^I + \phi^D + \phi^R \tag{2}$$

where ϕ^I, ϕ^D and ϕ^R are the velocity potential of the incident wave, diffracted wave, and the radiated wave, respectively. The two dimensional plane motion of the moored inclined floating breakwater can also be decomposed in terms of three unknown modes of motion. These modes of motion are expressed in terms of translation in x-direction (sway), translation in y-direction (heave) and rotation about z-axis (roll motion) so that V_n can be expressed in terms of these three components.

For the numerical implementation the finite element approximation is used near the body and eigenfunction expansions are used to express the solutions away from the floating object. It should be mentioned that the finite element approximation is used to estimate ϕ_1 in region 1 near the breakwater while ϕ_2 and ϕ_3 are approximated by a finite number of the eigenfunction expansions with unknown coefficients in regions 2 and 3, respectively. Then the solution near the body is matched with the eigenfunction expansions along the common boundaries between regions to obtain the final solution. Thus the solution to the system of simultaneous algebraic equations for the unknown node velocity potential, coupled with the three unknown amplitudes of motion of the floating breakwater are sought numerically.

The linearized equations of motion of the floating breakwater can be written as follows:

$$M\ddot{x} = F_{dx} + F_{sx} + \sum_{j=1}^{n} (F_{Mx})_j$$

$$M\ddot{y} = F_{dy} + F_{sy} + \sum_{j=1}^{n} (F_{My})_j \tag{3}$$

$$I\ddot{\theta} = M_{d\theta} + M_{s\theta} + \sum_{j=1}^{n} (F_{M\theta})_j$$

where M is the mass, and I is the mass moment of inertia of the floating body about its center of gravity. The terms $(F_{dx}, F_{dy}, M_{d\theta})$, $(F_{sx}, F_{sy}, M_{s\theta})$ and $(F_{Mx}, F_{My}, F_{M\theta})$ are forces and moments associated with hydrodynamic effects, hydrostatic effects and that due to moorings respectively.

To obtain, for example, the force and moment terms due to the hydrodynamic effect, integrations of hydrodynamic pressure and the moments due to this force must be performed. The pressures are related to the velocity potential function by the well known Bernoulli's equations.

A detailed presentation of the mathematical formulation and the numerical implementation using the finite element approximation is presented in Kharaghani (1986).

4. NUMERICAL RESULTS

A series of numerical calculations using the developed computed model of the theory is carried out to investigate the response of the inclined floating pontoon breakwater. The computed results are expressed in terms of wave transmission and reflection coefficients as well as sway, heave and roll modes of motion. The sensitivity of the solution on the parameters such as bottom gap size, angle of inclination, and mooring line stiffness are inestigated over a range of incident wave periods (see Kharagani,1986).

Fig.2 and 3 show the wave transmission and reflection coefficients as a function of the dimensionless wave number (kh) for a pontoon breakwater inclined at an angle of 18.43 degree with a bottom gap size of 30% as shown in the inserts of the figures. It is seen from Fig.2 that a substantial reduction in the wave transmission coefficient can be achieved for those wave frequency in the range of dimensionless wave number $kh > 0.6$. The wave numver k is defined as 2π/wave length and the water depth, h, is used as a characteristic

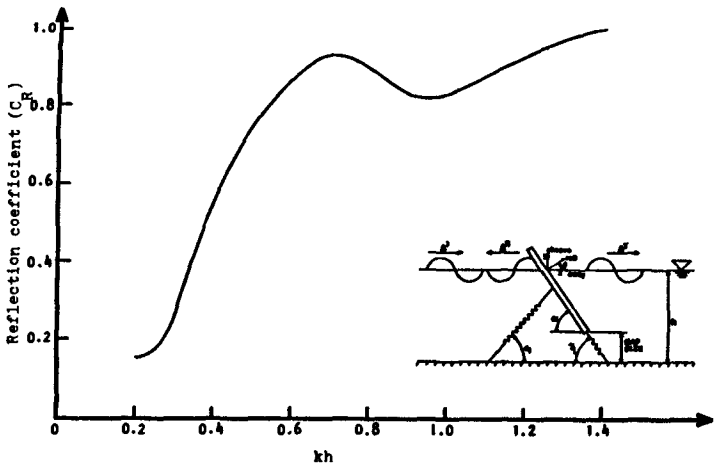

Figure 3. Reflection coefficient for 30% gap size and α= 18.43 degree angle of inclination as a function of dimensionless wave number (kh).

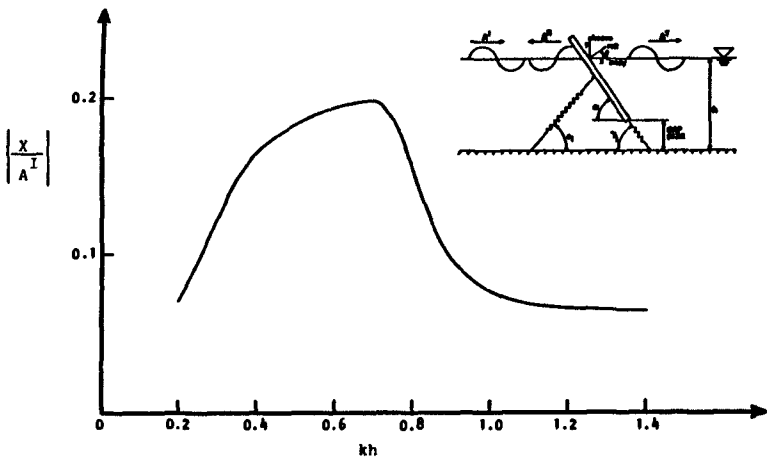

Figure 4. Sway mode of motion for 30% gap size and angle of inclination α=18.43 degree.

depth. It is noted that the transmission coefficient is defined as the transmitted wave amplitude divided by the incident wave amplitude which the reflection coefficient is defined as the reflected wave amplitude divided by incident wave amplitude. The computed amplitude for sway, heave and roll motion of the same sloping potoon breakwater are shown in Fig. 4, 5, and 6. These results indicated the relative dynamical response of the wave-structure interaction in the wave frequency range presented.

As extensive sensitivity analysis for the similar results for different gap size, inclination angle and mooring line stiffness has been conducted by Kharaghani (1986). The interested reader is referred to this for more detail presentation of the results. Similar trend has also been obtained by other investigators using different numerical technique. A comparison of the previous available theorectical results and experiments is given in Fig. 7. This shows a comparison of transmission coefficient for 30% gap size and 18.43 degree inclination angle for two different model thickness of the breakwater. A comparison with prior experimental data and the theoretical result indicates that the major trend is preserved. The result indicates if one could design the structure strong enough to withstand the wave forces a substantial large reduction in wave transmission can be achieved for a fairly large wave frequency range.

5. CONCLUSIONS

A numerical method has been developed to solve the two dimensional problem of the response of a moored inclined floating breakwater subjected to a sinusoidal incident wave. The present method is based on a suitable variational method using the hybrid finite element approximation to a fluid region near the body and the linear equations of motion of the floating breakwater. The body motions, transmitted wave and reflected wave are solved simultaneously. The investigation of the performance of the floating breakwater has been examined by studying the curves of the transmission, reflection, and the three modes of motion with respect to a large range of wave period (kh) that simulate the situation in an idealized incident wave condition from shallow water to deeper water. The results suggest that it is possible to design a moored inclined floating breakwater to be used as a temporary portable wave barrier in providing a sheltered environment against the incident waves in a certain frequency range.

CHAPTER 189

ON THE CONSTRUCTION OF HSIN-TA LNG TERMINAL IN TAIWAN

Shih-sheng Paul Lai*
Cheng-shiun Lee**

ABSTRACT

Since 1984 Hsin-Ta LNG Terminal has been under construction for the purpose of importing liquefied natural gas because of increasing demand and possible depletion of natural gas in Taiwan. Several alternatives were taken into account during the feasibility study. The Terminal is built with only a southern breakwater due to its good natural coastal conditions. Each construction item has been coordinated closely in order to advance the schedule. The first phase of land reclamation was finished by 1986. Three tanks have been under construction since soil improvement was finished. The entire project will be completed in 1989.

1. INTRODUCTION

With a booming of economics in Taiwan, there is an increasing demand for natural gas as new energy resources. In addition, the possible depletion of local natural gas reserves has been taken into account. Hence the Chinese Petroleum Corporation studied the feasibility of importing liquefied natural gas (LNG) in 1979. Since the utilization of LNG is helpful in diversifying the supply of energy resources and decreasing environmental pollution, the government of the Republic of China approved the project in 1984 and decided to establish the LNG Terminal in the Yung-An area. Because there should be no resident within a radius of 1.5 kilometers around the quay of the LNG unloading arm, spacious land is necessary. All of th required area is to be reclaimed by dredging from the locations of navigation channel and turning basin. Because the site for LNG tanks will be built prior to the offshore breakwater, the structure of the revetment should be able to withstand the open sea befoer the completion of breakwater.

2. PLANNING OF HSIN-TA LNG TERMINAL

2.1 Site Selection

The site selection criteria for LNG terminals are quite different from those for typical ports or harbors. In addition to desirable coastal conditions, special considerations must be examined .

* Manager, Planning Dept., BES Engineering Corporation, P.O. Box 335, Taipei, Taiwan, Republic of China.
** Engineer, Planning Dept., BES Engineering Corporation, P.O. Box 335, Taipei, Taiwan, Republic of China.

2.1.1 Soil stability

Taiwan is on the actively seismic circum-Pacific belt. Because of high safety requirements for LNG storage tanks, seismic effects must be taken into consideration. Furthermore the settlement of reclaimed land should be well treated. The sand compaction pile method and the sand drain method have been adopted to improve the soft soil.

2.1.2 Environmental safety

Environmental impacts related to human beings, aquatic vegetation, animals, water and air pollutions must be considered carefully. The required seawater circulation or dredging must not ruin valuable aquatic habitats or ecological systems. In addition, the site should not be chosen in an area where there might be a potential conflict with military training or important public utilities such as gunnery ranges or offshore oil/gas wells.

2.1.3 Storage facilities

There should be large territory available for the building of storage tanks, a regasification system, and control facilities. A buffer zone and a reserve for possible extention must also be included.

2.1.4 Economical transportation cost

The LNG terminal site should have the lowest unit cost for the total transportation system of freight and delivery.

All possible sites in western Taiwan were thoroughly investigated, including Tamsui, Taoyuan, Taichung, Changhau, Yung-An, and Kaohsiung. Since the Yung-An area satisfies the constraints stated above, it was selected to be the site of the first liquefied natural gas terminal in Taiwan, Republic of China.

2.2 Design of Hsin-Ta LNG Terminal

2.2.1 Littoral conditions

The coastline along the site is in the direction of NNW, which is favorable for a harbor in southwestern Taiwan. Since the local coastal data recorded from 1978 were not enough for analysis, data from Kaohsiung harbor had to be frequently referred to.

* Wind: The directions of strong blowing winds range from NW to NNE witn the northern direction most prevailing. Winds less than 10 m/sec occur 96.5% of the year.
* Fog: There are an average of 16.5 days per year.
* Water and tidal level: The highest high water level (HHWL) is 1.99 m above from the local chart datum. The maximum tidal range is 1.30 m in January. The astronomical tide and storm surge with return period of 100 years are +1.36 m and +1.5 m respectively. Hence the tidal level used for the design is +2.86 m.
* Current: Most currents are along the direction of SE-NW. The longshore current speed near the seabed is about 0.5~1.0 m/sec.

*Wave: Wave data show that 93% of the significant wave heights ($H_{1/3}$) are smaller than 1.0 m. Eight model typhoons passing through the site were adopted to calculate the design waves under typhoon conditions. The simulated maximum significant wave is of $H_{1/3}$ = 9.2 m, $T_{1/3}$ = 12.7 sec, S direction, with a return period of 100 years.

* Littoral drift: Since there is a lack of sand for littoral drift and most of the waves approach the beach perpendicularly, the coast is highly eroded with its relatively steeper slope.

2.2.2 Evolution of the Terminal

There are five design alternatives for Hsin-Ta LNG Terminal. They can be classified into three categories: on-shore, off-shore, and shelterless. Each of the former two categories comprises two kinds of storage tank: in-ground and above-ground. The last one is with in-ground tank. Although the general coastal conditions around the site are rather fair, the shelterless layout still can't meet economical and safety requirements. Through various comparisons such as investment, construction period, benifits, etc., on-shore layout is always preferable to off-shore layout except maneuvering security. Hence the general layout of Hsin-Ta LNG Terminal was decided to be an on-shore harbor with in-ground storage tanks, as shown in Fig.1.

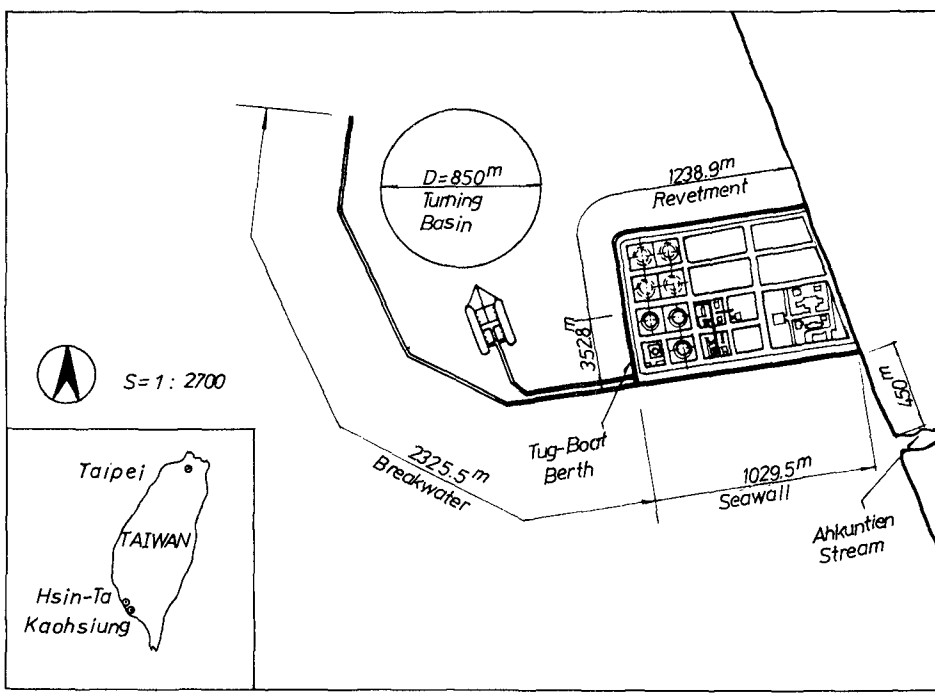

Fig. 1. General Layout of Hsin-Ta LNG Terminal

2.2.3 Cross sections of seawall and revetment

The seawall and revetment of Hsin-Ta LNG Terminal were first divided into a number of sections, and then designed according to each corresponding water depth and local wave conditions. The typical cross sections of rubble mound and composite caission type structures are plotted in Fig.2~Fig.4.

2.3 Feather of the Project

Perhaps the most interesting feature of this project in comparison with other typical ports is the single-armed southern breakwater. The orientation of the coastline along the site is in NNW direction, which effectively protects the Terminal against waves from N to E, whereas waves can approach the site directly from S to W. Hence the single-armed southern breakwater is secure enough to protect the berth from incident waves. The problem of seich is then relatively trivial, due to the opening nature of this harbor entrance.

3. Construction Process

This project has been scheduled to be completed within a short period of 5 years. Therefore the building procedure of the breakwater, land reclamation, storage tanks, and transportation pipes system need to be closely coordinated. In general, Hsin-Ta LNG Terminal consists of three major tasks, i.e., 1) construction of on-shore harbor; 2) land reclamation (about 70 hectares) for working-yards; 3) construction of in-ground LNG storage tanks & associated facilities. The actual execution of the project was started in September, 1984.

3.1 On-shore Harbor

In order to execute the project, BES Engineering Corporation has mobilized a lot of machines, vehicles, agitators, and working vessels. First of all, the rubble mound seawall and revetment were built to protect the reclaimed land from being washed away by waves. Graded seasands were dredged to supersede the soft soil for improving some parts of the foundation of seawall and revetment. Filter fabric was spread out along the orientation of the coastal structure against settlement. Next the rubble was dumped over the filter fabric by dump trucks or bottom-opening stone carriers. After being leveled by bulldozers or divers, the crown wall was then cast in place. The seaward toe of the rubble mound has been protected first by cobble of 4.0cm~10.0cm in size with a slope of 1:1.5 which is 1.5 m thick, and second by 2 layers of concrete armor units which are about 2.0 m thick with a slope of 1:2. On the other side, i.e. harbor side, the coastal structure was backfilled by dredged seasand and covered with a layer of masonry for protection.

As the water depth got deeper than - 8.5 m, the composite caission type structure was adopted. Caissions were made in Anping harbor where is about 30Km to the north of the site, and were towed to the site during suitable maritime conditions. Once the caission was placed on the designated position, concrete blocks were sunk immediately to guard the toe of the caission. in order to keep facilities inside the Terminal safe enough during storms, a "curtain wall " has been built up along the harbor side of the seawall and revetment against wave overtopping. Thus far, 1030.0 m of

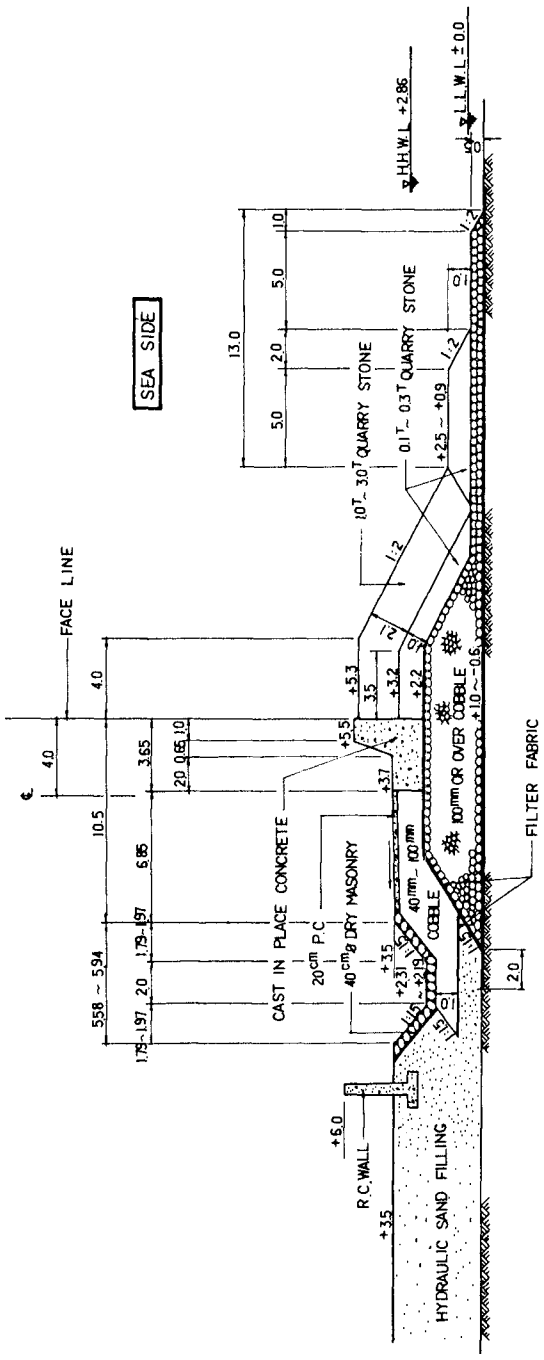

Fig. 2. Typical Cross Section of Revetment (rubble mound)

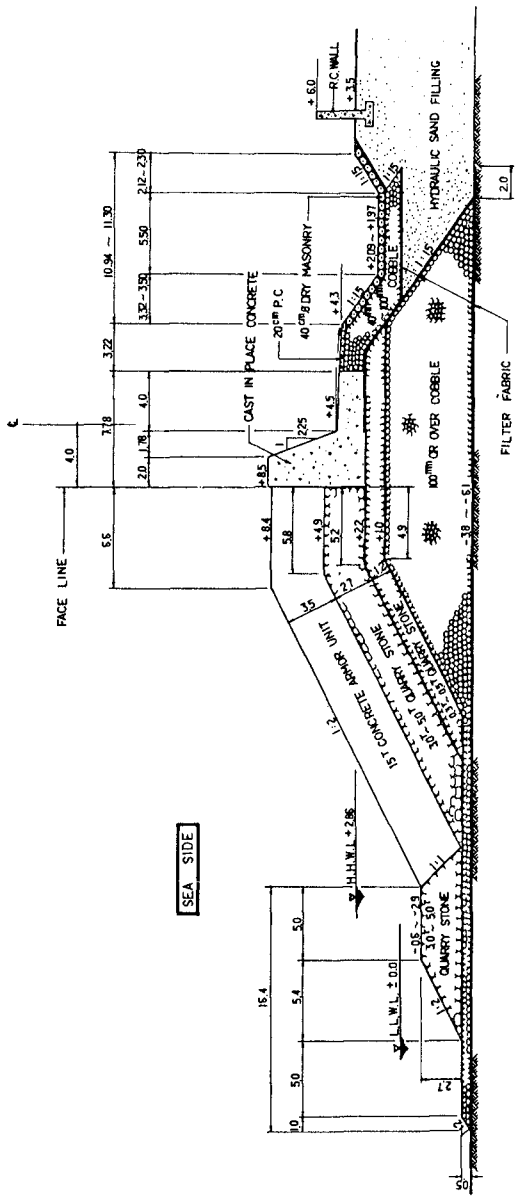

Fig. 3. Typical Cross Section of Seawall (rubble mound)

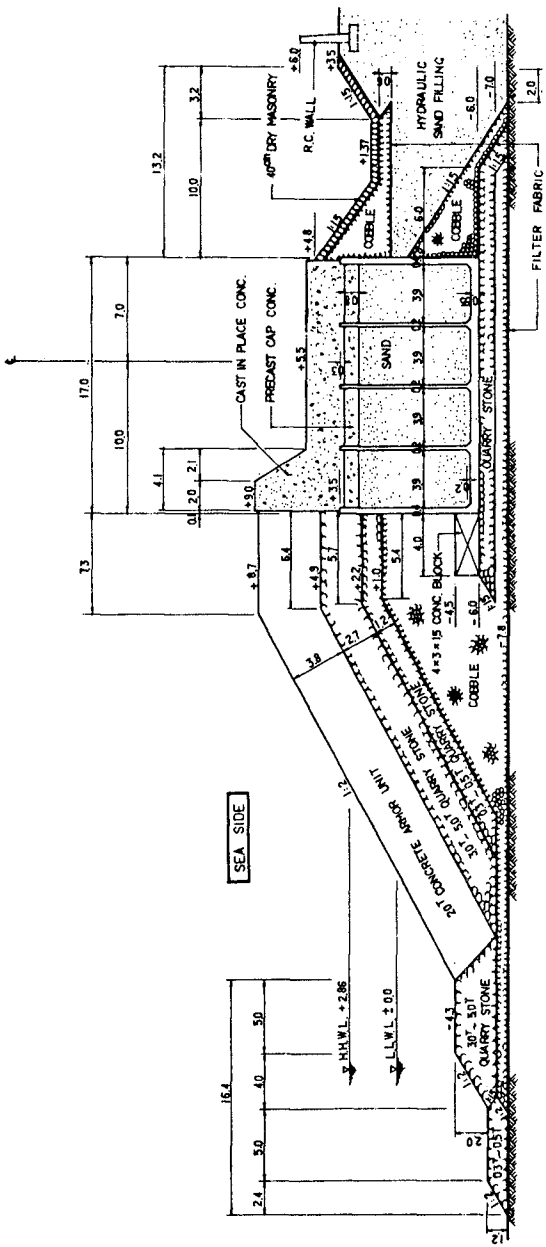

Fig. 4. Typical Cross Section of Seawall/Breakwater (composite caission type)

seawall, 670.0 m of revetment, 703.0 m of permanent and temporary workingboat wharves, and 730.0m of temporary revetment have been completed.

3.2 Land Reclamation

The required working-yards were reclaimed by hydraulic backfilling while building seawall and revetment, as shown in Photo. 1. More than 4.1 million cubic meters of filling volumes have been executed by suction dredger. The total dredged volumes will come to 7.1 million cubic meters.

Owing to the desire of completion by 1989 the storage-yards for the LNG Tanks were reclaimed prior to other places. Several types of concrete armor units were put in place to protect the reclaimed land after each subphase had been finished.

3.3 In-ground LNG Storage Tanks

The tanks are being constructed using the top-down method. The slurry wall was built first. After the excavation of earth was finished, draining filters and steel/butyl waterstops were fixed upon the slurry wall in order to drain and resist possible permeating groundwater respectively. Steel work and form work were subsequently installed. After adjusting each section into its designated position, concrete was then cast in place. With the similar procedure performed downwards, three tanks are expected to be completed by late 1988.

4. ACKNOWLEDGEMENTS

The authors wish to thank the Chinese Petroleum Corporation and the China Engineering Consultants Inc. for their assistance in providing relevant technical data. The support and encouragement from project manager F.C. Kuo and all colleagues in the Hsin-Ta Construction Station are also highly appreciated by the authors.

CHAPTER 190

THE INFLUENCE OF WAVES ON THE HYDRAULICS OF SEA OUTFALLS

by

Torben Larsen
University of Aalborg
Sohngaardsholmsvej 57, DK-9000 Aalborg, Denmark

1. INTRODUCTION

Most of the larger cities in Denmark are located near the sea. About 60% of the sewage is therefore discharged through sea outfalls. Most of these sea outfalls were built in the seventies. In most cases a plastic pipeline were used, and the pipeline was ballasted with armoured concrete blocks and burried in a trench 1 - 2 m underneath the seabottom. To give the necessary initial dilution a diffusor with one or several contracted, horizontal outlets ends the pipeline.

The Danish coasts are in general shallow and exposed to waves. The littoral sanddrift is considerably and the sea outfalls need to cross one or more bars. The diffusors are often placed outside the bars, but nevertheless sediment transport can occur around the diffusor. Figure 1 gives some typical data for Danish sea outfalls.

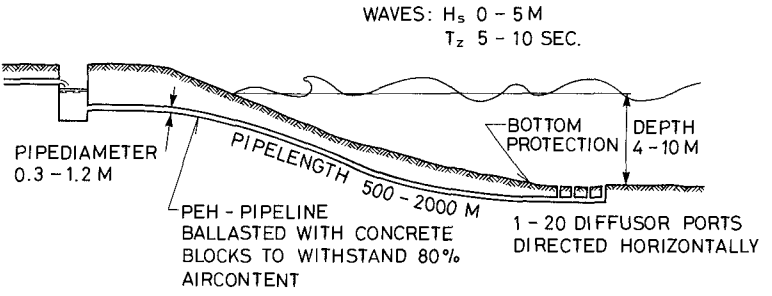

Figure 1. Range of data for Danish sea outfalls.

As a large number of outfalls were designed and established in a short span of time, the practical problems of placing such a rather sophisticated structure in one of the most difficult areas were often underestimated. Many failures have been seen and a considerably num-

ber of sea outfalls have an insufficient function. A typical problem is the sediment intrusion into the diffusor, which can block up the ports, and another example is the lifting of the pipeline due to airpockets and insufficient sandcover of the pipe.

This paper discusses some hydraulic aspects of the influence of waves on the pipeline and the diffusor. These effects have not been reported earlier and they might in some cases be connected to the mentioned failures, but it is not pretended that they are general key points in the design of sea outfalls.

2. NUMERICAL MODEL

It is obvious that the influence of waves on the hydraulics of sea outfalls needs an unsteady description and, furthermore, it is also obvious that due to the important non-linear friction analytical solutions are out of question. The straight-forward procedure is then to apply a numerical computer-model.

The numerical model is basically an extension of a water hammer model. The water hammer theory for the unsteady flow in an elastic pipeline is based on the simultaneous solution of the equations of motion for each discrete pipesection all along the pipeline. The equations of motion are the conservation of momentum (1) and theconservation of mass (continuity) (2) including the elasticity of the water and the pipe (Wylie and Streeter, 1983):

$$g \frac{\partial H}{\partial x} + V \frac{\partial V}{\partial x} + \frac{\partial V}{\partial t} + F \frac{V^2}{2d} = 0 \tag{1}$$

$$\frac{a^2}{g} \frac{\partial V}{\partial x} + \frac{\partial H}{\partial x} + \frac{\partial H}{\partial t} = 0 \tag{2}$$

where

g acceleration of gravity
H hydraulic head
x distance along pipeline
V velocity
t time
f Darcy-Weisbach friction factor
d diameter of pipeline
a wave celerety for unsteady flow

The wave celerety, a, for pressure and velocity changes is app. 300-400 m/sec in a plastic pipeline and 1,100-1,300 m/sec in a steel pipeline, which are the extremes of practical pipelines in this respect.

2.1 The method of characteristics

To solve the equations (1) and (2) the method of characteristics is convenient. The idea of

this method is to choose a computational grid, in which the equations are simplified to a pair of ordinary differential equations (see again Wylie and Streeter, 1983).

The unkowns are the hydraulic head H_p and the velocity in the new point P, figure 2. These are calculated from known values in the two points i−1 and i+1 one time-step earlicr.

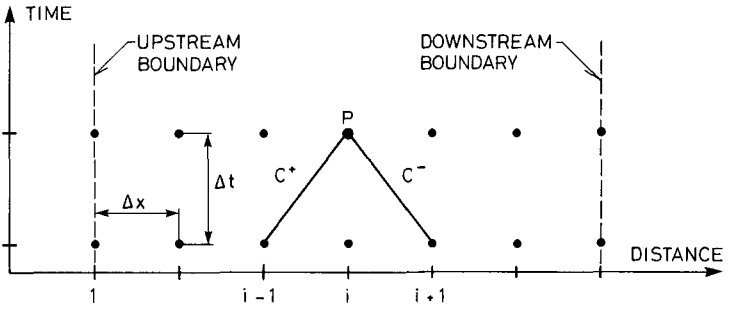

Figure 2. Computational grid for method of characteristics.

2.2 Upstream boundary condition

The upstream boundary condition will often be a pump or a reservoir. Most critical is the reservoir, because of the reflection of the fluctuations. A running pump on the other hand absorbs most of the fluctuations in pressure and flow. But a stopped pump with a closed check valve should be considered if necessary.

In this study the upstream boundary was described by assuming a fixed head in the upstream reservoir and a hydraulic entrance head loss between the reservoir and the pipeline.

2.3 The diffusor boundary

The downstream boundary is the multiport diffusor with the unsteady pressure field from the waves moving across the diffusor ports. From physical arguments it can be stated that the effect of elasticity can be neglected in the diffusor. Consequently the conservation of mass and momentum can be solved in an ordinary finite difference scheme where the non-linear terms required a solution by iteration.

The moving hydraulic head outside the ports was computed based on linear wave theory. Both the effect of monocromatic waves and complex wind waves have been studied. The wind waves were simulated accordingly to the JONSWAP - spectrum (Hasselmann, 1973). This rather narrow spectrum is known to fit well to the fetch limited wave climate around Denmark. It was assumed that the wave energy travelled in the same direction. This assumption showed out to be acceptable as seen later on.

The linear wave theory gives the following hydraulic head outside each diffusor port

$$H_D = \sum_{i=1}^{n} \left[a_i \sin(\omega_i t + k_i x + \varphi_i) \right] / (\cosh(k_i h))$$

where

H_D	head outside the diffusor
a_i	surface amplitude of wave component
$\omega_i = 2\pi f_i$	cyclic frequency of wave component
$k_i = 2\pi / L_i$	wave number
L_i	wave length
φ_i	random phase
h	depth of water

The surface amplitude a_i was found from the JONSWAP - spectrum

$$S(f) = \frac{\alpha g^2}{(2\pi)^4} f^{-5} \exp\left[-\frac{5}{4} \left(\frac{f}{f_m}\right)^{-4} \right] \gamma^{\exp\left[-\frac{1}{2\sigma^2} \left(\frac{f}{f_m} - 1\right)^2 \right]}$$

where

α	$= 0.076 x^{-0.22}$	factor
x	$= g F U_{10}^{-2}$	factor
f_m	$= \dfrac{3.5\, g\, x^{-0.33}}{U_{10}}$	peak frequency
γ	$= 3.3$	factor
σ	$= \begin{cases} 0.07 & \text{if } f \leqslant f_m \\ 0.09 & \text{if } f > f_m \end{cases}$	
F		fetch
U_{10}		wind velocity

3. RESULTS

As the result of this first step of research is the computer model described above, it feels naturally not to give general conclusions but only some typical examples. Figure 3 shows data for the sea outfall used in the following examples.

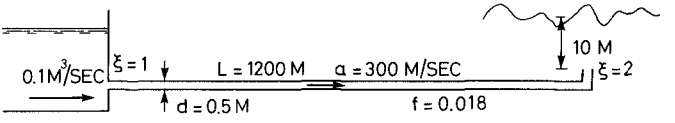

Figure 3. Data for examples.

3.1 Total hydraulic capacity

The total head loss in the pipeline is not significant increased due to the waves in the case of a single port diffusor. For the multiport diffusor a slight increase (0 - 5%) of the head loss can occur.

3.2 Resonance

It is well-known from physics that the wavelength of the basic mode standing wave in a pipeline open in each end is the double of the length of the pipe. The resonance period for a pipeline with L = 1200 m and a = 300 m/sec is then 8 sec. Figure 4 shows a timeplot of how this resonance built up from steady state.

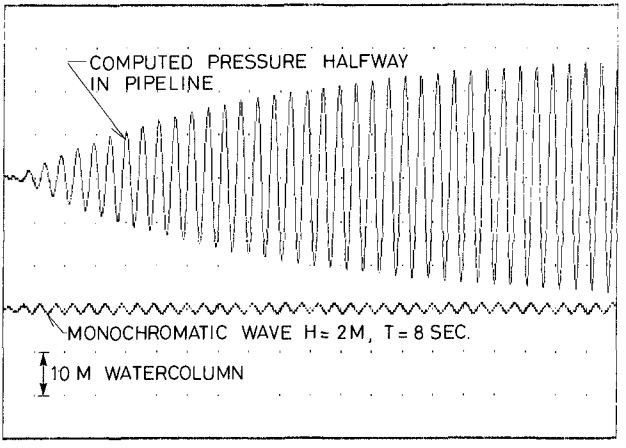

Figure 4. Resonance due to monochromatic waves.

Figure 5 shows the computed results if the waves are irregular according to the JONSWAP - spectrum.

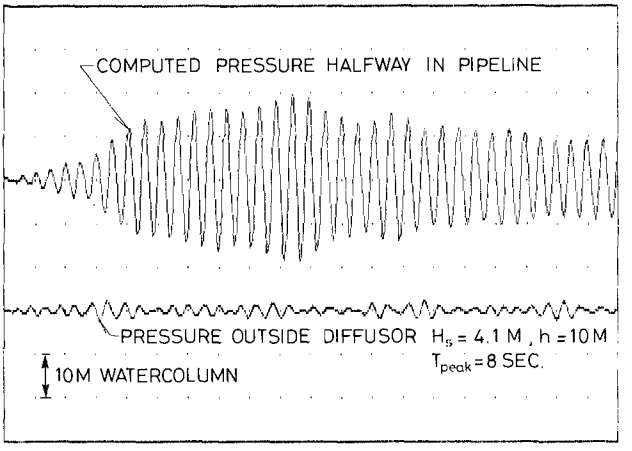

Figure 5. Resonance due to wind waves.

The figures show that the dampening of the standing waves apparently is very small and the pressure fluctuations are surprisingly large. For the moment this has not been experimental verified and the results can only be interpreted as an impulse to further studies.

The above mentioned examples are based on the basic mode of resonance in the pipeline. Resonance should of course be expected on other modes depending on the waves and the pipeline. The resonance periods for a pipeline open in each end are 2 L/a, L/a, 2/3 L/a, 1/2 L/a, etc. If the pipeline is closed in the upstream end (stopped pump and closed check valve) the first resonance periods are 4 L/a, 4/3 L/a, 4/5 L/a, etc. In this connection the long periods are expected to give the strongest resonance because of the lowest dampening.

3.3 Back flow in diffusor

In this example the outfall from figure 3 was connected to a diffusor with 5 ports with a diamater of 0.15 m and a head loss factor $\xi = 2.0$. Over this diffusor wind waves propagated as in figure 5 with $H_s = 4.1$m and $T_{peak} = 8$ sec. Furthermore, the length of the pipeline was L = 1500 m to avoid resonance. Figure 6 shows an instantaneous picture of the flow distribution, where the waves created a back flow in one of the ports.

From an analysis of the results it can be concluded that the unsteady flow in the diffusor to some degree follows the flow near the bottom due to the waves. As the head losses through the ports are smaller than the head fluctuations, it is understood that the local effect of the waves between two adjacent ports is most important. This knowledge can

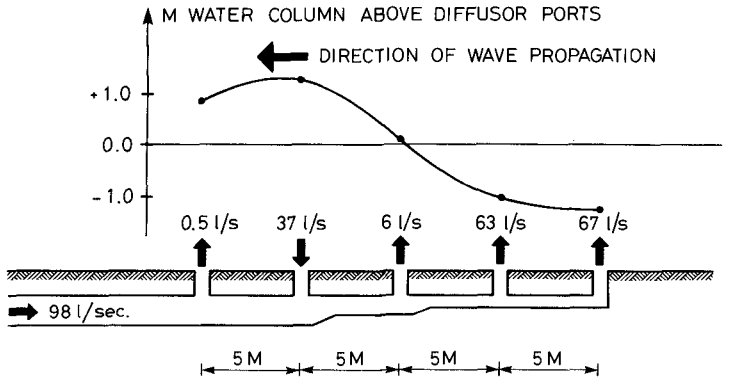

Figure 6. Instantaneous flow in diffusor under waves.

then support the assumption of only applying a uni-directional wave spectrum as the boundary condition to the computation; or with other words, the waves are not short-crested in relation to the distance between two diffusor ports, which only is a fraction of the water depth.

4. CONCLUSION

The results summarized above indicate that waves can cause interesting hydraulic phenomena in sea outfalls on shallow coasts. The results also explain why this has not been realized directly earlier; simply because the resonance in the main pipeline and the back flow in the diffusor cannot be observed in the upstream end of the pipeline.

The author will appreciate very much to be informed about observations on these effects.

CHAPTER 191

FIELD STUDIES OF BUOYANT JET IN COASTAL WATERS

Jeffrey P. Leighton (1), Associate Member, ASCE
Shuen-Wei Scott Tu (2), Member, ASCE

ABSTRACT

Studies were made on a surface buoyant jet from a coastal power plant. The cooling water discharges into shallow waters of irregular bottom topography forming a partially enclosed embayment that connects to the open ocean. Near field mixing was found to be influenced by bottom bathymetry, lateral confinement and a large obstruction. Surface centerline temperature decay, bottom separation and the heat and mass distribution within the embayment were analyzed.

INTRODUCTION

Much of the work on surface buoyant jets has been limited to the case where bottom and side boundary effects are absent. This is not the condition for Diablo Canyon Power Plant on the California Coast of the USA. The cooling water system discharges into shallow waters of irregular bottom topography forming a partially enclosed embayment that connects to the open ocean (see figure 1). Prototype studies were conducted during power ascension testing of both units.

A discharge structure drops the condenser water down to ocean level through two chutes, one for each power plant unit. Cut-outs in the center divider wall allow for cross-over mixing when the unit flow rates are different. There are two cooling water pumps available for each unit; each pump has a maximum capacity of 28 m^3/s. Data were collected during periods when the discharge waters represented: coflowing buoyant and non-buoyant jets (4 cooling water pumps and 1 power plant unit in operation-4P/1U); two coflowing buoyant jets of different densities less than ambient but similar discharge volume (4 pumps and 2 units in operation- 4P/2U); and two coflowing buoyant jets of similar density but different discharge volume (2 pumps and 1 unit in operation- 2P/1U). The tide level controls the initial jet depth. At full load and discharge flow, the temperature rise of the cooling water is 10.8^{o}C.

DATA COLLECTION

A field data collection program was implemented to describe the 3-dimensional receiving water temperature and velocity field. Near-field temperatures in the upper water column were measured along transects with a vertical temperature array. Thermistors were placed down to 10 feet below the surface; data were recorded at 10 second intervals automatically in a self-contained data recording unit. Vertical temperature profiles and far-field surface temperatures were measured with profiling and towed bathythermographs, respectively. A thermistor array with data recorder was configured to be used as a free-floating drogue to determine temperature decay along or near the plume centerline. Plastic drogues were also tracked to determine plume veloci-

(2) Research Engineer, Pacific Gas and Electric Company, 3400 Crow Canyon Rd., San Ramon, CA 94583

ties and ambient currents. Moored current meters were deployed in some tests at the cove entrances at two depths. Boats were equipped either with a range-azimuth microwave navigation system or with retroprisms for a shore-based laser electronic distance measuring system for boat position. Data were taken on intake and discharge temperatures, tide, wind and wave conditions.

The test methods and data analysis results during power ascension testing of Unit 1 are presented in Leighton et al. (1986), and for Unit 2 in Tu et al. (1986). Emphasis will be given here to test data collected during power ascension testing of Unit 1 (see Table 1). A total of more than 50 field tests were made. A test series usually consisted of multiple data collection periods with a common power plant discharge condition, but with differences in tide, wind, wave and offshore current direction and magnitude.

RESULTS

Centerline surface temperature decay

The excess surface temperature was plotted against the ratio of distance traveled to equivalent discharge diameter, $D = (h_o\, b_o)^{.5}$, where b_o = plume half-width, and h_o = initial plume depth. The power law index, n, was determined for the relation: $\Delta T(x)/\Delta T_o \sim (x/D)^{-n}$, where ΔT_o = discharge temperature rise.

With data for the 2P/1U case, for $x/D < 30$, with one exception, $n = 0$, and for x/D between 30 and 70, $0.5 < n < 1.0$. When the data for 7 tests (2P/1U) are plotted simultaneously, using the equivalent diameter as the length scale, there is significant scatter (see figure 2). When scaling is made with the initial densimetric Froude number (F_o) and aspect ratio (AR), there is significantly reduced scatter (see figure 3). The abscissa is divided by the formula for the transition distance for deep water jets developed by Stolzenbach and Harleman (1971): $12(h_o b_o)^{.5} F_o AR^{.05}$. The ordinate is scaled by the initial densimetric Froude number.

Bottom separation

Bottom detachment was estimated from vertical temperature profiles near the plume centerline, where the bottom excess temperature nearest to the outfall equals zero. The near-field penetration depth varied from 4.5 to 11 meters (see table 2).

The maximum plume depth was not correlated with tide, and poorly correlated with initial densimetric Froude number. The ratio of maximum penetration depth (h_{max}) to initial plume depth (h_o) does show a correlation with initial densimetric Froude number (F_o), based on the initial depth. The results of analyzing 14 tests (2P/1U and 4P/2U) with $5.4 < F_o < 38$ (Tu et al., 1986), gave a best-fit equation of:
$h_{max} = .46\, F_o^{.87}\, h_o$ with a correlation of .91. The empirical equation of Safaie (1978):
$h_{max} = .91\, F_o^{.50}\, h_o$ worked well in the range $5.4 < F_o < 12$, but was a poor predictor at extreme low tides, or high Froude number.

At lift-off (or bottom drop-off), the estimated local densimetric Froude number was of value 1.5, based on the results of 4 tests.

Heat and Mass Flux Balance

Since the discharge cove is semi-enclosed, it was possible to obtain velocity and temperature data sufficient to describe the cross-sectional variation in momentum and buoyancy. Vertical temperature profiles and thermistor transect data were used for temperature; drogues with center of mass at 1.2, 2.5 and 5 meters were tracked for velocity. Results are presented in Table 3.

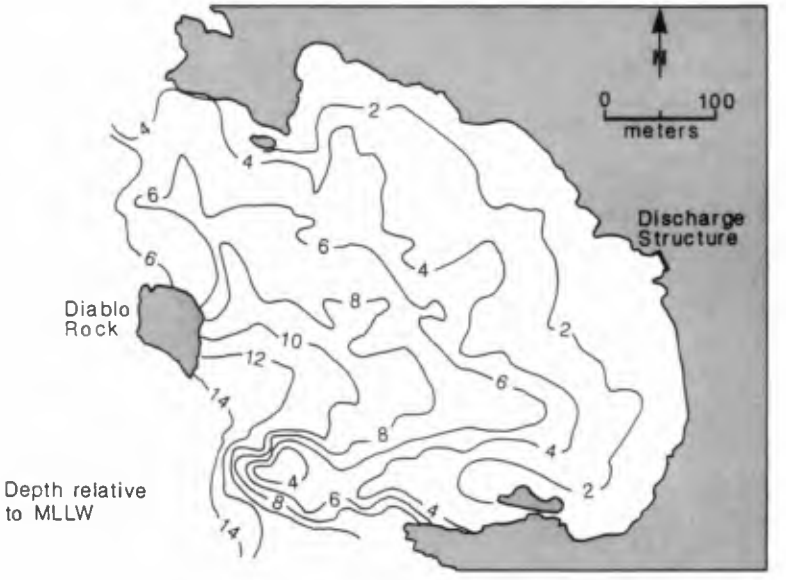

Figure 1. Bathymetry in Diablo Cove

Table 1. Conditions of Selected Tests

Test	Discharge Conditions[1] Unit 1		Unit 2		Tide	Wind[2]	Wave	Offshore[2] Current

6-3	34.0	11.0	22.6	10.7	-.1	2.2-	.8	.28+
6-4	34.0	11.1	22.6	10.9	.9	5.6+	.8	.13+

(1) The cut-outs in the center divider wall allow the cross-over of water whenever unit flows are different. The values given refer to conditions at the end of the discharge structure, after the exchange has occurred (Ryan and Tu, 1985)
(2) The direction in which the wind (or current) is headed. A "+" indicates a downcoast movement, a "-" is for an upcoast movement, and an "x" denotes roughly shore normal movement.

Among the conclusions one can draw from this analysis: The plume is a surface condition outside the discharge cove, with an average of 85% of the excess temperature flux within the top 3 meters of the water column. At low tide, the buoyant jet is deflected more to the north, a result of the presence of parallel rock ridges within 75 meters of the discharge structure, with an orientation towards the north. We have found that this effect is reduced at higher tide level (where the ridges serve as bottom roughness instead of as deflectors) and higher initial momentum (as indicated in test 5-1, with 4 pumps). Consistent over-estimation of the heat flux out of the cove suggests some return flow of buoyant water, most likely on the east side of the north entrance, where data is sparse or non-existent.

The effects of a large obstruction

Under most receiving water and discharge conditions, the buoyant jet trajectory is oriented towards Diablo Rock. This large obstruction to the flow has been observed to cause a bifurcation of the plume, upwelling in the wake of the island (see figure 4), and plume deepening on the inward side of the island. On the seaward side of the island, lateral temperature gradients as large as a $7^{o}C$ drop in 90 meters have been observed. The temperature of the water in the wake of the island is near or equal to the offshore ambient conditions. Imberger and McComb (1984) reported upwelling in the wake of Rattray Island in Australia.

Mixing between coflowing jets

Test 5-1 is a case involving coflowing buoyant and non-buoyant jets. We obtained data perpendicular to the jet, which showed the change with distance of the temperature gradient across the interface. Figure 5 shows that mixing between the coflowing jets is limited. The velocity shear between jets is less than between jet and stagnant ambient waters, which may explain why mixing is relatively limited.

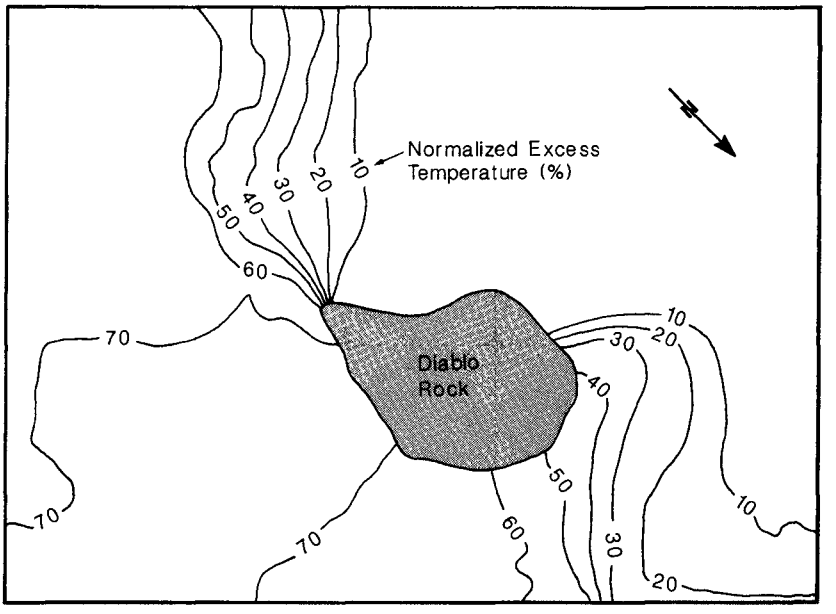

Figure 4. Surface Temperature Pattern around Diablo Rock

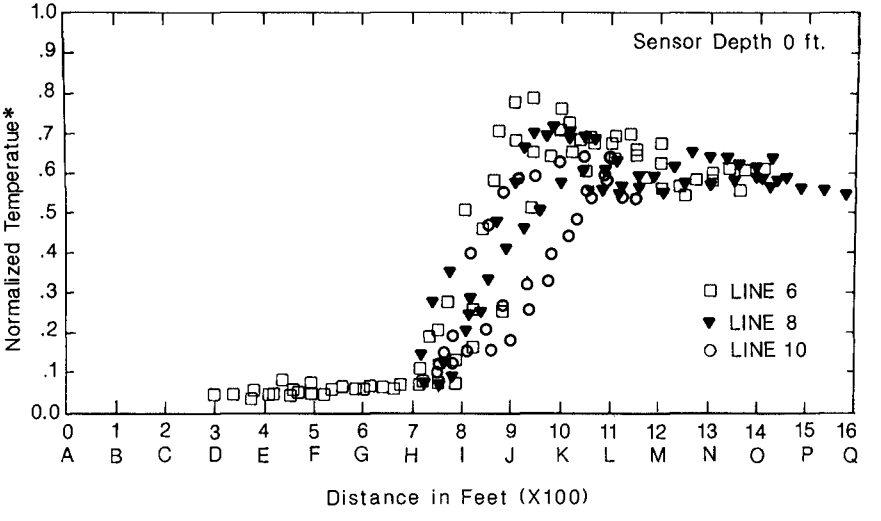

Figure 5. Temperature Transect Data for Test 5-1

Mixing at upcurrent edge between plume and receiving waters

A temperature gradient, as large as $4^{o}C$ in 25 meters, was measured at the upcurrent limit of horizontal spreading of the plume in the far-field. The presence of a warm water front, marked by a slick along which foam collected, has also been observed by Mimura and Horikawa (1982).

Offshore Plume Conditions

The offshore environment was found to have variable current conditions, in terms of both direction and magnitude. We see a variety of offshore plume centerline trajectories in figure 6. The ocean currents were found to be more a function of wind magnitude and directional persistence than the seasonal characteristics of the California Current. The winds at Diablo Canyon typically show a diurnal pattern and the plume can reverse direction within a day.

CONCLUSIONS

Data collection in the field has been made for a buoyant surface jet where near-field mixing is influenced by shallow waters, lateral confinement and a large obstruction. Maximum plume depth and centerline surface temperature decay can be described using standard scaling factors.

CHAPTER 192

Studies of Tsunami Hazard
I. Chen Lin[1] and C. C. Tung[2], M.ASCE

ABSTRACT: Tsunami hazard is investigated using the indirect approach with simple seismological and hydrodynamic models. It is assumed that earthquakes of random magnitude may originate anywhere with equal likelihood from a single straight fault and the site is located on the perpendicular plane bisecting the fault. The ground displacement is instantaneous and consists of a block uplift type of movement which may be circular or elongated in the plan view. The hydrodynamic model is based on linear long wave theory wherein the ocean is of constant depth and infinite in the horizontal extent, and the earth is flat. Tsunami hazard is computed for various values of the parameters and a sensitivity study is carried out to examine the effect of certain parameters on hazard.

INTRODUCTION

Tsunami hazard has been investigated using various approaches. Where historical information and measurements regarding tsunami innundation are available, a direct statistical analysis has been used (Houston et al. 1977, Loomis, 1976, Wiegel, 1970). Where such data are scarce, resort has been made to Bayesian estimation (Rascon, 1975) and the concept of indirect analysis (Garcia and Houston, 1975, Houston and Garcia, 1974). The indirect method follows closely the idea underlying seismic hazard analysis for facilities on land (Cornell, 1968, Der Kiureghian and Ang, 1975). The indirect approach, as carried out by Houston and Garcia (1974) and Garcia and Houston (1975), consists essentially of utilizing the information available regarding the magnitude, rate of occurrence and location of past tsunamigenic earthquakes in the region affecting the site, together with the knowledge of tsunami wave propagation based on hydrodynamic considerations to compute the hazard of tsunami at the site. Straightforward application of the indirect method of analysis, however, is time-consuming because of the large amount of numerical computation required to solve the hydrodynamic equations governing the propagation of tsunami waves from source to site. Since the frequency of occurrence, location, and magnitude of tsunamigenic earthquakes are random and there are uncertainties associated with some parameters and characteristics of ground motion, determination of the probability function of the wave elevation at the site due to tsunami by Monte Carlo simulation is difficult to achieve. It is therefore desirable that sensitivity studies be first performed to assess the importance of the various parameters on tsunami hazard. To conduct such an investigation,

[1]Assoc. Prof., Dept. of Hydraulic Engrg., Tam Kang Univ., Taipei, Taiwan Republic of China

[2]Prof., Dept. of Civil Engrg., North Carolina State Univ., Raleigh, NC, United States

the models employed must be sufficiently simple so that the probability computation may be kept at a minimum. For this purpose, an earlier study by Lin and Tung (1982) was undertaken.

In Lin and Tung (1982), it is assumed that earthquakes may originate anywhere with equal likelihood from a well-defined simple straight fault and the site is located on the perpendicular plane bisecting the fault (see Fig. 1a). The ground displacement consists of a block uplift type of movement which takes place instantaneously and is circular in the plan view with a uniform offset (see Fig. 1b). The source area S is empirically determined from the seismic moment m_o (see Fig. 2 and Eq. (4)) characterized by the value of the parameter C_1 and the magnitude of offset $\bar{D}$ is related to the seismic moment m_o by way of definition (see Eq. (3)). The seismic moment in turn depends on the frequency of occurrence of tsunamigenic earthquakes in the region (see Fig. 3) defined by the parameter β from which the probability density function of seismic moment is obtained (see Eq. (12) and Lin and Tung, 1982). The hydrodynamic model is that of linear dispersive waves given by Kajiura (1963) wherein the ocean is infinite in the horizontal extent, sphericity of the earth is ignored and water is of constant depth. The maximum wave elevation at the site due to earthquake of seismic moment m_o is shown by Lin and Tung (1982) to be given by

$$Z = CW\left(\frac{m_o}{r}\right) \tag{1}$$

where C is a constant, $W(\cdot)$ is a nonlinear function and

$$r = (D^2 + r_o^2)^{1/2} \tag{2}$$

is the distance from the source to the site (see Fig. 1) the probability density function of which may be obtained from that of the uniformly distributed random variable D. The tsunami hazard is shown to be simply dependent on $U(z) = P(Z > z) = 1 - F_Z(z)$ where $P(\cdot)$ denotes the probability of the event enclosed in the parentheses and $F_Z(z) = P(Z < z)$ is the probability distribution function of Z which is determined from the probability density functions of the statistically independent random variables m_o and r according to Eq. (1). A sensitivity study is performed to determine the influence of the various parameters on the hazard. The parameters considered are β (see Fig. 3), fault length L (see Fig. 1), C_1 (see Fig. 2) and the upper-bound seismic moment m_{ou}. It is found that values of β and L have little effect on the hazard but the hazard is sensitive to the values of C_1 and m_{ou} if one is interested in large values of tsunami wave elevation at the site. The obvious implication of this finding is that the values of C_1 and m_{ou} must be selected with care when important facilities are designed against extreme conditions.

In the above study, an important feature of the tsunamigenic earthquake that is left out of consideration is the shape of ground displacement. It is known that the ground displacements associated with tsunamigenic earthquakes are generally elongated in the plan view (see Figs. 4 and 5) and their orientation has significant effect on tsunami wave height at the site (Kajiura, 1970).

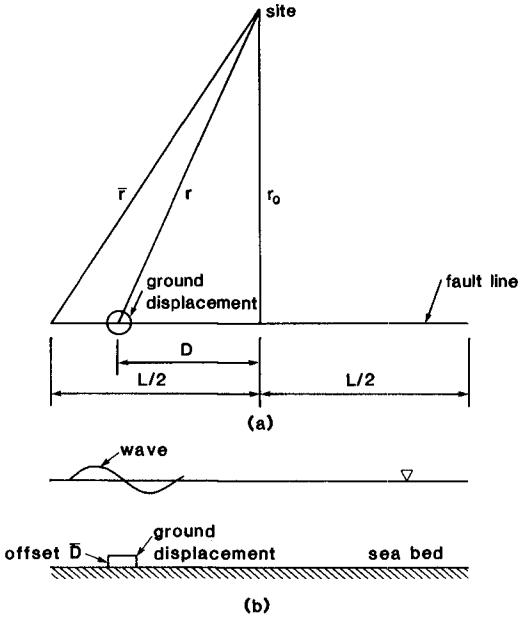

Figure 1. Seismic Model Used in Lin and Tung (1982)

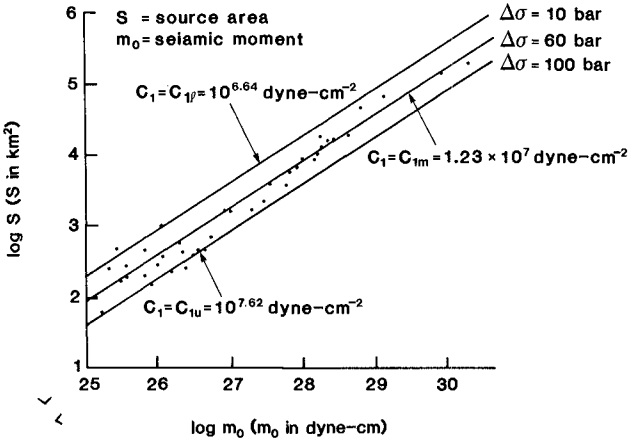

Figure 2. S - m_o Relation

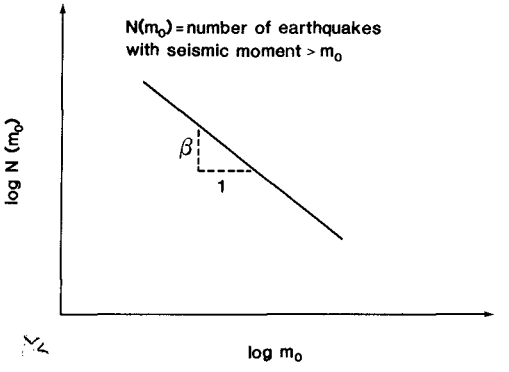

Figure 3. $N(m_o) - m_o$ Relation

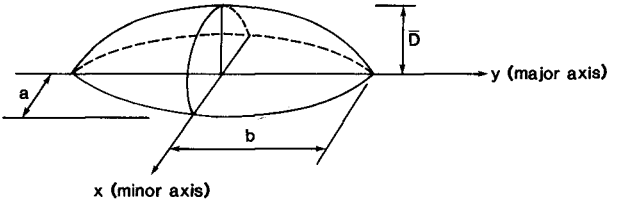

Figure 4. Ground Displacement

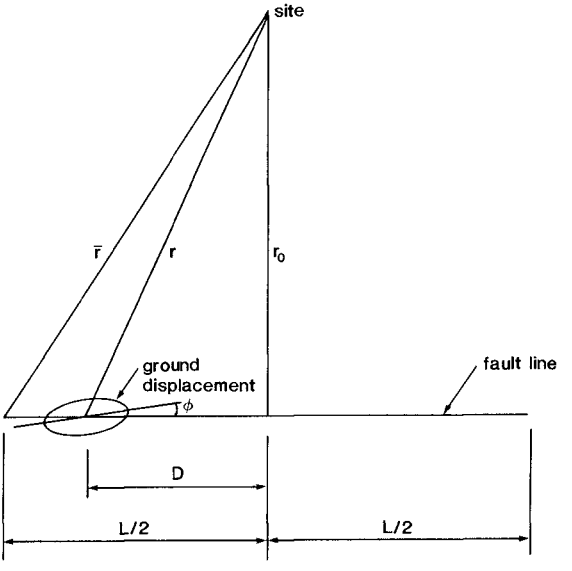

Figure 5. Source - Site Relation

The objective of this study is to consider elongated ground displacement. Specifically, the ground displacement is elliptical in the plan view with an elliptical crest (see Fig. 4). The remaining part of the seismological model is the same as that used in the earlier study (Lin and Tung, 1982) (see Fig. 1). That is, earthquakes may occur anywhere along a straight fault with equal likelihood and the site is situated on the perpendicular bisector of the fault. These assumptions may be removed without causing undue difficulty as pointed out by Der Kiureghian and Ang (1975). In fact, a finite number of fault lines with arbitrary orientation and location with respect to the site may be included. The major axis of the elliptical ground displacement may be inclined making an angle ϕ with the fault (see Fig. 5) and ϕ is taken as a random variable uniformly distributed in the arbitrarily chosen range $(-\pi/12, \pi/12)$. The hydrodynamic model in this study is different from the linear dispersive wave model used in Lin and Tung (1982) and is based on the linear non-dispersive long wave theory given by Kajiura (1970) wherein the ocean floor is also considered flat, the water is of constant depth and infinite in the horizontal extent. The reasons for selecting this particular model are (a) the resulting expression of wave elevation due to tsunami waves at the site is convenient to use and (b) when the elliptical ground displacement (see Fig. 4) is specialized to circular shape, the results may be checked against those obtained in the earlier study (Lin and Tung, 1982) to examine the sensitivity of the hazard to the two different hydrodynamic models used.

Numerical results of tsunami hazard are obtained for various value of the parameters. Since it is found in Lin and Tung (1982) that the values of β (Fig. 3) and fault length L (Fig. 1 or 5) have little effect on the hazard, these quantities are given fixed values. The remaining parameters, the site-fault distance r_o (see Fig. 5) and the shape factor B = b/a (see Fig. 4) are assigned various values in this study. A sensitivity study is performed to evaluate the effect of the upper bound seismic moment m_{ou} and the value of C_1 (see Fig. 2) on the hazard.

In the following, for easy reference, relevant details of the seismological and hydrodynamic models used in this study, shown in more detail in Lin (1985), are given.

SEISMOLOGICAL MODEL

The seismic moment denoted m_o is defined as (Kanamori and Anderson, 1975, Kanamori, 1977)

$$m_o = \mu S \bar{D} \tag{3}$$

where μ is the rigidity of the medium, S is the plane area of ground displacement and $\bar{D}$ is the average offset (see Fig. 4). Based on earthquake data, Kanormi and Anderson (1975) obtained the empirical relation between the seismic moment m_o and the source area S given by

$$m_o = C_1 S^{3/2} \tag{4}$$

as shown in Fig. 2 where the average value of C_1 is $C_{1m} = 1.23 \times 10^7$ dyne-cm^{-2} with S measured in square centimeters. From Eqns. (3) and (4), the average offset $\bar{D}$ is

$$\bar{D} = \frac{(m_o C_1^2)^{1/3}}{\mu} \tag{5}$$

For elliptical ground displacement

$$S = \pi ab = \pi a^2 B \tag{6}$$

where $B = b/a$ is the shape factor so that

$$a = \frac{(m_o/C_1)^{1/3}}{(\pi B)^{1/2}} \tag{7}$$

It is seen that the source area S (hence a and b) and the offset $\bar{D}$ of the ground displacement are all simply related to the seismic moment m_o.

HYDRODYNAMIC MODEL

The hydrodynamic model is that of linear non-dispersive long waves due to Kajiura (1970) in which the earth's sphericity is ignored and the ocean is assumed to be of infinite horizontal extent and constant depth. The maximum wave elevation at the site due to an instantaneous elliptical ground displacement shown in Figs. 4 and 5 is given by

$$Z = A_1 \frac{\sqrt{m_o}}{q} \tag{8}$$

Details of the derivation of Eq. (8) are given in Lin (1985) and are not shown here. In Eq. (8),

$$A_1 = \frac{0.495}{\mu} \left(\frac{C_1^2 B^3}{\pi}\right)^{1/4} \tag{9}$$

is a constant and

$$q = \frac{(A_2 D^2 + A_3 D - A_4 + A_2 r_o^2)^{3/4}}{(D^2 + r_o^2)^{1/2}} \tag{10}$$

where

$$A_2 = 1 + (B^2 - 1)\cos^2\phi$$

$$A_3 = r_o(B^2 - 1)\sin 2\phi \tag{11}$$

and

$$A_4 = r_o^2(B^2 - 1)\cos 2\phi$$

The quantities D, r_o and ϕ are all defined in Fig. 5.

Hazard Analysis

In Eq. (8), the maximum wave elevation Z at the site is a function of the random seismic moment m_o, the uniformly distributed random variable D specifying the location of the source, and the uniformly distributed random variable ϕ, representing the angle between the major axis of the ellipse and the fault line. The three random variables are assumed to be statistically independent and the probability density function of m_o was determined in Lin and Tung (1982) to be

$$f_{m_o}(m_o) = \nu\beta m_{o\ell}^{\beta} \frac{1}{(m_o)^{1+\beta}} \qquad m_{o\ell} \leq m_o < m_{ou} \tag{12}$$

where

$$\nu = \frac{1}{1 - \left(\frac{m_{o\ell}}{m_{ou}}\right)^{\beta}} \tag{13}$$

is a normalizing constant. Since earthquakes with seismic moments smaller than a certain lower limit have no engineering significance and the energy released by an earthquake is also limited, the lower and upper bound magnitudes, denoted $m_{o\ell}$ and m_{ou}, are specified.

The tsunami hazard is defined as the probability that for a given length of time, the water level Z at the site exceeds a certain specified value z. It is shown in Lin and Tung (1982) that the hazard depends on the knowledge of U(z), the probability that $Z > z$, given that an earthquake has occurred, which may be determined by the standard technique of transformation of random variables from Eqns. (8), (10), (11) and (12). Details of the manner in which U(z) is obtained is given in Lin (1985).

RESULTS

To compute U(z), the values of the parameters must be specified. It is assumed that the rigidity of the medium is $\mu = 3 \times 10^7$ dyne-cm^2, and the lower and upper-bound seismic moments are $m_{o\ell} = 10^{22.05}$ and $m_{ou} = 10^{29.55}$ dyne-cm which correspond to earthquake magnitudes $m_\ell = 4$ amd $m_u = 9$, respectively. In Lin and Tung (1980), it is found that the hazard is not sensitive to the values of β and fault length L. Thus, $\beta = 0.8$ and L = 6000 km are used here. In selecting the value of r_o, it is noted that the hydrodynamic model (Kajiura, 1970) used in this study requires that the site be at least moderately far away from the source; therefore values of r_o = 2000, 6000, and 10000 km are selected. To examine the effect of shape factor B = b/a on hazard, values of B = 1 and 5 are assigned, where B = 5 is the case as shown in Fig. 5 and B = 1 represents the case of circular ground displacement.

In Figs. 6 and 7, U(z) are plotted for B = 5 and 1 respectively and for r_o = 2000, 6000 and 10,000 km. The abscissa z is the wave elevation at the site in centimeters. Enlarged insets are inserted. Comparison

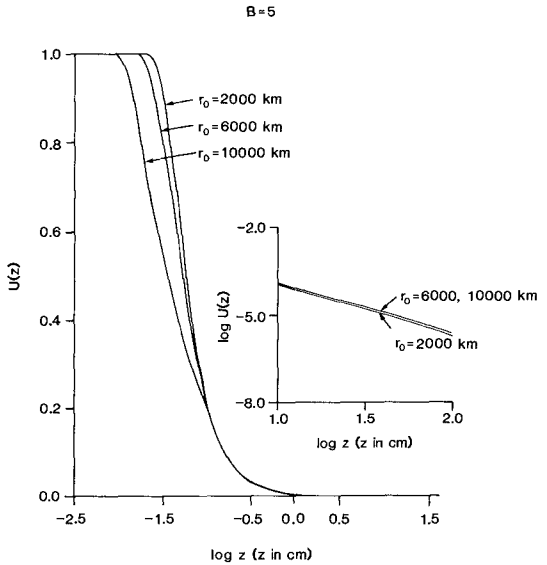

Figure 6. U(z) for B = 5

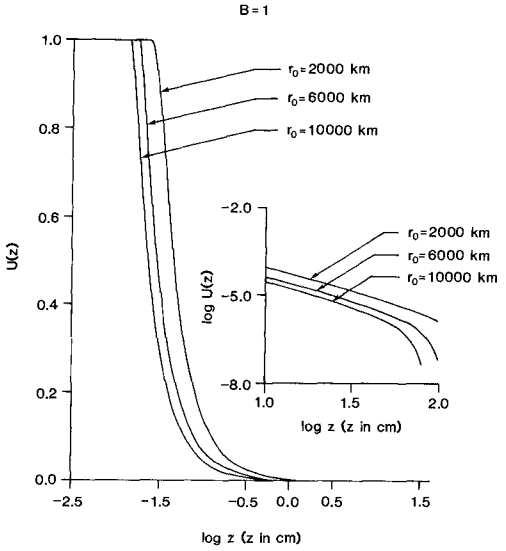

Figure 7. U(z) for B = 1

of Figs. 6 and 7 shows that the elongated ground displacement (B = 5) gives rise to larger values of the hazard.

It is of some interest to compare the results of the case B = 1 with those obtained in Lin and Tung (1982) in which the ground displacement is circular in its plan view. The hazard computed in the present case is much larger than in Lin and Tung (1982). This difference is due primarily to the two different hydrodynamic models used.

In obtaining the results shown in Figs. 6 and 7 we also considered the simplified case in which the angle ϕ between the major axis of the elliptical ground displacement (see Fig. 5) and the fault line is set identically equal to zero in which case the quantity q in Eq. (8) is simply related to the single random variable D as

$$q = \frac{(B^2D^2 + r_o^2)^{3/4}}{(D^2 + r_o^2)^{1/2}} \tag{14}$$

Our results show that the error incurred in U(z) is insignificantly small.

SENSITIVITY STUDIES

Many of the parameters in the models contain uncertainties. It is shown in Lin and Tung (1982) that uncertainties in the values of β and L do not affect the hazard to any significant extent. In this study, only the sensitivity of the hazard to the values of m_{ou} and C_1 are examined for different values of r_o and B.

Sensitivity of Hazard to Upper-bound Seismic Moment

To examine the sensitivity of the hazard to upper-bound seismic moment m_{ou}, U(z) is computed using different values of m_{ou} in much the same way as is done in Der Kiureghian and Ang (1975) and Lin and Tung (1982). For specified water level z, let $U_1(m_{ou})$ be the value of U(z) for the arbitrary value of m_{ou}, and U_2, the value of U(z) for $m_{ou} = 32$ dyne-cm. The ratio $\bar{R} = U_1(m_{ou})/U_2$, termed the hazard ratio, is plotted as a function of m_{ou} in Figs. 8 and 9 for B = 5 and B = 1 respectively for r_o = 2000 km and r_o = 10000 km. Fig. 8a (B = 5, r_o = 2000 km) shows that, for z = 50 cm, for example, if $m_{ou} = 10^{29}$ dyne-cm, the computed hazard is about 75% of that using $m_{ou} = 10^{32}$ dyne-cm. For $m_{ou} = 10^{31}$ dyne-cm, the ratio is close to unity. However, for z = 10 cm, a change of m_{ou} from 10^{32} to 10^{29} dyne-cm would result in a decrease of the hazard of only 3% (versus 25% for z = 50cm). That is, the influence of m_{ou} on the hazard is important when one is interested in large values of the maximum wave elevation at the site. Comparing Fig. 8a with Fig. 8b (r_o = 10000 km), it is seen that as r_o increases the curves become steeper indicating that the hazard is more sensitive to changes in m_{ou} if r_o is larger.

Figs. 9a and 9b are drawn for r_o = 2000 and 10000 km using B = 1 (circular ground displacement). The observations made above for the case B = 5 remain valid. Comparison of Figs. 8 and 9 shows that for the

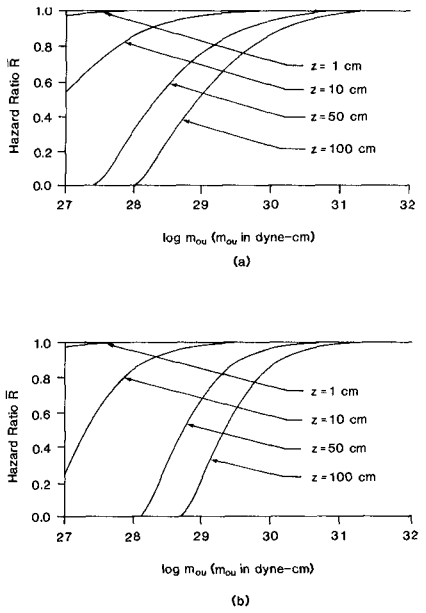

Figure 8. Hazard Ratio $\bar{R}$ for B = 5, r_o = 2000, 10000 km

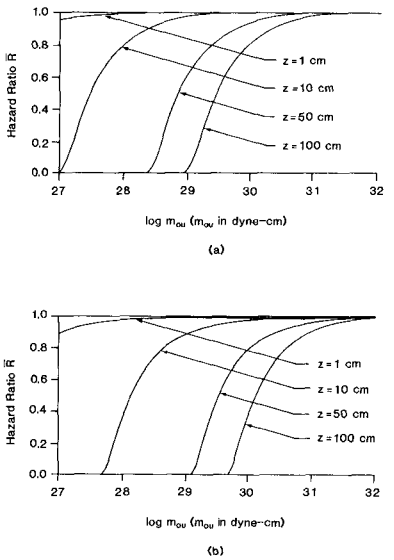

Figure 9. Hazard Ratio $\bar{R}$ for B = 1, r_o = 2000, 10000 km

same values of z and r_o, the curves in Fig. 9 are steeper. That is, the influence of m_{ou} on the hazard is more important when the ground displacement is considered to be circular in the plan view.

Sensitivity of Hazard to Value of C_1

Kanamori and Anderson (1975) used data of 41 earthquakes to construct Fig. 2 relating seismic moment and source area. The data points in the figure are scattered between stress drop values of $\Delta\sigma$ = 10 bars and $\Delta\sigma$ = 100 bars. The value of C_1 in Eq. (9) used in computing U(z) is $C_1 = C_{1m} = 1.23 \times 10^7$ dyne-cm^{-2} and is based on $\Delta\sigma$ = 60 bars. Corresponding to $\Delta\sigma$ = 10 and 100 bars, the values of C_1 are $C_{1\ell} = 10^{6.64}$ and $C_{1u} = 10^{7.62}$ dyne-cm^{-2} respectively. The subscripts ℓ, u and m are introduced to refer to lower and upper limits and mean value of C_1.

To examine the extent the value of C_1 affects the hazard, let $U_\ell(z)$, $U_m(z)$ and $U_u(z)$ be the hazard values corresponding to $C_1 = C_{1\ell}$, C_{1m} and C_{1u} respectively for arbitrary but specified values of z. The ratios $R_1 = U_\ell(z)/U_m(z)$ and $R_2 = U_u(z)/U_m(z)$ may be plotted as functions of z for various values of r_o and B. Fig. 10 gives R_1 and R_2 for r_o = 6000 km and B = 5. From the figure, it is seen that when z < 0.05 cm the ratios are near unity; for a wide range of z, from 0.05 cm to 50 cm, the ratios R_1 = 2.7 and R_2 = 0.4 remain practically constant and when z reaches 50 cm the ratios undergo a rather drastic change.

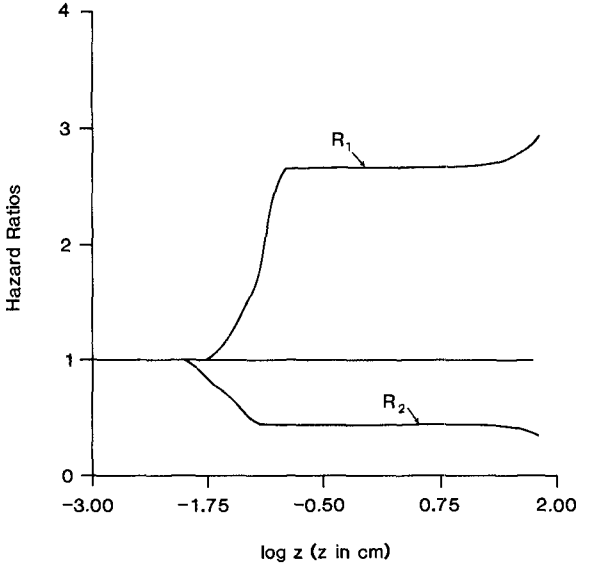

Figure 10. Hazard Ratios R_1 and R_2 for B = 5, r_o = 6000 km

Results were also obtained for B = 5 and r_o = 2000 and 10000 km, and for B = 1, r_o = 20000, 6000 and 10000 km. The ratios are almost identical to those shown in Fig. 10 and are therefore not given. Finally, comparison of these ratios with those of Lin and Tung (1982) shows that influence of C_1 on hazard is much more significant in the present case than in Lin and Tung (1982).

CONCLUSIONS

Based on the results of this study and those of Lin and Tung (1982), the following conclusions may be drawn:

(1) Shape of ground displacement (in plan view) has important effect on hazard; elongated ground displacement gives rise to larger values of hazard than circular ground displacement.

(2) The angle between the major axis of the elliptical ground displacement and the fault line need not be treated as random and may be set equal to zero without affecting hazard to any appreciable degree unless the geological condition indicates that the angle should assume a specific value.

(3) The hazard is critically dependent on water wave theory used.

(4) The value of upper-bound seismic moment has an important effect on the hazard if the maximum wave elevation of interest is large; more so if the site is further removed from the fault line and if ground displacement is circular in plan view.

(5) The hazard is appreciably affected by the value of C_1 for $z > 0.05$ cm.

(6) In future studies, elongated ground displacement should be used unless geological condition indicates otherwise.

CHAPTER 193

A Three Dimensional Model of the Gulf of Alaska

Shiao-Kung Liu and Jan J. Leendertse

Abstract

This paper presents the development of a three dimensional model of the Gulf of Alaska. The model extends between the Vancouver Island and the Aleutian Islands covering approximatedly 1.5 million square kilometers over the northern Pacific Ocean. Formulated on an ellipsoidal horizontal grid and variable vertical grid, the model is schematized over a 81 x 53 x 10 grid structure. The solution scheme is implicit over the vertical and is programmed using one-dimensional dynamic array for the efficient use of machine storage. The turbulence closure scheme for the non-homogeneous vertical shear is formulated so that the potential and kinetic energetics are monitored and transferred in a closed form.

The hydrodynamic model is coupled to a two-dimensional stochastic weather model and an oil-spill trajectory/weathering model. The former also simulates stochastically the cyclogenetic/cyclolytic processes within the modeled area.

The paper also compares the computed results with the available field data. Good agreements are found in tidal amplitude and phases as well as currents.

The Three-Dimensional Modeling System

The model of the Gulf of Alaska uses a modeling system which consists of a three-dimensional hydrodynamic model, a two-dimensional stochastic/deterministic weather model, and an oil spill trajectory/weathering model (Fig 1).

The hydrodynamic model is formulated according to the equations of motion for water and ice, continuity, state, the balance of heat, salt, pollutant and turbulent energy densities on a three-dimensional variable grid. In the vertical, the momentum and constituent transport over the variable layers are solved implicitly. The horizontal grid network coincides with the global ellipsoidal system and has a one-to-one mapping to a Mercator projection for graphical outputs. The derivation of the model equation and the comparison between other layered models are available in the open literature, eg. Liu and Leendertse, 1978, in which aspects such as open boundary conditions, numerical stability, solution discontinuity, and conservation properties are also discussed.

The RAND Corporation, Santa Monica, Calif. 90406, U. S. A.

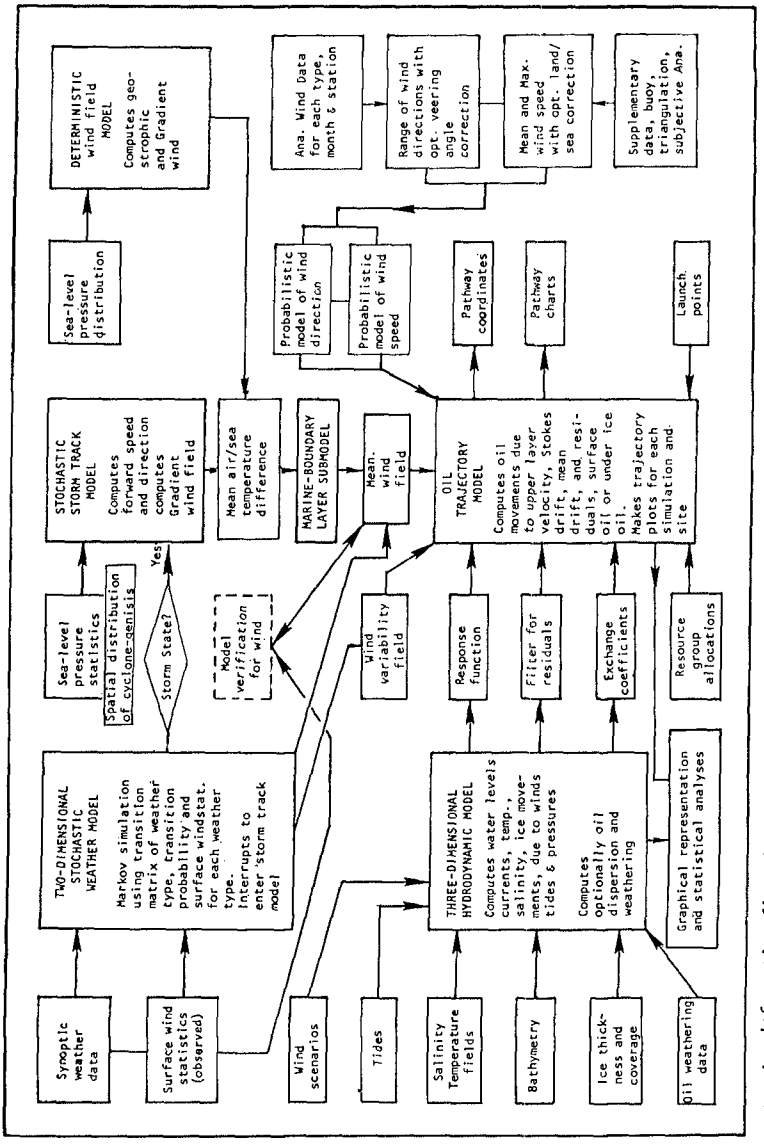

Fig. 1— Information flow chart showing that both the three-dimensional hydrodynamic and the weather model provide important parameters needed by the oil-spill trajectory model. These parameters are difficult and expensive to measure over the entire coastal waters. Observed wind roses, if available, can still be used to drive the trajectory model in its simplist mode.

In the vertical turbulence-closure scheme, the energy production term from the surface layer is computed from the parameterization of the wind-wave generation mechanism. This approach thus circumvents certain difficulties associated with the traditional two-equation model in which a symmetry condition is assumed (as a moving wall, same as the bottom).

The model is capable of having arbitrary layer number and layer thickness, therefore minimizes numerical (pseudo) mixing in deep water. In deep water, the stratification is usually more pronounced than in the shallower, well-mixed areas.

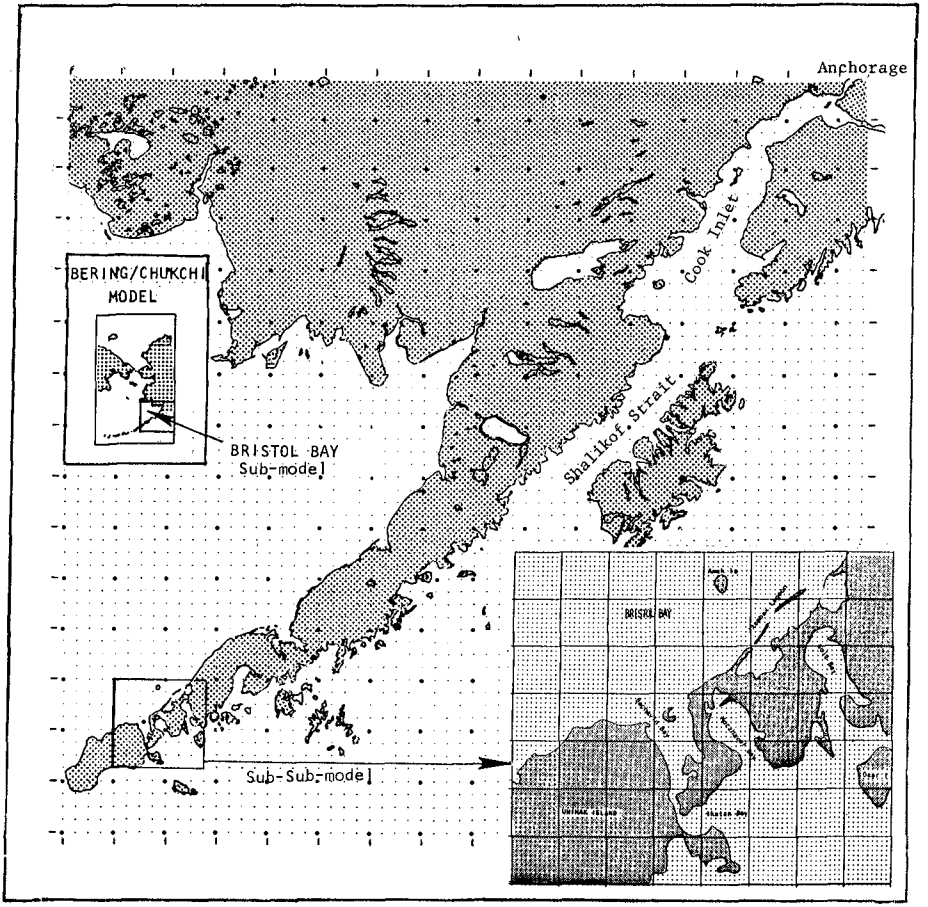

Fig. 2-- A sub-model of Bering Sea covering the area of Bristol Bay and a portion of the Gulf of Alaska. Insert map at the lower left corner is another sub-model of this one, covering the area of Izembak Lagoon.

The model of the Gulf of Alaska

The model of the Gulf of Alaska is the largest model covering the Alaskan coastal waters developed by the authors. Alaskan coast line stretches longer than the other states of the continental U. S. combined. Because of the complex coastal features, a series of nested submodels are needed to resolve the circulation dynamics of the near shore lagoons and the ecologically sensitive passages (Fig. 2). The nested models derive their boundary condition from the larger model because conducting field work in Alaska is both difficult and expensive. The embayment in the NE corner of Fig. 2 is the Cook lnlet, where the largest astronomical tides in the Pacific are found; sometimes reaching 13 meters. Also present are the strong currents and residual circulation induced by the nonlinear interaction between the advective mechanism and bethymetry of the coast.

The three dimensional perspective diagram in the upper part of Fig. 3 illustrates the along-shore view of the higher modes in the water level variation with the highest point at the head of Cook lnlet while the lower diagram shows the cross-shore variations.

Figure 4 shows the computed co-tidal chart for the semidiurnal component and the comparison between the computed amplitudes and phases at four locations where observed data are avaliable (Schumacher and Muench, 1980). Fig. 5 through 8 present the computed horizontal/vertical velocity components and the turbulent energy intensities at levels 1,3,5,7,8,9 at a location near the openning of Cook lnlet (Portlock Bank). At that location, the computed hodograph in Fig 9 nearly matches the observed current ellipse.

The computed tidal ellipses for the entire Gulf of Alaska, from Vancouver lsland to the Aleutian lslands are presented in Fig. 10. ln order to show the strong tidal currents within the Cook lnlet and over shelf areas, the plotting scale is set at 200 cm/sec per grid spacing. The maxmum tidal excursions are found in the middle of Cook Inlet where the tidal currents can reach 140 cm/sec in either direction. Currents over the shelf break can also reach 70 cm/sec. The computed tidal residual current distribution within the Gulf of Alaska is presented in Fig 11. In the figure, the maximum residual current in Cook lnlet is approximately 7.5 cm/sec, which is 5.5 percent of the local maximum tidal current. Over the shelf and in the Shalikof Strait, the direction of the residual current is primarily to the southwest.

Model Behavior and Discussion

In stratified geophysical flow, the density-induced vertical exchange often has a time scale much shorter than its horizontal baroclinic counterpart. lt also plays an important role in the coastal ecological balance via the euphotic/energetic processes.

It therefore creates stringent demands on the accuracy of modeling. On one hand, advances made in other discipline, such as the aerodynamic modeling, can often be applied to the geophysical flows, but, on the other hand, the differences in the free-surface and other boundary treatments makes the closure technique not necessarily identical for stratified flows. Specially

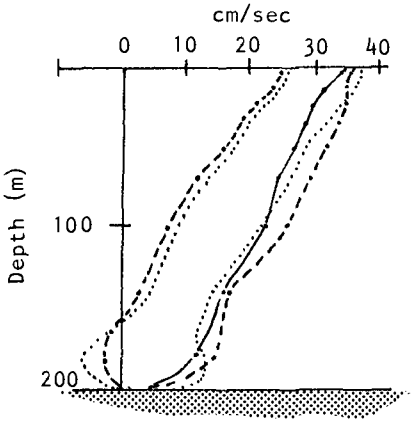
Comparison between the computed hodograph and the measured surface tidal current ellipse



Vertical distribution of magnitude of the computed currents illustrated in the hodograph (near Cook Inlet)

Fig. 9

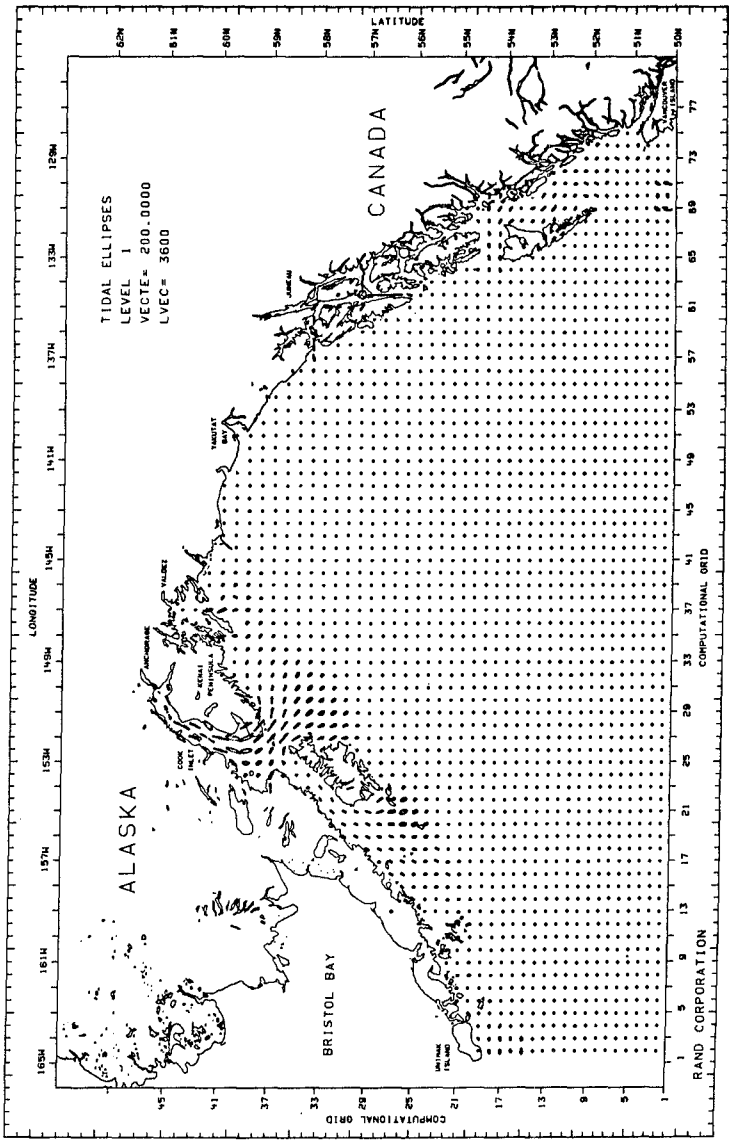


Fig. 10--Computed tidal ellipses in the Gulf of Alaska using a plotting scale of 200 cm/sec per grid spacing. Maximum tidal excursions are found in the middle Cook Inlet where the tidal currents can reach 140 cm/sec in either direction. Currents over the shelf-break near Kodiak are of elliptical rotary-type and can reach a maximum speed of 70 cm/sec.

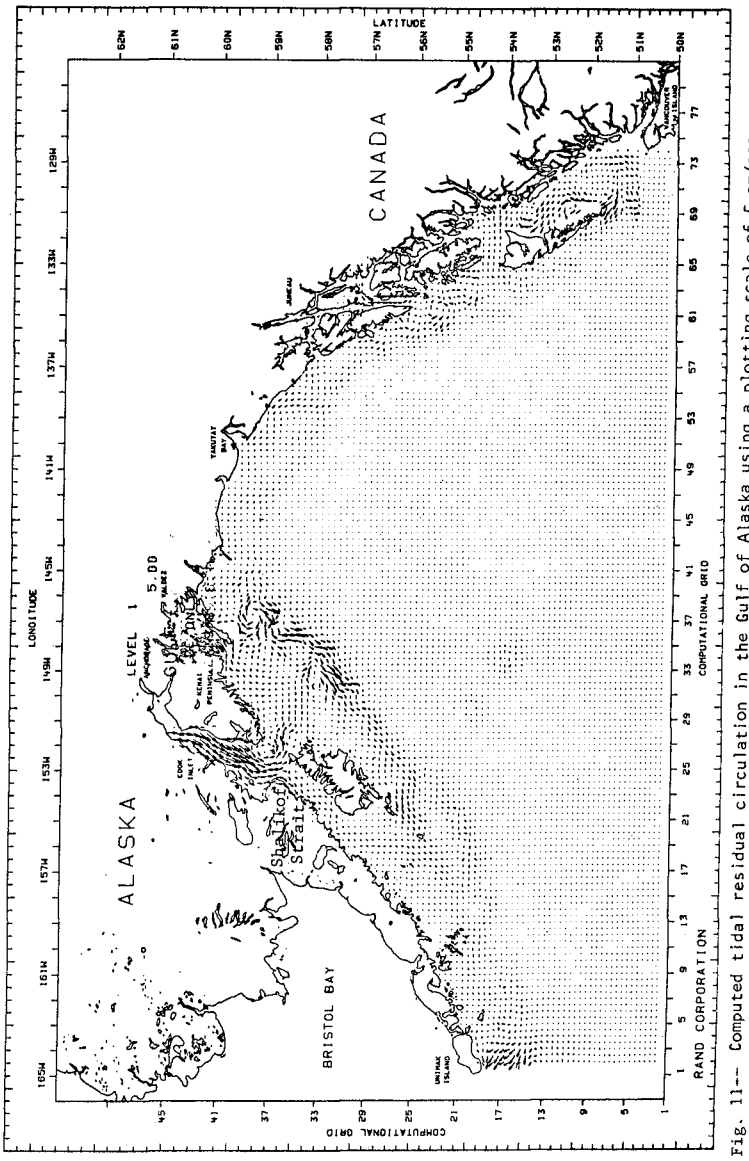

Fig. 11— Computed tidal residual circulation in the Gulf of Alaska using a plotting scale of 5 cm/sec per computational grid. Maximum residual current in the middle Cook Inlet can reach a speed of 7.5 cm/sec which is approximately 5.5% of the local maximum tidal current. Over the shelf break and in the Shalikof Strait, residual currents flow primarily toward the southwest.

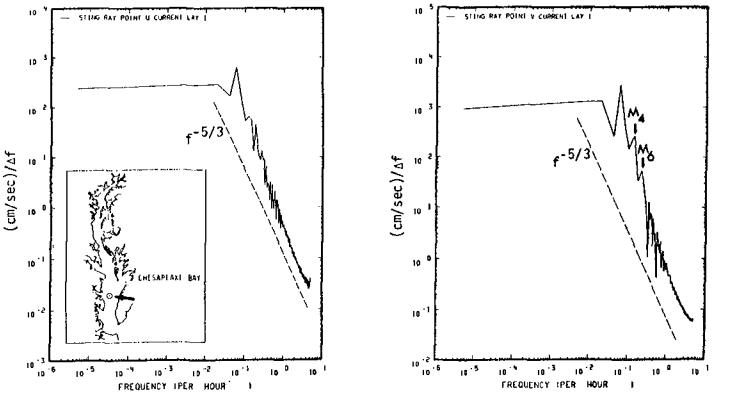
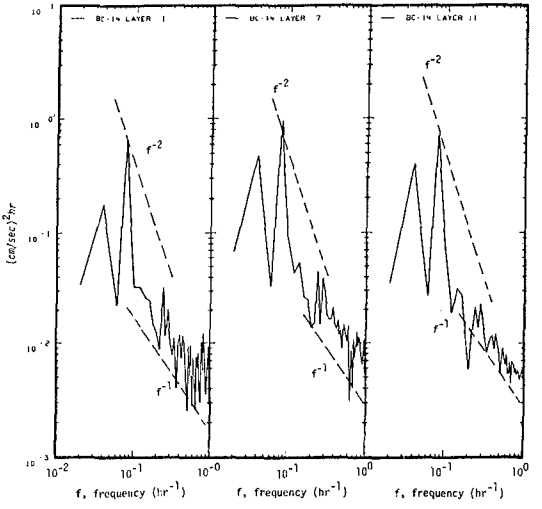


Driven only with M^2 tide (monochromatic wave) at the open boundary the proposed numerical scheme is capable of producing the cascade of energy distribution according to the universal "minus five-third" through the models nonlinear advective process (Hinze, 1959).



For the stratified fluid, the computed spectra of the vertical displacements (in the surface layer, within pycnocline and near bottom) and significant energy distribution agree with the observed spectra of the first mode of internal waves (Gordon, 1978).

Fig. 12

because coastal flows are primarily two-dimensional. Recent findings on the non-equilibrium statistical characteristics of turbulence have shown that even the universal Kolmogorof-constant of the tubulence spectrum has to be modified for two-dimensional turbulence. Models relying on the Richardson number-related parameters are specially susceptible to field measurement inaccuracies.

Consequently, over the past several years, we have modified our earlier models from requiring Richardson-number-related parameters to an energy balance approach. In the new method, the production and dissipation terms in the vertical energy turbulence-balance equation takes this form:

$$\bar{S}_e^z - D_e = \underbrace{a_3 \overline{L\sqrt{e}}^z \left[(\delta_z \bar{u}^x)^2 + (\delta_z \bar{v}^y)^2\right]}_{(1)} + \underbrace{a_3 \overline{L\sqrt{e}}^z \frac{g}{\bar{h}^z \rho} (\delta_z \bar{\rho}^z)}_{(2)} \underbrace{- a_2 e^{3/2}/L}_{(3)}$$

Where the first term denotes production, the second term represents the portion supplied that is used in potential energy increase, and the third term is dissipation. Some computational results are presented in Figs. 12 and 13. For example, when driven only with M2 tide (a monochromatic wave) at the open boundary, the numerical scheme is capable of producing the cascade of energy partition according to the universal "minus five-third" law through the model's non-linear advective process (top graphs of Fig. 12, also see the recent measurements by

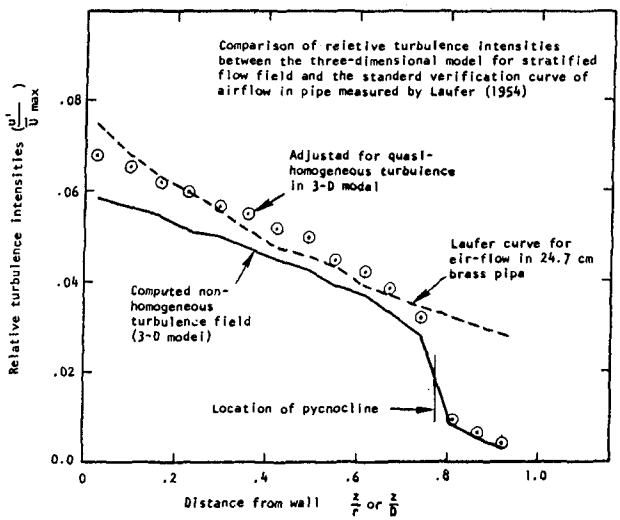


Fig. 13-- When the computed relative turbulence intensities at 15 layers are normalized with respect to the bottom distance, they are nearly the same when compared with the standard verification curve of airflow measured in brass pipe (made by Laufer for NACA, later NASA).

Heathershaw, 1979 and Elliott, 1984). Peaks of the spectra for two-dimensional turbulence are not uniquely located, however, it depends on the energy input and the relative location from the boundary (the so-called localization factor). The lower graphs of Fig 12 show the computed partitions of spectral energy of the vertical displacement near the pycnocline agree with the observed spectra of the first mode of internal waves (Gordon, 1978). When the computed relative turbulence intensities at various layers are normalized with respect to the bottom distance, they are nearly the same when compared with the NASA standard verification curve of airflow measured in brass pipe (made by Laufer). The insulation of momentum transfer across the pycnocline is evident . It is also clear that in stratified flows, more measurements and better model formulation are still needed.

Acknowledgments

This study was supported by the U. S. Bureau of Land Management through interagency agreement with the National Oceanic and Atmospheric Administration (NOAA), under which a multi-year program responding to needs of petroleum development of the Alaska Continental Shelf is managed by the Outer Continental Shelf Environmental Assessment Program Office.

Thanks go to our RAND colleagues Mr. A. B. Nelson and Mrs. G. Coughlan for their indispensable efforts in simulations and report preparation.

CHAPTER 194

Tsunami Threat Evaluation by Historical Documents, Numerical Model and Stochastic Model

Shigehisa Nakamura*

An evaluation of local tsunami threat was studied first refering to the historical documents and the catalogs. Secondly, an example of a numerical model of a finite difference method was discussed in relation to problems for reproducing the past local tsunamis and predicting a forthcoming tsunami. Lastly, a stochastic model was utilized in order to evaluate an exceedance probability of tsunami occurrencein an interested time period at an interesting local area where the concerened information or prediction was in need. The evaluation of a local tsunami threat is useful to get a more effective measure for the tsunami warning system and for protection works.

Introduction

In the coastal area, especially around the circum-Pacific seismic zone, they have had severe tsunami hazards repeatedly for thousands years. With recent higher utilization of the coastal area, they have felt it an urgent need to evaluate the nest tsunami threat of the interested location on the coast by an appropriate scientific techniques. Of cause, they have had learned well theirown way to reduce their loss and mitigate their damage with their experiences. If an evaluation of the threat is obtained properly, it can be a basic information for tsunami warning and protection.

As generally well known, the tsunami threat has locality. The author now wish to extend some concept about tsunami threat evaluation by historical documents, numerical model and stochastic model. With these, evaluation of local tsunami threat can be a more effective measure for establishing the tsunami warning system and for improving the concerned protection works.

Sources of Historical Tsunami Data

In order to get a glance of local tsunami threat, it is essential to refer to a tsunami catalog first. Such a catalog has been well composed afer compilation and reconfirmation of the historical documents. Iida, Cox and Pararas-Carayannis(1967) completed a preliminary catalog of tsunamis in the Pacific. Soloviev and Gao have published the russian editions for the western(1974) and eastern(1976) Pacific respectively. The most recent Japanese edition was published by Watanabe(1986). A more convenient tsunami hazard map was issued by NOAA and it seems very useful.

*Associate Professor, Shirahama Oceanographic Observatory, DPRI, Kyoto University, Katada-Hatasaki, Shirahama, Wakayama, Japan

The first step to compose these tsunami catalogs was to find out the old descriptions which included all of what was concerned the tsunamis and which were mostly kept in form of hand-written. So that, it has been necessary to confirm whether the descriptions are reliable or not at any step of compiling and/or composing them. Even at present, successive effort has been continued to search and reveal the fact out of the historical documents.

These documents are in form of a part of personal diaries, official documents, religious notes kept in Shinto-Shrines, Buddism Temples, Local Office of the Government or simple personal description. Occasionally, some specific merchants left vivid memories. Nakamura (1984a,b, 1985) has been continuing to find out yet any historical description which includes notes concerning the past significant tsunamis in order to get a more precise revision for the local forthcoming hazardous tsunami warning and protection.

As an example, the author take now a local tsunami problem in the coastal area of Tanabe and Shirahama(to the details, refer to the work by Nakamura, 1987, in Bull.DPRI,Kyoto Univ.). Tanabe and Shirahama have had suffered repeatedly from the past hazardous tsunamis accompanied by the big earthquakes, as well known. Tanabe and Shirahama are facing the northwestern Pacific and there are yet many of unpublished materials which inform us the facts which have been left as they have been without any aware of the importance(Nakamura,1984, 1987). A local tsunami catalog can be composed referring to the catalogs introduced above and adding the recently revealed facts out of the unpublished materials. With these additional local documents, a more detailed local tsunami catalog for Tanabe and Shirahama has been composed by Nakamura, 1984).

A brief list is shown as follows referring to the catalog. The significant events are chronologically listed following a format which includes the items of the date in AD or in Japanese era, estimated location of the epicenter taken from Watanabe's recent catalog, the magnitude of the earthquake denoted by M, the tsunami magnitude denoted by S(Nakamura, 1986a) and a brief note about the event.

(1) 684AD Nov.29(Temmu 2) A big earthquake, land falls, destroyed the government offices, warehouses, shrines and temples. Rice fields were drowneded by the tsunami flood. Hot spring ceased at Iyo(Ehime). Tsunami hits Kumano area. Hot spring at Muro also ceased. This is the oldest event confirmed and found in "Nihon-Shoki" and cited everywhere.
(2) 887AD Aug.26 16h(Ninna 9) 135.3E,33.0N, M=8.6, S=3. Big earthquake. Tsunami hits on the coast and lost many lives.
(3) 922AD(Engi 22) 137.7E,33.8N, M=7.0, S=1. A strong earthquake with tsunami.
(4) 1360 Nov.23 0h(Shohei 15) 136.2E,33.4N, M=7.0, S=2. Repeated shocks of the earthquake. On the next day also a big shock felt. Tsunami hits in morning the day after the next day.
(5) 1361 Aug.3(Shohei 16) 135.0E,33.0E, M=8.4, S=3. Description says an earthquake around Kii and tsunami hits Settsu(Osaka).

(6) 1403(Ouei 10) 136.5E,33.7N, M=7.0, S=1. Strong earthquake in Kumano district and tsunami hits.
(7) 1408 Jan.21 18h(Ouei 14) 136.9E,33.8N, M=7.0, S=1. Strong earthquake in Kumano. Possibly tsunami hits.
(8) 1498(Meio 7) High water caused hazards on the coast of Kii.
(9) 1510 Sep.21 4h(Eisho 7) 135.7E,34.6N, M=6.7, S=1. Estimated epicenter is located in Osaka Bay. Tsunami hits.
(10) 1520 Apr.4 18h(Eisho 17) 136.3E,33.6N, M=7.0, S=1. Temple's buildings destroyed by the earthquake. Houses drawnded.
(11) 1605 Feb.3(Keicho 9) 134.9E,33.0N, M=7.9, S=3. Big waves at Kumano. Hiro(1700 families) lost 700 families at the tsunami.
(12) 1707 Oct.28 12h30m(Hoei 4) 135.9E,33.5N, M=8.4, S=4. Details have been kept as the memory to give warning for their successors. Official reports described the damage and the fast-aid request for foods and living materials. After identifying the location appeared in these descriptions, an illustration was completed as a local hazard map which was shown in Fig.1.
(13) 1854 Dec.24 16h(Kaei 7 or Anse 1) 135.6E,33.2E, M=8.4, S=4. The more detailed descriptions of the earthquake and tsunami has been found to make the tsunami hazard map as in Fig.2. At a glance, there are little difference between the two maps of Figs.1 and 2 except learning what were written in the descriptions in 1707 and in 1854.
(14) 1944 Dec.7 13h35m(Showa 19) 136.2E,33.7N(depth 30 km), M=8.0, S=3. On the coast of Kii Peninsula facing the Pacific, houses washed away by the tsunami. No record was kept except only a limitted number of the mareograms which includede the tsunami.
(15) 1946 Dec.21 4h19m(showa 21) 135.6E,33.0N(depth 30 km), M=8.1, S=3. Several scientific records have been kept. With the local descriptions and hearings the tsunami hazard map was made as found in Fig.3 for the event of 1946. This map shows a successful protection works around the mouths of the Rivers, though the protection works have done against the flood of the river discharge. The illustration of Fig.3 shows the other new areas and coasts had the tsunami hit. This means that these areas had never used or lived by the end of the Second World War.
(16) 1960 May 23 19h11mGMT(Showa 35) 73.5W,41.0S, M=8.25, S=4. The Japanese Islands had hit by the tsunami on 24 May 1960 without any seismic shock in advance. The tsunami was highest at Isla Mocha in Chile(20 to 25 m) and it crossed the Pacific to hit the Japan Islands as well as the Chilean coast. In Chile, 909 persons died, 834 persons lost, 667 persons injured and many buildings had severe damage. Even in Japan, 119 persons died, 29 persons lost, 872 persons injured, 2830 houses destroyed, 19,863 houses drownded and the unexpected damage of boats.

Even when we are aware of the difference between the epicenters of 1707 event, 1854 event, 1946 event and 1960 event, the author cannot deny the active effect of the protection works completed by that time looking at and comparing the illustrations in Fig .1 for 1707, Fig.2 for 1854, Fig.3 for 1946 and Fig.4 for 1960. Adding to that, we have to be aware of any type of unexperienced tsunami damage.

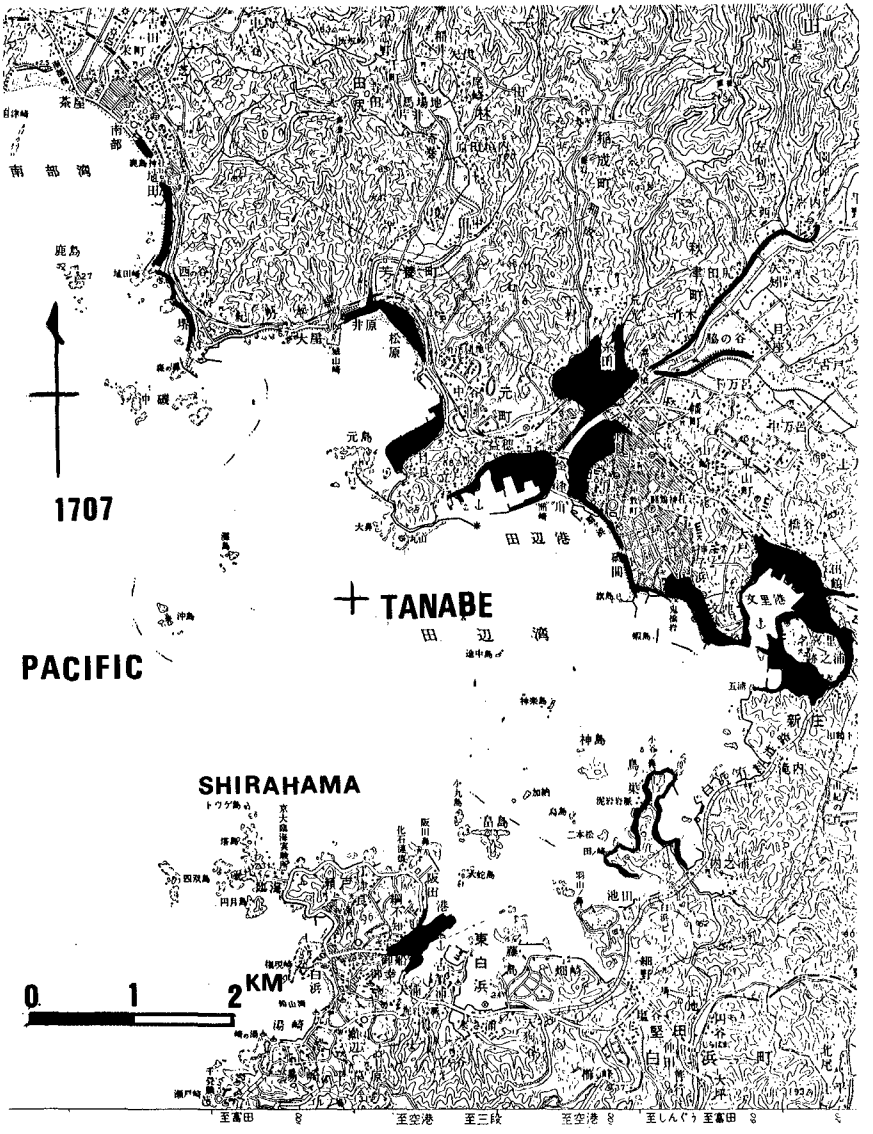

FIG. 1.— Hazard Map of 1707 Hoei Tsunami; Note: The Suffered Area by the Tsunami Flood Was Shown by a Black Coloured Patch or Black Lines along the Coast or along the River Levee and River Bank.
(Location of the cross is 135°21'E, 33°43'N)

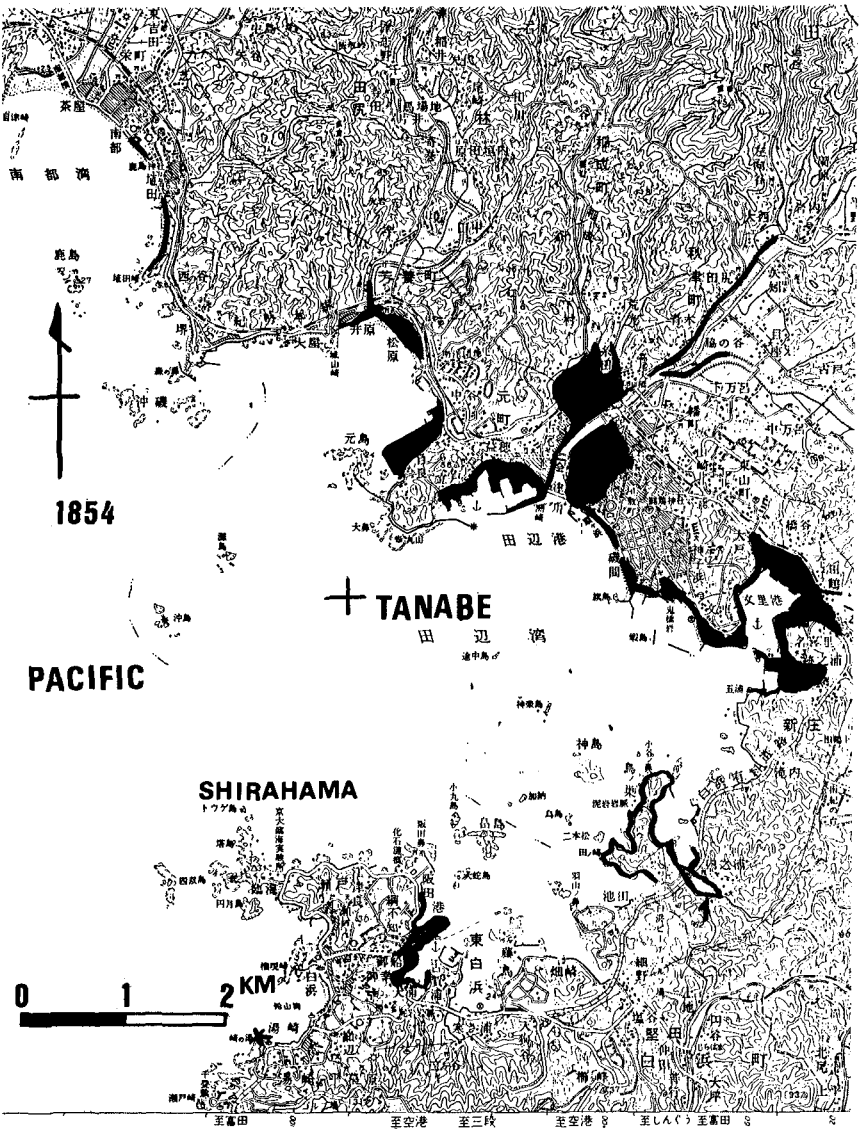

FIG. 2.— Hazard Map of 1854 Ansei Tsunami; Note: The Suffered Area by the Tsunami Flood Was Shown by a Black Coloured Patch or a Black Lines along the Coast or along the River Levee and River Bank. (Location of the cross is 135°21'E, 33°43'N)

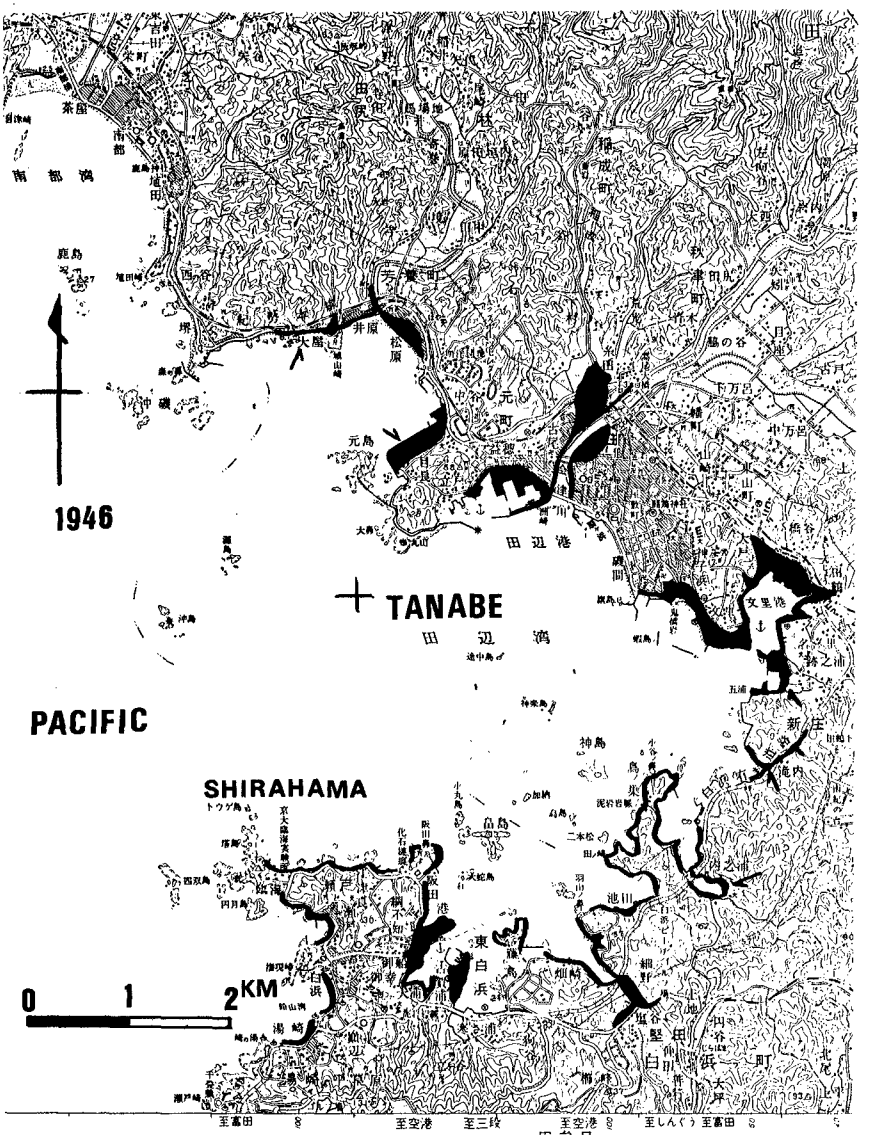

FIG. 3.— Hazard Map of 1946 Nankaido Tsunami; Note: The Suffered Area by the Tsunami Flood Was Shown by a Black Coloured Patch or Black Lines along the Coast or along the River Levee and River Bank (Location of the cross is 135°21'E, 33°43'N)

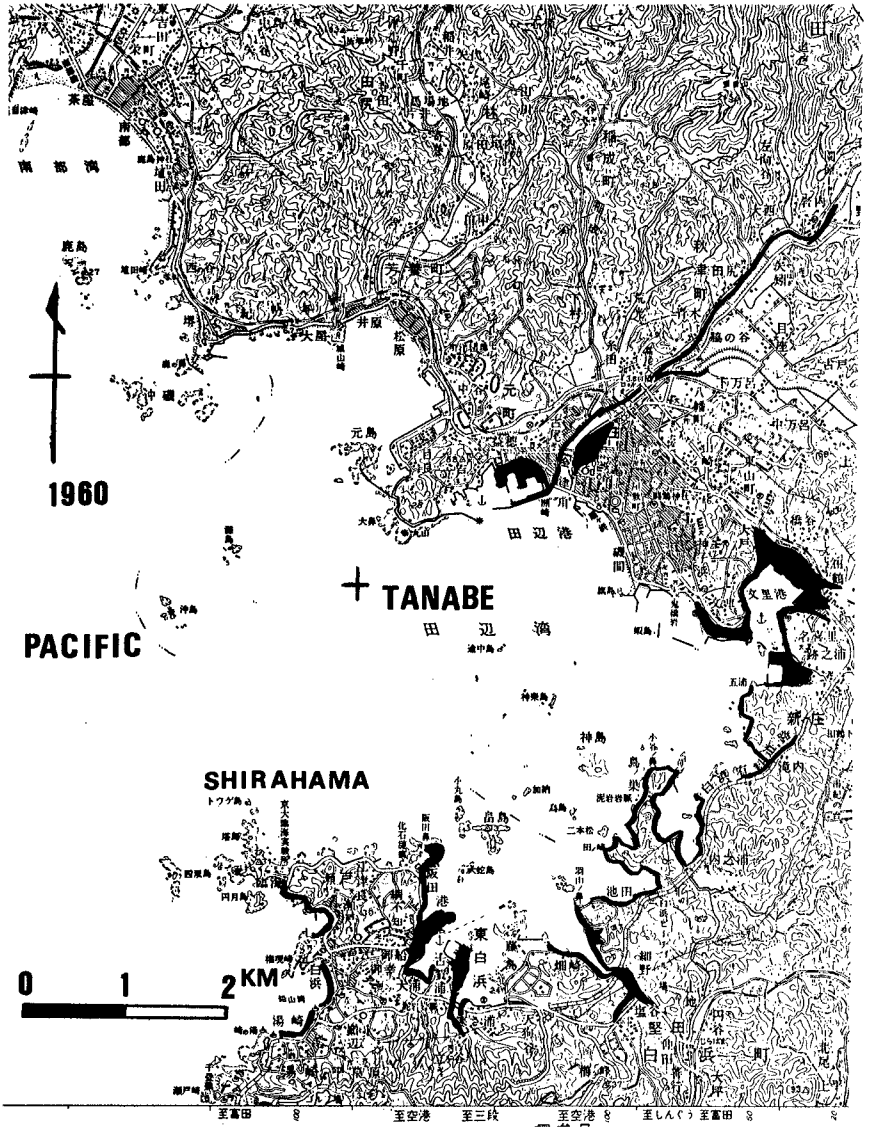

FIG. 4.— Hazard Map of Chilean Tsunami; Note: The Suffered Area by the Tsunami Flood Was Shown by a Black Coloured Patch or Black Lines along the Coast or along the River Levee and River Bank (Location of the cross is 135°21'E, 33°43'N)

Numerical Modelling

Techniques for numerical model has been accepted as a convenient to simulate any local tsunami and to reproduce the forthcoming one. This helpe us to establish an improvement of the present tsunami warning and protection worke. The author feels himself it hard to count up the tsunami model published by thie time. Here, the author introduces only the Japaneee recent works, i.e., by Hatori(1974), Aida(1983), Iwasaki(1983) and Iida et al.(1983). Ando(1982) has tried to reconstruct a fault formed by the main shock of the 1946 earthquake by using the available tsunami data. Nakamura(1983) has ueed and improved Loomis(1972)'s technique for long water waves in a finite difference scheme.

At the author's feeling, the most of the numerical scientists or engineere seem truet that the differential equation is equivalent to a difference equation. When a function u is given as a function of a variable t, it ie correct mathematically that

$$u'=du/dt=\lim_{\Delta t\to 0} \Delta u/\Delta t. \tag{1}$$

However, this does not mean that

$$u'=du/dt=\Delta u/\Delta t, \tag{2}$$

generally. The necessary condition is that the value of Δt is small enough for the given continuoue function, and the limit of (1) have to converge to a certain finite value.

Let ue consider a function $u(t;x,y,z)$ and write it u for our convenience. The first derivative is u'. As for a differential equation $u'=f$,

$$u(t+\Delta t)=u(t)+ f\cdot\Delta t, \text{and } f=f(t;x,y,z), \tag{3}$$

there is no promis to get a finite value of $u(t+\Delta t)$ mathematically if the function f is not continuous or has a specific property. For our convenience, we have to consider a case for

$$f= -u\frac{du}{dx} -v\frac{du}{dy} - \frac{1}{\rho}\cdot\frac{d\zeta}{dx} +\left[\frac{d}{dz}\left(K\frac{du}{dz}\right)\right], \text{ etc.} \tag{4}$$

The differential equation $u'=f$ has a quite similar form to that used for numerical computations of gravitational water waves in a shallow water, i.e., the equation of motion in hydrodynamics. There must bemany of worke not appeared to us as a erroneous solution or ae a simply unexpected solution without any consideration in the scope of mathematics,even if it is reasonable mathematically.

Some other engineer must consider a way to get only for his expected solution using the higher terms of the Taylor's power series expansion of the function u around its variable t. That is,

$$\frac{\Delta u}{\Delta t} = u' + \frac{\Delta t}{2!} u''. \tag{5}$$

Now, consider again similar way as that for (3) and (4), and take $\frac{\Delta u}{\Delta t} = f$, then we have

$$u'' + \left(\frac{2}{\Delta t}\right) u' - f = 0. \tag{6}$$

As for an expected periodical solution in form of $u=u_0\exp(ipt)$, The following relation should be satisfyed in (6).

$$p^2 - \frac{2i}{\Delta t} p + f = 0. \tag{7}$$

From (7),

$$p = \frac{i}{\Delta t} \pm \left[f - \left(\frac{1}{\Delta t}\right)^2 \right]^{1/2} . \tag{8}$$

Hence, the first term in (8) shows that any disturbance decreases monotonously in the model. The second term controls the property of the solution u satisfying (6). If

$$f - \left(\frac{1}{\Delta t}\right)^2 > 0 , \tag{9}$$

the solution u of (6) has a part of an oscillatory solution. If not, this solution must be a monotonous increasing or decreasing function. When the function f is known apriori, it is easy to distinguish whether the solution is oscillatory or not referring to (8) or (9). Although, for example as in case of the function f given by (4) or as a case of an unpredictable function f, we can only control it by a choice of the value of Δt. The necessary condition is that the value of Δt is preferable as small as possible.

This is a remark for a numerical model of a finite difference method which occasionally gives a troublesome unexpected solution or a divergent solution even when so-called"Neumann's criteria" for obtaining a stable solution is well satisfyed. Although, this remark is not neccessarilly exact in the scope of mathematics.

As far as we concern the tsunami researches by this time, one of the tasks for the coastal engineers at present must be to utilize well the numerical model for their successful purposes. When the tsunami source condition is given, we can now utilize a numerical model to simulate and predict a local tsunami only for satisfying given condition. We have to be careful pioneers to introduce some other improved techniques to know when the next tsunami occurs in our interested area in the expected time period. One of them must be that appearing in the next section where the tsunami catalogs are fully utilized as a reference data source.

Stochastic Model

Probability of tsunami occurrence frequency on the coast of California was evaluated first by Wiegel(1970). Rascon and Villareal (1975) worked a stochastic evaluation of possibility of tsunami hit on the Pacific coast of Mexico. Successively, similar studies has been undertaken to know the local property of the tsunami occurrence frequency. Even in Japan, the coastal area in the northwestern Pacific, a simple statistical evaluation about the forthcoming big earthquake and big tsunami. However, it cannot be given as any scientific value for a long time. Only documentation had been

the focus to spend their effort, which is at present highly evaluated in the field of coastal engineering for the basic data of tsunami warning and protection works. Almost all of the studies on tsunami occurrence frequency belongs to a stochastic problem. For example, Nakamura(1986a) has considered to introduce an extensive or modified Poisson process in order to get a better fit to the exceedance probability of local tsunami.

Referring to the tsunami catalogs, we can prepare to make a sequence of annual tsunami occurrence for an interested local area. If we take the tsunami event to be annual or the biggest tsunami in every year, then the annual exceedance frequency of tsunami occurrence in the interested area can be evaluated as a Poisson process or an extended Poisson process. Nakamura(for example, 1986a) has expressed exceedance probability P of tsunami occurrence as a function of an interested time interval t, i.e.,

$$P = 1 - \exp(-\Lambda t), \tag{10}$$

with

$$\Lambda = \Lambda_0 \exp[-\beta(h-h_0)^n], \tag{11}$$

where h is tsunami height and reference tsunami height h_0 is taken to be 1 m in this case. And the value of $\Lambda(=1/378)$ or $\Lambda_0(=58/378)$ is inverse of annual return period for h and h_0 respectively. The specific values of $\beta(=0.34)$ and $n(=1.0)$ characterize locality of the exceedance probability of tsunami occurrence. The above expression corresponds to the case of so-called "Poisson process" if n=1. The author uses tsunami scale S(or m) in the other cases instead of tsunami height h for a convenience. As a result, the author could obtain an exceedance probability of 25 % for a tsunami occurrence of the 1707 class(the local maximum of h was 13 m) at least once in a time period of 100 years.

Lastly, the author wishes to remark that a numerical model and a stochastic model are complementary each other as far as we refer to the historical tsunami descriptions and to the tsunami catalogs.

Conclusions

Evaluation of local tsunami threat was studied (i) using and referring to the historical descriptions and documents compiled by the author with an adjustment of what is written in the tsunami catalogs, (ii) using a numerical model of a finite difference method the author discussed what should be remarked mathematically in a simplified form, and a probability of local tsunami threat was evaluated using a stochastic model for an extended Poisson process. As seen above, evaluation of local tsunami threat is useful to establish a more effective measure for the tsunami warning or protection works.

This work was completed at the agreement for submitting the ASCE Proceedings of the 20th International Conference on Coastal Engineering by Setsuo Okuda, Director of the Disaster Prevention Research Institute, Kyoto University and Yoshito Tsuchiya, Head of the Shirahama Oceanographic Observatory. The author has to express his

thanks to the permission for using the published map of the Geographical Survey Institute at the preparation of the illustrations in this text. In addition, the author cannot forget to appreciate for those who have payed their consideration at the Conference in Taipei as well as for Dr. Billy L. Edge and his fellows.

CHAPTER 195

100 YEARS OF FORESHORE RECLAMATION IN SINGAPORE

S K PUI*, MICE, MASCE

ABSTRACT

Singapore is an island republic with about 10% of her land area reclaimed from foreshore during the last century. In this Paper, past reclamation works are reviewed and possible future reclamation works are predicted.

1 INTRODUCTION

Due to its strategic location, Singapore has since its founding in 1819, been centre for trade and commerce, transportation and other activities in the region. The result was a rapid growth in population, from about 200 in 1819 to 2.5 million todate, in a country with land area of only 636 km^2, inclusive of its 57 offshore islands and 53 km^2 of land reclaimed from foreshore (Information Division, 1986).

The resulting high population density has created a constant need to reclaim land from the foreshore for various development projects along the coastline, especially those related to airports, seaports, maritime and petroleum industries, housing, commerce and recreational parks. The calm wave environment and rather low tidal range (about 3 m) prevail along the coastline of Singapore, has enable the reclamation works to be executed economically.

2 EARLIER RECLAMATION WORKS

Earlier foreshore reclamation works were mainly confined at the southern tip of the main island of Singapore, from Kallang Basin at the east to Tanjong Berlayer at the west. Total land area reclaimed before self-rule in 1959 was about 3 km^2.

The first early major foreshore reclamation works was the reclamation at the then Telok Ayer Bay about 100 years ago, for the construction of a link road between the then commercial centre at Singapore River and a new deep-water port at Keppel Channel. Fill material was obtained by levelling of 2 hills at Tanjong Pagar (Bogaars, 1956). Covering approximately 7 ha, the project took more than 8 years to complete.

*Principal, S K Pui Chartered Consulting Engineers, No. 1 Magazine Road, #04-06B, Central Building, Singapore 0105.

This reclaimed land was subsequently further extended and completed in 1915 with the formation of Telok Ayer Basin. A comprehensive map, drawn 82 years ago, showing earlier reclamation proposals along Singapore coastline was contained in Reith's Handbook to Singapore (1907).

Earlier reclamation works also include reclamation of 9 ha land at the present Container Terminal by the then Tanjong Pagar Land Company in 1880's, and reclamation along Keppel Channel in 1900's for the construction of seaport and shipyards.

At the conference of Kallang and Geylang Rivers, about 1 km^2 of land was reclaimed in 1930's for the construction of Kallang Airport. Seven million m^3 of fill material was obtained from a hill situated some 6 km away from the site. Trains were used for the transportation of the fill material. This project took 4 years to complete. During the same period, the coastline from the mouth of Singapore River to the mouth of Rochore River was also reclaimed for the construction of an esplanade.

3 RECENT RECLAMATION WORKS

With the achievement of self-rule in 1959, and subsequently independence in 1965, various massive reclamation works were initiated to cater for rapid development in public housing, industry, commerce, recreation, air and seaport development, and for construction of express ways. To ensure that reclamation works can be executed without much hinderence, necessary amendments were made to the Land Acquisition and the Foreshore Ordinances in 1964.

Recent reclamation works are mainly carried out by three Statutory Boards as agents to the Government, namely Jurong Town Corporation (JTC), Housing and Development Board (HDB) and Port of Singapore Authority (PSA). Together, these three reclamation agents have reclaimed a total of about 48 km^2 land area, representing more than 90% of the total land area reclaimed from foreshore during the last 100 years. Since 1965, Singapore has been growing in land area at a rate of 8,000 m^2 per day (Radhakrishnan etal, 1983). About 285 million m^3 of fill material was moved in these reclamation works.

Major reclamation works executed by the JTC, mainly for industrial development, are Tuas foreshore reclamation, Jurong Port extension, Loyang Reclamation, Senoko Reclamation, reclamation at Seraya Island, Ayer Merbau Island, Busing Island and Sakra/Bakau Islands. The JTC is now reclaiming a further 6 km^2 of land area off Tuas, a project scheduled to complete in 1988.

Reclaimed lands executed by the HDB are mainly for housing, commercial and recreational purposes. Since 1963, the HDB had reclaimed the entire south-eastern coastline of Singapore Main Island, from Changi at the east to the city centre at the south. These works had been executed in 7 major phases, in tune with public housing development schemes during which hills at Bedok and Tampines were levelled for the building of new towns. The HDB is now reclaiming 9.6 km^2 of foreshore area at Punggol, expected to complete in 1993.

During the last 20 years, the PSA has carried out reclamation works at 21 offshore islands for various purposes, including catering for recreational needs. At the main island, about 10 km^2 of land was reclaimed by the PSA, mainly at Changi, for the building of Singapore Changi Airport, and at Pasir Panjang, for the development of a seaport. Unlike JTC and HDB, fill for the reclamation works executed by the PSA was mostly dredged from seabed.

4 AVAILABILITY OF FILL MATERIAL

Main sources of fill material for reclamation works in Singapore are earth obtained by levelling of hills and seabed sand obtained by dredging.

Before 1974, fill used for reclamation was obtained entirely from levelling of hills, an operation carried out in phase with development of public housing and industrial estates. Borrow area for East Coast Phases III and IV Reclamation Project was subsequently converted into a fresh water reservoir (Wei, 1983).

As land source is rapidly diminishing in capacity, seabed sand is dredged as fill. For the reclamation of offshore islands, seabed sand was the natural fill material. Dredging of seabed has enabled ships with deeper draught to call at Singapore Port, the World's 2nd busiest port after Rotterdam.

During the last 100 years, nearly 165 million m^3 of earth and 120 million seabed sand were moved to reclaim 53 km^2 of land.

5 SHORE-PROTECTION METHODS

When the reclaimed land is not used for wharf construction, shore-protection methods normally adopted for the reclaimed land are either revetment, or headland breakwaters or sandy beach.

Todate, more than 76 km of revetment was built involving at least 2.5 million m^3 of granite blocks, while nearly 20 km of reclaimed coastline is protected by headland break-

waters. The latter is concentrated at the eastern part of Singapore Island, where the reclaimed coastline is mainly catered for recreational purposes.

The remaining 40 km reclaimed coastline is unprotected resulting in formation of sandy beaches wherever sand is used as fill. One typical example of which is the creation of artificial beach at Singapore Changi Airport, where favourable angles of wave approach to the coastline result in negligible littoral drift and thus a remarkable stable beach is formed (Pui, 1983). With mild wave environment prevails around the entire Singapore Island, it is advisable that the sandy beach concept be adopted wherever there is no space limitation for beach formation.

6 FUTURE RECLAMATION IN SINGAPORE

Future reclamation works in Singapore would be executed in deeper water as most of the tidal flats at the fringe of the main island had been reclaimed. It is estimated that another 70 km^2 of land can be reclaimed without much affecting the tidal flows around the island, as well as on limited seaspace for navigation and anchorage, and for submarine services.

As fill is not readily available in large quantity for future major reclamation works, research is now being done in local university on use of marine clay as fill (Information Division, 1986). Marine clay covers much of the seabed around the island. If it is found suitable as fill, future reclamation works could proceed with less imported fill.

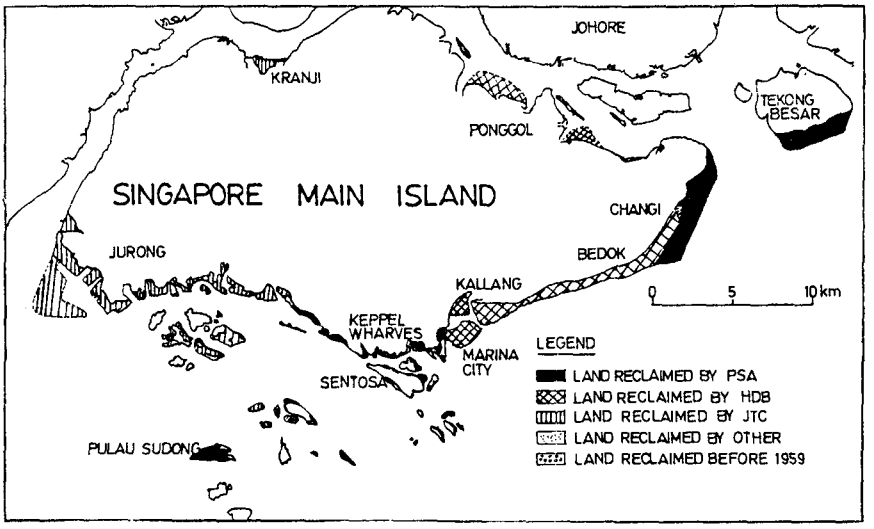
7 CONCLUSION AND RECOMMENDATIONS

In view of high population density, there is a constant need in Singapore for reclamation works in foreshore area for various development projects along the coastline.

Earlier foreshore reclamation works, commenced about 100 years ago, were mainly confined at the southern tip of Singapore Main Island. Works included reclamation for construction of road, and building of air and seaports.

Recent reclamation works are mainly carried out by three Statutory Boards as agents to the Government. Together, they have accounted for 90% of the land reclaimed from foreshore during the last 100 years.

Nearly 285 million m^3 of fill material was moved to reclaim 53 km^2 of land area during the last century. As a result, there is little suitable fill source left for further reclamation. Research works are now being done in



RECLAMATION MAP OF SINGAPORE

local university to verify the suitability of marine clay as fill, a material found in abundant quantity in Singapore.

With mild coastal environment prevails around the Singapore Island, it is suggested that sandy beach concept be adopted as a form of coastal protection method to reclaimed land, wherever there is space for development of beach slope. Saving up to US$1 million per kilometre is envisaged as compared with construction of revetment. Where littoral drift is significant, headland breakwaters can be provided to control the changes of the coastline.

Reclamation works in Singapore are envisaged to continue unabate as it is estimated that another 70 km² of foreshore could be reclaimed economically. This estimated area is more than the total land area reclaimed during the last 100 years.

CHAPTER 196

WAVE-INDUCED EFFECTS IN A COOLING WATER BASIN

Fredric Raichlen, F.ASCE*

Introduction

Wave-induced effects have been observed in a model of the cooling water intake basin of the Pacific Gas and Electric Company's Diablo Canyon Nuclear Power Plant. This model, built to an undistorted scale of 1:45, was constructed initially to study the design for the repair of the terminus region of the West breakwater damaged in storms of January 28, 1981. It was decided by PC&E to investigate, in the same model, the forces due to waves acting on two air intake structures for the auxiliary saltwater pumps and the pressures on the external and the internal walls and the ceiling of the cooling water intake structure located in the man-made cooling water intake basin. During the course of the experiments it was noticed that the mean water level in the breakwater enclosed basin changed as a function of the incident wave characteristics. This allowed waves to overtop the cooling water intake structure which, without the change in mean water level, would not have occurred. It is this difference between the mean water level and the still water level inside the cooling water basin, defined as ponding, which will be reported herein.

Diskin, et al. (1970) investigated this effect behind low and submerged permeable breakwaters in a two-dimensional wave tank model. As was mentioned by them, in normal breakwater tests it is a common practice to provide some means of communication between the seaward and shoreward side of the breakwater so that precisely this mean water level change due to overtopping of the structure does not occur. For their experiments the change in mean level varied from about 5% of the deep water wave height to 32% of the deep water wave height depending upon the submergence of the breakwater crest; the smallest change corresponded to the largest depth over the breakwater crest.

This effect was discussed by Dalrymple and Dean (1971), and they proposed an analytical model based on the conservation of mass. The estimated inflow was equated to an estimate of the return flow over and through the permeable structure. Some limited agreement with the results of Diskin, et al. (1970) were shown.

Seelig (1983) presents the results of laboratory experiments conducted to investigate reef-lagoon system hydraulics. The laboratory tests were two-dimensional wave flume experiments, and indicated that there could be a significant increase in the mean water level within the lagoon due to a seaward reef. Again, these experiments were two-dimensional.

*Prof. of Civil Eng., W.M. Keck Lab of Hyd. & Water Res., Calif. Inst. of Tech., Pasadena, CA 91125, U.S.A.

The study described here, which is an investigation in a three-dimensional undistorted hydraulic model, is in a sense a more realistic model of the actual dynamics of time-varying storage than the two-dimensional experiments summarized above. Due to complexities associated with the three dimensionality, no attempt has been made to develop a detailed analytical model to describe the observed differences between the still water level and the mean water level denoted here as ponding. Therefore, certain of the data obtained in the course of this experimental program will be presented here and discussed in terms of their physical significance without an attempt at a more general development. Somewhat different definitions of ponding are used for the regular and the irregular wave experiments; these will be defined clearly as the pertinent results are presented.

Experimental Equipment

Figure 1 shows the boundaries of the wave basin which was used and the bathymetric contours in the 1:45 undistorted hydraulic model. The highly contorted bottom contours were accurately represented in the model. The cooling water intake basin is seen in the upper right-hand portion of this figure with the two breakwaters (the West and East) forming the boundaries of the protected basin. The breakwaters are built on rock formations which themselves tend to form natural seaward boundaries to the basin.

Wave guides and the wavemaker plate are shown arranged for waves approaching approximately from the west. Numerical methods were used to refract waves from deep water to the depth of approximately 100 ft where the wavemakers are located. (In this paper all dimensions will be given in prototype units.) The wavemaker was divided into five segments, each driven by a programmable hydraulic system from one function generator; the units were portable and could be aligned to correspond to different wave approach directions.

The original breakwaters were constructed with tribars as their outer armor protection and with a concrete cap with a crest elevation of +20 ft MLLW. A detailed description of the model and the breakwaters is presented by Lillevang, et al. (1984). Two different crest elevations were used in these experiments: +20 ft MLLW and 0 ft MLLW. The latter represented an extreme case where the crest of each breakwater was assumed to have been degraded uniformly to MLLW by storm waves. A third case was tested without breakwaters; certainly an extremely conservative condition.

Both regular and irregular waves were used in these experiments. For periodic waves the cnoidal wave generation procedure presented by Goring and Raichlen (1980) was used. To minimize disturbances and provide more permanent waves in the limited space available, a procedure was developed always to begin the wave machine trajectory at a position which corresponded to a zero plate velocity.

Capacitance wave gages, which could be calibrated remotely, were located throughout the model; the locations are indicated by letter in Figure 1. Waves were not measured at all locations simultaneously.

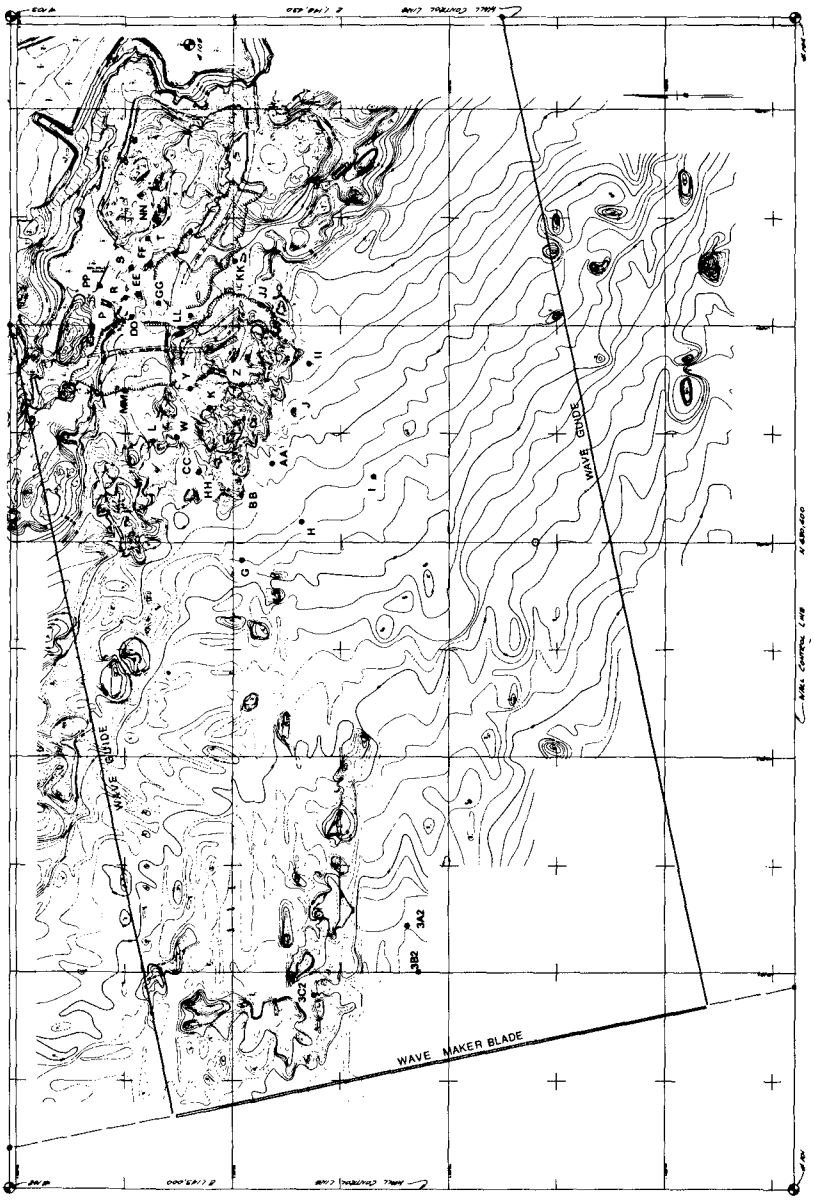

Figure 1 Wavemaker Placement in the Model Basin and Location for Probes, Waves from the West.

The three locations which will be referred to herein are those indicated as: 3B2 near the wave machine, and R and S in front of the cooling water intake structure inside of the cooling water intake basin. (The latter are each located approximately 100 ft seaward of the intake structure and spaced 150 ft apart.) The wave gage at location 3A2 was used with that at 3B2 to define approximately the reflectivity of the breakwater system in the model using a method presented by Goda and Suzuki (1976).

Irregular waves were generated using the wave plate transfer function determined experimentally and spectra defined by either offshore measurements or hindcasting procedures. The method of Goda (1970) was used to transform a spectrum into its harmonic components from which the wave machine trajectory was defined. For the irregular waves discussed herein the wave machine trajectory was determined from a wave spectrum measured on January 28, 1981 at 1800 hrs GMT by the National Oceanic and Atmospheric Administration (NOAA) Buoy 46011 located 18.6 nautical miles southwest of the Diablo Canyon Nuclear Power Plant.

Presentation and Discussion of Results

In this section results will be presented from the experiments conducted with both regular and irregular waves. An example of wave records taken at locations 3B2 near the wave machine and R and S inside the intake basin are presented in Figure 2 for an azimuth direction at the wave machines of 258°. The upper portion of the figure shows cnoidal waves with a period of 12 seconds and a height of approximately 40 ft near the wave machine; the water surface time histories at R and S are shown in the lower part. The breakwater crest for these experiments was degraded to 0 ft MLLW. The effects of wave breaking and overtopping of the structure are evident at stations R and S, and it is noted that the mean level is different from the still water level. As mentioned earlier, the difference between the mean level and the still water level (which is indicated on the figures by a line extending across the figure) for these periodic waves is termed "ponding". Referring back to Figure 1 it is seen that, for this three-dimensional arrangement, in addition to the return flow over and through the permeable breakwaters there is the return flow through the entrance of the basin. This unsteady flow back through the entrance would be defined by the time varying ponding level.

In Figure 3 the variation in the difference between the mean level and the still water level within the basin, denoted as Δ, is shown as a function of offshore wave height. The ponding level was obtained by taking the time average between the second and the sixth waves in the train such as that shown in Figure 2. These figures present data at positions R and S for different breakwater crest elevations (BRKWTR ELEV.), water depths (W.S. ELEV.), wave periods, and incident wave directions (AZIMUTH). (The extreme still water level of +17 ft MLLW was based on the simultaneous occurrence of an extreme high astronomical tide, storm tide, and tsunami.) It is interesting to see, especially at location R, there is a general trend of increasing ponding elevation with offshore wave height with little effect of direction or depth; at S there appears to be more of an influence of both direction and depth. The ponding elevation measured is approximately 10% of the offshore

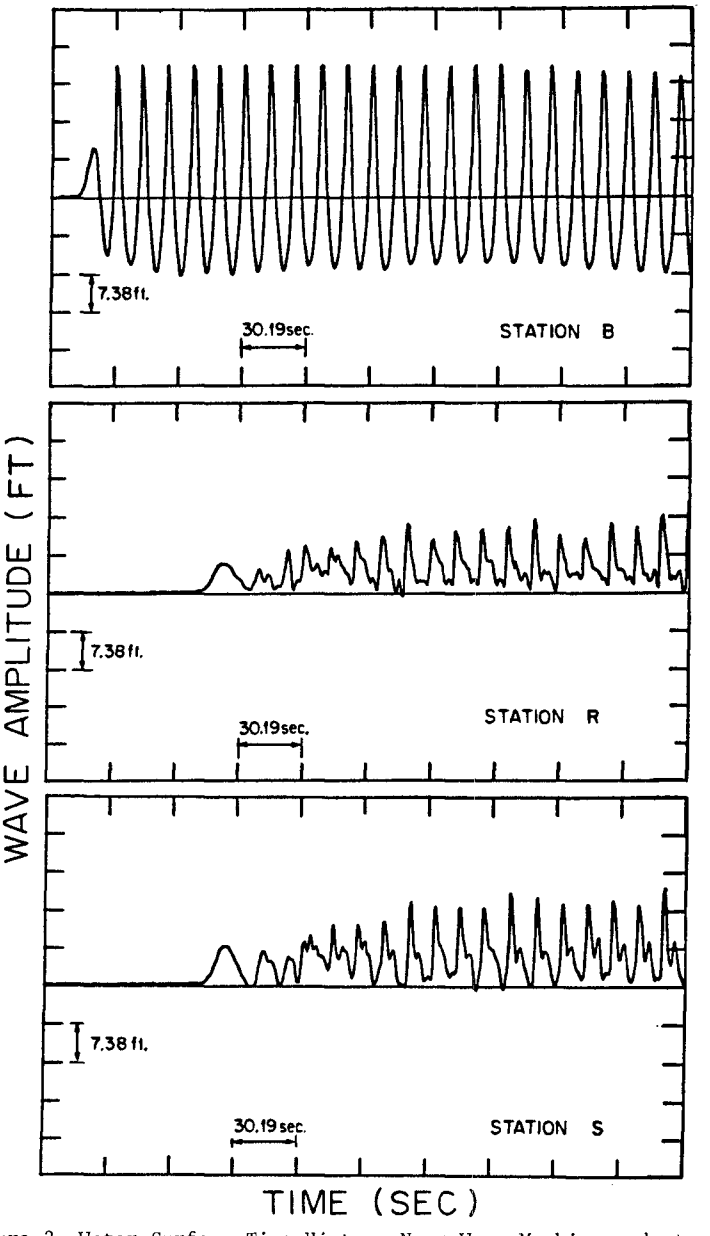

Figure 2 Water Surface Time History Near Wave Machine and at Locations R and S.

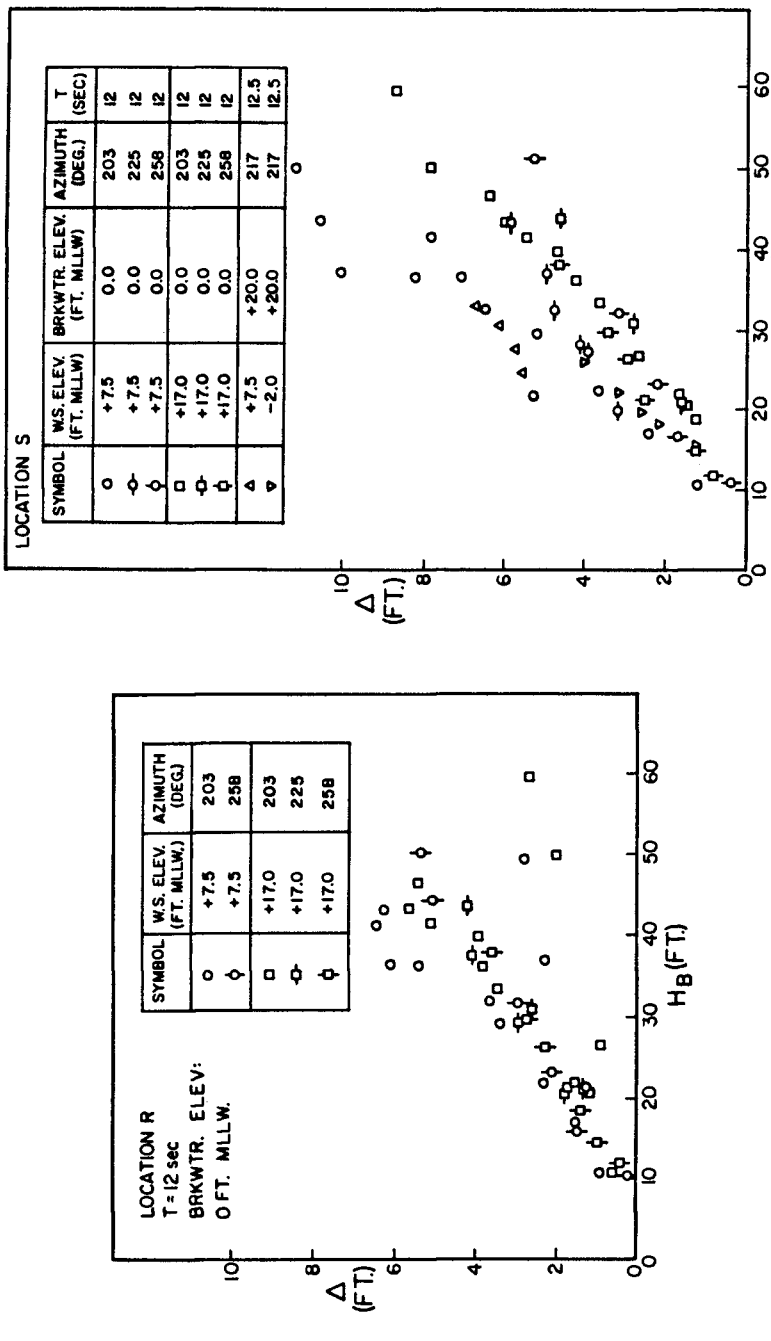

Figure 3 Variation of Ponding at Locations R and S with Offshore Wave Height.

wave height for this case. For the breakwater crest at 0 ft MLLW but with the still water level at +7.5 ft MLLW significantly more scatter of the data is apparent than for the larger depth over the breakwater. This probably can be attributed to the effects of wave breaking and the relatively small depth over the crest through which the broken waves must propagate before entering the intake basin. It should be realized that the width of the breakwater crest is increased significantly for the degraded condition compared to that for the crest at +20 ft MLLW, since in designing the degraded section the volume of the breakwater between 0 ft MLLW and +20 ft MLLW was placed on the shoreward side of the breakwater. (At a crest elevation of +20 ft MLLW the crest width is 21 ft, about three depths, but for the degraded section it would be about 90 ft or about 12 depths.) For the breakwater with its crest at +20 ft MLLW and for mean water levels at +7.5 ft MLLW and -2 ft MLLW the ponding for the former is somewhat greater than for the latter.

In Figure 4 examples are shown of the ponding as a function of the parameter HL; where H and L represent a wave height and wave length, respectively. (The wave height and wave length are defined from linear wave theory using the incident wave height measured at station B near the wave machine, and based on a depth of 50 ft MLLW plus the indicated "tide" elevation, e.g. for a "tide" of +17 ft MLLW a depth of 67 ft was used in the calculations.) This parameter is proportional to the volume under the crest of a periodic wave. The reason for using HL is that the quantity of water which overtops the breakwater and flows into the cooling water basin must be related to the "crestal" wave volume which would be a measure of the volume of the breaking wave which would be associated with overtopping. This is a relatively unsophisticated approach to the problem, and does not consider the detailed intricacies of both overtopping and return flow as, for example, Dalrymple and Dean (1971) did for a two-dimensional problem. The data shown in Figure 4 correspond to an azimuth approach near the wave machines of 203°, some of these data have been presented earlier in Figure 3. In addition, data corresponding to wave periods of 16 sec and 20 sec also are presented.

Data corresponding to the model without the breakwater in place also are presented in Figure 4. These data are for 10 sec and 16 sec waves approaching from 203° with the water surface elevation (W.S. ELEV.) at +7.5 ft MLLW. Generally, it appears that the ponding trends are similar to the cases with the breakwater enclosed basin. However, for a given crestal volume there is less ponding for this case than for the breakwater enclosed cooling basin with the same water depth. Thus, even though the bottom bathymetry acts to form a natural basin it is no doubt the impediment of the return flow imposed by the breakwaters which causes a larger volume storage (and ponding) in the basin.

Average curves obtained from data such as those presented in Figure 4 for R and S are shown in Figure 5; data corresponding to experiments with several different water surface elevations and for the breakwater crest at +20 ft MLLW and at 0 ft MLLW have been used. For convenience, one of the curves in the upper portion of the figure is presented in the lower part at an expanded scale. It is seen that with the exception of the largest depth with the degraded breakwater, all data are in

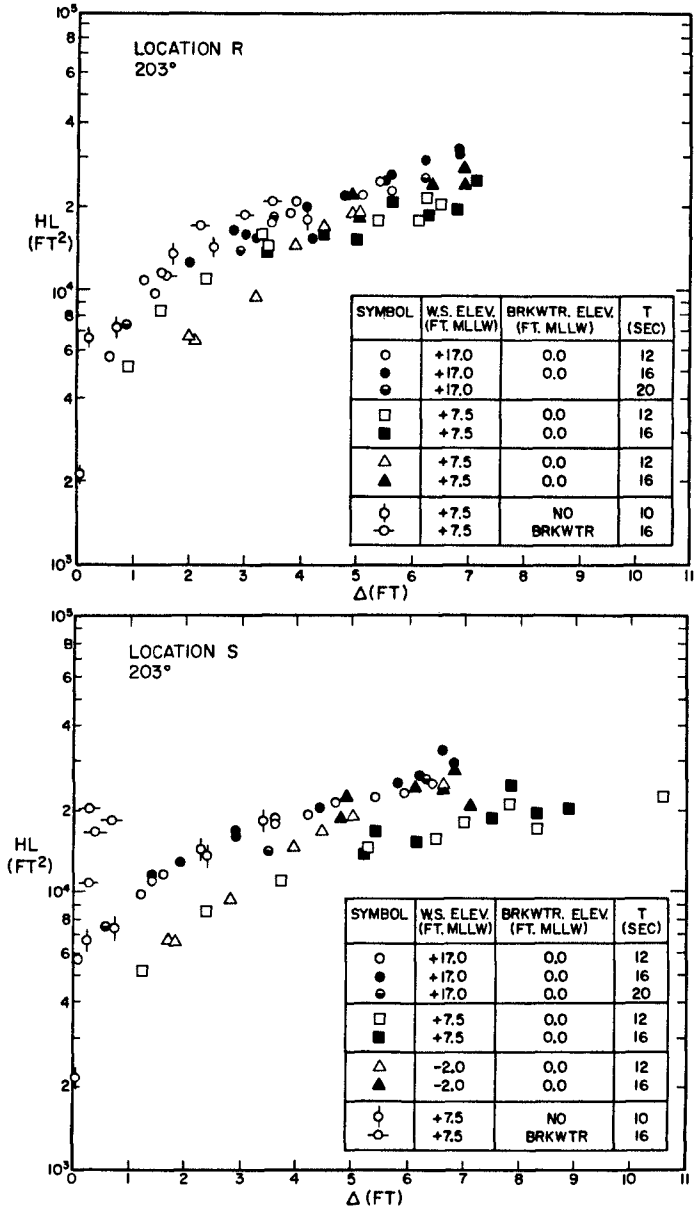

Figure 4 Variation of Ponding at Locations R and S with Wave Crestal Volume Function, HL.

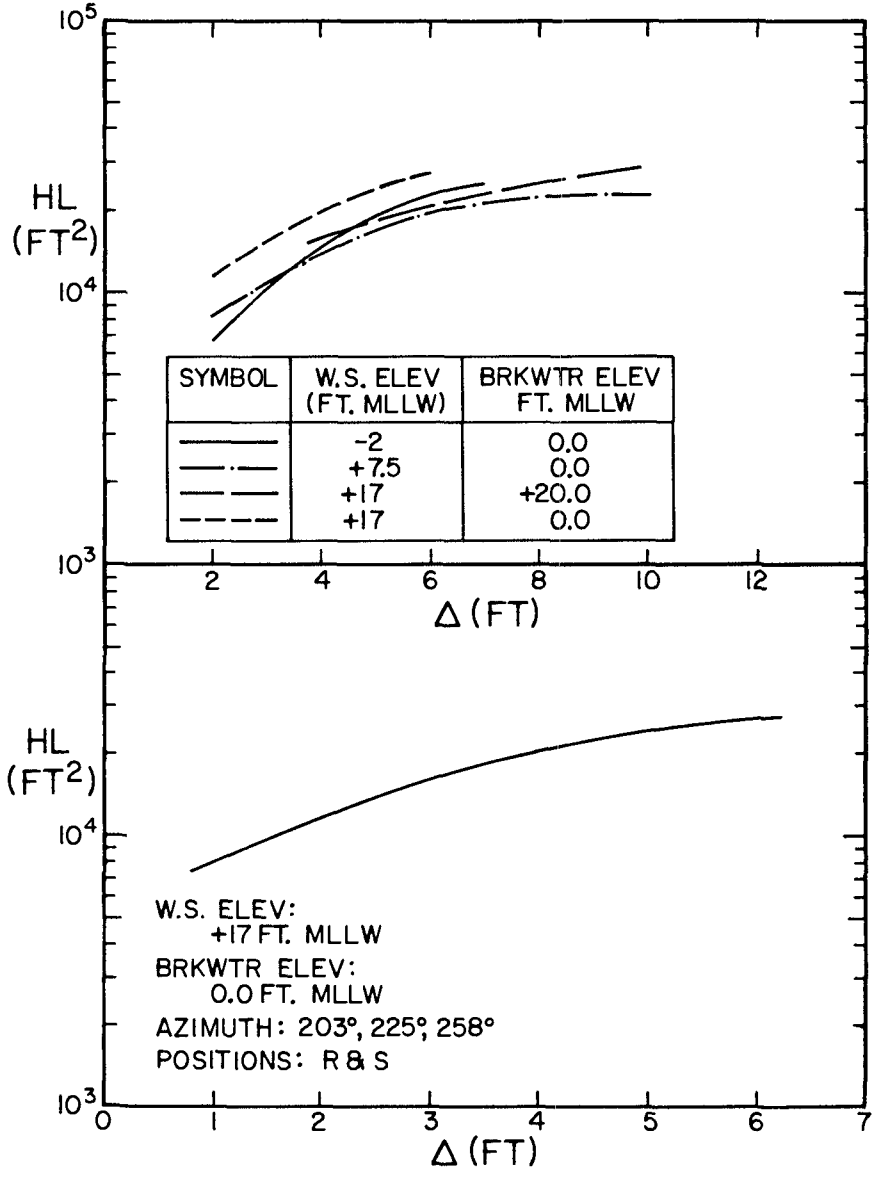

Figure 5 Variation of Average Ponding with Wave Crestal Volume Function, HL.

reasonable agreement when the ponding is presented in terms of the crestal volume parameter.

Experiments were conducted with irregular waves, and data relating to ponding for these cases also are presented. In Figure 6 the water-surface time history near the wave machine is shown for an irregular wave train whose spectral distribution of energy used in constructing the wave machine trajectory was obtained from measurements made by NOAA Buoy No. 46011 on January 28, 1981, at 1800 hrs GMT. (It should be noted that, relative to the still water level, the ordinate is scaled arbitrarily in Figure 6.) The corresponding relatively narrow-band wave spectrum (with the ordinate representing the energy density in units of ft^2sec) is presented in Figure 7 showing a concentration of energy at a frequency of about 0.06 Hz. The significant wave height as determined from the spectrum is about 28 ft.

In Figure 8 the frequency distribution of wave heights offshore as determined from measurements in the model is presented. The ordinate is the wave height normalized by the significant wave height and the abscissa is the percent by number of waves greater than the indicated height. A Rayleigh distribution is fitted to the data for comparison, and the agreement appears reasonably good except at the extremes, which is as would be expected.

The water surface time history measured at position S is shown in Figure 9; the difference between the mean level and the still water level is evident. The corresponding spectrum is presented in Figure 10 showing the modification of the wave spectrum due to the propagation of the waves over the degraded breakwater into the cooling water basin. Wave breaking tends to introduce the higher frequency components seen centered at about 0.15 Hz with a remnant of the original spectrum remaining at a frequency of about 0.045 Hz. A low frequency component, not seen before, appears at a frequency of about 0.02 Hz (50 sec) along with a mean, i.e., a zero frequency component. The latter reflects the direct effect of ponding whereas the former possibly is evidence of a mode of oscillation of the basin which may be excited by the impingement in the basin of breaking waves which overtop the breakwater.

It is interesting to compare Figure 10 with Figure 7. In the latter there is an absence of energy at frequencies less than 0.03 Hz whereas in the former, i.e., the spectrum of waves at location S, energy exists below that frequency. Since it is apparent that the energy below 0.03 Hz is due to the overtopping process, only this energy was retained in investigating ponding in the cooling water basin. This was done by eliminating all harmonic components at frequencies greater than 0.03 Hz; the resultant water surface time history is shown in Figure 11. This is used to determine a frequency distribution of water surface elevation for the filtered water surface time history as well as an average mean level. For irregular waves, where the long period oscillation is easily seen in Figure 11, the ponding is defined from this frequency distribution. It is defined in this way as opposed to evaluating only the mean of the water surface because it is apparent that there is a significant effect of the low frequency "carrier" component on the crest elevation of the wave. It is this elevation

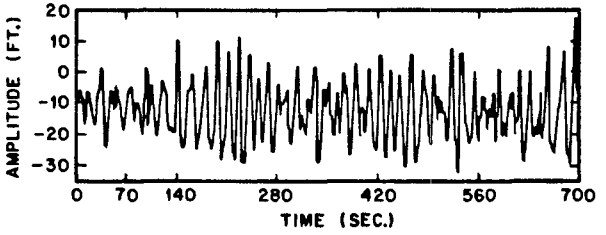

Figure 6 Water Surface Time History Offshore.

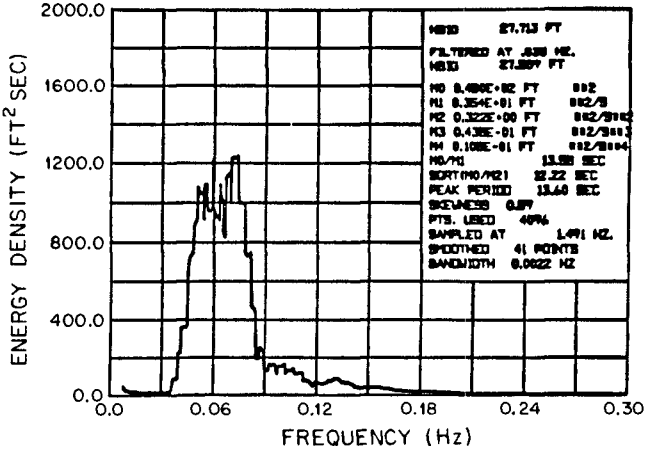

Figure 7 Energy Spectrum Offshore.

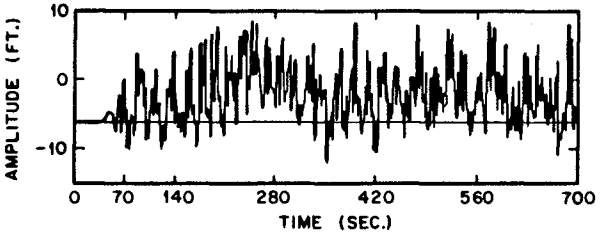

Figure 9 Water Surface Time History at Position S.

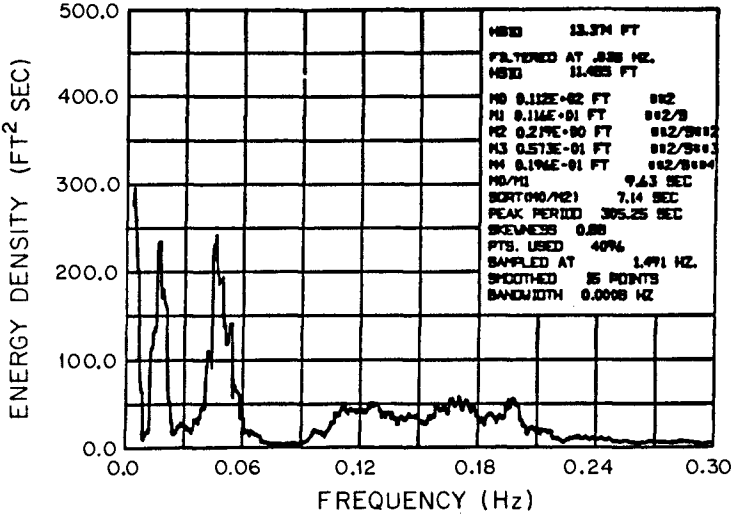

Figure 10 Energy Spectrum at Position S.

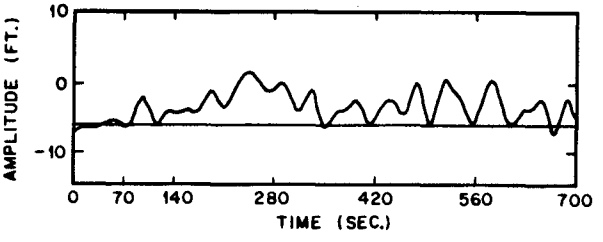

Figure 11 Filtered Water Surface Time History at Location S.

which is most important in the effect of waves in the breakwater protected basin on structures located around its boundary such as the cooling water intake structure. (Data corresponding to the mean alone will be presented also for completeness.)

A typical frequency distribution of the filtered water surface time history is presented in Figure 12. The ordinate is the ponding elevation, i.e., the elevation of the filtered water surface time history relative to the still water level, and the abscissa is the percent by number greater than the indicated elevation. The data shown are for positions R and S for a condition where the tide is -2 ft MLLW with the breakwater degraded such that the crest is at 0 ft MLLW.

Additional data are presented in Figure 13 for several different conditions of still water surface elevation and breakwater crest elevation. In this figure it is observed that the maximum still water surface elevation and the maximum breakwater crest elevation results in the lowest ponding. The maximum ponding occurs for the degraded breakwater with the lower of the two still water levels. If one defines the mean ponding for the irregular wave as the time average of the water surface time history shown in Figure 11 the following values are obtained for experiments 147, 148, and 231: 1.62 ft, 2.6 ft and 1.0 ft, respectively. Thus, there appears to be a somewhat different trend for the irregular wave case as compared to the regular wave results presented in Figure 5; this may be an effect of direction as the waves in experiment 231 are from the south, but those for 147 and 148 are more westerly.

As mentioned earlier, an important effect of the ponding in the cooling water basin is its effect on the elevation of the crest of the wave relative to the still water level. This relates, for example, directly to the overtopping of the cooling water intake structure located along the north boundary of the cooling water basin. Examples of this are shown in Figure 14 for periodic waves for three cases: a still water level of +17 ft MLLW and of -2 ft MLLW with the degraded breakwater and the higher still water level with the breakwater crest at elevation +20 ft MLLW. The ordinate in Figure 14 is the elevation of the crest of the wave in the basin relative to the still water level and the abscissa is the corresponding elevation of the crest of the wave outside of the basin also measured relative to the still water level; a line of equivalence is shown as a solid line in the figure. For 12 sec waves, the distance from the still water level to the crest of the wave at positions R and S appears to be relatively independent of whether the breakwater is at the full elevation of +20 ft MLLW or at 0 ft MLLW for the maximum still water surface elevation (+17 ft MLLW). This indicates, with regard to the elevation of the maximum instantaneous water level in the basin, the effect on the elevation of the wave crest of the elevation of the breakwater crest is small. This means that the effect of ponding must negate to some extent the reduction in wave height due to the increased protection to the cooling water basin afforded by the higher breakwaters.

Conclusions

The following major conclusions can be drawn from this investigation:

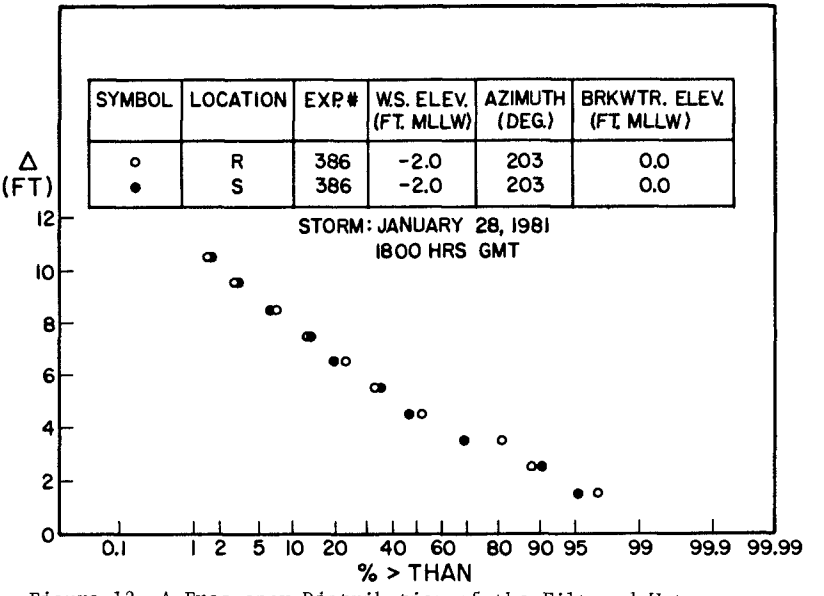

Figure 12 A Frequency Distribution of the Filtered Water Surface Time History.

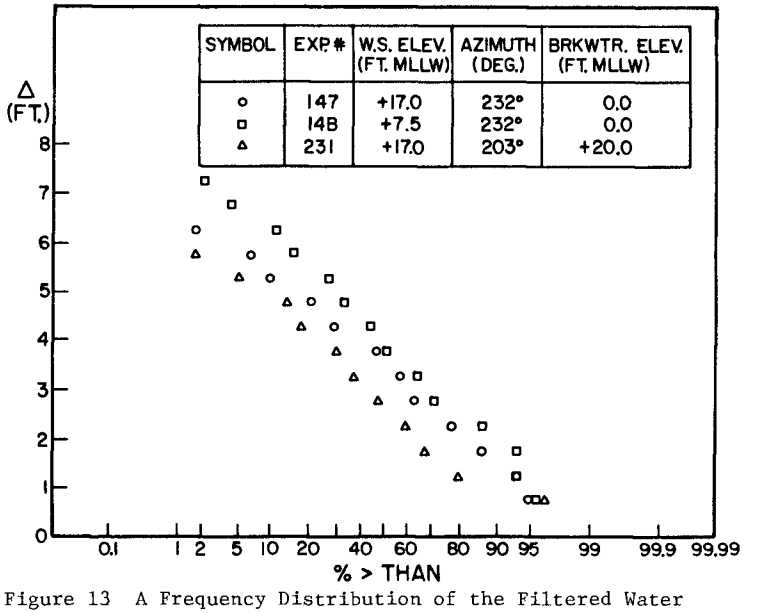

Figure 13 A Frequency Distribution of the Filtered Water Surface Time History.

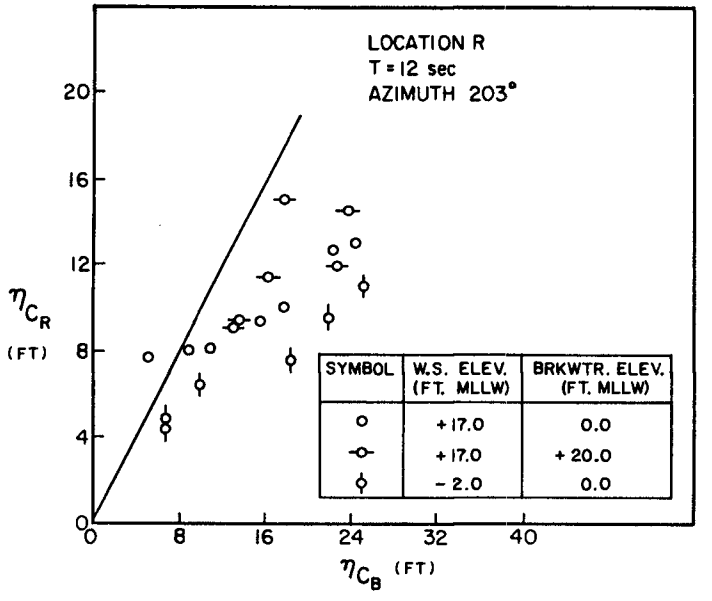

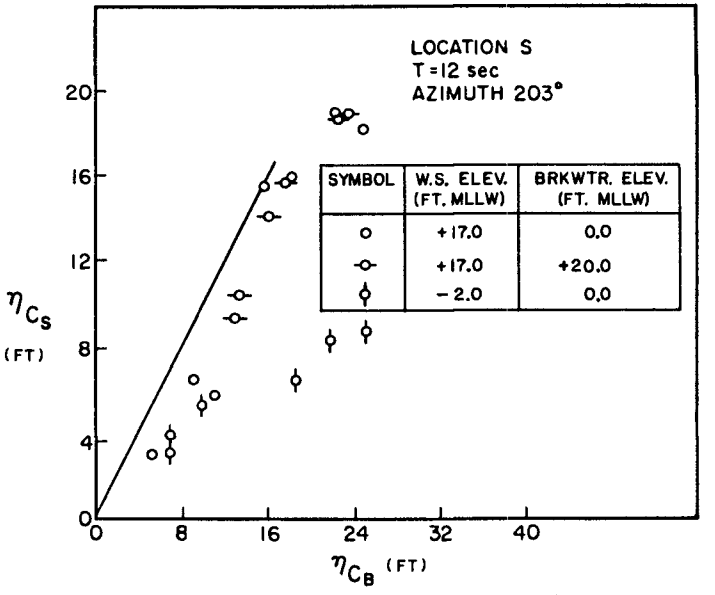

Figure 14 The Variation of the Amplitude of the Crest of the Wave Within the Basin to that Outside.

1. A significant change in the mean water level elevation in the cooling water basin can take place due to the overtopping of the West and East breakwaters. This has been defined in this study as ponding.

2. For regular waves the difference between the mean water level and the still water level can be about 10% of the offshore incident wave height.

3. For regular waves, it appears that the breakwater with its crest at +20 ft MLLW results in larger ponding than when the crest is at 0 ft MLLW.

4. Although the results for periodic waves show a direct dependence of ponding on the wave period, when the data are presented in terms of a measure of the overtopping wave volume, HL, the dependence on wave period is reduced significantly.

5. Irregular wave overtopping of the breakwaters tends to induce oscillations in the cooling water basin and increase the mean water level. Thus, an improvement of wave conditions inside a basin created by breakwaters which may be partially overtopped is, to some extent, reduced by these other wave-induced effects.

Acknowledgement

This study was supported by Pacific Gas and Electric Company; the assistance of Mr. Larry Harrison of PG&E and discussions with Mr. Omar J. Lillevang were appreciated. The Offshore Technology Corporation, Escondido, California, with Dr. J. Ian Collins and Mr. William G. Grosskopf involved, conducted the experiments. Mr. Ross Buchanan, of Bechtel Corporation, assisted in the data reduction.

CHAPTER 197

Surface currents remotely observed by means of RADAR

F. Schirmer [+]
H.-H. Essen [++]
K.-W. Gurgel [+++]

INTRODUCTION

Surface currents normally are difficult to measure. Only a set of Lagrangian drifters observed from fixed stations or from an aircraft or by satellite can give adequate information. Beneath this there is a new and powerfull field measuring tool which functions with a decametre backscatter radiowave RADAR. Two (or more) such fixed RADAR stations on land or on islands can remotely measure the surface currents in front of them with high resolution in space and time.

This paper has two aims: first, to give a short explanation of the physical principles of the backscatter RADAR and to show its requirements and its limits, and secondly, to demonstrate the possibilities offered by this RADAR with an example of the coastal surface current off Norway.

PHYSICS OF OPERATION

A radio pulse or wave train of frequency 29.85 MHz is transmitted from a place near to the shore. The sea surface acts to the radio wave train as a scattering grid due to BRAGG scattering mechanism: if the wavelength of the transmitted electromagnetic wave is λ_{EL} (approximately 10 m) only those spectral parts of the seas gravity waves (surface waves) with wavelength

$$\lambda_{GR} = 0.5\,\lambda_{EL}$$

are responsible for the intense backscatter of electromagnetic waves. All other elevations of the sea surface act

present address of authors:
University of Hamburg, Institut fuer Meereskunde,
Troplowitzstrasse 7, D 2000 Hamburg 54, W.-Germany.

as scattering targets too, but their combined scattered total energy is some orders less due to destructive interference.

The received backscattered echo from the sea has a somewhat different frequency compared to the transmit signal. This is caused by the phase velocity v_{GR} of those ocean gravity waves which fulfill the BRAGG-condition: If the transmit frequency is f_{EL} and the phase velocity of the gravity waves is

$$v_{GR} = \sqrt{g \cdot \lambda_{GR} / 2\pi}$$

where g is the acceleration due to gravity, the DOPPLER shifted backscattered frequency $f_{EL,D}$ becomes

$$f_{EL,D} = f_{EL} \cdot \left(1 \pm \frac{v_{GR}}{c}\right)^2$$

where c is the speed of light.

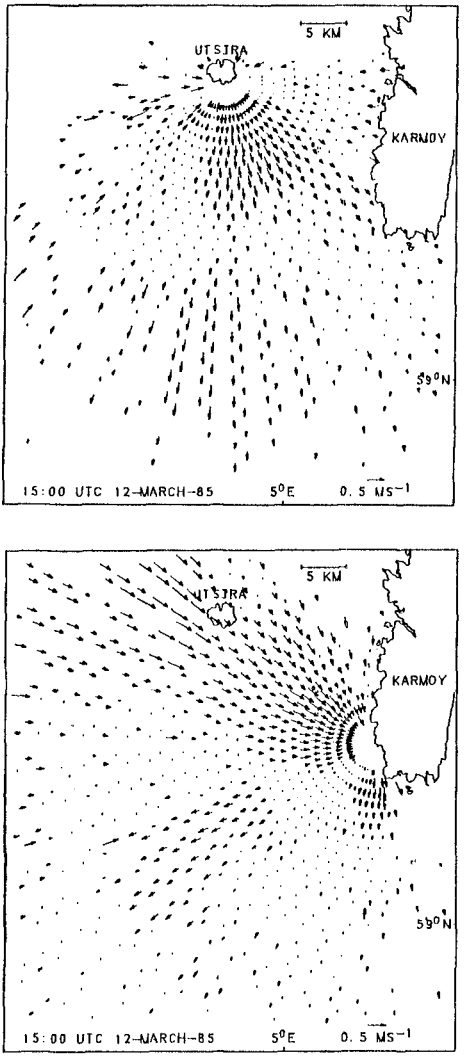
The difference in frequency between f_{EL} and the received DOPPLER-echo $f_{EL,D}$ is in the order of one Hertz. Because all variables are known, one can predict this difference. Early observations by D. D. Crombie (1955) turned out that there are differences between predicted and measured frequency shift values. He found, that underlying ocean current is increasing or decreasing the phase velocity of ocean gravity waves thus giving somewhat higher or lower echo frequency shifts. Later on Crombie and many other scientists, in particular D. E. Barrick (1977), B. J. Lipa (1977) and E. D. R. Shearman (1980) used HF-backscatter to remotely measure ocean surface current and wave hight, the latter from the strength of the echo.

THE CODAR

The ocean current mapping HF-RADAR used by us is originally evolved by the U.S.-NOAA's Wave Propagation Laboratory (WPL) in Boulder, Colorado. D. E. Barrick, M. W. Evans and B. L. Weber (1977) and others there developed a RADAR for current mapping which they called CODAR, an acronym for Coastal Ocean Dynamics Application Radar.

The CODAR consists of a transmit antenna near to the shore and a set of four receiving antennas for direction finding of the HF-echos from the sea. The transmitted (and received) electromagnetic wave is a ground wave which follows the curvature of the earth. The water in this case be electric conductive salt water. In the case of fresh water or of sea ice no ground wave is generated.

A single CODAR station can only measure the radial component of the surface current at each point of the sea in front of it. So a minimum of two stations separated by



igure 1: The radial portion of the total current field, as seen at the same time from a CODAR station on the island UTSIRA and a second one on the island KARMOY off Norway.

some ten kilometres is capable to give complete information about the two dimensional surface current field. During recent years we developed further both the hardware and the software of our original CODAR transceivers. One of the technical inventors of CODAR, M. W. Evans, founded a company offering CODAR's for sale +). Modern CODAR stations are lightweight and need only some kilowatts electric power.

As a first step each CODAR station is generating a map of measured radial current vectors as shown in figure 1. The azimutal resolution here is 6 degrees while the radial extension is staggered into range cells of 1.2 km depth each. Every radial current vector in fig. 1 is an average over 18 minutes of observation.

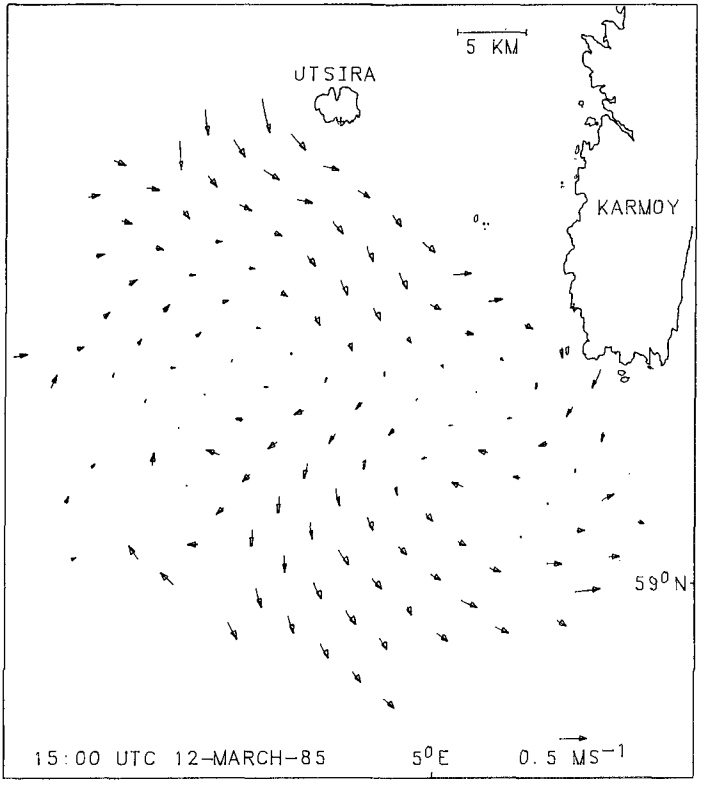


Figure 2: Total surface current field by combination from figures 1.

+) CODAR Technology, Inc., 1428 Florida Ave., Longmont, Colorado 80501, U.S.A.

From two - or more - sets of radial current vectors a final vector map of the total 2-dimensional surface current is produced by combining the radial shares. This is done at each point of a rectangular grid which is adjusted to the observation area. The result of this step is shown in figure 2.

The maximum range we obtained up to now is 50 km, depending on sea state, salinity of water and the place for erection of the antennas. Sometimes there is interference by strange transmitters, but the CODAR can change its own operation frequency.

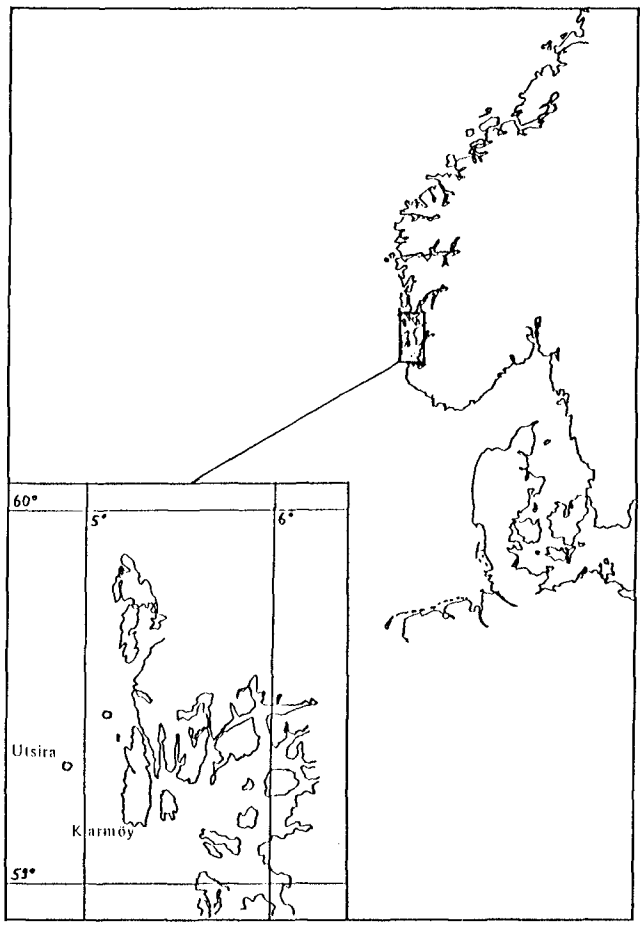

Figure 3, 4: Observation area off Norway. Distance between stations UTSIRA and KARMOY is 21 km.

SURFACE CURRENT MAPS

As an example some measurement results off Norway in 1985 are given here. The area under observation is shown in fig. 3 and enlarged in fig. 4. Two CODAR stations have been installed on the rocks of the coast: one on the island Utsira, the other on the island Karmoy, both sites belonging to Norway.

From satellite pictures it is known that eddies with radii from 10 to 50 km are generated here. Strong tidal and residual currents are typically. It is supposed that a sea bottom topography - given in fig. 5 - which is rich in contrasts is responsible for the generation of eddies. The

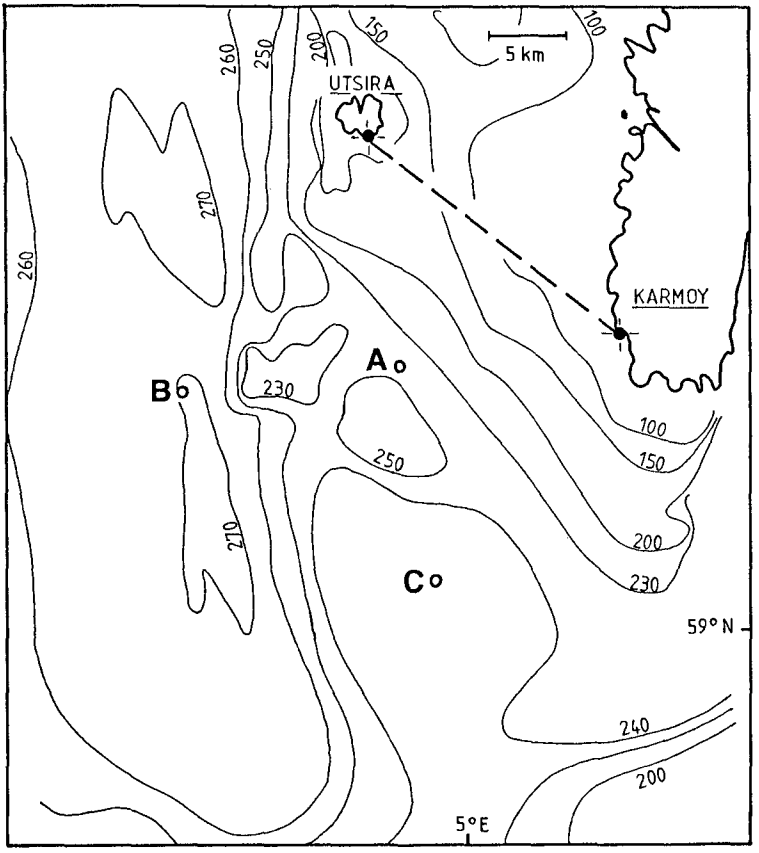

Figure 5: Sea bottom topography; depth given in meters.

consecutive pictures in figure 6, taken during 8 hours of observation, are an example from a set of 150 CODAR observations there.

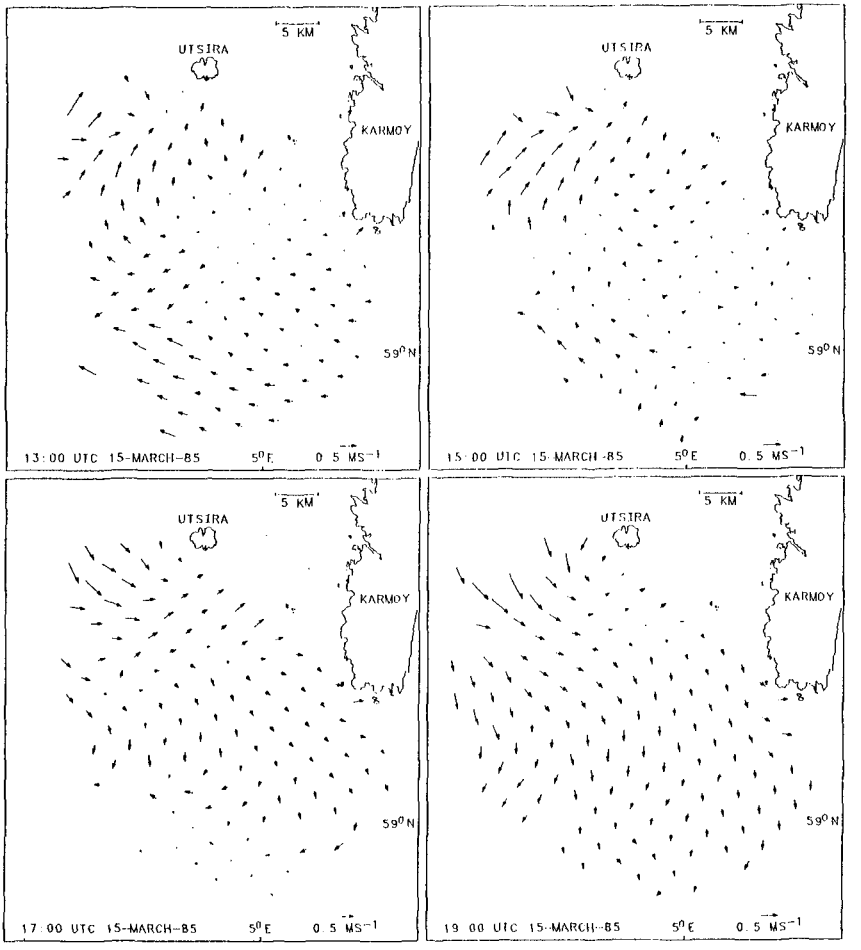

Figure 6: Four consecutive surface current patterns as observed every 2 hours.

TIME SERIES OF SURFACE CURRENT

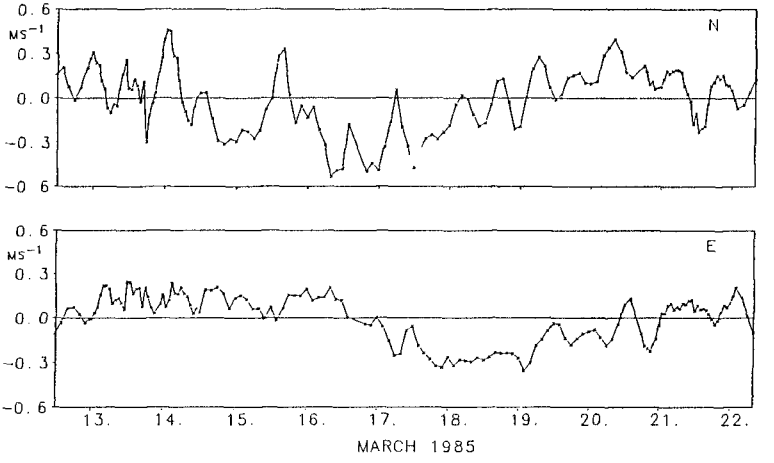

Figure 7: Current velocities at place C versus time.

From a set of consecutive current maps one can compute time series of the current velocity for each place of interest. An example for place C in fig. 5 is given in fig. 7. More detailed analysis of time series obtained from CODAR-results is given by Essen, Gurgel and Schirmer (1983) and by Essen, Freygang, Gurgel and Schirmer (1984).

TIDAL ELLIPSES

Given a set of consecutive CODAR-observations it is possible to compute the tidal ellipses for any place of interest in the current field. In figure 8 a set of 12 of such ellipses is given. Using a frequency filter according to Fourier, only the semi diurnal tidal components are left in this example. In a somewhat similar manner one can extract the residual current only.

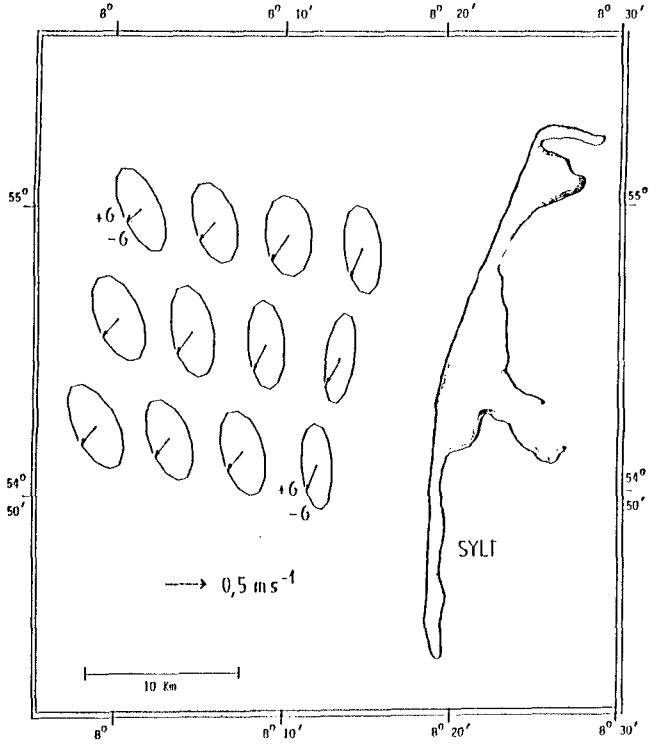

Figure 8: Tidal ellipses in front of the German island SYLT - only the semidiurnal component is given -.

UPWELLING AND DOWNWELLING

From an extensive set of surface current vectors the amount of upwelling or downwelling can be computed. If this is done separately with each snapshot of the surface current field, a time series of upwelling and/or downwelling can be gained. In figure 9 this divergence, taken from the vector fields, is plotted against time for the place A in fig. 5.

In the case of very low current velocities (less than 10 cm/s) the uncertainty becomes to large because differences between small numbers with random noise are to be computed.

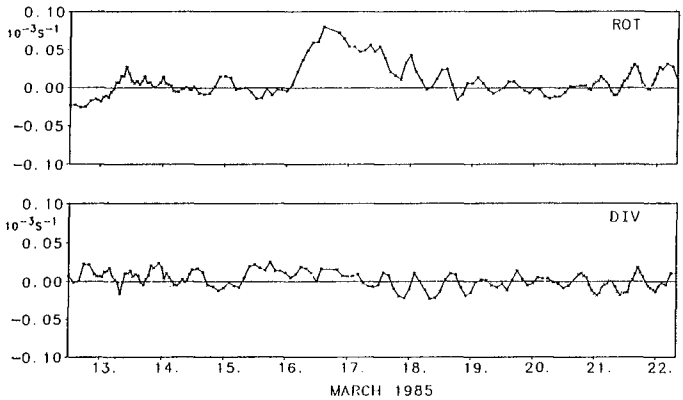

Figure 9 lower part: DIVergence - or upwelling and downwelling respectively - at place A in fig. 5 as a function of time.

upper part: The amount of ROTation at place A in fig. 5.

ROTATION

Finally the amount of rotation can be computed from the vector field of measured surface current. Again this is done - as an example - for place A in fig. 5. The amount of rotation as a function of time is given too in figure 9 - lower curve.

Studies on Thermal Diffusion and Verification of the Third Nuclear Power Plant in Taiwan

By

K.C. Tang[1] M.T. Tsai[2]

Y.R. Hwang[3] H.H. Hwung[4]

Abstract

In general, hydraulic model tests and numerical simulations can be used for securing enough informations in order to assess the environmental impact by thermal discharge after the power plant operation. However, the numerical simulations should be verified by the consequence of hydraulic model tests or the field data. Then, the numerical model can be used as a prediction model to foresee the nature of thermal diffusion when the additional generators will be operated.

The third nuclear power plant in Taiwan has been constructed in 1984. In order to protect the abundant corals which distributed on the rocky bottom around this power plant, a complete studies on thermal diffusion have been performed, accordingly, a verification with field measurements were also made in this paper.

4. Professor, Dr. Eng. Director of Tainan Hydraulics Laboratory,National Cheng Kung University, Tainan, Taiwan, R.O.C.

1. Introduction

The third nuclear power plant is located at the southest coast of Taiwan and beside Nan-Wan-Bay, 1984, two units (951MW) have been constructed and attended the commercial operation, afterwards, the other two units also performed at 1985. The intake and outlet are installed on the northern and western coastline of this bay as shown in Fig-1.

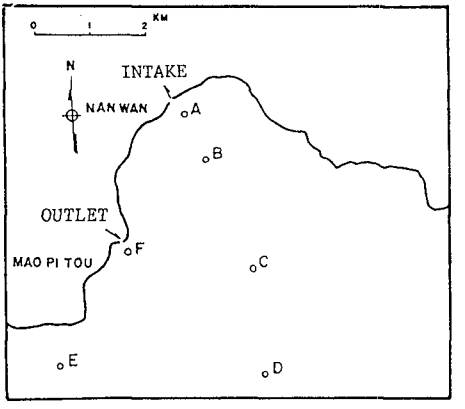

Fig-1

According to the marine ecology studies in the vicinity of Nan-Wan-Bay from August 1976 to December 1977, it showed that the abundant corals distributed on the rocky bottom about from 6m to 30m water depth. From the research of relationships between the growth of corals and water temperature, it points out that the corals will grow well in water below 29^0C,and they can not with stand long periods of exposure at 31^0C, then as water temperature increases more than 32^0C that the corals will die rapidly. Accordingly, in order to prevent the impact on corals resulting from the discharge of heated water, the complete studies on thermal diffusion and verification were made. And the results would be presented in this paper.

2. Field Surveys and Data Analysis

The complete analysis of field survey data had to be done before the hydraulic model tests and numerical simulations were progressed. They are:

(1). Topography, water depth and coastline surveys:

The field surveys should be done at least twice in a year for the necessity to discretize the continuous domain in numerical simulations or to construct the hydraulic model.

(2). Analysis of wind speeds and wind directions:

According to the results obtained from Nan-Wan station, it is obviously to see from Fig-2, that the wind contributes in NE direction for 48.9% of occurence is the main wind at Nan-Wan area. And the average wind velocity is about 10m/sec in this direction.

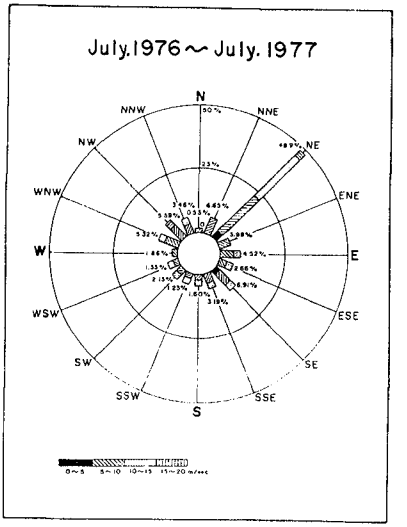

Fig. – 2 Monthly maximum wind velocity and wind direction at Nan–Wan Station

(3). Analysis of water temperature:

The temperature data were collected by Taipower Exploration Team from July, 1976 to July, 1977 at Nan-Wan area. Table-1 indicates the monthly average water temperature, monthly maximum and minimum water temperature throughout the interval.

Table – 1 Water Temperature

3. Hydraulic Model Tests

The hydraulic model tests have been completed by Tainan Hydraulics Laboratory according to the previous analysis. A distorted model (horizontal scale is 1/1152, vertical scale is 1/144) was determined by comparing the heat on sea surface which calculated from field data with those examined from laboratory. The results of far-field model tests were shown in Fig-4∿Fig-7.

Fig. — 8 Schematic diagram of measuring Points for vertical temperature distribution

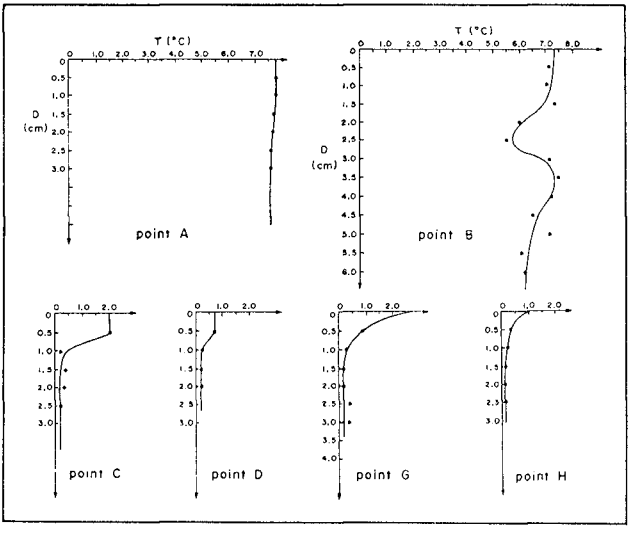

Fig-9

Fig-4 shows the envelope of 1 degree centigrade temperature increasing in conditions of two units operation, the cooling water discharge is 43.3 C.M.S., cooling water temperature rised is 10 degree centigrade and under strong flooding tide action. The result of Fig-5 is in the same conditions as Fig-4 excepts the ocean current is strong ebbing tides. Since the ambient water temperature in Nan-Wan Bay is so high that a great amount of cold water will be pumped from deep sea to mix with the hot water discharged from condensers. The results of this nature are shown in Fig-6 and Fig-7.

Besides, for the request to assure that the coral could grow well, an adjustment was made by installing a 120-meter-long flow-guided breakwater from the outlet to somewhere the water depth is 8 meters that it would keep the heated water floating on the surface layer. And the measuring points for vertical temperature distribution and the corresponding results in an undistorted model were described in Fig-8 and Fig-9 respectively.

4. Numerical Simulations

A two-dimensional model was used to simulate the flow patterns and temperature distributions under tides and currents action. The horizontal diffusion coefficient and thickness of warm water floating on surface layer in the numerical simulations could be determined from the hydraulic model tests. The currents boundary conditions were set at both sides in x-direction of the finite-difference grid domain, but the boundary condition in the south was controlled by tides. The numerical model covered an area of 8.5Km×10.0Km. That meant it had 34 grids in x-direction and 40grids in y-direction with a grid size of 250m. The numerical simulations were accomplished throughout 4500 time steps with a value of time step by 30 seconds. Fig-10∿Fig-13 show the simulated flow patterns at Nan-Wan area by a two-dimensional numerical model when the time level was the 3000th, 3300th, 3600th and 3900th respectively. And the corresponding temperature distributions were shown in Fig-14∿ Fig-17.

5. Verification and Conclusion

After the third nuclear power plant operation from 1984, monitoring program has been proceeded to thermal diffusion in Nan-Wan-Bay. Four fixed monitoring stations were installed around the outlet, and the thermisters (General Ocean 6070-type) were set below the water surface from 0.5m to 5.0m separately. In addition, a large scale survey was also performed by motor-boats for every season. Based on the above results, the numerical calculations of temperature distributions could be verified by field measurements from a large scale surveys. Fig-18 is the temperature distribution obtained from numerical calculation and Fig-19 is the results plotted from field data at the same tide condition . And the comparison of vertical temperature distributions between the hydraulic model tests and field data are also presented in Fig-20.

Fig-20

According to a number of elaborated hydraulic model tests and numerical simulations on thermal diffusion of the third nuclear power plant in Taiwan, the discharged warm water floating on the surface layer has been proved from field investigations that showed the abundant corals have not affected by warm water and they have grown well until now.

MODEL/FIELD COMPARISON - COASTAL BUOYANT JET

Shuen-Wei Scott Tu (1), Member ASCE
Patrick J. Ryan (2), Member ASCE
Jeffrey P. Leighton (3), Associate Member ASCE

ABSTRACT

Calibration and verification of a 1:75 scale undistorted hydraulic model is described. The model was used to simulate the waste heat distribution in shallow and semi-confined receiving waters. The study was carried out in the laboratory by analyzing the effect of several parameters in comparisons of model and field data. Because of the shallow receiving waters, it was found that the near-field bathymetry, bottom roughness and waves were the critical parameters in achieving a reasonable simulation.

INTRODUCTION

In recent years, there have been numerous studies investigating the behavior of turbulent jets discharging waste heat or sewage into the environment. Extensive non-buoyant and buoyant jets study programs have been carried out for various outfall conditions. In general, they can be characterized as (1) free jets (where no bounding effect is present), (2) submerged jets (where the free surface effect is unimportant), and (3) surface jets (where surface effect is important, but bottom shear is excluded). Few attempts have been made to study the condition of surface jets issuing into rather shallow receiving water. Giger, Jirka and Dracos (1985) conducted a model study for a two dimensional turbulent horizontal jet in both deep and shallow waters. They observed noticeably different jet behavior for the "shallow jets" with a relatively large amplitude meandering motion. For the present study, extensive efforts were made to calibrate a physical model with a comprehensive set of field data. Several factors that affect the jet trajectory and mixing were identified.

MODEL DESCRIPTION AND EXPERIMENTAL APPARATUS

The hydraulic model, constructed in 1975 (Wiegel et al., 1976), is an undistorted densimetric Froude model with a scale of 1:75 (Fig. 1). The model basin is 85 by 64 by 2.5 ft deep (25 X 19 X 0.8 m) and covers a prototype area of 6400 ft (1920 m) along the coast by 4800 ft (1440 m) normal to the coast. It is located at the Richmond Field Station of the University of California, Berkeley, California. The model studies were made under contract with the University, under the direction of Professor R.L. Wiegel.

(3) Civil Engineer, Pacific Gas and Electric Company, 3400 Crow Canyon Rd., San Ramon, CA. 94583

The offshore current direction and strength can be controlled through a system of valves and pumps. Waves are produced by a piston type paddle. The water level can be programmed to follow a selected sinusoidal tide curve. The temperature measuring system consists of an array of probes (each with five thermistors spaced 4 ft apart (prototype) in the vertical direction) with supporting structures and booms to allow three dimensional movement for sampling. The time constant of the thermistors is approximately 0.3 seconds. Mean values obtained by averaging 20 instantaneous measurements over a period of 200 seconds were found satisfactory for achieving good repetition in the model.

FIELD DATA

In late 1983, photos were taken of the unheated jet from an observation tower at 30 minute intervals. Analysis on these photos indicated that the jet appeared to head towards the north entrance at low tides and towards the west entrance at high tides (Fig. 2)

In late 1984, when the Unit 1 reactor was undergoing power ascension testing, an extensive prototype data collection program was initiated. The field data collection consisted of temperature measurements along five horizontal transects at four depths (Fig. 3), vertical profiles at various locations within Diablo Cove (the discharge cove), and surface temperatures in the offshore area (Leighton et al. (1986A), Leighton and Tu (1986B)).

Two representative power ascension field tests were chosen for model/prototype comparisons (Table 1). The first field test (corresponding to test 5-1 in Leighton et al., 1986A) included a condition of coflowing warm and cold jets from the discharge structure with 4000 cfs (114 m^3/s) total volumetric flow rate. The measured offshore current was 0.7 fps (0.21 m/s) towards the

Waves	Sg. Ht.	Period	Sg. Ht.	Period
	5 ft. (1.6m)	7 sec.	3 ft. (1m)	11 sec.

north (upcoast). The tides varied from 1.4 to 3.1 ft (0.4 to 0.9 m) with respect to Mean Lower Low Water (MLLW) datum over the two hour testing period. The second field test (corresponding to test 6-3 in Leighton et al.) consisted of two coflowing warm jets with a total flow rate of 2000 cfs (57 m^3/s). The offshore current was 0.9 fps (0.27 m/s) downcoast (southerly). The tide ranged from -1.3 to -0.7 ft MLLW (-0.4 to -0.2 m).

CALIBRATIONS

Three factors were found to significantly affect the model performance: (1) the near-field bathymetry, (2) the bottom roughness, and (3) waves.

Near-Field Bathymetry

At the start of the calibration, some preliminary model runs using dye visualization had indicated the model jet exhibited a meandering motion (a condition similar to the description by Giger et al., 1985) and exited through the west entrance (Fig. 1) for all tidal levels. The tide-independent plume trajectory in the model was contrary to the observations of the field photo study (Fig. 2). It was found that major bathymetric features near the outfall (covering a prototype area of 100 by 150 ft (30 X 50 m)), absent in the model, were important. In the prototype, striations and rock ridges formed at an oblique angle of 20-30 degrees to the discharge centerline are apparent. During low tides, these rock ridges are close to the surface, and act as a series of vanes to deflect the jet away from the discharge structure centerline. The effect of the incorporation of this bathymetric feature into the model was dramatic and the jet trajectory at low tides was improved (Fig. 2). Nevertheless, the jet meanders in the model still persisted causing too much mixing between the two coflowing jets. The results are depicted as curve 1 in Fig. 4.

Bottom Roughness

As a second step, 3/16" (5 mm) gravel was added to the model as random roughness to represent the presence of 1 to 3 ft (0.3 to 1 m) boulders in the prototype. The addition of the roughness greatly reduced the model jet meandering. In the region about 200 to 600 ft (60 to 180 m,

prototype scale) from the outfall, accurate bathymetric data were not available, and gravel was added in this wave breaking zone as a calibration tool. Model results now showed good agreement with the prototype data for areas within the first 600 ft (180 meters) from the outfall (see curve 2 in Fig. 4), but the agreement deteriorated offshore beyond line 8 (see curve 1 in Fig. 5).

Waves

As the 3rd step, different wave conditions and the corresponding effects were investigated. Waves in the model had a marked effect on profiles in the discharge cove. It was found that model waves scaled relative to the prototype condition had relatively little effect on the inshore temperature profiles (except in extremely shallow areas in the south cove where waves are breaking), but appeared to improve line 8 and line 10. Shown in Figure 5 are two temperature profiles simulated with and without waves. However, on line 14 at the west mouth of the discharge cove, model temperatures still showed poor agreement. It appeared that waves, which were observed breaking and dissipating energy near the seaward side of Diablo Rock (Fig. 1) were actually being reflected in the model. Wave absorption material (horse hair) was put in place in this area to absorb the wave energy. The improvement is shown in Figure 6.

MODEL SIMULATION RESULTS

The final model results are shown in Figures 7-10 for field test 1 and in Figures 11-14 for field test 2. In each figure, the normalized temperature is defined as the ratio of the excess temperature above the ambient to the discharge temperature rise. Figures 7-10 (case 1) and Figures 11-14 (case 2) showed the temperature distribution along transect lines 6,8,10 and 14 at two water depths respectively (i.e., near the surface and 10 ft (3 m) below the surface). Figure 15 (case 1) and Figure 16 (case 2) depict vertical profiles at two locations - one in the north portion and the other in the south portion of the discharge cove (see Fig. 3 for reference coordinates) for both cases. For case 2, inshore line 6 (Fig. 12) shows a marked temperature drop at the surface near the south cove. It was found that breaking waves at low tide in the shallow area in the south cove formed by a number of rock pinnacles produce significant mass transport and pump cold water into the area. During a sensitivity test, placing some wave absorbing material near these wash rocks significantly reduced this discrepancy.

Offshore surface plume behavior was investigated for case 2 and a similar test condition (case 2A). The two field tests examined had similar discharge and environmental conditions, i.e., low tides, low waves and low winds. Both tests had a downcoast (southerly) offshore current, with case 2A having a speed 10% higher than case 2, resulting in some difference in the plume bending (Fig. 17). Both cases were simulated (6-3 026 for case 2 and 6-3 027 for case 2A). The higher cross current model test (6-3 027) was produced with slightly higher waves in comparison to the lower current test (6-3 026). Both model tests showed good agreement with the corresponding prototype data for the plume trajectories (Fig. 17). The isotherm area comparison between model and field exhibited satisfactory results as shown by Figure 18. The isotherm contour configurations for the model test 6-3 027 and field test (case 2A) are shown in Figure 19, and are remarkably similar.

CONCLUSIONS

It appears that the bottom shear has a great impact on the behavior of a shallow water jet. The near-field bathymetry affects the jet trajectory, and random roughness inhibits the development of the jet meandering. Waves also play an important role in the interfacial mixing between two coflowing jets. In shallow areas where waves are breaking and are difficult to scale in a small scale model, material to absorb the wave energy can be used to improve model/field agreement.

CHAPTER 200

COOLING WATER RECIRCULATION IN THE OCEAN

by

Robert L. Wiegel,[1] F.ASCE, John T. Wells[2] and Michele A. Murdoch,[2] AM. ASCE

Abstract

In some configurations of cooling water systems for thermal-electric power plants, which use sea water as a source, a certain amount of recirculation occurs. A theory is developed to predict this recirculation. The resulting equation for the temperature rise due to a combination of the heat added to the water flowing through the condenser tubes and the build-up of heat by recirculation, the discharge temperature less the ambient temperature, is

$$T_d - T_a = \Delta T_r = \Delta T_0/[1 - (1/D)]$$

where T_d is the discharge water temperature, T_a is the ambient temperature of the sea water, ΔT_0 is the increase in temperature of the water flowing through the condenser tubes, D is the dilution that occurs by turbulent mixing of the warm water discharge with the sea water.

To test the validity of the above equation, a physical model was constructed to simulate the cooling water system, including a constant temperature cooling water source, intake and discharge structures, mixers and a heating system. Digital thermometers were used to measure the water temperatures, and dye was used to visualize the flow and the mixing of the water.

The increase in temperature due only to recirculation, $\Delta T'$, is ΔT_r minus the temperature due to heat added during a cycle, ΔT_0 (i.e., $\Delta T' = \Delta T_r - \Delta T_0 = T_i - T_a$), or

$$\Delta T_t' = T_i - T_a = [\Delta T_0/(1-1/D)] - \Delta T_0$$

where $\Delta T_t'$ is the theoretical value of $\Delta T'$, and T_i is the intake water temperature.

It was found from the experiments that the measured values of temperature increase, $\Delta T'$, were slightly lower (about 10%) in most instances than the values of temperature increase predicted by the equation, $\Delta T_t'$. A later series of tests was run in which the measured values were found to be about 15% higher than the predicted values; these data are suspect, however. If all of the data are considered, in about 60% of the tests the temperature increases were equal to or lower than predicted values, and in about 40% of the tests they were higher than the predicted values.

Introduction

In the cooling water system of a thermal-electric power plant, water is pumped from the ocean (or other source of water), through condenser tubes, and the heated water then discharged back into the ocean. If recirculation occurs, that is, if a portion of the warm water discharge is again taken through the cooling system, there will be a gradual build-up of heat to some equilibrium condition, and this would reduce the thermal efficiency of the plant and increase the effect of the discharge on marine organisms. Ideally, the intake and discharge structures are positioned so that the warm water from the discharge will not be recycled through the cooling system. However, such arrangements are not always possible, and it is desirable to be able to predict how much recirculation might occur.

In 1982, two of the coauthors (RLW and JTW) independently developed an equation for determining the amount of heat build-up that would occur in this type of cooling system, given the temperature of the cooling water source (i.e., the ocean), the amount of heat added to the cooling water during the cooling cycle, and the dilution by turbulent mixing of the recirculated water that occurs between discharge and re-intake. The reliability of this equation was tested by means of a physical model in which the predicted values of heat build-up could be compared to measured values.

This paper describes the theory, the laboratory arrangements and test procedures, the interpretation of the data, and the conclusions based on these experiments.

Theory

The primary assumption in the development of the theory is that cooling water is obtained from a large source, such as the Pacific Ocean, where a gradual temperature rise of the water due to the thermal discharge will not be measurable. This cooling water source maintains a constant ambient temperature, T_a. To simplify the concept of the theory, water is dealt with in terms of units rather than continuous flow until the end of the derivation.

The sketch in Figure 1 represents the circulation system being considered.

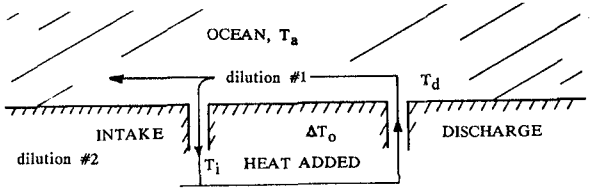

Figure 1. Definition Sketch

Let the amount of heat added to one unit of water during each cycle be proportional to ΔT_o, and the temperature of the discharge water at any time be T_d. When the system is started, one unit (= B) of water is taken in through the intake at temperature T_a, its temperature is increased by ΔT_o, and the discharge temperature after the first cycle is

$$T_d = T_a + \Delta T_o \tag{1}$$

This water is discharged into the ocean, and then diluted as it mixes with the sea water (dilution #1 on the sketch). Most of this diluted water remains in the ocean, becoming further diluted. A small amount is drawn back into the intake where subsequent dilution takes place by the water flowing in through the lower portion of the intake structure (dilution #2). Let the total dilution, from both the ocean and the intake structure, be D. A dilution of $D = 50$ would represent one unit of warm water mixed with 49 units of cool water, for a total of 50 units.

A heat balance gives the temperature of the water after one cycle, from intake to intake including heat added and total dilution:

Temperature after first cycle = $\dfrac{B(T_a + \Delta T_o) + B(D - 1)T_a}{BD}$.

$$T_i = T_a + \Delta T_o/D \tag{2}$$

where $B(T_a + \Delta T_o)$ = heat discharged, $B(D - 1)T_a$ = heat of mixture with sea water, and BD = total water.

For the second cycle, the temperature of the water being discharged, T_d, is

$$T_d = T_a + \Delta T_o/D + \Delta T_o .$$

Placing this value into the heat balance equation gives

$$T_i = \frac{B(T_a + \Delta T_o/D + \Delta T_o) + B(D - 1)T_a}{BD} = T_a + \Delta T_o/D + \Delta T_o/D^2$$

Similarly, for the third cycle,

$$T_i = \frac{B(T_a + \Delta T_o/D + \Delta T_o/D^2 + \Delta T_o) + B(D - 1)T_a}{BD} = T_a + \Delta T_o/D + \Delta T_o/D^2 + \Delta T_o/D^3$$

and so on.

Thus, the series for the intake temperature is

$$T_i = T_a + \Delta T_o/D + \Delta T_o/D^2 + \Delta T_o/D^3 + \cdots \tag{3a}$$

or

$$T_i = T_a + \Delta T_o \sum_{n=1}^{\infty} 1/D^n \tag{3b}$$

The series for the discharge temperature is

$$T_d = T_a + \Delta T_o + \Delta T_o/D + \Delta T_o/D^2 + \Delta T_o/D^3 + \cdots = T_a + \Delta T_o \sum_{n=0}^{\infty} 1/D^n \tag{4a}$$

$$T_d = T_a + \Delta T_o/(1 - 1/D) \tag{4b}$$

Now, consider N units going through the cycle each second; the heat balance equation is

$$\frac{NB(T_i) + NB(D - 1)T_a}{NBD} \tag{5}$$

N cancels out, leaving the resulting temperature the same as it was for discrete units of B. If B is one cubic meter, NB is cubic meters per second, or $NB = Q$ for Q = volumetric flow through the cooling system, and the equation is valid for continuous flow.

The temperature rise, due to the heat added to the water flowing through the condenser tubes and to the build up of heat by recirculation, is the discharge temperature less the ambient temperature

$$\Delta T_r = T_d - T_a = [T_a + \Delta T_o/(1 - 1/D)] - T_a = \Delta T_o/(1 - 1/D) \tag{6}$$

As an example, consider a rather small primary dilution in the ocean of ten to one and a secondary dilution within the intake structure of five to one, for a total dilution of fifty to one, that is, $D = 50$. Assuming the heat added during the cycle to be proportional to 20° F (ΔT_o), the eventual build-up of temperature would be

$$\Delta T_r = \Delta T_o(1 - 1/D) = 20° F/(1 - 1/50) = 20.4° F, \text{ and } \Delta T_l' = 0.4° F.$$

Similarly, dilutions of 100, 25 and 10 to 1 would give ΔT_r = 20.2, 20.8 and 22.2° F, respectively. Note that this is the difference between the discharge and ambient temperatures, and therefore includes the ΔT_o = 20.0° F ($\Delta T_l'$ = 0.2, 0.8, and 2.2° F).

Experimental Arrangements

To test the validity of the above equation, a physical model was constructed to simulate the cooling water system, including a constant temperature cooling water source, intake discharge structures, and a heating system. A value of ΔT_o of about 20° F was used in these tests, as this is the temperature increase used in some power plants. The values of dilution that were obtained were less than 20:1 owing to the small capacity of the current and the discharge available in the test facility.

The cooling water source was simulated by a steady flow of water through a rectangular channel. The amount of dilution occurring could be calculated knowing the speed of the ambient current and the flow of the thermal discharge. A concrete tank 150 feet long, 8 feet wide and 5 feet deep was used. A steady current could be maintained in the tank by means of a large recirculating pump system. The volume of water flowing through this system was sufficiently large that it would not heat up appreciably during the tests. It simulated reasonably well a constant temperature cooling source.

To reduce the scale of the model, which was necessary owing mainly to the limited capacity of the available water heater, a smaller channel was constructed within the large tank, which could carry a steady flow of water, but with a smaller flow rate. The large tank was equipped with a 16' x 8' x 3/4" plywood platform which was suspended from the sides of the tank, and could be adjusted to different depths and angles. The water current in the tank flowed freely both beneath and above this platform mounted in the tank. It was upon this suspended platform that the small channel was built (see Figures 2 and 3).

The platform was placed in a level position at a depth beneath the water surface which would allow the desired current to flow when the recirculating pump was operating at its maximum flow rate. The smaller channel, constructed of two pieces of 3/4" plywood, was 1' wide by 8' long, mounted onto the platform in the tank with the distance between the boards being 18 inches. The joints where the two boards met to form the 16' long channel were sealed with a waterproof putty to prevent infiltration of water from the large tank into the model channel. The leading edges of the barriers were beveled to assure smooth inflow of water into the model channel.

To assure thorough mixing of the thermal discharge and the ambient current, a set of eight mechanical mixers, each of which was geared to a variable speed motor, was suspended in the channel between the discharge and intake (see Figures 4 and 5, and Photo 1). By providing this extra mixing, the dilution of the discharge could be calculated as simply the ratio of the flow through the model to the flow of the discharge.

The intake was located two feet upstream from the end of the channel, to prevent the possibility of water from the "outer" tank further diluting the water at the intake. The intake was drilled through the bottom of the model channel, and a rubber hose (connected to the channel with a steel nipple) was used to carry the water over the side of the large tank to the heater. A pump with a maximum flow of about 20 gpm was used to pump the water from the intake through the heater and out the discharge structure.

The water was heated by a continuous flow type gas operated swimming pool heater. A valve was inserted in the line downstream from the heater to control the discharge flow rate.

A water-mercury manometer connected to a 1/2" orifice was used to determine flow rate through the intake/discharge line. It was calibrated at the start of the tests. The calibration was made by measuring the time required to discharge 100 lbs. of water into a tank, together with the manometer reading.

A pressurized dye injection tank was connected to the line upstream of the discharge outlet. Photo 2 shows the equipment used between the intake and discharge structures.

The discharge water was carried by a rubber hose back to the large tank, and connected to a steel nipple which was threaded through the side of the plywood barriers near the bottom of the channel (see photo 3). Both intake and discharge holes were sealed with waterproof putty to prevent leaking or entrainment of "outside" water. The discharge was located six feet downstream from the mouth of the channel, two feet upstream from the mixers and eight feet upstream from the intake (see Figure 2).

Three digital thermometers were used to monitor the temperature of the water in the intake, in the discharge, and the ambient water flowing through the channel. The temperature probe at the discharge was clipped to the barriers directly over the discharge hole (photo 3), and the probe at the intake gage (photo 4). The probe used to measure the ambient temperature was attached to the outside of the model channel near the mouth to prevent any of the heated water from interferring with the ambient temperature.

The water flow through the model channel was measured by a Kent "miniflow" anemometer-type current meter. The meter reading in hertz represented the number of times per second a propeller blade passed a reference point on the cylinder about which it rotated. The propeller had five blades, so one complete revolution per second would read five hertz. The meter was calibrated prior to the tests. The speed of the current was the most unreliable measurement made during the tests. The meter reading continually fluctuated, making an accurate reading difficult.

Test Procedure

At least thirty minutes before a test was started, the large recirculating pump in the concrete tank was turned on to allow sufficient time for a steady current to develop, and to disperse any temperature stratification that might exist in the water in the tank. The digital thermometers were turned on at the same time, as they required from twenty to thirty minutes to warm up before accurate readings could be made. Then, each of the three thermometers was calibrated relative to the temperature of the water in the trough which was measured with a mercury thermometer. (Note: In some instances the thermometers were not all calibrated to the same temperature due to time limitations; in these instances, the data were adjusted before being inserted into the equation. For example, if two of the thermometers were correctly calibrated to 53.4° F and the third thermometer read 53.5° F, the temperature readings from the third thermometer would be reduced by -0.1° F so that readings on all three thermometers would be in reference to the same base temperature, 53.4° F, in this example.

The intake/discharge cycle was then started, the desired flow rate set, and the manometer reading recorded. The mixers were started, and a small amount of dye injected into the discharge line to check visually that complete mixing was taking place, and that no substantial leaking or infiltration was occurring between the model channel and the outside tank. Dye crystals were dropped into the water near the current meter. As the crystals fell, they formed a dye trail which showed the current pattern through the water column. If the discharge was too high or the mixers were rotating too fast, the current did not flow smoothly into the model channel. If the dye trail did not indicate a smooth steady current, the

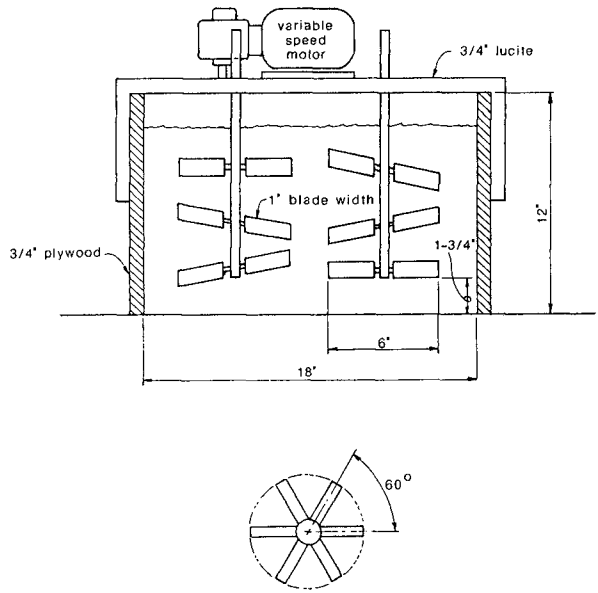

Figure 4. Schematic of Mixers, Elevation

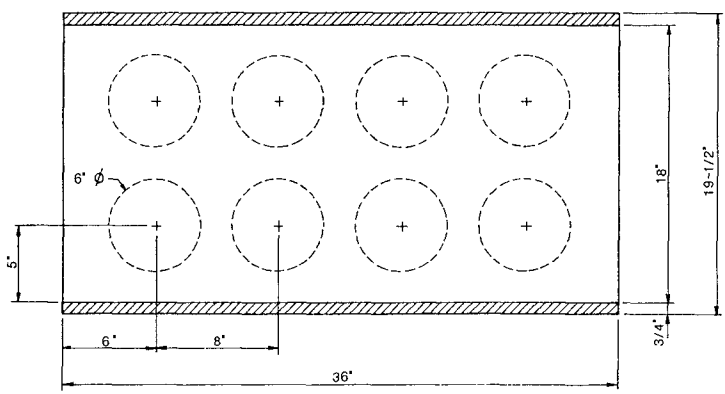

Figure 5. Schematic of Mixers, Plan

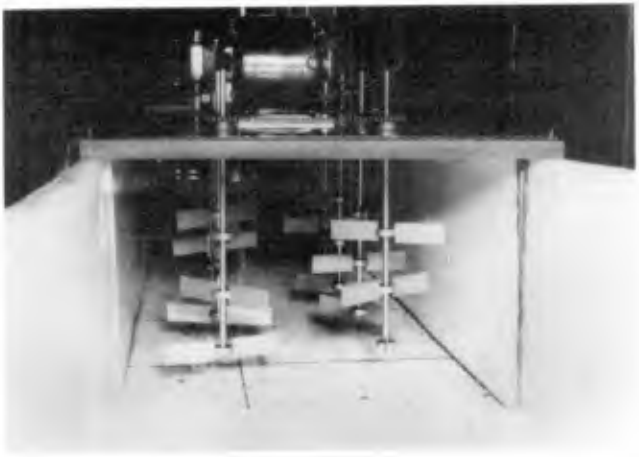

Photo 1.

Photo 2.

Photo 3.

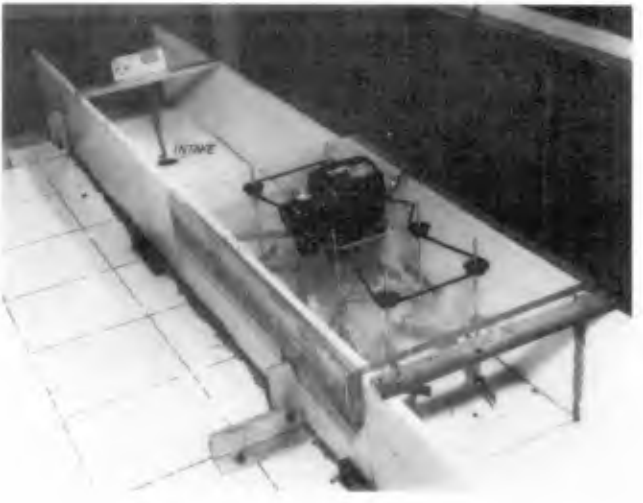

Photo 4.

discharge and mixers were adjusted to provide a good current and thorough mixing.

The heat was then turned on, and the time recorded. While the heater was warming up (this took only two to three minutes), the current meter reading was recorded. The temperatures were recorded at periodic time intervals, usually two to ten minutes, until the test was completed.

After a test was finished the heater was turned off, and cool water pumped through it for about five minutes. Then, the discharge was shut off. The large recirculating pump was left on for about an additional thirty minutes to cause the temperature throughout the tank to become uniform before the next test was begun. This length of time was very conservative as the thermometers indicated that only about five minutes were required to do this.

The thermometers were calibrated again before the next test and any large differences (0.3° F or larger) were noted, as this could be an indication that readings during the previous test were inaccurate. One of the thermometers had to be replaced about half way through the series of tests due to a malfunction. It was replaced by a thermometer which read in degrees Celsius, and these readings converted to °F prior to interpreting the data.

Interpretation of the Data

The velocity and depth of the water in the channel, together with the discharge rate, were used to calculate the dilution, D:

$$D = \frac{\text{total flow (calculated from current meter and depth)}}{\text{discharge flow (calculated from manometer reading)}}$$

A measure of the heat added during a recirculation cycle ΔT_o, was calculated by subtracting the intake temperature, T_i, from the discharge temperature T_d

$$\Delta T_o = T_d - T_i$$

The heat build-up that occurs during the cycle would be proportional to ΔT_r. The heat build-up due only to the recirculation of discharge water would be proportional to ΔT_r less the amount of heat added during a cycle, proportional to ΔT_o. This quantity is given the symbol $\Delta T'$ and is also equal to the temperature difference between intake and ambient waters, or

$$\Delta T' = T_i - T_a$$

$\Delta T'$ can also be calculated using the formula

$$\Delta T_t' = [\Delta T_o/(1 - 1/D)] - \Delta T_o$$

This value for $\Delta T'$ has the subscript "t" as it is calculated from theory.

Results and Conclusions

Measured values of $\Delta T'$ versus predicted values, $\Delta T_t'$, are shown in Figure 6. As can be seen, the measured temperature increases ($\Delta T'$) were slightly lower in most instances than the temperature increases predicted by the equation, $\Delta T_t'$. Thus, the equation gives a slightly conservative approximation to the long term increase of temperature which may be expected due to recirculation. The difference between measured and predicted values is rarely larger than about 10%, and the predicted value is conservative in nearly every case. A few additional tests were run at the end of the experiments in which the opposite effect occurred. That is, the measured temperatures were about 15% greater than the predicted temperatures.

However, other information led the investigators to believe that an error had occurred in the calibration of the digital thermometers at the start of this series of tests. If all of the data are considered, in about 60% of the tests the temperature increases were equal to or lower than predicted values and in about 40% of the tests they were higher than the predicted values.

It was found that during a test the values of ΔT_o gradually increased with time. It is believed that this was due to heat being added by the pump which provided the circulation of the intake/discharge system. The pump only operated at one speed, but the amount of water in the intake/discharge system was controlled by a valve located past the heater and therefore past the pump. When the valve was adjusted so that the flow was less than the maximum flow which could be provided by the pump, the "excess" energy from the pump may have been added to the water as heat. this mechanical heat would be in addition to the provided by the heater. This seemed to be the most reasonable explanation for the increasing ΔT_o.

For temperatures measured to one-tenth of a degree Fahrenheit, only two cycles of recirculation are required before the equation can be used to predict the heat build-up. Two cycles were easily completed in less than three minutes (from a conservative calculation of flow through the system). As the temperature increases described in the above paragraph occurred slowly in comparison, each set of readings taken during a test should truly simulate an individual situation; i.e., each set of readings was analyzed on the basis of the ΔT_o recorded for that instance. This assumption did not appear to affect the results. The results got neither better nor worse with increasing time during a test.

Two other comments regarding the data should be made. First, in a few tests, the mixers were not turned on. The data from these tests are no different than the data of the tests where the mixers were used. It appears from this that the mixers were not needed to obtain the required dilution, as the flow-induced turbulent mixing was sufficient. These data are included in this report. Secondly, in a few tests the ambient temperature changed by 0.1 or 0.2 degrees Fahrenheit (never more than this, however) and this change occurred over times equal to or greater than about thirty minutes. This should not affect the interpretation of the data, since all numbers used in the calculations are relative to the other temperatures. If the ambient temperature was raised 0.1 degree F, say T_i and T_d would also be 0.1 degree F higher, and the increase would cancel out in the equations used to interpret the data.

Despite the limitations of these tests, the consistency in results of the tests shows that the equation presented herein predicts reasonably well the build-up of heat that may occur in a cooling system of the type modeled.

SHIP MOTIONS

Composite Breakwater near Taipei—H. Lee Butler

CHAPTER 201

A Numerical Simulation of the Moored Container Ship Movements Induced by Wind

T Z Cheng * & N K Liang **

ABSTRACT

In the past, only the ship motion due to wave is studied. This study is focused on the ship motion induced by a steady oscillating wind. The oscillating wind is assumed to be sinusoidal of a constant frequency. The wind direction θ, number of mooring lines and the wind frequency are the parameters in simulating an Evergreen's Ever Garden class container ship. The results show that the worst angle between the quay and the prevailing wind direction is 45°. Surge and roll are the most significant motions induced by the oscillating wind. By changing the number of mooring lines, the natural frequency can be kept away from the dominant wind frequency, except roll.

INTRODUCTION

The wave affects the ship motion significantly. Hence, in the past only ship motion due to wave is studied (Lewis, 1929; Korvin-Kroukovsky, 1961; Salvesen, et al, 1970). However, there are harbours which are well sheltered by the breakwater from suffering the invasion of waves but attacked by strong moonson wind. It is self-understood that the wind is oscillating. The oscillating wind may induce ship motion. The purpose of this paper is to understand the characteristics of the wind-induced ship motion by numerical simulation qualitatively. The results can be used for the guide line of harbour design.

THEORY

There are two coordinate systems: One is the equilibrium axes (Fig. 1), which is fixed. C.G. is the center of gravity. O is the mean position of ship motion. The other one is the body axes which is moved with the ship (Fig. 2). The definition of 6 ship motions is also shown in Fig. 2. The 3 translation motions are surge $x(t)$, sway $y(t)$ and heave $z(t)$. The 3 angular motions are roll $\phi(t)$, pitch $\theta(t)$ and

* Graduate student, Institute of Oceanography, National Taiwan University, Taiwan, R.O.C.

** Director, Institute of Harbour & Marine Technology, Wuchi, Taiwan R.O.C.

yaw $\psi(t)$. In order to construct the equations of motion, the following assumptions are made:

1. The ship is a rigid body.
2. The ship is symmetric and slender.
3. The ship motion amplitude is small, equations can be linearized.
4. Except roll, the effect of viscosity is neglected.
5. The wind direction is fixed.
6. There is no incident wave.
7. No coupling between the longitudinal motion— surge, heave and pitch, and the transverse motion—sway, roll and yaw.

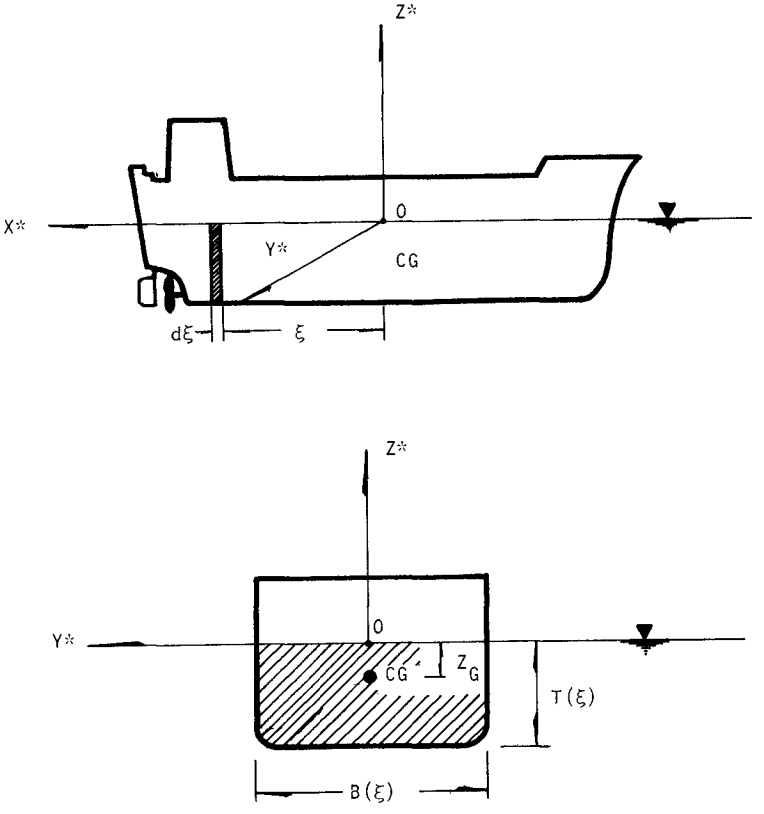

Fig 1. The definition of equilibrium axes

For longitudinal motion

$$\begin{aligned} M'\ddot{x} + M'Z_g\ddot{\theta} &= X_I + X_D + X_H + X_M + X_W \\ M'\ddot{z} &= Z_I + Z_D + Z_H + Z_M + Z_W \\ I_2\ddot{\theta} + M'Z_g\ddot{x} &= M_I + M_D + M_H + M_M + M_W \end{aligned} \tag{1}$$

For transverse motion

$$\begin{aligned} M'\ddot{y} - M'Zg\ddot{\phi} &= Y_I + Y_D + Y_H + Y_M + Y_W \\ I_1\ddot{\phi} - I_{13}\ddot{\psi} - M'Z_g\ddot{y} &= K_I + K_D + K_H + K_M + K_W \\ I_3\ddot{\psi} - I_{13}\ddot{\phi} &= N_I + N_D + N_H + N_M + N_W \end{aligned} \tag{2}$$

where,

M'	mass of ship
M	moment for pitch
K	moment for roll
N	moment for yaw
X	force for surge
Y	force for sway
Z	force for heave
I_1, I_2, I_3	moment of inertial with respect to X^*, Y^* and Z^* axes
I_{13}	Product of inertial with respect to $X^* - Z^*$ axes.

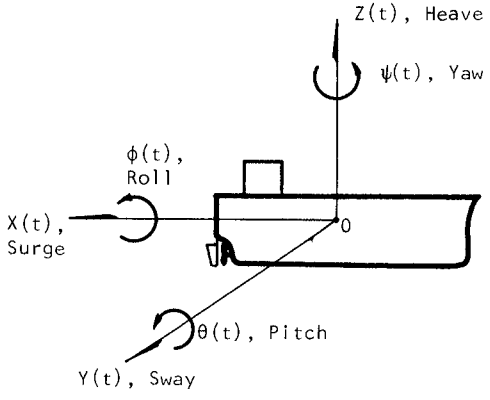

Fig. 2 The definition of six ship motions

the subindex

I	inertial

H	hydrostatic restoring
M	mooring line restoring
$\overline{W}$	wind excitation

8. Strip theory approximation
The hydrodynamic forces and moments can be integrated along the ξ - axis, i.e. the longitudinal axis of the ship.

For longitudinal motion

$$X_I = -\int m_x(\xi)d\xi\cdot\ddot{x} + \int Zs(\xi)m_x(\xi)d\xi\cdot\ddot{\theta}$$

$$X_D = -\int n_x(\xi)d\xi\cdot\dot{x} + \int Zs(\xi)n_x(\xi)d\xi\cdot\dot{\theta}$$

$$X_H = 0$$

$$Z_I = -\int m_z(\xi)d\xi\cdot\ddot{z} + \int \xi m_z(\xi)d\xi\cdot\ddot{\theta}$$

$$Z_D = -\int n_z(\xi)d\xi\cdot\dot{z} + \int \xi n_z(\xi)d\xi\cdot\dot{\theta} \qquad (3)$$

$$Z_H = -\rho_w g\int B(\xi)d\xi\cdot z + \rho_w g\int \xi B(\xi)d\xi\cdot\theta$$

$$M_I = \int Zs(\xi)m_x(\xi)d\xi\cdot\ddot{x} + \int \xi m_z(\xi)d\xi\cdot\ddot{z} - \int[\xi^2 m_z(\xi) + Z_s^2(\xi)m_x(\xi)]d\xi\cdot\ddot{\theta}$$

$$M_D = \int Zs(\xi)n_x(\xi)d\xi\cdot\dot{x} + \int \xi n_z(\xi)d\xi\cdot\dot{z} - \int[\xi^2 n_z(\xi) + Z_s^2(\xi)n_x(\xi)]d\xi\cdot\dot{\theta}$$

$$M_H = \rho_w g\int \xi B(\xi)d\xi\cdot z - \rho_w g\int \xi^2 B(\xi)d\xi\cdot\theta$$

where

$m_x(\xi)$	sectional added mass per unit length for surge.
$m_z(\xi)$	sectional added mass per unit length for pitch.
$n_x(\xi)$	sectional damping coefficient per unit length for surge.
$n_z(\xi)$	sectional damping coefficient per unit length for pitch.
$B(\xi)$	sectional width.
$Zs(\xi)$	distance between water surface to the center of the sectional added mass.

For transverse motion

$$Y_I = -\int m_y(\xi)d\xi\cdot\ddot{y} - \int \xi m_y(\xi)d\xi\cdot\ddot{\psi} - \int m_y\phi(\xi)d\xi\cdot\ddot{\phi}$$

$$Y_D = -\int n_y(\xi)d\xi\cdot\dot{y} - \int \xi n_y(\xi)d\xi\cdot\dot{\psi} - \int n_y\phi(\xi)d\xi\cdot\dot{\phi}$$

$$
\begin{aligned}
Y_H &= 0 \\
K_I &= -\int m_{y\phi}(\xi)\,d\xi\cdot\ddot{y} - \int m_{\phi}(\xi)\,d\xi\cdot\ddot{\phi} - \int \xi m_{y\phi}(\xi)\,d\xi\cdot\ddot{\psi} \\
K_D &= -\int n_{y\phi}(\xi)\,d\xi\cdot\dot{y} - \int n_{\phi}(\xi)\,d\xi\cdot\dot{\phi} - \int \xi n_{y\phi}(\xi)\,d\xi\cdot\dot{\psi} \\
&\quad -\int N_{\phi}'(\xi)\,d\xi\cdot\dot{\phi} \qquad (4) \\
K_H &= -\rho_w g \nabla\cdot\overline{GM}\cdot\phi \\
N_I &= -\int \xi m_y(\xi)\,d\xi\cdot\ddot{y} - \int \xi^2 m_y(\xi)\,d\xi\cdot\ddot{\psi} - \int \xi m_{y\phi}(\xi)\,d\xi\cdot\ddot{\phi} \\
N_D &= -\int \xi n_y(\xi)\,d\xi\cdot\dot{y} - \int \xi^2 n_y(\xi)\,d\xi\cdot\dot{\psi} - \int \xi n_{y\phi}(\xi)\,d\xi\cdot\dot{\phi} \\
N_H &= 0
\end{aligned}
$$

where

∇	displaced volume of the ship
$\overline{GM}$	metacentric height
$m_y(\xi)$, $n_y(\xi)$	sectional added mass and damping coefficient per unit length for sway.
$m_\phi(\xi)$, $n_\phi(\xi)$	sectional added mass and damping coefficient per unit length for roll.
$m_{y\phi}(\xi)$, $n_{y\phi}(\xi)$	sectional added mass and damping coefficient per unit length for coupling between roll and sway.
$n_\phi'(\xi)$	sectional damping coefficient due to viscosity for roll.

9. All unit added mass and damping coefficient are only a function of frequency.
Eq.(3) and (4) can be rewritten: (The coefficient Aij, Bij and Cij are calculated according to NSRDC ship-motion and sea-load computer program).

$$
\begin{aligned}
X_I &= -A_{11}\ddot{x} - A_{15}\ddot{\theta} & Y_I &= -A_{22}\ddot{y} - A_{24}\ddot{\phi} - A_{26}\ddot{\psi} \\
X_D &= -B_{11}\dot{x} - B_{15}\dot{\theta} & Y_D &= -B_{22}\dot{y} - B_{24}\dot{\phi} - B_{26}\dot{\psi} \qquad (5) \\
X_H &= 0 & Y_H &= 0
\end{aligned}
$$

where

Aij: added mass coefficient
Bij: damping coefficient
Cij: hydrostatic restoring coefficient

10. The tension of the mooring line follows Hooke's Law, the mooring line is assumed as a straight line.
The static mooring forces & moments and the resistance of fender

at the equilibrium position are balanced with the average wind force. Therefore only the dynamic mooring forces or moments are considered. The dynamic mooring forces and moments are the following:

$$
\begin{aligned}
X_M &= - k_{11}x - k_{13}z - k_{15}\theta \\
Y_M &= - k_{22}y - k_{24}\phi - k_{26}\psi \\
Z_M &= - k_{33}z - k_{31}x - k_{35}\theta \\
K_M &= - k_{44}\phi - k_{42}y - k_{46}\psi \\
M_M &= - k_{55}\theta - k_{51}x - k_{53}z \\
N_M &= - k_{66}\psi - k_{62}y - k_{64}\phi
\end{aligned}
\qquad (6)
$$

And the dynamic mooring line force coefficients are:

$$
\begin{aligned}
k_{11} &= \Sigma(K\cos^2\alpha) \\
k_{13} &= k_{31} = \Sigma(K\cos\alpha\cos\gamma) \\
k_{15} &= k_{51} = \Sigma(KZ_L\cos^2\alpha - KX_L\cos^2\gamma) \\
k_{33} &= \Sigma(K\cos^2\gamma) \\
k_{35} &= k_{53} = \Sigma(KZ_L\cos\alpha\cos\gamma - KX_L\cos^2\gamma) \\
k_{55} &= \Sigma[K(X_L\cos\gamma - Z_L\cos\alpha)^2] \\
k_{22} &= \Sigma(K\cos^2\beta) \\
k_{24} &= k_{42} = \Sigma(-KZ_L\cos^2\beta) \\
k_{26} &= k_{62} = \Sigma(KX_L\cos^2\beta) \\
k_{44} &= \Sigma(KZ_L^2\cos\beta) \\
k_{46} &= k_{64} = \Sigma(-KX_LZ_L\cos^2\beta) \\
k_{66} &= \Sigma(KX_L^2\cos^2\beta)
\end{aligned}
$$

where

E modulus of elasticity
A sectional area of the rope
$K = EA/L$ spring constant , L length of the rope
(X_L, Y_L, Z_L) coordinates of the end of rope on the ship's deck.
(α, β, γ) angles between the rope from the land-end and the X*, Y*, Z* axes (shown in Fig-3)
Σ summantion over the total ropes.

11. The air is an incompressible viscous fluid. It is assumed:

wind force is $F(t) = \frac{1}{2}\rho C_D A U^2(t)$

where

$U(t)$	the wind velocity
ρ	air density
C_D	drag coefficient
A	Projecting area of the object to the plane which is perpendicular to the wind direction.

$$U(t) = \bar{U} + u(t) = \bar{U} + u_o \cos \omega t, \quad u_o << \bar{U}$$

then $U^2(t) \doteq \bar{U}^2 + 2\bar{U} u_o \cos\omega t$

$$F(t) = \tfrac{1}{2}\rho C_D A U^2(t) \doteq \tfrac{1}{2}\rho C_D A\bar{U}^2 + \tfrac{1}{2}\rho C_D A(2\bar{U}u_o)\cos\omega t$$
$$= \bar{F} + f_o \cos\omega t$$

where $\bar{F} = \frac{1}{2}\rho C_D A\bar{U}^2$

$$f_o = \rho C_D A\bar{U}u_o$$

As shown in Fig(4), $F_x(t)$ and $F_y(t)$ are the wind force component in X* and Y* axes, respectively.

Because C_D and A are function of θ_o, then

$$F_x(t;\ \theta_o) = \overline{F_x}(\theta_o) + f_x(\theta_o)\cos\omega t$$
$$F_y(t;\ \theta_o) = \overline{F_y}(\theta_o) + f_y(\theta_o)\cos\omega t$$

where

$$\overline{F_x}(\theta_o) = \tfrac{1}{2}\rho C_{DX}(\theta_o)\ A(\theta_o)\ \bar{U}^2$$
$$\overline{F_y}(\theta_o) = \tfrac{1}{2}\rho C_{DY}(\theta_o)\ A(\theta_o)\ \bar{U}^2$$
$$f_x(\theta_o) = \rho C_{DX}(\theta_o)\ A(\theta_o)\ \bar{U}u_o$$
$$f_x(\theta_o) = \rho C_{DY}(\theta_o)\ A(\theta_o)\ \bar{U}u_o$$

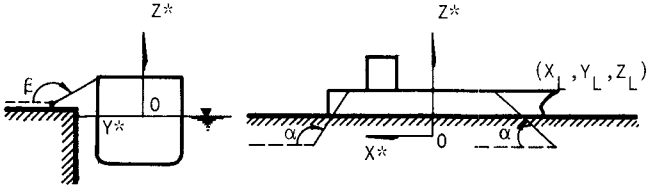

Fig.3 The definition of mooring line parameters

According to the above-mentioned assumptions, 6 second order simultaneous partial differential equations with 6 unknowns are as follows:

$$(M'+A_{11})\ddot{x} + B_{11}\dot{x} + k_{11}x + (A_{15}+M'Z_g)\ddot{\theta} + B_{15}\dot{\theta} + k_{15}\theta + k_{13}z = Xw$$

$$(M'+A_{22})\ddot{y} + B_{22}\dot{y} + k_{22}y + (A_{24}-M'Zg)\ddot{\phi} + B_{24}\dot{\phi} + K_{24}\phi + A_{26}\ddot{\psi} + B_{26}\dot{\psi} + k_{26}\psi = Yw$$

$$(M'+A_{33})\ddot{z} + B_{33}\dot{z} + (C_{33}+k_{33})z + k_{31}x + A_{35}\ddot{\theta} + B_{35}\dot{\theta} + (C_{35}+k_{35})\theta = Zw$$

$$(I_1+A_{44})\ddot{\phi} + B_{44}\dot{\phi} + (C_{44}+k_{44})\phi + (A_{42}-M'Z_g)\ddot{y} + B_{42}\dot{y} + k_{42}y + (A_{46}-I_{13})\ddot{\psi} + B_{46}\dot{\psi} + k_{46}\psi = Kw \quad (7)$$

$$(I_2+A_{55})\ddot{\theta} + B_{55}\dot{\theta} + (C_{55}+k_{55})\theta + (A_{51}+M'Z_g)\ddot{x} + B_{51}\dot{x} + k_{51}x + A_{53}\ddot{z} + B_{53}\dot{z} + (C_{53}+k_{53})z = Mw$$

$$(I_3+A_{66})\ddot{\psi} + B_{66}\dot{\psi} + k_{66}\psi + A_{62}\ddot{y} + B_{62}\dot{y} + k_{62}y + (A_{64}-I_{13})\ddot{\phi} + B_{64}\dot{\phi} + k_{64}\phi = Nw$$

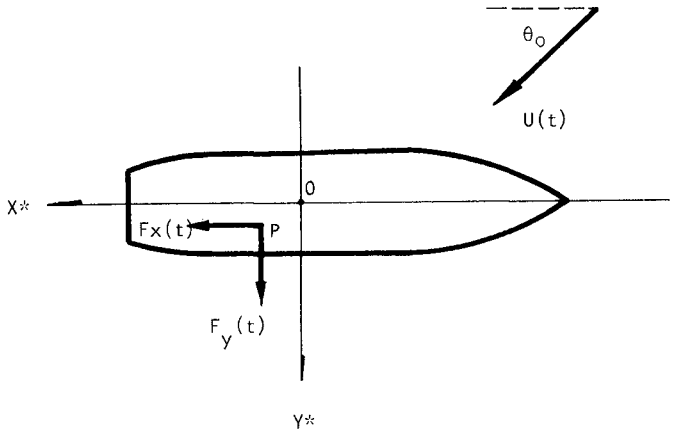

Fig. 4 The definition of wind direction θ_o

The wind force is sinusoidal, it can be represented as follows:

$$\begin{aligned} Xw &= \overline{W}_1 e^{-i\omega t}, & Yw &= \overline{W}_2 e^{-i\omega t} & Zw &= \overline{W}_3 e^{-i\omega t} \\ Kw &= \overline{W}_4 e^{-i\omega t}, & Mw &= \overline{W}_5 e^{-i\omega t} & Nw &= \overline{W}_6 e^{-i\omega t} \end{aligned} \tag{8}$$

$\overline{W}_1$, $\overline{W}_2$, ...$\overline{W}_6$ are the amplitudes of wind forces and moments. At steady state, the solution will be also sinusoidal, then

$$\begin{aligned} x &= x_o e^{-i\omega t}, & y &= y_o e^{-i\omega t}, & z &= z_o e^{-i\omega t} \\ \phi &= \phi_o e^{-i\omega t}, & \theta &= \theta_o e^{-i\omega t}, & \psi &= \psi_o e^{-i\omega t} \end{aligned} \tag{9}$$

substituding eq(8), (9) into eq(7), a new 6 simultaneous linear equcations are obtained.

To make the equations dimensionless M', L and $\sqrt{L/g}$ are used as mass, length and time scale. The index "'" to indicated the dimensionless symbols is omitted.

It can be written in the matrix form:

$$\{([C]+[k]) - \omega^2([M]+[A]) - i\omega[B]\} * [X] = [W] \tag{10}$$

in which

$$[X] = \begin{bmatrix} X_o \\ Y_o \\ Z_o \\ \phi_o \\ \theta_o \\ \psi_o \end{bmatrix}, \quad [W] = \begin{bmatrix} W_1 \\ W_2 \\ W_3 \\ W_4 \\ W_5 \\ W_6 \end{bmatrix}, \quad [M] = \begin{bmatrix} 1 & 0 & 0 & 0 & Z_G & 0 \\ 0 & 1 & 0 & -Z_G & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & -Z_G & 0 & I_1 & 0 & -I_{13} \\ Z_G & 0 & 0 & 0 & I_2 & 0 \\ 0 & 0 & 0 & -I_{13} & 0 & I_3 \end{bmatrix}$$

$$[A] = \begin{bmatrix} A_{11} & 0 & 0 & 0 & A_{15} & 0 \\ 0 & A_{22} & 0 & A_{24} & 0 & A_{26} \\ 0 & 0 & A_{33} & 0 & A_{35} & 0 \\ 0 & A_{42} & 0 & A_{44} & 0 & A_{46} \\ A_{51} & 0 & A_{53} & 0 & A_{55} & 0 \\ 0 & A_{62} & 0 & A_{64} & 0 & A_{66} \end{bmatrix}, [B] = \begin{bmatrix} B_{11} & 0 & 0 & 0 & B_{15} & 0 \\ 0 & B_{22} & 0 & B_{24} & 0 & B_{26} \\ 0 & 0 & B_{33} & 0 & B_{35} & 0 \\ 0 & B_{42} & 0 & B_{44} & 0 & B_{46} \\ B_{51} & 0 & B_{53} & 0 & B_{55} & 0 \\ 0 & B_{62} & 0 & B_{64} & 0 & B_{66} \end{bmatrix}$$

$$[C] = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & C_{33} & 0 & C_{35} & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & C_{53} & 0 & C_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}, [k] = \begin{bmatrix} k_{11} & 0 & k_{13} & 0 & k_{15} & 0 \\ 0 & k_{22} & 0 & k_{24} & 0 & k_{26} \\ k_{31} & 0 & k_{33} & 0 & k_{35} & 0 \\ 0 & k_{42} & 0 & k_{44} & 0 & k_{46} \\ k_{51} & 0 & k_{53} & 0 & k_{55} & 0 \\ 0 & k_{62} & 0 & k_{64} & 0 & k_{66} \end{bmatrix}$$

EXAMPLE

Evergreen's Ever Garden class container ship is used as an example to simulate the ship motion induced by the oscillating wind. The dimensions of the ship and the arrangement of the mooring lines are shown in Fig. 5. The other conditions are as follows:

D.W.T. 42,000 ton
$\bar{U}$ = 60 ft/sec, u_o = 30 ft/sec
wind direction θ_o= 0°, 45° 90°
number of mooring lines, 0, 2, 4, 6, 8, 10

Because the equations are linear, the amplitudes (x, y, z, θ, ψ, ϕ) are proportional to amplitude($\bar{W}$), which is proportional to $\bar{U}u_o$. If $\bar{U}u_o$ is changed, the relationship of the various ship motions remains the same. The results to the wind direction 45° are shown in Fig. (6) (7), (8), (9), (10), (11).

The results are samarized as follows:
1. Increasing the number of the mooring line increases the natural frequency, except roll.
2. The natural periods for different number of mooring lines are as follows:

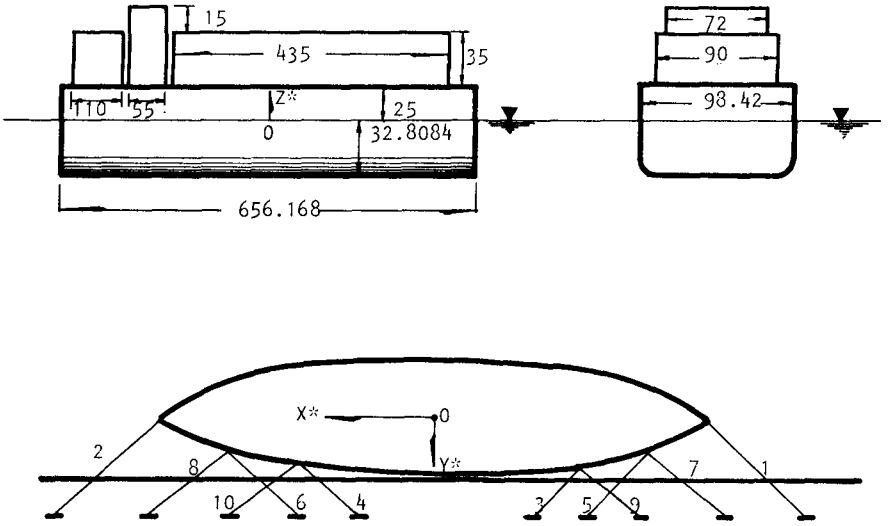

Fig. 5 Dimension of the container ship

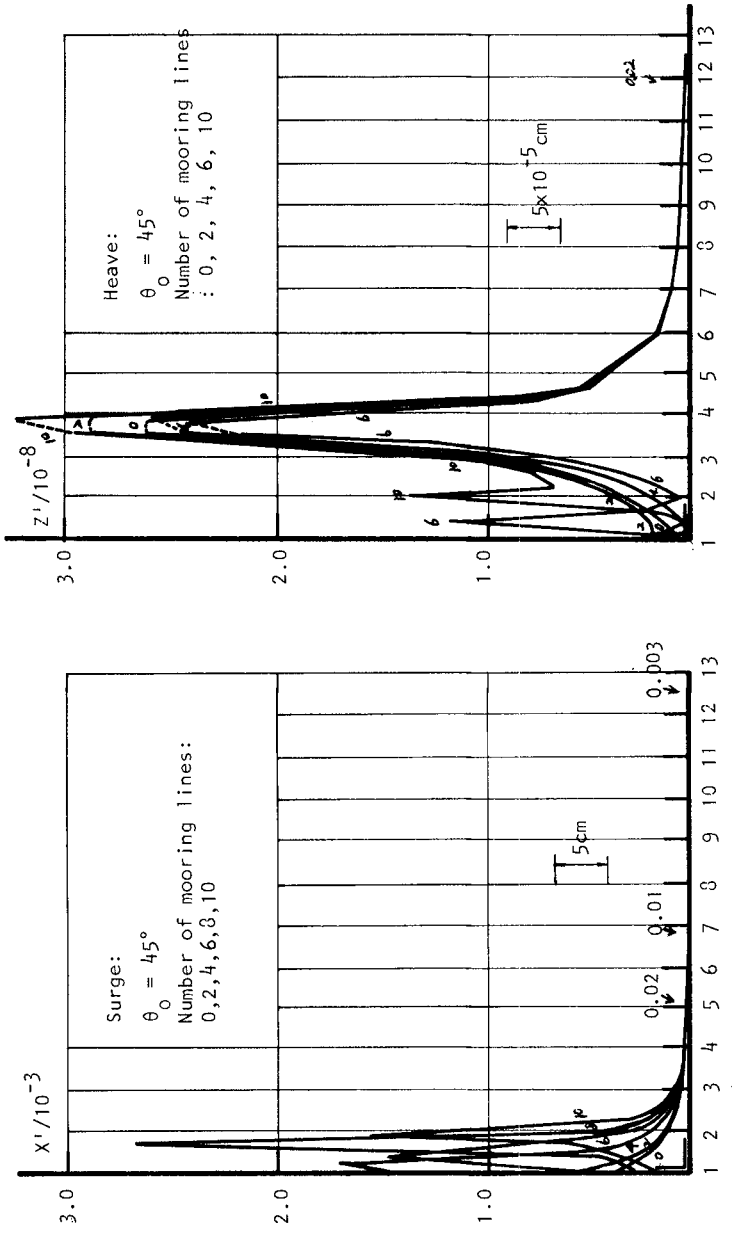

Fig. 6 Amplitude of surge

Fig. 7 Amplitude of heave

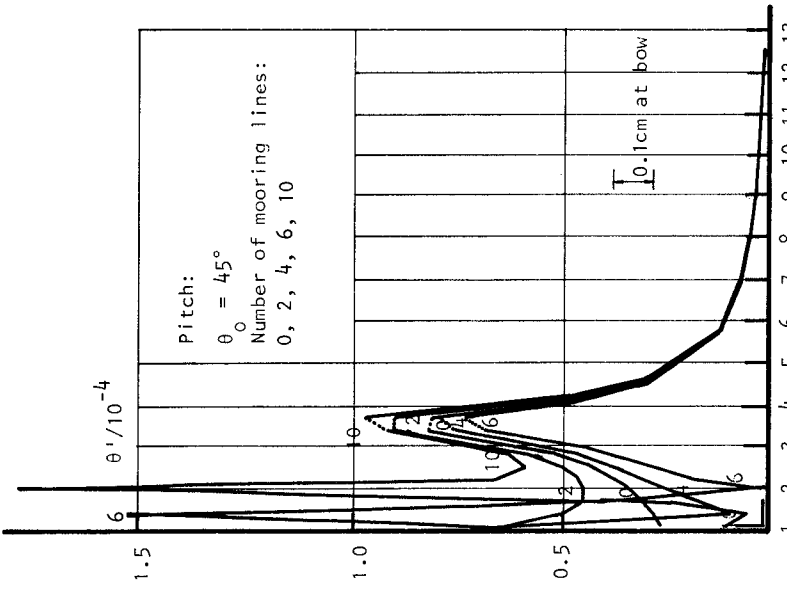

Fig. 8 Amplitude of pitch

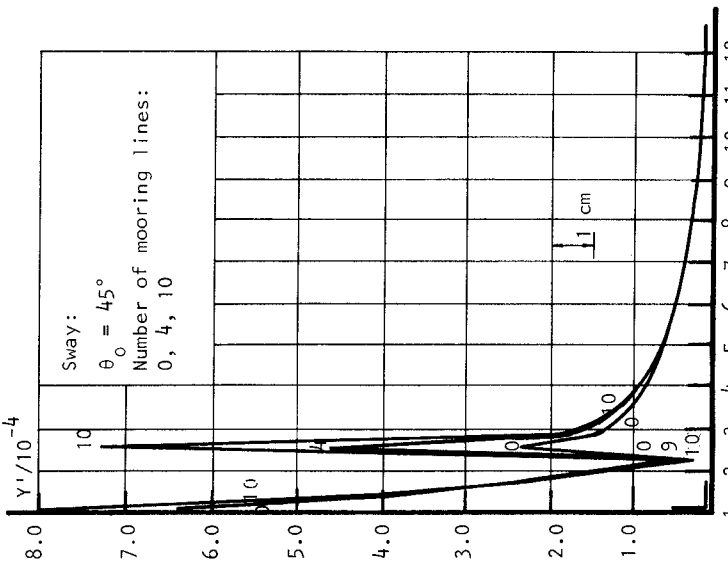

Fig. 9 Amplitude fo sway

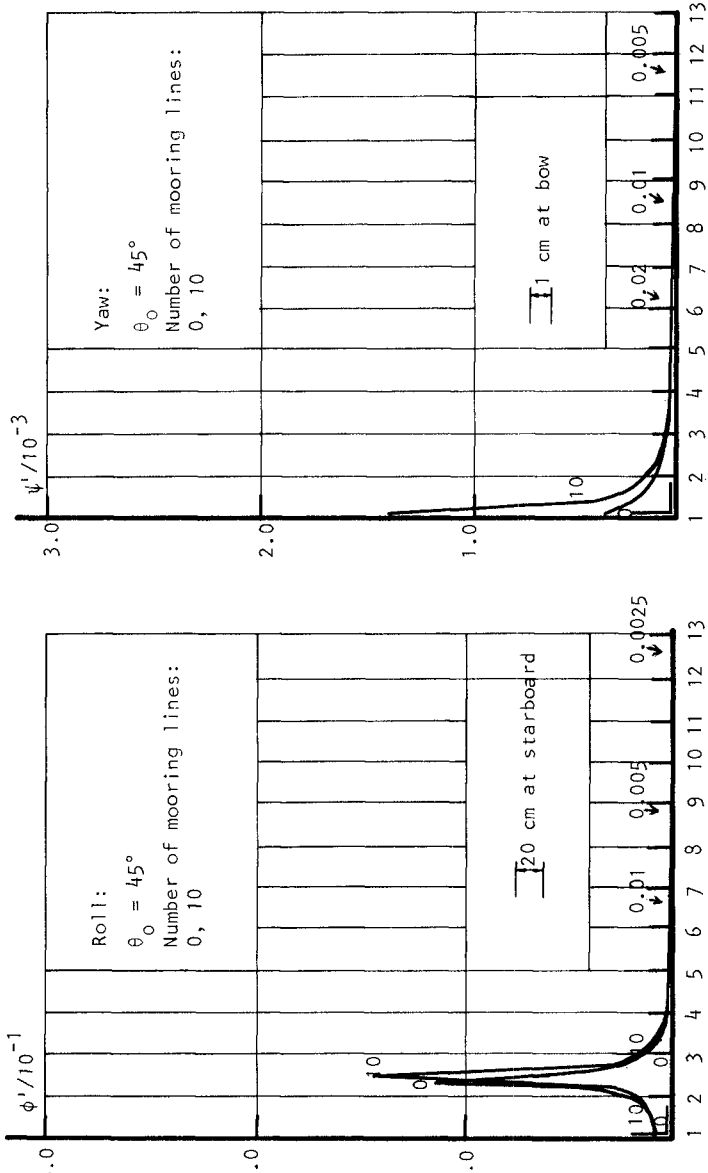

Fig. 10 Amplitude of roll

Fig. 11 Amplitude of yaw

surge	14-28 sec
heave	14-28 sec, 8sec.
pitch	14-28 sec, 8sec.
sway	14-28 sec, 11sec.
roll	11 sec
yaw	> 28 sec

3. Surge, pitch, heave, yaw and roll are maximum for $\theta_o = 45°$. However, sway is maximum for $\theta_o = 90°$.

4. The amplitude in the range of natural frequency for different number of mooring lines and $\theta_o = 45°$ are as follows:

surge	30-50 cm
sway	5-15 cm
heave	very small
yaw	5-15 cm
roll(interpretted as the heave at starboard)	170-220 cm
pitch(interpretted as the heave at bow)	0.7-1.7 cm

5. In the vicinity of natural frequency, the magnitude order of the 6 motions is as follows:

surge > sway >> heave
roll >> yaw > pitch

The only exception is sway (90°) > surge (90°)

CONCLUSIONS

1. The induced ship motions by the oscillating wind are the greatest, as the angle between the quay and the prevailing wind direction is 45°. Of course, the 0°-direction quay is the best design.

2. Surge and roll are the most significant motions induced by the oscillating wind.

3. By changing the number of mooring lines, the natural frequency can be kept away from the dominant wind frequency, except roll.

ABSTRACT

To optimize structure design it is useful to conduct detail physical model tests. Tests of various basic physical phenomena (e.g. resonance problems), reproducing a sea state ofprototype duration and then from the behavior of entire structure, the optimal design to the wharf structure will be obtained.

Preliminary analyses are made by basing upon experience for structure submitted to the similar action of wave or climates, combined with knowledge of available construction materials. i.e. selection of the rubber fender and the mooring system. Therefore, ship impaction force model simulation could lead to an ideal design.

A lot of experimental research work is conducted in order to facilitate determination of its test value when different factors are involved. Some design recommedations are commonly based on experimental results rather than that from mathematical iterations.

INTRODUCTION

It's well know that, when wave periods are close to the moored ships own periods of oscillation, increase movements take place. The reason for this is that the resonance period of moored ship fall in this range. The internal harbour layout should thus be designed in such a way that no strong resonance occur in this period range.

A differentitation was made between safe mooring and safe operation. Safe operation requires that the ship's movements must not be too great so that loading and offloading operations can be carried out safety. Safe mooring refers to conditions in which cargo handling must be stopped but the vessenal can remain at the berth. Several factors, such as layout of breakwaters, type of quay structure and mooring/fender arrangement, influence the movements of moored ships, It is thus necessary to carry out detailed mooring studies in order to collect safficient data on the behaviour of ship - mooring - fender system. Time and economic constraints make it very difficult to achieve an absolute optimal solution. Systematic testing in the labortory model of various alternatives greatly assisted in arriring at a satistactory solution.

MODEL EXPERIMENT

Model experiment study was carried out in the section channel of the Institute of Harbour and Marine technology at Taichung district in Taiwan. The model is simulated from of 34,500 D.W.T. container ship. The model was built in a 37^m by 7.6^m by 1.0^m have basin with an undistorted scale of one to hundredth. Model ship is moored at nearly the center of the wave basin with six mooring line as shown in Figure 1 & 2.

In the model experiment, following variables such as wave period, wave height, wave direction, characteristics of mooring ropes, loading condition of ship are considered. Ships movement, accelerations of translation, tension of mooring ropes are measured.

The purpose of this research is to arouse to interest of engineers and researchers concerned with ship moored problem. The results of such test may hopefully be used by designers and applied to the harbor planning.

Particular of model ship is given in Table 1. Characteristic of model mooring ropes as shown in Table 2 and Figure 3. Table 3 list experiment cases and variables.

CHARACTERISTICS OF MOVEMENT OF MOORED CONTAINER SHIP

In the section, some characteristics of moored container ship movements, which are obtained from the results of model experiment, are described as follows.

Particularly, the effect of loading condition of ship, characteristics of mooring ropes is described as shown from Figure 4 to Figure 22.

(I) For head sea:

1. Except the short period wave, for the same wave period, surge is increased as wave height increases. As the stiffness of the mooring line increases, then surge motion will be amplified, especially when the long period wave is acting on the vessel. The surge motin will be decreased as the loading the vessel increases, for the long period wave, such phenomena are obvious. For the large stiffness mooring line, the effect of load on the surge motion is small.

2. The obvious effects of the sway motion on the vessel by the wave action, are the test conditions of long period wave, light load vessel and large stiffness of the mooring line. It is found out that the peak value of the sway motion occurs at 15^{sec} wave period.

   The large sway motion occurs during the test conditions of the moored container ship are the light loading, and the large stiffness mooring lines.

3. The peak value of heave motion occurs during the case of the smaller load long period wave action and small stiffness cable. As the small stiffness cable light load vessel, the heave motion will be increased as the longer period wave is acting. While the large stiffness mooring line, large load vessel, the induced heave motion will be decreased as the longer period wave is acting.

4. The roll motion is obviously affected by the big wave action during the ship model is small load, and mooring line is small stiffness. The peak value of the roll motion occurs at the 15^{sec} wave period. The 15^{sec} wave period is possibly named as the natural period of the container ship model.

5. The pitch motion is increased as the wave height increases. The longer wave period action with smaller load vessel condition has the tendency to increase the larger pitch motion.

6. The mangitude of the yaw motion is not so large for this test case. It is probably due to the even anchoring situation. The yaw motion is slightly increased as the wave height increases. The bigger yaw motion occurs at the case of smaller load vessel and larger stiffness of mooring line.

(II) For the oblique sea.

1. For the wave period longer then 15^{sec}, the surge motion has the obvious effect as the wave height increases. The surge motion is general amplified as the incident wave period is longer. For the short wave period and small load of the

vessel, it will cause large surge motion, while the long period wave, the strong stiffness of the mooring line and big load of vessel will cause large surge motion, too.

2. The sway motion and the heave motion will be amplified as the wave height is bigger. The most obvious effect of both motions is during the condition of the longer period wave, the lower load of the vessel and the larger stiffness of the mooring line.

3. The pitch motion is amplified as the long period wave attacking, especially under the condition of lower load of the vessel and the larger stiffness of the mooring line.

4. The roll motion is governed by wave action, it shows the peak value occurring at 15^{sec} wave period, the longer period and large load cause the big roll motion, while the short period and low load also cause the big roll motion. The roll motion is increased under the test conditions of short period wave, large stiffness of mooring and heavy load of the vessel.

5. Both pitch and yaw motions show small effect under the test condition of normal wave action. They have large motion when the ship is of light load and under short wave action.

(III) For Transverse Sea.

1. The surge motion is increased under the test conditions of the long period wave action and light loading ship. It will be amplified during the big wave action and the situation of the large stiffness mooring line.

2. The sway motion is obviously increased under the big wave action. For short period wave action low stiffness cable and heavy loading ship, the induced sway motion is then decreased.

3. The roll motion is increased under the test conditions of the big wave action and the light loading ship. It is shwon that the peak value at 15^{sec} wave period of the light loading ship. For heavy load, the peak value of roll motion will be slightly decreased. The longer wave period and large stiffness cable shows the bigger roll motion against short period wave, small stiffness cable under heavy load of the ship.

4. The pitch motion doesn't show obvious effect. However, during the model ship is of light loading and of small

stiffness mooring line it shows a little effect during wave is acting. For long period wave, the pitch motion shows much effect as wave height increases.

5. The yaw motion has little effect during normal wave action, except long period and big wave. The long period wave and light load vessel will amplify the yaw motion a little bit.

CONCLUSION AND SUGGESTIONS

1. Current design recommendations probably require revision in order to reduce the present extensive destruction of fender on piers, wharves, and dophins beyond normal wear level.

2. The revisions could be provided in accordance with more of results and finding from test performance so far rather them from empirical derivations of simplistic design recommendations.

3. The mooring line and mooring system may be affected by the water depth, therefore it is suggested the dynamic effect of various water depth mooring system is need to be tested for the further study.

4. Short wave disturbance inside the port may cause problems which may result in excessive vertical motions (rolling, pitching and heaving), particularly for smaller ships, but the main problems for the moored VLC'S are caused by the long waves and possible resonances (30 to 150s periods).

CHAPTER 203

An Adjustable Marine Fender System programmed with the Aid of Numerical Models in order to minimize Berthing and Mooring Loads

Tj. J. Risselada M.Sc. *
&
C. Deelen M.Sc. * *

1. Introduction

An adjustable marine fender system, programmed with the aid of mathematical models, can substantially contribute to safer berthing and mooring of ships with various water displacements, operating at high or at low speed under varying wind, wave and current conditions. This doesn't only imply a reduction of risks to vessel and terminal structures but also in case of exposed sites or of unruly waters, a - possible substantial - reduction of ship's costly down-time.

2. The adjustable fender system

2.1. Why an adjustable fender?

Fenders as an interface between ship and rigid or resilient structure (viz. flexile dolphin) are an indispensable protective element both when berthing and when moored. More and more one has become aware that fenders designed to take a certain amount of energy fail to actually dissipate this energy and instead return it to the ship again (the recoiling effect) like the billiard ball against the table frame. Even in a sheltered port like Rotterdam with only modest tidal currents and with ample tug assistance the occurrence of such recoiling effect is not only known but at times even felt as a potential source of risk. This is illustrated in Fig.1 where a ship's movements fore and aft during berthing are rendered, Ref(1).

Also cases are known where the velocity of the far end of the vessel markedly increased or where the velocity during the second approach considerably exceeded that of the first.

This recoiling effect can be observed both when berthing and when mooring alongside. With regard to berthing the fenders are designed to take a certain amount of energy generated by a ship with a certain water displacement hitting them at a certain speed.

Other design specifications, apart from the area of the protective panel, hardly ever are given, primarily so because such specifications thusfar hardly were computable.

* Risselada & Partners, Consulting Engineers, Rotterdam.

(former Project Engineer, "Delft Hydraulics").

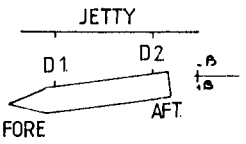

FIGURE 1

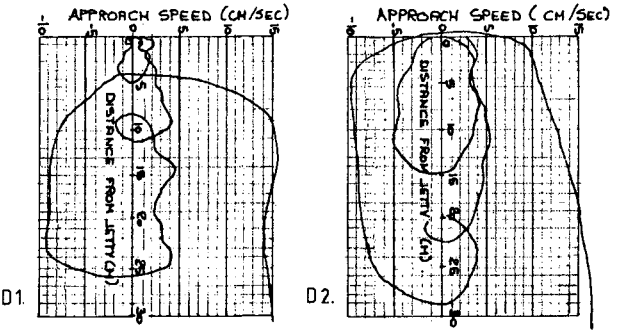

Ships moored alongside an offshore terminal and subject to certain types of waves, or ships moored in a protected harbour and subject to long period waves or seiches might show a very unruly behaviour. In case of swaying and sometimes in case of rolling ships's motions are aggravated instead of dampened when the fenders are not capable of dissipating a sufficient amount of energy or don't possess the required resilience. Also here pertinent specifications lack, be it that a good deal of investigation has been conducted into the functioning of mooring systems as a whole wherefrom it was established that soft fenders perform better.

Basically the problem of recoiling, irrespective whether in case of berthing or of being moored alongside, depends on the degree of hysteresis that occurs in the fender.
None of the current types of fenders is able to meet the demand of economically absorbing a large amount of energy without attaining an excessive compression force and at the same time possesing a high degree of hysteresis, (see reaction force compression and decompression diagrams of Fig.2a, 2b and 2c). Therefore, if not dictated by the outcome of a tender, the as most suitable selected fender(system) can at the best be a compromise on basis of experience.

A universal fender system capable of simultaneously meeting the often conflicting requirements of providing both smooth berthing and quiet mooring facilities under varying wind, wave and current conditions to larger as well as to smaller ships, fully laden or light, can only be achieved by resorting to an adjustable type of fender.

The load/(de)compression relation can now be established more or less arbitrarily, whilst the maximum height of the compression curve is confined by the permissible inside overpressure and the depth of the decompression curve is determined at zero overpressure (see Fig. 2d).

The application of such a universal system implies that first suites of fender characteristics, dealing with every possible situation, must be determined, which necessitates.

a) to thorougly know the wind, wave, and current climate;
b) to have an overview of the type and loading condition of all ships that are going to use a terminal and of the conditions whereunder;
c) to be familiar with the devices and aids for efficiently and reliably accomplishing the successive adjustments to the fender system.

The reguired characteristics can be determined by means of a whole series of scale model tests in a laboratory, but this actually would be prohibitive in view of time and cost.

2.2. The role of numerical models.

However since "Delft Hydraulics" has developed special numerical models to expedite this kind of research, there is no justification any longer for not drawing up more extensive and precise specifications. This in particular applies to terminals off shore or in exposed areas and to sheltered basins where long period waves or swell can penetrate. Thanks to the computer programs "BOTS" and "BAS" fender loads can be quintified more readily, thus enabling to quickly and rather inexpensively determine the required characteristics.

The program "BOTS" applies to ships hitting a resilient body, viz. a flexible dolphin or a rigid structure fitted with fenders. An extrensive description of this program can be found in Ref(2). The phenomena governing these collision processes are highly complicated. Conventional design methods often based on the energy to be absorbed during berthing manoeuvres fail to produce reliable results. A proper mathematical description includes the memory effect in hydronamic forces during the entire collision. This memory effect can be described by impulse reponse theory.

The fluid reactive forces are accounted for by means of freguency dependent hydrodynamic coefficients with regard to the added mass and to the damping, dependent on the ship's hull, water depth, and freguency and direction of motion. By integrating the impulse response functions the behaviour of the total ship-fluid-fender system can be determined. Hence for any specific case it can be computed how the characteristics (viz. kinetic capacity, spring stiffnes and damping power) should be in order to optimize the berthing procedure.

The computer program "BAS" (see Ref(3)) enables to calculate the motion response of the moored ship and the resulting hawser and fender forces for ships subject to every combination of external wind, wave and current forces.
As due to non-linear characteristics of the fender system, the classical solution of cumputing transfer functions by transformation of the equations of motion to freguency domain can not be used, these equations are solved here in the time domain. The main restriction of many mathematical models is that the calculation of the wave exciting forces makes use of linear first order diffraction theory. Present development at "Delft Hydraulics", however, also deals with the calculation of second order slowly varying drift forces.

Once all typical characteristics being known one can thus in conjunction with nautical experts specify for every situation the requirements the fender system has to meet. In case of computer controled operation this means that an all comprehensive program can be drawn up by feeding for every situation of berthing and subsequent mooring the relevant data into the processor. These data can be collected in advance from records together with site observations. But the quickest and most reliable way is to obtain them by means of a wave rider of similar device with respect to wave characteristics, and direction, a current meter for the velocity and direction of the current at the site and an anemometer for the wind. All these data can be automatically recorded in the computer and instantaniously fed into the specific program.

The value of the approach velocity -the most important variable- constitutes a problem apart. Figuring to the square in the calculation it namely can unlike the other variables not be determined in advance but must be instantly decided on it the very last moment when the ship is going to hit the fender. In event - as more and more is to be a rule with important terminals - this velocity is measured by means of special electronic "berthing aids" working either on basis of radar or sonar, this value can together with the angle of approach be directly input in the computer so that the fender further is automatically adjusted.

2.3. Implementation.

The present state of the art enables to devise hollow side or axially loaded compressible pneumatic of hydraulic cylindrical elements fitted with an adjustable valve for regulating the required, computer dictated, internal pump generated pressure. In contrast to current types of rubber fenders, which have heavy walls and consequently a compressibility in the order of 50%, this adjustable type will have much lighter walls consisting of neoprene rubber in a particular way reinforced with a specially designed fabric of aramide fibers, hence a compressibility of some 75%.

Both valve and pum are remote controled and follow exactly the commands from the program selected on the computer. Thus the fenders just can be precisely given those subsequent characteristics which are required

a) to take the amount of energy of a berthing ship with regards to the permissible compression at a varying internal pressure
b) hence to lower that pressure at the end of the travel thus generating sufficient hysteresis to minimize recoiling to the ship
c) to raise the pressure again to such a value that the fender dampens the motions of the moored ship in an optimum way.

As is clear this system entirely roots in the numerical modeling of a whole suite of possible situations with respect to fender characteristics and ship's reactions.

For any situation the appropriate program(s) must be selected, wherein the exogeneneous variables some way or other must be entered.

2.4. Typical fender characteristics.

The first generation fenders, as they may be designated, principally served to prevent direct contact between ship and quay, viz. brushwood bundles, old tyres, timber strips.

The majority of current types of (second generation) fenders consists of side or axially loaded predominantly hollow elements of neoprene rubber or similar material. Requirements as to energy absorption and maximum load to take underly the decision on their dimensions. The selection of the make often is the outcome of a tender, it being thus the price that rules.

It can be distinguished between the "soft" type marked by a convex load compression diagram, secondly the shear type ones which like bending piles habe a nearly linear load compression relation and thirdly the popular buckling types which are characterized by an initially strong concave diagram that conseguently runs horizontal and at the end bends steeply upward.

The shaded area of the typical load/(de)compression diagrams (Fig.2a, 2b, 2c) is indicative for the degree of hysteresis of the above mentioned types, whilst the shaded area of these diagrams (Fig.3a, 3b, 3c) renders their energy absorption capacity at egual ultimate load. In Fig.2d and 3d the same is depicted for a (third generation) adjustable fender, rendering the highest possible compression curve. Actually it can be programmed that the wanted load compression curve takes any random shape within the shaded area shown in Fig.2d. It should be noted that the ultimate compressibility of the current types is assumed to lie around the 50%, and that of the adjustable fenders at about 75%.

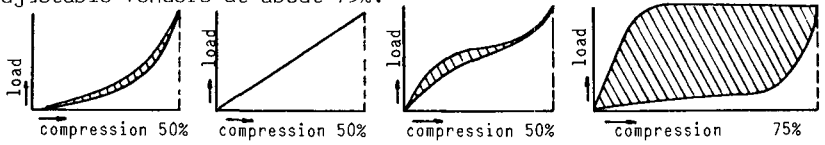

Figure 2. load compression/decompression diagrams and degree of hysteresis of various fender types

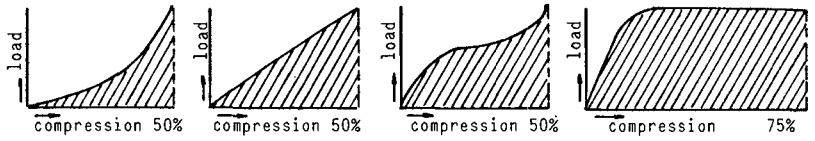

Figure 3. load compression energy absorption diagrams

In case such a fender(cluster) in conjunction with a flexible dolphin is applied a high degree of energy efficiency can be attained, which is greatest when the ultimate reaction forces of the dolphin and of the fenders are equal. In view of theri favorable energy/maximum load relation the buckling type and in particular the adjustable type excel.

2.5. Field of application and cost aspect.

In spite of its higher energy efficiency it is evident that such a custom-designed system is much more expensive than a system by means of one of the current "from the shelf" type fenders. Actually one should not evaluate the adjustable system im comparison with the existing ones solely on basis of the direct cost but also take the indirect returns duely into account.

Apart from a seizable risk reduction in event of unruly wheather conditions, the reduction of ship's downtime might provide sufficient compensation for the higher investment. The application of such a system even lead to bolder and from an operational view point eventually more economical lay-outs, thus (more than) offsetting the extra cost as compared to a traditional fender system fitted to a less exposed lay-out.

In this context it should be noted that such a system ofcourse will have no particular effect on heaving and surging motions.

3. Conclusions.

3.1. The present fenders are inadequate in so far that they more temporarely absorb energy rather than dissipate it and consequently rebound the vessel (recoiling effect), sometimes even aggravating the ship's motions instead of dampening them.

3.2. No current fender at present is universal enough to deal in an optimum way with larger as well as with smaller ships, with fully laden as well as light ones, approaching at higher as well as at lower velocity and operating under varying sea and wind conditions.

3.3. For designing a fender perfectly suited for every possible situation first a set of all the characteristics required hereto must be determined. Theoretically these can be found from scale model laboratory tests, but this actually is prohibitive in view of time and cost.

3.4. The numerical models "BOTS" and "BAS" developed by "Delft Hydraulics" now enable us to compute the desired characteristics in an expeditious and economic way and to compile them in one comprehensive computer program.

3.5. The only way to make a fender meet the many, sometimes conflicting, demands is to make it adjustable.

3.6. With the help of a valve and a pump one can regulate the pneumatic or hydraulic pressure inside a hollow element. viz. cylinder.
Inputting the ad hoc vriable data in a computer allows through said program to adjust the fenders by remote control to the

needs of the moment.

3.7. In exposed sites and in unruly harbour basins better berthing and quieter lying alongside will reduce risks and shorten ship's downtime, hence paying partly or wholly for the higher fender cost.

CHAPTER 202

Ship Motion Study for the 2010 and 2020 Plan in the San Pedro Bay, California

A.F. Yuen[1], M.G. Burke[2], and T.C. Leung[3]

Introduction

The Port of Long Beach, in cooperation with the Port of Los Angeles and the Corps of Engineers, has been working on the development of a Master Plan for the San Pedro Bay area. This Master Plan, nicknamed the "2020 Plan", is intended to project the Port's land and channel requirements through the year 2020. Any landfill expansion program would be implemented in phases throughout the life of the Master Plan. The initial phases of such a plan would greatly limit the ability of the Port to revise the future configuration of landfill phases, making it important for the Port to determine a final landfill configuration before implementing the early phases.

In developing the 2020 Plan, the Port projected a need for approximately 2,600 acres of additional land. In attempting to turn this 2,600 acre figure into a landfill scheme, the controlling agencies had to take a number of factors into consideration, including (1) water quality and tidal circulation; (2) potential ship motion problems; (3) additional berths required for future development; (4) land and waterside transportation corridors required; (5) availability of dredge material for creating the land; (6) available areas for creating landfills; (7) efficiency of land usage in various configurations; (8) types of ships anticipated to use the new landfills; (9) types of terminals anticipated to be located on the new landfills.

The Port of Long Beach developed two basic schemes which addressed the requirements listed above. In either case, the landfill configuration for the Port of Los Angeles remained the same. The first scheme (called the island scheme, Figure 1) had the advantage of more closely matching the proposed Port of Los Angeles development. Water quality and tidal circulation would be improved with this scheme. The second scheme (called the horseshoe scheme, Figure 2) created a channel on the Long Beach side which did not match the orientation of the channel on the Los Angeles side. This channel was better protected from wave forces than the island scheme, where ships would have to be berthed along the exposed southerly boundary.

(1) Director, Engineering Division, Tetra Tech, Inc./Honeywell, 630 N. Rosemead Blvd., Pasadena, CA 91107, U.S.A.
(2) Civil Engineer, Port of Long Beach, Long Beach, CA, U.S.A.
(3) Senior Engineer, Tetra Tech, Inc./Honeywell, 630 N. Rosemead Blvd., Pasadena, CA 91107, U.S.A.

Since environmental and political pressures were being put on the Port of Long Beach to adopt the island scheme, the Port felt it was necessary to adequately study potential ship motion problems with this configuration. Specifically, the Port wanted to study if it was feasible to berth ships along the southerly boundary line of the island scheme configuration. This area would not have the double breakwater protection afforded most berths in the harbors today, but would only be protected by the federal breakwater from exposure to wave forces.

While not experiencing catastrophic ship motion problems in the Port of Long Beach area, the Port has had a history of minor ship motion problems in its southeast basin. These problems have had a minimal effect on ship loading and unloading efficiencies in the past. The Port's governing criteria in all future developments was to attempt to create no new facilities which would have any potentially greater ship motion problems than those which already exist, and to make sure that any new development does not increase the ship motion problems in any existing facility.

The type of cargo anticipated to be handled at the new landfill was a key issue in studying any potential ship motion problem. Liquid bulk ships, for example, can tolerate a great deal of ship motion, since the main governing criteria is the strength of the mooring lines and the flexibility of the unloading arms. Container ships, on the other hand, have very tight tolerances, since the container crane must be able to pick up a container off the ship with very limited clearances. Unfortunately, the cargo projection in the 2020 Plan indicated that by far the greatest growth in cargo tonnage in the future would be in the container-handling area.

In order to adequately address this potential problem and help decide between the two landfill configuration schemes, the Port contracted with Tetra Tech, Inc., of Pasadena, California, to study a range of ships located along the southerly boundary of the island scheme in two different phases of development. The first phase, shown in Figure 1, was before any landfill will be constructed outside the federal breakwater. The second scheme, shown in Figure 2, was after landfill had been constructed south of the federal breakwater and would probably afford a greater level of protection to the southerly boundary of the island scheme.

While the Port contracted for Tetra Tech to analyze a range of ships, it was anticipated that container ships would be the governing factor, for the reasons listed above.

Environmental Conditions at the Project Site

The environmental conditions associated with ship motion and mooring analyses for this project are discussed in the following sections. These conditions basically include wind, wave, and current statistics over the project site as shown in Figure 3. Based on the derived statistics, a set of design criteria of these environmental conditions were determined for ship motion and mooring analyses.

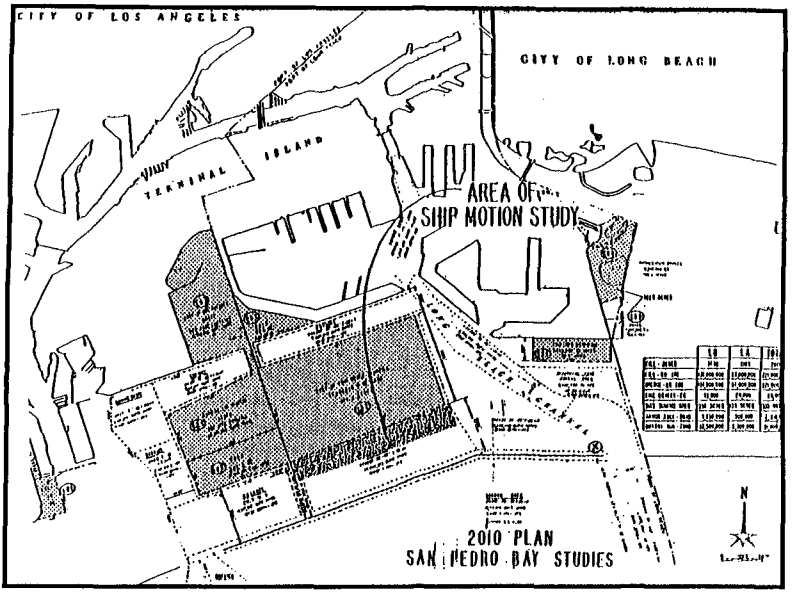

Figure 1 2010 Plan - San Pedro Bay Studies

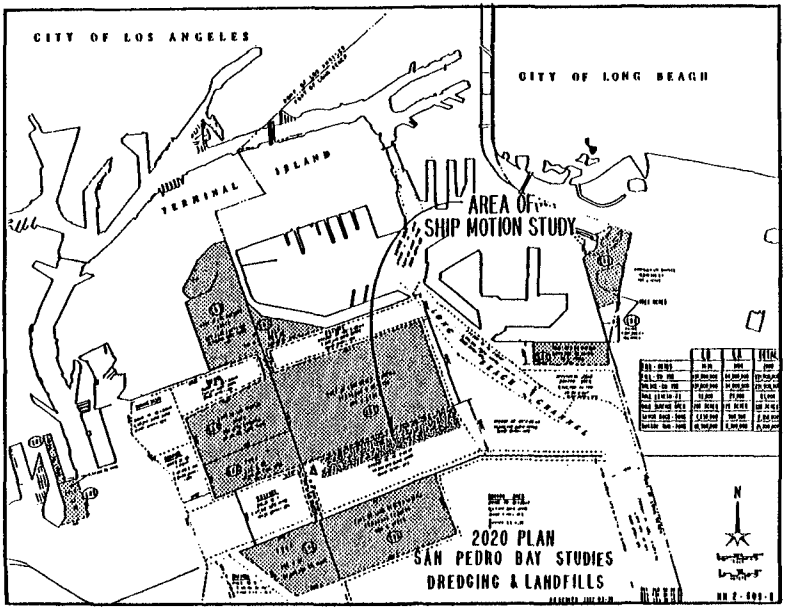

Figure 2 2020 Plan - San Pedro Bay Studies - Dredging and Landfills

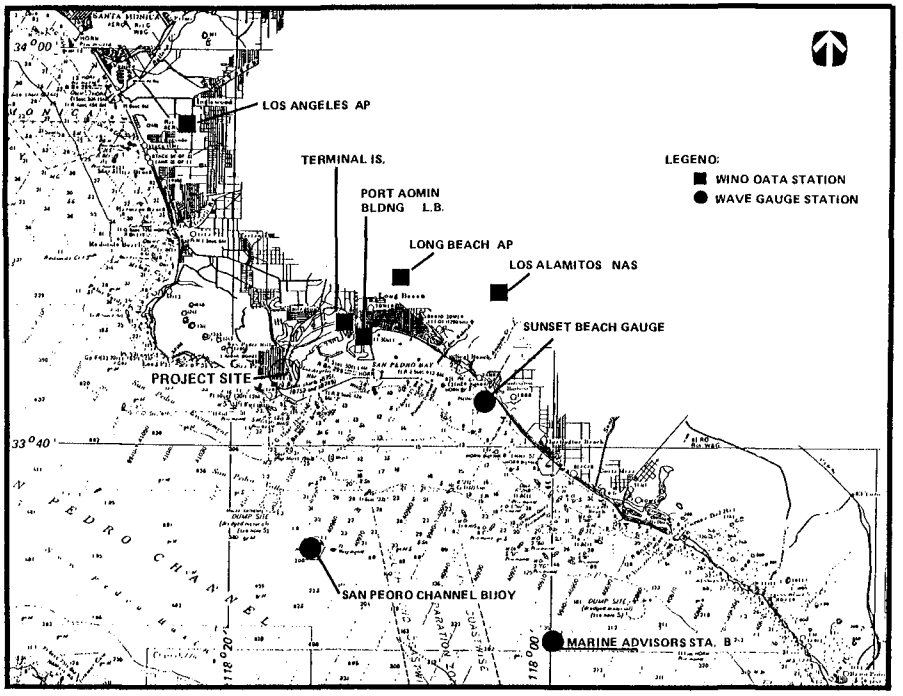

Figure 3 Wind and Wave Gauge Locations

Winds

According to Tetra Tech's previous studies associated with Los Angeles and Long Beach Harbors (Tetra Tech Report TC-3817, 1984), numerous wind information was reviewed and the most applicable wind statistics were discussed and summarized. Stations with available wind data which are used in this analysis are as follows:

	Station Name	Period of Record	Length of Record (Year)
1.	Terminal Island	1955-1977	23
2.	Long Beach AP	1959-1976	18
3.	Los Alamitos NAS	1950-1968	19
4.	Los Angeles AP	1951-1976	26
5.	Port Admin. Bldg. (Long Beach)	1975-1983	9

The locations of these wind stations are shown on Figure 3.

Based on the partial and annual series associated with the ranking of the selected large events and yearly maximum events, respectively, the return periods of the extreme wind speeds were analyzed. The statistics of Terminal Island were selected for study. This is primarily due to

its twenty-three year record and its location within the close proximity of the project site. The estimates of extreme winds, adjusted to an over-water, one-hour duration average from Terminal Island, are 38, 44, 53, and 61 MPH corresponding to 10, 20, 50, and 100 years return period, respectively. The other set of wind statistics derived from 9-year data of Long Beach Port Administration Building are 37, 40, 45, and 48 MPH corresponding to 10, 20, 50, and 100 years return period, respectively. These results have excellent comparison from those of Terminal Island for 10 and 20 year return period. However, it seems to be under estimated for 50 and 100 year return period due to its relatively short duration of wind record. In the ship mooring analysis, the following wind conditions, corresponding to the 60-second duration gust with 5-year return period, were used:

(i) SW wind of 34 knots
(ii) NW wind of 34 knots

Waves

The project site is relatively well protected from wave attack except the direction from south-southeast through south-southwest. Waves with 30 second periods or larger will propagate into the harbor area through the Gulf of Santa Catalina without encountering any effective natural barriers. Whereas the waves with the period less than 30 seconds will experience the effects of wave refraction and island sheltering. The data source of extreme wave condition includes direct measurement inside San Pedro Bay and transformation of hindcasted waves from deep water to the project site.

The relatively short period (less than 30 seconds) extreme waves were associated with major storms or extreme winds. This wave information was obtained by performing deep water wave hindcasting of the selected most severe ten cases during approximately 50 years (IRC, 1976). These deep water waves were transferred into the project site by considering the effects of wave refraction, shoaling, and island sheltering (Tetra Tech Report TC-3817, 1984). Table 1 presents the wave statistics in deep water and in the vicinity outside the breakwater. A 1.7-foot wave height, corresponding to a return period of 1 year, was selected as the representative wave height that would be encountered during daily operations. The transmission coefficient for waves penetrating through the breakwater was adjusted for waves with periods shorter than 16 seconds. Table 2 presents the estimated short period waves, which were used to simulate the ship motions under normal conditions, at the project site of 2010 Plan and 2020 Plan.

Table 1
Wave Statistics in Deep Water and Gate Entrance

Return Period (Yr)	H_{max} (ft, Deep Water)	H_{max} (ft, Gate Entrance)
10	32.8	14.8
20	39.3	19.7
50	45.9	29.5
100	52.5	39.4

Table 2
Estimates of Short Period Waves - Project Site (1-Year Return Period)

Wave Period (sec)	Wave Height (ft)
6	1.1
8	1.3
10	1.4
12 - 14	1.6
16 - 22	1.7

Note: Assume 0.3 transmission coefficient for the waves penetrating through the breakwater.

The characteristics of relatively long period waves (larger than 30 seconds) were measured at Angel's Gate and Queen's Gate during the year of 1971-1972. The long wave statistics are almost impossible to be estimated due to their very limited measurement duration. However, the maximum energy level was measured and the corresponding maximum wave height was estimated by spectral analysis. Wave data were measured by Bottin and Outlaw (1984) at certain locations for the existing conditions. Under the 2010/2020 landfill plans, the wave environment is different from the existing condition. A numerical model was applied to determine the wave environment for the proposed plan. The numerical model geometry and their 290 x 140 grid points for the 2010 and 2020 Plan is shown in Figures 4 and 5, respectively. The maximum long wave heights at the project site were estimated by applying the response factor obtained from the results of the numerical model. Table 3 summarizes the estimated maximum long period wave height at Queen's Gate and the project site of the 2010 and 2020 Plan.

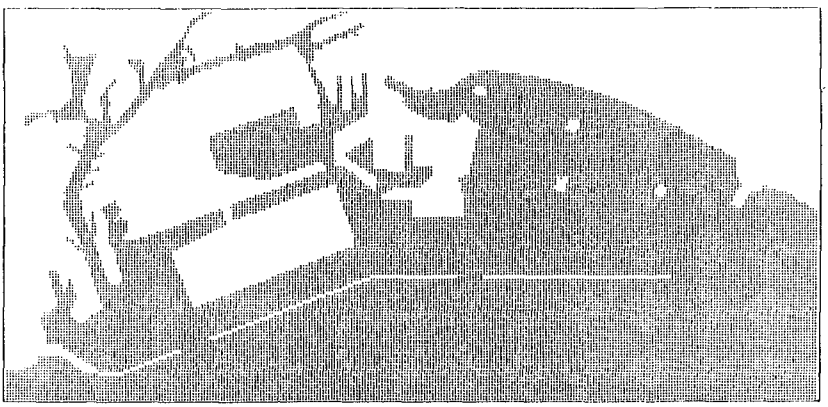

Figure 4 Grid Points in the Numerical Model for 2010 Plan

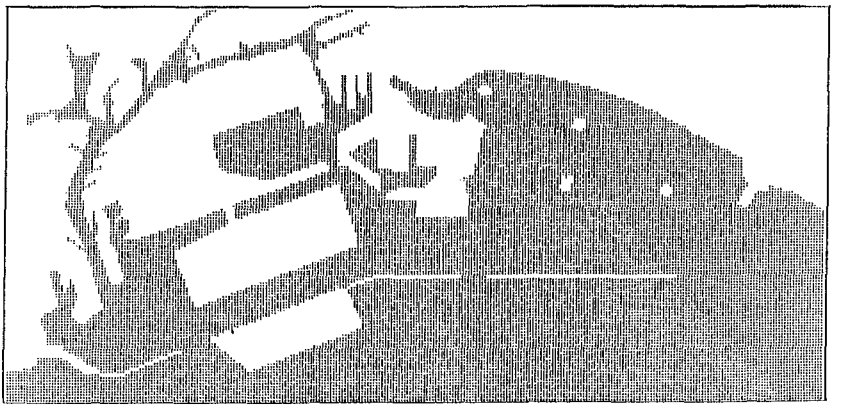

Figure 5 Grid Points in the Numerical Model for 2020 Plan

Table 3
Estimates of Maximum Long Wave Height

Wave Period (sec)	Wave Height (ft) Queen's Gate	Wave Height (ft) 2010 Plan	Wave Height (ft) 2020 Plan

In order to perform a downtime analysis of the ships, the wave data base in the vicinity outside the breakwater was established by transferring deep water waves to the shallow water site. The deep water waves were obtained from the Sea-State Engineering Analysis System which is maintained by the U.S. Army Engineer Waterways Experiment Station. The joint occurrence probabilities (%) of wave height and period near the breakwater are presented in Table 4.

Currents

The maximum tidal current measured at the project site is approximately 0.5 ft/sec. It is believed that this tidal current should have the least impact on the ship motion and mooring analyses.

Ship Motion and Mooring Analysis

Three representative ships, the D-9 class container ship, 265,000 DWT tanker, and 100,000 DWT dry-bulk carrier, that will frequent the project site of the 2010 Plan and 2020 Plan of the Port of Long Beach, were considered in the study. The principal particulars of these ships are presented in Table 5.

Table 5
Principal Particulars of the "Representative" Container Ship, Tanker, and Dry-Bulk Carrier

Principal Particulars	D-9 Class Container Ship	265,000 DWT Oil Tanker	100,000 DWT Dry-Bulk Carrier
Length Overall (ft)	745	1100	886
Length between Perpendiculars (ft)	699	1060	853
Beam (ft)	100	178	138
Depth (ft)	54	86	69
Draft (ft)	31	67	49

Several mooring configurations, some consisting of steel lines, some dacron lines, and some of a combination of steel and dacron lines, were used to evaluate the ship response under imposed environmental conditions. A typical mooring configuration for the D-9 class container ship is shown in Figure 6. Vessel and berth characteristics, loading condition, mooring line arrangement, fender system, and the excitation force were the input parameters for the Tetra Tech six-degree ship motion analysis program. The detailed description of this numerical solution procedure can be found in the reference report.

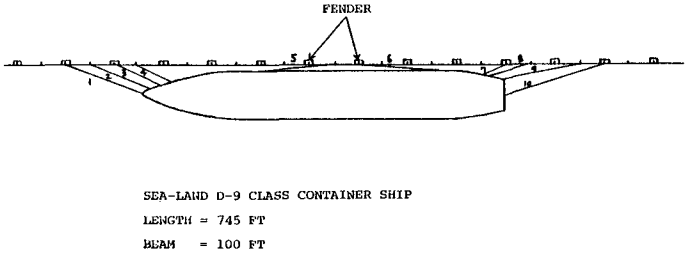

Figure 6 Mooring Line Arrangement - D-9 Class Container Ship Dacron and Steel Lines

Summary of Ship Motion Analysis Results

The primary direction of wave approach was assumed to be zero degree from the stern of the moored ship. It was anticipated that this wave approach angle should provide the information on the maximum longitudinal motion, the surge. For the D-9 class container ship, 265,DDO DWT tanker, and 100,000 DWT dry-bulk carrier, ship responses were computed as a function of the wave period and wave wave height as established in Table 3. Dnly the summary of the results of the maximum surge amplitude for the container ship, tanker and dry-bulk carrier are presented in Table 6. The fender force, hull pressure, and line load under various mooring conditions were determined. The typical line loads due to wave force, wind force, and combination of wave and wind force for a typical case are presented in Table 7.

Table 6
Summary of Maximum Surge Amplitudes

Ship	Plan	Maximum Surge Amplitude (ft)	Mooring Lines	Resonant Wave Period (sec)
Container (D-9 Class)	2D10	4.41	Dacron	100

Downtime Analysis

Berth downtime is defined as the length of time that the mooring capacity limits are exceeded. The following criteria were considered in establishing the mooring capacity limits:

- o mooring line loads
- o vessel motions
- o fender deflection and hull pressure

Mooring Line Loads

According to the guidelines followed by Butcher et al (1980) an ultimate mooring limit for a particular mooring situation is defined as 65% of the new wire breaking strength. The operating mooring limit, however, is recommended to be equal to the defined ultimate mooring limit divided by a load factor of 1.4 to 1.6. Consequently, 45% of the breaking strength is used as the allowable limit for steel wires. Similarly, the ultimate mooring limit for dacron line is defined as 55% of the breaking strength and 35% of the breaking strength is used as the allowable limit for dacron lines. Line loads in excess of the recommended operating limits are considered excessive and contribute to berth downtime.

Vessel Motions

Oscillatory vessel motions with an amplitude greater than the following limits, in the surge direction, are considered excessive and contribute to berth downtime. The Port of Long Beach provided the following limits for ship surge downtime:

- o Container ships, 0.5 feet of surge
- o Dry-bulk carriers, 5 feet of surge
- o Liquid-bulk carriers, 10 feet of surge

Fender Deflection and Hull Pressure

Hull pressure was taken as the critical condition over fender deflection if excessive lateral motions exist. Consequently, only the allowable hull pressure is checked for downtime analysis. The allowable hull pressure for the three ships considered in the present analysis is listed in the following:

Ship	Maximum Allowable Hull Pressure
D-9 Class Container Ship 265,000 DWT Tanker 100,000 DWT Dry-Bulk Carrier	9.88 long tons/yd^2

Hull pressures greater than these limits are considered excessive and contribute to berth downtime.

Downtime Results

Based upon the calculated results of line loads, vessel motions, and hull pressure presented in the previous section, the vessel downtime can be determined by checking the calculated results with the limiting criteria. The statistics of the short period waves (6-22 seconds) were obtained from Table 4. It should be noted, however, that since there is no data available concerning long period wave ($T > 22$ second) activity in the project sites of the 2010 Plan and 2020 Plan, only vessel response due to waves of periods between 6-22 seconds is considered in the downtime analysis.

Conclusion

Surge is the most significant motion response of the tanker, D-9 Class container ship, and dry-bulk carrier to waves approaching head on (head-sea condition). Since the waves at the project site of Plan 2010 are larger than the waves at the project site of Plan 2020, the ships have larger motion response at Plan 2010. The maximum surge amplitudes of 2.2 and 2.1 feet for the tanker and dry-bulk carrier, respectively, are within the operational limits of surge motion and would not contribute to berth downtime. For the container ship, the mooring system consisting of steel lines induces a smaller maximum surge amplitude than the mooring system consisting of dacron lines, while the mooring system consisting of combination of dacron and steel lines induces a maximum surge amplitude in between of the all steel and all dacron line systems. All the three mooring systems of the container ship result in maximum surge amplitudes larger than 0.5 feet and would contribute to berth downtime. This problem can be mitigated by introducing frictional force between the ship hull and the fender system.

The results of the significant surge amplitude are obtained by letting the ships respond to a spectrum of incoming waves. At the project site of Plan 2010, with the exception of the container ship which is moored by dacron and steel lines, the results of the significant surge amplitude are not smaller than those of the maximum surge amplitude, because the peaks of the ship response spectra sometimes occur close to the peaks of the wave spectra. However, the magnitudes of the significant surge amplitude can be reduced by imposing frictional forces between the ship hull and the fender systems. For instance, the significant surge amplitude of the container ship with the mooring system consisting of dacron and steel lines is redued from 1.96 feet to 1.28 feet when a frictional force of 12,8000 lb is imposed.

For the beam-sea wave conditions, the 1 year waves do not induce significant sway motion or line loads. The maximum fender loads are well within the rated reaction force of the proposed fender. Except for the case of the tanker under high frequency wave conditions (6-7 seconds), the ship hull pressures are also within the maximum allowable hull pressure limit. The problem of excessive hull pressure can be solved by employing additional breast lines to reduce the sway motion during short period beam-sea wave condition. Another solution is to increase the surface area of the fender or the number of fenders.

Tankers and dry-bulk carriers in ballast conditions and container ships in full load condition are more susceptible to wind forces due to the relatively large exposed area above the waterline. Consequently, wind forces are an important factor in regards to mooring safety in the present analysis. Wind forces are higher on the tanker, due to the larger exposed windage areas. The forces induced by the 34kt NW wind load the steel mooring line up to 25%, 25%, and 14% of the line breaking strength for the tanker, D-9 Class container ship, and dry-bulk carrier, respectively. Therefore, the 5-year, 60-second-duration gust does not impose a threat to mooring safety.

Using the wave statistics and the 5-year, 60-second-duration gust wind conditions, the downtime probabilities were calculated to be 0.34, 1.53, and 0% for the tanker, D-9 class, and dry-bulk carrier, respectively.

CHAPTER 205

IRREGULAR WAVE TRANSFORMATION IN A BOUSSINESQ WAVE MODEL

H.-H. Prüser * / H. Schaper * / W. Zielke *

1. INTRODUCTION

Numerical wave models for shallow water waves are of particular importance for the calculation of the wave climate in harbours and coastal areas. Especially nonlinear time domain models, which are based on the Boussinesq-Wave-Equations, may be helpful in the future for simulating the interaction of currents with refraction, diffraction, reflection and for simulating shoaling of irregular waves in natural areas; a potential which has not yet been fully developed.

During the last ten years numerical models, based on these equations, have been published; such as ABBOTT et. al. , HAUGUEL and SCHAPER / ZIELKE . Research on this topic is currently being carried on.

Some efforts have been made to verify the capability of the models to describe the various physical phenomena. However, up to now, verification has been limited to regular waves. The aim of this paper therefore is, to consider questions concerning irregular, nonlinear waves.

A numerical model, based on the solution of the Boussinesq equations, was used to calculate the behaviour of wave spectra and bichromatic waves in a one dimensional wave flume with constant water depth or with mild slope. The generation of long waves and the energy transfer between individual frequency components in the numerical model was of particular interest. Comparisons with analytical solutions and hydraulic measurements have been made.

2. NUMERICAL MODEL

All computations have been done using the Boussinesq wave model described in detail by SCHAPER / ZIELKE, 1984. Experimental data from a hydraulic wave flume were available. Therefore the study has been restricted to the onedimensional case. The basic equations read:

$$\frac{\delta p}{\delta t} + \frac{\delta}{\delta x}\left(\frac{p^2}{h}\right) + gh\,\frac{\delta \zeta}{\delta x} = \frac{Dh}{2}\,\frac{\delta^3}{\delta x^2 \delta t}\left(\frac{Dp}{h}\right) - \frac{D^2 h}{6}\,\frac{\delta^3}{\delta x^2 \delta t}\left(\frac{p}{h}\right)$$

$$\frac{\delta \zeta}{\delta t} + \frac{\delta p}{\delta x} = 0$$

$h = D + \zeta$: total water depth — D : mean water level

p : vertically integrated flux — ζ : waterelevation

g : acceleration due to gravity

Solitary and cnoidal waves can be regarded as special solutions of the Boussinesq equations. They have been used in the initial stage of model development to investigate the accuracy of the numerical solution for waves up to limiting height.

In short shallow water waves, the nonlinear amplitude-dispersive terms on the left hand side and the nonlinear frequency-dispersive terms on the right hand side are of the

same order. It is therefore necessary to include all these terms into the computation. In the numerical model, the Boussinesq equations are solved with a third order corrected, implicite finite difference method, using two time levels and central differences.

A nonreflecting boundary condition is used at the left end of the flume, instead of a model of the wave maker. Therefore, the re-reflection of waves returning from the right end of the channel is neglected. The input waves can be represented as a prescribed time serie f(t, x=0), which have been obtained from measurements in the flume. The unknown values for the flux and water elevation, as the result of incoming and outgoing waves, can be calculated by using the following equation:

$$p - c\zeta = -2c\, f(t)$$

with: $c = \sqrt{gh - p^4/h^2}$ wave velocity

3. TRANSFORMATION OF PIERSON-MOSKOWITZ SPECTRA

3.1 Hydraulic Test Programme

Hydraulic measurements were taken by Daemrich and Götschenberg from the Franzius-Institute of the University of Hannover to verify the numerical model. In a flume with a constant water depth of 0.5 m, some Pierson-Moskowitz spectra were generated by the wave maker. The amplitudes have been reduced by a constant factor in order to avoid wave breaking, which does occur, if this deep water spectrum is used in shallow water. Several wave gauges were placed along the flume for measuring the time series of the water elevation. Table 1 displays the significant wave parameter of the test program.

Peak-Period [sec] / Peak-Frequency [Hz]			Significant Wave-Height [m]		
1.5	/	0.666	0.04	0.06	0.08
3.0	/	0.333	0.04	0.06	0.08
4.5	/	0.222	0.04	0.06	0.08

Table 1: Test Program

The water elevation, measured at the gauge nearest to the wavemaker, is used to feed the waves into the numerical model at the left boundary.

3.2 Range of Application

Boussinesq equations are long-wave-equations with additional third order terms. They are able to describe wave phenomena in shallow water and in intermediate depths but not in deep water. If one assumes a water depth of 0.5 m, then the deep water waves are shorter than 1.0 m and have a corresponding frequency of higher than 1.25 Hz. Therefore it is to be expected, that the smaller the "deep water" part of the spectrum, the better the calculation of the wave spectra.

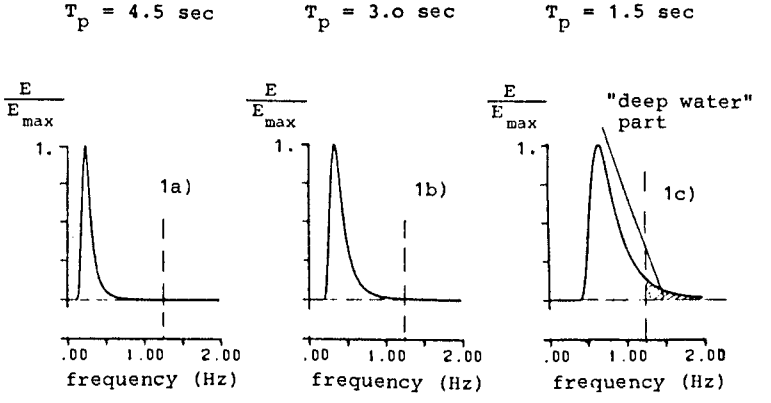

Figure 1: Normalized Pierson-Moskowitz Spectra

Figure 1 displays the normalized Pierson-Moskowitz spectra of the hydraulic test program. The deep water part of spectrum 1c is significant, thus the calculation cannot be accurate in this case. And indeed, verification shows that the Boussinesq wave model reproduces the time series of the water elevation for the spectra 1a) and 1b) very well, but worse for spectrum 1c).

3.2 Calculation and Comparison

3.2.1 Pierson-Moskowitz Spectra in a Flume with even Bottom and a mild Slope

3.2.1.1 Experimental Set-Up

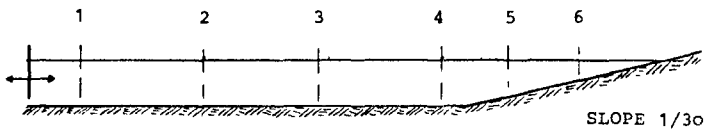
For the hydraulic model, a 54.0 m long flume with even bottom and a slope 1/30 at the right side was used. Two numerical models were created:

The first model was used for verification. The Boussinesq wave model does not contain the possibility of simulating breaking waves, which occur on the upper part of the slope. Instead a nonreflecting boundary was applied at that point of the slope, where the water depth was 0.2 m.

In the second model no slope is taken into account. Therefore, there is a possibility to extract the calculated slope influence by comparing these two numerical models.

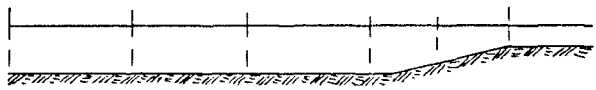
The measured time series of the water elevation at gauge 1 is used as wave input for the numerical model. Figure 2 shows the complete experimental set-up.

HYDRAULIC MODEL



NUMERICAL MODELS

- FOR VERIFICATION



OPEN
BOUNDARY

1, 2, 3, 4	GAUGES	WATER DEPTH = .5o m	
5	GAUGE	WATER DEPTH = .4o m	(.5o m)
6	GAUGE	WATER DEPTH = .2o m	(.5o m)

Figure 2: Experimental set-up / flume with slope

3.2.1.2 Results

Figure 3 displays a comparision between measured and calculated time series at different gauges for a Pierson-Moskowitz spectrum (peakperiod period = 3.sec. significant wave height = 0.08m). It can be seen that the numerical model describes the water elevation with a high degree of similarity in the range of horizontal bottom as well as on the slope.

Calculations with both numerical models (with and without a slope) indicate, that the influence of reflection at the mild slope is negligible for the chosen spectra.

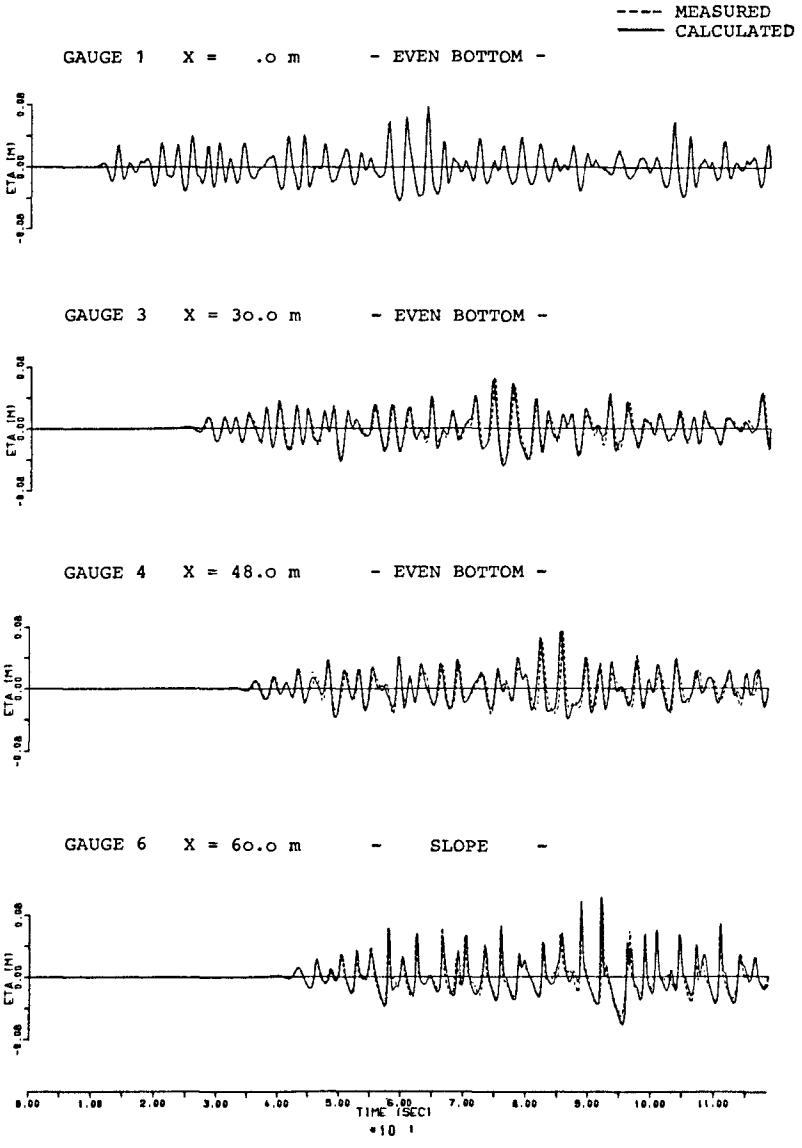

Figure 3: Transformation of wave spectra even bottom / slope, time domain

A better interpretation of the experimental and calculated results is possible by transforming the time series into the frequency domain.

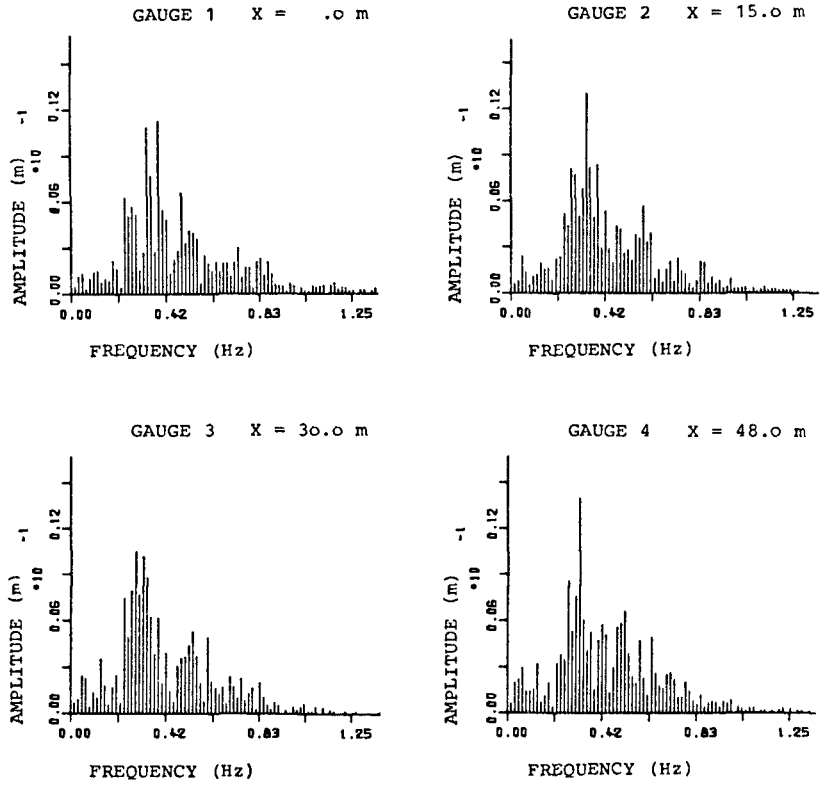

Figure 4: Transformation of wave spectra
even bottom / slope. frequency domain

In linear wave theory, the shape of the spectrum, generated at the wave maker, should not change along the flume if the water depth is constant. However, comparing the amplitude spectra at different locations (see figure 4), an energy transfer between individuel frequency components and the creation and increase of lower frequencies, not included in the original Pierson-Moskowitz spectrum, can be observed in the hydraulic as well as in the numerical model.

At the slope the water depth decreases and the waves turn to the typical cnoidal shape: The crests are higher and shorter and the troughs are longer and less deep than would be predicted for constant water depth.

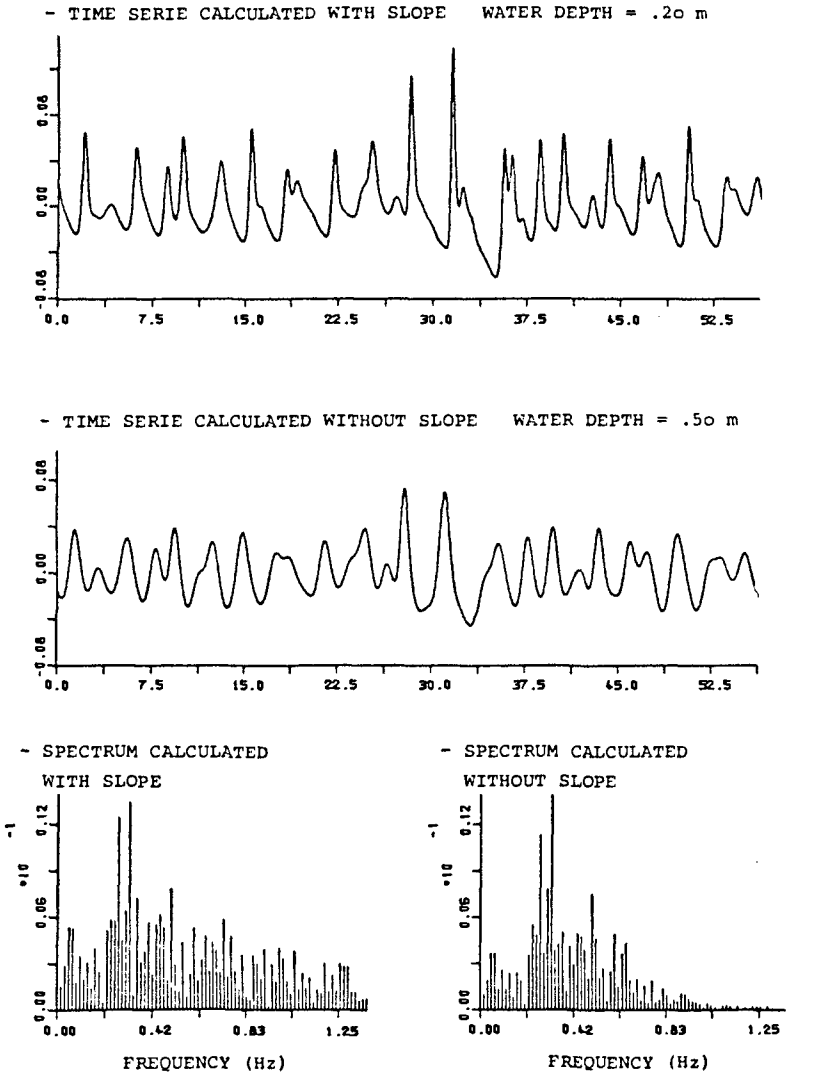

Figure 5: Slope influence calculated at gauge 6. Comparison in time and frequency domain

The increase of the long wave components and the generation of higher frequencies on the slope are results which can be detected in the frequency domain. Figure 5 displays a comparison of the time series and amplitude spectra at gauge 6, calculated with and without a slope.

3.2.2 Pierson-Moskowitz Spectra Reflected at a Wall

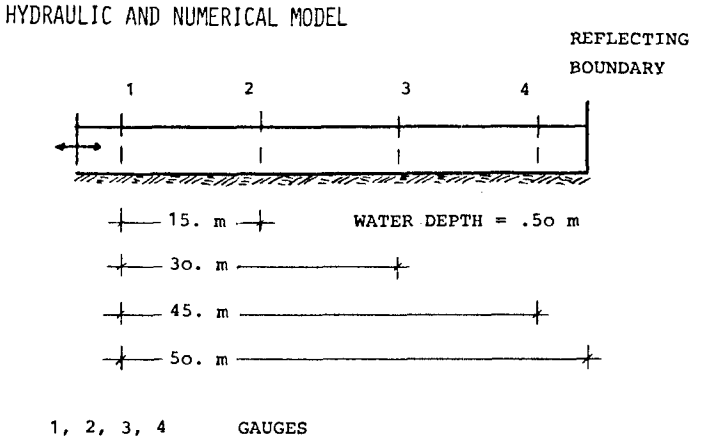

Figure 6: Experimental set-up

The test program was used to verify the reflecting boundary condition at the wall and the capability of the numerical model to calculate the nonlinear interaction of the initial and reflected waves. Figure 6 displays the experimental set-up, figure 7 compares measured and calculated time series of the water elevation at several gauges for the same spectrum used before. The distance between every gauge is 15.0 m. Therefore, it is possible to mark in figure 7, the front of the initial wave, as well as the first reflected wave and the first re-reflected wave. Also the time of the first reflection at the wall and the first re-reflection at the wave maker has been marked. The numerical model is able to describe the resulting wave climate very well. However a

comparison between measurements and calculations is not valid after the reflected wave has reached gauge 1.

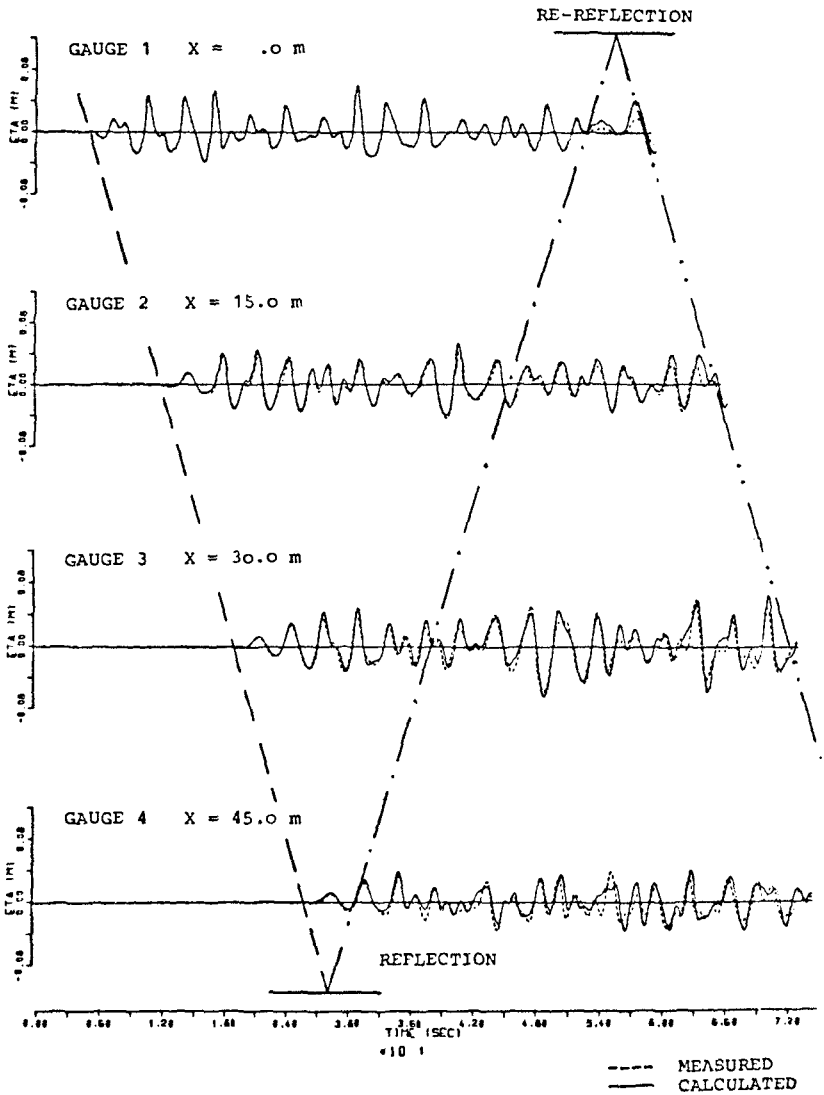

Figure 7: Comparison between measured and calculated time series of the water elevation in a flume with total reflection at a wall

The time series, measured in the hydraulic model at this gauge has been used as input data for the numerical model, which has a non-reflecting boundary at the wave maker. In reality the measurements include the reflection from the wave maker. This leads to significant differences after the first instance of re-reflection, as can be seen in figure 7.

4. LONG WAVES IN A BICHROMATIC WAVE SYSTEM

4.1 Long Wave Generation

OTTESEN-HANSEN pointed out, that two short period waves with the frequencies f_1 and f_2 create a bounded long wave with the frequency $\Delta f = f_1 - f_2$, which propagates with the group velocity. Bounded long waves are of second order with rather limited height. Resonance and shoaling effects can increase their influence.

In traditional first order wave generation, the boundary conditions at the wave board are not fulfilled and various free long waves with the same frequency Δf are generated. These waves appear also in the numerical model. Their velocity and wave length can be calculated by the dispersion relation (KOSTENSE).

Short waves		frequency	f_1 = 0.50 Hz
		amplitude	a_1 = 0.055 m
		frequency	f_2 = 0.40 Hz
		amplitude	a_2 = 0.011 m
Long Waves	Bounded:	frequency	f = 0.10 Hz
		amplitude	a_b = 0.0045 m
		wave length	L_b = 18.0 m
	Free :	frequency	f = 0.10 Hz
		wave length	L_f = 22.1 m

Table 2: Theoretical wave data

The numerical model was used to investigate the generation of bounded and free long waves in a flume with a constant water depth of 0.50 m. Initially a superposition of two harmonic waves was used. However, due to their inherent

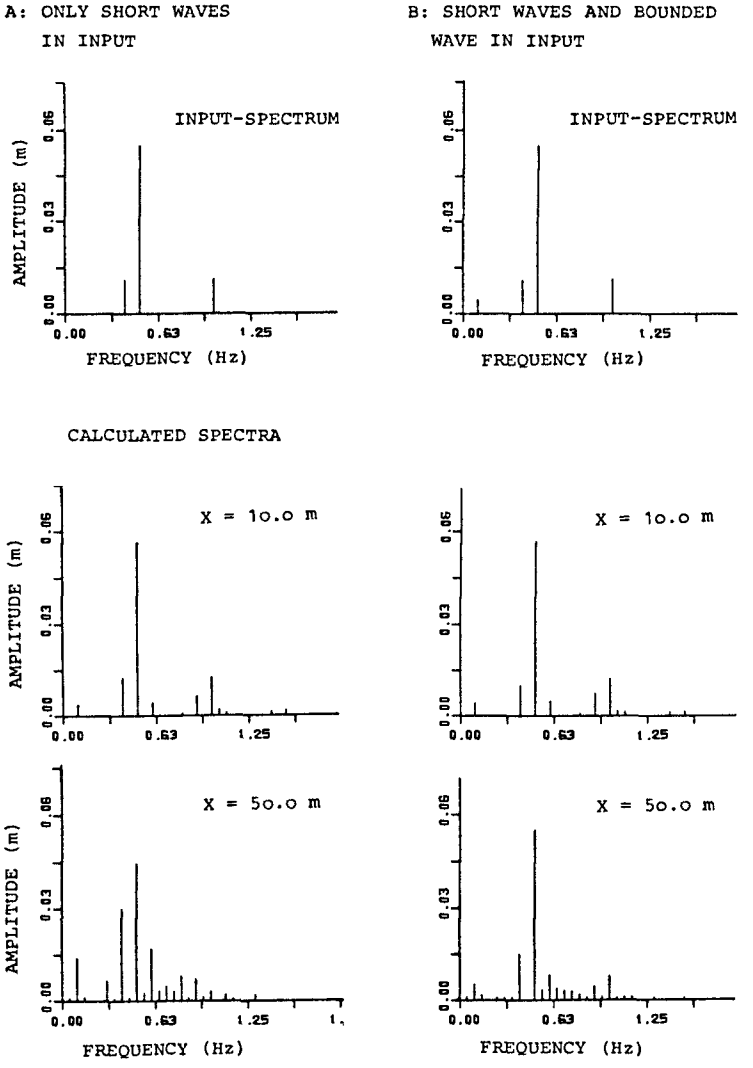

Figure 8: Long wave behaviour in a bichromatic wave system. Flume with horizontal bottom.

instability, complicated transformations occurred, which made the interpretation of the results very difficult. Therefore, a superposition of two cnoidal waves, i.e. waves of permanent form, was used. Table 2 shows a list of the theoretical wave data. The difference in wave lengths of bounded and free long wave leads to a standing wave in the flume, which has been calculated in agreement with theoretical values.

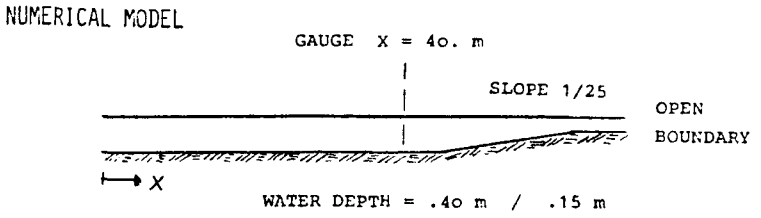
Figure 8A displays wave spectra, calculated at different locations along the numerical flume. It can be seen, that a long period wave, which is not included in the input spectrum has been generated. The input spectrum is unstable and a energy transfer towards the lower frequencies takes place. If, instead the long wave component is added to the input spectrum, the spectrum becomes more stable (see Figure 8B).

4.2 Reflection on a Slope

Investigation of the behaviour of a partial reflection on a slope has been carried out with an input of two short harmonic waves. The influence of the reflection is determined as the difference between calculations with and without a slope. Figure 9 shows the numerical model and the computed incoming and reflected spectra. The reflection coefficient of the long wave is about 3 times as high as that of the short waves. This result is qualitatively correct, but one should be aware that the wave breaking on a real beach has a significant influence on the amplitudes of the reflected waves.

5. CONCLUSIONS

The numerical model has been proven to be numerically stable for nearly breaking waves. The numerical diffusion appears to be insignificant, because cnoidal and solitary waves propagate with permanent form even after several wave lengths.



BICNOIDAL WAVE-INPUT:

1. AMPLITUDE = o.o3 m FREQUENCY = o.45 Hz
2. AMPLITUDE = o.o3 m FREQUENCY = o.5o Hz

CALCULATED SPECTRA

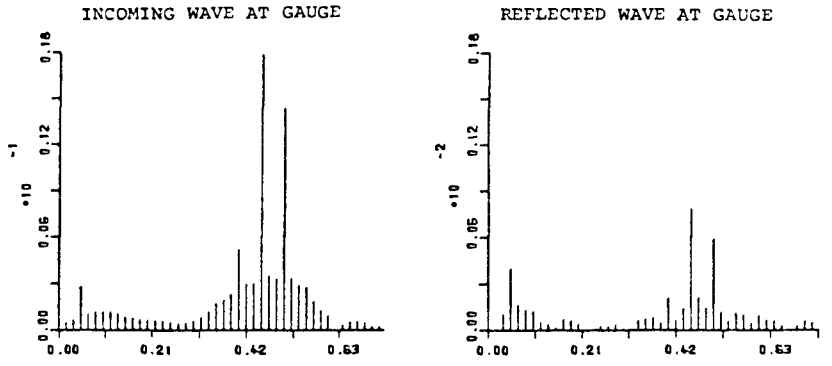


Figure 9: Reflection of bicnoidal waves on a slope

The nonlinear transformation of wave spectra has been studied for an even bottom , for a slope and for a reflection at a wall. A high degree of agreement between computations and measurements has been found, as long as the 'deep water' part of the spectrum is small: i.e. within the range of validity of the Boussinesq-wave-equations.

Long waves from a wave group (bicnoidal waves) are generated in the model in agreement with theoretical values. As should be expected, they are stronger reflected from a bottom slope than short waves.

CHAPTER 206

ON THE SQUATTING OF SHIPS IN SHALLOW AND RESTRICTED WATER

by Drs A M Ferguson and R C McGregor, Department of Naval Architecture and Ocean Engineering, University of Glasgow

1. INTRODUCTION

A major feature of the advances in marine technology is the increasing number, size and speed of ships and, consequently, an increased interest in hydrodynamic problems associated with water restricted in depth and/or lateral extent. The transport of dangerous cargoes and their impact on the benefits of resolving the areas of uncertainty.

Experience of 1,104 vessels of different flags and trades during 1978, shows that grounding/stranding is the third most frequent cause of damage[1]. An examination of the total expenditure of money and time required to repair the resulting damage shows this category to rank highly in both. Indeed, the total repair cost expended as a result of this cause rank top and account for more than 1/5th of the total. Although the shipowner bears a large proportion of the cost of lost revenue, grounding represents a significant cost to underwriters, shipowners and port authorities. The continuous increase in size and draught of vessels in relation to water depth ensures that this situation will continue unless there is a radical development in instrumentation.

To limit the risk of grounding it is extremely important to be able to predict which of a vessel's extremities will experience the greatest sinkage and ground. Where the underkeel clearance is low, reasonable accuracy is demanded in order to ensure safety and to avoid unduly reducing the earning capacity of the vessel by overcaution. This requires a sound knowledge of a vessel's tendency to 'squat'.

2. PRELIMINARY DEFINITIONS

All ships and offshore platforms, when underway, are subject to hydrodynamic pressure changes and friction induced trimming moments which alter their draught and trim in comparison with that when stationary. The term 'squat' includes both the change in draught and the contribution due to trim underway, at any hull extremity of interest. The usual approach to squat is to treat it as a steady-state problem, presenting curves for mean sinkage and trim at varying depths and speeds.

In the plotting of the results, certain non-dimensional parameters have been used:-

(a) The non-dimensional sinkage coefficient,

$$C_S = \frac{100(S_{FP} + S_{AP})}{2L}$$

(b) The non-dimensional trim coefficient,

$$C_\tau = \frac{100(S_{FP} - S_{AP})}{L} = 100\,\tau$$

where S_{FP} and S_{AP} are the sinkages measured at the forward and aft perpendicular, respectively, and τ is the trim angle at radians. Sinkage is assumed negative in the downward z-direction, while trim is defined negative when by-the-bow. Other terminology is explained more fully in reference[1].

3. THE PREDICTION

3.1 Theory

A comprehensive theoretical and experimental study of the ship-to-bottom interaction problem in both laterally restricted and unrestricted shallow water has been completed at the University of Glasgow[2]. It shows that, although both the hydrodynamic and hydraulic theoretical models provide a valuable insight into the squat problem (within the theoretical constraints of each case), a universally applicable theory which allows a routine solution with arbitrary Froude depth number and lateral restrictions, does not exist at present. The subsequent experimental work demonstrated limitations and illustrated features not apparent from the theoretical studies. A wide range of parameters affecting the vertical-plane forces in restricted water were examined, including effects of underkeel clearance, speed, self-propulsion, lateral restrictions, bulbous bow shape, initial trim, draught, a sudden variation in depth and the transverse location in the channel. A full discussion of the theoretical model developed is given in reference[2].

A computer program was written based on the above procedure. Figure 1 demonstrates its utility in predicting model squat in unrestricted shallow water by comparison with experiment. The method is broadly applicable to conventional full-form mono-hull models, towed or self-propelled at steady speed in shallow-water of uniform depth and any width.

3.2 Other Methods

Comparison in the laterally unrestricted shallow water between model data and two recent methods[3] shows that the BMT method gives the better predictions. The model used and the experimental data obtained are considered representative of the considerable data accumulated for the examined block coefficient range. The BMT method is recommended as the more accurate of the methods available and, on this evidence, could be used to derive GO/NO-GO curves, such as in fig. 2, for level or trimmed conditions of full-form vessels.

The inaccuracies of the Barrass formulae[4] stem from the fact that they do not take into account some of the important effects demonstrable by means of theory and model tests. It also appears that, by correlating results obtained on a wide range of hull features (ie, of varying geometry, static draught and trim, etc) and under different environmental conditions (such as water depth and/or lateral restrictions, etc) using various measuring apparatus, reliability has been unduly sacrificed in obtaining convenience. By comparison with model experiments the Barrass formulae are shown not to be conservative and not to possess sufficient limitations on their use under conditions which appear beyond their range of validity. As a result, under some circumstances their use may result in a false sense of security.

Table 1: Full Scale Test Conditions

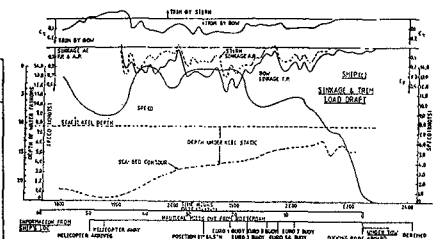

Fig 5

It is important to predict squat with reasonable accuracy particularly where the underkeel clearance is low in order to ensure safety and avoid unduly reducing the earning capacity of a vessel by overcaution. The reluctance of shipboard personnel to hazard vessels at depth-draught ratios less than 1.1 is easily understandable (particularly so when faced with two conflicting methods for predicting vessel behaviour). Because of this, the only significant advances in knowledge may be obtained by model tests.

4. FULL-SCALE MEASUREMENTS

4.1 Experiment Procedure for Full-Scale Measurements

To determine the sinkage and trim to forward speed at sea, it is necessary to record the change in trim and the change in vertical position of any part of the hull and, from such measurements, the sinkage at bow and stern can be computed. Changes in trim are relatively simple to measure and the method which was most successful in these experiments consisted of locating two micromanometers on the centreline of the ship approximately 10 metres apart, connected by a water or oil-filled tube. The recording of changes in sinkage necessitates a datum from which to measure the change in height (which arises from the motion) between a position on the hull and sea.

For this purpose, two ultrasonic transducers were mounted on a light portable boom extending forward from the stem at deck level. The boom was extended well clear of the bow wave system but it proved impossible to project it beyond the symmetrical disturbance of the water surface, which extends well ahead of the stem. The boom used for the most recent experiments extended 15.24m forward of the forward perpendicular. The pressure rise at this position is approximately 0.6m for a 200,000 tonne DW tanker at 14 knots and considerably less for ships of finer trim. Although this pressure rise represents a significant correction to the sinkage signal obtained from the transducer, it is generally accepted that the pressure rise due to the symmetrical disturbance of the water surface ahead of the ship scales linearly.

The effect of sea waves and pitching motion will appear as superimposed undulations on the ultra-sonic and trim signals. In this case, the sinkage and trim values are taken as the average values of the ultra-sonic and trim signals, respectively. To determine the influence of sea state on squat, measurements of ship motions have been included in later experiments.

The overall accuracy of full-scale measurements is estimated to be:-

(±60mm for the ultra-sonic transducer) +

(±30mm for the pressure rise) = ±90mm at the FP,

and (±90mm for the FP) + (±10mm for trim) +

(±70mm for any change in hog or sag under way) = ±170mm at the AP.

Table 2: Model Test Conditions

4.2 Full-Scale Results

Full-scale results were achieved for five ships, (see figs. 3-9). Ship characteristics and the test sequence for four of them are shown in Table 1. Ship (c) was a sister ship of ship (a).

5. MODEL EXPERIMENTS

It has been shown that even extensive and expensive full-scale tests, as described in the previous section, do not provide the systematic parametric coverage necessary to validate a predictive method close to the crucial point of grounding.

To provide the data needed for this and for the calibration of the squat indicator of section 7, extensive model tests have been undertaken. The Hydrodynamics Laboratory at the University of Glasgow has a 77m x 4.6m x 2.4m towing tank with a specially flat bed and has carried out many model tests in shallow water and restricted water conditions.

The results shown in figs. 10 to 13 are for a bulk carrier with the principal dimensions:

LBP = 160.0m Breadth(mld) = 27.2m

Draught(mld) = 10.19m Block coeff = 0.8

Displacement = 37,000 tonnes.

In this particular series the range of tests were as shown in Table 2 and involved two bulbous bows and level bed and simulated sandbank tests[5]. The tests were conducted with the model propelled by a screw propeller at the model self propulsion point for the speeds tested up to grounding.

6. FACTORS INFLUENCING SQUAT

6.1 Side Bank Interactions

Sway force and yaw moments depart from U^2 behaviour in shallow water with flooded banks. The yaw moment rises more steeply whereas the sway force can reverse at higher speeds. This is caused by the wave interaction between the bow and the bank and implies a higher rudder angle is required because of the bank effects. On some occasions with surface piercing banks, this leads to bodily rejection of a ship approaching a bank at a small incidence. At these times the trim changes from bow down to bow up as the bank approaches. With flooded banks the trim is slightly reduced relative to open water whereas the sinkage is significantly increased[6].

For a vessel travelling along the centre of a channel the effect of lateral restriction is shown in fig. 14. It is seen that sinkage is substantially increased but the effect on trim on this occasion is a small increase. It is found that the percentage changes may be generally used as correction factors to the open water results.

6.2 Underkeel Clearance

The effect of bed proximity is to increase the suction pressures applied to the ships hull and also to cause the ship's boundary layer to

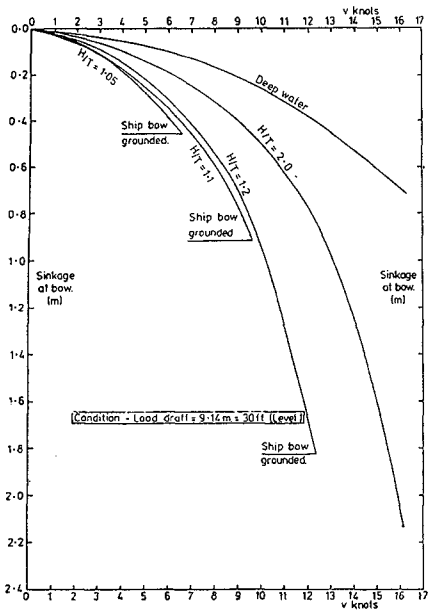

Fig 10

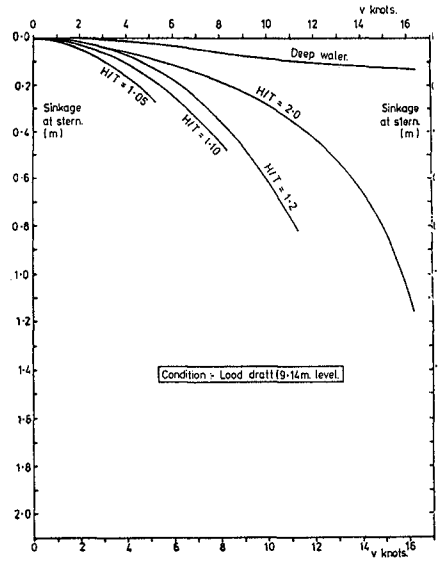

Fig 12

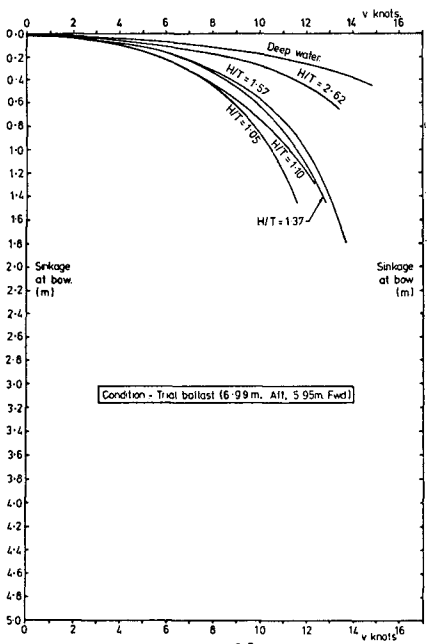

Fig 11

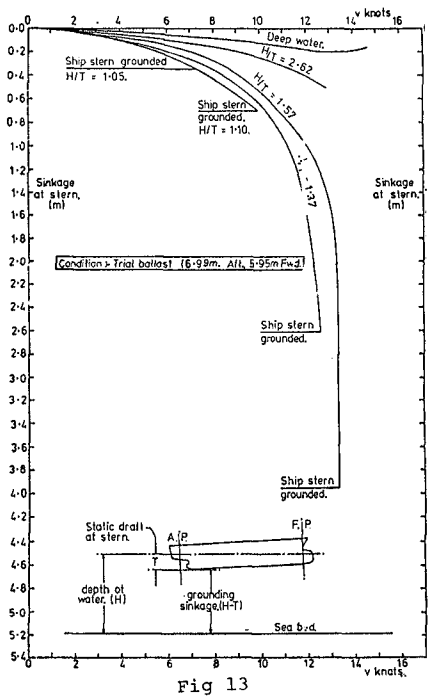

Fig 13

interact with the seabed boundary layer. These effects cause sinkage to increase as the water depth is reduced. Trim also changes rapidly but the manner of change depends on the initial trim as described in section 6.5.

6.3. Sandbanks

The approach to a sandbank leads to the vessel's pressure field interacting with the sandbank and consequently the vessel responds before the bank is reached. Model tests were conducted into a grounding of a bulk carrier in the River Plate. In this case the vessel in load draft experienced a transient trim by the bow (fig. 15) which caused the bow to dive into the sandbank more vigorously than would have been expected under level bed conditions. In ballast conditions (fig. 16) the bow after an initial sinkage is repelled as the stern is attracted leading to the stern being likely to ground almost on leaving the sandbank.

It is possible still to make use of the GO/NO-GO charts (figs. 2 and 17) which were deduced for level bed conditions proved the minimum depth over the sandbank is used.

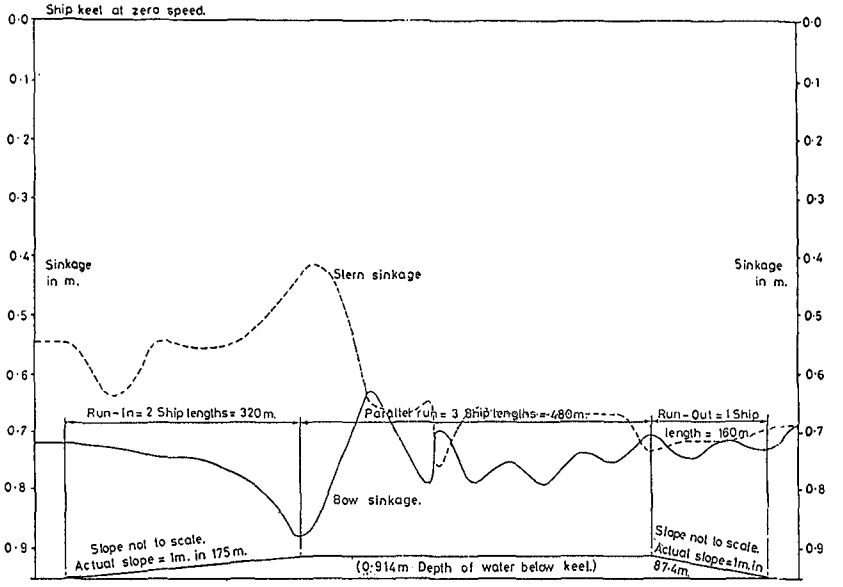
6.4 The Effect of Hull Geometry

Figure 18 presents a comparison of sinkage and trim data obtained on three models at the load draught, level-keel condition in unrestricted shallow-water. The models represent modern, full-form ships of varying hull parameters and displacement but with the block coefficient limited to between 0.8 and 0.9. The curves represent the mean of the data collected. Although no measurable effect on the mean sinkage may be observed, trim increases with increasing C_B and decreasing B/T ratio. These changes are confirmed by the comprehensive analysis of over 120 models by Ferguson[7] which showed that within the ranges B/T and C_B examined negligible changes in sinkage but marked changes in trim are to be expected. For the most part, the data shows the same trends as the theory but theory indicates that squat is inversely proportional to the L/B ratio while the data suggests the opposite.

The comparison shows that the hull geometry must be incorporated into any prediction method and it is not satisfactory to use simpler measures of ship shape such as C_B or B/T ratio. Consequently, a purely empirical method based on a parent form should be used with caution unless the effects of variations in the hull form are accounted for.

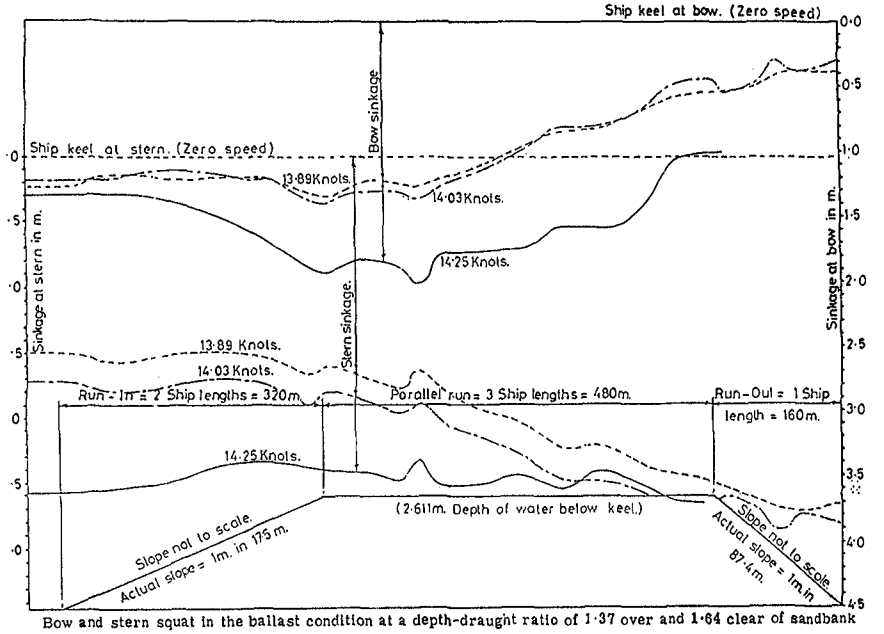
The observations support the view that sinkage results from the pressure changes due to the increased horizontal flow velocity around the hull. In the load draught, level keel condition, the flow velocity is dominated by the long parallel middle-body and negligibly affected by minor hull geometry changes aft and forward. The effect on trim is more complicated since it is the result of the form parameters and the resulting separated flow, depending on factors such as the bulbous-bow and type of propulsion.

The effect of fitting a radically different bulbous-bow design, as shown in fig. 19a, on the vessel's sinkage and trim was also examined by repeating a number of the original experiments[5]. A comparison of the two set of results, fig 19b being typical, showed that the modification leads to minor changes in the force distribution but not its overall magnitude. The resulting changes in close-to-grounding behaviour did not



Bow and stern squat over sandbank in the incident condition at a depth-draught ratio of 1·1 over and 1·3 clear of sandbank at a speed of 9·5 knots

Fig 15



Bow and stern squat in the ballast condition at a depth-draught ratio of 1·37 over and 1·64 clear of sandbank

Fig 16

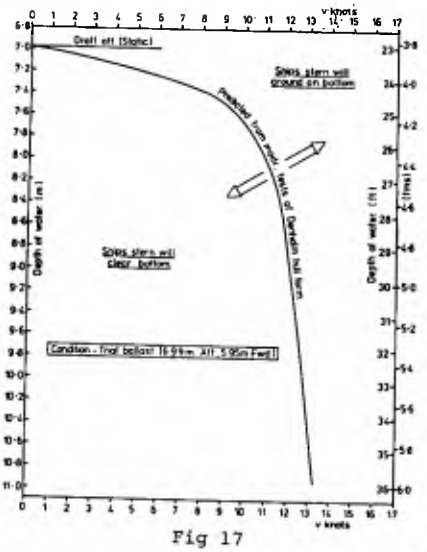


Fig 17

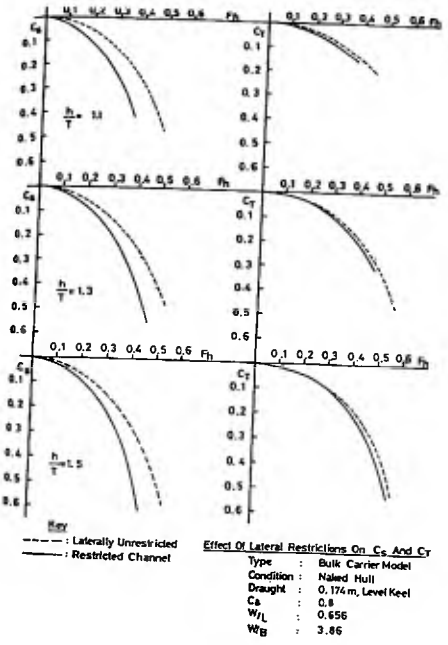

Fig 14

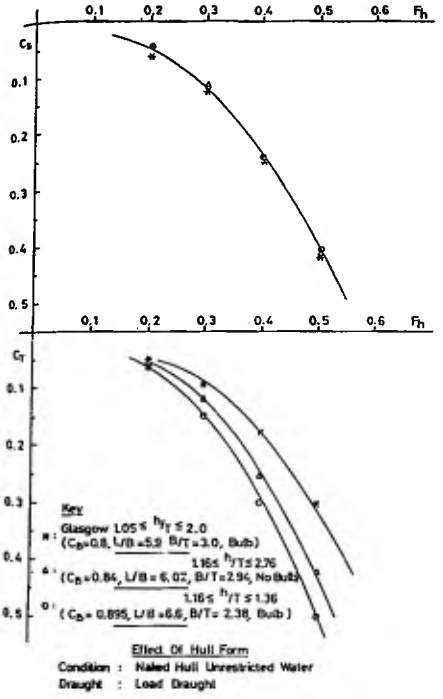

Fig 18

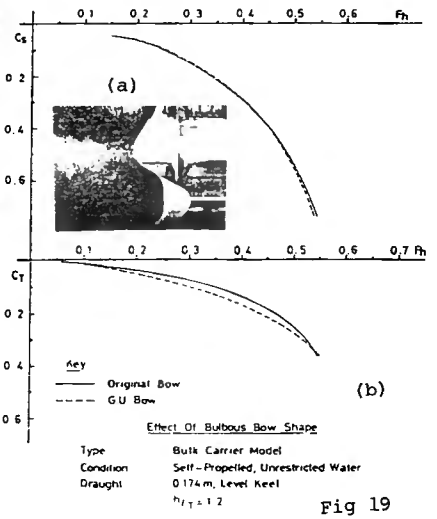

Fig 19

affect the grounding speed or qualitative behaviour and may be considered to have a very small effect and could be omitted from the input hull geometry. However, it should be borne in mind that effects of adding a bulb to an otherwise bulb-less hull will influence the boundary-layer development and the wave system along the hull. It is then to be expected that sinkage and, particularly, trim will be affected to a greater extent than by the above changes in shape.

6.5 Effect of Initial Trim

It is important to recognise that a fully loaded vessel, initially at a level keel in shallow water, will trim progressively by the head and ground with the bow first, whereas a vessel ballasted by the stern (to immerse the screw) will sink progressively with almost constant trim by the stern and ground by the stern, fig. 20. In deeper water the trim by the stern for the ballast condition will decrease with speed.

6.6 Squat and Trim Caused by Bed Mud

In general the sinkage forward and aft above mud appears to be less than above a hard bottom. Moreover, the sinkage values decrease with increasing thickness of the mud layer. There is no clear indication between sinkage above mud of 'winter' and 'summer' densities at the same layer thickness[8].

6.7 Acceleration and Deceleration

Full scale tests on ship(d) in deep water (fig. 6) showed that at moderate speeds an accelerating ship experiences increased sinkage but reduced trim by the bow whereas a decelerating ship sinks less and trims more. If this pattern of behaviour is repeated in shallow water, rapid deceleration could cause the ship to ground.

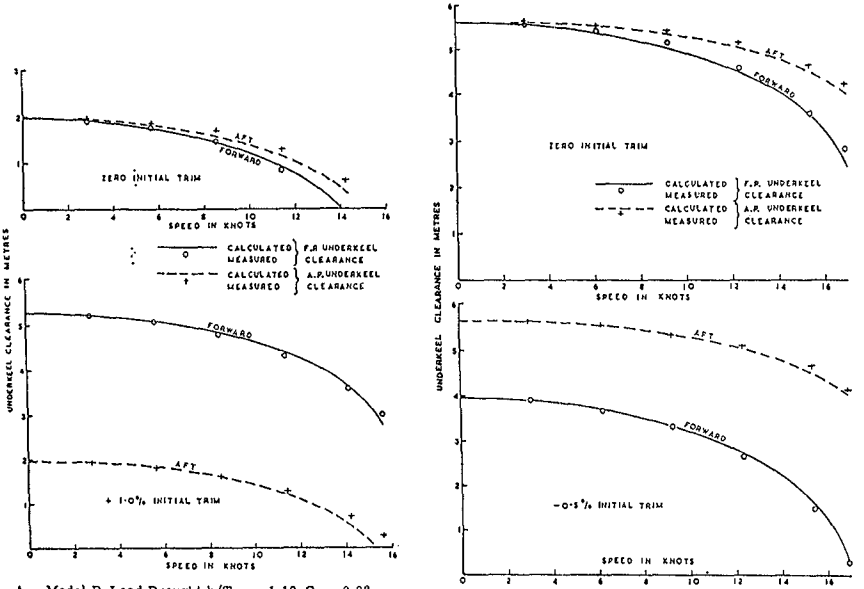
6.8 Self-Propulsion

The effects of self-propulsion are very important as a correction factor to the theoretical methods and for the model/full scale correlation. Figure 21 shows that sinkage is much increased while trim is substantially reduced.

7. EXTRAPOLATION TO FULL-SCALE

Owing to the significant amount of model data, the model-scale squat component of underkeel clearance is one of a deterministic character. The prediction of the full-scale sinkage and trim is still probabilistic. Consequently, the associated scaling problems present difficulties.

Full scale studies indicate that, at a depth-draught ratio of 1.42, correlation in the load-draught level-keel condition is very reasonable at speeds less than about 12 knots (fig. 3). This is particularly so for trim although the mean sinkage tends to be greater for the ship than for the model. Bearing in mind the importance of viscous effects to the scaling procedure in shallow water, this agreement is unexpected. Frictional resistance constitutes the major proportion of full-form ship resistance at low speeds and since the frictional coefficient is much lower on the full-scale, it is to be expected that model results for the trim component will over-estimate the full-scale. The good agreement is mainly because mean sinkage is almost entirely due to the predominance of pressure changes over the hull, allowing direct scaling of this



A. Model B, Load Draught $h/T_{AP} = 1{\cdot}10$, $C_B = 0{\cdot}83$
Results scaled to 330·71 L_{PP} Ship

B. Model B, Load Draught $h/T_{AP} = 1{\cdot}28$, $C_B = 0{\cdot}83$
Results scaled to 330·71 L_{PP} Ship.

Effect of Initial Trim on Underkeel Clearance

Fig 20

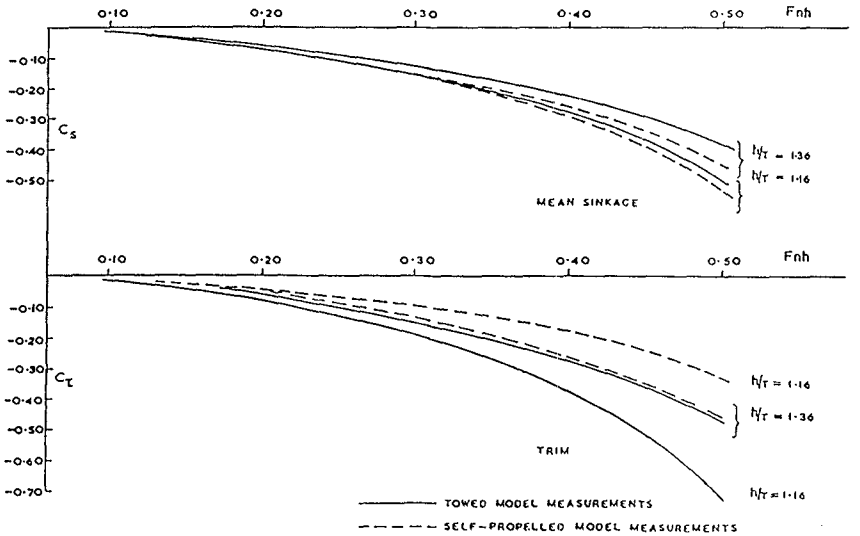


Fig 21 Effect of Self-Propulsion on Mean Sinkage and Trim of a Tanker Model

component without error of practical significance [9].

Although trim has an appreciable viscous component, this is probably counter-balanced by the pressure dominated self-propulsion effects. Any scaling difficulties in the self-propelled, load draught (level keel) condition, therefore, are effectively obscured. However, it is suggested that since the model scale boundary layers are relatively thicker than those at full-scale, they will interact at a greater depth-draught ratio and introduce scaling difficulties in very shallow water.

The model/full-scale comparisons in the self-propelled ballast (trim-by-stern) condition indicate that the normal extrapolation procedure may be in error. The bulb proximity to the free-surface will modify both the hull wave-system and the viscous flow and may induce vertical sinkage or lift forces [9]. It is suggested that since the magnitude of the complex changes induced by the proximity to the free-surface is uncertain, extrapolation to full-scale will be unreliable. Similarly, in the absence of self-propulsion, prediction for the towed, naked-hull condition will be generally unreliable for the trim components in the ballast case.

These problems can only be overcome by careful correlation of model and full-scale results with an adequate computational approach.

8. PRACTICAL NAVIGATION AID

During the trials described in Section 4 it became evident from discussions with Masters and Navigation Officers, that a bridge instrument capable of continually displaying the true dynamic draft, or the amount of squat, would be a useful aid to navigation and contribute to the safe handling of the ship in shallow or restricted waters.

8.1 A Continuous Reading True Draught Indicator

One of the results of the research reported in the preceding sections has been the development of a number of variations of instrumentation systems capable of continuously displaying either the true draught of the vessel, corrected for squat, or the amount of squat present continuously displayed as an increment of draught to be added to the static draught on the ship's bridge.

There is no practical method of obviating squat even though it may be reduced by a given vessel by decreasing speed or, more drastically, by designing a vessel with a higher B/T. Naturally, most operators of large vessels are aware of the dangers and speed is reduced by rule-of-thumb or by the use of squat diagrams posted on the bridge. These diagrams are useful (when accurate) but are easily ignored or overlooked. An instrument capable of continually displaying either the true draught (corrected for squat) or the squat (as an increment to be added to the static draught) would be more useful and more likely to be used. The development of such an instrument is described in Ref 1. Following discussion with tanker fleet operators, the present system is designed to be virtually maintenance free

The signal used is a measure of the water velocity next to the hull. This is responsible for the changes in pressure which cause the squat. In the same way as a particular pressure change results in a particular squat so will the water velocity next to the hull causing that pressure change have a fixed relationship with squat.

The system is shown schematically in fig. 22 and by a block circuit diagram. In an attempt to keep the installation and maintenance costs to a minimum the velocity transducer adopted is an ultra-sonic device which transmits through the hull and reads the velocity close to the hull surface.

8.2 Procedure to Calibrate and Commission the Squat Meter

(a) Using the program described in Section 3 the geometry of the hull is used to compute a complete set of squat information for the practical range of speed and depth of water.

(b) With the instrument properly installed on the ship (an operation which can be carried out during a normal voyage), the ship is sailed over a range of speeds at two or three depths of water. At each combination of speed and depth of water a reading will be displayed on the bridge instrument. This reading is adjusted, using the keyboard input, to read the correct squat according to the computer.

The squat meter should then read the true squat, or dynamic draught if the static draught is keyed in, regardless of the depth under hull and speed combinations even for combinations of speed and depths not covered in the calibration.

9. CONCLUSIONS

The squatting of larger vessels can be an important cause of marine casualties with a serious impact on ship owners and port managers alike. Many factors have a role to play and it should be amphasised that:-

(1) Approaching or leaving port with a trim by the stern does not lead to a more level keel at speed in shallow water.

(2) Transients approaching sandbanks can lead to groundings which may otherwise have been avoided.

(3) Restricted width of fairways has a range of effects and the side forces can exceed the ability of the rudder to control the ship.

(4) Rapid deceleration can lead to larger sinkage at the bow in the short term.

(5) A muddy layer on the seabed reduces sinkage and the idea of effective depth may be necessary for predictions.

It has been demonstrated that a combination of model tests, full scale tests and computer analysis have led to the situation where satisfactory predictions can be made of deterministic squat. The more probabilistic problems involving uncertainties regarding true seabed position, etc, can be ameliorated by a navigational aid as described.
